In 1955, in a lecture on new amino acids isolated in this laboratory, one of us [1] presented a two-dimensional paper chromatogram on which also the presence of a new amino acid (No. 88 in this laboratory) was indicated: "α-Aminosäure isoliert aus Preisselbeeren; Struktur noch nicht sichergestellt". This amino acid is dealt with in the present paper.

Isolation of the amino acid 88. About 12 kg (fresh weight) of cowberries were crushed and amino acids were extracted from them with 70 % ethanol (the water content of the berries taken into account). The extract was concentrated and passed through an Amberlite IR-120 column. Amino acids were eluted from the resin with 1 N ammonium hydroxide. The eluate was evaporated to dryness *in vacuo* and the residue (very dark) dissolved in 20 ml distilled water. It was then passed through an Amberlite IR-4B column. Neutral amino acids were removed from the column by elution with water, while acidic amino acids remained in the resin. On a two-dimensional paper chromatogram (solvents: *n*-butanol--acetic acid-water (63:10:27) and phenol water-ammonia) an unknown spot appeared below alanine among neutral amino acids. On drying at 70° C the spot was yellow but soon turned orange-brown and then violet. The spot was unaffected by hydrolysis with 6 N HCl. It disappeared on deamination with nitrous oxides and was therefore apparently an α-amino acid.

The eluate was evaporated to dryness and the residue dissolved in a small volume of 1.5 N HCl. The new amino acid emerged in fractions 375—455 (of 10 ml each) together with valine and proline. The fractions were evaporated to dryness and suspended in butanol, to which cellulose powder was added. The dry powder obtained was sprinkled on the top of a cellulose powder column. The unknown amino acid was eluted by *n*-butanol from the cellulose powder column, by which treatment valine was separated. Finally the amino acid was separated from proline on a one-dimensional paper chromatogram, using phenol-NH_3 as solvent. The zone containing the amino acid 88 was cut out from the papers and the paper strips were extracted with distilled water. The residue, evaporated to dryness, was passed through an Amberlite IR-120 column. It was crystallized from hot ethanol. Almost white needle-shaped crystals were formed. The crystals were very soluble in water but not in absolute ethanol, acetone or ether.

Characteristics of the amino acid 88: R_F-values (Whatman No. 4):

	Phenol-water-NH_3	*n*-BuOH-AcOH-water
88	0.67	0.33
Alanine	0.62	0.25

Total hydrolysis (6 N HCl, 24 h, 108 °C): Spot stable, traces of homoserine (51) are formed. *Alkaline hydrolysis* (saturated $Ba(OH)_2$, 1 h, 100 °C; 10 % NaOH, 2 h, 108 °C, 5 % Na_2CO_3, 2 h, 108 °C): Stable. *Deamination* with nitrous oxide: Spot disappears (as controls: proline, γ-aminobutyric acid and 5-oxypiperidine-2-carboxylic acid which do not disappear); the acid is an α-amino acid. *Oxidation* with $KMnO_4$ in acid solution (4 % $KMnO_4$ solution, 20 %

Fig. 1. Two-dimensional paper chromatogram of amino acid 88 after reduction with HI and red P (butanol-acetic acid-water, and phenol-water-NH_3; same solvents in Fig. 2). Alanine (2) and valine (3) added. 51 = homoser, 81 = lactone of homoser, 27 = α-aminobut. acid.

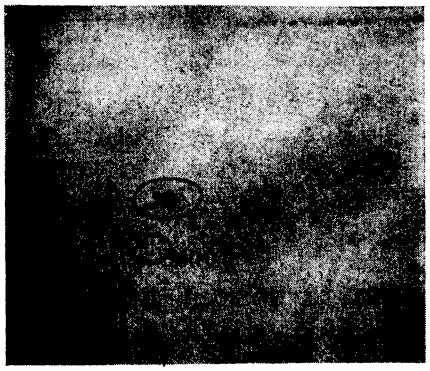

Fig. 2. Paper chromatogram of amino acid 88 after catalytic reduction. Alanine (2) and valine (3) added. 27 = α-aminobut. acid.

H_2SO_4) at +80 °C and with H_2O_2 at room temperature: No new amino acids were found on the paper chromatogram; part of the amino acids remained unoxidized. *Reduction* with HI and red P (140 °C, 1.5—4 h): Homoserine and its lactone as well as a small spot in the position for α-amino-*n*-butyric acid are formed (Fig. 1). Depending on circumstances either homoserine or the lactone of homoserine or both were formed. The reduction of pure homoserine gave a similar result as the reduction of 88. *Catalytic reduction* with PtO_2 and H_2 (Adams platinum oxide catalyst B 27, 6 h): α-NH_2-*n*-Butyric acid (27) is formed as well as faint spots in the position for alanine and in the vicinity of valine (Fig. 2). *UV spectrum:* Non-aromatic; resembling the uncharacteristic spectra of aliphatic amino acids. *Double bond:* Did not reduce alkaline $KMnO_4$ solution; no double bond. *Microtests:* The establishing of lactones as ferrihydroxamate; negative. The OH group in α-position to the amino group (Nessler); negative. The aldehyde or keto group (with 2,4-dinitrophenylhydrazine); negative. Isatin spraying (proline and its homologue); negative. Vanilline spraying; negative.

The above information on the new amino acid was obtained in the autumn of 1954 and in the winter of 1955. On the basis of the results we knew even then that the amino acid had a cyclic structure, and that homoserine or α-aminobutyric acid were formed from it on treatment with different reducing agents. The ring was very stable on hydrolysis, differing thus from the cyclic imino acid isolated from *Convallaria majalis* and *Polygonatum officinale*, respectively [2-4] (2-azetidinecarboxylic acid [3,4]). On paper chromatograms both substances also behaved differently. C, H, and N determinations of the new amino acid suggested a formula $(C_4H_{7-8}O_2N)_n$ but the molecular weight determination was lacking. At this stage the investigation was broken off because the younger author had to give up her research work for the time being and the amount (about 20 mg) of the pure amino acid isolated was used up.

In the autumn of 1956 the investigation was resumed. About 30 mg of the amino acid were isolated and the following additional information was obtained: *Microanalysis.* Found: C 47.62; H 6.89; N 13.91; O 32.59 (determ.). Calc. for $C_4H_7O_2N$: C 47.52; H 6.99; N 13.86; O 31.68. *Molecular weight* (Child's method): Values between 90 and 100 were found in different determinations; Calc. 101; n = 1. *Formation of CO_2 and NH_3* by ninhydrin (Linko's method): CO_2 is not formed, NH_3 to only about 30 % of the total N. Bromine is not taken up; no double bond. *Melting point:* Decomposes at about 234—236 °C. *Microtests:* Waser-Edlbacher (—N—CH_3); negative. Sodium nitroprusside + acet-

aldehyde . (secondary aliphatic amines); negative. α-Naphthoquinonesulphonate (secondary amino group):

	Solution A	Solution B
proline	blue	red
alanine	blue	blue
88	red	red

When at the end of February 1957 the molecular weight of the amino acid was established there were not many possibilities left for structure speculation. Then a paper was published by Burroughs [5] in which the isolation of 1-amino-*cyclo*propane-1-carboxylic acid from perry pears and cider apple was reported. The composition and characteristics of this amino acid are in complete agreement with the amino acid 88 isolated by us from cowberries. Any other structure than that presented by Burroughs cannot be given for the amino acid. Burroughs has also confirmed the structure of his amino acid by synthesis.

In August and September 1955 Mrs. Onerva Äyräpää performed isolation experiments of the amino acid 88 with ripe and unripe (on the one hand partly red and on the other hand quite green) cowberries. The amino acid was not found in unripe berries. The situation is thus the same in cowberries and in perry pears [5].

The content of the amino acid 88 in ripe cowberries is, according to paper chromatography determination, about 400 μg per 100 g fresh wt. and 3.2 mg per 100 g dry wt. or 0.4 % of ethanol soluble N.

Added in proof. Comparison of our preparation with a sample of Burrough's kindly sent by him has conclusively confirmed their identity.

Paper Chromatography of Amino Acids, Sugars and Acids

GUNNAR HÖGSTRÖM

Dept. of Physiological Chemistry, Wenner Grens Institute, Stockholm, Sweden

The solvents commonly used for the paper chromatography of amino acids, namely phenol, collidine and butanol-acetic acid, popular for their good separatory powers, have several disadvantages: phenol and collidine are toxic, and the butanol-acetic acid mixture is subject to esterification with concomitant change of R_F-values. Their smell is also rather offensive. Many attempts have been made to replace them with less obnoxious solvents. In this article will be described an attempt to use methyl ethyl ketone in mixtures with acetone, water and formic acid for the separation of amino acids. These solvents have also been used successfully for sugars and acids belonging to the citric acid cycle.

Experimental: Methyl ethyl ketone of puriss and acetone of pure grade is used. No purification is necessary. The chromatography chambers are made of glass, $20 \times 30 \times 60$ cm, with glass-lids and glass-troughs supported on a glass-frame. Since the R_F-values of amino acids and sugars are very low in the solvents described here, a relatively fast paper, such as Whatman 4, has been used for these compounds, and its lower edge serrated so as to allow the solvent to drip off easily. Whatman 1 is used for the acids. The amino acids are developed by dipping the chromatogram in a 0.2 % solution of ninhydrin in acetone with 0.1 % acetic acid and a little collidine to bring out the right colours of the spots. The sugars are developed with silver nitrate or aniline hydrogen phthalate. The acids are developed by dipping in an indicator solution prepared from a 1 % solution of bromophenol blue in 95 % alcohol by neutralizing to the first tinge of red and then adding about five times its volume of petroleum ether.

In water-saturated methyl ethyl ketone alone the R_F-values of amino acids and sugars are too low to be practical. The addition of acetone makes it possible to introduce more water and increase the

Paper Chromatography of Amino Acids, Sugars and Acids

GUNNAR HÖGSTRÖM

Dept. of Physiological Chemistry, Wenner Grens Institute, Stockholm, Sweden

The solvents commonly used for the paper chromatography of amino acids, namely phenol, collidine and butanol-acetic acid, popular for their good separatory powers, have several disadvantages: phenol and collidine are toxic, and the butanol-acetic acid mixture is subject to esterification with concomitant change of R_F-values. Their smell is also rather offensive. Many attempts have been made to replace them with less obnoxious solvents. In this article will be described an attempt to use methyl ethyl ketone in mixtures with acetone, water and formic acid for the separation of amino acids. These solvents have also been used successfully for sugars and acids belonging to the citric acid cycle.

Experimental: Methyl ethyl ketone of puriss and acetone of pure grade is used. No purification is necessary. The chromatography chambers are made of glass, $20 \times 30 \times 60$ cm, with glass-lids and glass-troughs supported on a glass-frame. Since the R_F-values of amino acids and sugars are very low in the solvents described here, a relatively fast paper, such as Whatman 4, has been used for these compounds, and its lower edge serrated so as to allow the solvent to drip off easily. Whatman 1 is used for the acids. The amino acids are developed by dipping the chromatogram in a 0.2 % solution of ninhydrin in acetone with 0.1 % acetic acid and a little collidine to bring out the right colours of the spots. The sugars are developed with silver nitrate or aniline hydrogen phthalate. The acids are developed by dipping in an indicator solution prepared from a 1 % solution of bromophenol blue in 95 % alcohol by neutralizing to the first tinge of red and then adding about five times its volume of petroleum ether.

In water-saturated methyl ethyl ketone alone the R_F-values of amino acids and sugars are too low to be practical. The addition of acetone makes it possible to introduce more water and increase the

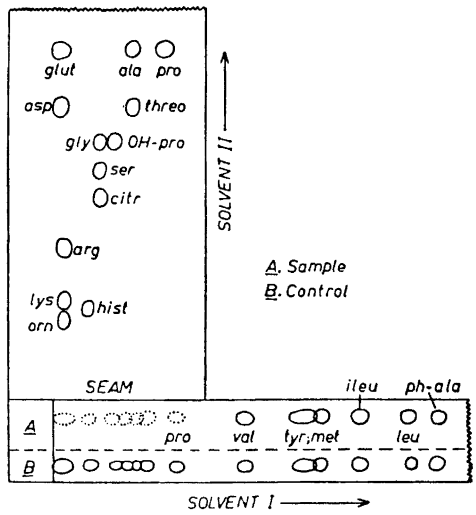

Fig. 1. Paper chromatogram of amino acids.

R_F-values. The following procedure has turned out to be useful for the amino acids:

On a 13 cm wide paper strip the unknown sample is applied on the starting-line 3 cm from one end and a mixture of the common amino acids 2 cm from the other end (Fig. 1). The chromatogram is run for about 30 h with a mixture of methyl ethyl ketone, acetone and water in the proportions 3:1:0.6 (solvent I) and dried at room temperature. A 4 cm wide strip containing the control mixture is separated from the main strip and developed with ninhydrin. The fastest amino acid, phenylalanine, will have travelled about 40 cm. The positions of proline and valine on the sample strip can be found with the aid of the control strip and the sample strip is cut between these two amino acids. The distal part is developed with ninhydrin. A new strip of paper is sewed on the undeveloped part at right angles to the direction of the first solvent and the remaining amino acids separated on this strip with solvent II — methyl ethyl ketone, acetone, water and formic acid in the proportions 3:1:1:0.1 — during 30 h. Here glutamic acid is the fastest amino acid. If the R_F-value of phenylalanine in solvent I and glutamic acid in solventII is arbitrarily designed as 1.00, the other amino acids will obtain the R_F-values collected in Table 1.

For sugars solvent I is used. Of the common sugars ribose is the fastest one and travels about 40 cm in 16 h. If its R_F-value is designed as 1.00, the other sugars will get the R_F-values collected in Table 2.

A mixture of methyl ethyl ketone, acetone, water and formic acid in the proportions 80:6:12:2 is convenient for the separation of some common acids, the R_F-values of which are found in Table 3. On Whatman 1 the front travels about 40 cm in 6 h.

Instead of solvent I a mixture with the proportions 15:3:? has sometimes been used with a little longer running time and somewhat improved separation. In this solvent tryptophan runs ahead of phenylalanine — in solvent I they coincide.

Salts in appreciable amounts have a pronounced effect on the separatory powers of these solvents, at least with respect to the amino acids. The only natural material, to which they have been applied so far, is acid-hydrolyzed *Neurospora*, and in this case this drawback has been obviated

by using a simple desalting apparatus, illustrated in Fig. 2. The sample is applied along a line 5 cm from one end of a paper strip, 21 × 5 cm, pointed at the other end. The strip is placed between two glass sheets, 16 × 6 cm, in such a way that the pointed end is 1 cm outside the sheets. The other end is immersed in a mixture of acetone, water and ammonia in the proportions 7:3:0.4. After about 8 h all the amino acids have travelled to the pointed end of the strip, leaving most of the salts behind. The end is cut off and eluted with water. The eluate is concentrated and applied for chromatography. The application can, more conveniently, be made automatically by allowing the pointed end of the paper strip to touch the starting-line of the chromatography strip. A blast of air, directed from underneath this strip, accelerates the evaporation and prevents the spot from becoming too big.

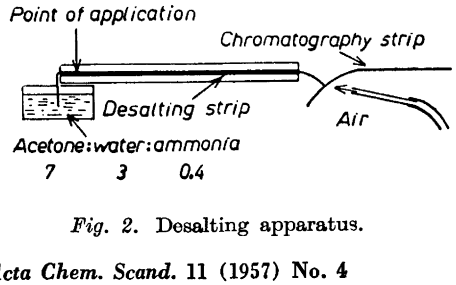

Fig. 2. Desalting apparatus.

About 20 cm has been found to be enough for the desalting strip in the case of *Neurospora*. Other materials may require greater length and time of desalting.

My thanks are due to Professor G. Ehrensvärd for much encouragement in this work.

The Reflection Spectra of Anhydrous Nickel(II) Chlorides and Bromides and Their Double Salts with Monovalent Cations

R. W. ASMUSSEN and OLE BOSTRUP

Chemical Laboratory B, Technical University of Denmark, Copenhagen, Denmark

It is generally assumed that the nickel ions in anhydrous $NiCl_2$, $NiBr_2$ and their double salts $MeNiCl_3$ and $MeNiBr_3$ have the coordination number six. The magnetic properties of the double salts have previously been measured by Asmussen and Soling [1]. The reflection spectra of ten solid compounds are given in Fig. 1 and in Table 1. The excited levels corresponding to the absorption maxima agree with the ligand field theory for d^8-systems in fields of the cubic-octahedral symmetry O_h. Thus a ligand field parameter Δ (also denoted by $(E_1 - E_2)$ or 10Dq) can be found for each compound. Further the Slater-Condon-Shortley integrals F^k seem to be decreased [2] in the complexes relative to the Ni^{+2}.

Fig. 1 shows that the ten absorption spectra are remarkably similar. However, the values of Δ given in Table 1 vary within a range of 6 800 – 7 600 K. Δ decreases with increasing radius of the anion (Cl^-, Br^-) and with increasing radius of the cation (Rb^+, Cs^+, $C_5H_5NH^+$). It has previously been discussed [3] whether this behaviour can be explained by an electrostatic model. However, it is very probable that partly covalent bonding, *i. e.* intermixing of the partly filled 3d-shell with the orbitals of the ligands, occurs. The latter

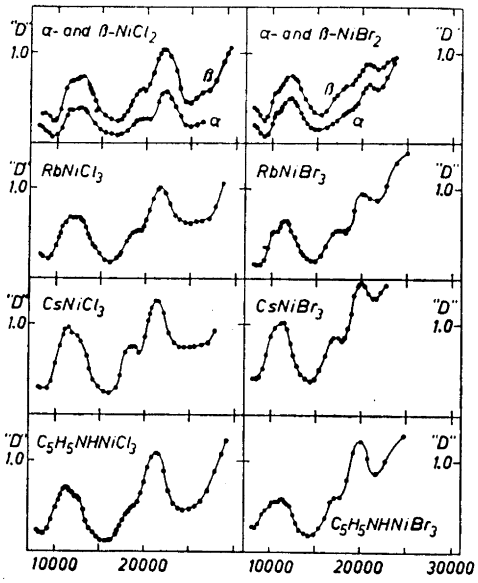

Fig. 1. Reflection spectra of nickel(II) halides measured by means of a Beckman DU spectrophotometer. (The optical density "D" is only a relative measure for the light absorbed).

possibility is supported by the fact that the values of a linear combination of F^k-integrals, *viz.* 15 B, is relatively more decreased among our examples, when Δ is large. For comparison with nickel(II) complexes with neutral ligands the values of Δ and 15 B for $Ni(OH_2)_6^{+2}$ and $Nien_3^{+2}$ are also given in Table 1. Even though the partly covalent bonding (as implied from decreased F^k-values) might seem rather important in nickel(II) halides compared with other nickel(II) complexes, it must be noted that similar or even stronger effects are observed in halide complexes of chromium(III) and rhodium(III) [2].

Further Fig. 1 shows that the wavenumbers of the absorption bands are identical for the α- and β-modifications of $NiCl_2$ and $NiBr_2$. Mr. P. Andersen [4] has demonstrated that α-$NiCl_2$ and α-$NiBr_2$ has more dis-ordered structure than the high-temperature β-forms. Generally the distribution of atoms, which are not directly coordinated to the transition group ion, has very small influence on the d^n-levels [5]. The nickel(II) halides, which do not contain monovalent cations, seem to be most tightly bound, *i. e.* Δ is large and 15 B much decreased.

Experimental. Preparation and analysis of the double halides are given elsewhere [1]. α- and β-$NiCl_2$ and α- and β-$NiBr_2$ were kindly supplied by Mr. P. Andersen [4].

Bound Homoserine in Fruits of Cowberry and Cranberry

MAIJA-LEENA VÄHÄTALO and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

The numerous new amino acids, found in recent years, generally occur as free amino acids. Only γ-hydroxyglutamic acid is found in bound form too in *Phlox* [1] and α-aminoadipic acid in proteins in maize [2]. Homoserine, which is a comparatively common free amino acid of plants and which is formed in germinating pea seeds in a surprisingly large quantity [3], has not been simultaneously found in free and bound form, whereas we have found it in bound form alone in berries and leaves of cowberry [1].

Fruits of cowberry were extracted with 70 % ethanol until no ninhydrin positive spots could be found on the paper chromatogram. The free amino acids in the ethanol extract can be seen in Fig. 1. No homoserine and hydroxyproline could be found on the chromatogram.

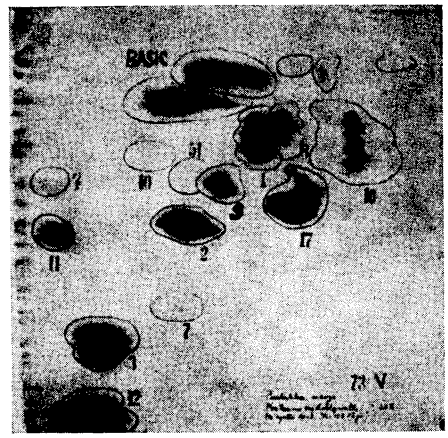

Fig. 2. Paper chromatogram of the hydrolyzed residue of 70 % ethanol extract of fruits of cowberry: 1 = gly, 10 = hydroxyproline, 51 = homoserine.

After ethanol extraction the residue of the berries was dried. 1 g of the residue was hydrolyzed with 15 ml of 6 N HCl for 24 h at 108 C°. Amino acids were separated in an Amberlite IR-120 column. Clear spots of homoserine and hydroxyproline were

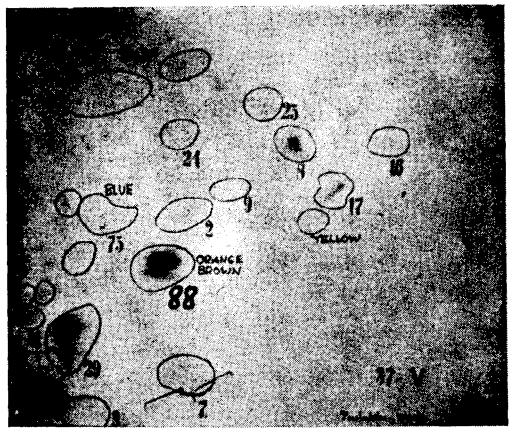

Fig. 1. Free amino acids of fruits of cowberry on a two-dimensional chromatogram (butanol-acetic acid-water, and phenol-water-NH_3; same solvents in Fig. 2). 2 = ala, 3 = val, 7 = tyr, 8 = ser, 9 = threo, 11 = pro,16 = asp, 17 = glu, 24 = glu-NH_2, 25 = asp-NH_2, 29 = γ-aminobut. acid, 60 = pipecolic acid, 75 = 5-hydroxypipecolic acid, 88 = new cyclic α-aminocarboxylic acid (1-*cyclo*propane-1-aminocarboxylic acid).

found on the paper chromatogram (Fig. 2). On the other hand *a*-aminobutyric acid (29), pipecolic acid (60), 5-hydroxypipecolic acid (75), and 1-*cyclo*propane-1-aminocarboxylic acid (88) which occur as free amino acids in the berries are not found on the paper chromatogram. Also in berries of cranberry *(Oxycoccus quadripetalus)* homoserine was found in bound form.

Disubstitution of Ethyl Acetoacetate in one Step by Means of Sodium Hydride

RUNE SANDBERG

Chemical Institute, University of Uppsala, Uppsala, Sweden

Hitherto it has not been considered possible to prepare the disubstituted derivatives of acetoacetic ester in one step. For instance, Finar [1] points out that "the introduction of two alkyl groups must be carried out in two steps; it *cannot* be done in one step". However, Wallingford and Homeyer [2,3] have reported that dimetallation and disubstitution of β-ketoesters is possible with alcohol-free sodium alkoxide in alkyl carbonate solution, and Weizmann [4] was able to dialkylate acetoacetic ester by means of a complex formed between potassium hydroxide and an acetal or dialkyleter of ethylene glycol.

The present writer has found that ethyl β-acetotricarballylate can be prepared in good yields from ethyl acetoacetate and ethyl bromoacetate, using sodium hydride as metallating agent in benzene solution.

It is the author's intention to further investigate the extent to which this method is applicable.

Experimental: The apparatus used was a three-necked flask, fitted with a dropping funnel, a sealed Hersberg stirrer and a condenser, the top of which had connections to a source of nitrogen and a vacuum line. The apparatus was evacuated, flame-dried and filled with nitrogen. With nitrogen flowing, the dropping funnel was closed and removed, and sodium hydride (28.8 g, 1.2 mole) rapidly placed in the flask and covered with benzene (700 ml). The funnel was then replaced, the flow of nitrogen stopped and the funnel filled with a solution of freshly distilled ethyl acetoacetate (65 g, 0.5 mole) in dry benzene (150 ml) and then stoppered with a calcium chloride tube. With stirring, this solution was added during 30 min and the reaction mixture then stirred until the evolution of hydrogen had stopped. The apparatus was now swept with nitrogen, before a solution of freshly distilled ethyl bromoacetate (200 g, 1.2 mole) in dry benzene (75 ml) was placed in the dropping funnel. This solution was added with vigorous stirring during two hours, the flask being gently heated to maintain a slight reflux (the reaction is exothermic). When the addition was finished, the reaction mixture was stirred and refluxed for another 45 min.

After cooling, the reaction mixture was washed three times with water, the water washings extracted once with ether and the combined benzene and ether solutions dried over anhydrous magnesium sulphate. The solvents were removed and the residual oil fractionated, yielding 116.5 g (77 %) of β-acetotricarballylate, b. p. 142°—47°/1.0—1.2 mm. Phenylhydrazone m. p. 99°—100.5°. Emery [5] reports 190°/16 mm and 100°—101°, respectively.

The author wants to express his thanks to Professor Arne Fredga for his interest in this work.

Studies of the Phospholipids of Human Bile and Small Intestinal Content

BENGT BORGSTRÖM

Department of Physiological Chemistry, University of Lund, Lund, Sweden

It has been demonstrated that lecithin is the only phospholipid present in human bile [1,2] and it is generally assumed that the bile lecithin is of importance for the digestion and absorption of fat from the small intestine.

Information as to the fate of the bile lecithin in the lumen of the small intestine during digestion is, however, incomplete, although different lecithin splitting enzymes have been demonstrated in pancreatic extracts and juice [3-5].

From preliminary studies with paper chromatography of small intestinal content collected from human beings by intubation, it appeared that most of the phospholipids present therein was in the form of lysolecithin. The studies were then extended and resulted in the isolation from human small intestinal content of β-palmitoyl-lysolecithin.

Ten ml of intestinal content collected from the upper jejunum of a normal adult human after a test meal free of phospholipids were mixed with 190 ml chloroform: methanol 2:1. After filtration the volumes were adjusted to 200 ml. Determination of total phosphorus [6] indicated a total of 2.40 mg P. The chloroform:methanol extract was mixed with 80 ml 0.9 % saline solution in a separatory funnel and the lower phase containing the lipid P (2.0 mg) passed through a 5 g column of silicic acid [7]. Three fractions were eluted: (I): chloroform, (II): chloroform with 30 volume % of 95 % ethanol, and (III): methanol.

(I) was free of phosphorus and contained neutral fat and free fatty acids [7]. (II) contained less than 5 μg phosphorus and (III) 1 960 μg phosphorus. In model experiment fraction II contains added lecithin and (III) added lysolecithin [8]. The phosphorus containing compound in fraction (III) from the intestinal content was identical with β-palmitoyl-lysolecithin prepared from egg lecithin by the action of *Crotalus adamanteus* venom [12] as indicated by paper chromatography [8,9], ester bond [10] to P ratio and hemolytic activity [11].

Similar results were obtained on several different samples of intestinal content, the percentage lysolecithin ranging from 62 to 100 of the total lipid phosphorus content.

After saponification the fatty acid of the isolated lysolecithin was identified as palmitic acid by chromatography on paper impregnated with liquid paraffin using 85 % acetic acid as the moving phase.

The fatty acid in the α-position of lecithin isolated from human bile was split off using lecithinase A from *Crotalus adamanteus* [12] and subsequently identified as oleic acid by chromatography directly and after hydrogenation.

The lecithin of human bile therefore is α-palmitoyl-β-oleyllecithin, thus conforming with other isolated lecithins in having an unsaturated fatty acid in the α-position and a saturated fatty acid in the β-position [13].

The occurrence of the highly surface-active lysolecithin in intestinal content has to be considered in connection with problems related to the digestion and absorption of fat.

The Enzymatic Hydrolysis of the β-Methyl Derivatives of Acetylcholine and Acetylthiocholine

KLAS-BERTIL AUGUSTINSSON and TORHILD ISACSHEN

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

Since the observation made in 1938 by Glick [1] that horse serum splits only the D-isomer of acetyl-β-methylcholine, the only report on this subject has recently been published by Hoskin and Trick [2]. The latter authors, using rat brain homogenate, showed that the brain acetylcholinesterase also exhibits stereospecificity, the D-isomer only of the substrate used by Glick being split. Similar observations have been made in this laboratory with other enzyme preparations and other substrates. The results obtained will be briefly reported in the following.

The enzyme activity was measured with the Warburg technique and, in addition to acetyl-β-methylcholine, a series of thiocholine esters (as iodides) were used as substrates. Purified enzyme preparations of the electric organ of *Torpedo marmorata* and human blood plasma were employed; in addition, the esterase activity of cobra venom was similarly tested. The initial substrate concentration was 6.12 μmoles in a total reaction mixture of 2.40 ml. After complete hydrolysis of the substrate, the same amount of substrate was added to the reaction mixture from a second side bulb of the flask, and the hydrolysis reaction followed up to renewed completeness.

The results obtained with the electric tissue acetylcholinesterase (I) and human plasma cholinesterase (II) are recorded in Fig. 1. The experiments carried out with the cobra venom enzyme gave results which were identical with those obtained with the electric tissue enzyme. The enzymatic hydrolysis of a racemic mixture of acetyl-β-methylcholine (MeCh) came to completion when exactly 50 % of the amount of added substrate (6.12 μmoles) was hydrolysed. When a second portion of enzyme was added to this reaction mixture, no further hydrolysis was observed. If the same amount of substrate (MeCh) as the initial one was added to the reaction mixture after complete hydrolysis of the first added substrate (60 min for the electric tissue enzyme, 90 min for the plasma enzyme in the experiments shown in Fig. 1), hydrolysis started again, and was complete when 50 % of the second portion of substrate was hydrolysed. For comparison, the 100 % hydrolysis of acetylcholine is inserted in the figure. Human plasma cholinesterase splits acetyl-β-methylcholine at a very low rate, and therefore a 100 times higher concentration of this enzyme was used compared with the concentration used for the hydrolysis of acetylcholine. Furthermore, it was observed that after 50 % enzymatic hydrolysis of the β-methyl derivative by the plasma enzyme, the hydrolysis reaction continued with a very low rate, approximately 20 times lower than the initial rate. This infers that the plasma enzyme does split both the stereoisomers of acetyl-β-methylcholine, the hydrolysis rate for one of these (presumably the D-isomer) being about 20 times higher than that for the other isomer.

The experiments were repeated with some thiocholine esters. In all cases where thiocholine was the reaction product, the total amount of CO_2 produced was higher than expected from a theoretical point of view, when one mole of substrate hydrolysed is equivalent to one mole of CO_2 evolved from the bicarbonate system. For the thiocholine esters, CO_2 was not produced in equivalent amounts to the substrate hydrolysed, and this was probably due to the acidic property of thiocholine at the pH of the reaction mixture (7.4). Studies made by Hansen [3] with the tertiary amino analogue of thiocholine have shown that one of the two pK_a values observed for this derivative is approximately 8 which possibly may be due to the protolysis of the mercapto group. The mercapto group of thiocholine may be suggested to have similar acidic property. This, partly at least, explains the observation first made by Koelle [4], with a technique similar to that used in the present investigation, that acetylthiocholine is hydrolysed at a higher rate than acetylcholine by certain cholinesterase preparations. It may also explain the higher hydrolysis rates for the thiocholine esters at pH 8.0 than at pH 6.4, which difference is more marked than that for the corresponding reaction rates for choline esters.

Acetyl-β-methylthiocholine (MeThCh) gave similar results, 7.5 μmoles of CO_2 being produced instead of 6.12 μmoles ex-

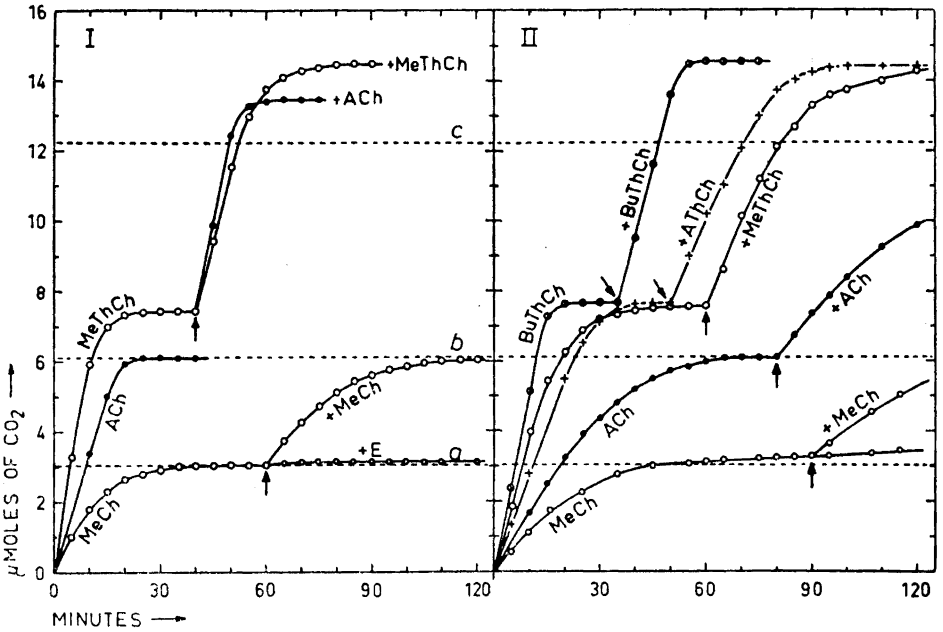

Fig. 1. The enzymatic hydrolysis of choline and thiocholine esters by purified cholinesterase preparations from *Torpedo* electric tissue (I) and human blood plasma (II). Initial amount of substrate 6.12 μmoles; total reaction mixture 2.40 ml. Arrows designate the addition of a second portion (6.12 μmoles) of substrate (or enzyme). The same enzyme concentration was used for various substrates, except in II where this concentration was 5 times higher for MeThCh and 100 times higher for MeCh. a = 3.06 μmoles; b = 6.12 μmoles; c = 12.24 μmoles. Symbols: ACh = acetylcholine chloride, MeCh = acetyl-β-methylcholine iodide, AThCh = acetylthiocholine iodide, BuThCh = butyrylthiocholine iodide, MeThCh = acetyl-β-methylthiocholine iodide. Symbols omitted for the initial hydrolysis curves in II for AThCh and MeThCh.

pected from a mole to mole basis. This optically active substrate used as racemic mixture thus behaved fundamentally different from its oxygen analogue. It has not been possible to find an explanation for this difference. It is very unlikely that the esterases show stereospecificity only for the choline esters and not for the thiocholine esters. It is more likely that the thioester is racemised during the enzymatic hydrolysis. A further difference between the S- and O-analogues of the β-methyl esters is that the former does not show the selective substrate specificity against acetylcholinesterases [5].

The thiocholine esters were kindly placed at our disposal by Messrs. Hoffmann-La Roche, Basel; for this generosity we wish to express our sincere thanks.

UV- und IR-Absorption von Kohlenstoffdiselenid

E. TREIBER, J. GIERER, J. REHNSTRÖM und K. E. ALMIN

Aus dem Centrallaboratorium der schwedischen Celluloseindustrie und dem schwedischen Holzforschungsinstitut, Stockholm, Schweden

Für Versuche, über die an anderer Stelle berichtet werden soll, war es notwendig, Kohlenstoffdiselenid (CSe_2) in grösserer Menge und grosser Reinheit darzustellen. Die Tatsache, dass wir so ein sehr reines Produkt zur Verfügung hatten, veranlasste uns, das bisher unbekannte Absorptionsverhalten im UV und IR zu untersuchen, worüber hier kurz referiert wird. Vorliegende Kurzmitteilung schliesst sich einer älteren Arbeit des einen von uns an [1,2], worin die UV-Absorption von Schwefelkohlenstoff und Kohlenoxysulfid studiert wurde.

Das ultraviolette Absorptionsspektrum. Kohlenstoffdiselenid, gelöst in Heptan, zeigt, wie erwartet, in Analogie zum Schwefelkohlenstoff 2 Absorptionsbanden im UV (2 660 mm^{-1} = 376 mμ und 4 115 mm^{-1} = 243 mμ). Beide Maxima sind gegenüber den analogen des Schwefelkohlenstoffs um ≈ 600 mm^{-1} gegen rot verschoben (Abb. 1). Die langwelligere Absorptionsbande dürfte vermutlich auch hier — wie beim CS_2 — als verbotener, angeregter Elektronenzustand interpretiert werden[1], der allerdings gegenüber CS_2 an Übergangswahrscheinlichkeit gewonnen hat. Die kurzwellige Bande darf dem CSe-Chromophor zugeordnet werden.

Die Infrarotabsorption. In Abb. 2 sind nun die analogen IR-Spektra von flüssigem CSe_2 und CS_2 wiedergegeben. Wie zu erwarten zeigen auch im IR beide Spektra sehr grosse Ähnlichkeit, wenn man von der Verschiebung zu niederer Wellenzahl im CSe_2-Spektrum absieht. Die bei 1 270 cm^{-1} beobachtbare Bande des CSe_2 besteht aus mindestens 3 getrennten Vibrationen und rührt offenbar von den Valenzschwingungen der C=Se-Bindung her. Diese Bande ist also analog der CS_2-Bande bei 1 523 cm^{-1}.

Experimentelles. Die Herstellung von Kohlenstoffdiselenid erfolgte in Anlehnung an die

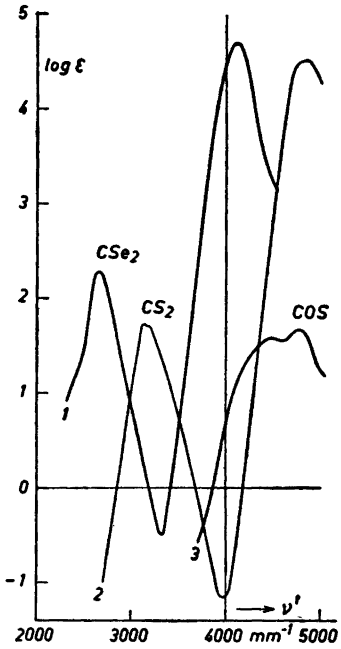

Abb. 1. UV-Absorptionsspektrum von: Kurve 1: CSe_2, Kurve 2: CS_2 [2], Kurve 3: COS [1].

von Ives u. Mitarb.[3] beschriebene Methode durch Einwirkung von Methylenchloriddämpfen auf schwach glühendes metallisches Selen. Die von uns verwendete Apparatur ist in Abb. 3 wiedergegeben. Zur Erhöhung der Ausbeute wurde das reichlich mit dem Gasstrom übergehende Selen wieder in den Reaktionsprozess zurückgeführt. Das im Kolben 3 kondensierte Substanzgemisch wurde nach Abfiltrierung des Selens einer Wasserdampfdestillation unterworfen. Die Methylenchlorid-Phase, die das Kohlenstoffdiselenid gelöst enthält, wurde abgetrennt, mit Natriumkarbonat sicc. getrocknet und im Vakuum bei ≈ 130 mm Hg fraktioniert. Kohlenstoffdiselenid — ein gelb gefärbtes Öl von äusserst widerlichem Geruch, die Schleimhäute reizend — wurde hierauf durch mehrfache Fraktionierung im Vakuum bei 110—115 mm Hg (Kp ≈ 66—67°C) über Hg-Metall und festem $Ca(OH)_2$ p.a. bis zur optischen Konstanz gereinigt.

In ähnlicher Weise erfolgte die Reinigung auf optische Konstanz von p.a. Schwefelkohlenstoff[2,4].

Die Reinigung von Heptan als optisch durchlässiges und inertes Lösungsmittel erfolgte in

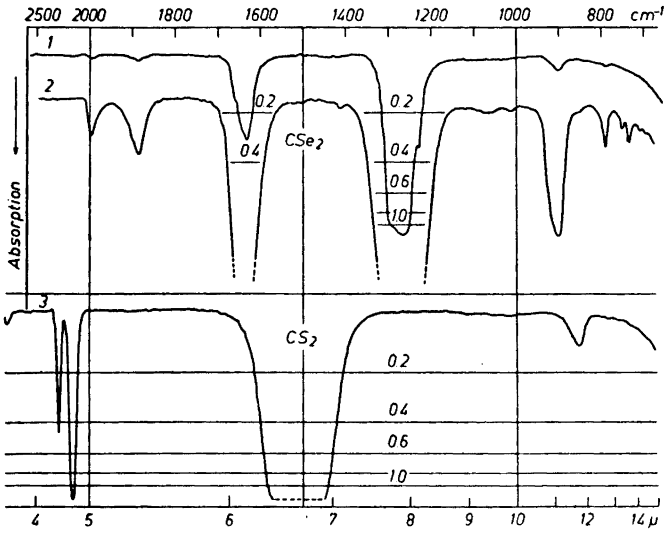

Abb. 2. Infrarotspektrum von CSe_2 (Kurve 1 und 2) und CS_2 (Kurve 3). (Kurve 1: CSe_2-Flüssigkeitsfilm zwischen zwei zusammengepressten Steinsalzplättchen; Kurve 2 und 3 flüssige Substanz in einer 0,1 mm Küvette.)

Anlehnung an übliche Reinigungsmethoden [4] durch Schütteln von Heptan mit konz. Schwefelsäure unter Zusatz von Silbersulfat, Waschen mit Wasser, alkal. Permanganatlösung und Wasser. Das abgetrennte Heptan wurde hierauf unter Zusatz von entsprechend gereinigtem Natriummetall fraktioniert; es erwies sich im gesamten, durch das Beckman-Spektrophotometer erfassbaren UV-Bereich als durchlässig.

Die IR-Aufnahme erfolgte in einem Perkin-Elmer-Spektrophotometer, Mod. 21 mit Steinsalzprisma. Für die Benutzung des Instruments danken wir Herrn Laborator A. Johansson von der analytisch-chemischen Abteilung der techn. Hochschule Stockholm.

N-Terminal Amino Acids Formed during Digestion of Bovine Fibrinogen by Plasmin

PER WALLÉN and KURT BERGSTRÖM

Kemiska Institutionen II, Karolinska Institutet, Stockholm, Sweden

The purpose of this work was to make a qualitative and quantitative estimation of the N-terminal amino acids, formed during the digestion of fibrinogen by plasmin, activated by urokinase. Besides the estimation of the N-terminal amino acids the decomposition of fibrinogen was followed by determination of coagulability. The determinations of N-terminal amino acids were carried out by Edman's phenyl-*iso*thiocyanate method [1]. The coagulability was determined after addition of lysine-ethylester in order to avoid further fibrinolysis [2]. The syneresis method of Morrison, as modified by Saifer and Newhouse [3], was applied.

The fibrinogen was prepared by the method recently published by Blombäck and Blombäck [4] and the coagulability of the preparations used by us varied from 95 to 99 %. Even these very pure preparations contain traces of plasminogen and after activation sufficient amounts of plasmin are formed to digest the fibrinogen.

The urokinase was prepared from human urine by adsorption on Hyflo Super Cel, and elution with ammonia. It was further purified by means of ammonium sulphate fractionation. By this method about 5 mg of dry substance was obtained from one liter of urine and the yield of activity was about 80 %.

500 mg of fibrinogen and 0.5 mg urokinase were dissolved in 50 ml of 0.02 M phosphate buffer pH 7.2 containing NaCl to a concentration of 0.3 M and incubated at 37 °C. At different times 10 ml of the reaction mixture was added to 10 ml pyridine containing 0.5 ml phenyl-*iso*-thiocyanate, thus interrupting the digestion. The coupling was continued for 2 h by keeping pH 8.5—9.0 with occasional addition of 1 N NaOH. The excess of phenyl-*iso*thiocyanate was removed by washing several times with benzene. The PTC-derivatives were transferred to the corresponding PTH-amino acids by heating with 1 N HCl at 100 °C for one hour. The PTH-amino acids were extracted and identified by paper chromatography. The solvents A, D, E and F of Edman and Sjöquist [5,6] and a solvent composed of D and E in equal parts [7] were used.

Blombäck and Yamashina [8] have recently reported that there are 2 tyrosyl and 2 glutamyl residues as N-terminal amino acids in the bovine fibrinogen molecule, when the molecular weight was estimated to be 340 000. During fibrinogenolysis the

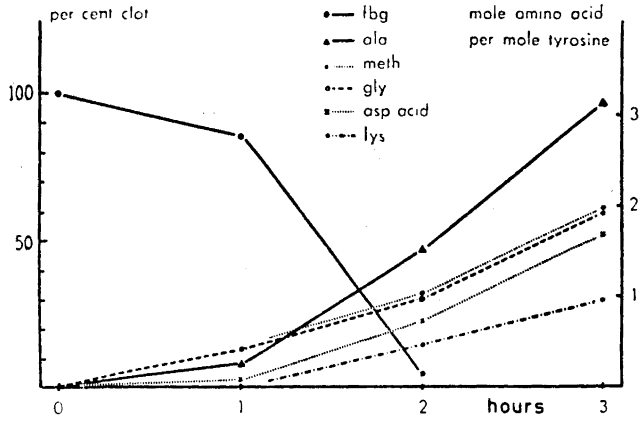

Fig. 1. N-Terminal amino acids released during fibrinogenolysis and correlated to coagulability.

following N-terminal amino acids appeared: aspartic acid, glycine, alanin, lysine and methionine. The glutamyl and tyrosyl residues did not show any significant change during the digestion time used. As the value of tyrosine was practically constant during the fibrinogenolysis, the released amounts of the N-terminal amino acids were expressed in relation to tyrosine (see Fig. 1). When the digestion of fibrinogen had proceeded so far that only traces could be coagulated with trombin, approximately one mole lysyl, two moles each of glycyl, aspartyl and methionyl, and three moles alanyl residues were formed from one mole of fibrinogen.

A/S Ferrosan, Copenhagen, Denmark

From an unidentified actinomycete No. 4279 isolated from a soil sample collected in North Zealand, Denmark, in 1953 we have succeeded in isolating a crude substance with antibiotic activity against a wide range of bacteria and fungi. This substance has properties very similar to those described by Schaffner, Rangaswami and Waksman [1,2] as regards the mycothricin complex though it differs from the latter in certain chemical respects. Optimum yield was obtained after 36 h at 25—28° in a medium containing the extractive material from 40 g of soy-meal per l in an aerated and stirred fermentator.

A crude preparation of the active substance was obtained from the broth by adsorption on activated carbon at pH 7—8 and elution with 80 % ethanol at pH 2.7. Purification was carried out (a) by treating a 20 % aqueous solution of the substance at pH 2.7 with activated carbon and subsequent precipitation by means of 10 volumes of acetone or ethanol and (b) by adsorption on Amberlite IRC-50 at pH 8 and elution with dilute hydrochloric acid; the active fractions were then neutralized with Amberlite IR-4B and evaporated *in vacuo* or, in some cases, lyofilized.

The substance is readily soluble in water and slightly soluble in ethanol. It is insoluble in chloroform, ether, benzene, toluene and *n*-butanol. Paper chromatograms developed with dilute ethanol at pH 3.0 showed the following R_F values: 0.38 (ethanol:water, 80:20), 0.70 (ethanol: water, 70:30), The total activity of the substance can be precipitated by ammonium reineckate, methyl orange, and picric acid, whereas only a fraction of the total activity can be precipitated by flavianic acid (pH between 5.0 and 5.5).

The following tests were negative: Ninhydrin, Pauly, Sakaguchi, Hopkins-Cole, Fehling, Tollens, Molisch, 9-hydrazinoacridin for hydrophilic aldehydes [3]. The biuret reaction was dubious. With sodium periodate the substance gave formaldehyde.

On hydrolysis in 2 N hydrochloric acid an amino acid and a sugar were formed.

following N-terminal amino acids appeared: aspartic acid, glycine, alanin, lysine and methionine. The glutamyl and tyrosyl residues did not show any significant change during the digestion time used. As the value of tyrosine was practically constant during the fibrinogenolysis, the released amounts of the N-terminal amino acids were expressed in relation to tyrosine (see Fig. 1). When the digestion of fibrinogen had proceeded so far that only traces could be coagulated with trombin, approximately one mole lysyl, two moles each of glycyl, aspartyl and methionyl, and three moles alanyl residues were formed from one mole of fibrinogen.

The amino acid has R_F 0.15 (*n*-butanol: acetic acid:water, 4:1:5). A sugar test was made in the following way: The substance was heated in a solution of 2,4-dinitrophenylhydrazine in 2 N hydrochloric acid for a few hours. On cooling, a red precipitate of a tetranitrophenylosazone was formed. On adding a few drops of N sodium hydroxide to a solution of the precipitate in ethanol a blue colour was obtained (modified Bamberger reaction [4]).

The purest product obtained has been tested in broth-dilution assay against different microorganisms.

In mice LD 50 was about 1 200 mg/kg body weight when administered intravenously. In rats 50—500 mg/kg subcutaneously caused no acute toxic symptoms but anuria developed after 3 or 4 days. Examination of the kidneys showed severe tubular damage. Unlike streptothricin, a 1 % aqueous solution did not produce local irritation in rabbits' eyes.

On the Glycogen in *Escherichia coli B*; Variations in Molecular Weight during Growth. I

T. HOLME, T. LAURENT and H. PALMSTIERNA

Bacteriological Department and Chemical Department I, Karolinska Institutet, Stockholm, Sweden

Molecular weight determinations have been performed on glycogen isolated from *Escherichia coli B* at different conditions of growth.

It was observed that the molecular weight increased when glycogen was accumulated by the cells. A decrease was noted when the glycogen was utilized.

In the experiments [1,2] published earlier it was shown that of the glucose residues incorporated into glycogen during an accumulation of this compound in *E. coli B*, those that were incorporated last were the first to be split off during a subsequent growth period, *i.e.* when the glycogen was utilized by the cells. A possible explanation of this could be that during accumulation the "excess synthesis" of glycogen proceeds by addition of glucose residues to the glycogen molecules that are already present at the beginning of the period. The glucose residues incorporated last would constitute a "peripheral tier" on the molecules, and would in turn be those most easily available during a subsequent utilization.

The purpose of the experiments described in this paper was to test this possibility. Molecular weight determinations by the light-scattering method revealed an increase in the molecular weight of the glycogen during the accumulation period, and a decrease during the utilization. These results seem to confirm the hypothesis, but the possibility that other types of glycogen rebuilding may proceed at the same time cannot be excluded.

METHODS

Molecular weight determination. The molecular weight of glycogen from different animal tissues has been measured by osmotic pressure [3], ultracentrifugation [4,5], and light scattering [6-9]. The values reported usually lie within a range of $1-10 \times 10^6$. The most recent report [9] gives values in the range of 50×10^6. Sedimentation studies on glycogen from *Mycobact. tuberculosis* [10] gave the value 12×10^6 and on glycogen from *Aerobacter aerogenes* [11] 9.2×10^6. The shape of the glycogen molecule has been reported to be spherical [12]. The present paper is the first report on glycogen from *E. coli B*. Light-scattering has been used to characterize the molecule.

Measurements were made in a Brice Phoenix Universal Light Scattering Photometer at a wavelength of 4 358 Å. The solutions to be measured were kept in a semioctagonal glass cell. The measurements were performed at 45°, 90° and 135° with respect to the direction of the direct beam. The molecular weight was calculated according to the formula [13]:

$$\frac{K \cdot c}{R_{90}^{\circ}} = \frac{1}{M \cdot P_{90}^{\circ}} + 2B \cdot c$$

where R_{90}° is the intensity scattered at 90° divided by the intensity of the direct beam, c the concentration of glycogen in g/ml, K a constant which includes the refractive increment of glycogen, M the molecular weight, P_{90}° a particle-scattering factor, and B a constant. The refractive increment used [7] was 0.136 ml/g, giving K a value of 2.94×10^{-7}. The particle-scattering factor can be obtained by using the relation $R_{45}^{\circ}/R_{135}^{\circ} = z = f(P_{90}^{\circ})$. This factor, z, is called the dissymmetry. P_{90}° has been tabulated for different values of z for spherical particles [13].

By measuring the scattering at several different concentrations, it was found that within the concentration range used, $2.5 \times 10^{-6} - 50 \times 10^{-6}$ g/ml, the scattering was independent of the concentration, and the constant B was thus zero. This agrees with light-scattering data on other glycogens [9]. The glycogen concentrations have been determined as described earlier [14].

The molecular weight obtained is a weight-average molecular weight, which is higher than the number-average obtained from, *e.g.*, osmotic pressure measurements. If a specimen is highly polydisperse, which is the case with glycogen, the results will be dominated by the highest molecular weight fraction.

It is possible to calculate the diameter of the molecules from dissymmetry data if the shape is spherical [13]. However, this value is a "z-average", which is even higher than a weight-average. The diameter of the molecules was found to be about 750 Å.

The glycogen specimens were quantitatively dissolved in an 0.1 M dust-free sodium chloride solution. The dust had been removed by filtration through a membrane filter with a pore diameter of 200—400 Å. When filtration or high speed centrifugation was used to take away dust from glycogen solutions, a large amount of glycogen was also removed. These solutions were therefore centrifuged in a small laboratory centrifuge in order to remove the largest extraneous particles. The amount of glycogen which sedimented during this centrifugation was within the limits of detection by the method of analysis. After this procedure, there conceivably may still remain some contamination of the glycogen specimens by dust; however this dust does not seem to disturb the measurements to any great extent. For one thing, the scattering from glycogen is very strong. Also, the dust would be expected to give high dissymmetries, but the measurements did not show excessively high values (1.60—2.50), or change if the solutions were kept overnight, when some of the dust ought to have settled. Finally, there was a high degree of reproducibility in the measurements, as shown in Table 1. Stetten *et al.*[9] also came to the conclusion that dust does not disturb the measurements.

Microbiological methods. Freeze-dried cultures of *Escherichia coli B* were cultivated in Friedlein's synthetic medium. Ammonium chloride was the sole nitrogen source and sodium lactate the carbon source. In the deficient media, ammonium chloride was used in 1.3×10^{-3} M (expt. B) or 1.0×10^{-3} M concentrations (expts .C and D). The cultivation methods and harvesting procedures have been reported earlier [14,15].

A typical nitrogen starvation experiment (expt. D) is presented graphically in Fig. 1. The amount of cells inoculated corresponded to about 20 mg of dry cells per litre of culture. The inoculum consisted of a suspension of cells grown for 16—18 h in Friedlein's medium, and washed once in nitrogen-free medium. Three h after the inoculation the dry weight of cells per litre of culture was about 90 mg. During the subsequent 90 min there was only a small increase; this period we call the starvation phase. This phase was interrupted by adding ammonium chloride to the culture. After this addition there was a second growth period. The glycogen per dry weight of cells in one litre of culture is recorded in the same figure. After collecting the cells of each sample by centrifugation, they were freeze-dried, and stored at −20°C until the material was weighed in for analysis.

Chemical methods. The glycogen was isolated by alkaline hydrolysis of the cells (30 % KOH, 100°C, 3 h), followed by precipitation with 66 % ethanol [14]. No shorter time

could be taken for the alkaline hydrolysis, nor could lower concentrations of the KOH be used if a low-nitrogen preparation was to be achieved. It was found necessary to perform the alkaline hydrolysis in new Pyrex tubes, since otherwise material was extracted from the glass, making it impossible to dissolve the glycogen completely. After the introduction of this modification, the molecular weight determinations were reproducible (see Table 1). The glycogen could be stored in neutral water solutions for several days at 0°C without undergoing any change in the molecular weight. The molecular weights of the bacterial

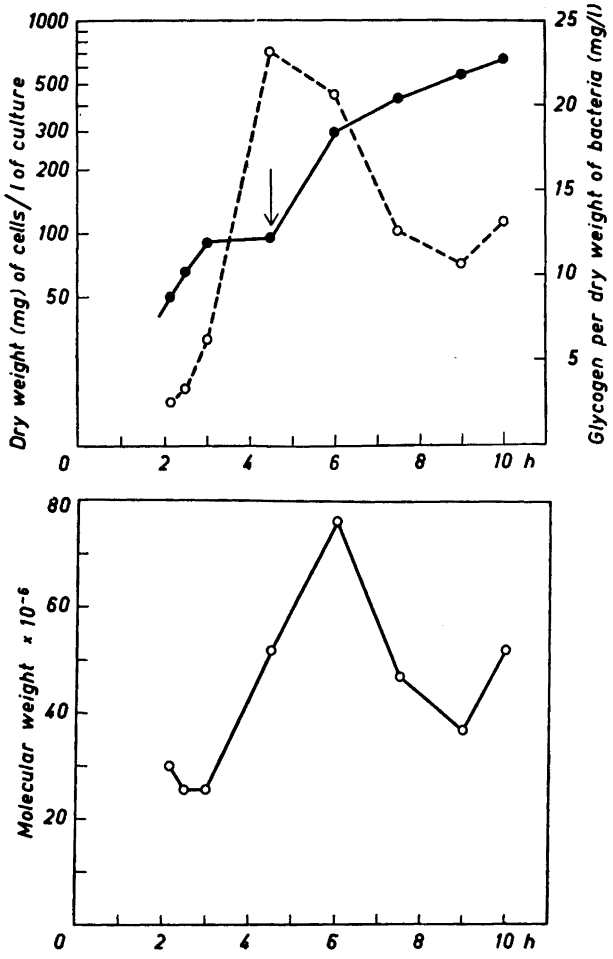

Fig. 1. Experiment D. Nitrogen-starved culture. The curve ● ——— ● represents the dry weight of cells per litre of culture (the glycogen content has been subtracted from the total weight). The arrow indicates the moment when ammonium chloride was added (see the text for further details regarding this experiment). The curve O — — — O represents the glycogen per litre of culture. In the lower part of the figure, the variation in molecular weight is shown.

glycogen isolated by the trichloro-acetic acid method used by Stetten *et al.*[9] were found to be considerably lower than those obtained by the alkaline isolation procedure.

In order to test the reproducibility of the methods used, the following experiment was carried out (expt. A). Cells from a 5-litre nitrogen-starved culture were harvested at 270 min after the inoculation, spun down and freeze-dried. The material was divided into eight equal parts. The glycogen was isolated separately from these samples by the methods described above. One part was taken for determination of the glycogen content of the cells; the molecular weights of the remaining seven samples of glycogen were then determined. The results are recorded in Table 1.

RESULTS

In determining the molecular weight, alkaline hydrolysis was found to be the most reliable method for the preparation of glycogen from *E. coli* cells (Table 1, expt. A).

During the accumulation of glycogen in the bacterial cells, the molecular weight of the glycogen increased considerably. When the glycogen content of the culture (calculated per dry weight of cells in one litre of culture) decreased during a subsequent utilization, the molecular weight decreased again (Table 2, Fig 1). This decrease was demonstrated most clearly in expt. D, in which the glycogen content of the culture reached lower values than in expts. B and C. The results are summarized in Table 2.

DISCUSSION

It is not possible to decide whether the glycogen isolated by one method is more "native" than that isolated by another. If a continuous change in the molecular weights is found during bacterial growth, however, extraction artefacts seem less likely.

On the basis of data obtained from isotope experiments (enzymatic degradation of ^{14}C-labelled rat liver glycogen), Stetten and Stetten [16,17] put forward the hypothesis that the glucose residues incorporated during glycogen synthesis may be added to pre-existing molecules, and preferentially attached to the end groups of these. This view was supported by the experiments reported earlier by Holme and Palmstierna [1,2], who investigated the glycogen metabolism of *E. coli B*. However, another explanation may be that the glycogen is inhomogeneous as regards its metabolic activity.

The possibility of obtaining accurate quantitative data on glycogen synthesis afforded by our system made it probable that molecular weight determinations on the glycogen would give valuable information. Our present results indicate that a correlation exists between the glycogen content of the bacteria and the molecular weight of this substance. However, the fact that the light-scattering method gives weight-average values, made a further analysis of the quantitative data impossible. It will probably be possible to obtain further information by fractionation of the glycogen.

In most cases there is no marked immediate decrease in glycogen per litre of culture after the addition of ammonium chloride to the nitrogen-starved cultures. A possible explanation may be that there has been a considerable overflow metabolism during the starvation period, *i.e.* low molecular intermediates have poured out into the medium [15,18]. These intermediates are possibly more easily utilized by the cells than the glycogen is. During this delay in glycogen utilization an increase in the molecular weight was observed. The explanation of this increase need not necessarily be that there has been a further synthesis of glycogen; it can just as well be due to the formation of larger molecules through the unification of smaller ones.

While this investigation was proceeding. Stetten *et al.*[9] published a work in which the light-scattering method was used for molecular weight determinations of liver and muscle glycogen from rat and rabbit. It was noted that the glycogens were metabolically inhomogeneous with regard to molecular weight.

The reproducibility of our results indicates that the nitrogen starvation technique offers definite advantages in the study of glycogen synthesis, and appears to be well suited for further investigation.

Continuous Culture Studies on Glycogen Synthesis in *Escherichia coli B*

T. HOLME

Bacteriological Department, Karolinska Institutet, Stockholm, Sweden

The correlation between the synthetic rates of nitrogen-containing compounds and of a nitrogen-free substance, glycogen, has been studied in *Escherichia coli B* by the continuous culture technique. The nitrogen source was used as the growth-rate-limiting factor. This kind of limitation did not reduce the synthetic rate of the glycogen in the cells. The net synthetic rate of glycogen was increased by a reduction in the synthetic rate of the nitrogen-containing compounds.

The possibility of maintaining steady-state growth in bacterial cultures was demonstrated in 1950 by Monod [1] and Novick and Szilard [2,3]. Since then a great number of continuous culturing devices have been described (for examples, see Refs. [1–7]), and some experimental work has been reported. Monod and Cohn [8] used the technique in studies on adaptive enzymes, and Novick and Szilard [2,9–11] demonstrated its usefulness in studies of bacterial genetics and physiology. Herbert and collaborators [5], using a 20-litre pilot-plant type apparatus, pointed out the advantages of the technique in industrial fermentation.

A continuous culture system consists in general of a growing bacterial culture, which is fed with a continuous flow of liquid, sterile nutrient medium at a constant rate. The culture volume is kept constant by removal of the bacterial suspension at the same rate as fresh medium enters the culture.

The increase of the bacterial mass in any exponentially growing culture may be expressed by

$$\frac{dx}{dt} = \mu x$$

where x is the dry weight of organisms per unit volume at time t and μ is the specific growth rate. If the flow-rate of fresh medium fed into a continuous culture is called f, the dilution rate, D, will be f/v, where v is the culture volume. In this case the expression for the increase in bacterial mass in the growth vessel is

$$\frac{dx}{dt} = \mu x - Dx$$

Equilibrium will be obtained, if $\mu = D$, *i.e.* if the flow-rate is equal to the specific growth rate. By utilizing the fact that the growth rate in a bacterial culture may be limited by reducing the concentration of one of the essential nutrients in the medium, it is possible to achieve equilibrium over a wide range of growth rates. While the concentration of one of the essential nutrients is low, all others are in excess. The low-concentration nutrient is called the limiting or controlling factor. The concentration of this factor is almost instantaneously reduced when the medium is mixed with the culture, and reaches a level which limits the growth rate. It can be shown that this system tends to attain a self-stabilizing equilibrium, where the growth rate is determined by the flow-rate of the incoming medium, and the bacterial mass is determined by the concentration of the limiting factor.

In equilibrium, the synthetic rate of every component of the cell is equal to the dilution rate, which in turn can be regulated by the experimenter at will to any values that do not exceed the maximum value of μ, *i.e.* the maximum synthetic capacity of the bacterium. Hence it should be clear that the continuous culture method provides definite advantages in the study of synthetic functions of bacteria, since the determinations of the rates of various processes are reduced to measurements of steady-state concentrations.

During continuous culture experiments with *Escherichia coli B* it was noted that the nature of the limiting factor had a profound influence on the chemical composition of the cells. Special attention was paid to the glycogen content of the bacteria. When the nitrogen source was used as the limiting factor, considerable variations in the glycogen content of the cells were noted at different growth rates.

In previous experiments in which conventional cultivation techniques were used Palmstierna [12] found that glycogen accumulated during the lag phase of growth in cultures of *E. coli B*. In collaboration with Palmstierna a number of experiments were carried out, the object of which was to throw light on different aspects of the glycogen synthesis in this bacterium [13–16].

In the experiments described in the present paper, the continuous culture technique has been used in a study of the correlation between the synthetic rates of glycogen and of nitrogen-containing compounds in *E. coli B*.* When the nitrogen source was used as the limiting factor, the synthetic rate of the nitrogen-containing compounds was selectively reduced. The rate of glycogen synthesis was not reduced by this limitation, and it attained its highest values at the lowest synthetic rates of the nitrogen-containing compounds. The main product of synthesis that accumulated inside the cells during nitrogen deficiency appeared to be glycogen.

METHODS

Continuous culture apparatus. In these studies it was possible to use a fairly simple device, which had the advantage of being easily operated. The culture vessel consisted of a 2-litre Erlenmeyer flask which was given a working volume of 1 litre by means of a

* In the present paper "synthesis" always refers to the net synthesis.

tubulature on the wall for removing the emergent bacterial culture. Good mixing and aeration was achieved by placing the flask on a rotary shaker working at 120 r.p.m., and by having the air stream forced through a sintered glass disc and entering the culture fluid as close to the wall of the flask as possible. The neck of the flask was sealed by a rubber stopper which was perforated by glass tubes for the supply of air and fresh medium, and for inoculation. Effluent air left the flask only through the tubulature mentioned, making the transfer of the emergent bacterial suspension to the cooling flask a matter of seconds. The air flow-rate was 1 litre per min, and was indicated by a rotameter. In some instances a small amount of carbon dioxide was added to the air, this also being indicated by a special rotameter. The rotary shaker with the culture vessel operated in a constant temperature-room at 37°C. Fresh medium was stored in 40-litre spherical pyrex flasks and supplied to the culture vessel by means of a hose pressure pump * through latex rubber tubes. The continuously expelled bacterial suspension was cooled on the walls of a cylindrical collecting vessel placed in ice water.

Operation. Deficient medium (40 litres in each storage flask) was sterilized separately. The culture vessel was sterilized containing 1 litre of the complete medium. It was inoculated with bacteria from an agar slant, and growth was allowed to proceed until the cell concentration reached a value of about 2×10^9 cells per ml, corresponding to about 500 mg of dry cells per litre. At this stage the continuous addition of deficient medium was started. In the steady-state, the dry weight of cells per litre of culture was usually kept about 120—200 mg. At the beginning of each experiment a dilution rate of about 0.3 h^{-1} was used. During the first 10 h of the continuous run, it was found necessary to add a certain amount of carbon dioxide to the air in order to prevent a complete wash-out of the cells (see Table 4 and Figs. 4 and 5).

When the steady-state was achieved at the selected flow-rate, two or three samples were taken daily. The duration of the test at each flow-rate was in most cases 2 days, but during a continuous run of 5—6 days at the same flow-rate, the variations in the polulation density and the glycogen content of the culture were found to be within the limits of the experimental errors. The flow-rate was changed to lower or higher values stepwise, big changes always being avoided. After a change of the flow-rate had been effected, the culture was run for about 18 h before sampling of the culture at the new steady-state was commenced. Control of the flow-rate was effected by measuring the volume of the bacterial suspension that had collected during a certain interval.

After a continuous run of about 12—14 days, wall-growth occurred in most cases, and the experiment was terminated. Wall-growth was never tolerated during the continuous run, because it affected both the yield of the bacteria and their glycogen content.

When the volume of the bacterial suspension in the collecting vessel was 800 ml, the cells of this sample were quantitatively spun down and dry weight determination was performed according to the method used by Palmstierna [12]. The freeze-dried material was kept at —20°C until it was weighed in for analysis.

The cell concentration was determined in 1 ml-samples taken directly from the outflowing culture. The bacteria were counted in a counting chamber under the phase contrast microscope.

Organism and culture media. Freeze-dried cultures of *Escherichia coli B* were used throughout. Two media were employed: one with sodium lactate ** and one with glucose *** as the carbon source. In both of the media, ammonium chloride was the sole nitrogen source. This nutrilite was used as the limiting factor in most of the experiments, but one experiment was also carried out with lactate as the limiting factor. In the nitrogen-deficient media, the concentration of ammonium chloride was usually about 1.5×10^{-3} M, but in one experiment a concentration of 3.9×10^{-3} M was used. After sterilization the ammonium-N concentration was determined, in every new batch of deficient medium. In the ex-

Expts. A and B. Carbon source: sodium lactate. Input concentration of ammonium-N: expt. A 20 mg/l; expt. B 22 mg/l. The values given in the last column of the tables represent the amount of glycogen synthesized in one hour per 100 mg bacterial nitrogen. These values were plotted against the dilution rate. The data of the best straight line being fitted by the method of least squares are given below (the values at higher dilutions rates than 0.7 h^{-1} are not included in the calculations). As regards the statistical methods the reader is referred to Fisher [19].

Regression equation: $y = 37.6 - 38.1\,x$
Regression coefficient: -38.1 ± 3.25 ($t = 11.74$; $p < 0.001$)
Correlation coefficient: -0.920 ± 0.030 ($t = 30.7$; $p < 0.001$).

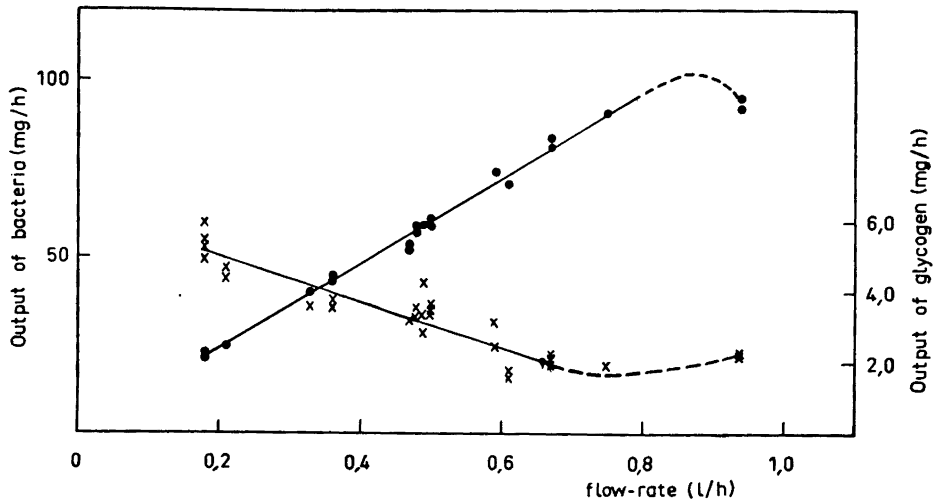

Fig. 1. Output of glycogen and bacteria at different flow-rates. Expts. A and B. Carbon source: sodium lactate. Culture volume: 1 litre. Input concentration of ammonium-N: 20 mg/l (the values of expt. B were corrected to correspond to this input concentration). The dry weight of cells per litre is indicated by dots (the glycogen content has been subtracted from the total dry weight values). The glycogen per litre is indicated by crosses, and the unbroken curve is fitted by the method of least squares.

Chemical methods. The isolation of glycogen and the estimation of the glycogen-glucose were performed as described by Palmstierna [12]. The micro-Kjeldahl method was used for the nitrogen determinations.

RESULTS

In continuous cultures of *Escherichia coli B* steady-state growth was obtained at different growth rates. Two media were employed: one with sodium lactate and the other with glucose as the carbon source. In other respects their composition was about the same. Using the nitrogen source as the limiting factor, specific growth rates * of 0.13—0.94 h^{-1} were established. The glycogen content and the total nitrogen content of the cells were determined. The results are presented in Tables 1 and 2. In experiments A and B (Table 1) sodium lactate was the carbon source; in experiments C and D (Table 2), it was glucose.

* The specific growth rate, μ, is defined by

$$\mu = \frac{1}{x}\frac{dx}{dt} = \frac{d\ (\log_e x)}{dt} = \frac{\log_e 2}{t_d}$$

where t_d is the doubling time, *i.e.* the time required for the concentration of organisms to double.

At equilibrium the specific growth rate (and the specific synthetic rate of every cell constituent) is equal to the dilution rate, D, defined as f/v, where f is the flow-rate in litres per hour and v is the culture volume.

The specific synthetic rate of glycogen increased considerably with decreasing dilution rates. The amount of glycogen synthesized in one hour at an input concentration of 20 mg ammonium-N per litre can be calculated by multiplying the per litre value of glycogen by the dilution rate value. In Figs. 1 and 2 the results are presented in that way. The output of bacterial cells (calculated as dry weight) is also recorded (the glycogen content has been subtracted from the total dry weight of the cells).

The values of the total nitrogen of the cells seemed to form a more accurate basis for the comparison of the synthetic rates of glycogen and nitrogen-

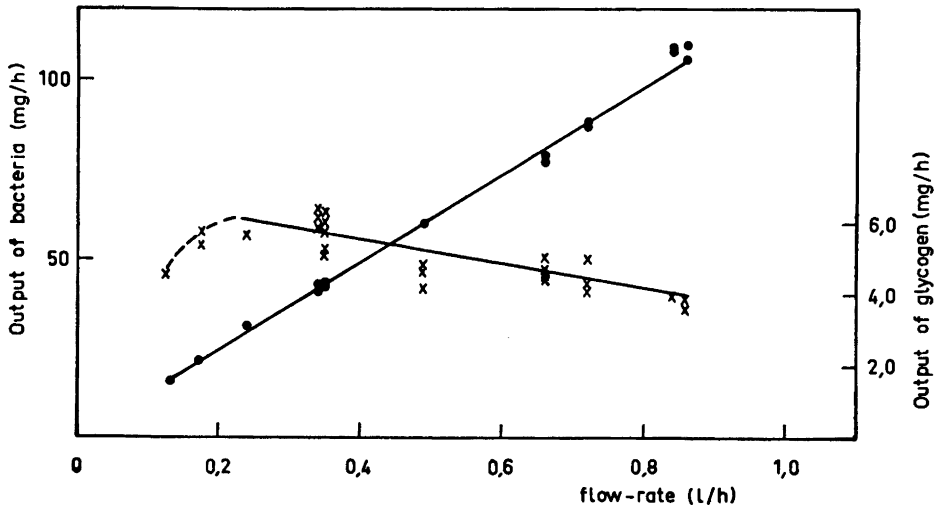

Fig. 2. Output of glycogen and bacteria at different flow-rates. Expts. C and D. Carbon source: glucose. Culture volume: 1 litre. The values are corrected to correspond to an input concentration of 20 mg ammonium-N per litre. For a description of the symbols see Fig. 1.

containing compounds. The amounts of glycogen synthesized in one hour per 100 mg bacterial nitrogen are recorded in the last column of the tables. It is seen that the synthetic rate of glycogen increases considerably when the dilution rate is diminished, *i.e.* when the synthetic rate of the nitrogen-containing compounds is reduced.

In the cultures grown in the lactate medium, the minimum content of glycogen in the continuously cultivated cells appeared to be reached at the highest dilution rates (>0.7 h^{-1}). A slight increase in the synthetic rate of glycogen might consequently have been expected with a further increase in the dilution rate. However, at the highest dilution rate, at which steady-state growth was obtained, the cell concentration was considerably lower than at the lower dilution rates. It is probable that the highest dilution rate, 0.94 h^{-1}, is very close to the maximum value of μ, and thus represents the highest dilution rate that can be attained. The quantitative relationships are best illustrated by the "output" curves in Fig. 1, representing the production of cells and glycogen by the continuous culture.

It appeared that the maximum content of glycogen in the continuously cultivated cells was reached in the cultures grown in glucose medium at the lowest dilution rates (<0.2 h^{-1}). The rate of glycogen synthesis, therefore, decreases at the lowest dilution rates in these cultures (Table 2, Fig. 2).

If the straight lines obtained from the values of the synthetic rate of glycogen in Tables 1 and 2 are drawn to the y axis, both will cut this axis at a value of about 40. This value is comparable with the initial synthetic rate of

glycogen * in batch cultures during nitrogen starvation, *i.e.* during a period when there is no synthesis of nitrogen-containing compounds [13]. This is also the case in the experiment recorded in Table 3, where continuously cultivated cells (dilution rate 0.46 h^{-1}) were used as inoculum in a batch culture. The medium contained no nitrogen source.

It was assumed in the calculations that the small differences in the input concentration of ammonium-N had no influence on the specific synthetic rate of glycogen. It was confirmed by one experiment in which the input concentration was increased to 54 mg ammonium-N per litre that this assumption was justified. The cell concentration was 385 mg dry weight per litre of culture. The synthetic rate of glycogen observed in this experiment was 26.5 ± 0.3 (mg per hour per 100 mg bacterial nitrogen; two determinations) at a dilution rate of 0.51 h^{-1} (carbon source: glucose).

In the continuous cultures where the carbon source was used as the limiting factor, no significant variations in the glycogen content of the cells were observed at different dilution rates. In one experiment in which sodium lactate was used as the limiting factor, glycogen determinations gave the following results: 1.5 % of the dry weight at a dilution rate of 0.33 h^{-1} and 1.1 % at a dilution rate of 0.14 h^{-1}.

Substances causing an absorption in the ultra-violet region poured out into the medium in the cultures with the nitrogen source as the limiting factor. The absorption increased considerably with decreasing dilution rates. The absorption curves for the cell-free culture medium from samples taken at different dilution rates are presented in Fig. 3.

During a certain period after the continuous addition of new medium had been started, it was found necessary to add carbon dioxide to the air

Table 3.

Cells from a continuous culture incubated in nitrogen-free medium. For further details, see the text.

* During the starvation phase in a nitrogen-starved culture the bacterial nitrogen per litre of culture is constant. The value of glycogen increase (calculated as mg glycogen per 100 mg bacterial nitrogen per h) was multiplied with $\log_e 2$ for the comparison with the values obtained in the continuous culture.

Calculated in this way the mean synthetic rate of glycogen during the first hour of the experiment recorded in Table 3 was 45.8.

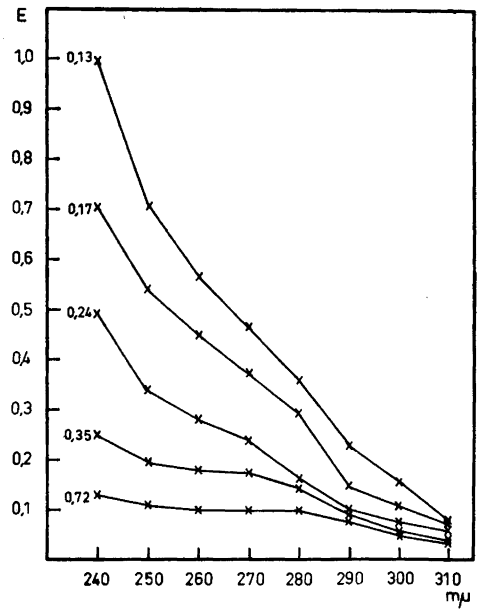

Fig. 3. Specific absorption (E) of the cell-free culture medium at different dilution rates, indicated by the figures at the end of each curve. Measurements were made on samples from expt. D, except those recorded at the dilution rate 0.72 h^{-1}, which were made on a sample from expt. C.

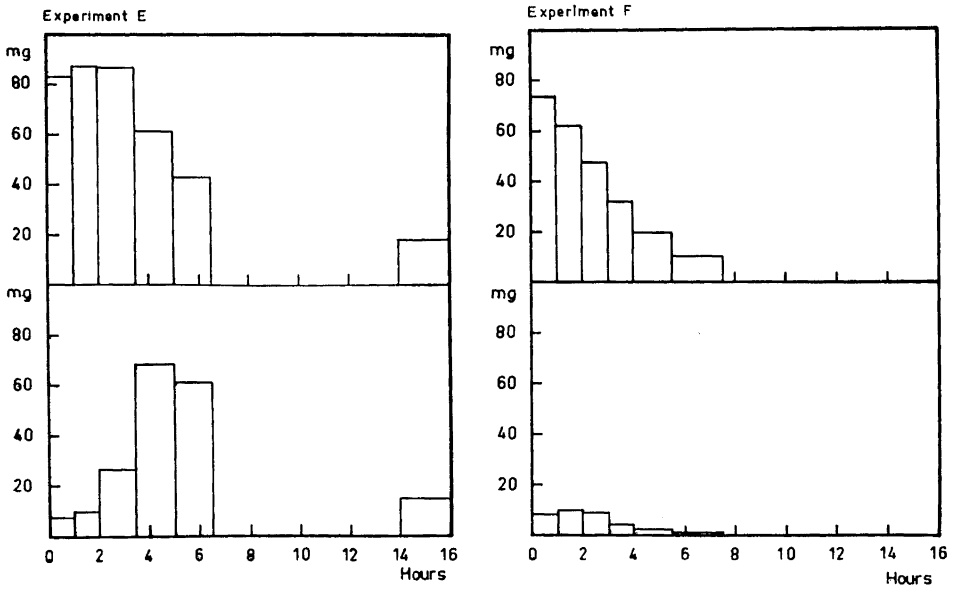

Fig. 4. Expts. E and F. The steeples in the upper parts of the figure indicate the total bacterial nitrogen per litre of culture. In the lower parts of the figure the glycogen per litre of culture is represented. At zero time the continuous addition of fresh medium was started. Dilution rate 0.29 h^{-1}.
Aeration: expt. E: Air+carbon dioxide (5 %); expt. F: Air only.

entering the culture, since otherwise the bacteria were completely washed-out. In order to investigate the role of the carbon dioxide during this period, the following experiment was carried out. Two cultures were allowed to grow in the lactate medium until they reached a cell concentration of about 2×10^9 whereupon the continuous addition of deficient medium (20 mg ammonium-N per litre) was begun. The dilution rate was 0.29 h^{-1} in both cultures. About 5 % carbon dioxide was added to the air entering one of the cultures (expt. E); the other was aerated with air alone (expt. F). The emergent bacterial suspensions were collected and the cells from each sample analyzed (Table 4, Fig. 4). The time required for collecting each sample was 1—2 h (see Table 4).

In expt. E, where carbon dioxide was added to the air, the glycogen content of the cells increased considerably during the first part of the contiunous run. The cell concentration decreased after an initial increase. Fourteen hours after the continuous addition of deficient medium had been started, steady-state concentrations of cells and glycogen were noted. Addition of carbon dioxide to the air in a culture in the steady-state had no measurable influence on the glycogen content of the cells. In expt. F, in which no carbon dioxide was added, the cell concentration decreased immediately. The glycogen content of the cells was low. Forteen hours after the start of the continuous run, no cells could be detected in the counting chamber.

expt. F: Air only.

DISCUSSION

The application of the continuous culture technique to metabolic studies has given valuable information concerning the regulation of the rates of various synthetic processes [8,11]. A substance of general interest, namely glycogen, shown by Palmstierna [12] to be present in *E. coli* cells was the subject of continuous culture studies in the present investigation. Due to its function as a pool of energy and carbon in the cell, the regulation of its synthesis seemed to be of special interest.

Since the glycogen contains no nitrogen, its synthesis is not prevented by nitrogen deficiency in *E. coli* cells. On the other hand, energy-consuming processes like the syntheses of nucleic acids and protein are readily arrested by nitrogen starvation. When the nitrogen source was used as a growth-limiting substance in the continuous culture, the glycogen synthesis proceeded without being reduced by this limitation, and the synthetic rate could be shown to depend on the synthetic rate of the nitrogen-containing compounds.

This system also offers the possibility of studying the influence of various environmental factors on the synthetic rate of glycogen in the bacterial cells, *e.g.* temperature, pH, oxygen tension, concentration of different medium constituents and other substances. In the present investigation it was observed that the rate of glycogen synthesis depended on the nature of the carbon source in the culture medium. At a high synthetic rate of the nitrogen-containing compounds there was a lower synthetic rate of glycogen when lactate was the carbon source than when glucose was used. A possible explanation of this could be that the lactate must undergo a long series of transformations before it can be incorporated into the glycogen. The glucose on the other hand, is more easily incorporated in spite of the rapid breakdown. The difference in the synthetic rates appears to diminish when the synthetic rate of the nitrogen-containing compounds is reduced, *i.e.* when the carbon source is not utilized to any great extent for the synthesis of these compounds and consequently a greater part is available for glycogen synthesis.

It should be pointed out that glycogen appears to be the main substance that accumulates in the cells of *E. coli B* during nitrogen deficiency. This is made probable by the constant values obtained when the glycogen content of the cells is subtracted from the total dry weight. This has also been confirmed by using the nitrogen starvation technique in batch cultures.

As a rough method of estimating the "overflow metabolism" to the medium the ultra-violet absorption of the cell-free culture medium has been determined. The nature of these substances has not been investigated. It has been shown by Dagley *et al.* [20] that pyruvate is poured out at high rates during nitrogen starvation in batch cultures of *Aerobacter aerogenes*.

Different methods for starting the continuous run of the cultures have been applied. In experiment E the method used in the present investigation is demonstrated. Carbon dioxide was added to the air during the dilution period. In experiment F, where no carbon dioxide was added, there was a more rapid decrease than in experiment E during the first two hours, when the concentration of ammonium chloride could not be limiting. During the following period of rapid dilution, the decrease in bacterial nitrogen per litre of culture

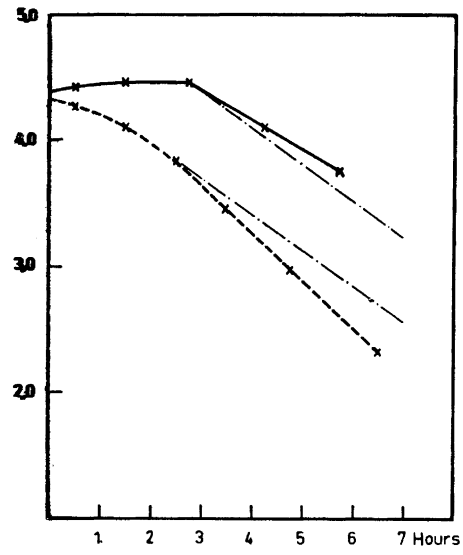

Fig. 5. The first part of the continuous run in expts. E (unbroken curve) and F (broken curve). The curves represent the $\log_e$ for the total bacterial nitrogen per litre of culture (the points are placed at the midpoints of the time intervals represented by the steeples in Fig. 4). The thin broken curves represent the "wash-out rate", *i.e.* the rate at which the organisms initially present in the vessel would be washed out if no growth occurred.

seemed to be more rapid than the wash-out rate (Fig. 5). This may be explained by a lysis of the cells. Fourteen hours after the start of the continuous addition, the number of cells in the culture vessel was less than 10^7 per ml and no increase was noted upon further incubation. In experiment E, where carbon dioxide was added to the air entering the culture the decrease in bacterial nitrogen per litre of culture seemed to be somewhat less rapid than the wash-out rate, but the difference is too small to be considered as significant (Fig. 5). It is however evident that during some part of the time required for stabilizing the culture, there must have been a stimulation of the synthesis of the nitrogen-containing compounds by the carbon dioxide since steady-state concentration of the cells was obtained at fourteen hours after the start of the continuous run.

Obviously the method of nitrogen limitation offers excellent possibilities for the control of glycogen yields. The relationships described might well serve as a model for the commercial production of nitrogen-free substances other than glycogen, cellular or extracellular.

On the Reaction between Urea and Formaldehyde in Neutral and Alkaline Solutions

VII. A Spectrophotometrical Method for Quantitative Determination of Urea and Methylol Ureas of the Reaction Mixture

NILS LANDQVIST

Rydboholms A.B., Rydboholm, Sweden

A spectrophotometrical method for quantitative determination of urea, mono- and dimethylol urea in reaction mixtures of urea and formaldehyde is described. The method is based on a colour reaction between the ureas and *p*-dimethylaminobenzaldehyde in the presence of hydrochloric acid. The influence of side reactions is sufficiently reduced when the reaction mixture sample is added to an excess of a methanolic solution of the reagent.

A comparatively selective colour reaction between urea and *p*-dimethylaminobenzaldehyde in acid solutions was described by Weltman and Barrenscheen [1], and was later on applied for spectrophotometrical determination of urea by Watt and Chrisp [2].

This kind of reaction has been found to be suitable for a quantitative determination of urea, mono- and dimethylol urea of urea-formaldehyde reaction mixtures, when combined with a determination of unreacted formaldehyde.

However, it is necessary to reduce the rates of reaction of the components of the reaction mixture in the presence of a strong acid, in order to obtain consistent results. This condition is realized when the reaction mixture sample is added to a large excess of a methanolic solution of the reagent.

In the following some experiments are described, on which the analytical method is based.

Reagent solution: 10 g/l *p*-dimethylaminobenzaldehyde, dissolved in methanol after addition of 10 ml/l concentrated hydrochloric acid. For one of the experiments a series of different concentrations was used. All chemicals of A. R. quality.

Other chemicals: Urea of A. R. quality; mono- and dimethylol urea prepared in accordance with Walter and Gewing [3]. Cryoscopic molecular weights: 90 ± 1 and 120 ± 1, respectively. Formaldehyde, containing only traces of methanol and formic acid.

Spectrophotometer: Hilger & Watt's "Uvispec". Cell length 20 mm.

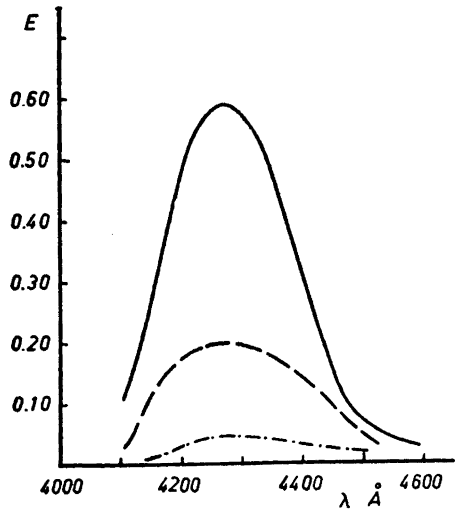

Fig. 1. Extinction curves of 0.0070 M urea (———), 0.0070 M monomethylol urea (— — —) and 0.0120 M dimethylol urea (—·—·). 2 ml sample + 10 ml reagent solution.

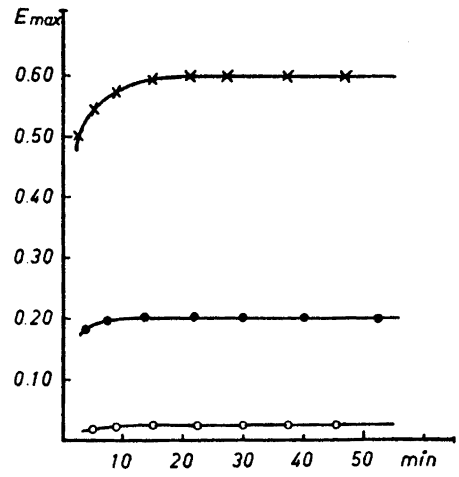

Fig. 2. Relationship between maximum extinction and time delay between preparation and spectrophotometry. 0.0070 M solutions of urea (×), mono- (●) and dimethylol urea (○). 2 ml sample + 10 ml reagent solution.

All experiments were carried out at 20 °C. The samples of the mono- and dimethylol urea solutions were added to the reagent solutions immediately after the dissolution of the ureas in distilled water. This was made in order to avoid disturbances from hydrolysis reactions.

A. To 2 ml of 0.0070 M urea, 0.0070 M mono- and 0.0120 M dimethylol urea, 10 ml of the reagent solution were added. When a constant extinction was attained (after ~20 min), the extinction curves were determined. The results are given i Fig. 1. From a preliminary study it was found that the wavelength at the extinction maximum is constant within the concentration range studied. $\lambda_{max} = 4\,270$ Å.

B. The dependence of the maximum extinction on the time elapsed between reagent addition and spectrophotometry is described by Fig. 2. The curves are related to 0.0070 M solutions, 2 ml sample and 10 ml reagent solution. At lower concentrations the asymptotic values were attained with less delay of time. As found from these measurements, 20—30 min interval between preparation and measurement is sufficient; the value attained is then constant during 1—2 h.

C. The relation between *p*-dimethylaminobenzaldehyde concentration of the reagent solution and maximum extinction is elucidated by Fig. 3, related to 0.0020 M urea, 2 ml sample + 10 ml reagent solution. The same behaviour was also observed for the methylol ureas. Below a reagent concentration of 20 g/l the curves are linear. From these results it might be concluded that the

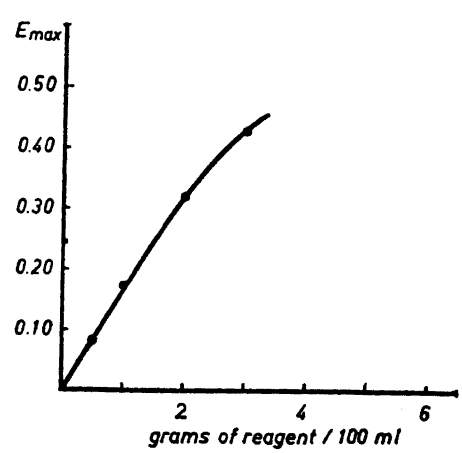

Fig. 3. Relationship between maximum extinction and reagent concentration. 0.0020 M urea. 2 ml sample + 10 ml reagent solution.

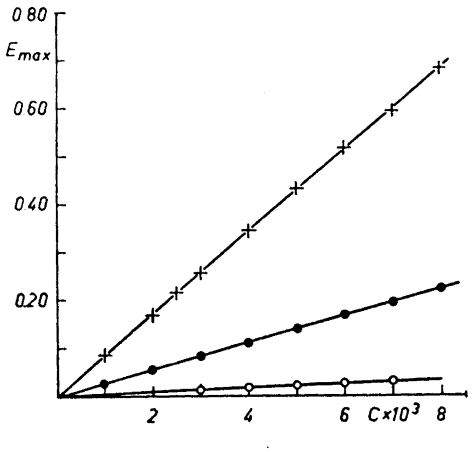

Fig. 4. Relationship between maximum extinction and sample concentration of urea (+), mono- (●) and dimethylol urea (○).

concentration of the coloured compound is determined by an equilibrium between the reagent and the ureas.

D. In Fig. 4 the relation between the concentration of urea, mono- and dimethylol urea of the reaction samples and the maximum extinction is shown. 2 ml sample added to 10 ml reagent solution; 30 min time delay between preparation and measurement.

A good linearity is present over the concentration range studied, $0 < C < 7 \times 10^{-3}$. The curves are described by the expressions:

$$C_U = 1.16 \times 10^{-2} \times E_{max} \quad (1)$$
$$C_M = 3.55 \times 10^{-2} \times E_{max} \quad (2)$$
$$C_D = 23 \times 10^{-2} \times E_{max} \quad (3)$$

where C_U = sample concentration of urea, C_M = sample concentration of monomethylol urea, C_D = sample concentration of dimethylol urea, E_{max} = maximum extinction.

E. To several of the solutions mentioned above formaldehyde was added in amounts corresponding to 0.1 M just before the addition of the reagent solution. No immediate or time dependent influence on the extinction was observed. The same behaviour was also found for mixtures of urea and methylol ureas.

F. In order to investigate whether the expressions (1)—(3) are valid also for solutions containing mixtures of urea and the methylol ureas, such mixtures were studied. The compositions and the results are given in Table 1. As can be seen, there is a good correlation between actual and calculated data. Thus, we can, for the concentration range investigated, accept the expression:

Table 1. Experimental and calculated maximum extinction data of urea, mono- and dimethylol urea solution mixtures.

$C_U \times 10^3$	$C_M \times 10^3$	$C_D \times 10^3$	E_{max}	
			measured	calculated
1.0	5.0	3.0	0.239	0.238
—	5.0	5.0	0.165	0.163
5.0	1.0	—	0.463	0.458
7.0	3.0	2.0	0.690	0.695
2.0	5.0	6.0	0.342	0.338
0.5	4.0	7.0	0.184	0.186
3.0	3.0	3.0	0.350	0.355
0.5	2.0	6.0	0.124	0.125
1.5	4.5	3.0	0.271	0.268
0.75	6.0	2.0	0.238	0.242

$$E_{max} = 86\ C_U + 28\ C_M + 4.3\ C_D \quad (4)$$

This expression is easily derived from (1)—(3).

For a reaction mixture of urea and formaldehyde, C_U° and C_F° are the initial urea and formaldehyde concentrations, and we have, provided mono- and dimethylol urea are the reaction products:

$$C_U^\circ = C_U + C_M + C_D$$
$$C_F^\circ = C_F + C_M + 2\ C_D$$

By means of this and eqn. (4) we obtain:

$$C_U = 0.0292\ E_{max} - 1.51\ C_U^\circ + 0.71\ C_F^\circ - 0.71\ C_F \quad (5)$$

Thus, from a determination of the concentration of unreacted formaldehyde, C_F, and the spectrophotometrical measurement, the actual composition of a reaction mixture might be determined with, from the technical point of view, good accuracy.

The author wishes to thank the board of Rydboholms A. B. for permission to publish this paper, and is also highly indebted to Mr. G. Johansson for his valuable assistance in the experimental work.

On the Reaction between Urea and Formaldehyde in Neutral and Alkaline Solutions

VIII. Studies of the Reactions and Equilibria at Formaldehyde-Urea Molecular Ratios in the Range 1.4—2.0

NILS LANDQVIST

Rydboholms A.B., Rydboholm, Sweden

Reactions and equilibria at formaldehyde-urea ratios in the range 1.4—2.0 were investigated experimentally at 20 °C.

The general reaction rate equation was solved by means of an electronic differential analyser, using rate constants previously determined for the different reactions involved. The equilibrium concentrations were calculated, and both the course of reaction and equilibrium show a good agreement between experimental and theoretically determined data.

An empirical relationship between free formaldehyde and reaction time is also given.

For several practical purposes, *e. g.* the use of methylol ureas for textile finishing purposes, the reaction between formaldehyde and urea at molecular ratios within the range 1.4—2.0 is of a great interest. The purpose of the following paper is to describe studies of the kinetics of such reactions at 20 °C and to give the results of investigations on the equilibrium state of said reactions.

The experiments were carried out by means of the chemicals and the technique previously described [1,9].

We introduce the following symbols:

Concentrations: U = urea; U_0 = urea, initial; F = formaldehyde; F_0 = formaldehyde, initial; M = monomethylol urea; D = dimethylol urea.

Reaction rate constants: monomethylol urea: k = formation, k' = hydrolysis; dimethylol urea: k_1 = formation, k_2 = hydrolysis.

Reaction time: t.

If mono- and dimethylol urea are assumed to be the reaction products, see *e. g.* de Jong and de Jonge [2-4], the general reaction rate equations can be written:

$$\left.\begin{aligned}
&\frac{dM}{dt} = k \cdot U \cdot F - k' \cdot M - k_1 \cdot M \cdot F + k_2 \cdot D \\
&\frac{dD}{dt} = k_1 \cdot M \cdot F - k_2 \cdot D \\
&U = U_0 - M - D;\ F = F_0 - M - 2\ D \\
&t = 0:\ U = U_0;\ F = F_0;\ M = D = 0 \\
&t \to \infty\ \frac{dM}{dt} = \frac{dD}{dt} = 0
\end{aligned}\right\} \quad (1)$$

If we write: $\tau = k \cdot t$; $k'/k = \alpha$; $k_1/k = \beta$; $k_2/k = \gamma$; we have:

$$\left.\begin{aligned}
&\frac{dM}{d\tau} = U_0 \cdot F_0 - [U_0 + (1 + \beta) \cdot F_0 + \alpha] \cdot M + (1 + \beta) \cdot M^2 + \\
&\qquad (3 + 2\ \beta) \cdot M \cdot D - (2\ U_0 + F_0 - \gamma) \cdot D + 2\ D^2 \\
&\frac{dD}{d\tau} = \beta \cdot F_0 \cdot M - \beta \cdot M^2 - 2\ \beta \cdot M \cdot D - \gamma \cdot D \\
&\tau = 0:\ M = D = 0;\ \tau \to \infty\ :\ \frac{dM}{d\tau} = \frac{dD}{d\tau} = 0
\end{aligned}\right\} \quad (2)$$

Since a simple solution to the system of differential equations given above cannot easily be found, numerical solutions were obtained by means of an electronic differential analyser, the EIDA of Chalmers University of Technology, Gothenburg.

The accuracy of the solutions are, as calculated on the initial formaldehyde concentrations, of the order 3 %. Thus, the figures related to high τ values, $\tau > 4$, are moderately accurate. However, the equilibrium concentrations can be calculated exactly, as will be shown later on.

Numerical solutions given as $F = f(\tau)$ curves in Figs. 1—3 refer to 1 M urea and formaldehyde-urea ratios 1.4, 1.6 and 2.0. The buffer concentration was 0.050 M and the temperature 20 °C. The buffers were KH_2PO_4, pH = 6.70; borax, pH = 9.20; Na_2CO_3, pH = 10.00 at cationic strengths as in previous studies [1,5–7]. The reaction rate constants were taken from these studies. As can be seen, experimental data agree closely with the calculated curves. From this is might be concluded that the reaction rate constants, as previously determined under specialized conditions, are applicable to the more general case.

An example of the concentration-reaction time relationships of the reactants and the reaction products is given in Fig. 4, as calculated by means of the electronic differential analyser for 1.0 M urea + 1.7 M formaldehyde, 0.050 M Na_2CO_3, pH 10.00, 20 °C. The concentrations of urea, mono- and dimethylol urea were determined in accordance with Landqvist [9]. As seen from Fig. 4, experimental data and calculated curves are in a close agreement.

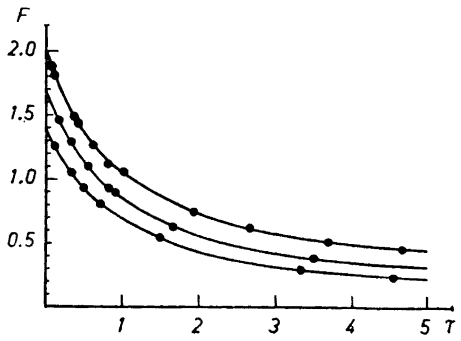

Fig. 1. Relationship between unreacted formaldehyde and the τ-value for the reactions between formaldehyde and 1 M urea at the molecular ratios 1.4, 1.7, 2.0; 0.050 M KH_2PO_4, pH 6.70. Temperature: 20 °C. The curve: theoretical solution, (●): experimental data.

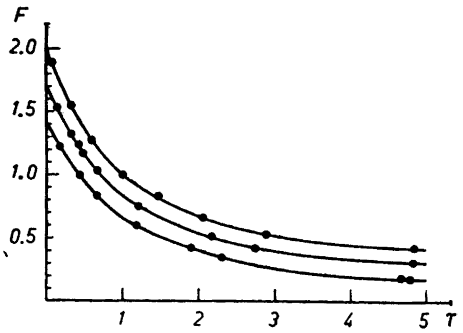

Fig. 2. Relationship between unreacted formaldehyde and the τ-value for the reactions between formaldehyde and 1 M urea at the molecular ratios 1.4, 1.7, 2.0; 0.050 M borax, pH 9.20. Temperature: 20 °C. The curve: theoretical solution, (●): experimental data.

In a previous paper [8], an empirical equation for the relationship between free formaldehyde and the reaction time was given:

$$\log \log \frac{F_0}{F} = A \cdot \log \log t + B \qquad (3)$$

This equation was found to be approximately valid in the case of equal con-

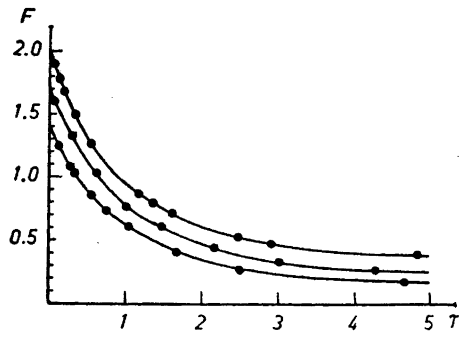

Fig. 3. Relationship between unreacted formaldehyde and the τ-value for the reactions between formaldehyde and 1 M urea at the molecular ratios 1.4, 1.7, 2.0; 0.050 M Na_2CO_3, pH 10.00. Temperature: 20 °C. The curve: theoretical solution, (●): experimental data.

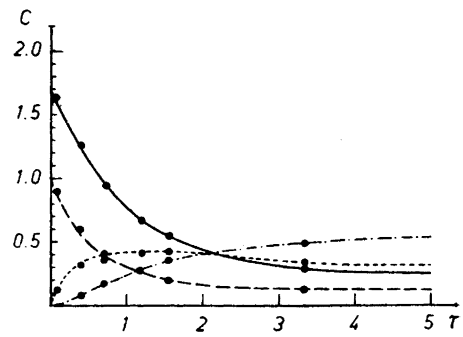

Fig. 4. Relationship between the reaction solution composition and the τ-value; 1.0 M urea and 1.7 M formaldehyde. 0.050 Na_2CO_3, pH 10.00, 20 °C. (———) formaldehyde, (— — —) urea, (. . . . .) monomethylol urea and (—.—.—) dimethylol urea. The curves: theoretical solutions, (●): experimental data.

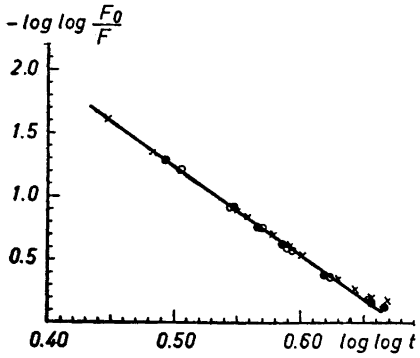

Fig. 5. The expression (3) applied to the reaction between formaldehyde and 1 M urea at the molecular ratios 1.4 (●), 1.7 (○) and 2.0 (×). 0.050 M KH_2PO_4, pH 6.70, 20 °C.

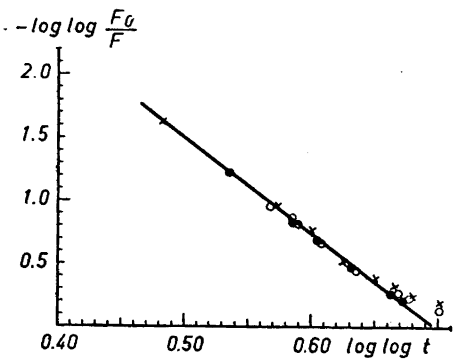

Fig. 6. The expression (3) applied to the reaction between formaldehyde and 1 M urea at the molecular ratios 1.4 (●), 1.7 (○) and 2.0 (×). 0.050 M borax, pH 9.20, 20 °C.

centrations of the reactants. The same equation applied to the solutions mentioned above is shown by the plots of Figs. 5—7. Curves of this kind may be of value when applied to practical work.

From the previous equations we find the equilibrium conditions:

$$t \rightarrow \infty : \frac{\mathrm{d}M}{\mathrm{d}t} = \frac{\mathrm{d}D}{\mathrm{d}t} = 0$$

$$M = \frac{k}{k'} \cdot U \cdot F = K_1 \cdot U \cdot F; \; D = \frac{k_1}{k_2} \cdot M \cdot F = \frac{k \cdot k_1}{k' \cdot k_2} \cdot U \cdot F^2 = K_2 \cdot U \cdot F^2$$

$$U_0 = U \; (1 + K_1 \cdot F + K_2 \cdot F^2); \; F_0 = F + U \; (K_1 \cdot F + 2 \cdot K_2 \cdot F^2)$$

and

$$\frac{F_0 - F}{U_0} = \frac{K_1 \cdot F + 2 \; K_2 \cdot F^2}{1 + K_1 \cdot F + K_2 \cdot F^2} \tag{4}$$

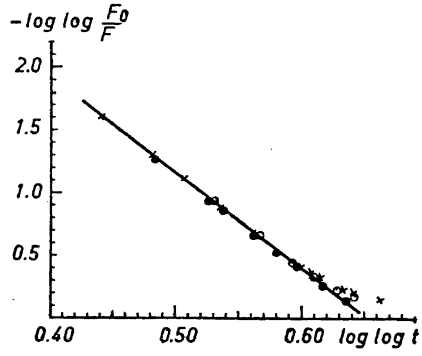

Fig. 7. The expression (3) applied to the reaction between formaldehyde and 1 M urea at the molecular ratios 1.4 (●), 1.7 (○) and 2.0 (×). 0.050 M Na_2CO_3, pH 10.00, 20 °C.

This equation can be solved straightforwardly, or by means of step by step approximation, starting from $F_0 - F \sim F_0$. Thus U, M and D can be calculated. The amounts of unreacted formaldehyde of the reaction solutions previously discussed in this paper were determined up to very long reaction times, ~100 h. From plots of the formaldehyde concentrations *versus* the inverse of the reaction time, the figures corresponding to infinite reaction time were found by extrapolation to zero. Further, these reaction solutions were diluted, and then subject to the same procedure. Finally, for some of the solutions the amounts of urea, mono- and dimethylol urea were determined in accordance with Landqvist [9]. The results can be found in Table 1, and we find that calculated equilibrium data agree with the observed values.

Table 1. Equilibrium data of reactions between formaldehyde and urea at the molecular ratios 1.4, 1.7 and 2.0. Temperature 20 °C. Buffer concentrations: 0.050 M.

On the Reaction between Urea and Formaldehyde in Neutral and Alkaline Solutions

IX. The Influence of Methanol on the Rates of Reaction

NILS LANDQVIST

Rydboholms A.B., Rydboholm, Sweden

The effects of methanol on the rates of the urea-formaldehyde reactions were studied. Decreased rates were observed at increasing amounts of methanol in the case of urea or monomethylol urea and formaldehyde reactions. No influence on the hydrolysis reactions was found.

The formation of a hemiacetal between methanol and formaldehyde was studied cryoscopically as regards the rate constants and the equilibrium. On the basis of the theory that the hemiacetal does not take part in the reactions mentioned above some rate and equilibrium relationships were derived and found to be in agreement with experimental data.

It has been observed by, *e. g.*, Smythe [1] that the presence of methanol in urea-formaldehyde reaction mixtures decreases the rate of reaction. Since commercially available formaldehyde solutions very often contain methanol, added in order to prevent polymer precipitation, the effect mentioned is of some technical importance. The scope of the following paper is to describe some investigations carried out in order to study the influence of methanol on the rates of the different urea-formaldehyde reactions.

It is known that methanol and formaldehyde form a hemiacetal as follows:

$$HCHO + CH_3OH = CH_3 \cdot O \cdot CH_2OH \qquad (A)$$

The role of such a compound in water-methanol solutions containing different amounts of formaldehyde was investigated cryoscopically.

Chemicals: Formaldehyde stock solutions prepared by means of distillation of A. R. paraformaldehyde solutions.

Procedure: All experiments refer to 20 °C. Formaldehyde solutions were prepared by dilution of stock solutions at least 24 h before the addition of the methanol; this was made in order to allow any depolymerisation reactions to be completed. The alcohol was then stirred into these solutions and samples were taken and investigated cryoscopically until a constant value was obtained. This means that from time to time samples at 20 °C

were cooled quickly and the freezing temperature determined; the total change in this temperature was calculated as the difference between the temperatures at extrapolated zero and infinite reaction time. The figure corresponding to zero reaction time was always in good agreement with calculated data.

The equilibrium constants of reaction (A) were calculated from:

$$\frac{C_{CH_3OCH_2OH}}{C_{HCHO} \cdot C_{CH_3OH}} = K \tag{1}$$

The reaction solution composition and the results obtained can be found in Table 1.

Table 1. Equilibrium constants of the hemiacetal formation between methyl alcohol and formaldehyde. 20 °C.

C_{CH_3OH}	C_{HCHO}	K liter / moles
0.100	0.100	0.67
0.100	0.274	0.63
0.250	0.264	0.63
0.500	0.264	0.64
1.018	0.274	0.66
0.250	0.537	0.63
1.018	0.537	0.68
0.500	1.048	0.64
		Av. 0.65

As seen from this table, the K values are acceptably constant, thus reaction (A) may be the most important one under the conditions here studied.

The reaction rate equation can be written:

$$\frac{dy}{dt} = k_1 \, (C_M - y) \cdot (C_F - y) - k_2 \cdot y \tag{2}$$

where

y = concentration of the hemiacetal.
C_M = initial concentration of methanol.
C_F = initial concentration of formaldehyde.
k_1 = formation rate constant.
k_2 = dissociation rate constant.
t = time of reaction.

Initial conditions: $t = 0$, $y = 0$.

The solution to eqn. (2) can be written:

$$\varphi = k_1 \cdot t = \frac{1}{\sqrt{b^2 - 4\,a}} \cdot \ln \frac{(2\,y + b - \sqrt{b^2 - 4\,a}) \cdot (b + \sqrt{b^2 - 4\,a})}{(2\,y + b + \sqrt{b^2 - 4\,a}) \cdot (b - \sqrt{b^2 - 4\,a})} \tag{3}$$

where $a = C_M \cdot C_F$; $b = -\,(C_M + C_F + \frac{1}{K})$; $K = \frac{k_1}{k_2}$.

Applied to the reactions studied, eqn. (3) gives relationships as exemplified by Fig. 1, when the equilibrium constant mentioned previously is introduced into the equation. Since the rate of reaction is high as compared with the experimental technique — *i. e.* the cryoscopic measurements — figures corresponding to the initial part of the reaction could not be obtained. Despite of this lack of accuracy, we may accept

$$k_1 = 0.65 \times 10^{-3} \text{ liter/moles} \cdot \text{sec.}$$

$$k_2 = 1.0 \times 10^{-3} \text{ sec}^{-1}.$$

These figures are related to unbuffered solutions. Since addition of buffer substances considerably increases the reaction rates, no accurate measurements could be made on solutions containing such substances.

The reaction between urea or monomethylol urea and formaldehyde and the hydrolysis of mono- and dimethylol urea were investigated as previously described [2-5]. The solutions were the same as the 0.050 M KH_2PO_4, pH 6.70, series of the previous papers, but they also contained methanol.

The experimental results can be found in Table 2.

Table 2. Reaction rate constants of the reactions between urea or monomethylol urea and formaldehyde and of the hydrolysis of mono- and dimethylol urea in the presence of methanol; 0.050 M KH_2PO_4, pH 6.70, 20 °C.

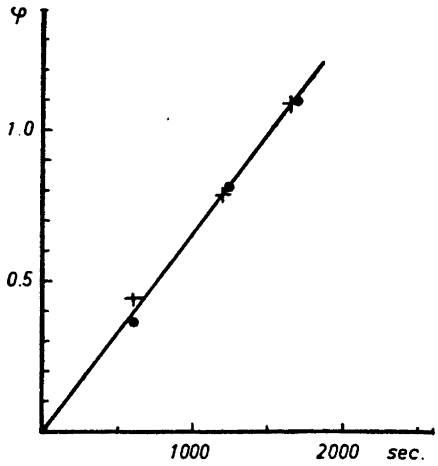

Fig. 1. Relationship in accordance with eqn. (3) of 0.500 M CH_3OH + 0.264 M HCHO (+) and 0.500 M CH_3OH + 1.048 M HCHO (●). 20 °C.

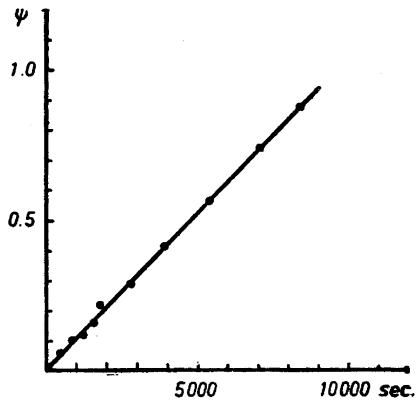

Fig. 2. Relationship in accordance with eqn. (6) for 4.0 M urea + 0.4 M formaldehyde; 0.050 M KH_2PO_4, pH 6.70, 20 °C; 1.34 M methanol.

If we compare the rate constant of hemiacetal hydrolysis and the rate constants of the urea — formaldehyde reaction systems, and remember that the hemiacetal hydrolysis appears to be catalysed by buffer substances, we may assume that the equilibrium in accordance with eqn. (1) is maintained throughout the urea or monomethylol urea and formaldehyde reactions. Assuming that the change in rates of the last mentioned reactions is dependent on the formation of a hemiacetal between methanol and formaldehyde [6], and further that this hemiacetal does not take part in the reactions with urea or monomethylol urea, we find that the rate constants *at zero reaction time* of the urea or monomethylol urea and formaldehyde reactions would be related as follows:

$$\frac{k_0}{k_{C_M}} = \frac{C_F}{C_F - y} \tag{4}$$

where

k_0 = reaction rate constant at zero methanol concentration.
k_{C_M} = reaction rate constant at C_M methanol concentration.
C_{C_F} = initial formaldehyde concentration.
y = initial hemiacetal concentration.

y as calculated from eqn. (2): $y^2 - (C_M + C_F + \frac{1}{K}) \cdot y + C_M \cdot C_F = 0$; symbols defined as previously.

The results, as found in Table 2, can be summarized: Within the range studied, 0—1.3 M methanol,

A. a considerable influence of methanol on the reaction rates of the urea or monomethylol urea and formaldehyde reactions is found;
B. the k_0-figures calculated by means of eqn. (4) are in agreement with the figures related to zero methanol concentration;
C. no effect of methanol on the rates of hydrolysis of mono- and dimethylol urea could be detected.

In the case of the urea-formaldehyde reactions, carried out with an excess of urea present (hydrolysis reactions negligible), we write:

$$\frac{dx}{dt} = k \cdot (C_U - x) \cdot (C_F - x - y)$$
$$\frac{y}{(C_M - y) \cdot (C_F - x - y)} = K = \frac{1}{\alpha} \qquad (5)$$

$t = 0$, $x = 0$;

Here is C_U = initial urea concentration; x = monomethylol urea concentration; k = rate constant and t = time of reaction. Other symbols as previously defined. If $y << C_M + C_F + \alpha - x$, we obtain the following solution to eqn. (5):

$$\psi = k \cdot t = \frac{\alpha + C_M + C_F - C_U}{(C_U - C_F) \cdot (C_U - C_F - \alpha)} \cdot \ln \frac{C_U}{C_U - x} + \frac{\alpha + C_M}{\alpha \cdot (C_U - C_F)} \cdot$$
$$\cdot \ln \frac{C_F}{C_F - x} - \frac{C_M}{\alpha \cdot (C_U - C_F - \alpha)} \cdot \ln \frac{C_F + \alpha}{C_F + \alpha - x} \qquad (6)$$

An example of the relationships according to this equation, plotted from experimental data, $C_M = 1.34$, $C_U = 4.0$, $C_F = 0.40$, in shown by Fig. 2. As seen a good linearity and agreement with the corresponding rate constant from Table 2 is present.

As a result of the fact that only the forward reaction rates are influenced by the presence of methanol, the equilibrium formaldehyde concentration, as determined analytically, may also be dependent on the amount of alcohol in the reaction mixtures.

Under the conditions used for the polarographic analysis of the amount of equilibrium formaldehyde of the reaction mixtures, all hemiacetal is completely hydrolysed. (The figures obtained on formaldehyde solutions with and without methanol present are the same, when samples of the solutions are added to the supporting electrolyte in accordance with the previous paper [2].) Thus, the analytically determined "equilibrium" formaldehyde concentration $C_{F\infty}$ is related to the concentration of "free" formaldehyde $C^{\circ}_{F\infty}$, *i. e.* the amount in actual equilibrium with urea, mono- and dimethylol urea, as follows: $C_{F\infty} = C^{\circ}_{F\infty} + y$; y is the concentration of the hemiacetal.

Eqn. (1) can be written

$$\frac{y}{(C_M - y) \cdot C^{\circ}_{F\infty}} = K \qquad (7)$$

Symbols defined as previously. If we combine this expression with $C_{F_\infty} = C^\circ_{F_\infty} + y$, we obtain:

$$C_{F_\infty} = C^\circ_{F_\infty} + \frac{C_M}{1 + \frac{1}{K \cdot C^\circ_{F_\infty}}} \quad (8)$$

From above we see that $C^\circ_{F_\infty}$ is independent of the presence of methanol and can be found from a determination of the analytical amount of formaldehyde in the urea-formaldehyde reaction mixtures at zero alcohol concentration. The validity of eqn. (8) is exemplified by the experimental data, extrapolated to infinite reaction time, obtained for the reactions between monomethylol urea and formaldehyde in accordance with the experiments of Table 2. The results are as follows:

$C_{methanol}$	C_{F_∞}	
	measured	calculated
0.00	0.22 *	—
0.22	0.25	0.25
0.85	0.33	0.33
1.47	0.40	0.39

* Thus, $C^\circ_{F_\infty} = 0.22$.

The principle introduced is, of course, generally applicable to these problems.

The influence of methanol on the reaction rates may also be attributed to influences on the ion activities of the catalysts. However, the behaviour of the mono- and dimethylol urea hydrolysis reactions, as seen from Table 2, shows that such effects may be negligible.

The conclusions to be drawn from the investigations described in this paper may be: The reduction in reaction rates of the urea or monomethylol urea and formaldehyde reactions caused by methanol depends mainly on the formation of a hemiacetal between methanol and formaldehyde. The hemiacetal does not take part in the reactions, and the equilibrium conditions of the hemiacetal are maintained throughout the reactions between the ureas and the formaldehyde.

The author wishes to thank the board of Rydboholms A. B. for permission to publish this paper, and is also indebted to Mr. A. Olofsson and Mr. L. Uppström for valuable assistance in the experimental work.

On the Reaction between Urea and Formaldehyde in Neutral and Alkaline Solutions

X. Notes on the Reaction Mechanism

NILS LANDQVIST

Rydboholms A.B., Rydboholm, Sweden

The rates of the reactions of the urea-formaldehyde system are compared with other experimental data connected with urea and formaldehyde. The conclusions drawn from such comparisons are partly in favour of previous assumptions, partly not.

Some of the conclusions are: It is probable that a tautomer of urea may be the activated state for reactions with formaldehyde, and the tautomer may be of a zwitter ion structure. If the reactive compound would be an anion, the anion is not present in any considerable quantities prior to the reaction collisions. Only dehydrated formaldehyde or a resonance structure of dehydrated formaldehyde may react with urea or monomethylol urea. The rates of the depolymerisation, dehydration or hydration reactions of formaldehyde are of such a magnitude that they do not influence the rates of the reactions of the urea-formaldehyde system. The buffer catalysis of the urea-formaldehyde reactions is probably not simply connected with a formation of a buffer-formaldehyde complex prior to the reactions with urea or monomethylol urea.

Some of the previous theories connected with the urea-formaldehyde reaction mechanism are:

A. An anion of urea is the reactive compound in reactions with formaldehyde [1–5].

B. Only dehydrated formaldehyde reacts with urea or monomethylol urea [1,2,4–6].

C. In concentrated solutions the slow depolymerisation of formaldehyde polymers influences the urea-formaldehyde reaction rates [7].

D. The main influence of the temperature on the urea-formaldehyde reactions is due to changes in the equilibrium between hydrated and dehydrated formaldehyde [4,5].

E. The hydrolysis of methylol ureas catalysed by hydroxyl ions is connected with a dissociation of the OH group of the compound: $—OH + OH^- = —O^- + H_2O$. The rate of hydrolysis is proportional to the concentration of the $—O^-$ compound [6].

THE STATE OF UREA SOLUTIONS

I. There are several reasons to assume that urea tautomers exist. In favour of this assumption is:

X-Ray analysis shows a decrease in the bond length between carbon and nitrogen atoms. This is a typical effect of resonance hybrids [8].

Raman- och infrared spectra of solid urea show that the force constants of the C — N and C = O bonds are 35 % above, respective 39 % below the expected figures. The occurrence of hydrogen bonds is not found to be probable [9]. The presense of such bonds was assumed by another author [10], and the occurrence of tautomers representing any considerable fraction of the total amount of urea was not found to be probable. However, in this latter investigation no force constant calculations were made. The differences in opinion are also connected with differences in the interpretation of the absorbtion bands.

II. A urea tautomer may be of a zwitter ion structure, and the reasons for this assumption are:

The dielectric constant decreases considerably when urea is added to water, and the same effect is produced by amino acids [8].

The melting point of urea is considerably above the figure to be expected. Amino acids show the same behaviour [8].

III. No alkaline dissociation of urea could be detected when titrations were made with a hydrogen electrode for the pH measurements [11].

As mentioned in a previous paper [12], pH measurements in highly alkaline solutions by means of hydrogen electrodes require a high degree of hydrogen purity. In order to examine the investigation referred to above, the titration curves of 1.0 M urea and of distilled water at 20 °C after addition of HCl have been determined by means of the glass electrode differential method [12]. Accuracy: $\pm$ 0.02 pH. The results are shown by Fig. 1. From this diagram it might be concluded that if any alkaline dissociation of urea occurs, $pK > 13$. Thus, the previous result is confirmed.

THE STATE OF FORMALDEHYDE SOLUTIONS

IV. In concentrated solutions is the formaldehyde partly present as linear polymers [13].

V. The rate of depolymerisation of the polymers is highly dependent on pH and temperature. A rate minimum exists in the pH range 3—4. From studies below and above this range the specific catalytic constants of hydrogen and hydroxyl ions were found to be 3.7 and 3.7×10^7 liter/moles $\times$ sec, respectively, at 20 °C. The activation energy is 17.4 kcal. The reaction is mainly monomolecular, and is assumed to include the formation of a polymer zwitter ion. Correspondingly, the polymerisation reaction would involve a monomer zwitter ion [14].

VI. From diamagnetic measurements it was found that the equilibrium between polymeric and monomeric aldehyde is dependent on pH; also at pH 10 the dependency is of a considerable magnitude [15].

In order to investigate this result further, cryoscopic measurements have

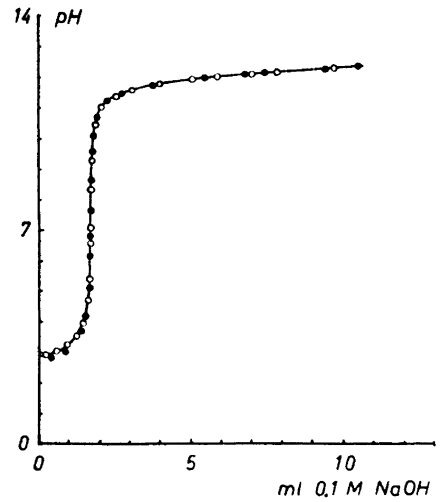

Fig. 1. Titration curve of 1.0 M urea (O) and of water (●) after addition of HCl to pH~3. 20 °C.

been made on pure formaldehyde solutions, pH 5.5, and after addition of NaOH to pH 10. A stock solution of formaldehyde, 12.6 M, was prepared by distillation of a paraformaldehyde-water mixture, and allowed to attain equilibrium before it was used for the experiments. The stock solution was then, with and without addition of NaOH, diluted to concentrations in the range 0—6 M. Temperature 20 °C. The cryoscopic measurements were made immediately after the dilution and after 24 h storage. The results obtained are shown by Table 1. As seen, there is a considerable deviation from unity in the $(t_C—t_0)_{pH\ 10}$ / $(t_C—t_0)_{pH\ 5.5}$ ratios * when the measurements were made immediately after the dilution. However, after the storage such a devia-

Table 1. The ratios between the differences in freezing temperatures at the formaldehyde concentrations C and zero at pH 10.0 and 5.5 when the measurements are made immediately after dilution from a 12.6 M stock solution and after 24 h storage. Temperature 20 °C.

$\sum_{n=1}^{\infty} nC_{(HCHO)_n}$	$(t_C-t_0)_{pH\ 10.0}$ / $(t_C-t_0)_{pH\ 5.5}$	
	Immediate measurements	After 24 h storage
1.0	1.67	1.00
2.0	1.43	1.00
3.0	1.35	1.00
4.0	1.31	1.00
6.0	1.28	1.00

* t_C and t_0 are the freezing temperatures at the formaldehyde concentrations C and zero, respectively.

tion does not exist. This effect may be a function of differences in rate of depolymerisation: after 24 h storage the equilibrium is probably attained at both pH values. Thus, it might be concluded that the pH influence referred to above is not found when the solutions are allowed to attain equilibrium conditions.

VII. The state of monomeric formaldehyde is described as an equilibrium between methylene glycol and dehydrated formaldehyde, and this equilibrium is highly in favour of the glycol [13]. The equilibrium constant [16,17] is $\sim 10^{-4}$. ($K = C_{HCHO} / C_{HOCH_2OH}$)

VIII. Both an acid and alkaline dissociation of formaldehyde is present [14,18,19]. At 20 °C the dissociation constants are: $pK = 5.8$ and 13.4, respectively.

IX. The methylene glycol dehydration is catalysed by buffer substances [17,20]. The activation energy of the dehydration reaction is 14 kcal [16]; the figure corresponding to the hydration reaction is close to zero [17]. The catalysis by buffer substances as studied in a previous paper [17], is further exemplified by Table 2.

X. The composition of formaldehyde solutions can be summarized as follows [21]; the data refer to 20 °C.

ΣC_{HCHO}	% polymers	% monomer
0.67	1	99
1.67	11	89
5.00	36	64
9.33	59	41

The temperature influence on the composition of the solutions was exemplified by the fact that the amount of polymers is below 1 % in 0.7 M solutions at 45 °C and in 7.3 M solutions at 100 °C.

Table 2. Polarographically determined dehydration rate constants of methylene glycol. Temperature 20 °C.

Analytical C_{HCHO}	Buffer *	pH	C_{buffer}	$k \times 10^2$ sec^{-1}
0.0157	KH_2PO_4	6.70	0.100	5.9
			0.050	3.4

* To all solutions such amounts of the chloride of the buffer cation was added that a cationic strength corresponding to the most concentrated solution was obtained.

THE UREA OR MONOMETHYLOL UREA AND FORMALDEHYDE REACTIONS

When the collision theory of reaction will be used here for discussions, this does not mean that the theory is generally accepted. However, the frequency factors calculated can be used as a base for probability discussions: from a distribution curve, made from a great number of experimental data [22], it can be seen that 8 % of the frequency factors exceed 10^{13}, and only 4 % exceed 10^{14}.

In the following the calculations refer to data given in a series of previous papers [23–26]. The activation energy to be used is 15.4 kcal [27], equal for both the reactions.

The rate constants of the reactions between urea or monomethylol urea and formaldehyde are, within the range studied, 2×10^{-5} —2×10^{-3} liter/moles × sec. 20 °C, pH 6.70—11.50. Not only the formation reaction, but also the hydrolysis is catalysed by buffer substances [1,5,23–26]. The rate constants mentioned correspond to the frequency factors 5×10^{6} —5×10^{8}, *i.e.* the values are considerably below the figure to be expected from the collision theory, $\sim 3 \times 10^{11}$.

However, if we apply the assumption (B, see above) that only dehydrated formaldehyde reacts, and use the equilibrium constant 10^{-4} for the methylene glycol—fomaldehyde equilibrium (VII), the "corrected" rate constants corresponding to this would be 0.2—20 liter/moles. sec., and the frequency factors 5×10^{10} —5×10^{12}. When we compare these figures with the probability of different frequency factors as mentioned above, we find that if the dehydrated aldehyde is the formaldehyde reactant, the reactive structure of urea probably ought to be at least 1 % of the total amount. As previously mentioned (A,B), several reaction mechanism theories include the assumption that an anion of urea reacts with dehydrated formaldehyde. Since $pK > 13$ (III) for the formation of such an anion, it is not very probable that a reaction mechanism of this kind would be of any considerable importance in neutral and moderately alkaline solutions, if the anion is assumed to exist prior to the reaction stage. The complex relationships between pH and the logarithm of the reaction rate constants extrapolated to zero buffer concentration [23,24], show that the reaction mechanism is not solely including the presence of an anion of urea, as regards the effect of pH on the rates. Further, the catalytic effect of buffers cannot simply be explained by assumptions on the formation of the anion prior to the reaction stage.

The order of the dissociation constants of formaldehyde (VIII) shows that it is not very probable that formaldehyde ions would be of importance for the reactions in neutral and moderately alkaline solutions.

At this stage of the discussion some of the previous experimental results ought to be examined. From one of the papers [23] (Fig. 9 of Ref.[23]) it is seen that the rate relationship curves of the equimolecular urea—formaldehyde reactions are practically independent of the reactant concentrations in the interval studied, 0.5—4 M, 20 °C. As regards the monomethylol urea—formaldehyde reactions, the same behaviour was observed [24] in the studied range, 0.25—1 M, 20 °C. From above (X) it is known that at the upper concentrations of the ranges mentioned, the fraction of formaldehyde polymers is not

negligible. This would mean that the monomer fraction decreases when the concentration increases, and the fraction of the dehydrated formaldehyde too. A consequence of this would be a decrease in the rate constants.

This decrease in the concentration of the dehydrated aldehyde is exemplified by some data previously given [28]. When repeating the experiments on which these data are based, a fairly good agreement with the 60 °C figures was obtained. At 30 °C the very low absorption did not permit any accurate calculations.

An explanation to the non—influence of the presence of a considerable fraction of polymeric formaldehyde may be that collisions involving polymers also are active for producing a state of the aldehyde which is able to react with urea. The number of collisions is, from the theoretical point of view, more dependent on the number of HCHO groups than on their state: polymers or monomers.

This is seen from the well-known expression

$$Z = \sigma_{1;2}^2 n_1 n_2 \sqrt{8\pi RT\left(\frac{1}{M_1} + \frac{1}{M_2}\right)}$$

Z = number of collisions pr ml and sec between the molecules 1 and 2. $\sigma_{1;2}$ = sum of molecular radii, n_1 and n_2 = number of molecules pr ml. M_1 and M_2 = molecular weights. When the number, n, of one of the molecules decreases by polymer formation, σ increases since polymerisation means an increase in molecular dimensions.

Another explanation could be that a concentration effect connected with the formaldehyde is compensated by an opposite effect connected with the urea. When examining the results of the previous paper [23] (Table 1 and Figs. 15 and 16 of Ref.[23]), we find that such an assumption is improbable.

As mentioned previously, (V), the specific catalytic constant of hydroxyl ions for the formaldehyde polymer depolymerisation is 3.7×10^7 liter/moles $\times$ sec at 20 °C. If we compare this figure with the data of Table 2, we find that the rates of depolymerisation considerably exceed the rates of methylene glycol dehydration. Thus, when dehydrated formaldehyde is liberated in solutions containing polymers, the rate of methylene glycol dehydration might be the rate determining step.

It may also be of some interest to compare the catalytic effect of some buffer substances at a constant cationic strength on the dehydration rate constants of methylene glycol, as given in Table 2, with the catalytic effect of the same buffers on the reactions of the urea—formaldehyde system [23–26]. Such a comparison is given in Table 3, where the constants of the equation describing the rate constant — buffer concentration relationship

$$k = k_0 + a \cdot C_{\text{buffer}} \qquad (1)$$

can be found. k = rate constant at the buffer concentration C_{buffer}, k_0 = rate constant at the extrapolated zero buffer concentration.

If we examine the data of Table 3, we find that the rates of methylene glycol dehydration is considerably greater than the figures related to the urea—formaldehyde system. Thus, the dehydration rates have no influence on the rates of the urea—formaldehyde forward reactions. Since the hydration

Table 3. The constants of eqn. (1) of the methylene glycol dehydration and of the urea-formaldehyde reactions. Temperature 20 °C. Dehydration and hydrolysis reactions: k_0 sec^{-1}; a liter/moles · sec, Formation reactions: k_0 liter/moles · sec, a liter^2/moles^2 · sec.

Reactioo	Buffers						$a_{KH_2PO_4}$: a_{borax} : $a_{Na_2CO_3}$
	KH_2PO_4, pH 6.70		borax, pH 9.20		Na_2CO_3, pH 10.00		
	$k_0 \times 10^5$	$a \times 10^5$	$k_0 \times 10^5$	$a \times 10^5$	$k_0 \times 10^5$	$a \times 10^5$	
Methylene glycol dehydration	1 200	45 000	23 000	34 0000	41 000	18 0000	1 : 7.6 : 4.0

$H_2N \cdot CO \cdot NH \cdot CH_2OH$ + HCHO	0.9	60	1.5	20	8.1	71	1 : 0.33 : 1.2
$H_2N \cdot CO \cdot NH \cdot CH_2OH$ hydrolysis	0.09	5.1	0.15	1.5	0.21	5.5	1 : 0.29 : 1.1
$HOCH_2 \cdot NH \cdot CO \cdot NH \cdot CHOH_2$ hydrolysis	0.11	8.7	0.18	2.4	0.72	7.3	1 : 0.28 : 0.8

reaction rates are 10^4 times greater than the dehydration rates, the same conclusion can be drawn regarding the hydrolysis reactions of the methylol ureas.

Another conclusion which might be drawn from Table 3 is that the mechanisms of methylene glycol dehydration and of the urea—formaldehyde reactions are probably not identical. This since the catalytic effect of the different buffers on the different reactions deviates considerably, as seen from the $a_{KH_2PO_4}$: a_{borax}: $a_{Na_2CO_3}$ ratios. The ratios connected with the urea—formaldehyde reactions are practically identical for all of these latter reactions. Thus, the catalysis of the rate determining step of the urea—formaldehyde reactions is probably not simply connected with the formation of an activated buffer—formaldehyde complex during the dehydration reaction, a complex which would represent an activated state for reactions with urea or monomethylol urea. However, the catalysts, *i.e.* buffers, H_2O and OH^-, increase the prior formaldehyde depolymerisation and dehydration reactions to such an extent that these reactions do not influence the rates of the urea—formaldehyde reactions.

Since polarographic investigation on formaldehyde in connection with the urea-formaldehyde reactions have previously [4] been used for discussions (A, B, D) regarding these reactions, some of the interpretations given will be examined.

The extent of formaldehyde dehydration was estimated from the ratios between actual "formaldehyde wave height" and the "total dehydrated wave height". The "total dehydrated wave height" was assumed to refer to a less steep slope appearing at increased temperatures when a log $i = f(1/T)$ curve is plotted from experimental data obtained on formaldehyde solutions containing buffer substances; (i = polarographic limiting current, T = temperature in °K). As easily seen from a previous paper [21], the change in slope mentioned does not mean that the formaldehyde is completely dehydrated; the less steep

slope appears when the rate of methylene glycol dehydration exceeds the rate of diffusion of this substance to such an extent that the latter rate controls the polarographic electrode process.

It was further found that the following expression, derived from the Arrhenius equation:

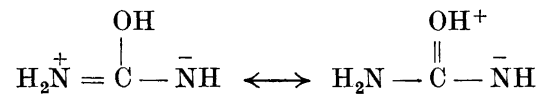
$$\log \frac{k_2}{k_1} = \frac{\Delta E_a}{\Delta E_{aa}} \cdot \log \frac{i_2}{i_1} \qquad (2)$$

is in a good agreement with experimental data. k_2 and k_1 = rate constants of the urea-formaldehyde reactions at two different temperatures but at the same buffer composition. i_2 and i_1 = the corresponding polarographic limiting currents of formaldehyde under the same conditions. ΔE_a and ΔE_{aa} = the "activation energies" of the urea-formaldehyde reaction, respectively the polarographic limiting current of formaldehyde. It is easily seen that eqn. (2) is self-consistent:

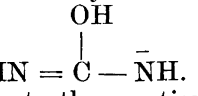
$$\log \frac{k_2}{k_1} = \log Z_k - \log Z_k - \frac{\Delta E_a}{M \cdot R} \cdot \left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

$$\log \frac{i_2}{i_1} = \log Z_i - \log Z_i - \frac{\Delta E_{aa}}{M \cdot R} \cdot \left(\frac{1}{T_2} - \frac{1}{T_1}\right)$$

(M = ln 10)



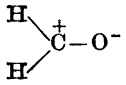
and thus eqn. (2) is obtained from these expressions. Any pair of reactions will give the coincidence observed, provided they obey the Arrhenius equation.



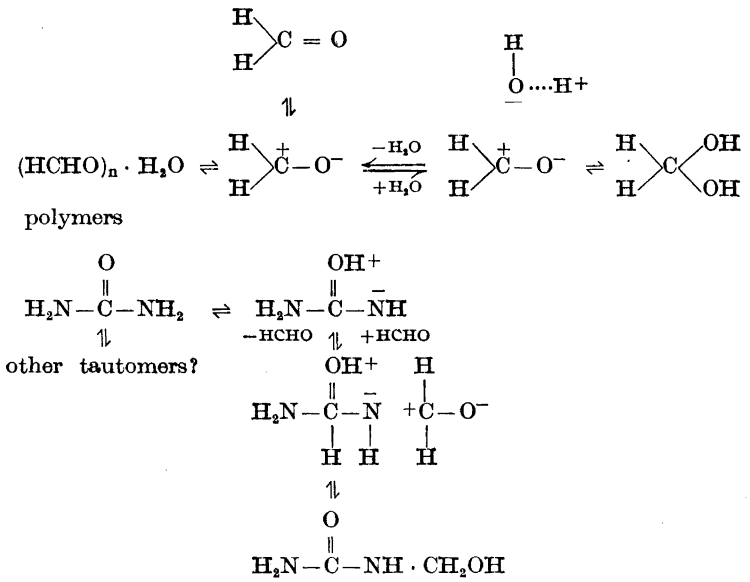
Finally, a relationship between urea-formaldehyde reaction rate constants and the polarographic limiting currents of formaldehyde at different pH values was given. However, this relationship is purely empirical [29].

It has previously been stated that the influence of the temperature on the urea—formaldehyde forward reaction rates is mainly due to changes in the equilibrium between hydrated and dehydrated formaldehyde (D); this assumption is also verified by comparisons between the activation energies referred to in this paper. Thus, the formation of an active state of urea would not be connected with any considerable change in energy.

Since our present knowledge of the state of urea in water solutions is highly limited, it is difficult to give any statement regarding the activated form of urea. However, it seems to be probable that urea tautomers exist, and that they may represent a considerable fraction of the total amount (I). Further, a zwitter ion structure of a tautomer is not improbable (II).



It has previously been assumed [3] that the urea structures



would be of importance for the urea—formaldehyde reactions. (The anion assumed to be necessary for the reactions would be obtained mainly through ionization to  The low probability of the formation of such an ion prior to the reaction with formaldehyde as a part of the reaction mechanism has been discussed above.)

The structures shown above may be in agreement with the requirements which follow from the experimental results regarding the state of urea previously mentioned in this paper. Further, a nitrogen atom is activated as a nucleophilic center.

In the polymerisation reactions of formaldehyde, a zwitter ion was assumed to be of importance (V), and the structure of the zwitter ion would be:

This structure may simply be regarded as a symbol for a resonance state of the dehydrated formaldehyde molecule, where the carbon atom is activated as an electrophilic center. With reference to the previous discussions regarding the formaldehyde polymers, and if we assume that the formaldehyde zwitter ion is in an activated state for both the hydration—dehydration reaction and for the reactions with urea or monomethylol urea, we get, *e.g.*, the following example of a possible reaction mechanism:

The proton exchange may be catalysed by proton donors and proton acceptors, *i.e.* buffer substances, and may represent the rate determining steps of the reactions.

A similar reaction scheme can also be applied to the monomethylol urea—formaldehyde system.

It will here be stressed that this scheme ought to be regarded as an example of a *possible* and not of a highly probable reaction mechanism description. Our present knowledge does not allow any conclusive statements.

THE HYDROLYSIS REACTIONS

A hydrolysis reaction mechanism previously assumed (E) may be within the scope of the scheme given above.

The shape of the rate constant—C_{OH^-} curve was shown to be in favour of the assumption that the anion of the methylol compound can be regarded as the activated complex for the hydrolysis reaction [6].

However, it is interesting to note that an assumption that the ionic form does *not* react, *i.e.* solely the -OH compound would be reactive and subject to a hydroxyl ion catalysis, is "verified" by the same experimental results.

This is found from the following:

$$R \cdot CH_2OH + OH^- = R \cdot CH_2O^- + H_2O$$

$$\frac{C_{R \cdot CH_2O^-}}{C_{R \cdot CH_2OH} \cdot C_{OH^-}} = K$$

$$C_{R \cdot CH_2OH} + C_{R \cdot CH_2O^-} = C_{total}$$

and

$$\frac{C_{total}}{C_{R \cdot CH_2OH}} - 1 = K \cdot C_{OH^-}$$

If only $R \cdot CH_2OH$ reacts and under the influence of hydroxyl ion catalysis, this means that the actual hydrolysis rate constant k is related to a rate constant k_0 at the same hydroxyl ion concentration and extrapolated from the slope of the $k = f(C_{OH^-})$ curve at $C_{OH^-} = 0$ as follows:

$$\frac{k_0}{k} = \frac{C_{total}}{C_{R \cdot CH_2OH}}$$

($C_{total} \ll C_{NaOH}$ in the experiments, thus $C_{OH^-} \sim C_{NaOH}$)
and thus:

$$K = \frac{1}{C_{OH^-}} \cdot \left(\frac{k_0}{k} - 1\right)$$

If we apply this expression to the figures taken from the experimental curves [6] related to monomethylol urea, MU, and also include the data for methylol benzamine, MB, methylol propioamide, MP and methylol chloroacetamide, MCh, we get the following K values:

C_{OH^-}	K_{MU}	K_{MB}	K_{MP}	K_{MCh}
0.2	1.7	6.9	5.6	16.0
0.3	2.0	6.7	5.7	15.3
0.4	2.1	6.8	6.0	15.1
0.6	2.1	7.0	6.0	14.6
1.0	2.1	7.1	6.2	14.7

When regarding the experimental accuracy to be expected, these results mean that no distinction between the two opposite reaction mechanism theories can be made.

However, the assumption (E) seems not to be unreasonable, even when there is a lack of significance in the experiments referred above. The initial stage of the hydrolysis reaction would, *e.g.*, be an ionization of the -OH group, followed by a proton transfer in accordance with the scheme above.

Table 4. The k_0 and a ratio between formation and hydrolysis reactions of the urea-formaldehyde system. k_0 and a formation, k_0' and a' hydrolysis. Temperature 20 °C.

Buffer	pH	Monomethylol urea		Dimethylol urea	
		k_0/k_0'	a/a'	k_0/k_0'	a/a'
KH_2PO_4	6.70	38	25	8.2	6 9
Borax	9.20	29	25	8.3	8.3
Na_2CO_3	10.00	32	24	11.3	9.7

It may be of some interest to compare the formation—hydrolysis k_0 and a ratios, respectively, at different buffer solution compositions calculated from the figures of Table 3. These ratios can be found in Table 4. As seen, the ratios of the urea or monomethylol urea and formaldehyde reaction systems are of the same order, and as regards the urea—formaldehyde reaction the a ratios are practically constant. This may be in favour of an assumption that the buffer catalysis mechanism of both the formation and the hydrolysis are identical. However, the variations in the other ratios do not exclude such an identity even in these cases; the ionization state of the reactants may influence the activites of the different buffer ions in different ways when these ions are approaching in order to promote a proton transfer.

The author whishes to thank the board of Rydboholms A.B. for permission to publish this paper.

Bestimmung kleiner Mengen von Ammoniak in Gasmischungen

YRJÖ KAUKO und SAADET DÖGER*

Aus dem Physikalisch-Chemischen Institut der Universität, Ankara, Türkei

Es wurde eine exakte potentiometrische Methode zur Ermittlung des Druckes von Ammoniak, p_{NH_3} ($< 10^{-3}$ Atm) in Gasmischungen ausgearbeitet. Die Bestimmung von p_{NH_3} wird als eine pH-Messung in einer NH_4Cl-Lösung, in Gleichgewicht mit dem unbekannten p_{NH_3}, ausgeführt. Zur Eichung wurde ein Gas mit bekanntem $p^b_{NH_3}$ benutzt. Die Messgenauigkeit is gut.

Ammoniak wird in Gasmischungen bekanntlich dadurch bestimmt, dass das Gas in Chlorwasserstoff absorbiert und die überschüssige Säure zurücktitriert wird [1]. Die Bestimmung des gelösten Ammoniaks kann man auch kolorimetrisch oder konduktometrisch nach verschiedenen Methoden ausführen [2,3]. Das Ammoniak kann durch verschiedene Oxydationsmittel zu Stickstoff oxydiert und dieser volumetrisch bestimmt werden [4].

Es lässt sich leicht feststellen, dass die Bestimmung von Ammoniak in Gasmischungen bis zu einem Druck von 10^{-3} Atm nach den obigen Methoden analytisch durchzuführen ist. Bei kleineren Gas-Konzentrationen aber müssen grosse Gasmengen und niedrige Durchströmungsgeschwindigkeiten angewandt werden. Deshalb wird die für die Analyse erforderliche Zeit lang und die Genauigkeit gering. Wenn man nämlich verdünnte Gase durch Flüssigkeiten leitet, ist eine ausserordentlich lange Zeit erforderlich zur vollständigen Diffusion der letzten Reste der Gase [5] aus der Gasphase in die flüssige Phase.

Airola [6] hat vorgeschlagen auf Grund des Gleichgewichtes zwischen gasförmiger und flüssiger NH_3-Phase aus dem pH-Wert der wässrigen Lösung den Ammoniakgehalt der Gasmischung zu ermitteln. Pekkarinen [7] hat festgestellt, dass zwar im Verlauf von etwa 5 Stunden ein Gleichgewicht zwischen den wässrigen und gasförmigen Phasen des Ammoniaks entsteht, dass aber die Methode in dieser Form praktisch kaum zu verwerten ist.

---

* Die Versuche dieser Arbeit wurden von Saadet Döger vorgenommen und als Doktorarbeit an der Universität Ankara in den *Communications de la Faculté des Sciences de l'Université d'Ankara* 1955 veröffentlicht.

THEORETISCHER TEIL

Ammoniak ist in Wasser leicht löslich (59 M/Atm bei 25°C) [8,9]. Der Übergang des Gases in die wässrige Phase nimmt eine verhältnismässig lange Zeit in Anspruch. Die Löslichkeit von Ammoniak kann durch Temperaturerhöhung und durch Anwendung von konzentrierten Ammoniumchloridlösungen herabgesetzt werden.

Das letztgenannte kann auf folgende Weise anschaulich gemacht werden. (Alle Molekelgattungen ausser $NH_3(g)$ sind in wässriger Lösung, [] Konzentration, {} Aktivität.) Nach den bekannten Gesetzen des Gleichgewichtes ist

$$NH_3\ (g) \rightleftharpoons NH_3 \qquad K_p = [NH_3] \cdot p_{NH_3}^{-1} \tag{1}$$

$$NH_3 + H_2O \rightleftharpoons NH_4^+ + OH^- \qquad K_b = \{NH_4^+\} \cdot \{OH^-\}\ [NH_3]^{-1} \tag{2}$$

Aus diesen Gleichungen kann abgeleitet werden:

$$NH_3(g) + H_2O \rightleftharpoons NH_4^+ + OH^- \qquad K_{pb} = \{NH_4^+\} \cdot \{OH^-\}\ p_{NH_3}^{-1} \tag{3}$$

$$K_{pb} = K_p \cdot K_b \tag{4}$$

Wenn wir nun annehmen, dass der Aktivitätskoeffizient für alle einwertige Ionen denselben Wert f_1 hat, erhalten wir unter Heranziehung der Gleichungen der Elektroneutralität für die Ammoniumchloridlösung:

$$[NH_4^+] + [H^+] = [OH^-] + [Cl^-] \tag{5}$$

$$[NH_3]_t = [NH_3] + [NH_4^+] = (\{OH^-\} + \{Cl^-\} - \{H^+\}) \cdot (\{OH^-\} \cdot K_b^{-1} + f_1^{-1}) \tag{6}$$

$$[NH_3]_t = K_{pb} \cdot \{OH^-\}^{-1} \cdot (\{OH^-\} \cdot K_b^{-1} + f_1^{-1}) \cdot p_{NH_3} \tag{7}$$

Die Konstanten K_p und K_b entnehmen wir der Literatur [8,9] und berechnen K_{pb}.

$K_p\ (25°) = 59\ M\ Atm^{-1}$ $\qquad K_p\ (40°) = 29{,}4\ \ M\ Atm^{-1}$

$K_b\ (25°) = 1{,}81 \times 10^{-5}\ M$ $\qquad K_b\ (40°) = 1{,}98 \times 10^{-5}\ M$

$K_{pb}(25°) = K_pK_b = 1{,}07 \times 10^{-3}\ M^2Atm^{-1}$ $\quad K_{pb}(40°) = K_pK_b = 0{,}582 \times 10^{-3}\ M^2Atm^{-1}$

Diese Werte sind auch mit Hilfe der thermodynamischen Daten der Reaktionskomponenten kontrolliert worden [10].

In der graphischen Darstellung der Fig. 1 haben wir als Freiheiten des Systems den totalen Ammoniakgehalt $[NH_3]_t$ und das pH der Lösung gewählt. Für Gleichung (6) wurde Konzentration bzw. Aktivität der Ammoniumchloridlösung als Parameter benutzt und für (7) der Druck von Ammoniak in der Lösung. Aus der Fig. 1 ergibt sich, dass für $p_{NH_3} < 10^{-3}$ Atm der $[NH_3]_t$-Gehalt der Lösung in den konzentrierten NH_4Cl-Lösungen eine schwache Abhängigkeit, pH dagegen eine starke Abhängigkeit von p_{NH_3} zeigt. In den konzentrierten NH_4Cl-Lösungen dürfte deswegen die Einstellung des Gleichgewichtes schnell vor sich gehen und infolgedessen die Empfindlichkeit der Methode gross sein.

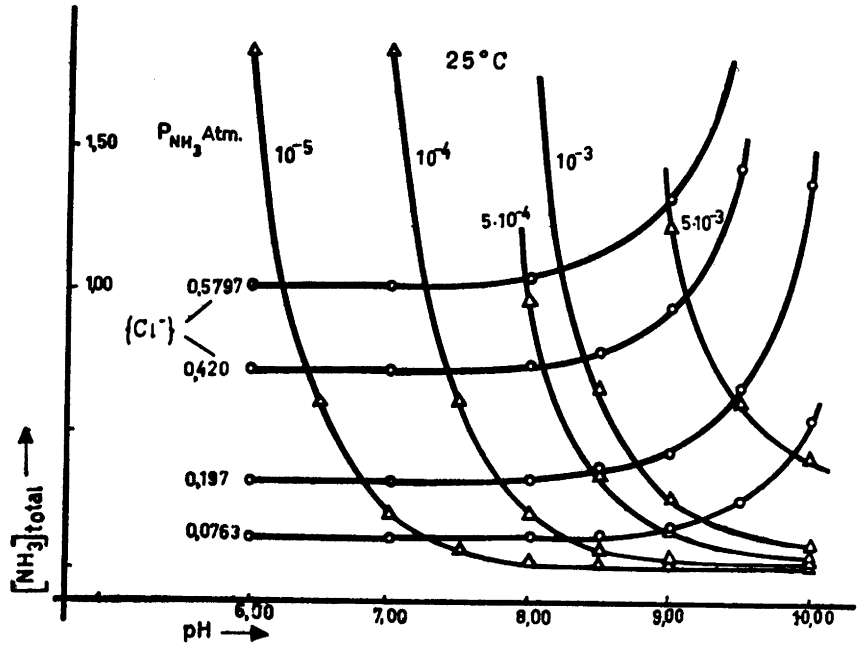

Fig. 1.

Für die praktische Anwendung lässt sich die Gleichung (3) auf folgende Weise schreiben, weil praktisch $[NH_4^+] = [Cl^-]$ ist:

$$\log p_{NH_3} = -\log [H^+] + \log C \qquad (8)$$
$$C = K_w \cdot K_{pb}^{-1} \cdot f_1 \cdot [Cl^-]$$

Wenn das gemessene "pH" mit einem (konstanten) Fehler Δ versehen ist

$$\text{"pH"} = -\log [H^+] + \Delta$$

so gilt

$$\log p_{NH_3} = \text{pH} + \log C' \qquad (9)$$
$$\log C' = \log C - \Delta$$

C und C' sind für eine bestimmte NH_4Cl-Lösung konstant. Durch Eichung mit einer Gasmischung mit bekanntem $p^b_{NH_3}$ kann man die Konstante C' bestimmen.

Wir erhalten schätzungsweise [11]

$$f_1 = 0{,}58 \qquad \text{für } [Cl^-] = 1 \text{ M}$$

Es berechnet sich folglich für $[Cl^-] = 1$ M

bei 25°C $\log C(25°) = -11{,}3 \pm 0{,}1$; $\log p_{NH_3} = \text{pH} - 11{,}3$

bei 40°C $\log C(40°) = -10{,}53 \pm 0{,}08$; $\log p_{NH_3} = \text{pH} - 10{,}53$ (10)

Die Bestimmung des NH_3-Druckes wird folglich auf die pH-Messungen in der folgenden Kette zurückgeführt:

Glaselektrode / 1 M NH_4Cl, $NH_3(g)$,H^+ / Bezugselektrode

EXPERIMENTELLER TEIL

Nach diesen Prinzipien haben wir Luft durch eine Ammoniaklösung, dessen $[NH_3]_t$ titrimetrisch genau bestimmt wurde, durch mehrere nacheinanderfolgende Waschflaschen im Ölthermostat geleitet. Das — mit NH_3-Druck der Lösung — gesättigte Gas ging zum Schluss durch eine NH_4Cl-Lösung, deren pH beobachtet wurde. Dass das pH konstant blieb, auch bei zunehmender Anzahl der Waschflaschen war ein Kennzeichen dafür, dass sich das Gleichgewicht sowohl zwischen den Gas- und Ammoniakphasen wie zwischen NH_3-Gas und NH_4Cl-Lösung eingestellt hatte.

Die pH-Messungen wurden mit Hilfe einer gesättigten Kalomelektrode als Bezugselektrode und mit einem Beckmann-Elektrometer (G-Model) von der Empfindlichkeit $\pm$ 0,01 pH ausgeführt. Der erhaltene pH-Wert wurde mit bekannten Pufferlösungen geeicht und noch mit einer Chinhydronelektrode in der *Veibel*schen Lösung (0,01 M HCl + 0,09 M KCl) mit angenommenem pH = 2,08 kontrolliert.

Aus der Konzentration der NH_3-Lösung wird $p^b_{NH_3}$ mit (1) errechnet und mit Hilfe des gemessenen "pH"-Wertes der obigen NH_4Cl-Lösung wird mit (9) ein Wert für C' erhalten.

Um das Gleichgewicht schnell herzustellen, haben wir kleine Mengen (0,2 bis 0,6 ml) NH_4Cl-Lösung in der Elektrode angewandt. Aus demselben Grunde werden die Flüssigkeit und das Gas durch dieselbe Kapillare von 1 m Länge und 0,3 mm Durchmesser (Fig. 2a) mit Geschwindigkeiten von 0,04 ml/St. und 25 ml/Min durchgeleitet. Es stellt sich schon in der Kapillare das Gleichgewicht ein, aber der Gasdruck ist jetzt nicht mehr derjenige der ursprünglichen Mischung. Aus diesem Grunde wurde nach einer Weile, etwa 20 Minuten, der Zustrom der Flüssigkeit abgestellt, und die vorhandene Elektrodenflüssigkeit mit dem Gas nachgesättigt, wonach das pH gemessen wurde.

Die Versuchsresultate sind in Tabelle 1 zusammengestellt. An Hand der Tabelle stellen wir fest, dass sich das Gleichgewicht schnell einstellt, falls beim Durchleiten des Gases der pH-Wert zunimmt (Kolonne 8 II). Dies wird erreicht, wenn die NH_4Cl-Lösung vermittels Durchleitens von Luft zuerst sauer gemacht wurde (Vgl. Fig. 1). Das Gleichgewicht wird in weniger als einer halben Stunde bei 25°C erreicht. Das endgültige Gleichgewicht stellt sich bei 40°C sehr schnell (in Minuten) sogar in der Kapillare ein. Die Anwendung von zwei Kapillaren hintereinander hatte keine nennenswerte Bedeutung.

In Kolonne 9 werden die log C'-Werte, die aus den $p^b_{NH_3}$ und pH-Werten errechnet wurden, wiedergegeben. Die Werte aus den verschiedenen Versuchen zeigen eine gute Übereinstimmung.

Mittelwert: $-\log C$ (40 °C) = 10,64 ± 0,02

Die praktische Ausführung der Bestimmung von p_{NH_3}

Die zu untersuchende, Ammoniak enthaltende Gasmischung wird bei 25°C bzw 40°C durch eine 1 M NH_4Cl-Lösung bis zur Einstellung des Gleichgewichtes geleitet und das pH durch Messung der folgenden Kette bestimmt:

Glas-Elektrode / 1 M NH_4Cl, p_{NH_3}, H^+ / Besugselektrode

Der Ammoniakdruck p_{NH_3} (in Atm ausgedrückt) ergibt sich aus der Tabelle 1 wie folgt

$$\log p_{NH_3}\,(25°) = \mathrm{pH}\,(25°) - 11{,}11$$
$$\log p_{NH_3}\,(40°) = \mathrm{pH}\,(40°) - 10{,}64 \qquad (11)$$

Um das Gleichgewicht in der Elektrode schnell zu erreichen, werden etwa 0,2 ml 1 M NH_4Cl mit einer Geschwindigkeit von 0,6 ml/St. durch eine Kapillare (1 m lang, 0,3 mm Diameter) und das Gas mit einer Geschwindigkeit von 25 ml/Min in die Elektrode geleitet. Der Zustrom der Flüssigkeit wird eingestellt, die im Elektrodengefäss gesammelte Flüssigkeit mit dem Gasstrom nachgesättigt und pH bestimmt. Die Versuchsanordnung ist aus Fig. 2 ersichtlich. Wenn das pH der NH_4Cl-Lösung am Anfang vermittels Durchleitens von Luft auf pH 6 eingestellt wird, nimmt die Bestimmung bei 25°C etwa eine halbe stunde in Anspruch. Bei 40°C kann die Bestimmung in einer noch kürzeren Zeit ausgeführt werden.

DISKUSSION

Durch das beschriebene Verfahren wird in Wirklichkeit das Verhältnis $p^b_{NH_3}$ ermittelt. Die folgende Kette wurde gemessen, wobei das Diffusionspotential vernachlässigt werden kann [13]:

$$H_2 / NH_4Cl,\ p^b_{NH_3},\ \{H^+\}_b / \text{gesätt. } KCl / \{H^+\},\ p_{NH_3},\ NH_4Cl / H_2$$

Der erzielte p_{NH_3} ist insofern richtig wie $p^b_{NH_3}$ richtig ist. Der Vergleich zwischen den thermodynamisch berechneten C-Werten in Gleichung (10) mit den experimentell gefundenen C' in Gleichung (11) zeigt Differenzen von nur 0,2 bzw 0,1, obwohl der thermodynamische Wert unsicher ist, weil der Aktivitätskoeffizient approximativ ist, und weiter die gemessenen Werte etwaige prinzipielle Fehler von $p^b_{NH_3}$ und von pH enthalten.

Aus Gleichung (11) errechnet man z. B. für eine 1 M NH_4Cl-Lösung bei 25°C $\log p_{NH_3} = -5{,}11$ für pH=6 und $\log p_{NH_3} = -3$ für pH = 8,11.

Nur ein Druck von 10^{-3} Atm lässt sich nach den analytischen Methoden einigermassen bestimmen. Kleinere Werte sind ohne sehr umständliche Versuchsanordnungen nicht kontrollierbar [14].

Mercury(II) Halide Mixed Complexes in Solution

IV. Mixed Bromo-Iodo Complexes

Y. MARCUS*

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Independent values for the mixed complex formation constants k_{ij} for $HgBr_{i-1}I_j + Br \rightleftharpoons HgBr_iI_j$ were obtained from mercury distribution data (D, a, r), where D is the Hg distribution ratio, a is free bromide concentration and r is ratio free iodide to free bromide, using cuts $D(a)_r$ and $D(r)_a$, and from iodine distribution data (D, a, B, M); D is the iodine distribution ratio, and B and M are total mercury and iodine. The constants are: $\log k_{21} = 1.85 \pm 0.03$, $\log k_{12} = 1.88 \pm 0.03$, $\log k_{31} = 1.49 \pm 0.06$, $\log k_{22} = 1.49 \pm 0.05$ and $\log k_{13} = 1.10 \pm 0.10$. Also, the constants for $HgBr_2 + 2I^- \rightleftharpoons HgI_2 + 2\ Br^-$, $\log p = 6.94 \pm 0.03$ and for $HgBr_2 + I^- \rightleftharpoons HgBrI + Br^-$, $\log q = 4.01 \pm 0.04$, and the distribution coefficient of HgBrI between benzene and the ionic medium $\log \lambda_{11} = 0.79 \pm 0.02$ were obtained. These constants are valid for 25° and 0.5 M (perchlorate + halide) ionic medium.

The mercury(II)-bromide-iodide system was subjected to a thorough study of possible mixed species. Use was made not only of mercury solvent distribution data but also of ligand—iodine—distribution. The rather difficult problem of having two independent variables was overcome in a number of ways, and complexity constants could be assigned to all mixed species.

Symbols. For a definition of the symbols used in this paper see part I, p. 330 [2]. The constants k'_{03} and k'_{04} will here be written k_{03} and k_{04}, since no mistake is possible. In addition, the terms $p = \beta_{02}\beta_{20}^{-1}$ and $q = \beta_{11}\beta_{20}^{-1}$ will be useful. The functions c_i and f_i are defined in eqns. (1), (1a), (2) and (8).

Experimental. For experimental details see part I, p. 331 [2]. Benzene was used as the organic solvent, the temperature was 25°, the ionic medium was 0.5 M (perchlorate + halide) and the phase volumes were equal.

General equations. In solutions of MA_2 and excess A^- and B^-, assuming maximum coordination number four [4], six mixed species might form. Introducing the ratio $r = ba^{-1}$, and selecting, for the sake of convenience, such formation reactions as either (I) are based on MA_2 for MB_j species, or (II) consist of the addition of one A^- to a precursor species for the mixed complexes, *e. g.*

* Permanent address: Israel Atomic Energy Commission, Hakiryah, Tel-Aviv, Israel.

(I) $MA_2+3\ B^- = MB_3^- + 2\ A^-$; pk_{03}, or (II) $MAB_2^- + A^- = MA_2B_2^=$; k_{22}, the concentration of the species present may be written as:

$[MA_2]$	$= u$	$[MB_2]$	$= upa^{-2}b^2 = upr^2$
$[MA_3]$	$= uk_{30}a$	$[MAB_2]$	$= upk_{12}a^{-1}b^2 = upk_{12}ar^2$
$[MA_4]$	$= uk_{30}k_{40}a^2$	$[MA_2B_2]$	$= upk_{12}k_{22}b^2 = upk_{12}k_{22}a^2r^2$
$[MAB]$	$= uqa^{-1}b = uqr$	$[MB_3]$	$= upk_{03}a^{-2}b^3 = upk_{03}ar^3$
$[MA_2B]$	$= uqk_{21}b = uqk_{21}ar$	$[MAB_3]$	$= upk_{03}k_{13}a^{-1}b^3 = upk_{03}k_{13}a^2r^3$
$[MA_3B]$	$= uqk_{21}k_{31}ab = uqk_{21}k_{31}a^2r$	$[MB_4]$	$= upk_{03}k_{04}a^{-2}b^4 = upk_{03}k_{04}a^2r^4$

At equilibrium with a benzene phase, the additional species

$$[MA_2]_{or} = u\lambda_{20} \quad [MAB]_{or} = uqa^{-1}b\lambda_{11} = uqr\lambda_{11} \quad [MB_2]_{or} = upa^{-2}b^2\lambda_{02} = upr^2\lambda_{02}$$

will be present.

The problem is to find the six mixed complex formation constants (q and the five k_{ij}) and also p.

EQUATIONS FOR MERCURY DISTRIBUTION

Cuts at constant r

In a recent paper [3] Sillén has described a way of treating data with three variables (here D, a and r), and the following derivation is based on this treatment.

Summing up the concentrations of the species listed above, the total concentration of mercury in the aqueous phase may be written as

$$M - M_{or} = u\ (c_0' + c_1'a + c_2'a^2)$$

$$c_0' = 1 + qr + pr^2 \qquad c_1' = k_{30} + qk_{21}r + pk_{12}r^2 + pk_{03}r^3$$

$$c_2' = k_{30}k_{40} + qk_{21}k_{31}r + pk_{12}k_{22}r^2 + pk_{03}k_{13}r^3 + pk_{03}k_{04}r^4 \qquad (1)$$

where the parameters c_i' are functions of r only, and constant for a series of experiments at constant r. Similarly, for the organic phase.

$$M_{or} = uc_0'' \qquad c_0'' = \lambda_{20} + q\lambda_{11}r + p\lambda_{02}r^2 \qquad (1a)$$

may be written, giving for the distribution ratio D the simple expression

$$D = M_{or}\ (M - M_{or})^{-1} = c_0\ (1 + c_1a + c_2a^2)^{-1} \qquad (2)$$
$$c_0 = c_0''c_0'^{-1} \quad c_1 = c_1'c_0'^{-1} \quad c_2 = c_2'c_0'^{-1}$$

The parameters c_i may then be obtained by curve fitting from plots log D (log a)$_r$. A set of $(c_i)_r$ values may then be obtained for a number of discrete values of r, and the resulting functions $c_i(r)$ solved for the equilibrium constants.

A provisional value of pq^{-1} may be obtained for high r by using the definition of c_0 (eqn. (2), (1a) and (1)) and neglecting the terms for MA_2: 1 in c_0' (1) and λ_{20} in c_0'' (1a):

$$pq^{-1} \approx (c_0 - \lambda_{11})\ (\lambda_{02} - c_0)^{-1}\ r^{-1} \tag{3}$$

(λ_{11} and λ_{02} being known [1,2]). With this, an estimate of q obtained at low r

$$q = c_0 r^{-1}\ [pq^{-1}\ (\lambda_{02} - c_0)r - (c_0 - \lambda_{11})]^{-1} \tag{4}$$

or, alternatively, $q = K(pq^{-1})$, with K from part III [1], may be used in the correction term to give a refined value for pq^{-1} by plotting the left hand side of

$$c_0\ (1 + q^{-1}r^{-1}) - \lambda_{11} = pq^{-1}\ (\lambda_{02} - c_0)r \tag{5}$$

against $(\lambda_{02} - c_0)\ r$.

From the definition of c_1 (eqn. (2) and (1)), the equation

$$c_1(q^{-1}r^{-1} + 1 + pq^{-1}\ r) - k_{30}q^{-1}r^{-1} - k_{03}pq^{-1}\ r^2 = k_{21} + k_{12}pq^{-1}\ r \tag{6}$$

is obtained. Since k_{30} and k_{03} are known [4], a plot of the left side of (6) against r gives the constants k_{21} and k_{12}.

Similarily, for c_2, knowing $k_{30}k_{40}$ and $k_{03}k_{04}$ [4], a plot of the left side of

$$c_2\ (q^{-1}r^{-1} + 1 + pq^{-1}\ r) - k_{30}k_{40}q^{-1}r^{-1} - pq^{-1}k_{03}k_{04}r^3 = k_{21}k_{31} + pq^{-1}k_{12}k_{22}r + pq^{-1}k_{03}k_{13}r^2 \tag{7}$$

against r yields the equilibrium constants $k_{21}k_{31}$, $k_{12}k_{22}$ and $k_{03}k_{13}$.

Cuts at constant a

A slightly different approach uses cuts at constant a instead of at constant r. Eqn. (1) may be written as

$$\begin{aligned} M - M_{or} &= uqr\ [f_0q^{-1}r^{-1} + f_1 + pq^{-1}f_2r + (f_3 + f(r))r^2] \\ f_0 &= 1 + k_{30}a + k_{30}k_{40}a^2 \\ f_1 &= 1 + k_{21}a + k_{21}k_{31}a^2 \\ f_2 &= 1 + k_{12}a + k_{12}k_{22}a^2 \\ f_3 &= pq^{-1}k_{03}k_{13}a^2 \qquad f(r) = pq^{-1}k_{03}a(1 + k_{04}ar) \end{aligned} \tag{8}$$

Eqns. (8) and (1a) — again neglecting λ_{20} — yield an expression for D, which, when rearranged, becomes

$$(\lambda_{11} + \lambda_{02}\ pq^{-1}r)D^{-1} - (f_0q^{-1}r^{-1} + f(r)r^2) = f_1 + pq^{-1}f_2r + f_3r^2 \tag{9}$$

Eqn. (9) may be solved graphically for f_i, and f_1 and f_2, in turn, for the required equilibrium constants, as will be shown below.

MERCURY DISTRIBUTION, EXPERIMENTAL RESULTS

Data (D, a, r) were obtained in the ranges $-2.1 < \log a < -1.0$ and $-3.4 < \log r < -1.5$. For experimental convenience, not r but $R = BA^{-1}$ was kept constant in a series of experiments with varying a. As A was about $10^3 - 10^4$ times M, $a \approx A$ is a very good approximation. B, however was not very large compared to M, since the specific

activity of the mercury did not permit the use of M values lower than about 10^{-5} M, and therefore the consumption of B by M made a correction necessary. Its magnitude was relatively large, but if $\bar{n}_B$ is obtained from any provisional constants (*e. g.* statistical values), $b = B - \bar{n}_B M$ is quite a good approximation. The values of $\bar{n}_B$ were mostly between 1.5 and 2.5. As a increased, b tended towards B and r towards R. A series of experiments log $D(a, B)_R$, where $\bar{n}_B M$ was particularily large is given in Table 1.

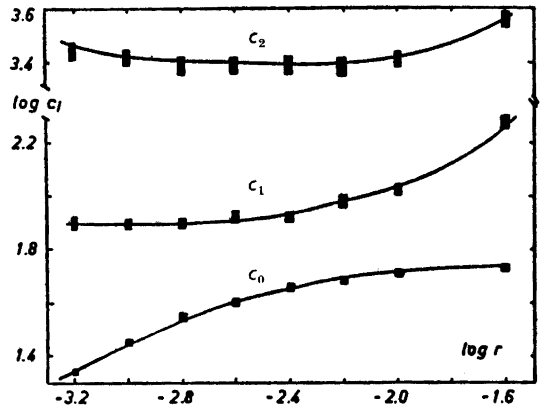

Fig. 1. The parameters c_i as function of r. ▮ values obtained by "curve fitting" log $D(\log a)_r$ plots, ———— calculated from the constants.

In Table 2 all the data are presented, with the observed D as function of the actual a and r values prevailing in the individual runs. The column D_{calc} is calculated for the individual a and r values with the constants found later, and summarized in Table 5.

Cuts at constant r

Values of log $D(\log a)_r$ were calculated by interpolation and were used to obtain the parameters $c_i(r)$ by curve fitting of eqn. (2). Plots of these parameters as log c_i(log r) are given in Fig. 1.

Considering c_0 first, a provisional value $pq^{-1} = 800$ was obtained from eqn. (3), using $\lambda_{11} = 6.1 \pm 0.6$ and $\lambda_{02} = 57.5 \pm 1.2$ from parts III and I[1,2]. From this and eqn. (4) the rough value of log $q = 4.2 \pm 0.2$, or using $q = Kpq^{-1}$ with log $K = 1.1 \pm 0.2$ from part III [1], log $q = 4.0 \pm 0.2$, was obtained. A refined value log $pq^{-1} = 2.90 \pm 0.05$ was then obtained by using eqn. (5) as shown in Fig. 2. A curve $c_0(r)$ calculated with the now known q and pq^{-1} is compared with the experimental values in Fig. 1.

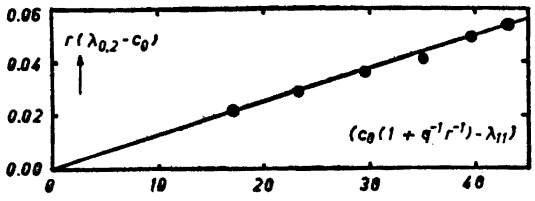

Fig. 2. Plots of eqn. (5) to find pq^{-1}, the slope of the best straight line through the origin and the points.

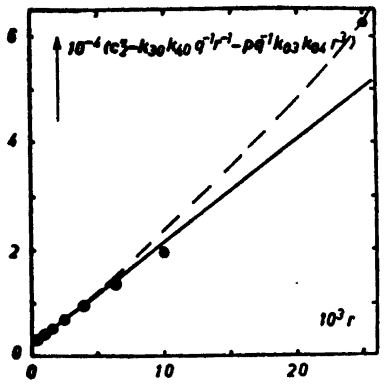

Fig. 3. Plots of eqn. (7). ● left side of (7) calculated from experimental points, ———— calculated with the constants $k_{12}k_{22}$ and $k_{22}k_{31}$. — — — — calculated with the additional constant k_{13}.

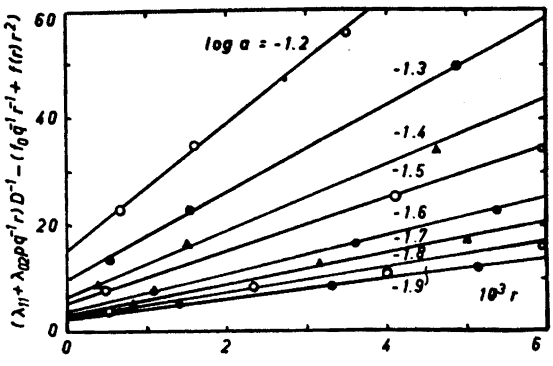

Fig. 4. Plot of eqn. (9) for low r values. ● ○ ▲ calculated from the experimental points, ———— best straight lines through the points.

The values of c_1 were inserted into eqn. (6) and the left side of it was plotted against r, and, divided by r, against r^{-1}, using $k_{30} = 185$ and $k_{03} = 4\,700$ [4]. From the slopes the values of the constants $\log k_{12} = 1.87 \pm 0.03$ and $\log k_{21} = 1.85 \pm 0.04$ were obtained. Inserted into a rearranged form of eqn. (6) they gave a $c_1(r)$ curve, which is compared with the experimental values in Fig. 1.

The values of c_2 were inserted into eqn. (7), and the resulting left hand term using $k_{30}k_{40} = 1.05 \times 10^4$ and $k_{03}k_{04} = 1.10 \times 10^6$ [4] was plotted against r in Fig. 3. Except for the last point, the plot is linear, and the constants $\log k_{12}k_{22} = 3.38 \pm 0.03$ and $\log k_{22}k_{31} = 3.35 \pm 0.04$ were obtained from it in the way outlined above for c_1. Using these two constants the straight line in Fig. 3 was obtained, which is seen to agree well with the data, except, again, for the last point. A value of $\log k_{13} \sim 1.0$ (eqn. (7)) may bring even the last point into line (the dashed curve in Fig. 3), although the fit for some of the remaining points is then somewhat poorer. The constants were inserted into a rearranged form of eqn. (7) to give a curve which is compared with the experimental c_2 in Fig. 1.

Cuts at constant a

Using data $\log D(\log r)_a$, again calculated by interpolation, and the constants $\log pq^{-1} = 2.90$ and $\log q \sim 4.2$ found above, the left hand term of eqn. (9) was calculated, and is plotted against r (up to $r = 0.005$) in Fig. 4. The best straight lines were drawn, one for each a value, with slopes f_2pq^{-1} and intercepts f_1. The functions $(f_1-1)a^{-1}$ and $(f_2-1)a^{-2}$ plotted against a gave straight lines of slopes $k_{21}k_{31} = 10^{3.34\pm0.05}$ and $k_{12}k_{22} = 10^{3.36\pm0.04}$,

while plots of $(f_1-1)a^{-2}$ and $(f_2-1)a^{-2}$ against a^{-1} yielded slopes $k_{21} = 10^{1.88\pm0.03}$ and $k_{12} = 10^{1.90\pm0.02}$. These constants agree very well with those obtained with cuts at constant r (see Table 5).

Using the functions f_1 and f_2pq^{-1} obtained above with eqn. (9) at $r > 0.005$, f_3 values were obtained for each a value, from which $\log k_{13} = 1.1 \pm 0.1$ was obtained. This value is a better approximation than that obtained with cuts at constant r.

The averages of the constants found for the two approaches were used to calculate the values of D_{calc} in Table 2.

EQUATIONS FOR IODINE DISTRIBUTION

The data for iodine distribution experiments will be discussed in terms of the species and complexity constants already employed above and listed on p. 812.

The experimental quantities studied are the independent variables a, B, and M, and the dependent variable D. Usually in solvent distribution studies, the concentration of free ligand is known, but in this case b = iodide is neither known nor negligible, and the situation is further complicated by the fact that the free ligand is a part of the material of which the distribution is studied.

The balances of mercury and iodine are:

$$M = \beta_{20}m[a^2(f_0+\lambda_{20})+qab(f_1+\lambda_{11})+pb^2(f_2+\lambda_{02})+pk_{03}b^3(1+k_{13}a+k_{04}b)] \quad (10)$$

$$B = b+\beta_{20}m\ [qab(f_1+\lambda_{11})+2pb^2(f_2+\lambda_{02})+3pk_{03}b^3(1+k_{13}+4/3k_{04}b)] \quad (11)$$

with the f_i defined in eqn. (8), and the distribution ratio of iodine:

$$D = \beta_{20}mb\ (qa\lambda_{11} + 2pb\lambda_{02})\ (B-\beta_{20}mb(aq\lambda_{11}+2pb\lambda_{02}))^{-1} \quad (12)$$

At sufficiently low B, and therefore b (for M values of the order of 10^{-5} M this means B lower than 2.10^{-4} M), the terms with b^3 are negligible. On the whole, it will be convenient to discuss the data in terms of three regions:
a) very low B, where terms with b^2 are negligible,
b) relatively high B, where terms with b (except for free B) are negligible, and
c) intermediate values of B, where terms with both b and b^2 are important.

Very low B

The very low range of B is practically defined by having

$$(\partial D/\partial B)_{a,M} \approx 0 \quad (13)$$

This means that b is eliminated from the expressions for D, which requires that the only B containing species be B and MA_iB.

Since B is very low, $\Sigma[MA_iB]$ will be negligible beside $\Sigma[MA_i]$, and therefore the mercury balance is

$$M = \beta_{20}ma^2\ (f_0 + \lambda_{20}) \quad (14)$$

where $a^2\ (f_0 + \lambda_{20})$ is known. The iodine balance is

$$B = b\ (1 + \beta_{20}qma\ (f_1 + \lambda_{11}) \tag{15}$$

Eliminating b and $\beta_{20}m$, the distribution of iodine will be

$$D = \lambda_{11}(f_0 + \lambda_{20})aq^{-1}M^{-1} + f_1) \tag{16}$$

Eqn. (16) may be transformed into a linear eqn. in M^{-1}

$$D^{-1} = (f_0 + \lambda_{20})a(q\lambda_{11})^{-1})\ M^{-1} + f_1\lambda_{11}^{-1} \tag{17}$$

whence the slope of a $D^{-1}\ (M^{-1})_a$ plot will give the value of $q\lambda_{11}$.

If plots $D^{-1}\ (M^{-1})_a$ are extrapolated to $M^{-1} = 0$ (*i. e.* $M = \infty$) and the values of log D (log $a)_{M=\infty}$ plotted, the constants λ_{11}, k_{21} and $k_{21}k_{31}$ may be obtained by curve-fitting methods. The constant q may then be obtained from λ_{11} and the value of $q\lambda_{11}$ obtained above from the slope of (17).

Relatively high B

The range of relatively high B will be defined by having as B containing species only B and MA_1B_2, whence

$$(\partial \log\ D\ /\ \partial \log\ (B/M))_a = -\ (1 - 2\lambda_{02}MB^{-1}\ (f_2+\lambda_{02})^{-1})^{-1} \approx -1 \tag{18}$$

The mercury and iodine balances are then

$$M = \beta_{02}mb^2\ (f_2 + \lambda_{02}) \tag{19}$$

$$B = b + 2\beta_{02}\ mb^2\ (f_2 + \lambda_{02}) = b + 2\ M \tag{20}$$

Introducing the distribution ratio D and eliminating b and $\beta_{02}\ m$,

$$f_2 = \lambda_{02}(2MB^{-1}\ (D + 1)\ D^{-1} - 1) \tag{21}$$

gives values for f_2, and plots log f_2 (log a) may be treated, *e. g.* by curve fitting methods, to yield values of k_{12} and $k_{12}k_{22}$.

Intermediate B

At intermediate values of B the species to be considered will be MA_i, MA_iB, MA_iB_2 and B. The mercury and iodine balances (10) and (11) combined, give then, neglecting terms with b^3

$$B/M = b\ /\ \mathrm{M} + \frac{qab\ (f_1+\lambda_{11})+2pb^2\ (f_2 + \lambda_{02})}{a^2\ (f_0 + \lambda_{20}) + qab\ (f_1 + \lambda_{11}) + pb^2\ (f_2 + \lambda_{02})} \tag{22}$$

Eliminating $\beta_{20}m$ from the iodine distribution ratio (12) and eqns. (10) and (11) gives

$$D = \frac{qa\lambda_{11} + 2\ pb\lambda_{02}}{(M^{-1}a^2(f_0+\lambda_{20})+qaf_1) + (M^{-1}qa(f_1+\lambda_{11}) + 2pf_2)b + (M^{-1}p(f_2+\lambda_{02}))\ b^2} \tag{23}$$

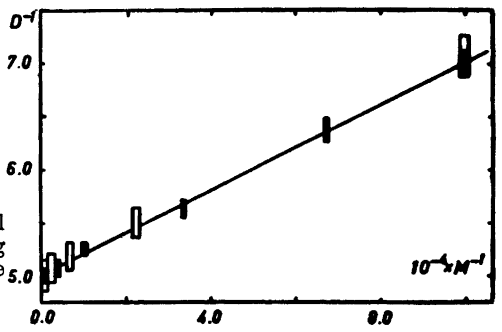

Fig. 5. Plot of eqn. (17). Experimental points: ■ for log $B = -5.9$, □ for log $B = -6.5$, ———— best straight line through the points.

Eqns. (22) and (23) are functions of b, known constants and the as yet unknown constant p (it is assumed that a and M are kept constant). The function log $D(\log p)_{a,b,M}$ is now plotted, calculated from (23) for discrete values of b. An approximate value for B/M may be obtained from

$$B/M \approx b/M + (1+a(f_0 + \lambda_{20})q^{-1}\ b^{-1}\ (f_1 + \lambda_{11})^{-1})^{-1} \qquad (22a)$$

Values of log $D(\log B/M)_{a,M}$ are now obtained experimentally, and the value of log D, corresponding to the B/M calculated for some value of b, gives then a provisional p value on the log $D(\log p)$ plot for this b value. The provisional values are used in conjunction with (22) to calculate a better value of B/M, the corresponding log D found from experiment is then used to give refined values of p, this process being repeated as much as necessary.

IODINE DISTRIBUTION, EXPERIMENTAL RESULTS

Very low B

One series of experiments was made at constant $a = 0.100$ M and at two log B values, -5.9 and -6.5, while log M changed from -4.0 to -2.0. At the highest M values, A was varied, so as to keep a constant, and was calculated from $A = a + n_A M$, n_A being calculated using the constants k_{i0} and a. The results, log $D(\log M)_{a,B}$, are given in Table 3 and were transformed to plots of eqn. (17), $D^{-1}(M^{-1})_{a,B}$, shown in Fig. 5.

As is seen the points for the two B values fall on the same straight line, so that eqn. (13) is fulfilled, and the slope is $(2.00 \pm 0.05) \times 10^{-4}$. Since $(f_0 + \lambda_{20})a = 12.6 \pm 1.1$ (part II[4]), the value found for log $q\lambda_{11}$ is 4.80 ± 0.04.

A second series of experiments, presented in Table 3, was made at constant log $B = -5.9$, and at two log M values: -4.00 and -3.00, for each a value, while log a varied from -3.5 to -1.0. The value of a was obtained by successive approximations from $a = A - n_A M$, when $A < 100\,M$. Two points were obtained for each a in plots $D^{-1}(M^{-1})$ and the best straight line with the known slope $a(f_0 + \lambda_{20})q^{-1}\lambda_{11}^{-1}$ was drawn through them, the points falling very neatly on the line. The intercept at $M^{-1} = 0$ gives log $D = \log \lambda_{11} - \log (1 + k_{21}a + k_{21}k_{31}a^2)$, which is plotted against log a in Fig. 6. The figure shows also the points log $D(M)_a$. At log $a < -2.3$, the points for the two M values coincide with that for $M^{-1} = 0$.

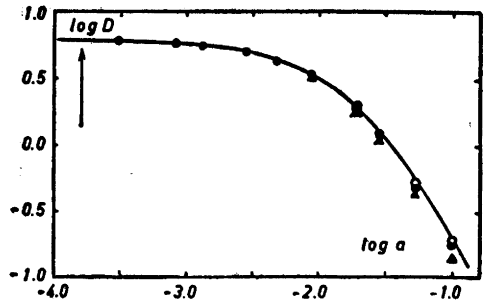

Fig. 6. Log D as function of log a for M^{-1} values extrapolated to zero: ○, and for experimental values $M^{-1} = 10^3$: ●, and $M^{-1} = 10^4$: ▲, ——— calculated with the constants λ_{11}, k_{21} and $k_{21}k_{31}$.

The plot of $\log D(\log a)_{M=\infty}$ was "curve fitted" and yielded the constants: $\log\lambda_{11} = 0.79 \pm 0.01$, $\log k_{21} = 1.84 \pm 0.02$ and $\log k_{21}k_{31} = 3.34 \pm 0.04$. The value of λ_{11} gave with the slope of eqn. (17) the value $\log q = 4.01 \pm 0.04$. A curve calculated with the constants is compared with the data in Fig. 6.

Relatively high B

Three series of experiments were made at constant $\log B = -3.70$, one having $\log M = -5.29$, the second having $\log M = -4.90$, and the third having $\log M$ varying between -4.70 and -5.28. In the first two series $\log a$ varied between -3.0 and -0.6, while in the third it was constant, $\log a = -1.00$ (see Table 4). The third series illustrates the validity of eqn. (18), since $(\triangle \log D/\triangle \log M)_a \approx 1$. The data were used to calculate f_2 by eqn. (21), and the values so found are plotted as $\log f_2(\log a)$ in Fig. 7.

As may be seen from the figure, points for different M values fall on the same curve, showing that the assumptions underlying eqn. (21) — in particular the species to be considered — are valid. The curve was "curve fitted" and

Table 3. Distribution of iodine at low B values.

Constant $a = 0.100$ M			Constant $\log B = -5.9$		
$-\log M$	$-\log D$		$-\log a$	$\log D$

yielded the constants log $k_{12} = 1.87 \pm 0.03$ and log $k_{12}k_{22} = 3.37 \pm 0.05$. A curve calculated with these constants is compared with the data in Fig. 7.

Intermediate B

A series of experiments at constant log $M = -4.00$ and at constant $a = 0.100$ M was made, with log B/M varying between -1.5 and $+1.6$. The results are plotted as log $D(\log B/M)_{a,M}$ in Fig. 8. In the range of low B/M, D is independent of B/M as expected (eqn. (12)). At high B/M the slope of the curve is -1 as expected from eqn. (18). At intermediate values of B/M the curve rises slowly towards a maximum.

Curves log $D(\log p)_{a,b,M}$ were calculated, using the constants q, λ_{11} and k_{ij} previously found, and the constant values of a and M, for the nine values of b: log $b = -5.52 + 0.15\,i$, $i = 0, 1, 2 \ldots 8$. The curves are shown in Fig. 9. Values of B/M corresponding to the above b were obtained, first from (22a)

and then by successive approximations, using provisional values of p, from (22). Log D values for these B/M were obtained from the experimental plot in Fig. 8, and the corresponding log p values were read off from the log D(log p) plots, until log p proved constant $= 6.94 \pm 0.03$, and this value was accepted. The values so obtained are shown in Fig. 9.

A calculated curve, using all the constants, is compared with the data in Fig. 8.

REPRESENTATION OF RESULTS

The constants obtained from the various experimental and calculation methods are compared in Table 5.

The significance of the constants may be better understood when presented in graphical form.

One way of doing this is to show predominance areas, in a diagram with log a and log b as independent variables. Areas in it are marked with the indices ij of the complexes MA_iB_j, and correspond to a predominace of a single species (inside the shaded contour the concentration is >50 %). Lines mean equal concentrations of the complexes of the adjacent areas, and at triple points, three complexes are present at equal concentrations. This way gives at a

The constants in parenthesis were calculated from others, directly obtained from the data, or were obtained from part III [1].

glance qualitative information as to the species important at given concentrations of both free A and free B. This diagram is shown in Fig. 10.

Another way to present two-dimensionally the three-dimensional diagram (% *formation*, *a*, *b*), is to present cuts at constant *a* (Fig. 11) or *b* (Fig. 12). This well known type of presentation shows the gradual addition of ligands, *e. g.* A in Fig. 12, while the ratios of the complexes with different numbers of the other ligand (*e. g.* B) remain constant (for cuts at constant *b*). Again, the complexes MA_iB_j are represented by their indices *ij* only.

DISCUSSION

A full discussion of the significance of the ternary complexity constants will be given in part V.

Previous work found on anionic mixed complexes of Hg(II) with halides is the Raman effect study of Delwaulle [5]. The mixed complexes HgA_nB_{4-n}

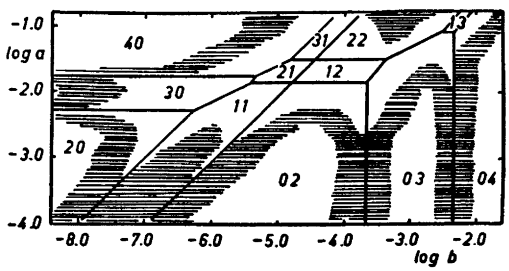

Fig. 10. Predominance area diagram. Areas correspond to predominance of the complexes MA_iB_j indicated by their indices *i j* (*e. g.* $HgBr_2I$ is (21)) (within shaded areas more than 50 %), as function of free bromide and free iodide concentrations.

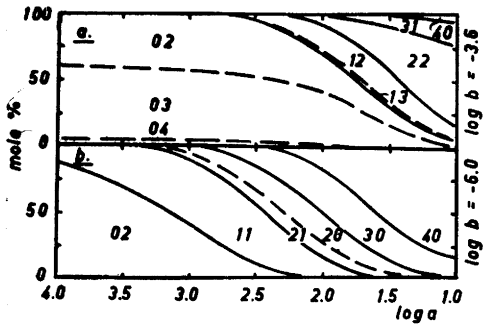

Fig. 12. Mole % of complexes as function of free bromide concentration, at constant iodide concentrations log $b = -3.6$ (a) and log $b = -6.0$ (b).

could all be identified for A and B being any two of Cl^-, Br^- and I^-, except that lines for $HgBrI_3^=$ could not be observed. This is in agreement with the rather weak formation of this complex found here, as is shown by its formation constant k_{13}. No complexity constants were, however, given by Delwaulle. A similar study, limited to the Br—I mixed complexes, is reported by Rolfe, Sheppard and Woodward [9].

The treatment of mercury distribution data is essentially similar to well known examples, like that mentioned in Ref.[3]. On the other hand, ligand distribution does not seem to have been used similarly to central-group distribution. In the present study, the system M—A—B has been studied by measuring the distribution of total B between two liquid phases, the relevant reactions being $M + iA + jB \rightleftharpoons MA_iB_j$ and $(MAB + MB_2)_{aq} \rightleftharpoons (MAB + MB_2)_{or}$. Of course, solvent distribution is but one example of employing a two-phase system where not all the components of the complex system are soluble in both phases. The following examples show in what ways the present method is similar to or different from other methods.

Consider, for instance, that the second phase is a gas, and J. Bjerrum's measurements of the ammonia vapour tension above metal-ammonia solutions [6] as an example of determining free A in a M—A system by two-phase distribution. The relevant reactions are then: $M + n\,A \rightleftharpoons MA_n$ and $A_{aq} \rightleftharpoons A_{vap}$ where M is the metal and A is ammonia.

If the second phase is a liquid, then the solvent distribution determination of free ligand may be illustrated by Dawson's study of the Hg—I system [7]. He determined the free iodide content of the solutions by measuring the iodine distribution between CS_2 or CCl_4 and the aqueous solutions, and, knowing the equilibrium constant for $I_2 + I^- \rightleftharpoons I_3^-$, he calculated $[I^-]$. In this case the relevant reactions are: $M + n\ A \rightleftharpoons MA_n$, $A + B \rightleftharpoons AB$ and $B_{aq} \rightleftharpoons B_{or}$, where M is again the metal, A is iodide, B is iodine and AB is triiodide.

For the second phase being a solid, Leden and Parck's work may be mentioned [8]. There the distribution of radioactive iodine between solid AgI and its solution in $AgClO_4$ was measured. The distributing species AgI is then a member of the series of complexes studied $Ag_nI^{(n-1)+}$. The relevant reactions are then: $MA + (n-1)\ M \rightleftharpoons M_nA$ and $MA_{aq} \rightleftharpoons MA_{solid}$.

The first two examples belong to a group where the concentration of free ligand is measured, and as such are analogous, for instance, to measuring the concentration of a free ligand that is the anion of a weak acid by measuring the pH (potentiometrically or otherwise), where the reaction $H^+ + Anion^- \rightleftharpoons H\ Anion$ is utilized.

The present work is similar to the third example in that the total distribution of an element is measured, the distributing species being members of the complex series to be studied. There is little real difference between measuring the distribution of the central group and of the ligand, and the polynuclear system of silver iodide complexes may be considered as "silvero" complexes of the central-group iodine.

Measurements of ligand distribution may be of wide applicability, particularly in cases where there is no convenient isotope of the metal, but there is of the ligand.

The author wishes to thank the *Israel Atomic Energy Commission* for a research grant abroad, Professor Lars Gunnar Sillén for the facilities provided, and particularly for his advice, comments and criticism, and Dr. Helen S. Dunsmore for improving the English presentation.

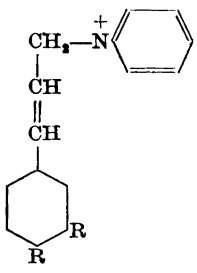
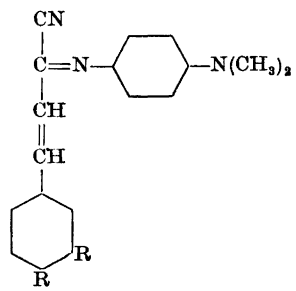
The Presence of Cinnamyl Alcohol Groups in Lignin



BENGT O. LINDGREN and HIROSHI MIKAWA

Department of Wood Chemistry, Swedish Forest Products Research Laboratory, Stockholm, Sweden



A colour reaction has been worked out for cinnamyl alcohol groups. It involves a transformation of these groups into *p*-dimethylamino-anilides of styryl-glyoxylonitriles (II). By this method the presence of a small amount of cinnamyl alcohol groups in spruce lignin has been indicated.

In 1896 Klason [1] found that coniferin is easily sulphonated when heated with an acid sulphite solution. This reaction was attributed to the presence of the cinnamyl alcohol group in coniferin. Partly because of this finding he suggested that the sulphonatable structures in lignin consist of cinnamyl alcohol groups. Later investigations [2] showed, however, that the main parts of these structures most probably are phenyl-carbinols and their ethers. On the other hand, the possibility of the presence of a small amount of cinnamyl alcohol groups in lignin has not been excluded.

This possibility may also be compatible with the modern view that gymnosperm lignin is formed by oxidative polymerization of coniferyl alcohol [3]. It may be possible that during such a process some of the coniferyl alcohol molecules are built into the lignin molecules without a change of their allyl alcohol side chains, thus forming cinnamyl alcohol groups in lignin.

Dotted lines. The unfractionated products after being kept in 1/15 N alcoholic hydrochloric acid for varying times at room temperature.

We have therefore tried to find a colour reaction for these groups in lignin. It was found that cinnamyl alcohol and its 3,4-dimethoxy derivative could be transformed into the strongly red coloured *p*-dimethylamino-anilides of styryl-glyoxylonitriles (IIa and b, respectively) in a two-step process *via* the N-cinnamyl-pyridinium salts (Ia and b, respectively).

The first step was accomplished at room temperature by treating the alcohols with tosyl chloride dissolved in pyridine. The pyridinium salts (Ia and b) were obtained in good yields. The second step was carried out according to the method used by Kröhnke [4] to transform N-phenacyl-pyridinium bromide into the *p*-dimethylamino-anilide of benzoyl-glyoxylonitrile. The pyridinium salts (Ia and b) were treated at room temperature with a water-alcohol solution of *p*-nitrosodimethyl-aniline and potassium cyanide. The nitriles (IIa and b) were obtained, after chromatographic purification, in yields of 46 and 26 %, respectively.

On the other hand, when coniferyl alcohol was treated with tosyl chloride and pyridine no pyridinium salt was obtained. It is hardly probable, however, that lignin contains such reactive structures as *p*-hydroxy-cinnamyl alcohol groups because they would have been easily oxidized during the lignin biosynthesis. This failure is therefore of no great importance in the present case.

The extinction curves for the two nitriles (IIa and b) had strong maxima at 475 mμ, ε being 29 800 for (IIa) and 32 700 for (IIb) (Fig. 1).

The light absorption of the unfractionated reaction products obtained from the pyridinium salt (Ib) had $\varepsilon_{max} = 15\,500$ at 475 mμ (Fig. 2), calculated on the basis of the amount of pyridinium salt used. This absorption was considerably higher than that which corresponded to the yield of the nitrile (IIb). Therefore some coloured compounds other than this nitrile were formed by the Kröhnke synthesis. This inference must be considered if the colour reaction is used for the photometric estimation of the amount of cinnamyl alcohol groups.

The glyoxylonitrile derivatives are easily destroyed by acid [4] with the disappearance of the extinction maximum at 475 mμ. Fig. 2 shows that after treatment of the unfractionated mixture with 1/15 N hydrochloric acid at room temperature for 1 h the absorption at 475 mμ had decreased to 5 % of its original value.

The great reactivity of cinnamyl alcohol structures makes their presence in isolated lignin preparations unlikely even if the original lignin contained such structures. The colour reaction was therefore performed on extracted wood slices, the thickness of which was about 20 μ. If not otherwise stated, they were freshly prepared from a newly cut spruce tree. The slices were first treated with a solution of tosyl chloride in pyridine, and then, after careful washing, with one of *p*-nitrosodimethyl-aniline and potassium cyanide in water-alcohol. After another very careful washing, the light absorption of the slices was determined with a Beckman spectrophotometer. The light scattering was minimized by wetting the slices with benzene.

The suitability of this method was tested on slices containing an approximately known amount of cinnamyl alcohol groups derived from the cinnamyl *aldehyde* groups of lignin. The procedure was as follows.

First, the slices were heated with a neutral sulphite solution for 20 h at 135°C. In this way the cinnamyl alcohol groups which might have been present in lignin were destroyed by transforming them into alkali stable sulphonic acid structures.

The conditions for the sulphite treatment were chosen from a study of 3,4-dimethoxy-cinnamyl alcohol. Fig. 3 shows that this compound was almost completely sulphonated when heated at 135°C for about 20 h with a sulphite solution of pH 6.

During the sulphonation of the alcohol, its UV absorption curve changed considerably (Fig. 4). The 265 mμ maximum was shifted to 280 mμ and its ε value decreased. The absorption in the vicinity of 300 mμ disappeared. These changes indicated that the aliphatic double bond became saturated. Accordingly, the sulphonation probably involved an addition of sulphite to the aliphatic double bond of the alcohol.

The sulphite treatment of the slices would also transform the cinnamyl aldehyde structures of lignin more or less completely into the hydrosulphonic acid derivative (III) and its sulphite addition product (IV) [5]. The carbonyl group in structure (III) causes the sulphonic acid groups of (III) and (IV) to be split off easily by alkali with reforming of the double bond. To regenerate

———— Sulphite solution at pH 6
The yield was determined as described for similar experiments with vanillyl alcohol [6].

the cinnamyl aldehyde structures the slices were therefore immersed in a sodium hydroxide solution.

Finally, the slices were treated with an aqueous sodium borohydride solution, to reduce the cinnamyl aldehyde groups of lignin to cinnamyl alcohol groups. As the yield of such a reduction is high, the amount of cinnamyl alcohol groups formed should be about the same as the amount of cinnamyl aldehyde structures originally present in lignin. Adler and Ellmer [5] have

estimated that spruce lignin contains one such aldehyde group per 40—60 phenylpropane monomers.

The presence of the cinnamyl alcohol groups in the treated slices was clearly demonstrated since the slices turned red when subjected to the colour reaction, and the absorption curve for the coloured slices had a distinct maximum at 475 mμ (Fig. 5). If the coloured slices were treated with acid the colour and the maximum disappeared (Fig. 5) in agreement with the acid labile nature of the glyoxylonitrile structures. (The wavelength of the maximum obtained on different slices varied between 475 ± 5 mμ. This uncertainty depended probably on the superposition of the absorption due to the aromatic structures of lignin, which caused the extinction to increase sharply at lower wavelengths as is shown in Fig. 5.)

As described above, slices which have been treated only with sulphite or with sulphite and alkali should contain no cinnamyl alcohol groups. In accordance with that no maximum was obtained when these slices were subjected to the colour reaction (Fig. 5).

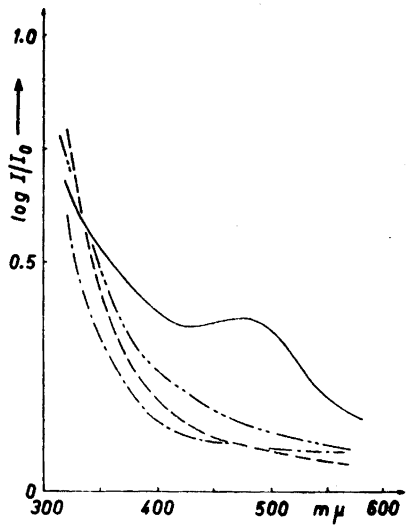

Fig. 5. Absorption curves on spruce wood slices first pretreated and then subjected to the colour reaction. Weight of the slices, 1.6 mg per cm². For the treatment conditions, see Table 1.

Thus, this experiment showed that even a small amount of cinnamyl alcohol groups in lignin can be demonstrated by this method.

The reaction was next performed on slices which had not been pretreated in any way but by extraction. A maximum was again obtained at about 475 mμ (Fig. 6). It disappeared when the coloured slices were treated with acid (Fig. 6). Accordingly, the presence of cinnamyl alcohol groups in lignin was indicated.

Slices which have been exposed to air during six months gave no maximum (Fig. 7). As cinnamyl alcohols are easily oxidized this could be expected. Stored Brauns lignin also gave no maximum (Fig. 8). After reduction with sodium borohydride, however, the presence of the cinnamyl alcohol groups formed was demonstrated in both materials (Figs. 7 and 8), even if the maximum obtained was not so distinct in the case of Brauns lignin.

The question now arises as to whether the 475 mμ maximum on coloured wood slices could be due to a type of group other than cinnamyl alcohol. Conceivable types might be phenyl and benzoyl-carbinols as the corresponding pyridinium salts (N-benzyl and N-phenacyl-pyridinium salts, respectively) are also transformed into anilides of glyoxylonitriles (phenyl and benzoyl-

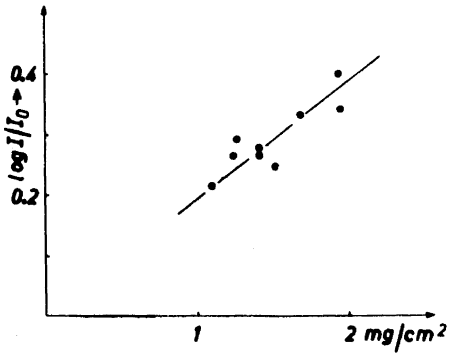

Fig. 9. The absorption at 475 mμ of coloured slices versus their weight per cm².

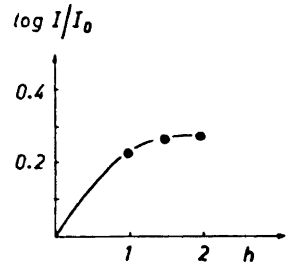

Fig. 10. The absorption at 475 mμ of coloured slices versus the time of treatment with the solution of *p*-nitrosodimethylaniline and potassium cyanide. The weight of the slices, 1.1 mg per cm².

glyoxylonitriles) by nitroso-dimethylaniline and potassium cyanide [4]. Furthermore, it was found that the anilide of benzoyl-glyoxylonitrile had a maximum in its extinction curve at 478 mμ (ε, 32 700) which was close to that of the nitriles obtained from cinnamyl alcohols. The maximum of the anilide of phenyl-glyoxylonitrile was determined to be at 458 mμ (ε, 21 200).

Only primary carbinols can be transformed into this type of nitrile as the central carbon atom in them is linked both with a double bond to a nitrogen atom and with a single bond to a nitrile group. If the 475 mμ maximum is caused by the presence in lignin of phenyl or benzoyl-carbinol structures lignin should then contain phenylmethane or phenylethane monomers, respectively. This does not seem probable according to the modern view of the lignin structure.

Another possibility is, however, not excluded. The maximum may be due to some type of structure which during the performance of the colour reaction is transformed into chromophoric groups structurally completely different from the anilides of glyoxylonitriles. However, the agreement between the maximum wavelength of the coloured slices and that of the model compounds, the destruction of the chromophoric groups by acid, and the inhibition of the colour reaction by pretreatment with sulphite and by air make it probable that the maximum is due to the presence of cinnamyl alcohol structures in lignin.

The data accounted for in Figs. 5—7 could be used to estimate approximately the concentration in lignin of the cinnamyl alcohol groups. In Table 1 the optical density at 475 mμ of the coloured slices (column 2) and of the same slices after decolourization with acid (column 3) have been put together. (The data in Figs. 5 and 6 have been determined on slices which had a weight of 1.6 mg per cm². On the other hand, the slices used for Fig. 7 had a weight of 2.0 mg. By using the fact that the absorption was roughly proportional to the weight per cm² of the slices (Fig. 9) the latter data were recalculated to correspond to a weight of 1.6 mg per cm².)

The optical density due to the glyoxylonitrile structures has been taken as the difference (Column 4) between the values in Columns 2 and 3 (Δ density). The table shows that the Δ density for the cinnamyl alcohol groups originally present in lignin was about 0.25. About the same value was obtained for the cinnamyl alcohol groups formed by reduction of the aldehyde structures with sodium borohydride. Consequently, the amount of cinnamyl alcohol structures in lignin is about the same as that of the cinnamyl aldehyde groups, *e. g.* one group per about 50 phenylpropane monomers.

If the slices were assumed to be optically homogeneous materials an approximate value of the concentration could be calculated in a simple way by using Beer's law. In this way it was estimated that lignin contained one cinnamyl alcohol group per 180 phenylpropane monomers. (The ε-value was assumed to be the same as that of the unfractionated reaction products from (Ib), which was $\varepsilon = 15\,500$ for $\lambda_{max} = 475$ mμ. The absorption due to the glyoxylonitrile structures was taken as the main value of Table 1, log $I_0/I = 0.22$.)

The difference between these two values may be caused by an incomplete reaction of the cinnamyl alcohol groups because of the failure of the reagents to penetrate the wood slices completely. As this obstacle ought to affect to a lesser degree the value obtained by a comparison with the cinnamyl aldehyde concentration, the latter value is assumed to be the more correct one.

Table 1. The optical density at 475 mμ of coloured and of acid decolourized slices.

Pretreated with [a]	Opt. density [b] for		Δdens. [d]	Structure [e]
	colour sl.	decol. sl. [c]		
no reagent	0.38	0.12	0.26	alc.
$NaBH_4$	0.57	0.17	0.40	alc. + ald.
sulphite	0.10	—	—	—
sulphite, alkali	0.10	—	—	—
sulphite, alkali and $NaBH_4$	0.38	0.15	0.23	ald.
air	0.13	—	—	—
air, $NaBH_4$	0.38	0.15	0.23	ald.

a) The conditions were:
$NaBH_4$; the slices were immersed in an aqueous sodium borohydride solution for 4 h.
Sulphite; the slices were heated with a sulphite solution (pH 6.1; total SO_2, 5 %) for 19 h at 135°C.
Alkali; the slices were immersed in N sodium hydroxide solution for 0.5 h.
Air; the slices were exposed for air during 6 months.
b) Determined as log I_0/I corrected to a slice weight of 1.6 mg per cm^2.
c) The coloured slices were immersed in N hydrochloric acid for about 15 h.
d) The difference of the values in columns 2 and 3.
e) The group in lignin which have been transformed into the glyoxylonitrile structure. Cinnamyl alcohol = alc; cinnamyl aldehyde = ald.

EXPERIMENTAL

The reaction of the model alcohols with tosyl chloride and pyridine

3,4-Dimethoxycinnamyl alcohol (2 g) and tosyl chloride (2 g) were dissolved in pyridine (3 ml). The solution was kept at room temperature for 2 days. Sodium hydroxide solution (2 N, 5 ml) was then added and the solution was concentrated *in vacuo* to a small volume. By repeated water additions and concentrations the solution was practically freed from pyridine. Dimethoxycinnamyl-pyridinium picrate was precipitated from the solution by addition of picric acid dissolved in alcohol. The product was recrystallized from aqueous alcohol. Obtained 2.9 g (yield 72 %), m. p. 139—141°. (Found: OCH_3 13.4. Calc. for $C_{22}H_{20}O_9N_4$: OCH_3 12.8.) The picrate was transformed into the perchlorate by using an anion exchanger. M. p. 106—107°. (Found: OCH_3 17.7; N 3.8. Calc. for $C_{16}H_{15}O_6NCl$: OCH_3 17.5; N 3.9.)

Cinnamyl alcohol (1.4 g) and tosyl chloride (1.9 g) were dissolved in pyridine (2 ml). The solution was kept at room temperature for 5 h. Perchloric acid solution (N, 20 ml) was added by which the cinnamyl-pyridinium perchlorate precipitated. It was collected and purified by precipitating from its methanol solution by ether addition. M. p. 70.5—71.5°, undepressed by authentic sample. Yield 60 %.

The synthesis of the *p*-dimethylamino-anilide of styryl-glyoxylonitrile (IIa) and its 3,4-dimethoxy derivative (IIb)

The pyridinium bromide (Ia or b) (1 g), *p*-nitrosodimethylaniline (0.6 g), and potassium cyanide (0.4 g) were dissolved in a mixture of water (2.5 ml) and alcohol (8 ml). The solution turned red. After being kept at room temperature for 1 h the solution was added to water (5 ml). The mixture obtained was extracted with benzene. The extract was passed through a column of alumina, and the column developed with benzene. The anilide was isolated from the coloured zone which moved most rapidly. It was recrystallized from alcohol.

The dimethylamino-anilide of styryl-glyoxylonitrile was obtained from N-cinnamyl-pyridinium bromide in a yield of 46 %. M. p. 116—117°. (Found: C 78.7; H 6.2; N 15.0. Calc. for $C_{18}H_{17}N_3$: C 78.5; H 6.2; N 15.3.)

The dimethylamino-anilide of 3,4-dimethoxy-styryl-glyoxylonitrile was obtained from N-(3,4-dimethoxycinnamyl)-pyridinium bromide in a yield of 26 %. M. p. 158—159°. (Found: C 71.7; H 6.4; N 12.5; OCH_3 18.9. Calc. for $C_{20}H_{21}O_3N_3$: C 71.7; H 6.3; N 12.5; OCH_3 18.5.)

The colour reaction performed on lignin samples

Wood slices. Radial slices about 20 μ thick of freshly cut spruce wood were extracted with hot water and benzene-alcohol (1:1). Some of the slices were then pretreated in accordance with the conditions given in Table 1. The slices were immersed in a solution of tosyl chloride (2 g) in pyridine (20 ml) for 24 h at room temperature. To facilitate penetration, the reaction mixture was placed in a desiccator which was repeatedly evacuated. After washing successively with benzene, alcohol, dilute hydrochloric acid and flowing water, the slices were immersed for 1.5 h (*cf.* Fig. 9) in a solution of *p*-nitrosodi methyl-aniline (1.1 g) and potassium cyanide (0.9 g) in aqueous alcohol (20 ml, 85 % v/v). The penetration was aided as before. The wood slices were then again carefully washed with alcohol and benzene. While wet with benzene they were pressed between two quartz plates, and their optical density was determined with a Beckman spectrophotometer.

Brauns lignin. Brauns lignin (10 mg) was dissolved in a solution of tosyl chloride (35 mg) in pyridine (300 mg), and left for 2 days at room temperature. Water was added and the precipitated lignin was washed well with water. The tosylated lignin was then

dissolved in dioxan-alcohol (0.5 ml, 1:1 v/v). To this solution *p*-nitrosodimethyl-aniline (65 mg) and potassium cyanide (52 mg) dissolved in water-dioxan (1.5 ml, 4:1 v/v) were added. The solution was kept at room temperature for 1 h. Water was added and the lignin suspension obtained was exhaustively extracted with benzene. The lignin was removed from the suspension by passage through a layer of fine sand. The sand was washed well with water, and then the lignin was extracted from it with dioxan. The optical density of the dioxan solution was determined with a Beckman spectrophotometer.

On the Conversion of 3α,7α,12α-Trihydroxycoprostanic Acid to Cholic Acid in Rat Liver Homogenates

Bile Acids and Steroids 46

S. BERGSTRÖM, R. J. BRIDGWATER and U. GLOOR

Department of Physiological Chemistry, University of Lund, Lund, Sweden

With tritium labelled 3α,7α,12α-trihydroxycoprostanic acid it has been found that the main reactions in a rat liver homogenate are the degradation to cholic acid followed by the conjugation with taurine. A minor part of the C_{27} acid was directly conjugated with taurine.

Recently Haslewood [1] isolated 3α,7α,12α-trihydroxycoprostanic acid (»coprocholic acid») from various members of the *Crocodylidæ* and it has also been found in certain species of *Amphibia* (see Ref.[1]). The two coprocholic acids stereoisomeric at C—25 have been prepared by Bridgwater [11]. These C_{27}-bile acids with the intact cholesterol carbon skeleton might be intermediates in the conversion of cholesterol into C_{24} bile acids in higher animals.

This would be in agreement with the suggestion that hydroxylation of the steroid nucleus might precede the β-oxydation of the side chain [2,3]. In connection with work done at this institute on the *in vivo* metabolism of 3α,7α,12α-trihydroxycoprostanic acid [4] we have also studied the reactions of this substance in rat liver homogenates.

EXPERIMENTAL

Tritium labelled L-3α,7α,12α-trihydroxycoprostanic acid was material prepared by Bridgwater and Lindstedt [4]. The radioactivity was 2.2×10^6 counts per min per mg counted in infinite thin layer in a windowless gas flow counter. Directly before use, the substance was purified twice by reversed phase partition chromatography in a system with chloroform/heptane 9:1 as stationary phase and 50 % methanol as moving phase [5-7]. The peak of the titration curve was at 65—70 ml effluent on the standard 4.5 g column at 23°.

Rat liver homogenates were prepared in 4 parts of Bucher medium [8] per part liver fresh weight as described earlier [9]. Unbroken cells and cell debris were spun down at 800 × g for 15 min at 0° and the supernatant used as total homogenate. In a typical experiment we used the following conditions: 38 ml 20 % rat liver homogenate and 2 ml buffer containing 40 mg adenosine triphosphate (crystalline, disodium salt, 3 H_2O,

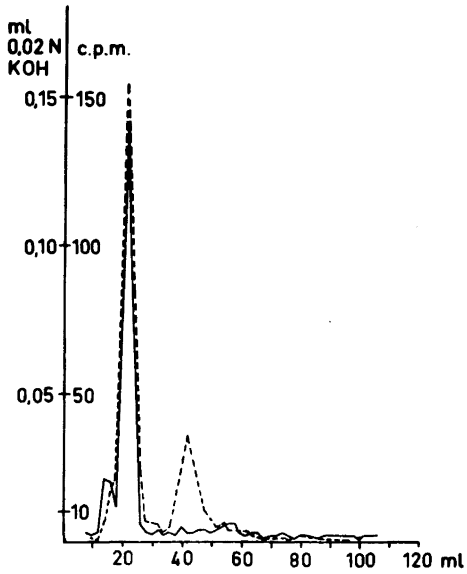

Fig. 1. Chromatography of the hydrolyzed taurine conjugates after incubating [T]-coprocholic acid with rat liver homogenates. Phase system F. Solid line: Titration values. Broken line: c.p.m. Absc. = ml effluent.

Sigma Chemical Corp., St. Louis, U.S.A.). 500 μg trihydroxycoprostanic acid sodium salt = 1.1×10^6 c.p.m. The incubation mixture was shaken in air for 2 h at 37°, pH 7.4 and at the end of this time 5 volumes ethanol were added to stop the reactions. The mixture was heated for 10 min in boiling water, cooled, the precipitate centrifuged off and the supernatant liquid evaporated under reduced pressure. The residue was partitioned between 1 N HCl and butanol and the combined butanol extracts again evaporated under reduced pressure. This gave the starting material for reversed phase column partition chromatography as worked out by Bergström, Sjövall and Norman [5-7]. The following solvent systems were used (Table 1).

Table 1. Solvent systems.

System	Stationary phase	Moving phase
C (Ref.[7])	chloroform / *iso*octanol 1:1	50 % methanol / water
D (Ref.[7])	butanol	water
F (Ref.[6])	chloroform / heptane 9:1	55 % methanol / water

Determinations of the radioactivity were done in "infinitely thin" layers on frosted aluminum or copper planchets in a windowless gas flow counter (Tracerlab).

After each experiment the extracts were first chromatographed with phase system D to separate the taurine conjugated acids from all distinctly less polar products, which stay in the stationary phase. The latter were then fractionated with phase system F. The taurine conjugated acids were saponified with 1 N NaOH for 8 h in sealed glass tubes at 120 °C, the acidified reaction mixture extracted with ether, washed, evaporated and chromatographed in phase system C together with unlabelled cholic acid.

RESULTS

In a typical experiment about 83 % of the activity was recovered in the taurine band (Phase system D). These fractions were combined and saponified and the isolated acids were rerun in phase system F together with unlabelled cholic acid. About 70 % were recovered in the cholic acid band near the front followed by a second band at 40—45 ml containing about 20 % *cf.* Fig. 1. When the material in the first band was rerun in system C the activity curve coincided with the titration curve of cholic acid. The identity of the labelled product with cholic acid was further strengthened by dilution with 100 mg unlabelled cholic acid and recrystallization four times from different solvents (aqueous ethanol, acetone, ethyl acetate) when the specific activity remained constant throughout the procedure.

The second band appeared at the same place as the coprocholic acid used. No unlabelled acid was available at that time for isotope dilution.

In vitro as *in vivo* the coprocholic acid was thus rapidly degraded to cholic acid that was conjugated with taurine. A minor part of the coprocholic acid was directly conjugated with taurine and thus protected from the degradation as has also been found *in vivo* [10].

The eluate of the butanol column, *i. e.* the acids that stayed on the column in this system, representing 17 % of the total activity, was rerun in phase system F when three distinct bands were obtained, with roughly equal isotope content, appearing at (a) 15, (b) 35, and (c) 75 ml. These minor peaks have not been identified with certainty but (b) follows coprocholic acid also in phase system C and might thus be unchanged coprocholic acid that has escaped conjugation, (a) is eluted before cholic acid in system C (glycocholic acid?). The structure of (c) is unknown. These compounds were not observed in the bile when labelled coprocholic acid had been injected intraperitoneally into bile fistula rats [4].

The investigation of the location of the various enzyme systems involved in the different fractions of the liver homogenate is being continued.

This work is part of investigations supported by *Statens medicinska forskningsråd* and *Knut och Alice Wallenbergs Stiftelse.*

Determination of the Number of Free *ortho* and *para* Positions in Phenols

BENGT SMITH

Institutionen för Organisk Kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

A method has been worked out for the determination of the number of free *ortho* and *para* positions in phenols, using bromide-bromate titration in glacial acetic acid and conductometric titration in ethyl alcohol-water. The majority of the phenols on which the method was tried gave the correct value for the number of free *ortho* and *para* positions. The significance of conductometric titration curves for the identification of various types of phenols has also been discussed.

On investigation of the structure of a phenol, a knowledge of the number of free *ortho* and *para* positions in the aromatic nucleus is of considerable value. The facile substitution by bromine of the hydrogen in the positions *ortho* and *para* to a phenolic hydroxyl should provide a suitable method for the determination of this number. However, there is no universal bromination procedure *, which can be used with confidence for the quantitative bromination of all types of phenols. This makes it more difficult to develop a successful application of the bromination method for the present structural problem. It is in general not possible to adapt the procedure to the type of phenol, since this is often unknown, and the same procedure must therefore be used in all cases. However, it must be remembered, that in this case a quantitative determination of the bromine consumption is not necessary since only an estimate of the number of bromine atoms entering the aromatic nucleus is required. Thus it is possible that a suitable compromise between the existing quantitative methods could be found which can give values accurate enough for this purpose. Recently [1] it was shown by the author that a large number of phenols could be quantitatively brominated in glacial acetic acid either by direct titration with bromide-bromate solution or by the use of an excess of this reagent. A hybrid between the two methods, applicable to the solution

* For a discussion of quantitative bromination methods for phenols, *cf.* Ref.[1].

of phenolic structural problems, has now been worked out and the results obtained are presented in this paper *.

The bromide-bromate titration gives only the number of equivalents of bromine consumed per gram of the phenol. To calculate the number of free *ortho* and *para* positions it is necessary to know the molecular weight of the phenol. Several methods are available for this purpose. Conductometric titration [8], titration in nonaqueous solvents [9,10] and, recently, high frequency titration [11] have been employed. Although the conductometric method might not be the most accurate one it has been chosen here because of its general applicability and its simplicity, which are important factors in identification work.

EXPERIMENTAL

Bromide-bromate titration. The phenol (50 mg) was weighed and dissolved in 20 ml of glacial acetic acid. Conc. hydrochloric acid (5 ml) was added and then 0.1 N potassium bromide-bromate dropwise until the solution of the sample had acquired a distinct yellow colour. Care should be taken not to add more than about 10 % excess of bromide-bromate solution. Five ml of a 10 % potassium iodide solution were then added and the iodine was titrated at once with 0.1 N thiosulphate using starch solution as indicator.

Conductometric titration. A Radiometer Conductometer model CDM2 was used. The phenol (300–500 mg) was weighed and dissolved in 25 ml of 96 % ethyl alcohol. The solution was then diluted with distilled water (usually 25 ml). For some phenols it was necessary to use a higher proportion of ethyl alcohol in order not to precipitate the phenol (see Table 1) but in all cases the total volume was 50 ml. From a microburette 0.5 N sodium hydroxide was added and the conductance read for each ml of the titrant. It is recommended that the addition should be carried on considerably beyond the first equivalence point in order to ascertain whether the molecule contains more than one acidic function. The observed conductance values were corrected for the dilution caused by the titrant by multiplying them by $(V+v) / V$ where V is the initial volume and v the volume of titrant added. The equivalence points were evaluated graphically by plotting the conductances against the volumes of titrant. The intersections of the straight lines drawn through these points define the equivalence points. The titration vessel was not thermostated but was shielded against rapid temperature changes.

RESULTS

Conductometric titrations. The accuracy of conductometric titrations of phenols is dependent on the concentration of the phenol in the solvent. Concentrations which are too low or too high should both be avoided. Here solutions which are 0.04 to 0.05 N have been titrated with good accuracy in most cases. It is of course difficult to weigh the correct amount of an unknown phenol. If, however, the first titration shows that the concentration of the solution has been considerably different from the values given above another titration should be made.

* Methods for the estimation of the number of free *ortho* and *para* positions in phenols by means of bromine have been described elsewhere. Veibel [2], for example, utilizes a modification of the well-known Koppeschaar procedure. In view of the reported inaccuracy of this method [3-7], which is partly connected with the replacement of various groups by bromine (Veibel mentions the risk of replacement of carboxyl groups) there is some doubt concerning the general usefulness of the Veibel procedure. There does not appear to be any published account of tests on different types of phenols of the procedure recommended.

Table 1. Bromide-bromate titration and conductometric titration of phenols.

* Titrated in 75 % ethyl alcohol.
** Titrated in 96 % ethyl alcohol.
*** Titrated in 60 % ethyl alcohol.

The accuracy is sufficient for the purpose (*cf.* Table 1) except in a few cases such as some alkylphenols with several alkyl groups or large alkyl groups (*cf.* Nos. 7, 17, 18 and 19). One of the reasons for the decreased accuracy is that some of the compounds mentioned were not sufficiently soluble in 50 % ethyl alcohol and a solvent with less water had to be used which lowers the accuracy by increasing the angle at the equivalence point. In the case of phenols with several acidic functions one or more of the equivalence points were often of inferior accuracy. It was generally observed that the equiv. weight calculated from the last inflexion point was the most accurate one, provided that the inflexion was not too small (*cf.* No. 51 and below).

The shape of the titration curves will be discussed in some detail because of its significance in the identification of various types of phenols.

The phenols in Table 2 have been divided into nine groups according to the shape of their titration curves. The first group contains only picric acid, the titration curve being that of a strong acid titrated by a strong base. Group 2 contains the bulk of the phenols. Nearly all monobasic phenols yield the curve shown in the last column when titrated with sodium hydroxide under the present conditions. Pyrocatechol, salicylic acid and 2,2′-dihydroxydiphenyl also behave as monobasic compounds and give no indication of a second acidic function. 2,4-Dihydroxybenzaldehyde represents the third group. Both of the hydroxyls are titrated but only one break in the curve, at the second equivalence point, is obtained. *o*-Vanillic acid and 2,4-dihydroxyacetophenone (group 4) give two inflexion points on titration, the angle at the second one, however, is nearly 180°. Group 5 is composed of *m*-hydroxybenzoic acid, two *p*-hydroxybenzoic acids, ferulic acid (p-$HOC_6H_4CH_2$=$CHCOOH$), and *p,p′*-dihydroxydiphenyl-2,2-propan. As in group 4, one inflexion point is obtained for each equivalence point but this time the main inflexion is at point 2, the

* Breaks in the titration curve.

** The values of the equiv. weights show, that these compounds cannot be monobasic and dibasic, respectively. It is also evident from the shape of the titration curve that the latter compound is tribasic.

angle at point 1 being nearly 180°. Resorcinol and hydroquinone which belong to group 6 are intermediate between the phenols in the two preceding groups, the angles at the two inflexion points being nearly alike.

Three phenols each with three acidic functions in the molecule were also titrated. The curves obtained for these compounds were all dissimilar and the

phenols accordingly placed into separate groups (Nos. 7, 8 and 9). According to Kolthoff * phloroglucinol behaves on conductometric titration as a dibasic acid and the curve has only one inflexion point. Under the present conditions phloroglucinol was found to behave as a tribasic acid. In addition to the inflexion point at the second equivalence point a slight change of the direction of the curve was obtained at the third equivalence point too. Pyrogallol also behaved as a tribasic acid, this time with an inflexion point at each equivalence point. Kolthoff [8] reported that pyrogallol behaved as a dibasic acid, giving two breaks in the curve. Gentisic acid (hydroquinonecarboxylic acid) also shows the three acidic functions, the main difference between this curve and that for pyrogallol being the large angle (small inflexion) at the third equivalence point.

It is evident from the foregoing that by using conductometric titration it is possible in most instances to determine the number of acidic functions present in a phenol molecule. For three phenols in group 2 the method failed, but in the case of 2,2′-dihydroxydiphenyl the bromide-bromate titration revealed the presence of two hydroxyl groups in the molecule (*cf.* below). Furthermore the shape of the titration curve often gives additional information about the structure.

Bromide-bromate titration. The results of the bromide-bromate titration of 57 phenols using the method previously described have been collected in Table 1, which gives the equiv. weights obtained and the number of bromine atoms entering each phenol molecule. The latter values were calculated from the molar weights determined by conductometric titration and the equiv. weights resulting from the bromide-bromate titration. As seen from the last column but one in Table 1 the results with few exceptions are satisfactory. For the 57 phenols collected in Table 1 the method gave the correct answer for the number of free *ortho* and *para* positions in 53 cases. It is, however, obvious that the method may give erroneous results in some cases.

The reaction, for example, between 2,4,6-trialkylsubstituted phenols (*cf.* Nos. 17 and 18) and bromine in acetic acid which proceeds easily with the formation of bromo*cyclo*hexadienones and other compounds [12–14] makes it difficult, using the present method, to ascertain the absence of free *ortho* and *para* positions in these compounds. The method also failed with *m*-nitrophenol, which has previously [1] been shown to be more resistant to attack by bromine than most other phenols. It has been pointed out that the quantitative bromination methods were less suited to the analysis of alkoxyphenols [1] and the same may be said about the method described in this paper. Although good values were obtained in many instances, rather divergent results were sometimes observed for phenols of similar structure (*cf.* Nos. 55 and 57). A contributory reason for this was that many of these compounds adopt a yellow colour as soon as the bromide-bromate solution is added, which makes it difficult to add the appropriate amount of this reagent.

Of the dihydric phenols tested, pyrocatechol consumed about 2 equivalents of bromine per mole and hydroquinone about 1. As seen from Table 1 the bromine consumption of phenols with the hydroxyl groups in *meta* position

* Kolthoff [8] used 1 N sodium hydroxide as titrant and water as solvent.

corresponds to the number of free *ortho* and *para* positions (*cf.* Nos. 51—54).

It is apparent from Table 1 that not more than 3 bromine atoms enter the molecule of a mononuclear phenol under the present conditions, provided that unsaturated or other bromine consuming side chains are absent. If the bromine consumption is found to exceed 6 equivalents per mole it is therefore an indication that a di- or polynuclear phenol may be present. Table 1 gives two examples of dinuclear phenols (Nos. 20 and 47). In the first case the presence of two hydroxyls was revealed by the conductometric titration, in the second, however, one break only was obtained in the titration curve. In both cases 4 bromine atoms entered, indicating that in the first the two hydroxyls were situated in separate rings and in the second not one but two hydroxyls were present, this time also in separate rings.

Guanine Metabolism in Fishes

I. The Occurrence of a Guanine-Deaminating Enzyme in Fish Skin

PER ERIC LINDAHL and PER OLOV SVÄRD

Institute of Zoophysiology, University of Uppsala, Sweden

Some properties of the guanine-deaminating enzyme of fish skin have been studied. The deaminase activity was found to be stimulated by the metal-chelating agent ethylenediaminetetraacetate (EDTA), indicating a sensitiveness of the enzyme towards metal ions. Among a number of cations tested Cu++ and Zn++ were by far the most potent inhibitors and their effect was greatly influenced by the pH. In view of this it is likely that a salt-like complex is formed between the inhibiting ions and negatively charged groups of the enzyme molecule. Experiments with iodoacetate gave no evidence for the necessity of sulfhydryl groups for the deaminase activity. Dialysis experiments failed to demonstrate any metalic-ion requirement.

As is well known guanine, chiefly recognized as one of the purine bases of the nucleic acids, also occurs in large amounts in the skin and on the scales of fishes, causing the silvery appearance characteristic of many species. Hitchings and Falco [1] and more recently Neckel [2] have convincingly demonstrated the identity of this silvery matter with pure guanine.

Fishes — like spiders — are unique in their ability to produce large amounts of non-nucleic acid guanine. In fishes this production exhibits some peculiarities, *e. g.* the rather sudden appearance of this substance, which accompanies the metamorphosis of the Salmon parr to smolt, as well as the disappearance that can be induced merely by preventing the smolt from getting into seawater as it normally does on completion of the metamorphosis. Further it was shown by Sumner [3] that the production of guanine is subject to variations caused by visual stimuli. Thus it was found that prolonged stay of the fish upon a dark background led to a decrease in the amount of guanine, while a light background produced the reverse effect. — In view of these facts fishes appear to be interesting objects for a study of the enzymes involved in the metabolism of guanine. The present investigation was intended to determine, whether or not the fishes are provided with the same or similar enzymes for the breakdown of "skin guanine", as are known to affect nucleic acid guanine.

In the present paper the existence in fish skin of a guanine deaminating enzyme is demonstrated, and some of its properties are studied.

EXPERIMENTAL

Materials. The guanine and xanthine preparations used were commercial products obtained from Schuchardt and Hoffman-La Roche Chemical Co., respectively. They were not purified prior to use.

Because of the scanty solubility of guanine at neutrality colloidal solutions according to Schmidt [4] had to be prepared for ammonia determinations. For the spectrophotometric studies, which occupied the main part of this investigation, true solutions of guanine containing, unless otherwise indicated, 10 μg per ml could be used.

Preparation of the enzyme. The fish, roach *(Leuciscus rutilus* Lin.), was skinned immediately after being killed. The skin plus scales (wet weight 8—12 g) were ground as soon as possible, and extracted at room-temperature with 3 volumes of glass-distilled water or, when indicated, with a 0.01 M solution of ethylenediaminotetraacetic acid (EDTA). The extraction was performed for 30 min in a shaking device. The mixture was centrifuged at 1 200 *g* for 15 min in order to remove insoluble material; the supernatant was then subjected to 11 000 *g* for 20 min at 0 °C. The resulting fluid containing the enzyme was not further purified, since this was not found necessary for the present study.

Dialysis of the enzyme solution. Samples of the enzyme solution were dialysed through cellophane membranes against glass-distilled water or against a 0.005 M EDTA solution in an apparatus, providing frequent and thorough stirring of both the enzyme solution and the surrounding fluid.

In some cases samples were electrodialysed against 0.005 M EDTA solutions.

Analytical. The enzymatic activity was followed either by measuring the ammonia liberated or by a spectrophotometric procedure. The ammonia estimations were carried out essentially according to Schmidt [4], involving vacuum-distillation of pre-formed ammonia according to Parnas [5] with subsequent titration, employing the Tashiro indicator. Generally the spectrophotometric procedure was chosen. It is based upon the change in optical density in U.V. caused by the deamination of guanine to xanthine. The values reported by Roush and Norris [6] for the maximum density change at 245 mμ, (for pH values below 7.5) at 250 mμ (for pH values 8—8.5) and at 255 mμ (for pH values above 9.0) obtainable with 10 μg per ml solutions of guanine were checked, employing solutions of pure guanine and pure xanthine in buffer. These values were then used in computing the per cent deamination of guanine. A Beckman model DU spectrophotometer with U.V. attachment was used throughout.

Standard conditions. The incubation was carried out in 10 mm quartz cuvettes. 0.2 ml of the enzyme solution was incubated with 3.1 ml of the buffered solution of guanine containing 10 μg per ml. The pH was varied in the region 6.0—9.5, using 0.067 M phosphate or 0.05 M tris -(hydroxymethylaminomethane) buffers. The final pH was checked electrometrically at the end of the incubation. Readings were taken with one min intervals at 245, 250, or 255 mμ depending upon the actual pH against blanks without guanine. The time of incubation was generally 15 min, but was sometimes extended to 60 min. The temperature was kept at 21°C. The total volume of the samples was always kept at 3.3 ml.

RESULTS

Aqueous extracts of fish skin were found to contain a guanine deaminating enzyme. As seen from Fig. 1 there is good proportionality between the amount of enzyme added and the ammonia liberated. The spectrophotometric approach to the enzymic reaction elucidated that the ammonia formed is a result of an actual deamination and not of a breakdown of the ring structure, since xanthine, characterized by its U.V. absorption curve, appears as the other reaction product (Fig. 2).

The effect of EDTA. Preliminary experiments aiming at a determination of the enzymatic activity at different pH values showed that the time course curves for pH values above 8 were not linear. As is seen from Fig. 3 rather

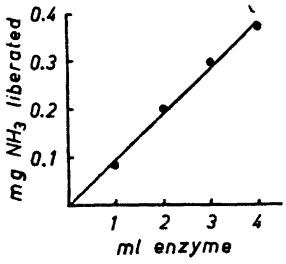

Fig. 1. The effect of varying enzyme concentration on the enzymatic activity as measured by the ammonia determination method. *Conditions:* 5.0 ml of a colloidal solution of guanine (0.88 mg per ml) and 10 ml of 0.067 M phosphate buffer pH 7.5 were incubated with the indicated amount of enzyme. The total volume of the samples was made up with distilled water to 20 ml. The incubation was carried out for 40 minutes at 40 °C, and was stopped by the addition of 4 per cent HCl. Aliquots were taken to ammonia estimations.

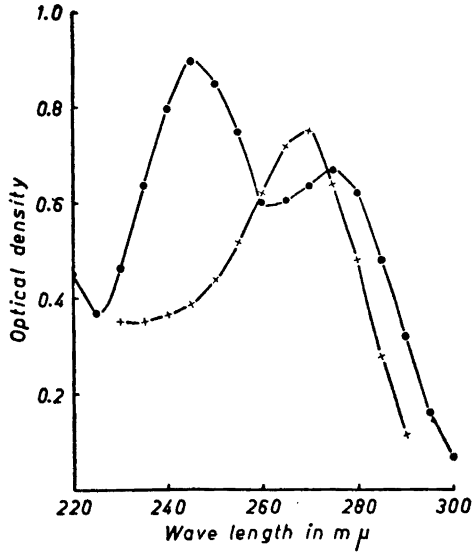

Fig. 2. The U.V. absorption changes caused by the deamination of guanine by the enzyme from fish skin. *Conditions:* 0.2 ml of the enzyme solution was incubated in a total volume of 3.3 ml with a buffered solution of guanine (15 μg per ml). Buffer: 0.067 M phosphate pH 7.5. Incubation time 30 minutes at 21 °C. ● — ●, the absorption curve at zero time, guanine. × — ×, the same after 30 minutes' incubation, xanthine.

abrupt drops in the activity occurred at these pH after about 10 min incubation. At pH 9.0 the enzyme seemed to be completely inactive. Pre-incubation of the enzyme for varying time periods with buffer at pH above 8 prior to the addition of substrate resulted in a considerably lowered deamination rate (Fig. 4). This effect of the pre-incubation increased with rising pH.

When EDTA was included in the reaction mixture this phenomenon disappeared (Fig. 3), the time course curves at all pH values being linear and the activity at pH 9.0 accounting for roughly 85 % of the optimum value. Although the activating effect of EDTA was more marked in the pH region above 8, it was also evident in the region below 8. Furthermore the stability of the enzyme solution was found to be greatly enhanced by the extraction of the enzyme with EDTA solution instead of glass-distilled water.

The effect of divalent cations. As a consequence of the above-mentioned findings the effect of divalent cations on the enzymatic activity was studied. For this purpose the enzyme was prepared by extraction with EDTA followed by

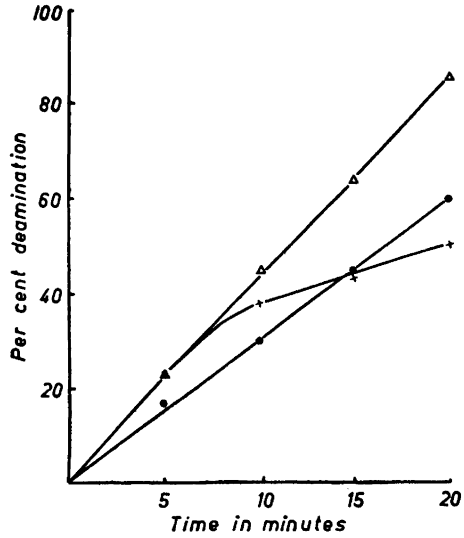

Fig. 3. The time course of the enzymatic activity. Standard conditions, 0.05 M TRIS buffer. ● — ●, obtained at pH 7.0. × — ×, obtained at pH 8.5. △ — △, obtained at pH 8.5 with the enzyme pre-treated with 0.01 M EDTA.

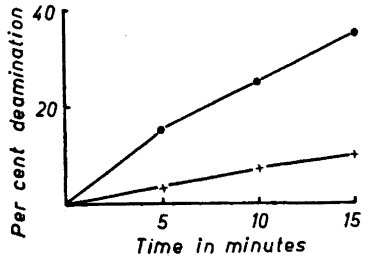

Fig. 4. The effect of pre-incubation on the enzymatic activity. Standard conditions, 0.05 M TRIS buffer pH 8.5, ● — ●, no pre-incubation. × — ×, pre-incubated for 10 minutes before the addition of substrate.

Table 1. The effect of cations on the enzymatic activity. Standard conditions: pH 8.5; 0.05 M TRIS buffer.

Inhibitor	Concentration	Relative activity
None	—	100
$CaCl_2$	1×10^{-2} M	96
$MgSO_4$	1×10^{-2} M	106
$MnCl_2$	1×10^{-2} M	104
$CoSO_4$	1×10^{-2} M	23
$ZnSO_4$	6×10^{-5} M	31
$Fe_2(SO_4)_3$	6×10^{-5} M	85
$FeSO_4$	6×10^{-5} M	85
$CoSO_4$	6×10^{-5} M	94
$CuSO_4$	6×10^{-5} M	29

Table 2. The effect of pH on the cationic inhibition. Standard conditions. The concentration of Cu^{2+} and Zn^{2+} = 6×10^{-5} M; 0.05 M TRIS buffer.

Inhibitor	Per cent inhibition at pH		
	7.3	8.5	9.0
$ZnSO_4$	0	69	100
$CuSO_4$	3	71	100

dialysis. By this treatment interferring ions together with EDTA were removed from the enzyme solution which was then suited for studies on ion promoted inhibition.

Among a number of ions tested (*cf.* Table 1) Cu^{2+} and Zn^{2+} were found to be by far the most potent inhibitors, effecting complete inhibition at concentrations of 6×10^{-5} M. The inhibition was found to be greatly influenced by the pH, being none or insignificant at pH 7, and complete at pH 9 (Table 2). When EDTA was included in the reaction mixture the mentioned ions were ineffective. However, once inhibited the enzymatic activity could not be restored by the addition of EDTA.

The effect of other inhibitors. The observation of Schmidt [4] that sodium fluoride inhibits the deamination of guanine could not be verified under the conditions of the present experiments. Neither when tested directly nor after pre-incubation with the enzyme before the addition of substrate did sodium fluoride exert any significant effect in concentrations as high as 0.01 M.

Iodoacetate was used for testing the possibility of an interaction between the inhibiting ions and sulfhydryl groups of the enzyme molecule. The enzyme was pre-incubated with iodoacetate at a concentration of 0.01 M for periods up to 60 min, yet without any effect (Table 4).

Table 3. The effect of sodium fluoride on the enzymatic activity. Standard conditions. 0.05 M Tris buffer pH 8.0.

Inhibitor	Per cent deamination	Per cent inhibition
None	37	0
NaF, 0.01 M not pre-incubated	36	2
NaF, 0.01 M pre-incubated for 20 min	35	5

Table 4. The effect of iodoacetate on the enzymatic activity. Standard conditions. 0.05 M Tris buffer pH 8.0.

Inhibitor	Per cent deamination	Per cent inhibition
None	35	0
Iodoacetate, 0.01 M not pre-incubated	35	0
Iodoacetate, 0.01 M pre-incubated for 20 min	33	5

Ammonia in a concentration of 0.01 M did not affect the enzymatic activity.

The effect of dialysis. When dialysis against 0.005 M EDTA was extended over 16 h no loss in activity occurred. On the contrary, when the enzyme had been prepared by extraction with glass-distilled water dialysis resulted in an activation (Fig. 5). No change in activity occurred when an enzyme solution prepared by extraction with EDTA was dialysed against glass-distilled water.

Electrodialysis during 5 h produced no inactivation.

The pH-activity curve and the effect of phosphate. The pH-activity curve is based on time course curves obtained for different pH values, while using enzyme solution freed from contaminating ions (Fig. 6). When studied in TRIS buffer the optimum pH was found to lie between pH 8.0 and 8.25. This is in agreement with Roush and Norris [6] using mammalian guanase. However, the

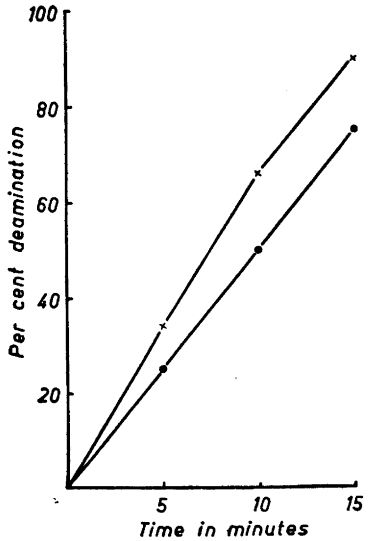

Fig. 5. The effect of dialysis on the enzymatic activity. The enzyme solution prepared by extraction with glass-distilled water was dialysed for 16 hours against 0.005 M EDTA. The activity was measured under standard conditions. ● — ●, non-dialysed enzyme. × — ×, dialysed enzyme.

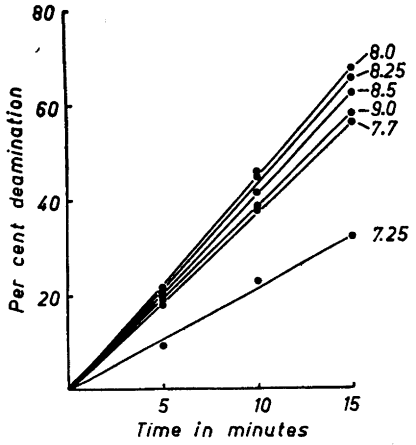

Fig. 6. Time course curve for the enzymatic activity at different pH values. Standard conditions, EDTA prepared enzyme, 0.05 M TRIS buffer, pH as indicated in the figure.

general appearance of the pH-activity curve for the enzyme in fish skin (Fig. 7) differs somewhat from that given by these authors, the discrepancies being essentially confined to the pH region below 8. This was found to be due to the kind of buffer substance used, and its concentration. When the reaction was studied in phosphate buffer of low concentration the curve more closely resembled that of mammalian guanase, the activity values at 7.3 accounting for 85 % of the optimum value as compared with 60 % in TRIS buffer (Fig. 8). With increasing concentration of the phosphate buffer the optimum pH was shifted towards the acid side. At a buffer concentration of 0.1 M the optimum was found to lie in the vicinity of 7.5.

DISCUSSION

In its pH dependency the guanine-deaminating enzyme of fish skin agrees with guanase of other origin studied previously [6]. The present authors could, however, not demonstrate any inhibition by sodium fluoride as reported by Schmidt [4]. Using bacterial guanase Rakosky, Zimmerman and Beck [7] were also unable to confirm this observation.

On account of the ineffectiveness of iodoacetate it is concluded that sulfhydryl groups are not essential for the enzymatic activity.

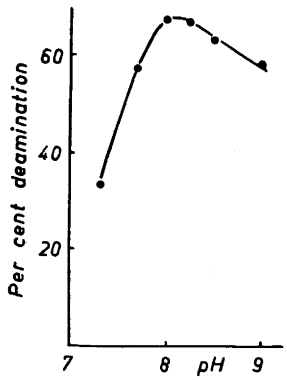

Fig. 7. The pH-activity curve of the fish skin enzyme. The curve is based on the time course curves in Fig. 6. The values corresponding to 10 minutes' incubation are plotted against the respective pH.

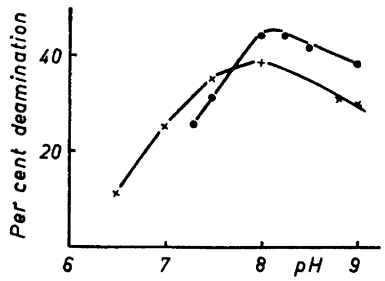

Fig. 8. The influence of the buffer system used on the pH-activity curve. Standard conditions, EDTA prepared enzyme solution. ● — ● Measured in 0.05 TRIS buffer. × — × Measured in 0.067 M phosphate buffer; the pH values 8.8 and 9.0 were obtained by the addition of phosphate up to 0.067 M concentration to TRIS buffer which latter determined the pH. The values correspond to 5 minutes' incubation time.

There is no evidence for a metal-ion requirement of the enzyme, as might be suspected from Schmidt's [4] observation. The dialysis experiments failed to demonstrate any need for a dialysable activator. On the contrary, some divalent cations were found to be potent inhibitors, and it was observed that their effect was counteracted by EDTA. On the basis of this fact the activating effect of EDTA was interpreted as being due to its metal-chelating property. It is likely that the enzyme solutions prepared by extraction with glass-distilled water are contaminated by ions which are thus removed by the action of EDTA.

As to the effect of dialysis illustrated in Fig. 5, the activation observed may most likely be ascribed to EDTA, since dialysis of an EDTA treated enzyme solution against glass-distilled water was unable to bring about any change in enzymatic activity.

In view of the dependency of the effect of the inhibiting ions on the pH it is likely that a salt-like complex is formed between the inhibiting cations and negatively charged groups of the enzyme molecule. This complex seems to be stable, since EDTA could not restore the activity when once inhibited. No macroscopic precipitate was, however, observed.

Ammonia, one of the reaction products, was found not to inhibit the activity at any concentration up to 0.1 M. Xanthine was not tested in this respect.

With respect to the pH-activity curve the enzyme from fish skin shows definite similarities with the mammalian guanase as studied by Roush and Norris [6], especially when measured in phosphate buffer of low concentration.

The mechanism behind the displacement of the optimum by increasing concentrations of the phosphate buffer as well as the somewhat different shape of the curve when measured in TRIS buffer remains, however, obscure.

Guanine Metabolism in Fishes

II. A Guanosine Phosphorylase in Fish Skin

PER OLOV SVÄRD

Institute of Zoophysiology, University of Uppsala, Uppsala, Sweden

Aqueous extracts of fish skin, previously found to contain a guanine-deaminating enzyme, are also capable of splitting guanosine. The reaction has been studied spectrophotometrically and the enzyme has been found to be phosphorolytic.

Enzymatic splitting of guanosine may be either hydrolytic or phosphorolytic. Tarr [1] has shown recently the existence in fish muscles of two hydrolytic enzymes, one with specific action upon inosine at pH 8.6, and another, non-specific, acting upon guanosine at pH 5.6. Since Kalckar [2] elucidated the phosphorolytic action of the nucleosidases which had formerly been looked upon as hydrolytic enzymes, it has, on the other hand, become obvious that phosphorolytic splitting is a more wide-spread phenomenon than had been thought earlier. The purine nucleoside phosphorylase was proposed to catalyze the reaction:

$$\text{Purine-1-ribose} + H_3PO_4 \rightleftharpoons \text{Purine} + \text{Ribose-1-phosphate}$$

and it was found to be active only with guanine or hypoxanthine as the purine.

The present investigation was intended as a study of the mechanism of the fission of guanosine which was observed to be caused by an enzyme from fish skin. The use of a spectrophotometric method for the identification of guanine was made possible by the fact that the liberated purine base was not deaminated, although the enzyme extract contained guanase in addition to the nucleoside phosphorylase, as shown in an earlier investigation [3]. The apparent inhibition of guanase is probably competitive, but the problem will be followed up later. Because of this inhibition, the enzymatic method of Kalckar [4] could not be used for the quantitative determination of guanine.

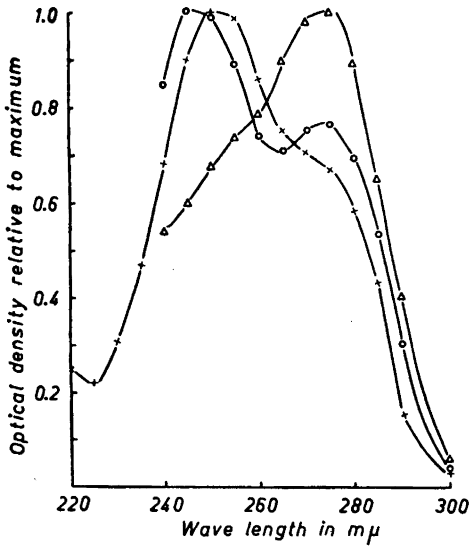

Fig. 1. Enzymatic splitting of guanosine by the fish skin enzyme. Conditions as described under Experimental. × — — — × absorption curve of the reaction mixture at zero time, pH 7.7. O — — — O absorption curve of the reaction mixture after 50 minutes incubation, pH 7.7. △ — — — △ the same as O — — — O made alkaline to pH > 11. The extinction at maximum (E_{max}) has been taken as 1.0.

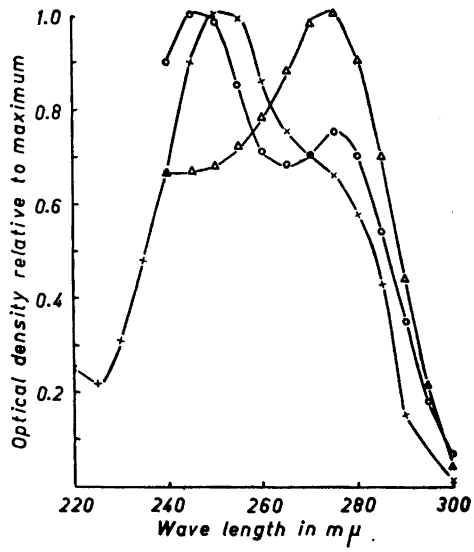

Fig. 2. Absorption curves of authentic guanosine and guanine. × — — — × guanosine at pH 7.7, O — — — O guanine at pH 7.7, △ — — — △ guanine at pH > 11, E_{max} = 1.0.

EXPERIMENTAL

Material. The guanosine and guanine preparations used were commercial products from Kebo Chemicals Ltd. and Schuchardt, respectively.

Preparation of enzyme. The fish (roach, *Leuciscus rutilus* Lin.) was skinned, the skins ground as soon as possible and extracted with 3 volumes of re-distilled water in a mechanical shaker at room-temperature for 30 min. The mixture was centrifuged at 1 200 *g* for 10 min, the supernatant was then subjected to 9 000 *g* for 15 min. The resulting fluid was used without further purification.

Analytical methods. The spectrophotometric method used for the identification of guanine, the reaction product, is based upon the characteristic absorption spectra of guanosine and guanine in U.V. The compounds are further differentiated and the identity of the reaction product is strengthened by raising the pH of the medium to pH > 11. A Beckman spectrophotometer model DU with U.V. attachment was used for the determinations.

3 ml of a solution of guanosine, containing 17 μg per ml in 0.067 M phosphate buffer of pH 7.7, was incubated in the Beckman cuvette with 0.3 ml of the enzyme solution. The absorption between 220 and 300 mμ was measured at zero time, and after the appropriate incubation time, usually 50 min, against a blank without guanosine. The reaction mixture was then made alkaline to pH > 11 with NaOH, and the absorption curve was re-read.

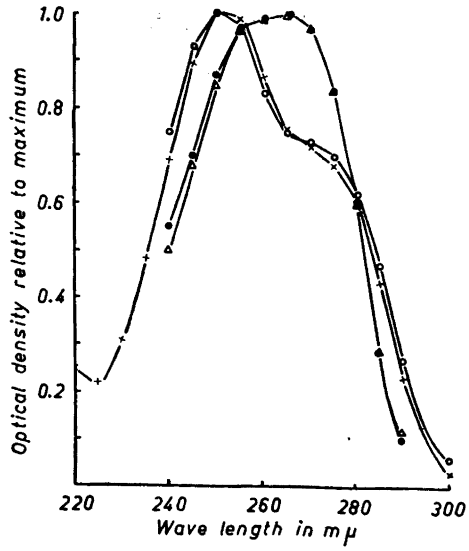

Fig. 3. The phosphate dependency of the fish skin enzyme. Conditions as described under Experimental except that phosphate buffer was exchanged for glycyl glycine buffer. × – – – × absorption curve of the reaction mixture at zero time, pH 7.8, O– – – O the same after 50 minutes incubation, pH 7.8, △– – – △ the same as O– – – O but pH > 11, ●– – – ● authentic guanosine at pH > 11.

The identification of the reaction product was further strengthened by subjecting to paper chromatography aliquots of a reaction mixture. This contained 5 μmoles of guanosine and 3 μmoles of phosphate in 0.02 M glycyl glycine buffer pH 7.8 which had been allowed to incubate with the enzyme at 37 °C for 60 min. A mixture of *iso*butyric acid-ammonia-ethylenediaminotetraacetic acid, according to Krebs and Hems [5], was used as solvent. The spots were detected with the aid of a U.V. lamp.

Guanine was determined quantitatively with Folin's phenol reagent as described by Hitchings [6] with minor modifications. Of reaction mixtures containing guanosine, phosphate, and enzyme solution in glycyl glycine buffer of pH 7.8, 1.0 ml was taken for guanine determination. The proteins were precipitated with 0.3 ml of 3 % perchloric acid, as recommended by Lowry and Lopez [7] for phosphate determination (see below). 1.0 ml of the protein-free centrifugate was mixed with 2.0 ml of the phenol reagent and 5.0 ml of a saturated solution of sodium carbonate. The mixture was brought up to 15 ml with distilled water, and readings were taken at 650 mμ in a Beckman spectrophotometer.

Compared with guanine, guanosine produces a very weak colour with the phenol reagent. This makes possible a quantitative determination of guanine in the presence of guanosine, as is also pointed out by Kalckar [4]. Before the addition of enzyme a 1.0 ml sample of the reaction mixture was taken and treated in the same way as the tests, and was used as a blank in these determinations.

Phosphate was determined according to Lowry and Lopez [7]. The colour reaction was made with 0.2 ml of the protein-free centrifugate mentioned in connection with the guanine determination.

RESULTS AND DISCUSSION

A comparison between Figs. 1 and 2 shows the similarity between the absorption curves of authentic guanine and the reaction product after 50 min incubation. The two figures in addition show the agreement between the respective absorption spectra at alkaline pH. The ratio values for authentic guanine at neutral pH: $E_{290} / E_{280} = 0.50$, $E_{250} / E_{260} = 1.37$, and $E_{280} / E_{250} =$

Table 1. Phosphorolysis of guanosine. 4.85 μmoles of guanosine and 3.35 μmoles of phosphate incubated with enzyme solution in glycyl glycine buffer at pH 7.8. Temp. 37 °C.

Incub. time, min	Inorg. phosph. μmoles	Inorg. + org. phosph. μmoles	Org. phosph. μmoles
0	3.33	3.35	0.02
200	2.55	3.31	0.76

Table 2. Phosphorolysis of guanosine and the formation of equivalent amounts of organic phosphate. 3.0 μmoles guanosine and 10.70 μmoles phosphate incubated with enzyme solution in glycyl glycine buffer. pH 7.8. Temp. 37 °C.

Incub. time, min	Inorg. phosph. μmoles	Org. phosph. μmoles	Guanine μmoles
0	10.68	0.02	—
10	9.99	0.71	0.76
20	9.24	1.46	1.53
30	8.91	1.79	1.81
40	8.76	1.94	2.04

0.71, given in the literature [8] should be compared with the corresponding values for the reaction product: 0.45, 1.35, and 0.70, respectively.

The paper chromatography confirmed the liberation of guanine during incubation of guanosine with the fish skin enzyme. The R_F values for authentic guanine and the fission product were identical and equal to 0.66, whereas guanosine had an R_F of 0.53.

Early experiments showed that the splitting of guanosine is effected only in the presence of inorganic phosphate. As is apparent from Fig. 3 no or only slight activity was noted when glycyl glycine was substituted for phosphate buffer.

The phosphate analysis indicated that inorganic phosphate disappears from the reaction mixture during the fission of guanosine. The phosphate obviously entered into a labile organic linkage, the substance formed being probably ribose-1-phosphate. The mild hydrolytic action of perchloric acid at 30 °C liberated all the organically bound phosphate (Table 1).

As is seen from the results of a typical experiment summarized in Table 2 there is good agreement between the liberated guanine and the phosphate bound in organic linkage. That the phosphate values throughout are somewhat too low might be explained by a slight, but unavoidable splitting of ribose-1-phosphate during the procedure of the determination as is pointed out by Lowry and Lopez [7], or by the existence in the enzyme solution of phosphatases as proposed by Kalckar [2].

The above-mentioned data show that the observed enzymatic splitting of guanosine by an enzyme extracted from fish skin is a phosphorolytic one.

The financial support of the Migratory Fish Committee is gratefully acknowledged.

Methyl-fluoro-phosphorylcholines

Two Synthetic Cholinergic Drugs and Their Tertiary Homologues

L.-E. TAMMELIN

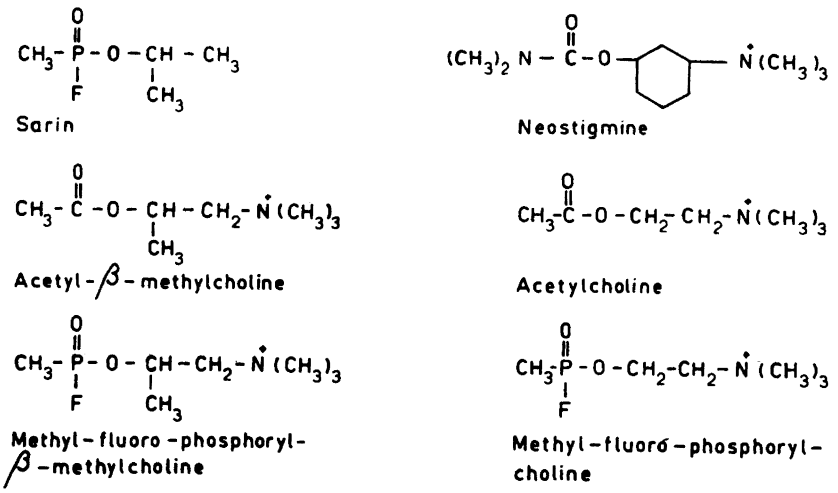
Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The syntheses of ω-dimethylaminoethoxy-methyl-phosphoryl and ω-dimethylamino*iso*propoxy-methyl-phosphoryl fluorides and their methiodides, which are choline esters, are described. It is shown that the ω-dimethylaminoalkoxy-phosphoryl fluorides are liquid compounds which solidify by storage at room temperature. This is suggested to be caused by an intramolecular rearrangement that quaternizes the amino group and breaks the fluorine-phosphorus linkage giving the molecule a cyclic structure with a phosphorus-nitrogen bond. Hydrolysis of the fluorine-phosphorus bond has been shown in aqueous solutions of the synthesized methyl-fluoro-phosphoryl esters. At pH 8 and 25°C the tertiary amino esters are hydrolysed almost instantly and the choline esters considerably faster than the corresponding alkoxy esters. The choline esters are more toxic when injected intraperitoneally than alkoxy esters as *e. g.* methyl-*iso*propoxy-phosphoryl fluoride (Sarin) and are potent cholinesterase inhibitors.

Cholinesterase inhibitors can be classified as follows. *Compounds which in their chemical structure resemble the substrates* but are not or only slowly hydrolysed by the enzyme. They are bound to the enzyme by qualitatively the same kind of forces which primarily bind the substrates during the course of enzymic hydrolysis. An ionic bond between an ammonium group and the enzyme is essential in this case [1].

Compounds of the phosphorylating type which during the first step of the inhibition process are bound to the enzyme qualitatively in the same way as the carbonyl-ester group of the substrates. Neostigmine is one inhibitor of the first type and Sarin, Tabun, Parathion and DFP belong to the second type.

Sarin is *iso*-propoxy-methyl-phosphoryl fluoride [2]. Exchange of the *iso*-propanol residue in Sarin against a choline or β-methylcholine (ω-trimethylammonium*iso*propanol) halogenide residue leads to compounds which structurally have properties in common both with substrates of cholinesterase and phosphorylating inhibitors. The structural formulas of some compounds having affinity for cholinesterases are shown in the chart (Fig. 1) where the two last are the choline esters described in this paper.



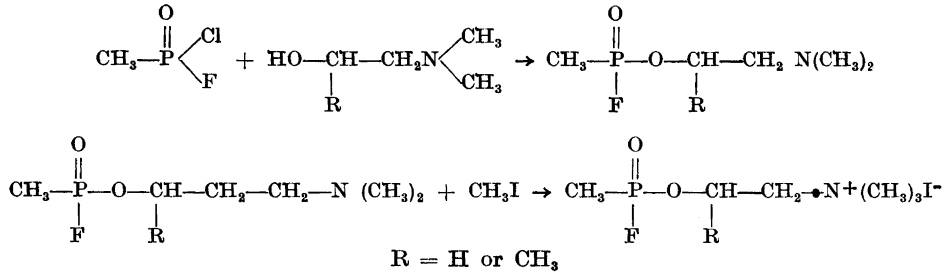


Fig. 1

SYNTHESES

The syntheses of the methyl-fluoro-phosphorylcholines were made according to the following scheme.

Both the dimethylaminoethoxy-methyl-phosphoryl fluoride and the dimethylamino*iso*propoxy-methyl-phosphoryl fluoride are colourless, water soluble oils with amine-like odours. They are unstable and are transformed into solid compounds by storage at room temperature.

Methyl-fluoro-phosphoryl choline iodide and methyl-fluorophosphoryl-β-methylcholine iodide are both colourless, water soluble crystalline compounds. *They are extremely toxic and care must be taken while handling them* to avoid direct contact with or the inhaling of the crystalline powder

Methyl-fluoro-phosphoryl chloride was synthesized from methyl-phosphoryl dichloride according to the schemes given by Collomp [4] as cited by Bocquet [5].

*ω-Dimethylaminoethoxy-methyl-phosphoryl fluoride and ω-dimethylamino*iso*propoxy-methyl-phosphoryl fluoride.* 2-dimethylaminoethanol (1 mole) is slowly added to 1 mole of methyl-fluoro-phosphoryl chloride which is dissolved in anhydrous ether (150 ml)

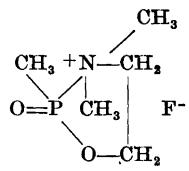
and 1.1 moles of triethylamine. The reaction mixture is refluxed for one hour. After cooling the precipitate formed is filtered off and the final product is isolated from the filtrate by means of distillation; for data see Table 1. The liquid compounds obtained are not very stable and form by storage at room temperature solid compounds which do not react with methyl iodide. It is thus recommended to do the next step immediately after the distillation.

Methyl-fluoro-phosphorylcholine iodide and methyl-fluorophosphoryl-β-methylcholine iodide The tertiary esters described earlier are quaternized by means of methyl iodide. One mole of the ester is treated with 1.1 moles of methyl iodide in ether solution at 25°C. A colourless precipitate is formed which is filtered off after six days and washed by ether and a small amount of alcohol; for data see Table 1.



REARRANGEMENT OF THE DIMETHYLAMINOALKYL ESTERS

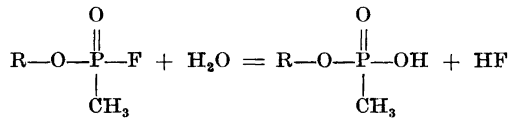
The dimethylaminoethoxy-methyl-phosphoryl and dimethyl-amino*iso*-propoxy-methyl-phosphoryl fluorides are liquid compounds which by storage at room temperature in sealed glass bottles are gradually transformed quantitatively into solid compounds. This occurs without noticeable pressure changes in the bottles and takes a few days for the ethyl derivative and a few months for the *iso*propyl derivative.

The solid ethyl derivative was used for an investigation in order to elucidate the kind of intramolecular rearrangement that causes the formation of the solid compounds.

The crystalline solid obtained has the same percent composition as the initial liquid. (Found: C 35.0; H 7.7; F 11.6. Calc. for $C_5H_{13}FNO_2P$ (169.1): C 35.5; H 7.8; F 11.3). The solubility in ether is low which is a difference from the liquid isomer. No melting point is found since the compound decomposes at 200°C. A reineckate precipitated from aqueous solution gives negative results when tested for fluorine according to Widmark [6]. Potentiometric titrations on aqueous solutions show that the compound has no protolytic properties in the pH range 3—10. The initial pH was slightly acid but the sodium hydroxide consumption is practically none between these pH limits. Investigations of hydrolytic properties using a "pH-stat" [7] shows no hydrolysis in a pH range from 10 to 6. In 0.1 M HCl, however, hydrolysis occurs and the hydrolysate has been shown to give equivalent amounts of three acids when investigated by means of potentiometric titration. One of the equivalents emanates from the hydrochloric acid yielding a salt with an amino group. Identical titration curves are obtained from hydrolysates of the liquid isomer. The amino pK_a is in both cases the same and about 7.6. Water solutions of the solid isomer give no Schoeneman [8] reaction whereas the liquid does. The Schoeneman reaction gives positive results on compounds containing $=\overset{\overset{\|}{O}}{P}-Hal$.

The high melting point, the low solubility in ether and the lack of protolytic properties indicate that a quaternary nitrogen compound has been formed. The lack of fluorine in the reineckate and the negative Schoeneman reaction indicate that an ammonium fluoride has been formed. The hydrolysis which occurs only at low pH values indicates a P—N bond [9]. A cyclic compound with the structure:

would have these properties and is thus suggested for this compound. By hydrolysis of the P—N bond in such a structure the same organophosphorus acid can be expected to be obtained as from hydrolysis of P—F in the liquid form. Identical amino pK_a values of the hydrolysis products have been found a fact which supports the suggested structure.



HYDROLYSIS

Sarin has been shown to be hydrolysed in aqueous solutions yielding the acid methyl-*iso*propoxy-hydroxy-phosphinoxide and hydrogen fluoride [10]. Choline and dimethylaminoethyl esters of the carboxylic acids have been shown to yield carboxylic acid and corresponding alcohol in aqueous solutions [1,11]. The P—O—C linkage is known to be hydrolyzable but the reaction rate at moderate pH values is known to be comparatively slow [12].

The qualitative course of the hydrolysis of the ω-dimethyl-aminoalkoxy-methyl-phosphoryl fluorides has been investigated as follows.

Aqueous solutions of the liquid compounds have been shown to yield fluorine ions which were precipitated as PbClF. The calculated amount of fluorine ions has been found after less than 2 h. Acidimetric potentiometric titrations have shown that equivalent amounts of two acids are obtained by the hydrolysis at room temperature.

The results show that the hydrolysis can be described with the following formula:

Using a "pH-stat" [7] the reaction rate of the hydrolysis has been determined at pH 8 with the following results. The half lives of the dimethylaminoethyl and dimethylamino*iso*propyl esters are very short and could not be determined. The choline and β-methyl-choline esters have half lives of 9 and 23 min, respectively. The corresponding value of Sarin [12] is 320 min. At pH = 6 the half life of the dimethylaminoethyl ester was 7 min. A more detailed investigation of the qualitative course and kinetics of the hydrolysis of the two choline esters has been done by Larsson [12]. The present results show, however, that the hydrolysis of these compounds is so fast, that special care must be taken in the determinations of toxicity and of enzyme inhibiting properties.

TOXICITY AND CHOLINESTERASE INHIBITION

Preliminary investigations of the toxicities have shown that aqueous solutions of dimethylaminoethoxy- and dimethylamino*iso*propoxy-methyl-phosphoryl fluorides show relatively low toxicity whereas the choline and β-methyl-choline esters are highly toxic. It was shown that when injected intraperitoneally into white mice both substances kill 50 % of the animals in doses close to 0.1 mg/kg body weight. The choline esters are thus more than three times

as toxic as Sarin, and they are among the most toxic synthetic compounds known. The low toxicity of the tertiary amino esters may be due to their rapid hydrolysis but also to other properties. A detailed description of the pharmacology of the compounds described in this paper is given by Fredriksson [13].

Preliminary investigations of the cholinesterase inhibiting properties have been done using an electrometric method [14]. The enzyme preparations were erythrocyte hemolysate and plasma from human blood. Before the addition of substrate the enzyme solution in Michel buffer solution was incubated for 30 min at 25°C with the inhibitors in varying concentrations. The substrate was acetylcholine, the concentration of which was 7.3×10^{-3} M. Starting pH was 8.

The negative logarithm of the inhibitor concentration in moles/l that causes 50 % inhibition of the enzyme activity in the system described above (pI_{50}) was determined. The rapid hydrolysis of the compounds made these determinations uncertain and the results obtained are to be considered as minimum values of pI_{50}. Methyl-fluoro-phosphorylcholine showed a pI_{50} of about 10 for erythrocytes and a pI_{50} of about 8.4 for plasma. Methyl-fluoro-phosphoryl-β-methyl-choline showed a $pI_{50} = 8.4$ for both erythrocytes and plasma. The corresponding pI_{50} values of Sarin are 8.8 for erythrocytes and 8.4 for plasma.

There are many factors influencing the pI_{50} values such as spontaneous or enzymic hydrolysis of the inhibitor. It is, however, evident from the experimental results that the inhibitors investigated are very potent, and it is highly probable that both of them are more potent than Sarin.

DISCUSSION

The present work originates from the idea that an ammonium group added to the structure of Sarin would yield a compound with more potent pharmacodynamic actions. On the whole this has been verified. It is, however, not quite evident that an added ionic bond between the inhibitor and vital proteins is the reason for the increased potency. Comparisons between Sarin and methyl-fluoro-phosphoryl-β-methylcholine on a simple structural basis are not very elucidating because of the great difference which has been found in the reactivity of the molecules by hydrolysis experiments. An increased reactivity of the P—F bond as an explanation for the increased inhibiting property of the ω-ammonium esters seems as valid as theories about the significanse of an ionic bond. Both effects are likely to contribute but it is impossible from the present experiments to judge which one is dominant.

The choline esters described in this paper are not very likely to become of direct practical value, as therapeutics or insecticides, and should not, contrary to Sarin, be considered as potential war gases, because of their physical properties and low chemical stability. However, Fredriksson [13] has shown that they are valuable tools in studies of cholinergic receptor effects.

My sincere thanks are due to the Director of the Research Institute of National Defence, Dept. 1, Professor G. Ljunggren, for his kind interest in this work.

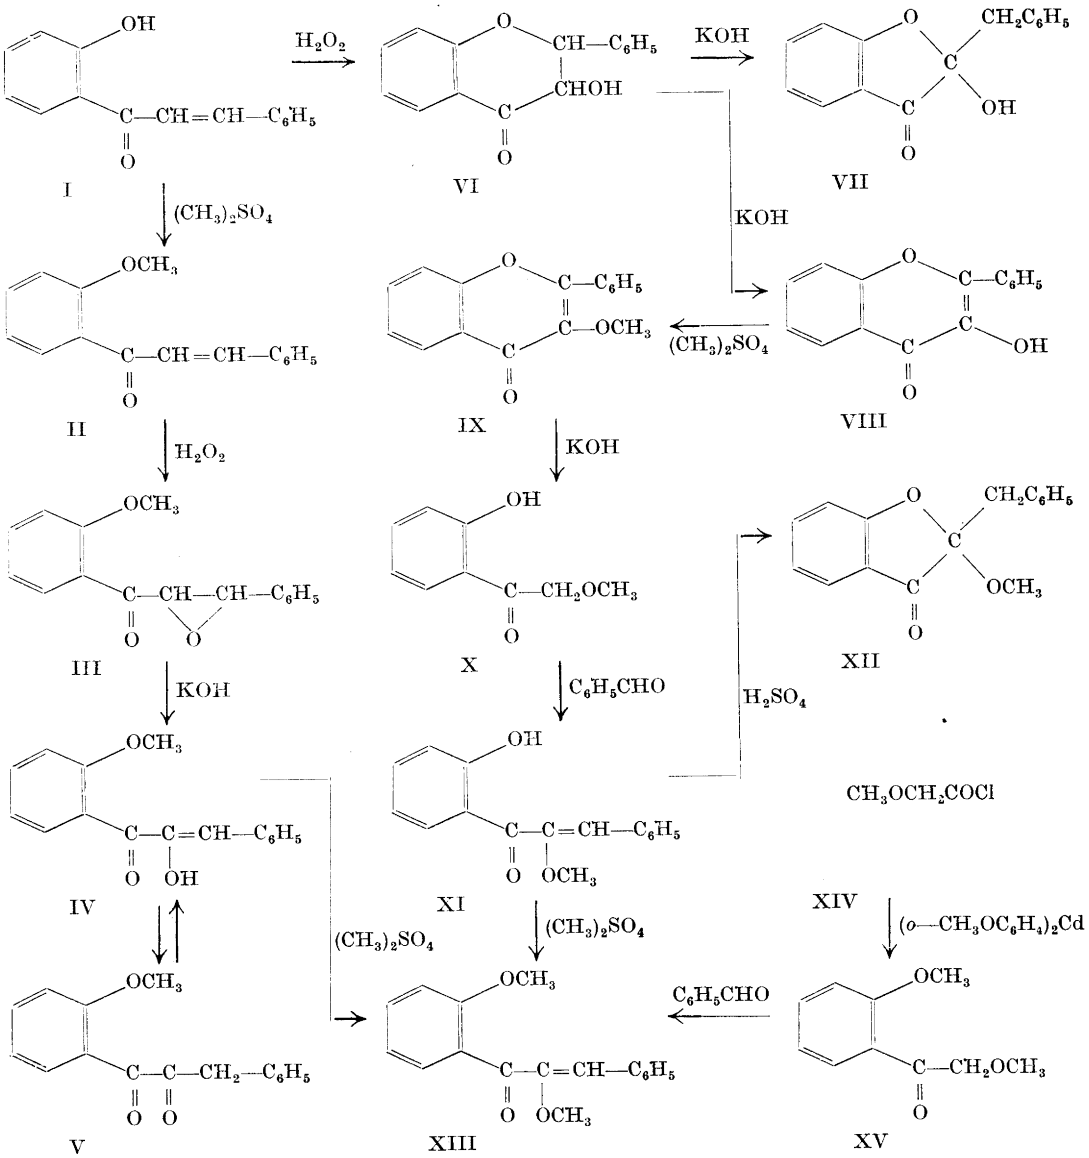
Confirmation of the Structure of 2-Benzyl-2-hydroxy-coumaran-3-ones

CARL ENEBÄCK and JARL GRIPENBERG

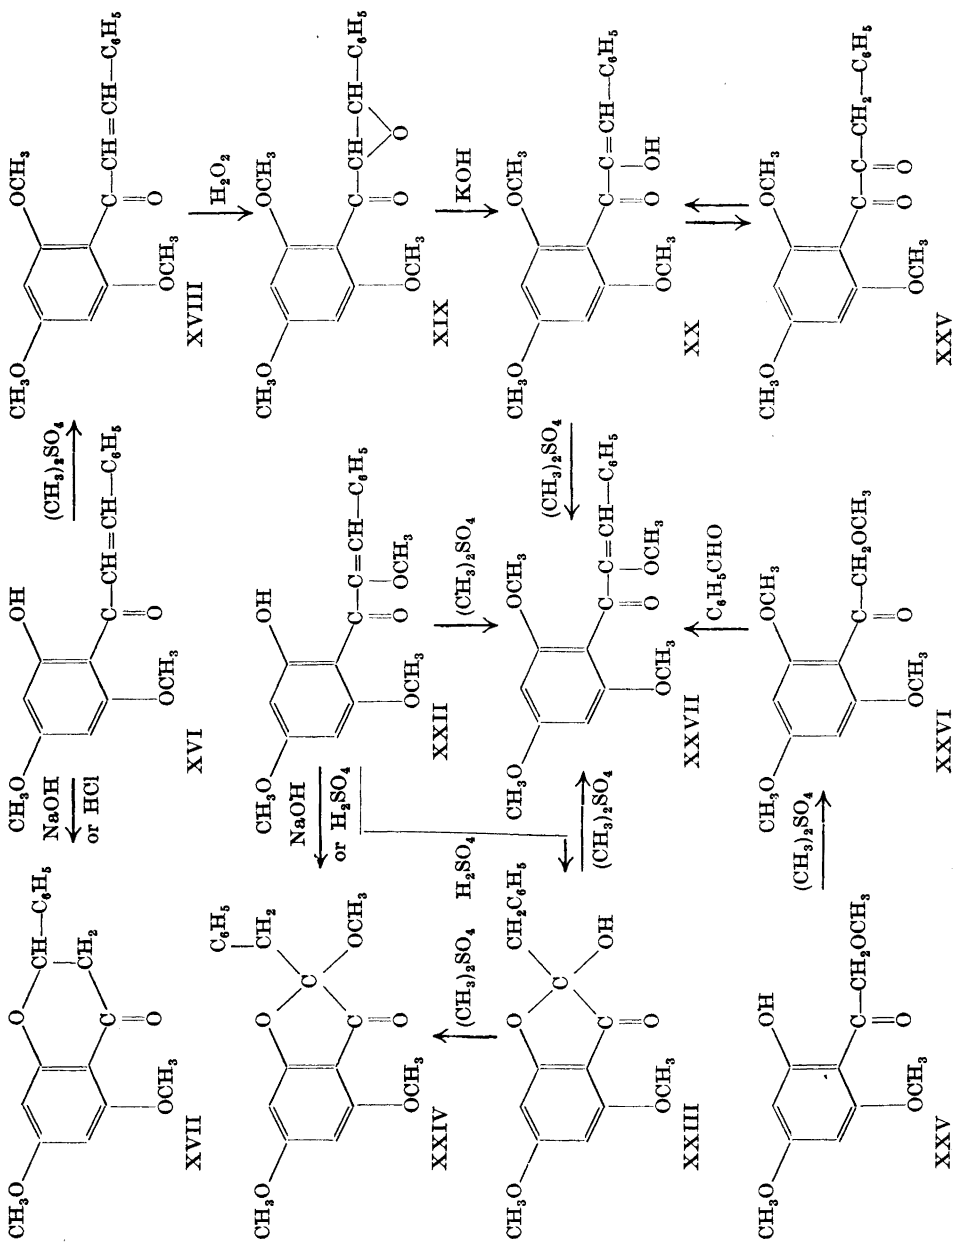
Department of Chemistry, Institute of Technology, Helsingfors, Finland

A number of hydroxy and methoxy derivatives of 2-benzylcoumaran-3-one, chalcone and 1,3-diphenylpropane-1,2-dione, corresponding to the tautomeric forms of 2-benzyl-2-hydroxycoumaran-3-ones [1], have been prepared. A comparison of the ultra-violet spectra and the carbonyl frequencies in the infra-red shows definitely the correctness of the 2-benzyl-2-hydroxycoumaran-3-one structure.



Some years ago, one of the present authors showed that a number of substances, earlier formulated as 3-hydroxyflavanones [1], were in all probability 2-benzyl-2-hydroxycoumaran-3-ones, a conclusion arrived at independently by Kubota [2] also. It was emphasised that the 2-benzyl-2-hydroxycoumaran-3-one(A) can be tautomeric with the hydroxychalcone (B) and the diketone (C)

The structure A could not be considered as definitely established, because of the possibility that this tautomeric shift takes place during the reactions used in the determination of structure.



It was therefore decided to try to find further support for this formula from a comparison of the ultra-violet and infra-red spectra with those of compounds corresponding to the three tautomeric forms A, B and C, but where the tautomeric shift is made impossible. This can be achieved either by methylation of the hydroxyls or by removing them. The latter method is permissible only if the hydroxyl is in such a position that it does not have any influence on the spectral properties of the compound in question.

Chart I

Reference has already been made [1] to one case, where the ultra-violet spectrum could be taken as support for the 2-benzyl-2-hydroxycoumaran-3-one structure.

Chart II.

Of the three tautomeric structures, A and C can give rise to one methyl ether, whereas two monomethyl ethers and one dimethyl ether can be derived from B. All these methyl derivatives in the two series, where R = H and

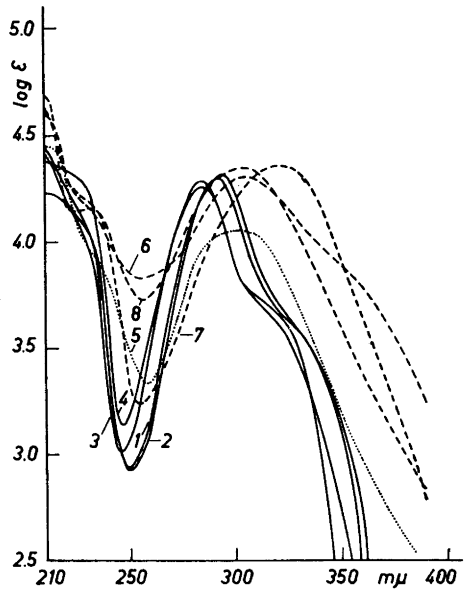

Fig. 2. Spectra of: 1. 2-Benzyl-2-hydroxy-4,6-dimethoxycoumaran-3-one(XXIII), 2. 2-Benzyl-2,4,6-trimethoxycoumaran-3-one(XXIV), 3. 2-Benzyl-4,6-dimethoxycoumaran-3-one, 4. 5,7-Dimethoxyflavanone(XVII), 5. 1-(2,4,6-Trimethoxyphenyl)-3-phenylpropane-1,2-dione(XXI), 6. 2′-Hydroxy-α,4′,6′-trimethoxychalcone (XXII), 7. α-Hydroxy-2′,4′,6′-trimethoxychalcone(XX), 8. α,2′,4′,6′-Tetramethoxychalcone(XXVII) (all in ethanol).

OCH_3, respectively, have been synthesised. The syntheses are outlined in Chart I and Chart II, which show the interrelationships between the different compounds, which serve to establish their structures.

The details of these reactions are given in the experimental part, but the following points require some further comments. Ring closure of 2′-hydroxychalcones to flavanones both by acids and by very dilute alkali is well established [3,4]. However, this does not hold when there is a methoxyl group in the α-position of the chalcone (*Cf.*, however Robertson *et al.*[5]). The formation of a 2-benzyl-2-hydroxycoumaran-3-one, when such a chalcone is treated with acids [1] was the starting point for this work, but it has now also been observed that the corresponding methoxy derivative is formed as well (*e. g.*, XXIV from XXII). A similar observation has been made also by Tsukamoto and Tominaga [6]. When 2′-hydroxy-α-methoxychalcone (XI) was treated in the same way only a neutral compound was obtained. This is thought to be 2-benzyl-2-methoxycoumaran-3-one (XII). Methylation of 2-benzyl-2-hydroxycoumaran-

3-one (VII) was expected to give the same compound, which should have confirmed its structure, but unfortunately all attempts to methylate VII failed. The structure of XII is therefore somewhat uncertain, although it is difficult to imagine any other structure, which could explain its properties.

It was further found that treatment of XXII with dilute alkali also gave XXIV, whereas XI was recovered unchanged from similar treatment.

The transformation of the enols IV and XX into the corresponding diketones V and XXI was achieved by distilling them in the presence of piperidine [7]. The enol was regenerated when an alkaline solution of the diketone was acidified.

The ultra-violet spectra of the different methyl derivatives and some other relevant compounds of the two series, where R = H and R = OCH_3 are reproduced in Figs. 1 and 2, respectively. (The spectra of compounds corresponding to the three structures A, B and C are drawn with different markings.)

From Fig. 1 it can be seen that the spectra of 2-benzyl-coumaran-3-one, 2-benzyl-2-hydroxycoumaran-3-one (VII), 2-benzyl-2-methoxycoumaran-3-one (XII) and flavanone are all very similar, but also that the spectrum of 1-(2-methoxyphenyl)-3-phenylpropane-1,2-dione (V) does not differ very much. The spectra of the chalcones IV and XIII are of a different type and close to that of I and chalcone (not shown in the figure).

The spectrum of 2′-hydroxy-α-methoxychalcone (XI) deserves further consideration, because it differs significantly from those of the other chalcones in having a maximum at 250 mμ, where the other have a minimum and having instead a minimum at 285 mμ. It thus shows some resemblance to the spectra of compounds with the *o*-hydroxyacetophenone chromophore. We would like to offer the following explanation for this difference (*Cf.* Black and Lutz [8]). Models show that when there is a methoxyl group in the α-position, the cinnamoyl group of the chalcone can be coplanar only if the other aromatic ring is out of this plane. In 2′-hydroxy-α-methoxychalcone the hydrogen bond between the hydroxyl and the carbonyl will, however, keep the carbonyl coplanar with this aromatic ring, whereby the coplanarity of the cinnamoyl group will be disturbed. The spectrum will therefore be more close to that of *o*-hydroxyacetophenone, than that of the other chalcones, where the cinnamoyl group will be the dominating factor.

From Fig. 2 it is obvious again that the spectra of the benzylcoumaranones are very close to that of the corresponding flavanone XVII, but in this case the diketone XXI differs clearly by the absence of the inflexion at 310—320 mμ. The spectra of the chalcones are very similar to those of the first series, but the difference between the chalcones on the one hand and the flavanones and benzylcoumaranones on the other hand is not so pronounced here. There is in this case no anomaly in the spectrum of 2′-hydroxy-α,4′,6′-trimethoxychalcone (XXII), although there is the same reason to expect a noncoplanarity of the cinnamoyl group as in XI. In this case, however, the absorption of the *o*-hydroxyacetophenone chromophore lies so close to that of the chalcones that it would not show up as a separate maximum.

As regards the tautomeric possibilities set forth in the beginning of this paper, it can be concluded that these spectra support strongly the benzyl-

hydroxycoumaranone structure (A), but that, particularly in the unsubstituted series, the diketone structure (C) cannot be definitely excluded. The spectra of the chalcones differ enough to make the structure B highly improbable.

In order to get more support for structure A the carbonyl frequencies in the infra-red were determined in chloroform solution (Table 1).

Table 1.

Compound	CO frequency cm^{-1}	Compound	CO frequency cm^{-1}
2-Benzyl-2-hydroxycoumaran-3-one (VII)	1 730	2-Benzyl-2-hydroxy-4,6-dimethoxycoumaran-3-one (XXIII)	1 706
2-Benzyl-2-methoxycoumaran-3-one (XII)	1 720	2-Benzyl-2,4,6-trimethoxycoumaran-3-one (XXIV)	1 696
2-Benzylcoumaran-3-one	1 713	2-Benzyl-4,6-dimethoxycoumaran-3-one [1]	1 690
Flavanone	1 695[9]	5,7-Dimethoxyflavanone (XVII)	1 665
3-Hydroxyflavanone (VI)	1 697	1-(2,4,6-Trimethoxyphenyl)-3-phenylpropane-1,2-dione (XXI)	1 710
1-(2-Methoxyphenyl)-3-phenylpropane-1,2-dione (V)	1 716 1 660	α,2′4′,6′-Tetramethoxychalcone (XXVII)	1 656 1 650
α,2′-Dimethoxychalcone (XIII)	1 650	α-Hydroxy-2′,4′,6′-trimethoxychalcone (XX)	1 666
α-Hydroxy-2′-methoxychalcone (IV)	1 655	2′-Hydroxy-α,4′,6′-trimethoxychalcone (XXII)	1 625
2′-Hydroxy-α-methoxychalcone (XI)	1 619		

All the coumaranone and flavanone derivatives in the series where $R = OCH_3$ have the carbonyl band at lower wave-numbers (24—30 cm^{-1}) than the corresponding compound in the unsubstituted series, in accord with expectation [10]. There is also a difference in the same direction between the diketones XXI and V but much smaller (4 and 6 cm^{-1} in the two bands). In the chalcone derivaties the differences are also small, but in the opposite direction. It should, however, be noted that the values for the chalcones are obtained from measurements in two different laboratories. The low values for XI and XXII are of course due to the hydrogen bond between the 2′-hydroxy group and the carbonyl [10].

The carbonyl frequency of a compound with structure B should be similar to XI and XXII, whereas a compound with structure C should show two carbonyl bands, one around 1 710 cm^{-1}, the other around 1 625 cm^{-1}. Instead the compounds VII and XXIII show only one carbonyl band close to that found in other coumaranone derivatives. The reason why the hydroxyl and, to a lesser extent, the methoxyl group in the 2-position of the benzylcoumaranones shifts the carbonyl frequency to higher wave-numbers is not clear, but it seems to be typical of these compounds.

The structure A must thus be correct, although the possibility that very small amounts of B and/or C exist in equilibrium in solution cannot be excluded on the present evidence. The infra-red data serve also to confirm the impossibility of a 3-hydroxyflavanone structure [1].

EXPERIMENTAL

(The analyses have been performed by Dr. A. Bernhardt, Mülheim, Germany.)

2'-Hydroxychalcone (I) was prepared according to Feuerstein and v. Kostanecki [11]. λ_{max} 222 mμ (log ε 4.09), 318 mμ (log ε 4.37), 355 mμ (infl.) (log ε 4.09), λ_{min} 216 mμ (log ε 4.07), 258 mμ (log ε 3.72).

2'-Methoxychalcone (II). 2'-Hydroxychalcone (I) (9 g) was methylated with dimethyl sulphate (3.9 ml) in acetone (100 ml) in the presence of potassium carbonate (10 g). Filtration and removal of the acetone was followed by washing the ether solution of the product with dilute sodium hydroxide and water. It was then twice distilled under vacuum, b. p. 214—215° / 8 mm. (Yield 6.1 g). v. Auwers and Brink [12] report b. p. 226° / 11.5 mm.

2'-Methoxychalcone oxide (III). 2'-Methoxychalcone (II) (6.1 g) was dissolved in methanol (50 ml) and the solution chilled in an ice-bath to +10°. Hydrogen peroxide (13 %; 9 ml) and 6 N potassium hydroxide (2.1 ml) were added, so that the temperature was kept below +35°. After a few minutes a volumious precipitate of 2'-methoxychalcone oxide was formed. This was recrystallised from methanol. Yield 5.8 g, colourless crystals, m. p. 125°. (Found: C 75.04; H 5.72. $C_{16}H_{14}O_3$ requires C 75.57; H 5.55).

α-Hydroxy-2'-methoxychalcone (IV). 2'-Methoxychalcone oxide (III) (2.5 g) was dissolved in ethanol (25 ml). To this was added 1 N potassium hydroxide (15 ml) and the mixture was refluxed for half an hour. About half of the ethanol was distilled off from the dark red solution. The cooled solution was then acidified with 2 N hydrochloric acid (15 ml), which precipitated a viscous mass. This was separated and crystallised when treated with methanol. Recrystallisation from methanol gave light yellow leaflets, m. p. 133.5°, λ_{max} 220 mμ (log ε 4.08), 234 mμ (infl.) (log ε 3.94), 325 mμ (log ε 4.36), λ_{min} 263 mμ (log ε 3.51). (Found: C 75.25; H 5.64. $C_{16}H_{14}O_3$ requires C 75.57; H 5.55). It gives a strong brown-violet colour with ferric chloride. Jörlander [13] has prepared the same compound in a different way, but he gives m. p. 118°.

1-(2-Methoxyphenyl)-3-phenylpropane-1,2-dione (V). α-Hydroxy-2'-methoxychalcone (IV) (100 mg) was placed together with 0.5 ml of a solution of piperidine in hexane (1 g/l) in a test tube with a side arm. The mixture was heated in an oil bath. When all the hexane had evaporated, a cold finger was inserted and the tube evacuated to 0.25 mm. The temperature of the oil bath was now regulated so that a slow distillation of the diketone to the cold finger was achieved. It formed an oil drop, which upon treatment with methanol gave yellow crystals, m. p. 72°, λ_{max} 259 mμ (log ε 3.93), 323 mμ (log ε 3.60), λ_{min} 233 mμ (log ε 3.57), 287 mμ (log ε 3.11). It gives no colour with ferric chloride. It dissolves in warm sodium hydroxide and acidification of this solution regenerates the enol form (IV), m. p. 133°.

2'-Hydroxy-α-methoxychalcone (XI). 3-Hydroxyflavanone [14] (VI), m. p. 188° was converted into a mixture of 2-benzyl-2-hydroxy-coumaran-3-one (VII) (λ_{max} 256 mμ (log ε 3.93), 336 mμ (log ε 3.58), λ_{min} 234 mμ (log ε 3.16), 284 mμ (log ε 2.34)) and 3-hydroxyflavone (VIII) upon treatment with alkali [1]. The last mentioned was also obtained according to v. Kostanecki and Szabrański [15]. Methylation of 3-hydroxyflavone with dimethyl sulphate and potassium carbonate in acetone gave 3-methoxyflavone (IX), m. p. 113°. Oyamada [16] reports m. p. 114°.

3-Methoxyflavone (4 g) was dissolved in 10 % potassium hydroxide in ethanol (100 ml) and the solution was refluxed for 4 h. Water (100 ml) was then added and the main part of the ethanol was distilled off. The remaining solution was extracted with ether and then acidified with acetic acid. The acid solution was extracted with ether, and the ether solution was washed with sodium hydrogen carbonate. Removal of the ether left 2-hydroxy-ω-methoxyacetophenone (X) (*Cf.* Ref.[17]) as an oil (1.5 g). This, without further purification, was dissolved in ethanol (15 ml) and benzaldehyde (2 ml), and 50 % sodium hydroxide (3 ml) were added. After standing for one day the solution was acidified with

2 N hydrochloric acid and extracted with ether. The ether solution was washed with sodium hydrogen carbonate and evaporated. The residue was crystallised from methanol and sublimed under vacuum, giving yellow needles of 2'-hydroxy-α-methoxychalcone, m.p. 52° (1.3 g), λ_{max} 250 mμ (log ε 4.03), 323 mμ (log ε 4.12), λ_{min} 227 mμ (log ε 3.96), 286 mμ (log ε 3.76). (Found: C 74.97; H 5.71. $C_{16}H_{14}O_3$ requires C 75.57; H 5.55).

2-Benzyl-2-methoxycoumaran-3-one (XII). 2'-Hydroxy-α-methoxychalcone (XI) (0.35 g) was boiled for 30 h with 2 N sulphuric acid (10 ml) in ethanol (50 ml). The ethanol was distilled off and the aqueous solution was extracted with ether. The ether solution was washed with sodium hydrogen carbonate and 2 N sodium hydroxide. Acidification of these washings gave only negligible amounts of material. The ether was removed, yielding an oil which soon crystallised. Recrystallisation from methanol gave 2-benzyl-2-methoxycoumaran-3-one (0.2 g) as colourless crystals, m. p. 50°, λ_{max} 257 mμ (log ε 3.99), 337 mμ (log ε 3.56), λ_{min} 233 mμ (log ε 3.45), 288 mμ (log ε 2.61). (Found: C 74.96; H 5.52; $C_{16}H_{14}O_3$ requires C 75.57; H 5.55). It gives no colour with magnesium and hydrochloric acid.

α,2'-Dimethoxychalcone (XIII). a). α-Hydroxy-2-methoxychalcone (IV) (0.5 g) was dissolved in acetone (10 ml) and dimethyl sulphate (0.3 ml) and potassium carbonate (4 g) were added and the mixture refluxed for 4 h. The α,2'-dimethoxychalcone (0.3 g), isolated in the usual way, was recrystallised from methanol, m. p. 55.5—56°, λ_{max} 221 mμ (log ε 4.13), 307 mμ (log ε 4.31), λ_{min} 215 mμ (log ε 4.11), 255 mμ (log ε 3.75). (Found C 76.06; H 6.42; $C_{17}H_{16}O_3$ requires C 76.10; H 6.01).

b) 2'-Hydroxy-α-methoxychalcone (XI) (0.3 g) was methylated in the same way as in a). Yield 0.2 g, m. p. 55—56°. It gives no depression of m. p. when mixed with material prepared according to a).

c) A benzene solution of bis-(*o*-methoxyphenyl)cadmium was prepared from *o*-bromoanisol (67 g) through the Grignard-compound. To this was added during 10 min methoxyacetyl chloride (XIV) (31 g), dissolved in benzene (53 ml). Heat was evolved and refluxing was continued for 15 min after the addition. The mixture was then poured into ice water (450 g) containing a little sulphuric acid. The benzene layer was separated, washed with sodium hydroxide and dried. Removal of the benzene left an oil from which 57 g of a fraction boiling at 88—182°/8 mm was obtained. 15 g of this fraction were treated with Girard-reagent-T (15 g) giving 2.3 g of ω,2-dimethoxyacetophenone (XV) as an oil. This (1.9 g), without further purification, was kept with benzaldehyde (5 g) and 10 % sodium hydroxide in 50 % ethanol (50 ml) for 1 day at room temperature and then for some days in the refrigerator. The crystals that had separated (1.3 g) were recrystallised from methanol. M. p. 55—56°, alone or mixed with material prepared according to a) or b).

5,7-Dimethoxyflavanone (XVII). A hot solution of 2'-hydroxy-4',6'-dimethoxychalcone [18] (XVI) (0.5 g) in ethanol (1.5 ml) was rapidly diluted with cold 1.5 % sodium hydroxide (15 ml). 5,7-Dimethoxyflavanone precipitated and was recrystallised from toluene, m. p. 145—146° (0.15 g). It gives no depression when mixed with material prepared from the same starting material by treatment with acid [19]. λ_{max} 284 mμ (log ε 4.26), 315 mμ (infl.) (log ε 3.65), λ_{min} 246 mμ (log ε 3.14).

2',4',6'-Trimethoxychalcone (XVIII). 2'-Hydroxy-4',6'-dimethoxychalcone [18] (XVI) (4.5 g) was methylated with dimethyl sulphate (2.4 ml) in acetone (40 ml) in the presence of potassium carbonate (6 g). 2',4',6'-Trimethoxychalcone (3.25 g) was obtained after recrystallisation from methanol as yellow crystals, m. p. 84°. (Found: C 73.01; H 6.11; $C_{18}H_{18}O_4$ requires C 72.46; H 6.08).

2',4',6'-Trimethoxychalcone oxide (XIX). 2',4',6'-Trimethoxychalcone (XVIII) (2 g) was dissolved in methanol (20 ml). This was cooled in an ice bath and hydrogen peroxide (13 %; 2.3 ml) and 6 N potassium hydroxide (0.52 ml) were added so that the temperature did not rise above + 20°. After a few minutes the 2',4',6'-trimethoxychalcone oxide precipitated. It was recrystallised from methanol, giving colourless crystals (1.8 g), m. p. 106.5°. (Found: C 68.21; H 6.01; $C_{18}H_{18}O_5$ requires C 68.78; H 5.77).

α-Hydroxy-2',4',6'-trimethoxychalcone (XX). 2',4',6'-Trimethoxychalcone oxide (XIX) (1.25 g) was dissolved in ethanol (10 ml) and 1 N potassium hydroxide was added. The mixture was refluxed for half an hour. Acidification produced a viscous mass, which rapidly solidified. After recrystallisation from methanol α-hydroxy-2',4',6'-trimethoxychalcone was obtained as light yellow needles (0.8 g), m. p. 138—139°. Recrystallisation from light petroleum (b.p. 60—80°) gave a mixture of bipyramidal crystals of m. p. 120° and the needles of the higher melting form. λ_{max} 230 mμ (log ε 4.17), 320 mμ (log ε 4.37),

λ_{min} 222 mμ (log ε 4.15), 255 mμ (log ε 3.24). (Found: C 68.67; H 5.91; $C_{18}H_{18}O_5$ requires C 68.78; H 5.77). It gives a dark brown-violet colour with ferric chloride.

1-(2,4,6-Trimethoxyphenyl)-3-phenylpropane-1,2-dione (XXI). This compound was obtained from α-hydroxy-2′,4′,6′-trimethoxychalcone in exactly the same way as described above for the preparation of 1-(2-methoxyphenyl)-3-phenylpropane-1,2-dione from the corresponding enol. Recrystallisation from methanol gave bright yellow leaflets, m. p. 98°. λ_{max} 303 mμ (log ε 4.06), λ_{min} 258 mμ (log ε 3.35). It gives no colour with ferric chloride, but dissolves upon warming in 1 N sodium hydroxide. Acidification regenerates the enol (XX), m. p. 138°.

2′-Hydroxy-α,4′,6′-trimethoxychalcone (XXII) was prepared according to Kimura and Hoshi [20]. M. p. 113°, λ_{max} 230 mμ (infl.) (log ε 4.18), 305 mμ (log ε 4.31), λ_{min} 255 mμ (log ε 3.84).

2-Benzyl-2-hydroxy-4,6-dimethoxycoumaran-3-one [1] (XXIII) was prepared according to Lindstedt [21] from 2′-hydroxy-α-,4′,6′-trimethoxychalcone (XXII). λ_{max} 290 mμ (log ε 4.30), 322 mμ (infl.) (log ε 3.66), λ_{min} 249 mμ (log ε 2.93).

2-Benzyl-2,4,6-trimethoxycoumaran-3-one (XXIV) a) 2-Benzyl-2-hydroxy-4,6-dimethoxycoumaranone (XXIII) (1.2 g) was methylated with dimethyl sulphate (0.57 ml) in acetone (18 ml) in the presence of potassium carbonate (2 g). The mixture was first allowed to stand 15 h at room temperature and then refluxed for 4 h. Treatment of the reaction mixture in the usual way gave a residue (1.2 g), which upon recrystallisation from methanol gave a mixture of colourless and yellow crystals. They were separated by hand picking, and further recrystallisation of the colourless crystals gave 2-benzyl-2,4,6-trimethoxycoumaran-3-one (0.57 g), m. p. 108—109°, λ_{max} 293 mμ (log ε 4.32), 325 mμ (infl.) (log ε 3.66), λ_{min} 251 mμ (log ε 2.92). (Found: C 68.66; H 6.03; $C_{18}H_{18}O_5$ requires C 68.78; H 5.77). It gives no colour with magnesium and hydrochloric acid. The yellow crystals, m. p. 134—135°, were identified as α,2′,4′,6′-tetramethoxychalcone (see below).

b) 2′-Hydroxy-α,4′,6′-trimethoxychalcone (XXII) (0.35 g) was dissolved in hot ethanol (0.75 ml). A cold 1.5 % sodium hydroxide solution (3.75 ml) was then added. The mixture was allowed to stand for 40 h, but no precipitation took place. After refluxing the mixture for one hour 2-benzyl-2,4,6-trimethoxycoumaran-3-one precipitated. Recrystallisation gave 0.13 g of m. p. 108—109°, not depressed by material prepared according to a).

c). In the preparation of 2-benzyl-2-hydroxy-4,6-dimethoxycoumaran-3-one (XXIII) according to Lindstedt [21] the ether solution remaining after washing with alkali was evaporated leaving a residue, which after recrystallisation from hexane and then from methanol gave a small amount of 2-benzyl-2,4,6-trimethoxycoumaran-3-one, m. p. 107—108°, undepressed by material prepared according to a) or b).

α,2′,4′,6′-Tetramethoxychalcone (XXVII). a). ω,2,4,6-Tetramethoxyacetophenone (XXV) was prepared by methylation of ω-methoxyphloracetophenone [22] (2 g) with dimethyl sulphate and potassium carbonate. It had m. p. 56.5—57°. (Slater and Stephen [22] report 50°). 0.1 g of this was dissolved in ethanol (2.5 ml) and benzaldehyde (0.4 ml), 10 % sodium hydroxide (2.5 ml) was added and the mixture allowed to stand at room temperature. Next day the yellow crystals of α,2′,4′,6′-tetramethoxychalcone were filtered off and recrystallised from methanol. Yield 0.1 g, m. p. 134—135°, λ_{max} 227 mμ (infl.) (log ε 4.23), 303 mμ (log ε 4.35), λ_{min} 255 mμ (log ε 3.73). (Found: C 69.41; H 6.10; $C_{19}H_{20}O_5$ requires C 69.50; H 6.13).

b). α-Hydroxy-2′,4′,6′-trimethoxychalcone (XX) (0.5 g) was methylated with dimethyl sulphate and potassium carbonate, giving 0.4 g of α,2′,4′,6′-tetramethoxychalcone, m. p. 135°.

c). 2′-Hydroxy-α,4′,6′-trimethoxychalcone (XXII) (1 g) was methylated with dimethyl sulphate and potassium carbonate, giving 0.7 g of α,2′,4′,6′-tetramethoxychalcone, m. p. 134—135°.

d). The yellow crystals obtained by methylation of 2-benzyl-2-hydroxy-4,6-dimethoxycoumaran-3-one (XXIII), m. p. 134—135° gave no depression when mixed with material prepared according to a), b) or c), which also gave no depression of m. p. when mixed.

2-Benzylcoumaran-3-one, was prepared according to v. Auwers [23] from ethyl 3-hydroxycoumarone-2-carboxylate. v. Auwers describes 2-benzylcoumaran-3-one as an oil, but in our hands the oil first obtained solidified after standing for some time. It had m. p. 50° but appeared to be still somewhat impure, because its infra-red spectrum shows a weak

peak at 1 750 cm^{-1}, attributable to an ester group. λ_{max} 252 mμ (log ε 3.94), 330 mμ (log ε 3.64), λ_{min} 231 mμ (log ε 3.41), 278 mμ (log ε 2.65).

2-Benzyl-4,6-dimethoxycoumaran-3-one [1] has λ_{max} 283 mμ (log ε 4.29), 315 mμ (infl.) (log ε 3.70), λ_{min} 246 mμ (log ε 3.01).

Some of the infra-red spectra were determined by Dr. L. A. Duncanson, ICI Research Department, Welwyn, and some by Mr. B. C. Fogelberg, Centrallaboratorium A. B., Helsingfors. We wish to thank also Mr. J. F. Grove and Professor W. Jensen, respectively, for these arrangements. This work has been financially supported by a grant from *Statens Naturvetenskapliga Kommission*, which is gratefully acknowledged.

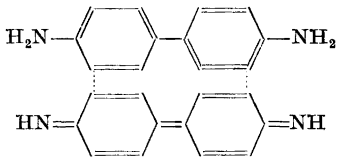
ACTA CHEMICA SCANDINAVICA 11 (1957) 876—880

On the Oxidation of Benzidine and *o*-Dianisidine with Hydrogen Peroxide and Acetylcholine in Alkaline Solution



GUNNAR AKSNES and KJELL SANDBERG

Forsvarets forskningsinstitutt, Kjeller, Norway

The oxidation of benzidine and *o*-dianisidine with hydrogen peroxide and acetylcholine in alkaline solution at 20°C has been investigated. From benzidine one single oxidation product has been isolated and shown to be identical with synthesized 4-amino-4′-nitrobiphenyl. From the oxidation of *o*-dianisidine three compounds have been isolated. One of these is identical with the previously known *bis* (3,3′-dimethoxy-4-amino)azobiphenyl, whereas the other two have been identified as the previously undescribed compounds, 3,3′-dimethoxy-4-amino-4′-nitrobiphenyl and 3,3′-dimethoxy-4-amino-4′-nitrosobiphenyl.

Benzidine and many of its derivatives have been extensively used as sensitive reagents for several types of oxidizing agents. As examples may serve the detection of lead peroxide [1], phosphomolybdic acid [2], silicomolybdic acid [3], peroxy disulphuric acid [4], peroxide [5] and aldehydes [6].

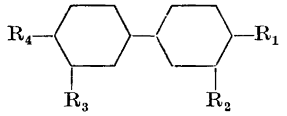
The methods described for the detection of these oxidants have a common characteristic feature, inasmuch as the oxidation is invariably carried out in a neutral or faintly acidic solution. One of the coloured compounds formed when benzidine is oxidized under these conditions, is the meriquinoid oxidation product "benzidine blue" (I).

(I)

The oxidation of benzidine and its derivatives in alkaline solution, seems to have attracted less interest. In this work we intended to isolate and identify the oxidation products arising from the oxidation with hydrogen peroxide of benzidine and *o*-dianisidine in alkaline solution.

When highly purified reagents are used, it is known that at a moderate temperature (20°C), benzidine and *o*-dianisidine are very sparingly oxidized by hydrogen peroxide in alkaline solution. However, impurities of various kinds are able to promote the reaction. At least when heavy metal ions are involved, the effect is in all probability a catalytic one.

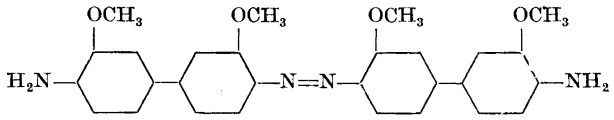
Among organic compounds, acid halogenides, acid anhydrides and esters all greatly accelerate oxidation with alkaline hydrogen peroxide. These agents, however, are consumed in certain stoichiometric proportions, so that their action is not strictly catalytic.



This paper is exclusively devoted to the isolation and identification of the coloured products formed in the oxidation reaction of benzidine and *o*-dianisidine with hydrogen peroxide in alkaline solution, and with acetylcholine as "activator".

REACTION CONDITIONS

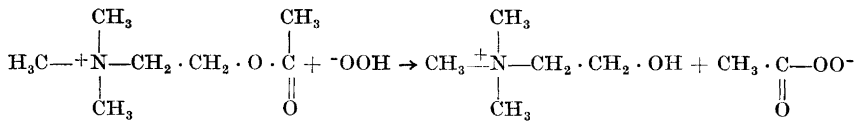
An alkaline solution of benzidine or *o*-dianisidine is obtained by using acetone as mixing solvent. The oxidation was carried out at a pH approximately equal to 11. As alkaline buffer solution, dipotassium hydrogen phosphate-potassium hydroxide was used, the reaction being carried out at room temperature.



Under these conditions the solution containing benzidine or *o*-dianisidine, alkaline buffer solution, acetone and hydrogen peroxide, stayed colourless for at least one hour, provided that the most carefully purified reagents were used. When acetylcholine was added to this solution in the form of the bromide or the chloride, a rapidly developing colour could be detected after a few seconds. The colour which at first appeared yellow, quickly changed through orange and red, and finally attained a deep red tone when *o*-dianisidine was used, whereas in the case of benzidine the solution remained intensely orange-yellow even after half an hour.

The oxidation products were isolated by chromatographic methods. 4-Amino-4′-nitrobiphenyl was isolated from benzidine as the only oxidation product: II, $R_1 = NO_2$, $R_2 = R_3 = H$, $R_4 = NH_2$)

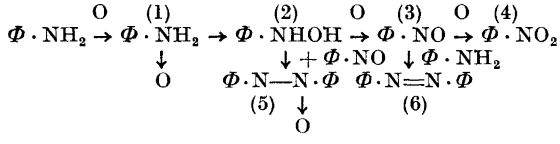
(II)



From the oxidation of dianisidine 3 substances were isolated, 3,3′-dimethoxy-4-amino-4′-nitrobiphenyl (II, $R_1 = NO_2$, $R_2 = R_3 = OCH_3$, $R_4 = NH_2$), 3,3′-dimethoxy-4-amino-4′-nitrosobiphenyl (II, $R_1 = NO$, $R_2 = R_3 = OCH_3$, $R_4 = NH_2$), and *bis*(3,3′-dimethoxy-4-amino)azobiphenyl(III).

(III)

DISCUSSION



The ability of acetylcholine to enhance the oxidizing action of hydrogen peroxide in alkaline solution, is due to the formation of peracetic acid [7] in a nucleophilic reaction:

In alkaline solution peracetic acid is rapidly decomposed, yielding acetic acid and active oxygen. By volumetric measurement of the oxygen liberation from an alkaline solution of hydrogen peroxide after adding acetylcholine, it was clearly demonstrated that 1 mole oxygen is evolved from every 2 moles of acetylcholine. Peracetic acid has furthermore been qualitatively detected under these conditions [7].

The chemical compositions of the isolated oxidation products of benzidine and *o*-dianisidine supply further evidence in favour of the assumption that oxidation is brought about by oxygen uptake of one of the amino groups.

The series of oxidation products of *o*-dianisidine described in this paper, bears a striking resemblance to another series found earlier by Bamberger [8], who examined the oxidation products of aniline with per sulphuric acid. Bamberger showed that the following mechanism applies in the case of aniline oxidation:

Of these products (1) and (2) are very unstable, and Bamberger has not succeeded in isolating them. The nitroso compound (3) on the other hand, can be isolated provided sufficient care is taken, and products (4), (5) and (6) are relatively easily isolated.

In our case the isolated oxidation products of *o*-dianisidine correspond to the products (3), (4) and (6) in Bambergers aniline series. We have not succeeded in isolating the azoxy compound corresponding to product (5) in Bambergers series, but this might be due to deficiencies in the experimental methods used. However in our opinion the absence of this compound may be due to an even stronger tendency of the hydroxylamine derivative of our series to further oxidation, than is shown by phenylhydroxylamine. In our experiments we have not isolated any product in which both of the two amino groups have been oxidized.

Comparing the product obtained from benzidine with those from *o*-dianisidine, it is to be noted that in the former case only one oxidation product is isolated, *viz.* the nitro compound corresponding to (4) in Bambergers series. We have no reason to believe that the nitroso compound and the azo compound should be present here in detectable quantities and yet have escaped our attention as long as they did not do so in the *o*-dianisidine series. In our opinion, therefore, the two methoxy groups in the *ortho* positions to the amino

groups of *o*-dianisidine may play an important role by stabilizing the nitroso compound of this series, thus retarding further oxidation to the nitro compound.

EXPERIMENTAL

Our experiments were all carried out in the following way, with only slight modifications specified in each particular case.

500 mg *o*-dianisidine hydrochloride (or benzidine respectively) was dissolved in 50 ml water. To this solution 100 ml buffer solution (1.65 g K_2HPO_4 and 1.0 g KOH per 100 ml H_2O) was added, followed by 200 ml acetone, 20 ml 2 % H_2O_2 solution and finally 500 mg acetylcholine bromide in 10 ml H_2O.

The reaction was allowed to proceed for half an hour, and the mixture was filtered, water was added to the filtrate, and extraction effected using approx. 100 ml of chloroform. The extract was washed twice with 0.1 N HCl, then twice with water, dried with Na_2SO_4 and evaporated to dryness *in vacuo* at room temperature. The residue was dissolved in 5 ml benzene and transferred to a chromatographic coloumn packed with activated alumina.

In the case of benzidine, the chromatogram was developed and the product eluted with 50 % benzene and 50 % ether. The eluate was again evaporated *in vacuo*, and the residue dissolved in benzene and rechromatographed twice using 90 % benzene and 10 % ether.

The oxidation products of *o*-dianisidine were first chromatographed using 50 % benzene and 50 % ether as developer, and three coloured zones became visible. The first and the second zone from the bottom (a yellow (I) and a brown (II) zone) were not clearly separated. Above them a red zone (III), relatively well separated from the others, could be collected. The red zone was purified by twice repeated chromatography from benzene, and the two lower zones were separated and purified by chromatographing two or three times from benzene.

Care was taken not to leave the compound from the brown zone (II) on the alumina for any length of time, since purification has to be carried out as fast as possible because this nitroso compound is relatively unstable. Even when purified, passage of the compound through the column leaves behind a brown colouring because of polymerization, so that no sharply defined zone is obtained.

In our experiments we have observed that we can increase the amount of nitroso compound by using acetylcholine chloride instead of the bromide, and at the same time the reaction is shortened to 10—15 min. The best yields of the azo compound are obtained when the unwashed chloroform extract is allowed to stand overnight before proceeding.

The Lipids of a Lysozyme Sensitive *Bacillus* Species (*Bacillus* "M")

CLAES WEIBULL

Central Bacteriological Laboratory of Stockholm City, Stockholm, Sweden

The lipids extracted from cells of a lysozyme sensitive bacterium, closely related to *Bacillus megaterium*, have been studied with respect to chemical constitution and to their distribution between various cell fractions. The total lipid content of the organism (*Bacillus* "M") is about 4 %. Part of the lipids can be extracted only after acid hydrolysis of the cell material. About 65 % of the total lipids are located in the cytoskeletons ("ghosts") remaining after the cells have been lysed with lysozyme. The lipids seem to consist of a mixture of neutral fat or fatty acids and phosphatidic acids. Cholesterol and lipids of the sphingolipid type seem to be absent altogether or are present only in small amounts.

A great number of investigations have been carried out on bacterial lipids. Earlier investigations (reviewed in Refs. [1–3]) were as a rule carried out using whole bacterial cells as experimental material. In some of the more recent studies, on the other hand, a fractionation of the cell constituents has preceded the extraction and characterization of the lipids. The first step in the fractionation procedure has been either a mechanical disintegration of the cells [4,5], or, in the case of lysozyme sensitive bacteria, a treatment of the cells with this enzyme [6]. A fractionation of the released cell constituents has then followed, carried out by means of differential centrifugations.

The procedure including enzymatic disintegration has been used in the present work. As has been shown earlier, lysozyme treatment of sensitive bacteria results in the dissolution of the cell wall and in the formation of bacterial "ghosts" [7–9]. The peripheral part of the "ghosts" represent the cytoplasmic membrane but probably these structures contain additional elements [6,10]. The "ghosts" could to some extent be compared to the stroma or post-hemolytic residue of red blood cells.

When lysozyme is allowed to act on bacteria suspended in a strong sucrose solution, the cell wall can be dissolved without ensuing lysis of the protoplasm [9]. The resulting free protoplasts retain most of the biochemical and biological capabilities of the whole cells [11]. The protoplasts are rather resistant towards

single centrifugations and can be separated from the bulk of the degraded cell wall material remaining in the supernatant. When protoplasts are suspended in dilute salt solutions or distilled water, lysis occurs instantaneously causing release of soluble protoplasm and the formation of "ghosts". The "ghosts" are precipitable by centrifugation at 15 000 × *g*, whereas the constituents of the soluble protoplasm may be sedimented only by ultracentrifugation.

It is thus possible to obtain a division of the cell material into three portions: "ghosts", soluble protoplasm and cell wall material. Since the protoplasts are somewhat fragile it is not always easy to effect a complete separation of the two last-mentioned fractions by means of resuspension and washing procedures.

The present investigation has been carried out on a lysozyme sensitive *Bacillus* species, designed as *Bacillus* M by Tomcsik [12]. It is closely related to *Bacillus megaterium* and has even been classified as a strain of this bacterium [13]. The distribution of the lipids of *Bacillus* M has been studied by means of the disintegration and fractionation procedure outlined above. A chemical characterization of the extracted and purified lipids has also been carried out.

MATERIALS AND METHODS

Organism, growth conditions and harvesting. Bacillus M [13] was used in all experiments. Cultures for experimental work were grown at 30°C in a medium containing 2 % Difco peptone and 0.05 % Difco yeast extract. 8 l Fernbach flasks, each containing 1 l substrate, were incubated for 16 h on a rotary shaker. The bacteria, then being in the stationary growth phase, were harvested by centrifugation, repeatedly washed with distilled water and resuspended in the same medium. The suspension was either immediately freeze-dried or subjected to the fractionation procedures outlined below. As a rule batches of about 5 g bacterial dry weight were prepared.

Preparation of bacterial cell fractions. The fractionation aimed at a division of the cell material into three parts: cell wall material, "ghosts" and soluble protoplasm. Often, however, wall material and soluble protoplasm were not separated from each other. In such a case, lysozyme and sodium chloride (final concentrations 0.01 – 0.02 % and 0.01 M, respectively) were added to 100 – 200 ml of a suspension of *Bacillus* M in distilled water (dry weight content 10 – 20 mg/ml). After completion of the lytic process the "ghosts" were spun down by centrifugation at 15 000 × *g*, and after resuspension washed three times with distilled water. The supernatants from the centrifugations thus contained both cell wall material, solubilized by lysozyme, and soluble protoplasm. Both this material and the "ghost" fractions were freeze-dried.

When a division of the cell material into the three fractions of wall substances, soluble protoplasm and "ghosts" was tried, sucrose, sodium chloride and magnesium chloride were added to the bacterial suspension at final concentrations of 0.5, 0.01 and 0.005 M, respectively. Lysozyme was then added as described above. When the cells had been converted into protoplasts, these bodies were spun down by centrifugation. The supernatant, containing the bulk of the wall material, was removed and the protoplasts were resuspended in 0.02 M phosphate buffer of pH 7. Lysis occurred immediately, resulting in the formation of "ghosts" and in the release of soluble protoplasm. The "ghosts" were separated from soluble protoplasm as described in the preceding paragraph. – A quite satisfactory separation of the cell wall material from the cytoplasm was, however, not achieved. First, it was found that a few per cent of the ultraviolet absorbing substances of the protoplasts leaked out into the medium. (Thus, the protoplasts of *Bacillus* M seemed to be somewhat less stable than the same bodies obtained from *Bacillus megaterium*, strain KM [9].) Second, noticeable lysis occurred when after centrifugation washing of the protoplasts with sucrose was tried. A few per cent of the cell wall material, remaining between the precipitated protoplasts, could consequently not be removed.

Extraction and purification of the bacterial lipids: a. Lipids extractable without acid hydrolysis of the cell material ("free" lipids). Two methods were tried, that one introduced by Bloor, using an ethanol-ether mixture (3:1) as extraction fluid [14], and that recommended by Folch *et al.*[15], employing for the same purpose chloroform-methanol in the proportion 2:1. When the former procedure was applied, the material to be extracted was suspended in about 20 times the amount of extraction fluid. The mixture was brought to boil, then allowed to cool and filtered. The filtrate was evaporated to dryness at 35—40°C. The solid residue was reextracted with petroleum ether. The resulting solution was filtered, evaporated as already described, dried *in vacuo* and weighed.

The extraction with chloroform was, if not otherwise mentioned, preceded by refluxing with methanol for one hour in order to break lipid-protein complexes [16]. Twice the amount of chloroform was then added. The solution was brought to boil, allowed to cool and filtered. Evaporation was carried out as described in the preceding paragraph. Purification of the extracted lipids followed the method given by Folch *et al.*[17]. The crude lipids were dissolved in chloroform-methanol. An amount of water equal to 1/5 of the volume of the lipid solvents was added. The system was thoroughly shaken and left overnight. Two liquid phases had then formed. The upper phase was removed, the lower one containing the lipids, was washed with a dilute calcium chloride solution [18]. After evaporation the solid lipids were dried *in vacuo* and redissolved in pure chloroform. The resulting solution was filtered and evaporated. Finally the purified lipids were weighed after drying.

b. Lipids extractable only after acid hydrolysis of the cell material ("bound" lipids). The material remaining after the extraction with chloroform-methanol was refluxed for 2 h with 6 M hydrochloric acid. (The wash water obtained when purifying the crude "free" lipids was also acidified and refluxed.) The acid solutions were shaken repeatedly with ether one hour each time. The combined etheral extracts were evaporated at about 30°C in a stream of carbon dioxide, the solid residue dried and redissolved in a small amount of ether. The solution was filtered, the solvent evaporated as just described and the lipids weighed after drying.

Chemical characterization of the lipids: a. Phosphorus content. Total phosphorus was determined according to Allen [19]. The amount of phosphorus liberated by mild alkaline hydrolysis was determined according to Schmidt *et al.*[20] and Brante [21]. The lipids were treated with 1 M sodium hydroxide at 37°C for 24 h. After neutralization trichloroacetic acid was added to a final concentration of 6 %. The suspension was filtered and the phosphorus in the filtrate was determined according to Allen.

b. Estimation of choline, serine and ethanolamine. The lipids were hydrolyzed with 6 M hydrochloric acid at 100°C for 3 h. The acid was evaporated and the residue was redissolved in a small amount of distilled water.

Suitable amounts of the hydrolysate were chromatographed on Whatman No. 1 filter paper. Butanol-acetic acid-water (6:1:2) was used as the solvent. Serine and ethanolamine were detected on the chromatograms by means of the ninhydrin reaction. Choline was detected with phosphotungstic acid according to Levene and Chargaff [22] or with dipicrylamine according to Augustinsson and Grahn [23]. By comparison with known amounts of choline, *etc.*, chromatographed in parallel with the lipid hydrolysate, an approximate estimation of the content of these compounds in the lipids could be made.

c. Estimation of hexoses and inositol. The lipids were hydrolyzed with 6 M hydrochloric acid for 45 min (hexoses) or 6 h (inositol) [21]. After evaporation of the acid *in vacuo* at room temperature and redissolving the residue in distilled water chromatography was carried out. Ethyl acetate-pyridine-water (2:1:2) was used as the solvent. The carbohydrates were detected on the papers by means of silver nitrate and alcoholic sodium hydroxide according to Trevelyan *et al.*[24]

d. Determination of cholesterol. The Liebermann-Burchard reaction was used, carried out according to Schoenheimer and Sperry [25].

e. Circular paper chromatography of intact lipids. The procedure outlined by Hack [26] was adopted. Whatman No. 1 filter paper disks were extracted with chloroform-methanol (4:1). About 25 μl of a chloroform-methanol solution containing 10—40 μg of lipids was placed in the center of the disk. The solvent was evaporated and 25—50 μl of chloroform-methanol was added until the lipids had spread to a ring 10 mm in diameter. Finally the desired solvent was added at such a rate that the diameter of the wet spot increased about 2 mm per second, not allowing the diameter to exceed 30—40 mm. As solvents

Table 1. Mg of bacterial lipids extracted from 1 g of dried cell fractions of *Bacillus* M.

Cell fraction	Extraction fluid used:	
	Chloroform-methanol	Ethanol-ether
"Ghosts"	150	153
Cell walls + soluble protoplasm	10.9	4.0

were used chloroform-methanol (4:1), chloroform, methanol, acetone, benzene, ethyl acetate and pyridine. Sometimes two different solvents were used one after another on the same chromatogram, letting the paper dry in between. The first solvent was allowed to spread to a diameter of 40 mm, the second to 30 mm.

Lipids in general were detected on the chromatograms by staining with a 0.1 % solution of Sudan black in 50 % aqueous ethanol and by washing with the same solvent. Phospholipids were detected by exposing the chromatograms to acid ammonium molybdate followed by hydrogen sulphide [27]. Unsaturated fatty acids were detected by exposing the chromatograms to osmic tetroxide vapors.

Dry weight determinations. The dry weight of bacterial cells and proteinaceous cell fractions were determined after drying samples at 100°C. The dry weight of purified lipids was determined after evaporating the lipid solvents at 30—40°C in a stream of carbon dioxide. The residue was dried *in vacuo* at room temperature using anhydrous calcium sulphate as desiccant, and weighed.

RESULTS

Comparison between lipid extraction using chloroform-methanol and alcohol-ether, respectively

The freeze-dried material to be extracted was divided into two halves. One half was extracted with chloroform-methanol, the other one with ethanol-ether. The purification of the extracted crude lipids was carried out as described in the methodological section. Table 1 gives the results.

According to the figures in Table 1 cell material that contains only small amounts of lipids seems to be extracted most completely by means of the procedure involving treatment with chloroform-methanol. This procedure was used as a standard method in the present investigation.

Completeness of the extractions

Freeze-dried cells and cell fractions were subjected to four successive extractions before and after acid hydrolysis. As is shown by Fig. 1 the extraction process can then be regarded as completed.

Lipid content of the bacterial cells

Extraction of whole cells. Four different batches of *Bacillus* M were investigated. Table 2, column a, gives the amounts of lipid extractable with chloroform-methanol ("free lipids"). Column b gives the amounts of "bound" lipids,

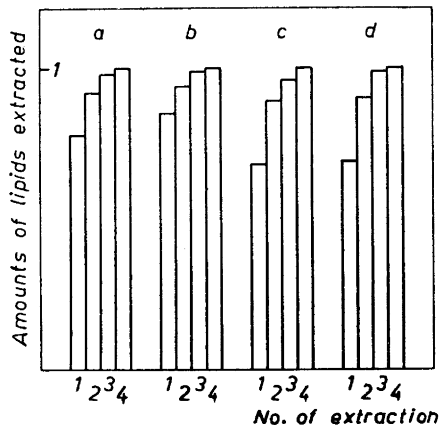

Fig. 1. Amounts of lipids extracted from cell material by repeated treatments with chloroform-methanol (experiments a, b and c) or with ether after acid hydrolysis (d). The total amount of lipids obtained in each of the experiments has been put equal to unity. "Ghosts" (a), cell wall + soluble protoplasm (b) and whole cells (c, d) were extracted.

i. e. the material obtained by acid hydrolysis of the residues from the chloroform-methanol extraction and by subsequent treatment of the hydrolysate with ether.

The figures in Table 2 (columns a—c) demonstrate rather wide variations in the lipid content of different batches of *Bacillus* M. On the other hand, the ratio "free" lipids/total lipids is remarkably constant (column d).

Table 2. Lipid content of whole cells of *Bacillus* M.

Batch	% lipids in dried cells			d. Free lip., % of total.
	a. Free lip.	b. Bound lip.	c. Total lip.	
IV	1.89	1.79	3.68	51

VIII	1.54	1.40	2.94	52
IX	1.65	1.73	3.39	49

Extraction of cell fractions: a. "Ghosts". The results are summarized in Tables 3 and 4. Table 3 shows the amounts of extracted lipids, expressed as percentage of the dry weight of the "ghosts". In Table 4 the dry weight and the lipid content of the "ghosts" is given as percentage of the dry weight of the intact cells.

It could be mentioned that in the case of batches V and VI the "ghosts" were obtained from the cells *via* protoplasts stabilized with magnesium chloride. The somewhat high dry weight of this material, and hence a lower lipid content, may be due to some protoplasmic material precipitable by magnesium ions [28].

Two batches (VIII and IX) were first extracted with chloroform-methanol, then refluxed with methanol and again extracted (in all other cases refluxing preceded the extraction). Batch VIII was extracted in the wet state, all other ones after being freeze-dried.

Table 3. Lipid content of "ghosts" of *Bacillus* M.

Batch	% lipids in dried "ghosts"			d. Free lip., % of total
	a. Free lip.	b. Bound lip.	c. Total lip.	
V	10.9	2.4	13.3	82
VI	15.0	1.5	16.5	91
VII	15.8	2.8	18.6	85
VIII	14.8[x] + 1.3[z]	0.8	17.1	95
IX	19.1[y] + 0.4[z]	1.5	21.0	93

Table 4. Dry weight and total lipid content of "ghosts" of *Bacillus* M, expressed as % of dry weight of whole cells.

Batch	a. Dry weight	b. Lipid content
V	18.8	2.50
VI	19.8	3.27
VII	14.9	2.78
VIII	15.3	2.61
IX	15.1	3.19

b. Cell wall and soluble protoplasm. Most determinations were carried out on material obtained by treating *Bacillus* M with lysozyme in dilute phosphate buffer and removing the ensuing "ghosts" by centrifugation. This material thus represents a mixture of cell wall material and soluble protoplasm. Tables 5 and 6 show the amounts of extracted lipids, expressed as percentage of the dry weight of the cell fraction and the whole cells, respectively.

Experiments were also carried out on cell wall material and soluble protoplasm separated from each other. As has been pointed out in the methodological section, however, a complete separation could not be achieved. The great amount of sucrose present especially in the wall fraction also made a quantitative determination of the lipids difficult. It could be concluded, however, that lipids must be present both in the cell wall and in the soluble protoplasm.

Table 5. Lipid content of cell wall + soluble protoplasm of *Bacillus* M.

Batch	% lipids in dried cell fraction			d. Free lip. % of total
	a. Free lip.	b. Bound lip	c. Total lip.	
II	1.18	0.37	1.55	76
VII	2.09	0.66	2.75	76
VIII	0.84	0.28	1.12	75
IX	1.29	0.52	1.81	71

Table 6. Dry weight and total lipid content of cell wall + soluble protoplasm of *Bacillus* M, expressed as % of dry weight of whole cells.

Batch	a. Dry weight	b. Lipid content
II	86.1	1.34
VII	85.1	2.34
VIII	84.7	0.95
IX	84.9	1.54

Comparison between the amounts of lipids extracted from whole bacteria and from the sum of the cell fractions. Three batches of *Bacillus* M were divided into halves. One half was extracted in the form of whole cells. The other one was fractionated into "ghosts" and cell wall material + soluble protoplasm. Table 7 shows the total amounts of lipids extracted from the whole cells and from the sum of the fractions, respectively.

Table 7. Amounts of lipids (free + bound) extracted from whole cells of *Bacillus* M and from fractionated material expressed as % of dry weight of whole cells.

Batch	Intact cells	Sum of fractions
VII	4.10	5.12
VIII	2.94	3.56
IX	3.39	4.73

It can easily be calculated from the figures of Table 7 that about 25 % more lipid material is extracted from the fractionated material than from whole cells. This fact will be discussed later in this paper.

Chemical nature of the bacterial lipids

As mentioned earlier the total amounts of phospholipids in the "free" lipids was estimated by total phosphorus determinations. For the estimation of monoaminophospholipids and phosphatidic acids the lipids were hydrolyzed with 1 M alkali and the liberated phosphorus determined. Table 8 gives the results.

Since pure phospholipids contain about 4 % of phosphorus it can be concluded that the lipids isolated from the "ghosts" (phosphorus content 3.3—4.0 %) to the greater part consist of such compounds. The phosphorus content of the lipids extracted from other cell fractions and from whole cells is considerably lower.

The results of the estimations of choline, serine, ethanolamine, inositol, hexoses and cholesterol in the "free" bacterial lipids are summarized in Table 9.

Table 8. Phosphorus content of "free" bacterial lipids of *Bacillus* M, expressed as % of lipid dry weight.

Lipids extracted from		Batch					
		IV	V	VI	VII	VIII	IX
Whole cells	NH[x]	2.44			2.40	2.16	1.82
	H[y]	2.32			2.32		1.76
"Ghosts"	NH		3.46	3.49	4.02	3.28	3.71
	H		3.36	3.36	3.55	3.22	3.71

	H				1.65	1.50	1.19

x Phosphorus determined without previous alkaline hydrolysis.
y » » after » » »

It is seen that only small amounts, if any, of the various compounds are present. This fact suggest that the phospholipids isolated from *Bacillus* M mainly consist of phosphatidic acids. Cholesterol could well be absent altogether, since the Liebermann-Burchard test was completely negative. (The "bound" lipids were also tested for cholesterol but with equally negative result.) No traces of choline, inositol and hexoses could be detected on the chromatograms. On the other hand, small amounts of serine and ethanolamine were present. The presence of several other ninhydrin positive compounds was revealed on such chromatograms that were run on hydrolyzed lipids isolated from whole cells or from cell fractions other than the "ghosts".

The circular chromatography experiments, carried out according to Hack [26], revealed the following facts. Well defined coloured rings were obtained by treating the dried chromatograms with suitable reagents. The position of the

Inositol	< 0.2	< 0.2	< 0.2
Hexoses	< 0.2	< 0.2	< 0.2
Cholesterol	< 0.2	< 0.2	< 0.2

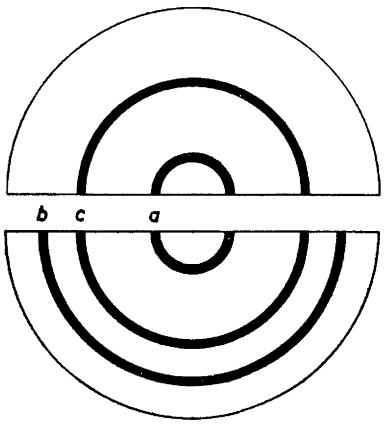

Fig. 2. Chromatograms of bacterial lipids, extracted with $CHCl_3$:CH_3OH. The chromatogram was developed to *a* with $CHCl_3$:CH_3OH (4:1), to *b* with acetone, to *c* with CH_3OH (this order) and dried in between. The lower half was treated with Sudan black (general test for lipids), the upper one with NH_4-molybdate and H_2S (test for phospholipids).

rings, compared to that of the solvent front, indicated that the lipids as a rule had a R_F value either close to unity or close to zero. The best differentiation was obtained by developing the chromatograms first with chloroform-methanol (radius of wet spot 10 mm), then with acetone (40 mm) and finally with methanol (30 mm). Three rings were obtained, all of which stained with Sudan black and osmic acid vapors. Only in the two central ones, however, could phospholipids be detected by means of the ammonium molybdate-hydrogen sulphide spot test. The results are illustrated by Fig. 2. A similar system of components was observed when commercial egg lecithin was chromatographed.

No certain differences could be detected in the chromatographic behavior of lipids extracted from "ghosts", cell wall, soluble protoplasm and whole cells, respectively. In all chromatograms the presence of both phospholipids and lipids free of phosphorus was indicated.

DISCUSSION

A great number of methods for the extraction and purification of lipids have been developed during the course of time. Of the two procedures for the isolation of "free" lipids that have been tried in the present study the one using chloroform-methanol seems to effect the most complete extraction of the investigated material. It is by no means excluded, however, that still more efficient methods could be developed by using other solvent mixtures or purification techniques.

As far as the "ghosts" are concerned, the refluxing technique recommended by Reichert [16] seems to increase the yield of chloroform-methanol extractable lipids by less than 10 %. The yield of such lipids remains approximately the same whether wet or freeze-dried material serves as starting material for the extractions (Table 3, column a, batches VIII and IX).

As is evident from Tables 2, 3 and 5 a considerable part of the bacterial lipids, the "bound" lipids, cannot be extracted without a chemical degradation (acid hydrolysis) of the cell material. This has earlier been pointed out by

Bloor and others [1]. From the tables it can be seen that the proportion of the "bound" lipids to totally extractable lipids diminishes from 50 to about 20 % as a consequence of the lysozyme treatment and the fractionation procedures. It remains to be investigated whether this change is due to breakage of chemical bonds or to the mere disintegration of the cell structure.

The decrease in the content of "bound" lipids that accompanies the preparation of the cell fractions may to some extent at least explain why more lipid material is obtained from these fractions, taken together, than from whole cells (Table 7). The acid hydrolysis of the cell material causes a degradation of the lipid molecules. Of the split products only the fatty acids are extracted when the hydrolysate is shaken with ether.

The total amount of lipid material extractable from *Bacillus* M ranges between 3 and 5 % (Table 7). Previous investigators have reported that cells of *Bacillus megaterium* contain 10—25 % of lipids [29]. The bulk of these lipids consists of polymerized β-hydroxy-butyric acid and is located in granules stainable with Sudan black [30,31]. The present author has only occasionally found similar granules in cells of *Bacillus* M. It could be mentioned in this connection that the presence or absence of lipid granules has been used as a means for the differentiation between various *Bacillus* species [29].

From the figures in Tables 4, 6 and 7 it can be calculated that 55—75 % of the bacterial lipids are located in the "ghosts". These structures represent about 15 % of the total cell dry weight(Table 4). Thus the greater part of the lipids are concentrated in a rather small fraction of the cell material. Lipid rich fractions of bacterial cells have earlier been described by Mitchell and Moyle [4], by Few [5] and by Georgi *et al* [6]. The "red fraction" obtained by the last-mentioned workers, containing about 50 % of the bacterial lipids, is probably equivalent to the "ghosts" described in the present paper. After the extraction with lipid solvents this "red fraction" was transformed into discrete granules. Some preliminary electron microscopical observations on the residue obtained after extraction of the "ghosts" of *Bacillus* M have not revealed characteristic granules but rather masses built up by not very well-defined subunits. On the other hand, granules are present in the intact "ghosts" of this bacterium [10].

The chemical analyses reported in this paper suggest a rather simple composition of the lipids of *Bacillus* M. Cholesterol is very probably absent altogether. The small differences between the phosphorus determinations carried out with and without alkaline hydrolysis indicate that the extracted phospholipids consist almost entirely of phosphatidic acids or of monoamino compounds. In addition since no hexoses could be detected in lipid hydrolysates (Table 9) sphingolipids are probably not present. This is in accordance with the findings of Čmelik [32]. He notes the absence of hexoses in lipids isolated from cells of *Salmonella paratyphi C*. Georgi *et al.*, on the other hand, report that the phospholipids of *Bacillus stearothermophilus* are mainly of the sphingomyelin type. The apparent dissimilarity between the lipids of the two *Bacillus* species could perhaps be explained by the fact that Georgi *et al.* used a weaker alkali (0.1 M) for the hydrolysis of the monoaminophospholipids [6].

The very low content of choline, serine, ethanolamine and inositol in the "free" bacterial lipids (Table 9) strongly suggests that the phospholipids pre-

sent in this material mainly consist of phosphatidic acids. This is in accordance with the findings of Few [5] and by Čmelik [32]. Few [5] reports that choline is absent in lipids isolated form a "small particle fraction" of disintegrated *Pseudomonas denitrificans* and *Staphylococcus aureus* cells. This fraction very probably represents disintegrated cytoplasmic membranes. Mostly phospholipids were isolated from *Pseudomonas denitrificans*, and these lipids had a high content of phosphatidic acids. Čmelik finds no choline in lipids extracted from whole cells of *Salmonella paratyphi C*.

It could be questioned, however, whether the phosphatidic acids exist as such in the living bacteria. Hanahan and Chaikoff have demonstrated the presence in plant tissues of an enzyme that rapidly splits nitrogen compounds from phosphatides [33]. Similar enzymes may be active in bacterial lysates as well. On the other hand, the "free" lipids isolated from whole cells also have a low content of choline, etc. In this case it seems less probable that a significant degradation of the lipids can have occurred as a consequence of lytic processes.

In the lipids isolated from cell wall and soluble protoplasm the presence of several ninhydrin-positive substances besides serine and ethanolamine was noted. Such substances, often identified as amino acids, have been found earlier in purified lipids [34,35]. Whether they represent contaminations or from complexes with the lipids does not seem quite clear [35].

The circular chromatography experiments indicate that the bacterial lipids contain phoshorus-free lipids in addition to the phospholipids or phosphatidic acids. The former substances probably represent neutral fat or fatty acids such compounds have been isolated from several bacteria [1–3].

The chromatographic characterisation of the phospholipids show in addition that these compounds can be divided into two fractions, one soluble in methanol, the other one methanol insoluble. A similar behavior of phospholipids isolated from typhoid bacteria has been demonstrated by Čmelik [32,35,36]. In the methanol-soluble fraction of Čmelik's lipids amino acids were present, whereas the fraction insoluble in the same solvent consisted of a mixture of cephalin and phosphatidic acids.

The greater part of the experimental work of this investigation was carried out by Mr. Ulf Nyström. His skilful assistance is gratefully acknowledged.

I also wish to thank Dr. Gunnar Brante for reading the manuscript and for valuable suggestions in this connection.

The investigation is part of a program on the submicroscopic structure of the bacterial cell, which is financially supported by the *Swedish Natural Science Research Council.*

Short Communications

Refractometric Determination of Diffusion Constants in the Critical Region of Partly Miscible Liquids

HANS LUDVIG LORENTZEN and BJØRN BERGSNOV HANSEN

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

Owing to the convenient critical temperature of about 30° the system chosen for starting off diffusion measurements was ethyl alcohol-succinonitrile. The diffusion constant approaches zero at the critical point.

The sample of about 50 mm³ liquid mixture was contained in a hollow, vertical 60° prism of about 10 mm in height. An astigmatic optical system was employed which showed directly on a photographic diagram the refractive indices of the liquids at different levels inside the prism, and thereby the composition of the liquid. The system has been described earlier [1,2].

Before being sealed off the prism was filled with a liquid mixture of roughly critical composition. By agitating the prism at a temperature above the critical point (where the components are entirely miscible) a certain gradient of composition was obtained, the liquid at the bottom being richer in the denser component than at the top.

The prism was then lowered into the thermostat [3], which was set just above the critical temperature. When the thermostat was then regulated to temperatures just below the critical, two phases developed. Both these phases will have constant composition as indicated by vertical lines on the diagram. When now the thermostat was again raised to a temperature above the critical, a diffusion commenced at the former surface between the two phases. The vertical composition lines on the diagram will thereby be connected by a sigmoid curve. Fig. 1 shows in principle the photographically obtained diagram, while Fig. 2 shows an actual photograph. The inclination of the tangent at the sigmoid curve's inflexion point was determined from the photographs, as were also the compositions of the two phases of constant compositions (C_1 and C_2).

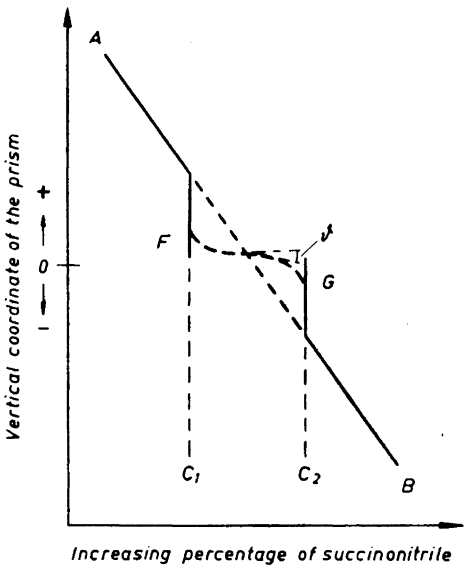

Fig. 1. Schematic drawing of photographically obtained diagram. Line AB shows the composition of the liquid at different levels inside the prism at the beginning of the experiment. The sigmoid curve FG is formed due to the diffusion when the temperature is raised to a selected temperature above the critical.

The composition was calculated to be the following function of the time and of the vertical coordinate z in the prism. z equals zero at the transition between the

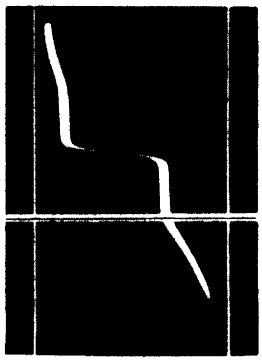

Fig. 2. Photographically obtained diagram. This belongs to a second system now under investigation, *i. e.*, triethylamine water. The straight lines are for orientation of the curve on the photographic plate, and are horizontal and vertical. The distance between the two vertical lines corresponds to a difference in refractive index of the sample of about 0.015. The total length of the curve corresponds to 17 mm vertically in the prism.

two phases, and the time t equals zero at the beginning of the diffusion. D is the diffusion constant to be determined.

$$C = \frac{C_2-C_1}{\sqrt{\pi}} \int_0^{z/2\sqrt{Dt}} e^{-x^2}\,dx + \tfrac{1}{2}(C_2-C_1)$$

This gives for $z = 0$ $\frac{\partial C(0)}{\partial z} = \frac{C_2-C_1}{2\sqrt{\pi Dt}}$ (1)

On the photographs we regard Z as ordinate, k_v as vertical magnification, X as abscissa, and k_h as horizontal proportional factor. Linearity was previously found to exist between the refractive index and X. Assuming linearity between the composition and the refractive index, we then get:

$$\frac{\partial c}{\partial z} = \frac{k_v}{k_h} \qquad \lim \frac{\delta X}{\delta Z} = \frac{k_v}{k_h}\,\frac{1}{\mathrm{tg}\vartheta}$$

On the other hand, when we assume that

$$C_2-C_1 = \frac{\Delta X}{k_h}, \text{ eqn. 1. gives } \frac{k_v}{\mathrm{tg}\vartheta} = \frac{\Delta X}{2\sqrt{\pi Dt}}$$

from which it will be seen that $\mathrm{tg}\vartheta$ is a function of time of the type: $\mathrm{tg}\vartheta = bt$

$$\text{This gives } D = \frac{k_v^2 \cdot b^2}{4\pi}\,\Delta X^2$$

From a series of photographs $\mathrm{tg}\vartheta$ was measured as a function of time and the factor b determined by the method of least squares.

The method employed presupposes equal diffusion constants for all compositions in the range between C_1 and C_2. The results seem to indicate that the presupposition is reasonably correct. In fact, when carrying out the measurements the difference between C_1 and C_2 has been kept rather on the low side (less than 5 %) and the compositions between C_1 and C_2 correspond to the very flat top of the coexistence curve.

The method requires the concentrations C_1 and C_2 to be constant during the individual series at the selected temperatures. The series had therefore to be terminated when the vertical lines C_1 and C_2 were disturbed due to diffusion. Actually the individual series has to be broken long before the vertical lines C_1 and C_2 on the photograph seem visually to be destroyed.

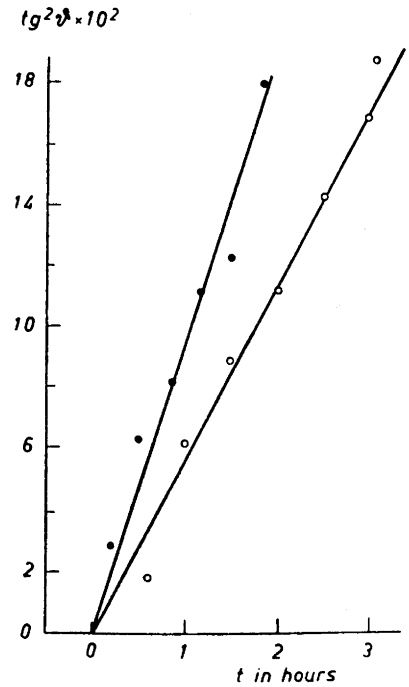

Fig. 3. $\mathrm{tg}^2\vartheta$ as function of time, for the two representative series 0.070° above Tc, C_1-C_2 = 4.6 % (solid dots) and 0.036° above Tc, C_1-C_2 = 4.9 % (open circles).

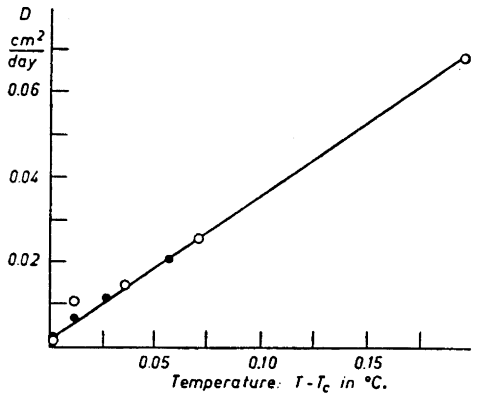

Fig. 4. Diffusion constant as function of temperature. The solid dots and the open circles belong to two different series. The deviation of the one open circle may be due to the thermostat working imperfectly.

In Fig. 4 the diffusion constants are plotted against the temperature distance from the critical point. The points belong to two different series with different prisms and samples used for filling up the prisms. Minor impurities in the samples are certainly different in the two series. Moreover, certain reactions seem to take place inside the prism. This is shown by the fact that the critical temperature has not been constant the whole time, but has decreased from day to day so that it had to be checked at all individual diffusion measurements at the selected temperatures.

In Fig. 4 the diffusion constant does not extrapolate exactly to zero at the critical temperature. However, no conclusions can be drawn from this, especially as the exact determination of the critical temperature has been a difficult undertaking, and the temperature regarded as critical may have been one or two millidegrees below the actual temperature.

The diffusion constant seems to approach zero by lowering the temperature down to the critical by 0.37 cm^2 per day and °C.

Thanks are extended to Professor Joseph E. Mayer of the University of Chicago and Dr. Bruno H. Zimm of General Electric Company, Schenectady, for valuable personal conferences, and to Cand. real O. Øgrim for his assistance with the calculations of the optical system.

Throughout the whole period of the investigations the encouragement and interest shown by Professor O. Hassel of the University of Oslo has been of inestimable value.

The Ultraviolet Absorption Spectra of Some Aroyl Compounds Derived from Phloroglucinol

CARL ENEBÄCK

Department of Chemistry, Institute of Technology, Helsingfors, Finland

The electronic absorption spectra of 2-hydroxy-4,6-dimethoxybenzaldehyde (Fig, 1; max. 294 mμ, log ε = 4.31; infl. 330 mμ, log ε = 3.58), 2-hydroxy-4,6-dimethoxyacetophenone (Fig. 2; max. 288 mμ. log ε = 4.24; infl. 320 mμ, log ε = 3.60) and 2-hydroxy-ω,4,6-trimethoxyacetophenone (Fig. 3; max. 288 mμ, log ε = 4.31; infl. 323 mμ, log ε = 3.62) in 95 % ethanolic solution show a close resemblance to each other and to the spectra of flavanones [1,2] and 2-benzylcoumaran-3-ones [1] that have the group

in common and are unsubstituted in the isolated phenyl group. It is, therefore, to be concluded that this type of spectrum represents the absorptional properties of the aroyl group in question when coplanar or nearly coplanar.

Methylation of the two acetophenones mentioned leads to a quite different type

The Ultraviolet Absorption Spectra of Some Aroyl Compounds Derived from Phloroglucinol

CARL ENEBÄCK

Department of Chemistry, Institute of Technology, Helsingfors, Finland

The electronic absorption spectra of 2-hydroxy-4,6-dimethoxybenzaldehyde (Fig, 1; max. 294 mμ, log ε = 4.31; infl. 330 mμ, log ε = 3.58), 2-hydroxy-4,6-dimethoxyacetophenone (Fig. 2; max. 288 mμ. log ε = 4.24; infl. 320 mμ, log ε = 3.60) and 2-hydroxy-ω,4,6-trimethoxyacetophenone (Fig. 3; max. 288 mμ, log ε = 4.31; infl. 323 mμ, log ε = 3.62) in 95 % ethanolic solution show a close resemblance to each other and to the spectra of flavanones [1,2] and 2-benzylcoumaran-3-ones [1] that have the group

in common and are unsubstituted in the isolated phenyl group. It is, therefore, to be concluded that this type of spectrum represents the absorptional properties of the aroyl group in question when coplanar or nearly coplanar.

Methylation of the two acetophenones mentioned leads to a quite different type

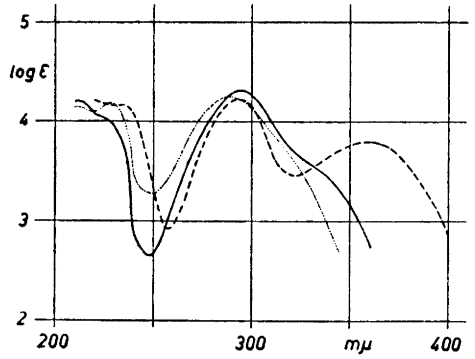

Fig. 1. ———— 2-hydroxy-4,6-dimethoxybenzaldehyde in 95 % ethanol. — — — — 2-hydroxy-4,6-dimethoxybenzaldehyde in 0.05 N NaOH in 48 % aqueous ethanol. ····· 2,4,6-trimethoxybenzaldehyde in 95 % ethanol.

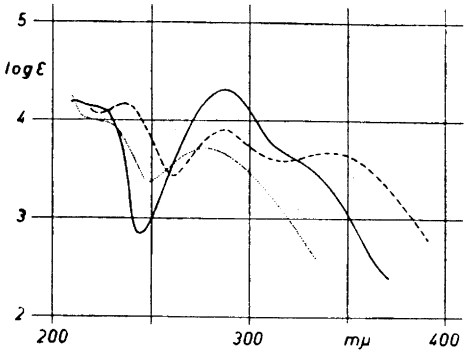

Fig. 3. ———— 2-hydroxy-ω,4,6-trimethoxyacetophenone in 95 % ethanol. — — — — 2-hydroxy-ω,4,6-trimethoxyacetophenone in 0.05 N NaOH in 48 % aqueous ethanol. ····· ω,2,4,6-tetramethoxyacetophenone in 95 % ethanol.

of spectra, characterised by much lower overall molar extinction, especially at longer wave-lengths. Cram and Cranz [3] already have observed this effect of two *o*-methoxyl groups in the case of the dimethyl ethers of 2,6-dihydroxyacetophenone and 2,6-dihydroxy-3-methylacetophenone. 2,4,6-Trimethoxyacetophenone (Fig. 2) has a maximum at 274 mμ, log $\varepsilon = 3.76$ and ω,2,4,6-tetramethoxyacetophenone (Fig. 3) a maximum at 278 mμ, log $\varepsilon = 3.72$. It cannot be seen from the spectra whether such a maximum results from two bands which presumably would correspond to the most intense band and the inflexion in the parent 2-hydroxy compound.

2,4,6-Trimethoxybenzaldehyde (Fig. 1), in contrast to the corresponding acetophenones, exhibits but a slightly lower molar extinction in the main band (max. 289 mμ, log $\varepsilon = 4.25$) compared with the parent 2-hydroxy compound. Again, the inflexion in the latter becomes less pronounced by methylation.

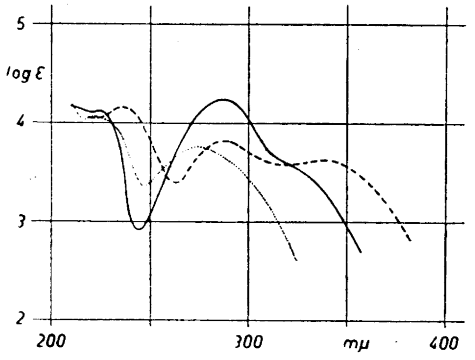

Fig. 2. ———— 2-hydroxy-4,6-dimethoxyacetophenone in 95 % ethanol. — — — — 2-hydroxy-4,6-dimethoxyacetophenone in 0.05 N NaOH in 48 % aqueous ethanol. ····· 2,4,6-trimethoxyacetophenone in 95 % ethanol.

The reduction of the *K*-band intensity due to steric hindrance of coplanarity in aroyl compounds with one or two ortho-methyl groups has been studied by Braude and Sondheimer [4]. They deduced a quantitative relation between the band intensity and the mean angle between the planes of the benzene nucleus and the acyl group in the ground electronic state of the molecule. The mean angles are smaller in the substituted benzaldehydes than in the acetophenones, as, beside the mere steric interaction between the carbonyl oxygen and an *o*-methyl group in the former, an overlap of an *o*-methyl group and the acetyl-methyl group is possible in the latter. This overlap, in addition, provides a much stronger hindrance to coplanarity than does the overlap of the carbonyl and *o*-methyl groups.

The low absorption intensities of the acetophenones with two *o*-methoxyl groups can be conveniently explained by the hindrance to coplanarity of the aroyl group mainly produced by the steric interaction of either of the *o*-

groups and the group forming the second link of the side carbon chain. In this respect, the effect of *o*-methoxyl resembles that of *o*-methyl groups. A hindrance to coplanarity by a steric interaction between the carbonyl oxygen and one *o*-methoxyl group is not evident from the intensity data, since the spectra of 2-methoxyacetophenone, 2-methoxybenzaldehyde, their parent hydroxy compounds, flavanone and 2-benzylcoumaran-3-one, are all very like each other [5,1]. In fact, slightly *higher* molar extinctions of the most intense bands are reported for the two mentioned methoxy compounds, of which 2-methoxyacetophenone shows rather marked hypsochromic shifts when compared with 2-hydroxyacetophenone: 5.5 mμ for the most intense band and 22 mμ for the band at the longer wave-length [5]. On the other hand, the slight reduction in the absorption intensity, which follows the methylation of 2-hydroxy-4,6-dimethoxybenzaldehyde, might be noted.

A steric interaction of the carbonyl group forming the second link of the carbon chain in 1-(2,4,6-trimethoxyphenyl)-3-phenylpropane-1,2-dione with either of the *o*-methoxyl groups possibly contributes to its somewhat individualistic spectral behaviour [1].

From the spectra in 0.05 N sodium hydroxide/48 % aqueous ethanol solution of 2-hydroxy-4,6-dimethoxybenzaldehyde (Fig. 1; max. 294 mμ, log ε = 4.21; max. 359 mμ, log ε = 3.79), 2-hydroxy-4,6-dimethoxyacetophenone (Fig. 2; max. 288 mμ, log ε = 3.82; max. 338 mμ, log ε = 3.62) and 2-hydroxy-ω,4,6-trimethoxyacetophenone (Fig. 3; max. 288 mμ, log ε = 3.90; max. 342 mμ, log ε = 3.67) it is seen that the phenolate ions of both acetophenone derivatives absorb much less intensely than the anion of 2-hydroxy-4,6-dimethoxybenzaldehyde. The overlap of the second chain link and either of two *o*-oxygen atoms thus seems to hinder coplanarity when the possibility of chelate ring formation is eliminated.

Experimental: 2-Hydroxy-4,6-dimethoxybenzaldehyde, m.p. 70.5° (71° reported [6]), was prepared by demethylation of 2 g of *2,4,6-trimethoxybenzaldehyde*, m.p. 120° (see acknowledgement) with aluminium bromide (1.05 moles) in benzene solution. It was purified by repeated recrystallisations from aqueous methanol and, finally, by sublimation under vacuum.

2-Hydroxy-4,6-dimethoxyacetophenone, m. p; 82° (various values from 80° to 88° reported. 83°, Ref.[7]) and *2-hydroxy-ω,4,6-trimethoxyacetophenone*, m. p. 104° (103—104° reported) were prepared by the procedure described for the latter compound [8]. They were purified by repeated recrystallisations from methanol and ethanol, respectively, and, finally, by sublimation under vacuum.

2,4,6-Trimethoxyacetophenone, m. p. 101.5° (102—103° reported [9]) was obtained by methylation of phloroacetophenone (2 g) in 30 ml of acetone with dimethyl sulphate (3.5 moles) and potassium carbonate. It was purified by washing the ether solution with alkali, recrystallisations from methanol-ethanol, and final sublimation under vacuum.

ω,2,4,6-Tetramethoxyacetophenone, m. p. 56.5°—57° [1], was purified by washing with alkali, repeated recrystallisation from ether and sublimation under vacuum.

The spectra were determined with a Beckman DU spectrophotometer from solutions of the sublimed compounds in concentrations of 10 to 20 mg/l. All determinations were carried out immediately after the dissolution. The measurement of 2-hydroxy-4,6-dimethoxybenzaldehyde in 0.05 N NaOH/48 % ethanol was repeated after 2 h and those of both aldehydes in neutral ethanol after 7 days, but the spectra were unchanged.

The author wishes to thank Mr. Kaj Silander, M. Sc., for the specimen of 2,4,6-trimethoxybenzaldehyde.

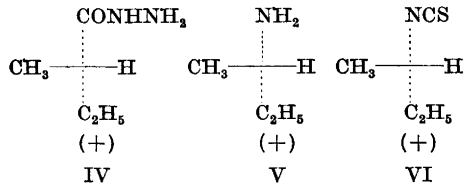
*iso*Thiocyanates XXVII *. The Absolute Configuration of Optically Active 2-Butylamine and 2-Butyl *iso*Thiocyanate

ANDERS KJÆR and SVEND ERIK HANSEN



Chemical Laboratory of the University of Copenhagen, Denmark

The isolation from natural sources of 2-butyl *iso*thiocyanate was effected by Hofmann [1] in 1874. Gadamer [2] later established the glycosidic origin and dextrorotatory character of the mustard oil and accomplished its synthesis from (+)-2-butylamine. The configuration of the latter, relative to glyceraldehyde, can be inferred from the kinetically controlled interconversions of 2-butylamine, 2-butyl halides and 2-butanol established by the Ingold school [3]. Various authors have correlated 2-butanol with glyceraldehyde through lactic acid as a key intermediate (*cf.* Ref.[4]).

In the course of current investigations in this laboratory, it became of interest to correlate optically active 2-butylamine, and hence 2-butyl *iso*thiocyanate, with glyceraldehyde through transformations not involving inversions at the asymmetric centre. This has been achieved in the following way:

I II III

IV V VI

(—)-2-Methylbutanol ('active amyl alcohol') (I) was oxidized to (+)-2-methylbutyric acid (II), and the latter further converted into (+)-methyl 2-methylbutyrate (III) and (+)-2-methylbutyric acid hydrazide (IV). Curtius rearrangement of the corresponding azide, followed by acid hydrolysis of the intermediate urethan, ultimately furnished *dextrorotatory* 2-butylamine (V), characterized as its hydrochloride and benzoyl derivative. Since Jones and Wallis [5] first demonstrated the Curtius rearrangement to take place without racemization, evidence has become abundant that this intramolecular displacement reaction proceeds with full retention of configuration (*cf. e. g.* Ref.[6]).

The above symbols (I)—(VI), represent the absolute configurations on following grounds: (I) has been configuratively related with (—)-glyceraldehyde through a rather circumstantial series of transformations, recently summarized by Crombie and Harper [7]. The assignment has been verified by Freudenberg's ingenious application [8] of dihydroshikimic acid for determining the configuration of (+)-3-methylhexane, which has been correlated with (I) many years ago [9]. The X-ray evidence of Bijvoet *et al.*[10] finally renders established relationship with glyceraldehyde equal to knowledge of the absolute configuration.

Correlation of (I) with C-3 in natural *iso*leucine has been achieved in various ways (*cf. e. g.* Ref.[11]). Hence, natural *iso*leucine and (+)-2-butyl *iso*thiocyanate (VI) belong to the same configurational series. The direct determination of the absolute configuration of the former by means of X-ray crystallography [12] provides an independent confirmation of the above assignments, which may prove useful also for the purpose of establishing the correlation of (+)-2-butyl *iso*thiocyanate with its glucosidic progenitor (glucocochlearin) as suggested by Ettlinger and Lundeen [13].

Experimental. Melting points are uncorrected. Rotations are measured in a 1 dm tube.

(+)-2-Methylbutyric acid (II). An optically active acid, produced by oxidation of essentially pure (—)-2-methylbutanol, served as a starting material for the following syntheses. The acid had the rotation value: $[\alpha]_D^{21}$ +19.6° (neat), D_4^{21} 0.937, somewhat higher than most literature values.

(+)-Methyl 2-methylbutyrate (III). Esterification of the above acid (65 g) with methanol

* Part XXVI of this series: *Acta Chem. Scand.* **11** (1957) *In press.*

(600 ml), and a few drops of sulphuric acid, afforded the methyl ester (44 g) as a colourless liquid, b. p. 115°, n_D^{25} 1.3916, D_4^{22} 0.888, $[\alpha]_D^{22}$ +23.6° (neat), $[\alpha]_D^{21}$ +26.0° (*c* 1.8, MeOH).

Guye [14] reported the value $[\alpha]_D^{22}$ +22.03° for the ester, corrected to supposedly optically pure condition, while von Doering and Aschner [15] listed the value $[\alpha]_D^{27}$ +21.1° (*c* 1.7, MeOH) for a specimen prepared from 2-methylbutyric acid, having $[\alpha]_D^{27}$ +17.75° (neat) and claimed to be 98 % optically pure. The enantiomeric ester, deriving from an acid with $[\alpha]_D^{17}$ —17.35°, was reported by Prelog and Zalán [16] with the rotation value $[\alpha]_D^{15}$ —19.42° (neat).

(+)-2-Methylbutyric acid hydrazide (IV). The methyl ester (30 g) was slowly added to a large excess of boiling 90 % hydrazine hydrate, and the mixture was refluxed for 2 h. On removal of hydrazine *in vacuo*, the crude hydrazide separated (29 g). Three sublimations afforded an analytical specimen as thin, colourless needles, m. p. 96°. $[\alpha]_D^{22}$ +41.3° (*c* 2.6, H_2O). (Found: C 51.80; H 10.54; N 24.24. Calc. for $C_5H_{12}N_2O$: C 51.68; H 10.43; N 24.21).

(+)-2-Butylamine (V). To a stirred solution of the hydrazide (28 g) in 1 N HCl (400 ml), covered with ether and cooled to 0°, was added a concentrated aqueous solution of $NaNO_2$ (22 g). The ether phase was separated, combined with two additional ether extracts, and briefly dried over Na_2SO_4. Anhydrous ethanol (*ca.* 300 ml) was added and the solution was refluxed for 2 h, when the N_2-evolution had completely ceased. A small fraction of the oily urethan, remaining upon removal of the solvents, was refluxed with 20 % HCl for 10 h, when removal of water and acid resulted in separation of the crystalline amine hydrochloride. This was covered with ether and strong alkali was slowly added to liberate the amine. Ether was removed from the carefully dried extract by distillation through a 3-feet helix-packed column, and (+)-2-butylamine distilled as a colourless liquid, b. p. 62.5°, n_D^{25} 1.3853. The rotation value, $[\alpha]_D^{22}$ +6.1° (neat), was measured on a fore-run probably still containing traces of water. Literature values are: $[\alpha]_D^{15.5}$ +6.42° (neat)[2b], $[\alpha]_D^{20}$ +7.44° (neat)[17], and $[\alpha]_D$ +7.4° (*c ca.* 25, H_2O) [18].

The hydrochloride separated from acetone in colourless, hygroscopic needles, m. p. 152—153° (closed tube), $[\alpha]_D^{19}$ —1.05° (*c* 13.3, H_2O) (Found: N 12.47; Cl 32.50. Calc. for $C_4H_{12}ClN$: N 12.78; Cl 32.34). Literature values: $[\alpha]_D^{20}$ —2.05° (*c* 7.3, H_2O)[2b], $[\alpha]_D^{20}$ —1.13° (*c* 14.0, H_2O) [17] and, for the enantiomorphous salt, $[\alpha]_D^{20}$ +0.90° (*c.* 3.7, H_2O) [19].

(+)-N-(2-Methylbutyl)-benzamide. Benzoylation of the above amine, performed under customary Schotten-Baumann conditions, furnished the benzamide, separating from 50 % ethanol in colourless needles, m. p. 97°, $[\alpha]_D^{21}$ +34.9° (*c* 1.1, EtOH) (Found: C 74.60; H 8.40; N 7.82. Calc. for $C_{11}H_{15}NO$: C 74.56; H; 8.54 N 7.91.) Previously reported data: m. p. 92°, $[\alpha]_D^{21}$ +30.7 (*c* 1, EtOH)[19], m. p. 92.0—92.5°, $[\alpha]_D^{25}$ +30.74° (*c* 4, EtOH) [20].

Microanalyses were performed in this laboratory by Mr. P. Hansen. The optically active 2-methylbutyric acid was generously supplied by Dr. A. Klit. The work is part of investigations supported by *The Danish State Research Foundation* and *The Carlsberg Foundation*. A special grant from *Kai Hansen's Fond* is gratefully acknowledged.

The Incorporation of $^{14}CO_2$-carbon into the Glycogen of *Escherichia coli* B

HANS PALMSTIERNA and RUNE STJERNHOLM*

Bacteriological Dept., Karolinska Institutet, Stockholm, Sweden, and Department of Biochemistry, School of Medicine, Western Reserve University, Cleveland 6, Ohio, U.S.A.

Under resting cell conditions *Escherichia coli* B ferments Na-lactate and accumulates a polysaccharide of glycogen-like nature. If aerated with a mixture of air and $^{14}CO_2$ in a 9:1 ratio (v/v) respectively, isotope is incorporated into the glucose units. A detailed description of the experimental conditions has been published previously [1]. A preliminary analysis by means of a bacterial degradation with *Lactobacillus casei* indicated that 95 % of the isotope was located in the 3 and 4 positions of the glucose molecule. However, the method of degradation did not permit differentiation of the individual carbon atoms in the glucose molecule. It is the purpose of this report to show the exact isotopic distribution pattern, since the value of this method for the preparation of glucose-3,4—^{14}C, rests upon an equal labeling of the 3 and 4 carbon atoms. In the standardized method the cells were allowed to ferment Na-lactate in the presence of $^{14}CO_2$ for 60 min. The glycogen was isolated by the usual alkaline hydrolysis method. Depolymerisation was accomplished by hydrolysis in 0.6 N HCl and the glucose thus obtained was purified by passing through Dowex 50 in the H^+-form and Dowex 2 in the acetate form. The ion exchangers must be used in the order mentioned. The glucose was further purified by chromatography according to Gardell [2]. The sugar was finally subjected to a bacterial degradation by means of *Leuconostoc mesenteroides*, which allows a complete separation of all C-atoms in the glucose molecule [3]. Carbon 1 is split off as carbon dioxide, carbon atoms 2 and 3 appear as ethanol, and carbons 4, 5 and 6 as lactic acid. Ethanol and lactic acid were chemically degraded by conventional methods. All samples were counted as CO_2 in a proportional gas counter [4].

The following specific activities for the different carbon atoms were found:

C-atom	c/min/mmole C
1	600
2	200
3	15 600
4	15 000
5	140
6	80

Total oxidation of glucose by the van Slyke combustion method gave 33 700 c/min/mole glucose. The counting accuracy was ± 2 % for the carbons 3 and 4, and ± 15 % for the other carbons. The activities were thus fairly evenly distributed in the 3 and 4 positions. Furthermore very little of the activity was found in the other carbon atoms.

The method described previously [1], thus provides a simple method of preparation of glucose-3,4-^{14}C.

The Base Strength of Hydrazoic Acid

THOR A. BAK and EIGIL L. PRÆSTGAARD

Universitetets Fysisk-Kemiske Institut, Copenhagen, Denmark

In his early work on the base strength of nitrogen compounds Hantzsch [1] investigated the cryoscopic behaviour of hydrazoic acid in concentrated sulfuric acid. From his measurements he concluded that in 100 % H_2SO_4 hydrazoic acid takes up three protons to form $H_4N_3^{+++}$. (Strictly speaking he stated that the salt $N_3H_4(HSO_4)_3$ is formed.)

Recalculation of Hantzsch's data shows that at most two protons are taken up. Using the value [2] −10.6 for Hammett's acidity function H_0 for 100 % H_2SO_4 we can from Hantzsch's data estimate the dissociation-constant for the acid $H_3N_3^{++}$. We get $pK = -10.1$, but this value should undoubtedly be taken with some reservation.

Since it is of importance to know the base strength of hydrazoic acid in order to study the mechanism of, *e. g.*, the Schmidt reaction [3,4] we have determined the dissociation constant for the acid $H_2N_3^+$ at 25.0°C by the following simple technique. HN_3 was equilibrated between a sulfuric acid phase and a chloroform phase, and the concentrations of HN_3 and $H_2N_3^+$ in the two phases were determined cerimetrically [5].

We use the symbols

$[HN_3]s$	concentration of HN_3 in the sulfuric acid phase
$[H_2N_3^+]s$	concentration of $H_2N_3^+$ in the sulfuric acid phase
$[HN_3]c$	concentration of HN_3 in the chloroform phase

The concentration of $H_2N_3^+$ in the chloroform phase is neglected. We also neglect the concentration of the ion $H_3N_3^{++}$ in both phases. The justification for this lies in the experimental data given below.

Defining two distribution constants:

$$f = \frac{[HN_3]s + [H_2N_3^+]s}{[HN_3]c}$$

$$n = \frac{[HN_3]s}{[HN_3]c}$$

we have, as a simple consequence of the definition [6] of H_0:

$$pK = H_0 + \log\left(\frac{f}{n} - 1\right). \qquad (1)$$

pK is the negative logarithm of the dissociation constant of the acid $H_2N_3^+$.

Since we neglect the concentration of $H_3N_3^{++}$ the distribution-constant f can be determined directly and proves to be constant over the range 25−40 % H_2SO_4. We conclude therefore that in this range $f = n$. The value of n is (accidentally) equal to one, $n = 1.00 \pm 0.04$.

Assuming that n will be constant equal to one also for higher sulfuric acid concentrations we can determine an approximate value of pK from the measurement of f, using eqn. (1). Under this assumption we obtained as an average of six measurements $pK = -6.21$ (see Table 1).

Table 1.

% H_2SO_4	H_0	f	pK
77.96	—6.55	3.22	—6.20
78.12	—6.57	4.22	—6.07
78.54	—6.64	3.84	—6.19
81.20	—7.04	6.66	—6.29
83.76	—7.44	15.80	—6.27
84.56	—7.54	19.95	—6.26

f is the distribution constant for hydrazoic acid between sulfuric acid and chloroform.

This approach is of course somewhat unsatisfactory, since we only know that n is constant over the range 25−40 % H_2SO_4. We therefore proceded to treat n, for higher sulfuric acid concentration, as an unknown, constant only over a small range in H_0.

Using the first four measurements for which H_0 is practically constant we determined the value of n by requiring that the mean square deviation of pK, regarded as a function of n, be minimum. This gives a value for n slightly below one ($n \sim 0.98$), but the correction in pK introduced in this way is immaterial. The above value for pK is therefore the best estimate of the dissociation constant we can give on basis of this method.

For higher concentrations of sulfuric acid we find unexpectedly small values of f (*e. g.*, $f \sim 85$ for 95 % H_2SO_4), indicating that n decreases rapidly with increasing concentration of sulfuric acid. This effect, which has nothing to do with the basicity

of HN_3, makes the present method unsuitable for studying the dissociation constant of, *e. g.*, $H_3N_3^{++}$. Similar effects have recently been reported by Deno and Perizzolo [7].

We thank Professor J. A. Christiansen for his interest in this investigation, and E. L. P. gratefully acknowledges financial support from *Carlsbergfondet.*

The Chemistry of the Natural Order Cupressales

XIX *. The Occurrence of Manool in *Cupressus sempervirens* L.

C. ENZELL and H. ERDTMAN

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

During routine examinations of the heartwood extractives of the conifers belonging to the genera *Cupressus* and *Chamaecyparis*, the heartwood of the Mediterranean cypress *Cupressus sempervirens* has been subjected to a brief study. Like Di Modica and Rossi [1] we have found that the main neutral constituents are carvacrol methyl ether and cedrol. The high boiling material, rather surprisingly gave manool [2](I). This diterpene alcohol is characteristic of a section of the genus *Dacrydium*, N. O. Podocarpales, and this is the first time it has been found in another genus of the conifers. Minor neutral constituents of the wood extractives are *d*-borneol, *d*-bornyl acetate and sesquiterpenes. From the acid material carvacrol, β-thujaplicin and nootkatin were isolated.

Experimental. Melting points were taken on the Koflerblock. Only upper limits of b.p. range of the fractions are given.

Finely divided heartwood (4.8 kg, from Le Lavandou, Provence, S. France) was extracted with acetone for 48 h. The acetone was removed and the residue poured, with vigorous stirring, into a tenfold volume of ether, which was filtered, concentrated and similarly poured into light petroleum. The filtered solution was successively shaken with 5 % aqueous potassium hydroxide, 10 % ethanolic potassium hydroxide and water. The alkaline fractions were combined, washed with light petroleum, acidified and extracted with light petroleum. The combined neutral solutions and the acid solution were dried (Na_2SO_4) and the solvent evaporated. The neutral fraction yielded 276 g (5.8 %) of a slightly coloured oil (N) and the acid fraction 20.4 g (0.4 %) of a yellow brown oil (A).

The neutral oil, N, (166 g) was fractionally distilled through a vacuum jacketed, packed column. Pressure 26 mm. Back pressure 10 mm. Fraction N_1, b. p. up to 104°, 1.9 g; N_2, 109°, 11.4 g; N_3, 110°, 70.0 g; N_4, 140°, 16.6 g; N_5, 162°, 9.6 g; N_6, 172°, 15.2 g; N_7, 178°, 2.1 g; N_8 (at lower pressure), 5.0 g. The remainder, after a simple distillation at lower pressure, yielded a distillate N_9 (31.9 g) and a residue (2.3 g, discarded).

Fractions N_{1-2} deposited a solid (2.5 g) which was recrystallized from ligroin and from nitromethane and sublimed. M. p. and mixed m. p. with *d*-borneol 204—207° (sealed tube, uncorr.), $[\alpha]_D^{22}$ +36.5° ($CHCl_3$; *c* 1.7).

Judging from the distillation curve the non-crystalline part of N_2 and fraction N_3 (total 79 g) contained the same compound, namely carvacrol methylether. Demethylation with HBr followed by etherification with chloroacetic acid yielded carvacroxy acetic acid, m. p. and mixed m. p. 150—152°. Fraction N_4 and the non-crystalline part of N_5 (see below) were combined (23.7 g) and distilled through a spinning band column. Pressure 26 mm.

Fraction N_{41}, b. p. up to 118°, 3.24 g, $[\alpha]_D^{22}$ +6.6°, n_D^{21} 1.4973; N_{42}, 120°, 3.59 g, +18.0°, 1.4882; N_{43}, 120°, 3.03 g, +29.5°, 1.4716; N_{44}, 128°, 2.31 g, +18.3°, 1.4800; N_{45}, 142°, 2.16 g, —7.7°, 1.4968; N_{46}, 144°, 2.96 g, —17.8°, 1.5003; N_{47}, 156°, 1.17 g, —22.8°, 1.5029; N_{48}, 173°, 2.76 g, —17.8°, 1.5071; N_{49}, tailings/10 mm 1.31 g, +8.5°; Residue 1.25 g.

The Chemistry of the Natural Order Cupressales

XIX *. The Occurrence of Manool in *Cupressus sempervirens* L.

C. ENZELL and H. ERDTMAN

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

During routine examinations of the heartwood extractives of the conifers belonging to the genera *Cupressus* and *Chamaecyparis*, the heartwood of the Mediterranean cypress *Cupressus sempervirens* has been subjected to a brief study. Like Di Modica and Rossi [1] we have found that the main neutral constituents are carvacrol methyl ether and cedrol. The high boiling material, rather surprisingly gave manool [2](I). This diterpene alcohol is characteristic of a section of the genus *Dacrydium*, N. O. Podocarpales, and this is the first time it has been found in another genus of the conifers. Minor neutral constituents of the wood extractives are *d*-borneol, *d*-bornyl acetate and sesquiterpenes. From the acid material carvacrol, β-thujaplicin and nootkatin were isolated.

Experimental. Melting points were taken on the Koflerblock. Only upper limits of b.p. range of the fractions are given.

Finely divided heartwood (4.8 kg, from Le Lavandou, Provence, S. France) was extracted with acetone for 48 h. The acetone was removed and the residue poured, with vigorous stirring, into a tenfold volume of ether, which was filtered, concentrated and similarly poured into light petroleum. The filtered solution was successively shaken with 5 % aqueous potassium hydroxide, 10 % ethanolic potassium hydroxide and water. The alkaline fractions were combined, washed with light petroleum, acidified and extracted with light petroleum. The combined neutral solutions and the acid solution were dried (Na_2SO_4) and the solvent evaporated. The neutral fraction yielded 276 g (5.8 %) of a slightly coloured oil (N) and the acid fraction 20.4 g (0.4 %) of a yellow brown oil (A).

The neutral oil, N, (166 g) was fractionally distilled through a vacuum jacketed, packed column. Pressure 26 mm. Back pressure 10 mm. Fraction N_1, b. p. up to 104°, 1.9 g; N_2, 109°, 11.4 g; N_3, 110°, 70.0 g; N_4, 140°, 16.6 g; N_5, 162°, 9.6 g; N_6, 172°, 15.2 g; N_7, 178°, 2.1 g; N_8 (at lower pressure), 5.0 g. The remainder, after a simple distillation at lower pressure, yielded a distillate N_9 (31.9 g) and a residue (2.3 g, discarded).

Fractions N_{1-2} deposited a solid (2.5 g) which was recrystallized from ligroin and from nitromethane and sublimed. M. p. and mixed m. p. with *d*-borneol 204—207° (sealed tube, uncorr.), $[\alpha]_D^{22}$ +36.5° ($CHCl_3$; *c* 1.7).

Judging from the distillation curve the non-crystalline part of N_2 and fraction N_3 (total 79 g) contained the same compound, namely carvacrol methylether. Demethylation with HBr followed by etherification with chloroacetic acid yielded carvacroxy acetic acid, m. p. and mixed m. p. 150—152°. Fraction N_4 and the non-crystalline part of N_5 (see below) were combined (23.7 g) and distilled through a spinning band column. Pressure 26 mm.

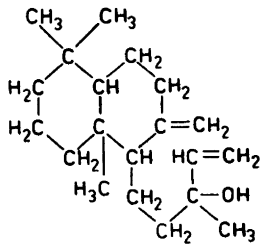
Fraction N_{41}, b. p. up to 118°, 3.24 g, $[\alpha]_D^{22}$ +6.6°, n_D^{21} 1.4973; N_{42}, 120°, 3.59 g, +18.0°, 1.4882; N_{43}, 120°, 3.03 g, +29.5°, 1.4716; N_{44}, 128°, 2.31 g, +18.3°, 1.4800; N_{45}, 142°, 2.16 g, —7.7°, 1.4968; N_{46}, 144°, 2.96 g, —17.8°, 1.5003; N_{47}, 156°, 1.17 g, —22.8°, 1.5029; N_{48}, 173°, 2.76 g, —17.8°, 1.5071; N_{49}, tailings/10 mm 1.31 g, +8.5°; Residue 1.25 g.

* Part XVIII *Acta Chem. Scand.* **11** (1957) *In press.*

For the fractions N_{41-44} the above data, the carbonyl absorption in the I.R. and the odour indicated *d*-bornylacetate. Saponification and back titration showed the presence of 45 % of the ester. *d*-Borneol was easily isolated by chromatography from the hydrolysate. M. p. and mixed m. p. 204—207° (sealed tube, uncorr.) $[\alpha]_D^{22}$ +36.3° ($CHCl_3$, *c* 3.2). Fractions N_{45-48} showed carbon-carbon double bond absorptions in I.R. and the main part behaved chromatographically as a hydrocarbon while N_{49} was fairly pure cedrol. The hydrocarbon, boiling between bornylacetate and cedrol, may therefore possibly be a mixture of cedrenes.

Fractions N_{6-7} and the crystalline material from N_5 were combined (19.9 g), recrystallized from aqueous methanol and sublimed *in vacuo*. M. p. and mixed m. p. with cedrol 87.5—88° $[\alpha]_D^{22}$ +10.0° ($CHCl_3$, *c* 1.1).

Fraction N_9 (31.9 g) was distilled through the spinning band column. Pressure 14 mm.



Fraction N_{91}, b. p. up to 110°, 0.45 g, $[\alpha]_D^{22}$ —8.5°, n_D^{21} 1.5029; N_{92}, 184°, 3.61 g, —6.5°, 1.5136; N_{93}, 189°, 2.4 g, +20°, 1.5178; N_{94}, 190°, 3.61 g, +29°, 1.5160; N_{95}, 192°, 3.40 g, +30°, 1.5148; N_{96}, 192°, 2.13 g, +28°, 1.5147; N_{97}, 198°, 2.83 g, +30°, 1.5139; N_{98}, 210°, 1.86 g, +30°, 1.5167; N_{99}, 217°, 1.42 g, +32°, 1.5273; N_{910}, 224°, 0.71 g, +23°, 1.5344; N_{911}, 229°, 2.34 g, +16°, 1.5348; N_{912}, 233°, 0.83 g, +25°, 1.5412; Residue 6.3 g.

Fractions N_{94-97} (12 g or 0.3 %) distilled at fairly constant temperature. Molecular weight determinations (Rast, 289, 292), optical rotation, refractive index and I.R. absorption properties indicated manool. When the thick oily material was seeded with authentic manool it immediately started to crystallise. The solid was recrystallized from light petroleum, m. p. and mixed m. p. 53—53.5°. The infra red absorption spectra were identical.

The acid fraction A on standing deposited nootkatin (0.2 g). The remaining oil was distilled at low pressure yielding 13.9 g volatile material, which was subjected to a fractional distillation in the spinning band column. Pressure 27 mm.

Fraction A_1, b. p. up to 129°, 1.44 g; A_2, 129°, 1.33 g; A_3, 156°, 0.86 g; A_4, 175°, 0.94 g; A_5, 175°, 0.43 g; A_6, 216°, 2.46 g; tailings/13 mm, 1.03 g. Residue 5.7 g. The rotation of all fractions was close to zero.

Fractions A_1 and A_2 according to I. R. data and paper chromatography (in light petroleum, on dimethyl sulphoxide impregnated paper)[3] contained carvacrol and etherification with chloracetic acid gave carvacroxy acetic acid, m. p. and mixed m. p. 150—2°. Fractions A_3 and A_4, according to paper chromatographic results [4] contained β-thujaplicin (0.5 g), which crystallized when seeded with this compound. M. p. and mixed m. p. 51.5—52.0°. The solid fractions A_6 and A_7 were largely nootkatin, identified by paper chromatography [4], m. p. and mixed m. p. 95—96°.

Syntheses of Nonan-1,2-diol and Nonan-1,3-diol

GERD BENDZ and MARGARETA KARTH

Chemical Institute, University of Uppsala, Uppsala, Sweden

During the investigation of the structure of some natural products two diols hitherto not prepared *viz.* nonan-1,2-diol and nonan-1,3-diol have been synthesised. The two diols are, when solid, white, odorless and waxy products, soluble in all the common organic solvents. They react with 3,5-dinitrobenzoyl chloride and yield, under mild conditions, mono-dinitroben-

zoates and, under somewhat more rigorous conditions, di-dinitrobenzoates.

A diol with the molecular formula $C_9H_{20}O_2$ was obtained by Anchel [1] on catalytic reduction of the polyacetylene biformin. Later Bohlmann [2] and Bu'Lock [3] mention that biformin is probably nona-4,6,8-triyne-1,2-diol, as its hydrogenation product on oxidation with chromic acid gave octanic acid. Consequently the glycol obtained from biformin ought to be nonan-1,2-diol. According to the figures published there is, however, a small discrepancy as to its melting point compared to that of the glycol now synthesised. Anchel [1] reports that the glycol from biformin, after purification in a sublimation vessel, melted at 40—43°, whereas the synthetic glycol, purified by several sublimations at reduced pressure, melted at 33.5—34°. The derivatives of the glycol from biformin, *viz.* mono-3,5-dinitrobenzoate and the α-naphthylamine addition compound of the di-3,5-dinitrobenzoate melt 6—9° lower than the corresponding derivatives of the nonan-1,2-diol, but these low melting points may depend on the difficulties to purify small amounts of natural products. If the hydrogenation product of biformin really is nonan-1,2-diol the different melting points of the two glycols can either be due to the fact that nonan-1,2-diol can exist in two different modifications as for instance nonan-4,5-diol [4], or that the glycol from biformin is an optical antipode whereas the synthetic one is a racemic compound.

Experimental. Nonan-1,2-diol was prepared by hydroxylation of 1-nonen with performic acid according to the method used by Swern *et al.*[5] for the preparation of octan-1,2-diol.

To a well stirred mixture of 1-nonen [6] in formic acid 25.6 % hydrogen peroxide (in 2.5 % excess) was added in one portion. The mixture was heated and stirred at 40° for about 15 h at which time the solution was homogeneous. The formic acid was removed by distillation at reduced pressure and the residue was refluxed for about one hour with excess of 3 N alcoholic potassium hydroxide. After the alcohol had been evaporated, the residue was treated with ether and water. The ether was removed and the residue distilled. The glycol boiled at 155°/17 mm and solidified at once to a crystalline product which after several sublimations in vacuum melted at 33.5—34° (Found: C 67.90; H 12.43. Calc. for $C_9H_{20}O_2$: C 67.45; H 12.58).

Nonan-1,3-diol was prepared by a Grignard reaction. To an ether solution of *n*-hexylmagnesium bromide β-hydroxypropionaldehyde [7] was added dropwise. The solution was refluxed for half an hour and then worked up in the usual way. The diol boiled at 144—146°/12 mm and after cooling in an ice mixture solidified to a waxy product melting at 14—16°. Purification in a sublimation vessel did not raise the melting point (Found: C 67.13; H 12.42).

The mono-3,5-dinitrobenzoates of the diols were prepared by treating their benzene solutions with an equimolecular amount of 3,5-dinitrobenzoyl chloride and a few drops of pyridine. The solutions were heated to boiling, cooled and worked up as usual. The benzoates were recrystallised from benzene-petroleum ether and that of the 1,2-diol melted at 60—61° (Found: C 54.30; H 6.21. Calc. for $C_{16}H_{22}O_7N_2$: C 54.23; H 6.26). The corresponding derivative from biformin is reported [1] to melt at 50—55°. The benzoate of the 1,3-diol melted at 66.5—67° (Found: C 54.03; H 6.03).

In order to obtain the di-3,5-dinitrobenzoates the benzene solutions of the diols were treated as before but with the reagent in excess and by refluxing the solutions for half an hour before they were worked up. As the di-ester of the 1,2-diol was obtained as an oil its ethereal solution was treated with α-naphthylamine in excess. After recrystallisation from absolute ethanol, the addition compound with two moles of α-naphthylamine was obtained as rosettes of orange needles melting at 120—121°. (Found: C 61.90; H 4.88. Calc. for $C_{43}H_{42}O_{12}N_6$: C 61.86; H 5.07). The corresponding addition compound obtained by Anchel [1] melted at 111—112°.

The di-ester of the 1,3-diol, after recrystallisation from aqueous acetone, melted at 113.5—114° (Found: C 50.21; H 4.34. Calc. for $C_{23}H_{24}O_{12}N_4$: C 50.37; H 4.41).

Our thanks are due to *A. B. Astra*, Södertälje, for financial support and to Mr. R. Öhberg for the analyses.

Crystalline Cytochrome c from Beef Heart Muscle

SVEN PALÉUS and HUGO THEORELL

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

For the past two years we have been concerned with the crystallization of beef cytochrome c. The yield of crystals by the alcohol precipitation method [1] is, however, very poor. In order to get a starting material for crystallization with reproducible properties we worked out the following preparation method *. 6 kg fresh cow hearts were minced, 15 liters of distilled water added and the pH adjusted to 4.1 with 1 N H_2SO_4. After passing cheese cloth the mince was extracted further with 6 liters of water, all at 4° C. The extract was neutralized with 4 N ammonia and centrifuged. 140 g of Amberlite XE-64 (in the ammonia form) were added to the supernatant. The resin with the adsorbed cytochrome was collected on a Büchner funnel, washed with 30 liters of distilled water and eluted with 2 500 ml 0.15 M phosphate of pH 7.0. The eluate was dialyzed against 0.002 M ammonia and centrifuged. The cytochrome was adsorbed again on 10 g of the same resin and eluted with a volume of 250–300 ml 0.09 M phosphate of pH 7.5. The eluate was saturated to 85 % with ammonium sulphate, centrifuged and filtered. The filtrate was dialyzed against 0.01 M glycine buffer pH 8.5. The cytochrome, about 500 mg, now had an iron content of 0.41 % and $E^{1\,\%}_{1\,cm}$ 550 mμ = 20.9. It was now placed on a column of CM–W cellulose (1.5 × 15 cm) prepared according to Peterson and Sober [2], buffered with 0.01 M glycine of pH 8.5. On chromatographing cytochrome c with this buffer and 0.01 M glycine buffer of pH 10.5 some small, colored fractions separated. The main part was finally eluted with 0.05 M glycine buffer of pH 10.5, dialyzed and concentrated by lyophilization.

During the course of this work Hagihara *et al.*[3] published the crystallization of cytochrome c from yeast, beef and pig. Since they gave no analytical data, except the ratio E_{550}/E_{280}, or any convincing proofs of homogeneity of their material we repeated their procedure to produce beef cytochrome c. Crystals were obtained entirely in agreement with their description. Electrophoresis at pH 7.2 in the large Spinco apparatus * revealed three different peaks of the completely reduced cytochrome, all moving towards the cathode. The main component, comprising about 80 %, was the fastest one.

The cytochrome c prepared according to our method, described above, was now submitted to electrophoresis under the same conditions. It was found to show a similar electrophoretic pattern. The main fraction was isolated electrophoretically. This material crystallized in a few hours from ammonium sulphate and ammonia, whereas the crystallization before electrophoresis took a couple of days, just as described by the Japanese workers. Crystals and supernatant showed practically the same spectrophotometrical data. However, for some reason, the ratio E_{550}/E_{280} does not seem to be a very reliable criterion. The crystals contained 0.435 % Fe. Somewhat higher values for the iron content have been reported [4,5] but traces of non-heme iron cannot be excluded in these cases. The light absorption per dry weight (E_{550}, 1 %, 1 cm) was found to be 22.7.

Our conclusion is that crystallization of cytochrome c does not give homogeneous preparations unless followed by further purification, for example by electrophoresis. This is a common experience in protein chemistry.

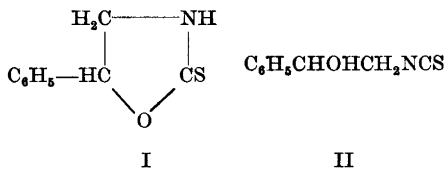
*iso*Thiocyanates XXVIII *. A New *iso*Thiocyanate Glucoside (Glucobarbarin) Furnishing (-)-5-Phenyl-2-oxazolidinethione upon Enzymic Hydrolysis



ANDERS KJÆR and ROLF GMELIN

Chemical Laboratory of the University of Copenhagen, Denmark

Paperchromatographic analysis in this laboratory of the *iso*thiocyanate glucoside contents in seed extracts of several species of the genus *Barbarea (Cruciferae)* revealed the presence of two glucosides, one of which was gluconasturtiin, enzymically hydrolyzed to the steam-volatile 2-phenylethyl *iso*thiocyanate and recognized many years ago by Gadamer [1] as a constituent of, *inter alia*, *Barbarea praecox* R. Br.

The second, and preponderant, glucoside, for which we propose the name *glucobarbarin*, does not seem to have been recognized previously. Its identity has now been established by investigation of a purified seed extract of *Barbarea vulgaris* R. Br.** On paper chromatography in *n*-butanol: ethanol:water (4:1:4), glucobarbarin travels at the same rate as glucotropaeolin, the glucoside producing benzyl mustard oil, while gluconasturtiin possesses a definitely higher R_F-value. The new glucoside does not afford steam-volatile material on enzymatic hydrolysis but possesses the notable property of yielding a compound with ultra-violet absorption data suggestive of a cyclic thiocarbamate structure (*cf. e. g.* Ref.[2]), in keeping also with the blue-green colour produced with Grote's reagent. In addition, the enzymic hydrolysis results in the formation of the traditional fragments, sulphate and glucose, the latter identified by paper chromatography in two solvent systems.

On a preparative scale, a seed extract of *B. vulgaris*, purified by passing through a column of anionotropic alumina, was buffered to pH 6.7 and subjected to enzymic hydrolysis with a cell-free myrosinase preparation. The semi-crystalline, Grote-positive reaction product, isolated by chloroform extraction, was transformed into thin, colourless needles on repeated recrystallizations from aqueous ethanol and ethyl acetate-hexane mixtures, m. p. 125° (uncorr.), $[\alpha]_D^{23} = -70.8° \pm 1.5°$ (*c* 2.0, MeOH). Analytical data suggested the composition C_9H_9NOS for the new compound (Found: C 60.30; H 4.96; N 7.76; S 17.78. Calc. C 60.31; H 5.06; N 7.82; S 17.89). Its UV-spectrum in 96 % ethanol exhibited a minimum at 224 mμ (ε 4 300), and a maximum at 245 mμ (ε 19 000), the latter displace hypsochromically on addition of alkali, a pattern characteristic for 2-oxazolidinethiones [2,3]. Subtraction of the elements of the heterocyclic ring from the empirical formula above, leaves a phenyl grouping to be accommodated. Previous evidence that 5-substituted 2-oxazolidinethiones are secondarily formed from enzymically liberated 2-hydroxysubstituted *iso*thiocyanates [2,5,6], renders it very likely that the new compound is (−)-5-phenyl-2-oxazolidinethione (I), a cyclic artifact deriving from one of the stereoisomeric 2-hydroxy-2-phenylethyl *iso*thiocyanates (II), enzymically liberated from glucobarbarin.

I II

For the purpose of comparison, (±)-5-phenyl-2-oxazolidinethione (I) has been synthesized. Racemic 2-amino-1-phenylethanol, prepared by lithium aluminium hydride reduction of (±)-mandelonitrile, was transformed into optically inactive (I), following the procedure designed by Hodgkins and Ettlinger [4] for the synthesis of *iso*thiocyanates from amines. An analytical specimen separated from benzene in colourless needles, m. p. 140° (uncorr.) (Found: C 60.25; H 5.16; N 7.88. Calc. for C_9H_9NOS: C 60.31; H 5.06; N 7.82). On paper chromatography in three solvent systems, the racemic compound was indistinguishable from the

** The seed material was commercially obtained from H. Bornträger, Offstein/Kr. Worms, Germany.

levorotatory, natural isomeride. Their identity, save for the steric arrangement around 5-C, is further supported by their nearly coinciding infra-red spectra.

More recently, the synthesis of both isomerides of (I) from the enantiomeric 2-amino-1-phenylethanols [7] has been accomplished in this laboratory. Upon critical comparison, the synthetic, levorotatory enantiomorph proved identical with the specimen of natural origin.

The synthesis of levorotatory (I) from (−)-2-amino-1-phenylethanol further establishes its absolute configuration, and hence that of the mustard oil derivable from glucobarbarin, because the (−)-amine results from a series of reactions not involving inversions and starting with (−)-mandelic acid [7] whose relationship with (+)-glyceraldehyde has been established by several investigators (*cf.* Ref.[8]). Consequently, the heterocyclic enantiomorph of natural provenance should be depicted as (I), yet with the bonds to the hydrogen atom and phenyl grouping in 5-position projecting above and below the plane of the paper, respectively.

The work is part of investigations supported by *The Danish State Research Foundation* and *The Carlsberg Foundation*. A special grant from *Kai Hansen's Fond* is gratefully acknowledged.

Infrared Investigation of the Location of the Ethylenic Bonds in the Newly Discovered Palustric Acid

HENRIK H. BRUUN

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden and The Institute of Wood Chemistry, Åbo Akademi, Åbo, Finland

Recently Loeblich, Baldwin and Lawrence [1,2] isolated a new acid, which they named palustric acid, from the oleoresin of *Pinus palustris* and *Pinus caribaea* by means of partition chromatography. Palustric acid is a primary acid of the abietic type which these authors also isolated as an intermediate product in the acid and heat isomerization of levopimaric acid to abietic acid. This new member of the abietic series is interesting from the standpoint of rosin acid chemistry and may be of value for the elucidation of the conversion of rosin acids into one another.

Palustric acid is reported to contain two conjugated double bonds which according to the location of the maximum in the ultraviolet spectrum appear to be situated between carbon atoms 5—6 and 7—8 (Fig. 1). On the other hand, the close relationship between palustric and *l*-abietic acid shown by the heat isomerization of levoabietic suggests a structure for palustric acid in which the double bonds are located between carbon atoms 7—8 and 13—14 [1,2].

Infrared Investigation of the Location of the Ethylenic Bonds in the Newly Discovered Palustric Acid

HENRIK H. BRUUN

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden and The Institute of Wood Chemistry, Åbo Akademi, Åbo, Finland

Recently Loeblich, Baldwin and Lawrence [1,2] isolated a new acid, which they named palustric acid, from the oleoresin of *Pinus palustris* and *Pinus caribaea* by means of partition chromatography. Palustric acid is a primary acid of the abietic type which these authors also isolated as an intermediate product in the acid and heat isomerization of levopimaric acid to abietic acid. This new member of the abietic series is interesting from the standpoint of rosin acid chemistry and may be of value for the elucidation of the conversion of rosin acids into one another.

Palustric acid is reported to contain two conjugated double bonds which according to the location of the maximum in the ultraviolet spectrum appear to be situated between carbon atoms 5—6 and 7—8 (Fig. 1). On the other hand, the close relationship between palustric and *l*-abietic acid shown by the heat isomerization of levoabietic suggests a structure for palustric acid in which the double bonds are located between carbon atoms 7—8 and 13—14 [1,2].

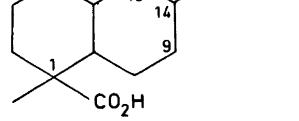

Fig. 1.

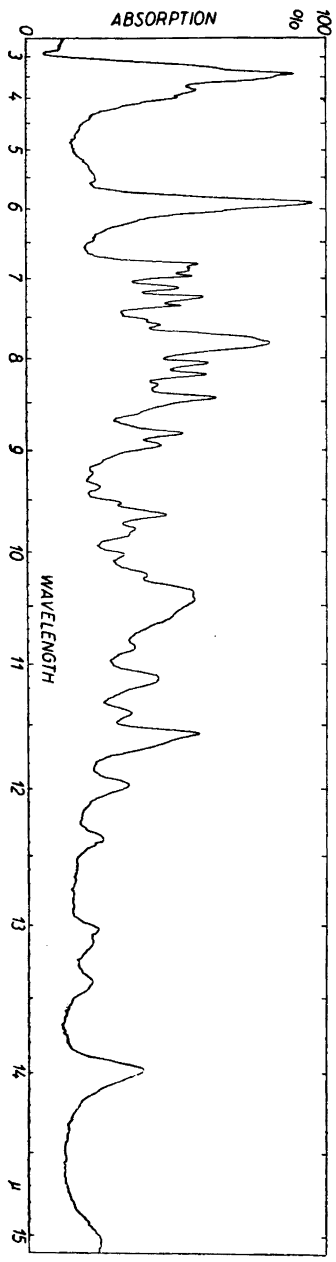

Fig. 2. Infrared absorption spectrum of palustric acid.

The infrared absorption spectrum of the acid could be expected to permit a decision as to the actual locations of the double bonds. Their locations between carbon atoms 5—6 and 7—8 would imply that both would absorb in the infrared range since the bonds would be di- and trisubstituted ethylenic bonds with properties similar to those of the double bonds in *l*-abietic, levopimaric and neoabietic acids, while with the alternative locations between carbon atoms 7—8 and 13—14, only the former double bond would be expected to give rise to infrared absorption bands resembling those of the trisubstituted ethylenic bond in a dihydroabietic acid.

The infrared absorption spectrum of palustric acid is reproduced in Fig. 2. A comparison of this spectrum with the spectra for the other resin acids mentioned above (*l*-abietic acid [3], levopimaric acid [4], dihydroabietic acid [5,3]) * shows that the former spectrum most closely resembles the spectrum of dihydroabietic acid. The following interpretation of bands is presented which confirms that the second alternative, *i. e.* double bonds between carbon atoms 7—8 and 13—14, is the most probable one.

The C=C stretching vibration gives rise to a sharp peak at 6.15—6.17 μ in the spectra of abietic, levopimaric and neoabietic acid, while in the spectra for dihydroabietic and palustric acids there is no peak or possibly only very indistinct shoulder at 6.04 μ. The =C—H out-of-plane vibration gives rise to a sharp absorption band at 12.65 μ in the abietic acid spectrum and at 12.62 μ in the levopimaric acid spectrum. In the spectra of dihydroabietic, neoabietic and palustric acid which, in contrast to the preceding acids, have only one bond of this type (assuming palustric acid to have its double bonds at 7—8 and 13—14), weak bands are seen at 12.48, 12.50 and 12.38 μ, respectively.

Levopimaric and neoabietic acids have in their spectra a band at 14.35 and 14.42 μ, respectively, that is possibly due to the vibration of the ethylenic bond. No bands of this kind are seen in the spectra for dihydroabietic and palustric acids. If the first alternative for the location of the

* The spectrum of neoabietic acid in the solid state differs in several respects from the spectra of the other resin acids, evidently owing to intramolecular transformation and shows a double peak due to the carbonyl group (at 5.93 and 5.80 μ) and a band due to polymer associated OH (at 3.12 μ[4]).

double bonds were correct for palustric acid, one would expect to find bands due to the *cis*-disubstituted double bond between atoms 5 and 6 in its spectrum.

Experimental. The palustric acid employed in the study was kindly sent to the author by E. L. Patton, Head of the Naval Stores Research Section, Naval Stores Section, The United States Department of Agriculture.

The absorption spectrum was recorded with an automatic double-beam spectrophotometer of the type described by Hornig, Hyde and Adcock [6]. The sample was examined using the potassium bromide technique. For further informations, see Ref.[3].

The Formation of Anhydro Vitamin A_1 in the Study of Vitamin A_1 Isomers

B. BARNHOLDT

Statens vitamin-laboratorium, Copenhagen, Denmark

As described by Edisbury *et al.*[1] and later by Meunier *et al.*[2] and Schantz *et al.*[3] the action of an anhydrous (N/30) ethanolic solution of hydrogen chloride on vitamin A_1 results in the conversion of the vitamin into the hydrocarbon anhydro vitamin A_1. Robeson and Baxter [4] have shown that the two isomers 13-*cis* and all-*trans* vitamin A_1 form the same substance when treated with hydrogen chloride in ethanol, but the rate of reaction (in 0.02 N ethanolic hydrogen chloride) is not the same in the two cases.

During recent years a number of new vitamin A_1 isomers [5-7] have been added to those already known, and when faced with the problem of identifying the individual components — isolated for instance by chromatography — of a mixture of vitamin A_1 isomers, it will be natural, side by side with other identification tests, to utilize the process of anhydro vitamin A_1 formation. The aim of the present work has been to develop a convenient procedure for the formation of anhydro vitamin with a view to the utilisation of this reaction for purposes of identification.

It is possible to follow the course of the reaction by spectrophotometry of the reaction mixture, since the formation of anhydro vitamin A_1 causes an increase in the extinction at wavelengths above approx. 340 mμ. Maximum increase is observed at wavelengths of approx. 350, 368.5 and 390 mμ, *i. e.* very near the three maxima of anhydro vitamin A_1 — 351, 371, 392 mμ[3]. Under the action of the hydrogen chloride solution the process continues, and anhydro vitamin A_1 is converted into *iso*anhydro vitamin A_1 (maxima at approx. 330, 350 and 370 mμ [3,8,9]), causing the maximum at 390 mμ to disappear again. The value of E_{390} measured for the reaction mixture thus does not only comprise the extinction due to the anhydro vitamin A_1, but also the extinction of unconverted vitamin A_1 and *iso*-anhydro vitamin A_1. However, the maximum value of E_{390} will almost exclusively be due to anhydro vitamin A_1.

For the purpose of following the process of anhydro vitamin formation the following two magnitudes may be used: (1) the maximum value of the ratio $E_{390} / E°_{max.}$ and (2) the corresponding time $t_{max.\ anh.}$ In the ratio $E_{390} / E°_{max.}$ is E_{390} the extinction (cell length 1 cm) of the reaction mixture at 390 mμ. $E°_{max.}$ is the extinction (cell length 1 cm) of the reaction mixture being due to vitamin A_1 at zero time, *i. e.* at the moment when the vitamin A_1 solution and the hydrogen chloride solution are mixed. $E°_{max.}$ is not measured directly, but is calculated from the value of $E_{max.}$ already measured for the vitamin A_1 solution. The value of these two magnitudes, $E_{390} / E°_{max.}$ and $t_{max.\ anh.}$ have been determined for all-

During recent years a number of new vitamin A_1 isomers [5-7] have been added to those already known, and when faced with the problem of identifying the individual components — isolated for instance by chromatography — of a mixture of vitamin A_1 isomers, it will be natural, side by side with other identification tests, to utilize the process of anhydro vitamin A_1 formation. The aim of the present work has been to develop a convenient procedure for the formation of anhydro vitamin with a view to the utilisation of this reaction for purposes of identification.

It is possible to follow the course of the reaction by spectrophotometry of the reaction mixture, since the formation of anhydro vitamin A_1 causes an increase in the extinction at wavelengths above approx. 340 mμ. Maximum increase is observed at wavelengths of approx. 350, 368.5 and 390 mμ, *i. e.* very near the three maxima of anhydro vitamin A_1 — 351, 371, 392 mμ[3]. Under the action of the hydrogen chloride solution the process continues, and anhydro vitamin A_1 is converted into *iso*anhydro vitamin A_1 (maxima at approx. 330, 350 and 370 mμ [3,8,9]), causing the maximum at 390 mμ to disappear again. The value of E_{390} measured for the reaction mixture thus does not only comprise the extinction due to the anhydro vitamin A_1, but also the extinction of unconverted vitamin A_1 and *iso*-anhydro vitamin A_1. However, the maximum value of E_{390} will almost exclusively be due to anhydro vitamin A_1.

For the purpose of following the process of anhydro vitamin formation the following two magnitudes may be used: (1) the maximum value of the ratio $E_{390} / E°_{max.}$ and (2) the corresponding time $t_{max.\ anh.}$ In the ratio $E_{390} / E°_{max.}$ is E_{390} the extinction (cell length 1 cm) of the reaction mixture at 390 mμ. $E°_{max.}$ is the extinction (cell length 1 cm) of the reaction mixture being due to vitamin A_1 at zero time, *i. e.* at the moment when the vitamin A_1 solution and the hydrogen chloride solution are mixed. $E°_{max.}$ is not measured directly, but is calculated from the value of $E_{max.}$ already measured for the vitamin A_1 solution. The value of these two magnitudes, $E_{390} / E°_{max.}$ and $t_{max.\ anh.}$ have been determined for all-

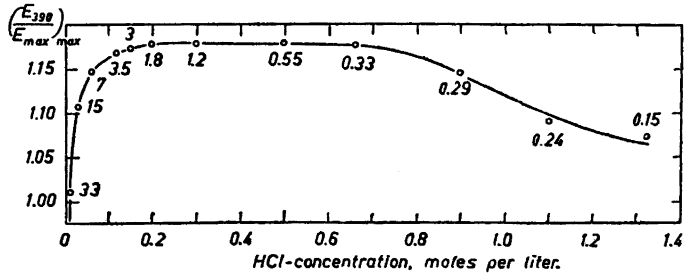

Fig. 1. Maximum values of E_{390}/E°_{325} obtained in the conversion of all-*trans* vitamin A_1 into anhydro vitamin A_1 at different concentrations of hydrogen chloride in ethanol. For each of the experimentally determined points,, the value of $t_{max.\ anh.}$ (in minutes) are stated $t_{max.\ anh.}$ being the time which has elapsed from the moment when the vitamin A solution and the hydrogen chloride solution are mixed and until the reaction mixture exhibits maximum extinction at 390 mμ.

trans vitamin A_1 at different hydrogen chloride concentrations. After mixture of for instance 2.5 ml ethanolic hydrogen chloride solution and 2.5 ml vitamin A_1 solution (containing about 10 μg vitamin A_1 per ml) the reaction mixture was poured into a quartz cuvette, and the course of the reaction was followed by measurements by means of a Beckman DU spectrophotometer. The temperature of the reaction mixture was 25—26°C.

In Fig. 1 the maximum value of the ratio E_{390} / E°_{325} and the corresponding reaction time have been represented as a function of the hydrogen chloride concentration in the reaction mixture. It will be seen that $(E_{390}$ / $E^{\circ}_{325})$ max. does not assume values above 1.18. If a further conversion of anhydro vitamin A_1 did not take place, complete conversion of all-*trans* vitamin A_1 into anhydro vitamin A_1 should be expected to result in a value of $\frac{3\,180 \times 268}{1\,850 \times 286} = 1.61$ of E_{390} / E°_{325} [E (1 %, 1 cm, 390 mμ) = 3 180[3] of anhydro vitamin A_1, molecular weight 268, E (1 %, 1 cm, 325 mμ) = 1 850 [5] of all-*trans* vitamin A_1, molecular weight 268].

When ethanolic hydrogen bromide (0.15 —0.50 N) is used, the same values of $(E_{390}$ / $E^{\circ}_{325})$ max. are obtained as when using 0.15—0.50 N hydrogen chloride. The use of ethanolic sulphuric acid or acetic acid results in lower values of E_{390} / E°_{325} and higher $t_{max.\ anh.}$ values than those obtained with hydrogen chloride in the same molar concentration. Even 50 % (v/v) acetic acid in ethanol results in a considerably slower rate of reaction with a lower value of E_{390} / E°_{325} than that obtained with, for instance, 0.01 N ethanolic hydrogen chloride. If anhydro vitamin A_1 is formed in a mixture of 1 volume of sulphuric acid (95—97 %) and 9 volumes of absolute ethanol, $t_{max.\ anh.}$ is found to be about 1.0 min, while E_{390} / E°_{325} reaches a value of 1.04 only. Lower concentrations of sulphuric acid result in higher values of $t_{max.\ anh.}$ and lower values of E_{390} / E°_{325}.

The course of the dehydration reaction for all-*trans* vitamin A_1 dissolved in ethanolic *p*-toluenesulphonic acid has also been examined. Schantz [10] used *p*-toluenesulphonic acid as catalyst in the preparation of anhydro vitamin A_1. A 10 % (w/v) solution of *p*-toluenesulphonic acid hydrate (anhydrous *p*-toluenesulphonic acid was not available commercially) in absolute ethanol gives $t_{max.\ anh.}$ = about 1 min, while E_{390} / E°_{325} reaches a value of about 0.5 only. Reduction of the *p*-toluenesulphonic acid concentration changes the course of the reaction in the same way as decribed with respect to the other acids.

To prepare anhydro vitamin in ethanolic solution at room temperature hydrogen chloride thus seems to be the most suitable of the dehydration agents examined in the present investigation. It may be added that the presence of merely a few per cent of water in the hydrogen chloride mixture will cause a considerable increase in $t_{max.\ anh.}$ and reduce the maximum value of E_{390} / $E^{\circ}_{max.}$.

The influence of variations in the vitamin A_1 concentration on $t_{max.\ anh.}$ and E_{390} / $E^{\circ}_{max.}$ at constant hydrogen chloride concentration has been examined for all-

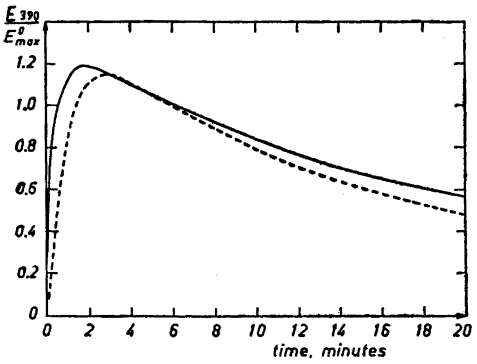

Fig. 2. Conversion of all-*trans* (————) and 13-*cis* (— — — —) vitamin A_1 into anhydro vitamin A_1 in anhydrous 0.20 N ethanolic hydrogen chloride. The graph represents $E_{390}/E°_{max.}$ plotted against time.

trans and 13-*cis* vitamin A_1 in 0.20 N ethanolic hydrochloric acid, and both magnitudes were found to be independent of $E°_{max.}$ in a concentration range corresponding to $E°_{max.} = 0.1-1$.

Fig. 2 illustrates the difference in the dehydration reactions in the case of all-*trans* vitamin A_1 and 13-*cis* vitamin A_1, respectively, in 0.20 N ethanolic hydrochloric acid. It must be considered probable that the magnitudes $t_{max.\ anh.}$ and the maximum values of $E_{390} / E°_{max.}$ for the different vitamin A_1 isomers will depend on the number of *cis* configurations and their positions in the molecule and on the molar extinction-coefficient of the vitamin A_1 isomer concerned.

An example of the application of the identification test described in the above will be published elsewhere [11].

The author wishes to thank Dr. phil. Willy Hjarde for his very kind interest in this study and for many valuable discussions.

Depolymerization of 1,2-Dithiolane and 1,2-Diselenolane Polymers

GÖRAN BERGSON and GÖRAN CLAESON*

Chemical Institute, University of Uppsala, Uppsala, Sweden

On hydrolysing trimethylendiselenocyanate, according to Hagelberg [1], Morgan and Burstall [2] a yellow powder is formed which was regarded as the monomer of 1,2-diselenolane (1,2-diselena-*cyclo*pentane) by Morgan and Burstall. Since this molecule is of great interest in connection with the spectrochemical investigations of diselenides, which are in progress at this institute by one of us [3], we tried to dissolve it in the common spectroscopic solvents. It was, however, found to be quite insoluble at ordinary temperatures, but when heated to about 60° the yellow powder darkened and went into solution. This solution was yellow and showed an absorption maximum at about 4 500 Å (Fig. 1). The colour persisted for several days at room temperature and then the yellow powder slowly precipitated. These facts indicate that the solution contains the monomer and that the yellow powder is a polymer, which depolymerizes when heated.

The corresponding sulphur compound (m. p. *ca.* 73°) prepared from trimethylendibromide and sodium disulphide [4] was also investigated. It dissolved without

* Both authors contribute equally.

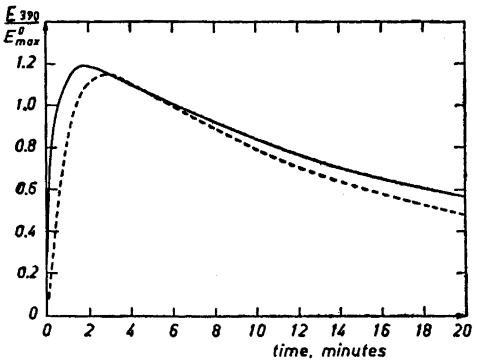

Fig. 2. Conversion of all-*trans* (————) and 13-*cis* (— — — —) vitamin A_1 into anhydro vitamin A_1 in anhydrous 0.20 N ethanolic hydrogen chloride. The graph represents $E_{390}/E°_{max.}$ plotted against time.

trans and 13-*cis* vitamin A_1 in 0.20 N ethanolic hydrochloric acid, and both magnitudes were found to be independent of $E°_{max.}$ in a concentration range corresponding to $E°_{max.} = 0.1-1$.

Fig. 2 illustrates the difference in the dehydration reactions in the case of all-*trans* vitamin A_1 and 13-*cis* vitamin A_1, respectively, in 0.20 N ethanolic hydrochloric acid. It must be considered probable that the magnitudes $t_{max.\ anh.}$ and the maximum values of $E_{390} / E°_{max.}$ for the different vitamin A_1 isomers will depend on the number of *cis* configurations and their positions in the molecule and on the molar extinction-coefficient of the vitamin A_1 isomer concerned.

An example of the application of the identification test described in the above will be published elsewhere [11].

The author wishes to thank Dr. phil. Willy Hjarde for his very kind interest in this study and for many valuable discussions.

Depolymerization of 1,2-Dithiolane and 1,2-Diselenolane Polymers

GÖRAN BERGSON and GÖRAN CLAESON*

Chemical Institute, University of Uppsala, Uppsala, Sweden

On hydrolysing trimethylendiselenocyanate, according to Hagelberg [1], Morgan and Burstall [2] a yellow powder is formed which was regarded as the monomer of 1,2-diselenolane (1,2-diselena-*cyclo*pentane) by Morgan and Burstall. Since this molecule is of great interest in connection with the spectrochemical investigations of diselenides, which are in progress at this institute by one of us [3], we tried to dissolve it in the common spectroscopic solvents. It was, however, found to be quite insoluble at ordinary temperatures, but when heated to about 60° the yellow powder darkened and went into solution. This solution was yellow and showed an absorption maximum at about 4 500 Å (Fig. 1). The colour persisted for several days at room temperature and then the yellow powder slowly precipitated. These facts indicate that the solution contains the monomer and that the yellow powder is a polymer, which depolymerizes when heated.

The corresponding sulphur compound (m. p. *ca.* 73°) prepared from trimethylendibromide and sodium disulphide [4] was also investigated. It dissolved without

* Both authors contribute equally.

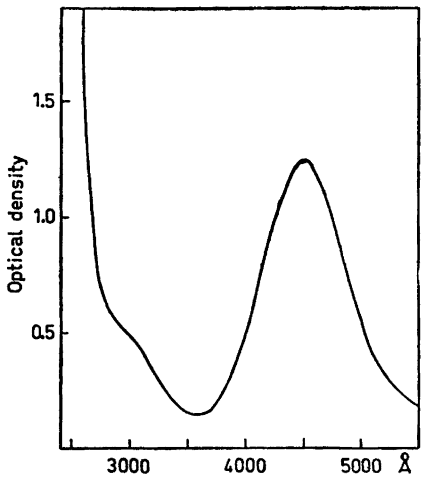

Fig. 1. UV-absorption of 1,2-diselenolane in nujol.

colour change in hot lowboiling solvents and precipitated on cooling. On treating the above mentioned sulphur compound with paraffin oil or nujol a yellow solution was obtained at about 160°. The U.V.-absorption of the cooled, still yellow solution was recorded. It showed a peak at 2 630 Å and a weak shoulder at about 3 300 Å (Fig. 2). The peak comes from the normal absorption of linear disulphide and the shoulder indicates the presence of the 1,2-dithiolane. To confirm the presence of the characteristic 1,2-dithiolane peak (3 300 Å), we heated the solution and collected the vapors in ethanol. The U.V.-spectrum of the ethanol solution showed two distinct peaks; one from the polymer (2 620 Å) and one from the monomer (3 270 Å). The small shifts from the normal values of λ_{max} are in the expected directions for an absorption curve composed of two functions D_1 (λ) and D_2 (λ).

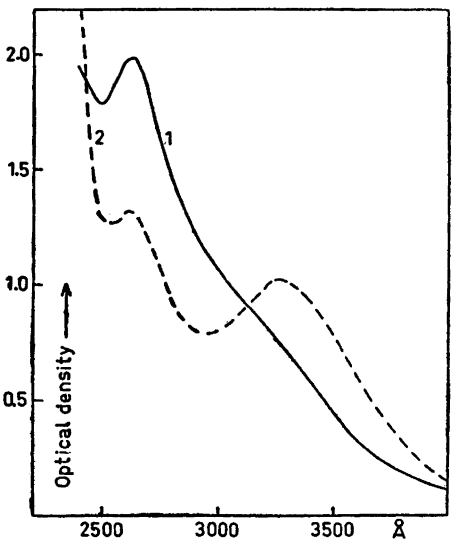

Fig. 2. Curve 1: UV-absorption of 1,2-dithiolane and polymer in nujol. Curve 2: UV-absorption of vapors collected in ethanol.

To complete our investigation of the depolymerization we determined the molecular weights by the Rast camphor-method. The molecular weight of the selenium compound was found to be 240 (calc. 200). This high value is in agreement with the shoulder in the spectrum (Fig. 1), indicating the presence of small amounts of polymer. Morgan and Burstall [2] found the molecular weight 225 in benzene. This misled them to believe that the substance was a monomer also in solid state.

No boiling point elevation could be detected, when an attempt was made to determine the molecular weight of the sulphur compound in benzene. This is in agreement with our assumption that the substance is dissolved as a polymer in lowerboiling solvents. The compound has earlier been considered as a dimer [5]. In molten camphor, however, it should be expected to be partly depolymerized. This was also found. The molecular weight depended on the time which the sample was in molten state. A rapid determination gave the molecular weight 740. After 3 h at 180° the mol.wt. was 205.

A similar depolymerization method for thioctic acid has recently been reported by Thomas and Reed [6].

The very easy depolymerization of the selenium compound as compared with the sulphur compound is remarkable.

The investigations on cyclic disulphides and diselenides are being continued.

Experimental. The spectra were determined with a Beckman model DU (2 450—4 000 Å) and a Beckman model B (4 000—5 500 Å) photoelectric spectrophotometer.

The molecular weights were determined in a Kofler hot-stage microscope.

We are indebted to Dr. Lennart Schotte for valuable discussions. We also wish to thank

New Synthesis of 3-Hydroxy-2-piperidone

NIELS ELMING*

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

Catalytic hydrogenation of 2,3-pyridinediol has been shown to give the expected 3-hydroxy-2-piperidone *cf.* [1, 2]. This compound has previously been obtained by cyclization of *α*-hydroxy-*δ*-amino-*n*-valeric acid, but no detailed directions were reported [3].

* Present address: A/S Pharmacia, Copenhagen, Denmark.

Experimental. 2,3-Pyridinediol [4-6] (0.56 g) and anhydrous methanol (40 ml) were shaken (6 h) with Raney nickel (0.2 g) under hydrogen (140 atm) at 160—180°. The Raney nickel was removed by filtration and the filtrate evaporated in a vacuum. The crystalline residue was crystallized from methanol-ether. The yield was 0.47 g (81 %) of 3-hydroxy-2-piperidone [white crystals, m. p. 133—135° (Hershberg apparatus, corr.), previously found [3] 134.3°]. (Found: C 52.3; H 7.8; N 12.2. Calc. for $C_5H_9NO_2$ (115.1): C 52.2; H 7.9; N 12.2).

Sublimation (100—110°/0.05 mm) also gave white crystals, m. p. 133—135°.

In a first experiment carried out at 95—100° under 110 atmospheres of hydrogen for one hour only starting material was isolated.

On the Mechanism of Alkylation of β-Keto Esters

I. Methylation of β-Hydroxycoumarilic Acid Ethyl Ester

ARNE BRÄNDSTRÖM and INGEMAR FORSBLAD

Chemical Institute, University of Uppsala, Uppsala, Sweden

The mechanism of the alkylation of metallic derivatives of tautomeric substances has been the subject of many investigations and theories [1]. As late as 1953 Brändström [2,3] published a new theory and in 1955 Kornblum *et al.* [4] proposed a theory seen from a different aspect.

In an attempt to elucidate the mechanism we have begun to study the alkylation of *β*-keto esters. The methylation of *β*-hydroxycoumarilic acid ethyl ester was

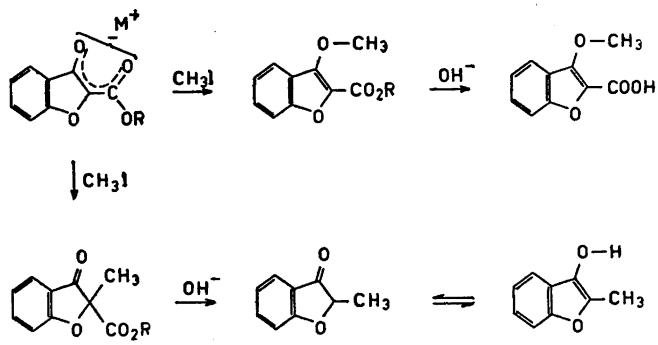

Fig. 1.

selected for study. The reaction has earlier been the subject of a somewhat superficial investigation [5,6] and is well suited to the present purpose as it gives both the C- and O-alkyl product. In order to find out the extent to which the free anion and the metal chelate give C- and O-alkylation, the rate and order of the different reactions must be studied under conditions which lead to different degrees of dissociation.

The β-hydroxycoumarilic acid ethyl ester was prepared in a pure enol-form by an improved method according to Friedländer [7]. Through IR-spectra we have shown that it changes only very slowly into the keto-form at 0°C.

A method to determine the proportion of C- and O-alkyl product formed in alkylation has been worked out. The alkylation reaction is stopped by adding acid; the mixture is diluted with water and the ester extracted with carbon tetrachloride. The residue is titrated with NaOH to determine the velocity of the total reaction. From the carbon tetrachloride solution the unalkylated ester is extracted with 1 N KOH and the residue saponificated, decarboxylated, acidified and extracted with ether.

The acid from the O-alkyl product, which does not decarboxylate, is titrated to pH 6.5—7.0. At that pH the enol-form of 2-methyl coumarone does not interfere. The difference between the rate of the total reaction and that of the O-alkylation is taken as the rate of C-alkylation.

Table 1. Methylation in CH_3OH.

Metal	k_{C+O}	k_C	k_O	C/O
Li	1.20	1.03	0.17	6.0
Na	2.96	2.26	0.70	3.2
K	3.45	2.78	0.67	4.2

Table 2. Methylation with Li.

Solution	k_{C+O}	k_C	k_O	C/O
CH_3OH	1.20	1.03	0.17	6.0
C_2H_5OH	0.89	0.76	0.13	5.7
n-C_3H_7OH	0.54	0.44	0.10	4.5
n-C_4H_9OH	0.36	0.27	—0.09	—3

k_{C+O}, k_C and k_O are, respectively, the velocity constants for the total, C- and O-alkylation. They are given in units of $10^{-2} \cdot$ l/mole $\cdot$ min. C/O is the quotient of the rates of the C- and O-alkylation.

Hitherto the methylation reaction has been studied at 50°C with methyl iodide in methanol solution using Li, Na and K as catalysts, and in ethanol, *n*-propanol and *n*-butanol with Li as catalyst. The concentration of alkali was 0.1 M; the ester was used in 5 % and the methyl iodide in 100 % excess. Both the C- and O-alkylation reactions are of the second order. The preliminary results are shown in Tables 1 and 2.

It has been found that the rate of the C-alkylation decreases more rapidly than that of the O-alkylation through the solvent series $CH_3OH > C_2H_5OH > n\text{-}C_3H_7OH > n\text{-}C_4H_9OH$. Thus the yield of C-alkyl product falls in the same series. In methanol the rate of C-alkylation increases through the series Li<Na<K and the O-alkylation through the series Li < Na ~ K. Thus the ratio C/O decreases in the series Li > K > Na.

This suggests that the mechanism is rather complicated and depends on more factors than the dissociation degree.

In order to find out the extent to which the results depend on the occurence of the alkali salts as ions or a chelate in the reaction medium, the degree of dissociation must be known. We have begun to determine this quantity, by a method due to Brändström [8], from electrical conductance measurements. The complete elucidation of the mechanism requires that other aspects of the reaction should be investigated. Further studies along these lines are in progress at this institute.

Experimental: Salicyl-O-acetic acid [O-(carboxymethoxy)-benzoic acid] was prepared from salicylic acid and chloroacetic acid [9]. Unchanged salicylic acid was separated from the product by continued extraction with benzene.

Salicyl-O-acetic acid diethyl ester was prepared by esterification in the usual way with benzene as water-removing agent [10]. Yield 84 %; m. p. 43.0—44.5°C (not earlier published).

β-Hydroxycoumarilic acid ethyl ester was prepared according to Friedländer [7] with the following modification: After condensation and acidification with 50 % H_2SO_4 at 0°C the product was dried in air at room temperature for a few hours, and than in a desiccator over night. Yield 93 %; m. p. 70.5—71.5°C. The ester contained a little Na_2SO_4 and after recrystallization from dry ether it was obtained as white needles with the same m. p. The low m. p. (65°) earlier reported is probably due to the change of ester into its keto-form during recrystallization from water-alcohol mixture (The velocity of tautomerisation increases with the temperature and polarity of the solvent [11]). It is important that the ester after acidification be kept at as low a temperature as possible.

New Synthesis of 3-Hydroxy-2-piperidone

NIELS ELMING*

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

Catalytic hydrogenation of 2,3-pyridinediol has been shown to give the expected 3-hydroxy-2-piperidone *cf.* [1, 2]. This compound has previously been obtained by cyclization of *α*-hydroxy-*δ*-amino-*n*-valeric acid, but no detailed directions were reported [3].

* Present address: A/S Pharmacia, Copenhagen, Denmark.

Experimental. 2,3-Pyridinediol [4-6] (0.56 g) and anhydrous methanol (40 ml) were shaken (6 h) with Raney nickel (0.2 g) under hydrogen (140 atm) at 160—180°. The Raney nickel was removed by filtration and the filtrate evaporated in a vacuum. The crystalline residue was crystallized from methanol-ether. The yield was 0.47 g (81 %) of 3-hydroxy-2-piperidone [white crystals, m. p. 133—135° (Hershberg apparatus, corr.), previously found [3] 134.3°]. (Found: C 52.3; H 7.8; N 12.2. Calc. for $C_5H_9NO_2$ (115.1): C 52.2; H 7.9; N 12.2).

Sublimation (100—110°/0.05 mm) also gave white crystals, m. p. 133—135°.

In a first experiment carried out at 95—100° under 110 atmospheres of hydrogen for one hour only starting material was isolated.

On the Mechanism of Alkylation of β-Keto Esters

I. Methylation of β-Hydroxycoumarilic Acid Ethyl Ester

ARNE BRÄNDSTRÖM and INGEMAR FORSBLAD

Chemical Institute, University of Uppsala, Uppsala, Sweden

The mechanism of the alkylation of metallic derivatives of tautomeric substances has been the subject of many investigations and theories [1]. As late as 1953 Brändström [2,3] published a new theory and in 1955 Kornblum *et al.* [4] proposed a theory seen from a different aspect.

In an attempt to elucidate the mechanism we have begun to study the alkylation of *β*-keto esters. The methylation of *β*-hydroxycoumarilic acid ethyl ester was

Thiamine Phosphates and Phosphate Transport in Liver Mitochondria

KARL-HEINZ KIESSLING

Institute of Zoophysiology, Uppsala, Sweden

Incubation of mitochondria with radioactive inorganic phosphate results in an incorporation of ^{32}P into the intramitochondrial thiamine diphosphate. The incorporation is localized mainly to the terminal phosphate group (βP), and is higher with, than without pyruvate as a substrate.

Synthetic thiamine compounds (thiamine, thiamine mono-, di-, tri-, and tetraphosphate) added to mitochondria do not, however, take part in the phosphate turnover in the same degree as the endogenous compound. No further synthesis from the added compounds could be found, nor did the thiamine phosphates transfer their phosphate directly to the adenylic system at any appreciable rate. Only a very slight incorporation of ^{32}P into the added thiamine phosphates could be obtained.

In animal tissues thiamine occurs mainly as thiamine diphosphate and only to a smaller extent as thiamine. The occurrence of thiamine triphosphate * in rat liver has been reported by Rossi-Fanelli, Siliprandi, and Fasella [1].

Only few investigations dealing with the role of thiamine phosphates in the phosphate transport have been published. Kiessling and Lindahl [2] found a turnover of the phosphorus of TDP in a cyclophorase system isolated from guinea pig liver when incubated with inorganic ^{32}P, and the turnover rate was higher when pyruvate is metabolized than without added "sparker". No synthetic TDP was added, *i. e.* the only TDP present during the incubation was that initially existing in the liver (endogenous TDP) **.

* The following abbreviations have been used: T thiamine, TMP thiamine monophosphate, TDP thiamine diphosphate, TTP thiamine triphosphate, TTeP thiamine tetraphosphate, ADP adenosine diphosphate, ATP adenosine triphosphate, G-6-P glucose-6-phosphate, P_i inorganic phosphate, ^{32}P radioactive phosphate, TCA trichloroacetic acid, P/O ratio of number of micromoles of esterified phosphate to the number of microatoms of oxygen consumed.

** Endogenous thiamine phosphate: thiamine phosphate originating from the tissue. In this paper two types of endogenous thiamine phosphate have been distinguished between, *viz.* intra- and extramitochondrial thiamine phosphate.

Synthetic thiamine phosphate: thiamine phosphate added to the samples and hence not originating from the tissue.

Bartley [3] on the other hand was able to demonstrate only a rather low turnover of phosphate in TDP, when adding this substance to a kidney cyclophorase system with pyruvate or α-ketoglutarate as a substrate.

However, using ^{32}P-labelled synthetic TDP, Ogata, Nohara, Morita, and Kawai [4] found a direct transport of phosphate from TD^{32}P to ADP with a liver cyclophorase system.

The first part of this paper deals with the incorporation of radioactive phosphorus into endogenous TDP in mitochondria. In the second part the participation in the phosphate transport of synthetic thiamine phosphates added to mitochondria has been studied (Fig. 1).

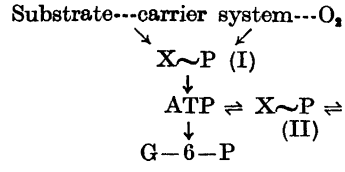

Fig. 1.

Two possibilities for the participation of thiamine compounds in the phosphate metabolism are proposed in Fig. 1. X~P indicates a thiamine phosphate. This thiamine phosphate can either be involved in the phosphate transport from the substrate-carrier level to glucose (I), or be in equilibrium with ATP in a side reaction (II). The second part of the investigation has been carried out along these alternative possibilities.

MATERIALS AND METHODS

Mitochondria were prepared from rat and guinea pig liver mainly according to the method of Schneider and Hogeboom [5]. The medium for isolation was 0.25 M sucrose, and after two washings the mitochondria were suspended in 0.25 M sucrose. The pH of the suspension was adjusted to 7.4 with TRIS-buffer or potassium phosphate buffer to a final concentration of 0.03 M.

In the experiments with rat liver, mitochondria from 10 g of liver were suspended in the buffers mentioned, and made up with sucrose to a final volume of 20 ml. To each Warburg vessel 1 ml of the mitochondrial suspension was added together with 1.2 ml of other solutions (*cf.* below); 0.2 ml KOH 2 M was added to the center well.

When isolated from guinea pig liver, large quantities of mitochondria were used in each sample (mitochondria from 5—10 g of liver). For this reason these incubations were performed in Fernbach flasks. The size of the flasks was about 200 ml. 3 ml from each sample were transferred to Warburg vessels for respiration measurements. At the end of the experiment 0.2 ml H_2SO_4 5 M was added to the Warburg vessels, and TCA to a concentration of 9 % to the Fernbach flasks in order to stop the reaction. The precipitate formed was centrifuged down and pH adjusted to 3.

From the Warburg incubations with rat mitochondria the thiamine phosphates were separated by paper chromatography [13] directly after pH had been adjusted to 3. From the Fernbach incubations with guinea pig mitochondria TDP was isolated, except in one case, by adsorption on Fuller's earth, eluated with pyridine, and purified by paper chromatography as described by Kiessling [6]. Finally a second paper chromatographic solvent (Siliprandi and Siliprandi [7]) was used in both cases as an additional purification of the thiamine phosphates. With the two solvents used the R_F values of the thiamine phosphates and of P_i differ greatly, and after the application of the two methods no inorganic phosphate could be found to contaminate the thiamine phosphates.

In the experiments with guinea pig mitochondria only endogenous TDP was present during the incubations. To facilitate the isolation synthetic TDP (2–5 mg) was added after the proteins were detached, and pH adjusted to 3. The TDP isolated in this way was a mixture of endogenous and synthetic TDP. According to Goethart [8] mitochondria from 1 g of liver contain about 4 μg TDP. Hence a rough estimate of the radioactivity of the intramitochondrial TDP can be obtained by multiplication with a dilution factor.

ATP+ADP was precipitated with Lohmann's reagent [9], and isolated by means of paper chromatography [10]. In the experiments with hexokinase present the amount of ATP was low. The specific radioactivity therefore was determined on hydrolyzable phosphate from ATP+ADP isolated from the samples.

The radioactivity was measured in an M 6 standard liquid counter tube from 20th Century Electronics Ltd. The radioactivity figures always refer to counts per 5 min.

Phosphorus was determined according to Berenblum and Chain [11]. TDP supplied by Roche Products Ltd. contained only traces of TMP. ATP and ADP in the form of the sodium salt were purchased from Sigma Chemical Company.

In my experiments I needed TDP, TTP, and TTeP labelled only in their hydrolyzable phosphate groups. By heating thiamine and unhydrous phosphoric acid Viscontini *et al.*[12] had obtained a mixture of thiamine phosphates from which they could separate TMP, TDP, and TTP by means of paper chromatography. Using another solvent I had been able to isolate from this mixture, besides the compounds mentioned, also TTeP and four additional thiamine phosphates with more than four phosphate groups [13]. By heating TDP (or TMP) with a mixture of anhydrous phosphoric acid and radioactive inorganic phosphate I obtained a mixture of thiamine phosphates labelled in the desired way. They could be separated by paper chromatography as described for the non-labelled compounds above [13]. The radioactivity of the hydrolyzable and non-hydrolyzable phosphate (the latter value in brackets) was for TDP 70 700 (600), TTP 31 600 (208), and TTeP 10 600 (160). These figures are intended only to give an idea of the relative distribution of ^{32}P within the molecules *.

The yeast hexokinase was prepared at the Wenner Gren Institute in Stockholm according to Berger *et al.*[14], except for the cytolysis in toluene, which was performed as described by Bailey and Webb [15]. The purification was followed up to step five.

RESULTS

Incorporation of ^{32}P into endogenous TDP in liver mitochondria

The mitochondria from a guinea pig liver (20 g liver) were isolated, and distributed on two Fernbach flasks, one with and one without substrate. The supernatant obtained at the preparation of the mitochondria from 10 g of liver was added to a third flask together with substrate. The substrate was pyruvate together with small amounts of α-ketoglutarate (*cf.* Table 1). To all flasks ATP, glucose, hexokinase, cytochrome c and cozymase were added. Besides these additions each flask contained radioactive inorganic phosphate. The final volume was 45 ml. From each sample 3.0 ml were transferred to Warburg vessels for respiration measurements. The oxygen consumption is shown in Fig. 2. 5 mg synthetic TDP was added to each sample to facilitate the isolation of endogenous TDP.

From the figures in Table 1 it appears that the highest specific radioactivity of TDP has been obtained in the sample with mitochondria and substrate (1.6×10^3 counts/100 μg hydrolyzable P). In accordance with the calculations

* Ogata *et al.*[4] have prepared radioactive TDP in which, however, the αP and βP were equally labelled.

Table 1.

Incubation	Radioactivity of endogenous + synt. TDP	Radioactivity of endogenous TDP	Radioactivity of ATP—ADP	Radioactivity of inorg. P
Mitoch. + substrate	1.6×10^3	2.00×10^5	4.20×10^5	1.34×10^6
Supernatant + substrate	0.30×10^3	0.30×10^5	1.20×10^5	1.05×10^6
Mitoch. without substrate	0.46×10^3	0.57×10^5	0.53×10^5	1.09×10^6

Radioactivity of TDP, inorganic and organic phosphate after incubation of mitochondria and supernatant from guinea pig liver with radioactive inorganic phosphate.

No synthetic TDP was added to the samples until the incubation was terminated, and then only to make possible the isolation of endogenous TDP. The figures given in the table for TDP refer to 100 μg synthetic + endogenous TDP, or to 100 μg endogenous TDP only.

The vessels contain 10 mg ATP, 0.5 ml cytochrome c 0.1 %, 0.5 ml DPN (0.3 mg/ml), 0.3 ml α-ketoglutarate 0.3 M, 1.0 ml pyruvate 0.3 M, 1.0 ml $MgCl_2$ 0.1 M, 75 mg glucose, hexokinase in excess, non-radioactive and radioactive inorganic phosphate. Mitochondria or supernatant was added as is seen in the table, and the volume made up to 45 ml with sucrose 0.25 M. In the third flask α-ketoglutarate and pyruvate were omitted. The figures refer to 100 μg phosphorus (for TDP and ATP this means hydrolyzable phosphorus). Time of incubation 20 min.

mentioned above 100 μg hydrolyzable intramitochondrial TDP phosphorus gives 2.0×10^5 counts, *i. e.* nearly half that of ATP—ADP (4.2×10^5 counts/100 μg hydrolyzable P).

In the sample with supernatant and substrate the TDP exhibited radioactivity, possibly depending on synthesis of TDP from thiamine as the synthesis of TDP is mainly localized to the supernatant according to Leuthardt and Nielsen [16]. The radioactivity was about 1/5 of that of intramitochondrial

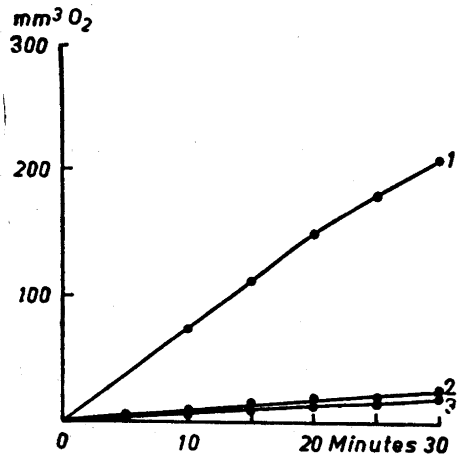

Fig. 2. Oxygen consumption in mitochondria and supernatant from guinea pig liver. 3 ml from each Fernbach flask (Table 1) were added to Warburg vessels. The center wells contained 0.2 ml KOH 2 M, and the gas phase was air.
1. mitochondria + substrate.
2. supernatant + substrate.
3. mitochondria without substrate.

TDP. Thus the radioactivity of the intramitochondrial TDP cannot, to any great extent, come from TDP synthesized in the mitochondria during the incubation.

A modification of the previous type of experiment was carried out as a control. The mitochondria were incubated with substrate as described above. The vessel contained mitochondria from 5 g of liver, the final volume being 20 ml. The radioactivity of the added phosphate was six times stronger than in the experiment above. After 20 min at 30°C the sample was rapidly cooled down to 0°C, the mitochondria centrifuged down, and washed once with sucrose. By this procedure most of the radioactive inorganic phosphate and other additions were removed, and in this way a small extract could be obtained for isolation of TDP. TCA was added to the washed mitochondria to a final volume of 5 ml giving a concentration of 9 %. After removal of the precipitated proteins and adjustment of pH to 3, 2 mg synthetic TDP were added. One ml of the sample was put as a line on a Whatman No. 1 paper, and TDP isolated by chromatography [13].

The radioactivity of the hydrolyzable phosphate, referred to 100 μg of endogenous TDP-phosphate was 2.87×10^6 counts and 4.3×10^6 for ATP—ADP. The inorganic phosphate gave 7.6×10^6 counts per 100 μg P.

In a third type of experiment the ratio between the amount of mitochondria present and the radioactive labelling of the intramitochondrial TDP was examined. Mitochondria from 10 g of liver were added to vessel 1, and from 5 g to vessel 2. Otherwise the additions were the same to both vessels. The same amount of radioactive inorganic phosphate was added to the two vessels, and the final volume of both made up to 33 ml with 0.25 M sucrose. After incubation the proteins were removed with TCA, 2 mg synthetic TDP added, and the synthetic + intramitochondrial TDP isolated by adsorption on Fuller's earth and by paper chromatography as described above. The results are given in Table 2.

Table 2.

Sample	Oxygen consumption	Radioactivity of endogenous + synt. TDP	Radioactivity of endogenous TDP	Radioactivity of ATP—ADP	Radioactivity of inorg. P
1. (10 g liver)	121	3.30×10^4	1.66×10^6	2.26×10^6	4.23×10^6
2. (5 g liver)	54	1.77×10^4	1.77×10^6	3.11×10^6	5.68×10^6

Results from an experiment with various amounts of mitochondria.
The oxygen consumption is given as mm^3/20 min/3 ml sample. The radioactivity of TDP and ATP—ADP is expressed as counts/100 μg hydrolyzable P, and of inorganic phosphate as counts/100 μg P. Apart from mitochondria the Fernbach flasks contained 10 mg ADP, 1 mg cytochrome c, 0.3 mg cozymase, 0.3 ml α-ketoglutarate 0.3 M, 1.5 ml pyruvate 0.3 M, 1.0 ml Mg^{2+} 0.1 M, 75 mg glucose, hexokinase and radioactive inorganic phosphate. Mitochondria from 10 g of liver suspended in 20 ml sucrose-phosphate medium pH 7.4 were added to sample 1 and from 5 g to sample 2, and the volume made up to 33 ml with 0.25 M sucrose. The samples were incubated at 30°C for 20 min.

The figures show that the specific radioactivity of the total TDP (synthetic + intramitochondrial) from sample 1 (10 g of liver) is about twice that of sample 2 (5 g of liver). The specific radioactivity is the same in both samples as far as only the intramitochondrial TDP is concerned.

Comparing the radioactivity in TDP of the βP with that of the αP it appears that mainly the βP becomes labelled. The ratio between the radioactivity of βP and αP varies from 8—14 in the three types of experiments reported above.

The figures from the experiments show that the intramitochondrial TDP incorporates ^{32}P, and mainly in the hydrolyzable phosphate (βP). This incorporation is more rapid when a substrate as pyruvate is metabolized than when no substrate is added.

In the following experiments the role of added synthetic thiamine phosphates in a mitochondrial system is studied.

Synthetic thiamine derivatives as phosphate acceptors in mitochondria

Rat liver mitochondria in a 0.01 M phosphate buffer in 0.25 M sucrose were incubated with T, TMP, TDP, or TTP. One mg of the thiamine compound in 0.5 ml water was added to each vessel. Besides, the vessels contained 0.8 mg ATP, 0.1 ml 0.3 M glutamate, hexokinase, 4 mg glucose, 0.05 ml Mg^{2+} 0.1 M, and 0.05 mC radioactive inorganic phosphate. The samples were made isotonic by addition of 1 M sucrose. Finally 1 ml mitochondria suspension was added. After 20 min incubation at 30°C 0.2 ml of 5 M H_2SO_4 was added, samples were taken for determination of organic and inorganic ^{32}P and, after neutralization, the thiamine phosphates were isolated on paper chromatograms. The presence of synthetic thiamine compounds did not affect the P/O value which was about 2. No spots could be found on the chromatograms suggesting any further phosphorylation of the thiamine compounds during the incubation. On the contrary a slight hydrolysis of the thiamine phosphates had taken place. TTeP had partly been hydrolyzed to TTP, and TTP to about 20 % to TDP.

TTeP did not contain any radioactivity at all. The hydrolyzable phosphate of TTP gave 600 counts/100 μg hydrolyzable P and of TDP 520 counts/100 μg hydrolyzable P.

The results show that added thiamine or thiamine phosphates do not at all or only at a very low rate act as phosphate acceptors in a respirating mitochondria system. The incorporation of ^{32}P into TDP is slow compared with that of the mitochondrial TDP, described above.

Possibly thiamine phosphates are in equilibrium with ATP in a side reaction (Fig. 1, alternative II). In the presence of glucose and hexokinase, however, no AT^{32}P would accumulate and, as a consequence, no formation of thiamine phosphates would occur to give rise to radioactive thiamine phosphates. An accumulation of AT^{32}P could experimentally be effected by excluding hexokinase. Incubation of TMP and TDP with ADP in the same way as described above but without hexokinase did, however, not give rise to TTP from TDP or TDP from TMP, nor was a higher incorporation of ^{32}P obtained compared with that found in the experiments with hexokinase present. Neither

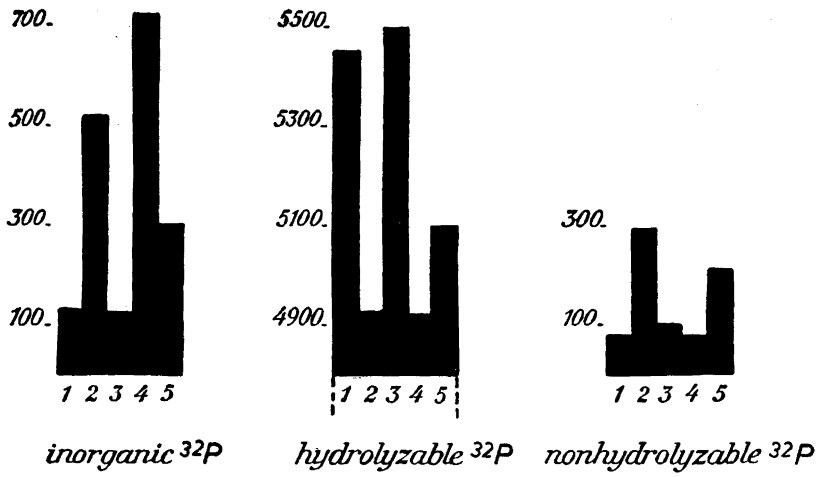

Fig. 3. The radioactivity in the inorganic, hydrolyzable, and non-hydrolyzable phosphate fraction from a mitochondria experiment with labelled TDP.

1. mitochondria + ADP + $TD^{32}P$ + hexokinase + glucose (0 min)
2. mitochondria + ADP + $TD^{32}P$ + hexokinase + glucose (20 min)
3. mitochondria + ADP + $TD^{32}P$ (20 min)
4. ADP + $TD^{32}P$ + hexokinase + glucose (20 min)
5. mitochondria + ADP + $TD^{32}P$ + hexokinase + glucose + inorganic non-radioactive phosphate (50 μM) + 0.1 ml glutamate 0.3 M (20 min)

The rat mitochondria were suspended in a TRIS-sucrose medium pH 7.4. 0.4 ml $TD^{32}P$ (1 000 μg/ml) was added to each flask together with 1 mg ADP, hexokinase, and 4 mg glucose (except in flask 3). To vessels 1—3 and 5 was added 1 ml mitochondria, and the volumes of all samples were made up to 2.2 ml with sucrose. Incubation time 20 min at 30°C. The oxygen consumption in sample 5 was 108 mm^3 in 20 min. The radioactivity was measured on 0.1 ml of the samples.

did exclusion of substrate influence upon the radioactivity in the added thiamine phosphates.

In the experiments without hexokinase no hydrolysis of the thiamine phosphates was observed. It therefore seems that the hexokinase preparation, purified to this special stage, still contains a phosphatase which attacks thiamine phosphates.

Synthetic thiamine phosphates as phosphate donors in mitochondria

From the above results it is obvious that added thiamine phosphates do not take part in the phosphate transport from the substrate-carrier level *via* ATP to glucose in the system used (Fig. 1, alternative I). Neither was the supposition confirmed that thiamine phosphates are in equilibrium with ATP in a side reaction (Fig. 1, alternative II), as it was impossible to transfer ^{32}P to the thiamine phosphates when $AT^{32}P$ was accumulated by excluding hexokinase.

This indicates that no equilibrium exists between added thiamine phosphates and ATP in a side reaction, or that the equilibrium is displaced far towards ATP.

In order to examine the second alternative thiamine phosphates were prepared containing radioactive phosphorus only in their hydrolyzable phosphate groups. If a direct phosphate transfer exsists from thiamine phosphates to ADP, the ATP formed would be radioactive. The γP should be trapped off by the hexokinase and the glucose, and rediscovered as non-hydrolyzable glucose-6-phosphate. Thus a decrease in the hydrolyzable phosphate and an increase in the non-hydrolyzable phosphate would be easy to follow without previously isolating the thiamine phosphates or the phosphate acceptor.

The results of an experiment are seen in Fig. 3.

As was pointed out earlier the hexokinase preparation used is contaminated with a phosphatase which slowly hydrolysis thiamine phosphates. When hexokinase is present the phosphatase splits off phosphate from TDP, and this gives rise to the radioactivity in the inorganic fraction in samples 2 and 4 (Fig. 3). With hexokinase present but no mitochondria (sample 4) the radioactivity in the inorganic fraction is higher than when mitochondria have been added. Very likely this is effected by ADP being phosphorylated to ATP in the presence of mitochondria, as these may contain traces of substrate. In the sample without mitochondria (sample 4) no inorganic phosphate is eliminated in this way. Therefore the radioactivity of the inorganic fraction in this sample is somewhat higher than in sample 2.

The radioactivity in the non-hydrolyzable fraction rises in the sample where both mitochondria and hexokinase are present (sample 2). This rise is, however, not larger than what corresponds to the decrease in the inorganic fraction in sample 2, which fraction can be assumed initially to have been as high as in sample 4.

In the fifth sample the components present were the same as in samples 1 and 2. In addition glutamate and inorganic non-radioactive phosphate were added. With a substrate and inorganic phosphate present TDP was not hydrolyzed to the same degree as without these additions as is seen in Fig. 3. The radioactivity peak of the hydrolyzable phosphate in sample 5 is somewhat higher than in 2 and 4, and the radioactivity of the inorganic fraction is lower than in 2. The radioactivity of the non-hydrolyzable fraction is even lower than the inorganic fraction. This indicates that the phosphate of the glucose-6-phosphate can not originate directly from the highly labelled TDP-phosphate. It must have been diluted primarily with inorganic non-labelled phosphate before being transferred *via* ATP to glucose. From this it may be concluded that intact mitochondria do not contain an enzyme system which transfers phosphate from added TDP to ADP without previous hydrolysis to inorganic phosphate, or if such an enzyme system exists, the rate of transfer must be very low.

The same results were obtained by using TTeP or TTP instead of TDP. With TMP no liberation of inorganic phosphate took place, nor could any rise in the radioactivity of the non-hydrolyzable fraction be observed.

DISCUSSION

In this paper the incorporation of radioactive phosphorus into intramitochondrial TDP has been studied as well as the extent to which synthetic thiamine phosphates added to mitochondria take part in the phosphate metabolism.

The results show that intramitochondrial TDP and added synthetic thiamine phosphates do not take part in the phosphate metabolism to the same extent.

The specific radioactivity of the intramitochondrial TDP was high after incubation (1/2—2/3 of that of ATP—ADP), whereas the added synthetic thiamine phosphates neither incorporated ^{32}P in any appreciable degree, nor supplied phosphate to ADP.

In a previous note [2] an incorporation of ^{32}P into TDP was found to take place in a cyclophorase system from guinea pig liver. Only the endogenous TDP was present during the incubation. The incorporation into TDP depended on the metabolization of a substrate, in this case pyruvate, and was proportional to the oxygen consumption.

Bartley could not verify these results [3]. He used a kidney cyclophorase system to which synthetic thiamine phosphates were added. The specific radioactivity of the added thiamine phosphates was fairly low. These investigations on incorporation of ^{32}P into thiamine phosphates by a cyclophorase system are in keeping with the results obtained with mitochondria in the present paper which show that intramitochondrial TDP incorporates ^{32}P in a much higher degree than added synthetic thiamine phosphates.

From Bartley's experiments it is not possible to decide to what extent the thiamine phosphates furnish ADP with phosphate, and then appear as phosphate compounds with a reduced number of phosphate groups, as he only determines the incorporation of ^{32}P into the added thiamine compounds. The transfer of phosphate from added synthetic TDP to ADP in a cyclophorase system has been examined by Ogata *et al.*[4]. They found a direct transfer of phosphate from TD^{32}P to ADP. My experiments, however, supply no evidence for the existence of an active enzyme system in intact mitochondria which catalyses phosphate transport from added thiamine phosphates to ADP.

These discrepancies may depend on the fact that no intact mitochondria exist in a cyclophorase system. TDP added to the system might easily come in contact with the actual enzyme. In so doing it forms a short-lived and unstable combination and, after delivering one phosphate, leaves room for another TDP. In the intact mitochondria the intramitochondrial TDP would be much stronger bound in the enzyme. Hence it would not be split off after delivering phosphate, but the generated TMP would be rephosphorylated to TDP.

To explain the differences as depending exclusively on difficulties of TDP to penetrate the membrane of the intact mitochondria is not convincing, as TDP in the tissues is mainly synthesized outside the mitochondria [16], and thus must penetrate the membrane to reach its apoenzyme.

Acknowledgements. I am indebted to Prof. P. E. Lindahl for valuable discussion and to Prof. O. Lindberg for the privilege of carrying out part of this work in his laboratory, and for the interest he has shown in it. I also wish to express my thanks to Dr. L. Ernster and Dr. H. Löw for stimulating discussions and helpful criticism. Thanks are also due to Mrs. Margot Aunver for technical assistance, to the technical staff at the Wenner-Gren Institute for help with preparation of rat mitochondria, and to Dr. A. L. Morrison, Messrs. Roche Products Ltd., for the gift of TDP.

This work was made possible by grants from the *Swedish Natural Science Research Council*, and from *Magn. Bergvalls Stiftelse*.

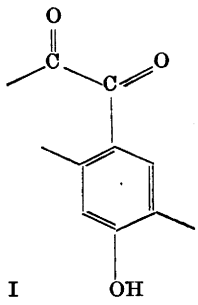
The Structure of Xanthoperol

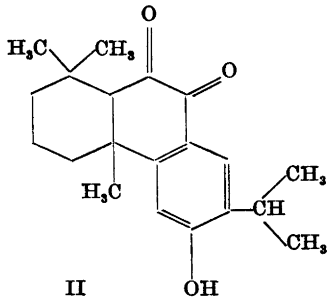
JOHAN B-SON BREDENBERG

Department of Chemistry, Institute of Technology, Helsingfors, Finland



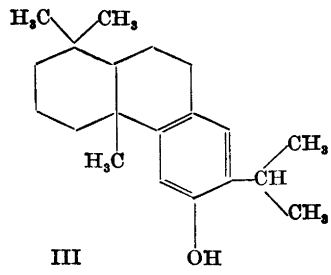
The structure V is proposed for xanthoperol, an artefact from the wood of *Juniperus communis* L. Xanthoperol is formed, without intervention of atmospheric oxygen, during the alkaline hydrolysis of wood extract from a substance having a *p*-ketophenol chromophore.

In a previous paper, the isolation of the diterpene phenol xanthoperol has been described [1], *. In the same paper, a partial structure (I) was proposed and the possibility that xanthoperol might have the structure 9,10-diketoferruginol (II) was discussed and regarded with doubt.



In continuation of the work, xanthoperol was subjected to Clemmensen reduction. As it is an α-diketone, it was considered possible that it might yield a mixture of various stages of reduction. This was also borne out by the experiment. The bulk of the reduction product was a mixture corresponding in its properties to a mixture of ferruginol (III), Δ^9-dehydroferruginol and hydroxyferruginols. As a side product a substance was isolated which showed properties corresponding to 9-ketoferruginol. On chromic oxide oxidation of the acetylated main part this same substance was obtained, besides xanthoperol. The substance, melting between 240 and 250° with decomposition, had an ultraviolet spectrum with the same shape as that of 9-ketoferruginol, *i. e.* a sharp maximum at 236 mμ (log ε 4.17) and a broad maximum at 286 mμ (log ε 4.09). The infrared spectrum likewise confirmed the conclusion that it was analogous to 9-ketoferruginol.

The reduced xanthoperol was dehydrogenated with selenium, but owing to the small amount of starting material, no pure product could be isolated. The ultraviolet spectra of some fractions of the chromatographed reaction product, however, showed full correlation with the spectrum of retenol-6 (IV) with maxima where retenol-6 has its major bands and plateaus or inflexions where retenol-6 has its side bands. These must be regarded as a strong indication that the dehydrogenation yielded retenol-6. Further evidence for the



* In the theoretical part of this paper the wave-number of the hydroxyl band is erroneously given as 3 436 cm^{-1}; it should be 3 380 cm^{-1}.

presence of an *iso*propyl group in xanthoperol is afforded by the occurrence of bands at 1 163 cm^{-1} in xanthoperol and 1 172 cm^{-1} in the reduction product.

The retenol accounts for 18 carbon atoms. The remaining two carbon atoms, in the form of two methyl groups or, less probably, an ethyl group, must be placed in such positions that they are lost during the dehydrogenation, *i. e.* in the positions 1, 11 or 12, on the assumption that the aromatic ring in the partial structure (I) corresponds to the C-ring. This last assumption is strongly supported by the nature of the other compounds isolated from the wood of the juniper: ferruginol, Δ^9-dehydroferruginol and 9-ketoferruginol [2,3]. In the previous paper [1], it was shown that all structures proposed for xanthoperol where the 10-ketogroup could be enolised must be regarded with doubt. One methyl group must consequently be placed in the 11-position to hinder the enolisation. This leaves two structures: V, where a methyl group from the 1-position has migrated to the 11-position in comparison with the common diterpene phenols, and VI, where the methyl group from the 12-position has migrated to the 11-position. A third structure, the C_{19}-structure VII, which must also be taken into consideration at this stage, would apparently imply that the migration C-1—C-11 and C-12—C-13 of the methyl groups has occurred, as postulated in the case of columbin [4], with subsequent loss of the methyl group at the 13-position by aromatisation of the C-ring.

Decision can be made from among these structures by a C-methyl determination. The model 9-ketoferruginol gives the value 1.12, while xanthoperol gives 1.98. This at once excludes the structure VI as well as 9,10-diketoferruginol (II), which have the same side chains as 9-ketoferruginol. A short calculation shows that structure VII can also be ruled out. It is known that a *gem.*-dimethyl group contributes to the C-methyl determination with a value of 0.4 [5]. Hence the *iso*propyl group and the angular methyl group contribute with a joint value of 0.72. This would give the value 1.98—0.72 = 1.26 for the methyl group in the 1-position in structure VII, an obviously impossible value. If we assume that the *iso*propyl group also contributes with a value of 0.4 (the angular methyl group = 0.32), we would obtain the value 0.94 for the methyl group in the 1-position in structure V, which tallies well with the expected value. Even if one must be cautious in drawing inferences from detailed calculations of the C-methyl values, the results, nevertheless, strongly support the correctness of structure V. The reduction product, m. p. 240—250°, consequently has the structure VIII.

In most of the experiments performed, the diketo group proved to be sterically hindered. An attempt to prepare a disemicarbazone thus failed and oximation yielded only a nonresolvable mixture. Condensation with *o*-phenylene diamine gave in low yield a substance, m. p. 250—252°, which can be regarded as the corresponding quinoxaline (IX). Oxidation with periodic acid gave a quantitative recovery of xanthoperol. Treatment of xanthoperol with a large excess of alkaline hydrogen peroxide at room temperature for a long period (two days) yielded a small amount of an impure substance, m. p. 200—202°, to which the corresponding dicarboxylic acid structure X must be assigned.

Xanthoperol has a structure with no known counterpart in diterpene chemistry. It was therefore of special interest to study its formation. As

previously remarked [1], xanthoperol does not occur as such in wood. Closer examination, especially by spectrophotometry in ultraviolet, revealed that the precursor is a substance which is eluted directly after 9-ketoferruginol and that it has a chromophore which is the same or very nearly the same as the chromophore of 9-ketoferruginol. Atmospheric oxygen does not take part in the formation of xanthoperol during hydrolysis. The yield is actually higher in an atmosphere of hydrogen. The results appear to point to the structure XI or its equivalent, which would be oxidised during the hydrolysis by substances occurring simultaneously in the fractions. In spite of several attempts, the precursor could not be obtained in pure form.

EXPERIMENTAL

(All m. p. s are determined on a Kofler microscope. The microanalyses have been performed by Dr. A. Bernhardt, Mülheim, and the infrared spectra by Mr. B. C. Fogelberg, B. Sc.).

Clemmensen reduction of xanthoperol. Xanthoperol (60 mg) in ethanol-benzene (10 ml, 1:1) was reduced with amalgamated zinc (5 g) and concentrated hydrochloric acid (4 ml) at reflux temperature. After 1 1/2 h, when both layers were colourless, the heating was stopped, conc. hydrochloric acid (10 ml) was added and the mixture was allowed to stand overnight. Water was added and the solution was extracted with ether. The solvent was evaporated and the residue extracted with light petroleum, which left undissolved 0.5 mg of crystals, m. p. 240—250° (decomp.). The ultraviolet spectrum of these crystals in ethanol showed a sharp maximum at 236 mμ and a broad maximum at 286 mμ. The part soluble in light petroleum, having a maximum at 285 mμ, was acetylated with acetic anhydride and pyridine. The acetylation yielded a slowly crystallising sticky mass (44 mg), m. p. 75—95°, λ_{max} (in ethanol) 271 mμ (log k 0.92). Purification by chromatography or crystallisation did not sharpen the melting point.

Oxidation of the reduction product with chromic oxide. Xanthoperol (85 mg) was reduced as before. The reduced product was oxidised with chromic oxide (40 mg) in acetic acid (8 ml) on the water bath for 1 h. After dilution with water, the product was extracted with ether and the ether was evaporated. The residue was chromatographed on an Al_2O_3 column with light petroleum-ether-methanol. Ether-methanol eluted xanthoperol. In the ether eluates, before xanthoperol came out, about 20 mg of impure 10-deketoxanthoperol (VIII) could be demonstrated spectrophotometrically. These fractions were purified by crystallisation and sublimation, yielding 3 mg of needles, m. p. 240—250° (decomp.), λ_{max} (in ethanol) 236 mμ (log ε 4.17) 286 mμ (log ε 4.09). Principal IR-maxima (KBr): 3 280 (s), 2 920 (s), 2 835 (m), 1 642 (s), 1 590 (s), 1 568 (s), 1 502 (m), 1 464 (m), 1 385 (w), 1 366 (m), 1 340 (s), 1 309 (w), 1 288 (m), 1 257 (s), 1 192 (m), 1 172 (m), 1 055 (w), 970 (w) and 876 cm^{-1} (w). The properties of the compound resembled those of 9-ketoferruginol.

Selenium dehydrogenation of reduced xanthoperol. Reduced xanthoperol (80 mg) was mixed with selenium (300 mg) and heated at 290° for 24 h. The product was extracted with ether and the ether evaporated. The residue was chromatographed on an Al_2O_3 column with benzene-ether-methanol. The fractions eluted by ether-methanol, showing the expected ultraviolet spectra of phenanthrene derivatives, were rechromatographed. The elution was followed by spectrophotometry, but no fraction having a pure spectrum could be obtained. The purest fractions had UV-spectra of the following form: (in ethanol) maxima at 223, 258, 342 and 360 mμ, plateaus or inflexions at 270 and 308 mμ; (in *cyclo*hexane) maxima at 222, 260 and 360 mμ and plateaus or inflexions at 277, 306, 327 and 340 mμ.

Retenol-6 (IV) from 6-aminoretene. Retenol-6 was obtained from an authentic sample of 6-aminoretene by diazotisation. The product formed needles, m. p. 178—179°. (Found C 86.3; H 7.7. Calc. for $C_{18}H_{18}O$ C 86.4; H 7.3.) UV-spectrum of retenol-6: (in ethanol) mμ (log ε): 220 (4.44), 257 (4.68), 279 (4.19), 310 (4.03), 342 (3.39) and 359 (3.40); (in *cyclo*hexane) mμ (log ε): 221 (4.40), 258 (4.69), 278 (4.25), 295 (3.98), 308 (4.11), 325 (3.11), 340.5 (3.32), 357.5 (3.38).

Derivatives of xanthoperol. In attempts to prepare the disemicarbazone from xanthoperol and semicarbazide hydrochloride by heating on a water bath with sodium acetate in ethanol for one day or in pyridine-water for three days, a quantitative recovery of xanthoperol was obtained. Oximation with hydroxylamine hydrochloride in pyridine-ethanol for two days on a water bath gave crystals, m. p. 111—114°, but a sharp melting point could not be obtained by further purification.

Condensation with o-phenylene diamine. Xanthoperol (26 mg) and *o*-phenylene diamine (20 mg) were heated in acetic acid (1 ml) for 19 h on a water bath and thereafter for 2 h with reflux. Water was added and the precipitate was filtered. The precipitate was dissolved in ether and unreacted xanthoperol was extracted with 2 N sodium carbonate. After evaporation of the ether, the residue was crystallised from benzene-light petroleum, m. p. 250—252° (4 mg). The compound (IX), which was shown by paper chromatography to be free from xanthoperol, gave a deep red to violet colour with conc. sulphuric acid. λ_{max} (in ethanol) 241 mμ (log ε 4.19), 383 mμ (log ε 4.25), plateau at 260—290 mμ (log ε 4.1).

Oxidation with periodic acid. No reaction occurred between xanthoperol and periodic acid in acidic aqueous ethanol, even at water-bath temperature. The recovery of xanthoperol was quantitative in all experiments.

Oxidation with alkaline hydrogen peroxide. After preliminary experiments had shown that no reaction occurred in milder conditions, the oxidation was carried out by keeping xanthoperol (17 mg) and 30 % hydrogen peroxide (0.5 ml) in N sodium hydroxide (5 ml) for two days at room temperature. The now colourless solution was acidified and the flocky precipitate (4 mg) filtered. The precipitate (X), m. p. 200—202°, sublimed as needles from 150°. λ_{max} (in ethanol) 247 mμ (log ε 3.72), 290 mμ (log ε 3.62), Principal IR-maxima (KBr): 3 300 (broad) 2 900 (broad), 1 720 (broad), 1 680, 1 595, 1 558, 1 513, 1 460, 1 415, 1 343, 1 235, 1 165, 1 115, 940 and 872 cm^{-1}.

The formation of xanthoperol. The neutral non-hydrolysed part of the wood extract was chromatographed on an Al_2O_3 column with light petroleum-ether. Samples were taken from the fractions, which had been eluted by light petroleum-ether and ether, and UV-spectra were run in ethanol and in alkaline solution. After hydrolysis, spectra were again taken in ethanol and in alkaline solution. These spectra showed that the precursor was eluted after 9-ketoferruginol, and that it had an ultraviolet spectrum resembling that of 9-ketoferruginol: maxima at about 230 and 280 mμ in neutral and at 350 mμ in alkaline solution. The yield of xanthoperol was higher when the hydrolysis was performed in an atmosphere of hydrogen than in an atmosphere of oxygen. The precursor could not be obtained pure.

The author is indebted to Dr. J. Gripenberg for valuable suggestions. He also wishes to express his thanks to Dr. K. J. Karrman for a sample of 6-aminoretene.

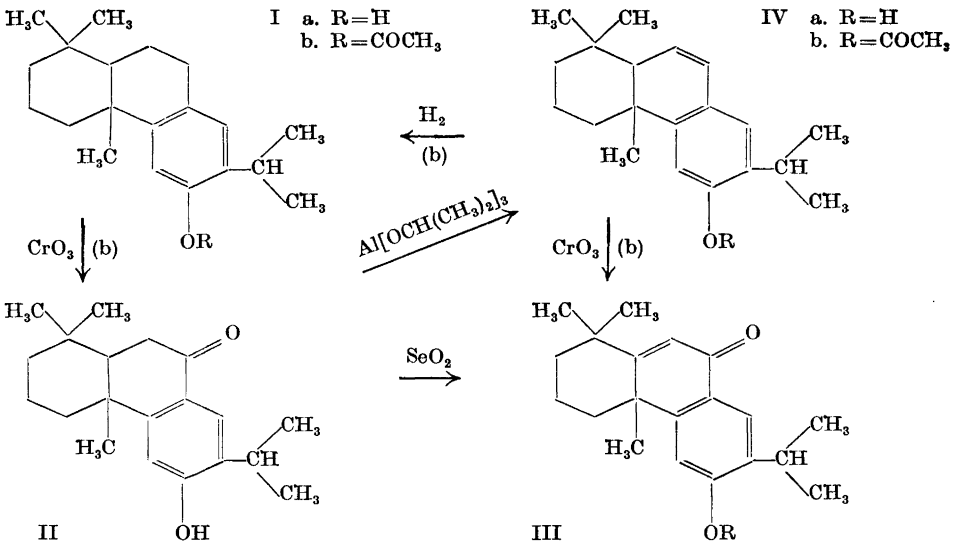
Ferruginol and Δ^9-Dehydroferruginol

JOHAN B-SON BREDENBERG



Department of Chemistry, Institute of Technology, Helsingfors, Finland

The phenolic substance, acetate m. p. 92—93°, from the wood of *Juniperus communis* L. has been shown to be a mixture of ferruginol and Δ^9-dehydroferruginol. The previously isolated ferruginol from *Podocarpus ferrugineus* D. Don and *Dacrydium cupressinum* Solander also contains small amounts of Δ^9-dehydroferruginol. This compound has been synthesised.

The isolation of a phenolic substance in the form of a crystalline acetate, m. p. 92—93°, has previously been described [1]. This substance was at first thought to represent a pure compound "katajol" [2], but later this was doubted. In particular, the fact that only partial crystallisation of the phenol could be effected, was taken as an indication of non-homogeneity. It was suggested that the substance was a mixture of ferruginol (Ia) and a dehydro derivative [1]. Definite evidence of its nature came from an oxidation of the acetate with chromic oxide. After hydrolysis, this yielded a substance which was identified as a mixture of 9-ketoferruginol (II) and 9-keto- Δ^{10}-dehydroferruginol (III) by comparison of its ultraviolet and infrared spectra with those of the authentic compounds. On selenium dioxide dehydrogenation of the mixture, pure 9-keto- Δ^{10}-dehydroferruginol was obtained.

The acetate was subjected to catalytic hydrogenation, and it consumed 0.42 moles of hydrogen per mole of substance. The hydrogenated acetate formed rods, m. p. 81—82°, $[\alpha]_D^{20}$ +62° (ethanol). On hydrogenation, the ultraviolet spectrum (in ethanol) was altered from one absorption maximum at 268 mμ (log ε 3.71) to two maxima at 269 mμ (log ε 3.08) and 278 mμ (log ε 3.12). There is only one position, the conjugated 9-position, where the double bond could be placed in order to explain the large hypochromic shift in the ultraviolet spectrum and the formation of 9-keto- Δ^{10}-dehydroferruginol. During the chromic oxide oxidation the double bond in the 9-position obviously migrates to the 10-position. The acetate, m. p. 92—93°, thus consist of ferruginyl acetate (Ib) and Δ^9-dehydroferruginyl acetate (IVb). In order to verify this, Δ^9-dehydroferruginyl acetate was prepared in a 70 % yield by aluminium *iso*propoxide reduction of 9-ketoferruginol and acetylation of the reduced product. The reduction yielded in one stage the desired dehydro

derivative as a result of the easy dehydration that occurred in the intermediate 9-hydroxyferruginol. The Δ^9-dehydroferruginyl acetate had the constants m. p. 108—109°, $[\alpha]_D^{20}$ —92° (ethanol), λ_{max} (in ethanol) 220 mμ (log ε 4.39), 266 mμ (log ε 4.01), all of which are in good correlation with the constants

calculated from the pure ferruginyl acetate, the acetate mixture and the hydrogen consumed by it. Ferruginyl acetate and Δ^9-dehydroferruginyl acetate were investigated by the contact method of Kofler [3] and found to form mixed crystals of Roozebom's type I.

Ferruginol, $[\alpha]_D^{18}$ +65° (ethanol), λ_{max} (in ethanol) 284 mμ (log ε 3.50) prepared from ferruginyl acetate resisted crystallisation. By prolonged chromatography a few crystals, m. p. 56—57°, could be obtained, but the greater part could not be crystallised. Even a trace of impurity seems to be able to inhibit crystallisation. Δ^9-Dehydroferruginol, $[\alpha]_D^{20}$ —60° (ethanol), λ_{max} (in ethanol) 218 mμ (log ε 4.29), 280 mμ (log ε 3.97) also resists crystallisation.

The formation of mixed crystals between ferruginyl acetate and its dehydro derivative explains some discrepancies in the literature and our observations. From *Podocarpus ferrugineus* D. Don, Brandt and Neubauer [4] isolated ferruginol, $[\alpha]_D^{16}$ +40.6° (ethanol). A sample of the acetate from this ferruginol was kindly supplied by Prof. H. Erdtman. After catalytic hydrogenation, this acetate, m. p. 82—83°, $[\alpha]_D^{20}$ +57° (ethanol), λ_{max} (in ethanol) 269 mμ (log ε 3.19), 278 mμ (log ε 3.19) gave the values m. p. 81—2°, $[\alpha]_D^{20}$ +62° (ethanol), λ_{max} (in ethanol) 269 mμ (log ε 3.09), 278 mμ (log ε 3.12). Hence it contained about 3 % Δ^9-dehydroferruginyl acetate. For the acetate of ferruginol obtained from *Dacrydium cupressinum* Solander, Brandt and Thomas [5] reported

log ε 3.3 at λ_{max} 269 mμ (in ethanol). This would be equivalent to a content of about 9 % of the dehydro form.

In the partial synthesis of ferruginol from dehydroabietic acid and podocarpic acid, Campbell and Todd [6] reported rotations of the ferruginyl acetates and of the crude ferruginols, which are in good correlation with the present values, but in the purification of ferruginol from podocarpic acid the rotation was lowered from $[\alpha]_{Hg}^{25}$ +59° to $[\alpha]_{Hg}^{27}$ +37.8° (ethanol). No explanation for this behaviour has been found.

The isolation of ferruginol from the wood of *Juniperus communis* L. in a yield of 0.1 % would at least partially explain the durability of the wood, for this phenol is a fungicide [7].

EXPERIMENTAL

(All m. p.'s are determined on a Kofler microscope. The microanalyses have been performed by Dr. A. Bernhardt, Mülheim.)

Oxidation of the acetate, m. p. 92—93°, with chromic oxide. The acetate (200 mg) and chromic oxide (80 mg) in acetic acid (10 ml) were heated on the water bath for 45 min. After dilution with water, the product was extracted with ether. The crystals obtained from the ether melted after recrystallisation between 115 and 130°. This mixture was chromatographed, yielding 48 mg of colourless prisms, m. p. 287—289°. Both the UV- and the IR-spectrum proved that the crystals consisted of a mixture of 9-ketoferruginol and 9-keto-Δ^{10}-dehydroferruginol.

9-Keto-Δ^{10}-dehydroferruginol (III). 9-Ketoferruginol (30 mg) and selenium dioxide (11 mg) in nitrobenzene (2 ml) were heated at 190° for 2 h. The dark-coloured solution was filtered and the precipitate washed with ether and ethanol. The combined filtrates were washed with sodium carbonate, and the ether and ethanol evaporated. After chilling, 13 mg of pink-coloured rods, m. p. 281—283°, crystallised out. Recrystallisation from benzene-light petroleum yielded colourless crystals, m. p. 288—290°. (Found C 80.2; H 8.9. Calc. for $C_{20}H_{26}O_2$ C 80.5; H 8.8.) UV-spectrum: λ_{max} (in ethanol) 246 mμ (log ε 4.21), 316 mμ (log ε 4.02); (in 0.05 N Na_2CO_3) 245 mμ (log ε 4.30), 381 mμ (log ε 4.18). IR-spectrum, principal bands (KBr): 3 060 (s), 2 905 (s), 2 840 (m), 1 630 (s), 1 610 (s), 1 575 (s), 1 555 (s), 1 500 (s), 1 460 (s), 1 383 (s), 1 340 (s), 1 310 (s), 1 282 (s), 1 258 (s), 1 178 (s), 1 150 (m), 1 090 (m), 887 (s), 875 (m) and 866 cm^{-1} (s).

A sample of the previously obtained mixture of 9-ketoferruginol and 9-keto-Δ^{10}-dehydroferruginol (25 mg) was oxidised with selenium dioxide (9 mg) as described above. After purification, 9 mg of rods, m. p. 287—289°, were isolated. The IR- and UV-spectra of this product were identical with those of authentic 9-keto-Δ^{10}-dehydroferruginol.

Hydrogenation of the acetate, m. p. 92—93°. The acetate (300 mg) in ethanol (10 ml) was subjected to catalytic hydrogenation with a Pt-catalyst (16 mg PtO_2). The reduction stopped after 1 h, 0.38 mmoles of hydrogen having been consumed. The product (290 mg) crystallised from ethanol as rods, m. p. 81—82°, $[\alpha]_D^{20}$ +62° ± 2° (ethanol, *c* 2.2). (Found C 80.1; H 9.8. Calc. for $C_{32}H_{32}O_2$ C 80.4; H 9.8), λ_{max} (in ethanol) 269 mμ (log ε 3.08), 278 mμ (log ε 3.12).

Hydrogenation of the "Brandt-Neubauer" ferruginyl acetate. The ferruginyl acetate, m. p. 82—83°, $[\alpha]_D^{20}$ +57° ± 2° (ethanol, *c* 2.3), λ_{max} (in ethanol) 269 mμ (log ε 3.19), 278 mμ (log ε 3.19), was hydrogenated as above, yielding crystals, m. p. 81—82°, $[\alpha]_D^{20}$ + 62° ± 2° (ethanol, *c* 2.1), λ_{max} (in ethanol) 269 mμ (log ε 3.09), 278 mμ (log ε 3.12). The mixed m. p. of the hydrogenated acetates was 81—82°.

Ferruginol (Ia). Ferruginyl acetate (hydrogenated) (100 mg) was refluxed in N potassium hydroxide (20 ml) for 40 min. The product, 85 mg of a nearly colourless resin, $[\alpha]_D^{18}$ + 65° ± 2° (ethanol, *c* 2.4), λ_{max} (in ethanol) 284 mμ (log ε 3.50), resisted crystallisation. By chromatography a few crystals, m. p. 56—57°, could be obtained in one fraction, but crystallisation could not be effected by seeding in the bulk.

Δ^9-Dehydroferruginyl acetate (IVb). 9-Ketoferruginol (145 mg) and aluminium *iso*-propoxide (350 mg) (Riedel-de Haën) in abs. *iso*propanol (5 ml) were heated on a water bath in a flask equipped with a 40 cm Vigreux column. After 5 h, no acetone could be detected in the distillate. Abs. *iso*propanol (5 ml) was added and the solution was kept at total reflux for 1 h. The acetone reaction was negative in the distillate taken after this time. The cooled solution was hydrolysed with 2 N hydrochloric acid (30 ml) and extracted with ether. The ether was evaporated on the water bath and the residue was acetylated with acetic anhydride and pyridine at room temperature (two days). The mixture was poured into water and the precipitate crystallised from aqueous ethanol, giving 110 mg (70 %) of prisms, m. p. 108–109°, $[\alpha]_D^{20}$ −92° ± 2° (ethanol, *c* 2.3), λ_{max} (in ethanol) 220 mμ (log ε 4.39), 266 mμ (log ε 4.01), inflexion at 298 mμ (log ε 3.2). (Found C 80.3; H 9.3. Calc. for $C_{22}H_{30}O_2$ C 80.9; H 9.3). The acetate was partially hydrolysed by chromatography on alumina.

Δ^9-Dehydroferruginol (IVa). *Δ^9*-Dehydroferruginyl acetate (90 mg) was refluxed in N potassium hydroxide (10 ml) for 30 min. The product (75 mg) was a light yellow resin, $[\alpha]_D^{20}$ −60° ± 2° (ethanol, *c* 3.2), λ_{max} (in ethanol) 218 mμ (log ε 4.29), 280 mμ (log ε 3.97). All attempts to effect crystallisation failed.

Isomorphy of ferruginyl acetate and Δ^9-dehydroferruginyl acetate. The acetates were brought into contact by the method of Kofler [3]. On cooling and heating the acetates formed mixed crystals of Roozebom's type I.

The author is indebted to Dr. J. Gripenberg for valuable advice. He also wishes to thank Mr. B. C. Fogelberg, B. Sc., Centrallaboratorium Ab., Helsingfors, who has taken the infrared spectra.

A New Approach to the Determination of Distribution Functions, Especially for Polymers

KARL ERIK ALMIN and BÖRJE STEENBERG

Swedish Forest Products Research Laboratory, Paper Technology Department, Stockholm, Sweden

Inherent weaknesses in current methods for the determination of molecular weight distribution functions are pointed out and a new method based on liquid-liquid distribution at equilibrium conditions is outlined.

The object in characterisation of a sample by fractionation methods is to determine the distribution function of the sample under study in respect to a chosen parameter. The experimental method involves a series of physical or chemical processes, resulting in a number of fractions, the weights of which are determined. From the experimental data the distribution function can then be calculated. The mathematical treatment is a simple one provided that any fraction does not contain such parts of the original sample, which appear in other fractions. This is the case for instance at the fractionation of spheres of different sizes by a series of screens.

If, and this is the important case, each fraction contains all types of units represented in the unfractionated sample, the problems become more complicated.

Let us assume that the original sample has a weight frequency function which, in respect to the separation parameter, γ, is

$$y = f(\gamma)$$

then the quantity of substance in the fraction numbered p can be written

$$W_p = \int_0^\infty F(\gamma, p) \cdot f(\gamma) \mathrm{d}\gamma \qquad (1)$$

where $F(\gamma,p)$ is a function determined by the program used in the fractionation and by the nature of the physical or chemical process used.

The first condition required to solve the integral equation given in (1) with respect to $f(\gamma)$ using the experimentally determined W_p values is that the functions $F(\gamma,p)$ are known. These functions may be derived from theoretical considerations or from independent experiments. It is true that even with this function unknown, it is possible to characterize the sample by a relation between W_p and p, provided that the fractionating process is completely standardized. The basic information which was sought for is, however, not reached.

In the determination of molecular weight distribution functions of high polymers (see *e. g.* Ref.[1]) it is customary to utilize methods with maximum selectivity. Even so the fractions are far from homogeneous in molecular weight. It may very well be so that the width of the frequency function of single fractions are comparable to that of the original sample. The reaction mechanism in such fractionation methods is incompletely understood which, in other terms, implies that the function $F(\gamma, p)$, where now γ stands for the molecular weight, is unknown.

It is customary in the mathematical treatment of the experimental results of the type discussed to make some assumptions concerning the shape of the distribution functions of the fractions. In the method described by Mark and Raff [2] it is supposed that the fractional frequency curves are symmetrical and narrow. Beall [3], working on the basis that the fractional frequency curves "must tend to be unimodal", worked out a time-consuming but probably more reliable method. Such methods may imply a gross oversimplification especially at low and high molecular weights. The chief weakness of these methods is that basic assumptions are introduced at early stages of the calculations.

What possibilities exist to surmount these difficulties? The possibilities to derive the function $F(\gamma, p)$ theoretically or from experimental data seem small. In precipitation or dissolution fractionation methods knowledge regarding the relation between the activities of the polymer in the solution and the precipitate have to be known. Although such relations have been worked out by Huggins [4] and Flory [5], they are still incomplete and their usefulness in this case at least debatable. Experimental determination of the function $F(\gamma, p)$ requires access to preparations with unique molecular weight or known distribution functions. Preparations of polymers of medium or high DP undisputably of this type are unknown.

The solution must consequently rest in a new method of fractionation, where the mechanism of reaction is known. As far as the authors know nobody has explicitely stated that the problem is composed of two parts. The first part is to determine the distribution function with respect to some suitable parameter. The second part is to determine a relation between this parameter and the molecular weight. Only then the molecular weight distribution function can be derived. The method should preferably be chosen in such a way that the function $F(\gamma, p)$ is theoretically known.

The reason why it is desirable to treat the problem in this way is that the relation between the parameter and the molecular weight is not necessarily a monotonous function. Thus Morey and Tamblyn [6] investigating the precipitation method report that low molecular weight material under certain conditions can precipitate before high molecular weight material.

Let us discuss the possibilities to solve the problem. It seems obvious that only a chemical equilibrium method can be useful. This implies that diffusion methods or chromatographic methods have to be ruled out.

The liquid distribution methods, closely related to the precipitation and dissolution methods, can, however, be expected to fulfill the requirements. Such a method has been used by Schulz and Nordt [7]. They concluded that the method is relatively ineffective in fractionation. These writers have, however, used different composition of the liquid system at different stages of the fractionation procedure. Such a procedure is certainly efficient if the object is to obtain fractions of as widely different molecular weights as possible, but if the object is to determine the molecular weight distribution function of the original sample it will result in the same difficulties as classical precipitation procedures.

It must be a pre-requisite that the fractionation parameter γ is kept constant for every type of molecules present at all steps of the fractionation.

If the partition coefficient is chosen as the parameter this implies that it is necessary to have constant composition of the liquid system at all steps in the procedure.

It is obvious that this will lead to a decreased fractionation effect, but this can be compensated by a method of multiplication. The Craig countercurrent system seems to lend itself admirably to investigations of this type. Countercurrent fractionation according to related principles for high polymers have been used successfully by Swenson and coworker [8,9] in this laboratory. His method did, however, not involve equilibrium conditions.

In a series of papers of one of the authors the possibilities to apply countercurrent methods to this problem will be analyzed theoretically and experimentally. It will be shown that if the polymer is distributed between two immiscible liquids in a counter current apparatus the quantity of polymer in each fraction can be written

$$W_p = \binom{n}{p} \int_0^\infty \frac{k^p}{(1+k)^n} f(k)\, \mathrm{d}k$$

where k is the partitition coefficient for a specific size of molecules and $f(k)$ denotes the weight frequency function for the polymer with respect to the parameter k. The number of the fractions is p ($p = 0,1,2.....n$), the total number of fractions being $n + 1$. From this integral equation $f(k)$ can be derived by a properly chosen approximation method.

If the average molecular weight $\overline{M}_p$ in each fraction is determined experimentally one can write

$$\overline{M}_p^a = \frac{1}{W_p} \cdot \binom{n}{p} \int_0^\infty \frac{k^p}{(1+k)^n} \cdot f(k) \cdot M^a\, \mathrm{d}k$$

where a is a parameter fixed by the conditions of the method [10]. Because $f(k)$ is known it is possible to calculate M as a function of k. The molecular weight frequency function can be derived from the formula

$$g(M) = f(k) \cdot \frac{dk}{dM}$$

DISCUSSION

The principle for the determination of molecular weight distribution functions outlined has its merits in the possibilities of a more precise mathematical treatment than is theoretically possible with earlier used methods.

From a practical point of view it is first of all necessary to find a pair of immiscible liquids, both being solvents for the polymer to be studied. It seems probable that such systems are not easily found except in a few cases, but already the existence of one such system may allow studies leading to deeper insight into the laws of high polymers.

It is also necessary that a thermodynamic equilibrium is reached when the polymer is distributed between the liquids. Interaction between molecules of different size should be negligible, or in other words the partition coefficient shall be independent of the presence of reasonable quantities of other size molecules. From a mathematical point of view this means that the function $F(\gamma, p)$ shall be independent of the molecular frequency function of the sample.

Only experimental studies can ascertain whether the mentioned conditions can be realized. Preliminary experiments with polyglycols and two phase liquid systems composed of trichloroethylene, chloroform, ethanol and water are promising, and detailed results will be published.

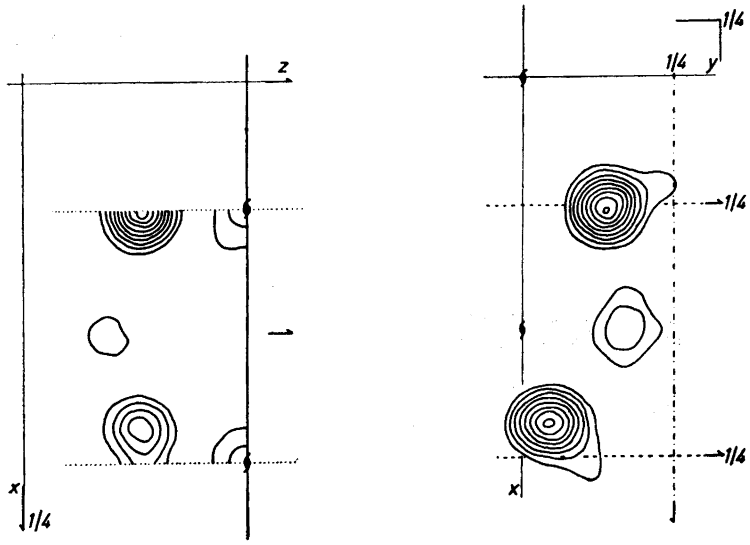
The Crystal Structure of $N_4S_4H_4$

E. WANG LUND and SVEN R. SVENDSEN*

Kjemisk Institutt, Universitetet i Oslo, Blindern, Norway

An X-ray crystallographic study of $N_4S_4H_4$ has been carried out. The analysis shows that that the molecule has the form of a puckered eight-membered ring with alternating sulphur and nitrogen atoms. The positions of the hydrogen atoms have not been determined.



Several authors have regarded as a plausible structure of $N_4S_4H_4$ one which is based on an 8-membered ring with alternating sulphur and nitrogen atoms [1,2]. For the attachment of the hydrogen atoms two different opinions have been held. Some chemical evidence [1,5] is said to point in favour of a structure with hydrogen atoms linked to sulphur atoms. A study of the infrared spectrum [6] indicates, however, the presence of NH rather than SH bonds in the molecule.

The aim of the present investigation is to establish the arrangement of sulphur and nitrogen atoms in the molecule by means of X-ray crystallographic methods. It has not been possible or even tried to locate hydrogen atoms. A crystal structure determination of the same substance has been performed previously by Jaeger and Zanstra [3], using rotation and powder X-ray diagrams. We have, however, not been able to find correspondence between some of their data and results and ours.

The substance was prepared by the method described by Meuwsen. N_4S_4 in benzene was reduced by stannous chloride in alcoholic solution. From acetone needle-shaped crystals of $N_4S_4H_4$ were obtained, but also small bipyramidal plates were observed.

Oscillation and rotation X-ray diagrams showed that $N_4S_4H_4$ crystallizes in the orthorhombic system. The unit cell dimensions were found to be $a = 6.75$ Å, $b = 7.97$ Å, $c = 12.19$ Å. These values are assumed to be accurate to within one half per cent. With four molecules in the unit cell the dimensions lead to a calculated density of 1.907 gcm^{-3} which compares favourably with the observed value [3] of 1.88 gcm^{-3}.

* Present address: Statens råstofflaboratorium, Trondheim, Norway.

Figs. 1 and 2. Projections of the asymmetric unit of $N_4S_4H_4$ on (001) and (010), respectively. Electron density maps with interval between contour lines corresponding to 10 electrons per Å^2, the lowest lying at 10 electrons per Å^2.

Weissenberg diagrams, taken with Cu-*K* radiation show extinctions of reflexions characteristic of the space groups *Pbnm* or *Pbn*. The Wilson ratio $\langle|F|\rangle^2 / \langle|F|^2\rangle$ was computed for seven different sets of reflexions lying within concentric areas in reciprocal *h0l* plane. The mean value of the ratio was found to be 0.63, which indicates the most symmetric space group *Pbnm*. With four molecules in the unit cell this space group requires two halves of a molecule to be crystallographically equivalent.

Intensities of *h0l* and *hk*0 reflexions were estimated visually by means of a standard scale, using the multiple film technique. Patterson projections were computed and found to be compatible with a structure based on an 8-membered ring with alternating S and N atoms and having the point symmetry 4 *mm*. If this is the main feature of the structure one of the symmetry planes of the molecule has to coincide with the symmetry plane of the space group.

A model was tentatively assumed with N—S distance equal to 1.77 Å and with the angles N—S—N and S—N—S equal to 105° and 109°, respectively. Patterson projections served to locate such a model in the unit cell with a satisfactory degree of correspondence between observed and calculated structure factors. Fourier projections on (001) and (010) planes were computed. The contour maps are shown in Figs. 1 and 2. The interval between contour lines corresponds to 10 electrons per Å^2.

From these electron density maps rather reliable coordinates of sulphur atoms can be derived. Only one nitrogen atom gives rise to a well separated peak. The other two nitrogen atoms of the molecule cannot be located accu-

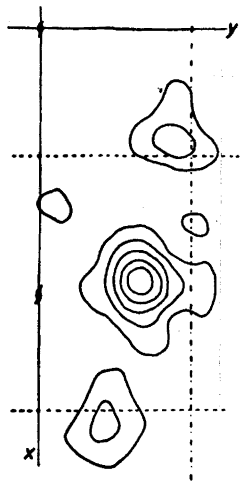


Fig. 3. Difference electron density projection on (001), amplitudes being $F_0 - F_s$. Interval between contour lines corresponding to 3 electrons per Å², the lowest lying at 3 electrons per Å².

rately due to overlap from other atoms in the projections. In order to determine the coordinates of these nitrogen atoms a difference synthesis $F_0 - F_s$ was performed in the projections on (001), F_s being the calculated contribution of the sulphur atoms to the structure factor. In Fig. 3 the resulting difference electron density map is reproduced. From this map the x and y coordinates of the nitrogen atoms were derived. Figs. 4 and 5 show the arrangement of the molecules in the unit cell.

In Table 1 the final coordinates are listed. These coordinates lead to four independent determinations of the N—S distance of the magnitude 1.65 ± 0.02 Å and further to three independent values of the angle S—N—S lying in the range 122° ± 3° and two values of the angle N—S—N within 109° ± 1°.

In Table 2 observed and calculated structure factors are given. The calculated values include temperature factors B equal to 3.00 and 3.65 Å² for the projections on (010) and (001), respectively. No correction for absorption has

In order to establish the position of the hydrogen atoms in the molecule it would be of interest to study derivatives in which hydrogen is replaced by a heavier atom or group. The formaldehyde derivative $N_4S_4(CH_2OH)_4$ has been prepared according to Meuwsen. X-Ray diagrams show that this compound belongs to the space group *Pbca* with axial lengths 12.0 Å, 13.1 Å and 15.8 Å. The observed density is 1.55 gcm^{-3} whereas the calculated density assuming eight molecules in the unit cell is 1.74 gcm^{-3}. A more detailed crystallographic study of this compound has not been carried out. The preparation of a compound $N_4S_4F_4$ has been reported [4] and the compound is said to belong to the space group $P\ \bar{4}\ 2_1c$ with two molecules in the unit cell. The point symmetry of the molecule must then necessarily be $\bar{4}$. Assuming that the structure of this molecules also is based on an 8-membered ring, this point symmetry leads to a structure different from that found for $N_4S_4H_4$. It will be of interest to see a more detailed analysis of the structure of the fluorine derivative.

One of the authors (E. W. L.) wants to thank *Norsk Hydros Fond* for financial aid.

Syntheses of some Thiolacetic Acid Derivatives

I. Trichlorothiolacetic Acid

BERTIL SJÖBERG

Research Laboratories, Skoghallsverken, Uddeholms AB, Skoghall, Sweden

The trichlorothiolacetic acid has been synthesised by addition of hydrogen sulfide to trichloroacetic acid anhydride. The infra-red spectrum of the trichlorothiolacetic acid has been recorded and compared with the corresponding spectra of trichloroacetic acid and trichloroacetyl chloride.

Thiolacetic acid reacts easily with many olefins giving thiolacetates, from which by hydrolysis thiols in good yield can be obtained [1–3]. Cunneen [4] has shown that the chloro-substituted thiolacetic acids have still more additive activity depending on their higher acidity. From rubber and chlorinated thiolacetic acids Cunneen easily obtained adducts, but the reaction was difficult to bring about with thiolacetic acid.

Cunneen prepared the chlorinated thiolacetic acids by reacting the corresponding acetyl chlorides with hydrogen sulfide in the presence of aluminium chloride.

Trichlorothiolacetic acid, the most reactive of these acids, was conveniently prepared in this laboratory through addition of hydrogen sulfide to trichloroacetic acid anhydride:

$$(CCl_3CO)_2O + H_2S = CCl_3COSH + CCl_3COOH.$$

In a similar way we had earlier prepared thiolacetic acid from hydrogen sulfide and acetic anhydride [5].

The necessary trichloroacetic acid anhydride was obtained by dehydration of trichloroacetic acid with phosphoric anhydride and was purified by distillation in vacuum.

The addition of hydrogen sulfide to the trichloroacetic acid anhydride was carried out at room temperature. As a catalyst a small amount of pyridine was added. From the reaction mixture trichlorothiolacetic acid was isolated and purified. Physical data for trichloroacetic anhydride and trichlorothiolacetic acid do not seem to be reported in literature. Some data obtained are therefore given in Table 1.

Table 1. Physical data.

Compound	Boiling point °C/mm Hg	d_4^{20}	n_D^{20}	MR_D	AR_D of S
Trichloroacetic anhydride	105/12	1.6900	1.4857	52.43	—
Trichlorothiol-acetic acid	40/4	1.6136	1.5300	34.36	8.31

In Table 1 the molar refraction MR_D is calculated from the physical data, using the Lorentz-Lorenz formula. According to the values given by Eisenlohr [6] for the atomic refractions the molar refraction of the trichloroacetic acid anhydride ought to be only 51.54. The higher value we have found indicates a considerable exaltation.

Using the values of Eisenlohr for the atomic refractions of carbon, hydrogen, chlorine and oxygen we have calculated the atomic refraction for the sulfur atom in the trichlorothiolacetic acid from the found molecular refrac-

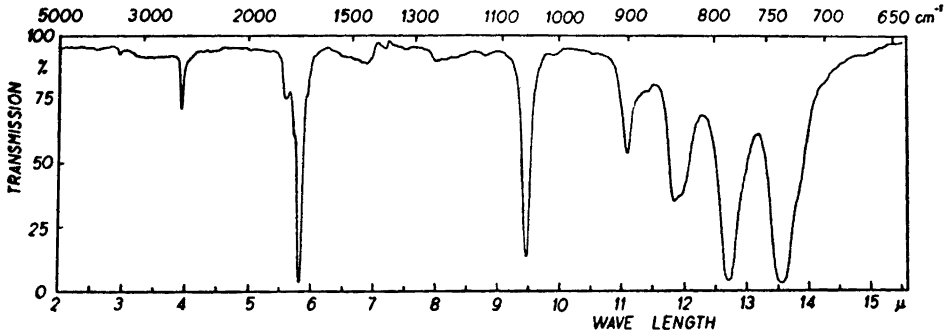

Fig. 1. The infra-red spectrum of trichlorothiolacetic acid in CS_2-solution.

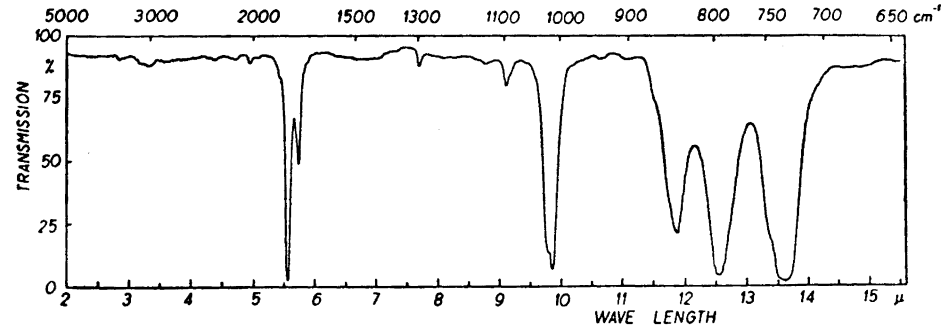

Fig. 2. The infra-red spectrum of trichloroacetyl chloride in CS_2-solution.

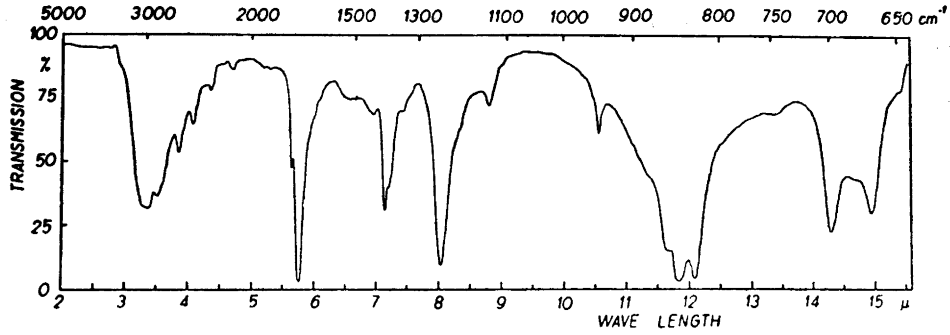

Fig. 3. The infra-red spectrum of trichloroacetic acid in CS_2-solution.

tion. The calculated value 8.31 is in good agreement with the values we have found for other thiolacetic acids.

The infra-red spectrum of the trichlorothiolacetic acid has been recorded in a solution of carbon disulfide (Fig. 1). As a comparison the infra-red spectrum of the trichloroacetyl chloride (Fig. 2) and trichloroacetic acid (Fig. 3) are also given.

It is apparent from the spectra that the trichlorothiolacetic acid is free from trichloroacetic acid. The similarity of the spectra of trichlorothiolacetic acid and trichloroacetyl chloride is striking. The same relation between thiolacetic acid and acetyl chloride has been pointed out by Sheppard [7]. The absence of carbon-hydrogen bonds makes the spectrum of the trichlorothiolacetic acid comparatively simple, and the absorption bands in the region of the group-frequencies are very few. At 2 554 cm^{-1} we find the weak S—H stretching band. At 1 726 cm^{-1} the C = O stretching gives a strong absorption. The band at 1 058 cm^{-1} seems to correspond to the trichloroacetyl chloride band at 1 017 cm^{-1}, which has been assigned by Seewann-Albert [8] to C—C stretching. The weak band of the trichlorothiolacetic acid at 903 cm^{-1} has no counterpart in the trichloroacetyl chloride spectrum and therefore seems to belong to the S—H deformation. The three absorption bands at the end of the spectrum

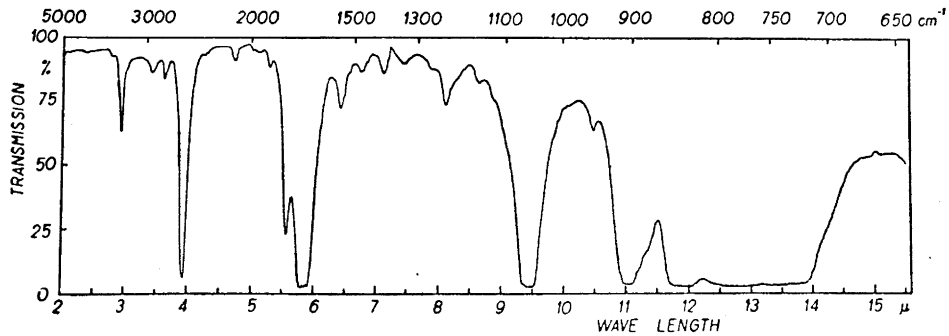

Fig. 4. The infra-red spectrum of liquid trichlorothiolacetic acid.

belong to chlorine stretching and skeletal vibrations and cannot safely be assigned without corresponding Raman-spectra.

From the spectrum of the trichlorothiolacetic acid and the similarity of this spectrum with that of the trichloroacetyl chloride, it can be concluded that trichlorothiolacetic acid predominantly must exist in form of CCl_3COSH. Earlier Sheppard [7] and later Mecke and Spiesecke [9] have stated the same relation for the thiolacetic acid. In the thiolacetic acid, however, a small percentage of the isomeric thionform CH_3CSOH was found. This isomer could be identified by a weak band at 1 225 cm^{-1} belonging to the C=S stretching. The two isomeric forms are in equilibrium and the amount of the thionform increases at higher temperature.

In order to further investigate the spectrum of the trichlorothiolacetic acid we made a recording of the liquid acid in a thin layer (Fig. 4).

The absorption at the higher wave lengths is too strong but in the shorter wave length region there are interesting absorption bands. The absorption band at 3 431 cm^{-1} most probably can be assigned to the O—H group. Since there is also a distinct band at 1 232 cm^{-1}, which can be attributed to the C=S stretching, the existence of a small quantity of the thionform CCl_3CSOH must be assumed.

EXPERIMENTAL

Preparation of trichloroacetic acid anhydride: 300 g pure trichloroacetic acid was heated in an oil bath with 130 g phosphoric anhydride (the theoretical amount) at 210 °C for 10 h. After cooling to room temperature the liquid layer was decanted from the viscous phosphoric acid and distilled in vacuum. At 93—97 °C and 8 mm Hg 207 g trichloroacetic acid anhydride was obtained (yield 73 %). This product was redistilled in vacuum in a fractionation column according to Todd [10] with about 40 theoretical plates. The main fraction boiled at 105 °C and 12 mm Hg. (Found: Cl 68.5. Calc. for $C_4O_3Cl_6$: Cl 68.9).

Preparation of trichlorothiolacetic acid: Hydrogen sulfide was disperged through a fritted glass disc into 183 g trichloroacetic anhydride and 1 ml pyridine at room temperature. To get a sufficient absorption height a narrow glass tube was used for the mixture. The rate of absorption was followed by weighing the reaction tube and titrating the reaction product with iodine (*cf.* the preparation of thiolacetic acid [5]). The reaction velocity was comparatively low and came to a stop after 40 h. Vacuum distillation gave 60 g trichlorothiolacetic acid (yield 56 %). The acid was purified by vacuum distillation with a Widmer-column, b. p. 40 °C at 4 mm Hg. (Found: Cl 59.4; S 17.73; equiv. wt. 180.5. Calc. for C_2HOSCl_3: Cl 59.3; S 17.87; equiv. wt. 179.45).

The infra-red spectra

The infra-red spectra were recorded with a *Perkin-Elmer* double-beam spectrometer Model 21 a with rock-salt prism. Slit schedule 927, corresponding to program 4. Speed: 3 min/μ. The frequencies of the absorption bands are given below.

Trichlorothiolacetic acid (Fig. 1). 100 g/l CS_2-solution. Cell: 0.1 mm 2 554 (w), 1 787(w), 1 726(s), 1 058(s), 903(m), 846(s), 788(s), and 738(s).

Trichloracetyl chloride (Fig. 2). 26.4 g/l CS_2-solution. Cell: 0.459 mm 1 803(s), 1 750(w), 1 023(m), 1 017(s), 844(s), 797(s), and 736(s).

Trichloroacetic acid (Fig. 3). 99.9 g/l CS_2-solution. Cell: 0.1 mm. At 3 008 broad band with small peaks at 2 878, 2 628, 2 478, and 2 323. 1 787(w), 1 747(s), 1 407(s), 1 252(s), 1 141(w), 951(w), 847(s), 830(s), 701(s), and 671(s).

The Influence of Water Content on the Action of Ionizing Radiation on Starch

L. EHRENBERG, M. JAARMA, and E. C. ZIMMER

Institute for Organic Chemistry and Biochemistry, University, Stockholm, Sweden

In order to elucidate the "protective effect" of water in various biologic materials irradiations of polysaccharides of various water contents have been carried out and some chemical changes measured. It was found that the number of breaks produced in the polysaccharide chains of the molecules per energy absorbed decreases with increasing water content, in quantitative parallelism to the effects in biologic materials. This effect can be explained by assuming that in materials of low water content excitations lead to chemical changes with higher efficiency than in materials containing more water. There were also found chemical effects showing an entirely different dependence on water content.

When studying the induction of mutations by irradiating plant seeds, it was found at an early stage of the investigations that the material showed a radiation sensitivity varying irregularly between the individuals in a sample as well as between different samples. The variation was observed to be greater with sparsely ionizing radiations (such as γ- and X-rays) than with densely ionizing radiations (secondaries produced by neutrons). An analysis of possible causes led to the conclusion that the seemingly irregular variation obtained in experiments with sparsely ionizing radiation could be explained by the influence of the water content of the seeds on the radiation sensitivity.[1]

Desiccated seed material with a water content of 6—8 % was found to be most sensitive to X- and γ-rays, and a maximum "protective effect" was observed at a water content of about 20 % (the water content corresponding to minimum sensitivity somewhat depending on the material and on the test reaction studied). The dose reduction factors brought about by increased water content range from 2.5 for mutation rate in barley [2] to 3—4.5 for inhibition of growth in the same material [1]. In contradistinction no dependence of sensitivity on water content has been found using fast neutron irradiation [1-4]. At water contents above 20 % the sensitivity increases for all kinds of radiation, due, partly at least, to an increase in metabolic activities, involving, *e.g.*, chromosome multiplication and initiation of germinative processes [6].

Qualitatively, the influence of the water content is the same for all radiation effects studied: gene mutation, chromosome aberrations, sterility, growth inhibition and lethality, all these effects possibly resulting from disturbances in the nuclear material. The phenomenon is, decidedly, a very general one, since it has been observed in seeds of many different species (barley [1–5], tomato [7], pea [8], and others) and also in pollen [9] and in bacteria [10].

A more detailed analysis of the ways by which water brings about this very pronounced effect might well furnish important clues as to the mechanisms of action of radiations in general. No physiological or biochemical factors have thus far been found that depend on water content in such a way as to explain the modifying action of water on radiosensitivity [6]. On the other hand the water content exerts a qualitatively and quantitatively very similar influence on the radiation induced chemical changes in non-living hydrophilic colloids [6,11]. Consequently, it seems quite reasonable to look for an explanation on the physicochemical level.

The present paper describes investigations into the radiation induced changes in systems of polysaccharides of the starch type (α-polyglucosides), irradiated at different water contents. In a way these experiments are exploratory, as they strive to find which chemical changes depend on water content in the same manner as the biological effects, and which do not.

EXPERIMENTAL

Samples of potato starch, amylose from potato starch, or maize amylopectin ("Amioca" from National Starch Products) were treated, in desiccators, with streaming air of different relative humidities in the range of 0 to 95 %. When, after 4—6 days at 20°C, equilibrium was reached, the samples were irradiated in glass stoppered test tubes.

γ-Irradiation was carried out at distances 3—18 cm from a 70 Curie ^{60}Co source. The (average) dose rates at these distances and in the tubes used were determined actinometrically [12] by measuring the oxidation of $FeSO_4$ in 0.8 N H_2SO_4, a G-value of 15.5 Fe^{3+} per 100 eV absorbed being used. At a distance of 3 cm the dose rate amounted to 10^5 r/h.

Roentgen irradiation was given by means of a therapy apparatus run at 175 kV; filtering 2 mm Al; dose rate 800 r/min. The dose was measured during the irradiation by means of a wave-length independent thimble chamber connected to a valve electrometer and integrating counter calibrated in Roentgens (r).

The analytical methods are mentioned in connection with the experimental results.

RESULTS

Common potato starch becomes soluble in water after irradiation by about 10^5 r of γ- or X-rays, and aqueous solutions can therefore be investigated above this dose.

Solutions of irradiated starch are acidic. In order to get amounts of acid groups, easy to titrate, starch was irradiated with 10 and 24 Mr and the groups were titrated electrometrically with 10^{-3} M NaOH. Within this dose range, the amount of acid groups is proportional to the dose. Probably a mixture of different groups is obtained, with an average pK_s amounting to 4 or a somewhat lower value. The titrations are disturbed by the presence of starch, and therefore the values obtained somewhat approximate. Up to 16 % water the

20.8	1.4	1.8	0.78
Dose range:	10—24 Mr		0.3—1 Mr

yield of acid groups per ion pair * is fairly constant or slowly decreasing (Table 1), whereas a much higher value is obtained at 20 % water. Considering the fact that the decomposition of starch decreases monotonically with increasing water content, as measured by the viscosity (Table 1, last column), there is no simple correlation of acidity to decomposition. The number of reducing groups determined according to Somogyi [13] (column 3), is totally independent of the water content, and cannot be related at all to the net degradation. The reducing groups are also formed in proportion to the dose. — When intact seeds were irradiated by 5×10^5 r of X-rays the number of glucosidic bonds split was somewhat greater at 17 % H_2O than at 8 % H_2O [14]. Obviously biochemical and physiological factors have to be considered in the irradiation of tissue.

It seems logical to assume that the formation of one reducing group, *i.e.*, the hydrolysis of a glucoside bond, leads to a break of the polysaccharide chain (although the formation of a new bond not affecting the reducing group is, of course, not excluded). Since the net degradation of starch, in contradistinction to the formation of reducing groups, depends on the water content at irradiation, it was of interest to estimate the total number of breaks in the polysaccharide chains obtained per unit dose. Obviously chemical reactions other than the hydrolysis of glucoside bonds are responsible for part, at least, of the net degradation.

A prerequisite for a direct determination of the number of breaks in the polysaccharide chains would be, of course, the use of a material permitting the study of aqueous solutions of the unirradiated material. Starch derivatives made soluble by chemical treatments, *e.g.*, the carboxymethyl ether used in preliminary experiments, were regarded unsuitable for the purpose due to a possible disturbing influence of the introduced groups or changes. Moreover, since the average molecular weights of α-polyglucosides obtained, for instance, from determinations of viscosity, are rather uncertain, we preferred the following indirect method of estimating the number of chain breaks at a given degree of degradation.

* The term "ion pair produced" is used for convenience and in a strictly formal way, implying no other meaning than the absorption of 32.5. eV of radiation energy in the medium.

In amylose, irradiated at different water contents by 30 Mr of γ-radiation, the degradation was estimated from the displacement towards shorter wavelengths of the absorption maximum of the complex with iodine, and from the decrease of the optical density at 650 mμ. The number of breaks in the polysaccharide chains was calculated from the reduction values measured at the same optical changes caused by very dilute solutions of α-amylase. Since amylose consists mainly of long unbranched chains, both agents can be supposed to attack the molecules at randomly situated points. The optical properties can be supposed to depend exclusively on the chain length, irrespective of the chemical nature of the end groups. This assumption is supported by the fact that the displacement of the absorption maximum agrees fairly well with that expected from the degree of decomposition calculated (see Table 2), *i.e.*, the absorption curve changes equally after irradiation and enzymatic hydrolysis. The yield of chain breaks per ion pair produced is found to decrease from 4—5 at 6 % H_2O to about 2 at 20 % H_2O.

A similar result was obtained with the branched polysaccharide, amylopectin, from which stable 1 % solutions could be prepared. A 50 % decrease of the viscosity of 1 % solutions was obtained by irradiating desiccated samples

Table 2. Amylose, irradiated with 30 Mr (5.0×10^{19} ion pairs) γ-radiation, at different water contents. Number of chain breaks calculated from the extinction decrease at 650 mμ. The colorimetric determinations were done with 0.0002—0.0006 % amylose solutions containing excess iodine (0.004 %)

Water content %	Decrease of extinction at 650 mμ, %	Maximum extinction at mμ	No. of chain breaks		Maximum extinction expected from degree of hydrolysis, mμ
			per g amylose	per ion pair (32.5 eV of energy absorbed)	
6.6	70	570	$23.5 \cdot 10^{19}$	4.4 ($\pm$2)	555
10.1	49	590	$16.7 \cdot 10^{19}$	3.2 ($\pm$2)	580
13.6	37.5	600	$12.5 \cdot 10^{19}$	2.4 ($\pm$1)	595
19.8	29.0	595	$9.8 \cdot 10^{19}$	1.8 ($\pm$1)	605

Table 3. Doses of γ- and X-rays causing 50 % reduction of the viscosity of 1 % amylopectin solutions, and ionic yields for chain breaks.

Water content at irradiation %	50 % dose of γ-rays, Mr	50 % dose of X-rays, Mr	No. of chain breaks per ion pair (32.5 eV of energy absorbed)
4—6	0.2	0.200	4.7$\pm$0.6
14	0.6		1.6 *
20	1.0		0.9 *

* Calculated from dose reduction according to column 2.

(4—6 % H_2O) at 200 kr of X-rays or γ-rays (Table 3). The dose reduction factor for obtaining the same viscosity at higher water contents (about 20 % H_2O) was somewhat greater for this compound than for starch and amylose, amounting to about 5 times. From simultaneous determinations of viscosity and reduction value, the number of breaks at different viscosities could be estimated. Since the reduction value is too low to be measured at 50 % viscosity, an extrapolation backwards had to be done on the reduction/time curve; this extrapolation is justified, the curve being linear at the beginning. The yield of chain breaks per ion pair was found, in agreement with the amylose value, to be about 5 in the desiccated material, and about 1 at 20 % H_2O.

DISCUSSION

Genetic as well as many other biologic radiation effects can possibly be ascribed to changes in desoxyribonucleic acids (DNA) or their complexes with proteins. The polysaccharides might therefore seem to constitute systems, which are chemically too unrelated to the biological materials mentioned to permit drawing any conclusions. The influence of the moisture content on radiation sensitivity seems to be a general phenomenon, however, also being at work for certain changes in proteins (unpublished) and DNA (after UV irradiation [15]). The possible significance of the present results for biological effects might therefore be discussed on general terms.

Different chemical effects induced in the polysaccharides depend differently on the water content: Some effects, as the degradation measured spectrometrically or viscosimetrically, are greatest at low water contents and are inhibited by the presence of water quantitatively to the same degree as the biological effects. The degradation of amylopectin irradiated at different water contents was followed also in pure nitrogen atmosphere, and quantitatively identical results were obtained; in the biologic material water exerts the same protective influence in nitrogen (which, in addition, causes some protection).[1] From the similar displacement of spectra after irradiation and enzymatic hydrolysis it does not seem plausible that the degradation measured can be ascribed to a breaking of great numbers of hydrogen bonds [16]. Chemical changes involving rupture of the polysaccharide chains are certainly at work. That chemical changes involving covalent bonds do follow the degree of degradation is further indicated by the ability of irradiated starch to reduce iodine in solution, the ionic yield for this ability decreasing from about 0.5 at 6 % H_2O to 0.2 at 20 % H_2O. (The chemical nature of the iodine consuming groups is being studied further.) Other reactions show the inverse dependence on the water content, especially the oxidation of adsorbed iodide [11] and possibly also the induction of acid groups at high water contents. Still other reactions are independent of the water content, such as the rupture of glycosidic bonds, probably also the induction of acid groups below 16 % H_2O. The occurrence of these different modes of reaction gives, in principle, means to elucidate the chemical changes, leading to moisture-dependent biologic radiation effects.

The validity of the estimations of the number of chain breaks per ion pair is strengthened by the quantitative agreement between the two very different

systems: amylose, *i.e.*, an unbranched polysaccharide, irradiated with 10—24 Mr, and the branched amylopectin irradiated with a 100 times lower dose. It is therefore reasonable to assume that per ion pair, *i.e.*, 32.5 eV absorbed, about 5 breaks occur when the material is irradiated at about 6 % H_2O. Taking into consideration the many experimental difficulties and possible sources of error, the latter value can be said to be certainly higher than 3 breaks per ion pair and accordingly greater than the yields of acid groups or glucosidic bonds hydrolyzed. An increase of the water content to about 20 % at irradiation decreases the yield of chain breaks by 2—5 times, in similarity with the biological experience, bringing it to a value close to one break per ion pair. The high ionic yield obtained when irradiating the desiccated material may be taken as an indication that excitations are chemically effective here. — The possible biologic importance of excitations has but infrequently been discussed. As a rule they have been regarded unimportant (*cf.* Lea [17]).

Due to difficulties in measuring the number of excitations in materials such as those we are considering here, the frequency at which they occur is still a matter of dispute. For various materials values amounting to 1—3 excitations per ion pair have been given [16–18]. If all of them were leading to chemical reactions, ionic yields amounting to 2—4 would be obtained. We have therefore some justification to suppose, at present as a working hypothesis, that in biologic materials as well as in non-living model systems, water exerts its maximum "protection" at high water contents (about 20 % H_2O) by eliminating the chemical rearrangements following excitation, whereas the chemical consequences of ionization are not affected to the same degree. Regarding the number of excitations per ion pair this would mean a dose reduction factor of 2—4, in agreement with the experiments. The idea is further supported by the fact that Kaplan [15], irradiating by UV bacteria as well as DNA at different water contents, finds a dose reduction factor, in both systems amounting to about 22. The low energy of the UV-photons makes the frequency of ionizations relatively much more rare, and, consequently, a protection against excitation leads to a much more pronounced "protective effect" than in the case of ionizing radiations.

Thanks are due to Professor Karl Myrbäck and Dr. K. G. Zimmer for valuable discussions. The investigation was supported financially by grants from the *Agricultural Research Council* and from the *Hierta-Retzius Research Foundation.*

Studies on Local Anesthetics XIII *

BJÖRN LÜNING

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Stockholm, Sweden

Two compounds related to xylocaine *i.e. α-diethylamino-2,6-dimethylthioacetanilide* and *α-diethylamino-2,4,6-trimethylthioacetanilide* have been synthesized, and tested for their local anesthetic potency by subcutaneous anesthesia on man. Furthermore, the lethal dose in white mice was determined.

The compounds synthesized in this work have the following structure:

I: R = H
II: R = CH_3

They were both prepared from the corresponding oxygen compounds (xylocaine and LL 31) [2] by replacing the carbonyl oxygen with sulphur, P_2S_5 in pyridine solution being used for the exchange reactions. The compounds were tested for their anesthetic potency by subcutaneous injection on man, and for compound I the duration was found to be approximately 40 % shorter than that of xylocaine whereas compound II gave practically no effect. The LD_{50} values measured by subcutaneous injection in white mice and calculated as g of I, II and xylocaine per kg of body weight are 0.9, 1.2 and 0.4, respectively **.

EXPERIMENTAL

α-Diethylamino-2,6-dimethylthioacetanilide

α-Diethylamino-2,6-dimethylthioacetanilide (xylocaine[2]), 23.4 g (0.100 mole), was mixed with 33 g (0.15 mole) of phosphorus pentasulphide, dissolved in 300 ml of dry pyridine (dried by CaH_2) and the mixture was gently refluxed for two hours. The product was

* For paper XII of this series see Löfgren, Lundquist, Lindström [1].
** Experiments performed by S. Wiedling.

allowed to cool, and was poured under vigorous stirring, into 2 000 ml of 6 N hydrochloric acid containing 500 g of ice. A thick grey precipitate (sulphur) formed. After standing overnight, the precipitate was filtered off. The solution was extracted three times with 300 ml of carbon disulphide and twice with 300 ml of ether. The aqueous solution was made weakly alkaline (pH 8—9) with 25 % ammonia and was then extracted twice with 150 ml of ether. The ether was distilled off at atmospheric pressure until a quantity of about 40 ml of pyridine remained, which was evaporated at 18 mm Hg (bath temperature 40°). The last traces of pyridine were removed in a desiccator over silica gel. The resulting brownish crystals were dissolved in ether which was extracted with 60 ml of 1 N hydrochloric acid. The aqueous solution was made alkaline (pH 9) with 2 N ammonia and extracted with ether (60 ml). This purification step was repeated once. The ethereal solution thus obtained was dried over Na_2SO_4 and then chromatographed through an aluminium oxide (Brockmann's Standardized) column (diam. 14 mm; height, 50 mm), coloured impurities being retained at the top of the column. The resulting ethereal solution — after evaporation — gave 9.2 g (0.037 mole; 37 %) of almost colourless crystals. Recrystallization from a mixture of 20 ml of ligroin (b.p. 110°—125°) and 10 ml of *n*-butyl ether yielded 7.4 g (0.029 mole, 29 %) of colourless prisms; m.p. 106.5°—107° (corr.). (Found: C 67.0; H 8.92; equiv. wt.* 250. Calc. for $C_{14}H_{22}N_2S$ (250.4): C 67.1; H 8.86; equiv. wt. 250.)

Nitrate. Long colourless prisms from absolute ethanol; m.p. 150° (decomp.). (Found: C 53.7; H 7.35. Calc. for $C_{14}H_{23}N_3O_3S$ (313.4): C 53.7 ;H 7.40.)

Picrate. Yellow needles from 96 % ethanol; m.p. 193°—194° (corr.). (Found: C 50.2; H 5.12. Calc for. $C_{20}H_{25}N_5O_7S$ (479.5): C 50.1; H 5.25.)

Perchlorate. Colourless rhomboidal prisms from absolute ethanol; m.p. 188° (decomp.). (Found: C 47.9; H6.59. Calc. for $C_{14}H_{23}ClN_2O_4S$ (350.9): C 47.9; H 6.60.)

α-Diethylamino-2,4,6-trimethylthioacetanilide

α-Diethylamino-2,4,6-trimethylacetanilide,[2] 51 g (0.21 mole), was treated with phosphorus pentasulphide as described above. The yield was 4.75 g (0.0180 mole; 8.7 %) of an almost colourless crystalline mass. After two subsequent recrystallizations from *iso*propyl ether, 3.3 g (0.0125 mole; 6 %) of colourless needles were obtained; m.p. 121° (corr.). (Found: C 68.1; H 9.15; equiv. wt. 264. Calc. for $C_{15}H_{24}N_2S$ (264.4): C 68.2; H 9.15; equiv. wt. 264.)

Nitrate. Short prisms from ethanol, melting at 119°—120°. (Found: C 55.0; H 7.82. Calc. for $C_{15}H_{25}N_3O_3S$ (327.4): C 55.0; H 7.70.)

Picrate. Small yellow prisms from 70 % ethanol; m.p. 207°—208° (decomp., corr.). (Found: C 51.2; H 5.60. Calc. for $C_{21}H_{27}N_5O_7S$ (493.5): C 51.1; H 5.52.)

Perchlorate. Small colourless laths from absolute ethanol-*iso*propyl ether; m.p. 164°—165° (corr.). (Found: C 49.2; H 6.90. Calc. for $C_{15}H_{25}N_2O_4SCl$ (364.9): C 49.4; H 6.91.)

A new compound related to xylocaine [2] *i. e. α-diethylamino-2-vinylacetanilide* has been synthesized, and tested for its local anesthetic potency by subcutaneous anesthesia on man. Furthermore, the lethal dose in white mice was determined.

The compound synthesized in this work has the following structure:

I

Synthesis of the compound was carried out according to the following scheme:

2-Nitrostyrene was prepared as described by Einhorn [3] with some minor alterations. By reduction of this nitro compound according to Komppa [4], 2-vinylaniline was obtained. Due to the instability of the pure amine, it was not isolated. The amine was obtained as an ethereal solution which directly was used in the reaction with chloroacetyl chloride.

The ultraviolet absorption curves of I and α-diethylamino-2-ethylacetanilide are given in Fig. 1. Compound I was tested for its anesthetic activity by subcutaneous injection on man. The duration was found to be approximately 30 % shorter than that of xylocaine. The LD_{50} value measured by intravenous injection on mice was found to be the same as for xylocaine, *i.e.* 0.041 g of base per kg of white mouse **.

* For paper XIII of this series see Lüning [1].
** Experiments performed by S. Wiedling.

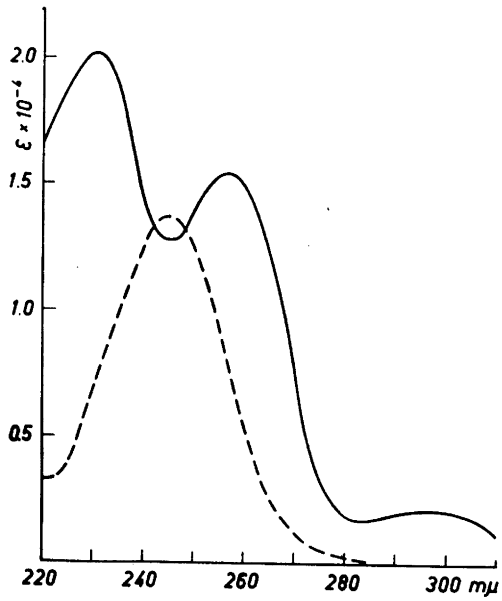

Fig. 1. Ultraviolet absorbtion curves of I (————) and α-dimethylamino-2-ethylacetanilide (— — — — —).

EXPERIMENTAL

β-Bromo-β-(2-nitrophenyl)propionic acid. This acid was prepared according to Einhorn [3]. Since Einhorn's description is rather incomplete, the experimental conditions had to be determined. Acetic acid saturated with hydrogen bromide at 0° was prepared in the following manner. Acetyl bromide, 50 g ,was mixed with 34 g of glacial acetic acid in a thick walled tube of resistant glass. The tube was cooled to 0°, and 10 ml of aqueous hydrobromic acid (d = 1.49) were added in 0.5 ml portions. If in this procedure addition be too fast, hydrogen bromide will escape resulting in an unsaturated solution. In this operation the temperature should be kept at 0°.

To the solution thus prepared, 2-nitrocinnamic acid, 10 g (0.052 mole), was added and the tube sealed. Under shaking, the tube was heated in a water bath at 75°—80° for one hour. During this time all 2-nitrocinnamic acid went into solution and a brown syrup formed. The tube was cooled to about —25° and then opened. Excess of HBr was removed at a bath temperature of 60° and the contents poured into 500 ml of ice-water. The brown precipitate thus formed was sucked off and washed with 100 ml of benzene. The yield was 9.9 g (0.036 mole; 72 %) of a brown crystalline powder; m.p. 138° (decomp.).

2-Nitrostyrene. 2-Nitrostyrene was prepared from β-bromo-β-(2-nitrophenyl)propionic acid according to the method given by Einhorn [3]. However, since Einhorn's yield of 2-nitrostyrene is very low (10 %) some improvements were made. A solution of 30 g of dry sodium carbonate in 150 ml of boiling water was introduced into the distilling flask of a steam distillation apparatus. β-Bromo-β-(2-nitrophenyl)propionic acid, 4 g, was added and the 2-nitrostyrene formed was steam distilled until no more came over. Another portion of 4 g of acid was added and the procedure repeated until a total amount of 23 g (0.084 mole) of the acid had been added. The distillate was made acid with a few drops of concentrated hydrochloric acid and the 2-nitrostyrene was taken up in 50 ml of ether. The ether was washed with 25 ml of dilute sodium carbonate solution and twice with 50 ml of water. The ethereal solution was dried over Na_2SO_4 and the ether evaporated.

The residue consisted of 2.2 g (0.015 mole; 17 %) of a brownish oil which solidified in the refrigerator. The crude 2-nitrostyrene was dissolved in ether and chromatographed through an Al_2O_3 (Brockmann's Standardized) column (diam. 14 mm; height 40 mm), coloured impurities being retained at the top of the column. After evaporation of the solvent the remaining oily material was crystallized from a solvent mixture ether-light petroleum 1 : 1 (v/v) at a temperature of −27°. Long pale yellow needles melting at 13°−14° (corr.) were obtained. (Found: C 64.4; H 4.73. Calc. for $C_8H_7NO_2$ (149.2): C 64.7; H 4.69.)

2-Vinylaniline. This compound was prepared according to Komppa's [4] method by reduction of 2-nitrostyrene with $SnCl_2$; however, the following alterations were made: (1) the reduction was carried out in a vessel that was cooled in a bath of running cold tap water, (2) the base obtained as an ethereal solution in the procedure was used directly for the synthesis of α-chloro-2-vinylacetanilide (*cf.* above).

α-Chloro-2-vinylacetanilide. To a mixture of a solution of 2-vinylaniline, prepared from 5.0 g (0.034 mole) of 2-nitrostyrene in 100 ml of ether (*cf.* above), and 12 g (0.15 mole) of dry sodium acetate, a solution of 3.0 g (0.038 mole) of chloroacetyl chloride in 50 ml of dry ether was added under vigorous stirring. After a period of 5 min, 25 ml of water were added and stirring was continued for another 15 min. Without separation of the two phases the ethereal layer was driven off under reduced pressure. α-Chloro-2-vinylacetanilide which precipitated during the evaporation was sucked off and dried. The dry product was dissolved in benzene and purified with charcoal. After evaporation, the residue was recrystallized once from absolute ethanol and once from benzene. Yield (based on 2-nitrostyrene): 1.9 g (0.0095 mole; 30 %) of colourless needles m.p. 92°−92.5° (corr.). Found: C 60.9; H 5.15. Calc. for $C_{10}H_{10}NOCl$ (195.65): C 61.4; H 5.15.)

α-Diethylamino-2-vinylacetanilide. α-Chloro-2-vinylacetanilide 1.8 g (0.0092 mole), was mixed with 2 g (0.0273 mole) of diethylamine in 16 ml of benzene (dried over $CaCl_2$) and the mixture refluxed for 5 h. After cooling, 20 ml of ether were added. The precipitated diethylamine hydrochloride was filtered off and the solution evaporated to dryness. The residue consisted of 2.0 g (0.0086 mole; 94 %) of a pale brownish oil. The oil was dissolved in ether and chromatographed through an Al_2O_3 (Brockmann's Standardized) column (diam. 14 mm; height, 40 mm), coloured impurities being retained at the top of the column. The effluent was washed with 100 ml of water. The base was extracted from the ether with 250 ml of 0.5 N hydrochloric acid. This solution was washed three times with 100 ml of ether. The base was liberated by means of saturated sodium carbonate solution and taken up in 50 ml of ether.

From this ethereal solution the *perchlorate* was prepared. The salt was recrystallized twice from absolute ethanol m.p. 166° (corr.). (Found: C 50.6; H 6.50. Calc. for $C_{14}H_{21}ClN_2O_5$ (332.8): C 50.5; H 6.36.)

The pure perchlorate was dissolved in 20 ml of water and 3 g of dry sodium carbonate were added. The separated oily base was taken up into ether. This ethereal solution was dried over potassium carbonate and then filtered. The ether was evaporated, leaving 1.45 g (0.0063 mole; 68 %) of a colourless oil; $n_D^{20} = 1.5480$. (Found: C 72.0; H 8.67. Calc. for $C_{14}H_{20}N_2O$ (232.3): C 72.4; H 8.68.)

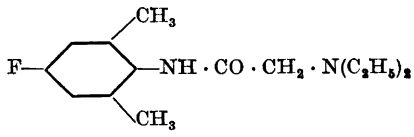
Studies on Local Anesthetics XV *



SVEN LINDSTRÖM

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Stockholm, Sweden

The thermodynamic ionization constants, the apparent molar refractions and the ultraviolet absorption spectra of α-diethylamino-4-fluoro-2,6-dimethylacetanilide and of xylocaine have been determined. The electronic effect induced by the fluorine atom is discussed, and finally, a possible explanation is offered for the fact that α-diethylamino-4-fluoro-2,6-dimethylacetanilide as compared with xylocaine has such a low local anesthetic potency.

In a previous work [2] some xylocaine analogues, each with a fluorine atom in the benzene nucleus, were synthesized and studied for their local anesthetic activity. In comparison with xylocaine, the fluoro derivatives were found to have a lower potency, and contrary to xylocaine they exercised an irritant action.

One of these compounds, α-diethylamino-4-fluoro-2,6-dimethylacetanilide, with the formula

had a duration on rabbit cornea which was about one tenth of that of xylocaine. As this compound is so closely related to xylocaine, (the non-fluorinated derivative), the low potency is rather astonishing.

Löfgren [3], Fischer and Löfgren [4] investigated some physico-chemical properties of xylocaine and closely related compounds. In making a comparison between xylocaine and its nuclear isomers and homologues, xylocaine was found to have: (a) a very low exaltation in its molar refraction, (b) a low pK_a value, (c) the ultraviolet absorption bands displaced towards shorter wave lengths, and (d) the intensities of the bands appreciably lowered. Now, it seemed to be of interest to us to study how the fluorine atom in the

* For paper XIV of this series see Lüning [1].

4-position affects these properties of xylocaine. The fluorinated compound and also xylocaine have therefore been subjected to measurements of thermodynamic ionization constants in water at 25°, apparent molar refractions in benzene solutions at 20° and ultraviolet absorption spectra in hexane solution.

Determination of the thermodynamic ionization constant. For the thermodynamic ionization constant, K_a, we have

$$pK_a = pH - \log \frac{C_B}{C_{BH^+}} - pf_{BH^+} \quad (1)$$

C_B is the concentration of the uncharged base B, C_{BH^+} is the concentration of the acid BH^+, $pf_{BH^+} = -\log f_{BH^+}$, and f_{BH^+} is the activity coefficient of BH^+. The pH values were measured with the aid of a cell of the type:

(—) "Glass electrode" / H^+ (aq) / / KCl (satd.) / Hg_2Cl_2, Hg (+)

For this cell we have

$$pH = \frac{E - E'}{k} \quad (2)$$

where E is the e.m.f. of the cell in mV and E' is the standard potential of the cell including the liquid junction potential (assumed to be constant). At 25°, k is 59.16 mV. Kielland [5] has calculated activity coefficients for a large number of ions at different concentrations in water at 25° by use of the Debye-Hückel formula:

$$-\log f_i = pf_i = \frac{0.358 \cdot z_i^2 \cdot \Gamma^{1/2}}{1 + 10^8 \cdot d_i \cdot 0.2325 \cdot \Gamma^{1/2}} \quad (3)$$

where f_i is the activity coefficient of the ith ion with valence z_i and effective diameter d_i. Γ is the ionic concentration, given by $\Gamma = \Sigma C_i z_i^2$ with C_i in moles per litre.

According to measurements by Löfgren [3] the effective diameter for the BH^+ ions were assumed to be 8×10^{-8} cm. The values of f_i for ions with this effective diameter were logarithmed, and pf_{BH^+} was plotted against $\frac{1}{2}\Gamma = C_{salt}$ in a diagram from which pf_{BH^+} could be read off directly at any concentration.

Since it is difficult to obtain a clear survey of the systematic errors, (above all, errors caused by liquid junction potentials) we have confined ourselves to an accuracy of two decimals for pK_a. For mutual comparison, however, the values can be given with greater accuracy; the error here seldom exceeds $\pm$ 0.005.

The experimental data from the measurements of the ionization constants are compiled in Table 1. The double e.m.f. values arise from the two glass electrodes used. From Table 1 it is seen that the fluorinated compound ($pK_a = 7.78_1$) is a weaker base than xylocaine ($pK_a = 7.84_8$; previously found (Löfgren [3]) 7.85_5).

Determination of the apparent molar refraction. For a mixture, the following equation is valid

$$\frac{n^2 - 1}{n^2 + 2} \cdot \frac{m_0 + m_1}{d} = \frac{n_0^2 - 1}{n_0^2 + 2} \cdot \frac{m_0}{d_0} + (r_1)_{app.} \cdot m_1 \quad (4)$$

Table 1. Determination of the ionization constants. NaOH-solution = 0.0265_0 M; test solution = 100 ml. $AHNO_3$ = xylocaine hydronitrate; $BHNO_3$ = α-diethylamino-4-fluoro-2,6-dimethylacetanilide hydronitrate.

where n is the refractive index, d is the absolute density, m is the amount weighed and $(r_1)_{app.}$ is the apparent specific refraction of the solute; quantities referring to the solution are designated by no index, those referring to the solvent by the index 0 and those referring to the solute by the index 1. The apparent molar refraction is obtained from $(r_1)_{app.}$

$$(R_1)_{app.} = (r_1)_{app.} \cdot M_1 \tag{5}$$

The figures from the measurements of the molar refractions are compiled in Table 2. For the computation of the molar refraction from atomic refractions, the usual published values have been employed; see Table 3. Whereas xylocaine has a small exaltation = 0.16 (previously [3] found to be 0.24), the fluorinated compound has a small depression = 0.17.

Calculation of the errors in the molar refractions. According to Kohner and Johnson (see Weissberger [6]) an expression for the maximum error is

$$(\nabla R_1)_{app.} = \frac{1\,000}{C}\left[\frac{6n_0}{(n_0^2+2)^2}\cdot\nabla(\Delta n) + \frac{\Phi_0}{d_0}\cdot\nabla(\Delta d)\right] \tag{6}$$

where C is the concentration in moles per litre,

$$\Delta n = n - n_0,\ \Delta d = d - d_0 \text{ and } \Phi_0 = \frac{n_0^2 - 1}{n_0^2 + 2}$$

The "Pulfrich" used gave a maximum error in reading = ± 30″. This means that $(\nabla n)_a = \pm 4 \times 10^{-5}$. For a temperature change = 0.02° we obtain for

Table 2. Determination of apparent molar refractions [a]). A = xylocaine; B = α-diethylamino-4-fluoro-2,6-dimethylacetanilide.

Compound	Weighed amount (g) of		d_{20}	$(n_D^{20})^2$	$(R_1)_{app.}$	$(R_1)_{app.}$ average	Exalt.
	compound	benzene					
A	2.17328	7.29727	0.90513	2.26646	71.13		
	2.22808	7.56269	0.90498	2.26646	71.13	71.14	+0.16
	2.17145	7.40230	0.90483	2.26646	71.16		
B	2.24338	7.08697	0.91698	2.25695	70.72		
	2.27927	7.59943	0.91529	2.25639	70.67	70.71	−0.17
	2.26824	7.44430	0.91587	2.25695	70.73		

[a] The calculations are based on the refractive index $n_D^{20} = 1.50110$ for benzene. If, however, one should use another recorded value [20] ($n_D^{20} = 1.50144$) for benzene, the mean values of the apparent molar refractions will be 71.18 and 70.75 for A and B, respectively.

Table 3. Atomic refraction (D-line) of element or structural feature.

C	H	F	O in carbonyl group	Double bond	N in tert. amine	N in sec. amide
2.418	1.100	0.997 [a]	2.211	1.733	2.840	2.676

[a] Value according to Schiemann [21] (*cf.* also v. Auwers [22]).

benzene [7] $(\nabla n)_t = \pm 1.3 \times 10^{-5}$ and for aniline [7] the change is about the same. For these reasons we take ∇n for our substances to be $\pm 5 \times 10^{-5}$. For the same inaccuracy of temperature $(\nabla d)_t$ is estimated [8] to 2×10^{-5} and $(\nabla d)_{weight}$ to 5×10^{-5}. The total error ∇d is therefore estimated to be 1×10^{-4}.

For the following values

$$\nabla(\Delta d) = \pm (|\nabla d| + |\nabla d_0|) = \pm 2 \times 10^{-4}$$

$$\nabla(\Delta n) = \pm (|\nabla n| + |\nabla n_0|) = \pm 1 \times 10^{-4}$$

$$n_0 \sim 1.50,\ C \sim 1.0,\ d_0 \sim 0.88$$

is obtained $(\nabla R_1)_{app.} = \pm 0.1$.

The apparent molar refraction has therefore been given to two decimals.

In a previous paper [2], the nitration of 3,5-dimethylfluorobenzene yielding two mononitro derivatives was described. One of them was proved to be 4-nitro-3,5-dimethylfluorobenzene. The other nitro derivative was consequently considered to consist of 2-nitro-3,5-dimethylfluorobenzene. This assumption has now been proved experimentally. By heating 2-nitro-3,5-dimethylfluoro-

benzene with KOH in methanolic solution, the fluorine atom was replaced by the methoxy group and the resulting methoxy compound was identified as 2-nitro-3,5-dimethylanisole.

DISCUSSION

The strengths of aromatic bases are influenced by methyl groups in the *ortho*-position in a way which could not be predicted on the basis of the inductive and mesomeric effects. Thus *o*-toluidine and 2,6-xylidine are weaker bases than aniline (Thomson [9]). This means that the methyl groups decrease the electron-availability of the nitrogen atom. "In o-$CH_3C_6H_4NH_2$ the proton from the methyl group may go to the unshared pair of electrons of the amino group" (Branch and Calvin [10]), *i. e.* in this compound it is supposed that there is a hydrogen bond between the amine nitrogen and the methyl group. This type of hydrogen bond should, of course, be more pronounced in the di-*ortho*-methylated compound.

From measurements of ionization constants, Löfgren [3] suggests that the same type of hydrogen bond occurs in α-diethylamino-2,6-dimethylacetanilide ("xylocaine"). This compound, when compared with α-diethylaminoacetanilide, has a pK_a value about 0.2 units lower. It is particularly interesting to note that the *ortho*-effect is so strongly emphasized throughout the relatively long chain. From investigations on molar refractions and spectra, Löfgren concludes that the mobility in the resonance system is suppressed. Further, the steric conditions in this molecule indicate strongly that the interaction between the unshared electron pair of the amide nitrogen and the π-electronic system of the nucleus is suppressed. In other words, the electron-attracting capacity of the benzene nucleus is smaller in the 2,6-xylidide than in the anilide. One would then think that the pK_a value of the xylidide should be greater than that of the anilide. Supposing, however, that the unshared electron pair of the amide nitrogen is not only prevented from interfering with the nucleus but is also so influenced (by the *o*-methyl groups) that it becomes "bound", this would influence the electronic state at the carbonyl group. In the anilide, for instance, the key-oxygen-atom may have its electronic density increased by a mesomeric effect from the unshared electron pair of the amide nitrogen, but also by an inductive attraction which also affects the unshared electron pair of the diethylamino group at the end of the molecule. Through the *ortho*-effect described above, the mesomeric effect of the amide group on the carbonyl group in the 2,6-xylidide may be considered reduced, and therefore the inductive electron-attraction of the key-atom is more strongly pronounced. This means a weaker proton-binding capacity and appears in a low pK_a value.

Concerning *p*-substituted fluorine, it is known to induce a weak electron-attractive effect; in some cases *p*-F is even weakly electron-repulsive. *m*-F, however, exerts throughout clearly an electron-attractive effect (Watson [11], Hammet [12]). For our investigations it is of special value to recognize the influence of *p*-substituted fluorine on the amino group. From measurements of ionization constants (Bennet *et al.*[13], *cf.* also Watson [11]) of aniline and of *p*-fluoroaniline it is evident that there is an approximate equality between the

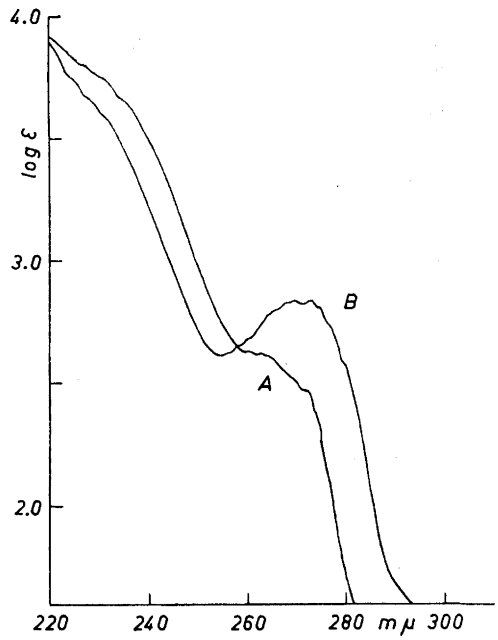

Fig. 1. Ultraviolet absorption spectra of hexane solutions of xylocaine (A) and α-diethylamino-4-fluoro-2,6-dimethylacetanilide (B)

constants of the two bases. Hence, we consider that *p*-F has very little influence on the electron pair of the amine nitrogen. On account of the steric conditions, the influence of the fluorine atom *para* to the nitrogen in 4-fluoro-2,6-dimethylaniline must be still less than in *p*-fluoroaniline.

We therefore conclude that the fluorine atom in α-diethylamino-4-fluoro-2,6-dimethylacetanilide has a negligible effect on the unshared electron pair of the amide nitrogen, but that the fluorine atom must exert a certain electron-attractive effect on the methyl groups (*cf.* above concerning *m*-substituted fluorine), *i. e.* the methyl groups must to a certain degree be "protonized". This should favour chelation of hydrogen bond type methyl group — amide nitrogen. The electron pair of the amide nitrogen in the fluorinated compound is therefore supposed to exert less interference with the carbonyl group than in the non-fluorinated compound, and for that reason (*cf.* above) the fluorinated compound has a lower pK_a value than the non-fluorinated compound, *i. e.* xylocaine. — To sum up, we put forward as a theory that the lower basicity of the fluorinated compound as compared with xylocaine is due to a stronger hydrogen bonding methyl group — amide nitrogen.

The differences in the molar refractions and absorption spectra are too small to permit any assumptions as regards the difference in the electronic states of the actual molecules. However, the findings from those measurements

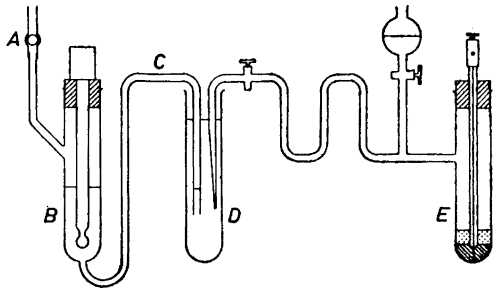

Fig. 2. Diagram of the cell. A = rubber tube with glass pellet (valve). B = glass electrode vessel. C = junction tube. D = junction vessel. E = satd. KCl calomel electrode.

do not in any way contradict what has been said above concerning the electronic effect of fluorine.

Finally, we want to make a possible explanation of the fact that the fluorinated compound, in comparison with xylocaine, has such a low local anesthetic potency. Generally it may be stated that the introduction of a fluorine atom in a physiologically active molecule changes to a marked degree its physiological activity, and this change in activity is probably due to the introduction of a strongly polarized C—F bond (*cf.* Burger *). According to Löfgren [3,15], there is a general rule for anilides of this type, *viz.* that the introduction of a strongly polar group in *p*-position to the amide nitrogen results in a low local anesthetic potency.

EXPERIMENTAL

Benzene, "Merck pro anal." was subjected to the usual purifying procedure, stored over sodium wire and distilled immediately before use; $d^{20} = 0.87902$; $n_D^{20} = 1.50110$ (recorded value [16]).

α-Diethylamino-2,6-dimethylacetanilide (xylocaine), prepared according to Löfgren [3], was recrystallized six times from petroleum ether; m. p. 67°. — The hydronitrate was prepared according to Löfgren [3], and then recrystallized three times from absolute ethanol; m. p. 133° (decomp.).

α-Diethylamino-4-fluoro-2,6-dimethylacetanilide, prepared according to Löfgren *et al.*[2], was recrystallized six times from petroleum ether; m. p. 56°. — The hydronitrate was obtained as colourless, thin needles from methyl ethyl ketone; m. p. 98°. (Found: C 53.2; H 6.99. Calc. for $C_{14}H_{22}FN_3O_4$ (315.3): C 53.3; H 7.03).

Solutions for pK_a determinations were made by dissolving the hydronitrates in water, neutralizing to 30—60 % with sodium hydroxide and diluting to definite volume.

The sodium hydroxide solution, practically carbonate free, was standardized against potassium hydrogen phthalate using phenolphthalein as an indicator. The distilled water had a specific conductivity of about 6×10^{-6} ohm^{-1} cm^{-1}.

The complete cell (see Fig. 2) was placed in a thermostat at 25° ± 0.05 °C. The vessel containing the glass electrode was filled by sucking up the solution through the junction

* According to Burger [14] fluorinated compounds appear to be much less physiologically active than derivatives containing other halogens, and even less than the corresponding non-fluorinated substances.

tube. To be able to measure the test solution with two different glass electrodes, the junction vessel was connected with two glass electrode vessels. Before use, each glass electrode vessel, with its electrode in place, was rinsed several times with distilled water and three times with the test solution. The boundary surface, originally at the end of the junction tube, was automatically raised 1.5 cm into the tube when the tube was lowered into the saturated potassium chloride solution. After ten minutes, readings were taken every other minute on each electrode until they became constant to within 0.1 mV (15—20 min.). With this apparatus the constancy and reproducibility of the measurements were very good.

The electromotive force was measured with an accuracy of 0.1 mV by a valve potentiometer (type PHM 3a made by Radiometer, Copenhagen). The standard cell of the potentiometer was checked against a Weston cell from the Cambridge Instrumental Company.

As a standard for the pH measurements, the buffer solutions recommended by Hitchcock and Taylor [17] were used.

The E' values of the glass electrodes (type G102A, Radiometer) were based on measurements with two freshly prepared different buffers, both before and after each day's work. The glass electrodes were also tested with the borate buffer (pH = 9.180) and no alkaline errors could be found.

The indices of refraction for the sodium D line, n_D, were determined with a Zeiss-Pulfrich refractometer at a temperature of 20° ± 0.02 °C. Repeated readings were taken in order to get a mean value. The refractive index of the prism was determined by means of carefully purified benzene. In this determination two different benzene preparations, "Merck pro anal." and "Stockholms Gasverk pro anal.", were used. Both benzene preparations showed the same angle of emergence.

The *absolute* density, d^{20}, of benzene and the benzene solutions were determined in Sprengel-Ostwald pyknometers, the weight being reduced to vacuum. The same thermostat and the same calibrated thermometer (graduated in 0.1°) were used in the measurements of the indices of refraction and the density. The density of benzene was determined by six separate measurements and the mean value agreed with a recorded value [16].

The ultraviolet absorption spectra were measured on a Beckman quartz spectrophotometer with a hydrogen lamp as a light source. The solvent was spectroscopically pure hexane and the concentrations were about 3×10^{-4} M. The interval between two readings was 1 mμ, except in the more interesting regions where the interval was 1/4 mμ

Proof of the position of the nitro group in 2-nitro-3,5-dimethylfluorobenzene. The nitro compound was treated with KOH in methanol in the same manner as described previously [2] for the determination of the position of the nitro group in the 4-nitro derivative. The melting point of the crude product was found to be 43—44°; yield 93 % (assuming the product to be a nitro-3,5-dimethylanisole). The substance was recrystallized from methanol. Pale yellow crystals melting at 44—45° were obtained; yield 75 % (*cf.* above). This melting point agrees with that of 2-nitro-3,5-dimethylanisole [18,19]. 2-Nitro-3,5-dimethylanisole was prepared according to the method of Rowe *et al.*[18] (nitration of 3,5-dimethylphenol and subsequent methylation of the 2-nitro derivative). The mixed m. p. showed no depression, and therefore the nitro compound must be 2-nitro-3,5-dimethylfluorobenzene.

The author wishes to thank Dr. N. Löfgren for valuable discussions.

Ultraviolet Absorption Spectra of Chain Molecules Consisting of Alternating Benzene Rings and Ethylenic Bonds

JOHANNES DALE

Forsvarets Forskningsinstitutt, Kjeller, Norway

The electronic absorption spectra of styrene, stilbene, 1,4-diphenylbutadiene, *p*-distyrylbenzene, *p*-(phenylbutadienyl)stilbene, *p,p'*-distyrylstilbene and diphenylacetylene have been measured, most of them down to 195 mμ. Mono-*cis*-isomers of *p*-distyrylbenzene and *p*-(phenylbutadienyl)stilbene have been prepared and their spectra also recorded. The observed bands are of three types: 1) a stationary band at 200—210 mμ; 2) a semi-stationary band at 210—250 mμ; and 3) polyene-like bands which can be interpreted as fundamental- and overtone-transitions of the full chromophore.

The spectra of the cross-conjugated compounds *m*-terphenyl and *m*-distyrylbenzene have been measured and compared with the spectra of biphenyl and stilbene.

The syntheses of *p,p'*-distyrylstilbene, *p*-chloro-*p'*-styryl-stilbene and *o*-chloro-*p'*-styrylstilbene are described.

Compounds of structure intermediate between the polyphenyls and the pure polyenes are of considerable interest for the interpretation of electronic absorption spectra of conjugated chain molecules in general. The chemical structure of alternating benzene nuclei and ethylenic bonds is such that a multiplicity of "partial chromophores" would be expected to be active in addition to the "full chromophore", if it is at all justified to divide a conjugated system arbitrarily into independent partial chromophores in order to explain the more complex spectra. It has already been shown that the concept of partial chromophores had to be rejected in discussions of polyene and polyenyne spectra [1,2] in favour of the simple, and more successful, overtone interpretation, which requires that the wave length position of the minor bands must be independent of the detailed structure and correspond to integral fractions of the total chromophore length. The transitions are, however, subject to selection rules which depend on the over-all shape of the molecule.

Among compounds of this type, styrene [3,4], as well as *cis*- and *trans*-stilbene [5,6], have already been investigated in the ultraviolet; for the stilbene isomers an interpretation based on rather implausible assumptions of several partial chromophores has been given by Braude [7]. For the first stilbene

homolog, *p*-distyrylbenzene, only an incomplete spectrum has been reported [8]. The solution spectra of these compounds have now been remeasured to down below 200 mμ (Figs. 1—3).

The next stilbene homolog, *p,p'*-distyrylstilbene, has been synthesized for the first time (see Experimental Part), but its extremely low solubility made it difficult to obtain a spectrum in the lowest wave length region (Fig. 4).

In addition, the closely related compounds, 1,4-diphenylbutadiene and *p*-(phenylbutadienyl)stilbene have also been investigated, the latter for the first time (Figs. 5—6).

The spectra of mono-*cis*-isomers of stilbene [6] and 1,4-diphenylbutadiene [9] have been redrawn from the literature (Figs. 2 and 5). Mono-*cis*-isomers of *p*-distyrylbenzene and *p*-(phenylbutadienyl)stilbene were not known and have been prepared by illumination of the all-*trans*-isomers; the spectra are given in Figs. 3 and 6.

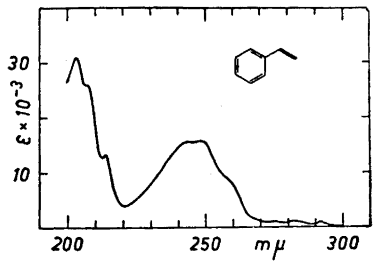

Fig. 1. Molecular extinction curve of styrene in hexane.

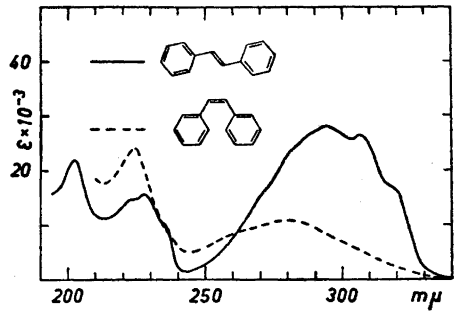

Fig. 2. Molecular extinction curves of *trans*-stilbene in hexane, and of *cis*-stilbene in ethanol (the latter curve from Beale and Roe [6]).

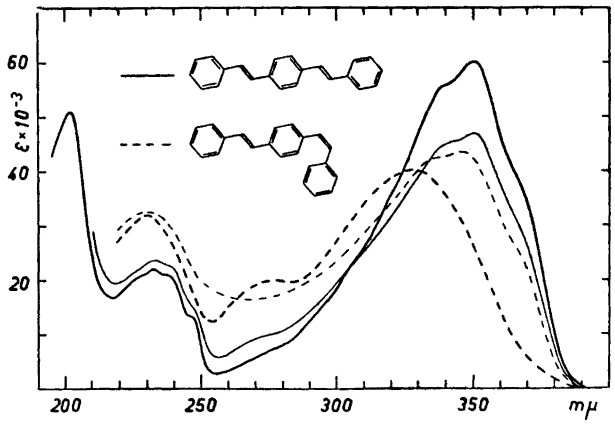

Fig. 3. Molecular extinction curves of all-*trans*- and of mono-*cis*-*p*-distyrylbenzene in hexane. Heavy lines represent fresh solutions; thin lines the same solutions after iodine catalysis.

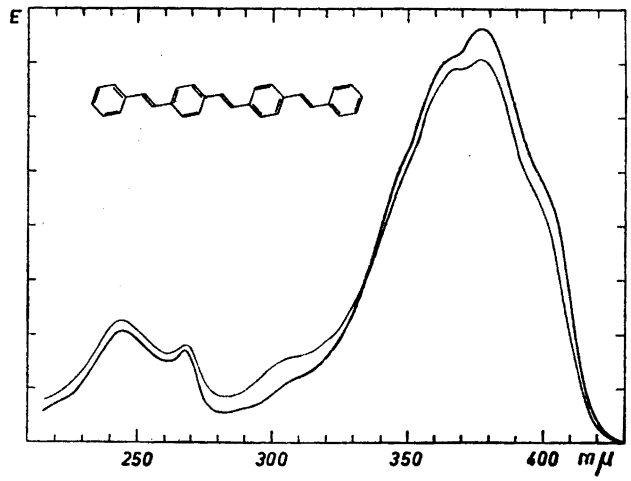

Fig. 4. Extinction curve of all-*trans*-*p,p'*-distyrylstilbene in *cyclo*hexane. Heavy line represents a fresh solution; thin line the same solution after iodine catalysis. Cell length 5 cm.

None of the compounds mentioned above contain benzene nuclei linked in other than the *para* position. It was the plan of this work to prepare similar chains containing also *ortho*-disubstituted benzene links, but none of the numerous attempts were successful (see Experimental Part), either because the methods that were used may not be suitable, or because the compounds may not be obtainable in crystalline form. It is noteworthy that only one such compound has been reported in the literature, namely, *o*-distyrylbenzene, claimed to be obtained in a Meerwein reaction between *o*-aminostilbene and cinnamic acid[10], and that a sample of this product proved, on closer examination, to be impure stilbene (see Experimental Part). The experience of the present writer indicates that the Meerwein reaction proceeds readily in the *para* position, but is replaced mainly by a Sandmeyer reaction in the *ortho* position (see Experimental Part). It should be mentioned, however, that chromatographically separated oily fractions showing the spectra expected for the desired *ortho* compounds could be obtained in some cases, but the quantities were far too small for identification.

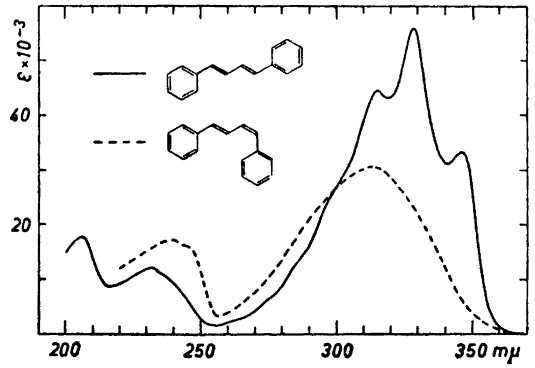

Fig. 5. Molecular extinction curves of all-*trans*- and of mono-*cis*-1,4-diphenylbutadiene in hexane (the latter curve from Pinckard, Wille and Zechmeister[9]).

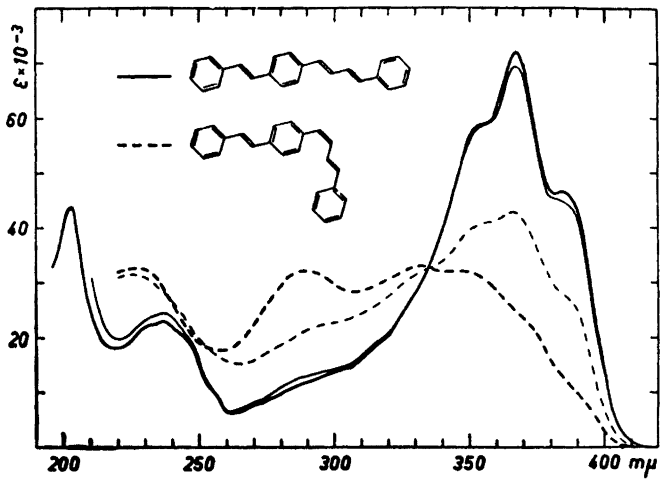

Fig. 6. Molecular extinction curves of all-*trans*- and of mono-*cis*-*p*-(phenylbutadienyl)-stilbene in hexane. Heavy lines represent fresh solutions; thin lines the same solutions after iodine catalysis.

In order to predict the wave length position of overtone bands [1] the wave lengths of the main bands have been plotted against the number of chromophoric units in Fig. 7. It was found that the smoothest curve could be obtained if each benzene ring is set equal to two ethylenic bonds. This choice is also in agreement with the molecular orbital picture of such systems [4].

The predicted and observed wave lengths have been compared in Table 1.

The polyene-like bands

From Figs. 3, 4 and 6 it is at once seen that there are no bands in the spectra of these compounds that could be assigned to any of the partial chromophores that would seem most reasonable. For instance, in the spectrum

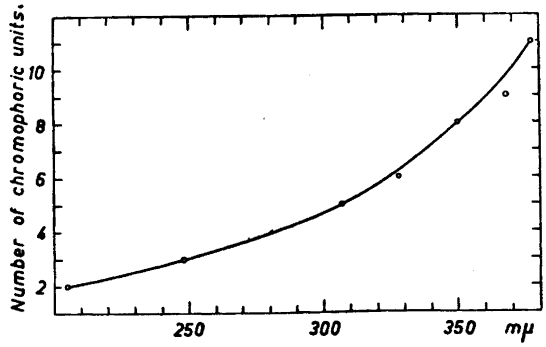

Fig. 7. Wave length position of the main band of the compounds from the preceding figures, plotted against number of chromophoric units (benzene ring = 2; ethylenic bond = 1).

Table 1. Predicted and observed wave lengths of overtone bands (in mμ).

	Number of chromophoric units	λ_2		λ_3		λ_4	
		calc.	obs.	calc.	obs.	calc.	obs.
Stilbene	5	228	224				
1,4-Diphenylbutadiene	6	248	~246	205	(~207)		
p-Distyrylbenzene	8	280	~275	235	~230	205	
p-(Phenylbutadienyl)-stilbene	9	295	~288	248	(~246)	217	~225
p,p'-Distyrylstilbene	11	315	~305	270	268	240	(~244)

of *p*-distyrylbenzene (Fig. 3) there is no band in the 300 mμ region where the stilbene chromophore should absorb; and in the *p*-(phenylbutadienyl)stilbene spectrum (Fig. 6) no bands appear that can be due to either the stilbene- or the diphenyl-butadiene-chromophore. Furthermore, in the *p,p'*-distyryl-stilbene spectrum (Fig. 4) bands corresponding to the stilbene- and the *p*-distyrylbenzene-chromophore are both lacking.

On the other hand, the spectra can be satisfactorily explained in terms of overtone transitions of the total chromophore (Table 1). Thus, in the region predicted for the first overtone (λ_2-band) no bands are observed as long as the ethylenic bonds remain in the stable *trans*-configuration obtained by synthesis (no dipole moment for this transition in a straight chain), but bands appear upon *cis*-isomerization. This behaviour is just what should be expected [1], and the bands correspond with the "*cis*-peak" in polyene spectra. It can also be inferred from this spectral behaviour that the *p*-divinylbenzene system must assume the "*trans*-like" configuration already implied in the drawings of the skeleton models shown in the figures.

In the lower wave length region the situation is complicated by the presence of typical bands which are relatively stationary at 210—250 mμ and at 200—210 mμ through the whole series, and which apparently must have another origin than the polyene-like bands (for further discussion see below). Thus, in *cis*-stilbene (Fig. 2) a λ_2-band at 224 mμ must be superimposed on the stationary band which is at 228 mμ in *trans*-stilbene, while in mono-*cis*-diphenylbutadiene (Fig. 5) the λ_2-band is on the long wave side of the stationary band.

The λ_3-band, which should be allowed in all isomers, seems to be superimposed on the short wave side of the stationary band in *p*-distyrylbenzene; it coincides with it in *p*-(phenyl-butadienyl)stilbene; and in *p,p'*-distyrylstilbene it appears well separated on the long wave side. A λ_4-band must be held responsible for the increased absorption at 225 mμ in mono-*cis*-*p*-(phenylbutadienyl)stilbene (Fig. 6); it is forbidden in the all-*trans*-isomer [1].

The stationary bands

A discussion of the origin of the "stationary" bands is strictly beyond the scope of this paper, but it is tempting to correlate the strong band at 200—210 mμ with allowed transitions between orbitals with no longitudinal node

localized in each benzene ring, $e \rightarrow e$ in Platt's notation [4], although the intensity does not seem to be a clear function of the number of rings. The strongest band in the polyphenyl spectra is always found very constantly at the same wave length, and has been given this interpretation as a real "partial" [11].

A further confirmation of these assignments could be obtained by checking experimentally a few predictions based on the following reasoning: In each benzene ring there are two sets of doubly degenerate π-orbitals, one filled and one empty, between which the electron jumps observable as absorption bands in the accessible ultraviolet region occur. When the rings are either mono-substituted or *para*-disubstituted links in a conjugated chain, one orbital of each set has a longitudinal node and remains isolated, whereas the other orbital of each set interacts with neighbouring π-orbitals to give polyene-like whole-molecular orbitals [4]. If, however, a *para*-disubstituted link is replaced by a *meta*-disubstituted ring, one orbital of each set will interact mainly with one conjugated system, while the other two orbitals interact mainly with another conjugated system, so that, instead of through-conjugation, we get cross-conjugation in Dewar's sense [12]. The whole situation is very analogous to what happens if an allenic link is introduced into an aliphatic unsaturated system [13,14]. The effect is to break the conjugation; one double bond in the allenic grouping being conjugated with an unsaturated system in one plane, while the other allenic bond is conjugated with another planar system rotated by 90° from the former plane.

It is thus understandable that *m*-terphenyl should show a conjugation band corresponding to twice that of biphenyl *, which was already noted by Gillam and Hey in 1939 [16]. In contrast, the band at 205 mμ should be expected to have the same intensity in both compounds since isolated orbitals will now be present only in the phenyl groups at both ends. This prediction could be

* The spectra of a series of polyphenyls containing *m*-disubstituted benzene rings [15], acting like insulating groups, can be similarly explained as superpositions of bands due to cross-conjugated partial chromophores corresponding to biphenyl, *p*-terphenyl or *o*-terphenyl.

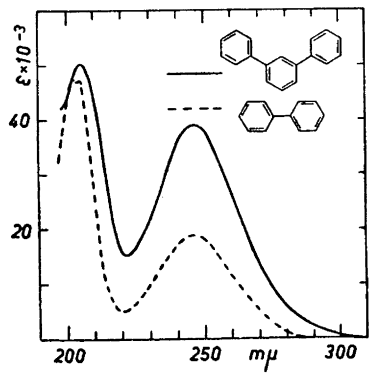

Fig. 8. Molecular extinction curves of *m*-terphenyl and biphenyl in hexane.

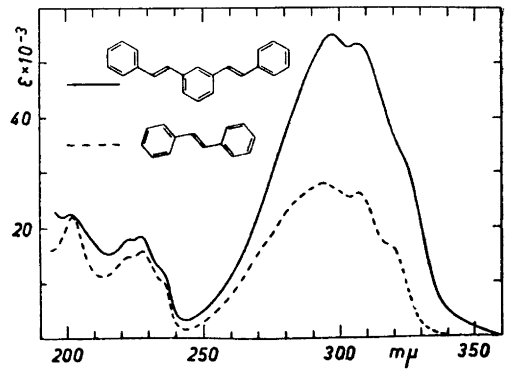

Fig. 9. Molecular extinction curves of *m*-distyrylbenzene and stilbene in hexane.

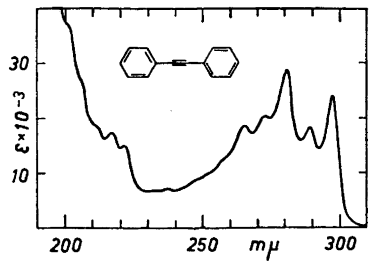

Fig. 10. Molecular extinction curve of diphenylacetylene (tolan) in hexane.

verified as shown in Fig. 8. Exactly the same relationships were found between the spectrum of *m*-distyrylbenzene and that of stilbene (Fig. 9).

The other "stationary" band at 228 mμ shows an intensity change intermediate between that of the conjugation band at 300 mμ and that of the true "partial" at 200 mμ. With increasing length of the conjugated system it undergoes a slight red-shift, from about 228 mμ in stilbene to about 244 mμ in *p,p'*-distyrylstilbene, so that the band is really only semi-stationary. We may therefore have to do with the transitions between an isolated π-orbital (*e*) and a polyenelike π-orbital (*p*) discussed by Platt [4]. The difficulty is that there is no counterpart in the polyphenyl spectra; furthermore, there should be two different transitions, $e \rightarrow p$ and $p \rightarrow e$ in Platt's notation, and they should be weak. There does not seem to be more than one band, and it is rather strong. The alternative assignment of both stationary bands to $e \rightarrow p$ and $p \rightarrow e$ transitions has been proposed [17], but the arguments do not seem decisive.

It may be significant that the pattern of vibrational structure in the semi-stationary band is very similar to that of the conjugation band [6]. Even for styrene this feature is apparent; it now seems to overlap on the long wave side of the stationary band at 204 mμ (Fig. 1). When the vibrational spacings of the conjugation band change and the peaks sharpen, as upon replacement of the ethylenic bond in stilbene with an acetylenic bond (Fig. 10), the structure of the semi-stationary band, now at 205—25 mμ, changes correspondingly.

Band width and steric hindrance

The absorption spectrum of mono-*cis*-*p*-(phenyl-butadienyl)stilbene requires a few comments. As is well known, the introduction of sterically hindered *cis*-bonds in a polyene- or diphenylpolyene-chain *etc.* shifts the absorption maximum of the main band considerably towards the ultraviolet. This is usually explained as an increase in the pure electronic transition energy due to a greater reduction of the resonance energy in the excited state than in the ground state. The present spectrum, however, shows rudimentary vibrational structure with the peaks not far from the positions in the all-*trans*-isomer (Fig. 6). The observed shift of the maximum, also in the completely structureless bands of *cis*-isomers of stilbene, diphenylbutadiene, *etc.*, must therefore be due mainly to a larger change in bond order upon excitation, so that according to the Franck-Condon principle more vibrational quanta are co-excited, and the maximum in the intensity distribution shifted towards the ultraviolet.

Similar spectral evidence is also available from Karrer's hindered *cis*-isomers of lycopene [18] and diphenyl-tetramethyl-octadecanonaene [19]. It is here quite clear that the pure electronic transition energy is only increased from that of the all-*trans*-compound by the same small amount as for the unhindered *cis*-isomers [20], but the transition probability maximum is shifted to much higher vibrational levels, and a greater band width results.

EXPERIMENTAL

The *spectra* were recorded in a Beckman DK-1 instrument using hexane as a solvent except when otherwise noted. In the lowest wave length region 2 mm silica cells were used. The sparingly soluble compounds were also measured in 5 cm cells.

Biphenyl, *m*-terphenyl, styrene, stilbene, 1,4-diphenylbutadiene, and diphenylacetylene (tolan) were purified commercial samples. Professor L'Ecuyer, Québec, most kindly provided samples of *m*-distyrylbenzene, *p*-distyrylbenzene and *p*-(phenylbutadienyl)-stilbene prepared by the Meerwein reaction [10].

p-Distyrylbenzene could also be prepared in good yield from *p*-dibromobenzene and phenylacetaldehyde in a Grignard reaction. The intermediate diol was dehydrated by boiling with toluenesulfonic acid. M. p. 265 °C.

p,p'-Distyrylstilbene. *p,p'*-Dinitrostilbene, prepared according to Walden and Kernbaum [21], was reduced with stannous chloride [22] to *p,p'*-diaminostilbene, m. p. 228 °C. 1.05 g of this compound (0.005 moles) was dissolved in 2.2 ml of 25 % HCl, and, after cooling and addition of 2.2 g of ice, diazotized with 0.37 g of $NaNO_2$ in 0.75 ml of water. The solution of the diazonium salt was poured into a cooled mixture (0 °C) of cinnamic acid (0.74 g), acetone (7.5 ml), anhydrous sodium acetate (0.8 g), and cupric chloride (0.23 g). The mixture was stirred vigorously and allowed to warm up slowly until the gas evolution started. The reaction mixture was steam-distilled, the water decanted off while hot, and the dry residue successively extracted in a Soxhlet apparatus with ethanol, acetone, hexane and chloroform. The earlier fractions contained *p,p'-dichlorostilbene*, m. p. 170 °C (Sandmeyer reaction), and a yellow substance which proved to be *p-chloro-p'-styryl-stilbene*, m. p. 238—40°, λ_{max} in hexane 353 mμ; this product is to be expected in a combination of the Meerwein and Sandmeyer reactions. The boiling chloroform deposited orange-yellow crystals of *p,p'-distyrylstilbene* already during the extraction. These were redissolved in chlorobenzene and precipitated with hexane. The very fine crystals were centrifuged, washed several times with hexane and finally sublimed *in vacuo*. The substance decomposes without melting at 310 °C, and is so extremely insoluble in the solvents commonly used for ultraviolet spectroscopy that even with chloroform quantitative extinction values could not be obtained.

Attempts to prepare o-*distyrylbenzene.* In a Grignard reaction between α,α'-dibromo-*o*-xylene and benzaldehyde no crystalline material was obtained. In a Grignard reaction between benzyl bromide and *o*-phthalaldehyde the only crystalline product was bibenzyl. In a Meerwein reaction between the diazonium salt of *o*-aminostilbene and cinnamic acid, following the prescription of L'Ecuyer and Turcotte [10], only stilbene and *o*-chlorostilbene could be isolated as crystalline materials. Furthermore, a sample of the compound described by these authors as *o*-distyrylbenzene, m. p. 120—22 °C, and kindly put at my disposal by professor L'Ecuyer, was examined spectroscopically both in the U.V. and the I.R. and proved to be stilbene, which melts at 124 °C when pure, admixed with some yellow impurity.

Attempt to prepare o,o'-distyrylstilbene. *o,o'*-Dinitrostilbene was prepared according to Bischoff [23] and reduced with stannous chloride [22] to *o,o'*-diaminostilbene, m. p. 174—75 °C. An attempted Meerwein reaction gave as the only crystalline material a good yield of the Sandmeyer product *o,o'-dichlorostilbene*, m. p. 98 °C.

Attempt to prepare o,p'-distyrylstilbene. *o,p'*-Dinitrostilbene was made in a cross-reaction between *o*- and *p*-nitrobenzylchloride. In order to keep the less reactive *o*-compound in excess during the reaction, the procedure was as follows: A solution of 17 g of *o*-nitrobenzylchloride and 2 g of *p*-nitrobenzylchloride in 72 ml of ethanol was placed in a three-necked flask equipped with a stirrer and two dropping funnels. A solution of 15 g of

p-nitrobenzylchloride in 56 ml of warm ethanol in one of the funnels and a solution of 11.5 g of KOH in 140 ml of ethanol in the other funnel were allowed to run slowly into the flask over the same period of time. After cooling, the crystal mass was filtered off and boiled with benzene. The insoluble residue was recrystallized from acetone; it consisted of *p,p'*-dinitrostilbene. Upon cooling the benzene solution, white-yellowish needles of *o,o'*-dinitrostilbene deposited. On further cooling, yellow needles of *o,p'*-dinitrostilbene started growing from the bottom of the vessel. The reaction products could also be resolved by chromatography of the benzene solution on alumina; the *o,o'*-compound is adsorbed less strongly than the *o,p'*-compound. After recrystallization, *o,p'*-dinitrostilbene melts at 143 °C, as compared with 138—140 °C reported for a sample made by a different method [24]. *o,p'-Diaminostilbene* was obtained by reduction with stannous chloride, and melted at 125 °C. A Meerwein reaction of its diazonium salt with cinnamic acid gave as the only crystalline products, *o,p'-dichlorostilbene*, m. p. 71 °C, and a good yield of a yellow substance which proved to be *o-chloro-p'-styrylstilbene*, m. p. 200 °C, λ_{max} in hexane 350 mμ.

Isomerization of p-distyrylbenzene. A solution of *p*-distyrylbenzene in benzene was exposed to daylight for several weeks. Extensive destruction took place. The benzene was distilled off and the residue dissolved in hexane and chromatographed on alumina with benzene/hexane as developer. The first few fractions that were collected were empty. Then came the only fraction containing more than traces of substance; it yielded a compound melting at about 95° C, which must be the mono-*cis*-isomer. Upon illumination in the presence of catalytic amounts of iodine the spectrum changed towards the characteristic spectrum of the all-*trans*-isomer, but the rearrangement was apparently accompanied by much destruction.

Isomerization of p-(phenylbutadienyl)stilbene. The illumination and the separation of the mixture was performed as for *p*-distyrylbenzene (see above). The only fraction containing any quantity of substance was collected quite early. The substance did not crystallize and may be one or more of the three possible mono-*cis*-isomers. In view of the intense *cis*-peak in the U.V. spectrum the *cis*-bond is most probably centrally located. Upon illumination in the presence of iodine the spectrum reverted very quickly to the characteristic spectrum of the all-*trans*-isomer.

Acknowledgements. The author is indebted to Professor P. L'Ecuyer, Québec, for generous gifts of some of the compounds, and to siv.ing. Eirik Raknes for valuable help in preparing the diaminostilbenes and *p,p'*-distyrylstilbene.

Absorption Spectra of Dysprosium(III), Holmium(III), and Erbium(III) Aquo Ions

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The narrow f^n-bands of aqueous Dy(III), Ho(III), and Er(III) perchlorates are measured in the range 800—210 mμ. The application of the theory of Slater, Condon, Shortley, and Racah to the distribution of multiplet terms is discussed. The lowest term with the total spin S one unit lower than of the groundstate often decays with fluorescence in the lanthanides and actinides, *e.g.* Sm(III), Eu(III), Sm(II), Dy(III), Pu(III), and Am(III).

Stewart [1] investigated trivalent lanthanides lighter than terbium. The present author has studied thulium [2]. The remaining three lanthanides, Dy, Ho, Er, have not been completely measured in aqueous solutions by modern spectrophotometry. Thus, Gorter *et al.*[3] do not report the spectra below 360—370 mμ, and Holleck and Hartinger [4] and Banks and Klingman [5] indicate only the wavelengths of the high peaks of analytical interest. The former authors [4] assume the absorption limit at a wavelength so high that they do not recognize the erbium(III) band at 255.2 mμ, discovered by Moeller and Brantley [6]. Therefore, the present author has procured the pure Dy_2O_3, Ho_2O_3, and Er_2O_3, prepared by Professor F. H. Spedding, and has measured the spectra with high dispersion on a Cary spectrophotometer. It was not felt useful to duplicate the measurements [3-6] above 800 mμ on a Beckman DU. Tables 1—3 give the band groups.

A conspicuous result is the absence of strong bands, such as those caused by $4f^n \rightarrow 4f^{n-1}5d$ transitions in Ce(III), Sm(II), and Eu(II). The molar extinction coefficient ε of Dy(III), Ho(III), and Er(III) is well below 2 at 220 and 3 at 210 mμ. Likewise, Yb (III) does not exhibit such bands [7].

SEXTET AND QUARTET LEVELS OF DYSPROSIUM(III)

Dieke and Singh [8] have recently expressed doubt whether the present author [9] is correct in assuming the multiplet ^6F in the infra-red and ^6P in the near ultra-violet part of the Dy(III) spectrum. This illustrates two different opinions on the most practical method of identifying f^n-energy levels. Dieke and

Table 1. Absorption bands of dysprosium(III) aquo ions. The bands are arranged in groups thought to correspond with the levels of the gaseous ion. Shoulders are given in parenthesis. λ denotes the wavelength in mμ and σ the wavenumber in K = cm^{-1} (not corrected for the refraction of air) of the maxima. δ is the half-width in K, *i.e.* the distance from the maximum to the wavenumber with half the value of ε, the molar extinction coefficient. (−) and (+) indicate the values of δ of unsymmetrical bands, towards lower and higher σ, respectively. The oscillator strength P is given in units of 10^{-6} from the equation $P = 9.2 \times 10^{-9}\ \varepsilon\delta$.

Singh prefer the (physically very sound) way to identify J of each level by different methods: selection rules for polarized light, Zeeman effect and, most important, the maximum number of possible sub-levels ($2J+1$ for an even and $J+\frac{1}{2}$ for an odd number of electrons). When J is known for all levels, they can be assembled in multiplets with defined L and S if the deviations from Russell—Saunders' coupling are not too large.

Although the success of this method is evident in some cases, it must be realized that it has developed rather slowly. The present author attempted to stimulate the search for correct assignments of energy levels by drawing attention [9,10] to the fact that the theory of Slater, Condon, and Shortley [11] as refined for f^n-configurations by Racah [12] seems remarkably close to the large-scale distribution of multiplets in the absorption spectra of lanthanides and actinides. Thus, the large gap between 10 000 K (= cm^{-1}) and a fairly

energy differences between the terms with maximum S are multipla of one linear combination, E^3, of these parameters, Bethe and Spedding [13] and Satten [14] succeeded in identifying the spin-allowed bands of Tm(III) and Nd(III), respectively, while the spinforbidden bands of Nd(III) agree better [9] with ratios $F^2 \cong 1.5\, F^4 \cong 2\, F^6$. Independently, Judd [15] applied similar ratios to Eu(III) and Gd(III). Hence, it would be a surprising irregularity, if the order of ^{6}F and ^{6}P was reversed in Dy(III), especially since the hole-equivalent systems Sm(III) and Pu(III) exhibit analogous behaviour [9].

The present author does not believe that this reversal is finally proven. Dieke and Singh [8] have not observed the levels with $J = 11/2$, $9/2$, and $1/2$ of ^6F and hence concluded that the remaining levels actually are ^6P. It would not be surprising if the observed and calculated levels in Table 7, Ref. [9], were shifted one unit in J, since the interest was concentrated more on the multiplets than on the individual levels. However, the behaviour reported by Dieke and Singh [8] is more remarkable: the level called $^6P_{5/2}$ has five sub-levels, two more than the highest possible number. The collision between ^6H and ^6F may produce rather strong overlapping between levels, even with identical J, since the non-diagonal elements in intermediate coupling are zero [10] between levels with the maximum value of S. If $^6F_{1/2}$ is not the excited level at 13 200 K, the transition may be too weak to be observed with the large decrease of J from $^6H_{15/2}$. The two levels $^6F_{11/2}$ and $^6F_{9/2}$ may be hidden by the other levels, or simply be too improbable as final states for the fluorescence (in absorption they should occur below 9 000 K).

The fluorescent level at 20 958.8 K has seven sub-levels [8]. Dieke and Singh do not assume $J = 13/2$, but identify the level * as $^6F_{11/2}$ with subsequent ^6F-levels in the blue. Dieke and Singh [8] maintain that the intensity is too high for spin-forbidden transitions to quartet levels. However, in Table 1 there are three bands at 325.5, 350.6, and 364.5 mμ, which are 20 times stronger than the bands in the blue (*cf.* Fig. 1). The sextet character is evidently concentrated in the former bands. If they are identified as transitions to ^6P (they do not necessarily all have different values of J, but may be intermixed), E^3 is slightly greater than assumed previously [9], since the bands below 360 mμ were not known [3]. The new value $E^3 = 575$ K is more likely, compared to 480 K in Sm (III) and 630 K in Tm(III), than the old value 520 K.

Since $\zeta_{4f} = 1\,920$ K in Dy(III)[16], the quartet levels $\sim$21 000 K are expected to have $\sim$6 % sextet character, as actually observed.

FLUORESCENCE OF TRIVALENT LANTHANIDES AND ACTINIDES

Dieke and Singh [8] remark, "Moreover, the whole intensity of the fluorescence spectrum is due to the transitions from the resonance level to sextet levels. It would be hard to explain this as quartet-sextet transitions. This could only be so if there were no quartet levels below the resonance level." In the author's opinion, the latter hypothesis corresponds to a rather necessary condition for a f^n-level to decay with fluorescence: it shall be the lowest level with S one unit lower than the groundstate. This condition is satisfied by $^5D_0$ in Eu(III)[17] (however, $^5D_1$ can also be observed) and by $^5D_4$ in Tb(III)[18]. Butement [19] observed a fluorescent level at 14 514 K of Sm(II) in $BaCl_2$. This result implies [28] that the F_k-integrals in Sm(II) are $\sim$16 % smaller than in the iso-electronic Eu(III).

The fluorescent level of Sm(III) at 17 800 K agrees well with the spin-forbidden band of lowest wavenumber; there is a gap without absorption bands

* It can hardly have one of the very high J-values of ^4M, but is rather $^4I_{15/2}$ or $^4I_{13/2}$.

10 500—17 800 K in Sm(III), as there is between * 13 200—20 900 K in Dy(III). In Pu(III), the analogous gap [9] between 17 900 and 19 800 K is much smaller. Actually, a fluorescent level has been observed [20] of Pu(III) in $LaCl_3$ at 19 200 K, while Am(III)[21] in $LaCl_3$ has a group of fluorescent levels in the blue. The fluorescent levels of actinides can be utilized to find the excited levels of the ground multiplet (as initiated by Gobrecht [22] in the case of lanthanides) and hence to determine the large values of ζ_{5f}. Thus, a level seems to occur at 3 100 K in Pu(III), implying $\zeta_{5f} = 4\,400$ K, if the effects of intermediate coupling are neglected. (However, ζ_{5f} is probably 20 % smaller, since Judd [16] has proven that the distances between the lowest levels of a ground multiplet generally are increased, and the distances between the highest levels decreased, compared to the Landé interval rule). It is interesting to compare the ^7F levels of Sm(II)[19], Eu(III), and Am(III) implied by fluorescence (f) and absorption (a):

$J =$	0	1	2	3	4	5	6
Sm(II)	0	269f	834f	1 493f	2 296f	?	?
Eu(III)	0	370f	1 058f	1 906f	2 872f	3 936f	4 964f
Am(III)	0	~800f	2 600f	5 300f	?	9 500a	12 300a

The wavenumbers have roughly the ratios 0.8 : 1 : 2.5. Although the determinants of intermediate coupling are not known, $^7F_4$ seems to be somewhat decreased in all cases.

ENERGY LEVELS OF HOLMIUM(III) AND ERBIUM(III)

It is common to f^2-, f^5-, f^9-, and f^{12}-systems that the P-term with maximum spin is 42 E^3 above ** the ground term H, and the F-term only 9 E^3 above H. Thus, Pr(III), Sm(III), Dy(III), and Tm(III) all have a P-term at a high wavenumber, preceded by a large gap with no bands towards the red and spin-forbidden bands towards the blue limit. f^3-, f^4-, f^{10}-, and f^{11}-systems have another characteristic distribution of terms with the maximum value of S: I, F, S, G, and D at 0, 21, 21, 33, and 54 E^3, respectively. Hence, two gaps exist, one in the near infra-red between I and F, and one in the near ultra-violet between G and D. The behaviour of Nd(III) and Pm(III) has previously been discussed [9]. Tables 2 and 3 and Fig. 1 present similar evidence from Ho(III) and Er(III).

The lowest triplet level of Ho(III) appears to occur at 20 600 K, probably $^3K_8$. It has a small chance to be fluorescent. It would be interesting to know, whether the excited states (before the fluorescent level is reached) decay with internal conversion into vibrational energy, or infra-red light is irradiated by sharp transitions.

* The extremely weak bands reported [8] of $DyCl_3$, $6H_2O$ at 17 151, 18 462, and 18 486 K may be caused by impurities of Nd(III), Ho(III), etc.

** These energies refer to the baricenters, *i.e.* the average of the energy levels, when weighted by their degeneracy numbers.

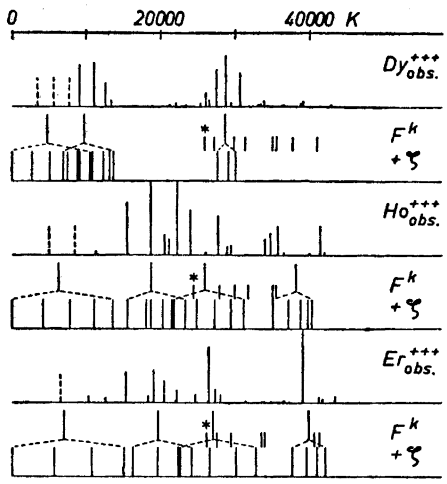

Fig. 1. The energy levels of dysprosium(III), holmium(III), and erbium(III). Three rows are given for each element: First, the wavenumbers of the observed band groups are indicated by lines, whose heights are proportional to the oscillator strength P (except the dotted lines in the infra-red, where P is not known). Second, the predicted baricenters of multiplets are given as high and low lines, representing terms with the maximum value of S and lower values, respectively. Third, the splitting of the terms with maximum value of S, assuming Russell-Saunders' coupling, is given. E^3, a linear combination of F_k-integrals [9], is estimated to 575 K, 590 K, and 610 K in the three ions (it is 460 K in Pr(III) and 630 K in Tm(III)) while the three values [16, 9] of ζ_{4f} are 1 920, 2 080, and 2 350 K (the values in Ce(III) is 644 K and in Yb(III) 2 950 K). The lowest multiplet with S one unit lower than of the groundstate is marked by an asterisk.

Especially in Fig. 1, a large gap is evident between the last level of Ho(III) with largely ^{5}G-character at 27 800 K and the likely ^{5}D-levels at 34 800—41 500 K. In the red, no bands are reported between the last ^{5}I-level * at 11 200 K and the first ^{5}F-level at 15 300 K.

The effects of intermediate coupling are very large in Er(III)[9], and the property "lowest spin-forbidden transition" to $^2H_{11/2}$ and to $^2H_{9/2}$ must be rather dispersed among the ^{4}I levels with the same J. The very high band at 39 200 K has probably some ^{4}D-character, but the exact nature is perhaps rather complicated. It has not been possible to observe an extremely narrow band of the type $^2P_{1/2}$ at 23 400 K of Nd(III). It may be connected with the low transition probablity of a transition in Er(III) from $^4I_{15/2}$ to a level with $J = 1/2$ (the $^2P_{1/2}$ of Nd(III) has ~30 % quartet character, and nevertheless, the oscillator strength is only ~2 % of ordinary $^4I_{9/2} \rightarrow$ quartet transitions in Nd(III)). Generally, transitions where J decreases strongly have rather low

* The author has not been able to observe $^5I_4$ reported [22] at 13 300 K. This may be due either to vanishing intensity (the transition to $^5I_5$ is also very weak, *cf.* Fig. 1) or to a partial reversal of the upper-most levels of ^{5}I, as is perhaps the case in ^{4}I of Er(III) and certainly in ^{3}H of Tm(III). The latter effect corresponds to strong effects of 'averaged' intermediate coupling, as studied by Judd [16].

probabilities [9]. However, the absolute oscillator strengths, which probably are caused by forced electric dipole radiation induced by vibrations or ligand fields without a centre of inversion [23], are not easily calculated. Thus, some, but not all, bands of the acetylacetonates [24] are much higher than of the aquo ions. In particular, some bands of Ho aca_3 and Er aca_3 have ~50 times larger oscillator strengths than the corresponding bands of the aquo ions.

SUMMARIZING REMARKS

It is seen from Fig. 1 that the general distribution of spin-allowed and spin-forbidden transitions in Dy(III), Ho(III), and Er(III) agrees with the theory [9,10], as is also the case for the other trivalent lanthanides. This agreement is caused mainly by the fact that radial functions of highly different shape produce a smooth decrease of F_k with increasing k. Since interactions probably occur with other electron configurations (but not much more in the aquo ions than in the gaseous ions), the theory has always an uncertainty between 500 and 2 000 K of the baricenter of a given multiplet. On the other hand, it does not usually predict a multiplet 5 000 K in error.

It is hoped that this treatment may aid the future identification work, as J of a few levels of Ho(III) and Er(III) recently have been reported [25]. Especially the ultraviolet regions have been very little studied by more refined methods. It must be admitted that the determination of J of the individual levels is not yet completed, even in the much studied Nd(III) (the present author is inclined to believe that the groups at 680 and 630 mμ are caused by $^2H_{9/2}$ and $^2H_{11/2}$, respectively, and that the low J-values of ^4G must be dispersed in an irregular way between the stronger quartet bands of this ion). The intentions of ligand field studies of lanthanide salts at low temperature [26, 27] are very admirable, but they seem to be more fruitful when connected with the general theory of multiplet distribution in the f^n-systems.

EXPERIMENTAL

0.5 g Dy_2O_3 was dissolved by boiling with a slight excess of 2 M $HClO_4$ and measured in 2 cm silica cells. In the same way, 0.3 g Ho_2O_3 and 0.3 g Er_2O_3 were measured in1 cm silica cells. The purity of the rare earths is better than 99.9 %. The spectra were measured twice (in opposite directions) at the lowest possible rate of dispersion change, *viz.* 1.25 mμ per division (0.83 cm of paper) in the visible and 0.5 mμ in the ultraviolet. No attempt was made to compare with $HClO_4$ in the double-beam Cary spectrophotometer 11 MS-50; rather, water was placed in the reference cell, and 2 M $HClO_4$ later measured against this water in order to evade spurious behaviour of the multipots.

Acknowledgement. I am grateful to Professor F. H. Spedding, Iowa State College, Ames, for the supply of the pure rare earths.

Electroorganic Preparations III. Polarography and Reduction of N-Nitrosamines

HENNING LUND

Leo Pharmaceutical Products, Copenhagen, Denmark

N-Nitrosamines of secondary aliphatic, heterocyclic, and aromatic amines are investigated polarographically. The formation of N-nitrosamines is used for the polarographical determination of secondary amines. The polarographic reductions of the N-nitrosamines are shown by controlled potential electrolysis to be, in acid solution a four electron reduction to the hydrazine, whereas the reduction in alkaline solution is a two electron reduction to the secondary amine with the formation of nitrous oxide.

Dimethylamine has been determined by polarography of its N-nitroso derivative [1,2], but no polarographic investigation of other N-nitrosamines has been reported. N-Nitroso phenylhydroxylamine has been investigated by Kolthoff and Liberty [3]. As there might be a possibility to determine secondary amines in the presence of primary and tertiary amines by polarography of their N-nitrosamines a polarographic investigation of N-nitrosamines was undertaken. The course of the reduction of the N-nitrosamines at a macro mercury electrode was proved by means of controlled potential electrolysis.

POLAROGRAPHIC INVESTIGATION

Effect of pH on half-wave potentials. In Table 1 are compiled the half-wave potentials and diffusion currents of N-nitroso dimethylamine (I), N,N'-dinitroso piperazine (II), N-nitroso morpholine (III), N-nitroso N-methylaniline (IV), and N-nitroso diphenylamine (V) at different pH-values.

The half-wave potentials of (I), (II) and (III) vary linearly with pH from pH about 0 to pH about 6. The slopes of the $E_{\frac{1}{2}}$ *vs* pH plots in this pH interval were 0.100, 0.097 and 0.098 V per pH-unit for (I), (II) and (III), respectively. At pH-values higher than about 7 the half-wave potentials were independent of pH. The half-wave potentials of (IV) vary from pH 1 to pH 7 linearly with pH with a slope of 0.082 and are independent of pH at higher pH-values. At pH-values lower than 1 the half-wave potentials are less negative than required

Table 1. Half-wave potentials (*vs* S.C.E.) and diffusion currents at different pH-values of N-nitroso dimethylamine (I), N,N'-dinitroso piperazine (II), N-nitroso morpholine (III), N-nitroso N-methylaniline (IV), and N-nitroso diphenylamine (V). Concentration 1.00×10^{-3} M, 0.01 % gelatin added as maximum suppressor.

× No wave § Poorly defined wave

by the straight line in the $E_{\frac{1}{2}}$ *vs* pH plot. The half-wave potentials of (V) vary linearly with pH at pH values lower than 1 with a slope of 0.130 V per pH-unit. From pH about 2 to pH about 7 the slope of the $E_{\frac{1}{2}}$ *vs* pH plot is 0.063 and at pH-values higher than 8 the half-wave potentials are independent of pH.

In Table 2 are given the half-wave potentials and diffusion currents at different pH-values for *p*-nitroso N,N-dimethylaniline. The half-wave potentials vary linearly with pH in the examined pH interval with a slope of 0.068 V per pH-unit.

Effect of pH on diffusion current. The diffusion currents are for the N-nitrosamines fairly constant from pH 0 to pH about 5. In an interval around pH 7 the diffusion currents drop to a value which is half the value in acid solution. At pH-values higher than about 9 the diffusion currents again are fairly independent of pH. As shown in Fig. 1 the plot of the diffusion current *vs* pH has its highest slope at the same pH as that, at which the half-wave potentials start to be independent of pH. The diffusion currents of *p*-nitroso N,N-dimethylaniline are fairly constant in the examined pH-interval and have

Table 2. Half-wave potentials (*vs* S.C.E.) and diffusion currents at different pH-values of *p*-nitroso N,N-dimethylaniline. Concentration 1.0×10^{-3} M, 0.01 % gelatin added as maximum suppressor.

a value nearly equal to the value of the diffusion current of N-nitroso N-methylaniline in acid solution.

Effect of mercury height on limiting current. The data presented in Table 3 for limiting currents of N-nitroso dimethylamine and N-nitroso diphenylamine at different mercury column heights indicate that the limiting currents both in acid and alkaline solution are diffusion controlled. A diffusion controlled limiting current is nearly proportional to the square root of the corrected mercury column height and it is seen in Table 3 that $i_d/h^{1/2}$ is fairly constant.

Variation of diffusion currents with concentration. The variation of diffusion currents with concentration is substantially linear for the compounds between 1.5×10^{-4} and 2×10^{-3} M. At higher concentrations there is a slight negative deviation.

Wave form. The waves of N-nitroso dimethylamine, N,N'-dinitroso piperazine, and N-nitroso morpholine are somewhat drawn out whereas those of

N-nitroso N-methylaniline and N-nitroso diphenylamine more approach the form of a reversible wave. None of them are, however, reversible. The plots of log $(i/i_d—i)$ *vs* the electrode potential at pH about 1 yield straight lines for N-nitroso N-methylaniline and N-nitroso diphenylamine with the slopes of 0.068 and 0.047, respectively. For N-nitroso dimethylamine, N,N'-dinitroso piperazine, and N-nitroso morpholine the first part of the waves yield a straight line with the slopes of 0.080, 0.125 and 0.115, respectively, whereas the second part of the waves yield a curve which deviates from the straight line corresponding to a drawn out wave. As a reversible one-electron reduction would yield a straight line with the slope of 0.059 the slope of N-nitroso diphenylamine 0.047 suggests that more than one electron is involved in the potential determining step.

Discussion. The half-wave potentials depend upon the structure in a manner which was to be expected. The introduction of a phenyl group lowers the half-wave potential, but at the same time both the form of the wave and the dependence of the half-wave potential upon pH approach the behaviour of a reversible reduction. This is probably due to the increased resonance possibilities of the primarily formed radical present when a phenyl group participates in the resonance system.

The polarographic analysis shows that the electrode reaction in acid solution involves twice as many electrons as the electrode reaction in alkaline solution as the limiting currents are twice as high in acid as in alkaline solution and both of them are diffusion controlled. This would be in accordance with the assumption that the reduction in acid solution yielded the hydrazine and in alkaline solution either the tetrazene or the amine and nitrous oxide. It seems reasonable to assume that in acid solution it is the protonated nitrosamine $RR'N—NOH^+$ which is reduced whereas the free nitrosamine is reduced in alkaline solution. This is consistent with the fact that the half-wave potentials in alkaline solution are independent of pH, whereas they in acid solution have a linear dependence upon pH. It seems necessary to assume the reduction of a doubly protonated molecule $(C_6H_5)_2NH^+—N=OH^+$ in order to explain the behaviour of N-nitroso diphenylamine in strongly acid solution, where the half-wave potentials are dependent upon the square of the hydrogen ion concentration. A similar pH dependence was found [3] for N-nitroso phenylhydroxylamine. The electrode reaction of N-nitroso diphenylamine in strong acid solution is a four electron reduction.

The reduction of *p*-nitroso N,N-dimethylaniline requires the same number of electrons in acid and alkaline solution, whereas the reduction of N-nitroso phenylhydroxylamine in acid solution involves six electrons and in alkaline solution four electrons [3]. The polarographic behaviour of N-nitrosamines, N-nitroso phenylhydroxylamine, and *p*-nitroso N,N-dimethylaniline is thus different.

ANALYTICAL INVESTIGATION

English [2] found that methylamine on reaction with nitrous acid in strong acetic acid yielded some nitromethane which interfered with the determination of dimethylamine. Trimethylamine in high concentration yielded some N-nitroso dimethylamine under the same conditions.

Using the procedure described below only negligible side reactions took place for the following primary amines: methylamine, ethylamine, and *cyclo*-hexylamine. Trimethylamine was nitrosated to some extent, whereas triethylamine was only slightly attacked and N-ethylpiperidine reacted only to a slight degree with nitrous acid when the concentration of the tertiary amine was less than 5×10^{-3} M in the final solution.

Primary aromatic amines form diazonium compounds on reaction with nitrous acid and these [4] or their coupling products are reducible at potentials in the neighbourhood of those of secondary nitrosamines. Tertiary aromatic amines form *p*-nitroso compounds on reaction with nitrous acid and these are reducible at potentials lower than those of N-nitrosamines. High concentrations of primary and tertiary aromatic amines will thus make a determination of secondary amines difficult.

In a mixture containing secondary aromatic and aliphatic amines it is possible to determine both kinds of amines as there is a difference of more than 0.2 volt between the half-wave potentials of the nitrosamines of secondary aromatic and aliphatic amines.

Nitrosation of amines. Attempts to nitrosate amines in dilute hydrochloric acid with excess of sodium nitrite were successful for amines as diphenylamine and N-methylaniline, whereas diethylamine and piperidine did not yield the nitrosamines under these conditions. Morpholine and diethanolamine yielded some nitrosamine but the yield was not quantitative. As it apparently was the weak bases which reacted with nitrous acid under acid conditions it was tried to nitrosate the strong amines at higher pH-values. It was found that in an acetate buffer, pH about 4, all the amines tried gave quantitative yields of the nitrosamines.

Procedure. For the quantitative determination of secondary amines the following procedure was found suitable. To 1.00 ml of an amine solution containing about 1 mg of the amine is added 1 ml of acetate buffer (10 ml glacial acetic acid + 10 ml 2 N NaOH + 80 ml water) and 1 ml 20 % aqueous sodium nitrite (prepared daily). The mixture is warmed for about 15 min in a water bath at 80°. After cooling there is added 1 ml 4 N HCl, 5 ml saturated potassium chloride solution, 5 ml ethanol and 1 ml of an aqueous 5 % ammonium sulfamate solution and the volume is adjusted to 25.0 ml. This is quantitatively transferred to the polarographic cell and purified nitrogen is bubbled through for 10 min. At the end of that time the last traces of nitrite are destroyed by adding 1.00 ml 5 % ammonium sulfamate solution and the solution is polarographed.

By using this procedure a linear connection between wave height and concentration (from about 2×10^{-4} to about 4×10^{-3} M) was found for the following amines: diphenylamine, N-methylaniline, diethylamine, piperidine, piperazine, morpholine and diethanol amine.

As mentioned above high concentrations of aromatic amines will invalidate the results. The same is the case with ethylene diamine. The reason is probably that ethylene diamine forms ethylene oxide on treatment with nitrous acid [5]. The ethylene oxide reacts with excess of nitrous acid [6] or nitrogen dioxide [7] with the formation of nitroethanol [6] or nitroethanol nitrate [7] which is reduced at about the same potential as aliphatic nitrosamines.

PREPARATIVE REDUCTIONS

Preparative reductions at controlled potential at a macro mercury electrode have been used to prove the course of the polarographic reduction. It was found that the N-nitrosamines at pH 1 and 5 yielded the corresponding unsymmetric hydrazine by a four electron reduction in isolated yields of about 80 %. No other reduction products were isolated.

$$RR'N-N=OH^+ + 4\,e^- + 4\,H^+ \rightarrow RR'N-NH_3^+ + 2\,H_2O$$

In alkaline solution the reduction consumed two electrons per molecule and the secondary amine was isolated in high yield. Besides nitrous acid could be isolated.

$$2\,RR'N-N=O + 4\,e^- + 3\,H_2O \rightarrow 2\,RR'NH + N_2O + 4\,OH^-$$

The course of the reductions is not surprising in view of the facts that the nitrosamines in acid solution by chemical reduction mostly yield the hydrazines and that as found by Schueler and Hanna [8] N-nitroso diphenylamine by reduction with $LiAlH_4$ yielded diphenylamine as the main product.

EXPERIMENTAL

The polarograph was a recording polarograph Radiometer Type PO 3a. The capillary delivered 2.346 mg of mercury per second at a corrected mercury column height of 48.5 cm; the drop time t = 3.12 sec (20 % alcohol, 1 N KCl, open circuit); the capillary constant $m^{2/3}t^{1/6}$ = 2.14 $mg^{2/3}\,sec^{-\frac{1}{2}}$.

The reference electrode was a silver/silver chloride electrode in aqueous saturated KCl solution separated from the test solution with an agar plug and a fritted glass diaphragm. The reference electrode was measured against the saturated calomel electrode (S.C.E.).

The cell and circuit used for the controlled potential reductions was the same as used in part I[9]. The coulometer was an oxygen-hydrogen coulometer adapted from Lingane [10].

To the polarographic investigation was used a medium consisting of 1 M KCl in 20 % aqueous ethanol. The buffer solutions were the same as used in part I. The nitrosamines were prepared according to wellknown procedures. The compounds were distilled or recrystallized before use. The solvents and reagents were analytical grade.

Reduction of N-nitroso diphenylamine in acetate buffer. 1.0 g of N-nitroso diphenylamine was dissolved in 120 ml methanolic 2 N LiCl + 10 ml glacial acetic acid + 15 ml aqueous 2 N LiOH. The nitrosamine was reduced at a cathode potential of −1.05 V (*vs.* S.C.E.) with an initial current of 0.4 A. The reduction was followed polarographically. In the coulometer were evolved 385 ml (22°, 760 mm) corresponding to a consumption of 4 electrons per molecule. After completion of the reduction the reaction mixture was diluted with water, made alkaline and extracted several times with ether which was dried over potassium carbonate. To the ether was added alcoholic hydrogen chloride and the precipitate (980 mg) was recrystallized from alcohol-ether (870 mg 78 %). (Found: C 65.25; H 6.00; N 12.55; Cl 15.99. Calc. for $C_{12}H_{13}N_2Cl$: C 65.31; H 5.93; N 12.70; Cl 16.06). The compound was identified as unsymmetric diphenylhydrazine hydrochloride by its analysis.

Reduction of N-nitroso diphenylamine in alkaline solution. 4.0 g of N-nitroso diphenylamine was dissolved in 140 ml methanolic 2 N LiCl + 15 ml methanolic 1 N LiOH and reduced at −1.15 V *vs* S.C.E. The initial current was 0.3 A, 540 ml $O_2 + H_2$ were evolved (23°, 756 mm) corresponding to a consumption of 2 electrons per molecule. When the reduction was completed the reaction medium was diluted with water and the precipitate filtered off. The mother liquor was extracted with ether, which was dried and evaporated.

The precipitate and the residue (3.15 g) were recrystallized from dilute ethanol yielding 2.80 g (82 %) of a compound which was identified as diphenylamine by its m.p. 50–51° (53°), its analysis (Found: C 85.08; H 6.78; N 8.09. Calc. for $C_{12}H_{11}N$: C 85.17; H 6.55; N 8.28) and the analysis of the hydrochloride (Found: C 70.13; H 5.86; N 6.80; Cl 17.26. Calc. for $C_{12}H_{12}NCl$: C 70.14; H 5.89; N 6.82; Cl 17.25).

Reduction of N-nitroso morpholine. 7.0 g of N-nitroso morpholine was dissolved in 150 ml aqueous 2 N potassium chloride and 10 ml 2 N sodium hydroxide. The cathode chamber was deaerated with purified nitrogen and a slow current of nitrogen was passed through the solution during the reduction. After bubbling through the catholyte the nitrogen passed through a wash bottle immersed in an acetone-carbon dioxide cooling bath, then through a cold finger immersed in boiling nitrogen and finally through a solution of ferrous sulfate. The reduction was conducted at a cathode potential of −1.30 V with an initial current of 1.2 A. After completion of the reduction the cooling of the cold finger with boiling nitrogen was stopped. The cold finger contained a white solid which disappeared rapidly when not cooled in boiling nitrogen. No colour was detected in the ferrous sulfate solution. The white solid was identified as nitrous oxide by the following facts: Its m.p. and b.p. were between −80° and −200° (N_2O has b.p. −88° and m.p. −102°), it was colourless and did not react with ferrous sulfate.

The reaction mixture was saturated with potassium hydroxide and repeatedly extracted with ether. The ether was dried with potassium carbonate. On addition of alcoholic hydrogen chloride a precipitate, 3.9 g, was obtained. It was identified as morpholine hydrochloride by its analysis. (Found: C 39.09; H 8.30; N 11.24; Cl 28.69. Calc. for $C_4H_{10}NOCl$: C 38.87; H 8.16; N 11.33; Cl 28.68).

The Sterols of Coconut Oil

BENT ANDERSEN and BØRGE KRAWACK

Aarhus Oliefabrik A/S, Århus, Denmark

The investigations were first and foremost carried out on sterols from the pitch, which is produced at the distilling of coconut fatty acids ("pitchsterols"), but in addition a preliminary investigation has been made on sterols extracted from crude coconut oil ("crude oil sterols").

For the separation of the sterol mixtures was used fractional crystallization from ethyl ether, ethanol-hexane mixture or propanol, and as a measure for the separation was used the consumption of bromine according to Rosenmund-Kuhnhenn.

In the pitch sterols, the presence of α-spinasterol, stigmasterol, β-sitosterol, and fucosterol was proved. No pure compound was isolated from the crude oil sterols, but it contained in addition to the four sterols found in the pitch one sterol with conjugated double bonds in the 5,7-position and one sterol with a 7-double bond.

In search for raw materials for the production of steroide hormons it was found that coconut oil sterols had a comparatively high content of sterols with more than one double bond. As the literature only contained one statement about coconut sterols, namely that they contain stigmasterol [1], an investigation was made, which may not have solved all problems, but which does give a fairly comprehensive account of the composition of this complicated mixture.

The coconut sterols were obtained from the fatty pitch which results from the distillation of the soap-stock fatty acids from the refining of coconut oil. These sterols will be referred to as "pitch sterols". Besides, a preliminary investigation has been made on sterols from crude coconut oil ("crude oil sterols").

For an initial characterization of the two kinds of sterols, the following determinations were made:

1. By saponification of the acetate, the average molecular weight of the pitch sterols was determined as 414 (29 carbon atoms).

2. On quantitative hydrogenation of the pitch sterols, 1.31 moles H_2 per mole sterol were consumed, which means that there is 31 % sterol with two hydrogenatable double bonds. In the same way the crude oil sterols were found to contain 36 % sterols with two hydrogenatable double bonds.

3. On bromination according to Rosenmund-Kuhnhenn [2], 1.53 moles bromine per mole pitch sterol and 1.84 moles bromine per mole crude oil sterol were consumed. This means that substitution takes place at the brominations, and that sterols with non-hydrogenatable double bonds may occur.

4. Idler and Baumann's modified Lieberman-Burchard reaction [3] shows that the pitch sterols contain 3 %, and the crude oil sterols 10 % sterol with a double bond at carbon atom No. 7.

5. The pitch sterols have only a negligible absorption in the ultraviolet region down to 2 500 Å, so that sterols with conjugated double bonds cannot occur. The crude oil sterols, on the other hand, have their absorption maxima at 2 930, 2 820, and 2 715 Å, which is characteristic of sterols with conjugated double bonds in the 5,7 position [4]. The intensities of the maxima indicate 4.5 % sterol of this kind.

6. Addition of bromine to the acetate of the pitch sterols according to Windaus and Haut [5] produced a precipitate corresponding to 18—20 % stigmasterol in the pitch sterols. This precipitate, however, was a mixture, and only after a fractional crystallization from ethanol, pure tetrabromostigmasteryl acetate was obtained in a quantity corresponding to 4—8 % stigmasterol in the pitch sterol. Some derivates of stigmasterol have been prepared, and their melting points and specific rotations are compared with values from the literature (Table 1).

THE PITCH STEROLS

The pitch sterols were further investigated by fractional crystallization. A number of solvents was examined for their fractionating power, the change in the consumption of bromine after one re-crystallization being used as the criterion. Ethyl ether proved to be the best, but considerable fractionation was also obtained from a mixture consisting of equal portions of 96 % ethanol and hexane, and from *n*-propanol.

The fractional crystallization was performed in the usual way [6]. So much solvent was used that about half the quantity of substance was crystallized off each time. First ethyl ether was applied, and after 10 series of crystallizations, the least soluble component, fraction A, was found to consume 3.10 moles bromine per mole sterol, whereas the most soluble component, fraction B, consumed 1.25 moles bromine. Further crystallization from ether brought no alteration in these values.

Fraction A could not be separated into its constituents by crystallization as sterol or acetate. From the benzoate pure stigmasteryl benzoate was isolated by crystallization from a mixture of chloroform and ethanol, while other components could not be isolated.

Eventually the separation was successful by fractional crystallization of the ketone (Oppenauer-oxidation [7]) from ethanol, and pure α-spinastadienone was isolated as the less soluble and stigmastadienone as the more soluble component.

Fraction A, then, is a mixture of α-spinasterol and stigmasterol, and a quantitative hydrogenation shows that it consists of 70 % stigmasterol and 30 % α-spinasterol, the 7-double bond not being hydrogenated. The optical rotation of sterol, acetate, and benzoate, is in accordance with this (Table 1).

* Calculated for 30 % α-spinasterol and 70 % stigmasterol.

Fraction B consumed 1.25 moles bromine per mole sterol ,and as mentioned above, fractional crystallization from ethyl ether gave no further separation. But by a great number of fractional crystallizations from a mixture of ethanol and hexane (1:1), the following four main fractions were obtained: B 1 consuming 1.50, B 2 1.17, B 3 1.65, and B 4 1.50 moles bromine per mole sterol.

In fraction B 1 stigmasterol and α-spinasterol have again been concentrated.

Fraction B 2 was exposed to fractional crystallization from *n*-propanol, and it was possible to reduce the consumption of bromine to 1.08 moles per mole, which figure was also found on quantitative hydrogenation. Although, then, the substance is not entirely pure, melting points and optical rotations of sterol, acetate, and benzoate show that it is β-sitosterol (Table 1).

Fraction B 3 could not be further separated. Attempts were made with several other solvents and with fractional crystallization of ketone and benzoate; but in no case could a pure substance be isolated.

As mentioned above, the fraction B 3 consumes 1.65 moles bromine per mole sterol, and the same value is found on a quantitative hydrogenation, so that the mixture must consist of 35 % of a sterol with one double bond and 65 % of a sterol with two double bonds.

On ozonizing according to Mac Phillamy [8] acetaldehyde was isolated as carboxyphenylhydrazone and as 2,4-dinitrophenylhydrazone, the latter in a yield corresponding to 32 % of the available quantity of sterol with two double bonds.

On ozonizing the acetate according to Idler and Fagerlund [9] acetaldehyde was again obtained as 2,4-dinitrophenylhydrazone, while the non-volatile portion was chromatographed on a mixture of celite and silicagel, as described by Idler and Fagerlund. Unreacted sterol was eluted with benzene, after which a ketone was eluted with a mixture of benzene and chloroform (4:1 by volume).

Melting point and optical rotation of this ketone, as well as the melting point of the 2,4-dinitrophenylhydrazone showed that the ketone was 24-ketocholesterylacetate, whereby the easily soluble component with 2 double bonds has been identified as fucosterol.

Fraction B 4 is slightly yellow, indicating that it contains decomposition products of the sterols. In the ultraviolet absorption curve of the fraction there is an obvious maximum at 2 400 Å, whereas all the other fractions here have only a faint shoulder on the absorption curve rising steeply towards the absorption maximum of the isolated double bonds at 2 050 Å.

The maximum at 2 400 Å is no doubt caused by a conjugated system of C = C and C = O-double bonds, a ketone group at the allylic 7-carbon atom constituting such a system with the C-5-double bond This theory is in accordance with Bergström and Wintersteiner [10] who have shown that by oxidation of a colloid solution of cholesterol with oxygene, the 7-keto compound is actually produced, this compound having its absorption maximum at 2 400 Å.

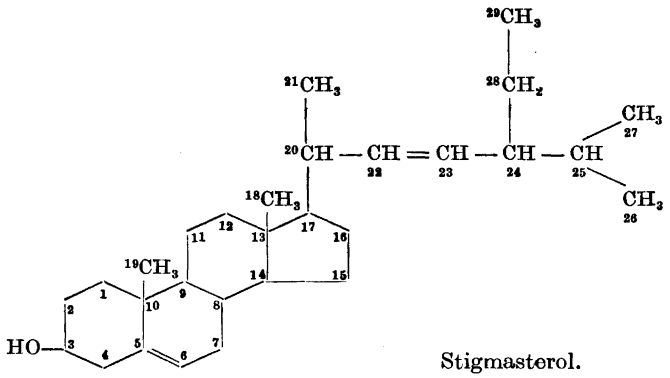
Fraction B 4 consumes less bromine than fraction B 3, and this is due to the fact that the conjugated system is more stable than the isolated double bond. Thus cholestenone, which has a conjugated system analogous with the 7-ketosterols, consumes only approximately 25 % of the theoretical quantity of bromine at the Rosenmund-Kuhnhenn-bromination.

As will be mentioned later the more soluble fractions of the crude oil sterols contain sterols with a double bond at C-7, but no evidence of such sterols was found in fraction B 4 from the pitch sterols.

Consequently, fraction B 4 is supposed to consist of the same sterols as fraction B 3, but contaminated by 7-ketosterols formed during the many crystallizations.

Hence, the structure of the pitch sterols must be as shown in Table 2, the percentages being rather uncertain.

THE CRUDE OIL STEROLS



The attempt at isolating pure substances from the crude oil sterols was unsuccessful, but it is, however, possible to indicate their composition with some accuracy.

On fractional crystallization from ethanol-hexane mixture (1:1) the sterol with conjugated double bonds was concentrated in the least soluble fractions, together with stigmasterol and possibly α-spinasterol. A quantitative hydrogenation showed that the conjugated sterol has 2 hydrogenatable double bonds. Hence, there is some reason to presume that it is $\Delta^{5,7,22}$-stigmastatrienol.

At the fractional crystallization an additional series of fractions of medium solubility was obtained, probably consisting of fucosterol and β-sitosterol, and, finally, an easily soluble fraction, which shows strong substitution at bromination. Presumably it contains a Δ^{7}-stenol, analogous with Fieser's lathosterol [11], which is also concentrated in the more soluble fractions.

Hence, the composition of the crude oil sterols can be as indicated in Table 2.

When the composition of the two kinds of sterols is compared, it is seen that the sterol with the conjugated double bonds has been totally destroyed

Stigmasterol.

All the sterols from coconut oil are derivatives of stigmasterol.

Table 2. The composition of the sterols from coconut oil.

	Double bonds	Pitch Sterols, %		Crude Oil Sterols, %	
Stigmastatrienol	5, 7, 22	0		4.5	
Stigmasterol	5, 22	6—10	31		31.5
Fucosterol	5, 24 (28)	20—25			
α-Spinasterol	7, 22	3			6.0
Stenol	7	0			
β-Sitosterol	5	66		58.0	

at the high temperature during the distillation of the fatty acids, whereas the quantity of sterols with an isolated double bond at C-7 has been considerably reduced. On the other hand, the ratio of the quantity of β-sitosterol to the total quantities of stigmasterol and fucosterol has not been substantially changed.

EXPERIMENTAL

The melting points were determined on Kofler Heizbank and optical rotations in 1 dm macro tubes (about 0.2 g in 10.0 ml chloroform). U.V.spectra were measured on a Beckman model DU instrument.

To obtain the pitch sterols, the pitch, which contained 15—30 % unsaponifiable matter, was saponified with alcoholic KOH and extracted with hexane. After the distilling of the hexane a viscous, dark brown substance containing 50—70 % sterol was obtained. By re-crystallization from a mixture consisting of equal portions of hexane and ethanol, the pitch sterols were obtained as a yellowish product, and it was difficult to obtain perfectly white crystals. Accordingly, the yield was only 50—60 % of the sterols in the pitch.

From crude coconut oil 0.17 % unsaponifiable matter was obtained, and from this again 30 % sterol.

Bromination according to Rosenmund-Kuhnhenn was carried out according to *Handbuch der Lebensmittelchemie* [2]. Surplus of bromide (15—25 %) was titrated iodometrically. The transformation into acetate, recommended by B.I.O.S.[12] was found unnecessary.

Benzoates and acetates were prepared by the usual methods. The yields were 90—95 % of theory. Derivatives of fraction A were only re-crystallized once in order to avoid

fractionation, while pure substances were re-crystallized until the melting points remained constant.

Quantitative hydrogenations were carried out in an apparatus which was a modification of the apparatus of Prater and Haagen-Smit [13], and of Savacol and Ullyot [14].

Derivatives of fucosterol: 2,4-dinitrophenylhydrazone of acetaldehyde m.p. 162—64° (lit. value [21] 163.5—64.5°); *p*-carboxyphenylhydrazone of acetaldehyde m.p. 209—10° (210—11°). Molecular weight found [22] 178 and 186 (theoretical 178). 24-Ketocholesteryl-acetate m.p. 126.5°, $[\alpha]_D$ −42° (lit. value [9] 126—27° and −43°). 2,4-Dinitrophenylhydrazone of 24-ketocholesterylacetate m.p. 169° (lit. value [9] 170°).

Acid-soluble Nucleotides of the Earthworm (*Lumbricus terrestris*)

ROY NILSSON

Department of Zoophysiology, University of Lund, Sweden

The acid-soluble nucleotides of the body wall musculature of the earthworm have been analysed by chromatographic methods. The following nucleotides were identified:* AMP, ADP, ATP, ADPR, DPN, IMP, GMP, GDP, GTP, UMP, UTP and CTP. The identifications are based on elution positions in ion-exchange, paper chromatography before and after hydrolysis, ultraviolet absorption spectra and estimation of the phosphorus, pentose and base contents. Two fractions, a CMP derivative and an UDP derivative containing ninhydrin-positive components have not been fully identified.

In recent years the isolation of ATP from muscle [1,2] has been supplemented by the isolation of further nucleoside polyphosphates. It was shown [3,4] that the muscle of vertebrates contains beside AMP, ADP and ATP, the corresponding derivatives of guanosine, uridine and cytidine. In the muscle of invertebrates, however, only adenosine nucleotides have hitherto been demonstrated [5–8]. An investigation of the acid-soluble nucleotides in invertebrate material was therefore undertaken. The earthworm is a suitable object for such work as it has a well defined body wall musculature which is easy to handle, and furthermore it is easy to obtain large numbers of the animal. In the present work, therefore, earthworm was chosen for the analysis of the acid-soluble nucleotides of invertebrate muscle.

* AMP = adenosinemonophosphate
ADP = adenosinediphosphate
ATP = adenosinetriphosphate
ADPR = adenosinediphosphoribose
DPN = diphosphopyridine nucleotide
IMP = inosinemonophosphate
GMP = guanosinemonophosphate
GDP = guanosinediphosphate
GTP = guanosinetriphosphate
UMP = uridinemonophosphate
UTP = uridinetriphosphate
CTP = cytidinetriphosphate

MATERIAL AND METHODS

Preparation of trichloroacetic acid extract. The earthworm species *Lumbricus terrestris* was used and the animals were handled immediately after collection. Before extraction the animals were dipped into cold alcohol (−60°C) for a few seconds. They could then easily be gutted, and the muscle was immersed into cold alcohol. After enough tissue had been collected (usually 100−125 g) it was homogenized with one volume of ice-cold 10 % trichloroacetic acid in a Turmix blendor and pressed through madapolam. The extraction was repeated three times with 5 % trichloroacetic acid and the combined extracts filtered through Hyflo Supercel. The filtrate was shaken six times with ether to remove the bulk of the trichloroacetic acid, neutralized with a drop of ammonia and freed from ether by aeration. The protein free extract thus obtained was used for phosphorus analysis and paper chromatography.

The crude extract could also be used directly for ion-exchange chromatography. The presence of non-nucleotide constituents (amino acids etc.) results, however, in high background absorption and impairs on the separation and quantitative analysis of the smaller nucleotide fractions. These disadvantages could be avoided by treatment of the extract with norite prior to chromatography.

Purification of the nucleotide fraction by the norite method. The extract containing the nucleotides was acidified with hydrochloric acid to pH 1 and shaken for 30 min with an appropriate amount of norite. After filtration the norite was washed free from acid and sucked dry. The nucleotides were eluted with 50 % ethanol containing 1 % ammonia. In order to obtain a quantitative yield several elutions were necessary. Table 1 shows the nucleotide content of consecutive eluates as measured by ultraviolet absorption at 260 mμ. No differences in the type of ultraviolet absorption were seen between the first and the seventh eluate (Fig. 1).

Ion-exchange chromatography. Dowex-1 (200−400 mesh) in the formate form was used and elution was carried out with a modification of the formate system used by Bergkvist and Deutsch [9]. Fractions were collected by a time-operated fraction collector and every fraction was read at 250, 260 and 270 mμ in a Beckman DU spectrophotometer. Appropriate fractions were pooled and the nucleotides concentrated by the norite method.

Paper chromatography. Two dimensional chromatography [10] was used to resolve the nucleotides in the crude trichloroacetic acid extract, with *n*-propanol-ammonia (*d* 0.880)-water (60:30:10) in the first direction and saturated ammonium sulphate solution-water-*iso*propanol (79:19:2) in the second.

One dimensional chromatography in *iso*propanol-hydrochloric acid-water (97:25:28) was used for the separation of the products obtained on hydrolysis of the different nucleotide fractions from ion-exchange chromatography. Hydrolysis was carried out in N hydrochloric acid for one hour at 100 °C.

For determination of the individual nucleotides before hydrolysis the fractions were run in the *n*-propanol-ammonia-water system, together with the authentic substances.

Descending chromatography on Whatman No. 1 paper was used throughout and the spots on the finished chromatogram were located by ultraviolet photography.

For quantitative estimations, the spots were cut out together with blank areas and eluted with 0.1 N hydrochloric acid over night; the eluates were used for ultraviolet spectrophotometry and phosphorus analysis.

Analytical procedures. Phosphorus was determined by the method of Allen [11] using a Klett Summerson photoelectric colorimeter with a red filter and was differentiated in

Table 1. Elution of nucleotides from norite. Elution with 50 % ethanol containing 1 % ammonia. Every eluate *ca* 6 ml.

Elution-number	1	2	3	4	5	6	7
ΣE_{260}	1 485	909	455	241	153	109	56

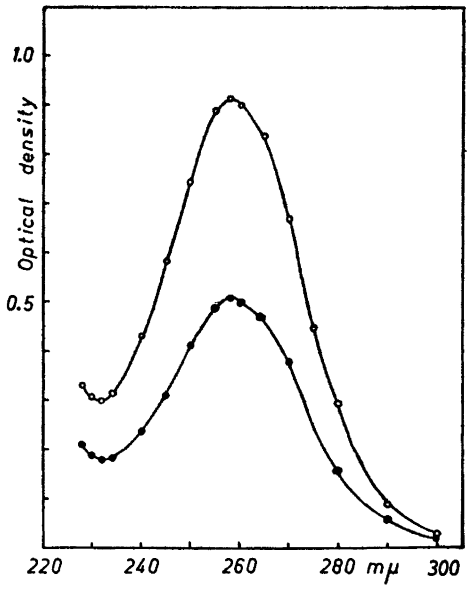

Fig. 1. Ultraviolet absorption curves for norite-eluates. O—O—O Eluate No. 1. 10 μl eluate + 3.0 ml 0.1 M hydrochloric acid. ●—●—● Eluate No. 7. 150 μl eluate + 3.0 ml 0.1 M hydrochloric acid.

separate analyses into total phosphorus (P_T) inorganic phosphorus (P_i) and acid-labile phosphorus (P_{10}) determined after 10 min hydrolysis in N hydrochloric acid at 100°C.

Pentose was determined by the method of Mejbaum as modified by Albaum and Umbreit [12]. A Klett Summerson photoelectric colorimeter was used with a red filter.

Optical densities were measured in a Beckman Universal Spectrophotometer Model DU in 0.1 N hydrochloric acid, the molecular extinction coefficients of 14 200 at 260 mμ for adenosine phosphates, 13 200 at 250 mμ for inosine phosphates, 10 850 at 256 mμ for guanosine phosphates, 10 050 at 262 mμ for uridine phosphates and 13 000 at 280 mμ for cytidine phosphates, being used.

Cyanide complex formation for the identification of DPN was carried out in M NaCN according to Colowick, Kaplan and Ciotti [13], using the increase in absorption at 325 mμ as a measure for N-substituted nicotinamide derivatives.

Oxidation with periodate for the estimation of 5′-substitution was carried out by the method of Dixon and Lipkin [14].

(1) GTP, (2) ATP, (3) ADP, (4) AMP, (5) uridinederivative.

RESULTS

Phosphorus analysis of the trichloroacetic acid extract showed that *Lumbricus* muscle contains considerable quantities of acid-soluble phosphorus both as inorganic phosphate and as acid-labile and acid-stable phosphates (Table 2). Nearly all acid-labile phosphate was adsorbed on norite and recovered in the norite eluate indicating that most of this phosphorus fraction consists of nucleotides. Only about one-third of the acid-stable phosphorus, however, was adsorbed on norite; the phosphate fraction not adsorbed was probably composed of lombricine [15] and of sugar phosphates. Lombricine was isolated from the norite filtrate by precipitation of the barium-salt with three volumes of alcohol and was identified as guanidoethylserylphosphoric acid by paper chromatography of the compound and its products of hydrolysis, as previously described by Thoai and Robin [15].

Paper chromatography of the hydrolysed extract (Fig. 2a) gave a large spot for adenine besides smaller spots for guanine and uridylic acid, indicating that the main ultraviolet-absorbing components of the extract before hydrolysis were adenine derivatives besides guanine- and uridine nucleotides. The slightly lower R_F-value of the uridylic acid spot as compared with that from RNA may possibly indicate the presence of 5′-derivative in the extract (Fig. 2a). Two dimensional chromatography of the unhydrolyzed extract comfirmed these results. The major components as shown by Fig. 2b were

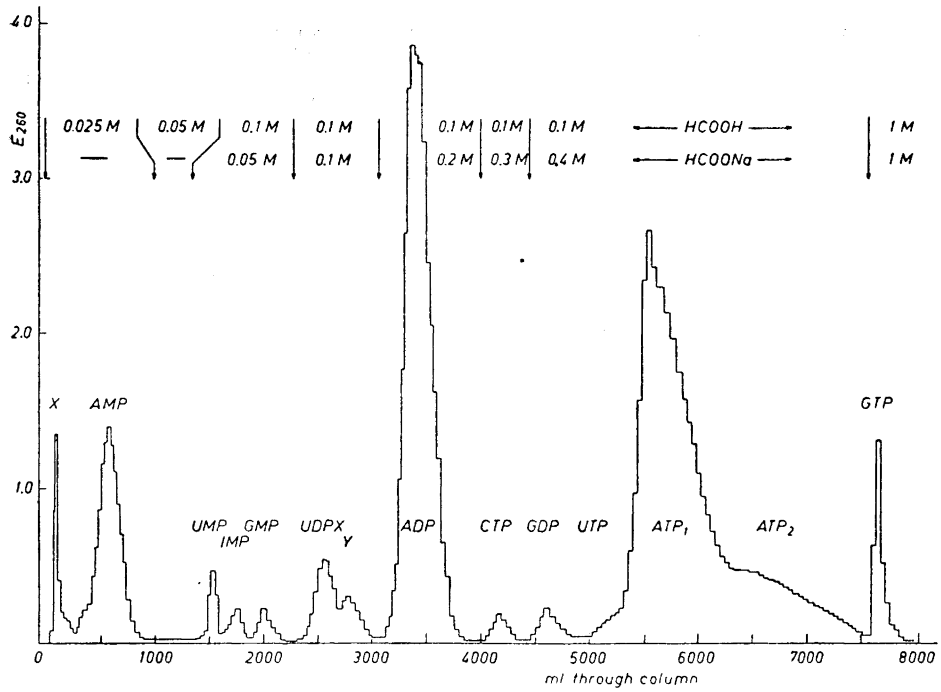

Fig. 3. Ion-exchange chromatography of a purified trichloroacetic acid extract from earthworm muscle. Dowex-1 (200–400 mesh) column, 1 cm^2 × 13 cm in the formate system. Adsorbed material: extract with optical density E_{260} = 3 900. Recovery 101 %.

ATP, ADP and AMP besides weak spots indicating the presence of other nucleotide compounds.

Paper chromatography of a complex mixture like that in the trichloroacetic acid extract, however, gave only a rough picture of the main components. For the detailed analysis of all the different nucleotides ion-exchange chromatography is the method of choice. Therefore, both the crude trichloroacetic acid extract and the purified norite-eluates were analysed by chromatography on Dowex-1 in a formate system, giving in the main the same results. However, the purified extract gave — for the reason mentioned above — the clearer separation. Fig. 3 shows the results of ion-exchange analysis of the acid-soluble nucleotides from the body wall musculature of the earthworm.

The first tentative identification of the components was made according to elution positions in ion-exchange and the ultraviolet absorption curves. For further identification, the appropriate fractions were pooled and concentrated *via* norite adsorption-elution as described above. In the next step the base components were determined by chromatography of the fractions after hydrolysis in N hydrochloric acid at 100°C for one hour. The R_F-values of the products of hydrolysis are shown in Table 3 together with those for the authentic compounds.

Table 3. R_F-values of ion-exchange fractions from earth-worm muscle after hydrolysis in N hydrochloric acid at 100 °C for one hour, compared with the R_F-values of known substances. Solvent: *iso*propanol-hydrochloric acid-water (97 : 25 : 28). Descending chromatography on Whatman No. 1 paper for 24 h.

Fraction	R_F	Marker	R_F
AMP	0.30		
Y	0.29	Adenine	0.28
ADP	0.28		
ATP_1	0.28		
ATP_2	0.29		
IMP	0.28	Hypo-xanthine	0.29
GMP	0.21		
GDP	0.21	Guanine	0.21
GTP	0.21		
		2′-UMP	
UMP	0.69	3′-	0.76
UDPX	0.69	5′-UMP	0.70
UTP	0.68		
		2′-CMP	
X	0.55	3′-	0.57
CTP	0.48	5′-CMP	0.50

As seen from the table, the nucleotides from *Lumbricus* muscle comprise derivatives of the five bases adenine, hypoxanthine, guanine, uracil and cytosine. Adenine and hypoxanthine have the same R_F-values but are easily distinguished by their different ultraviolet absorption curves. The fractions containing pyrimidine derivatives showed R_F-values corresponding to the 5′-monophosphates with the exception of fraction X. This fraction had the elution position of CMP and yields on paper chromatography after hydrolysis a spot with nearly the same R_F-value as 2′- and 3′-CMP. The ultraviolet spectrum, however, was different from that of the cytidylic acids, the absorption maximum in 0.1 N hydrochloric acid being at 270 mμ instead of around 280 mμ.

After the purine and pyrimidine components of the different nucleotides had been established, the degree of phosphorylation was determined by phosphorus analysis. The purity of the fractions was checked by paper chromatography before analysis. The propanol-ammonia-water system was used which separates the different phosphates of the same nucleoside well, and gave a further qualitative identification of the compounds. Table 4 gives the R_F-values of the different fractions in comparison with those of the authentic compounds.

With a few exceptions (fractions UDPX, X and Y) the R_F-values found are in good agreement with those expected from the elution positions in ion-exchange and the results of paper chromatography after hydrolysis.

The pure fractions were analysed for pentose, acid-labile and total phosphates. In those cases where paper chromatography indicated an impure fraction

Table 4. R_F-values of ion-exchange fractions from earthworm muscle, compared with the R_F-values of authentic substances. Solvent: propanol-ammonia-water (60 : 30 : 10). Descending chromatography on Whatman No. 1 paper (a 120 cm long strip) for 70 h.

Fraction	R_F	Marker	R_F	Fraction	R_F	Marker	R_F
AMP	0.30	AMP	0.30	GDP	0.13	—	—
ADP	0.21	ADP	0.21	GTP	0.11	GTP	0.12
ATP_1	0.17	ATP	0.17	UMP	0.23	5′-UMP	0.23
ATP_2	0.18			UDPX	0.30	—	—
Y	0.30			UTP	0.13	UTP	0.13
IMP	0.21	IMP	0.21	X	0.25	5′-CMP	0.23
GMP	0.15	GMP	0.14				

the analysis was made on the eluted spots after further purification by paper chromatography. Only purinebound pentose was determined quantitatively. The presence of pyrimidinebound pentose was detected by qualitative orcinol tests before and after treatment with bromine [16]. No quantitative data were, however, obtained. The results of the analyses are shown in Table 5.

The analytical data together with evidence both from ion-exchange and paper chromatography confirm the identifications made in Fig. 3. After hydrolysis the purine derivatives AMP, ADP, ATP, IMP, GMP, GDP and GTP gave the corresponding bases: adenine, hypoxanthine and guanine, respectively (Table 3). The state of phosphorylation was determined by paper chromatography and direct analysis (Tables 4 and 5). Furthermore, all the nucleotides were established as 5′-phosphates by periodate oxidation, which showed that the 2′- and 3′-positions of pentose were unsubstituted. On a molar base, every nucleotide consumed 0.95—0.99 moles of periodate.

The ATP-fraction appears in the ion-exchange chromatogram as a very asymmetric peak, which could indicate a heterogeneous fraction. For this reason the fraction was divided into two parts, ATP_1 and ATP_2, each of which were analysed separately. They gave, however, identical ultraviolet absorption curves, the same R_F-values on paper chromatography both before and after hydrolysis. In addition they gave the same values for acid-labile and acid-stable phosphorus, for pentose and on periodate oxidation. For these reasons both fractions were considered to be ATP.

The pyrimidine derivatives were identified as UMP, UTP and CTP as shown in Fig. 3 and Tables 3, 4 and 5. They are 5′-phosphates: on hydrolysis 5′-uridylic and 5′-cytidylic acid are formed and not the 2′- or 3′-derivatives as shown by paper chromatography.

Three fractions are not yet fully identified, namely those designed X, Y and UDPX. Fraction Y is in all probability 5'-adenosinediphosphoribose derived from DPN by degradation with alkali during elution. It contains two moles of phosphate and two moles of pentose per mole adenine and has a higher R_F-value than ADP on paper chromatography (Table 4).

The UDPX fraction was shown to be a derivative of 5′-UMP by the ultraviolet absorption curve and the R_F-value after hydrolysis which was identical

with that of 5′-UMP. Phosphorus analysis gave the uracil: acid-labile phosphate: total phosphate ratio (1:1:2) of UDP. The R_F-value of the unhydrolysed fraction in propanol-ammonia-water, however, was much higher than that of UDP indicating a derivative of UDP. On chromatography after hydrolysis in N hydrochloric acid at 100 °C for 10 min the fraction gave only one ultraviolet absorbing spot, corresponding to 5′-UMP and phosphorus spots corresponding to UMP and orthophosphate. Spraying with ninhydrin revealed a strongly positive spot which did not coincide with the ultraviolet absorbing one. The unhydrolysed fraction gave, however, only a very weak ninhydrin reaction. Spraying with carbohydrate reagents gave no definite results. Oxidation with periodate gave a consumption of 0.95 mole periodate per mole base indicating that the 2′- and 3′-positions of the ribose moiety of UDP were unsubstituted. Our results so far characterize the UDPX fraction as a 5′-UDP derivative which on hydrolysis liberates a strongly ninhydrinpositive component.

Fraction X gave one ultraviolet absorbing spot both before and after hydrolysis in N hydrochloric acid at 100 °C. The ultraviolet absorption curve

and the elution position in ion-exchange chromatography indicate the presence of a cytidine derivative. The R_F-value after hydrolysis was that of 2′- or 3′-CMP. Beside the ultraviolet absorbing spot several ninhydrinpositive components were revealed by paper chromatography of this fraction, the complexity of which hindered further identification with the small amounts hitherto available.

The same results were obtained on ion-exchange chromatography of the crude trichloroacetic acid extract as with the norite eluates. The amounts of the different nucleotides from the earthworm muscle obtained by ion-exchange chromatography of the two types of extracts are shown in Table 6. There are a few qualitative differences in the nucleotide fractions between these two types of extracts. DPN was not eluted from norite by our procedure unless degraded to adenosinediphosphoribose and was consequently not found in the norite-purified extract. From the crude extract, however, DPN was obtained in the first chromatographic fractions together with other phosphorus compounds. DPN was estimated as the cyanidecomplex according to Colowick, Kaplan and Ciotti [13]. The earthworm muscle contains 4 μmoles DPN per 100 g, calculated from the molar extinction coefficient (6×10^{-6}) for the DPN—CN complex at 325 mμ.

Fraction Y is almost lacking in the DPN containing crude extract but is present in the DPN free extract obtained after norite adsorption, in further support of the identification of fraction Y as ADP-ribose originating from DPN. 4 μmoles of fraction Y were obtained from 100 g muscle, in good agreement with the figures for the DPN content of the crude extract. Otherwise the same nucleotides are obtained in both types of extracts, as seen from Table 6.

The acid-soluble nucleotide content of the earthworm muscle shows the following general pattern: predominance of adenine nucleotides (nearly 90 %), equal amounts of guanine and uridine derivatives (about 5 % of each) and a small amount of cytidine compounds. The same pattern is shown by rabbit skeletal muscle although the absolute amount of nucleotides was about 3 times greater in the latter case.

The resemblance in nucleotide composition between these two muscles of widely different origin is not surprising since their functions are similar.

The earthworm muscle, however, can hardly be considered as true striated muscle and is — compared with vertebrate skeletal muscle — a slow working muscle, a fact which may explain the quantitative difference in the nucleotide contents.

The author wishes to thank Laborator A. Deutsch, Statens Mejeriförsök, Alnarp, for his kind advice and stimulating criticism. This work was carried out with grants from *Kungl. Fysiografiska Sällskapet i Lund* and the *Lilly Foundation.*

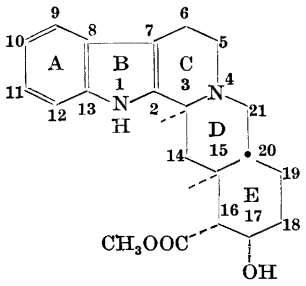
Conversion of Yohimbine into β-Yohimbine and 3-*epi*-β-Yohimbine

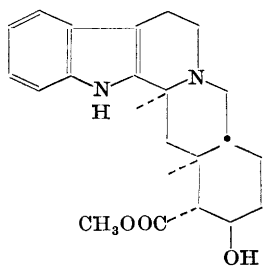
W. O. GODTFREDSEN and S. VANGEDAL

Leo Pharmaceutical Products, Copenhagen, Denmark



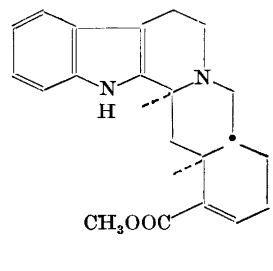
A four step conversion of yohimbine into β-yohimbine is described. Epimerization of β-yohimbine at C_3 affords a new yohimbine stereoisomer, 3-*epi*-β-yohimbine. Finally, the correlation between R_F-values and conformations of some yohimbine stereoisomers is discussed.

Three of the four possible 16-carbomethoxy-17-hydroxy-(—)-yohimbanes are known, *viz.* yohimbine, corynanthine, and β-yohimbine *.



In yohimbine (I) the 16-carbomethoxy group is equatorially and the 17-hydroxyl group axially oriented [2,3]. Corynanthine is the 16-epimer of yohimbine [4] and, consequently, β-yohimbine must contain an equatorial 17-hydroxyl group. The 16-carbomethoxy group is considered to be of equatorial conformation since β-yohimbic acid is not epimerized by prolonged treatment with alkali [5].

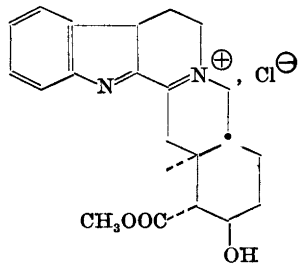
In the following, a four step conversion of yohimbine (I) into β-yohimbine (II) will be described.



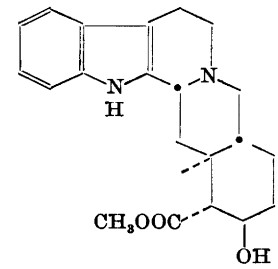
The first step, which consists in dehydration of yohimbine (I) to apoyohimbine (III), is well known [6].

I

II



III



* The fourth stereoisomer is possibly represented by the alkaloid Serpine [1].

Treatment of apoyohimbine (III) with sodium methoxide in boiling methanol causes addition of methanol to the 16,17-double bond with the formation of a 16-carbomethoxy-17-methoxy-(—)-yohimbane, which upon heating with 48 % hydrobromic acid and subsequent esterification of the resulting 16-carboxy-17-hydroxy-(—)-yohimbane with diazomethane yields β-yohimbine, identical in every respect with an authentic sample.

In a previous paper [7] the dehydrogenation of alkaloids of the yohimbine type with *tert*-butyl hypochlorite was described. When β-yohimbine (II) is dehydrogenated in this way 3-dehydro-β-yohimbine chloride (IV) is obtained in good yield.

IV

V

Reduction of this compound with zinc and 50 % acetic acid according to Weisenborn and Diassi [8] yields a mixture of β-yohimbine (II) and a new yohimbine stereoisomer, 3-*epi*-β-yohimbine (V). For the separation of these two epimers their different solubilities in acetone were utilized. While β-yohimbine is readily soluble in this solvent, 3-*epi*-β-yohimbine forms a practically insoluble solvate.

The new yohimbine stereoisomer crystallizes nicely from alcohol, ethyl acetate, and benzene, but in solvated forms from which the solvent, in spite of intensive drying, could not be completely removed. For analysis the recrystallized material was therefore sublimed.

The melting point (203—204°C) and the optical rotation ($[\alpha]_D^{25}$ —83° in pyridine (c = 1)) seem to exclude that 3-*epi*-β-yohimbine is identical with any of the unidentified yohimbine isomers isolated from *Rauwolfia* species.

Table 1. R_F-values in Bush's B5-system.

Substance	R_F-value	D/E ring juncture	Orientation of the		
			C_3-hydrogen	16-carbomethoxy group	17-hydroxyl group
Corynanthine [4]	0.37	*trans*	axial	axial	axial
β-Yohimbine [5]	0.43	—	—	equatorial	equatorial
Yohimbine [2,3]	0.55	—	—	equatorial	axial
Allo-yohimbine [11]	0.67	*cis*	—	axial	equatorial
α-Yohimbine [12]	0.79	—	—	equatorial	equatorial
3-*epi*-β-Yohimbine	0.28	*trans*	equatorial	equatorial	equatorial
Pseudo-yohimbine [2]	0.40	—	—	equatorial	axial

In accordance with the equatorial orientation of the hydrogen atom at C_3, 3-*epi*-β-yohimbine is not dehydrogenated by mercuric acetate [8].

It has previously been pointed out [7] that Bush's B5 system [9] is well suited for paper chromatographic separation of alkaloids of the yohimbine type; in Table 1, the R_F-values of seven yohimbine stereoisomers are given. It will be seen that a substance containing an equatorial hydroxyl group is absorbed more strongly than its axial epimer (β-yohimbine — yohimbine; 3-*epi*-β-yohimbine — *pseudo*yohimbine), a phenomenon which is well known from the steroid series [10]. In addition, it appears from the table that compounds with an equatorial hydrogen atom at C_3 have lower R_F-values than their C_3-epimers (3-*epi*-β-yohimbine—β-yohimbine; *pseudo*yohimbine—yohimbine), and that compounds with an axial 16-carbomethoxy group are absorbed more strongly than their equatorial epimers (corynanthine — yohimbine; *allo*yohimbine — α-yohimbine).

EXPERIMENTAL

All melting points are corrected.

16-Carbomethoxy-17-methoxy-(—)-yohimbane (β-yohimbine methyl ether)

Apoyohimbine (22.4 g) and methyl acetate (25 ml) were added to a sodium methoxide solution containing 12.0 g of sodium in 350 ml of absolute methanol, and the mixture was refluxed for three days. The resulting clear solution was cooled and the crystals were collected on a filter and washed with methanol and water. Addition of water to the filtrate gave a further crop of crystals.

The combined precipitates were dissolved in 10 % acetic acid, reprecipitated with aqueous ammonia, and dried over P_2O_5 to give 21.7 g of white crystals with m.p. 196—200 °C. Recrystallization from *iso*propanol yielded 21.6 g of a product containing one mole of *iso*propanol. M.p. 204—206 °C (sealed tube). $[\alpha]_D^{20}$ −49° in pyridine (c = 1). (Found: C 70.05; H 8.57; N 6.40. Calc. for $C_{22}H_{28}N_2O_3$, C_3H_7OH: C 70.06; H 8.47; N 6.54).

Three recrystallizations from benzene gave solvent free crystals with m.p. 214.5—215.5 °C (sealed tube). $[\alpha]_D^{20}$ −54.5°±1 in pyridine (c = 1). (Found: C 71.53; H 7.76; N 7.68. Calc. for $C_{22}H_{28}N_2O_3$: C 71.71; H 7.66; N 7.60).

β-Yohimbine (II).

β-Yohimbine methyl ether, C_3H_7OH (2.0 g), was triturated in a mortar with a few ml of 48 % hydrobromic acid. The resulting paste was transferred to a 100 ml round-bottomed flask fitted with a reflux condenser; freshly distilled 48 % hydrobromic acid (20 ml) was added, and the mixture was heated cautiously with occasional shaking. When the excessive foaming which occurred during the first period of heating had ceased (about 30 min), the mixture was refluxed until a clear solution was obtained (another 30 min).

The solution was evaporated *in vacuo* and the last traces of hydrobromic acid were removed by drying over potassium hydroxide The residue was dissolved in methanol (30 ml) and excess of an ethereal solution of diazomethane was added. The solution was warmed on the steam bath to expel excess reagent and then evaporated *in vacuo* to a volume of 20 ml. After standing, 1.3 g of white plates, m.p. 234.5—235.5°C, were collected by filtration. Recrystallization from methanol raised the melting point to 236—237°C, and this was not depressed by admixture with an authentic sample of β-yohimbine, 2 CH_3OH. The I.R.-spectra of the two products and their R_F-values were identical too.

The optical rotation was found to be: $[\alpha]_D^{23}$ −42° in pyridine (c = 1). Le Hir and Goutarel [5] report $[\alpha]_D^{18}$ −46.6° in pyridine (c = 0.5).

3-Dehydro-β-yohimbine chloride (IV).

To a stirred solution of 1 360 mg (3.25 mmoles) of β-yohimbine, 2 CH_3OH and 0.50 ml of triethylamine in 25 ml of dry methylene chloride, a solution of 0.50 ml of *tert*-butyl hypochlorite in 5 ml of carbon tetrachloride was added at −25 °C during a period of 10 min. The cooling bath was removed and, after standing for about 15 min, the solution was washed with two 10 ml portions of water, and dried. The solvent was removed *in vacuo*, the residue dissolved in 5 ml of methanol, and the solution acidified with methanolic hydrogen chloride. Upon standing, 1 025 mg of yellow needles m.p. 267—269 °C (decomp.) were obtained. Recrystallization from methanol raised the melting point to 268—269.5 °C (decomp.). Ultraviolet absorption spectrum: λ_{max}^{MeOH} 246 mμ, log ε 4.03; 354 mμ, log ε 4.38. (Found: C 63.97; H 6.74; Cl 9.06. Calc. for $C_{21}H_{25}ClN_2O_3$, ½ CH_3OH: C 63.78; H 6.72; Cl 8.76).

3-*epi*-β-Yohimbine (V)

Zinc dust (800 mg) was added to a solution of 3-dehydro-β-yohimbine chloride, ½ CH_3OH (1 600 mg) in 50 % acetic acid (40 ml) and the mixture was shaken at room temperature until all zinc had dissolved (about 4 h). After addition of crushed ice, the solution was made alkaline with conc. aqueous ammonia (pH 9) and extracted three times with 30, 15 and 10 ml, respectively, of methylene chloride.

The combined extracts were dried over $MgSO_4$ and the solvent was removed *in vacuo* The residue was treated with 20 ml of boiling acetone to bring the β-yohimbine into solution. Cooling, filtration and washing with acetone gave 680 mg of crude 3-*epi*-β-yohimbine. Recrystallization from absolute ethanol afforded 505 mg of pure material which sintered at 141—142 °C (loss of solvent) and melted at 203—204 °C (dec.).

Recrystallizations from ethyl acetate and benzene gave also solvated forms and, for analysis the material was therefore sublimed. The sublimed material had m.p. 203—204 °C (decomp.) and $[\alpha]_D^{25}$ −83° in pyridine (c = 1).

Ultraviolet absorption spectrum: λ_{max}^{EtOH} 225 mμ, log ε 4.54; 282 mμ, log ε 3.88; 290 mμ, log ε 3.81. λ_{min}^{EtOH} 248 mμ, log ε 3.29; 288 mμ, log ε 3.80. (Found: C 70.99; H 7.25; N 7.71. Calc. for $C_{21}H_{26}N_2O_3$: C 71.16; H 7.39; N 7.90).

The acetone filtrate, containing mainly β-yohimbine, was evaporated to dryness *in vacuo* and the residue dissolved in 10 ml of boiling methanol. After cooling, 660 mg of β-yohimbine, 2 CH_3OH, m.p. 233—235 °C, were recovered.

Acknowledgement. The authors wish to thank professor M.-M. Janot, Paris, for an authentic sample of β-yohimbine. We are also indebted to Dr. P. Mørch for the ultraviolet and infrared spectra, and to Mr. G. Cornali for the microanalyses.

A New Interferometric Method for the Determination of Diffusion Coefficients of Very Dilute Solutions

OLOF BRYNGDAHL

Institute of Optical Research, The Royal Institute of Technology, Stockholm 70, Sweden

A new simple and rapid interferometric method is described for studying diffusion and other phenomena giving rise to a refractive index gradient in a solution. The method utilizes birefringence interferences and is found to possess a high degree of precision which probably cannot be attained by methods where the optical power of resolution sets a serious limit to the amount of accuracy attainable. In addition the method is particularly valuable in the study of cases where the refractive index gradient has a low value. By virtue of this fact, measurements can be extended to very low concentration differences. The possibility of arranging differential diffusion experiments with very low concentration gradients also provides a convenient means of studying the concentration dependance of the diffusion coefficient. The new method should further offer a possibility of verifying the Fuoss and Onsager theory for the diffusion coefficients of very dilute electrolytic solutions.

The observation of diffusion processes includes delicate and troublesome measuring problems because of the difficulty in arranging the experiments and the great demands made upon the optical methods. The methods used most for the determination of diffusion coefficients are: the "scale"- and schlieren methods of Lamm with a series of modifications and the Gouy interference method. To enhance the precision of the diffusion measurements the resolution of the optical method must be increased and the influence of the concentration dependance decreased. In order to diminish the influence of the concentration dependance of the diffusion coefficient, it is necessary to work with a small concentration difference, implying that the relative accuracy of the concentration measurement must be correspondingly increased. Under these conditions all the methods mentioned are subject to the fundamental difficulty of the limitation of the optical resolution. This is primarily based on a wave uncertainty principle, analogous to that of Heisenberg to which Wolter, among others, has called attention.[1] A method using birefringence interferences, which contains no resolution-limiting stops, has been introduced in this field by Ingelstam [2a,2b]. As will be described below, there were indi-

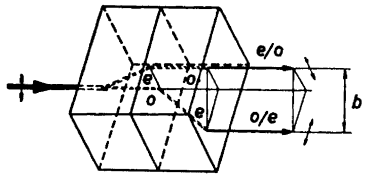

Fig. 1. The Savart plate. The splitting up of an entering ray into an extraordinary-ordinary and an ordinary-extraordinary ray is shown. The arrows at the rays indicate polarization directions.

cations *a priori* that this method would be capable of giving a greater accuracy than earlier ones, and would be especially convenient for very low concentrations. The experiments described in the following sections seem to confirm these expectations.

I. THE OPTICAL METHOD

A plane wave front is distorted in passing through a diffusion cell (of rectangular cross section with plane parallel glass windows) in accordance with the variation of the concentration within the solution. A wave front, defined as the locus of the same optical paths traversed by an originally plane wave front, gives a representation of the optical paths Z. In the diffusion process examined here, Z varies with one space coordinate x (the diffusion direction), and with time t. The relation between Z and the refractive index n and the cell thickness a is as follows:

$$Z(x,t) = n(x,t)a = [k_0 + k_1c(x,t) + k_2c^2(x,t) + \ldots]a \approx [k_0 + k_1c(x,t)]\ a, \quad (1)$$

the last form presupposing that the linear relation between the concentration and the refractive index holds (with is a good approximation in most cases).

By means of a shearing interferometer [3] the derivative of such a concentration curve can be conveniently measured. The wave front is to be split up, in the x-direction, into two parts separated from each other a small distance Δx. This shearing is easily realizable using a birefringent double crystal plate in parallel light. The Savart plate, (Fig. 1), with the incident light plane polarized in such a direction that the oscillation plane bisects the two principle planes of the crystal plate, divides the wave front into two equally strong, perpendicularly polarized, and coherent wave fronts which are at the same time sheared. In Fig. 1 it is also seen how the shear, $\Delta x = b$, results from the fact that the extraordinary rays are oblique in both parts of the Savart plate. The double plate makes the oscillations of the two wave fronts perpendicular, and by means of an analyzer introduced at 45° in relation to the principal planes of the crystal plates, the two wave fronts are enabled to interfere. As will be described below, the interference pattern consists of a set of horizontal fringe pairs. The number of fringe pairs corresponds to the total Z-increment Z_0, in the notation of eqn. (1) $Z_0 = Z(+\infty, t) - Z(-\infty, t)$, *i.e.*, the cell thickness times the total refractive increment of the solution. There is a difference of the optical thickness Z of one wave length between two fringes.

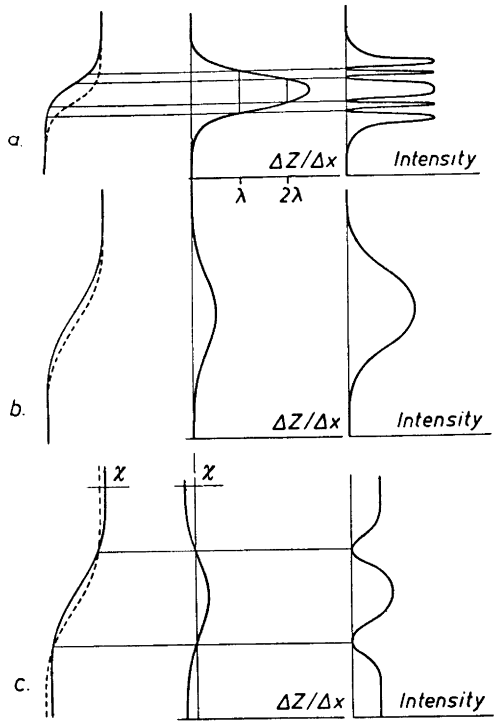

Fig. 2. The optical path as a function of x governed by the concentration gradient is shown (left). The optical path difference between the two separated wave fronts is seen in the middle and the light intensity of the interference pattern at the right. *a* represents an earlier time than *b* when the derivative curve has diminished so that no fringe pair remains. By tilting the Savart plate a constant path difference, χ, between the two wave fronts is introduced and a fringe pair has arisen as shown in *c*.

To the left in Fig. 2, the two laterally displaced wave fronts are shown. The path difference, ΔZ, between two rays emerging from the double crystal plate at the same spot, but originating from different parts, at the distance b, of the entering wave front (Fig. 2) is measured interferometrically. The resulting wave fronts interfere destructively or constructively when the path difference $\Delta Z = m\,\lambda/2$ (m = whole number). If the axes of the two polarizers, P_1 and P_2 in Fig. 3, are perpendicular to each other, the light is extinguished when $m = 0, 2, 4$, etc., and dark fringes are obtained at the corresponding x-coordinates. Similarly for polarizers whose axes are parallel dark fringes arise when $m = 1, 3, 5$, etc. The situation with crossed polarizers is represented in Fig. 2. As shown in Fig. 2a, the fringe pairs correspond to path differences of 0, λ, 2λ, etc., and the possibility of constructing $\Delta Z/\Delta X$ as function of x from the positions of the fringe pairs is clear. When the derivative curve is so low that $\Delta Z < \lambda/2$, which means that no fringes are obtained (Fig. 2b), the Savart plate can be tilted a slight amount and, on account of this, the wave fronts

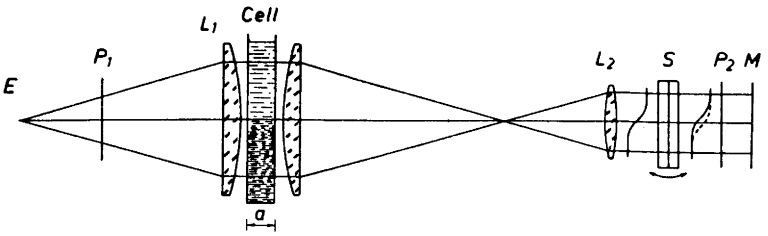

Fig. 3. Optical arrangement. For notation see text.

are displaced a desired path difference χ and a fringe pair has arisen according to Fig. 2c. Thus this method makes it possible to work with concentration differences corresponding to an optical path difference as small as about one wave length.

The interference pattern produced is related to the Gaussian curve, which represents the ideal concentration gradient. An evaluation method used by Lamm in the schlieren method is modified here and the diffusion coefficient is deduced from the rate at which the fringe pattern changes.

II. APPARATUS

1. *The lens system.* The lens system is shown schematically in Fig. 3. E is a horizontal slit illuminated by monochromatic light. It is located in the focal plane of the first lens in the system L_1. The system L_1 is composed of two equal lenses, each having a focal length of 1 m, and corrected for both chromatic and spherical aberrations. By means of the lens L_2, $f = 12$ cm, an image of the cell plane is obtained in the object plane M. The strict collimation necessary in the wavefronts traversing the crystal plate is accomplished by the displacement of L_2. During the experiments the cell is placed between the lenses L_1 where the light is parallel. The numerical value of the optical magnification, G, is 0.120.

2. *The Savart plate.* The crystal plate, which is traversed by strictly parallel light, introduces a displacement between of the wavefronts in the x-direction equal to b. If the Savart plate is adjusted so as to be perpendicular to the optical axis, so that no phase shift is introduced between the two wavefronts, b is determined by the equation,

$$b = e\sqrt{2}\ \frac{n_e^2 - n_0^2}{n_e^2 + n_0^2} \tag{2}$$

where e is the thickness of each part of the double plate and n_e and n_o are the principal refractive indices. The quartz plate, which is used in the experiments with very dilute solutions, has $e = 10$ mm and $b = 84.2\ \mu$. If the magnification is G, the real distance at the object is not b but b_1 which is equal to b/G.

3. *The cell.* The diffusion cell used was a flowing-junction cell, having a stainless steel body, kindly lent to us by Dr. H. Svensson, who designed and

used it in his earlier developmental work.[4] In this type of cell the initially sharp boundary is formed by allowing solution and solvent to flow together into a narrow horizontal exit slit in the side wall of the diffusion channel, the horizontal cross section of which is 3×50 mm^2 and the height of which is 70 mm. The cell windows are 10 mm thick and the flatness before clamping is about one wave length.

4. *The monochromator.* The horizontal entrance slit is illuminated by a 100 W mercury lamp with a filter that transmits only the green Hg-line (5 461 Å).

5. *The camera.* In the experiments with liquid gradients, where a quick registration of the beginning of the run is desired (an exposure every tenth second), a Robot camera which automatically feeds the film is used. Together with this a Leitz bellow adjustment apparatus and an Elmar objective ($f = 5$ cm) is used.

6. *Photography.* For all photographic recordings Ilford HPS film is used with Ilford Microphen fine grain developer. HPS film is used to attain a minimum time of exposure (about 2 sec).

7. *Control of temperature.* Unfortunately, no thermostat is available during the experiments, but they are carried out in a room with a remarkably constant temperature, held within $\pm$ 1 degree with an electric radiator for 10 h before the experiment. The cell part of the arrangement is shielded with an aluminium box to give radiation equilibrium. A thermometer placed close to the cell shows, in general, a variation in temperature of less than $\pm$ 0.05° during an experiment. Care was taken not to warm up the thermostat by touching or by radiation from the body.

8. *Support.* All the optical components are mounted on a 3 m steel beam resting on sheets of sponge rubber on concrete tubes which stand on the floor. In this way vibrations communicated to the optical system through the floor are effectively damped out.

III. CALCULATION

At small concentration differences, the skewness of the gradient arising from the concentration dependance of the coefficient disappears and Fick's second law is presumed to be valid. The derivative of the optical path gradient can be written

$$\frac{\partial Z(x,t)}{\partial x} = \frac{Z_0}{2} \cdot \frac{1}{\sqrt{\pi Dt}} \cdot e^{-(x/\sqrt{4Dt})^2} \qquad (3)$$

The correction between the path difference $\Delta Z/b_1 = \Delta Z/\Delta x$ that is measured, and the path derivative desired, eqn. (3), can easily be calculated [2a, 2b]. In the neighbourhood of the inflexion points the magnitude of the corrections is extremely small, and for a birefringence displacement, b_1, less than 3 σ, where $\sigma = \sqrt{2Dt}$ is half the distance between the inflexion points of the Gaussian curve, the correction is practically negligible over the whole curve.

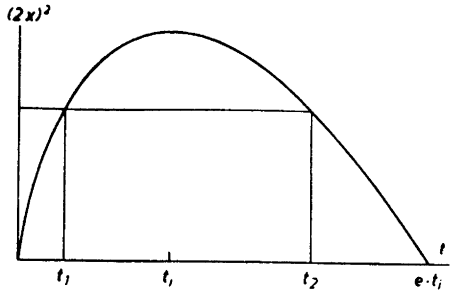

Fig. 4. The square of the distance between the fringes as function of time. The diffusion coefficient is obtained from pairs at certain distances and their corresponding times, as

$$D = \frac{(2x)^2(1/t_1 - 1/t_2)}{8 \ln t_2/t_1}$$

The difference ratio measured can be expanded in a series and the derivatives substituted by polynomists in x/σ as follows:

$$\frac{\Delta Z(x)}{b_1} = \frac{Z(x + \frac{1}{2}b_1) - Z(x - \frac{1}{2}b_1)}{b_1}$$

$$= Z'(x)\left\{1 + \frac{1}{3!}\left(\frac{b_1}{2}\right)^2 \frac{Z^{III}(x)}{Z'(x)} + \frac{1}{5!}\left(\frac{b_1}{2}\right)^4 \frac{Z^{V}(x)}{Z'(x)} + \cdots\right\} \quad (4)$$

$$= Z'(x)\left\{1 + \frac{1}{2^2 \cdot 3!}\left(\frac{b_1}{\sigma}\right)^2 (x^2 - \sigma^2) + \frac{1}{2^4 \cdot 5!}\left(\frac{b_1}{\sigma}\right)^4 (x^4 - 6x^2\sigma^2 + 3\sigma^4) + \cdots\right\}$$

From this it appears that when b_1/σ is small the corrections for obtaining the gradient are conveniently small.

The curve constructed from the interference pattern (the fringe pairs represent symmetrical points with a fixed value of $\Delta Z/\Delta x$) can easily be corrected and the derivative determined.

An accurate evaluation method, due to Lamm [5], having the advantages of using only the region not far from the inflexion points of the Gaussian curve, is modified for this method. From the set of fringes, a distance $2x$ between corresponding fringes in the interference pattern is measured. Following a definite fringe pair with time, we may plot $(2x)^2$ *vs.* t (Fig. 4). The diffusion coefficient is then obtained from a value of $(2x)^2$ and its co-ordinate times t_1 and t_2 by the equation

$$D = \frac{(2x)^2 (1/t_1 - 1/t_2)}{8 \ln t_2/t_1} \quad (5)$$

The equation of the curve in Fig. 4 is

$$(2x)^2 = 8Dt \left(1 + \ln \frac{t_i}{t}\right) \quad (6)$$

where t_i represents the time corresponding to maximum distance between the fringes. When $t = t_i$

$$(2x_i)^2 = 8Dt_i \quad (7)$$

and $2x_i = 2\sigma$, which is the distance between the inflexion points of the Gaussian curve.

At higher concentration differences a group of such curves is obtained and the information about the diffusion process is very copious.

IV. ZERO-TIME CORRECTION

Since the infinitely sharp initial boundary, required for rigorous application of the equations, cannot be obtained experimentally, the observed time, t, after a certain time zero point in the formation of a boundary must be corrected by a small constant increment Δt, in order to arrive at the zero point where the boundary would have been infinitely sharp.

Method 1. In experiments with concentration differences giving many fringes, a *rough* estimate of the diffusion coefficient and the zero-time correction can be made. By combining the maximum points in Fig. 9 a straight line, $(2x)^2 = 8Dt$, is obtained. The slope of the line is $8D$ and from the intersection with the abscissa axis the zero-time correction is determined.

Method 2. A more accurate method exploiting only the variation of one fringe pair is obtained by the following.

A diffusion coefficient D' is computed by using the measured time in eqn. (5). The true diffusion coefficient D is related to D' by the expression

$$D = \frac{(2x)^2 \left(\frac{1}{t_1 + \Delta t} - \frac{1}{t_2 + \Delta t}\right)}{8 \ln \frac{t_2 + \Delta t}{t_1 + \Delta t}}$$

$$\approx \frac{(2x)^2 \left(\frac{1}{t_1} - \frac{1}{t_2}\right)}{8 \ln \frac{t_2}{t_1}} \cdot \frac{1}{\left(1 + \Delta t \frac{t_1 + t_2}{t_1 t_2}\right)\left(1 - \Delta t \frac{\frac{1}{t_1} - \frac{1}{t_2}}{\ln \frac{t_2}{t_1}}\right)}$$

$$\approx \frac{D'}{1 + \Delta t \cdot \vartheta} \qquad (8)$$

$$\text{where} \quad \vartheta = \frac{t_1 + t_2}{t_1 t_2} - \frac{\frac{1}{t_1} - \frac{1}{t_2}}{\ln \frac{t_2}{t_1}}$$

and D and Δt are readily obtained from a plot of D' *vs.* ϑ (Fig 10). This method is not applicable at very short experimental times, *i.e.*, when $(\Delta t)^2$ no longer can be neglected in comparison with $t_1 \cdot \Delta t$.

Method 3. An iteration method has been adopted for obtaining higher accuracy and an estimation of the precision of the calculation. Fig. 11 shows how D varies with $(2x)^2$ for different values of the parameter Δt. In this way a Δt giving the most constant D can be determined.

V. EXPERIMENTAL TEST

Work with the present apparatus has been confined to solutions of glycine and sucrose. In the experiments with glycine a small downward drift of the diffusion coefficients was observed. Reaction products between glycine and iron were found which is equivalent to an absorption process. In the experiments, discussed here, sucrose of analytical purity has been used. Accurate measurements of the diffusion of this material have recently been performed elsewhere [6-8].

The solvent and solution are put in the thermostat, and after about 10 h when thermal equilibrium is obtained, the stopcocks of the reservoirs, which are provided with handles for operation from outside the aluminium box, are opened. After another half an hour, when the gradient is very sharp and temperature equilibrium is obtained, the stopcocks are closed and the outflow stopped so that diffusion may take place. About 50 exposures are taken during the diffusion process, more frequently at the beginning.

For obtaining the highest precision measurement of the films, a photometer is used. The distance, $2x$, between corresponding centres of the density minima are measured with an accuracy of 1 μ. In one of the experiments, (II), a comparator reading to 1 μ has been used.

From the data taken in these experiments it is evident that, in general, no advantage is gained from photometric measurements. Photometry is advisable in working with concentration differences corresponding to an optical path difference of about one wave length. At the very end of the diffusion process, when the derivative curve is low (Fig. 2 b and c), the asymmetry and blurring of the fringes are troublesome when the distance between coordinate fringes is small (representing points at the very top of the derivative curve). As a rule, in these cases, one has no interest in following the fringes so long that the asymmetry and broadness of the fringes will be troublesome. The higher the concentration difference, the sharper the fringes, since this depends on the slope of the gradient curve (*cf.* Fig. 2). For determination of the fringe pair positions at smaller concentration differences (with a small broadening of the density minima in the film) an increase of the exposure time will give sharper fringes ("Minimumstrahlkennzeichnung", Wolter [1]).

A procedure, "Äquidensitenverfahren", designed by Krug and Lau [9] has been tried for obtaining greater measuring accuracy at wide interference strips. It must be stressed that this procedure has only an advantage for wide fringes, which appear here when working with concentration differences corresponding to an optical thickness of about one wave length.

For density curves, running more or less steep, points with the same density (these curves are called Äquidensiten) can be connected by a photographic procedure [9]. Practically this can be done by making a positive on hard film from the original negative. When it is nearly developed, the film is illuminated by uniform light, which has most influence on the positions not illuminated before. So by the Sabattiereffect a plate is obtained in which a positive and a negative are in precise covering and the Äquidensiten arise where the negative and positive have about the same density.

Here, however, one is looking for the minima in the negatives, but then the method fails because of the impossibility of computing the density values corresponding to the Äquidensiten, neither does it give a comprehension of the amount of asymmetry. Thus it is impossible to find the minimum point by producing Äquidensiten at different density values and extrapolating to the minimum.

The difference between the refractive index of water and a solution of 1 g sucrose in 100 cm^3 water gives a retardation of 132 (air) wave lengths for the cell used (around 50 mm thick). From this it is evident, that as low a concentration as about 0.01 %, corresponding to an optical path difference of 1.32 wave lengths, can be used.

A series of exposures taken during a diffusion run is shown in Fig. 5. The position of the fringes is very accurately determined by constructing the medians in the photograms (Fig. 6).

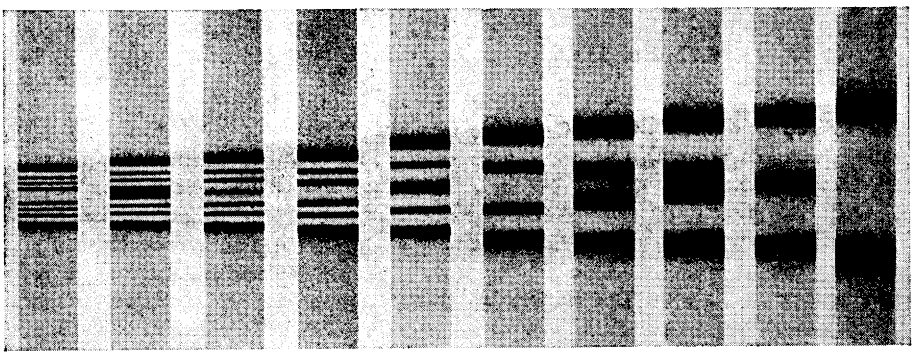

Fig. 5. Exposures taken during a diffusion experiment (Expt. IV).

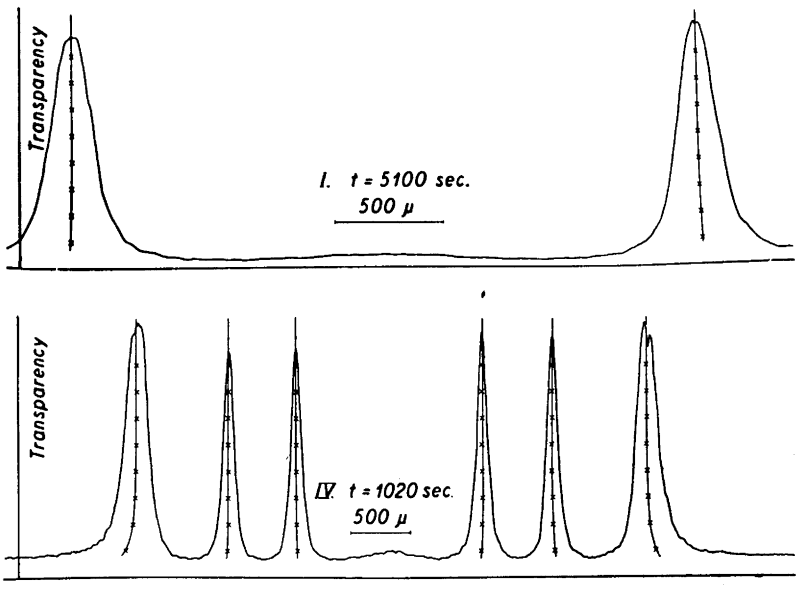

Fig. 6. Photograms showing how the exact positions of the fringes are found by constructing the medians of the curves. Observe how precisely the position can be measured with such low a concentration difference as in expt. I.

Four experiments with different concentrations were performed (Table 1). Every run has been calculated in detail.

Table 1.

Run	Sucrose conc. above/under the boundary %	Thermostat temp. °C	Fringe pairs at the beginning (in air wavelengths)	χ Å
I 31.1.57	0/0.0112	21.33±0.07	1.48	470
II 30.1.57	0/0.0500	20.76±0.20	6.60	1 890
III 4.2.57	0/0.1018	23.62±0.05	13.48	3 680
IV 5.2.57	0.7249/0.8253	23.84±0.06	13.25	2 430

Eqn. (6) has been adapted to the experimental points of run I in Fig. 7. Good agreement over the whole curve, except for very low time values, is clear from the diagram. Despite the fact that the method gives high values at the very beginning of the process, all distances were found to be smaller than the theoretical ones. This indicates that a high zero-time correction is obtained, owing to the difficulties of producing sharp boundaries at such a low concentration. The results obtained using the iteration method on run I (concentration corresponding to an optical path difference of 1.48 wave lengths) are shown in Fig. 8. The dotted part of the curves, represents disturbances at the beginning, which are found to die out very quickly. With the parameter $\Delta t = 205$ sec, the curve runs well horizontally and the corresponding value of the diffusion coefficient is determined very accurately.

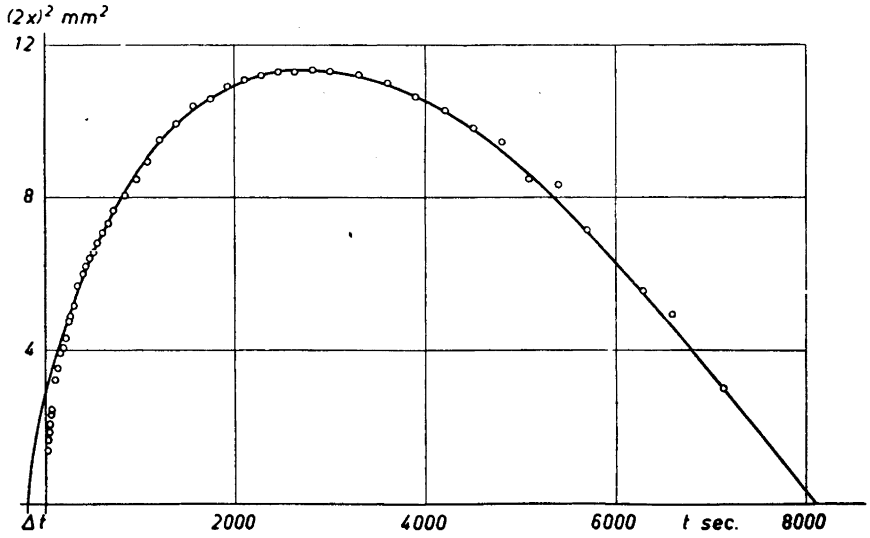

Fig. 7. $(2x)^2$ as function of time for expt. I. Eqn. (6) has been adapted to the experimental points.

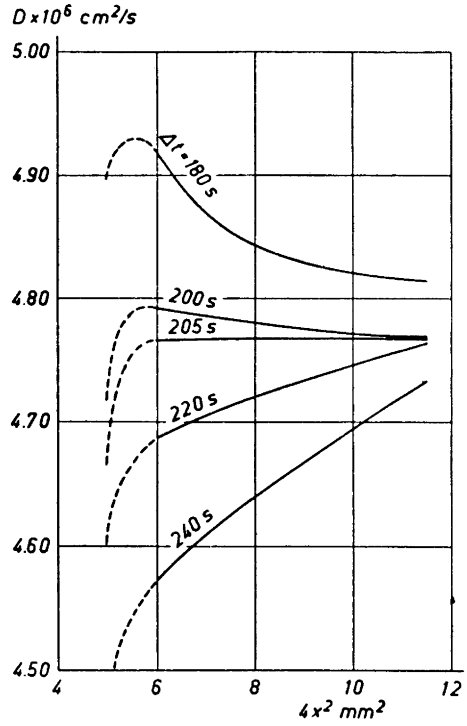

Fig. 8. D as a function of $(2x)^2$. The dotted part represents disturbances. *Cf.* Fig. 7.

In order to illustrate the simplicity, rapidity, accuracy and amount of information given by this method, the above mentioned ways of finding the zero-time correction are applied to run III (Figs. 9, 10 and 11). In Figs. 10 and 11 the curves refer to the next outermost fringe pair. From a comparison with the values calculated from the curves corresponding to the other fringe pairs a good agreement, within 0.02 %, is obtained. In Fig. 11 the influence of the correction between the difference and the derivative appears. The dotted parts represent the uncorrected values. It must be observed that this curve at the beginning corresponds to points far from the inflexion points of the Gaussian curve. Nevertheless, the influence of the correction is dying out very fast and can be ignored in all practical measurements. In order to compare the diffusion coefficients obtained with the values given in Refs.[6–8], corrections were applied to 25.0 °C using Stoke-Einstein's relation. These data are given in Table 2, where values extrapolated from the measurements in Ref.[7] are also found.

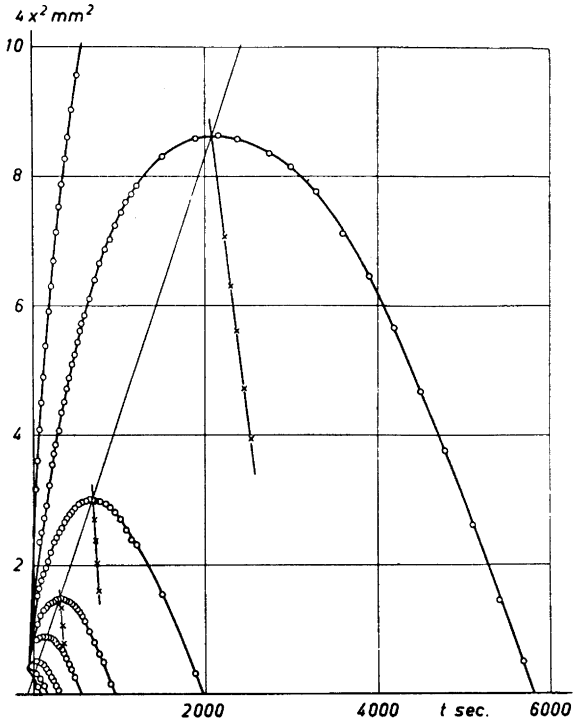

Fig. 9. $(2x)^2$ as a function of time for expt. III. The maximum points of the curves are easily found by constructing the medians, and the line combining the maximum points gives a rough estimate of the diffusion coefficient and the zero-time correction.

Table 2.

Run	c %	Δc %	Δt sec.	$D_{25} \times 10^6$ cm²/s	$D_{25} \times 10^6$ cm²/s extracted from Ref.[7]
I	0.0056	0.0112	205	5.229±0.011	5.228
II	0.0250	0.0500	54	5.193±0.042	5.224
III	0.0509	0.1018	47	5.235±0.008	5.222
IV	0.7751	0.1004	55	5.193±0.011	5.170

In Fig. 12 it is clearly seen how the results obtained by this method agree with the values extracted from the equation of the concentration dependance of the diffusion coefficient stated in Ref.[7]. From this diagram it is evident that a *very* small concentration difference can be used. The exactness of the measurements is also indicated. Experiment II with poor temperature control has given too low a value.

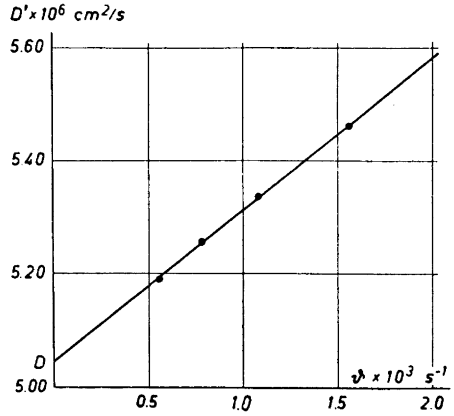

Fig. 10. The calculated diffusion coefficient D' as a function of the factor ϑ (see IV, 2). D is obtained from the intersection with the ordinate axis. The slope of the line is $\Delta t D$.

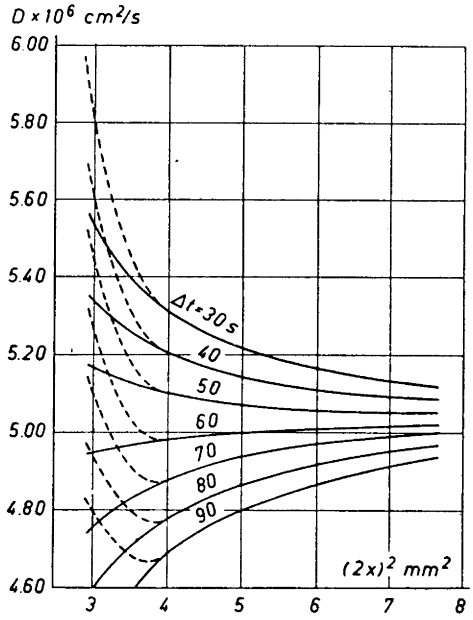

Fig. 11. D as a function of $(2x)^2$ obtained from the next outermost fringe pair. The dotted parts represent values obtained without regard to the correction between difference and derivative. Observe in this curve, that in the part representing points far from the inflexion points (for $(2x)^2 < 5$ mm^2), the corrections are obtainable and die out fast.

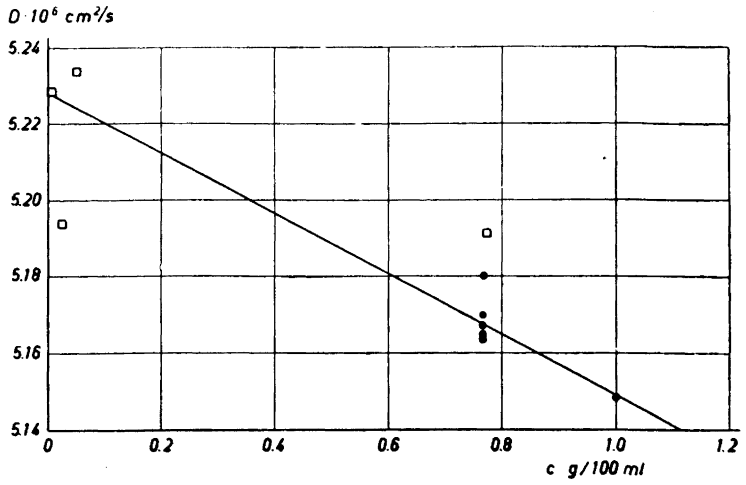

Fig. 12. Determination of diffusion coefficients for sucrose. Filled circles, Refs. [6-8], having been determined with the Gouy interference method. The line drawn is obtained from Akeley and Gosting [7]. Empty squares, results from the investigations presented in this paper.

VI. DISCUSSION

The determined diffusion coefficients deviate from the values in Refs.[6-8] by less than 0.5 %, which is very small compared with the accuracy in the referenced values quoted above. It should be stressed that the results do not really give the method full justice, since these experiments were carried out without careful thermostating and that large temperature corrections (the uncertainty in the absolute value of temperature is about 0.1 °) have been applied.

It is difficult to give a quantitative estimate of the effect of the sources of error on the accuracy and precision of the measurements. In the method described the following factors have an influence on the calculated diffusion coefficient:

a. insufficient control of temperature (about 0.2 %),

b. overlapped thermal gradient (a temp. gradient of 0.1 ° corresponds to an optical path difference of about 5 000 Å, this effect dies out in a few minutes),

c. the concentration dependance of the diffusion coefficient (about 0.05 % in these experiments),

d. correction between difference and derivative (has an exceedingly small influence in these calculations, where only points not far from the inflexion points of the Gaussian curve have been used),

e. determination of the distance between the fringes; the measurements are performed with an accuracy of 1 μ at the beginning and about 3 μ

at the end (consistent with the sharpness of the fringes), see Fig. 4. Here also a possible error in the magnification factor has an influence,

f. calculation (the last two sources introduce an error of about 0.05 %),
g. error of focusing,
h. non-parallel light through the cell,
i. lens effect of the cell (can be compensated by displacement of L_2),
j. a wedge shaped diffusion column (has an extremely small influence in this method).

The maximum error in the estimates (except II with bad temperature constancy) is about 0.2 % (with regard to the uncertainty in the absolute temperature about 0.5 %) which in its greater part arises from the variation of temperature. With accurate temperature control, it would easily be possible with the present method to determine the diffusion coefficient within 0.1 %.

The cell used gives an extremely great zero-time correction compared with other measurements with flowing-juction diffusion cells. Longsworth [10], for example, stated 4—6 sec. Thus, in general, the determination of the zero-time correction will not give rise to such a marked problem. It should be emphasized that the zero-time correction does not appreciably increase with the dilution and so the values found here show good agreement with those obtained by Svensson [11] with the same cell at higher concentration difference.

Contrary to expectation the method is not extremely sensitive to minor imperfections in the optical system, nor to contaminations in the cell. However, good quality optical equipment is essential in order that the advantages of the method be fully utilized. The importance of proper focusing is naturally also more prominent in working with a method giving such a precision in the measurements as the above mentioned, than in less sensitive methods. We owe a good deal to Svensson for his prethought of developing the theory of second and third order aberrations in the interferometric measurement of concentration gradients. The adjustment of our optical system was carried out in conformity with his prescriptions.

Svensson has shown [12, 13] that the aberration corresponding to the Wiener skewness of the gradient curve disappears if the camera is focused on a plane 1/3 of the cell thickness from the front wall. The photographic enlargement factor is determined experimentally by placing an object in the plane of the middle of the cell, although this is not optically conjugate to the plate. If the light through the cell is converging, it gives rise to an aberration, which may be corrected for by determining the optical magnification factor of the cell from the slightly defocused plane through the middle of the cell [12].

A result of Svensson's calculations [14] is that the third order aberrations depend on the entrance angle, and that there is a certain entrance angle (the light source should be situated below the optical axis) that is more favourable than any other angle. The third order aberrations are found to decrease very rapidly with time. The critical time of diffusion (when all aberrations have decreased to 1/50 of a light wave) in these measurements with low concentration differences is surprisingly small, about a few seconds.

There seems to be little justification in stating a diffusion coefficient within a few tenths of a per cent, using a total concentration difference corresponding to an optical path difference of about 100 wave-lengths, bearing in mind that the coefficient varies to the extent of several per cent in the concentration region examined. The present method on the contrary works with very low concentration differences and thus the concentration dependance of the diffusion coefficient is correspondingly smaller. This is one of the great advantages of this method. Other advantages are that only part of the Gaussian curve near the inflexion points is used and that an image of the whole diffusion column is obtained.

Another striking feature of the new method is that it enables diffusion experiments to be carried out in a very short time — 20 min or even less (observing inner fringe pairs or very dilute solutions). No doubt, this is to be ascribed to the greatly enhanced power of resolution, which makes the method equally well suited to measurements on medium and very low refractive index gradients.

The present method has by no means an unlimited power of resolution — this would rule out the wave uncertainty relation completely. But a great enhancement results from choosing the conditions of the experiment and the method of registration in a suitable way. The described method possesses the same degree of high precision which is achieved by Wolter [1] who modified the schlieren method by changing the slit to a 180° phase plate. "Minimumstrahlkennzeichnung" and all advantages attaching thereto (as *e.g.*, unlimited high beam sharpness and enhancement of the measuring precision making photometry superfluous) are exploited by birefringence interferometry in polarized light. *The Savart plate has some advantages compared to the phase plate:* it is simpler to realize in practical measurements and gives more information (many fringe pairs) about the process.

The fact that the extrapolated values obtained by Akeley and Gosting [7] show a fair agreement with the results of the exceedingly accurate experiments reported in this paper is probably a mere coincidence.

The conductance method of Harned and French [15], which implied a considerable improvement in accuracy at concentrations ten times lower than optical methods existing at that time, was applicable to cases where the original concentration differences was of an order of magnitude not less than 0.0025 molal in KCl. Our method enables measurements to be carried out with a concentration difference of 0.0015 molal in KCl. The precision of our measurements would be of the order of $\pm$ 0.1 % while the accuracy reported by Harned and French is approximately $\pm$ 0.9 % which was later reduced to about $\pm$ 0.1 % with concentrations down to 0.00125 molal [16].

As pointed out by Svensson [12], it is desirable to carry out experiments with very low concentration gradient when studying polydisperisity, in order that the influence of the concentration dependance of the diffusion coefficient can be disregarded and the effect of polydispersity studied separately.

Equilibrium Studies of Polyanions

II Polyborates in $NaClO_4$ Medium

NILS INGRI, GÖSTA LAGERSTRÖM, MINA FRYDMAN, and LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, The Royal Institute of Technology, Stockholm 70, Sweden

The pH equilibria of boric acid and borate ion have been studied in 3 M sodium (perchlorate) medium at 25°C by electrometric titration using a hydrogen electrode. The total boron concentration B had values between 0.010 and 0.600 M. With the total boron concentration $B \leqq 0.025$ M, essentially only the mononuclear species boric acid $B(OH)_3$ and the ion $B(OH)_4^-$ seem to be present; the data for $B > 0.025$ M give evidence also for two polynuclear species, $B_3O_3(OH)_4^-$ and $B_3O_3(OH)^{2-}$. (The data may also be explained, though not so well, by assuming $^5B_3O_3(OH)_4^-$ and $B_4O_4(OH)_6^{2-}$).

Reactions and constants:

$B(OH)_3 + H_2O \rightleftharpoons B(OH)_4^- + H^+$ $\quad \log K_{11} = -9.00 \pm 0.05$

$3B(OH)_3 \rightleftharpoons B_3O_3(OH)_4^- + H^+ + 2H_2O$ $\quad \log K_{13} = -6.84 \pm 0.10$

$3B(OH)_3 \rightleftharpoons B_3O_3(OH)_5^{2-} + 2H^+ + H_2O$ $\quad \log K_{23} = -15.44 \pm 0.20$

In aqueous solution boric acid shows a number of irregularities which indicate the existence of polyborate ions. The aim of this work has been to investigate the pH equilibria of boric acid at various total boron concentrations (B), and from this to deduce the formulas of the predominating species, and the equilibrium constants for their formation.

In the following survey we shall for brevity, and to conform with the notations in the general papers [1], use the symbols

$$A^- \text{ or } A = -H^+ \qquad\qquad B = H_3BO_3$$

The charge of the species A_pB_q will then be $p-$; we shall sometimes write it out, sometimes not. When we apply the law of mass action to the equilibria, we shall write

$$[A] = a = [H^+]^{-1} = h^{-1}; \quad [B] = b$$

and denote by K_{pq} the equilibrium constant for the reaction

$$p\,A + q\,B \rightleftharpoons A_pB_q; \quad [A_pB_q] = K_{pq}a^pb^q = K_{pq}h^{-p}b^q \qquad (1\,a)$$

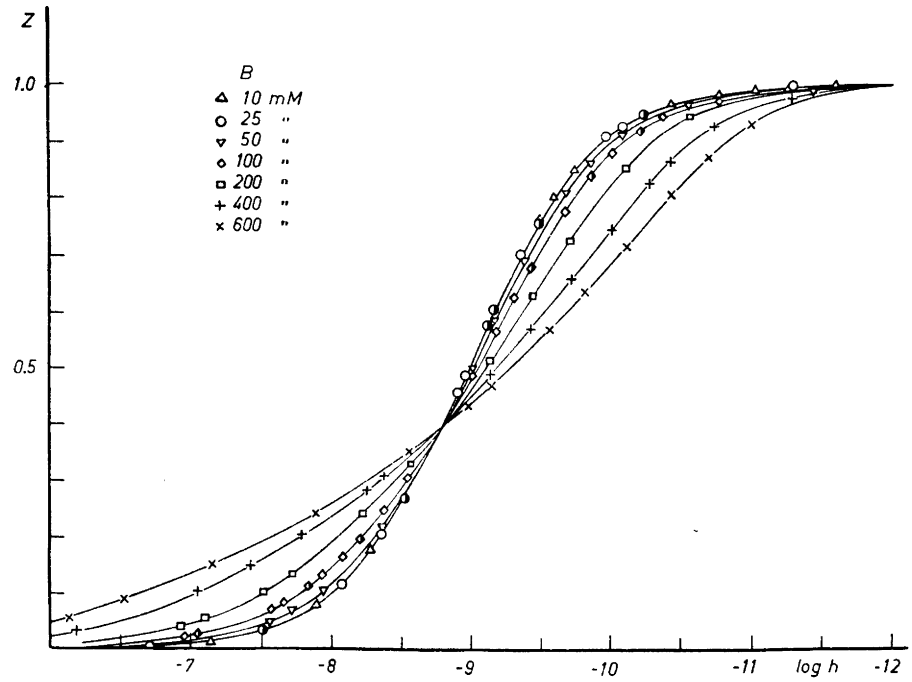

Fig. 1. Average number of OH bound per boron, Z, as a function of $-\log h$. The curve through the points for the two lowest concentrations is that calculated for a normal weak acid with $\log K_a = -9.00$. For the other concentrations smooth curves have been drawn through the experimental points. Half-filled symbols represent points from backtitrations.

or

$$n\,H_2O\text{—}p\,H^+ + q\,H_3BO_3 \rightleftharpoons B_q(OH)_{3q+p}(H_2O)_{n-p}^{p-}; \qquad (1\,b)$$

$$[B_q(OH)_{3q+p}^{-p}] = K_{pq}h^{-p}[H_3BO_3]^q = K_{pq}h^{-p}b^q$$

The important factors are the number of protons and H_3BO_3 groups. The number of water molecules n cannot be determined from the equilibria.

Then K_{11} for the simplest mononuclear reaction is the acidity constant of boric acid

$$A^- + B \rightleftharpoons AB^-; \quad K_{11} = [AB]a^{-1}b^{-1} = [AB]hb^{-1} \qquad [(2\,a)$$

$$H_3BO_3\text{—}H^+ + H_2O \rightleftharpoons B(OH)_4^-; \; K_{11} = h[B(OH)_4^-][H_3BO_3]^{-1} = K_a' \quad (2\,b)$$

The behavior of boric acid is well illustrated by Fig. 1, which gives our data for the titration of B (H_3BO_3) with A (Na^+OH^-). Each set of points represents a titration (or rather two duplicate titrations) where the total boron concentration B was maintained constant, at 0.010, 0.025, 0.050, 0.100, 0.200, 0.400 or 0.600 M. The activity factor effects were largely eliminated by keeping $[Na^+] = 3$ M in all experiments by addition of $NaClO_4$. The abscissas represent $\log h$ and the ordinates Z, the average charge per boron atom.

With decreasing B, all of the curves approach the steepest curve, which is the one calculated for a normal weak acid with log $K_a = -9.00$. At these low concentrations, the only species that need be considered would be B and AB^-. According to Konopik and Leberl [2], H_3BO_3 should split off two more protons, with log K_a values of —12.3 and —13.3; in our notation A_2B^{2-} and A_3B^{3-} would be formed. With the present data, Z does not seem to exceed 1.0, so there was no definite indication of a dissociation beyond the step AB^-. However, our measurements were not pursued to very high values of the pH.

At higher total concentrations of B, the curves deviate from the mononuclear one; for low values of Z, the solutions are more acidic and at high values of Z more alkaline, than would be expected, if the mononuclear reaction were the only one.

The curves intersect at $Z \approx 0.40$. Such an intersection point was referred to as an isohydric point by Carpéni [3]. Byé [4] and Souchay [5] have pointed out that at such a point the condensation to polyions must be at a maximum.

Before trying to analyse these curves, we shall survey some previous work on borates in solutions.

PREVIOUS SOLUTION DATA

Reversibility of equilibria. Kahlenberg and Schreiner [6] were the first to check that whatever reactions there may be between monoborate ions, boric acid, and polyborate ions, they must come very rapidly to equilibrium. For instance, no difference was found between a solution prepared from water and $Na_2B_4O_7(H_2O)_{10}$, and one prepared by mixing the corresponding amounts of NaOH and H_3BO_3. All subsequent work, including our own, seems to lead to the same conclusion.

Freezing point data. According to Menzel [7] the freezing point depression of aqueous solutions of H_3BO_3 is quite normal up to the highest concentrations studied by him, 0.358 M; thus the formation of uncharged polyboric acids, B_q, seems to be negligible Also freezing point data for Na^+AB^- ("$NaBO_2(H_2O)_2$", $Na^+B(OH)_4^-$) up to 2 m solution do not deviate significantly from those of other 1—1 salts like $K^+HCO_3^-$ (Menzel [7], Menzel and Schulz [8]). Doucet and Rollin [9] measured the depression of the freezing point of $Na_2SO_4(H_2O)_{10}$, which largely eliminates the uncertainty caused by ionic strength effects, and still found no association for B (up to 0.25 M) or Na^+AB^- (up to 0.11 M).

Freezing point data for salts like borax, $Na_2B_4O_7(H_2O)_{10}$, and $NaB_5O_8(H_2O)_5$ in dilute solution indicate that they give chiefly mononuclear species B and AB^-. At higher concentrations there are, however, signs of association (Menzel [7]). Souchay [10] gives curves for the freezing point depression for a series of solutions corresponding to a titration at constant total concentration B (0.10 or 0.25 M) and constant ionic medium. He found that the number of molecules per boron atom is 1.0 at the B and AB^- sides, whereas at the isohydric point it has a minimum value, approximately 0.7 at the higher value for B.

We may thus conclude that the polynuclear species formed are neither polymers B_q nor polymers $(AB)_q^{q-}$ but rather of the mixed type $A_pB_q^{p-}$.

Conductance and pH of pure B solutions. Owen [11] has found log $K_a^\circ = -9.236$ for H_3BO_3 (B) at 25°C, using cells without liquid junctions, and extrapolating to zero concentration.

Concentrated solutions of B are more acidic than would correspond to the dissociation of B to H^+ and AB^-. Kolthoff [12] and Thygesen [13] measured the conductivity of B solutions as a function of concentration. Both assumed that the high acidity is due to the single reaction

$$qB \rightleftharpoons H^+ + AB_q^-; \text{ equilibrium constant } = K_{1q}, \tag{3}$$

and neglected all other species. Kolthoff moreover assumed $q = 4$ and found values for log $K_{14} \approx -9$ at 18°C. Thygesen tested various values for q; the equilibrium constant

calculated showed the smallest variation with $q = 3$ ($\log K_{13} \approx -7.5$ at 18°C). However, Thygesen preferred to assume $q = 4$ ($\log K_{14} \approx -7.1$), with a small amount of $q = 2$; probably he was (like Kolthoff) influenced by the net formula of borax. The complexes would then be AB_4^- and AB_2^-; no attempt was made to estimate the formation constant of the latter.

Stetten [14] measured the pH of various B solutions. Assuming the main reaction (3), he found an average $q = 3.2$ and $\log K_{1,3.2} = -6.86$. From similar pH measurements, Edwards [15] concluded that the main species is AB_3^- with $\log K_{13} \approx -7.5$; deviations at the highest concentrations were ascribed to AB_6^- with $\log K_{16} \approx -6.8$.

Antikainen [16] titrated boric acid of various concentrations B in a number of salt media. From the slope of the titration curve at the isoelectric point (which gives the buffer value of a pure B solution), he calculated the apparent ionization constant of B and concluded the average value for q to be 3.87 ± 0.04. This would indicate that the main species is AB_4^-, and $\log K_{14} = -7.06$ (extrapolated to zero ionic strength).

Solubilities. From the solubility of B in Na^+AB^- solutions of increasing concentration, Auerbach [17] concluded that the complex formed contained 4 to 5, probably 5, B per Na (B per A^-, in our notation).

pH titrations. A number of pH titrations of B were carried out by Kolthoff and Bosch [18]. The data were discussed qualitatively, and the formula AB_5 was favored, in all probability because of the existence of a salt $KB_5O_8(H_2O)_4$. Carpéni and Souchay [19] carried out a series of titrations in 1 M NaCl medium. They obtained curves very much like those given in Fig. 1. These curves gave rise to a rather long discussion in French journals between Carpéni, Souchay and Byé. Whereas Carpéni and Souchay [19] originally concluded that $HB_2O_4^-(AB_2^-)$ and $B_5O_8^-(AB_5^-)$ are formed, Carpéni [3] in 1948 coined the name "isohydric point" for such a point of intersection and claimed [20,21] (1949, 1952) that it proved the existence of a single complex with $Z = 0.40$, which should be $HB_5O_9^{2-}(A_2B_5^{2-})$. To some extent, Carpéni [22] corroborated this conclusion by the preparation of a new solid borate, $K_2HB_5O_9(H_2O)_3$. On the other hand, Byé [4] has criticized Carpéni's mathematical arguments. Souchay [5] prefers to think that the solutions contain the ions $B_5O_8^-(AB_5^-)$ and $B_4O_7^{2-}(A_2B_4^{2-})$, corresponding to "well known types" of salts.

LIST OF SYMBOLS

A	total concentration of A $= -H^+$, proton deficiency $= -H$
a	"concentration of free A" $= h^{-1}$
B	total concentration of B $= B(OH)_3$
B_1	total concentration of mononuclear species, $[B]+[AB^-] = [B(OH_3)] + [B(OH)_4^-]$.
B	a normalized quantity corresponding to B (21)
E	the measured emf in mV.
E_{oa}	$= E+59.15 \log h - 59.15 \log K_w - E_j$ (eqn. 5 c)
E_{oh}	$= E+59.15 \log h - E_j$ (eqn. 5 a)
E_j	$= 17\,h - 8[OH^-]$ (eqn. 7), liquid junction emf
H	total analytical excess concentration of hydrogen ions assuming no hydrolysis; in most experiments H was negative
h	concentration of free hydrogen ions

K_a	acidity constant
K_{1q}	equilibrium constant for the formation of AB_q^- (3)
K_w	ionic product of water
K_{pq}	equilibrium constant for formation of A_pB_q from B and A (1 a)
p	number of A in complex A_pB_q
$\bar{p}_{poly}$	average number of A per polynuclear complex
q	number of B in complex A_pB_q
$\bar{q}_{poly}$	average number of B per polynuclear complex
R^{-1}	average degree of condensation of B
R_{poly}	$= (\bar{q}_{poly})^{-1}$
u	a normalized quantity corresponding to a (22)
v	a normalized quantity corresponding to b (22)
α	constant defined by (21)
Z	average number of A per B (4)
Z_1	average number of A per B in the mononuclear species

Chemical symbols are in Roman, concentrations in italic type. Concentrations and equilibrium constants will be expressed in M (mole/l) throughout (except that in Fig. 1 mM is used for B).

METHOD OF MEASUREMENT

This study of the hydrolysis of boric acid has been carried out as a number of potentiometric titrations at 25°C. In order to use concentrations instead of activities in the formulas for emf and equilibrium constants, all solutions were made 3 M in Na^+ by the addition of sodium perchlorate. For the mathematical analysis we decided to give the experimental data in the form $Z(\log h)_B$ or $\log B(\log h)_Z$.

In each titration the total boron concentration, B, was kept constant while the analytical proton deficiency $A = -H$ was varied. A hydrogen electrode was used to determine h. The quantity Z which is the average negative charge per B and may be described as the average number of hydroxyl ions bound per boric acid unit, was calculated from each point of the titration using the relationship

$$BZ = h - H - K_w h^{-1} \qquad (4)$$

where K_w is the ionic product of water in 3 M $NaClO_4$.

The hydrogen electrode was used in combination with the half-cell

SE = Ag,AgCl/0.010 M $AgClO_4$, 2.990 M $NaClO_4$/3 M $NaClO_4$.

For the cell

— Pt, H_2 (1 atm)/H^+ // SE +

the measured emf, assuming the activity factors to be constant, may be represented by the equations

$$E = E_{oh} - 59.15 \log h + E_j \qquad (5\ a)$$
$$E = E_{oa} + 59.15 \log[OH^-] + E_j \qquad (5\ b)$$
$$E = E_{oa} + 59.15 \log K_w - 59.15 \log h + E_j \qquad (5\ c)$$

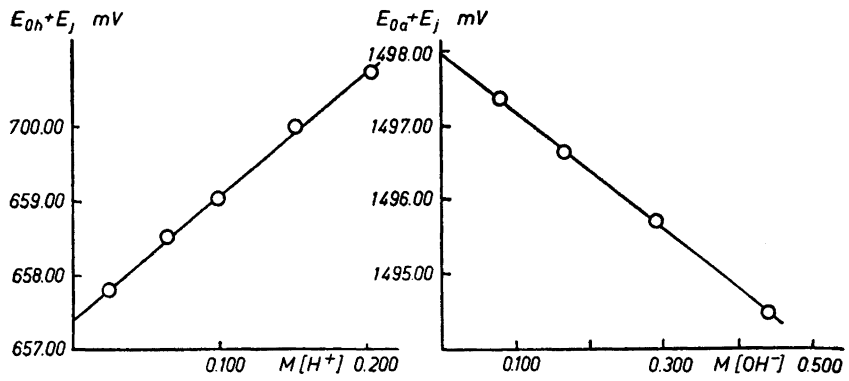

Fig. 2. $E+59.15 \log h = E_{oh}+E_j$ as a function of $[H^+] = h$, and $E-59.15 \log [OH^-] = E_{oa}+E_j$ as a function of $[OH^-]$.

where E_{oh} and E_{oa} are constants, E_j the liquid junction potential and K_w the ionic product of water in 3 M $NaClO_4$.

The ionic product of water was determined in separate titrations by adding a $NaOH+NaClO_4$ solution to a $HClO_4+NaClO_4$ solution. The sum $E+59.15 \log h$ was plotted as a function of h and $E-59.15 \log [OH^-]$ as a function of $[OH^-]$. These functions were approximately straight lines, as shown in Fig. 2, and the slope of the lines was a measure of E_j/h and $E_j/[OH^-]$. By extrapolation to $h = 0$ and $[OH^-] = 0$ the constants E_{oh} and E_{oa} were obtained and the ionic product of water in 3 M $NaClO_4$ was determined as

$$-\log K_w = \frac{E_{oa}-E_{oh}}{59.15} = 14.22 \pm 0.02 \qquad (6)$$

Ågren [23] has obtained $\log K_w = -14.15 \pm 0.10$ in 3 M sodium perchlorate.

From the slopes E_j/h and $E_j/[OH^-]$ in the determination of K_w, we found for *the liquid junction potential* the relation

$$E_j = 17\ h - 8[OH^-] \qquad (7)$$

where h and $[OH^-]$ are in M, and E_j in mV. For acid solutions this agrees well with the relation $E_j = +18\ h$ found by Biedermann and Sillén [24].

The *constants* E_{oh} *and* E_{oa} were, moreover, determined in most borate titrations; E_{oh} was obtained from points in the acid range where boron is practically not hydrolysed ($Z \approx 0$), and E_{oa} from the points with the highest values of $-\log h$ ($Z \approx 1$).

We could then calculate $-\log h$ for each point of the titration in two different ways from E, using either E_{oh} or E_{oa}.

$$-\log h = \frac{E-E_{oh}-17h+8[OH^-]}{59.15} \qquad (8\ a)$$

$$-\log h = \frac{E-(E_{oa}+59.15 \log K_w)-17h+8[OH^-]}{59.15} \qquad (8\ b)$$

These two values of —log h were not identical. The difference was very small at low total concentrations B but appreciable at higher B.

Since both h and $[OH^-]$ in (4) are usually negligible in comparison with $-H$ (except for the highest values of —log h), the variation of the E_0 does not significantly affect the values of Z but only —log h.

The variation of E_{oh} and E_{oa} with the boron concentration

In different titrations with the same B, E_{oh} was always the same within ± 1 mV, but in titrations with different B, E_{oh} decreased with increasing boric acid concentration.

In order to investigate this variation we made a separate titration where B was varied and H was constant and positive. The relationship between E_{oh} and B (Table 1) proved to be approximately linear

$$E_{oh} = \text{const} - 8\,B \qquad (9\text{ a})$$

if E_{oh} is expressed in mV and B in M.

This deviation is probably due to a variation of the activity coefficients with the ionic medium. If some more acidic species like $H_4BO_3^+$ were formed, this would cause a trend in the opposite direction.

In titrations with the same B, E_{oa} was the same within ± 1 mV but varied in titrations with different B. In a separate titration, where $[OH^-]$ was constant ($Z \approx 1.00$) and B was varied, we found the relationship between E_{oa} and B to be approximately linear (Table 1)

$$E_{oa} = \text{const} + 5\,B \qquad (9\text{ b})$$

if E_{oa} is expressed in mV and B in M. This deviation must also be due to a variation of the activity factors. The formation of species like $H_3BO_4^{2-}$ would cause a deviation in the other direction.

Table 1. The variation of E_{oa} and E_{oh} with B.

EXPERIMENTAL DETAILS

Reagents and analysis

Sodium perchlorate was prepared by carefully neutralizing recrystallized Na_2CO_3 (p.a.) with perchloric acid (p.a.). The sodium perchlorate solution was concentrated until a thin layer of the salt formed on the surface, filtered while hot, and the filtrate stirred vigorously while cooling. The salt crystallized well with one molecule of water. The salt was recrystallized twice, after which no Cl^-, ClO_3^- or silica could be detected, and was then found to be free from acid impurities. The $NaClO_4$ solutions were analysed by evaporating a known weight of solution at 120°C and drying at the same temperature until a constant weight was attained.

Perchloric acid. The ordinary p.a. product was used, and was standardized against $KHCO_3$ and standard NaOH. The determinations with different standard substances agreed within ± 0.1 %.

Sodium hydroxide. A 50 % solution was prepared from the commercial p.a. material, filtered through a G4 Jena glass filter, and stored in a polyethylene bottle. Dilute solutions were prepared from de-aerated water and 50 % stock solution. The alkali solutions were standardized against $HClO_4$ which had been standardized in turn against $KHCO_3$. Hydrazine sulfate and acid potassium iodate have also been used for the standardizations giving values in good agreement (± 0.1 %) with the $HClO_4$ value.

The carbonate ion concentration in the NaOH solutions used was about 0.1 % of the NaOH concentration, as estimated from the difference between the methyl red and the phenolphthalein points in a titration.

Boric acid. The ordinary crystallized p.a. product was used. A stock solution was prepared by weighing a known amount of boric acid and diluting with water to a certain volume. The concentration was checked by adding mannitol and titrating with standard alkali using α-naphtholphthalein as indicator.

Silver perchlorate solutions were prepared by adding a slight excess of Ag_2O to a boiling $HClO_4$ solution. The excess of Ag_2O was filtered off, and the Ag^+ content in the solution was determined by Volhard's method using a silver wire as a standard.

Titration vessel solution (S_0). Measured quantities of boric acid, perchloric acid, and sodium perchlorate were added to a volumetric flask to give the concentrations wanted. After waiting until the temperature had become equalized, the flask was carefully filled to the mark with de-aerated water.

Buret solution (T). The procedure was the same as described for the titration vessel solution, S_0, except that the solutions were mixed in a CO_2-free N_2 atmosphere.

Apparatus

Since the work was carried out with alkaline solutions, all glassware may be appreciably attacked by alkali. To avoid this, polythene or alkali resistant glass vessels may be used. Lagerström [25] pointed out in his study of silicate solutions that polythene has so many disadvantages that the use of Jena-Geräte glass was to be preferred. He estimated that an amount of silica corresponding to 0.03 mM is dissolved from the glass vessel during a titration similar to ours (to pH $\approx$ 12). Since this is negligible, Jena-Geräte glass has been used all through this work.

The electrode vessel and the salt bridge were of the "Wilhelm" type described in previous papers [26] from this institute.

Commercially available hydrogen was purified by passing it through a) a column of activated copper at around 180°C to remove traces of oxygen, b) a wash bottle containing 10 % H_2SO_4 to remove alkaline impurities, and c) a wash bottle with 10 % NaOH to remove acidic impurities. Before entering the titration vessel, the gas was saturated with water by passage through two wash bottles containing the ionic medium, 3.0 M $NaClO_4$.

The *hydrogen electrode* was prepared according to Bates [27] (p. 166). Immediately after the preparation, the electrode was electrolysed as the cathode in 0.1 M H_2SO_4 for 20 min. An even distribution of H_2 bubbles on the electrode surface was good evidence of a completely active surface. Electrodes with an uneven distribution of bubbles were immediately taken out of service. A new hydrogen electrode was prepared for each titration,

and the electrode gave a steady potential after 10 to 20 min, regardless of the velocity of the hydrogen stream.

The *silver-silver chloride electrode* was prepared by electro-depositing Ag on a Pt foil and afterwards electrolysing the silver electrode in dilute HCl.

The emf measurements were made with a Jensen compensator (type 10A) and a Multiflex galvanometer. The compensator could be read to a hundredth of a mV.

Titration procedure

The titrations were carried out at 25.0±0.1°C with the cell and the titration vessel immersed in an oil thermostat and the whole equipment in a thermostated room at 25.0±0.5°C.

For each titration two solutions were prepared: S_o (in the titration vessel) and T (in the buret) ,with the following analytical composition.

Solutions	[Na+] M	B M	H M	[ClO_4^-] M
Titration vessel (S_o)	3	B	C_1(C_1M H^+)	$3+C_1$
Buret (T)	3	B	$-C_2$(C_2M OH^-)	$3-C_2$

The manner of titration is best described by an example, and Table 2 gives a representative part of a titration with B = 0.100 M.

In the titration shown in Table 2, the analytical hydrogen ion concentration was checked with aid of the points obtained in the unhydrolysed acid range and in the alkaline part with Z = 1. The end-point was found by Gran's method[28] of extrapolation. The two straight lines, corresponding to free H^+ and free OH^-, intersect in two points on the volume axis. The total hydrogen ion concentration obtained from the intersection of the H^+ line agreed very well with that calculated from the analytical concentrations of solutions S_o and T. The distance between the intersections of the H^+ and OH^- lines on the volume axis corresponds to the amount of A, necessary to give the species AB^-.

In some cases the hydrolysed solution was back-titrated with acid; the points $Z(\log h)$ always fell on the same curve as the points obtained by adding alkali, indicating that the equilibria are completely reversible. (Half-filled symbols in Fig. 1.)

TREATMENT OF THE DATA AND RESULTS

Using the eqns. (4), (8 a) and (8 b), the $Z(\log h)_B$ curves have been obtained from the emf measurements. The data are shown in Table 3 and plotted in Fig. 1.

For values of $B \leqq 0.025$ essentially the same $Z(\log h)$ curve was obtained, which indicates that for these low boron concentrations only the mononuclear species B = $B(OH)_3$ and AB^- = $B(OH)_4^-$ need be considered. Moreover, the curve has the shape characteristic of equilibria with only two mononuclear species.

Table 2. A titration with $B = 0.100$ M

S_0 : $H_3BO_3 = 0.100$ M, $HClO_4 = 0.0434$ M, $NaClO_4 = 3.000$ M, 50.0 ml
T_1 : $H_3BO_3 = 0.100$ M, NaOH = 0.1083 M, $NaClO_4 = 2.892$ M, v_1 ml
T_2 : $H_3BO_3 = 0.100$ M, NaOH = 0.3777 M, $NaClO_4 = 2.622$ M, v_2 ml

Atmospheric pressure = 772.0 mm Hg. The vapor pressure of pure water at 25.0°C = 23.7 torr. This value has been used instead of that valid for 3 M $NaClO_4$. The correction 29.58 log p_{H_2} is +0.20 mV. E_{oh} from the first acid points (8 a) = 658.20 mV. E_{oa} = 1500.00 mV at $Z \approx 1.0$; E_{oh} from E_{oa} and K_w (8 b) = 658.89 mV.

v_1 ml	v_2 ml	Total volume	E mV	E_{corr} mV	−log h calc with E_{oh}	−log h calc with $E_{oa} + 59.15 \log K_w$	$K_w h^{-1} \cdot 10^{-3}$ M	$H \cdot 10^{-3}$ M	$\frac{h - H - K_w h^{-1}}{B} = Z$

For concentrations >0.025 M, different $Z(\log h)$ curves were obtained for different values of B. This shows that besides the mononuclear complexes there must also be polynuclear complexes.

The first step in our calculation has been an approximate determination of the average number of boron atoms and the average charge of the polynuclear complexes, $\bar{q}_{poly}$ and $\bar{p}_{poly}$.

With aid of the values $\bar{q}_{poly}$ and $\bar{p}_{poly}$, we have then tested various hypotheses and determined the equilibrium constant for the most probable complexes.

Table 3. Experimental data. The $-\log h$ values calculated with ($E_{oa} + 59.15 \log K_w$) are omitted in the table for $B = 0.010$, 0.020, 0.025 and 0.050 M since these values are approximately the same as calculated with E_{oh}.

$B = 0.010$ M		$B = 0.020$ M		$B = 0.025$ M		$B = 0.050$ M		$B = 0.100$ M

The average charge and the average number of boron atoms in the polynuclear complexes.

It has been possible to obtain the average composition of the polynuclear complexes from the experimental $Z(\log h)_B$ curves without any special assumptions about the complexes formed using the formulas given by Sillén [29], which give the quantities B_1 and R.

$$\log B_1 = \log B - \int_{-11.60}^{\log h} \left[(Z_1 - Z) - \left(\frac{\partial Z}{\partial \log B} \right)_h \right] \mathrm{d} \log h \text{ at constant } B \quad (10)$$

$$R = 1 - \int_{-11.60}^{\log h} \left(\frac{\partial Z}{\partial \log B} \right)_h \mathrm{d} \log h \text{ at constant } B \quad (11)$$

where B is the total concentration of boron, B_1 the boron concentration in the mononuclear species, R the reciprocal of the average degree of condensation of B and Z_1 = the average number of A per B in the mononuclear species.

The average charge of the polynuclear complexes $\bar{p}_{\mathrm{poly}}$, has been calculated from the equation

$$\bar{p}_{\mathrm{poly}} = \frac{Z_{\mathrm{poly}}}{R_{\mathrm{poly}}} = \frac{BZ - B_1 Z_1}{BR - B_1} \quad (12)$$

and the average number of boron, $\bar{q}_{\mathrm{poly}}$, from

$$\bar{q}_{\mathrm{poly}} = \frac{1}{R_{\mathrm{poly}}} = \frac{B - B_1}{BR - B_1} \quad (13)$$

where BZ = the number of moles A that are bound to B per liter, $B_1 Z_1$ = the number of moles A that are bound to B in the mononuclear species, and BR = the sum of the molar concentration of B and of all complexes containing boron.

Previous solution data, especially the freezing-point data [9], make it appear very likely that the species at the highest and lowest pH are mononuclear, *i.e.* H_3BO_3 (B) at the acid, and $B(OH)_4^-$ (AB) at the alkaline end. In the above formulas borate is assumed to be mononuclear with $Z = 1.00$ for $-\log h \geqq 11.60$.

The integration has been carried out numerically from the experimental $Z(\log h)$ curves at given value of B. As is clear from the above formulas, the determination of R is a step in calculating B_1. Keeping h constant, the slope $(\partial Z/\partial \log B)_h$ from any experimental value for B was assumed to be the average of the difference quotients $(\Delta Z/\Delta \log B)$ for the two neighboring intervals.

An example of the various steps in the calculation is given in Table 4. As follows from (10) and (11), the values of B_1 and R have a minimum at the intersection point. B_1 approaches the value B, and R approaches 1 at the highest values of h when $Z \approx 0$; this fact corroborates our assumption that boric acid and borate ion are chiefly mononuclear at $Z = 0$ and $Z = 1.00$. In Table 4, natural logarithms were used when (10) and (11) were applied.

Table 5 gives $\bar{p}_{\mathrm{poly}}$ and $\bar{q}_{\mathrm{poly}}$ for $B = 0.100$, 0.200, and 0.400 M at various $-\log h$. The data in this table indicate that the most probable complexes in the solution contain three boron and have the charge one or two; however, the

solution may also contain species with two or four boron atoms. In order to see which complexes occur, we have in the following tested various hypotheses with the aid of normalized graphs [30] $\boldsymbol{B}(\log u)_Z$.

The method of normalized $\boldsymbol{B}(\log u)_Z$ graphs [30].

It may be instructive to illustrate by an example the use of normalized graphs in the analysis of the experimental data. If we assume the four species B, AB, AB_3 and A_2B_3 — the combination that we finally have found the most likely one — the law of mass action gives the following equations:

$$[AB] = K_{11} b h^{-1} \quad (14)$$
$$[AB_3] = K_{13} b^3 h^{-1} \quad (15)$$
$$[A_2B_3] = K_{23} b^3 h^{-2} \quad (16)$$

where b is the concentration of free B

$$B = [B] + [AB] + 3[AB_3] + 3[A_2B_3] = b + K_{11} b h^{-1} + 3K_{13} b^3 h^{-1} + + 3K_{23} b^3 h^{-2} \quad (17)$$

$$BZ = [AB] + [AB_3] + 2[A_2B_3] = K_{11} b h^{-1} + K_{13} b^3 h^{-1} + 2\ K_{23} b^3 h^{-2} \quad (18)$$

We wish to transform these expressions to the normalized form:

$$\boldsymbol{B} = v(1 + u) + 3v^3 u(1 + \alpha\ u) \quad (19)$$
$$\boldsymbol{BZ} = uv + v^3 u(1 + 2\alpha\ u) \quad (20)$$

where $$\alpha = \frac{K_{23}}{K_{11} K_{13}} \quad (21)$$

This is achieved by the substitutions:

$$u = K_{11} h^{-1};\ \ v = b(K_{13} K_{11}^{-1})^{\frac{1}{2}};\ \ \boldsymbol{B} = B(K_{13} K_{11}^{-1})^{\frac{1}{2}} \quad (22)$$

From the normalized eqns. (19) and (20) we can get

$$2 \log \boldsymbol{B} = 2 \log [1 - 2u(1 - \alpha) - \alpha u^2] + \log (2 + Zu - u) - 3 \log [(1 + 2\alpha u) - -3Z\ (1 + \alpha u)] - \log u \quad (23)$$

If the constant α is known one may calculate $\boldsymbol{B}$ as a function of Z and $\log u$.

Graphs $\log \boldsymbol{B}\ (\log u)_Z$ were calculated for some values of α and compared with the experimental graph. From the graph which fitted best with the experimental data we obtained the constants K_{11} and K_{13} as differences along the coordinate axes.

$$\log \boldsymbol{B} - \log B = \tfrac{1}{2} (\log K_{13} - \log K_{11}) \quad (24)$$
$$\log u - \log h = \log K_{11} \quad (25)$$

and the constant K_{23} from the value of α giving the best fit.

Survey of the projection map

The normalized $\log \boldsymbol{B}\ (\log u)_Z$ graph calculated from (22) with $\alpha = 0.25$ is given in Fig. 3c, and the various complexes have been put down in the range where they dominate.

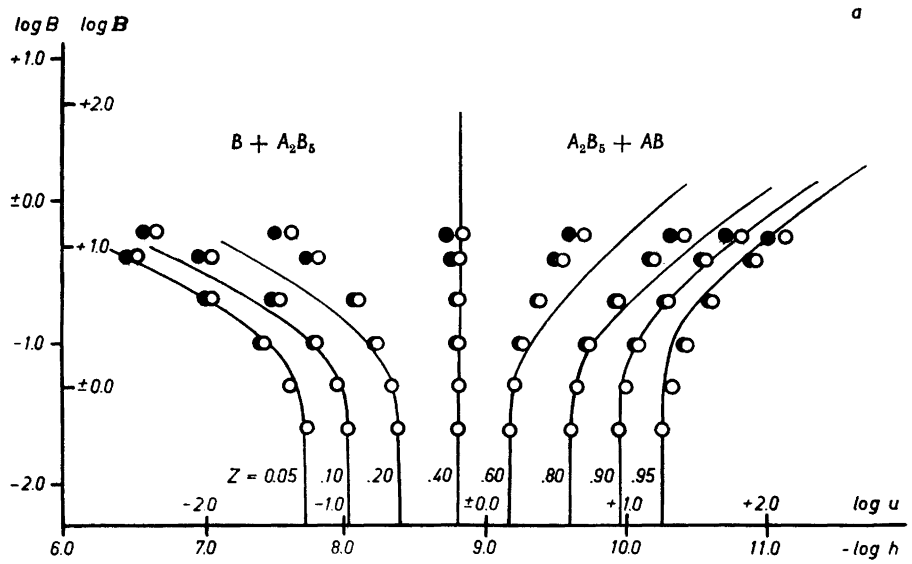

Fig. 3. "Surface-fitting" of the experimental data for the hydrolysis of boric acid and borate ion plotted as log B(log h)$_Z$ (open circles, experimental $-\log h$ calculated from E_{oh} and filled circles $-\log h$ calculated from $E_{ca} + 59.15 \log K_w$). The curves give the projection map log B (log u)$_Z$ in the best fit, calculated for the following species:

a) B, AB and A_2B_5 (the hypothesis of Carpéni [22])

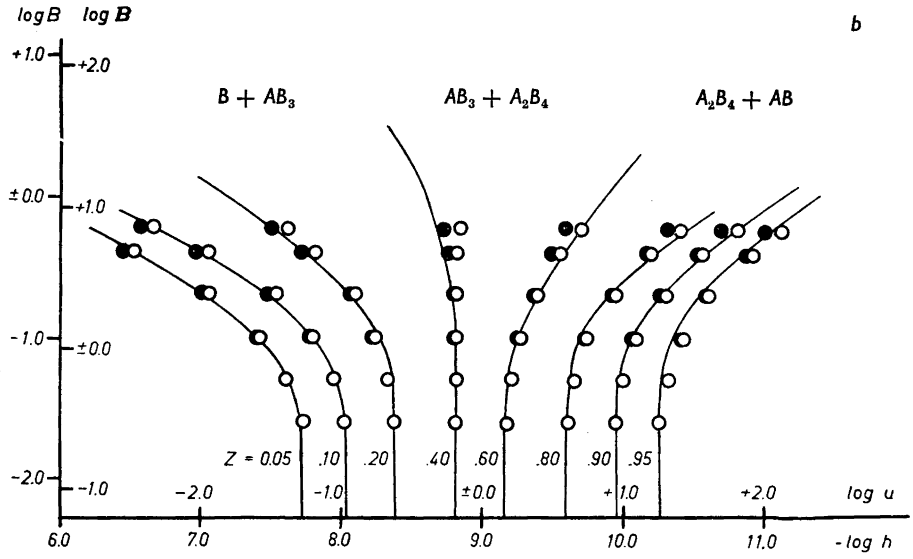
$AB + B$. In the lower part of the graph the value of (log u)$_Z$ does not change with B, and the vertical lines correspond to a system with two mononuclear species AB and B. The u values for different Z are given by

$$u \approx \frac{Z}{1-Z} \tag{26}$$

as may be derived from (19) and (20), with $v \ll 1$.

$B + AB_3$ From the eqns. (19) and (20) for $u \ll 1$ and $\alpha u \ll 1$ we get

$$B = v + 3v^3u; \quad B\bar{Z} = v^3u \tag{27}$$



which means that practically only the complexes B and AB_3 are formed and

$$\log B = \tfrac{1}{2} \log \frac{Z}{(1-3Z)} - \tfrac{1}{2} \log u \tag{28}$$

Thus log B (log u)$_Z$ is the family of straight lines with the slope $-\frac{1}{2}$ in the left upper part of the graph.

$A_2B_3 + AB$. In a similar way the rectilinear curves to the right in the graph correspond to a range with practically only the complexes AB and A_2B_3, and log B(log$u$)$_Z$ is given by

$$\log B = \tfrac{1}{2} \log \frac{Z-1}{(3Z-2)^3} - \tfrac{1}{2} \log \alpha + \tfrac{1}{2} \log u \tag{29}$$

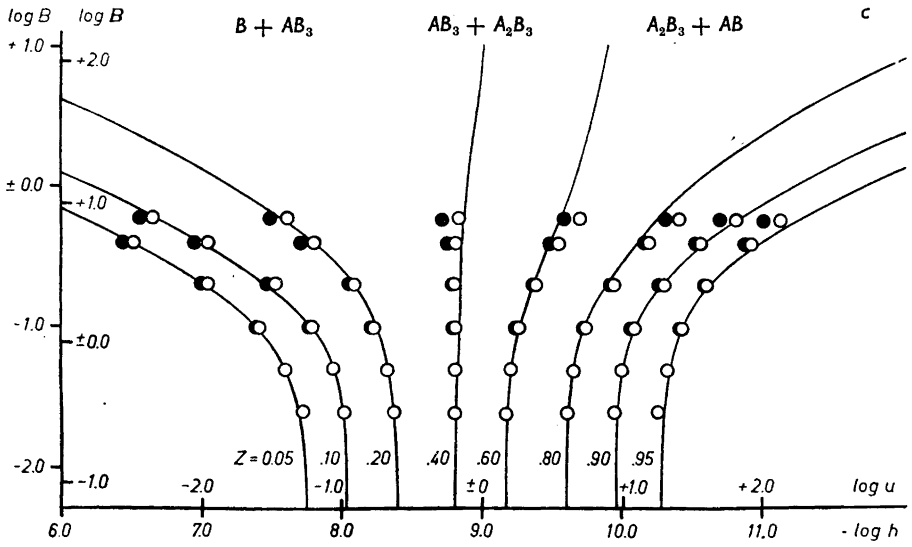


Fig. 3. (Continued) -

b) B, AB, AB_3 and A_2B_4 assuming $\frac{K_{24}}{K_{11} \cdot K_{13}} = 1.25$

c) B, AB, AB_3 and A_2B_3 assuming $\frac{K_{23}}{K_{11} \cdot K_{13}} = 0.25$

$AB_3+A_2B_3$. The upper almost vertical lines in the graph correspond to the predominance of the two polynuclear complexes AB_3 and A_2B_3, and the log u value for different Z is given by

$$\log u = \log (1-3Z) - \log \alpha - \log (3Z-2) \qquad (30)$$

Hypotheses tested

We have tried to explain the experimental data with as few polynuclear complexes as possible. The value of $\bar{p}_{poly}$ and $\bar{q}_{poly}$ indicates that the number of boron atoms does not rise above four and the charge not above minus two in any complex.

If only *one polynuclear complex* exists, the Z value ≈ 0.40 of the intersection point of the curves would correspond to the formula of that complex. The only possible formula is then A_2B_5 which has been suggested by Carpéni [20,21]. Although the value of $\bar{q}_{poly}$ indicated that the complex A_2B_5 was not to be expected, normalized graphs were constructed with the function B, assuming B, AB and A_2B_5 to be the species present. For all values of Z the agreement was so poor (Fig 3a) that an explanation with only the complex A_2B_5 can be ruled out.

Next it was assumed that *B, AB and only two polynuclear* complexes exist and that these contain two, three or four boron and the charge minus one or two. All such combinations that can give an intersection at $Z \approx 0.40$ are as follows:

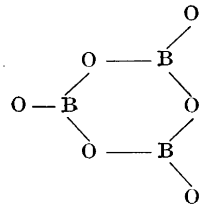
$B + AB_3 + A B_2 + AB$	$(1_3 1_2)$
$B + AB_3 + A_2B_4 + AB$	$(1_3 2_4)$
$B + AB_3 + A_2B_3 + AB$	$(1_3 2_3)$
$B + AB_3 + A_2B_2 + AB$	$(1_3 2_2)$
$B + AB_4 + A B_2 + AB$	$(1_4 1_2)$
$B + AB_4 + A_2B_4 + AB$	$(1_4 2_4)$
$B + AB_4 + A_2B_3 + AB$	$(1_4 2_3)$
$B + AB_4 + A_2B_2 + AB$	$(1_4 2_2)$

Normalized graphs log B (log $u)_Z$ were constructed for the combinations $(1_3 1_2)$, $(1_3 2_4)$, $(1_3 2_3)$ and $(1_4 2_4)$.

The calculated graph with *the combination* $(1_4 2_4)$ gave a fair fit in the range of A_2B_4 and AB, but did not fit at all at the low values of Z where B and AB_4 would predominate. We thus concluded that there is no range where B and AB_4 predominate *which rules out all the combinations containing* 1_4 ($1_4 1_2$, $1_4 2_4$, $1_4 2_3$ *and* $1_4 2_2$).

In *the combination* $1_3 2_2$ the intersection Z must vary between 0.33 and 1.00. Higher B increases the ratio $AB_3(A_2B_3)^{-1}$ and consequently decreases the intersection point. However, from the experimental Z (log $h)_B$ we found a tendency of the intersection point to increase or to be constant; therefore *the combination* $1_3 2_2$ *has been ruled out* as being unlikely.

The calculated graph *for the combination* $1_3 1_2$ *agreed too poorly* with the experimental curves to explain them.

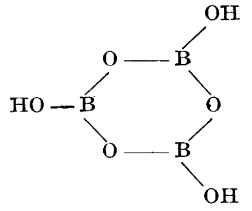


The normalized graph for the *combination* $1_3 2_4$ fitted fairly well with the experimental data (Fig. 3b) but not as well as the remaining *combination* $1_3 2_3$ (Fig. 3c).

Before a discussion of possible structures for the complexes found, it is necessary to survey some previous works on borate in crystals.

STRUCTURAL DATA

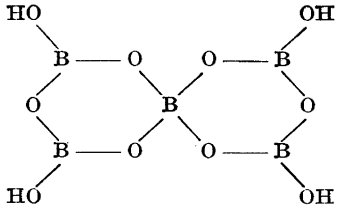
Structures of anhydrous borates. In such hydrogen-free compounds as may be obtained at high temperatures, isolated BO_3 triangles are very often encountered. For instance BO_3^{3-} triangles are found in $LaBO_3$ with the aragonite structure, in $InBO_3$ and $ScBO_3$ with the calcite structure (Wells [31], p. 598), and in $Co_3(BO_3)_2$ and $Mg_3(BO_3)_2$ (Berger [32]).



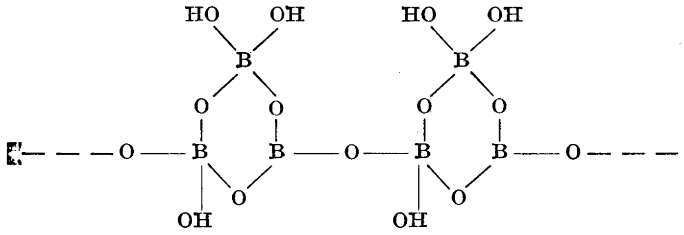
An almost planar group $B_2O_5^{4-}$, consisting of two BO_3 triangles sharing a corner, was found in $Co_2B_2O_5$ (Berger [33]) and $Mg_2B_2O_5$ (Takéuchi [34]). In CaB_2O_4 the BO_3 triangles form infinite chains, each BO_3 group sharing two of its O atoms with neighbors (Zachariasen and Ziegler [35]). Finally, the BO_3 groups can also join to form planar rings $B_3O_6^{3-}$ in the salts $K_3B_3O_6$ and $Na_3B_3O_6$ previously written as KBO_2 and $NaBO_2$ (Zachariasen [36] and Fang [37]).

Four-coordinated B (BO_4 tetrahedra) is found in B_2O_3 (Berger [38,39]), in BPO_4 and $BAsO_4$ (Schulze [40]), and in $CaB_2Si_2O_8$ (Machatschki and Stradner [41]). According to Ito, Morimoto and Sadanaga [42], $Mg_3B_7O_{13}Cl$ (boracite) contains both BO_4 tetrahedra and flat BO_3 pyramids.

Structures of borates containing hydrogen. The crystal structure of boric acid is built up of layers with flat $B(OH)_3$, triangles, joined by hydrogen bonds (Zachariasen [43,44]). The metaboric acid, $HBO_2(\beta)$, contains chains with boron both in three- and four-coordination, according to a preliminary report by Zachariasen [45].



The α-form of metaboric acid has been investigated by Tazaki [64]. According to him the structure is built up of ringshaped trimeric units:



These units are bound together by hydrogen bridges to give a layer structure.

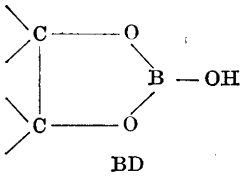
Tetrahedral ions $B(OH)_4^-$ have been found in the structures of the minerals teepleite, $Na_2B(OH)_4Cl$ (Formaseri [46]) and bandylite, $CuB(OH)_4Cl$ (Collin [47]). From the close similarity of the Raman spectra of teepleite and of concentrated potassium borate solutions, Edwards *et al.*[48] concluded that the mononuclear borate ion in solution has the formula $B(OH)_4^-$.

Only two polyborates, to our knowledge, have been thoroughly studied. One is the salt "$KB_5O_8(H_2O)_4$", which is more properly written as $KH_4B_5O_{10}(H_2O)_2$. According to Zachariasen [49], this salt contains the group B_5O_{10}, where two B_3O_3 rings have one B atom in common; this B has a tetrahedral configuration, whereas the others are triangular. From measurements of nuclear magnetic resonance, Smith and Richards [50] concluded that there are four protons attached to this group, the remaining protons being bound in H_2O (Zachariasen originally proposed two H in the B_5O_{10} group, and two H_3O^+ ions). The formula of the group would thus be (the planes of the two rings form right angles)

The crystal structure of colemanite, $CaB_3O_4(OH)_3H_2O$ has been described as containing chains of three-boron rings:

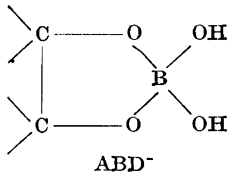
where one B has triangular, two tetrahedral surroundings (Christ, Clark, and Evans [51]).

A Spanish research group has proposed structures for some other polyborates, but according to the *Structure Reports* (1947—45, p. 428—432, 1949, p. 264) these cannot be considered as certain. If they are correct, the structures contain BO_3 and B_3O_6 rings, combined to form sheets.



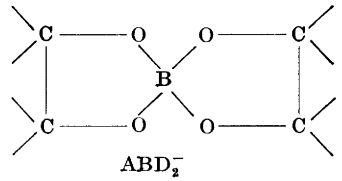
The fact that the mineral kernite, $Na_2B_4O_7(H_2O)_4$, has a fibrous structure indicates that it contains polyborate chains (Menzel and Schulz [52]). This is also indicated by a preliminary X-ray structure analysis (Berger [53]).

It seems very likely that the "sodium metaborate" $NaBO_2(H_2O)_2$ is really $Na^+B(OH)_4^-$. However, from the mere existence of salts like $Na_2B_4O_7(H_2O)_{10}$ and $NaB_5O_8(H_2O)_5$, it is not safe to conclude that ions $B_4O_7^{2-}$ and $B_5O_8^-$ would exist as separate units, even in the crystal structures. The structures of silicate



minerals would give a warning against such conclusions; the structures may well contain infinite units (chains, sheets) or several different ionic species.

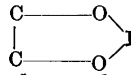
Complexes with polyols. Boric acid forms complexes with a number of polyols, *i.e.* organic compounds containing several OH groups. Such complexes are put to practical use, as for instance, when mannitol is added before titration of boric acid; the latter then behaves like a strong acid. Since these complexes may show analogies with the polyborate ions, we shall here try to summarize the main facts about them.



Most of the borate complexes prepared or proved to exist from equilibrium data may be written in one of the following three forms (see *e.g.* Böeseken [54]):

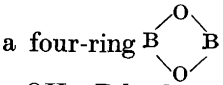
BD

ABD^-



ABD_2^-

(D = diol). Compounds of type BD, when they have been prepared, have proved to be very weak acids, still weaker than boric acid (Hermans [55]). It has not been definitely proved whether the ions ABD^- formed with polyols have the four-coordinated configuration written above, or a three-coordinated configuration with a single O bound to B instead of 2 OH. However, considering the general weakness of the B—O—H acidity, it seems likely that negative ions which can exist where $B(OH)_3$ would not be ionized are generally four-coordinated. For ions of the form ABD_2^- the tetrahedral configuration has been proved by the resolution of optical isomers.



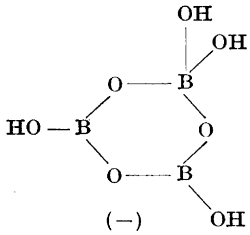
The existence of complexes ABD^- and ABD_2^- has been proved in many instances by analysis of pH and conductance data (later work, *e.g.* Deutsch and Osoling [56], mannitol; Ross and Catotti [57], mannitol; Schäfer [58], pyrocatechol, salicylic acid, and mannitol; Torsell [59], mannitol and fructose). In all of the cases quoted only ABD^- and ABD_2^- were found. Occasionally there is evidence for uncharged BD (which has then probably the form above, Böeseken and Niks [60]) but never for uncharged BD_2.

Boric acid is rather particular in the choice of diol (Schäfer [61], Isbell *et al.* [62], and especially Böeseken [54]). With glycol or glycerol it reacts only at high concentrations, whereas a strong reaction is observed with polyols like mannitol and erythritol. Considering aromatic diols, it reacts only with the ortho-compounds, but with *cyclo*pentane-1,2-diol it reacts only with the *cis*form. It does not seem to react at all with any form of *cyclo*hexane-diol. Steric explanations have been proposed (Böeseken [54]).

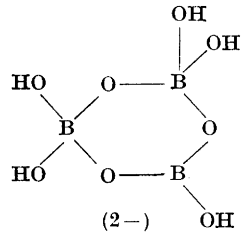
It seems essential that a five-membered-ring  is formed (a six-membered-ring with one more C has occasionally been obtained). Complexes where a carbonyl C—O may react like a $C(OH)_2$ group are known; however, such OH groups do not seem to react with the same B atom forming a four-ring.

General rules for borate structures. From the equilibrium data, we may deduce the number of boron atoms and the charge for a certain polyborate ion

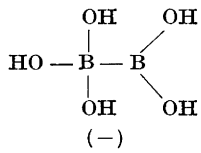
in solution. This still leaves us a number of possible formulas that differ by one or several H_2O, like $B_3O_3(OH)_4^-$, $B_3O_4(OH)_2^-$, $B_3O_5^-$ etc; one cannot decide between them from equilibrium data alone. However, the structures of borate crystals and organic borate complexes may give some aid in proposing a formula and a reasonable structure.



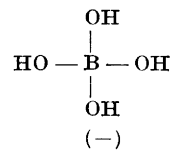
BO_3 or BO_4 groups, as a rule, are joined by sharing an O atom, thus forming a B—O—B bridge. In B_2O_3, some oxygen atoms are said to be shared between three B atoms (Berger [39]); however, no case with a four-ring  seems to be known. There is also no structure known with B—OH—B bridges.



The sharing of an oxygen between more than two B has not been proved in any other compound than B_2O_3 where there is a great shortage of oxygen. We shall assume that it does not occur in aqueous solutions, where a large number of oxygen atoms are available.



It seems very unlikely that polyborate ions in aqueous solution would be held together by hydrogen bonds between OH groups attached to different B, considering that solutions of pure boric acid show no association (Menzel [7]).



As for the *unshared oxygen* atoms bound to boron, it seems reasonable to assume as a working hypothesis that they are *always OH groups*. Thus Edwards *et al.*[48] suggest that $B(OH)_3$ forms an ion not by splitting off H^+ to form $BO(OH)_2^-$, but by addition of OH^- to boron $B(OH)_4^-$. This also agrees with the crystal structures of $KH_4B_5O_{10}(H_2O)_2$ and $CaB_3O_4(OH)_3H_2O$ given above.

If these rules are general, we can easily see that in any borate ion there will be one negative charge for each four-coordinated boron atom, *e.g.*

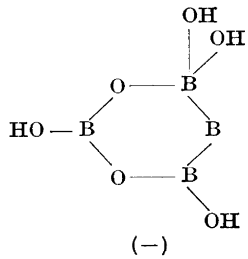
The ion $H_4B_5O_{10}^-$ agrees well with these principles.

The ease with which boron can switch over between three- and four-coordination is probably one of the reasons why the polyborate equilibria are so rapidly achieved.

CONCLUSIONS

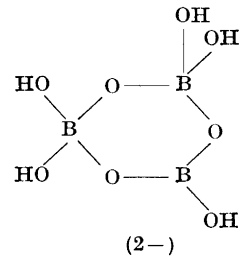
From the measurements made in this work, we have obtained the following equilibria:

$$B(OH)_3 + H_2O \rightleftharpoons B(OH)_4^- + H^+; \quad \log K_{11} = -9.00 \pm 0.05$$
$$3\,B(OH)_3 \rightleftharpoons B_3O_3(OH)_4^- + H^+ + 2H_2O; \quad \log K_{13} = -6.84 \pm 0.10$$
$$3\,B(OH)_3 \rightleftharpoons B_3O_3(OH)_5^{2-} + 2H^+ + H_2O; \quad \log K_{23} = -15.44 \pm 0.20$$



The experimental data may also be explained if the last equilibrium is replaced with

$$4\,B(OH)_3 \rightleftharpoons B_4O_4(OH)_6^{2-} + 2H^+ + 2H_2O; \quad \log K_{24} = -15.71 \pm 0.20$$



In both cases the agreement between the experimental and calculated data is satisfactory except for small deviations at high values of Z and B. These deviations may be explained as a variation in the activity factors. The agreement between the constant obtained in this investigation and in other investigations seems to be satisfactory — Owen [11] (log $K_a^\circ = -9.236$), Thygesen [13] (log $K_{13} = -7.5$ at 18°C), Stetten [14] (log $K_{1,3.2} = -6.86$) and Edwards [15] (log $K_{13} = -7.5$).

From general chemical considerations, the polynuclear combination AB_3 and A_2B_4 seems to be very unlikely.

The possibility that AB_3 and A_2B_3 could be chains must be ruled out since it would be very hard to explain why a certain number should be preferred. It seems to be more likely that the complexes contain a six membered B—O—B ring

(−)

(2−)

Note. When our work was completed a structure determination by Christ and Clark [63] appeared which corroborated our conception that the most likely two-charged polynuclear complex was to be $B_3O_3(OH)_5^{2-}$. Christ and Clark [63] showed in a X-ray investigation of the mineral mayerhofferite, $2CaO \cdot 3B_2O_3 \cdot 7H_2O$ that the crystal contains polyions consisting of two $BO_2(OH)_2$ tetrahedra and a $BO_2(OH)$ triangle linked to form a ring of the composition $B_3O_3(OH)_5^{2-}$, which is the same complex that we have proposed above.

This work is part of a program financially supported by *Statens Naturvetenskapliga Forskningsråd (Swedish Natural Science Research Council)*. It has also received much stimulation from research work supported by Columbia-Southern Chemical Corporation, in this laboratory.

Some Electron Diffraction Studies of 1,4-Dibromo-butyne-2

A. ALMENNINGEN, O. BASTIANSEN and F. HARSHBARGER

Universitetets Kjemiske Institutt, Blindern, and Institutt for teoretisk kjemi, N.T.H., Trondheim, Norway

Heat capacity measurements [1,2] of $CH_3-C\equiv C-CH_3$ have indicated an almost free rotation between the methyl groups. In the case of $CH_3-C\equiv C-CF_3$ there have been contraversial views [3-5] over the possibility of internal free rotation. It seemed of interest to study the internal rotation in a similar molecule by electron diffraction. The diffraction power of bromine made $CBrH_2-C\equiv C-CBrH_2$ suitable for our studies.

The diagrams were taken by the Oslo electron diffraction apparatus [6] using distances between the diffraction point and photographic plate of 48 cm and 19 cm. The intensity data went out to $s = 27$. The data were treated in our usual manner [7], but with a very strong damping factor of 0.006, as we were primarily interested in the longer distances. The information about these distances is found in the inner part of the intensity curve.

The radial distribution curve is presented in Fig. 1 and is compared with the theoretically determined distances. The positions of the distances are indicated by perpendicular lines. These values were calculated using the following parameters: $C_1-H_1 = 1.09$ Å, $C_2-C_3 = 1.21$ Å, $C_1-C_2 = 1.45$ Å and $Br_1C_1C_2 = 111.5°$. The height of each line is proportional to $n\,Z_1Z_2/r$, where Z_1 is the atomic number of one atom, Z_2 is the atomic number of the second atom, n is the number of times the distance occurs in the molecule, and r is the distance.

If we subtract from the radial distribution curve the contribution of distances which would be invariable under rotation, we obtain the contribution of the distances which are dependent upon the rotation. This curve is presented in Fig. 2 as the solid line and should give information about the Br_1-Br_4 and the Br_1-H_4 distances.

If the molecule were rigid, there would be only one Br—Br peak. For a *cis* molecule the peak would occur at 5.55 Å and for a *trans* molecule at 6.63 Å. The difference curve shows no single simple peak. On the contrary, the double peak in Fig. 2 suggests free rotation.

The theoretical radial distribution curves for the Br_1-Br_4 distance were calculated assuming free rotation. These curves were made by assuming normal curves whose areas were proportional to the probability of the corresponding r-value. Gaussian normal curves were used. The three different theoretical curves (Fig. 2)

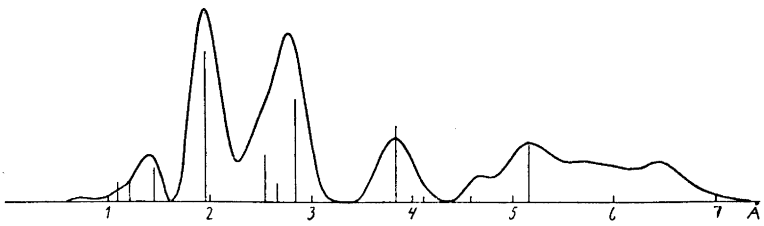

Fig. 1. Radial distribution curve for $BrH_2C-C\equiv C-CH_2Br$ ($k = 0.006$).

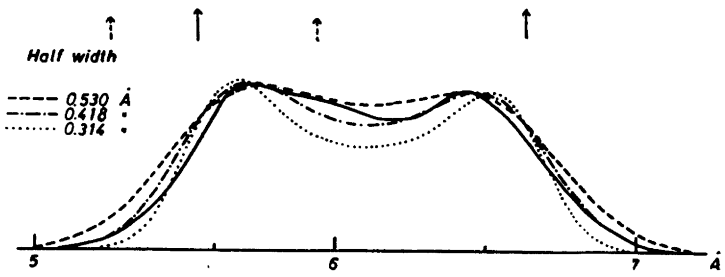

Fig. 2. Experimental difference curve and theoretical curves calculated on the assumption of free rotation.

represent three different choices for the half-width, *i. e.*, 0.314 Å, 0.418 Å, and 0.530 Å. The theoretical curves were normalized to the experimental curve.

The agreement between the theoretical and experimental curves is good. The discrepancies are easily understood: 1) The choice of the subtracted envelope [7] is somewhat arbitrary, 2) the subtraction of the invariable distances leaves some uncertainty, and 3) the Br_1-H_4 distances are expected to give rise to a detectable effect. The Br_1-H_4 distances should have a probability curve similar to that for Br_1-Br_4, but with peaks at about 5.37 Å and 5.87 Å and a total area about 15 % of the Br_1-Br_4 area. The maximum and minimum Br_1-H_4 distances are marked by dashed arrows in Fig. 2. The maximum and minimum Br_1-Br_4 distances are marked by solid arrows.

There remains one unexplained point in the radial distribution curve, namely the comparatively large area located at 4.67 Å. The C_1-H_4 distance at 4.58 Å should not give rise to such a large area. Even though we are not able to interpret this point, we feel it has no essential effect on our conclusion that there is internal rotation in the gaseous $CBrH_2-C\equiv C-CBrH_2$ molecule.

Phenol Dehydrogenations

VII. *. Dehydrogenation of Chavicol to Magnolol

H. ERDTMAN and J. RUNEBERG

Institutionen för organisk kemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

The biosynthetic importance of dehydrogenative coupling of phenols with the formation of diphenyl or diphenyl-oxide derivatives has recently been discussed by Erdtman and Wachtmeister [1]. Magnolol (II) is a particularly simple example with a structure indicating that it has been formed by the coupling of two molecules of chavicol (I) or an aromatic precursor.

I II

Magnolol occurs in the bark of a number of *Magnolia* species. The compound was isolated and its structure elucidated by Sugi [2] who also synthesised tetrahydro-magnolol.

We have now obtained magnolol in a yield of about 25 % by dehydrogenation of chavicol with ferric chloride. During this work Ohta and Mori [3] reported the formation of tetrahydromagnolol from *p*-(*n*-propyl)-phenol by dehydrogenation with a mixture of hydrogen peroxide and aqueous ferrous sulphate. Tetrahydro-magnolol was also obtained recently by Haynes, Turner and Waters [4] during their studies on the dehydrogenation of various phenols with potassium ferricyanide.

Experimental *. *Dehydrogenation of 1-allyl-4-hydroxy-benzene (chavicol):* Ferric chloride (28 g) was dissolved in distilled water (2 500 ml) in a three-neck flask. 1-Allyl-4-hydroxy-benzene (10 g) in 95 % ethanol (40 ml) was added dropwise during 4 h with stirring while a stream of air was bubbled through. The solution turned first green and then black. Stirring and aeration was continued for 48 h more. When the stirring was stopped at the end of this period, a viscous red oil collected at the bottom of the flask. The reaction mixture was acidified and extracted with ether, the ether solution extracted with 2 N sodium hydroxide and the alkaline solution acidified and extracted with ether. After washing and drying the ether extract was evaporated and the remaining oil distilled yielding first, unchanged starting material (5.9 g), then a liquid fraction (0.79 g) boiling at 120—130°/0.8 mm which was not further investigated and finally a crystalline fraction (1.02 g) consisting of magnolol boiling at 175—177°/0.8 mm. Allowing for recovered starting material the yield of crude magnolol was 25 %.

Magnolol phenylurethan: The above crude magnolol (1.0 g) was heated with phenyl *iso*-cyanate (1.2 g) at 110° for one hour in a sealed tube. Excess reagent was evaporated under vacuum on a waterbath. A benzene solution of the crystalline residue was filtered through a 20 cm column of aluminum oxide soaked with ligroin. The first product leaving the column was the phenylurethan. The impurities moved at a slower rate. Evaporation of the solvent gave the phenylurethan (1.3 g) which after recrystallisation from 95 % ethanol melted at 143.5—144.5° undepressed by magnolol phenylurethan obtained synthetically from 2,2-dihydroxydiphenyl [5].

Magnolol from magnolol phenylurethan: Magnolol phenylurethan (2.0 g) was heated overnight in a high vacuum at 200° in a tube sealed at one end and surrounded by a coil providing a decreasing thermogradient towards the open end of the tube where the magnolol formed was deposited. Yield 0.87 g. The product was resublimed twice; m. p. 101.0—101.5° (lit. 103°), undepressed by magnolol obtained synthetically from 2,2′-dihydroxydiphenyl [5].

Isomagnolol: In a nickel crucible, powdered potassium hydroxide (0.25 g) was dissolved in hot amyl alcohol (0.36 g). Magnolol (0.1 g) was added and the melt heated at 140° for 20 h. After cooling, water (10 ml) was added and the amyl alcohol removed by steam distillation. The remaining solution was filtered and acidified. The crystalline precipitate formed was collected, washed with water, dried and recrystallised from ligroin, m. p. 142—143° (lit. 143.5°).

The Incorporation of ^{32}P into Mitochondrial Thiamine Diphosphate* in the Presence of Different Substrates and Inhibitors

KARL-HEINZ KIESSLING

Institute of Zoophysiology, Uppsala, Sweden

The incorporation of radioactive phosphate into intramitochondrial TDP has been studied in a series of investigations [1-4]. The incorporation was found to depend on the simultaneous metabolization of pyruvate or succinate, whereas α-ketoglutarate was less effective [4]. These results are partly in agreement with those of Bartley [5], who, when incubating a kidney cyclophorase enzyme complex with synthetic TDP and $^{32}P_i$ found a somewhat higher incorporation in the presence of pyruvate and succinate than when using α-ketoglutarate. However, in Bartley's experiments the incorporation was slow compared with that observed by me, since added thiamine phosphates do not take part in mitochondrial phosphate metabolism to the same degree [2] as intramitochondrial TDP. That the incorporation of ^{32}P into TDP was higher with succinate than with α-ketoglutarate was surprising, for since the investigations of Auhagen [6] and Lohmann and Schuster [7], TDP has been known especially to function as a coenzyme in the decarboxylation of α-ketoacids. However the incorporation with succinate as a substrate might depend on succinate being transformed into pyruvate in the mitochondria and, when the pyruvate thus formed was oxidatively decarboxylated, an exchange of the phosphate in TDP might take place. If this were the case fumarate, which is primarily formed when succinate gives rise to pyruvate, should have the same effect as succinate on the incorporation into TDP. Results from an experiment aiming to answer this question are seen in Table 1. The experimental conditions were the same as in the previous paper [3] except that the concentration of phosphate buffer present in the mitochondrial suspension was twice that of the earlier amount (3 ml 0.5 M, pH 7.4, instead of 1.5 ml) and pyruvate and α-ketoglutarate were replaced by succinate or fumarate. From the table it is seen that when fumarate is metabolized the incorporation of ^{32}P into intramitochondrial TDP is slower than when succinate is present, the incorporation being of the same extent as that during incubation without added substrate. Thus the incorporation into TDP with succinate as a substrate does not depend on succinate being transformed into pyruvate.

Amytal (5-ethyl-5-*iso*amylbarbiturate), in a concentration of 1.8 mM has been shown by Ernster *et al.*[8] to inhibit completely hydrogen transfer from mitochondrial dehydrogenases to oxygen in DPN-linked oxidation systems, while at the same time having no effect on the aerobic oxidation of succinate, or on the phosphorylations coupled to it. This is explained as depending on the action of amytal on the electron transport pathway between FAD and Slater's factor at a site not present in the succinate oxidation pathway.

Incubating mitochondria in the same way as in the experiments described in Table 1 with succinate and amytal gave the same or only slightly lower incorporation of ^{32}P into TDP than when amytal was omitted (Table 2). The oxidation of fumarate was completely inhibited with the same concentration of amytal. This provides further evidence that the incorporation into TDP is not caused only by oxidative decarboxylation of the pyruvate eventually formed from succinate.

Succinic dehydrogenase has been shown not to contain TDP. Up to now the only known reaction including succinate which requires the presence of TDP is the decarboxylation of succinate to propionate found by Whitely [9] to occur in certain bacteria, and the carboxylation of propionate recently shown by Lardy and Adler [10] to occur in liver mitochondria. However, the reverse reaction of the propionate carboxylation they found to proceed slowly, at least in extracts of mitochondria, making this reaction less probable as a possible explanation of the results above.

Sodium fluoride (final concentration 0.02 M), when used in my experiments, inhibited the incorporation into TDP completely and reduced the oxygen consumption to

* Abbreviations: TDP, thiamine diphosphate; ADP, adenosine diphosphate; DPN, diphosphopyridine nucleotide; DNP, 2,4-dinitrophenol; FAD, flavin adenine dinucleotide; $^{32}P_i$, radioactive inorganic phosphate; P/O = the ratio of μmoles esterified phosphate to μatoms consumed oxygen.

Table 1. Incorporation of radioactive phosphate into intramitochondrial TDP in the presence of succinate or fumarate. Experimental conditions see text. Volume of sample 14.22 ml. Two ml of this volume were transferred to Warburg vessels for determination of the O_2-consumption. Incubation temp. 30°C. Incubation time 25 min. No synthetic TDP was present during incubation. In order to facilitate the isolation of the intramitochondrial TDP three mg were, however, added after the reaction had been stopped with TCA. The radioactivity of intramitochondrial TDP was estimated according to values given in an earlier paper [3].

Substrate	TDP counts/μg hydrolyzable P	Oxygen consumption mm^3/25 min/2 ml sample	P/O
Succinate	1.45×10^4	151	2.45
Fumarate	0.66×10^4	145	2.28
None	0.72×10^4	40	1.86

Table 2. The effect of amytal on the incorporation of radioactive phosphate into intramitochondrial TDP with succinate as a substrate. Experimental conditions see Table 1. Incubation time 20 min. When amytal is present its final concentration is 1.8 mM.

Substrate	Inhibitor	TDP counts/μg hydrolyzable P	Oxygen consumption mm^3/20 min/2 ml sample	P/O
Succinate	None	4.6×10^4	133	2.3
Succinate	Amytal	4.4×10^4	135	2.1
None	None	2.1×10^4	48	1.9

20 %. DNP (final concentration 10^{-4} M) had no effect on the incorporation. The substrate was in both cases pyruvate.

Ochoa [11] when investigating the enzymic synthesis of TDP in animal tissues found that NaF in a concentration of 0.04 M only slightly affected the synthesis. This may be taken as additional evidence, aside from that given earlier [2], that the incorporation of ^{32}P into TDP, reported above, is not only the result of a mere synthesis of TDP from thiamine present in the mitochondria.

The results with DNP are in agreement with those of Ogata *et al.*[12] who found no inhibition with DNP of the transfer of ^{32}P from labelled TDP to ADP in a liver cyclophorase system.

Quantitative Mass Spectrometric Analysis of Mixtures of Unsaturated and Saturated Fatty Acids

BO HALLGREN, EINAR STENHAGEN and RAGNAR RYHAGE

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, and Laboratory for Mass Spectrometry, Biochemical Institute, Karolinska Institutet, Stockholm

It has been shown [1] that with the aid of a high-resolution mass spectrometer it is possible to obtain excellent mass spectra of methyl esters of saturated long chain carboxylic acids. Two series of peaks are prominent, *viz.* ionized hydrocarbon fragments and methoxycarbonyl-containing fragments, respectively. The latter type of fragments dominates quantitatively over the former. The spectra show comparatively large parent peaks due to the ionized unfragmented molecules. These allow a direct determination of the molecular weights of the compounds studied. In mixtures, the peak heights of the parent peaks can be used for the quantitative analysis of mixtures of normal chain fatty acids of high molecular weight (*cf.* Ref.[1]). The general principles of the analysis of mixtures in the mass spectrometer are outlined in standard texts (*cf.*, *e.g.*, Refs. [2-4]).

If we have a mixture of a saturated methyl ester and methyl esters of mono- or poly-ethenoid acids having the same number of carbon atoms the mass spectrum will show a series of parent peaks corresponding to the different molecular weights. The high-mass range of the mass spectrum for a mixture of C_{18} acids is reproduced in Fig. 1. The saturated ester (methyl stearate) has a parent peak at m/e = 298, the mono-ethenoid ester (methyl oleate) at 296, the di-ethenoid ester (methyl linoleate) at 294 and the tri-ethenoid ester (methyl linolenate) at 292 (*cf.* Figs. 1 and 2). The strong isotope peaks (m/e = M+1) are at odd mass numbers and do not overlap the parent peaks. The sensitivity coefficients of the parent peaks in the mass spectrum of the different esters studied are not the same, and in order to derive the quantitative composition of the mixture it

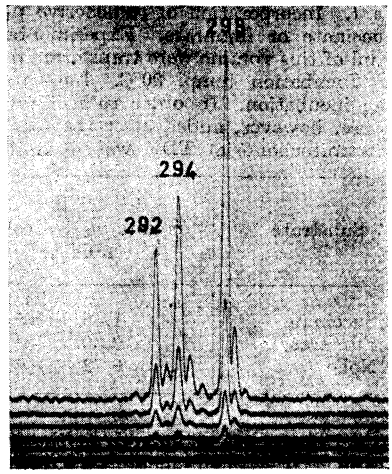

Fig. 1. High-mass end of the mass spectrum of a mixture containing 25 % methyl stearate, 38 % methyl linoleate, 36 % methyl linolenate and approximately 1 % methyl oleate.

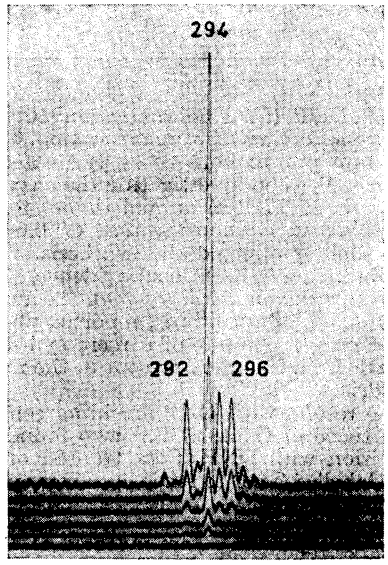

Fig. 2. High-mass end of the mass spectrum of a mixture containing 31 % methyl oleate, 55 % methyl linoleate and 14 % methyl linolenate.

is necessary to apply empirical corrections. If this is properly carried out it is possible to determine the percentage of the various components of the mixture directly. If pure components are available it is easy to check the results by running artificial mixtures and thus to get a very high accuracy in the quantitative analysis.

The mass spectra of the samples of methyl linoleate and methyl linolenate studied show a peak at $m/e = 290$. In the case of methyl linoleate the height of this peak is 1.7 % of the parent peak ($m/e = 294$). For methyl linolenate the height of the $m/e = 290$ peak is 18 % of the parent peak at $m/e = 292$. This peak appears to be the parent peak of the methyl ester of a C_{18} acid containing four double bonds. Whether this acid is present as an impurity in the original samples or whether it is formed by a dehydration reaction in the heated intake system of the mass spectrometer cannot be said at present. The present evidence, however, is in favour of the first mentioned possibility. It has been proposed that acids of this type may be formed from linoleic and linolenic acids by dehydrogenation between the existing double bonds and the carboxyl group in such a way that all unsaturation is methylene-interrupted and all *cis*. (*cf.* Ref.[5]). C_{18} tetra-ethenoid acids have been found in the fats of marine animals [5,6].

In a complex mixture it is not possible to distinguish between geometrical and positional isomers within each group of unsaturated esters. The peak at $m/e = 296$ in the figure might thus be due to, *e.g.*, methyl oleate (methyl *cis*-$\Delta^{9,10}$-octadecenoate), methyl elaidate (methyl *trans*-$\Delta^{9,10}$-octadecenoate), or methyl petroselinate (methyl *cis*-$\Delta^{6,7}$-octadecenoate) or due to a mixture of mono-ethenoid esters. It may be possible to overcome this difficulty by examining suitable derivatives.

The high-mass, high-resolution mass spectrometer thus offers a convenient method for determining the fatty acid distribution ("fatty acid spectrum") of natural or synthetic fats. The analysis can be performed on a few milligrams of material.

Note on the Crystal Structure of Niobium Monoxide

GEORG ANDERSSON and ARNE MAGNÉLI

Institute of Chemistry, University of Uppsala, Uppsala, and Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

In connection with studies on transition metal compounds of defective sodium chloride structure, *e.g.* vanadium monoxide [1] and titanium monoxide [2], the powder pattern of niobium monoxide was registered by means of an X-ray G.M. diffractometer (CuK radiation). The structure derived by Brauer [3] for this substance (a defective sodium chloride structure with the positions 000 and $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ vacant) is supported by our measurements, but as our investigation is based on quantitative data it may be worth mentioning.

The lattice parameter of the niobium monoxide sample as obtained from a Guinier powder photograph (internal standard potassium chloride $a = 6.2919$ Å at 20°C) was found to be 4.210_8 Å in excellent agreement with the value given by Brauer 4.2103 ± 0.0004 Å (21°C). The density was found to be 7.3 likewise in perfect agreement with Brauer's value of 7.30 and the value 7.27 calculated for a cell content of three formula units of NbO.

Table 1 gives the F values for the first fourteen reflexions as obtained from the diffractogram. The alternative structures (2)—(4) are among those discussed by Brauer *viz.* 3 Nb in $\frac{1}{2}\frac{1}{2}0$, $\frac{1}{2}0\frac{1}{2}$, $0\frac{1}{2}\frac{1}{2}$ for (2)

is necessary to apply empirical corrections. If this is properly carried out it is possible to determine the percentage of the various components of the mixture directly. If pure components are available it is easy to check the results by running artificial mixtures and thus to get a very high accuracy in the quantitative analysis.

The mass spectra of the samples of methyl linoleate and methyl linolenate studied show a peak at $m/e = 290$. In the case of methyl linoleate the height of this peak is 1.7 % of the parent peak ($m/e = 294$). For methyl linolenate the height of the $m/e = 290$ peak is 18 % of the parent peak at $m/e = 292$. This peak appears to be the parent peak of the methyl ester of a C_{18} acid containing four double bonds. Whether this acid is present as an impurity in the original samples or whether it is formed by a dehydration reaction in the heated intake system of the mass spectrometer cannot be said at present. The present evidence, however, is in favour of the first mentioned possibility. It has been proposed that acids of this type may be formed from linoleic and linolenic acids by dehydrogenation between the existing double bonds and the carboxyl group in such a way that all unsaturation is methylene-interrupted and all *cis*. (*cf.* Ref.[5]). C_{18} tetra-ethenoid acids have been found in the fats of marine animals [5,6].

In a complex mixture it is not possible to distinguish between geometrical and positional isomers within each group of unsaturated esters. The peak at $m/e = 296$ in the figure might thus be due to, *e.g.*, methyl oleate (methyl *cis*-$\Delta^{9,10}$-octadecenoate), methyl elaidate (methyl *trans*-$\Delta^{9,10}$-octadecenoate), or methyl petroselinate (methyl *cis*-$\Delta^{6,7}$-octadecenoate) or due to a mixture of mono-ethenoid esters. It may be possible to overcome this difficulty by examining suitable derivatives.

The high-mass, high-resolution mass spectrometer thus offers a convenient method for determining the fatty acid distribution ("fatty acid spectrum") of natural or synthetic fats. The analysis can be performed on a few milligrams of material.

The financial support of *Statens Tekniska Forskningsråd* and *Statens Medicinska Forskningsråd* is gratefully acknowledged. We are indebted to Dr. W. O. Lundberg, The Hormel Institute, Austin, Minnesota, for the gift of methyl esters of unsaturated fatty acids.

Note on the Crystal Structure of Niobium Monoxide

GEORG ANDERSSON and ARNE MAGNÉLI

Institute of Chemistry, University of Uppsala, Uppsala, and Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

In connection with studies on transition metal compounds of defective sodium chloride structure, *e.g.* vanadium monoxide [1] and titanium monoxide [2], the powder pattern of niobium monoxide was registered by means of an X-ray G.M. diffractometer (CuK radiation). The structure derived by Brauer [3] for this substance (a defective sodium chloride structure with the positions 000 and $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ vacant) is supported by our measurements, but as our investigation is based on quantitative data it may be worth mentioning.

The lattice parameter of the niobium monoxide sample as obtained from a Guinier powder photograph (internal standard potassium chloride $a = 6.2919$ Å at 20°C) was found to be 4.210_8 Å in excellent agreement with the value given by Brauer 4.2103 ± 0.0004 Å (21°C). The density was found to be 7.3 likewise in perfect agreement with Brauer's value of 7.30 and the value 7.27 calculated for a cell content of three formula units of NbO.

Table 1 gives the F values for the first fourteen reflexions as obtained from the diffractogram. The alternative structures (2)—(4) are among those discussed by Brauer *viz.* 3 Nb in $\frac{1}{2}\frac{1}{2}0$, $\frac{1}{2}0\frac{1}{2}$, $0\frac{1}{2}\frac{1}{2}$ for (2)

Table 1. X-Ray diffractometer data for niobium monoxide.

hkl	F_{obs}	F_{obs}—F(Nb)	Structure (2)		Structure (3)		Structure (4)	
			F_{calc}	F(O)	F_{calc}	F(O)	F_{calc}	F(O)

222	80	13	75	8	75	8	75	8
320	$\overline{22}$	0	$\overline{20}$	2	$\overline{22}$	0	$\overline{18}$	4
321	$\overline{24}$	$\overline{3}$	$\overline{24}$	$\overline{2}$	$\overline{21}$	0	$\overline{21}$	0

—(4) and 3 O in $\frac{1}{2}00$, $0\frac{1}{2}0$, $00\frac{1}{2}$ (structure (2)), 3 O randomly distributed in $\frac{1}{2}\frac{1}{2}\frac{1}{2}$, $\frac{1}{2}00$, $0\frac{1}{2}0$, $00\frac{1}{2}$ (structure (3)) and 3 O randomly arranged in 000, $\frac{1}{2}00$, $0\frac{1}{2}0$, $00\frac{1}{2}$ (structure (4)). For each of the structure alternatives, the values of F_{calc} for the two components of the unresolved reflexion (221 + 300) are identical and the corresponding values of F_{obs} are thus calculated considering the multiplicity of the reflexions. The signs alloted to F_{obs} are those determined by the arrangement of the Nb atoms.

The consistency is definitely better for structures (2) and (3) than for (4) (and for still another structure (5) discussed by Brauer). The difference between F_{calc} and F_{obs} for (2) and (3) is relatively small, as may be anticipated from the similarity of these two alternatives, but the data speak in favour of structure (2) in accordance with Brauer's opinion. The quotients $\Sigma||F_{obs}| - |F_{calc}||/\Sigma|F_{obs}|$ are 0.058, 0.079 and 0.109 for (2), (3) and (4), respectively. The table also gives the differences between F_{obs} and F(Nb) (the contribution of the niobium atoms to F_{calc}) which may represent the share in F_{obs} of the oxygen atoms. The quotients $\Sigma||F_{obs}-F(\mathrm{Nb})| - |F(\mathrm{O})||/\Sigma|F_{obs} - F(\mathrm{Nb})|$ are 0.44 for (2), 0.56 for (3) and 0.78 for (4).

Melting of niobium monoxide (small tablets) in an electric arc furnace with subsequent rapid quenching from the melting temperature did not change the structure of this compound. Evidently there is no indication of a phase transition similar to that found in titanium monoxide [2]. Thus high-temperature studies would be necessary to decide definitely whether there occurs a rapid transition to a random niobium monoxide at a certain temperature.

This investigation forms part of a research program on metal oxides and related compounds, financially supported by the *Swedish Natural Science Research Council.*

Preparation of Some Hydroxycoprostanes; 3α, 7α- and 3α, 12α-dihydroxycoprostane

Bile Acids and Steroids 49

SUNE BERGSTRÖM and
LENNART KRABISCH

Department of Physiological Chemistry, University of Lund, Lund, Sweden

In connection with studies on the transformation of cholesterol into bile acids it was of interest to study the metabolism of the coprostanes corresponding to the common bile acids. These compounds have now all been prepared through electrolysis of the appropriate bile acid with *iso*valeric acid. The data for 3α, 7α, 12α-trihydroxycoprostane, that was described recently,[1,2] has also been included for comparison. Some results of the metabolic studies with these compounds have already been published [1,3,4].

Experimental. 3α,12α-dihydroxycoprostane. Deoxycholic acid (2.0 g) was dissolved in methanol (450 ml) and *iso*valeric acid (13.5 ml, isomer-free) and a solution of sodium (290 mg) in methanol (50 ml) was added. The solution was placed in a beaker surrounded by ice. The electrolysis was run for 80 min with 4.2 A between platinum electrodes (5.2 cm^2) placed 0.2 cm from each other.

The mixture was then evaporated to dryness *in vacuo*, the residue was dissolved in a mixture of water and ether, the phases were separated and the aqueous phase reextracted twice with ether. The combined ether phases were washed with dilute sodium hydroxide and water and taken to dryness. The residue (1.84 g) was brought onto a column of silicic acid (30 g, dried at 120° for 24 h) prepared with methylene dichloride. The column was eluted with methylene dichloride containing 1.5 % of methanol, each fraction being 30 ml. Fractions 4 and 5 that contained the bulk of the material (1.35 g) were combined and recrystallized from aqueous acetone three times, when a constant melting point had been reached. Yield 550 mg, m.p. 108—110°C.

In the same way 3α, 7α-dihydroxy and 3α-hydroxycoprostane were prepared from chenodeoxycholic and lithocholic acid, respectively. The 3α-hydroxycoprostane was chromatographed in the system described by Danielson [5] for the reversed phase partition chromatography of monosubstitued C_{27}-steroids.

The data for these compounds together with those obtained earlier for the 3α-7α,12α-trihydroxycoprostane are listed in Table 1. Analysis by Microanalytical Laboratory, Department of Chemistry, University of Copenhagen. All rotations were made in chloroform, m.p.'s are corrected.

Theoretical Determination of the Electronic Polarizability of Lithium and Scandium

INGA FISCHER-HJALMARS and MARIANNE SUNDBOM

Institute of Theoretical Physics, University of Stockholm, Stockholm, Sweden

Different experimental investigations, *e.g.* of the crystal structure of certain Al-Si-Me compounds [1], make it plausible to assume that the electronic polarizability of atoms and ions with partly filled *d*-shells (transition elements) should be considerably larger than the polarizability of closed shell atoms. This assumption can be supported by simple, theoretical considerations. However, no detailed theoretical investigation of this problem seems to have been published before. As the problem is of great interest in several connections, we have made an attempt to find the order of magnitude of this polarizability from a simple perturbation calculation.

The electronic polarizability of atoms with rare-gas-like configurations, *i.e.* s^2p^6 and $s^2p^6d^{10}$, has recently been treated as a perturbation problem by Sternheimer [2]. We have carried out a similar perturbation calculation for the case of atoms with one electron outside the closed shells and applied the result to Li $1s^22s$ and Sc $3d\,4s^2$. Using an one-electron model the unperturbed wave function can be written as a single Slater determinant of unperturbed one-electron functions φ_i. The first-order perturbation of these functions, φ_i', is determined by the equation

$$(H_0 - E_0)\ \varphi_i' = -V\ \varphi_i, \qquad (1)$$

where V is the perturbing potential. The electronic polarizability α is

$$\alpha = -\frac{2}{E^2}\sum_i \int \varphi_i^*\, V\, \varphi_i'\, d\tau \qquad (2)$$

where the sum is to be taken over all filled orbitals.

In the case of Sc the $3d$ orbital of the unperturbed atom cannot be given a definite m-value. We have shown, however, that the correct zeroth-order wave function for the $3d$ electron corresponds to $m = 0$. The differential equations (1) have been solved by numerical methods, using the Swedish electronic digital computor BESK. Hitherto, we have programmed the problem for one-electron orbitals of the simple analytic form $r^n e^{-\mu r}$. However, the programme can easily be modified so that also numerically given orbitals can be used. As the computed value of α is strongly depending on the choice of unperturbed functions, we can only expect to get a rough estimate by the use of simple analytical orbitals. As a check on our programme we have computed the polarizability of Ca^{2+}, previously calculated by Sternheimer [2].

Preliminary results for the polarizabilities of Li and Sc are given in Table 1. In the case of Li the contribution to α from the inner shell is negligible. In the case

of Sc the same is true and the main contribution orginates from $3d\ 4s^2$. In order to discriminate between $3d$ and $4s^2$ we have also computed a of Ca $4s^2$. Table 1 shows that a of Ca and Sc both are much larger than a of Ca^{2+}.

An extension of the present investigation to include atoms with several d-electrons outside the closed shell is going on. It would be of special interest to look at Ni, for which an experimental value of a is available [3].

Note on the Crystal Structures of Hexagonal HgO and Hg_2O_2NaI

KARIN AURIVILLIUS and
INGA-BRITT CARLSSON

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

The hexagonal modification of mercury (II)oxide and the compound Hg_2O_2NaI have been prepared according to Laruelle [1] and studied by X-ray diffraction methods.

HgO. Hexagonal form. Space group $P3_121$ No. 152. Unit cell dimensions $a = 3.577$ Å, $c = 8.681$ Å in agreement with the values given by Laruelle. The cell content is 3 formula units of HgO. The positions of the mercury atoms have been derived by means of trial methods from powder data registered with a Geiger-Mueller diffractometer using Cu$K\alpha$ radiation. A probable arrangement of the oxygen atoms has been obtained from space considerations. The point positions are:

3Hg in $3(a)$:$x0\frac{1}{3}$, $0x\frac{2}{3}$, $\bar{x}\bar{x}0$ with $x = 0.745$
3O in $3(b)$:$x0\frac{5}{6}$, $0x\frac{1}{6}$, $\bar{x}\bar{x}\frac{1}{2}$ with $x = 0.46$

This structure is built up of infinite spiral chains -O-Hg-O- running parallel to the c axis of the hexagonal unit cell. The distances and angles within the chains are:

Hg-O 2.03 Å The angle Hg-O-Hg 109°
Hg-Hg 3.30 Å The angle O-Hg-O 180°

This atomic arrangement is isostructural with the hexagonal modification of mercury(II)sulphide (cinnabar)[2]. The Hg-O distance and the bond angles are identical with those found in the planar zigzag chains -O-Hg-O- in orthorhombic mercury(II)oxide [3].

This investigation is to be continued by means of neutron diffraction methods in order to investigate the proposed oxygen arrangement. Studies on the stability relations between the modifications of mercury(II)oxide are in progress.

Hg_2O_2NaI. Space group $P6_222$ No. 180. Unit cell dimensions $a = 6.667$ Å, $c = 10.054$ Å. Cell content 3 formula units of Hg_2O_2NaI.

The positions of the mercury and iodine atoms have been derived on the basis of single crystal data.

6 Hg in $6(f)$:$\frac{1}{2}0z\frac{2}{3}, 0\frac{1}{2}\frac{2}{3}+z, \frac{1}{2}\frac{1}{2}\frac{1}{3}+z$
$\frac{1}{2}0\bar{z}, 0\frac{1}{2}\frac{2}{3}-z, \frac{1}{2}\frac{1}{2}\frac{1}{3}-z$ with $z=\frac{1}{3}$
3 I in $3(c)$:$\frac{1}{2}00, 0\frac{1}{2}\frac{2}{3}, \quad \frac{1}{2}\frac{1}{2}\frac{1}{3}$

This investigation is being continued in order to find the positions of the sodium and oxygen atoms.

A Simple Procedure for the Preparation of Single Crystals of Orthorhombic Mercury(II)oxide

KARIN AURIVILLIUS and
INGA-BRITT CARLSSON

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

The procedures described in the literature for the preparation of single crystals of orthorhombic mercury(II)oxide [1] have been found to be rather uncertain and give poor results. In connection with studies on the hexagonal modification of this substance a simple method was found for the synthesis of beautiful crystals of the orthorhombic form. One part of 0.1 M K_2HgI_4 was mixed with two parts of 10–13 M NaOH and poured into a gold tube which was covered with a gold lid. The tube was slid into a pyrex glass tube which was sealed and placed in an oven at 100–175°C for about 70 h.

The crystals appeared in the form of light red rods with lustrous faces of up to 2 mm extension. Amply exposed powder patterns obtained in a Guinier focusing camera did not show any reflexions not belonging to the pattern for orthorhombic mercury(II)oxide.

This convenient method has been discovered in connection with work on mercury compounds which has been financially supported by the *Swedish Natural Science Research Council.*

Separation of Acid Mucopolysaccharides by Paper Electrophoresis

STIG D. SCHULTZ-HAUDT*

Johan Throne Holst's Institute for Nutrition Research, University of Oslo, Blindern, Norway

The separation of acid mucopolysaccharides from various sources by means of paper electrophoresis has been reported by several investigators [1-4]. The conditions for the electrophoresis as well as the methods of locating the separated mucopolysaccharide fractions have differed in each particular case. For the purpose of investigating the mucopolysaccharide contents of mucous membranes a number of methods were tested, but no particular procedure was found to be entirely satisfactory. However, a system was developed which allowed a distinct separation of hyaluronic acid and chondroitin sulphate. This system represents a combination of some of the methods referred to above.

Methods. A box, similar to that described by Grassmann [5], was constructed from parts cut out of 0.5 cm thick Perspex acrylic sheet to serve as support for the paper.

The buffer solution employed was made by combining 100 ml of 0.9 M sodium chloride with 50 ml of 0.2 M phosphate buffer (pH 7.0) and diluting to a total volume of one liter with distilled water.

The paper used was Whatman No. 3 MM ilter paper for chromatography.

The electrophoresis was carried out at 160 V for 18 h at room temperature.

Prior to electrophoresis, a paper strip, 57 cm in length and 4 cm wide, was moistened with buffer from both ends to within 1 cm from the midline and blotted dry with filter paper. The paper was next placed in the box, and the vertical ends of the paper were dipped into the buffer. The horizontal stretch of the paper strip in position in the box was 40 cm. Buffer equilibration was allowed to proceed for 30 min. From 50 to 100 μl of a crude mucopolysaccharide mixture dissolved in the buffer were then applied along the midline to the wet paper. Another 30 min were allowed to pass before the current was connected.

Following electrophoresis, the paper strip was dried at 110°C for 30 min. Acid mucopolysaccharide fractions were next located in the manner described by Bera *et al.*[2] In order to obtain satisfactory results, however, it was necessary subsequent to the immersion of the paper in Cetavlon to wash it in hot running tap water for 45 min. The paper was then dried at 110°C for one hour, sprayed with the bromocresol purple reagent, and again dried at 110°C for 15 min.

* The present investigations are supported financially by the *Norwegian Dental School*, by the *Norwegian Institute of Dental Research* and by *New York Community Trust.*

Fig. 1.

In order to identify the separated fractions, two paper strips were run at the same time. Following electrophoresis, one paper was developed with Cetavlon/bromocresol purple [2]. The areas of the second paper corresponding to the spots on the first paper were cut out and eluted in the manner described by Rienits [1]. Concentrated hydrochloric acid was added to the eluates in amounts sufficient to make the solution 7 N in terms of the acid. Hydrolysis was carried out in sealed test tubes at 100°C for 4 h. The solutions were treated with Norit A for a few minutes, centrifuged, and the supernates were taken to dryness by lyophilization. The residues were dissolved in appropriate amounts of distilled water and paper chromatography of these solutions were carried out by the method of Stoffyn and Jeanloz [6] for the identification of the aminosugars present.

In cases where larger amounts of mucopolysaccharide mixtures were applied to paper strips for electrophoretic separation, milligram amounts of each fraction could be obtained after elution by precipitating with ethanol in the presence of sodium acetate. Following hydrolysis, the mucopolysaccharides obtained in this fashion were shown by paper chromatography and paper electrophoresis to be of a satisfactory purity.

Results and discussion. Fig. 1 represents a typical result of paper electrophoresis of a crude mucopolysaccharide mixture obtained from human gingiva, followed by staining with Cetavlon/bromocresol purple.

By means of the method described, it was shown that the slowest moving component contained glucosamine as the only aminosugar, whereas the fastest moving component contained galactosamine, but no glucosamine.

Paper electrophoresis of a number of crude mucopolysaccharide mixtures extracted in different manners from various tissues and of widely different purities were carried out. The results obtained showed that acid mucopolysaccharides could readily be separated and identified in the manner described, and the results were entirely reproduceable. Amounts of 5—6 mg of crude mixtures could be applied on the paper for electrophoresis. When amounts of a particular acid mucopolysaccharide were below 100 μg the spot produced by the staining reaction was very weak.

None of the other staining reagents tested gave as distinct results as those obtained with the Cetavlon/bromocresol purple method.

The separation of hyaluronic acid and chondroitin sulphate in the manner described compared favorably to all of the other systems tested.

The above described system provides a simple tool for a comparatively rapid demonstration of the presence of acid mucopolysaccharides in biological materials and for a ready separation of hyaluronic acid and chondroitin sulphate from a mixture.

A Simple Procedure for the Preparation of Single Crystals of Orthorhombic Mercury(II)oxide

KARIN AURIVILLIUS and
INGA-BRITT CARLSSON

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

The procedures described in the literature for the preparation of single crystals of orthorhombic mercury(II)oxide [1] have been found to be rather uncertain and give poor results. In connection with studies on the hexagonal modification of this substance a simple method was found for the synthesis of beautiful crystals of the orthorhombic form. One part of 0.1 M K_2HgI_4 was mixed with two parts of 10–13 M NaOH and poured into a gold tube which was covered with a gold lid. The tube was slid into a pyrex glass tube which was sealed and placed in an oven at 100–175°C for about 70 h.

The crystals appeared in the form of light red rods with lustrous faces of up to 2 mm extension. Amply exposed powder patterns obtained in a Guinier focusing camera did not show any reflexions not belonging to the pattern for orthorhombic mercury(II)oxide.

This convenient method has been discovered in connection with work on mercury compounds which has been financially supported by the *Swedish Natural Science Research Council.*

Separation of Acid Mucopolysaccharides by Paper Electrophoresis

STIG D. SCHULTZ-HAUDT*

Johan Throne Holst's Institute for Nutrition Research, University of Oslo, Blindern, Norway

The separation of acid mucopolysaccharides from various sources by means of paper electrophoresis has been reported by several investigators [1-4]. The conditions for the electrophoresis as well as the methods of locating the separated mucopolysaccharide fractions have differed in each particular case. For the purpose of investigating the mucopolysaccharide contents of mucous membranes a number of methods were tested, but no particular procedure was found to be entirely satisfactory. However, a system was developed which allowed a distinct separation of hyaluronic acid and chondroitin sulphate. This system represents a combination of some of the methods referred to above.

Methods. A box, similar to that described by Grassmann [5], was constructed from parts cut out of 0.5 cm thick Perspex acrylic sheet to serve as support for the paper.

The buffer solution employed was made by combining 100 ml of 0.9 M sodium chloride with 50 ml of 0.2 M phosphate buffer (pH 7.0) and diluting to a total volume of one liter with distilled water.

The paper used was Whatman No. 3 MM ilter paper for chromatography.

The electrophoresis was carried out at 160 V for 18 h at room temperature.

Prior to electrophoresis, a paper strip, 57 cm in length and 4 cm wide, was moistened with buffer from both ends to within 1 cm from the midline and blotted dry with filter paper. The paper was next placed in the box, and the vertical ends of the paper were dipped into the buffer. The horizontal stretch of the paper strip in position in the box was 40 cm. Buffer equilibration was allowed to proceed for 30 min. From 50 to 100 μl of a crude mucopolysaccharide mixture dissolved in the buffer were then applied along the midline to the wet paper. Another 30 min were allowed to pass before the current was connected.

Following electrophoresis, the paper strip was dried at 110°C for 30 min. Acid mucopolysaccharide fractions were next located in the manner described by Bera *et al.*[2] In order to obtain satisfactory results, however, it was necessary subsequent to the immersion of the paper in Cetavlon to wash it in hot running tap water for 45 min. The paper was then dried at 110°C for one hour, sprayed with the bromocresol purple reagent, and again dried at 110°C for 15 min.

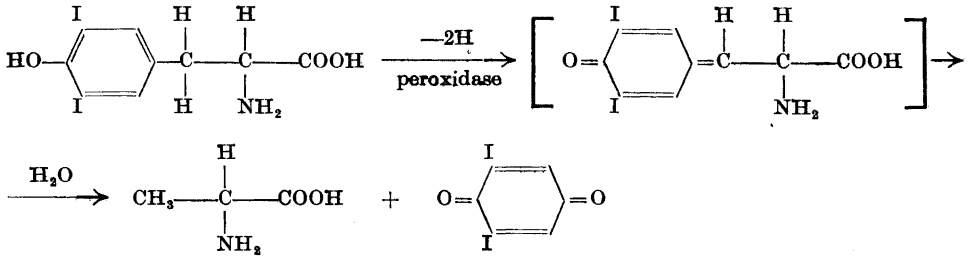
On the Action of Peroxidase on 3,5-Diiodotyrosine

JAN-GUSTAF LJUNGGREN

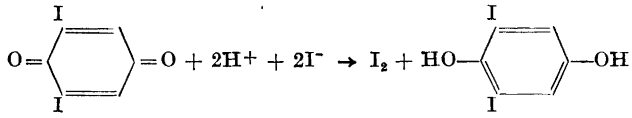


Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

It has been suggested [1] that thyroxine is formed from 3,5-diiodotyrosine through the action of peroxidase but no attempts to verify this theory experimentally seem to have been made.

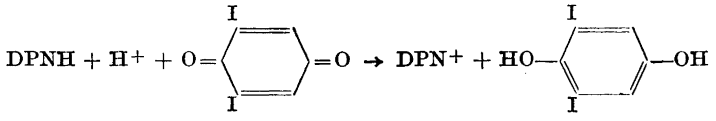
When 3,5-diiodotyrosine, hydrogen peroxide and peroxidase were incubated no formation of thyroxine could in fact be detected. However, another reaction product was observed which might be a possible intermediate in the conversion of 3,5-diiodotyrosine into thyroxine.

3,5-diiodotyrosine was incubated as described below with crystallized verdoperoxidase and hydrogen peroxide and a sample of the solution was studied by paper chromatography. The chromatograms were developed with butanol:acetic acid:water (4:1:1) and the spots visualised with ninhydrin. Alanine was thus identified as one of the reaction products.



A possible reaction giving alanine as a reaction product would be the following:

The other hypothetical reaction product, 2,6-diiodobenzoquinone, was identified in the reaction mixture by extraction with petroleum ether and crystallization from the same solvent. The melting point of the product was 177°C, as reported for 2,6-diiodobenzoquinone [2], and the mixed melting point with an authentic sample of the quinone prepared according to Ref.[2] was unchanged.



The identity of this reaction product was also confirmed by incubating the latter with potassium iodide in acid solution. Free iodine and a compound identified by paper chromatography as 2,6-diiodohydroquinone were found.

Thus the reaction was the following:

The 2,6-diiodobenzoquinone might be a precursor to thyroxine. It is, however, evident that it must first be reduced to 2,6-diiodohydroquinone.

Wosilait and Nason [3] have previously found that some benzoquinones, *e.g.* 2,6-dichlorobenzoquinone, were easily reduced by DPNH to hydroquinones non enzymatically. We have found that 2,6-diiodobenzoquinone also reacts rapidly with DPNH. The oxidation of DPNH to DPN+ by 2,6-diiodobenzoquinone was followed in a Beckman DU spectrophotometer at 340 mμ

When 2,6-diiodobenzoquinone was incubated with DPNH, 2,6-diiodohydroquinone could be isolated by extraction with ethyl ether, the ether evaporated and the product crystallized from water. The melting point was as reported for 2,6-diiodohydroquinone [4] (144°C) and the mixed melting point between the isolated substance and an authentic sample of 2,6 diiodohydroquinone was the same. They also had the same R_F value on paper chromatogram.

The 2,6-diiodohydroquinone was quantitatively determined both by paper chromatography and a colorimetric method [5]. The latter is based upon the reduction of ferric ions to ferrous ions by a hydroquinone followed by a colorimetric determination of the ferrous ions with *o*-phenantroline. Here DPN^+ does not interfere but the solution must be free from DPNH in order to prevent a new formation of hydroquinone from the benzoquinone formed when ferric ions are reduced to ferrous ions.

The yield of 2,6-diiodohydroquinone was found to be 20 % of theory when 20 ml 3,5-diiodotyrosine (10^{-3} M) in 0.05 M phosphate buffer, pH = 7.2, temperature = 20°C, was incubated with 0.5 ml crystallized verdoperoxidase (3.2 mg VPO/ml) and 0.5 ml H_2O_2 (10^{-2} M). The hydrogen peroxide was added slowly by means of a motor driven micrometer syringe; the 0.5 ml volume requiring 10 h. The hydrogen peroxide had to be added slowly in order to prevent a destruction of the verdoperoxidase, as observed by Agner. When all the hydrogen peroxide had been consumed 1.85 ml DPNH (1 mg DPNH/ml) was added and its oxidation followed spectrophotometrically at 340 mμ.

We have verified that peroxidase is present in the thyroid gland and probably in higher amounts than previously reported [6].

Thus, 2,6-diiodobenzoquinone and 2,6-diiodohydroquinone might be intermediates in the conversion of 3,5-diiodotyrosine into thyroxine. The formation of thyroxine by the condensation of one molecule 3,5-diiodotyrosine and one molecule 2,6-diiodohydroquinone, is now being investigated. Attempts are also being made to purify peroxidase from the thyroid gland. The results of these studies will be reported in this journal.

Acknouledgements. The author wishes to thank Professor Hugo Theorell for valuable help and encouragement during this work. Thanks are also due to Dr. K. Agner for kindly supplying the crystalline verdoperoxidase, to Drs. B. Sörbo, K. G. Paul and S. Åkerfeldt for valuable discussions and to Dr. George D. Ludwig for correction of the language.

Hexadecenoic Acid as a Feature of Beef and Horse Subcutaneous Fat

OLLE DAHL

Scans Centrallaboratorium, Malmö, Sweden

Recently the fatty acid composition of some typical fats from domestic animals was examined by the author [1]. Among these fats a beef subcutaneous fat from hide trimmings showed a remarkably high content of hexadecenoic acid, *viz.* 13.0 mole-%. Subsequently, when studying the relationship between iodine value and content of various fatty acids as well as between the content of the fatty acids themselves in natural fats [2], the said subcutaneous fat behaved differently from the others, evidently dependent on the high content of hexadecenoic acid. Furthermore, in an extensive investigation of the characteristics of more than 700 animal fats [3], the beef subcutaneous fats showed a lower saponification equivalent throughout and, besides, the relations between the characteristics were divergent from those of other fats. (In various investigations (for references, *cf.* Ref.[2]) pig subcutaneous fat (back fat) was proved to contain but moderate amounts of hexadecenoic acid, about 3 mole-%.)

These findings gave rise to a further confirmation of hexadecenoic acid as a feature of beef subcutaneous fat. The most abundant depot of subcutaneous fat is the brisket. The brisket fat from 10 cows was collected, mixed and extracted by means of ethyl ether, saponified and esterified by

methyl alcohol. The component fatty acids were determined by fractional distillation of the methyl esters as previously described [1]. The cows were killed at the end of March, *i. e.* prior to the pasture-feeding.

With regard to pure horse subcutaneous fat, no data of its composition are available whatsoever. It was decided, therefore, to examine the wither fat, which generally is the most abundant horse subcutaneous fat, in the same way as the brisket fat from cows. For this purpose the wither fat from 4 horses — 3 geldings and 1 mare — was collected. The animals were slaughtered at the same time as the cows. The results are summarized in Table 1.

As is seen from Table 1 the content of hexadecenoic acid is considerable both in brisket and in wither fat, the content of the former being still higher than that previously found in beef hide fat [1].

Dugan *et al.*[4] investigated the composition of beef brisket fat but disregarded the hexadecenoic acid, the content of which was simply included in that of oleic acid. In a review of the formation of animal fats Shorland [5] refers to unpublished data on the composition of beef subcutaneous fat, indicating a content of 4.6 mole-% hexadecenoic acid only.

The fairly high content of hexadecenoic acid previously found by the author in horse fats [1] may partly be due to the presence of 17 % wither fat in the fatty tissue mixture.

Finally it may be mentioned that, among fats of land animals, bone fat occasionally holds significant amounts of hexadecenoic acid. Thus, beef bone fat contains up to 10 or even 11 mole-% of this acid (for references, see Ref.[2]). In hoof oil and "offal oil" from horse, the latter deriving from bones and trimmings mixed in indefinite proportions, Brooker and Shorland [6] found no less than 20.5 and 11.5 mole-% hexadecenoic acid, respectively.

Plant Growth Regulators II

Methyl- and Methoxysubstituted Naphthylboronic Acids

SVEN-OLOV LAWESSON*

Department of Organic Chemistry, Chemical Institute, University of Uppsala, Sweden

1- and 2-Naphthylmethylboronic acids have earlier been shown to be conspicuous anti-auxins [1]. As the aralkylboronic acids are very sensitive to atmospheric oxygen and difficult to handle, arylboronic acids have also been included in the investigation. Thus the writer has recently prepared a number of thiopheneboronic acids[2]. As he is not in a position to pursue these investigations for the time being, the data for some lately prepared naphthylboronic acid are given here.

Substituted phenylboronic acids have been investigated biologically by several authors [3-7] and Professor B. Åberg is now testing the thiophene- and naphthylboronic acids. According to preliminary reports, they have about the same effect [8] as those investigated by Torssell [7]. The results will be published elsewhere.

The naphthyl boronic acids were prepared *via* the lithium reagents at a low temperature following usual procedures. The lithium reagents were obtained by lithium-halogen exchange reactions from the corresponding bromine compounds, except for 3-methoxy-2-naphthylboronic acid; in this case the lithium reagent was prepared by metalating 2-methoxynaphthalene by the method of Sunthankar and Gilman [9].

Experimental. Reactions with lithium were performed under dry oxygen-free nitrogen in a standard assembly.

As a typical example we will describe the preparation of 2-methyl-1-naphthylboronic acid: 11 g of 1-bromo-2-methylnaphthalene in 75 ml of absolute ether was cooled to 0°C and then treated with 50 ml of 1 M butyllithium in ether. After stirring for 15 min the lithium reagent was slowly added with stirring to 20 g of tributyl borate in dry ether, cooled to —70°C. The stirring was continued for 4 h and then the reaction mixture was treated with 1 M hydrochloric acid, the ether layer separated and the aqueous phase extracted with ether. The combined ether layers were extracted with sodium hydroxide. The alkaline solution was acidified with hydrochloric acid, precipitating the acid as a white powder. After recrystallisation from water-ethanol and drying in air the acid was obtained as small, white needles. M. p. 125—127 °C. Weight 3.8 g. Yield 41 %.

The data for this and the other boronic acids are tabulated in Table 1.

The author is indebted to Professor B. Åberg for private communications. A grant from the *Swedish Natural Science Research Council* is gratefully acknowledged.

* Present address: Department of Organic Chemistry, University of Chicago, Chicago 37, Ill.

The Enzymic Amination of Xanthosine-5-phosphate to Guanosine-5-phosphate

Ulf Lagerkvist

Biochemical Department, Karolinska institutet, Stockholm, Sweden

In a previous communication [1] the occurrence of two enzyme-catalyzed reactions in extracts of pigeon liver acetone powder was reported, leading from inosine-5-phosphate to guanosine-5-phosphate *via* xanthosine-5-phosphate. The first reaction took place only in the presence of DPN * while the second reaction required ATP, Mg^{++}-ions and L-glutamine as an aminogroup donor. NH_4^+-ions or L-aspartate could not substitute for L-glutamine while L-glutamate was active at higher concentrations owing to the presence of glutamine synthease in the crude extract.

Inosine-5-phosphate $\xrightarrow{\text{DPN}}$ Xanthosine-5-phosphate (1)

Xanthosine-5-phosphate $\xrightarrow[\text{L-glutamine}]{\text{ATP}}$ Guanosine-5-phosphate (2)

At the same time Abrams and Bentley [2,3] demonstrated the occurrence of similar reactions in extracts of rabbit bone marrow while Gehring and Magasanik [4] reported on the partial purification of an enzyme catalyzing reaction (1) from *Aerobacter aerogenes*. Magasanik *et al.*[5] have later reported briefly on the purification of an enzyme from *E. coli* that aminated XMP by a different mechanism using NH_4^+-ions as aminogroup donors.

The enzyme (or enzymes) catalyzing reaction (2) has been purified 80—90 fold over the crude extract. Acetone powder of pigeon liver was extracted with dilute phosphate buffer pH 7.4 and after acidification to pH 6 fractionated with ammonium sulfate between 30 and 50 % saturation. The precipitate was dissolved in phosphate buffer pH 7.4 and inactive protein removed by adding $MnCl_2$. The centrifugate was again fractionated with ammonium sulfate between 39 and 55 % saturation. The precipitate was dissolved in dilute phosphate buffer pH 7.4, dialyzed shortly and chromatographed on DEAE-cellulose in PO_4-form by gradient elution with phosphate buffer pH 6.0. A typical preparation is shown in Table 1.

Table 1. Purification of the enzyme.

Purification step	mg protein	Spec. act.	Total units
Crude extract	8 600	0.21	1 810
1st ammonium sulfate precipitate	3 660	0.54	1 970
Adsorption on manganous phosphate	1 830	0.93	1 700
2nd ammonium sulfate precipitate	500	1.70	850
Chromatography on DEAE-cellulose	14	19	266

Using the purified enzyme no amination of XMP was obtained in the presence of L-glutamate instead of L-glutamine. Balance experiments indicate the following stoichiometry for reaction (2):

XMP + L-glutamine + ATP → GMP + L-glutamate + AMP + pyrophosphate

* The following abbreviations are employed: AMP = adenosine-5-phosphate, ATP = adenosine-5-triphosphate, DEAE = diethylaminoethyl, DPN = diphosphopyridine nucleotide, XMP = xanthosine-5-phosphate.

Enzymic Formation of Uridine-5′-phosphate from Uracil

Ola Sköld and Peter Reichard

Biochemical Department, Karolinska Institutet, Stockholm, Sweden

Most mammalian tissues studied show a relatively poor utilization of uracil for pyrimidine nucleotide synthesis. In the Ehrlich ascites tumor, however, uracil was incorporated into polynucleotide pyrimidines as rapidly as orotic acid. In a study of the enzymic mechanism of this process it was found that uridine-5′-phosphate(UMP) formation from uracil in acetone powder extracts of the tumor proceeded according to:

$$\text{Uracil} + \text{ribose-1-phosphate} \xrightarrow[\text{phosphorylase}]{\text{nucleoside}} \text{uridine} + \text{phosphate}$$

$$\text{Uridine} + \text{ATP} \xrightarrow[\text{kinase}]{\text{uridine}} \text{UMP} + \text{ADP}$$

Both enzymes involved are known to occur in mammalian organs, *e. g.* liver, which form very little UMP from uracil.

We have now investigated the amount of these two enzymes in the ascites tumor and in rat liver. Furthermore, the breakdown of uracil to CO_2 was also studied, since it had been proposed that this process might determine uracil utilization in different tissues [2].

A significant difference was found in the amount of nucleoside phosphorylase as measured by a spectrophotometric assay. Uridine kinase was consistently *ca.* 10 times more active in extracts of the tumor than in liver extracts. A high concentration of uridine was necessary for optimum UMP synthesis. In accordance with earlier findings of other investigators we observed a quite rapid breakdown of uracil to CO_2 in rat liver preparations. No such degradation was observed in tumor extracts, however. In both cases a high TPNH level was maintained during the reaction.

It seems likely that uracil utilization by different tissues will depend on a competition between catabolic reactions which degrade uracil to CO_2 and the anabolic formation of UMP.

Dephosphorylation of Nucleoside Triphosphates by Rat Diaphragm *in vitro* *

Aa. Rye Alertsen, O. Walaas and E. Walaas

Institute of Medical Biochemistry and Physiology, Department of Biochemistry, University of Oslo, Norway

When the isolated rat diaphragm is incubated in saline phosphate medium at pH 7.4 at 37 °C a marked ATPase and adenylic acid deaminase activity is present. These properties have been studied by determination of the degradation products of ATP in the diaphragm during incubation. The products formed have been separated by an ion exchange resin method on Dowex-1. By the same technique the conversion products of nucleoside triphosphates added to the medium during incubation of rat diaphragm have been studied

The breakdown of ATP in the diaphragm has been studied in experiments where diaphragms from 20 rats, weighing 6—7 g, were incubated in 15 ml saline phosphate medium. During incubation for 30 min in oxygen, 25 % of ATP initially present in the diaphragm (2.2 μmole per g initial level) was broken down and almost quantitatively recovered as IMP and inosine. In anaerobiosis the breakdown of ATP was greatly accelerated, amounting to 90 % in 30 min. The same high rate of breakdown was observed in oxygen if 5×10^{-5} M 2,4-dinitrophenol or 0.01 M NaCN was present in the medium. In these experiments nucleotides were not detected in the medium which, however, contained a considerable amount of inosine.

The breakdown of nucleotides added to the medium was studied by incubating 2 hemidiaphragms weighing 250 mg in 2 ml saline phosphate medium. 10 μmole ATP added at the start of the experiment was rapidly broken down in oxygen atmosphere. Thus after 30 min 95 % of ATP was broken down and accumulation of ADP, AMP, IMP and inosine was demonstrated. The dephosphorylation and deamination probably did occur on the surface of the diaphragm muscle as no enzyme activity was liberated into the medium when 2 hemidiaphragms were incubated for 30 min. The experiments indicate that the following sequence of reactions takes place:

ATP → ADP → AMP → IMP → Inosine

* Supported by grants from *Eli Lilly and Co.* and from *Norwegian Research Council for Science and the Humanities.*

Experiments on studies of the breakdown of other nucleoside triphosphates CTP, UTP, GTP and ITP will be reported.

Some Properties of the Uridine Diphosphate Glucose Pyrophosphorylase

Agnete Munch-Petersen

The Fibiger-Laboratory, University of Copenhagen, Denmark

In a previous communication [1] the purification and isolation of uridine diphosphate glucose (UDPG) pyrophosphorylase from yeast is described. This enzyme catalyses the following reversible reaction:

$$UDPG + P—P \rightleftharpoons UTP + G—1—P$$

Experiments were described, which showed that incubation of uridine triphosphate (UTP) and ^{32}P-labelled pyrophosphate (P—P) with the enzyme rendered ^{32}P-labelled UTP. Likewise incubation of UDPG with ^{32}P-labelled glucose-1-phosphate (G-1-P) rendered ^{32}P-labelled UDPG. These exchange experiments have been interpreted as an indication of the formation of a free uridyl-enzyme complex as an intermediate in the pyrophosphorolytic transfer of uridyl groups.

In view of the findings of Neufeld *et al.*[2] that UDPG pyrophosphorylase, isolated from seedlings of mungbeans, does not bring about an incorporation of $^{32}P—^{32}P$ into UTP as described above, the exchange experiments with the yeast enzyme have been repeated under more quantitative conditions. The incorporation rate of $^{32}P—^{32}P$ into UTP has been measured by an assay, similar to that described by Berg [3], *i. e.* after incubation of the enzyme with UTP and ^{32}P-labelled P—P, the incubation mixture is treated with charcoal; the charcoal is suspended in 50 % ethanol, and the radioactivity of an aliquot of this suspension is measured. During the purification procedure for the enzyme the different fractions have been tested for exchange activity, measured by the above described charcoal assay, as well as for UDPG pyrophosphorylase activity measured spectrophotometrically [2], and the ratio between these two activities per mg protein remains constant during the different stages (35 fold purification).

If, however, the purified UDPG pyrophosphorylase is treated with crystalline phosphoglucomutase, the exchange activity may be completely abolished; at the same time the enzyme activity as measured spectrophotometrically remains unchanged. This finding together with the fact that addition of G-1-P or UDPG greatly enhances the exchange indicates that the exchange ability of the purified UDPG pyrophosphorylase is not an intrinsic quality of the enzyme, but rather caused by some tightly bound UDPG or G-1-P which cannot be removed by the ordinary purification methods.

The charcoal assay offers an extremely sensitive assay for the pyrophosphorylase reaction. Less than 0.005 μmoles of UDPG or G-1-P may be easily detected and, since this assay, contrary to the spectrophotometric assay, requires no other enzyme system present, it is well suited for kinetic investigations. Measured with this technique the purified UDPG pyrophosphorylase shows specificity for G-1-P as uridyl acceptor among a number of hexose and pentose phosphate esters tested, while crude yeast extract and extracts of fresh spinach leaves contain several uridyl-linked pyrophosphorylases.

Some Studies on Amino Acid Decarboxylases

Gunnar Steensholt and P. E. Joner

Biochemical Institute, University of Oslo, Norway

Glutamic acid decarboxylase is known to have pyridoxal-5-phosphate as cofactor. We found it to require in addition a metal cofactor, namely Zn^{++}, Fe^{+++} or Co^{++} for the enzyme from carrots, and Mn^{++} for the rat brain enzyme. SH-groups appear to be essential. Cysteic acid decarboxylase also requires pyridoxal-5-phosphate as cofactor, and also Fe^{++}, Zn^{++} or Mn^{++}. The presence of SH-groups in this enzyme is doubtful. Cysteine sulphinic acid decarboxylase is also a pyridoxal-5-phosphate enzyme, with essential SH-groups and requiring Fe^{++}, Fe^{+++} or Zn^{++}. The authors consider cysteic acid decarboxylase and cysteine sulphinic acid decarboxylase to be two different enzymes. All three enzymes have been purified to some extent.

Enzymic Formation of Uridine-5′-phosphate from Uracil

Ola Sköld and Peter Reichard

Biochemical Department, Karolinska Institutet, Stockholm, Sweden

Most mammalian tissues studied show a relatively poor utilization of uracil for pyrimidine nucleotide synthesis. In the Ehrlich ascites tumor, however, uracil was incorporated into polynucleotide pyrimidines as rapidly as orotic acid. In a study of the enzymic mechanism of this process it was found that uridine-5′-phosphate(UMP) formation from uracil in acetone powder extracts of the tumor proceeded according to:

$$\text{Uracil} + \text{ribose-1-phosphate} \xrightarrow[\text{phosphorylase}]{\text{nucleoside}} \text{uridine} + \text{phosphate}$$

$$\text{Uridine} + \text{ATP} \xrightarrow[\text{kinase}]{\text{uridine}} \text{UMP} + \text{ADP}$$

Both enzymes involved are known to occur in mammalian organs, *e. g.* liver, which form very little UMP from uracil.

We have now investigated the amount of these two enzymes in the ascites tumor and in rat liver. Furthermore, the breakdown of uracil to CO_2 was also studied, since it had been proposed that this process might determine uracil utilization in different tissues [2].

A significant difference was found in the amount of nucleoside phosphorylase as measured by a spectrophotometric assay. Uridine kinase was consistently *ca.* 10 times more active in extracts of the tumor than in liver extracts. A high concentration of uridine was necessary for optimum UMP synthesis. In accordance with earlier findings of other investigators we observed a quite rapid breakdown of uracil to CO_2 in rat liver preparations. No such degradation was observed in tumor extracts, however. In both cases a high TPNH level was maintained during the reaction.

It seems likely that uracil utilization by different tissues will depend on a competition between catabolic reactions which degrade uracil to CO_2 and the anabolic formation of UMP.

Some Studies on Amino Acid Decarboxylases

Gunnar Steensholt and P. E. Joner

Biochemical Institute, University of Oslo, Norway

Glutamic acid decarboxylase is known to have pyridoxal-5-phosphate as cofactor. We found it to require in addition a metal cofactor, namely Zn^{++}, Fe^{+++} or Co^{++} for the enzyme from carrots, and Mn^{++} for the rat brain enzyme. SH-groups appear to be essential. Cysteic acid decarboxylase also requires pyridoxal-5-phosphate as cofactor, and also Fe^{++}, Zn^{++} or Mn^{++}. The presence of SH-groups in this enzyme is doubtful. Cysteine sulphinic acid decarboxylase is also a pyridoxal-5-phosphate enzyme, with essential SH-groups and requiring Fe^{++}, Fe^{+++} or Zn^{++}. The authors consider cysteic acid decarboxylase and cysteine sulphinic acid decarboxylase to be two different enzymes. All three enzymes have been purified to some extent.

Incorporation *in vitro* of Purine Ribosides into Deoxyribonucleic Acids of Ehrlich's Ascites Tumor Cells

Hans Klenow and
Eleanor Lichtler
The Fibiger-Laboratory, University of Copenhagen, Denmark

In *in vivo* experiments with rats Roll *et al.*[1] have found that the adenosine part of adenylic acid b may serve as a precursor of the deoxyribose of all four deoxyribonucleosides of deoxyribonucleic acid (DNA), and that some of the adenosine may have been converted to an adenine deoxyriboside derivative with the glycosidic linkage intact. There was no suggestion that the guanosine part of guanylic acid b was directly converted to a guanosine deoxyriboside derivative.

We have studied the incorporation *in vitro* of purine ribosides into deoxyribonucleic acids of ascites tumor cells. Suspensions of Ehrlich's ascites tumor cells in Tyrode's solution were incubated with glucose (10 mg/ml cell suspension), sodium succinate (10 mg/ml cell suspension), deoxycytidine (3 μmole/ml cell suspension), and uniformly ^{14}C-labelled adenosine or uniformly ^{14}C-labelled guanosine. After incubation at 37 °C with shaking for 3—4 h the suspensions were treated with ice-cold perchloric acid. The precipitate was washed with alcohol and with an alcohol-ether mixture (3:1), and digested with KOH overnight. After neutralization and dialysis of the digest the DNA present was degraded by incubation with DNA'ase and snake venom phosphodiesterase. The individual deoxyribonucleotides formed were separated and isolated by paper chromatography, and their specific radioactivity was determined.

It was found that when the cells had been incubated with uniformly ^{14}C-labelled adenosine most of the radioactivity (70—90 %) of the DNA was present in the deoxyadenylic acid, whereas the pyrimidine deoxyribotides contained insignificant amounts of radioactivity. The deoxyribose-5-phosphate of DNA-deoxyadenylic acid from such experiments was obtained by paper chromatography after acid hydrolysis. It was found that the average radioactivity per μmole carbon of this compound ranged from 70—100 % of to the average radioactivity per μmole carbon of the deoxyadenylic acid from which it had been derived. The experiments suggest, therefore, that under the conditions used adenosine serves as a precursor of DNA-deoxyadenylic acid, and that 50 % or more of labelled DNA-deoxyadenylic acid could have been formed from adenosine without cleavage of the glycosidic linkage.

In a similar way it was found that guanosine could serve as a precursor of DNA-deoxyguanylic acid. Furthermore, the average specific activity of the carbon atoms in DNA-deoxyguanylic acid obtained from such experiments ranged from 70—100 % of the average specific activity of the carbon atoms of its deoxyribose-5-phosphate part. This suggests that 50 % or more of the labelled DNA-deoxyguanylic acid could have been formed from guanosine without cleavage of the glycosidic linkage.

These results are only in partial agreement with the *in vivo* experiments of Roll *et al.* carried out with uniformly labelled purine ribotides.

Reversible Inactivation of Ribonuclease

Lars Josefsson
Department of Physiological Chemistry, University of Lund, Lund, Sweden

It has previously been shown that anhydrous formic acid induces an N,O-acyl migration in lysozyme followed with a loss of the enzymatic activity. However, titration of the inactivated enzyme with alkali at pH 7.5 reversed the peptidyl shift and restored the activity completely [1-3].

In the same way ribonuclease now has been studied to elucidate the mechanism of the enzymatic activity. In contrast to lysozyme the inactivation and reactivation of ribonuclease proceed slower. Furthermore the activity of ribonuclease is not completely restored at pH 7.5 but requires a further reaction at pH 8.5. However, the reactivation and alkali consumption strictly follow each other.

A General Method for Reduction of Pyrimidine Nucleosides and Nucleotides

S. Laland, J. McKinley McKee and E. Roth

Biochemistry Department, The University, Blindern, Oslo, Norway

The reduction of the pyrimidine ring in nucleosides and nucleotides has recently attracted considerable attention. Burke [1] reported the reduction of pyrimidine nucleosides with sodium in liquid ammonia and ethanol. Cohn and Doherty [2] reduced catalytically pyrimidine nucleosides and nucleotides using a rhodium catalyst and simultaneously with this latter work the reduction of thymidine with sodium amalgam and the subsequent isolation of the sugar component was reported [3].

This simple reduction method has now been extended to the following substances: deoxycytidine, deoxycytidylic acid, thymidylic acid, thymidine diphosphate, deoxycytidine diphosphate, cytidylic acid, uridylic acid, cytidine and uridine. In all cases the reduction is carried out by shaking for a few hours at room temperature an aqueous solution of the substance with 3 % sodium amalgam. The complete reduction of the 4,5-ethylenic linkage in the pyrimidine ring was demonstrated by the disappearance of the UV absorption at 260 mμ[4]. With thymidylic acid and thymidine diphosphate the rate of reduction was slower. The present report concerns in particular the reduction of the deoxyribose nucleosides and nucleotides. The completeness of the reduction was also shown by the fact that the modified Dische diphenylamine test [5] after the reduction revealed the presence of between 90 and 100 % of the theoretical amount of 2-deoxy-D-ribose. Examination of the reduction products by paper chromatography, paper electrophoresis and ion exchange chromatography revealed the presence of several deoxyribosyl substances as was the case with thymidine [3]. This is due to the fission of the dihydropyrimidine ring under the prevailing alkaline condition. The reduction products are interesting. First some of them may be intermediates in the biosynthesis of nucleosides and nucleotides. Work to establish this is in progress. Secondly, for tracer work where the isolation of sugar and sugar phosphates is necessary, these reduction products are convenient because of the lability of the glycosidic linkage towards acid, which enables isolation of the free sugar or the sugar phosphate. After short heating of reduction mixtures of thymidine, deoxycytidine, deoxycytidylic and thymidylic acid, respectively, with Amberlite IR-120 (H), 2-deoxy-D-ribose and 2-deoxy-D-ribose 5-phosphate were isolated in good yield by paper chromatography in propanol-ammonia (conc.), 6:4. Finally, subsequent to reduction, colour tests for the sugar component may be used for detecting and estimating pyrimidine nucleosides and nucleotides. Using the modified Dische diphenylamine method [5] for 2-deoxy-D-ribose, standard curves for the determination of thymidine, deoxycytidine, deoxycytidylic acid and thymidylic acid after reduction with 3 % sodium amalgam were made. Linear curves were obtained. It was shown that quantities of 50 μg of nucleosides or nucleotides could be estimated. This method for deoxyribose pyrimidine nucleosides and nucleotides is particularly useful when the presence of other UV absorbing material, prevents the use of UV absorption spectroscopy.

The Synthesis and Characterization of Some AMP-Sulphates

N. R. Ringertz and Peter Reichard

Department of Cell Research and Biochemical Department, Karolinska Institutet, Stockholm, Sweden

Adenosine-5′-phosphosulphate has been implicated as an intermediate in the enzymic activation of sulphate [1]. It has been synthesized by the condensation of a sulphur trioxide-pyridine complex with adenosine-5′-monophosphate [2] (AMP), and by the carbodiimide method [3].

The carbodiimide method was used for the synthesis of some structurally related AMP-sulphates, containing sulphate linked to the hydroxyl groups of the ribose moiety. The following compounds were synthesized and characterized:

AMP-monosulphates: Adenosine-5′-phosphosulphate (APS). Inorganic sulphate was rapidly liberated from this compound by acid hydrolysis. It was somewhat more resistant to alkaline and CaO hydrolysis. It was degraded to adenosine, phosphate and sulphate by snake venom and prostatic phosphatases. It was an intermediate in the enzyme system for sulphate activation [4]. Adenosine-2′-sulphate-5′-phosphate and adenosine-3′-sulphate-5′-phosphate decomposed at a slower rate than APS during acid hydrolysis and were very slowly degraded by alkaline and CaO hydrolysis. Digestion with snake venom phosphatase produced adenosine, phosphate and sulphate. Prostatic phosphatase produced adenosine-sulphates + phosphate.

AMP-disulphates: The disulphates were probably a mixture of three different compounds, which were not further separated. Two of the compounds conceivably contained one phosphosulphate and one ribose-sulphate linkage. The third compound contained both sulphates attached to ribose.

AMP-trisulphate: Adenosine-2′,3′-disulphate-5′-phosphosulphate was degraded to adenosine-2′,3′ - disulphate - 5′-phosphate and sulphate during acid, alkaline and CaO hydrolysis. Further decomposition occurred at a slower rate. Snake venom phosphatase produced adenosine-2′,3′-disulphate-5′-phosphate + sulphate. Prostatic phosphatase produced adenosine-2,3′-disulphate, phosphate and sulphate.

The factors influencing the yield of the different AMP-sulphates were studied. APS appeared as the primary product. By increasing the amount of sulphuric acid in the reaction mixture and prolonging the reaction time a total yield of AMP-sulphates amounting to 90—100 % (calc. on AMP) could be obtained. It was possible to obtain a 40—50 % conversion of AMP to APS without more than small amounts of other AMP-sulphates.

The different AMP-sulphates could be separated from each other by column electrophoresis on a gram scale.

Complex Formation of Nucleoside Triphosphates with Metal Ions *

E. Walaas

Institute of Medical Biochemistry and Physiology, Department of Biochemistry, University of Oslo, Norway

Transphosphorylation reactions with nucleoside triphosphates as the phosphate donor require metals as cofactors, especially Mg^{2+}, Mn^{2+} or Ca^{2+}. It has therefore been suggested that metal nucleotide complexes are the actual coenzymes. In the present work the dissociation constants of several nucleoside triphosphates of Ca^{2+}, Mg^{2+}, Co^{2+} and Mn^{2+} have been determined. An ion exchange method according to the principle reported by Schubert has been adopted. An anion exchange resin (Dowex-1) in the chloride form has been used. The dissociation constants of mononucleotides with different metals have been determined under the following conditions. A total volume of 20 ml contained (concentrations): 0.5×10^{-4} M nucleotide, 0.1 M NaCl, 0.005 M tris(hydroxymethyl)aminomethane buffer, pH 8.2, and usually 50 mg resin. Equilibration was obtained without and with addition of metal salts to the mixture by shaking for 3 h at 23 °C. The concentration of nucleotide not bound to the resin was determined by reading the extinction at appropriate wavelenghts in ultraviolet region on a Beckman spectrophotometer. From these data the dissociation constants k_c for ATP with metals have been calculated.

$$k_c\ \mathrm{Ca} > k_c\ \mathrm{Mg} > k_c\ \mathrm{Co} > k_c\ \mathrm{Mn}$$
$$1.7 \times 10^{-4}\quad 0.9 \times 10^{-4}\quad 0.23 \times 10^{-4}\quad 0.17 \times 10^{-4}$$

Dissociation constants for different metal complexes with ADP and AMP show the same sequence as reported for ATP. However, as an approximation complexes with ADP are 10 times more dissociated and complexes with AMP are 100 times more dissociated than the corresponding ATP metal complexes. This can be illustrated in the case of complexes with Mg

$$\mathrm{ATP} < \mathrm{ADP} < \mathrm{AMP}$$
$$0.9 \times 10^{-4}\quad 6.4 \times 10^{-4}\quad 1.1 \times 10^{-3}$$

The dissociation constants for CTP, GTP, UTP and ITP with the different metals show, with a few exceptions, the same sequence as reported for ATP. The values approximately correspond to those given for ATP metal complexes.

A General Method for Reduction of Pyrimidine Nucleosides and Nucleotides

S. Laland, J. McKinley McKee and E. Roth

Biochemistry Department, The University, Blindern, Oslo, Norway

The reduction of the pyrimidine ring in nucleosides and nucleotides has recently attracted considerable attention. Burke [1] reported the reduction of pyrimidine nucleosides with sodium in liquid ammonia and ethanol. Cohn and Doherty [2] reduced catalytically pyrimidine nucleosides and nucleotides using a rhodium catalyst and simultaneously with this latter work the reduction of thymidine with sodium amalgam and the subsequent isolation of the sugar component was reported [3].

This simple reduction method has now been extended to the following substances: deoxycytidine, deoxycytidylic acid, thymidylic acid, thymidine diphosphate, deoxycytidine diphosphate, cytidylic acid, uridylic acid, cytidine and uridine. In all cases the reduction is carried out by shaking for a few hours at room temperature an aqueous solution of the substance with 3 % sodium amalgam. The complete reduction of the 4,5-ethylenic linkage in the pyrimidine ring was demonstrated by the disappearance of the UV absorption at 260 mμ[4]. With thymidylic acid and thymidine diphosphate the rate of reduction was slower. The present report concerns in particular the reduction of the deoxyribose nucleosides and nucleotides. The completeness of the reduction was also shown by the fact that the modified Dische diphenylamine test [5] after the reduction revealed the presence of between 90 and 100 % of the theoretical amount of 2-deoxy-D-ribose. Examination of the reduction products by paper chromatography, paper electrophoresis and ion exchange chromatography revealed the presence of several deoxyribosyl substances as was the case with thymidine [3]. This is due to the fission of the dihydropyrimidine ring under the prevailing alkaline condition. The reduction products are interesting. First some of them may be intermediates in the biosynthesis of nucleosides and nucleotides. Work to establish this is in progress. Secondly, for tracer work where the isolation of sugar and sugar phosphates is necessary, these reduction products are convenient because of the lability of the glycosidic linkage towards acid, which enables isolation of the free sugar or the sugar phosphate. After short heating of reduction mixtures of thymidine, deoxycytidine, deoxycytidylic and thymidylic acid, respectively, with Amberlite IR-120 (H), 2-deoxy-D-ribose and 2-deoxy-D-ribose 5-phosphate were isolated in good yield by paper chromatography in propanol-ammonia (conc.), 6:4. Finally, subsequent to reduction, colour tests for the sugar component may be used for detecting and estimating pyrimidine nucleosides and nucleotides. Using the modified Dische diphenylamine method [5] for 2-deoxy-D-ribose, standard curves for the determination of thymidine, deoxycytidine, deoxycytidylic acid and thymidylic acid after reduction with 3 % sodium amalgam were made. Linear curves were obtained. It was shown that quantities of 50 μg of nucleosides or nucleotides could be estimated. This method for deoxyribose pyrimidine nucleosides and nucleotides is particularly useful when the presence of other UV absorbing material, prevents the use of UV absorption spectroscopy.

The Synthesis and Characterization of Some AMP-Sulphates

N. R. Ringertz and Peter Reichard

Department of Cell Research and Biochemical Department, Karolinska Institutet, Stockholm, Sweden

Adenosine-5′-phosphosulphate has been implicated as an intermediate in the enzymic activation of sulphate [1]. It has been synthesized by the condensation of a sulphur trioxide-pyridine complex with adenosine-5′-monophosphate [2] (AMP), and by the carbodiimide method [3].

The carbodiimide method was used for the synthesis of some structurally related AMP-sulphates, containing sulphate linked to the hydroxyl groups of the ribose moiety. The following compounds were synthesized and characterized:

AMP-monosulphates: Adenosine-5′-phosphosulphate (APS). Inorganic sulphate was rapidly liberated from this compound by acid hydrolysis. It was somewhat more resistant to alkaline and CaO hydrolysis. It was degraded to adenosine, phosphate and sulphate by snake venom and prostatic phosphatases. It was an intermediate in the enzyme system for sulphate activation [4]. Adenosine-2′-sulphate-5′-phosphate and adenosine-3′-sulphate-5′-phosphate decomposed at a slower rate than APS during acid hydrolysis and were very slowly degraded by alkaline and CaO hydrolysis. Digestion with snake venom phosphatase produced adenosine, phosphate and sulphate. Prostatic phosphatase produced adenosine-sulphates + phosphate.

AMP-disulphates: The disulphates were probably a mixture of three different compounds, which were not further separated. Two of the compounds conceivably contained one phosphosulphate and one ribose-sulphate linkage. The third compound contained both sulphates attached to ribose.

AMP-trisulphate: Adenosine-2′,3′-disulphate-5′-phosphosulphate was degraded to adenosine-2′,3′ - disulphate - 5′-phosphate and sulphate during acid, alkaline and CaO hydrolysis. Further decomposition occurred at a slower rate. Snake venom phosphatase produced adenosine-2′,3′-disulphate-5′-phosphate + sulphate. Prostatic phosphatase produced adenosine-2,3′-disulphate, phosphate and sulphate.

The factors influencing the yield of the different AMP-sulphates were studied. APS appeared as the primary product. By increasing the amount of sulphuric acid in the reaction mixture and prolonging the reaction time a total yield of AMP-sulphates amounting to 90—100 % (calc. on AMP) could be obtained. It was possible to obtain a 40—50 % conversion of AMP to APS without more than small amounts of other AMP-sulphates.

The different AMP-sulphates could be separated from each other by column electrophoresis on a gram scale.

Complex Formation of Nucleoside Triphosphates with Metal Ions *

E. Walaas

Institute of Medical Biochemistry and Physiology, Department of Biochemistry, University of Oslo, Norway

Transphosphorylation reactions with nucleoside triphosphates as the phosphate donor require metals as cofactors, especially Mg^{2+}, Mn^{2+} or Ca^{2+}. It has therefore been suggested that metal nucleotide complexes are the actual coenzymes. In the present work the dissociation constants of several nucleoside triphosphates of Ca^{2+}, Mg^{2+}, Co^{2+} and Mn^{2+} have been determined. An ion exchange method according to the principle reported by Schubert has been adopted. An anion exchange resin (Dowex-1) in the chloride form has been used. The dissociation constants of mononucleotides with different metals have been determined under the following conditions. A total volume of 20 ml contained (concentrations): 0.5×10^{-4} M nucleotide, 0.1 M NaCl, 0.005 M tris(hydroxymethyl)aminomethane buffer, pH 8.2, and usually 50 mg resin. Equilibration was obtained without and with addition of metal salts to the mixture by shaking for 3 h at 23 °C. The concentration of nucleotide not bound to the resin was determined by reading the extinction at appropriate wavelenghts in ultraviolet region on a Beckman spectrophotometer. From these data the dissociation constants k_c for ATP with metals have been calculated.

$$k_c\ \mathrm{Ca} > k_c\ \mathrm{Mg} > k_c\ \mathrm{Co} > k_c\ \mathrm{Mn}$$
$$1.7 \times 10^{-4}\quad 0.9 \times 10^{-4}\quad 0.23 \times 10^{-4}\quad 0.17 \times 10^{-4}$$

Dissociation constants for different metal complexes with ADP and AMP show the same sequence as reported for ATP. However, as an approximation complexes with ADP are 10 times more dissociated and complexes with AMP are 100 times more dissociated than the corresponding ATP metal complexes. This can be illustrated in the case of complexes with Mg

$$\mathrm{ATP} < \mathrm{ADP} < \mathrm{AMP}$$
$$0.9 \times 10^{-4}\quad 6.4 \times 10^{-4}\quad 1.1 \times 10^{-3}$$

The dissociation constants for CTP, GTP, UTP and ITP with the different metals show, with a few exceptions, the same sequence as reported for ATP. The values approximately correspond to those given for ATP metal complexes.

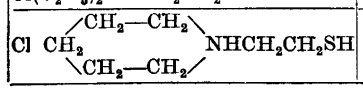
Equilibrium Constants of Thiol-Disulphide Systems. The Relative Oxidation-Reduction Potential of Cysteine-Glutathione *

Alexander Pihl and Lorentz Eldjarn

Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway

Previously we have presented evidence that the accessible thiols and disulphides of the body exist in a state of dynamic equilibrium, governed by the appropriate equilibrium constants and by the total SH/SS-ratio [1,2]. Clearly, information on the relevant equilibrium constants and reaction rates is necessary for the understanding of the role and mode of action of thiols and disulphides in biochemical processes.

* Supported by grants from the *Norwegian Cancer Society*.



A method for the analysis of thiol-disulphide equilibria has previously been presented [1,2]. Recently, by a modification of this procedure, we have succeeded in measuring directly the concentrations of three of the five constituents of thiol-disulfide equilibria, permitting the straight-forward calculation of the appropriate equilibrium constants. In the improved method, which is described in detail elsewhere [3], the ^{35}S-labeled constituents of the systems tested are separated by electrophoresis at pH 2 in mercuric acetate treated paper.

The procedure has been used for the determination of the equilibrium constants, at pH 7.4 and 37 °C, of systems containing cystine or oxidized glutathione and various sulphur containing X-ray protective thiols. The data are summarized in Table 1. Here is also given the approximate time needed to obtain equilibrium under these conditions.

The K-values found, imply that in these systems high amounts of mixed disulphides are present at equilibrium. The data confirm our previous findings [4,5] that sulphur-containing agents possessing high ability to protect animals against ionizing radiation, exhibit a pronounced tendency to form mixed disulphides with biological thiols and disulphides.

Table 1. The equilibrium constants K_2 and K_3 of various thiol-disulphide systems *.

						Mean	0.0101

* The measurements were carried out at pH 7.4 and 37 °C.

** E_0' = standard oxidation-reduction potential, at pH 7.4 and 37 °C, relative to that of glutathione ($E_{0\,GSSG/GSH}' = 0$ volts), with sign opposite to that used by Latimer [6].

From the equilibrium constants the relative oxidation-reduction potential of the 15 thiol-disulphide couples involved in the 10 systems studied, can be calculated. Of particular interest is the fact that the above equilibrium constants can be used for the calculation of the oxidation-reduction potential of cysteine, relative to that of glutathione. It is clear from Table 1 that the calculations, based on 5 independent sets of data, show good agreement. The results seem to present a solution to this controversial question.

Enzyme Kinetics in Univalent Buffers

J. S. McKinley McKee

Biochemical Institute, University of Oslo, Blindern, Oslo

Many ions have different effects on the kinetics of the fumarase-catalyzed reaction [1]:

$$\text{fumarate} + H_2O \rightleftharpoons \text{L-malate}$$

With buffer ions specific effects arise due to the binding of the different buffer ions. Kinetic studies in phosphate buffers [2] proved unsatisfactory due to the presence of HPO_4^{--} and $H_2PO_4^-$ ions, each with its own effect on the enzyme and the relative concentration of which varied with pH. As the kinetic constants are unaffected by the buffer cation, while being very sensitive to the anion concentration and type, univalent buffers of the uncharged base type (*e. g.* imidazole, tris, ammidol-chloride, fluoride or perchlorate) have been used. Thus specific buffer effects can be studied as there is a single anion, the concentration of which can be held constant over a wide pH range.

The experiments have consisted of determining the pH variation of the maximum velocities (V_M, V_F) and Michaelis constants (K_M, K_F) for the forward and reverse reactions. These were obtained from Liveweaver-Burk plots. It was important to use substrate concentrations (range 4K—K/4) which gave neither substrate activation or inhibition [2], as otherwise erroneous kinetic constants resulted. The enzyme solutions were prepared from crystalline fumarase, and the kinetics were followed on the 80—100 % transmission expanded scale of a Beckman DUR spectrophotometer [2]. The Michaelis constants for malate and fumarate in 5 mM chloride, perchlorate or acetate buffers rise markedly above pH 8.0. With malate, the K_M values are approximately constant below pH 7.0, while with fumarate this represents a minimum. Plots of V_M, V_F, V_M/K_M, and $V_F/4.4K_F$ *vs.* pH are symmetrical and bell shaped. For each buffer the data were consistent with the ionisation of two groups in the enzymatic site, having different ionisation constants in the free enzyme and the fumarase and L-malate complexes. In the various buffers the pK values vary markedly. Good agreement was found between the experimental points and theoretical curves calculated from pH independent kinetic constants and the pK values [3]. In interpreting the data the secondary ionisations of the substrates have to be taken into account at the lowes pH values. A comparison of the kinetic constants in phosphate (approximate values) with those in the univalent buffers shows that while neither buffer type or concentration markedly affect the pH independent maximum velocity or turnover number, yet the corresponding Michaelis constants are much greater in phosphate, presumably due to the divalent ions present. As both substrates give the same ionisation constants for two essential groups in the free enzyme (V_M/K_M and $V_F/K_{eq}K_F$ superimposable) it seems that it is the same enzymatic site that is involved in the proton transfer reactions resulting in hydration or dehydration.

Insulin-like Activity of a Dialyzable Factor in Human Blood Plasma *

R. Haavaldsen and O. Walaas

Institute of Medical Biochemistry and Physiology, Department of Biochemistry, University of Oslo, and Lier Mental Hospital, Norway

Human blood serum or plasma exerts an insulin-like activity shown by the stimulating effect on glucose uptake of the rat diaphragm *in vitro*. Based on this observation a method for determination of the insulin content in plasma or serum has been worked out by Groen *et al.*[1] and later by others. However, a definite proof that the effect of serum is due solely to the content of insulin is lacking. This can be questioned from the fact that wide variations in values obtained by different investigators have been reported, as well as from a theoretical point of view.

The present investigation has been undertaken to show if the insulin-like activity of plasma specifically can be related to the content of insulin or if other compounds contribute to this effect. The following experimental technique has been adopted. Blood is drawn into a syringe previously heparinized and plasma immediately separated by centrifugation. A sample of plasma was dialysed against Krebs Ringer solution for 12 h at +2 °C. The solution was buffered either with bicarbonate or with phosphate to pH 7.4 and glucose added to a final concentration of 140 mg per 100 ml. The effect of plasma and dialysate on glucose uptake of the rat diaphragm has been investigated by a procedure used for some years in our laboratory.

The dialysate from serum as well as from plasma stimulated glucose uptake in the isolated rat diaphragm. This was a significant and reproducible effect. As an average of 10 experiments 30 % stimulation was obtained. The stimulating effect was stable against heat. Thus, if the dialysate was kept at 80 °C for 20 min or boiled for 5 min the stimulating effect was increased by another 30 %. This indicated thermal inactivation of an inhibitory factor in the dialysate. The stimulating effect in the dialysate was not due to insulin. 0.1 unit crystalline insulin added to plasma did not influence the effect of the dialysate on glucose uptake of the rat diaphragm and insulin could be recovered in the plasma inside the bag after dialysis. — The insulin like effect of plasma was reduced after dialysis. After prolonged dialysis for 48 h even inhibition of the glucose uptake in rat diaphragm by the dialysed plasma has been observed.

So far, we have not been able to confirm that the insulin-like activity of plasma solely is due to the content of insulin. Of particular interest is that a dialysable factor from plasma or serum exerts insulin-like activity in the rat diaphragm method. Further studies on the nature of this factor is in progress.

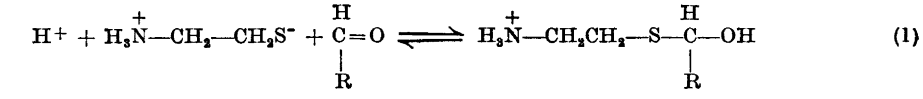
The Interaction of Cysteamine and Cysteine with various Carbonyl Compounds *

Lorentz Eldjarn, Karl F. Nakken** and Alexander Pihl

Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway

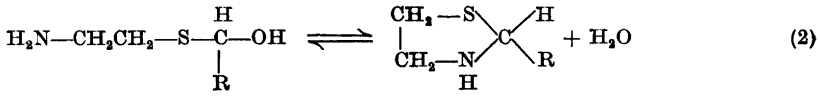
Numerous important metabolites and several therapeutic agents possess reactive carbonyl groups. A study of the interaction of thiols with carbonyl compounds has therefore been undertaken.

In the present paper data on the interaction of the 1-mercapto-2-amines cysteamine and cysteine with several carbonyl compounds, will be reported. The procedure previously described for the analysis of thiol-disulphide interactions [1,2], was found suitable for this purpose. The sulphur labeled thiols were incubated with the carbonyl compound at 37 °C and the desired pH. After acidification the labeled products were separated from the reactants by paper electrophoresis in phthalate buffer at pH 2.



The reaction mechanism has been studied in some detail in the system cysteamine and glyceraldehyde. It was observed that at pH 6.8—7.4 the rate of formation of the labeled product followed the kinetics of a bimolecular one-way reaction of the type $A+B \rightarrow C$. No evidence for the formation of dithials was

* Supported by grants from the *Norwegian Cancer Society.*



** Fellow of the Norwegian Cancer Society.

obtained, even when a large excess of cysteamine was used. Over a wide pH range (1.4—8.3) the observed reaction rate paralleled the concentration of the ionized thiol ($pK_{SH}=8.6$), which constitutes evidence that in this reaction thiol is indeed the reactive molecular species. It also demonstrates that, in the pH range studied, no marked proton activation of the carbonyl group takes place. At pH 7.4 and 37 °C the radioactivity of the labeled product did not decrease when an excess of non-labeled cysteamine was added.

On the basis of the above data the following reaction mechanism is suggested:

(1)

(2)

Since the formation of cyanohydrins, acetals and bisulphite addition products are known to be reversible [3], reaction 1 would similarly be expected to be reversible. The fact that the formation of the product appears as a one-way reaction, can be explained by assuming that reaction 2 is faster than reaction 1 and is displaced to the right.

The rate of interaction of cysteamine with cortisone was found to be negligible at pH 7.4 and 37 °C. However, significant reaction rates were found with glyceraldehyde, methylglyoxal [4], dihydroxyacetone and α-ketoglutaric acid. The rate constants

$$k = \frac{[\text{Product}]}{[RS^-]\,[R'\text{—}CO\text{—}R'']}\ \text{min}^{-1} \times \text{M}^{-1} \times (10^3)\text{l}$$

were 2.5, 1.2, 0.2 and 0.01 respectively.

Since streptomycin is known to be inactivated by cysteamine and cysteine [5], it is of interest that cysteine was found to react stoichiometrically with streptomycin at a fairly rapid rate, whereas no interaction was observed with dihydrostreptomycin. This latter finding indicates that the reaction takes place at the carbonyl group of streptomycin.

The Isolation of Prostaglandin

S. Bergström and J. Sjövall

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The presence of a smooth muscle stimulating factor in sperm and in extracts of the accessory genital glands of man and certain animals was demonstrated by Goldblatt [1] and von Euler [2]. A concentrate of the factor from sheep prostate gland was prepared by von Euler [3] who studied some of its chemical properties.

Some preliminary data on the further purification of this concentrate have been published [4].

We have succeeded in isolating one "prostaglandin" factor (PGF) in crystalline form The. compound (102°—103°) is an unsaturated hydroxyacid, that does not contain nitrogen. A good response is obtained on a rabbit's duodenum at a concentration of $\sim 5 \times 10^{-9}$ g per ml.

At least one other active acidic factor is present in sheep prostate glands.

The isolation procedure and some of the properties of the pure compound will be discussed.

obtained, even when a large excess of cysteamine was used. Over a wide pH range (1.4—8.3) the observed reaction rate paralleled the concentration of the ionized thiol ($pK_{SH}=8.6$), which constitutes evidence that in this reaction thiol is indeed the reactive molecular species. It also demonstrates that, in the pH range studied, no marked proton activation of the carbonyl group takes place. At pH 7.4 and 37 °C the radioactivity of the labeled product did not decrease when an excess of non-labeled cysteamine was added.

On the basis of the above data the following reaction mechanism is suggested:

(1)

(2)

Since the formation of cyanohydrins, acetals and bisulphite addition products are known to be reversible [3], reaction 1 would similarly be expected to be reversible. The fact that the formation of the product appears as a one-way reaction, can be explained by assuming that reaction 2 is faster than reaction 1 and is displaced to the right.

The rate of interaction of cysteamine with cortisone was found to be negligible at pH 7.4 and 37 °C. However, significant reaction rates were found with glyceraldehyde, methylglyoxal [4], dihydroxyacetone and α-ketoglutaric acid. The rate constants

$$k = \frac{[\text{Product}]}{[RS^-]\,[R'\text{—}CO\text{—}R'']}\ \text{min}^{-1} \times \text{M}^{-1} \times (10^3)\text{l}$$

were 2.5, 1.2, 0.2 and 0.01 respectively.

Since streptomycin is known to be inactivated by cysteamine and cysteine [5], it is of interest that cysteine was found to react stoichiometrically with streptomycin at a fairly rapid rate, whereas no interaction was observed with dihydrostreptomycin. This latter finding indicates that the reaction takes place at the carbonyl group of streptomycin.

The Isolation of Prostaglandin

S. Bergström and J. Sjövall

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The presence of a smooth muscle stimulating factor in sperm and in extracts of the accessory genital glands of man and certain animals was demonstrated by Goldblatt [1] and von Euler [2]. A concentrate of the factor from sheep prostate gland was prepared by von Euler [3] who studied some of its chemical properties.

Some preliminary data on the further purification of this concentrate have been published [4].

We have succeeded in isolating one "prostaglandin" factor (PGF) in crystalline form The. compound (102°—103°) is an unsaturated hydroxyacid, that does not contain nitrogen. A good response is obtained on a rabbit's duodenum at a concentration of $\sim 5 \times 10^{-9}$ g per ml.

At least one other active acidic factor is present in sheep prostate glands.

The isolation procedure and some of the properties of the pure compound will be discussed.

Studies of Transphosphorylating Enzymes. The Incorporation Rate of ^{32}P into Trichloroacetic Acid Soluble Nucleotides, Protein-Phosphoserine and Phosphothreonine of Baker's Yeast

Gunnar Ågren and Lorentz Engström

Institute of Medical Chemistry, University of Uppsala, Sweden

In a recent paper [1] it was demonstrated that radioactive phosphoserine could be isolated from a yeast hexokinase preparation incubated with AT^{32}P or glucose-6-^{32}P. The results were interpreted in the way that the transfer of phosphorus in the hexokinase system is at least a two-step reaction with the formation of an enzyme-phosphate as an intermediate. It seemed to be of considerable interest if similar types of transphosphorylations could be demonstrated in later steps of the carbohydrate metabolism.

As in animal cells [2] the only phosphorylated amino acids present in partial hydrolysates of the Schneider protein residue from yeast cells were phosphoserine and phosphothreonine [3]. Recently Schmitz [4] also found that the perchloric acid soluble mononucleotides from yeast were the same as present in the corresponding extracts from animal cells [5]. Yeast cells were accordingly cultivated in a glucose medium and the rate of phosphorus incorporation into the phosphorylated amino acids and some of the metabolically active nucleotides were determined and compared.

In preliminary experiments the cells were preincubated in a 1 % glucose medium for 30 min followed by the addition of ^{32}P-phosphate at the beginning of each series. The specific activity values of the trichloroacetic acid soluble mononucleotides were determined at 0.5, 2, 5, 10, and 20 min of cultivation, mainly in the same way as Brumm *et al.*[6]. The values were compared with the specific activity values of the phosphoserine and phosphothreonine fractions isolated from the Schneider protein residues of each batch of cells [1,2]. With the increase in time there was a parallel increase of the phosphorus incorporation into the different mononucleotides and phosphoamino acids.

In several experiments the yeast cells were grown in the presence of enzyme inhibitors acting on enzymes in metabolic steps after the initial hexokinase system. In each series one of the inhibitors was added after 20 min of preincubation in a 1 % glucose medium. 10 min later the radioactive phosphate was added. The specific activities of the different compounds were determined after 2 and 20 min of cultivation. A control without inhibitor was always run parallel. The inhibitors, iodoacetic acid, potassium fluorid, sodium azide [7] or phlorhizin [8] were added to a final concentration of 2×10^{-3} M in the different series.

As compared with the controls there was always a decrease of the specific activity values of the trichloroacetic acid soluble nucleotides in the different inhibitor series. A parallel decrease in the specific activity values of the phosphorylated amino acids from the Schneider protein residues was also observed. This is taken as further evidence that several phosphoproteins in the later steps of the carbohydrate metabolism may also function as transphorylating enzymes in the same way as has previously been demonstrated for the hexokinase system.

Yeast Lactic Dehydrogenase

Agnar P. Nygaard

Johan Throne Holst's Institutt for Ernæringsforsking, Blindern, Oslo, Norway

The enzyme has been isolated from bakers yeast after mechanical disruption of the cells. Preparations of the enzyme are able to reduce cytochrome c to a remarkable extent without substrate added. Enzymatic properties will be discussed.

The Use of Mixed Solvents in the Study of Enzyme Kinetics

E. W. Westhead and
Bo G. Malmström

Biokemiska Institutionen, Uppsala Universitet, Uppsala, Sweden

Possible advantages to be obtained through the use of aqueous-organic solvent mixtures in the study of enzyme kinetics are twofold: the influence of the nature of the solvent on the reaction might give information on the mechanism of the reaction, as it has in the case of many non-enzymic reactions, and the resultant depression of the freezing point of the solution might be useful in extending the temperature range over which the reaction can be studied.

To determine the extent to which these possibilities may be realized, the effects of dioxan, ethanol, methanol, and glycerol on the enolase reaction have been studied in detail. To avoid the danger of artefacts, the solvent study was accompanied by careful investigation of all factors influencing the kinetic behavior. This led, for example, to the discovery that buffer ions played an unexpected role in the reaction, resulting in changes of apparent activation energy and in low-temperature inhibition.

The results of this investigation have shown that serious misinterpretations of data may be made by assuming that the same factors are involved in solvent effects on enzymic reactions as on nonenzymic reactions. Specifically, dielectric constant changes in the medium were found to have no appreciable effect on the reaction.

The use of organic solvents to lower the freezing point of the medium was found to be justified for the enolase reaction since it did not cause any change in the temperature dependance of the reaction; hence the reaction mechanism is apparently unaffected despite the lowering of the activity. Through this technique it has been found possible to lower the reaction rate sufficiently to investigate kinetic behavior at higher enzyme concentration than would otherwise be possible without the use of advanced electronic equipment, such as that used by Chance and others [1]. The use of high enzyme concentrations is desirable both to avoid certain types of artefacts (*e. g.* inactivation by surface denaturation or traces of metal ions) and to increase the information obtainable by kinetic means. Results of these investigations, including studies of "low temperature inhibition", will be presented.

Ornithine Carbamyl Transferase

Peter Reichard

Biochemical Department, Karolinska Institutet, Stockholm, Sweden

The enzyme which catalyzes the formation of citrulline [1,2] was purified from rat liver mitochondria. The final preparation moved as a single compound during paper electrophoresis between pH 5 and 8.5. During ultra centrifugation an impurity amounting to *ca.* 5—8 % was detected.

The enzyme catalyzed the following stoichiometric reaction:

L-ornithine + carbamyl phosphate ⇌ L-citrulline + phosphate

Out of 26 tested amino acids only L-ornithine could accept the carbamyl group of carbamyl phosphate. The name ornithine carbamyl transferase is proposed for the enzyme. The reversibility of the reaction was demonstrated with the aid of isotopic substrates and the equilibrium constant was found to be about 10^5. The liver enzyme described by Krebs *et al.*[3] which catalyzed the phosphorolysis or arsenolysis of citrulline was found to be identical with ornithine carbamyl transferase.

The reaction is strongly inhibited by *p*-chloromercuribenzoate. Ornithine and carbamyl phosphate can to some extent protect the enzyme from inhibition. Isotope exchange experiments gave no indication for the formation of a carbamylated enzyme. The reaction mechanism will be discussed.

Carbamyl aspartate was formed from citrulline + aspartate in the presence of phosphate by the combined action of ornithine carbamyl transferase and aspartate carbamyl transferase [4].

On the Migration of the Phosphoryl Group in Phosphoproteins

Gunnar Ågren and
Carl-Henric de Verdier

Institute of Medical Chemistry, University of Uppsala, Sweden

In a previous paper [1] on the phosphorus-containing proteins of cells we discussed the possible migration of phosphorus from a phospho-amide linkage in serine to the hydroxyl groups. Plapinger and Wagner-Jauregg [2] have shown this to occur, when N-di*iso*propylphosphorylserine is hydrolysed with aqueous hydrochloric acid. Elliott [3] also found a transfer of approximately 60 % of the peptide chains linked to the nitrogen atoms of serine residues to the hydroxyl groups of these residues. Possible migration within the serine molecule when the corresponding phenylthiohydantoin is formed has been discussed by Edman and Lauber [4].

Müller *et al.*[5] recently published an interesting report where they demonstrated that aminophosphate (AP) at 25° and pH 7.2 phosphorylated the imidazole group of histidine. They also isolated a phosphorylated insulin containing 1 % of phosphorus when the protein was incubated with AP. They suggested that the phosphoryl group was linked to histidine in the protein molecule. This compound offered an unique opportunity to investigate a possible phosphorus migration within a phosphoprotein with known amino acid sequences, probably only containing nitrogen-bound phosphorus.

AP was synthesized according to Stokes [6] as modified by Müller *et al.*[5] 7 g of bovine crystalline insulin * was incubated at pH 8.0 and 25° with 4.37 g AP, divided in five equal parts and added with intervals of 2 h. Samples of the incubation mixture containing 120 mg of insulin were purified from AP by electrodialysis for 1 h at pH 8. pH was kept constant by adding ammonia. The yield was 6 g of lyophilised material containing 0.48 % P. After partial acid hydrolysis and repeated purification on Dowex-50 colums it was possible to isolate a ninhydrin-positive substance which on paper chromatograms with different solvents and on paper-electrophoresis strips at different pH moved as O-phosphoserine. It contained about 0.4 % of the phosphorus present in phosphoinsulin. The partial hydrolysis used always gives a mixture of phosphopeptides [1,7]. In a similar manner the partial hydrolysis of phosphoinsulin resulted in several phosphopeptides containing serine and threonine.

Model experiments with several basic and neutral amino acids including serine, threonine and cysteine are in agreement with the hypothesis that the phosphoryl group is primarily attached to the imidazole- and ε-amino groups of histidine and lysine, respectively. The isolation of O-phosphoserine seems to demonstrate a nitrogen to oxygen migration of the phosphoryl-group from one amino acid to another within the molecule. Perlmann [8] recently showed that the phosphate in some phosphoproteins can be N-, O-, and pyrophosphate bound. The amide-bound phosphorus, as representing high-energy linked phosphorus, is of special interest in metabolic reactions. Recent results from this laboratory [1,9-11] seem to demonstrate that several of the intracellular phosphoproteins must function as transphosphorylating enzymes. It is likely that many of these phosphoproteins contain the nitrogen-linked type of phosphate. The O-phosphoserine and O-phosphothreonine isolated from such proteins by our standard procedure originally may have been nitrogen-linked as in phosphoinsulin and then by the partial acid hydrolys migrated to the O-position in serine and threonine.

Yeast Carboxylase and Cell Permeability

Heikki Suomalainen and Erkki Oura

Research Laboratories of the State Alcohol Monopoly, Helsinki, Finland

The effect of cell permeability on the metabolic functions of micro-organisms has been repeatedly discussed in the literature, but very little direct evidence has been presented [1-3]. In this work the question has been studied by comparing the decarboxylating activity of yeast carboxylase preparations and of intact yeast cells.

Yeast carboxylase decarboxylates not only pyruvic acid but also other straight-chain α-keto acids, at least up to acids with 8 carbon atoms. Our results with dried brewer's yeast as a crude carboxylase preparation show that, in accordance with earlier observations [4,5], the decarboxylating power of the enzyme decreases with increase of the carbon chain length (Table 1).

It has been generally supposed that the enzyme carboxylase is located in the interior of the yeast cell. Thus the cell wall may form a barrier tending to prevent the substrate from coming in contact with the enzyme. The longer the carbon chain the faster the normal fatty acids penetrate into a yeast cell [6,7].

Table 1. Decarboxylation of different α-keto acids by dried brewer's yeast at pH 5.8. α-Keto acids were used at a concentration (0.04 M) at which the enzyme was saturated with the substrate.

Substrate	CO_2, μl/3 min/10 mg dry yeast
Pyruvic acid	192
α-Ketobutyric acid	143
α-Ketovaleric acid	122
α-Ketocaproic acid	58
α-Ketooenanthic acid	33
α-Ketocaprylic acid	28

The same tendency in decarboxylating power was found both in dried baker's yeast and in brewer's or baker's yeast disintegrated by freeze-thawing.

Table 2. Decarboxylation of different α-keto acids by intact brewer's yeast, in two substrate concentrations.

Substrate	CO_2, μl/3 min/80 mg fresh yeast Concentration of the keto acid	
	0.0015 M	0.0075M
Pyruvic acid	2	11
α-Ketobutyric acid	7	31
α-Ketovaleric acid	8	38
α-Ketocaproic acid	11	51
α-Ketooenanthic acid	22	—
α-Ketocaprylic acid	27	—

Analogous results were obtained with intact baker's yeast.

Consequently it is possible that in intact yeast the permeability of the cell wall determines the velocity of the decarboxylation of α-keto acids. Because only undissociated acid molecules can penetrate, the experiments with intact yeast were performed at a lower pH, at which, however, the longer-chain keto acids can be used in low concentrations only. Examples of the results are given in Table 2.

From these results it would appear that the velocity of decarboxylation of α-keto acids by intact yeast bears an inverse relation to the velocity of decarboxylation of dried yeast preparations or of disintegrated yeast cells. The explanation that this difference is due to the limiting effect of the cell permeability has been confirmed by potentiometric measurements of the penetration velocities of the α-keto acids.

Pasteur Effect, Malonate Pasteur Effect and Crabtree Effect in Ehrlich Ascites Tumor Cells

Elling Kvamme

Ullevål sykehus, Centrallaboratoriet, Oslo, Norway

In confirmation of earlier reports by others, it was found that ascites tumor cells exhibit a clear cut Pasteur effect, *i. e.*, they have a lower aerobic than anaerobic glucose utilization. A similar type effect was also demonstrated in malonate blocked cells, incubated aerobically. Under these conditions, fumarate stimulated the oxygen uptake markedly and reduced the glucose uptake as well as the lactic acid formation (malonate Pasteur effect). In the absence of malonate, fumarate had no such action upon glycolysis and respiration.

It has been shown that the concentration of inorganic phosphate in the incubation medium is limiting for the rate of aerobic glycolysis in the Ehrlich ascites cells. The same was found when the cell suspensions were incubated in partial vacuum, as well as in the presence of malonate. It has further been demonstrated that the concentration of inorganic phosphate within the cells decreased to immeasurable values during aerobic glycolysis. An almost complete depletion of intracellular inorganic phosphate was also found to accompany the malonate Pasteur effect.

The Pasteur effect as well as the malonate Pasteur effect decreased by increasing the phosphate concentration of the medium. More ^{32}P was taken up by the cells during aerobic glycolysis than during anaerobic glycolysis. In the latter case, phosphate was given off from the cells to the medium.

An accumulation of acid soluble phosphate esters, including fructose-diphosphate, glucose-6-phosphate and adenosine-triphosphate (ATP), did only accompany aerobic glycolysis. The ATP concentration increased at the expence of ADP and AMP. The amount of acid labile phosphate esters which accumulated, declined by reducing the phosphate concentration of the medium, in contrast to the acid stable phosphate esters. In the presence of iodoacetic acid (10^{-4} M) glucose further reduced the ADP and AMP, a reduction which was not counteracted by the corresponding increase in ATP.

The data indicate that the accumulation of phosphate esters during aerobic glycolysis further restrict the intracellular availability of inorganic phosphate, resulting in a reduced rate of aerobic glycolysis, *i. e.* a Pasteur effect.

The aerobic accumulation, especially of acid labile phosphate esters in the presence of glucose and phosphate, may also have some bearing upon the Crabtree effect. As this effect was more or less counteracted by removal of phosphate from dilute suspensions of glycolyzing cells, it is probably not directly caused by intracellular phosphate limitation. The Crabtree effect may possibly be explained by a depletion of mitochondrial phosphate acceptors, due to the ATP accumulation during aerobic glycolysis.

Chromatographic Separation of Urinary Corticoids

R. Emberland and K. F. Stöa

The Endocrinological Research Laboratory, University Clinic, Bergen

Dirscherl *et al.* [1] have found that individual steroid hormones can be separated by means of partition-chromatography on cellulose columns.

This principle has been applied to the fractionation of urinary corticosteroids, and several individual hormone metabolites have been separated and identified.

The procedure involves hydrolysis of the urinary steroid conjugates, either with acid or by means of β-glucuronidase. The steroids are then extracted with ether, the ether extract washed with 0.1 M NaOH and with water. After evaporation of the ether, the residue is dissolved in 2 ml toluene saturated with 1,2-propylene glycol. This solution is chromatographed on a cellulose column impregnated with 1,2-propyleneglycol. Elution fluid: toluene saturated with 1,2-propyleneglycol. The corticoids are determined as reducing steroids.

By means of this method we have determined the loss of several individual corticosteroids when the urine is hydrolyzed with acid and with β-glucuronidase, respectively.

Likewise we have determined the percentage of free and glucuronic acid bound urinary corticoids.

Fragmentation of Mast Cells Caused by Some Phenothiazine Derivatives

Bertil Högberg

Research Department, AB Leo, Hälsingborg

and Börje Uvnäs

Department of Pharmacology, Karolinska Institutet, Stockholm, Sweden

Chlorpromazine has been reported to give rather frequent side effects such as pruritus, dermatitis and other cutaneous reactions, rhinitis and icterus. The side effects have been proposed to be of an allergic nature. If so, the manifestations should be due to or accompanied with release of histamine. As phenothiazine derivatives have a pronounced antihistamine effect, it is, however, difficult to use current methods for biological testing of histamine liberated by these derivatives. Since "histamine releasers" have been observed to disrupt mast cells we have tested some phenothiazine derivatives on their ability to cause disruption of mast cells. A slight modification of the technique described by Norton was used [1].

The disrupting actions of chlorpromazine, chlorpromazine sulfoxide, oxypromazine, promethazine and promazine are compared with that of compound 48/80, a very potent "histamine liberator". All the phenothiazine derivatives except chlorpromazine sulfoxide, the major metabolite of chlorpromazine, have a disrupting action on mast cells, although to a lesser degree than 48/80. The ED_{50} value (50 % disruption of mast cells) is for 48/80 0.32 μg/ml (0.18—0.56), and for chlorpromazine, the most active of the phenothiazine derivatives studied, ED_{50} is 45 μg/ml (42.1—48.2). The log-dose response curve obtained for chlorpromazine is of the same character as that obtained for 48/80, a fact indicating that the mechanism of action on the mast cell membrane is identical for the two substances.

It is of interest to note that chlorpromazine produces an action in cases of essential hyperlipemia similar to that produced by intravenous heparin [2]. The "clearing effect" of chlorpromazine might be explained as the result of its disruptive action on mast cells. These cells contain, at least in some species and in some tissues, not only histamine but also heparin, which substances occur in the blood on fragmentation of the mast cells.

On treatment of mental illnesses it has been proved that chlorpromazine is the most active of the phenothiazine derivatives studied. It can therefore be discussed if not only the side effects but also the clinical effect may be explained partly by the disruption of the mast cells.

Formic Acid Oxidation in *Aspergillus niger*

J. G. Hauge

Institute for Nutrition Research, University of Oslo, Norway

Preformed mycelial pads of *Aspergillus niger* discharge large amounts of oxalate when incubated with sodium formate. Based on this finding Bernhauer postulated a C_1—C_1 condensation to take place in the organism [1]. As noticed by Butkewitsch, oxalate is, however, also produced when the mycelium is incubated on a buffer in the absence of organic carbon [2].

These findings were confirmed in the present investigation. When ^{14}C-labelled formate was employed, a small but significant incorporation into oxalate was observed. This incorporation may well have passed through carbonate as an intermediate, since labelled carbonate was converted to oxalate to the same extent as formate.

Carbonate is readily formed from formate by the organism or extracts thereof, provided the organism has been exposed to formate during growth. The inducible and soluble enzyme catalyzing this reaction has been partly purified and some of its properties studied. It carries out the oxidative decarboxylation of formate with oxygen as the only effective electron acceptor and H_2O_2 as the reaction product together with CO_2. No dialyzable cofactors participate in the reaction. The enzyme has a pH optimum of 6.2 and a Michaelis constant of 0.013 M.

Bile Acids in Newborn and Adult Humans

Jan-Carl Encrantz and Jan Sjövall

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Using quantitative paper chromatography [1] taurocholic (TC), taurochenodeoxycholic + taurodeoxycholic (TCD+TD), glycocholic (GC), glycochenodeoxycholic (GCD) and glycodeoxycholic (GD) acids have been determined in human bile and intestinal contents. In 34 analyses of the bile acids in the duodenal contents of 21 newborn babies (1—7 days old) the total bile acid concentration expressed as free bile acids varied between 84 and 1 182 mg/100 ml. Only conjugated bile acids could be found. With the method used free bile acids should have been detected when present as 2—3 % of the total amount of bile acids. The ratio of glycine conjugated acids to taurine conjugated acids (G/T) rose with age. Thus in children between one and four days old a mean value of 0.45 was found whereas the ratio 0.93 was obtained in children 5—7 days of age. No TD or GD could be found but an unidentified spot moving slightly faster than GD was in some cases observed on the paper chromatograms. There was approximately 2.5 times more cholic acid than chenodeoxycholic acid. When the children had reached an age of about eight months the bile acids were again analyzed in some subjects. The G/T ratio had risen to about 2 and deoxycholic acid could still not be found.

The proportions between the various bile acids in the duodenal contents of 19 medical students has been determined. No free bile acids could be detected. The mean G/T ratio was 3.1 and the proportions between cholic, chenodeoxycholic and deoxycholic acids were 1.2:1:0.6. When several analyses were made on the same subject at different times variations were noted in the G/T ratio as well as in the proportions between the different bile acids. Some factors influencing the G/T ratio will be discussed.

Cholic acid was by far dominating in human fistula bile. It was noteworthy that deoxycholic acid was usually absent. This resembles the bile acid composition of the newborn babies. In the normal adult, however, the relative amount of cholic acid is diminished and deoxycholic acid is now present. This suggested that deoxycholic acid is formed by bacterial action on cholic acid during the entero-hepatic circulation. At the same time Lindstedt in his work on the turnover of cholic acid in man observed that radioactive cholic acid gave rise to a labelled dihydroxycholanic acid which was identified as deoxycholic acid [2].

The Influence of Whole Body X-Irradiation of the Biosynthesis of Cholesterol in Liver

H. K. Hanel, G. Hjort, G. Johansen and P. R. Purser

Radium Centre Copenhagen, Radiobiological Laboratory, Copenhagen, Denmark

Earlier work [1] has shown disturbances in hepatic synthesis of cholesterol in rats after 2 400 r whole body X-irradiation. We have preferred to study the effects of 400 r whole-body irradiation, considering that this would throw more light on the biochemical changes in "radiation sickness" and induce negligible histological changes. Three series of experiments are reported here.

In the first series we studied the *in vivo* incorporation of 2-^{14}C acetate injected intraperitoneally, in liver cholesterol in mice, and the disturbances caused by whole body X-irradiation. We found a decrease in synthesis immediately after X-irradiation, probably a response to the X-irradiation, and a subsequent rise, probably a response to the liver cholesterol concentration.

In the next series we studied in vitro synthesis by incubation of rat liver slices with 2-^{14}C acetate after whole body X-irradiation. Here we found an immediate rise in the rate of synthesis as a response to the X-irradiation. Subsequent changes in the rate of synthesis could be attributed to the effect of the liver cholesterol concentration. The changes in carbon dioxide metabolism were studied simultaneously.

The third series was carried out *in vivo* with mice. We studied the effects of synkavit (naphthohydroquinone) injected intraperitoneally alone and followed by irradiation. The amount of synkavit we used, 2 mg, gave an effect, similar to but greater than that produ-

ced by radiation alone. The conbined treatment gave an immediate depression in synthesis rate though smaller than that produced by radiation or synkavit alone; this was followed by an increase above normal, which was not produced by either treatment alone.

The Formation of Bile Acids from Cholesterol in the Rabbit

Sven Lindstedt

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Cholesterol-4-^{14}C has been administered intravenously into rabbits with a bile fistula. More than 90 % of the activity in the bile acids was present as cholic acid, which normally constitutes only about 10 % of the total bile acids in the rabbit. The origin of deoxycholic acid — the main bile acid in intact animals — will be discussed.

Thiamine in Baker's Yeast

Olof Forsander and Heikki Suomalainen

Research Laboratories of the State Alcohol Monopoly, Helsinki, Finland

During the anaerobic growth of the common industrial yeasts, thiamine added to the medium is taken up by the cells and mainly esterified to cocarboxylase. During the aerobic cultivation of brewer's yeast and of *Torulopsis utilis*, however, the whole amount of thiamine lost from the medium has not been traced in the yeast cells by the thiochrome method [1].

A balance experiment on the uptake of thiamine by baker's yeast was performed on an industrial scale. The cultivation was performed in the usual way for the production of commercial baker's yeast under strongly aerobic conditions. Thiamine was added to two out of three batches. After cultivation, the thiamine content of the yeast cells was determined by the thiochrome method. Table 1 shows the result of the experiment.

The loss may depend on a transformation of thiamine into some compound which cannot be determined by the thiochrome method. It is known that as pyrophosphate ester thiamine has different functions under aerobic and under anaerobic conditions but it is assumed that it acts aerobic in some other form too. Myrbäck [2] suggested that thiamine or cocarboxylase may be transformed into a disulfide form.

In order to study the question baker's yeast was cultivated under aerobic conditions on a laboratory scale with the addition of ^{35}S-labelled thiamine. After the cultivation, thiamine compounds were extracted from the yeast with TCA at pH 1—2. The extract was examined by paper chromatography [3]. No thiamine disulfide compounds could be found in this extract. The only labelled compounds found in this extract were cocarboxylase and free thiamine.

30 g thiamine added	3.7	29.2	54.3

Bile Acids in Newborn and Adult Humans

Jan-Carl Encrantz and Jan Sjövall

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Using quantitative paper chromatography [1] taurocholic (TC), taurochenodeoxycholic + taurodeoxycholic (TCD+TD), glycocholic (GC), glycochenodeoxycholic (GCD) and glycodeoxycholic (GD) acids have been determined in human bile and intestinal contents. In 34 analyses of the bile acids in the duodenal contents of 21 newborn babies (1—7 days old) the total bile acid concentration expressed as free bile acids varied between 84 and 1 182 mg/100 ml. Only conjugated bile acids could be found. With the method used free bile acids should have been detected when present as 2—3 % of the total amount of bile acids. The ratio of glycine conjugated acids to taurine conjugated acids (G/T) rose with age. Thus in children between one and four days old a mean value of 0.45 was found whereas the ratio 0.93 was obtained in children 5—7 days of age. No TD or GD could be found but an unidentified spot moving slightly faster than GD was in some cases observed on the paper chromatograms. There was approximately 2.5 times more cholic acid than chenodeoxycholic acid. When the children had reached an age of about eight months the bile acids were again analyzed in some subjects. The G/T ratio had risen to about 2 and deoxycholic acid could still not be found.

The proportions between the various bile acids in the duodenal contents of 19 medical students has been determined. No free bile acids could be detected. The mean G/T ratio was 3.1 and the proportions between cholic, chenodeoxycholic and deoxycholic acids were 1.2:1:0.6. When several analyses were made on the same subject at different times variations were noted in the G/T ratio as well as in the proportions between the different bile acids. Some factors influencing the G/T ratio will be discussed.

Cholic acid was by far dominating in human fistula bile. It was noteworthy that deoxycholic acid was usually absent. This resembles the bile acid composition of the newborn babies. In the normal adult, however, the relative amount of cholic acid is diminished and deoxycholic acid is now present. This suggested that deoxycholic acid is formed by bacterial action on cholic acid during the entero-hepatic circulation. At the same time Lindstedt in his work on the turnover of cholic acid in man observed that radioactive cholic acid gave rise to a labelled dihydroxycholanic acid which was identified as deoxycholic acid [2].

The Influence of Whole Body X-Irradiation of the Biosynthesis of Cholesterol in Liver

H. K. Hanel, G. Hjort, G. Johansen and P. R. Purser

Radium Centre Copenhagen, Radiobiological Laboratory, Copenhagen, Denmark

Earlier work [1] has shown disturbances in hepatic synthesis of cholesterol in rats after 2 400 r whole body X-irradiation. We have preferred to study the effects of 400 r whole-body irradiation, considering that this would throw more light on the biochemical changes in "radiation sickness" and induce negligible histological changes. Adaptation of *E. coli* to 2-Deoxy-D-ribose

J. Jonsen and S. Laland

Biochemistry Department, The University, Blindern, Oslo, Norway

The degradation of the sugar component of deoxyribonucleosides has been demonstrated with whole cells and extracts of *E. coli* [1,2] but little is known concerning the bacterial utilization of the free pentose.

The present paper describes preliminary studies on the adaptation of *E. coli* to utilize 2-deoxy-D-ribose.

Standard techniques, *i. e.* incubation of the microorganisms on solid media in the presence of 0.25 % of specific substrate, was not practical because of a limited supply of 2-deoxy-D-ribose. A technique was therefore worked out in which a fairly large yield of adapted cells (1 g dry weight) was obtained in a fluid medium containing 20 mg of 2-deoxy-D-ribose. To obtain a similar yield of adapted cells on solid medium, 2.5 g of 2-deoxy-D-ribose was needed. The adaptation was made as follows: A loop inoculum from a slope was seeded into 5 ml of broth containing 1 % glucose. After 4 h growth at 37 °C, 0.2 ml of the culture was evenly distributed on each of 50 agar plates containing 1 % glucose. After 12 h at 37 °C the bacterial growth was scraped off the agar. The bacteria were suspended in ice-cold 0.05 M tris-HCl buffer (pH 7.4), filtered through gauze, centrifuged down at 0° and washed five times with cold buffer. The washed sediment was then suspended in 200 ml of fluid medium containing 2-deoxy-D-ribose (0.01 %), tryptic digested peptone (1 %), and sodium chloride (0.5 %). The mixture was stirred slowly in a 500 ml beaker at 37 °C. The degradation of 2-deoxy-D-ribose was followed by the disappearance of the Dische diphenylamine colour on aliquots withdrawn after different times of incubation. When about 90 % of the sugar was degraded, the bacteria were rapidly centrifuged down at 0° and washed repeatedly with cold 0.9 % saline. The degradation of 2-deoxy-D-ribose by cells adapted in this manner is shown in Table 1. A comparison is made with cells adapted on solid medium and non adapted cells.

Adapted cells could be lyophilized or stored at 4 °C without appreciable loss of activity. In the presence of glucose no adaptation occurred. By subcultivation of adapted cells in media containing no 2-deoxy-D-ribose, the adaptive ability was lost in one generation.

With cell free extracts, no significant degradation has been obtained in the presence of ATP and Mg++, neither could the formation of deoxyribose-5-phosphate be demonstrated. Under similar conditions the same strain of *E. coli* readily gave cell free extracts which metabolized D-ribose when adapted to this pentose. Under certain conditions [3] 44 % of the available D-ribose was isolated as D-ribose-5-phosphate. The formation of ribose-5-phosphate is the first step in the degradation of this sugar [3] by *E. coli*, and a similar pathway was anticipated for 2-deoxy-D-ribose. The

failure to prepare a deoxyribokinase extract, compared to the ease with which a ribokinase could be prepared from *E. coli* make us believe that the degradation of 2-deoxy-D-ribose does not start with the formation of 2-deoxy-D-ribose-5-phosphate. It is also possible that the difference is due to extreme lability of the enzymes attaching 2-deoxy-D-ribose.

The Effect of Estradiol Pretreatment on Hexokinase Activity of Rat Uterine Muscle *

O. Walaas and R. Lange

Institute of Medical Biochemistry and Physiology, Department of Biochemistry, University of Oslo, Norway

Previous investigations in this laboratory have shown that administration of estradiol monobenzoate to rats increases glycogen content of uterine muscle and stimulates glucose uptake of the surviving uterine muscle. These findings indicated a study of whether hexokinase activity is increased after pretreatment with estradiol.

Hexokinase activity of extracts from uterine muscle of rats has been determined 48 h after subcutaneous injection of 50 μg estradiol monobenzoate in previously ovariectomized animals. 10 % homogenate of uterine muscle was prepared in 0.03 M tris(hydroxymethyl)-aminomethane buffer, pH 8.2, which contained 0.0012 M EDTA (versene). After centrifugation at 4 000 × *g* for 20 min the supernatant was used for determination of hexokinase activity. Aliquots of the extract (usually 20 mg tissue equivalent) were incubated with 1.5 μM glucose, 4 μM ATP, 5 μM $MgCl_2$, 20 μM KF at 37 °C for 30 min. Incubation was made in 0.033 M tris buffer in a total volume of 1.0 ml. Hexokinase activity was determined by the glucose disappearence method.

Hexokinase activity increased in linear correlation with time during incubation up to 30 min and was proportional with the amounts of extract added. After pretreatment with estradiol monobenzoate hexokinase activity was increased by 100 % above the control values in ovariectomized rats. This was a relatively specific effect as the "specific activity" (μmole glucose phosphorylated per mg protein in 30 min) was increased by 75 %.

Experiments were performed to decide if the increased hexokinase activity was due to activation of pre-existing enzyme or to stimulation of enzyme synthesis by pretreatment with estradiol. Therefore several properties of hexokinase activity of uterine muscle in controls and after administration of estradiol were studied. These experiments included the effect of pH, the affinity to ATP, protection by EDTA, inhibition by glucose-6-phosphate, inhibition by *p*-chloromercuribenzoate. No indication was obtained that these properties were changed after pretreatment with estradiol. The results indicate that administration of estradiol monobenzoate increases hexokinase activity of uterine muscle by stimulation of enzyme synthesis.

ACTA CHEMICA SCANDINAVICA 11 (1957) 1097--1102

On the Possible Existence of Tetrahedral Nickel(II) Complexes

R. W. ASMUSSEN and OLE BOSTRUP

The Chemical Laboratory B, Technical University of Denmark, Copenhagen, Denmark

The magnetic moments and the reflection spectra of a series of apparently tetrahedral Ni(II) complexes have been measured. Comparison with corresponding data for definitively octahedral complexes seems to show that most of the complexes investigated in reality are octahedral.

The magnetic susceptibilities of several Ni(II) complexes have been measured by one of us [1]. The calculated magnetic moments are in agreement with the Pauling theory for bond type and spatial arrangement of the ligands in the complexes. Representative compounds and experimental data are given in Table 1.

It should, however, be pointed out that the distinction between tetrahedral and octahedral configurations cannot be founded upon magnetic measurements and moments alone but should principally be based upon a knowledge of the chemical properties of the ligands, in particular their usual coordination capa-

city. This means, *e.g.*, that a complex as $Nitren(SCN)_2$ can either be considered as $[Nitren(SCN)_2]$ or as $[Nitren]\ (SCN)_2$, both structures are in agreement with the magnetic moment found.

Magnetic measurements on paramagnetic Ni(II) complexes show that the orbital magnetic moment contributes in higher or lesser degree to the total moment. The Penney-Schlapp approximation makes it probable that the orbital contribution will be smaller in octahedral complexes than in tetrahedral [2]. According to Table 1 we may consider some of these complexes, which hitherto have been formulated as tetrahedral, as octahedral.

Our study of the reflection spectra of some of the tabulated apparently tetrahedral complexes has shown that in all cases three bands approximately situated as the three bands in undoubtedly octahedral Ni(II) complexes and reasonable values for the parameters Δ and 15 B can be found. Table 2 gives a summary of our results. Some examples of the measured reflection spectra are given in Figs. 1—3.

An X-ray investigation carried out by Cox and Webster [3] showed that $Nitren(SCN)_2$ either has the tetrahedral structure $[Nitren]\ (SCN)_2$ or the *cis*-octahedral $[Nitren(SCN)_2]$. Our measurements of magnetism and reflection spectrum seem to indicate the latter possibility. If the compound $Nitren(SO_4)$, $7\ H_2O$ has octahedral structure (*cis*) then it is either an aquo or a sulphato complex. Since two of the seven water molecules in $Nitren(SO_4)$, $7\ H_2O$ are

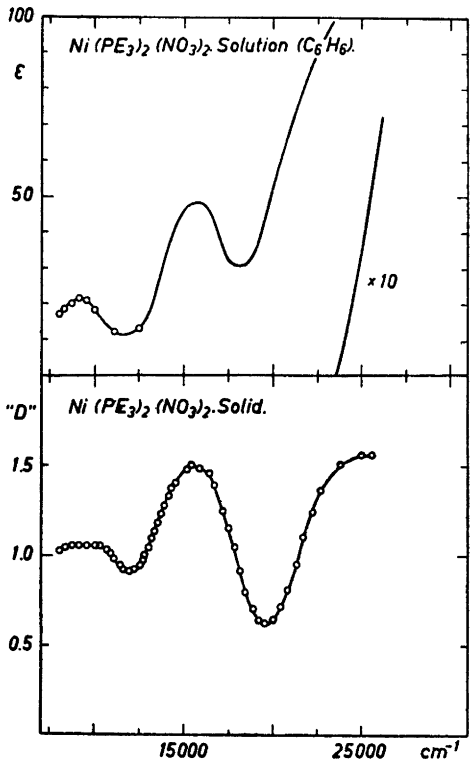

Fig. 4. Absorption spectrum and reflection spectrum of $[Ni(P(C_2H_5)_3)_2(NO_3)_2]$

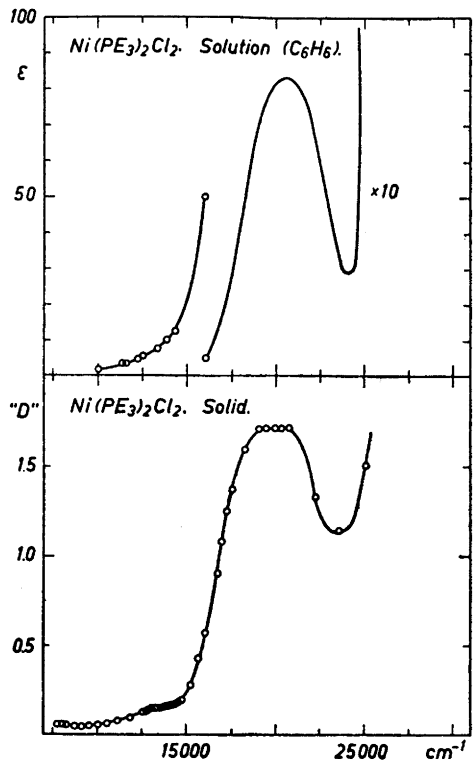

Fig. 5. Absorption spectrum and reflection spectrum of $[Ni(P(C_2H_5)_3)_2Cl_2]$

stronger bound than the others [4], and since the absorption bands are situated at the same places as in the aqueous solution of equivalent amounts of tren and $Ni(NO_3)_2$ investigated by Ballhausen and Klixbüll Jørgensen [5] it is reasonable to consider the heptahydrat as a *cis* diaquo complex. It is, however, difficult for the authors to imagine the anhydrous complex Nitren(SO_4) with octahedral configuration since as far as we know it has never been verified that SO_4^{-2} can act as a ligand with the coordination capacity 2. However, the experimental data indicate nothing unique with the properties of this compound.

Particular interest is connected with the paramagnetic green compound $Ni(P(C_2H_5)_3)_2(NO_3)_2$. The absorption spectrum in solution (benzene) and the reflection spectra are shown in Fig. 4. In Fig. 5 we give the spectra for the diamagnetic red chloro-compound [6]. The similarity between the spectra in Fig. 4 indicates that a monomer is also present in the crystal. The magnetic moment [6] is 3.10 μ_B which may be interpreted as corresponding with an octahedral structure. This assumption requires the ligand NO_3^- to be bidendate;

this seems to be rather unprobable although the isoster ion CO_3^{-2} can have the coordination capacity two, *e.g.* in $[Co(NH_3)_4(CO_3)]^{+1}$. Furthermore we do not observe 3 bands in the spectra and are forced to postulate that the band corresponding to $^3F(\Gamma_4)$ is masked of the high electron-transfer band in ultraviolet. The octahedral structure thus involves 2 unproven assumptions. However, it must be admitted that the 2 bands observed occur nearly at the wavenumbers required for an octahedral Ni(II)-complex. The possibility of the tetrahedral configuration cannot be ruled out, but we want in this connection to point out that the absorption curves for $Ni(P(C_2H_5)_3)_2(NO_3)_2$ and for $[Ni(OH_2)_6]^{+2}$ differ less than the corresponding curves for $[Co(OH_2)_6]^{+2}$ and $[CoCl_4]^{-2}$. The last ion has after all experimental evidences tetrahedral structure. The last possibility for the structure of $Ni(P(C_2H_5)_3)_2(NO_3)_2$ is the *cis*-planar configuration. As for the present we have no knowledge of how far it is possible that the action of this asymmetric field may result in such splittings that the configuration will allow for the observed magnetic moment, we are of the opinion that the lack of theoretical and experimental evidence makes it impossible to solve this problem with security. We consider an X-ray structure analysis to be more conclusive than the conclusions drawn from the spectra and magnetic moments alone.

EXPERIMENTAL

The solid samples were prepared according to the methods previously described [1,6]. The following abbreviations are used:

tren = β,β',β''-triaminotriethylamin
ptn = 1,2,3-triaminopropane
DH_2 = dimethylglyoxime

The magnetic measurements were carried out by means of the Guoy method described in earlier papers [9].

The reflection spectra were measured by means of a Beckman DU spectrophotometer equipped with a photomultiplier. In order to estimate the accuracy of the apparatus we measured the reflection spectrum of $NiSO_4$, $7H_2O$ and compared it with the known absorption curves for $[Ni(OH_2)_6]^{+2}$-solutions. These results will be published elsewhere [7] but it is worth while to note that all the bands known from solutions [8] were found in the reflection spectrum.

Acknowledgement. Our thanks are due to Professor, Dr. F. G. Mann, Cambridge, who kindly supplied us with a collection of trencomplexes, and to Mr. S. E. Rasmussen, who kindly supplied us with a sample of Nitren(SCN)$_2$. One of the authors (R.W.A.) thanks "*Statens teknisk-videnskabelige Forskningsraad*" for a grant which made it possible to procure the Beckman DU spectrophotometer and photomultiplier.

Electrophoresis of Proteins in the Presence of Interacting Ions *

KURT SCHILLING

Biological Institute of the Carlsberg Foundation, Copenhagen, Denmark

The interaction of human, bovine and equine serum proteins with various protein precipitating ions was investigated by means of moving boundary electrophoresis. As these reactions are reversible, the total buffer used for the electrophoresis contained the interacting ion in the equilibrium concentration.

A detailed study of the interaction of cadmium ions with bovine serum albumin showed that at low concentrations the mass action law was obeyed with a binding constant in agreement with that found by earlier authors to apply for attachment to the histidine residues. At higher concentrations further binding, presumably to carboxyl groups, could be demonstrated.

Certain correlations were found between degree of interaction and precipitating power of the various ions.

Human, bovine, and equine serum albumin could be resolved in two separate peaks in the positive branch, when electrophoresis was performed in acetate buffer pH 6, $\Gamma/2 = 0.1$.

A change in the pattern of whole serum was observed by electrophoresis in the presence of various interacting ions.

Addition of interacting ions resulted in electrophoretic separations, which are not obtained in ordinary buffers.

It has previously been reported, that a number of anions and cations, such as tungstate, sulfosalicylate, cadmium, and lead can be used for the fractional precipitation of the serum proteins from various species [1, 2]. The interaction is reversible, and it was possible to remove the ions by dialysis, the regenerated proteins showing no signs of denaturation in subsequent electrophoresis. Marked differences were encountered between the behaviour of the various ions used, as well as between the proteins of different species.

Whether a protein is precipitated by addition of these ions under certain conditions will depend partly on the degree of interaction and partly on the solubility of the compounds formed. In order to investigate these factors, the

* A preliminary account of this work was presented at the Third International Congress of Biochemistry, Brussels 1955.

interaction was studied at pH-values, where a precipitation did not occur. As the combination with the ions is accompanied by a change in the net charge of the protein molecule, electrophoresis was considered an adequate approach to the problem. One important feature of this method is the possibility to investigate the interaction with the various components of a complex protein mixture. As the examined reactions are fully reversible, all electrophoreses were performed with the total buffer containing the interacting ion in the equilibrium concentration. The observed boundary velocities would then directly yield the constituent mobilities of the complexes.

MATERIALS AND METHODS

Human, bovine and equine serum were obtained from spontaneously coagulated blood. The samples were either used immediately or stored at −20°C.

Crude albumin fractions were prepared by precipitation with 55 % saturated ammonium sulfate and dialysis of the supernatant against distilled water followed by lyophilization. A bovine albumin of high purity prepared by lead and cresol precipitation [2] was used in some of the experiments.

Crude γ-globulin fractions were prepared by repeated precipitation with 38 % saturated ammonium sulfate. The precipitate was separated by centrifugation and used immediately or stored at −20°C.

The composition of the various buffers is recorded in Table 1. The samples were dissolved in the buffer and dialyzed against an excess until equilibrium had been established. Electrophoresis was then performed using the same buffer. A moving boundary Tiselius apparatus with Philpott-Svensson optical system was employed. The temperature of the bath was 1.5°C, and the duration of the experiments 2−3 h with a potential gradient of 5−8 V/cm.

RESULTS AND DISCUSSION

Effect of ion concentration. As a typical example Fig. 1 shows the influence of increasing cadmium concentration on the mobility of bovine serum albumin at pH 6.0. There is evidence of a strong interaction. The addition of cadmium

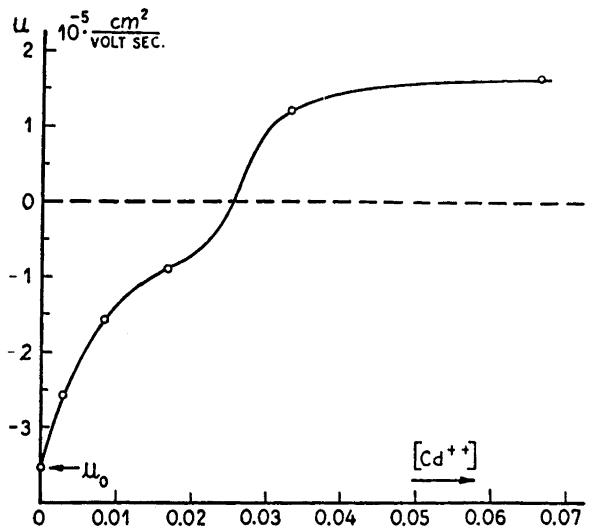

Fig. 1. Electrophoretic mobility of bovine serum albumin in acetate buffer pH 6.0 containing increasing amounts of cadmium ions. The composition of the buffers is recorded in Table 1. Nos. 11—16.

in low concentrations reduces the mobility markedly and higher concentrations even cause a reversal of the direction of migration. This shows that cadmium is still being bound after the protein compound has acquired a positive net charge.

It is possible to arrive at a quantitative interpretation of these results and to compare them with earlier investigations on the combination of cadmium ions with bovine serum albumin. From polarographic studies Tanford [3] concluded that cadmium as well as zink are bound chiefly to the histidine residues of the albumin. In the case of zink Gurd and Goodman [4] arrived at the same result by means of equilibrium dialysis.

If we thus assume that the cadmium-ions are bound by n equal sites, where they are competing with hydrogen ions, we get the following mass law equations

$$\frac{\nu}{(n-\nu-\nu_H)} = K \cdot [Cd^{++}]$$

$$\frac{\nu_H}{(n-\nu-\nu_H)} = K_H \cdot [H^+]$$

where ν denotes the number of sites occupied by cadmium, ν_H those occupied by hydrogen, and K and K_H the equilibrium constants including a possible electrostatic correction. The observed mobility change (Δu) in the electrophoresis experiment would be determined by

$$\Delta u = \frac{2\nu + \nu_H - \nu_{Ho}}{f}$$

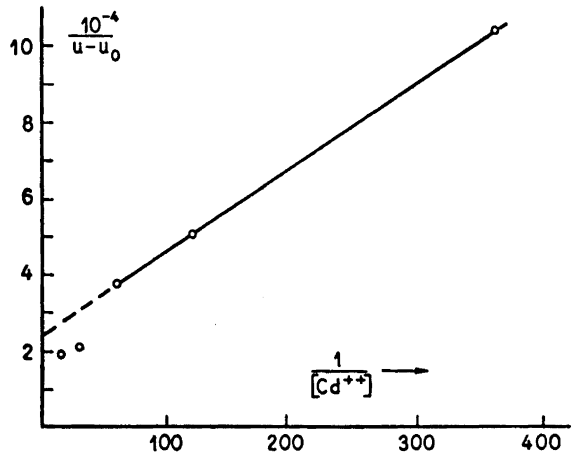

Fig. 2. Reciprocal mobility change by addition of cadmium ions to bovine serum albumin in acetate buffer plotted against reciprocal cadmium concentration.

where f denotes the number of charges corresponding to a mobility change of 1 unit, and ν_{Ho} the number of the n sites occupied by hydrogen at zero cadmium concentration. Combining these equations we get

$$\frac{1}{f \cdot \Delta u} = a \cdot \frac{1}{[Cd^{++}]} + b$$

with

$$a = \frac{(1+K_H \cdot [H^+])^2}{nK(2+K_H \cdot [H^+])}; \quad b = \frac{1+K_H \cdot [H^+]}{n(2+K_H \cdot [H^+])}$$

Plotting $1/\Delta u$ against $1/Cd^{++}$ we should expect a straight line, provided the electrostatic corrections contained in K and K_H do not change appreciably. Considering the great variation in the net charge of the protein over the experimental range this assumption appears rather questionable. However, as shown in Fig. 2, at low cadmium concentrations a straight line is obtained. Adopting the value $5.0 \cdot 10^5$ for f according to Longsworth and Jacobsen [5] and making n equal to 17 (the probable number of histidine residues in bovine albumin), the constants obtained for the working temperature of 1.5°C are log $K = 2.8$ and log $K_H = 6.7$, which is in satisfactory agreement with the intrinsic constants determined by Tanford [3].

Taking the electrostatic effect of the protein charge into account we should expect the experimental points at higher cadmium concentrations to lie above the straight line. The fact that they are situated below the line indicates, that at these concentrations further sites with lower affinity, presumably carboxyl groups, participate, resulting in binding of more cadmium ions. It should be pointed out that these concentrations greatly exceed those used by Tanford [3].

Table 2. Relative amounts of the two components obtained with various albumin samples in the positive (ascending) branch after electrophoresis in acetate buffer, pH 6.

Buffer (*cf.* Table 1)	Sample	Fast comp. %	Slow comp. %
11	Bovine serum albumin, crude	40	60
11	Bovine serum albumin, purified	43	57
10	Bovine serum albumin, crude	39	61
11	Human serum albumin, crude	50	50
10	Human serum albumin, crude	31	69
11	Equine serum albumin, crude	39	61

Heterogeneity of the serum albumin. Interestingly, all albumin preparations, which appeared quite homogeneous in phosphate buffer, showed a sharp separation into two peaks in the positive branch during electrophoresis in acetate buffer of pH 6.0 (Fig. 3). When the pH was decreased to 5.3, no separation was observed.

The total area of the two peaks was equal to that found in the negative branch and to that found in phosphate buffer. The relative amounts of the two components as determined by planimetry of the electrophoresis curves are recorded in Table 2.

When half of the acetate was substituted by chloride in the buffer the separation became less sharp. In the case of the human albumin a different

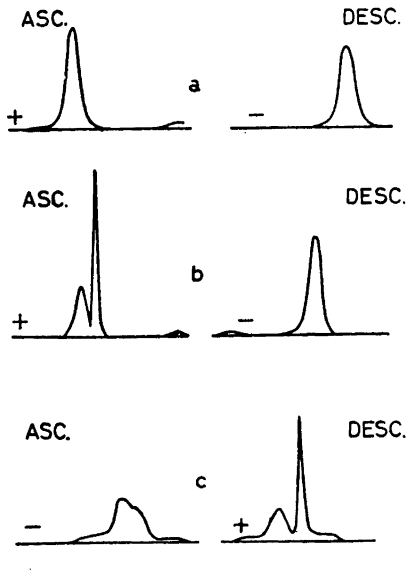

Fig. 3. Electrophoretic pattern of bovine serum albumin in (a) phosphate, (b) sodium acetate and (c) cadmium acetate buffer at pH 6.0, $\Gamma/2$ 0.1. Buffers Nos. 9, 11 and 15 (Table 1).

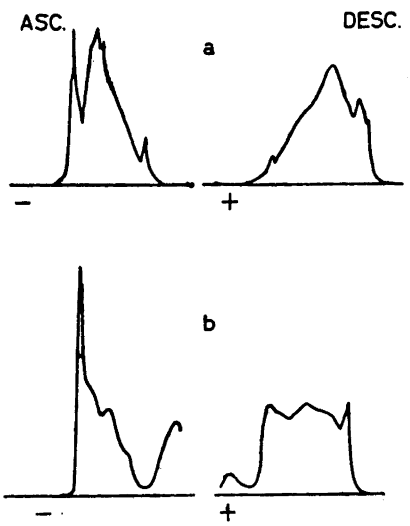

Fig. 4. Electrophoretic pattern of equine serum in (a) lead and (b) cadmium acetate at pH. 4.5, $\Gamma/2$ 0.1.

Table 3. Mobility of bovine serum albumin in various buffers. In the column denoted Δu the change in mobility is recorded relative to that found in buffers consisting of the sodium salt (cation interaction) or of phosphate or acetate (anion interaction). The values used for subtraction at pH 4.2, pH 4.5 and pH 7.2 have been interpolated.

Buffer (*cf.* Table 1)	Interacting ion	pH	u cm^2V^{-1} sec^{-1}	Δu
1	Ac	4.1	2.37	
2	Ag	4.2	5.60	3.63
3	Pb	4.2	6.76	4.79
4	Pb	4.5	5.41	4.63
5	Cd	4.5	2.33	1.55
6	Ac	5.3	−2.42	
7	Zn	5.3	0.51	2.93
8	Sulf.	5.3	−4.47	−2.05
17	Phosph.	7.1	−5.50	
18	Sulf.	7.2	−6.50	−0.85

value for the percentage of the two components was found, but on account of the poor separation of the peaks this change may not be real. On the other hand it might be explained by accepting a specific reversible ion interaction with a fraction of the albumin resulting in different mobility.

With bovine albumin exactly the same result was obtained, whether the albumin had been prepared solely by ammonium sulfate fractionation or by purification through precipitation with lead ions and cresol.

The shape of the electrophoresis curves indicates that the separation is due to a pronounced boundary sharpening effect with one albumin component. It was not obtained with whole serum and could be abolished by adding the globulin fraction. Addition of cadmium ions had no effect on the relative mobilities of the two components. Fig. 3 shows the electrophoretic diagrams of bovine serum albumin in sodium and in cadmium acetate buffer. In cadmium acetate the direction of migration is reversed, but the shape of the two peaks in the positive, now descending branch remains on the whole unaltered. They can, however, be distinguished in the negative branch and, in addition, minor components seem to separate.

It is well known that albumin is split up electrophoretically at pH 4, well below its isoelectric point. At other pH-values separations have been attained using long lasting experiments or buffers of extremely low ionic strength. A specific effect of acetate ions on the electrophoretic pattern at pH 4.7 was reported by Phelps and Cann [6]. In the present experiments other conditions are described, which lead to similar separation effects. The heterogeneity of bovine serum albumin is thus emphasized. Experiments by Christiansen *et al.*[7] indicate that molecules of different size may exist in solutions of bovine serum albumin. Investigations are in progress to show whether this could explain the present observations.

Correlation between ion interaction and precipitation behaviour. One purpose of the present work was to see if electrophoresis experiments of this kind may yield information, which can be used for fractionation by means of specific precipitations.

The interaction of bovine serum albumin with cadmium ions was described above. When compared with earlier fractionation experiments [2] it seems probable that precipitation produced by cadmium addition is mainly due to the ions bound to carboxyl groups, as at this pH an extensive binding as well as precipitation occurs only at high cadmium concentrations.

This assumption is confirmed by experiments with lead. At pH 4.5 where the metal ions will be attached chiefly to carboxyl groups, the change in mobility with 0.033 M lead acetate is thrice that noted with cadmium at the same concentration (Table 3). Correspondingly, lead ions added to bovine serum precipitate the albumin selectively at a pH about 5 in contrast to cadmium [2] which, in the same concentration range, precipitates the albumin only at pH-values above 7. Gurd and Murray [8] using purified human mercaptalbumin found intensive binding of lead ions to carboxyl groups and insolubility of the compounds formed, in close analogy to the present findings.

Various anions which previously [1] had proved suitable for serum protein fractionation were included in the investigation.

Sulfosalicylate showed a marked interaction with bovine serum albumin at pH 5.3, well above the isoelectric point (Table 3). At pH 7.0 the mobility still changed considerably when sulfosalicylate was partly substituted for phosphate in the buffer.

With bovine γ-globulin a notable interaction was observed with various ions. The isoelectric point of the preparation was found to be about pH 5.9, indicating that it contained mainly γ_1-globulin. The mobilities measured in phosphate and sulfosalicylate buffer at pH 7.2 were —1.69 and —2.66 $cm^2 V^{-1} sec^{-1}$, respectively. The change in mobility is thus of the same magnitude as that of albumin at the same pH (Table 3).

In tungstate buffer at pH 7.1 the mobility increased even to —3.37 $cm^2 V^{-1} sec^{-1}$ which is in accordance with the fact that γ-globulin is precipitated from bovine serum by tungstate [1] at relatively high pH.

The electrophoresis experiments reported have thus proved valuable for estimating the interaction with the various anions used for precipitation, and distinct correlations have been found. It is on the other hand evident that the mobility change due to addition of a certain ion is no strict criterion of the efficiency of this ion as a precipitating agent, as the solubility of the compound will also greatly depend on the binding sites and on other factors.

In this connection electrophoresis experiments performed in phosphate buffer pH 7.7 in the presence of phenol may be mentioned. Addition of phenols is known to influence profoundly the precipitation properties of the serum proteins [9, 10]. The experiments demonstrated that the mobilities of the proteins were unchanged by phenol addition. The change in their solubility is thus in the present case not associated with variation in the net charge.

Experiments with whole serum. In a number of experiments electrophoresis of whole sera was performed in the presence of interacting ions at different pH-values. The purpose was to see if better separations could be obtained, and if any qualitative differences from the usual electrophoretic diagrams could be observed. Addition of lead or cadmium at pH 4.5 caused striking changes in the electrophoretic pattern, corresponding to the different interaction with

the various components (Fig. 4). However, the exact interpretation of the electrophoresis diagrams awaits further experimental study.

Mehl and Golden [11] recommended electrophoresis of pathological sera at pH 4.5 as a valuable supplement to those generally performed at pH 8—9. The present results render it probable, that further informations may be gained by addition of suitable ions such as lead or cadmium.

Electrophoresis of bovine serum in the presence of tungstate at pH 7 gave a pattern rather similar to that achieved with phosphate buffer. Since tungstate interaction is strongest with the slower moving globulins, a more compressed picture was obtained, which made it desirable to prolong the analysis. On the other hand a considerable boundary sharpening was observed, which made the various fractions better discernible than in phosphate buffer.

Specific separation effects. It might have been expected, that mixtures of protein components of very similar mobilities would show greater variations when combined with added ions, resulting in better electrophoretic separation. The result with bovine albumin in cadmium buffer (Fig. 3) indicates, that this is indeed the case, and that the procedure can be used analytically. With human albumin in cadmium acetate buffer at the same pH a similar effect was obtained. Electrophoresis of bovine γ-globulin in the presence of sulfosalicylate made it possible to distinguish several subfractions, but the separation was poor. In this case the effect of the added sulfosalicylate may possibly be due to a suppression of the protein-protein interactions between the various γ-globulin components. A number of further experiments indicate that the best conditions for such separations will probably be found with low ionic strengths of strongly interacting ions.

The Stability of Metal Halide Complexes in Aqueous Solution

III. The Chloride, Bromide and Iodide Complexes of Bismuth

STEN AHRLAND and INGMAR GRENTHE

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The chloride, bromide and iodide complexes of Bi^{3+} have been studied in an acid perchlorate medium by means of emf and solubility measurements. The overall stability of these complex systems increases in the order mentioned; Bi^{3+} thus belongs to the central ions of the second group (*cf.* Ref.[1]). The first bromide complex is however a little weaker than the first chloride one. Thus Bi^{3+} also possesses certain properties of the first group central ions, as could perhaps be expected from its position in the outskirts of the second group area. The sixth complex is the one finally formed in all the systems measured; in the case of chloride and bromide the fifth complex has a remarkably wide range of existence.

With respect to the strength of their halide complexes, central ions may be divided into two groups. The first one shows decreasing stability of the complexes in the order $F^- \gg Cl^- > Br^- > I^-$, the second one in the opposite order $F^- < Cl^- < Br^- < I^-$. In part I of this series [1] it was pointed out that the ions of the second group were all situated within a roughly triangular area of the periodic system, centered around the noble metals. The primary aim of the present investigation has been to decide whether Bi^{3+} is also within this area, a question which was left open in the previous paper.

As Bi^{3+} is readily hydrolysed [2], the measurements have to be performed in acid solutions so that the halide complex formation is not mixed up with intricate hydrolytic reactions. In this work all solutions had $[H^+] = 1$ M, an acidity ensuring that no perceptible amounts of soluble hydroxo complexes exist at the bismuth concentrations used. Due to their very low solubility, the oxyhalides BiOCl and BiOBr are nevertheless precipitated even from solution of quite low $[Bi^{3+}]$. When further halide is added the precipitates however dissolve again owing to the strong decrease of $[Bi^{3+}]$ caused by the increasing complex formation. In the case of the iodide, the neutral third complex

BiI_3 is precipitated, as being the least soluble solid phase in the medium used. This precipitate also dissolves with the formation of higher complexes when further amounts of ligand are added.

As to methods available for the investigation, emf measurements of the concentration of free central ion, $[Bi^{3+}]$, by means of a bismuth amalgam electrode seemed most convenient (*cf.* Ref.[2]). According to the experience gained here this method worked well if the total bismuth concentration, C_M, was $\gtrsim 0.5$ mM. Where the halide concentration, C_A, of the solutions allowed such values of C_M, the complex formation could therefore be followed by emf measurements. This turned out to be the case for the greatest part of the complex formation of the chloride and bromide systems, where only the first constant could not be determined. In the case of the iodide, on the other hand, only the constant of the final (*i. e.* the sixth) complex could be obtained in this way.

The investigation could, however, be extended to lower ligand concentrations by means of solubility determinations (*cf.*, *e. g.*, Leden [3,4]). With the method employed here, solutions of a C_M (= the solubility l) as low as ≈ 0.02 mM could be analysed. For the calculation of the stability constants, the solubility products of the solid phases BiOCl, BiOBr and BiI_3 were also needed. The determination of these quantities sometimes required the measurement of $[Bi^{3+}]$ in solutions of $C_M \approx 0.2$ or even 0.1 mM. This was often successfully accomplished especially if C_A was not too low, but great care had to be exercised in these measurements and evidently this range of C_M is not very suitable for emf measurements.

Good values of the first constant of the chloride and bromide system could be determined by these solubility measurements, which also confirmed some of the constants previously determined potentiometrically. For the iodide system values of the last three constants could be obtained. The two methods employed thus complement each other rather satisfactorily.

All values of constants found refer to the acid perchlorate medium used which had a total ionic strength $I = 2$ M. As usual, sodium perchlorate was used as supplementary neutral salt. The temperature has been kept at 20°C.

CALCULATION OF COMPLEXITY CONSTANTS FROM MEASUREMENTS OF $[Bi^{3+}]$ (=[M]) WITH THE BISMUTH AMALGAM ELECTRODE

Experimentally, the emf E of cells of the following type were measured

$$+ \text{RE} \;\Big|\; \begin{matrix} C_M \text{ mM Bi(III)} \\ C_A \text{ mM ligand} \\ [H^+] = 1 \text{ M};\ I = 2 \text{ M} \end{matrix} \;\Big|\; \text{Bi-Hg} \; -$$

where RE is a quinhydrone reference electrode. This emf can be written as

$$E = E_{RE} + E_d - E^\circ - \frac{RT}{3F} \ln f_M \cdot [M] \qquad (1)$$

In this expression E_{RE} and E° are of course independent of variations of C_M and C_A and the same will be very nearly true for the liquid junction potential

E_d and the activity factor f_M in the approximately constant medium used. Hence (1) can be written

$$E = E_k - \frac{RT}{3F} \ln [M] \tag{2}$$

where E_k is a constant. If the emf of the special case of $C_A = 0$, $[M] = C_M$ is denoted E' we obtain:

$$E - E' = E_M = \frac{RT}{3F} \ln \frac{C_M}{[M]} \tag{3}$$

From the quantity $C_M/[M]$ thus found, the stability constants β were calculated by Leden's [5,6] method as developed by Fronæus [7] (*cf.* also Ref.[8]):

If only mononuclear complexes MA_n are formed then

$$C_M / [M] = 1 + \sum_{n=1}^{N} \beta_n [A]^n = X([A]) \tag{4}$$

The value of [A] for a certain value of X thus found is obtained by a method of extrapolation. E_M is determined as a function of C_A in solutions containing different C_M. From the resulting family of curves values of C_A are read off for a number of values of E_M. Every value of E_M then corresponds to a certain constant value of [A], as seen from (3) and (4), andt herefore also to a constant ligand number $\bar{n}$ (*cf.* Ref. [5-8]). Thus if corresponding values of C_A and C_M are plotted for a certain E_M a straight line $C_A = \bar{n} \cdot C_M + [A]$ will result, with the intercept on the C_A-axis = [A] and the slope = $\bar{n}$. When corresponding values of X and [A] have thus been found, the constants β are calculated from (4). Different methods of calculation have however to be used for the chloride and bromide on the one hand and the iodide system on the other.

For the chloride and bromide systems where, at the pH used in this investigation, most of the complex formation can be covered by the emf measurements, the constants are calculated in the usual way [9], by extrapolation of functions X_n. Thereby β_1 is obtained first and then successively the following constants up to β_N.

In the case of the iodide system on the other hand emf measurements can be performed only for the very last part of the complex formation due to the low solubility of the neutral complex MA_3. In the whole measurable range, MA_N is the dominating species. Its constant is conveniently calculated by forming a new function

$$X'_N = \frac{X}{[A]^N} = \beta_N + \beta_{N-1} \cdot [A]^{-1} + \sum_{n=2}^{N-1} \beta_{N-n} [A]^{-n} + [A]^{-N} \tag{5}$$

When X'_N is plotted against $1 / [A]$, β_N will be found as the intercept of the X'_N -axis, and β_{N-1} as the slope of the curve at the point of intersection * (*cf.*[6] p. 16).

* In the present case only β_N can be calculated, owing to the predominance of the highest complex in the range measured. In principle however further constants may be calculated by successively forming new functions X', in the first instance

$$X'_{N-1} = (X'_N - \beta_N) \cdot [A] = \beta_{N-1} + \beta_{N-2}[A]^{-1} + \sum_{n=3}^{N-1} \beta_{N-n} \cdot [A]^{1-n} + [A]^{1-N}$$

If the complex formation is not entirely mononuclear, (4) no longer holds, C_M / [M] being a function of both [A] and [M]. By extrapolating the C_M, C_A-lines of constant E_M to $C_M = 0$ (implying [M] = 0), corresponding values of [A] and X will nevertheless be found and hence correct values of β calculated, as shown by Fronæus (Ref.[7], p. 20). The slope of these lines will however not be $= \bar{n}$ in this case but a quantity $< \bar{n}$. By comparing the genuine complex formation function $\bar{n} = f([A])$, calculated from the found values of β with the values obtained from the C_A, C_M slopes, the existence of polynuclear complexes can thus be revealed.

CALCULATION OF COMPLEXITY CONSTANTS FROM MEASUREMENTS OF THE SOLUBILITY OF Bi(III) IN HALIDE SOLUTIONS

If only mononuclear complexes are assumed to exist in solutions of Bi(III), the solubility l can written as

$$l = [M]\left(1 + \sum_{n=1}^{N} \beta_n [A]^n\right) = [M] \cdot X \tag{6}$$

bearing in mind that soluble hydroxo complexes certainly do not exist in the medium used [2]. Now in the cases of chloride and bromide the formula of the solid phase is MOA which we may consider as formed according to the reaction $M + 2\ OH^- + A \rightleftharpoons MOA + H_2O$. Thus

$$[M][OH^-]^2[A] = L = [M][A] \cdot \frac{K_w^2}{[H^+]^2} \tag{7}$$

As $[H^+]$ is kept constant throughout the measurements a new constant L' may be introduced:

$$[M][A] = \frac{L}{K_w^2} \cdot [H^+]^2 = L' \tag{8}$$

Combining (6) and (8) we arrive at

$$l - \frac{L'}{[A]} = L'\left(\beta_1 + \sum_{n=2}^{N} \beta_n [A]^{n-1}\right) = L' \cdot X_1 \tag{9}$$

The value of [A] corresponding to a certain value of l is given by

$$[A] = C_A - (C'_M - l) - \bar{n} \cdot l \tag{10}$$

where C'_M is the stoicheiometric concentration of Bi(III) added, most of it $(= C'_M - l)$ being precipitated. In all the solubility measurements, l is fairly low and $\bar{n} \cdot l$ only a correction term. Therefore a sufficiently good value of $\bar{n}$ is obtained by taking from the complex formation curve of the emf measurements the value corresponding to $[A] = C_A - (C'_M - l)$. Using this value of $\bar{n}$, a value of [A] is calculated from (10). This value of [A] gives in turn a better value of $\bar{n}$ which however when inserted in (10) does not appreciably change the value of [A] already obtained.

Provided only that L' can be found, $L' \cdot X_1$ is therefore known as a function of [A]. From this function the constants β can be calculated in the same way

as from the simple X-functions, *cf.* p. 000. The function $L'\cdot X_1$ has an intercept on the ordinate axis $= L'\cdot\beta_1$. The next constant β_2 is conveniently found by forming the function

$$\frac{L'X_1 - L'\beta_1}{[\mathrm{A}]} = L'\Big(\beta_2 + \sum_{n=3}^{N} \beta_n[\mathrm{A}]^{n-2}\Big) = L'\cdot X_2 \qquad (11)$$

whose extrapolation to $[\mathrm{A}] = 0$ gives $L'\cdot\beta_2$. Analogously further constants may be found.

For the determination of $L' = [\mathrm{M}]\,[\mathrm{A}]$, [M] of saturated solutions of known [A] has to be measured. This is done by measuring emf of cells of the type written on p. 1112. From the values of L' thus determined it is further possible to calculate the solubility product L of the oxyhalides if K_w of the solvent medium is measured.

In the case of the iodide system where MA_3 is present as solid phase,

$$L = [\mathrm{M}][\mathrm{A}]^3 \qquad (12)$$

which combined with (6) gives

$$l\,[\mathrm{A}]^3 = L\Big(1 + \sum_{n=1}^{N} \beta_n[\mathrm{A}]^n\Big) = L\cdot X \qquad (13)$$

When calculating the value of [A] belonging to a certain value of l, correction must be applied for that part of the iodide which has been oxidized during the time of equilibration. Even at the lowest values of [A] used here, the iodine formed will appear mainly [10] as I_3^-. If it is assumed that this species does not form complexes with Bi^{3+}, [A] is then given by the formula

$$[\mathrm{A}] = C_A - 3(C_M' - l) - \bar{n}\cdot l - 3[\mathrm{I}_3^-] \qquad (14)$$

Here $[I_3^-]$ is determined by analysis of a sample of the saturated solution. As to $\bar{n}$, a sufficiently correct value (*viz.* $\bar{n} = 6$) is known only in the range of [A] covered by the emf measurements where the highest complex MA_N ($= MA_6$) is practically the only one existing. At lower [A], $\bar{n} = 3$ has been used as a first approximation. This value certainly represents a lower limit of $\bar{n}$ in the range of [A] used, as shown by the following evidence. At the value of [A] where $\bar{n} = 3$ is correct, the concentration of the complex MA_3 relative to the other complexes will be at a maximum [7, p. 30]. The concentration of MA_3 in the solution is however constant, because of its presence as a solid phase. The total solubility, l, will therefore show a minimum when $\bar{n} = 3$. As seen from Fig. 1, the iodide solubility curve is in fact flattening out very much at the lowest [A] measured, but it does not reach its minimum. So $\bar{n}$ must be >3 along the whole curve.

As it can be foreseen that the upper complexes are also the dominating ones in the range covered by the solubility measurements, the constants are calculated downwards in much the same manner as that used for the potentiometric measurements. From (13) the following function is formed

$$l\,/\,[\mathrm{A}]^{N-3} = L\left(\beta_N + \sum_{n=1}^{N-1} \beta_{N-n}[\mathrm{A}]^{-n} + [\mathrm{A}]^{-N}\right) = L\cdot X_N' \qquad (15)$$

When $1 / [A] \rightarrow 0$, $l / [A]^{N-3} \rightarrow L \cdot \beta_N$. Then the following function is formed:

$$(l/[A]^{N-3} - L \cdot \beta_N) \cdot [A] = L\left(\beta_{N-1} + \sum_{n=2}^{N-1} \beta_{N-n}[A]^{1-n} + [A]^{1-N}\right) = L \cdot X'_{N-1} \quad (16)$$

which gives $L \cdot \beta_{N-1}$ when $1 / [A] \rightarrow 0$. Further constants $L \cdot \beta_n$ are calculated analogously, and as L can be determined in the same way as L' of the chloride and bromide systems, all the constants β can be found. From these constants a complex formation curve is calculated allowing us to insert approximately correct values of $\bar{n}$ in (14). Better values of [A] are thus obtained giving a better set of constants β. In fact this second approximation gives the final values of β of the present system as the correction term $\bar{n} \cdot l$ of (14) is fairly small.

EXPERIMENTAL

Chemicals: All chemicals were, if not otherwise stated, of analytical grade and used without further purification.

Liquid *bismuth amalgam*, containing ≈1 % bismuth, was prepared [2] by dissolving Bi in Hg under water at about 90 °C. To prevent formation of oxide films it was stored under dilute perchloric acid. Before use it was washed with boiled water. During the measurements, no changes of emf due to changes of the bismuth activity in the amalgam could be detected, therefore no perceptible oxidation of the amalgam seems to occur.

Bismuth perchlorate solution was prepared by dissolving Bi_2O_3 in an approximately 50 % excess of ≈ 6 M $HClO_4$. By diluting this solution, a stock solution for the measurements was prepared and analysed for C_M and free acid.

The determination of C_M was carried out by precipitating and weighing BiOI, in the main according to the procedure described by Vogel [11]. Due to the slight solubility of $KClO_4$, NaI had to be used instead of KI as a precipitant. It was necessary to adjust pH to about 4.5 with sodium acetate to ensure that all the originally precipitated brown-black BiI_3 and all the yellow iodide complexes of the solution were converted into purple BiOI. The final value of the pH was checked by spots tests, as the addition of an indicator would have masked the decolourization which accompanies complete hydrolysis of the bismuth solution. The stock solution had C_M = 0.496 M.

The concentration of free acid in this solution was determined by alkalimetric titration after the removal of the bismuth by means of cation exchange, *cf.* Ref.[12]. A value of $[H^+]$ = 0.92 M was found, in good agreement with the value of $[H^+]$ = 0.93 M which was calculated from the amount of acid used in the preparation.

Two preparations of *sodium perchlorate* was used. The first one (from G. Frederick Smith) was recrystallized twice. The second one was made by neutralization of perchloric acid. The main part of the acid was neutralized by sodium carbonate, the carbon dioxide boiled off, and the last trace of acid finally neutralized with sodium hydroxide. Both the preparations contained <0.01 % of Cl^- and ClO_3^-. A 2 M stock solutions was prepared by weighing the dried salt.

Stock solutions, close to 2 M, were also prepared of *perchloric, hydrochloric* and *hydrobromic acids*, as well as of *sodium chloride, bromide and iodide*, and their exact concentrations determined by analysis.

The potentiometric measurements: Two different reference electrodes were used, *viz.*:

Au	0.01 M $HClO_4$ 1.99 M $NaClO_4$ quinhydrone(s).	2 M $NaClO_4$	and	Au	1 M $HClO_4$ 1 M $NaClO_4$ quinhydrone(s).	1 M $HClO_4$ 1 M $NaClO_4$

denoted RE (0.01) and RE(1), respectively. RE (0.01) was used in the earlier measurements, RE(1) in the later ones. The change of RE(0.01) for RE(1) ought to improve the constancy of E_d of (1). Moreover the risk of diffusion or flow between the cell compartments should be much less.

Table 1. The validity of Nernst's law for the bismuth amalgam electrode in 2 M perchlorate medium. — Series I: $[H^+]_0$ = 9.99 mM; 2 M $NaClO_4$ in the junction between the half-cells. Series II: $[H^+]$ = 1 M throughout the whole cell.

33.2			425.5	396.8
39.7	333.4	306.2		

First, the behaviour of the bismuth amalgam electrode in the medium used was investigated. In the amalgam half-cell, a known volume was placed of a solution containing 1 M $HClO_4$, and 1 M $NaClO_4$. Portions of bismuth perchlorate solution of the same $[H^+]$ and I were then added and the emfs of the resulting cells measured. As no complexing agent is present, these cells have $[M] = C_M$, and E_k can therefore be calculated according to (2). From Table 1 it is evident that E_k really is a constant. Thus a variation of C_M within the given limits does not cause appreciable changes of E_d or f_M. Nernst's law is obeyed in the form (2).

The main measurements were also carried out as titrations mostly in the following way. A solution, S, of known C_M but containing no ligand was prepared in the amalgam half-cell and the cell connected. Dissolved air was then expelled by bubbling nitrogen gas, free from oxygen, through the bismuth solution, the bubbling being continued through the whole titration in order to keep the solution free from air and thoroughly mixed. After E' had been read, a ligand solution T, of the same C_M, $[H^+]$ and I as the solution S, was added in portions. In the beginning a precipitate (BiOCl, BiOBr or BiI_3) was formed which however was dissolved by further addition of ligand solution. When a clear solution had thus been obtained, measurements of E could begin. Titrations were performed at four or five different values of C_M and they were continued to as high C_A as could conveniently be reached within the ionic strength used.

In order to extend the measurements to as low values of C_A as possible titrations were also performed in the opposite direction, with decreasing C_A. Portions of S were then added to a solution S′ in the electrode vessel, S′ containing a ligand concentration high enough to secure a clear solution. In this way values of E could be determined even in solutions somewhat supersaturated with respect to the slightly soluble halide. When at last precipitation really occurred, this was at once indicated by a rapid drift in the emf measured, even in cases where the precipitate was hardly visible. A value of E' could however not be directly determined in these titrations. As the value of E' varied a little between parallel titrations, being dependent on small differences in E_k between different cells, it was desirable to find the value of E' corresponding to the values of E measured in a particular titration. This was done by comparing the values of E found when titrating over a common range with increasing and decreasing C_A. The difference between E of such series leads to a fairly safe estimate of the difference between E'. The value of E' for the series with decreasing C_A can then be found as E' for its companion series was measured directly.

In the case of the iodide, a ligand solution of $[H^+]=1$ M would have been rather unstable. In these titrations, neutral iodide solution was therefore added from one burette and perchloric acid from another. In this way iodide was kept in acid solution only in the electrode vessel, where its oxidation was minimized by the presence of an inert atmosphere.

The values of E_M given in the following tables are as a rule the mean of three titrations. In the chloride and bromide systems the values of emf measured were very stable. They were reached, moreover, almost immediately after the solutions had been mixed, with the exception of E' whose adjustment to the final value sometimes took about half an hour. The emfs could be reproduced within about ± 0.5 mV, as a rule somewhat better at lower values of C_A and somewhat worse at higher ones. In the iodide system it often took 5—10 min for the emfs to reach their final value; they were also markedly less reproducible, especially at high values of C_A. At the very highest values of C_A tried, they were even unstable and drifted erratically, especially if C_M was also high. Often a tarnishing of the amalgam surface was observed in such solutions and their colour gradually faded to light yellow on standing.

The solubility measurements: Solutions of 50 ml total volume, with known initial concentrations of bismuth and ligand were prepared in glass-stoppered bottles of 100 ml volume. The concentrations were chosen so that a precipitate formed. The bottles were shaken in a thermostat for about a week. After that time equilibrium had been established, as was proved by shaking a few bottles for another week. The same results were obtained in both cases.

Samples of the saturated solutions thus obtained were filtered by suction through a sintered glass disc (filter stick) direct into a pipette. The total bismuth concentration of these solutions, *i.e.* the solubility l, was then determined spectrophotometrically by the iodide method [13].

This method utilized the very intense colours of the bismuth iodide complexes, especially that of the highest. In order to bring about maximum absorption, the iodide concentration should be at least ≈ 100 mM. At this value of [A] the formation of the highest complex is practically completed, therefore further addition of iodide does not alter the absorption appreciably. The extinction curve has a maximum at 4 600 Å, where the iodide complex has a molar extinction coefficient $\varepsilon \approx 11\,000$ $M^{-1} \cdot cm^{-1}$. This very high value of ε permits a convenient determination of bismuth concentrations down to $\approx 10^{-5}$ M. The extinction values are however not very reproducible if steps are not taken to prevent the formation of I_3^- which also absorbs strongly at 4 600 Å. Following Wiegand *et al.*[13] we have successfully used hypophosphorous acid (≈ 0.3 M) to prevent the formation of I_3^-. In the absence of Bi(III) the medium used is completely colourless, and distilled water can therefore be used in the solvent absorption cell of the spectrophotometer (Beckman DU). A calibration curve giving the connexion between C_M and the specific extinction* e was constructed by measuring solutions of known C_M. Only slight deviation from Beer's law was found.

The statement above that practically all the bismuth is present as the highest iodide complex when the iodide concentration = 100 mM may of course be invalidated if other ligands are present in the solution, competing with the iodide. This is the case when analysing chloride or bromide solutions. It was found experimentally however that if the iodide concentration was increased to 250 mM, chloride or bromide could be present in a concentration of at least 50 mM, without changing the extinction perceptibly. This could also have been expected from the values of the stability constants of the different systems, previously found by the potentiometric measurements.

The solubility l for a certain C_A could as a rule be reproduced within ≈ 10 % except at the lowest values of C_A in the chloride and iodide system where the reproducibility was very poor. This is evident from Tables 4, 7 and 10 where the solubility experiments have been tabulated.

In most cases a second sample of the saturated solutions was filtered off and used for a potentiometric determination of $[Bi^{3+}]$ in order to find L' and L. For the bromide system useful values of E_M could then be obtained in the whole range of C_A used, whereas C_A must be at least 20 or 30 mM in chloride or iodide solutions before even acceptable values of E_M could be read. At lower values of C_A, unsteady and drifting potentials were obtained. This is of course mainly due to the very low value of C_M ($= l$) in such solutions, but to judge from the figures of the chloride system, the value of C_A (or [A]) itself must also be of importance. Thus E_M can be measured for $C_A = 20$ mM, but not at lower C_A in spite of the fact that l has already reached its minimum value at $C_A = 20$ mM (Table 4).

* $e = E/d$, where E = extinction measured and d = thickness of absorbing layer.

111.1	53.0	53.7	53.9	1200	138.4	140.8	142.1	142.6	142.1

* These values belong to the series titrated from higher to lower values of C_A, while all other values belong to the series titrated in the opposite direction.

Evidently the bismuth species dominating at [A] = 20 mM have a more favourable electrode kinetics than those dominating at lower [A], as has also been directly proved by the impedance measurements of Randles and Somerton [14].

In the case of the iodide system a third sample of the saturated solution was filtered off and analysed by thiosulphate titration for the amount of I_3^- formed during the shaking, in order to find the true value of [A] according to (14).

In order to find L from L', K_w of the medium used was finally determined by measuring $[H^+]$ of solutions of known $[OH^-]$ by means of a hydrogen electrode. As mean of three determinations a value of $K_w = (0.75 \pm 0.05) \cdot 10^{14}$ M^{-2} was found.

RESULTS

The chloride and bromide systems: In Tables 2 and 5, E_M is given as a function of C_A with C_M as a parameter. These functions are cut at a number of E_M, thus giving corresponding values of [A] and X, Tables 3 and 6. An accurate value for the constant β_1 cannot, however, be found from the function X_1 thus formed, as the latter is not known at sufficiently low values of [A]. Reliable values of β_1 can, however, be found from the solubility measurements, where the lowest values of [A] measured are 3.94 mM for the chloride and 2.12 mM for the bromide, as compared with 23.4 mM and 8.5 mM, respectively, in the potentiometric measurements. In order to find the value of [A] corresponding to a certain value of l measured, it is, however, necessary to know beforehand $\bar{n}$ approximately as a function of [A] (*cf.* eqn. (10)). By calculating a set of provisional stability constants from the X-functions found potentiometri-

cally, using a value of $\beta_1 = 0$, complex formation functions good enough for this purpose are obtained.

For both the systems, the values of L' found are constant within the experimental error in the whole range of [A] covered. Thus the solid phases really do have a ratio M:A = 1, as postulated in (7) and (8). Furthermore, samples of the precipitates have been filtered off, and, after drying, analysed for bismuth, and in the case of the bromide, halide also. For bismuth the complexometric method of Malat *et al.*[15] has been used, and it was then found that direct titrations with EDTA could be performed for the chloride also. Bromide was determined according to Volhard. (Found for the chloride: Bi 80.4 %, calc. for BiOCl: 80.2 %. Found for the bromide: Bi 68.0 %, Br 26.23 %, calc. for BiOBr: Bi 68.4 %, Br 26.21 %.)

The mean value of L' is found to be $(208 \pm 20) \times 10^{-9}$ M^2 for the chloride and $(303 \pm 10) \times 10^{-9}$ M^2 for the bromide. Using these values of L', β_1 is calculated from the corresponding values of l and [A], according to (9). The values of β_1 thus found are then used for calculating X_2 from the potentiometrically found X_1. From X_2 (Tables 3 and 6), β_2 is found by extrapolation to [A] = 0. Further X-functions are then formed and the corresponding constants determined. For both the chloride and the bromide the function X_5 is found to be a straight line, the sixth complex thus being the highest one existing in the range of [A] investigated. The complex formation curves, as

calculated from the constants found, show very distinct tendencies of asymptotically approaching $\bar{n} = 6$, Fig. 2. The coordination number of bismuth in these two halide systems thus seems to be $N = 6$. In fact even the sixth complex is a little reluctant to form from the fifth one. In addition to the values of β_1 used in connexion with the potentiometric data, values of some of the higher constants can also be determined from the solubility measurements (*cf.* eqn. (11)). In this way β_2 of the chloride system and β_2 to β_4 of the bromide system are calculated and found to be in reasonable agreement with the values found potentiometrically, as seen from Table 11, where all the constants are tabulated.

As C_M must be kept rather low in the potentiometric measurements in order to avoid precipitation as much as possible, the determination of the slopes of the C_A, C_M lines of constant E_M becomes rather uncertain, all the more as the error in E_M is not very small (*cf.* p. 1118). In such cases the slopes found cannot be expected to coincide completely with the complex formation curve even if the complex formation is in fact entirely mononuclear. As seen from Fig. 2, discrepancies are found for the chloride system especially, but they can most certainly be explained by the poor accuracy of the slope values. The general trends of these nevertheless coincide with the curve found from the

stability constants and no doubt the complex formation is mononuclear for both systems.

The iodide system: In Table 8, E_M is given as a function of C_A at different C_M. A fairly high value of C_A is necessary in order to prevent precipitation of BiI_3 even at C_M as low as 1 mM. As the values of E_M obtained for a certain C_A are remarkably high the system must be strongly complex. Only the highest complexes can therefore be expected to exist in the range of [A] covered by the emf measurements. The calculation should in such a case start with β_N (*cf.* p. 1113). From the results of the chloride and bromide systems, it may be

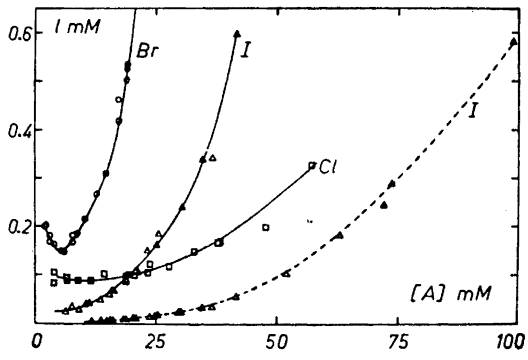

Fig. 1. The solubility l of Bi(III) as a function of [A] in halide solutions. Squares, circles and triangles refer to the chloride, bromide and iodide systems respectively. The dashed curve of iodide refers to values of l ten times greater than those given on the ordinate axis.

assumed that $N = 6$ also for the iodide. In Table 9, where corresponding values of X and [A] are found, the function X_6' is also given, calculated according to (5). It is found to be a constant, $= \beta_6$, from the highest value of [A] down to [A] $\approx$ 80 mM, thereby confirming that $N = 6$. For [A] $<$ 80 mM, X_6' increases as lower complexes become perceptible, but further constants cannot be safely calculated from the present figures.

A substantial extension of the measured range of [A] is obtained by the solubility measurements, Table 10. A value of [A] $\approx$ 4 mM can be reached, as compared with [A] $\approx$ 60 mM in the emf measurements. In that range of [A] (>25 mM) where [M] can be measured and thus values of L determined (from eqn. (12)), L is found to be constant within the experimental errors (Table 10). Thus the solid phase really is MA_3, as postulated in (12). Using the established value of $N = 6$, $L \cdot X_6' = l / [A]^3$ is then calculated, *cf.* eqn. (15), and from the extrapolation to $1 / [A] = 0$, $L \cdot \beta_6$ and hence β_6 is found. Then $L \cdot X_5'$ is formed according to (16), and from this function β_5 and β_4 are found from the intercept on the axis and the slope at the point of intersection. The function is not linear, so the third complex must be present in appreciable amounts, at least in the solutions of lowest [A]. The accuracy of l is not good enough however to permit the calculation of a further constant from a function $L \cdot X_4'$, formed analogously to $L \cdot X_5'$.

The constants found are given in Table 11. As can be seen, the two values of β_6 found agree tolerably well. We believe, however, that the figure found by the solubility measurements is the more reliable one, on the following grounds. As pointed out above (p. 1118) a reaction involving the amalgam electrode is evidently taking place in iodide solutions of high [A]. From the bleaching of the solutions it is obvious that Bi(III) is being reduced by the metallic Hg. Such a reduction is rendered possible by the formation of very strong iodide complexes of Hg(II) which greatly stabilize this oxidation state relative to Hg(0). A calculation based on the data of Sillén [16] for Hg(II) and those of the present paper for Bi(III) also confirms that the reduction is possible. On the other hand Sillén's data seem to indicate that the existence of Hg(I) in appreciable amounts (as solid Hg_2I_2) is not to be expected at those values of [A] where a perceptible reduction of Bi(III) can take place. Similar calculations for the chloride and bromide system prove that no reduction of Bi(III) is to be feared in these cases, as is also experimentally confirmed.

Even at lower values of C_A where the function of the amalgam electrode is not obviously erratic, minor irregularities occur which may indicate the beginning of its break-down. Thus the corresponding values of C_M and C_A at constant values of E_M do not fall as well as they should along straight lines. Moreover the best straight lines which can be drawn have slopes much greater than $\bar{n}$. Obviously the values of E_M measured cannot be considered as quite realiable, and more weight should therefore be placed on the measurements of solubility.

The observed slopes of course do not suggest any polynuclear complex formation, being greater than $\bar{n}$. As their value seems doubtful however, no conclusions ought to be drawn. But from the behaviour of the other halide systems it may perhaps be concluded that the iodide system also is probably mononuclear.

CONCLUSIONS. COMPARISON WITH PREVIOUS WORK

The halide complexes of Bi^{3+} increase in strength in the order $Cl^- < Br^- < I^-$, and Bi^{3+} thus belongs to the second group of central ions, *i. e.* those centered about the noble metals. This is evident from Table 11 and also from Fig. 2, where the complex formation curves are drawn as calculated according to Ref.[9], p. 785.

Fig. 2 also shows that the curves of the chloride and bromide systems are similar, implying that the complex formation proceeds in much the same way

* β_4 and β_5 measured in 1.5 M HNO_3 for the chloride, in 1.2 M HNO_3 for the bromide. β_6 of all systems measured in 0.6 M HNO_3. The solutions also contain KNO_3 to a total $I = 2.3$ or 3 M. Temperature 20°C.

** The first two consecutive constants (β_n/β_{n-1}) were measured in 1 M $HClO_4$, the three following ones in a medium of the same $[H^+]$, but with $I = 5$ M.

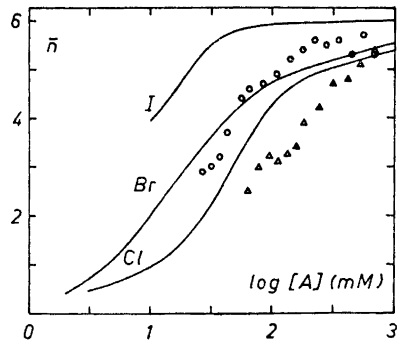

Fig. 2. The complex formation functions of the bismuth chloride, bromide and iodide systems. The curves are calculated from the values of β found. The points obtained from the slopes of the C_A, C_M-lines of constant E_M are indicated by circles for the bromide and by triangles for the chloride system.

in these two systems. A characteristic feature is the slow formation of the sixth complex, which means that the fifth one has a broad range of existence. This stands out well in Fig. 3, where the distribution of Bi(III) on the different complexes is given as a function of log [A] (*cf.* Ref.[9], p. 787). The graphical representation is the one first used by Bjerrum [17], *cf.* also J. Bjerrum [18] (p. 287). A still more interesting thing is that the value of β_1 for bromide is about the same as that for chloride (or even a little less). In this respect Bi^{3+} thus behaves as an intermediate between the two groups of central ions, in accord with its position in the outskirts of the second group. As the formation curve of the bromide is much steeper than that of the chloride, the overall complexity of the former system is nevertheless considerably stronger. As to the solubility products of the oxyhalides, that of the bromide seems to be just greater than that of the chloride, which is also contrary to the general rule for halide systems of the second group ions, as exemplified by the halides of Cu^+, Ag^+, Hg_2^{+2} and Hg^{2+}.

In the iodide system, on the other hand, the fifth complex does not have a wide range of existence, instead the formation curve goes steeply up $\bar{n} = N = 6$. Moreover the difference in stability between the iodide and bromide complexes is much greater than between the bromide and chloride ones.

Quantitative investigations of the complex formation in solutions of the bismuth halides have also been performed by Babko and Golub [19] and by Newman [20]. Babko and Golub measured $[Bi^{3+}]$ by means of bismuth metal electrodes, as well as measuring the corresponding $[Cl^-]$ or $[Br^-]$ by silver halide electrodes. The pure metal electrodes did not give emfs as reproducible as those of the present amalgam electrodes, in accordance with the general observation that electrodes of hard metals are not easy to get working satisfactorily. The measurements were performed in nitrate media of such high acidity that a definite risk of oxidation of the metal electrode certainly must have existed, especially in solutions of high halide concentration where bismuth is much less noble than in non-complexing media. In the case of iodide, moreover, it was necessary to add sulphite in order to prevent oxidation of the ligand. This addition, however, is objectionable, as sulphate and sulphite are

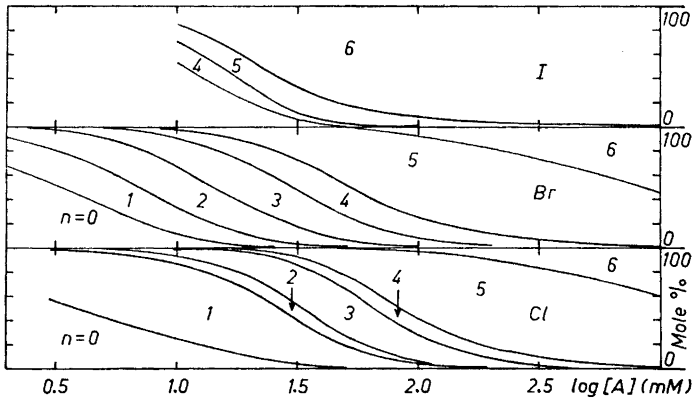

Fig. 3. The distribution of bismuth between the various complexes as a function of [A].

thereby introduced as new ligands in the solution whose concentration of acid is simultaneously reduced.

Dissociation constants, K_n, have been calculated for the three highest complexes of the chloride and bromide systems and for the highest (= sixth) iodide complex. The corresponding stability constants, $\beta_n = 1/K_n$, are as a rule perceptibly lower than those found by the present authors, Table 11. As to the chloride and bromide systems, they are nevertheless of the same order of magnitude. The value of β_6 of the iodide system is however quite different.

Newman has measured spectrophotometrically the consecutive constants of the first five complexes of the chloride system, as well as constants for mixed chloride bromide complexes containing one bromide ion. The constants β calculated from his data, Table 11, agree on the whole tolerably well with ours, especially if the differences of method and medium are taken into account. The most remarkable discrepancy is found for β_5. The sixth complex has escaped discovery because the measurements were not extended into that range of [A] where it exists in perceptible amounts, according to the present investigation.

This investigation has been supported by a generous grant from *Statens naturvetenskapliga forskningsråd (Swedish Natural Science Research Council)*. Our thanks are due to Dr George Gamlen, I.C.I. Dyestuffs Division, Blackley, Manchester, for his kind and thorough revision of the English in our manuscript.

Note added in proof: Slightly revised, Newman's [20] work has recently been definitively published (Newman, L. and Hume, D. N. *J. Am. Chem. Soc.* **79** (1957) 4571, 4576, 4581.

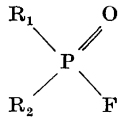
The Alkaline Hydrolysis of *iso*Propoxy-methyl-phosphoryl Fluoride (Sarin) and some Analogues



LENNART LARSSON

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The alkaline hydrolysis of Sarin and ten analogues have been studied at different temperatures with an electrometric method. The bimolecular rate constants and the energies and entropies of activation of the reactions have been calculated. The hydrolysis products have been examined with paper chromatographic technique. The results indicate that the hydrolysis proceeds as an one-stage reaction (S_N2) and involves a nucleophilic attack of the hydroxyl ion on the phosphorus atom. The attraction between them is controlled by the inductive and mesomeric effects of the substituents which also influence the strength of the P—F bond. On the basis of the theories of Kirkwood and Westheimer a semi-quantitative treatment of the electrostatic effects of the substituents on the rates has been performed, and a fairly good agreement between calculated and found rate constants has been obtained.

Since the fundamental investigation of the hydrolysis of di-*iso*propoxyphosphoryl fluoride, DFP, performed by Kilpatrick [1], several papers concerning different reactions of fluorine derivatives of organic phosphorus compounds have been published. Especially the reactions of Sarin and of DFP with catechols [2,3], hydroxamic acids [4,5] and oximes [6] have attracted attention. The hydrolysis of Sarin catalyzed by hydroxyl ions has also been touched in some papers [4,7].

Sarin has caught interest because of its potent effects on the cholinergic transmission. It has also been considered as a potential war gas. The hydrolysis of Sarin is thus of practical importance for chemical and pharmacological studies as well as for its decontamination. The purpose of this investigation was to determine the pH-dependence of the hydrolysis of Sarin and to elucidate the reaction mechanism of its alkaline hydrolysis. It was also of interest to study the effect of substituents on the rates of hydrolysis of compounds with the general formula

Because the hydrolysis of Sarin as well as the hydrolysis of its analogues is catalyzed by several ions, it is rather complicated to study the pH-dependence of the reaction in various buffer solutions. The hydrolysis has instead been studied by an electrometric method developed by Larsson and Hansen [8]. The nomenclature used in this paper conforms to the Swedish proposition [9].

EXPERIMENTAL

Materials. The methyl-fluoro-phosphorylcholine derivatives were synthesized in this institute by Tammelin [10]. The other organic phosphorus compounds except the bromoethoxy- and dimethylbutoxy-derivatives were synthesized by Tammelin and Fagerlind [11]. 2-Bromoethoxy-methyl-phosphoryl fluoride and 3,3-dimethylbutoxy-methyl-phosphoryl fluoride were synthesized by reacting methyl-fluoro-phosphoryl chloride with 2-bromoethanol and 3,3-dimethylbutanol [12], respectively, according to the scheme given by Tammelin [10]. Analytical data of these two compounds are shown in Table 1. The densities, determined with a self-filling pycnometer [13], and refractive indices of the liquid compounds as well as the formulae of all the compounds are given in Table 2. Methylphosphoryl-dichloride used in the chromatographic study was prepared according to Kinnear and Perren [14]. The salts were recrystallized and the liquids freshly distilled before use.

Paper chromatographic technique. The phosphorus compounds to be chromatographed were hydrolyzed in 0.1 M ammonium hydroxide. The choline chloride used was dissolved in distilled water. Five μl of 0.5 % solutions of the compounds were placed with micropipettes on a filter paper, Whatman No. 1, Ascending technique was used, and the chromatograms were run at 25°C. Both acid and alkaline solvents were tested. The composition of the acid solvent was: *n*-butanol : ethanol : acetic acid : water (8 : 2 : 1 : 3)[15], and that of the alkaline solvent was: *tert.*-butanol : *iso*propanol : 2 M ammonium hydroxide (2 : 2 : 1).

The development of the spots from the phosphorus compounds was carried out by spraying the paper with an acid solution of ammonium molybdate and treating the dried paper with hydrogen sulfide [16].

An attempt to develop the chromatographed hydrolyzate of one of the phosphorylcholine derivatives in respect of the choline group was made in three different ways: by spraying with a solution of dipicrylamine [15], by immersing in a solution of Reinecke salt [17], and by immersing in a solution of phosphomolybdic acid with subsequent reduction with stannous chloride [18]. Choline chloride was developed with dipicrylamine.

Kinetic measurements. The rates of the hydrolysis of the compounds were studied by means of an automatic recording titrator [8]. The principle of this instrument is that acid products formed in the hydrolysis are neutralized by addition of alkali in such a rate

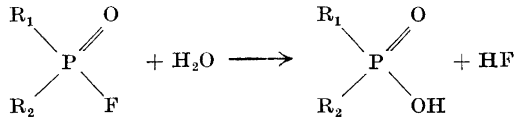
of potassium chloride; in dilute alkali solutions this value seems to be more reasonable to use than that given for potassium hydroxide [21].

The choline derivatives were dissolved in abs. ethanol; the solutions were freshly prepared every day. The other compounds studied were dissolved in dioxan, *E. Merck c.p.*, purified from peroxides and redistilled over sodium. The concentration of the compounds in the stock solutions were 10 mM. In the reaction vessel 1 to 2 ml of the stock solution was diluted to 40.0 ml with 0.100 M solution of potassium chloride which before the addition of the stock solution had been adjusted to the desired pH-value. The concentration of the sodium hydroxide added was 0.050 M. The slight dilution during the reaction due to the volume of the alkali was neglected. The potassium chloride solution was used to maintain the ionic strength constant. In one series of experiments the concentration of potassium chloride was varied and in one case sodium fluoride was used. The final concentrations of the compounds varied between 0.25 and 0.50 mM.

RESULTS

Hydrolysis products



When Sarin or its analogues studied in this paper are hydrolysed in alkaline solution exactly two equivalences of acid are formed. In the hydrolyzates fluoride ion was indicated with zirkon alizarin paper.

The hydrolyzates of Sarin and of methyl-fluoro-phosphorylcholine were analysed with paper chromatographic technique to investigate the products which were formed. Only one spot indicating a phosphorus compound was obtained on the two chromatograms. As comparison solutions of methyl-dihydroxy-phosphine oxide, obtained from methylphosphoryl dichloride, and of choline chloride were analysed in the same manner. The R_F value of the hydrolyzate of Sarin does not agree with that of methyl-dihydroxy-phosphine oxide. It is thus proved that this compound is not formed in the hydrolysis and that the hydrolysis product containing phosphorus must be methyl-*iso*propoxy-hydroxy-phosphine oxide. Neither the R_F value of choline nor that of methyl-dihydroxy phosphine oxide agree with the R_F value of the hydrolyzate of methyl-fluoro-phosphorylcholine. This indicates that these compounds are not formed in the hydrolysis, and that the hydrolysis product must be methyl-hydroxy-phosphorylcholine. The R_F values of the four compounds in acid and alkaline solvents are given in Table 4. It is, however, remarkable that the choline group in methyl-hydroxy-phosphorylcholine was impossible to indicate with any of the three developers used for choline.

Table 4. The R_F values in acid and alkaline solvents.

Compound	R_F	
	Acid solvent	Alkaline solvent
Methyl-dihydroxy-phosphine oxide	0.26	0.02
*iso*Propoxy-methyl-hydroxy-phosphine oxide	0.64	0.48
Methyl-hydroxy-phosphorylcholine	0.22	0.18
Choline chloride	0.43	0.31

These results indicate that the hydrolysis proceeds according to the following scheme:

and that any further hydrolysis of the reaction products does not seem to occur under the present conditions.

pH-Dependence of the hydrolysis of Sarin

The pH-dependence of the hydrolysis of Sarin was studied at 25°C at the pH-values 8.00, 8.40, 8.70, 9.00, 9.40 and 9.80 and at 35°C at the pH-values 8.30, 8.68 and 9.13. The hydrolysis curves obtained from the recorder were treated according to the method given by Guggenheim [22]. Straight lines were obtained indicating that the hydrolysis proceeds as a first-order reaction when the pH is maintained constant. If the rate of the hydrolysis only depends upon the hydroxyl ion activity and the reaction with water molecules can be neglected, the pH-dependence of the hydrolysis at constant ionic strength may be equated as

$$k_1 = k_2' \cdot a_{OH^-} = k_2' \cdot \frac{K_w}{a_{H^+}} \tag{2a}$$

or in logarithmic form

$$\log k_1 = \log k_2' - \text{pOH} \tag{2b}$$

where k_1 is the pseudo first-order rate constant, k_2' the second-order rate constant at constant ionic stregth and K_w the ionic product of water.

When the logarithms of the pseudo first-order constants in sec.$^{-1}$ obtained from three runs at each pH are plotted against pOH, using the values of pK_w given in Table 3, straight lines are obtained as shown in Fig. 1. The equations of the two lines were calculated by the method of least squares, and were found to be:

$$\log k_1 = 1.519 - 0.995 \times \text{pOH at } 25°C, \text{ and}$$
$$\log k_1 = 1.731 - 0.995 \times \text{pOH at } 35°C.$$

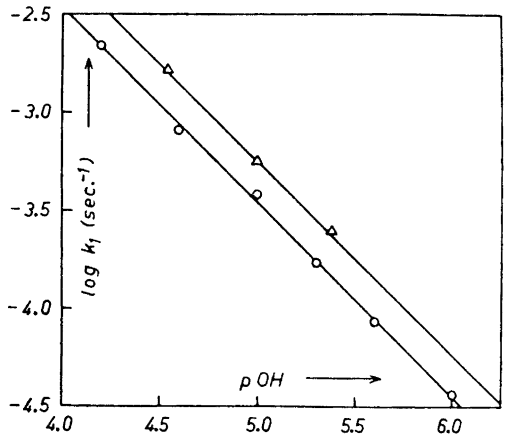


Fig. 1. The pOH dependence of the hydrolysis of Sarin ○ at 25°C and △ at 35°C. The sizes of the points indicate the standard deviations in log k_1.

The error in the found coefficients of pOH is ± 0.013 and ± 0.021, respectively. The coefficients are within the limits of error equal to 1.00 which thus confirms the correctness of the proposed eqn. (2).

Effect of ions on the hydrolysis of Sarin

It appears from Table 5 that the rate of the hydrolysis of Sarin is increased when increasing the ionic strength at constant pH. If, however, the second-order rate constant, k_2, is calculated from the hydroxyl ion concentrations in question, this constant is found to be independent of the ionic strength within the limits of error. This will probably depend upon the activity coefficient of the hydroxyl ion canceling the activity coefficient of the charged activated complex and the activity coefficient of the uncharged Sarin molecule being unaffected in the ionic strength range in question. For that reason eqn. (2 a) has been transformed to the following equation:

$$k_1 = k_2 \cdot c_{OH^-} = k_2 \cdot \frac{a_{OH^-}}{f_{OH^-}} \qquad (3)$$

where the bimolecular rate constant k_2 is independent of the ionic strength to at least 0.5.

From Table 5 it is also shown that the fluoride ions have no effect on the the rate of the hydrolysis.

Temperature dependence of the hydrolysis of Sarin and its analogues

The temperature dependence of the hydrolysis of Sarin was determined at 20°C, 25°C, 30°C and 35°C. The pseudo first-order rate constants obtained

Table 5. The effect of ionic strength and fluoride ions on the hydrolysis of Sarin at pH 9.00 and 25°C.

M_{KCl}	M_{NaF}	f_{OH^-}	$c_{OH^-} \times 10^5$	$k_1 \times 10^4$ sec.$^{-1}$	k_2 l mole^{-1} sec.$^{-1}$
0.050	—	0.813	1.23	3.73	30.3
0.100	—	0.766	1.31	3.81	29.1
0.200	—	0.715	1.40	4.32	30.9
0.500	—	0.649	1.54	4.42	28.7
—	0.100	0.766	1.31	3.83	29.2

were converted into second-order rate constants by means of eqn. (3). The first-order rate constants at 20°C and 30°C were calculated from three runs at each temperature at pH 9.17 and 8.83, respectively, *i.e.* at pOH 5.00. The second-order rate constants at 25°C and 35°C were calculated from the results of the study of the pH-dependence.

The Arrhenius activation energy, E_a, was calculated in usual manner by plotting log k_2 against $1/T$ as shown in Fig. 2. The line was drawn according to the method of least squares and the equation obtained was found to be

$$\log k_2 = 8.049 - 1.979 \times 10^3 \; 1/T$$

The value of the activation energy of Sarin obtained from this equation is given in Table 6.

In the same table there is also given the entropy of activation of the reaction, $\Delta S^{\ddagger}$; which is calculated according to Eyring [23a] for reactions in solution:

$$k_2 = e \cdot \frac{kT}{h} \cdot e^{-Ea/RT} \cdot e^{\Delta S^{\ddagger}/R} \qquad (4)$$

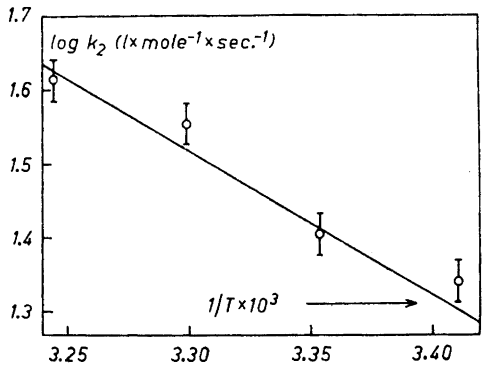

Fig. 2. The temperature dependence of the hydrolysis of Sarin. The values at 20°C, 25°C, 30°C and 35°C are mean values of 3, 18, 9 and 3 determinations, respectively. The lines through the points indicate the standard deviations in log k_2.

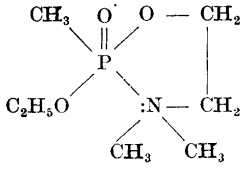
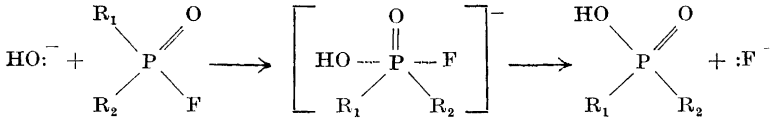
* pOH = 6.00 ; † pOH = 5.00



The pseudo first-order rate constants of the hydrolysis of the ten analogues to Sarin were determined at 25°C and 35°C and most of the experiments at pOH 5.50; the most rapid hydrolyses were measured at pOH 6.00 and the slowest ones at pOH 5.00. The values are shown in Table 6. The second-order rate constants were calculated on the presumption that the rate of the hydrolysis in conformity to the hydrolysis of Sarin is direct proportional to the hydroxyl ion concentration. This proved to be valid for the hydrolysis of methylfluoro-phosphorylcholine within the limits of error, when the rates of hydrolysis were determined at pOH 5.50 and pOH 6.00 at 25°C. From the rate constants obtained, the energy and entropy of activation of the ten Sarin analogues are calculated by means of Arrhenius' and Eyring's equations. The values of the second-order rate constants calculated from the mean values of the first order constants, and the energies and entropies of activation are given in Table 6. The errors reported are maximum errors with the exception of those of Sarin which are the standard deviations.

DISCUSSION

The direct proportionality of the reaction rate to the hydroxyl ion concentration in the hydrolysis of Sarin and its analogues indicates a bimolecular reaction mechanism. In the study of the hydrolysis of Tabun [24] the author suggested the hypothesis that the hydrolysis proceeded as a two-stage reaction involving an intermediate like



formed by utilization of one of the vacant 3d orbitals of phosphorus. If phosphorus shows such a tendency to expand its valence shell, it would be expected to coordinate the unshared electron pair on the nitrogen of ethoxy-dimethylaminoethoxy-methyl-phosphine oxide the formula of which can be designed:

If a bond of marked strength is established between the phosphorus and nitrogen atoms, this compound would be a considerably weaker base than the corresponding acetyl ester. Tammelin [25] has, however, shown that the difference between their dissociation constants is relatively small ($\Delta pK_a = 0.21$) which indicates that no expansion of the valence shell of phosphorus occurs, and that only a weak bond of dipole-dipole character thus may be formed. This contradicts the hypothesis of the formation of an intermediate in the hydrolysis of Sarin and its analogues and favours a simple one-stage displacement mechanism (S_N2). Dostrovsky [26] has also come to the same conclusion from his study of the hydrolysis of ^{18}O-labelled diethoxy-phosphoryl chloride.

The low effect of the ionic strength as well as the negligible effect of the fluoride ion concentration exclude a S_N1 mechanism and support the S_N2 mechanism. The alkaline hydrolysis can thus be described with the usual bimolecular scheme:

A polarimetric examination of the hydrolysis of one of the optical isomers of for example methyl-fluoro-phosphorylcholine is likely to give further evidence of the mechanism. The proposed mechanism would thus lead to inversion of the configuration without racemization.

The influence of the substituents on the rate of hydrolysis has been discussed on the basis of the theory of the inductive and mesomeric effects of the substituents (Ingold's terminology) and on the presumption that the reaction involves a nucleophilic attack of the hydroxyl ion on the phosphorus atom which will carry a small positive charge. A change from methyl to *iso*propyl in the alkyl or akoxy group involves a decrease in the rate of the hydrolysis as appears from Table 6. This can be explained by the increasing positive inductive effect, *i.e.* electron-releasing effect, when passing from methyl to *iso*propyl. This effect tends to increase the electronic density of the phosphorus atom and in this way to diminish the attraction of the hydroxyl ion. The decrease in rate is especially pronounced in the variation of the alkyl group. The low values of entropy of activation in these cases indicate a decreased probability of the transition state caused by steric hindrance. A substitution of hydrogen in the alkoxy group with an electron-attracting group such as bromine or a trimethylammonium group, which lower the electronic density of the phosphorus atom, causes a strong increase in the rate of hydrolysis.

If the methyl group in Sarin is exchanged against a *iso*propoxy group, the rate is decreased ($k_2 = 0.83$ l mole^{-1} sec.$^{-1}$ at 25°C)[1] which depends upon the increased mesomeric effect of the unshared electrons in the added oxygen atom. This effect is expected to be still greater in a dimethylamino group which is illustrated by the strong decrease in rate in the hydrolysis of bis-dimethylamido-phosphoryl fluoride ($k_2 = 5.7 \times 10^{-5}$ l mole^{-1} sec.$^{-1}$ at 25°C)[27]. The very strong decrease of the rate may also be attributed to the steric effect of the two dimethylamino groups.

As appears from Table 6 the activation energies of the reactions studied are approximately independent of the different substituents, even though some variations were expected. Similar results have been obtained in the alkaline hydrolysis of alkyl halides [28]. It is, however, essentially the free energy of activation which determines the rate of a reaction because the entropy of activation is not constant in the various reactions. The activation energy or really the heat of activation is rather to consider as an expression for the temperature dependence of the reaction.

From the results of the influence of the substituents on the rate of hydrolysis one can conclude that the rate of hydrolysis of Sarin and its analogues is mainly controlled by the strength of the P-F bond and by the ease with which the hydroxyl ion can attack the phosphorus atom. The approach of the hydroxyl ion depends upon the electronic density of the phosphorus atom, which is controlled by inductive and mesomeric effects of the substituents, and upon the steric hindrance by these substituents. The strength of the P-F bond is also influenced by the electron distribution of the substituents.

An attempt to a semi-quantitative treatment of the electrostatic effects of the substituents on the rates of hydrolysis has been performed on the basis of the theories improved by Kirkwood and Westheimer [29], and their equations for charged substituents (5) and dipolar substituents (6) have been used in the computation of the rate constants:

$$\ln k_2''/k_2 = \frac{e^2}{kTD_E d} \qquad (5) \qquad\qquad \ln k_2''/k_2 = \frac{e\mu \cos v}{kTD_E d^2} \qquad (6)$$

where k_2'' is the rate constant of the substituted compound to be calculated and k_2 is the found rate constant of the unsubstituted compound.

The computations were made on the assumptions that the molecule was a sphere with the radius R, and that the oxygen atom of the hydroxyl ion in the transition state and the charged atom or the center of the dipole were placed equidistant from the center on a diameter of the sphere. The diameter, $2R$, of the molecule was estimated from molecular models (Catalin Products Ltd.) as the geometric mean value of the lengths of three axes at right angles. The mean square distance, d, between the oxygen atom and the charged atom or the center of the dipole was calculated on the basis of free rotation about all the bonds [29]. The effective dielectric constant, D_E, is defined by the expression [29]: $1/D_E = f_1/D + f_2/D_i$, where D is the dielectric constant of the medium, D_i is the internal dielectric constant estimated as 2.0, and f_1 and f_2 are functions of the ratio $\frac{d}{2R}$. The value 1.48×10^{-18} e.s.u. was used for the dipole moment of the C-Br bond [30], and the angle, v, between the dipole and the line joining it to the oxygen atom was estimated to 31° from the fully extended molecule. Values of the angle found in this manner differ in general only little from those obtained from successive approximations [31].

The calculated rate constants, k_2'', and the found rate constants, k_2°, are given in Table 7. The found rate constants of the choline derivatives have been corrected to infinite dilution according to the theory of the influence of ionic strength on reactions between ions[23b]. The computations from eqns. (6) and (5) of the rate constants, k_2'', of bromoethoxy-methyl-phosphoryl fluoride and of methyl-fluoro-phosphorylcholine are based on the rate constant, k_2, of ethoxy-methyl-phosphoryl fluoride. Those of the homocholine- and β-methylcholine-derivatives are analogously based on the rate constants of propoxy-methyl-phosphoryl fluoride and Sarin, respectively.

Table 7. The rate constants of the hydrolysis of 2-bromoethoxy-methyl-phosphoryl fluoride and the choline derivatives at 25°C calculated according to Kirkwood and Westheimer.

Compound	$2R$ Å	d Å	D_E	$\log k_2''/k_2$	$\log k_2''$	$\log k_2^\circ$
2-Bromoethoxy-methyl-phosphoryl fluoride	6.45	4.65	5.38	0.55	2.33	2.21
Methyl-fluoro-phosphoryl-choline iodide	7.02	4.87	24.2	2.06	3.84	3.29
Methyl-fluoro-phosphoryl-homocholine iodide	7.25	5.34	31.5	1.45	3.18	2.80
Methyl-fluoro-phosphoryl-β-methylcholine iodide	7.27	4.87	21.2	2.36	3.77	2.90

The calculated rate constants agree fairly well with the found ones. The discrepancies are mainly due to the low accuracy in the estimation of the distances R and d and the disregard of the influence of the substituents on the strength of the P-F bond. The relatively great discrepancy between the calculated and found rate constants of methyl-fluoro-phosphoryl-β-methylcholine is probably caused by no consideration being taken of the steric effect of the β-methyl group in the estimation of the distance d. To compensate for

the steric effect of the trimethylammonium group the rate constant of methyl-fluoro-phosphorylcholine has also been calculated from the rate constant of 3,3-dimethylbutoxy-methyl-phosphoryl fluoride, at which calculation the logarithm of the rate constant was reduced from 3.84 to 3.75. These results demonstrate that the employment of the theories of Kirkwood and Westheimer leads to reasonable values in the calculation of the rate constants of the hydrolysis of organo-phosphorus compounds.

My sincere thanks are due to Professor G. Ljunggren, Director of this Institute, for the kind interest he has shown in this work.

The author wishes also to express his sincere thanks to Docent L. Melander, Nobel Institute of Chemistry, for stimulating criticism and discussions.

Die Geschwindigkeit der Äthanolyse und der Hydrolyse des Äthylbromids in Wasser-Äthanolgemischen

S. KILPI

Chemisches Institut der Universität Helsinki, Finnland

Auf Grund der Geschwindigkeitskoeffizienten der Solvolyse des Äthylbromids in Wasser-Äthanolgemischen wurden die Geschwindigkeitskoeffizienten der Hydrolyse und der Äthanolyse berechnet. In den wasserärmsten Gemischen ist die Geschwindigkeit der Äthanolyse und der Hydrolyse nach den Messungen annähernd proportional der stöchiometrischen Konzentration des Äthanols bzw. des Wassers. Die auf Grund der Geschwindigkeitskoeffizienten bei verschiedenen Temperaturen berechneten Temperaturkoeffizienten ändern sich mit der Zusammensetzung des Gemisches. In den wasserärmsten Gemischen wurde diese Abhängigkeit der Temperaturkoeffizienten von der Zusammensetzung des Lösungsmittels als von der Veränderung der Solvatationsverhältnisse verursacht erklärt.

Aus den Geschwindigkeitskoeffizienten der Solvolyse des Äthylbromids in wasserfreiem Äthanol und in einem Gemische, welches Wasser und Äthanol im Molverhältnis von 1:10 enthielt, berechnete der Verfasser [1] die Geschwindigkeitskoeffizienten der Äthanolyse und der Hydrolyse. Die Reaktionsgeschwindigkeit hat sich bei vielen Reaktionen, insbesondere in wasserarmen Äthanollösungen, als von der Zusammensetzung des Gemisches stark abhängig erwiesen. Es war deshalb von Interesse, zu untersuchen, inwieweit die Koeffizienten der obigen Solvolyse von der Zusammensetzung der Lösung abhängig sind. Zu diesem Zweck wurden in der vorliegenden Arbeit die Geschwindigkeitskoeffizienten der Solvolyse bei verschiedenen Temperaturen in wasserfreiem Äthanol und in Gemischen mit den stöchiometrischen Molverhältnissen 1:10, 1:6, 1:3 und 1:1 für $[H_2O]/[C_2H_5OH]$ bestimmt.

Die Materialien. Wasserfreies Äthanol wurde aus 96 %igem Äthanol durch Behandeln mit CaO und darauf mit Magnesium, welches mit Jod aktiviert worden war [2], und zuletzt mit wasserfreiem $CuSO_4$ hergestellt. Das in den folgenden Messungen verwendete Äthanol war 99,95—99,99 %ig.

Äthylbromid wurde aus Äthanol und Kaliumbromid durch Behandeln mit konz. Schwefelsäure bereitet.[3] Sp. 38,5°C bei 765 mm.

DIE MESSUNGEN

Die Messungen wurden bei 45°, 55°, 65° und 75°C ausgeführt und in einigen Fällen auch bei 25°, 35° und 40°C. Die Temperatur des Thermostaten verblieb innerhalb 0,02°C konstant. Der durch die Solvolyse gebildete Bromwasserstoff wurde titrimetrisch mit ca. 0,01 N $Ba(OH)_2$ oder mit kohlensäurefreiem NaOH gemessen. Als Indikator wurde Phenolphthalein verwendet. Da das Lösungsmittel zur Farbenveränderung selbst Alkali verbrauchte, wurden alle Titrationen in der Weise ausgeführt, dass die Lösung am Ende der Titration ca. 10 ml Äthanol und 40 ml Wasser enthielt. Dann verbrauchte das Lösungsmittel 0,40 ml 0,01 N Base, welche von der verbrauchten Basenmenge abgezogen wurde.

Bei den Titrationen wurden geeichte Mikrobüretten von 2 oder 5 ml Inhalt mit Einteilung von 0,01 bzw. 0,02 ml verwendet.

Alle Konzentrationen sind im folgenden in Mol pro 1 000 g Lösungsmittel angegeben. Das Äthylbromid wurde in dünnwandige Ampullen eingewogen und diese in abgewogenen Mengen Äthanol zerbrochen. Wenn die Reaktionsgeschwindigkeit in einem Wasser-Äthanolgemisch bestimmt werden sollte, wurde zu der alkoholischen Lösung eine berechnete Menge Wasser hinzugefügt. Etwa 10 ml Lösung wurden in eine gewogene, mit einem kapillaren Hals versehene Ampulle abgefüllt, die Ampulle zugeschmolzen und gewogen. In der Ampulle befand sich nur so viel Luft, dass ein Zerspringen der Ampulle wegen der Ausdehnung der Flüssigheit nicht zu befürchten war.

Die Konzentration des Äthylbromids war ca. 0,1 M. Der Geschwindigkeitskoeffizient verblieb in dem Konzentrationsbereich 0,05 — 0,15 M des Äthylbromids innerhalb der Versuchsfehler konstant. Nach einer gewissen Zeit wurde der gebildete Bromwasserstoff titriert. Die Titrationen wurden möglichst am Anfang der Reaktion ausgeführt, denn die von dem gebildeten Bromwasserstoff verursachte Gegenreaktion erschwert die Berechnung des Geschwindigkeitskoeffizienten der Solvolyse wegen der starken Elektrolytwirkung auf die Reaktion von HBr mit Äthanol.[5,6]

Entsprechend den Geschwindigkeitsgleichungen bei der Einwirkung von Chlorwasserstoff auf Äthanol[4] gilt bei der Solvolyse von Äthylbromid[5]:

$$dx/dt = k_2 (a - x) - k_1 x^2 \qquad (1)$$

wo k_2 und k_1 die Geschwindigkeitskoeffizienten der Solvolyse bzw. der Einwirkung von Bromwasserstoff auf Äthanol sind. Die Anfangskonzentration des Äthylbromids wird mit a bezeichnet und x ist die Konzentration des gebildeten Bromwasserstoffs. Wenn die Wirkung der Gegenreaktion zu vernachlässigen ist, erhält man k_2 nach der Gleichung:

$$k_2 = \frac{2{,}303}{t} \log \frac{a}{a-x} \qquad (2)$$

Im allgemeinen konnte die Gleichung (2) verwendet werden. Nur in absolutem Äthanol musste bei höheren Temperaturen die Berechnung nach der Gleichung (1) ausgeführt werden wegen der Gegenreaktion des Bromwasserstoffs mit Äthanol. Weil der Wert des Geschwindigkeitskoeffizienten k_1,

insbesondere bei kleinen Konzentrationen des Bromwasserstoffs, sich mit der Zunahme der Konzentration von Bromwasserstoffsäure sehr stark verändert, war die Integration der Gleichung (1) graphisch auszuführen [2] nach den Gleichungen:

$$k_2 t = \int_0^x dx/\{(a-x)-(k_1/k_2)_0 x^2/\varphi(x)\}$$
$$\log\varphi(x) = 2A'\sqrt{x}/(1 + a\sqrt{x}) \qquad (3)$$

Durch die Funktion (x) wird die Elektrolytwirkung nach der Debye-Hückelschen Theorie bei kleinen Elektrolytkonzentrationen ausgedrückt. Der Koeffizient A' wurde unter Anwendung der von Åkerlöf [7] bestimmten Werte der Dielektrizitätskonstante in den Wasser-Äthanolgemischen berechnet. Auf Grund der Werte von Grunwald und Winstein [5] wurde für a bei 55°C der Wert 1,20 berechnet. In der Tabelle 1 sind die Werte von $2A'$ und a bei 55°C und die gemäss der Debye-Hückelschen Gleichung auf 65°C und 75°C reduzierten Werte bezeichnet. Diese Werte gelten für die Darstellung der bezüglichen Elektrolytwirkung, wenn die Konzentration des Bromwasserstoffs nicht über 0,01 N steigt.

Tabelle 1.

t °C	$2A'$	a	pk_1 bei 0,00373 N	$pk_{1,0}$
75	7,54	1,24		2,02
65	7,02	1,22	3,05	2,65
55	6,70	1,20	3,70	3,32

Die Werte von $pk_{1,0}$ sind aus den von uns bei 55° und 65°C in 0,00373 N Bromwasserstofflösung gemessenen Werten mit Anwendung von $2A'$ und a der Tabelle berechnet worden. Der Wert 2.02 für $pk_{1,0}$ bei 75°C wurde mit der Arrheniusschen Gleichung aus den Werten bei 55° und 65°C berechnet. Wenn die Konzentration in Mol pro Liter Lösung ausgedrückt wird, erhält man mit $d_{55} = 0{,}7585$ aus 3,32 für $pk_{1,0}$ bei 55°C den Wert 3,20, der gut mit dem von Grunwald und Winstein [5] erhaltenen 3,185 übereinstimmt.

Aus den Tabellen 2—4, in denen die Messresultate in Äthanol bei 55°, 65° und 75°C angeführt sind, ist der Einfluss der Gegenreaktion des Bromwasserstoffs auf k_2 zu ersehen. Diese Messungen sind zugleich Beispiele für die Bestimmung der Geschwindigkeitskoeffizienten in dieser Arbeit. In den Tabellen bezeichnet g das Gewicht der Lösung in Gramm, v die von HBr verbrauchte Menge 0,01056 N $Ba(OH)_2$ in ml. x_∞ ist die Konzentration von HBr im Gleichgewicht, ermittelt mit Hilfe der entsprechenden nach der Debye-Hückelschen Gleichung aus $(k_1/k_2)_0$ berechneten Werten k_1/k_2. Beim graphischen Integrieren kann zuerst der nach der Gleichung (2) sich ergebende Wert für k_2 verwendet werden. Wenn nötig, muss man mit dem durch die graphische Integration erhaltenen Wert von k_2 die Berechnung von neuem ausführen.

Tabelle 2. Äthanollösung; 75°C; $a = 0{,}1347$; $(k_1/k_2)_0 = 5\,200$.

g	t (sec.)	v	$x \times 10^3$	pk_2 (nach 2)	pk_2 (nach 3)	k_1/k_2	$x_\infty \times 10^3$

9425	$7{,}47 \times 10^4$	5,05	5,75	6,25	6,23	1205	
8891	$8{,}17 \times 10^4$	5,19	6,25	6,25	6,22	1150	10,7

Tabelle 4. Äthanollösung; 55°C; $a = 0{,}1430$; $(k_1/k_2)_0 = 2\,340$.

g	t (sec.)	v	$x \times 10^3$	pk_2 (nach 2)	pk_2 (nach 3)	k_1/k_2	$x_\infty \times 10^3$
9,904	$7{,}35 \times 10^4$	1,97	2,13	6,69	6,69	1198	
8,978	$1{,}292 \times 10^5$	3,00	3,58	6,71	6,69	987	
10,220	$1{,}292 \times 10^5$	3,48	3,65	6,70	6,68	975	
9,938	$1{,}358 \times 10^5$	3,72	4,02	6,68	6,66	942	
8,400	$1{,}418 \times 10^5$	3,17	4,05	6,69	6,67	935	
10,727	$1{,}637 \times 10^5$	4,70	4,70	6,69	6,67	880	12,19

Der Einfluss der Gegenreaktion auf die Berechnung des Geschwindigkeitskoeffizienten der Solvolyse ist bei 75°C am grössten, weil die Geschwindigkeit der Einwirkung von Bromwasserstoff auf Äthanol viel stärker mit der Temperatur steigt als die der Solvolyse. Dennoch hält sich der mit Hilfe der Gleichung (2) berechnete Geschwindigkeitskoeffizient beim Fortlaufen der Reaktion innerhalb der Versuchsfehler konstant. Dies wird dadurch verursacht, dass sich der Geschwindigkeitskoeffizient der Gegenreaktion bei der Zunahme von HBr wegen der Elektrolytwirkung stark vermindert. Zugleich wächst die Konzentration x_∞ des Bromwasserstoffs bei dem Gleichgewicht, das dem bezüglichen Wert von k_1/k_2 entspricht. Bei 65° und 55°C sind die nach den Gleichungen (2) und (3) berechneten Werte innerhalb der Versuchsfehler gleich gross. In den wasserhaltigen Gemischen braucht die Gegenreaktion nicht berücksichtigt zu werden.

Die von Grunwald und Winstein [5] für den Geschwindigkeitskoeffizienten der Solvolyse bei 55°C erhaltenen Werte, welche mit dem Fortschreiten der Reaktion kleiner werden, nähern sich bei zunehmender HBr-Konzentration dem von uns erhaltenen Wert. Der grössere Unterschied im Anfang der Reaktion bei niedrigerer HBr-Konzentration ist wahrscheinlich dadurch verursacht, dass in unseren Messungen die von dem Lösungsmittel verbrauchte Basenmenge von der in der Titration verbrauchten Menge abgezogen wurde (s. 1144).

In Tabelle 5 sind die gemessenen Geschwindigkeitskoeffizienten k_2 zusammengefasst. Mit Hilfe der bei 45°, 55°, 65° und 75°C gemessenen Werte wurden die in den Tabellen 6 und 7 angeführten Geschwindigkeitskoeffizienten $k_2'/[C_2H_5OH]$ und $k_2''/[H_2O]$ der Äthanolyse und der Hydrolyse berechnet, wobei die folgende Bezeichnung angewendet wurde:

$$k_2 = k_2' + k_2''$$

Tabelle 5. Die bei verschiedenen Temperaturen gemessenen pk_2-Werte in Äthanol (I) und in den Äthanol-Wassergemischen II, III, IV und V.

Lösungsmittel / Temperatur in °C.	I $[C_2H_5OH]$ = 21,73		II $[C_2H_5OH]$ = 20,9 $[H_2O]$ = 2,09		III $[C_2H_5OH]$ = 20,4 $[H_2O]$ = 3,40		IV $[C_2H_5OH]$ = 19,23 $[H_2O]$ = 6,41		V $[C_2H_5OH]$ = 16,51 $[H_2O]$ = 16,51

Die auf Grund der Werte von k_2 in absolutem Äthanol (Lösung I) berechneten Werte von $k_2'/[C_2H_5OH]$ befinden sich in der zweiten Kolumne der Tabelle 6. Aus diesen Werten ergeben sich für die Koeffizienten E und A der Arrheniusschen Gleichung:

$$k = Ae^{-E/RT}$$

folgende Werte:

a) $E = 24{,}05$ kcal; $\log A = 7{,}90$

Diese, sowie alle anderen hier angegebenen Werte von E und A sind nach der Methode der kleinsten Quadrate berechnet worden. Die berechneten Werte der Kolumne 3 in Tabelle 6 sind mit Anwendung der Werte *a*) berechnet worden. Die 6. Kolumne enthält die Werte $k_2''/[H_2O]$, aus den Werten von k_2 in den Lösungen I und II berechnet. Ausserdem wurden $k_2'/[C_2H_5OH]$ und $k_2''/[H_2O]$ auf Grund der Werte von k_2 in den Lösungen I, II, III und IV nach der Methode der kleinsten Quadrate berechnet. Die in dieser Weise erhaltenen Werte befinden sich in den Kolumnen 4 und 7 der Tabelle 6. Ein Vergleich der letztgenannten, unter Berücksichtigung aller mit Lösungen I, II, III und IV erhaltenen Werte, mit den Werten der Kolumnen 2 bzw. 6 zeigt, dass die Übereinstimmung in Bezug auf $k_2'/[C_2H_5OH]$ besser ist als in Bezug auf $k_2''/[H_2O]$. Die Unterschiede bei $k_2'/[C_2H_5OH]$ übersteigen kaum die Versuchsfehler. Doch ist auch in Bezug auf $k_2'/[C_2H_5OH]$ mit Änderung der Temperatur ein merkbarer Gang zu erkennen. Dies ist ersichtlich, wenn man die sich aus den Angaben der Kolumne 4 ergebenden Werte

b) $E = 25{,}11$ kcal ; log $A = 8{,}59$

mit den Werten *a*) vergleicht. Die Kurven 1 der Abbildung 1 zeigen die nach den Werten *a*) und *b*) berechnete Abhängigkeit des Geschwindigkeitskoeffizienten von der Temperatur.

Wegen der verhältnismässig nahen Übereinstimmung der Werte $k_2'/[C_2H_5OH]$ der Kolumnen 2 und 4 der Tabelle 6 sind die Werte der Kolumne 4 wahrscheinlich annähernd gleich den Werten von $k_2'/[C_2H_5OH]$ in je einem der Gemische II, III und IV. Deshalb wurde $k_2''/[H_2O]$ mit Hilfe der nach den Werten *b*) sich ergebenden Werte von $k_2'/[C_2H_5OH]$ in jeder der Lösungen II, III und IV einzeln berechnet. Auch in dem von den übrigen Gemischen betreffend Zusammensetzung am meisten abweichenden Gemische V wurde $k_2''/[H_2O]$ in derselben Weise berechnet, obgleich es in die obigen Berechnungen nicht aufgenommen war, da in diesem Fall die Äthanolyse neben der Hydrolyse von untergeordneter Bedeutung ist und die Berechnung von $k_2''/[H_2O]$ deshalb weniger von der Genauigkeit des Wertes von $k_2'/[C_2H_5OH]$ abhängt. Die nach dem obigem erhaltenen Werte von $k_2''/[H_2O]$ sind in Tabelle 7 angegeben.

Ausser den Messungen bei 45°, 55°, 65° und 75°C sind in den Tabellen 5 und 7 auch die Ergebnisse der Messungen bei einigen niedrigeren Temperaturen angegeben. Die berechneten Werte der Tabellen 5, 6 und 7 sind mit den in der Tabelle 9 angeführten Werten von $\log A$ und E erhalten worden. Die Übereinstimmung der berechneten Werte mit den gemessenen ist auch bei den Temperaturen 25°, 35°, und 40°C gut; die bei diesen Temperaturen

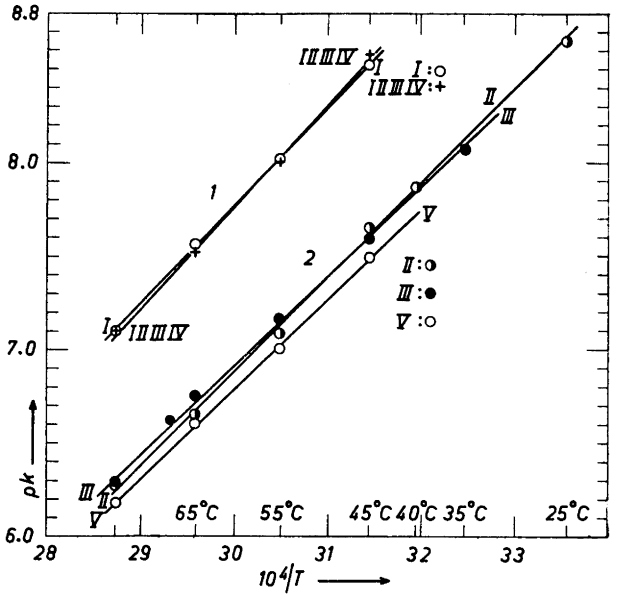

Abbildung 1. Die Abhängigkeit der Geschwindigkeitskoeffizienten von der Temperatur. 1 : p(k_2'/[C_2H_5OH]) nach den Messungen in Äthanol (I) und in den Gemischen I, II, III und IV. 2 : p (k_2''/[H_2O]) in den Gemischen II, III und V.

ausgeführten Messungen wurden zur Berechnung der Temperaturkoeffizienten nicht verwendet.

Die Abhängigkeit der Geschwindigkeitskoeffizienten k_2'/ [C_2H_5OH] und k_2''/ [H_2O] von der Temperatur in verschiedenen Gemischen ist aus der Abbildung 1 ersichtlich.

DISKUSSION

Wie aus Tabellen 6 und 7 und aus der Abbildung 1 zu ersehen ist, übersteigt die Änderung von k_2'/ [C_2H_5OH] mit der Zusammensetzung des Wasser-Äthanolgemisches kaum die Versuchsfehler der bei 45° bis 75° ausgeführten Messungen der Gemische I, II, III und IV. Auch betreffend k_2''/ [H_2O] ist ist die Änderung der Gemische II, III und IV verhältnismässig klein. Danach ist die Geschwindigkeit der Äthanolyse und der Hydrolyse in den genannten Gemischen annähernd proportional der stöchiometrischen Konzentration des Äthanols bzw. des Wassers. In dem Gemisch V weicht der erhaltene Wert von k_2''/ [H_2O] etwas mehr von den in den anderen Gemischen berechneten Werten ab, als sich die in diesen erhaltenen Werte voneinander unterscheiden.

In Tabelle 8 ist der Wert des Verhältnisses k_2''/ [H_2O] : k_2'/[C_2H_5OH] in verschiedenen Wasser-Äthanolgemischen und bei verschiedenen Temperaturen dargestellt. Der Wert nimmt beim Abnehmen der Temperatur zu. Das Gemisch V unterscheidet sich von den übrigen Gemischen II, III und IV

dadurch, dass der Geschwindigkeitskoeffizient der Hydrolyse im Gemisch V im Vergleich mit dem Geschwindigeitskoeffizienten der Äthanolyse grösser ist in den anderen Gemischen.

Tabelle 8. Das Verhältnis $k_2''/[H_2O]:k_2'/[C_2H_5OH]$.

Lösungsmittel / °C	II	III	IV	V
75	6,7	5,7	6,0	7,8
65	7,3	6,6	7,0	9,0
55	8,0	7,6	8,1	10,2
45	8,6	8,8	9,5	10,7

Tommila, Tiilikainen und Voipio [8] haben die Geschwindigkeitskoeffizienten der Hydrolyse verschiedener Alkylhalogenide in Aceton-Wassergemischen gemessen und auf Grund der Abhängigkeit der Aktivierungsenergie und der Aktivierungsentropie von der Zusammensetzung des Gemisches den Einfluss der Solvatation auf die Hydrolysegeschwindigkeit diskutiert.

Auch in den Wasser-Äthanolgemischen ist wegen der Bildung der Wasser-Äthanolsolvate die Solvatation bei der Diskussion der Abhängigkeit der Hydrolyse- und Äthanolysegeschwindigkeit von der Zusammensetzung des Gemisches zu berücksichtigen. Der Einfluss der Zusammensetzung des Wasser-Äthanolgemisches auf die Geschwindigkeit der Solvolyse von Äthylbromid erscheint am deutlichsten in der Abhängigkeit der Geschwindigkeitskoeffizienten von der Temperatur und dementsprechend auch in den in der Tabelle 9 dargestellten Werten der Aktivierungsenergie E, der Aktionskonstante A und der Aktivierungsentropie ΔS^*.

Tabelle 9. Aktivierungsenergie, Aktionskonstante und Aktivierungsentropie der Solvolyse von Äthylbromid in Wasser-Äthanolgemischen.

Reaktion	Lösungsmittel	E (kcal)	log A	ΔS^* (cal)
Äthanolyse	I	24,05	7,90	−22,8
»	I II III IV	25,11	8,59	−19,6
Hydrolyse	II	23,28	8,28	−21,5
»	III	21,95	7,38	−25,2
»	IV	21,79	7,30	−25,6
»	V	22,17	7,65	−24,0

Der verhältnismässig geringe Einfluss der Änderung der Zusammensetzung des Lösungsmittels auf die Geschwindigkoeffizienten der Äthanolyse und der Hydrolyse wird von den miteinander parallelen Veränderungen von E und ΔS^* verursacht. Entgegen der durch das Steigen von E verursachten Verkleinerung des Geschwindigkeitskoeffizienten wirkt das gleichzeitige Steigen

der Aktivierungsentropie, welches auf den Geschwindigkeitskoeffizienten nach der Gleichung [9].

$$A = 2{,}1 \times 10^{10}\ T\ e^{\Delta S^*/T}$$

erhöhend einwirkt.

Beim Hinzufügen von Wasser zu Äthanol steigt sowohl E als ΔS^* der Äthanolyse. Dieses kann als von der Solvatation der Äthanolmoleküle durch die Wassermoleküle verursacht erklärt werden. Denn hierdurch sinken die Äthanolemoleküle auf ein niedrigeres Energieniveau, was eine Vergrösserung der Aktivierungsenergie veranlasst. Zugleich wirkt die Solvatation auf die Ordnung der Atome der reagierenden Komponente vergrössernd, weshalb die Verkleinerung der Entropie bei der Bildung des einen grösseren Ordnungsgrad und eine niedrigere Entropie besitzenden Übergangskomplexes geringer ist als in dem wasserfreien Äthanol. Dementsprechend ist die Aktivierungsentropie der Äthanolyse in wasserhaltigem Äthanol weniger negativ als in wasserfreiem Äthanol.

Weil die Berechnung von $k_2''/[H_2O]$ nur indirekt aus k_2 durch Anwendung der mit gewissen Annahmen berechneten Werte von $k_2'/[C_2H_5OH]$ auszuführen ist, kann die Abhängigkeit der Aktivierungsenergie und der Aktivierungsentropie von der Zusammensetzung des Gemisches in Bezug auf $k_2''/[H_2O]$ nur in grossen Zügen betrachtet werden. In entsprechender Weise wie bei der Äthanolyse kann das Steigen von E und ΔS^* der Hydrolyse bei Zunahme der Äthanolkonzentration in den Gemischen II, III und IV als von der Solvatation verursacht erklärt werden. Denn in diesem Fall ist die Solvatation der Wassermoleküle durch die Äthanolmoleküle verhältnismässig um so vollständiger, je geringer die Konzentration des Wassers ist. Beim Übergang von IV zu V ist die Veränderung von E und ΔS^* von den erwähnten Verhältnissen abweichend, indem sowohl E als ΔS^* bei der Abnahme der Äthanolkonzentration steigen. Das Ansteigen des ΔS^* beim Übergang von IV zu V könnte erklärt werden durch Abnahme der Entropie der Wassermoleküle, z.B. durch Assoziation, welche bei kleineren Äthanolkonzentrationen eine grössere Wirkung auf die Aktivierungsentropie hat als die Solvatation durch die Äthanolmoleküle.

Nach der obigen Betrachtung kann bezüglich der Werte von E und ΔS^* der behandelten Solvolysereaktionen die Abhängigkeit von der Zusammensetzung des Lösungsmittels in den wasserärmsten Gemischen als von den veränderten Solvatationshältnissen verursacht erklärt werden. Die trotz der Änderung von E und ΔS^* relativ gute Konstanz der Geschwindigkeitskoeffizienten bei der Veränderung der Zusammensetzung des Gemisches beruht darauf, dass die Veränderung von E und die von ΔS^* in ihrer Wirkung auf die Geschwindigkeitskoeffizienten sich zum grössten Teil gegenseitig kompensieren.

Bei der Ausführung der Messungen sind mir K. Arnala, Eva Lindell, P. Ollari, Hilkka Siltanen, und L. Uino behilflich gewesen.

Die Ausführung dieser Arbeit ist von *Valtion Luonnontieteellinen Toimikunta* mit einem Stipendium unterstützt worden, wofür ich meinen Dank ausspreche.

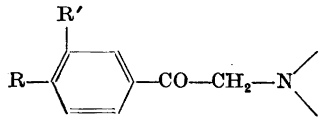
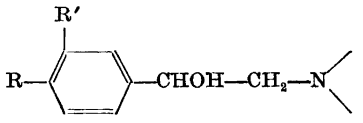
Amines Related to Adrenaline Containing Nuclear Chlorine



RICHARD DAHLBOM and ALFONS MISIORNY

Research Laboratories, AB Astra, Södertälje, Sweden

A number of amines related to adrenaline and noradrenaline containing nuclear chlorine have been prepared and tested for antiadrenaline and antinoradrenaline activity.

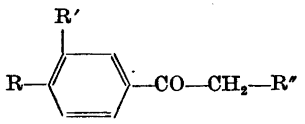


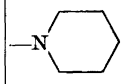
Several investigators have been interested in amines related to adrenaline and noradrenaline containing chlorine in the 3- and/or 4-position of the benzene nucleus. Thus Glynn and Linnell [1] prepared α-3,4-dichlorophenyl-β-aminoethanol from 3,4-dichloro-ω-aminoacetophenone. Edkins and Linnell [2] synthesised a number of ω-aminoacetophenones containing halogen substituents in 3- or 4-position but were unable to reduce them to the corresponding alcohols. Similar difficulties met Hansen [3] who prepared 3-chloro-4-hydroxy-ω-methylaminoacetophenone. However, the synthesis of α-(3-chloro-4-hydroxyphenyl)-β-methylaminoethanol and its ethyl analogue was performed by Fosdick, Fancher and Urbach [4] by catalytic hydrogenation of the corresponding N-benzylated acetophenones. Finally Lutz *et al.*[5] during their search for new antimalarials prepared a number of halogen substituted dialkylaminoacetophenones which were reduced to the corresponding alcohols by means of aluminium *iso*propoxide.

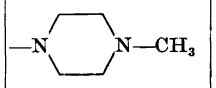
In the course of an investigation on drugs with potential antiadrenaline effect, a number of compounds of type I and II were synthesised. As amino components, piperidine and substituted piperazines were mainly used because of the presence of these amines in well-known adrenergic blocking drugs [6,7].

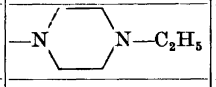
R = Cl, OH; R′ = H, Cl

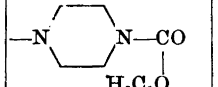
I

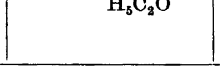












R = Cl; R′ = H, Cl

II

The compounds of type I were easily obtained from the appropriate ω-chloroacetophenone and the desired amine. The compounds of type II were prepared by the reduction of the corresponding amino ketone with lithium

aluminium hydride. The new compounds are listed in Tables 1 and 2. They have been tested for antiadrenaline and antinoradrenaline activity by Professor U.S. von Euler, Department of Physiology, Karolinska Institutet, Stockholm. In experiments on the blood pressure of cats, a weak antagonism towards adrenaline and noradrenaline was shown by the piperidino compounds 1, 10, and 11.

EXPERIMENTAL

Preparation of the amino ketones. The halogen substituted ω-chloroacetophenones required as starting material were prepared according to procedures described in literature [1,3,8].

The amino ketones were all prepared in essentially the same way. The appropriate ω-chloroacetophenone (0.025 mole) and the amine (0.065 mole) were dissolved in toluene (usually 25 ml) and the reaction mixture was kept at room temperature overnight. The amine hydrochloride was removed by filtration and the toluene solution was washed with water and then extracted with 2 N hydrochloric acid. The extract was made alkaline with sodium carbonate solution and the precipitated base was extracted with ether. The ether was dried over sodium sulphate and the amino ketone was then isolated as the hydrochloride by the addition of ethereal hydrogen chloride and recrystallised. The physical properties of these compounds are listed in Table 1.

Preparation of the amino alcohols. A solution of the free amino ketone (0.02 mole) in ether (100 ml) was prepared from the pure hydrochloride and was added, with mechanical stirring, to a suspension of lithium aluminium hydride (0.015 mole) in ether (100 ml). The mixture was stirred under reflux for 15 min. Excess hydride was destroyed with water and the mixture was made alkaline with 2 ml of 5 N sodium hydroxide. The ethereal layer was then decanted and dried over sodium sulphate. Evaporation of the solvent yielded the almost pure crystalline amino alcohol. In one case (compound 12), an oily product was obtained which was purified by distillation. The physical properties of the amino alcohols are listed in Table 2.

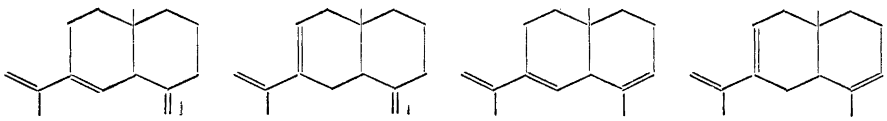
The Chemistry of the Natural Order Cupressales

XVIII *. Nootkatene, a New Sesquiterpene Type Hydrocarbon from the Heartwood of *Chamaecyparis nootkatensis* (Lamb.) Spach.

H. ERDTMAN and J. G. TOPLISS

Organisk-kemiska institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

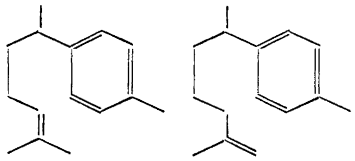


A preliminary study of the neutral constituents of the heartwood extractives of "Alaska yellow cedar" (*Chamaecyparis nootkatensis*) has been carried out. Terpenoid hydrocarbons, alcohols and carbonyl containing compounds were obtained in addition to carvacrol methyl-ether previously reported. A sesquiterpene hydrocarbon "nootkatene" was isolated in an apparently pure state. It contains three double bonds, two of which are conjugated and since it yields eudalene on dehydrogenation appears to be a dehydroselinene. The alcohol fraction similarly yielded 1-methyl-7-ethyl-naphthalene. Like the carbonyl fraction it appears to contain C_{14}-components, presumably related to nootkatene

Earlier investigations [1] have shown that the heartwood of *Chamaecyparis nootkatensis* contains a large quantity of extractable neutral material in addition to nootkatin [2], carvacrol [1] and chamic and chaminic acids [3]. A previous examination of the low boiling neutral oils revealed the presence of carvacrol methyl ether [4].

The sesquiterpene fraction of the neutral oil has now been examined and we wish to give a preliminary account of the findings. Fractional distillation has shown the main hydrocarbon component to be a liquid b.p. 134°/11 mm, n_D^{25} 1.5222, $[\alpha]_D$ —177° ($CHCl_3$), d_{24}^{24} 0.933, $[R_L]_D$ 66.86, for which the name *nootkatene* is proposed. The carbon-hydrogen analysis corresponds to a molecular formula of $C_{15}H_{22}$ and catalytic hydrogenation revealed the presence of 3 double bonds in the molecule. Dehydrogenation with selenium gave eudalene in moderate yeld, identified as the picrate. Moreover, the ultraviolet absorption spectrum of the compound shows a maximum at 235 mμ, ε 13 500, indicative of a conjugated diene system with three or four substituents, and the infra-red absorption spectrum (very strong band at 890 cm^{1-} and strong

* Part XVII *Acta Chem.Scand.* **10** (1956) 1563.



band at 827 cm^{-1}) points to the presence of a terminal methylene group and a trisubstituted double bond. Ozonolysis afforded formaldehyde but no acetone. Hence these preliminary studies reveal that nootkatene can be regarded as a dehydroselinene, the most probable structral possibilities being I to IV although certain other structures are not rigidly excluded on the basis of the present evidence.

I II III IV

The conjugated double bond system as given in formulae I to IV would give on 1,4-addition a tetrasubstituted double bond which might be expected to be rather unreactive. Since catalytic hydrogenation of nootkatene using 10 % palladium charcoal in ethanol and the action of bromine in chloroform resulted in incomplete addition to the third double bond the results may be cited as evidence in favour of the position of the diene system as shown.

The only previously reported naturally occurring $C_{15}H_{22}$ sesquiterpene type hydrocarbon appears to be *ar*- curcumene [5] (V and VI). Further studies on the structure of nootkatene are in progress.

V VI

The sesquiterpene "alcohol" fraction of *Chamaecyparis nootkatensis* has also been briefly examined. Selenium dehydrogenation yielded 1-methyl-7-ethylnaphthalene in fair yield, identified as the picrate. Chromatography of the fraction revealed the presence of a small proportion of a component or components having an α/β-unsaturated carbonyl function. Both the latter and the alcohol portion appear to be mixtures containing mainly C_{14} compounds. Efforts are now being made to find a suitable procedure for separating these compounds.

EXPERIMENTAL

Isolation of sesquiterpene components from the heartwood. Finely divided heartwood (12 kg) was extracted with acetone and the extract separated into crude acidic, phenolic and neutral fractions as described previously [1]. The crude "neutral" material (294 g) thus obtained, was distilled *in vacuo* yielding 215 g of distillate b.p. 100–190°/5 mm. This oil was then subjected to careful fractional distillation *in vacuo* using a silvered, vacuum jacketed double glass spiral column. A section of the distillation data obtained is given in Table 1.

Table 1. Pressure 11 mm. Back pressure 15 mm. Reflux ratio 25:1. Take off rate *ca.* 10 ml/hour

Fraction	Vol. of fraction (ml)	Temp.* °C	$n_D^{16.5}$	$[\alpha]_D$ ($CHCl_3$)
a	3	132.0	1.5171	−41.5
b	3	132.5	1.5175	−53
c	4	133.25	1.5298	−82
d	3	133.75	1.5211	−107
e	3	133.75	1.5220	−126
f	3	134.0	1.5233	−146
g	3	134.0	1.5240	−160
h	3	134.0	1.5247	−169
i	3	134.0	1.5250	−175
j	3	134.0	1.5256	−177
k	3	134.0	1.5256	−166
l	3	141.5	1.5247	−149

* Temperatures were taken at the end of each fraction.

Fraction (j) was analysed by the sorption method of Blohm [6] with the following results. Sample n_D^{25} 1.5221. Fractions, as removed from silica gel column (1) n_D^{25} 1.5212 (2) n_D^{25} 1.5221 (3) n_D^{25} 1.5222 (4) n_D^{25} 1.5222 (5) n_D^{25} 1.5222 (6) n_D^{25} 1.5220. Thus this result coupled with the distillation data provides good evidence for the fact that fraction (j) is an essentially pure sample of a new sesquiterpene hydrocarbon, *nootkatene*. The physical data relating to nootkatene (all determined on fraction j) may then be stated as follows: b.p. 134°/11 mm; n_D^{25} 1.5222; $[\alpha]_D$ −177° (*c* 2.02 in $CHCl_3$); d_{24}^{24} 0.933; $[R_L]_D$ 66.86; ultra-violet spectrum, max 235 mμ (ε 13 500); infra-red spectrum, very strong band at 890 cm^{-1} and strong band at 827 cm^{-1}. (Found: C 88.60; H 10.77. $C_{15}H_{22}$ requires: C 89.02; H 10.96)

Nootkatene did not give a crystalline adduct on refluxing with maleic anhydride in dry xylene for 5 h nor a crystalline hydrochloride on treatment with dry hydrogen chloride in dry ether at −10° for 1 h.

Hydrogenation experiments. (a) Nootkatene (0.268 g) was hydrogenated in glacial acetic acid solution (25 ml) in the presence of Adams' catalyst (0.051 g) at room temperature and atmospheric pressure. Hydrogenation ceased after 108 ml (3.1 mole) of hydrogen had been absorbed in 40 min. The rate of uptake of the third mole was somewhat slower than that of the first two.

(b) A further sample of the hydrocarbon (0.202 g) in ethanol (20 ml) was reduced at atmospheric pressure and room temperature in the presence of a 10 % palladium charcoal catalyst (0.071 g). 51 ml (2 mole) of hydrogen were absorbed in 18 min. The rate of uptake then dropped noticeably and 70 % of a third mole of hydrogen was absorbed over 65 min at which point the hydrogenation ceased.

Bromine titration. To nootkatene (0.5111 g) in chloroform (10 ml) was added a solution of bromine in chloroform of known concentration from a burette. 39.4 ml of the bromine solution (≡ 2 mole of bromine) was rapidly decolourised. A further 8.7 ml was then decolourised at an appreciably slower rate after which the uptake became too slow for effective measurement.

Dehydrogenation. Nootkatene (0.53 g) was heated with selenium powder (1 g) for 13 h at 300°±10°. The product was extracted with ether and after filtration the ether was evaporated and the residue distilled *in vacuo*, giving a faintly coloured oil (0.423 g), b.p. *ca.* 130°/7 mm, showing an ultra-violet absorption spectrum typical of a naphthalene hydrocarbon *viz.* max 227, 280, and 320 mμ, ε 36 000, 2 000 and 240, respectively. The picrate which crystallised out on mixing concentrated warm ethanolic solutions of the hydrocarbon (0.40 g) and picric acid (0.40 g) had m.p. 93−94° (corr) and amounted to 0.110 g. The mother liquors on concentration yielded a further 0.125 g of picrate m.p. 89−91° (corr). Recrystallisation of the first picrate batch from ethanol gave pure eudalene picrate as fine needles m.p. 93.5−94.5 (corr.), undepressed on admixture with authentic eudalene picrate.

Ozonolysis. Nootkatene (0.483 g) dissolved in a mixture of dry chloroform (8 ml) and dry carbon tetrachloride (2 ml) was ozonised until no more ozone was being taken up as indicated by iodine titration (*ca.* 30 min). The exit gases were bubbled through a trap containing a small quantity of water and after the ozonolysis was complete the water in the trap was mixed with an equal volume of concentrated aqueous dimedone solution and on scratching a small quantity of formaldehyde-dimethone separated m.p. 190—191° (corr), undepressed on admixture with authentic formaldehyde-dimethone. The ozonide was obtained as a glass by evaporation of the solvent under water pump vacuum at 0°. The exient vapours during this evaporation were passed through an aqueous solution of 2,4-dinitrophenylhydrazine hydrochloride but no significant precipitate was obtained. Water was added to the ozonide and the mixture was refluxed for 30—60 min with precautions for trapping any outgoing vapours with 2,4-dinitrophenylhydrazine hydrochloride solution. However no volatile aldehydes or ketones were detected during this period. The mixture was then distilled into aqueous 2,4-dinitrophenylhydrazine hydrochloride solution whereupon an insoluble 2,4-dinitrophenylhydrazone was precipitated. After a short time this was collected by filtration and dried, m.p. 162—165° (corr), undepressed on admixture with authentic formaldehyde 2,4-dinitrophenylhydrazone, m.p. 167—168° (corr). The non-steam volatile product was extracted with ether and the acidic material was separated by alkali extraction and isolated as a gum by acidification and ether extraction in the usual way (0.193 g). The neutral portion, obtained as an oil, amounted to 0.083 g. Both the acidic and neutral products failed to crystallise.

Sesquiterpene "alcohol" fraction. From the continuation of the fractional distillation of the oil described in the isolation of nootkatene a considerable number of fractions, amounting in all to 50—60 ml of viscous oil, b.p. 140—150°/3 mm, $n_D^{16.5}$ 1.5179—1.5254, $[\alpha]_D$ +31 — +107°, were obtained. The physical constants of the various fractions showed a definite drift between the limits given but it was clear that no clear cut separation of the components had occurred. The middle fractions, which showed an appreciable absorption in the ultra-violet with a maximum at 235 mμ and ε values of 2 000—3 000 were further investigated as described.

Dehydrogenation. "Alcohol fraction" (1.2 g) was heated with selenium powder (2.0 g) at 290—300°. After 4 h a further 1.0 g of selenium was added and the dehydrogenation was continued for a further 18 h at the same temperature. The product was isolated by ether extraction and distilled *in vacuo* affording 0.482 g of distillate b.p. 120—160°/7 mm (bath temp) which was then passed through a short alumina column in petroleum ether (40—60°) yielding 0.334 g of purified product. The ultra-violet absorption spectrum of the product showed maxima at 228, 280 and 321 mμ typical of a naphthalene hydrocarbon. The hydrocarbon picrate prepared in the usual manner melted at 95.5—96.5° (corr) after recrystallisation from ethanol (Found: C 57.03; H 4.78; N 10.54. Calc. for $C_{19}H_{17}O_7N_3$: C 56.99; H 4.28; N 10.50). Thus the analysis of the picrate suggests that the molecular formula of the hydrocarbon is $C_{13}H_{14}$. The hydrocarbon trinitrobenzene adduct prepared from the hydrocarbon and somewhat less than the theoretical quantity of 1,3,5-trinitrobenzene in methanol crystallised from methanol as yellow needles, m.p. 106.5—107.5° (corr.) (Found: N 11.12. $C_{19}H_{17}O_6N_3$ requires N, 10.96). The melting point of the picrate was not depressed on admixture with a synthetic specimen of 1-methyl-7-ethylnaphthalene picrate, kindly supplied by Prof. D. H. R. Barton, or with a specimen of the same compound prepared from santonin and kindly supplied by Prof. W. Cocker.

Chromatography of "Alcohol fraction". "Alcohol fraction" (1.89 g) was dissolved in a small volume of petroleum ether (40—60°) and chromatographed on a column of alumina (175 g). Elution with 15 % ether in benzene removed a component (0.317 g) having the following constants: n_D^{22} 1.5269, $[\alpha]_D$ +189 (*c* 1.7 in $CHCl_3$), ultra-violet absorption spectrum: max 235 mμ (ε 10 900); 306 mμ (ε 74). (Found: C 81.50; H 10.13. $C_{14}H_{20}O$ requires C 82.30; H 9.87. $C_{14}H_{22}O$ requires C 81.30; H 10.75). The ultra-violet absorption data is compatible with the component containing an α/β-unsaturated carbonyl function which was confirmed by the preparation of a semicarbazone using semicarbazide hydrochloride and sodium acetate in aqueous ethanol. The semicarbazone crystallised in ill defined prisms from ethanol or ethyl acetate, m.p. 190—192° (corr), unchanged on further recrystallisation, $[\alpha]_D$ +210° (*c* 0.2 in $CHCl_3$). Ultra-violet absorption, max 268 mμ (ε 28 500). (Found: C 68.47; H 9.05; N 14.61; 14.77. $C_{15}H_{24}ON_3$ requires C 68.68; H 9.21; N 16.02).

The indications are that the semicarbazone is not a single compound. The chromatography did not appear to give a very good separation of the other components of the mixture.

We are indebted to *Statens Naturvetenskapliga Forskningsråd* for financial support and to Dr. G. Widmark, Stockholms Högskola, for the sorption analysis.

Characterization of Polyelectrolyte Solutions

I. Molecular Fractionating on Ion Exchange Resins

NILS HARTLER

Uddeholms Aktiebolag, Cellulose Research Laboratory, Skoghall, Sweden *

The screening effect of anion exchange resins upon a polyelectrolyte solution containing anions of varying size is discussed. In experiments with polystyrene sulphonic acid no change in this screening effect has been found when under equilibrium conditions resins of varying degree of cross-linking are used. However, a variation in the porosity of the resin gives a change in the screening properties; a resin of high porosity being able to retain larger ions as compared with a resin of low porosity.

Resins of varying porosity are used in an ion exchange battery for the fractionation, based on differing ion size, of polyelectrolyte solutions. The limitations of the method are pointed out.

Several years ago Samuelson [1] demonstrated that anion exchange resins have a screening effect on the ions in a solution of a polyelectrolyte. When such a solution is passed through a column containing an anion exchange resin, the ions whose size is large enough to prevent penetration into the resin structure will pass through together with any non-ionic components whereas low-molecular-weight anions are retained by the resin. This arbitrary separation into low and high-molecular-weight anions is governed by a number of experimental conditions. There are indications [2] that this method classifies a low-molecular-weight anion as one with the ionic size equal to or less than 30 Å. The use of this separation has been reported by many authors in later years.

As is pointed out in many papers [3,4,5], it would be reasonable to expect a change in the screening effect by varying the degree of cross-linking of the resin, *i. e.* a resin with low degree of cross-linking (highly swollen) should be able to retain larger ions than a resin with a normal degree of cross-linking. In the present paper it is shown that under the conditions obtained in a laboratory ion exchange column with a flow-rate of about 1 ml $cm^{-2}min^{-1}$ there exists no difference in screening properties between anion exchange resins of varying

* The main part of the experimental work was done during 1953 at the College of Forestry in Syracuse, N.Y., U.S.A.

degree of cross-linking as far as a solution of polystyrene sulphonic acid is concerned. This means that under the conditions and in the system in question, a variation in the degree of cross-linking of the resin does not affect the screening properties. On the other hand, under non-equilibrium conditions a difference in screening properties between resins of different degree of cross-linking is obtained as a result of the differences in penetration rate between ions of varying size which are obtained when the degree of cross-linking is altered [6].

The above statements seem to be true for all resins of the translucent type. As demonstrated in the present paper, resins of the porous type (obtained from the Chemical Process Company, Redwood City, California, U.S.A., under the special trade name Porous Duolite) show, however, varying screening properties.

The promising results with the porous resins justified investigating them as possible fractionating agents for polyelectrolytes. Provided that a porous resin gives a sharp fractionation based on the degree of polymerisation or preferably the ionic size, the prime requisite for satisfactory fractionation exists.

EXPERIMENTAL

Materials

The resins. All the resins were ground and screened to a particle size 0.25—0.42 mm. The cation exchange resins were regenerated with 3 N hydrochloric acid and the anion exchange resins with a 2 N ammonium hydroxide solution.

The polyelectrolyte solution. The ammonium salt of sulphonated polystyrene, stated by the manufacturer to have an average molecular weight of about 10 000 was obtained from the Monsanto Chemical Company. The salt was dissolved in water and the free acid liberated by passing the solution through a column containing a cation exchange resin of the sulphonic acid type in the hydrogen form.

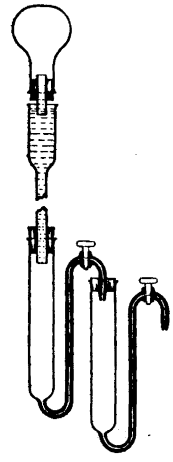

Fig. 1. Apparatus with two columns coupled in series and with arrangement for constant flow-rate through the system.

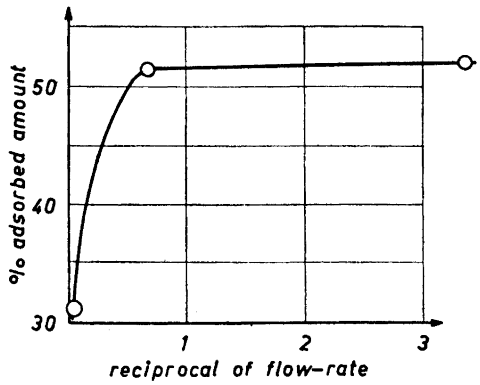

Fig. 2. The adsorbed amount of acid at different flow-rates. Column: Dowex 3.

Experiments

Fractionations with anion exchange resins of the translucent type. The separation of the polyelectrolyte into two fractions by the passage through an anion exchange column was studied under varying experimental conditions. For this study the weakly basic anion exchange resin Dowex 3 was used. The arrangements to get a constant flow-rate and to couple two columns in series are shown in Fig. 1. The polystyrene sulphonic acid liberated in the first column entered the second column, containing the anion exchange resin under study (Dowex 3). Part of the anions was adsorbed and the larger ions that were not adsorbed were found in the effluent. After washing the column with distilled water, the effluent plus the washings were titrated with 0.1 N sodium hydroxide solution using phenolphthalein as indicator. Knowing the amount of acid in the original solution, the adsorbed amount of acid was calculated by

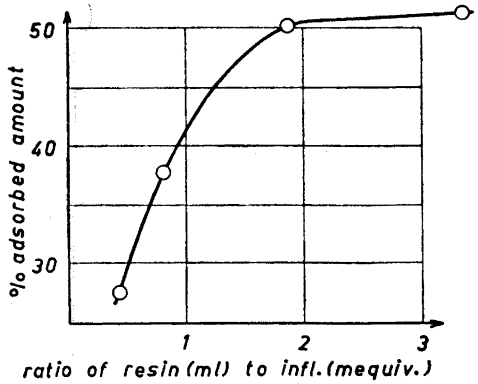

Fig. 3. Variation of the amount of adsorbed acid with varying ratios of resin to influent. Column: Dowex 3.

Table 1. Effect of resin cross linkage on ion adsorbtion. Influent: 2.8 % solution containing 1.38 mequiv acid; flow-rate: 1 ml min^{-1}; ratio resin (ml) to influent (mequiv): 7.

Type of resin	Degree of cross-linking	Amount of acid in the effluent, mequiv	Adsorbed acid as per cent of acid in influent
Dowex 1	about 8	0.645	53.2
» 1	1	0.652	52.8
» 1	10	0.654	52.6
Amberlite IRA-400	—	0.643	53.4
Amberlite IR-4B	—	0.647	53.1

difference. In some experiments this procedure was checked by elution with 1 N sodium hydroxide solution and estimation of the retained acids, and good agreement was obtained.

As is seen from Fig. 2, a flow-rate of 1 ml per min or lower represents equilibrium conditions. Furthermore, a resin to influent ratio of 2 or higher is needed to give a sharp fractionation, Fig. 3. The exchange capacity of the resin is about 0.5 mequiv/ml for this particular range of ionic size as compared with 2.7 mequiv/ml for really low-molecular-weight ions.

The same experimental technique was used in order to study the influence of the degree of cross-linking of the resin. In Table 1 the fractionation results are given for the strongly basic anion exchange resin (Dowex 1) against varying degrees of cross-linking which is given as per cent and is equal to the amount of divinylbenzene used in the polymerisation step in the preparation of the resin. In Table 1 two Amberlite resins are also included, one strongly basic (Amberlite IRA-400) the other weakly basic (Amberlite IR-4B).

As seen in Table 1 a variation from 1 to 10 in the degree of cross-linking does not give any difference, within experimental error, in the screening properties of the resin.

Fractionation with a combination of anion exchange resins of the translucent and of the porous type. With the same experimental conditions, porous resins adsorb a greater amount of acids from a given polyelectrolyte solution in comparison with translucent ones, and furthermore, there are resins with different acid retaining capacity, representing a variation in porosity. For one and the same resin, however, the capacity changes with the ratio resin (ml) to influent (mequiv) with the range that has been studied (Fig. 4). For fractionating on an absolute basis this is a very great draw-back that cannot be overcome but for comparative purposes, on a qualitative basis, this type of resin can be used to obtain a rapid answer as to the distribution of the degree of polymerisation for a polyelectrolyte.

As an illustration the following experiment was made. An exchange battery of the type illustrated in Fig. 1 was used with four columns coupled in series according to Fig. 5. In the first column the conversion to polystyrene

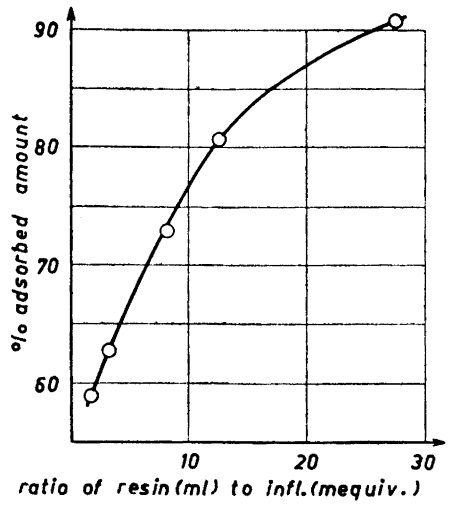

Fig. 4. Variation of the amount of adsorbed acid with varying ratios of resin to influent. Column: Duolite A2.

sulphonic acid occurred and in the last three columns the anions were selectively adsorbed. 50 ml of the polyelectrolyte solution containing 14.11 mequiv were passed through the battery followed by washing with distilled water. The effluent was collected, reference fraction 4, and the columns were separated. Each column was separately eluted with 100 ml 1 N sodium hydroxide solution with subsequent washing with distilled water. In order to remove excess of sodium hydroxide and to convert the salts into the corresponding acids, the collected eluates were passed through columns containing a sulphonic acid cation exchange resin in the hydrogen form. The processed eluate from column 2 was termed fraction 1, that from column 3 fraction 2, and that from column 4 fraction 3. The amount of acid in each fraction was then determined by titration with 0.1 N sodium hydroxide solution against phenolphthalein.

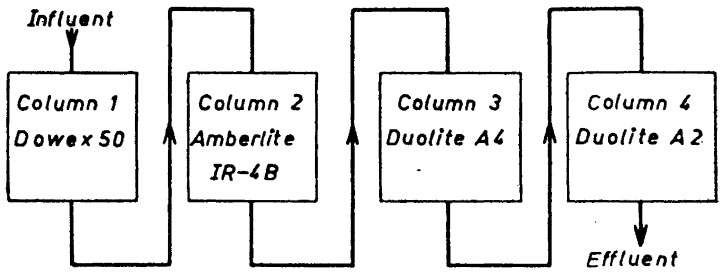

Fig. 5. Ion exchange battery for fractionation.

Table 2. Fractionation of a sample with an average molecular weight of 10 000. Influent: 50 ml containing 14.11 mequiv; flow-rate: 1 ml min^{-1}.

Fraction No.	Amount of acid		Specific viscosity at 25°C of a solution containing 8 mequiv per litre
	mequiv	%	
1	7.26	52.4	0
2	1.278	9.2	0.08
3	1.502	10.8	0.30
4	3.805	27.5	0.71
total	13.85	99.9	

An aliquot of each fraction was diluted to a concentration of 8 mequiv acid per litre and the specific viscosity was measured at 25°C in Ostwald viscometers. The results are given in Table 2.

There is no doubt that the procedure used separated the polystyrene sulphonic acid into fractions with gradually increasing molecular weight. However, as already pointed out, the great disadvantage is that the amount of acid in each fraction depends not only on the properties of the sample and of the resins used but also to a great extent on the experimental conditions.

The fractionating battery according to Fig. 5 gave results as reported in Table 2 for a sulphonated polystyrene with an average molecular weight of 10 000. Another sample of sulphonated polystyrene with a higher average molecular weight (70 000) has been fractionated on the same battery and with the same experimental conditions. The results are given in Table 3. As might be expected the polyelectrolyte with the higher average molecular weight gives smaller amounts of acid in fractions 2 and 3 and higher in fraction 4.

CONCLUSIONS

A variation in the degree of cross-linking from 1 to 10 % for the strongly basic anion exchange resin Dowex 1 did not cause any change in the screening properties of the resin (Table 1). This means that the various resins when used

Table 3. Fractionation of a sample with an average molecular weight of 70 000. Influent: 60 ml containing 15.60 mequiv acid; flow-rate: 1 ml min^{-1}.

Fraction No.	Amount of acid	
	mequiv	%
1	8.21	53.1
2	0.95	6.15
3	0.50	3.23
4	5.80	37.7
total	15.46	100.2

in excess in column operation, retained the same amount of acid from a given polystyrene sulphonic acid solution. It is further interesting to note that the same amount of acid is taken up also by the strongly basic resin (Amberlite IRA-400) and the weakly basic resin (Amberlite IR-4B).

It should be pointed out that the above observations have been made under equilibrium conditions, *i. e* at a low flow-rate. Under non-equilibrium conditions, however, the uptake may very well be different for different resins of the translucent type.

As shown in Tables 2 and 3 porous resins with the general trade name Duolite can retain larger ions in comparison with translucent resins. If three columns containing resins of varying porosity are coupled in series, Fig. 5, this ion exchange battery can, as shown in Tables 2 and 3, be used for fractionating the polystyrene sulphonic acid. The solution to be analysed is passed through resins of successively increasing porosity. Each resin retains ions within a specific size range. Hence, a fractionation based on ionic size takes place.

The results from fractionations according to the proposed method can, however, only be used for comparative purposes, because the range of size of retained ions for a particular resin is not constant but varies with the ratio of the amount of resin to the amount of added ions.

Characterization of Polyelectrolyte Solutions

II. Separation of Strong and Weak Acids by means of Ion Exclusion

NILS HARTLER

Uddeholms Aktiebolag, Cellulose Research Laboratory, Skoghall, Sweden *

Ion exclusion as applied to quantitative separation on a laboratory scale is described in detail. A separation based on ionic size of the acid components in sulphite waste liquor by means of ion exchange and on the basis of acid strength by means of ion exclusion reveals interesting facts as regards the composition of such a liquor.

The method as applied to a mixture of weak and strong acids gives information as to whether the weak acid groups are attached to the same or to separate molecules as the strong acid groups.

When an electrolyte solution is brought into contact with an ion exchange resin and the counter ions in the resin and in the solution are the same, no ion exchange takes place but a redistribution of the ions between the outer solution and the inner resin phase results. A strong electrolyte is excluded from the resin phase (usually by as much as a factor of 10), whereas a weak electrolyte will be almost evenly distributed. These phenomena have formed a basis for the development of a new technique termed ion exclusion [1]. The method is used for the separation of strong electrolytes from weak or non-electrolytes. As is evident, the main feature with ion exclusion as compared with ion exchange chromatography is that no regeneration of the resin is needed.

EXPERIMENTAL

A. Experiment to establish suitable experimental conditions

A mixture of hydrochloric and acetic acid was passed at constant flow-rate through an ion exchange column containing a cation exchange resin of the sulphonic acid type in the hydrogen form. The mixture was followed immediately by distilled water. The effluent was collected in small fractions and each fraction analysed for the total acid content by titration with sodium hydroxide solution. Furthermore, each fraction was tested for the presence of chloride ions.

* The main part of the work was done during 1953—54 at the College of Forestry in Syracuse, N.Y., U.S.A.

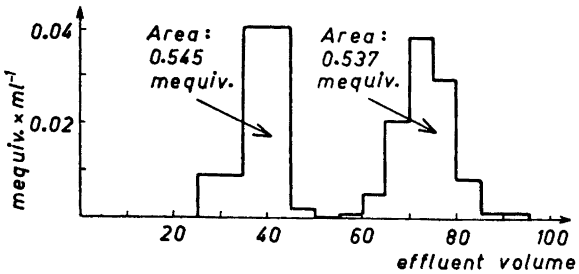

Fig. 1. Separation of hydrochloric and acetic acids by means of ion exclusion.

A number of resins with varying degree of cross-linking and of varying particle size were tested, the effect of varying the ratio of influent volume to resin volume was examined and the flow-rate varied. Only with one type of resin and with one set of variables was the separation found to operate satisfactorily. These were: Dowex 50 with 4 % cross-linking and a particle size 50—100 mesh, a ratio of influent volume to resin volume of 1 : 7, and a flow-rate of 1 ml min^{-1} cm^{-2}. A column was charged with 70 ml of such a resin in the hydrogen form and 10 ml of a solution containing 0.542 mequiv of hydrochloric acid and 0.526 mequiv of acetic acid was passed through, followed by distilled water. Fractions of 5 ml were collected and the acid concentration was plotted against the effluent volume, Fig. 1. After 50 ml had passed through the column, *i.e.* after the first peak in the curve, Fig. 1, no chloride was detected in the subsequent fractions. The total amount of acid between 25 and 50 ml effluent volume corresponded within experimental error, to the amount of hydrochloric acid in the influent, and a similar correspondance was found between the total amount of acid between 50 and 100 ml effluent volume and the amount of acetic acid in the influent.

Other mixtures of a strong and a weak acid have been tested and in all instances the strong acids have been found in the effluent fraction between 25—50 ml and the weak acids between 50—100 ml with the intermediate 50—10 ml containing no acid at all.

B. Ion exclusion and ion exchange as applied to the analysis of sulphite waste liquor

A mixture of strong and weak acid polyelectrolytes can be analysed both by means of ion exchange based on ionic size [2] and by means of ion exclusion as described above. These methods were applied to a waste liquor from a laboratory sulphite paper pulp cook

Table 1. Analytical data for the various fractions. All measurements of optical density were made at a dilution of 1 : 5 000.

Fraction	Description	Acidity		Optical density at 280 mμ
		Strong acids mequiv/ml	Weak acids mequiv/ml	
a	Original liquor	—	—	0.138
b	Hydrogen ion exchanged liquor	0.315	0.113	0.135
c	Strong acids in fraction b	0.317	0.042	0.133
d	Weak acids in fraction b	—	0.063	0.002
e	High polymer acids in fraction b after "screening" by ion exchange	0.169	0.093	0.132
f	Strong acids in fraction e	0.170	0.032	0.133
g	Weak acids in fraction e	—	0.055	0.004

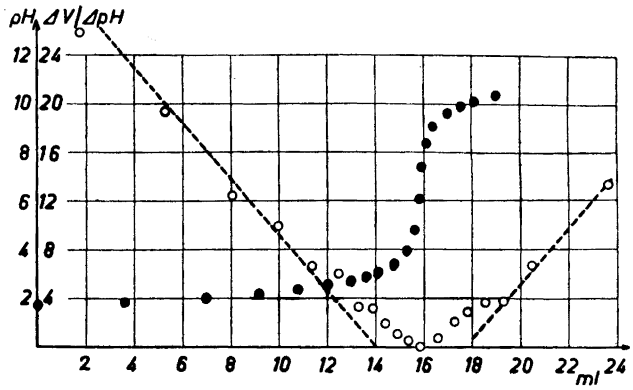

Fig. 2. Potentiometric titration plot according to Gran [3] for fraction c (Table 1).

on spruce. The metal cations in the liquor were first replaced by hydrogen ions by using a cation exchange resin of the sulphonic acid type (resulting in fraction b, Table 1). Part of this acid fraction was passed through a column containing the weakly basic anion exchange resin, Amberlite IR-4B. The high polymer acids were found in the effluent (fraction e, Table 1), whereas the low-molecular-weight acids were adsorbed by the resin. By means of the ion exclusion technique described above the original hydrogen ion exchanged liquor (fraction b) and the high polymer acid fraction (fraction e) were each separated into two fractions, *viz.* the strong acid fraction and weak acid fraction. The various fractions were analysed for the total content of acid by potentiometric titration with 0.1 N sodium hydroxide solution and for lignin content by measuring the optical density in a Beckman spectrophotometer, model DU, at 280 mμ after suitable dilution. The results from the potentiometric titrations were evaluated according to the Gran method [3] in order to determine separately the weak and strong acids. The results are given in Table 1.

In fraction c and f only strong acids should be present but when a molecule contains strong as well as weak acid groups, the latter will necessarily be found in the strong acid fraction. The potentiometric titration diagrams are given in Fig. 2 for fraction c and in Fig. 3 for fraction d. The abnormal shape of the curve in Fig. 2 between pH 7 and 10 is caused by the alkali consumption of the originally present phenolic groups as well as those formed during the titration. The weak acid fraction, Fig. 3, does not contain any appreciable amount of strong acids and in addition the curve shows normal behaviour in the alkaline pH-range.

DISCUSSION

Although the necessary conditions to obtain a satisfactory separation by means of ion exclusion require the maintenance of rather critical experimental variables within narrow limits, the method operates very well according to the procedure described above. This method is most useful when a separation of weak and strong electrolytes is desired for purification purposes. The method also gives information as to whether the weak acid groups are attached to the same molecule as the strong acids or whether they belong to separate molecules. In the former case the weak acid groups appear in the strong acid fraction but in the latter case they are found in the weak acid fraction.

The results reported in Table 1 show that the lignin sulphonic acids are found quantitatively in the high polymer fraction and in the strong acid frac-

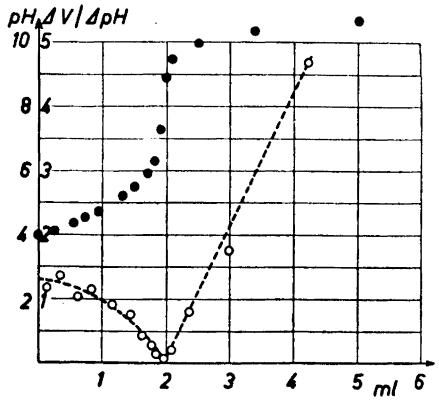

Fig. 3. Potentiometric titration plot according to Gran [3] for fraction d (Table 1).

tions. From this it can be concluded that all the lignin sulphonic acids are of high polymer nature. Similar experiments with a waste liquor from a sulphite rayon pulp cook show that the lignin sulphonic acids in this instance are partly of a low-molecular-weight nature, *i. e.* they are partly retained by an Amberlite IR4B resin. Further, it can be concluded from the results in Table 1 that only about 50 % of the strong acids in the liquor are of a high polymer nature and that the high polymer molecules containing strong acid groups also contain about 15 % weak acid groups. The liquor contains about 15 % of molecules containing only weak acid groups (calculated on an acidity basis).

Studies on the Extraction of Metal Complexes

XXVIII. The Distribution of some Actinides and Fission Products between Tributyl Phosphate (TBP) and Aqueous Solutions of HNO_3 and $Ca(NO_3)_2$

BRITA BERNSTRÖM and JAN RYDBERG

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The distribution ratios of U(VI), Pu(VI), Pu(IV), Th(IV), Ru, Zr(IV), Nb(V), La(III), Sr(II) and Ca(II) between tributyl phosphate (TBP) and aqueous solutions of varying concentrations of HNO_3 have been determined at room temperature for different (constant) concentrations of $Ca(NO_3)_2$ in the aqueous phase. The extraction curves are discussed with respect to the different complexes formed and to the possibility of using the investigated systems for separating plutonium and uranium from the fission products.

In the previous paper of this series of investigations (Part XXVII [1]) the extraction of plutonium, uranium and some fission products from aqueous solutions into the organic solvent methyl *iso*butyl ketone (hexone) was studied as a function of the HNO_3 and $Ca(NO_3)_2$ concentrations in the aqueous phase. These investigations have here been extended to the organic solvent tributyl phosphate (TBP); in this paper, only the case of pure TBP is reported (*i.e.* no organic diluent added). No extensive investigations of metal extractions with 100 % TBP seem to have been reported previously [2,3].

The following metals (valency states in aqueous solutions — if known — are given within parenthesis) have been studied: U(VI), Pu(VI), Pu(IV), Th(IV), Ru, Zr(IV), Nb(V), La(III), Sr(II) and Ca(II). The concentration of the metal nitrates never exceeded 0.1 M (except for Ca), while the HNO_3 concentration was varied from $\sim$ 0.1 to 10 M, and the $Ca(NO_3)_2$ concentration from 0 to $\sim$ 4 M. The results are given in the form of curves (Figs. 1—7) showing the distribution ratio of a metal as a function of the equilibrium HNO_3 concentration in the aqueous phase at constant $Ca(NO_3)_2$ concentration.

EXPERIMENTAL

Chemicals. Tributyl phosphate, $(C_4H_9)_3PO_4$, of technical grade was obtained from AB Kebo. The solvent was treated with 5 % sodium carbonate and then washed with several portions of water.

UO_3 obtained from AB Atomenergi was dissolved in concentrated HNO_3, filtered and diluted. The uranium content was determined by weighing the oxide U_3O_8 after evaporation and ignition.

^{234}Th (UX_1) was used as tracer for thorium. The solutions were made $\sim 10^{-5}$ M by the addition of ^{232}Th.

A tracer solution of Pu(IV) in 10 M HNO_3 was available. Pu(VI) was obtained by oxidizing the Pu(IV) solution with 0.1 M $K_2S_2O_8$ in 1 M HNO_3 using Ag^+ as catalyst immediately before use. In one case the oxidizing agent was 0.2 M $KBrO_3$.

A carrier free solution of $^{95}Zr + ^{95}Nb$ in 0.3 M HCl and with 2 % oxalic acid was obtained from AERE, Harwell. In the distribution experiments this solution was diluted 1:50.

^{106}Ru in 0.4 M HCl was purchased from AERE, Harwell. The solution was carrier free and diluted 1:1000 before use.

^{140}La was obtained as the neutron irradiated oxide. The oxide was dissolved in 1 M HNO_3 to make the metal concentration $\sim 10^{-5}$ M.

^{89}Sr-carbonate was dissolved in concentrated HNO_3 and diluted.

The $Ca(CO_3)_2$ used was of reagent grade as were all other reagents.

Distribution experiments. All distribution experiments were carried out at room temperature (20 ± 2°C) and were run with each metal separately. The metal nitrate was mixed with varying amounts of HNO_3 and $Ca(NO_3)_2$ and shaken vigorously for 5 min with an equal volume of TBP; equilibrium is usually attained within a few minutes. The two phases were separated by centrifuging. Samples of each phase were withdrawn to determine the HNO_3 concentration of the aqueous phase as well as the metal concentration in each phase. The distribution ratio q, *i.e.* the ratio of the metal concentration in the organic phase to that in the aqueous phase, could then be calculated.

Analyses. Ca was determined by a substitution titration with EDTA (ethylenediamine tetraacetic acid) at pH 10 using Eriochrome Black T as indicator [4]. Before the titration, Ca in the TBP phase was transferred to an aqueous phase by mixing 20 ml of water with 0.5 ml of the TBP phase diluted with 20 ml of benzene.

Uranium was determined spectrophotometrically by the thiocyanate method [5,6]. Only the water phase which contained the smallest fraction of U was analysed, whereas the uranium content of the TBP phase was obtained as the difference between the initially added uranium concentration (0.1 M) and that found in the aqueous phase.

HNO_3 was determined by titration with NaOH.

The α activity of Pu was measured by an argon-methane proportional counter. By means of the TEG-method [7] dry, thin samples were obtained.

The β, γ counting of ^{140}La, ^{106}Ru (^{106}Rh) and ^{234}Th (UX_1) was made on dry samples, whereas ^{89}Sr was measured with a liquid counter. In order to increase the sensitivity of the determinations at very low and at very high distribution ratios, the volume ratio V_{TBP}/V_{aq} was varied, *i.e.* for $q_{Sr} \leq 10^{-2}$ $V_{TBP}/V_{aq} = 5$, for $q_{Th} \geq 10^2$ $V_{TBP}/V_{aq} = 0.1$. In the latter case, the small amount Th in the water phase was concentrated by a hydroxide precipitation with La as carrier thus increasing the counted activity.

For the determination of Zr and Nb separately in a mixture of both of them, the following procedure was used. By means of a lead absorber (200 mg/cm²) the β-activity was filtered away and the total γ-activity of the solution of ^{95}Zr (0.40 MeV β,; 0.71 MeV γ) $+ ^{95}Nb$ (0.15 MeV β, 0.76 MeV γ) was determined from measurements on dry samples. The fraction of γ-activity contributed by ^{95}Zr on this solution was determined by precipitating [8] the zirconium as $BaZrF_6$ and counting the precipitate through the same absorber; inactive zirconium was added as a carrier. From an average of four determinations 37.5 % of the total γ-activity was ascribed to ^{95}Zr. For the ratio $R = I_{Zr}/I_{Nb}$ we then calculate the value 0.60.

In the distribution experiments, the total γ-activity of each phase was determined (I_{TBP} respectively I_{aq}) as well as the Zr content of the water phase ($I_{Zr\ aq}$), by measuring precipitated $BaZrF_6$. q_{Zr} was calculated from the relation

$$q_{Zr} = \frac{R}{(R+1)} \cdot \frac{(I_{TBP} + I_{aq})}{I_{Zr,aq}} - 1$$

The ratio I_{TBP}/I_{aq} was found to depend on the time of mixing and increased with time, probably because equilibrium was slowly attained for Nb. For a shaking time of 5 min the distribution ratio q_{Nb} was calculated according to

$$q_{Nb} = \frac{1}{(R+1)} \cdot \frac{(I_{TBP} + I_{aq})}{(I_{aq} - I_{Zr,aq})} - 1$$

Good material balance was obtained.

RESULTS AND DISCUSSION

The distribution curves

The distribution ratio q_M (subscript refers to the metal investigated) has been plotted against the molarity of HNO_3 in the aqueous phase at equilibrium. The curves are shown in Figs. 1—7 for initial $Ca(NO_3)_2$ concentrations of 0, 1, 2, 3 and 4 M. In all cases the distribution ratios increase with increasing $Ca(NO_3)_2$ concentration. The distribution ratios also increase with increasing HNO_3 concentration except at high $Ca(NO_3)_2$ concentrations.

The distribution of HNO_3 is presented in two different ways. Fig. 1a shows the HNO_3 concentration of the TBP phase as a function of the aqueous HNO_3 concentration. Fig. 1b shows q_H as a function of the HNO_3 concentration.

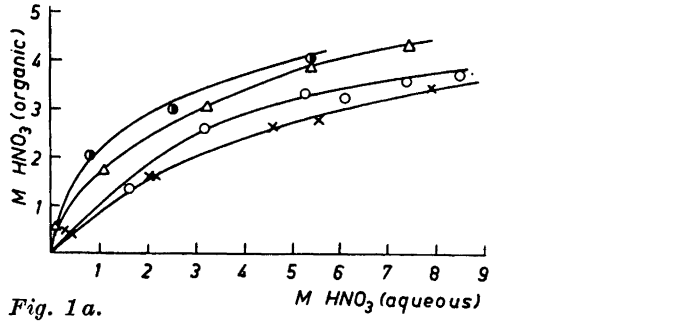

Fig. 1 a.

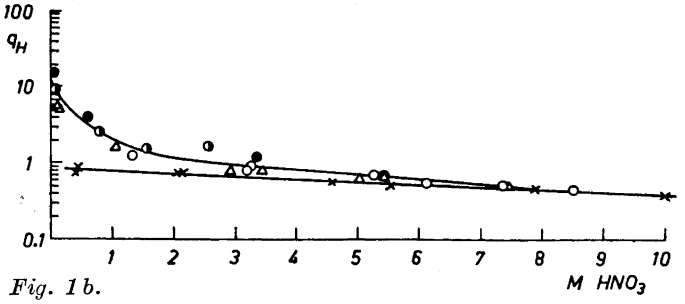

Fig. 1 b.

The distribution of HNO_3 as a function of the equilibrium concentration of HNO_3 in the aqueous phase in two different graphical representations. Concentrations of initial $Ca(NO_3)_2$: ● 4M, ◑ 3 M, △ 2 M, ○ 1 M, × no $Ca(NO_3)_2$ present.

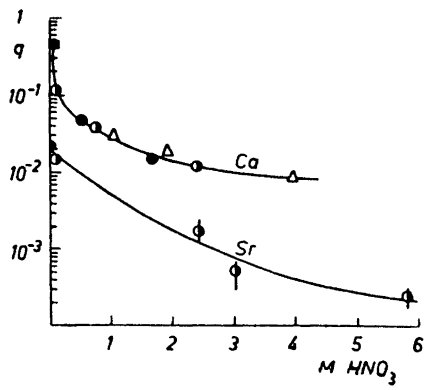

Fig. 2. The distribution ratio q of calcium and strontium as a function of the equilibrium concentration of HNO_3 in the aqueous phase. Concentrations of initial $Ca(NO_3)_2$: ● 4 M, ◑ 3 M, △ 2 M.

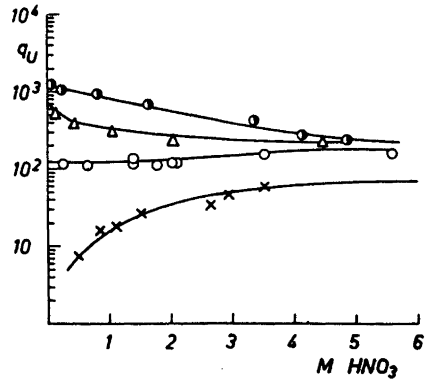

Fig. 3. The distribution ratio q_U of hexavalent uranium as a function of the equilibrium concentration of HNO_3 in the aqueous phase. Concentration of initial $Ca(NO_3)_2$: ◑ 3 M, △ 2 M, ○ 1 M, × no $Ca(NO_3)_2$ present.

These results can be compared with some data available in the literature. The distribution curve of HNO_3 with no $Ca(NO_3)_2$ present (Fig. 1a) agrees closely with that determined by Alcock *et al.*[10] It is noteworthy that at low HNO_3 concentration our results agree better with their calculated curve for a 1:1 complex of $HNO_3 \cdot TBP$ than their experimental data do[Ref. 10, Fig. 4]. Peppard *et al.*[11] report the extraction of Th and Zr into 100 % TBP from HNO_3 solutions containing no $Ca(NO_3)_2$. Their results for Th agree

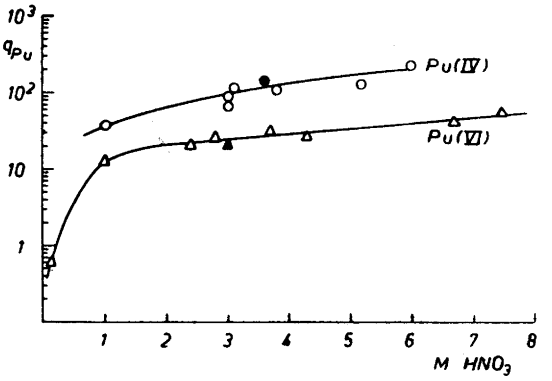

Fig. 7. The distribution ratio q_{Pu} of tetravalent and hexavalent plutonium as a function of the equilibrium concentration of HNO_3 in the aqueous phase. No $Ca(NO_3)_2$ present. Plutonium pretreated with 10 M HNO_3 ○, $NaNO_2$ ● (*cf.* Ref. 9), BrO_3^- ▲, and $S_2O_8^{2-}$ △.

with the present work except for high acidities where we obtain a lower value of q_{Th}. The presence of $H_2C_2O_4$ in our stock solution of Zr probably explains our lower value of q_{Zr} compared with Peppard's (*cf.* Bruce [12] who shows the effect of $H_2C_2O_4$ on q_{Zr}). Scadden and Ballou [13] report the extraction of Zr and Nb from HNO_3 solutions into 100 % TBP. Their data are, however, for TBP as received, which yields quite different results because of small impurities of hydrolysis products as, *e.g.*, dibutylphosphate (DBP). Peppard *et al.*[14] report $q_{La} = 0.33$ for 100 % TBP and an aqueous phase 15.6 M in HNO_3, a value which is of the same order as that determined here *.

The extraction mechanism

It can be shown [15] that if a metal M (charge N+) is extracted as a nitrate complex into TBP, the distribution Q_M of the metal between the two phases should follow eqn. (1), if only mononuclear complexes of the type $M(NO_3)_n(TBP)_s^{N-n}$ are formed (neglecting waters of hydration).

$$Q_M = \frac{\sum_0^S \lambda_{Ns}\varkappa_{Ns} \{NO_3^-\}^N \{TBP\}^s}{1 + \sum_{1,1}^{ns} \varkappa_{ns} \{NO_3^-\}^n \{TBP\}^s} \qquad (1)$$

Here { } are used to indicate activities, which all refer to the aqueous phase; $\varkappa_{ns}$ is defined as the complexity constant and λ_{Ns} as the distribution constants of the uncharged complexes $M(NO_3)_N(TBP)_s$. If the concentration of all

* *Note added in proof.* D. Scargill *et al.*[21] report q_{La} for 100 % TBP and varying HNO_3 solutions in close agreement with our data.

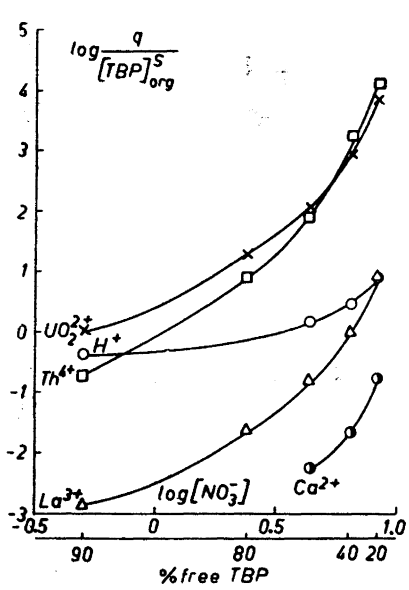

Fig. 8. The variation of $\log \frac{q}{[TBP]^S_{org}}$ with the nitrate concentration for constant $[HNO_3]_{(aq)} = 0.5$ M.

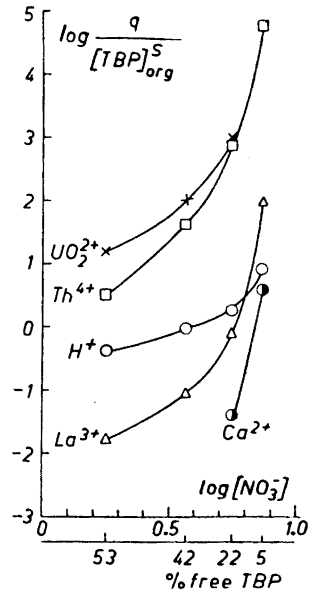

Fig. 9. The variation of $\log \frac{q}{[TBP]^S_{org}}$ with the nitrate concentration for constant $[HNO_3]_{(aq)} = 2$ M.

complexes of M in the aqueous phase is small compared to the concentration of M^{N+}, the second term in the denominator of eqn. (1) can be neglected. If it is further assumed that only one complex of M is extracted, *e.g.* $M(NO_3)_N(TBP)_S$, eqn. (1) can then be rewritten (using [ ] for concentration):

$$\log \frac{q_M}{[TBP]^S_{org}} - (N+1) \log f_{\pm} + \log \frac{f_{MC}}{f^S_{TBP}} = N \log [NO_3^-]_{aq} + \log K \quad (2)$$

Here all constants are included in K. The activity factor $f_{\pm}$ refers to the metal nitrate in the aqueous phase, f_{MC} to the metal complex and f_{TBP} to the free TBP in the organic phase; for 100 % TBP we define $f_{TBP} = 1$; f_{MC} is also = 1 in this case since the organic phase is infinitely dilute with respect to the metal complex. Q_M in eqn. (1) has been substituted by q_M to indicate that the distribution ratio in eqn. (2) refers to the concentration of the metal.

If the concentrations of the species present in large (molar) amounts are unaltered throughout the experiments, the activity factors can usually be regarded as constant. It is seen from eqn. (2) that a plot of $\log q_M/[TBP]^S_{org}$ against $\log [NO_3^-]_{aq}$ should then give a straight line of slope N. Such plots have been made in Figs. 8 and 9.

The q-values corresponding to different $Ca(NO_3)_2$ concentrations were taken from Figs. 1—5 at a constant acidity of 0.5 M and 2 M. $Ca(NO_3)_2$ was assumed to be completely

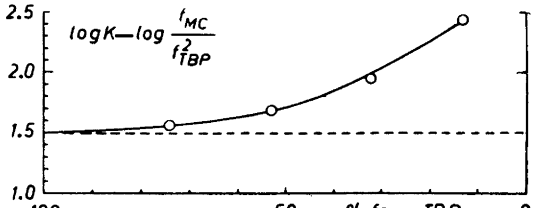

Fig. 10. Plot for $UO_2(NO_3)_2$ of $\log (q \cdot [TBP]_{org}^{-2}[NO_3^-]^{-2} \cdot f_{\pm}^{-3}) = \log K - \log \frac{f_{MC}}{f^2_{TBP}}$ at varying concentration of free TBP in the organic phase. *Cf.* equation 2, p. 1178.

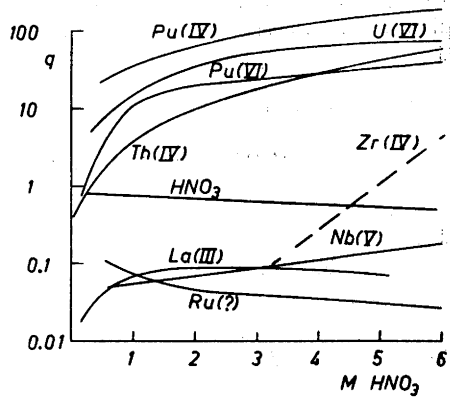

Fig. 11 The distribution ratios of the investigated metal ions and HNO_3 as a function of HNO_3 in the aqueous phase, when no $Ca(NO_3)_2$ is present.

dissociated in HNO_3 solutions <2 M, whereas a small correction for undissociated HNO_3 at high NO_3^- concentrations has been made [16].

The concentration of free, uncomplexed TBP in the organic phase, $[TBP]_{org}$, was calculated by subtracting the TBP bound to HNO_3[10] and to metal complexes [17,18] (see below) from the original TBP concentration ($[TBP]_{org,init}$) according to the equation

$$[TBP]_{org} = [TBP]_{org,init} - [HNO_3]_{org} - \Sigma S[M(NO_3)_N]_{org} \quad (3)$$

which is valid if HNO_3 and $M(NO_3)_N$ are bound to a constant number (1 or S, respectively) of TBP molecules in the organic phase. $[TBP]_{org,init} = 3.4$ M when 100 % TBP is equilibrated with water and 3.2 M when at equilibrium with 2 M HNO_3[22] due to a small volume change.

S has been taken from investigations by McKay *et al.* for the complexes $UO_2(NO_3)_2 \cdot 2TBP$ [17,18], $Th(NO_3)_4 \cdot 2TBP$ [17,18], $La(NO_3)_3 \cdot 3TBP$ [18], $Ca(NO_3)_2 \cdot 3TBP$ [18] and $HNO_3 \cdot TBP$ [10].

It is seen from Figs. 8 and 9 that a straight line is not obtained in any case; all curves (except for HNO_3) start at low NO_3^- concentrations with a slope $<$ N and end up with a slope $>$ N. Apparently it is impossible to adequately describe the systems without considering activity factors (the ionic strength of the aqueous phase varies from 3 to 12 molar, or 0.5 to 8 molal, and the concentration of free TBP from 90 to only 10 %).

The activity factors are only known for one of the metal complexes in these systems. They have been determined by McKay [19] for $UO_2(NO_3)_2$ in solutions of $Ca(NO_3)_2$; these activity factors include possible complex formation between UO_2^{2+} and NO_3^- ions in the aqueous phase. Introducing these values for $f_{\pm}$ in eqn. (2), one can calculate $\log K - \log f_{MC}/f^2_{TBP}$ as a function of $[TBP]_{org}$; this has been graphed in Fig. 10 where, on the abscissae, % free TBP is given instead of molarity. With increasing percentage of

TBP, the concentration of HNO_3 as well as of the metal complex in the organic phase decreases. By extrapolating the curve in Fig. 10 to 100 % TBP, we thus obtain log $K = 1.5$, since by definition $f_{TBP} = 1$ and also $f_{MC} = 1$.

It can easily be shown that this K is the equilibrium constant for the reaction

$$UO_2^{++}{}_{(aq)} + 2NO_3^-{}_{(aq)} + 2\ TBP_{(org)} = UO_2(NO_3)_2(TBP)_{2(org)}$$

It follows from Fig. 10 that the vertical distance between the curve and the horizontal line represented by log K must be equal to log f_{MC}/f_{TBP}^2. For 13 % free TBP one obtains $f_{MC}/f_{TBP}^2 = 0.1$. It can be deduced from this ratio that one or both of the activity factors f_{MC} and f_{TBP} must deviate from 1 by a factor of at least 2. Much greater variations have in fact been shown by McKay to exist for solutions of TBP, though in his case the solutions consisted of mixtures of highly polar TBP and HNO_3 in a solvent (kerosene) of low dipole moment *; in our case, when all components most probably are very polar, the change in the activity factors is expected to be smaller, which is in agreement with the findings.

The deviation of the curves in Figs. 8 and 9 from straight lines may not solely be due to variations in activity factors. Since at high NO_3^- concentrations a considerable part of the TBP is tied up in complexes with HNO_3 and $M(NO_3)_N$, it seems probable that the HNO_3 and metal complexes here are deficient in TBP. This is definitely indicated by the result in Fig. 9, where the TBP concentration according to eqn. (3) is < 0 at the highest NO_3^- concentration. It can also be seen from Fig. 1a that the ratio $[HNO_3]_{org}/[TBP]_{org}$ exceeds 1 (*i.e.* $[HNO_3]_{org} > 3.4$ M) at high values of HNO_3, indicating that HNO_3 is extracted in other forms than the complex $HNO_3 \cdot TBP$. This means that eqn. (3) is no longer correct; the concentration of free TBP is probably somewhat higher. The consequence of this is that the ordinate values log $q/[TBP]_{org}^N$ in Figs. 8 and 9 should be lowered, and the higher the NO_3^- concentration is the greater the decrease, which would give the curves a less steep slope at high values of log $[NO_3^-]$. It should further be noted that the formation of complexes of M in the aqueous phase (*i.e.* $[M^{N+}] \gg \sum_{1,1}^{n,s} [M(NO_3)_n(TBP)_s]_{aq}$) will lead to the same consequence, *i.e.* to a less steep slope of the curves at high NO_3^- concentrations. Thus, *e.g.*, Ahrland [20] has shown that in 2 M NO_3^- about 50 % of U(VI) is in the form of $UO_2NO_3^+$. It therefore seems incorrect to explain the deviation from straight lines in Figs. 8 and 9 solely as due to variations in activity factors. Certainly part of the deviations are due to the formation of more than one type of complex for HNO_3 and for the metals in the organic as well as in the aqueous phase.

* It should be observed that in Ref.[10] another reference state for the activity factor of TBP is used, *i.e.* $f_{TBP} = 1$ for 0 % TBP in 100 % kerosene.

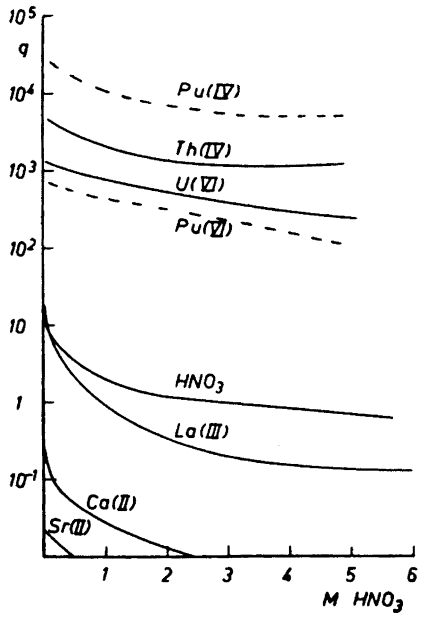

Fig. 12. The distribution ratios of the investigated metal ions and HNO_3 as a function of HNO_3 in the aqueous phase. Concentration of $Ca(NO_3)_2$: 3 M. (The curves for Pu(VI) and Pu(IV) have been extrapolated assuming Pu(VI) parallels U(VI) and Pu(IV) parallels Th(IV)).

Separation of uranium and plutonium from other metals.

The distribution curves for the different metals and HNO_3 are given in Fig. 11 for no $Ca(NO_3)_2$ present, and in Fig. 12 for 3 M $Ca(NO_3)_2$. The dashed curves for Pu(IV) and Pu(VI) in Fig. 12 are calculated on the assumption that $q_{Pu(IV)}$ changes approximately like q_{Th}, and $q_{Pu(VI)}$ like $q_{U(VI)}$, when going from 0 M to 3 M $Ca(NO_3)_2$ solutions. Similar curves for 1, 2 and 4 M $Ca(NO_3)_2$ can be obtained from Figs. 2—7.

By comparing Figs. 11 and 12 it is seen that the distribution factors increase with increasing $Ca(NO_3)_2$ concentration, and that this increase is greatest for the tetravalent and hexavalent actinides. As a consequence of this, highly salted aqueous solutions and pure TBP would seem to be a suitable system for separating Th, U and Pu from the other metals. Now it is a well-known fact that the best separation between two metals *e.g.* M_1 and M_2, is obtained if $q_{M_1} = q_{M_2}^{-1}$ at equal phase volumes. If M_1 represents Th, U or Pu, and M_2 represents the other metals, it can be seen from Fig. 12 that this optimum relation between q_{M_1} and q_{M_2} cannot be obtained with 3 M $Ca(NO_3)_2$ solutions. In fact, it is difficult to obtain an organic phase containing Th, U and Pu, which is free of the other metals. It can therefore be concluded that 3 M $Ca(NO_3)_2$ solutions are not suitable for separating U and Pu from the fission products.

In certain instances it may be of importance to determine small amounts of plutonium or uranium in aqueous solutions very dilute with respect to these elements. If the aqueous phase then is strongly salted, as with $Ca(NO_3)_2$, and mixed with a small volume of pure TBP, practically all Pu(IV), Pu(VI)

and U will move over into the organic phase. This concentration of Pu and U which may amount to a factor of 50, will make it easier to analyse for these metals.

It is seen from Fig. 11 where no $Ca(NO_3)_2$ is present that between 1 and 3 M HNO_3 the difference in distribution ratios between the tetravalent or hexavalent actinides and the other metals is about a factor 100. The conditions for separating U and Pu from the fission products (F.P.) at equal phase volumes are here optimum ($q_U \approx q_{Pu} \approx q_{F.P.}^{-1}$). It can be calculated[1] that in a counter-current extraction with 3 extraction stages and 3 stripping stages, about 99.9 % of Pu(IV), Pu(VI) and U are extracted, with a decontamination factor from the fission products investigated in Fig. 11 of the order of 10^6.

Acknowledgement. The authors wish to thank the head of FOA 1, Prof. G. Ljunggren, for his continuous support of this work and for the permission to publish the results. Sincere thanks are also due to Miss V. Dahlberg for elaborate experimental aid, and to Dr. S. Tobias for correcting the English text.

Local Anaesthetics I.
N-Alkyl Pyrrolidine and N-Alkyl Piperidine Carboxylic Acid Amides

BO af EKENSTAM, BÖRJE EGNÉR and GÖSTA PETTERSSON

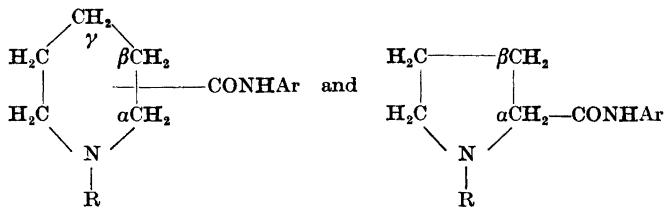
The research Laboratory, AB Bofors Nobelkrut, Bofors, Sweden

General methods and detailed examples are given for the preparation of 35 new aromatic amides of N-alkyl pyrrolidine and N-alkyl piperidine carboxylic acids. The compounds were prepared in order to test them as local anaesthetics. Pharmacological and clinical work has proved these compounds to be good local anaesthetics. The effect of compounds orginating from α-, β- and γ-carboxylic acids, respectively, compare as 7 : 2 : 1, while corresponding values for the toxicity compare as 2.7 : 1 : 1.

An extension of the N-alkyl group attached to the heterocyclic ring and an increase of the number of alkyl groups in the aromatic ring causes an increase in the effect as well as in the toxicity. The introduction of alkoxygroups in the aromatic ring lowers the toxicity but causes an increase in the irritation of living tissue. Alkylation of the amidic nitrogen as well as the introduction of an alkyl group between the amide and the aryl group decreases the effect. There appears to be no difference in pharmacological respect between the optical isomers.

dl-N-Methyl pipecolic acid 2,6-xylidide (Carbocaine) has proved suitable for clinical use.

In a number of papers [1-9], covering a period of some fifty years, local anaesthetics of amide type have been described. Though, as far as we know, no compounds were prepared where the carbonyl group of the amide was directly linked to one of the carbon atoms in a saturated or partly saturated heterocyclic ring.



As it could be of interest to test compounds of this type, a number of aryl amides were synthesized starting from pyrrolidine and piperidine carboxylic acids.

A juxtaposition of the compounds prepared is given in Table 1. Their structure is apparent from the formulae.

Table 1

No.	Ar	R	Mol.weight	Melting point °C Base	Hydrochloride
		dl-N-Alkyl pipecolic acid amides			
1	C_6H_5	C_2H_5	232.15	108–110	186–188
2	C_6H_5	n-C_4H_9	260.17	83–84	158–160
3	C_6H_4, 2-CH_3	C_2H_5	246.16	97–98	224–225
4	C_6H_4, 2-CH_3	n-C_4H_9	274.18	oil	213–215
5	C_6H_4, 3-CH_3	C_2H_5	246.16	50–52	140–143
6	C_6H_4, 4-CH_3	C_2H_5	246.16	88–90	224–226
7	C_6H_3, 2,4-$(CH_3)_2$	C_2H_5	260.17	59–60.5	241–243
8	C_6H_3, 2,6-$(CH_3)_2$	CH_3	246.16	150–151	262–264
9	C_6H_3, 2,6-$(CH_3)_2$	C_2H_5	260.17	132–133	252–254
10	C_6H_3, 2,6-$(CH_3)_2$	n-C_3H_7	274.18	121	262
11	C_6H_3, 2,6-$(CH_3)_2$	n-C_4H_9	288.19	107.5–108	258.5
12	C_6H_3, 2,6-$(CH_3)_2$	*cyclo*-C_5H_9	300.20	158	268–269

* Amide nitrogen also ethylated

Yet in No. 20 a methylene group has been introduced between NH and Ar, and in No. 21 an alkyl group has been coupled to the amidic nitrogen.

For the preparation of these compounds there are several possible ways; only the most suitable will be described here. In the following survey of the methods there is for every reaction a roman numeral which refers to the corresponding description in the experimental part.

Method A. A pyridine carboxylic acid is transferred into an aryl amide (I), which is then catalytically (II) hydrogenated and alkylated at the ring nitrogen (III). (I) is most conveniently carried out over the acid chloride, which is prepared by treating a suspension of the sodium salt in toluene with phosphorus pentachloride. The hydrogenation was carried out according to a method by Barnes [10] for the preparation of piperidine carboxylic acid esters. The pressure was however kept at 4—5 atm and the temperature at *ca.* 80°. The alkylation is easily carried out according to common methods.

The pyrrole carboxylic acid amide cannot be hydrogenated in this way.

Method B. The amides of the saturated carboxylic acids (IV) are prepared before (V) or after (VI, VII) the alkylation of the ring nitrogen. (V) was carried out over the acid chloride, which was prepared according to Fischer [11] in acetyl chloride with phosphorus pentachloride. It should be observed that for a complete reaction piperidine carboxylic acid requires a temperature of 35°, while the formation of prolyl chloride according to Fischer occurs at 0°. This causes a racemization during the preparation of the amide from optically active pipecolic acid, while the amide of *l*-proline can be prepared with unchanged optical activity. N-Alkylated piperidine carboxylic acids were preferably prepared by alkylation and hydrolysis of the corresponding ester. β- and γ-Amides are easily prepared *via* the acid chlorides, which are obtained by treating the acids with thionyl chloride (VI). The acid chlorides of the α-carboxylic acids cannot be prepared in this way. The amides of these can also be prepared by treatment with *iso*cyanate (VII).

Method C. By modifying methods given by Albertson *et al.*[12] and Putochin [13] for the synthesis of proline, the heterocyclic nitrogen ring was obtained by ring closure as the last step before the N-alkylation. Thus an acid with the formula $H_2N \cdot (CH_2)_n \cdot CHClCOOH$ was prepared according to Albertson and thereafter transferred into an arylamide. Ring closure was then achieved in alkaline environment (VIII). The method of Putochin was modified so that as the first step one of the carbonyl groups in diethyl malonate was reacted with the desired arylamine to give a monoamide according to Chattaway and Olmsted [14] (IX). The synthesis was continued essentially according to Putochin. From the monoaryl amide the *iso*nitroso compound (X) was prepared,

nitrosylchloride being used as nitrosating agent as suggested by Whiteley [15]. After reduction to amine (XI), this was reacted with alkylene dibromide, whereafter ring closure was achieved in strongly acid environment (XII).

Only α-compounds were prepared according to method C. Tetrahydro quinaldinic acid amides and tetrahydro *iso*quinaldinic acid amides were also prepared according to the methods A—B. In a forthcoming communication an account will be given of these compounds.

In order to investigate if there was any difference in pharmacological respect between the optical isomeres of the α- and β-compounds *l*- and *dl*-N-ethyl proline 2,6-xylidide was synthesized. In addition *dl*-N-methyl pipecolic acid 2,6-xylidide was separated into its optical isomeres with the aid of tartaric acid.

PHARMACOLOGY

A full account of the pharmacological characteristics of the substances will be published elsewhere. However, some results of general interest will be reported here. Thus it has been established that the α-amides possess the best local anaesthetic effect. Derivatives where R was C_2H_5 and Ar was C_6H_3-2,6-$(CH_3)_2$ (Nos. 9, 23 and 31 in Table 1) and where the only difference was in the amide position were compared at blockage of *N. ulnaris*. With respect to duration α-, β- and γ-derivatives compared roughly as 7 : 2 : 1. The corresponding proline amide gave approximately the figure 3. These results agree well with the observation of Erdtman and Löfgren [5] of a decreasing effect in the amide series of aliphatic amino acids with an increasing distance between the amide and amino groups. β- and γ-Amides turned out to have about the same toxicity while the α-amide was 2.7 times as toxic. As, however, the effect is manifolded the α-amides appear to possess a better therapeutic index.

At weal tests and determination of LD_{50} on mice no statistical difference could be established between the two optical isomers.

An extension of the heterocyclic hydrocarbon chain R results in an increase in effect at the same time as the toxicity is aggravated. N-Alkyl-proline amides have a lower effect than the corresponding pipecolic acid amides even if the shortening of the hydrocarbon chain in the heterocyclic ring is considered. Alkylation of the arylamide nitrogen (No. 21) and the introduction of an alkyl group between the amide and aryl groups (No. 20) appear to decrease the local anaesthetic power.

The introduction of side chains into the aryl group cause an increase both in effect and toxicity. The replacement of an alkyl chain in the aryl group by an alkoxy group causes a decrease in the toxicity but makes the substance irritating on living tissues. Replacement of the group by chlorine increases the toxicity while the effect decreases.

The one for clinical use most suitable compound appeared to be No. 8, *dl*-N-methyl pipecolic acid 2,6-xylidide. The compound was given the name Carbocain and has been subjected to pharmacological examination by Ulfendahl [16] and to clinical by Dhunér *et al.* [16, 17]

The toxicity values for some comparable derivatives are summarised in Table 2.

Table 2.

No. in Table 1				R	Ar	LD_{50} on mice, mg/kg

EXPERIMENTAL

A description of the synthesis of every compound in Table 1 is not given. However, an account is rendered below of all the methods mentioned in the introduction.

Iso*nicotinic acid 2,6-xylidide (I)*. *Iso*nicotinic acid sodium salt (145 g) was suspended in toluene (550 ml) and phosphorus pentachloride (80 g) added. After 1 h at 90° the solution was filtered, and 2,6-xylidine (120 g) added drop by drop to the filtrate under vigorous stirring. The precipitate was drawn off on a funnel, and washed with toluene and ether to give the hydrochloride as white crystals. Yield 210 g (93 %); m.p. 250—251°C. The hydrochloride (150 g) was dissolved in water (500 ml), carbon treated and precipitated with NaOH. Yield 123 g (95 %); m.p. after recrystallization from alcohol and ether 154—155°C. (Found: N 12.27. Calc. for $C_{14}H_{14}ON_2$: N 12.39).

Iso*nipecotic acid 2,6-xylidide (II)*. *Iso*nicotinic acid 2,6-xylidide (36 g) was dissolved in abs. alcohol (100 g) and acetic acid (20 g) and hydrogenated in the presence of platinum oxide (0.5 g) at 80° and *ca.* 4 atm. The catalyst was filtered off and to the filtered solution was added 50 % caustic soda lye (27 g) and ether (150 ml). After filtering off, precipitated sodium acetate the solution was evaporated to dryness under vacuum. The residue was dissolved in diluted hydrochloric acid, carbon treated and the base was precipitated with NaOH. Yield 33 g (89 %); m.p. after recrystallization from alcohol and ether 181—182°C. (Found: N 11.99. Calc. for $C_{14}H_{20}ON_2$: N 12.07).

N-Ethyl iso*nipecotic acid 2,6-xylidide (III)*. *Iso*nipecotic acid 2,6-xylidide (50 g) was heated on a steambath together with diethyl sulphate (100 g) for 30 min. Complete dissolution was obtained. After cooling down, the solution was washed with water (400 ml). The layer consisting of unreacted diethyl sulphate was separated and washed with a further lot of water (100 ml). The combined water phases were washed with ether (3 × 200 ml), the remaining ether removed from the water solution and this was then treated with carbon. The reaction product was precipitated with NaOH. Yield 53 g (92 %); m.p. after recrystallization from alcohol 181—182°C (gives a depression with unalkylated product). (Found: N 10.71. Calc. for $C_{16}H_{24}ON_2$: N 10.77).

dl-Pipecolic acid hydrochloride (IV). Picolinic acid (70 g) was dissolved in abs. alcohol (300 g) and acetic acid (70 g) and hydrogenated in the presence of platinum oxide (1 g) at *ca.* 80°C and 4—5 atm. When no more hydrogen was absorbed (after 1,5—2 h), the mixture was cooled and filtered. Conc. hydrochloric acid (60 g) was added to the filtrate and cooled to —20°C. Yield 75 g (80 %); m.p. 262—264 °C. (Found: Cl 21.40. Calc. for

$C_6H_{12}O_2NCl$: Cl 21.42). By evaporating the mother liquor to dryness more product was obtained. The total yield amounted to 92—95 %.

dl-Pipecolic acid 2,6-xylidide (V). *dl*-Pipecolic acid hydrochloride (100 g) was suspended in acetylchloride (1 000 ml). Phosphorus pentachloride (100 g) was added under vigorous agitation. After a reaction time of 8 h at 35° with a second addition of phosphorus pentachloride (50 g) after 6 h the mixture was cooled to 10—15° and filtered. The precipitate was washed with toluene and acetone and suspended in acetone (600 ml). All in one 2,6-xylidine (180 g) was added under stirring. The mixture was heated to boiling for 30 min. After cooling the precipitate formed was drawn off and washed with acetone and dryed. In order to remove remaining xylidine the product was steam distilled at pH 5.5, carbon treated and precipitated with NaOH. Yield 112 g (80)); m.p. 116—117°. After recrystallization from alcohol the m.p. rose to 121°. (Found: N 12.03. Calc. for $C_{14}H_{20}ON_2$: N 12.07).

dl-N-Methyl pipecolic acid 2,6-xylidide (III). *dl*-Pipecolic acid 2,6-xylidide (100 g) was dissolved in methyl alcohol (200 ml) and potassium carbonate (45 g) added. Dimethyl sulphate (55 g) was added under stirring, and the mixture refluxed for 6 h. After cooling the mixture was filtered, and the filtrate evaporated to dryness. The residue was dissolved in conc. hydrochloric acid (37 ml) and water (750 ml), carbon treated and precipitated with NaOH. Yield 80.5 g (76 %); m.p. 148°C. After recrystallization from ether the m.p. rose to 150—151°C. (Found: N 11.37. Calc. for $C_{15}H_{22}ON_2$: N 11.38).

dl-Proline-2-chloro-6-methyl anilide (V). To a suspension of the hydrochloride of *dl*-prolinechloride (prepared according to Fischer [11]) (5 g) in acetone (30 ml) 2-chloro-6-methyl aniline (10 g) was added. The mixture was heated on a water bath for 30 min. Water was added until complete solution of any precipitate formed, and the acetone driven off under vacuum. The pH of the solution was adjusted to 5 and the excess of amine removed by extraction with ether. The water solution was made strongly alkaline with NaOH, and the base then extracted with ether. After drying the ether solution with sodium sulphate the ether was evaporated, and *dl*-proline 2-chloro-6-methyl anilide was obtained as an oil. Yield 6 g (85,5 %). (Found: N 11.63. Calc. for $C_{12}H_{15}ON_2Cl$: N 11.74).

dl-N-n-Butyl proline 2-chloro-6-methyl anilide (III). *dl*-Proline 2-chloro-6-methyl anilide (6 g) was dissolved in *n*-butyl alcohol (30 ml) and then under stirring refluxed with potassium carbonate (3 g) and *n*-butyl bromide (3.6 g) for 20 h. The reaction mixture was filtered and the filtrate evaporated under vacuum. The residue was dissolved in diluted hydrochloric acid and carbon treated. A crystalline precipitate was obtained with NaOH. Yield 6 g (81 %); m.p. after recrystallization from ether 77—78°C. (Found: N 9.41. Calc. for $C_{16}H_{23}ON_2Cl$: N 9.52).

dl-N-Ethyl nipecotic acid 2-chloro-6-methyl anilide (VI). *dl*-N-Ethyl nipecotic acid (50 g) was treated with thionyl chloride (150 g). When the reaction subsided, the mixture was heated on a water bath for 30 min, when a clear solution was obtained. The excess of thionyl chloride was driven off under vacuum, until crystallization occurred. In order to make the crystallization complete, ether (100 ml) was added and the mixture shaken, after which the crystal slurry was drawn off and washed with ether. Without drying the crystals were suspended in acetone (300 ml). To the suspension 2-chloro-6-methyl aniline (65 g) was added drop by drop. The mixture was refluxed for 15 min after which the acetone was driven off under vacuum. The residue was dissolved in water (500 ml). The pH was adjusted to 5.5 and unreacted 2-chloro-6-methyl aniline removed by ether extraction. The water solution was cleared from ether and the base precipitated with NaOH. Yield 75 g (84 %); m.p. after recrystallization from alcohol and ether 122—123°C. (Found: N 9.99. Calc. for $C_{15}H_{21}ON_2Cl$: N 9.98).

dl-N-Ethyl pipecolic acid o-toluidide (VII). *dl*-N-Ethyl pipecolic acid (50 g) was heated on a steam bath under stirring with 2-methyl phenyl *iso*cyanate (100 g). When the evolution of carbon dioxide had ceased the excess of *iso*cyanate was driven off under vacuum. The residue was boiled for 15 min with 27 ml of conc. hydrochloric acid and 250 ml of water. The mixture was cooled down and filtered. After carbon treatment and precipitation with NaOH the base was obtained in the form of crystals. Yield 52 g (65 %); m.p. after recrystallization 97—98°C. (Found: N 11.40. Calc. for $C_{15}H_{22}ON_2$: N 11.38).

dl-Proline 2,6-xylidide (VIII). 2-Chloro-5-aminovaleric acid hydrochloride (94 g) prepared according to Albertson *et al.*[12] was chlorinated in acetyl chloride (450 ml) with phosphorus pentachloride (188 g) under cooling with ice water. After 7 h the crystals

formed were washed with toluene and suspended in acetone. 2,6-Xylidine (120 g) was added to the suspension, and the mixture heated on a water bath for 30 min. Water was added and the acetone driven off under vacuum. The pH was adjusted to 5 and the excess of xylidine removed by ether extraction. The water solution was carbon treated and NaOH added to pH 12, when an oil began to precipitate. After stirring for 2 days at room temperature a crystalline product was formed. This was extracted with ether, and after evaporation of the ether an oil was obtained which crystallized after some time. Yield 53.5 g (49 %). (Found: N 12.71. Calc. for $C_{13}H_{18}ON_2$: N 12.84).

After ethylation with diethyl sulphate according to III, a product was obtained, identical with *dl*-N-ethyl proline 2,6-xylidide prepared from *dl*-proline.

Malonic acid ethylester 2,6-xylidide (IX). 2,6-Xylidine (121 g) was heated with diethyl malonate (400 g) at 155—160° for 1 h and the ethanol distilled off as it was formed. Then the excess of diethyl malonate was distilled off under vacuum. To the crystalline residue ethanol (500 ml) was added. After cooling down the crystals of malonic acid dixylidide formed were filtered off. The alcohol solution was diluted with water (2 l) under agitation, when malonic acid ethylester xylidide crystallized out. The monoxylidide was filtered, washed with water and recrystallized from 50 % ethyl alcohol. Yield 138 g (58.8 %); m.p. 100—101°C. (Found: N 6.08. Calc for $C_{13}H_{17}O_3N$: N 5.96.)

Isonitrosomalonic acid ethylester 2,6-xylidide (X). To a solution of malonic acid ethylester 2,6-xylidide (60 g) in chloroform (400 ml) nitrosyl chloride was added during 6 h at 0°C. The crystals of the *iso*nitroso compound formed were filtered off washed with chloroform and dryed in vacuum. Yield 56 g. From the mother liquor a further 5 g were obtained by vacuum evaporation. Total yield 61 g (90.5 %); m.p. 193—194°C. (Found: N 10.51. Calc. for $C_{13}H_{16}O_4N_2$: N 10.60).

Aminomalonic acid ethylester 2,6-xylidide (XI). *Iso*nitrosomalonic acid ethylester 2,6-xylidide (60 g) was dissolved in formic acid (200 ml). Zinc powder (36 g) was added in portions during 1 h at 90—95°. After a further hour at 90° the hot solution was filtered and evaporated under vacuum. The evaporation residue was dissolved in hot amyl alcohol, washed neutral with 5 % bicarbonate solution and filtered. The amyl alcohol was driven off under vacuum and the residue recrystallized from 50 % ethyl alcohol. Yield: 47.2 g (83 %); m.p. 195°C. (Found: N 11.18. Calc. for $C_{13}H_{18}O_3N_2$: N 11.20).

dl-Pipecolic acid 2,6-xylidide (XII). In a sodium ethylate solution, prepared by dissolving sodium (4.6 g) in abs. alcohol (125 ml), aminomalonic acid ethylester 2,6-xylidide (50 g) was dissolved. Tetramethylene dibromide (87 g) was added at 70° during 20 min. The reaction mixture was then refluxed for 6 h, cooled down and filtered. The ethanol and excess of tetramethylene dibromide were distilled off with steam. The remaining oil was separated from the water and refluxed with conc. hydrochloric acid (150 ml) for 3 h, after which the solution was evaporated to dryness under vacuum. The residue was dissolved in water and the pH adjusted to 5 with caustic soda. The water solution was extracted with ether, carbon treated and precipitated with NaOH at pH 13. Yield: 16 g (34.5 %). M.p. 115—116°C. After recrystallization from ethyl alcohol the m.p. rose to 120—121°C. (Found: N 11.98. Calc. for $C_{14}H_{20}ON_2$: N 12.07).

On Vitamins in Sewage Sludge

V. The Effect of Antibiotics on Vitamin B_{12} Contents of Microbially Decomposing Sewage Sludge

HALINA Y. NEUJAHR

Division of Food Chemistry, Royal Institute of Technology, Stockholm, Sweden

The effect of the addition of antibiotics to microbially decomposing sewage sludge was studied with respect to the amount of vitamin B_{12} activity formed and its distribution between the different factors. *Aureomycin* was found to stimulate the formation of vitamin B_{12} activity if added at a sludge decomposition stage characterized by pH 6.5–7.0. Under anaerobic conditions the addition of aureomycin caused an enhanced synthesis of factors with R_F-values related to that of factor III, whereas under aerobic conditions the synthesis of cyanocobalamin was stimulated. — Under aerobic conditions *terramycin* was found to have a similar, but less pronounced, effect. — Both active and inactivated *penicillin* stimulated the synthesis of cyanocobalamin and of other vitamin B_{12} factors when incubated with sludge. The effect was more pronounced with the inactivated agent, thus suggesting the possibility that the latter may be the factor stimulating the vitamin B_{12} synthesis. — *Neomycin* stimulated the synthesis of cyanocobalamin and of other vitamin B_{12} factors. Heat and alkali treated (but not inactivated) neomycin had a detrimental effect on the synthesis of cyanocobalamin.

Antibiotics are known to exert a vitamin B_{12} "sparing action" on several animals and are extensively used as "feed supplement" for pigs and chickens. The mechanism of this action has not yet been elucidated and the experimental evidence is contradictory on some points.

Many investigators support the view that antibiotics enhance the growth of young poultry and swine merely through alterations of the normal intestinal microflora, whereas others postulate that the antibiotic molecule or a fragment thereof is involved as a metabolite in the host. The latter hypothesis is based on experiments with inactivated antibiotics, administered perorally and parenterally to chickens [1] and pigs [2].

Peterson and Johanson [3] in their experiments with rats have shown that both the active and inactivated agents, regardless of the route of administration, induced marked changes in the intestinal microflora which, however,

were not always accompanied by a growth effect in the host. It has been shown by several workers that feeding with a diet containing antibiotics — but limited in vitamin B_{12} — results in increased synthesis (or contents) of vitamin B_{12} in the intestines of chickens [4] and rats [5].

According to Pawe kiewicz [6] the addition of aureomycin to a culture of propionic acid bacteria increases the formation of cyanocobalamin and cobalamin X at the expense of vitamin B_{12p} (which has been identified as factor B). Mannino and Pipitone [7], however, have reported that in *Bacterium coli* the amount of vitamin B_{12} produced in the presence of antibiotics was less than in their absence.

The process of formation of vitamin B_{12} factors during aerobic and anaerobic fermentation of municipal sewage sludge has previously been studied in this laboratory [8].

The attempt has now been made to investigate in what way this process may be influenced by addition of antibiotics.

Fresh sewage sludge with graded levels of aureomycin, terramycin, penicillin and neomycin was fermented aerobically and anaerobically. Samples were taken at definite time intervals and analyzed for vitamin B_{12} activity by means of microbiological tests; the different vitamin B_{12} factors were identified by bioautographic methods.

EXPERIMENTAL

Fresh sludge from a settling tank of the Stockholm municipal sewage plant was disintegrated in a "Turmix" blendor, mixed with *ca.* 20 % of digested sludge and diluted with water. The substrate thus obtained had a dry solid content of *ca.* 4 % and pH 5.0—5.5. It was fermented aerobically and anaerobically at 33°C with addition of some antibiotics. The experimental conditions of the different investigations are summarized in Table 1. Experiments Nos. 2 and 3 were performed in glass fermenters each of 10 litres capacity, provided with stirrers, heating coils, arrangements for inlet of gas and for removal of samples. The appropriate temperature (33°C) was obtained by circulating warm water from constant temperature baths through the coils of the fermenters with simultaneous stirring. In the anaerobic fermentation (expt. No. 2) a gas mixture of CH_4 and CO_2 (6:4) was blown through the sludge until all air was removed, this procedure being used every time the sludge came in contact with air, *e. g.* after removal of a sample. In expt. No. 3 air was blown through the sludge, 2 × 30 min every day.

Experiments Nos. 1, 4, 5, 6, and 7 were performed in conical flasks placed in rooms with thermostatically controlled air temperature. Shaking table was used for the aerobic fermentations, whereas for the anaerobic fermentations no special arrangements were made — the flasks were filled with sludge with only a very small space left above and incubated in the thermostat. Samples were treated as described elsewhere [8]. Vitamin B_{12} activity was estimated with the aid of the cup plate, the tube and the bioautographic methods using *Escherichia coli* 113—3. In some few cases ionophoretic estimations in combination with bioautography were carried out.

Bioautography. For chromatography it proved to be more convenient to modify the technique used in the earlier experiments [9]. In the present investigation the following procedure was adapted:

Paper: Whatman 1. Each spot corresponded to 1 μl of the solution to be tested. The paper strips were prepared in duplicate and developed for 48 h in two different solvent systems at 18°C.
Solvent system I: *sec.* butanol: H_2O:HAc (75:24:1) + 0.01 % KCN.
Solvent system II: *sec.* butanol: H_2O:NH_3 (75:24:1) + 0.01 % KCN.
Two standard solutions were used:
Standard solution 1 (S1): cyanocobalamin + factor III + factors (Z2 + Z3) [10].
Standard solution 2 (S2): factor A + factor B.

The resolution of factors Z2 and Z3 could not be achieved by this technique but instead factor III could be separated from factor A in solvent system II.

However, after the chromatographic resolution of the initial spots of the samples, the spots with R_F-values corresponding to that of factor A may not represent this factor or perhaps not only this factor. In an earlier investigation [10] it has been shown that sewage sludge contains at least 6 different factors with R_f-values closely related to that of factor A and of ψ -B_{12}. As only the two latter factors had been obtained in crystalline state [11,12], the author found it appropriate to use factor A as standard instead of a mixture of factors isolated from sewage sludge. In the following the spots corresponding to factor A will be designated as "A". Obviously, "A" may signify a mixture of the following factors: A + ψ-B_{12} + XI + X2 + X3 + X4 + III + W in solvent system I, whereas in solvent system II factors III + W can be resolved from the other factors. The spots corresponding to factor III may also contain factor W.

Paper electrophoresis of the samples in combination with bioautography revealed in several instances that "A" corresponded to more than one factor but it was not possible to obtain sufficient information about the nature of these factors.

Following preparations of antibiotics were used in the different experiments:

Aureomycin: Aureomycin HCl crystalline, Lederle.
Terramycin: Terramycin HCl crystalline, Pfizer.
Penicillin: Benzylpenicillin, AB Kabi.
Neomycin: Mycifradin sulphate, The Upjohn Company.

Heat and alkali treatment of penicillin and neomycin. The solutions were autoclaved at 121°C for 15 min at pH 12.

Table 1.

Expt. No.	Antibiotic added	Type of fermentation	Apparatus	Amount of sludge fermented ml	Time of addition: Days after the start of the ferment.	Time of addition: pH of the sludge
1	Aureomycin	Anaerobic	conical flasks (2 l); no stirring	1 800	0	5.5

* by heat and alkali.

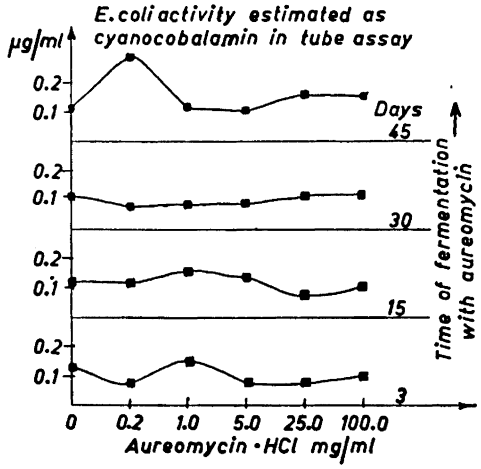

Fig. 1. (Expt. No. 1). Effect of the addition of aureomycin to fresh sewage sludge, subsequently anaerobically fermented.

RESULTS

The pH changes of the fermenting sludges to which antibiotics had been added were essentially the same as the corresponding changes in sludges containing no added antibiotics.

The results of the different experiments are shown in Figs. 1—7 *.

Experiment No. 1. The bioautographic estimation of vitamin B_{12} activity in samples taken 3, 15, 30, and 45 days after the start of the fermentation did not reveal any significant variations in the distribution of *E. coli* activity between the different vitamin B_{12} factors. The estimation in tube assay gave somewhat varying values of the total *E. coli* activity. These values are represented in Fig. 1. A slight maximum in *E. coli* activity can be noticed after 3 days of anaerobic fermentation of the sludge to which 1 mg aureomycin/l sludge had been added. This maximum is still maintained after 15 days of fermentation and it disappears after 30 days while, after 45 days, an unexpected maximum appears in the sludge with 0.2 mg aureomycin/l added. In view of the instability of aureomycin at the actual pH ($\sim$ 6) the results can hardly be explained by the antibiotic effect of aureomycin.

Experiments Nos. 2 and 3. The addition of aureomycin (10 mg/l) to sewage sludge which had already undergone certain microbial decomposition (pH $\sim$6.5) resulted in enhanced formation of cyanocobalamin under aerobic condi-

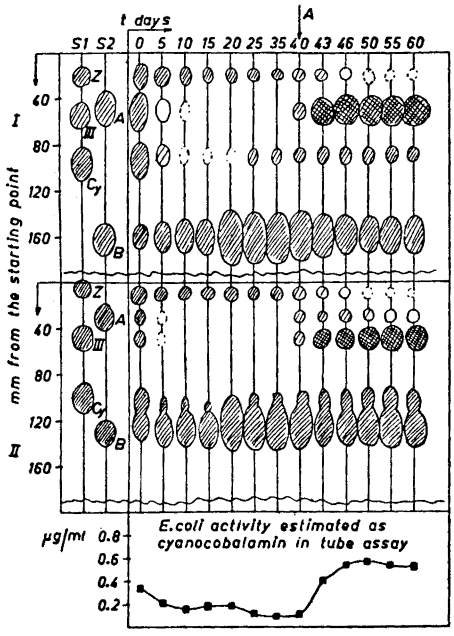

Fig. 2. (Expt. No. 2). Effect of the addition of aureomycin to anaerobically fermenting sewage sludge. Bioautogram *. A — addition of aureomycin . HCl (10 mg/l sludge).

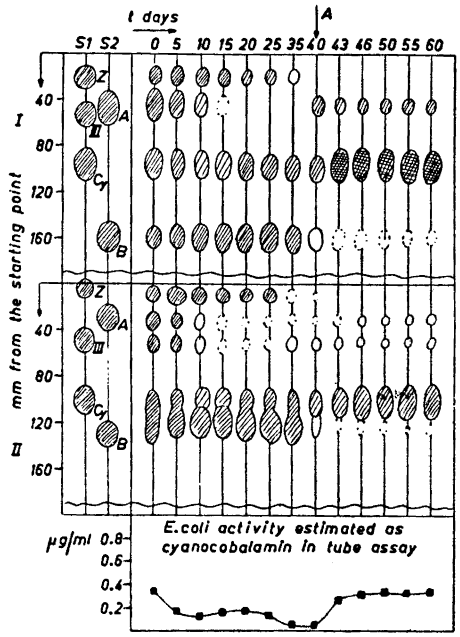

Fig. 3. (Expt. No. 3). Effect of the addition of aureomycin to aerobically fermenting sewage sludge. Bioautogram *. A — addition of aureomycin · HCl (10 mg/l sludge).

tions (*cf.* Fig. 3) and of factor III under anaerobic conditions (*cf.* Fig. 2). This is also clearly reflected in the significant increase of the total *E. coli* activity as estimated in tube assay (*cf.* Figs. 2 and 3).

Experiment No. 4. The results of this experiment further confirm the finding (expt. No. 3) that aureomycin stimulates the formation of cyanocobalamin in aerobically fermented sludge if added at the stage when the pH of the sludge has risen to about 7. The effect was most pronounced with 5—25 mg aureomycin per litre sludge after 40—90 h of fermentation, but was partly abolished by further fermentation as seen in the samples taken after 160 h **. During the first 40 h aureomycin also seemed to stimulate the formation of factors Z, whereas after 90 and 160 h its effect was the opposite. The same phenomenon could be observed with factors "A". The formation of factor III was only slightly stimulated by the addition.

* For abbreviations see footnote on p. 1194.

** This is apparently not fully in agreement with the results of expt. No. 3, where the increased contents of cyanocobalamin persisted for several days (*cf.* Fig. 3). It is possible that the relatively quicker destruction of cyanocobalamin in expt. No. 4 as compared with expt. No. 3 was due to the more vigorous aeration employed in this experiment (*cf.* Table 1).

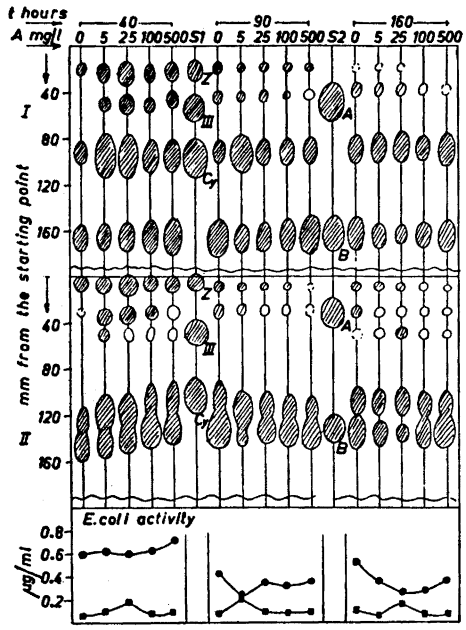

Fig. 4. (Expt. No. 4). Effect of the addition of aureomycin to aerobically fermenting sludge. Bioautogram *. A — aureomycin · HCl, graded amounts. ●—● cup assay; ■—■ tube assay.

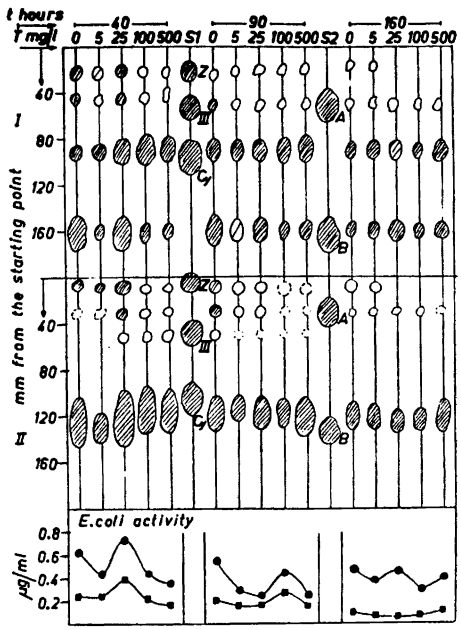

Fig. 5. (Expt. No. 5). Effect of the addition of terramycin to aerobically fermenting sewage sludge. Bioautogram *. T — terramycin · HCl, graded amounts. ●—● cup assay; ■—■ tube assay.

Experiment No. 5. 25—100 mg terramycin per litre aerobically fermented sludge stimulated formation of cyanocobalamin after 40 h of fermentation. This effect was partly abolished during continued fermentation. The effect upon other factors was more obscure. 5 mg terramycin/l sludge seemed to cause a minimum in the amount of factors B and Z, while 25 mg/l caused a maximum in the amounts of these factors as well as in those of factors "A".

Experiment No. 6. a) Addition of active penicillin stimulated the formation of cyanocobalamin; the effect was strongest with 20 mg penicillin/l sludge and could be noted after 10 days as well as after 30 days of anaerobic fermentation. With increasing amounts of penicillin increasing amounts of factors Z could be observed after 10 days of fermentation; the amount of factors "A" and factor III simultaneously decreased. The amount of factor B was almost unaffected. The effect was quite different after 30 days of fermentation. A pronounced maximum in the amounts of factor B, cyanocobalamin and factor III could then be observed with 20 mg/l. Factors Z disappeared.

b) The addition of increasing amounts of inactivated penicillin caused an increased formation of cyanocobalamin. The effect was strongest with 50

* For abbreviations see footnote on p. 1194.

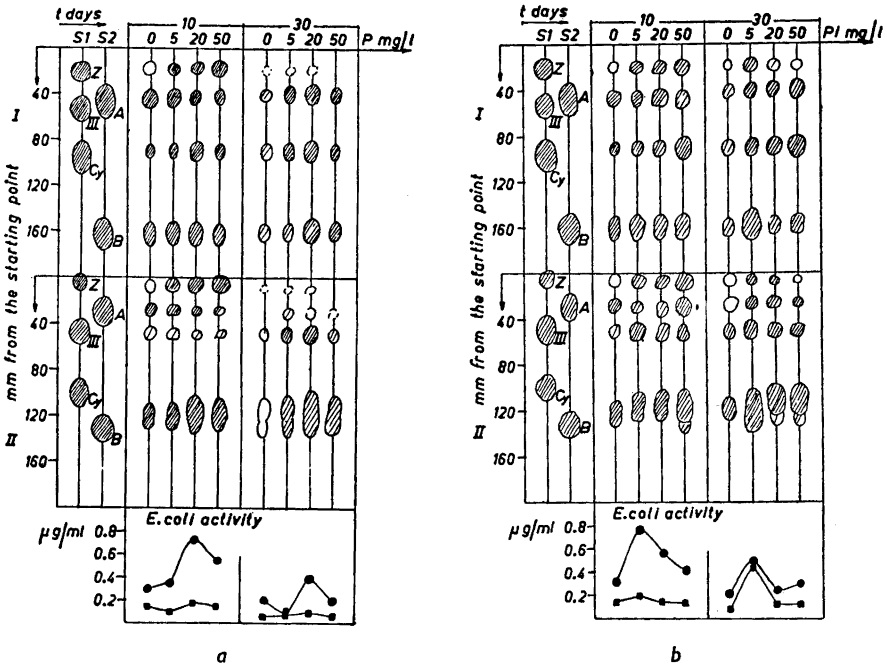

Fig. 6. (Expt. No. 6). Effect of the addition of penicillin to fresh sewage sludge, subsequently anaerobically fermented. Bioautograms *. a) P — active benzyl penicillin; b) Pi — heat and alkali inactivated benzyl penicillin. ●—● cup assay; ■—■ tube assay.

mg/l and could be noted after 10 days of fermentation as well as after 30 days. With increasing amounts of penicillin added, increased amounts of factors Z were observed after 10 days; after 30 days a maximum in the amount of these factors corresponded to the addition of 5 mg/l. The effect on the formation of factors "A" and III was less pronounced although a slight stimulation of their synthesis could be observed also here. The amount of factor B was unaffected after 10 days, but showed a clear maximum after 30 days in the sludge to which 5 mg/l had been added.

Experiment No. 7. a) 5—25 mg neomycin/l sludge caused an increased synthesis of cyanocobalamin and of factors Z, "A" and III after 10 days, but after 30 days the effect of neomycin upon the two latter factors was abolished. The synthesis of factor B was slightly stimulated by the addition of neomycin.

b) Increasing amounts of heat and alkali treated (but not inactivated) neomycin caused a decrease in the vitamin B_{12} activity as estimated in tube assay. The detrimental influence was exerted mainly upon cyanocobalamin, whereas the amount of factor Z showed a slight maximum after 10 days of fermentation in the sludge to which 5 mg neomycin per litre had been added. The amount of factor B was essentially unaffected by the addition.

* For abbreviations see footnote on p. 1194.

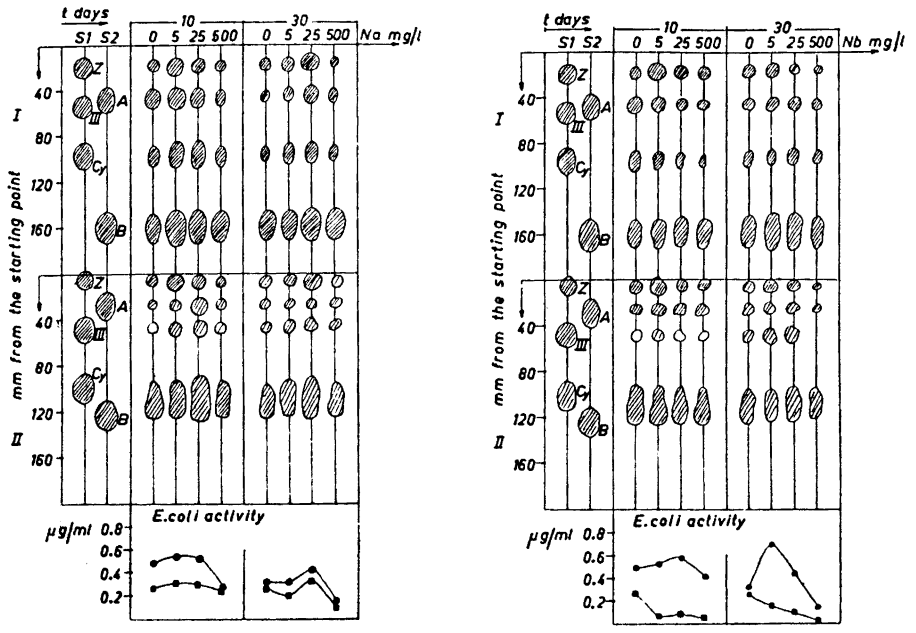

Fig. 7. (Expt. No. 7). Effect of the addition of neomycin to fresh sewage sludge, subsequently anaerobically fermented. Bioautograms *. a) Na — mycifradin sulphate; b) Nb — heat and alkali treated but not inactivated mycifradin sulphate. ●—● cup assay; ■—■ tube assay.

As can be seen in Table 2, antibiotics (except for the heat and alkali treated neomycin) generally increased the total vitamin B_{12} activity of microbially decomposing sewage sludge and most of them caused an increase of that part of the activity which is due to cyanocobalamin. The following circumstances seemed to exert a particular influence on this phenomenon.

1) the type of fermentation: aerobic or anaerobic.

2) the degree of decomposition of the sludge at the moment of addition, as characterized by the pH of the sludge.

Thus, under anaerobic conditions aureomycin had only a very slight effect on the vitamin B_{12} activity of decomposing sludge if added to "fresh" sludge (pH 5.5). Under similar conditions its addition to partly decomposed sludge (pH 6.5—6.8) caused a significant increase in the vitamin B_{12} content mainly due to the synthesis of *factor III*. Corresponding addition to intermittently aerated sludge resulted in an increased synthesis of *cyanocobalamin* accompanied by the disappearance of factor B, whereas with continuous aeration (shaking) a simultaneous formation of cyanocobalamin and of factor B was obtained. It is difficult to decide whether the effect of aureomycin depended on its antibiotic action or whether it was used as a "metabolite" enhancing the synthesis of vitamin B_{12} (*cf.* Pawelkiewicz, 1955[6]). The "immediate"

(40 h) effect of the addition of aureomycin to partially decomposed sludge (expts. Nos. 2 and 3) may suggest the latter possibility, or it may indicate that the growth of some strains consuming different vitamin B_{12} factors has been inhibited, thus causing the accumulation of the corresponding factors in the sludge. Probably both mechanisms were involved *.

The results obtained with penicillin differ from those obtained with aureomycin (expt. No. 1) in that the addition to *fresh sludge* of active as well as of inactivated penicillin followed by anaerobic fermentation caused an increase of the vitamin B_{12} activity. Both agents seemed to enhance the synthesis of

* The reservation must here be made that due to some variations in experimental conditions as stirring, shaking, amount of sludge fermented (*cf.* Table 1) not all the experiments are fully comparable.

cyanocobalamin, strikingly accompanied by the synthesis of factors Z which may suggest the possibility of a metabolic relationship between cyanocobalamin and these factors. Active penicillin caused a decrease in the amounts of factors III and "A" and did not affect the amount of factor B in the beginning but increased it during continued fermentation. On the other hand inactivated penicillin increased the amount of all these factors. It seems likely, therefore,, that inactivated penicillin is the agent responsible for an enhanced synthesis of vitamin B_{12} factors in digesting sewage sludge, as the benzylpenicillin used in the experiments must have been inactivated very soon after the beginning of the fermentation.

Acknowledgements. The author is grateful to Professor H. Lundin, Head of the Division, for his encouraging interest in and valuable advice on the execution of this work; she also wishes to thank AB Kabi, Stockholm, for their kind gift of antibiotics. Thanks are also due to Miss R. Wolf for technical assistance. The financial support from *Statens Tekniska Forskningsråd* is gratefully acknowledged.

ACTA CHEMICA SCANDINAVICA 11 (1957) 1201—1208

An Ultra Micromethod for the Determination of Total Cholesterol in Bile Based on the Tschugaeff Color Reaction

KLAVS H. JØRGENSEN and HENRIK DAM

Department of Biochemistry and Nutrition, Polytechnic Institute, Copenhagen, Denmark

In the present method all operations, including the development of the color, take place in one and the same vessel (a centrifuge tube). The final volume of the reaction mixture is small (0.5 ml). Hence the method permits the determination of as little as 2 μg cholesterol. When used on a hamster bladder bile extract the Tschugaeff reaction gives rise to a yellow color besides the red color due to cholesterol. A correction for this yellow color is described.

The method was developed for the purpose of determining cholesterol in bladder bile of syrian hamsters where the volume obtainable from one animal usually is between 5 and 50 microliter. The amount of cholesterol present in such a sample may be as low as 2 μg. In principle it may be possible to use the method on other biological fluids than bile, such as blood plasma.

EXPERIMENTAL

Reagents

Standard cholesterol, prepared from crude cholesterol by purification through the dibromide,

Aqueous KOH solution, 1 M.

Chloroform, Ph.Dan.

Acetyl chloride, analytical grade (E. Merck, A.G.). This reagent should not be used for a longer period than 1 month after the first opening of the ampoule, and should be stored at a temperature below 5°C.

Glacial acetic acid, analytical grade (E. Merck, A.G.).

$ZnCl_2$, anhydrous, in sticks, analytical grade (M & B, Ltd.).

A 20 % solution (w/w) of $ZnCl_2$ in glacial acetic acid was prepared by heating on a water bath at 65°C under occasional shaking. The solution which is turbid is clarified by standing or centrifugation. It can be used for at least one month.

Procedure

A. Extraction. 0.003 to 0.010 ml hamster bladder bile * is introduced by means of a Carlsberg pipette [1] into a centrifuge tube having a standard taper female joint 10/15 (shown in Fig. 1). The shape and size of the tube is so chosen that with a content up to

Fig. 1. The vessel in which all operations take place. It is furnished with a standard taper female joint 10/15. Total length: 116 mm, max. diameter: 12 mm, volume up to the joint: about 7 ml.

1 ml nothing will escape from the vessel during violent shaking on a "Microid Flask Shaker" (Griffin & George Ltd.). 0.5 ml of a 1 M KOH solution is added and mixed with the bile by shaking on the just mentioned shaker. The bile alkalized in this way is quite clear. 0.3 ml of chloroform is added and the tube is shaken violently on the shaker for 1/2 min, whereby an emulsion is formed. The tube is then centrifuged (3 000 r.p.m.). In order to ensure extraction of that part of the layer which at the beginning of the shaking may have been thrown up on the upper interior surface of the tube, the latter is again shaken 1/2 min and centrifuged until a yellow, clear aqueous layer is completely separated from a bottom layer which consists of an upper white emulsion and a lower colorless chloroform part. As much as possible of the clear aqueous layer is carefully removed by suction by means of a Carlsberg pipette equipped with a rubber cap. 1/2 ml of water is poured down along the inner wall of the tube. The tube is shaken on the shaker for about 10 sec, centrifuged, and the clear supernatant sucked off. This washing procedure is carried out 4 times in all. The last aqueous layer which is sucked off shall be of neutral reaction, and the emulsion layer shall have disappeared or be reduced to a thin white film between the chloroform and water layers. After the last sucking off, 0.3 ml chloroform is poured down along the inner wall of the tube.

Simultaneously with two samples of bile, a blank and a known amount of cholesterol, 4 μg for instance, serving as a standard, are treated similarly. The cholesterol standard is introduced into the tube by pipetting, say 0.5 ml of a chloroform solution, which is thereafter evaporated.**

B. Evaporation. The evaporation of the 0.3 + 0.3 ml chloroform and about 0.050 ml water (the rest of the washing liquid) is carried out in the following way: The tube is placed in one of the clamps of the shaker and furnished with a standard taper male joint which through a rubber tube fixed in an other clamp of the shaker can be connected with a water suction pump or an oil pump. First the water suction pump is connected with the tube and the chloroform evaporated under shaking while the tube is immerged in a water bath of room temperature. When the pressure has fallen to 15 – 20 mm Hg the temperature of the water bath is raised to 40 – 50°C. Hereby the water in the tube is evaporated. The last trace of water is removed by means of the oil pump. The evaportion procedure requires only a few minutes for each tube.

C. The color reaction. To the residue in each of the tubes (2 with cholesterol from bile, one with standard cholesterol and one with the blank) is added 0.100 ml freshly prepared reagent mixture *** consisting of chloroform, acetyl chloride and 20 % $ZnCl_2$ acetic solution in the proportion 3 : 1 : 1 (by vol.). The tubes are sealed with polyethylene stoppers coated on the upper part of the conical surface with a thin layer of starch-glycerol

* After puncture of the gallbladder of the killed animal the bile is taken out in a capillary tube by suction (not directly with the Carlsberg pipette).

** Concerning the technique of evaporation, see under B.

*** For the pipetting of $CHCl_3$ and reagent mixture Carlsberg pipettes equipped with rubber caps were used.

grease [2]. The stoppers are turned down into the grounds until they fit quite tightly *. The whole inner surface, but not the stopper, is brought in contact with the reagent mixture by suitable gentle turning of the tube. The tubes are then placed in a water bath of 65°C and remain there for exactly 6 min, whereafter they are cooled in ice water for some minutes and are then warmed to room temperature. The stoppers are removed, and the contents of the tubes are diluted with 0.400 ml of the reagent mixture. The stoppers are again inserted and the tubes shaken on the shaker, whereafter the contents are transferred by pipettes to semimicro cuvettes (internal measures: height 40 mm, width 4 mm, and length (ligth path) 10 mm). These cuvettes may be used for contents of about 0.5 ml in a Beckman Spectrophotometer DU when the slit of the instrument is covered with a metal plate furnished with a small opening and the cuvettes are raised about 5 mm from the bottom of the holder. Finally, the extinctions ($E = -\log (I/I_0)$) are measured within 15 min against the blank at 522 mμ and at 440 mμ.

CALCULATION OF THE CHOLESTEROL CONTENT

As mentioned later, the red color developed in the Tschugaeff reaction will be accompanied by a yellow color when the reaction is applied to a hamster bladder bile extract. This yellow color will absorb to a certain extent at the maximum of the red color (522 mμ). It is possible, however, to compute the extinction E'^{bile}_{522} caused by cholesterol alone, by making use of the observed extinctions E^{bile}_{522} and E^{bile}_{440} for the bile sample examined, and the corresponding values E^{st}_{522} and E^{st}_{440} for the standard:

$$E'^{\text{bile}}_{522} = E^{\text{bile}}_{522} \frac{1-0.43\ E^{\text{bile}}_{440}/E^{\text{bile}}_{522}}{1-0.43\ E^{\text{st}}_{440}/E^{\text{st}}_{522}}$$

Thereby the cholesterol content m_{bile} of the sample may be calculated from the amount of standard cholesterol m_{st}:

$$m_{\text{bile}} = m_{\text{st}}\ E'^{\text{bile}}_{522}/E^{\text{st}}_{522}$$

or

$$m_{\text{bile}} = \frac{E^{\text{bile}}_{522} - 0.43\ E^{\text{bile}}_{440}}{E^{\text{st}}_{522} - 0.43\ E^{\text{st}}_{440}}\ m_{\text{st}}$$

DISCUSSION OF THE METHOD

Experiments with standard cholesterol

The colorimetric determination of as little as 2 μg of cholesterol with a reasonable accuracy in cuvettes with a light path of 1 cm and a final volume of the reaction mixture of 0.5 ml requires the use of either the Tschugaeff or the Zlatkis reaction [3]. The Tschugaeff reaction is preferred because of the relative unspecificity of the Zlatkis reaction as pointed out by Lovern [4].

Several methods based on the Tschugaeff reaction are described in the literature, but they all use a final volume of 5 ml or more.

* Polyethylene stoppers fitting to standard taper joints are now commercially available.

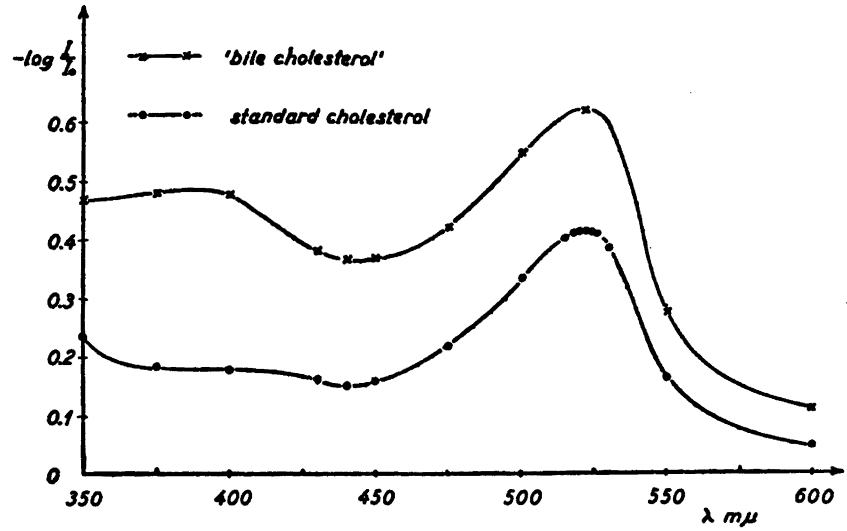

Fig. 2. Absorption curves for the Tschugaeff reaction on 8 μg standard cholesterol and "bile cholesterol" from 0.025 ml hamster bladder bile. Total volume of reaction mixture: 1/2 ml.

Recently, Schön and Gey [5] have described a method in which the color is developed by standing 3 h at room temperature. We could, however, not obtain the agreement with Beer's law reported by these authors.

The same applies to methods using a reaction temperature of 65°C, *e.g.* that of Hanel and Dam [6], when only a few μg of cholesterol shall be determined. The reason for these discrepancies is not clear.

If the reaction mixture is diluted 5 fold after the color has been developed (at 65°C and at a ratio by vol. between chloroform, acetyl chloride and $ZnCl_2$ reagent of 3 : 1 : 1) we have found that Beer's law will be followed in the extinction interval 0.1 to 1.7.

With a final volume of 0.5 ml it was necessary to use primarily 0.100 ml reagent mixture which is later diluted with 0.400 ml of the reagent mixture.

Table 1. Extinctions for various amounts of standard cholesterol per 0.5 ml total volume.

cholesterol μg	E_{522}	E_{522} per 2 μg	E_{440}	E_{440} per 2 μg
0.8	0.036	0.090	0.014	0.035
2	0.105	0.105	0.035	0.035
4	0.215	0.108	0.070	0.035
8	0.420	0.105	0.145	0.036
16	0.860	0.108	0.295	0.037
32	1.750	0.109	0.552	0.035

In order to prevent the escape of part of the volatile reaction mixture the afore-mentioned small tubes with polyethylene stoppers are required. When such stoppers are greased with starch-glycerol grease and turned firmly into the standard taper joints, they can withstand the vapor pressure during the heating of the reaction mixture.

Fig. 2 shows the results of measurements at different wavelengths for a cholesterol standard. A maximum occurs at 522 mμ and a minimum at 440 mμ.

The results obtained for various concentrations of cholesterol at the maximum and the minimum are shown in Table 1.

Beer's law is followed with sufficient accuracy in the concentration interval 2 to 32 μg per 0.5 ml total volume.

If the solution of $ZnCl_2$ had been stored for several weeks deviation from Beer's law occurred. However, the solution could be used at least 1 month after its preparation. Deviation from Beer's law was also found if the acetyl chloride had been stored for a longer time after the first opening of the bottle. If stored cool the acetyl chloride could be used for at least 1 month.

The red color developed in the reaction was not absolutely stable. However, the decrease in intensity during 15 min was low (3—4 %) and nearly proportional to the concentration of cholesterol. Thus, the instability of the color is not an important source of error if only the photometer reading is carried out within 15 min after the development of the color and as simultaneously as possible for the bile sample and the reference standard.

Experiments with hamster bladder bile

As postulated by Zuckerman and Natelson [7], diluted alkali will split cholesterol from protein without heating in the presence of chloroform. This is confirmed by the results presented in Table 2.

Hydrolysis by heating with KOH is, therefore, superfluous. It is possible that esters of cholesterol will not be hydrolysed by the treatment chosen in our method, but cholesterol esters are not known to occur in bile, and, further, in the Tschugaeff reaction esters give the same extinction on a molar basis as free cholesterol [4].

In order to examine the purity of the "Tschugaeff color" when the reaction is applied to bile, the formerly described procedure was carried out on a bile sample and the extinction was measured at different wavelengths (Fig. 2.).

III	1	1.08	0.541	2.00		
0.025 ml	2	0.076	0.168		0.452	
bile	3	0.035	0.086			0.407
IV	1	>3	1.60	—		
0.025 ml	2	0.114	0.235		(0.485)	
bile	3	0.090	0.205			0.439
				Average:	0.435	0.426

The absorption curve for "bile cholesterol" has another shape than the curve for standard cholesterol. In both cases the maximum is found at 522 mμ and the minimum at 440 mμ, but the absorption at the lower wavelengths is relatively higher for "bile cholesterol" than for standard cholesterol. Thus, $E^{st}_{522}/E^{st}_{440}$ is about 2.7, whereas $E^{bile}_{522}/E^{bile}_{440}$ is about 1.7. Therefore, the color obtained with "bile cholesterol" has a yellow tinge.

Several attempts to eliminate the yellow color were carried out such as heating of the alkalized bile before the extraction, further washing of the chloroform extract with water, alkali or acid, or the use of other solvents than chloroform, but without success.

In order to isolate the chromogenic impurities, and to ensure that the proposed procedure gives a complete extraction of cholesterol the following experiment was carried out: bile+0.5 ml 1 M KOH were shaken on the shaker with 0.3 ml chloroform and centrifuged in the usual way. The first supernatant was pipetted into another tube with 0.3 ml chloroform. After shaking for 1 min and subsequent centrifugation the supernatant was pipetted into a third tube with 0.3 ml chloroform. After renewed shaking for 1 min and subsequent centrifugation the supernatant was discarded. The 3 portions of chloroform were washed as usual and the analytical procedure was carried out as formerly described on all three samples and a blank. The colors given by the second and third extracts were not visibly red, but in most cases distinctly yellow. The results are presented in Table 3.

The experiments show that the yellow color given by the second and third extracts gives a certain extinction at 522 mμ. Therefore, the same must be the

Table 4. Experiment showing that the yellow color and the red "Tschugaeff color" do not interfere with each other.

Sample	No.	E_{522}	E_{440}
"Bile cholesterol" from 0.0125 ml bile	1	0.189	0.114
The same amount of "bile cholesterol" + 8 μg standard	2	0.595	0.261
8 μg standard	3	0.404	0.146

case for the yellow color included in the color from the first extract. Thus, a correction for the yellow color is necessary.

The table shows that the values E_{522}/E_{440} are increasing with increasing cholesterol concentration: this means that the relative contamination by the yellow color decreases.

Excluding the high value E_{522}/E_{440} for the second extract from sample IV, which apparently is extremely rich in cholesterol, the average values of E_{522}/E_{440} for the second and third extracts are nearly identical: about 0.43. This suggests that the cholesterol is completely extracted by the first extraction as a small amount of cholesterol in the second extract would have caused a significant increase of E_{522}/E_{440} compared with the corresponding value for the third extract.

To see whether the red color produced by cholesterol and the yellow color from the impurities interfered with each other, the following experiment was made: The extraction and evaporation procedures were carried out on 0.050 ml bile. The residue was dissolved in 1 ml chloroform. From this solution 0.250 ml was pipetted into a tube. 0.250 ml of the same solution was pipetted into another tube containing 8 μg of the standard cholesterol. A third tube contained only 8 μg of standard cholesterol. Thereafter, the rest of the procedure was carried out on the three samples and the blank, *cf.* Table 4.

Table 5. Double analyses of some samples of bile.

Sample No.	Bile for analysis ml	Cholesterol per ml bile μg	Mean	Deviation between single determinations in % of mean
I	0.005	765	779	3.6
	0.010	793		
II	0.003	1360	1290	10.9
	0.006	1220		
III	0.005	645	633	3.8
	0.010	621		
IV	0.005	571	597	8.9
	0.010	624		
V	0.005	540	537	1.1
	0.010	534		
			Average:	5.7

It is seen that the sum of the extinctions for samples 1 and 3 is equal to the extinction for sample 2 at 522 mμ as well as at 440 mμ. Thus, the yellow color which is included in the color for sample 1 does not interfere with the "Tschugaeff color" but is directly superposed on the latter.

Since, further, Beer's law is followed for the "Tschugaeff color" both at 522 and 440 mμ it is possible to correct for the yellow color in the following way:

With the designations

E^{bile}_{522} and E^{bile}_{440} = the observed extinctions for bile cholesterol,

E'^{bile}_{522} and E'^{bile}_{440} = the corrected extinctions, *viz.* the extinctions obtained if the yellow color were not present in the bile,

E^{st}_{522} and E^{st}_{440} = the observed extinctions for the standard,

and supposing that E_{522}/E_{440} for the yellow color is 0.43 (*cf.* Table 3), the following equation is obtained:

$$E'^{bile}_{522} = E^{bile}_{522} - (E^{bile}_{440} - E'^{bile}_{440})\ 0.43.$$

Introducing $E'^{bile}_{440} = E'^{bile}_{522} \frac{E^{st}_{440}}{E^{st}_{522}}$, the equation is transformed to:

$$E'^{bile}_{522} = E^{bile}_{522} \frac{1-0.43\ E^{bile}_{440}/E^{bile}_{522}}{1-0.43\ E^{st}_{440}/E^{st}_{522}}$$

The ratio $E'^{bile}_{522}/E^{bile}_{522}$ is usually between 0.8 and 0.9.

The content of cholesterol in the bile sample is thereafter calculated as formerly described (p. 1203).

In addition to the afore-mentioned recovery experiment (*cf.* Table 4), three recovery experiments were carried out in which the added cholesterol was introduced already at the beginning of the procedure. The results showed full recovery of the added cholesterol, *viz.* 102, 102, and 99 %, respectively.

In order to evaluate the accuracy with which cholesterol can be determined in hamster bile, a series of double estimations were carried out (Table 5).

To introduce as great a variation in the experimental conditions as possible, different amounts of the two samples corresponding to one double analysis were used. Further, the two samples were treated at different times, and the colors developed were measured together with different amounts of standard.

The average deviation between the individual determinations corresponding to a double analysis is 5.7 %.

Ion Exchange Equilibria

I. Sodium-Zinc, Sodium-Copper, Sodium-Manganese in Nitrate Solutions

RALPH DJURFELDT and OLOF SAMUELSON

Department of Engineering Chemistry, Chalmers Tekniska Högskola, Göteborg, Sweden

Results from measurements of ion exchange equilibria and swelling with a sulfonated resin in solutions of Na-Zn, Na-Cu, and Na-Mn nitrate are presented. The selectivity coefficient is independent of a dilution of the outer solution, but depends on the ionic composition of the resin. As the variations in swelling are very small this dependency must be ascribed to variations in the activity coefficients in the resin phase.

Exhange equilibria in ion exchange resins have been the object of numerous investigations, but most published work deals with the exchange between ions of the same valence. In the present paper data on the exchange in nitrate solutions between sodium ions and the following bivalent ions will be given: zinc, copper and manganese. The ion exchanger was a sulfonated resin of phenolic type (Wofatit KS). The aim of the investigation was to calibrate the resin so that it could be used for determinations of the complexity of metaphosphate solutions [1,2], but as the experimental results may be of general interest it seemed appropriate to present the experiments with nitrate solutions as a separate paper. Ion exchange equilibria with metaphosphate solutions will be given in Part II of the present series.

EXPERIMENTS

Ion exchange resin. The ion exchanger used was Wofatit KS of 0.4—0.5 mm particle size, which, after purification [2], was completely converted into the sodium form by treatment with a sodium chloride solution. This treatment was followed by washing with distilled water and drying in the air. The air dried resin was stored in flasks with close-fitting stoppers. The exchange capacity was determined by displacing the sodium ions with hydrochloric acid, evaporation to dryness and chloride titration according to Mohr. The exchange capacity per gram of air dry resin is given in the tables. The same resin was used in several experimental series and the differences in exchange capacity depend upon the somewhat varying moisture content after air drying.

For resins of the same type as used in the present investigation it has been shown that under similar conditions the counter ions have a negligible effect upon the exchange

Table 1. Exchange capacity and swelling

Counter ion	Exchange capacity mequiv./g Na+ resin (air dried)		n_r equiv./1000 g water		Average
Na	2.24;	2.24	3.76;	3.78	3.77
Cu	2.24;	2.24	3.63;	3.64	3.64
Zn	2.26;	2.26	3.67;	3.65	3.66
Mn	2.25;	2.25	3.71;	3.74	3.73

capacity [3]. This was checked by percolating 0.05 M nitrate solutions of the bivalent cations through columns containing a known weight of the sodium form of the resin until the effluent concentration was unchanged. After washing with water the bivalent cations were eluted with hydrochloric acid and transformed to sulfates by addition of sulfuric acid and evaporation to dryness. The sulfates were determined using the alkalimetric ion exchange method [4]. The results presented in Table 1 confirm that the differences in exchange capacity are small.

In the same table are given results from swelling determinations performed in pure water. For this type of resin the deswelling in the dilute solutions used in the ion exchange experiments can be neglected [4]. The experiments were performed according to the centrifuge technique [5]. In all experiments the sodium form of the resin (air dried) was weighed in and transformed into other forms as described above. The moisture content of the air dried Na-resin (26.1 % H_2O) was determined by drying over magnesium perchlorate in vacuum at 55°C.

A correction was applied for the increase in weight because of the ion exchange and instead of tabulating the amount of water per unit weight of resin the results are given as equivalents of metal ions per 1 000 g of water (n_r). In a separate series of experiments the swelling was studied for resins containing varying amounts of sodium and manganese ions. The results are given in Table 2.

Table 2. Swelling of Na—Mn-resin

Equivalent fraction, X_{Mn}	0.00	0.09	0.27	0.48	0.68	0.87	1.00
Equivalent concentration, n_r	3.77	3.74	3.74	3.74	3.73	3.73	3.73

Solutions. Solutions of 0.1 M sodium nitrate (for some experiments 0.2 M) and of 0.05 M copper-, zinc- and manganese-nitrate were prepared by dissolving calculated amounts of c.p. reagents in distilled water. The concentration of the solutions was determined according to the ion exchange method by passing known volumes through a cation exchange resin in the hydrogen form and titrating the liberated acid [3].

Procedure. In each experiment 40.00 ml 0.1 M sodium nitrate solution, a certain volume (a ml) of the nitrate solution containing the bivalent metal and (10—a) ml water were mixed in an Erlenmeyerflask. After addition of 1.000 g dry resin the flasks were closed and shaken for 17—18 h in a shaking apparatus. Preliminary experiments showed that equilibrium was attained within 4 h. After shaking, the solution was analyzed. In some experiments the order of the additions was altered in order to make sure that the equilibrium was reversible. — With manganese, experiments were performed also at higher dilution (at a total volume of 150 and 500 ml).

The determination of copper was made iodometrically in a biphthalate buffer [6]. For zinc a polarographic method was applied [7], using the Radiometer polarograph, PO3. Manganese was determined colorimetrically with a Coleman spectrophotometer after oxidation to permanganate with potassium periodate in phosphoric and nitric acid solution [6]. A number of duplicate experiments were performed and at least two analytical determinations were made in each experiment. The agreement was very good and only the average values are presented in the tables and diagrams. Some duplicate experiments were made about three months after the first experiments with manganese. In the meantime the resin had been run through three or four exchange cycles with metaphosphate solutions. In spite of this only small deviations could be detected.

CALCULATIONS

From the concentration of the bivalent cation in the equilibrium solution the amount of bivalent ions in the resin is calculated by difference. In this calculation the change in volume of the outer solution caused by the swelling of the resin is not taken into consideration. For the ion exchanger used the swelling was very small compared to the volume of the outer solution. Therefore, the errors in the calculations are insignificant. Furthermore, the nitrate concentration in the resin has been neglected. For this type of resin this is permitted when working at a low concentration in the outer solution [4].

The equivalent fraction of the bivalent ion in the resin (X) is obtained as the ratio between milliequivalents of M found in the resin and the total exchange capacity of the resin. Under the conditions used in these experiments the exchange capacity can be considered as a constant independent of X.

It has proved useful to calculate the selectivity coefficient K_X which for the exchange between sodium ions and a bivalent ion (M) can be defined by the following expression:

$$K_X = \frac{X}{(1-X)^2} \frac{n^2_{Na}}{n_M} \quad (1)$$

In this equation the equivalent concentrations (n) in the outer solution and equivalent fraction (X) of the bivalent ion in the resin phase are used to express the equilibrium.

DISCUSSION

According to the thermodynamic treatment by Donnan and Guggenheim [8] the exchange between sodium ions and a bivalent ion (M) may be represented by the following equation

$$\pi(2v_{Na} - v_M) = RT \ln \left[\frac{x_{MR} \cdot f_{MR}}{x_M \cdot f_M} \times \left(\frac{x_{Na} \cdot f_{Na}}{x_{NaR} \cdot f_{NaR}} \right)^2 \right] \quad (2)$$

where π is the swelling pressure [9], v the partial molar volume, and RT the product of the gas constant and the absolute temperature. Mole fractions and rational activity coefficients are represented by x and f. The subscript R is used for ions belonging to the resin phase.

Combining eqns (1) and (2) and substituting practical (molal) activity coefficients (γ) for rational activity coefficients gives

$$\pi(2v_{Na} - v_M) / RT = \ln(K_X / n_r) + \ln \gamma_{MR} / \gamma^2_{NaR} + \ln \gamma^2_{Na} / \gamma_M$$

where n_r is the total ion concentration in the resin phase in equivalents per 1 000 g water.

The left hand side in this equation contains the pressure-volume term. Data, which permit a calculation of this term, are not available for the resin used in the present investigation, but as the swelling has been shown to be independent of X (Tables 1 and 2) this term may be considered as constant [9,10]. In addition, for the systems investigated n_r is independent of X and, as the

8	0.361	0.0314	9.56	2.57
9	0.405	0.0420	9.76	2.59
10	0.448	0.0550	9.96	2.65
12	0.531	0.093	10.30	2.75
16	0.675	0.269	10.94	2.84
20	0.772	0.675	11.34	2.83
24	0.823	1.23	11.58	2.86

experiments have been performed at a low concentration, the last term on the right hand side can be neglected.

Therefore, it must be concluded that any variations in K_X with varying X must be ascribed to variations in the ratio $\gamma_{MR}/\gamma^2_{NaR}$. A reservation must be made for the intervals in which one of the components is present in very small amounts, since here certain complications may occur [11].

The experiments presented in Tables 3—5 show that for the system Na-Mn the volume of the outer solution, which has been varied between 50 and 500 ml, has no or in any case only a very small influence upon the selectivity coefficient K_X. On the other hand, there is in all experimental series with manganese a significant variation in the selectivity coefficient when the composition changes in the resin phase, K_X being higher for increasing equivalent fraction

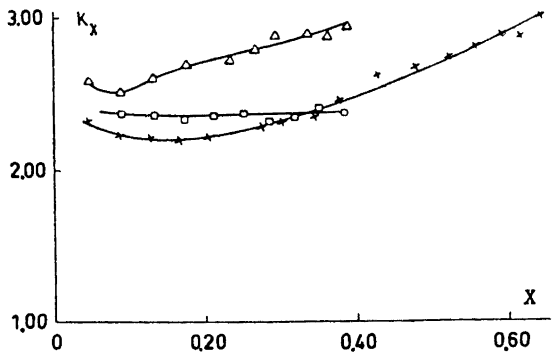

Fig. 1. The selectivity coefficient (K_X) as a function of the equivalent fraction (X) of the bivalent ion in the resin. △ System Na—Cu, □ System Na—Zn, × System Na—Mn.

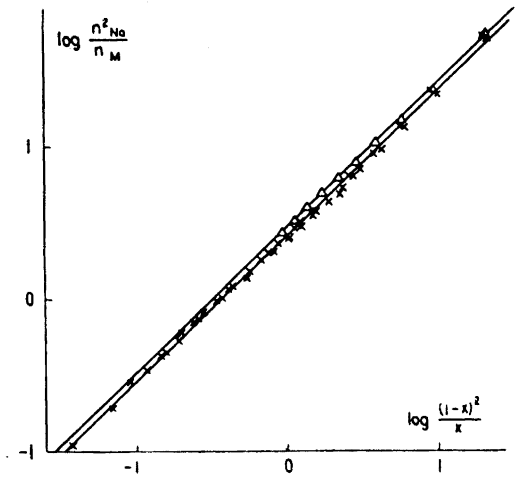

Fig. 2. Log n^2/n_M *versus* log $(1-X)^2/X$. △ System Na—Cu, × System Na—Mn.

(X) of the bivalent ion in the resin phase. As may be seen from Fig. 1 similar variations are obtained also for copper. For zinc the variations in K_X are very small within the interval in X covered in the present investigation. Diagrams of the type given in this figure are useful for calculations of ion exchange equilibria and this type of diagram has been used in the investigations on metaphosphate solutions presented in Part II.

For all three systems the variations in K_X when the equivalent fraction in the resin phase is altered are comparatively small compared with the variations established in other ion exchange reactions. Furthermore the ions studied in the present investigation give remarkably small differences in swelling (Tables 1 and 2). As already mentioned it must be concluded that the variations in K_X arise from variations in the ratio $\gamma_{MR}/\gamma^2_{NaR}$. It may also be pointed out that the differences in K_X for the three systems are comparatively small.

From a practical point of view it may be of interest to find out if the results can be represented by a simple empirical equation. The two-parameter equation proposed by Rothmund and Kornfeld [12] for equilibria in inorganic zeolites has also proved useful to describe the distribution between organic ion exchangers, sulfonated coal[13] as well as resinous exchangers [4,14] and an electrolyte

Table 6. Parameters in Rothmund and Kornfeld's equation

System	k	p
Na—Cu	0.33	1.06
Na—Mn	0.37	1.05

solution. For the exchange between monovalent and bivalent cations the equation can be written:

$$\frac{(1-X)^2}{X} = k\left(\frac{n^2_{Na}}{n_M}\right)^p \quad (3)$$

where k and p are empirical parameters. A plot of log n^2_{Na}/n_M against log $(1-X)^2/X$ is presented in Fig. 2 and as may be seen from the figure a straight line is obtained. From this graph the parameters have been determined. The results are given in Table 6.

Ion Exchange Equilibria

II. A Study of the Association in Sodium Polymetaphosphate Solutions Containing Zinc, Copper, and Manganese

RALPH DJURFELDT and OLOF SAMUELSON

Department of Engineering Chemistry, Chalmers Tekniska Högskola, Göteborg, Sweden

Using a cation exchange resin, the exchange of sodium ions for bivalent ions (Zn, Cu, Mn) has been studied in polymetaphosphate solutions. The experiments indicate that not only the bivalent ions but also sodium ions are associated with the polyanion and that there is a competition between the bivalent cations and the sodium ions for places in the polymer coil. The results suggest that the association equilibrium in metaphosphate solutions can as a first approximation be calculated using the Rothmund and Kornfeld formula originally suggested to describe ion exchange equilibria between a solid exchanger and electrolyte solutions.

Sodium polymetaphosphate (Graham's salt) is known as an efficient complex forming agent, which gives complexes with various metal cations. Several methods have been used to study the properties of these complexes but the results are contradictory.

In the present paper solutions containing zinc, copper, and manganese polymetaphosphate have been studied by means of an ion exchange method. The method is in principle the same as described in an earlier paper on iron(III)polymetaphosphate [1] (*cf.* also Ref. [2]).

EXPERIMENTS

Materials. The ion exchange resin and the nitrate solutions were the same as described in Part I [3]. Polymetaphosphate was prepared by heating $NaH_2PO_4 \cdot 2\ H_2O$ at 725°C for 2 h in a platinum dish and subsequently quenching with ice water. The metaphosphate glass was dissolved in a calculated volume of water to obtain a 0.1 N solution. The molecular weight of the metaphosphate was about 12 000 determined according to the end group method [4]. The solution was kept in a refrigerator to depress depolymerization, which occurs more rapidly at higher temperature. The solutions used in the experiments have never been more than a week old. The concentrations were checked according to the ion exchange method by passing the solution through a cation exchanger in the hydrogen form and subsequent titration against standard alkali using methyl red as

indicator [2]. As a check the sodium ions taken up by the resin were eluted with hydrochloric acid and determined as chlorides. Good agreement was obtained for the two methods.

Procedure. The ion exchange equilibria were studied in a way similar to that used in Part I. Instead of sodium nitrate, varying proportions of sodium nitrate solution and polymetaphosphate solution were added. The flasks were shaken for 17—18 h in a shaking apparatus. Preliminary experiments had shown that equilibrium was attained within 4 h and that the equilibrium was independent of the sequence in which the reagents were added. Afterwards the resin was separated from the solution and collected quantitatively on a small glass filter. The equilibrium solution was drained off as completely as possible and subsequently the resin was washed with water. The ions taken up by the ion exchanger were displaced with 3 N hydrochloric acid, the hydrochloric acid driven off by evaporation and the bivalent ion determined in the residue.

The analycital methods were those described in Part I. In the case of manganese the equilibrium solution was also analysed in some experiments. It was observed that the colorimetric determination of manganese was not affected by the presence of metaphosphate. Good agreement was obtained between the two methods. The calculations presented in Tables 1—4 are based upon the analysis of the resin when the main part of the manganese was present in the solution and vice versa.

Calculations. From the determination of the bivalent ion (M) in the resin or in the solution the equivalent fraction X in the resin is calculated and inserted in eqn. (1) in Part I. The selectivity coefficient K_X at a given value for X is taken from the experimental data obtained for nitrate solutions (*cf.* Part I) and the ratio n_M/n^2_{Na} calculated from eqn. (1) in Part I. The results obtained with solutions containing manganese are given in the Tables 1—4.

If it is valid to assume that sodium metaphosphate is completely dissociated (and that there is no associate formation of any kind between sodium ions and metaphosphate ions) the equivalent concentration of free M-ions (n_M) can be calculated by putting n_{Na} equal to the total concentration of sodium ions in the solution. The activity coefficients can, at least at present, not be accounted for in these polyelectrolyte systems and in the present work all deviations from ideality are included in the degree of dissociation. The calculations presented under Method I were made with the assumption that sodium metaphosphate is completely dissociated.

However, as discussed below, this approach cannot explain the behaviour of the metaphosphate solutions and therefore the assumption had to be made that not only bivalent ions but also sodium ions are strongly bound to metaphosphate. This is in agreement with results recently published by Schindewolf and Bonhoeffer [5] as well as by Wall *et al.*[6] Sufficient data are lacking for a quantitative interpretation of the systems studied in the present work. Therefore as a first approximation we have chosen the alternative of considering every PO_3-unit, which is not bound to a bivalent cation as being bound to sodium. The results are given in the tables under Method II.

As may be seen from the tables the two methods of calculation give values for n_M which differ considerably, the differences being largest for systems which contain a considerable excess of metaphosphate in comparison with the bivalent ion. Independent

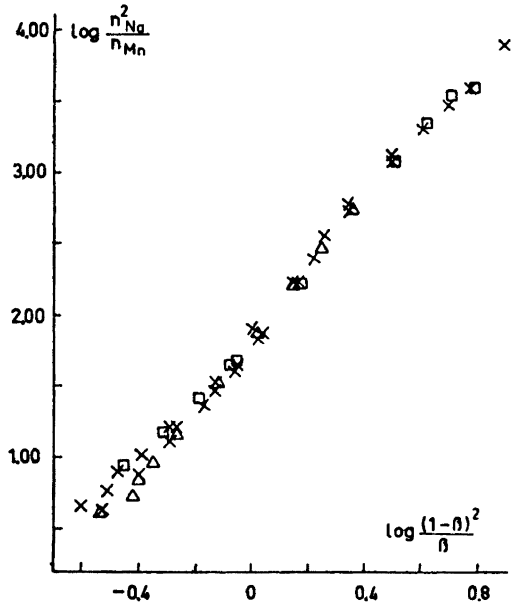

Fig. 1. log n^2_{Na}/n_{Mn} *versus* log $(1-\beta)^2/\beta$. Volume of solution: □ 50 ml; × 150 ml; △ 500 ml.

of the method of calculation the equivalent concentration of M-ions bound to the metaphosphate (n_{MP}) is calculated as the difference between the total concentration of M-ions in the solution and n_M. The data presented in the tables show that the differences in n_{MP} when calculations are made according to the two methods are rather small and in certain cases negligible. Consequently it may be of interest to find a correlation between n_{MP} and the ratio n_M/n^2_{Na}. The discussion in the subsequent part of this paper is restricted to calculations based upon Method II, but from the above it is obvious that even if Method I had been chosen the influence upon the empirical constants in the equation representing this correlation would be small. The symbol β is used for the ratio n_{MP}/n_{PO_4} where n_{PO_4} is the total equivalent concentration of metaphosphate. In accordance with the assumption made in the calculations according to Method II, the concentration of sodium ions bound to the metaphosphate is $(1-\beta)n_{PO_4}$.

DISCUSSION

When a solution containing a complex salt is diluted, the complex equilibrium is changed in the direction towards a decomposition of the complex. For the metaphosphate solutions studied in the present investigation this rule does not hold true. A probable explanation is that not only the bivalent ions but also the sodium ions are associated in some way with the metaphosphate. An attempt has been made to find an empirical equation which can represent the experimental results.

Figs. 1 and 2 show a plot of log n^2_{Na}/n_M against log $(1-\beta)^2/\beta$. It is observed that over a considerable range of concentration all experimental points fall upon one curve. Fig. 1 contains all experimental data with manganese from

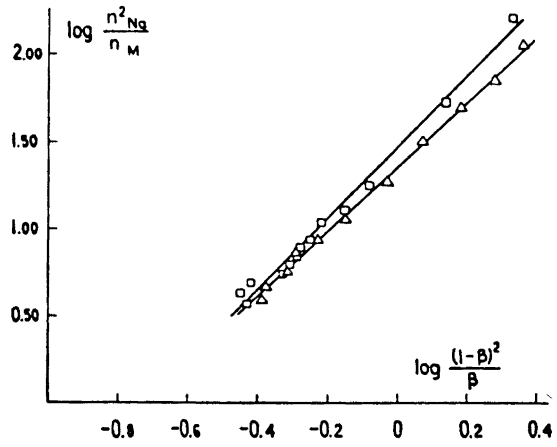

Fig. 2. log n^2_{Na}/n_M *versus* log $(1-\beta)^2/\beta$. □ System Na—Zn; △ System Na—Cu.

Tables 1—4. At low values for n^2_{Na}/n_{Mn}, *i.e.* at high values for β, there seems to be some deviations, but as the experimental errors may have a considerable influence no attempt will be made to account for these deviations. As a first approximation the curve can be considered as a straight line represented by the following equation:

$$(1-\beta)^2/\beta = k\ (n^2_{Na}/n_M)^p \qquad (1)$$

The numerical values for the parameters are reproduced in Table 5.

Experiments have been performed over a large concentration interval (volume 50—500 ml) and it is obvious that β, *i.e.* the association of manganese to metaphosphate, increases when diluting the solution. This peculiar behaviour might be explained by the polyelectrolyte character of the metaphosphate. For ion exchange resins, which are cross-linked polyelectrolytes, it is known that the uptake of bivalent ions by the resin increases when a solution containing bivalent and monovalent ions is diluted. Furthermore eqn. 1 shows that there is a competition between bivalent ions and sodium ions for metaphosphate in a similar manner as in a solid cation exchanger. Formally eqn. (1) is equivalent to the Rothmund and Kornfeld equation [7]

Table 5. Parameters in equation (1).

System	k	p
Na—Zn	0.19	0.49
Na—Cu	0.18	0.54
Na—Mn	0.17	0.42

which is an empirical formula used to represent ion exchange equilibria. This equation has been used successfully to describe ion exchange equilibria in inorganic as well as in organic ion exchangers. In general this equation has proved to be the best among the numerous formulas proposed for this purpose. From the present investigations it is evident that this equation can be useful also for calculations of the association equilibrium in solutions, which besides metaphosphate contain an ordinary salt, *e.g.* nitrate, the polymer metaphosphate being formally considered as an ion exchanger, *i.e.* as a separate phase. The coincidence might be explained by the ability of linear polyelectrolytes to coil, the cations being held in the coil in a similar manner as the counter ions in an ion exchanger.

The results from experiments with metaphosphate solutions, containing zinc and copper, are reproduced in an analogous manner in Fig. 2. As may be seen from the figure, the curves can as a good approximation be considered as straight lines. The parameters are given in Table 5. From these data it is obvious that the differences in behaviour between manganese, zinc and copper are rather small. Manganese is associated more strongly with the metaphosphate than zinc and copper.

The present approach can only be considered as a first approximation, the use of which is restricted to polymetaphosphate solutions containing besides another electrolyte. It has been observed that besides associated sodium ions, a considerable amount of free sodium ions are present in a pure solution of sodium polymetaphosphate [5], but sufficient data are not available to permit the application of a correction.

The experimental work reported in the present series of papers was performed during the years 1947—1949 at the Department of Inorganic Chemistry, The Royal Institute of Technology, Stockholm. Thanks are due to Professor Oscar Collenberg for putting the resources of his institute at our disposal and for his great interest in the investigations. The financial support of the *State Technical Research Council* (*Statens Tekniska Forskningsråd*) is gratefully acknowledged.

The Decrease of F^k-Integrals, Tetragonal Perturbations and Effects of Average Environment in the Reflection Spectra of Nickel(II) Complexes

OLE BOSTRUP and CHR. KLIXBÜLL JØRGENSEN

Chemical Laboratories B and A, Technical University of Denmark, Copenhagen, Denmark

The reflection spectra of 25 paramagnetic nickel(II) complexes are compared with the predictions of the ligand field theory for d^8 in O_h. The results are: the ligand field strength Δ can be implied in mixed complexes from the "rule of average environment" and is within 2 % independent of atoms outside the first co-ordination sphere. The effects of tetragonal contributions to the ligand field are surprisingly small and can be empirically described by a certain deviation of the band differences. The integrals F^k, inversely proportional to the extension of the partly filled shell, are decreased 15—40 % relative to the gaseous ion. As also found in molybdenum(III), the decrease has the same order of magnitude for γ_6- and γ_3-electrons.

It is possible to apply [1,2] the ligand field theory [3,4] for d^8 in the symmetry O_h to the absorption spectra of nickel(II) complexes in solution with some effects of intermediate coupling, intermixing levels with total spin $S = 1$ and 0. Hence, a nickel(II) complex can be characterized by two parameters, Δ (also called $(E_1—E_2)$ or 10 Dq) and the percentage decrease of the Slater-Condon-Shortley integrals F^k. The deviation of the ligand field from spherical to octahedral-cubic symmetry determines Δ, while the decrease of F^k is an effect of partly covalent bonding, decreasing the central field of spherical symmetry [5], compared to the central field in the gaseous ion.

The present paper is a comparison of the absorption spectra of solutions with the reflection spectra of solid nickel(II) complexes. The study of absorption spectra of solutions and solids have differing advantages: In the former case, physico-chemical methods [6] can prove the existence of complexes, of which no solid compounds are known. With modern spectrophotometers, the measurements of solutions can be made more easily, and a reliable molar extinction coefficient ε can be found, while the reflection spectra present a monotonic, but not a linear, function of ε. The latter function cannot be predicted and depends on the pulverization etc.; although the effective light

Table 1. Wavenumbers of band maxima of nickel(II) complexes. The excited levels are indicated. The unit is 1 kK = 1 000 K = 1 000 cm^{-1}.

path is larger for coarse-grained than for fine-powdered material, it decreases with increasing ε, and for very high values of ε, a flat "roof" is observed of the band (corresponding to light scattering from the surface). Thus, only the position of the band can be measured exactly in the reflection spectrum; the relative heights of the bands and their half-widths cannot easily be deduced from the data. On the other hand, the crystallographic structure of solids may be known, and several complexes cannot be dissolved in any solvent without decomposition or isomerization.

Table 1 gives the observed maxima, while the Figures illustrate selected examples. The material of Table 1 is taken partly from other papers [1,2,7,17]. One of the most conspicuous results is the similarity between the spectra of a given complex in solution and in solid state. This is a special case of N. Bjerrum's rule [8] that atoms outside the first co-ordination sphere have a very small influence on the absorption spectrum. This rule is valid mainly for the Laporte-forbidden transitions within the partly filled shell of the complex (as explained by ligand field theory) while the electron transfer spectra can be more depend-

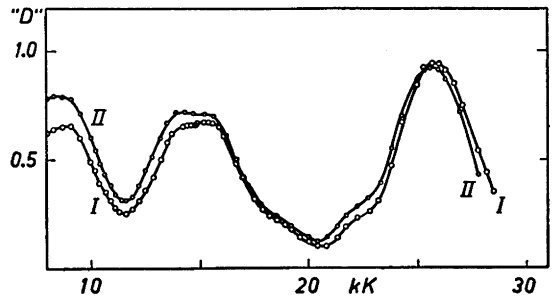

Fig. 1. Reflection spectra of I. $(NH_4)_2Ni(SO_4)_2$, $6H_2O$ and II. $NiSO_4$, $7H_2O$.

ent on the solvent [9,23]. The high bands of Fe *o*-phen$_2$(CN)$_2$ are, *e.g.*, shifted 10 %, while most other solvent effects do not exceed 2 %.

It is seen from Fig. 1 that the Tutton salt $(NH_4)_2Ni(SO_4)_2$, $6H_2O$ exhibits a slightly larger deviation from $Ni(H_2O)_6^{++}$ in solution or in other salts. It is interesting that the double band in the red [6], having $^3\Gamma_4$(F) and $^1\Gamma_3$(D) as excited levels [1], evolves in the manner predicted [1] for a larger Δ in the Tutton salt, *viz.* that the triplet percentage (and hence the intensity) wanders from the part with low to that with high wavenumber. Analogous to this greenish blue salt at room temperature, other samples, containing nickel(II) hexaaquo ions, turn sky-blue at the temperature of liquid air. Both the effects of crystal environment and temperature seem to be larger for aquo ions than for other complexes, perhaps caused by the changed polarization of the loosely bound water molecules.

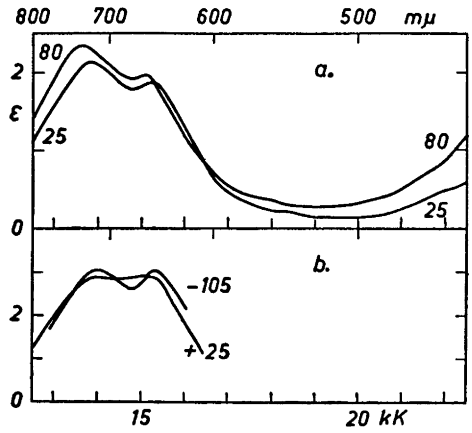

Fig. 2 a. Absorption spectra of 0.1 M $Ni(ClO_4)_2$ in 0.01 M $HClO_4$ measured in 5 cm cells on a recording Cary spectrophotometer. at 25° and 80°C. *b.* Absorption spectra of 0.5 M $Ni(NO_3)_2$ in 10 % water, 40 % glycerol 50 % ethanol, measured by Mr. Arne Jensen by photographic methods at −105° and 25°C as described in the experimental section.

Mr. A. Jensen of the Pharmaceutical College has kindly informed us about photographic measurements * of the spectrum of 0.05 M $Ni(NO_3)_2$ in 10 % H_2O, 40 % glycerol, and 50 % ethanol at —105°C, demonstrating similar effects (Fig. 2 b). Schäffer and Klixbüll Jørgensen have later measured the spectra of aqueous $Ni\,ClO_4)_2$ at 25°C and 80°C on a Cary spectrophotometer (Fig. 2 a). In all cases, the effect of cooling resembles that of Tutton salt, compared to other nickel(II) salts.

Fig. 1 of Ref. [7] demonstrates similar effects in the anhydrous chlorides and bromides. The position of $^1\Gamma_3$(D) might seem anomalously low. This effect is caused by the low values of F^k-integrals in anion complexes [4,5,10]. Δ is slightly larger in $NiCl_2$ than in the double chlorides $MNiCl_3$ and larger in $NiBr_2$ than in $MNiBr_3$, decreasing for increasing radii of the occurring anions and cations. All these compounds have an octahedral environment of six halide atoms around each nickel atom.

Table 2 gives the values of Δ and [2,4] the two quantities $B = \frac{1}{49} F^2 - \frac{5}{441} F^4$ and $C = \frac{5}{63} F^4$, derived from

$$^3\mathrm{P}-{}^3\mathrm{F} = 15\,B = \sigma_2 + \sigma_3 - 3\,\Delta \text{ with } \Delta = \sigma_1$$

$$\frac{4}{7}(^1\mathrm{D}) + \frac{3}{7}(^1\mathrm{G})-{}^3\mathrm{F} = 8\,B + 2\,C = \sigma(^1\Gamma_3)_{\mathrm{corr}}$$

σ_1, σ_2, σ_3 are the wavenumbers of the baricenters of the bands, representing transitions from $^3\Gamma_2$(F) to $^3\Gamma_5$(F), $^3\Gamma_4$(F), and $^3\Gamma_4$(P), respectively. σ_1 is corrected for the effects of intermediate coupling [1] and in some complexes inferred from the Orgel diagram, when σ_1 cannot be directly observed in the infra-red. σ_2 and $\sigma(^1\Gamma_3)$ are also corrected for the influence of intermediate coupling, when needed.

Table 2 gives the ratios β_1 and β_2 between the values of 15 B and 8 B+2 C in the complex and the gaseous ion, assuming the latter values to be 16 900 K (= cm^{-1}) and 17 900 K, respectively. However, this is equivalent to assuming an effect of (L, S)-coupling = $-\frac{3}{2}\zeta_{3d}$ = —950 K on the groundstate $^3I'_2$(F). If the effect of (L, S)-coupling is completely quenched, all the ratios β_1 and β_2 mentioned above are increased by 0.06 from the values, given in Table 2. If the interaction with $^1\Gamma_3$(G) is considered, β_2 is increased by ~0.03.

The decrease of β from 1 seems to be a rather monotonic function of the extent of the partly covalent bonding. However, it cannot be assumed that $\sqrt{\beta}$ is exactly equal to the intermixing in the squares of the wavefunctions, [5,12,15] forming linear combinations of atomic orbitals from the ligands and the nickel ion. It could not be assumed *a priori* that the molecular orbital theory might be applied to the complexes, assuming sharply defined configurations. However, the agreement of the Orgel diagram (the energy levels as function of Δ or rather [3] of Δ/β) with the gerade levels of d^n-complexes suggest that configuration interaction is relatively unimportant in the case of the γ_3- and γ_5-subshells.

* These measurements were carried out at Chemistry Department A, where Mr. Arne Jensen worked as a guest with Professor J. Bjerrum.

Table 2. The values of the parameters $\triangle$, 15 B, and 8 $B+2\,C$ in kK for nickel(II)-complexes in solid state and in aqueous solution. The ratios β_1 and β_2 of the two latter parameters, compared to those for the gaseous Ni^{++}, are given. The observed energy difference X_{obs} between $^3\Gamma_4(F)$ and $^3\Gamma_4(P)$ is compared to X_{calc} calculated from the ligand field symmetry O_h and the parameters $\triangle$ and β_1.

There is no doubt that γ_3-electrons are more anti-bonding than γ_5-electrons in all octahedral d^n-complexes, *i.e*, $\triangle$ is positive, agreeing with σ-bonding in the direction from the ligands to the central ion, or π-bonding in the opposite direction. If π-bonding from the ligands occurs, it decreases $\triangle$. It might thus be presumed that sub-shell configurations with many γ_3-electrons would exhibit larger effects of partly covalent bonding than the less anti-bonding configurations. It is seen from Table 2 that β is not essentially different for 15 B,

derived from $\gamma_5^5\gamma_3^3$ and $\gamma_5^4\gamma_3^4$ and for 8 B+2 C, derived from $\gamma_5^6\gamma_3^2$. Similar evidence is obtained [14] from molybdenum(III) in $MoCl_5(H_2O)^{--}$, where both the positions of $^2\Gamma_3$ and $^2\Gamma_5$ of γ_5^3 and $^4\Gamma_5$ and $^4\Gamma_4$ of $\gamma_5^2\gamma_3$ and $\gamma_5\gamma_3^2$, relative to the γ_5^3-groundlevel $^4\Gamma_2$, can be explained by the set B = 450 K and C = = 1 800 K. Hence, the decrease of β is equally effective for γ_5 and γ_3 electrons.

It is surprising that Jahn-Teller distorted systems such as vanadium(IV) [14] and copper(II) [1,2,15] have a ligand field of distinctly tetragonal symmetry, D_{4h}, even when the ligands are nearly or completely identical, while on the other hand, the regular d^3-, d^5-, d^6- and d^8-systems (with $S = \frac{3}{2}, \frac{5}{2}$, 0 and 1, respectively) agree very nicely with the theory for the cubic-octahedral symmetry O_h with only one ligand field parameter Δ.

In chromium(III) and cobalt(III) complexes [10], the deviations from O_h are not conspicuous, even in the case of highly different ligands. This is even more pronounced in the case of nickel(II) complexes [1,2] in solution. The latter effect can be explained by the insufficient difference between N and O in Tsuchida's spectrochemical series, which can be written [16]

$$Br < Cl < F < O < N < C$$

according to the bonding atom of the ligand. Table 1 gives one probable case of tetragonal splitting *, *trans*-Ni py_4Cl_2, where the level $^3\Gamma_5$(F) is markedly split, analogous [10] to $^4\Gamma_5$(F) of *trans*-Cr $en_2Cl_2^+$, corresponding to the larger difference between Cl and N.

Since no tetragonal splitting generally can be perceived, the rule of "average environment" can be directly applied to the absorption bands, *viz.* that they correspond to an average value of Δ, found by interpolation between Δ for the complexes with six equal ligand atoms. Tables 1 and 2 extend the investigated class of "average environments" considerably, as discussed by Asmussen and Bostrup in the case of polyamine nickel(II) complexes [17]. Especially, the tetradentate amine tren is shown to form no tetrahedral complexes in solid state [17], but to have two residual places for other ligands [2] (*cf.* also Ref.[18]).

Even though a genuine tetragonal splitting has been found only in Ni py_4Cl_2, it is possible to dinstinguish between purely cubic and tetragonally distorted complexes by a closer study of the observed wavenumbers: The two levels $^3\Gamma_4$(F) and $^3\Gamma_4$(P) have energies, which are the roots E in the weak field determinant

$$\begin{vmatrix} 0.6\,\Delta - E & 0.4\,\Delta \\ 0.4 & 15\,B - E \end{vmatrix} = 0$$

* The *trans*-configuration is demonstrated by Porai-Koshits [11] from crystallographic X-ray studies. The compound has the same spectrum in anhydrous pyridine and in ethanol with maxima at the same wavenumbers as the solid. By addition of 10 % water to the ethanolic solution, or more water to the pyridine, the greenish blue colour is changed to sky-blue with the same maxima as produced by $Ni(NO_3)_2$ in pyridine. Hence, the Katzin effect [12] seems to occur in the exchange of chloride and water on the two residual places of Ni py_4^{++}, when dissolved in an organic solvent.

or the equivalent strong field determinant

$$\begin{vmatrix} 3B + 0.8\,\Delta - E & 6B \\ 6B & 12B - 0.2\,\Delta - E \end{vmatrix} = 0$$

if the energy of the groundlevel $^3\Gamma_2$(F) is written -1.2Δ. Thus, with two parameters Δ and B, the three spin-allowed bands σ_1, σ_2, and σ_3 can be described. It is possible to compare the distance X_{obs} between the two bands σ_2 and σ_3 with the distance between the two roots E

$$X_{calc} = \sqrt{225\,B^2 - 18\,B\,\Delta + \Delta^2}$$

Table 2 demonstrates that within the uncertainty of the parameters Δ and B (amounting to 0.2 or 0.3 kK in X_{calc}) the complexes with six identical ligands have $X_{obs} = X_{calc}$, while for the tetragonal complexes, X_{calc} is 600—2 000 K *larger* than X_{obs}. When $X_{calc} - X_{obs}$ is very large, the treatment in Table 2 loses some of its validity; in this case, Δ is undoubtedly larger than indicated by σ_1, and 15 B thus calculated too large.

The deviation from the conservation of baricenters is probably caused by the interaction of the three $^3\Gamma_{t_5}$ levels. Schäffer and one of the authors [19] have discussed this problem. On the analogy of chromium(III) complexes, the tetragonal splitting is expected to occur in a complex with weaker ligand field along the tetragonal axis than along the two axes in the plane:

$^3\Gamma_2$(F)	$^3\Gamma_5$(F)	$^3\Gamma_4$(F)	$^3\Gamma_4$(P)
↓	↙ ↘	↙ ↘	↙ ↘
$^3\Gamma_{t_3}$	$^3\Gamma_{t_5}$ $^3\Gamma_{t_4}$	$^3\Gamma_{t_2}$ $^3\Gamma_{t_5}$	$^3\Gamma_{t_5}$ $^3\Gamma_{t_2}$

However, the splitting is smaller than expected from any electrostatic model. The effect in Table 2 is probably connected with the fact that the maximum absorption occurs in the doubly degenerate part $^3\Gamma_{t_5}$ of the bands $^3\Gamma_4$.

It is seen from Table 2 that SCN^- introduces a slightly larger value of Δ than the corresponding aquo complexes. By comparison of the data for $Ni\,py_4(SCN)_2$ and nickel(II) nitrate in 90 % pyridine [2], the latter complex probably contains only four molecules py, as previously foreseen. It is seen from Table 1 that the blue hydrochloride of nickel(II) dimethylglyoximate [20] has a large ligand field strength Δ.

The last problem to be discussed in this paper is the identification of the two next singlet levels $^1\Gamma_b$ and $^1\Gamma_c$ of Table 1. The three most probable levels are $^1\Gamma_1$(G) of $\gamma_5^6\gamma_3^2$ and $^1\Gamma_5$(D) and $^1\Gamma_4$(G) of $\gamma_5^5\gamma_3^3$. The slope of $^1\Gamma_c$ as function of Δ indicates that it is $^1\Gamma_5$(D) with the wavenumber $\sigma \simeq \Delta + 8\,B + 2\,C$, except in $RbNiCl_3$ and $NiCl_2$. It has previously been discussed [2] whether $^1\Gamma_b$ $\sim$15 kK is caused by a tetragonal splitting or is $^1\Gamma_1$(G) with a highly decreased value of $\sigma \simeq 16\,B + 4\,C$. Hence, $^1\Gamma_4$(G) with $\sigma \simeq \Delta + 12\,B + 2\,C$, is probably in most cases situated at a slightly higher wavenumber than $^3\Gamma_4$(P).

The main result of this paper is that the ligand field theory can be applied to paramagnetic nickel(II) complexes, both in solid state and in solution, with assumption of octahedral symmetry and one ligand field parameter Δ, if one

further variation is admitted: the parameters F^k (*i.e.* B and C) are multiplied by a factor $0.5 < \beta < 1$ in complexes, compared to gaseous Ni^{++}. Even though the levels may show individual behaviour, caused by interaction with other levels having the same S and Γ_n, it seems demonstrated that the partly filled shell is expanded, relative to the 3d-shell in Ni^{++}. This expansion has the same order of magnitude in the γ_3- and γ_5-sub-shells. The final explanation of this by molecular orbital theory will probably be rather complicated. However, the present authors believe that the ligand field theory is remarkably close, ~2 %, in predicting the d^n-energy levels, if the wavefunctions of the partly filled shell are written as antisymmetrized products of orbitals, each being the product of a hydrogen-like angular part (influenced by the group-theoretical conditions of the complex) and a radial part. The latter varies from one complex to another as indicated by the variation of the parameters F^k of electrostatic interaction between the electrons in a mainly spherical symmetrical field [5].

EXPERIMENTAL

The preparation and the analyses of the solid nickel(II) compounds are described elsewhere [7,11,17,20]. The ligands are abbreviated:

py	=	pyridine (1 N)
en	=	ethylenediamine (2 N)
den	=	diethylenetriamine = bis(2-aminoethyl)imine (3 N)
tetren	=	tetraethylenepentamine (5 N)
tn	=	trimethylenediamine = 1,3 diaminopropane (2 N)
bdn	=	1.3 diaminobutane (2 N)
dtn	=	bis (3-aminopropyl)imine (3 N)
ptn	=	1,2,3-triaminopropane (3 N)
tren	=	tris (2-aminoethyl(nitrogen (4 N)
$enta^{-4}$	=	ethylenediaminetetraacetate (2 N, 4 COO)
ata^{-3}	=	nitrogentriacetate (1 N, 3 COO)
gly^-	=	aminoacetate (1 N, 1 COO)
dmg H	=	dimethylglyoxime

The numbers in parentheses denote the number of nitrogen atoms and carboxyl groups available for co-ordination.

The reflection spectra were measured on the Beckman DU spectrophotometer. The absorption spectra of solutions were measured in the infra-red on this instrument and in the visible on the Cary MS-11 recording spectrophotometer.

Mr. Arne Jensen determined the absorption spectra of 0.05 M $Ni(NO_3)_2$ in a mixture of 10 volume % H_2O, 40 % glycerol and 50 % ethanol with a Zeiss spectrograph. The solutions were contained in a test tube, suspended in a double-wall plastic box, 20 × 20 × 20 cm. In the bottom of this box, liquid air was placed in order to evade condensation of ice inside the box, and the test tube was cooled by immersion in the liquid air. The temperature was measured with a thermoelement. The Schwarzschild exponent p was determined for the photographic plate, according to Kortüm [21]. The extinction coefficients were determined by comparison with the spectrum of the mixture, which was both photographed and measured on the Cary spectrophotometer. Since ε is definitely larger than for the aquo ion (*cf.* Ref. [22]), solvates with glycerol or nitrate must occur. It cannot be excluded that the composition of the solution changes with temperature, caused by the heat of formation of these complexes. However, a definite narrowing and shift towards higher wavenumbers by cooling can be inferred from Mr. Arne Jensen's measurements, and Mr. Claus E. Schäffer and Klixbüll Jørgensen have later determined on the Cary the effect on 0.1 M $Ni(ClO_4)_2$ in 5 cm layer of aqueous solution of warming from 25°C to 80°C, and obtained the predicted change: broadening and bathochromic shift of the bands, and the change of singlet-triplet intermixing corresponding to a decreased value of Δ.

Acknowledgments: We thank Mr. C. J. Ballhausen and Professor Jannik Bjerrum for having drawn our attention to the effect of temperature on the absorption spectrum of nickel(II) salts. Further, we are indebted to Dr. F. G. Mann, Cambridge, who provided samples of tren- and ptn-complexes. Finally, we want to thank Professor R. W. Asmussen for many valuable discussions.

O-Phosphorylserine

GEORG FÖLSCH and OLOF MELLANDER

Department of Medical Biochemistry, University of Gothenburg, Sweden

A synthesis of the L-, D- and DL-forms of O-phosphorylserine (phosphoserine, serinephosphoric acid or 2-amino-2-carboxy-ethyl-phosphoric acid) is described. The L-isomer was shown to be identical with the phosphorylated serine isolated from phosphoproteins.

A large part of the phosphoprotein phosphorus is considered to be ester bound to serine hydroxyl groups. This view was first expressed by Lipmann after the isolation of O-phosphorylserine from casein and vitellin hydrolysates [1–4]. Later, phosphorylated serine was obtained from several phosphoproteins [5–12], and was also found in free form [13–14]. The occurrence of phosphoric acid diester bound serine in phospholipids such as phosphatidyl serine is well known, and, in addition, serine-guanidoethanol- [15] and serine-aminoethanol [16] diesters have been found. Furthermore, O-phosphorylserine has been isolated from enzymes deactivated by *diiso*propylphosphoryl fluoride and related compounds [17].

Phosphoproteins and phosphopeptides have been studied for a long time [18] in our laboratory. We have observed that, when cow's casein is hydrolysed by proteolytic enzymes under conditions similar to the physiological ones [19] a considerable part of the casein molecule is left as an enzyme-resistant residue. This residue consists of a complex mixture of phosphorylated peptides. The amino acid composition and the phosphorus content of this peptide fraction [20] allow all of the serine hydroxyl groups to be bound as monophosphate esters, although other structures are possible, *e. g.* diester bridges, polyphosphate bridges, N-phosphoryl groups *etc.*[21] The enzyme resistance of these peptides seems to be due to their phosphorylation. Another property of these phosphorylated peptides, the tendency for metal complex formation, is of great biological interest. The calcium salts are, for example well utilised in bone calcification [22,23]. One of us (F.) has made a study of the synthesis of phosphorylated serine peptides as a link in this chain of investigation [24,25]. Here a new synthesis of the keycompound in such peptides, O-phosphorylserine, will be described.

An esterification of serine was mentioned by Langheld in 1911 [26], but the first synthesis of O-phosphorylserine was reported by Levene and Schormüller [27]. These obtained the racemic form in a yield of about 15 % by esteri-

fication of DL-serine with a mixture of phosphoric acid and phosphorus pentoxide. The barium salt of the naturally occurring L-isomer was later isolated after fractional crystallisation of the brucine salts of the racemic mixture [28].

Modifications of this phosphoric acid esterification were reported by Plimmer, who obtained somewhat higher yields [29]. More recently, appreciably higher yields, 40 %, were reported by Canali *et al*[30]. who replaced the aforegoing phosphorylation mixture with polyphosphoric acid. Unlike Canali *et al.*, Cherbuliez and Rabinowitz [31], however, found no phosphorylation of serine with polyphosphoric acid of low degree of polymerisation. Cherbuliez and Rabinowitz obtained a yield of 15 % when serine methyl ester was used instead of the free amino acid [31].

It has been stated several times that the direct esterifications of serine as reported by Levene and Schormüller or by Plimmer give low yields and impure compounds [32]. The same drawbacks seem to accompany the method of Canali *et al.* by which method we have obtained at most a 10 % yield.

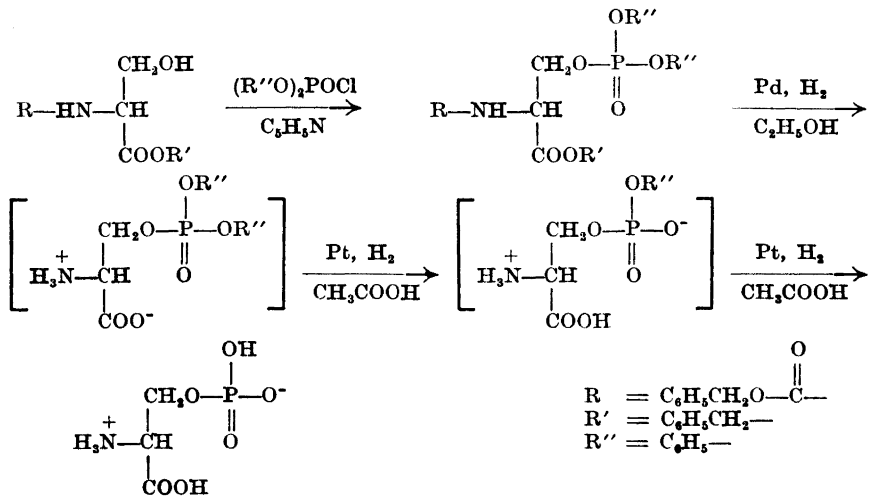
These difficulties have forced us to work out a new way to synthesise O-phosphorylserine. The route we used is very similar to the one we used for synthesising phosphorylated peptides [24] and to that used by Baer and Stancer in their synthesis of phosphorylethanolamine [33]. N-Carbobenzoxyserine benzyl esters are phosphorylated by diphenylphosphoryl chloride [34], and the resulting triesters are cleaved by catalytic hydrogenolysis. By this procedure, L-, D- and DL-forms of O-phosphorylserine are obtained in pure, crystalline state and in good yields.

The pure compounds were characterised by their melting points, optica rotations, elementary compositions, R_F-values in different solvents, X-ray powder diffraction patterns and by their infrared absorption spectra *.

In preliminary experiments, dibenzylphosphoryl chloride [36] and di-(*p*-nitrobenzyl) phosphoryl chloride [37] were used as phosphorylating agents. These acid chlorides reacted readily with serine hydroxyl groups ** but the yields were not satisfactory in some cases. Better results were obtained with the easily available and stable diphenyl derivative [34]. The phosphorylation step takes place practically quantitatively (*cf.* Riley *et al.*[39]). The triesters obtained are hydrogenolyzed more slowly than the corresponding benzyl esters, but the yields are good. Two intermediates, O-diphenylphosphorylserine and O-monophenylphosphorylserine can easily be isolated during the hydrogenolysis. This indicates the stepwise elimination of blocking benzyl- and phenyl groups shown in the reaction scheme.

EXPERIMENTAL

When not otherwise stated, the compounds were before analysis dried at room temperature *in vacuo* over phosphorus pentoxide. The melting or decomposition points were determined by using sealed capillary tubes and a well stirred oil bath. They are uncorrected.



Elementary analyses were made in the Microanalytical Laboratory of the Institute of Medical Chemistry, Uppsala University.

Infrared absorption spectra were recorded with a double beam in time spectrophotometer of the Hornig type built by Dr. M. Skogh at the Institute of Medical Chemistry,

* A study of some metal complexes of the DL-compound has been reported by Österberg [35].

** Li and Eakin [38] observed no reaction between dibenzylphosphoryl chloride and DL-serine methyl ester.

Reaction scheme

Uppsala University. Sodium chloride prism was used. The compounds (1.4 mg) were pressed into freeze dried potassium bromide (300 mg) pellets.

X-Ray powder diffraction patterns were taken with a Guinier camera using quartz monochromated Cu$K\alpha$-radiation (λ = 1.5418 Å). The solvent mixtures used in the paper chromatography were: (I) Phenol-water (80/20 v/v), ascending, about 6 h. (II) *n*-Butanol-acetic acid-water (40/10/50 v/v), descending; 18 h.

N-Carbobenzoxyserine benzyl esters

These compounds were obtained by an azeotrope distilling procedure similar to that of Cipera and Nicholls [40]. Ten g of N-carbobenzoxyserine [41] and 20 ml of benzyl alcohol were distilled with 100 ml of carbon tetrachloride in the precence of 0.5 g of *p*-toluenesulphonic acid. Carbon tetrachloride was added periodically to keep the volume constant. After a reaction time of 5 h the carbon tetrachloride solution was allowed to cool and was then washed with 50 ml of 20 % sodium bicarbonate solution and three 50 ml portions of water. It was dried over anhydrous sodium sulphate. Light petroleum (b. p. 20—40°) was added to the warmed solution. After some hours at room temperature most of the ester had crystallised and was filtered off. More material was obtained by cooling of the concentrated mother liquor to —16°. The yields varied between 70 and 78 %. The physical constants of the three isomers agreed well with the values reported by Baer and Maurukas [41]. Jones and Lipkin [42] recently prepared the DL- and L-compounds, and Skinner *et al.*[43] the D-compound by other procedures.

N-Carbobenzoxy-L-serine benzyl ester, m. p. 83—84°, $[\alpha]_D^{21}$ + 5.5° (chloroform, *c* 4.1, *l* 1); N-Carbobenzoxy-D-serine benzyl ester, m. p. 84—85°, $[\alpha]_D^{21}$ —5.6° (chloroform, *c* 4.0, *l* 1); N-Carbobenzoxy-DL-serine benzyl ester, m. p. 72—73°.

O-Diphenylphosphoryl-N-carbobenzoxy-L-serine benzyl ester

To a solution of 6.6 g (20 mmole) of N-carbobenzoxy-L-serine benzyl ester in 10 ml of anhydrous pyridine 6.4 g (24 mmole) of diphenylphosphoryl chloride [34] was added within 10 min. The reaction mixture was shaken and was held below 40° by occasional cooling in

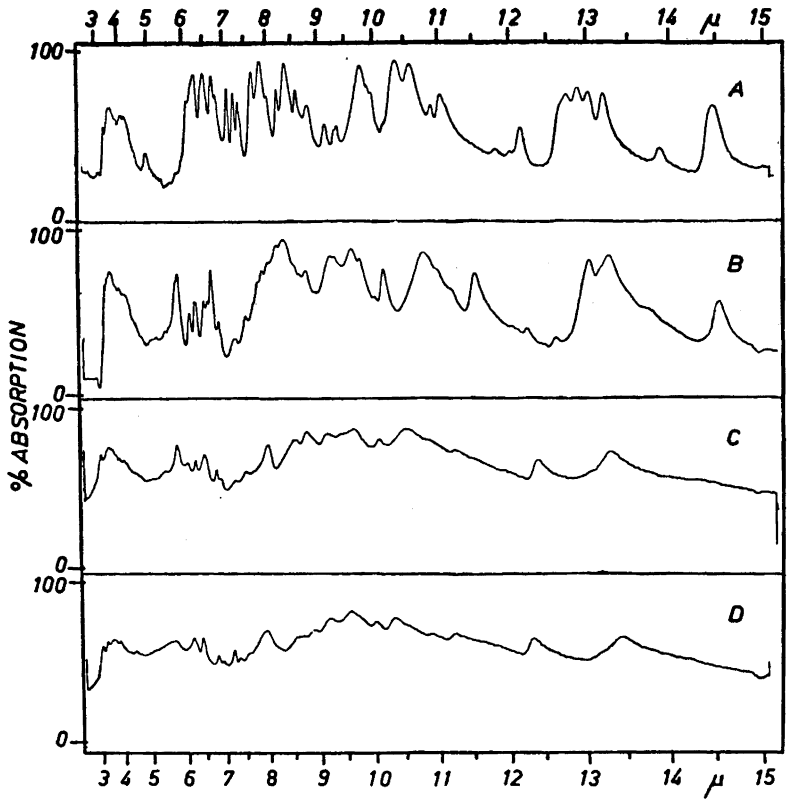


Fig. 1. Infrared absorption spectra of O-diphenylphosphoryl-DL-serine (A), O-monophenylphosphoryl-DL-serine (B), O-phosphoryl-DL-serine (C) and O-phosphoryl-L-serine (D). Compounds in potassium bromide pellets.

cold water. A crystalline precipitate of pyridinium chloride was formed. After 4 h at room temperature, the excess of diphenylphosphoryl chloride was decomposed with 1 ml of water. After an additional hour the mixture was poured into 150 ml of ice water and 150 ml of ether. The ether extract was washed successively with 2 × 50 ml of cold 4 N sulphuric acid, 50 ml of water, 50 ml of 20 % sodium bicarbonate and 50 ml of water.

After drying over anhydrous sodium sulphate the ether was distilled off at reduced pressure, finally at 0.1 mm Hg. The triester remained as a colourless oil, weighing 10.8 g (96 % of theory), $n_D^{22°}$ 1.5640. It was dissolved in 30 ml of 99 % ethanol, and light petroleum (b. p. 20—40°) was added to slight turbidity whereupon O-diphenyl phosphoryl-N-carbobenzoxy-L-serine benzyl ester slowly crystallised out. After a night at room temperature and a few hours at 4° the chrystallisation was complete: 10.5 g (95 % of theory); m. p. 53—53.5°; $[\alpha]_D^{18}$ −3.8° (abs. ethanol, *c* 10.1, *l* 1); $[\alpha]_D^{18}$ +18.0° (chloroform, *c* 5.3, l 1). (Found: C 64.29; H 5.15; N 2.58; P 5.12. Calc. for $C_{30}H_{28}O_8NP$ (561.5): C 64.17; H 5.03; N 2.49; P 5.52).

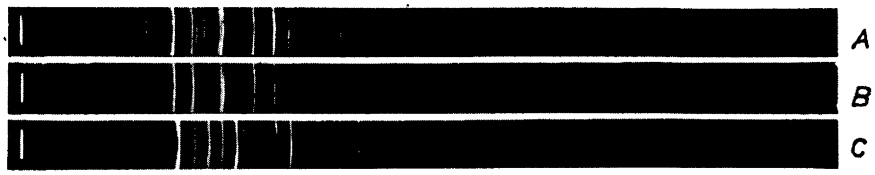

Fig. 2. X-Ray powder diffraction patterns of synthetic (A) and natural (B) O-phosphoryl-L-serine and of O-phosphoryl-DL-serine (C). The strongest reflections are listed in the following table.

O-Diphenylphosphoryl-N-carbobenzoxy-D-serine benzyl ester

The D-isomer was prepared in the same way as the aforegoing compound from 3.3 g of N-carbobenzoxy-D-serine benzyl ester. The yield was 5.3 g (95 % of theory); m. p. 52—53°; $[\alpha]_D^{18}$ +3.7° (abs. ethanol, *c* 10.2, *l* 1); $[\alpha]_D^{18}$ −18.3° (chloroform, *c* 5.0, *l* 1). (Found: C 64.37; H 5.10; N 2.67; P 5.06. Calc. for $C_{30}H_{28}O_8NP$ (561.5): C 64.17; H 5.03; N 2.49; P 5.52).

O-Diphenylphosphoryl-N-carbobenzoxy-DL-serine benzyl ester

The DL-compound was prepared in the same way as the enantiomers. From 16.5 g of N-carbobenzoxy-DL-serine benzyl ester was obtained 25.8 g (92 % of theory); m. p. 47—48°; Found: C 64.21; H 5.20; N 2.62; P 5.26. Calc. for $C_{30}H_{28}O_8NP$ (561.5): C 64.17; H 5.03; N 2.49; P 5.52).

O-Phosphoryl-L-serine

To a solution of 5.6 g (10 mmole) of O-diphenylphosphoryl-N-carbobenzoxy-L-serine benzyl ester in 50 ml of 99 % ethanol was added 1.5 g of palladium oxide catalyst [44], and the mixture was shaken in an atmosphere of pure hydrogen. Eight hours later,

practically no more hydrogen was being consumed and a precipitate, largely consisting of O-diphenylphosphoryl-L-serine, had been formed. This material was dissolved by adding 50 ml of a warm water and acetic acid (1:1) mixture. The catalyst was filtered off and washed with more hot water. The combined solutions were then evaporated to dryness at reduced pressure (bath temperature 40°). The solid residue was redissolved in 50 ml of glacial acetic acid and again shaken in a hydrogen atmosphere, now together with 1 g of platinum oxide catalyst [44]. After about 20 h no more hydrogen was absorbed *. Twenty-five ml of hot water was added to dissolve some precipitated material and the catalyst filtered off. The filtrate and water washings were evaporated to dryness at reduced pressure and the residue dissolved in 100 ml of water. Ten g of cation exchange resin Amberlite IR-120 (H^+-form) was added and the mixture was shaken for 1.5 h. The resin was filtered off and washed with water. The combined solutions were again evaporated to dryness *in vacuo*. The solid residue was finally dissolved in 8 ml of boiling water, and 99 % ethanol was added to faint turbidity. The solution was left to slowly attain room temperature **, when crystals of O-phosphoryl-L-serine were formed. These were washed with ethanol-water (2:1) and dried *in vacuo* at room temperature over phosphorus pentoxide. The yield was 1.55 g (84% of theory); m. p.*** 168—172° (decomp.); reported 167° (decomp.)[9]; $[\alpha]_D^{19}$ +7.4° (water, *c* 3.4, *l* 1); $[\alpha]_D^{21}$ +16.2° (2 N HCl, *c* 3.0, *l* 1); reported $[\alpha]_D^{23}$ +7.2° (water, *c* 4.2)[9]; $[\alpha]_D^{25}$ +16.3° (10 % HCl, *c* 6). (Solution prepared from the *barium* salt) [28]. (Found: C 19.81; H 4.45; N 7.57; P 16.73. Calc. for $C_3H_8O_6NP$ (185.1): C 19.47; H 4.36; N 7.57; P 16.74). R_F-values ****: In solvent I 0.08, in II 0.05.

The infrared absorption spectrum (Fig. 1) and the X-ray powder diffraction pattern (Fig. 2) of this compound were both identical with those obtained from O-phosphoryl-L-serine isolated from casein by Ågren and de Verdier [9] (a sample was kindly given us by Dr. Carl-Henric de Verdier).

O-Phosphoryl-D-serine

This isomer, which has not been reported before, was prepared from 2.80 g of the corresponding triester by hydrogenolysis in exactly the same way as the preceding isomer. The yield was 0.76 g (80 % of theory); m. p. 170—173° (decomp.); $[\alpha]_D^{21}$ −7.0° (water, *c* 3.0, *l* 1); $[\alpha]_D^{21}$ −15.6° (2 N HCl, *c* 3.2, *l* 1). (Found: C 19.62; H 4.40; N 7.55; P 16.81. Calc. for $C_3H_8O_6NP$ (185.1): C 19.47; H 4.36; N 7.57; P 16.74).

The infrared absorption spectrum and X-ray powder diffraction pattern were identical with those of the L-derivative.

O-Phosphoryl-DL-serine

The racemic compound was prepared from the corresponding racemic triester. 22.4 g of this gave a yield of 5.8 g (72 % of theory) of the well crystallising and hitherto unreported *monohydrate;* m. p. 153—156° (decomp.) after sintering at 135°. (Found: C 17.62; H 5.00; N 6.79; P 15.16. Calc. for $C_3H_8O_6NP$, H_2O (203.1): C 17.73; H 4.96; N 6.90; P 15.25).

---

* The progress of the hydrogenolysis after different times can easily be determined by paper chromatography in solvent II. At the end of the reaction only traces of O-diphenylphosphoryl-serine (R_F 0.59) and O-monophenylphosphorylserine (R_F 0.18) should be present beside O-phosphorylserine (R_F 0.05).

** To obtain complete crystallisation, it was often necessary to gradually add several volumes of absolute ethanol and to store the solution in the icebox for some days.

*** The melting points of O-phosphorylserines and O-phosphorylated serine peptides vary appreciably with the conditions during the determination. When heated very slowly, they decompose at temperatures below those reported here. Much more characteristic are the infrared spectra and the X-ray diffraction patterns.

**** Practically the same R_F values were obtained for the L-, D, and DL-forms.

The water of hydration was not removed by drying *in vacuo* at 100°. When the compound was dried at 120°, considerable decomposition occurred.

The anhydrous compound could be prepared by precipitation with ethanol and ether from the 5 % solution of the *monohydrate* in water; m. p. 167—170° (decomp.); reported 165—166° (decomp.) [29], 166—167° [32]. (Found: C 19.45; H 4.52; N 7.52; P 16.50. Calc. for $C_3H_8O_6NP$ (185.1): C 19.47; H 4.36; N 7.57; P 16.74).

The infrared absorption spectrum of the racemic product could be distinguished from the spectra of the optically active isomers, although they were very similar (Fig. 1). The X-ray powder diffraction pattern of the racemic compound was quite different from the pattern of the L- and D-isomers (Fig. 2). However, its infrared spectrum and X-ray diffraction pattern were identical with those obtained from O-phosphoryl-DL-serine prepared according to Plimmer [29] and Canali *et al* [30].

O-Diphenylphosphoryl-DL-serine

O-Diphenylphosphoryl-N-carbobenzoxy-DL-serine benzyl ester in ethanol solution was shaken as usual in a hydrogen atmosphere together with palladium oxide catalyst. The precipitate formed during the hydrogenolysis was filtered off and dissolved in a minimum amount of a hot mixture of acetic acid and water (2:1). The solution was filtered to remove the palladium catalyst and was then allowed to cool. After some hours at +4° the crystals of O-diphenylphosphoryl-DL-serine were collected and dried *in vacuo* over potassium hydroxide; m. p. 129—130° (decomp.). (Found: C 53.39; H 4.76; N 4.14; P 9.16. Calc. for $C_{15}H_{16}O_6NP$ (337.3): C 53.41; H 4.78; N 4.15; P 9.19).

Further hydrogenolysis of this compound in glacial acetic acid solution using platinum oxide catalyst, gave O-phosphorylserine, identified by paper chromatography.

Free amino group was indicated by the colour reaction of the compound with ninhydrin. R_F value in solvent I 0.9, in II 0.59. The infrared absorption spectrum is shown in Fig. 1. In contradistinction to the O-phosphorylserines and to O-monophenylphosphorylserine, there was no carbonyl absorption band near 5.75 μ. Instead, the strong band at 6.04 μ indicated the presence of an ionised carboxyl group.

O-Monophenylphosphoryl-DL-serine

This phosphoric diester was isolated in another hydrogenolytic experiment. O-Diphenylphosphoryl-N-carbobenzoxy-DL-serine benzyl ester was hydrogenated as usual using palladium as a catalyst and, after evaporation of the ethanol, the residue was dissolved in glacial acetic acid. The hydrogenolysis was started again, now with platinum oxide catalyst. After an hour, during which the hydrogen was rapidly consumed, the reaction slowed down and was interrupted. The catalyst was removed and the solvent distilled off *in vacuo*. The solid residue was then dissolved in a minimum amount of boiling water, and the filtered solution was left at room temperature for four hours. Crystals of O-monophenylphosphoryl-DL-serine were formed. After one more recrystallization from hot water, the crystals were collected, washed with ice-cold distilled water and dried (the mother liquor and washings contained O-phosphorylserine); m. p. 163—165° (decomp.). (Found: C 41.62; H 4.69; N 5.38; P 12.01. Calc. for $C_9H_{12}O_6NP$ (261.2): C 41.39; H 4.33; N 5.36; P 11.86).

The compound was ninhydrin positive. The R_F value in solvent I was 0.36, in II 0.18. Hydrogenolysis in glacial acetic acid solution and with platinum oxide catalyst gave O-phosphorylserine, identified by paper chromatography. The infrared absorption spectrum is shown in Fig. 1.

On the Chemical Composition of some Mucous Substances of Fish

ERLAND WESSLER and IVAR WERNER

Institute of Medical Chemistry, University of Upsala, Sweden

The mucous substances of some fishes have been studied. The predominant component of the external surface mucus seems to be a simple protein, in the case of myxinoids a protein which precipitates in fibres. Together with the simple protein there are also small, varying amounts of nucleic acid and glycoproteins. The glycoproteins contain hexosamine, galactose, fucose, and sialic acid, and thus seem to be of the same types as are present in mucous secretions of other vertebrates.

In addition to ribose (nucleic acid) and in some cases small amounts of fucose, and/or glucose, the fish-roe preparations contained hexosamine, galactose, mannose, and sialic acid as monosaccharide constituents. The carbohydrate moiety probably forms the substantial part of the jelly coat of the roe.

The epithelial mucus of mammals has a fairly uniform composition, its main components being two glycoproteins[1]. One of these has a prosthetic group containing acetylated hexosamine, galactose, and fucose; the other contains acetylated hexosamine and sialic acid. As a rule they occur together, and are usually inseparable by ordinary physico-chemical procedures. The chemical differences found in mucus specimens from different organs, species, or individuals may be differences in proportion between the two types of prosthetic groupings, differences in the relative content of some monosaccharide constituent such as fucose or galactosamine, or slight variations in the acyl groups substituted to the sialic acid molecule. Up to now no exception from this pattern has been reported.

Investigations on frog spawn have shown the mucous, gelatinous coating of the spawn to contain the same main carbohydrate constituents, *viz.* hexosamine, galactose, fucose, and probably, sialic acid [2,3].

Preliminary analyses of mucosal scrapings from birds (pheasants and geese) have shown the same main carbohydrate components (Werner, unpublished data).

Thus the same types of glycoproteins seem to be prevalent in the epithelial mucus of mammals, birds, and amphibians. We therefore decided to investigate some mucous substances of the lower vertebrates, fishes, and cyclostomes.

MATERIAL

The external mucous coatings of plaice (*Pleuronectes platessa*), cod (*Gadus callarias*), whiting (*Gadus merlangus*), eel (*Anguilla vulgaris*), pike (*Esox lucius*), ray (*Raja sp.*), and hagfish (*Myxine glutinosa*) were collected, care being taken to avoid contamination from both external and internal sources (roe, milt, *etc*,). The preparations were dehydrated in ethanol, acetone, and ether, and subsequently analysed.

Samples of roe from perch (*Perca fluviatilis*), pike-perch (*Lucioperca sandra*), cod (*Gadus callarias*), burbot (*Lota vulgaris*), whitefish (*Coregonus lavaretus*), and Baltic herring (*Clupea harengus*), and of milt from burbot (*Lota vulgaris*) were freed from membranes, washed with aqueous (50 %) ethanol, dehydrated by treatment with ethanol, acetone, and ether, and analysed.

Some other samples of roe from pike-perch, burbot, and whitefish, and of milt from burbot were instead lyophilized, and subsequently analysed. These preparations, however, gave slightly turbid solutions in the orcinol-sulphuric-acid reaction, probably owing to the presence of some lipid constituents, and they were therefore not used for quantitative analysis.

ANALYTICAL METHODS

Nitrogen was determined by the Kjeldahl method [4].

Hexosamine was assayed according to Blix's modification of the Morgan-Elson method [5]. Before analysis the samples were hydrolysed for 14 and 18 h with 2 N hydrochloric acid at 100°C. The two hydrolysis-times gave nearly identical hexosamine values. The readings were made at 530 mμ in a Beckman B spectrophotometer.

Hexose, *pentose*, and *methylpentose* were determined by the orcinol-sulphuric-acid method in Vasseur's modification [6]. After a heating time of 20 min the absorbancies were measured at 495 mμ, where the sugars present have roughly the same extinction coefficients. As chromatography revealed galactose to be the predominant sugar in most preparations this sugar was chosen as standard.

The *methylpentose* content was determined separately by Dische's method [7]. A heating time of 10 min was used. A standard with 10 μg of fucose was run simultaneously with the unknown samples. The readings were made 4 to 6 h after the addition of cysteine, because at this time the absorbancy depending on the fucose content has reached a maximum and nearly constant value [8,9].

Most of the preparations were found to contain material interfering with the determination. When cysteine was added, a colour with maximum absorption at about 395 mμ developed instantly, and then gradually disappeared in 2 to 3 h. The absorption due to fucose seemed to develop, independently of the interfering reaction, in the course of 4 to 6 h. Thus when very little or no fucose was present there was only a fading of the initial colour after addition of cysteine; but when the fucose content was higher, the absorption first decreased and later increased. When the fucose content exceeded about 1 % there was no fading, the colour intensity rising from the beginning. Thus the influence of the interfering material was probably eliminated by not making the readings until at least 4 h after the addition of cysteine.

The absorptions developing during the heating with sulphuric acid were read off before the addition of cysteine, and subtracted from the values obtained 4 to 6 h after cysteine had been added.

The methylpentose values found are reported as fucose, because this sugar was the only methylpentose revealed by chromatography.

Sialic acid was assayed by the quantitative Ehrlich and Bial reactions described previously [10]. The results obtained with the two methods tallied very well, and it is thus probable that the preparations contain a sialic acid. This is further supported by the fact that the absorption spectra in all but two cases (ray and hagfish) showed absorption maxima at the same wavelengths as crystalline sialic acid.

For qualitative demonstration of *hexuronic acid* most of the preparations were examined by the naphthoresorcinol method of Fishman *et al.*[11] No hexuronic acid could be traced by this method.

Table 1. Percentage composition of the dried external mucus of some fishes. The figures are corrected for ash and moisture content.

[1] No fucose spot could be detected on the chromatogram.
[2] A fucose spot could not with certainty be detected on the chromatogram.

All analytical figures given are means of at least two separate determinations, and are corrected for ash and moisture content.

Chromatography. The carbohydrate composition was studied by one-dimensional chromatography on Munktell OB filter-paper. Lutidine-*n*-amyl alcohol [12] proved to be the most suitable solvent. The papers were sprayed with the aniline hydrogen phthalate reagent of Partridge [13]. The preparations were hydrolysed with 2 N sulphuric acid at 100°C for one hour. $Ba(OH)_2$ was added to pH 6, and, after centrifuging, the clear supernatant was taken for analysis. A hydrolysis time of one hour was found suitable. Mannose was the sugar most slowly split from the protein. After about one hour it had reached a concentration high enough to be demonstrable by chromatography. A ribose spot was visible on all chromatograms after hydrolysis for one hour, but after a hydrolysis time of 2 h no ribose could be traced by paper chromatography.

The amino acids were assayed by two-dimensional paper chromatography, using ascending phenol-ammonia-cupron in one direction and descending pyridine—amyl-

alcohol in the other. The technique described by de Verdier and Ågren was employed [14]. This procedure allows good separation of all ordinary amino acids except phenylalanine, leucine, and isoleucine.

RESULTS

In the dried state the preparations of external mucus were light white-greyish powder, except the one from the hagfish. The hagfish mucus maintained throughout the drying and grinding procedure (several different methods were used) a distinct fibrous structure and was, in the dry state, similar to

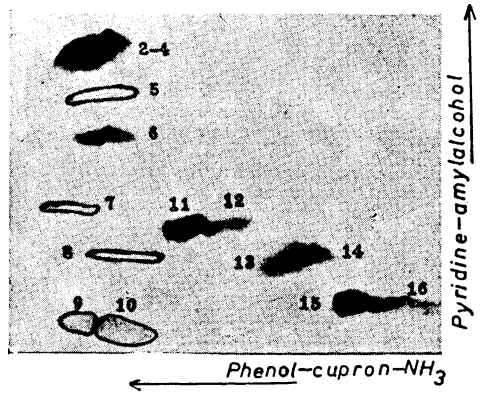

Fig. 2. Two-dimensional chromatogram showing the amino acid pattern of the external mucus of ray. Solvents and designation as in Fig. 1.

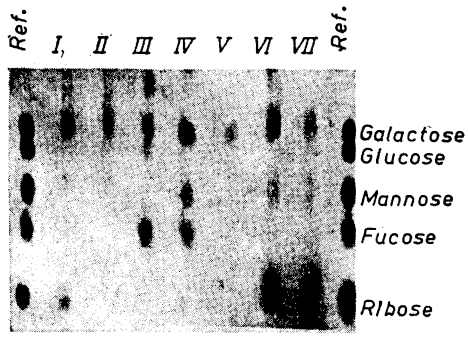

Fig. 3. Chromatogram showing sugar components of the external mucous coatings of some fishes. I, cod; II, eel; III, plaice; IV, ray; V, hagfish; VI, pike; VII, whiting. Solvent, lutidine-*n*-amyl alcohol.

short-clipped cotton wool. The dried roe and milt preparations were yellowish powders.

The analytical figures are given in Tables 1 and 2.

Amino acid chromatography of the mucous coatings revealed in most preparations the presence of all the common amino acids. A characteristic chromatogram is shown in Fig. 1. In the mucus of the ray no tyrosine could be demonstrated (Fig. 2).

The sugar chromatograms are shown in Fig. 3 and 4. A rough quantitative evaluation based on the size and intensity of the spots is given (Tables 3 and 4). This evaluation holds only for the individual chromatograms, and should not be used for mutual comparison of different chromatograms.

DISCUSSION

The presence of carbohydrate in some piscine mucins has been observed earlier. In a study of the surface slime of the Pacific hagfish (*Polistotrema stouti*), Ferry [15] found carbohydrate contents of 1.4 and 2.9 % (expressed as glucose) in two different preparations. From loach (*Misgurnus anguilli caudatus*) Turumi and Saito [16] obtained a mucous product said to contain 17.9 % glucosamine, 9.8 % galactose, and sialic acid.

Hammarsten [17] examined roe from perch and found that the yolk protein was not a glycoprotein, whereas the egg-jelly gave, after acid hydrolysis, large quantities of a reducing substance, the nature of which he did not further investigate. Young and Inman [18] found 1.0 % glucosamine in the protein of the egg-casings of the salmon. A few per cent of reducing substance has also been reported in roe from *Barbus fluviatus* [19], pike [19], king salmon [20], trout [21], herring [22-24], and salmon [25].

All our preparations of external fish mucus contained carbohydrate. The carbohydrate content is comparatively low, and the quantitative variation between different species is small, except that the ray mucus contains about twice as much as that of other fishes.

The main constituent of the mucus seems to be a simple protein component containing very little or no carbohydrate. In all species investigated the amino-acid pattern of the protein seemed to be mainly the same except in the ray, the mucus protein of which does not contain tyrosine and thus also differs in this respect.

Besides this simple protein component, the mucus also contains variable amounts of one or more glycoproteins. The presence of hexosamine, galactose, fucose, and sialic acid indicates the same types of glycoproteins as are present in mucous secretions of higher vertebrates, *viz.* fucomucin and sialomucin [1]. It is interesting to note that sialic acid is present in the mucus of all ordinary fishes, but not in the mucus of the ray and the hagfish.

In addition to the sugars mentioned, all the preparations except perhaps that of the hagfish, contained ribose and mannose, and one of them also glucose. The ribose probably derives from nucleic acid. The presence of nucleic acids in the mucus is not unexpected, as it is known that many of the epidermal cells discharge their entire contents directly onto the surface. Mannose is

a well-known component in many serum and tissue glycoproteins, and is often found in small amounts in mucous secretions of mammals. The mannose might thus be explained as belonging to some tissue protein present. The possibility of mannose belonging to some of the mucous glycoproteins mentioned above cannot of course be excluded. The glucose probably derives from glycogen, which has been shown to be present in the epidermal cells [26].

The view that the mucus is a mixture of one major, simple protein component and smaller amounts of one or more glycoproteins is supported by histological observations. Firstly, there are in most fishes several different types of "glands", specific glandular structures such as the large mucous glands of the myxinoids, the simple pouch-like epidermal organs, and the monocellular "glands" of the goblet-type, indicating a complex nature of the secretion [27]. Secondly, the mucus and some of the epidermal cells, especially the goblet cells, take various degrees of staining with fuchsin after pretreatment with per-iodic acid. They also show metachromasia with toluidine blue in the same way as do many glycoproteins [26, 28].

The finding of fucose- and sialic acid containing glycoproteins in secretion from external mucous epithelium is notable. Glycoproteins of this type so far known have all been of entodermal or closely related origin. Here we find tissues of obviously ectodermal origin producing the same types of substance.

The same monosaccharides as in the external mucus are also found in hydrolysates of fish roe. It is reasonable to assume here, too, that the ribose derives from nucleic acid. Galactose, mannose, hexosamine, and sialic acid are invariable constituents, and are probably due to the presence of glycoproteins. Some of the preparations also contained glucose and/or fucose. The origin of the glucose is obscure. The method of preparation employed (treatment of the pulverized roe with aqueous ethanol) is certain to remove free glucose, which is known to occur in fish eggs [29]. Glycogen has not been found in undeveloped fish eggs [21, 25]. Fucose may indicate the presence of small quantities of mucus of the usual epithelial mucus type.

The largest carbohydrate content is found in those roe specimens that have the thickest mucous layers, *viz.* whitefish and perch, and the smallest content in those with very thin layers, *e.g.* cod and burbot. Considering that

the mucous layer only contributes a minor part of the total dry weight of the roe, and assuming that the carbohydrates are mainly derived from this, it is clear that the relative carbohydrate content of this mucous layer must be high and similar to that of frog-spawn mucin [2].

Ribose was the predominant sugar in the milt sample examined.

Insulin Crystals

VII. The Growth of Insulin Crystals

JØRGEN SCHLICHTKRULL

Novo Terapeutisk Laboratorium, Copenhagen, Denmark

Pig insulin is crystallized from a clear solution containing sodium citrate and acetone. The decreasing concentration of insulin is determined during the process. The final distribution of crystal sizes is similar to that found earlier in the crystallization of beef insulin from a saline suspension of amorphous insulin [2].

The rate of pig insulin crystallization is

$$\frac{dC}{dt} = 2.8 \times 10^{-7} \times C(95.8-C)^3$$

where C is the crystalline fraction in per cent of total insulin (1.43 mg insulin nitrogen/ml), and t stands for time in min.

The linear rate, R_d, of deposition of insulin on the crystal faces is calculated from the previous [2] and the present data:

saline, beef: $R_d = 1.63\ (c_i-0.080)^2\ \mu$/min
citrate, pig: $R_d = 0.38\ (c_i-0.066)^3\ \mu$/min

where c_i is the concentration of dissolved insulin in millimoles per l, each molecule containing 65 atoms of nitrogen (M = ca. 5 700).

Rhombohedral insulin crystals of perfect shape may be obtained either from pig insulin or by crystallizing beef insulin from a saline solution containing precipitated amorphous insulin [1]. The latter process of crystallization has been analyzed by an experiment using mathematics devised for the purpose [2]. The ratio, r, between the total surface, S, and volume, V, of crystals was found to be constant during crystallization, except for the initial stage. It was assumed that crystals grow with identical rates of linear growth and it was then concluded by mathematical argument that the logarithm of the cumulative size distribution, $P(l)$, is linear, having the slope

$$\frac{d\ln P}{dl} = -3r = -3S/V \qquad (1)$$

This relation was confirmed by the $P(l)$ estimates obtained by counting the crystals according to size. From the constancy of r it was further concluded that the rate of nucleation is proportional to the product of the linear growth

rate and the total number of crystals present. It was demonstrated that this number is proportional to the total length, L, surface, S, and volume, V, of the crystals during crystallization. A chemical interpretation was suggested to the effect that the crystals are self-reproducing at a rate proportional to their linear growth rate. This rate could be expressed by

$$\dot{l} = \text{const.} \ (c_s - c)^2$$

where c_s was the actual and c the final concentration of dissolved insulin, the dot symbol indicating differentiation with respect to time.

The crystallization of pig insulin from a clear solution without addition of sodium chloride has been examined by counting the crystals according to size when crystallization was finished [2]. The cumulative size distribution was found to be very similar to that found for beef insulin, indicating crystal self-reproduction and proportionality during crystallization between the total surface and volume.

It is the purpose of the present investigation to determine the rate of linear growth as a function of the insulin concentration also in this crystallization.

The relation between the rate of growth, $\dot{l}$, and the rate, R_d, of insulin deposition on the crystal faces has been established in experiments with stained crystals [3]. Thus, the rates of deposition will be calculated from the rates of growth.

SYMBOLS

l = size of crystals, *i.e.* the largest diagonal in the crystal projection on a plane through one of the faces. As the crystals lie on their faces, the plane is parallel to the slide on the microscope stage. l is measured in μ.

$\dot{l}$ = $\mathrm{d}l/\mathrm{d}t$ = rate of linear growth of crystals. The time is counted in minutes.

$P(l,t)$ = cumulative distribution of crystal sizes at the moment t, *i.e.* the number per ml of suspension of crystals which are greater than l at the moment t.

$p(l,t) = -\frac{\delta P(l,t)}{\delta l}$, *i.e.* distribution of crystal sizes at the moment t.

$N(t) = \int_0^{l_{max}} p(l,t)\mathrm{d}l$ is the number of crystals per ml of suspension.

$L(t) = \int_0^{l_{max}} lp(l,t)\mathrm{d}l$ is the total length of crystals per ml of suspension

$S(t) = \int_0^{l_{max}} l^2 p(l,t)\mathrm{d}l$ is the total surface of crystals per ml of suspension, the unit area being the area of a rhombohedron with size $l = 1\mu$.

$V(t)$ = $\int_0^{l_{max}} l^3 p(l,t) dl$ is the total volume of crystals per ml of suspension, the unit volume being that of the rhombohedron with size $l = 1\mu$.

r = S/V.

λ = distance in μ between parallel crystal faces.

α = obtuse angle of the rhombohedron ($\alpha = 114°22'$) [1].

R_d = $\dot{\lambda}$ = the linear rate of deposition of insulin on the faces of the growing crystal.

c_s = the concentration of dissolved insulin in per cent of the initial concentration which is 1 % or 1.43 mg insulin nitrogen per ml.

C = the crystallized fraction in per cent of the initial insulin concentration ($C = 100 - c_s$).

c_i = insulin concentration in millimoles per l. An amount of insulin containing 65 atoms of nitrogen is considered equivalent to one molecule (M = 5 778).

METHOD

Crystallization. The method of crystallization has been described recently [1,4]. The crystallization mixture contains: 1 % insulin, 0.04 % Zn^{++}, 0.05 M sodium citrate, 15 % (v/v) acetone, pH = 6.4. Two solutions are made, one of them contains insulin, the other one is a buffer solution.

(A) 10 g recrystallized insulin from pig pancreas is dissolved in 500 ml water containing 9 ml 1 N HCl. The solution is sterilized by filtering through an asbestos filter previously rinsed with diluted HCl. 125 ml acetone and water are added to the filtrated solution to make a total of 875 ml.

(B) 0.05 mole sodium citrate, 0.80 g $ZnCl_2$, 25 ml acetone+water to make 125 ml. When (A) and (B) are mixed in the proportion 7 : 1, pH = 6.4. It may be necessary to add NaOH or HCl to solution (B) in order to produce this pH

The solutions (A) and (B) are mixed at the time $t = 0$ in a glass beaker The surface of the liquid is covered with a layer of paraffin oil to prevent evaporation and the beaker is covered with a glass lid. The mixture is stirred slowly for 24 h at 21°—22°C.

Determination of the insulin concentration, c_s. At intervals, 20—50 ml samples are filtered on sintered glass. The moments, t_1, at the beginning of filtration and those at the end, t_2, are noted. The averages of t_1 and t_2 are used as the t-estimates in the calculations. The concentrations of nitrogen in the filtrates are determined by semi-micro Kjeldahl analyses. Determinations of total nitrogen are also made to check that evaporation is insignificant.

Determination of the cumulative distribution of crystal sizes, $P_*(l)$. $P_*(l)$, the number per ml of suspension of crystals greater than l, is determined when crystallization is finished, using the technique described earlier [5].

THEORY

The linear growth rate, $\dot{l}$. It follows from the definition of S and V (see list of symbols) that

$$dV = 3Sdl \tag{3}$$

and

$$\dot{V} = 3S\dot{l}. \tag{4}$$

Assuming a constant ratio, r, between surface and volume, it follows that

$$(\dot{\ln} V) = 3r\dot{l} \tag{5}$$

and, as V and C are proportional,

$$\dot{l} = \frac{(\dot{\ln} C)}{3r} \tag{6}$$

from which $\dot{l}$ can be calculated by the t, C data when r is known. The ratio r is calculated from *eqn.* (1)

$$r = -\frac{d\ln P_*(l)}{3dl} \tag{7}$$

Hence

$$\dot{l} = -\frac{(\dot{\log}\ C)}{d\log P_*(l)/dl} \tag{8}$$

The linear rate, R_d, of insulin deposition on the crystal faces. During crystallization insulin is deposited on the plane crystal faces which thereby move outwards in directions perpendicular to the faces. The relation between the linear rate of deposition, R_d, and the linear growth rate, $\dot{l}$, is found by geometrical calculus. The distance between the parallel faces of the obtuse rhombohedron is called λ. It can be demonstrated that

$$\lambda = \sin\left(\frac{\alpha}{2}\right) \cdot \sqrt{1 + 2\cos\alpha} \cdot l \tag{9}$$

where α is the obtuse angle of the rhomb and l is the crystal size, *i.e.* the greatest diagonal in the crystal projection on a plane through a face. The angle, α, has been estimated by goniometric measurement [1] as 114°22′. Thus,

$$\dot{\lambda} = 0.351\ \dot{l} \tag{10}$$

It has been shown by experiment that the insulin is not deposited on the three crystal faces meeting in one of the obtuse vertices, but that it is deposited on the three remaining faces, with identical rates of deposition [3]. Hence,

$$R_d = 0.351\ \dot{l} \tag{11}$$

ANALYSIS OF THE DATA

The ratio between surface and volume ($r = S/V$). In the crystallization of beef insulin from a saline suspension of amorphous insulin, perfectly shaped rhombohedral single crystals were developed. However, in the pig insulin crystallization from clear solution, crystal agglomeration occurs to such an extent as to weaken the significance of the notions. The crystals are counted, irrespective of whether they are single or attached to other crystals, and as the shape of attached crystals varies, it follows that the relations between size, surface and volume of a crystal also vary. Thus, the equations set up on the assumption of geometrical similarity do not strictly hold true in this crystallization. It is nevertheless assumed that the deviations from similarity do not significantly alter the significance of the relations leading to eqn. (1). It is assumed that

$$S/V = r = -\frac{\mathrm{d}\ln P_*(l)}{3\mathrm{d}l} \tag{12}$$

in the main part of crystallization, *i.e.* from the moment when a few per cent of insulin have crystallized onwards. This assumption is based upon the similarity between the observed distributions of sizes in this experiment and in the former experiment on cattle insulin crystallization, but it may be incorrect.

The $P_*(l)$ estimates from three countings are shown in Fig. 1.

The slope, $-3r\mathrm{M} = -0.029$ was calculated by using the method of least squares on the section $l < 75\ \mu$. Thus, $r = 0.022$ which is identical with the ratio found earlier in beef-insulin crystallizations [2].

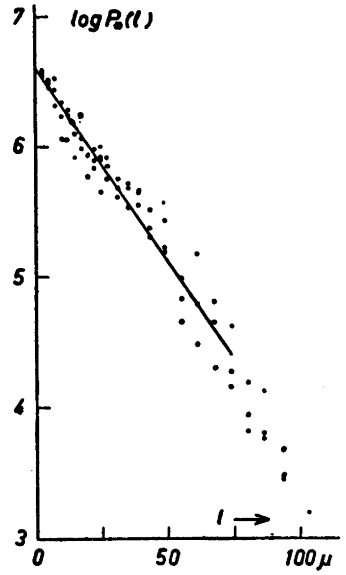

Fig. 1. The cumulative distribution of crystal sizes.

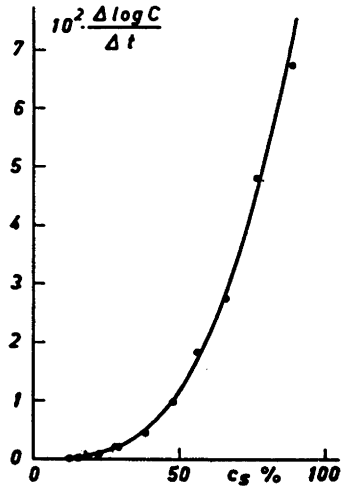

Fig. 2. ($\dot{\log}\ C$) as a function of c_s.

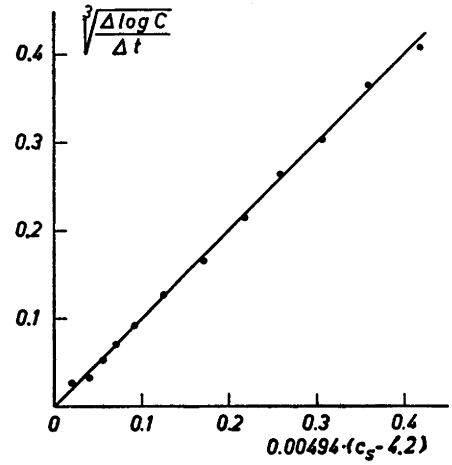

Fig. 3. The third root of ($\dot{\log}$ C) as a function of c_s.

The growth rate, $\dot{l} = (\dot{lnC})/3r$. The t and C estimates are listed in Table 1. Estimates of ($\dot{\log}$ C) are obtained by the approximation

$$(\dot{\log} C_i) \approx \frac{\log C_{i+1} - \log C_{i-1}}{t_{i+1} - t_{i-1}} \tag{13}$$

where i is the sample number. The estimates are plotted in Fig. 2 against the concentration of insulin, c_s.

It appears that $\dot{l}$ is a power function of c_s. The curve drawn into the figure is

$$\frac{\Delta \log C}{\Delta t} = 1.206 \times 10^{-7} \, (c_s - 4.2)^3 \tag{14}$$

The constants in this equation were determined by trial and error using the chronometric integral below and aiming at the best agreement between observed and calculated C-values.

The third root of $\Delta \log C/\Delta t$ is plotted in Fig. 3 against the third root of $1.206 \times 10^{-7} \, (c_s - 4.2)^3$.

Thus, using eqns. (8) and (14)

$$\dot{l} = \frac{1.206}{0.029} \times 10^{-7} \, (c_s - 4.2)^3 = 4.2 \times 10^{-6} \, (c_s - 4.2)^3 \tag{15}$$

The chronometric integral, $t(C)$. is calculated from eqn. (14) which (since $C + c_s = 100$) is written as follows:

$$\mathrm{d}t = \frac{10^7 \cdot \mathrm{M} \cdot \mathrm{d}C}{1.206 \cdot C(95.8 - C)^3} \qquad (\mathrm{M} = 0.4343) \tag{16}$$

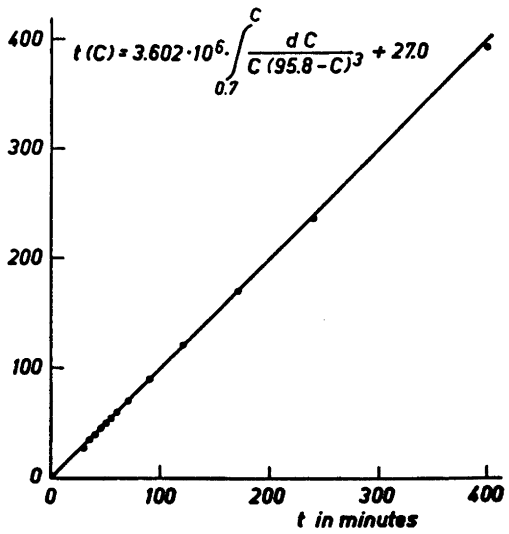

Fig. 4. The chronometric integral as calculated for each of the observed C-values.

It follows by integration that

$$t(C)—t(C_1) = 3.60 \times 10^6 \int_{C_1}^{C} \frac{dC}{C \cdot (95.8—C)^3} \tag{17}$$

Estimates of $t(C)—t(C_1)$ have been calculated for $C_1 = 0.7$ using the formula

$$\int \frac{dx}{x(a—x)^3} = (3a—2x)/2a^2(a—x)^2 + a^{-3} \cdot \ln[x/(a—x)] \tag{18}$$

By subtracting these estimates from the experimental $t(C)$ values, t (C_1) was found to be 27.0 min (in the average). Thus,

$$t(C) = 3.60 \times 10^6 \int_{0.7}^{C} \frac{dC}{C \cdot (95.8—C)^3} + 27.0 \tag{19}$$

The t-values calculated from eqn. (19) are tabulated (Table 1) and plotted (Fig. 4) against the experimental t-values. The discrepancies are within the range of the experimental error.

The analytical estimates, $C(t)$, of insulin which has crystallized at the time t are plotted against t in Fig. 5. The curve in the figure represents eqn. (19), the chronometric integral. The difference between the observations and the curve is insignificant. Hence, it is possible to account for the course of crystallization by a simple mathematical expression.

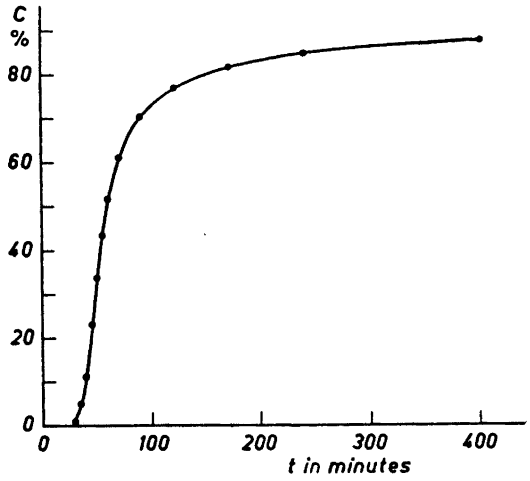

Fig. 5. The percentage of crystalline insulin, C, as observed — the dots — and as calculated from eqn. (19) — the curve.

THE RATE OF DEPOSITION ON THE CRYSTAL FACES

Saline. When beef insulin was recrystallized from a saline medium it was found [2] that

$$\dot{l} = 4.64\ (c_i - 0.080)^2\ \mu/\text{min} \qquad (20)$$

where c_i is the concentration of insulin in millimoles per l. An amount of insulin containing 65 atoms of nitrogen is considered equivalent to one molecule, M = 5 734. It follows from eqns. (11) and (20) that

$$R_d = 1.63\ (c_i - 0.080)^2\ \mu/\text{min} \qquad (21)$$

Table 1. The experimental data.

i	t_1	t_2	t	C	$10^2 \Delta \log C/\Delta t$	$t(C)$
1	1'30″	2'30″	1.8	0.0		
2	29'45″	30'00″	29.9	0.7		27.0
3	34'45″	35'15″	35.0	4.9		35.6

15	1400'	1400'	1400	91.7		1268

The maximum $R_d = 0.7$ μ/min occurred at $c_i = 0.73$.

Citrate buffer. Provided that eqn. (12) is valid in this crystallization just as in the former, it follows from eqn. (15) that

$$\dot{l} = 1.1\ (c_i - 0.066)^3\ \mu/\text{min} \tag{22}$$

from which

$$R_d = 0.38\ (c_i - 0.066)^3\ \mu/\text{min} \tag{23}$$

The maximum $R_d = 1.3$ μ/min occurred at $c_s = 100$ %, *i.e.* at $c_i = 1.57$ mmole/l.

Acknowledgements. My thanks are due to Dr. Hallas-Møller for his critical advice which has been of considerable benefit to the work. In the mathematical part of the study I have received encouragement, advice and technical assistance from Dr. A. Hald, Professor of Statistics at the University of Copenhagen. It is with pleasure I express my sincere gratitude for this kind help.

I also want to thank K. Petersen, with whom I have had many discussions, my colleagues I. Nøring and F. Sundby who contributed to the experimental work.

Determination of Molecular Weights and Diffusion Coefficients in the Ultracentrifuge

ANDERS EHRENBERG

Nobel Medical Institute, Biochemical Department, Stockholm, Sweden

A simple method of using the boundary condition at the meniscus in the sector shaped centrifuge cell for the determination of the ratio S/D or M is described. Some pure proteins are studied and the results compared to other data, especially analytical ones. The diffusion coefficients are also computed separately. The homogeneity of the sample is investigated by following the time dependence of M at the meniscus. Information about inhomogeneous samples is thus gained, and reversible dimerizations or polymerizations can be studied.

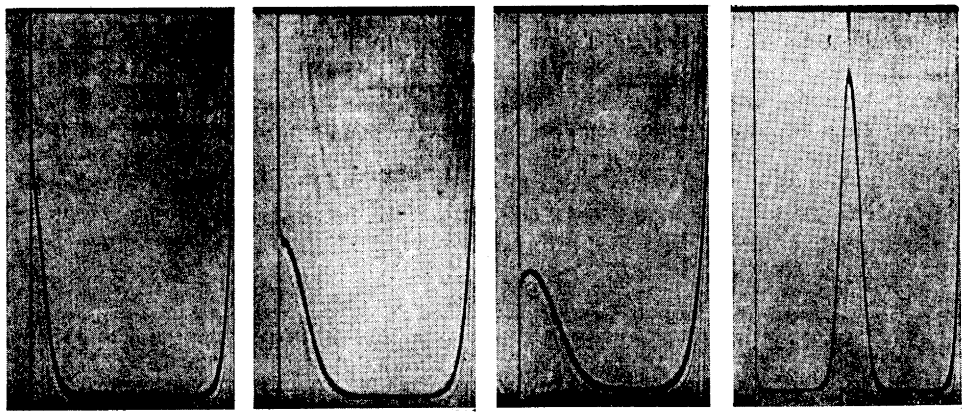
The possibility of obtaining a value of the ratio of the sedimentation coefficient and the diffusion coefficient from the boundary condition at the meniscus in the centrifuge cell was demonstrated by Archibald [1]. Its value as a purity test has been emphasized by Pedersen [2] and the importance of simplifying and standardizing the method has been discussed [2]. The method seems to have been experimentally applied only in a few cases, first by Li *et al.*[3] and by Porath [4] using an oil turbin centrifuge, and more recently by Brown *et al.*[5] and by Klainer and Kegeles [6,7] using an electrically driven Spinco centrifuge. In these cases the methods of evaluation appears to be rather involved and time consuming. In the present work Archibald's method has been applied in a fashion rather similar to that used by Klainer and Kegeles, but the mode of evaluation has been simplified considerbly.

TECHNICAL

A Spinco analytical ultracentrifuge, model E, was used. The diaphragm of the schlieren optics had been replaced by a phaseplate [6,8,9], and a Wratten light filter, 77A, was used in all the experiments, where it was possible to work with the green monochromatic light of 546 mμ wavelength. A 12 mm synthetic boundary cell with a rubber valve was employed throughout the work. An automatic temperature control, also supplied by the centrifuge manufacturer, was an important additional facility, since the sedimentation and diffusion coefficients depend differently on the temperature and since any convection in the cell would have decreased the accuracy of the method. All the experiments were conducted at temperatures between 18 and 23°C. The surface measurements were made by means of a mechanical planimeter.

DETERMINATION OF THE RATIO S/D AND THE MOLECULAR WEIGHT

Let us consider a sector shaped cell in a rotor revolving at the angular velocity ω. The amount of sedimenting and diffusing solute transported per second through a concentric cylindrical surface in the cell at a distance r from the axes of rotation is Φ (r).



$$\Phi(r) = \Theta r h \left(\omega^2 rcS - D\frac{\partial c}{\partial r}\right) = D\,\omega^2 rc\Theta h \left(\frac{S}{D} - \frac{1}{\omega^2 rc}\cdot\frac{\partial c}{\partial r}\right) \qquad (1)$$

Here Θ denotes the sector angle and h the cell height; c is the concentration, S the sedimentation coefficient and D the diffusion coefficient of the solute. At equilibrium $\Phi(r) = 0$ and

$$\frac{S}{D} = \frac{1}{\omega^2 rc}\cdot\frac{\partial c}{\partial r} \qquad (2)$$

at every distance r in the cell. The same condition (2) is valid during the whole experiment at the meniscus and at the bottom of the cell as both are impervious to the substance. The ratio $\frac{\partial c}{\partial r}/c$, between the concentration grandient and the concentration, at these boundaries the whole time adjusts itself to fulfill eqn. (2). How this boundary condition is utilized for the determination of the quantity S/D will be made clear from the description of an actual experiment.

A solution of the substance under investigation is prepared in a suitable buffer and dialyzed against the same buffer for at least 12 h. After the dialysis some of the buffer is saved. In experiment I a centrifuge run is made at

a b c d

Fig. 1. Some of the photographs taken in the experiments on the old yellow enzyme. Experiment I a) 3 700 s, b) 11 400 s, and c) 19 050 s. Experiment II d) 3 700 s after that 12 590 rpm was attained.

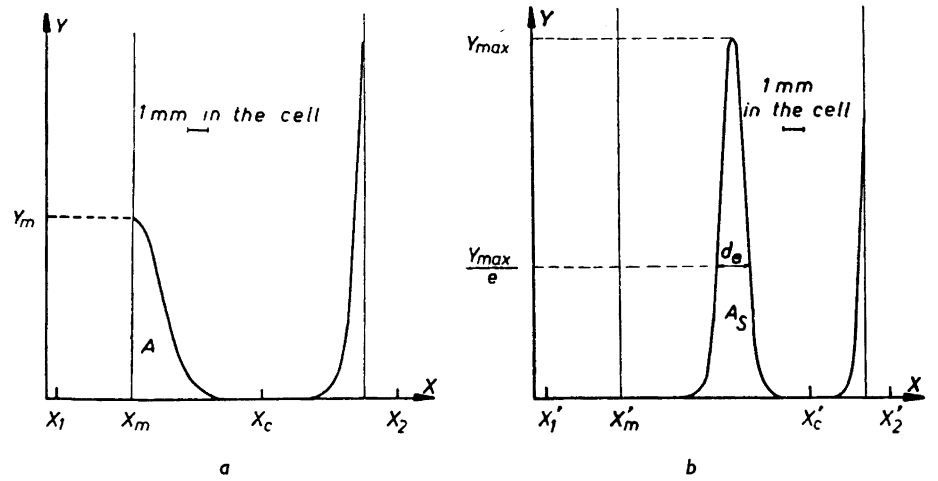


Fig. 2. Reproductions of drawings, with inlayed coordinate axes, made from photographs corresponding to a) Fig. 1 b and b) Fig. 1 d. 1 cm on the original drawings corresponds to 1 mm in the cell. For further explanation see text.

a low speed in the 12 mm synthetic boundary cell but without using the layering technique. Fig. 1 a — c shows three of the exposures taken, one in the beginning, one in the middle and one at the end of the experiment. The pictures are placed in a magnifying apparatus and drawings made of the refractive index gradient curves in a convenient scale (1 cm on the paper corresponded to 1 mm in the cell). Fig. 2 a shows such a drawing with inlaid coordinate axes. The y-coordinate of the refractive index gradient is proportional to the concentration gradient of the substance. At the meniscus we thus have

$$\left(\frac{\partial c}{\partial r}\right)_m = k_1 y_m \tag{3}$$

where the subscript m refers to the meniscus and k_1 is the constant of proportion. Because of optical distortion near the meniscus the curve has to be extrapolated the last few millimeters on the paper. The most accurate values of y_m are hence obtained from the exposures in the middle period of the experiment for which the refractive index gradient curves are horizontal or nearly so at the meniscus *. A relation similar to (3) is also valid at the bottom of the cell, but because of the piling up of material the curves are usually steep there and the y-coordinate of the intercept at the bottom is difficult to determine with the precision needed. Because of these reasons we have so far only treated the data obtained at the meniscus.

* *Note added in proof:* This eliminates to a large extent the influence of the error in the meniscus image, recently discussed by P. J. Cheng, *J. Phys. Chem.* **61** (1957) 695.

It is essential that a region in the middle of the cell remains with a flat baseline and with the concentration varing according to the formula given by Pedersen [10]

$$c = c_0 e^{-2\omega^2 St} \tag{4}$$

Here c is the concentration of solute at time t and c_0 the initial concentration. The concentration at the meniscus at time t is thus obtained by the equation

$$c_m = c - \int_{r_m}^{r_c} \frac{\partial c}{\partial r}\, \omega r \tag{5}$$

or

$$c_m = c_0 e^{-2\omega^2 St} - k_1 k_2 \int_{x_m}^{x_c} y \mathrm{d}x \tag{6}$$

x_m is the x-coordinate of the meniscus, x_c that of a point in the part of the cell where eqn. (4) is valid. k_2 is the inverse of the enlargement in the x-direction. y corresponds to an exposure taken at time t. The integral of eqn. (6) is the surface A between the curve, the meniscus and the x-axes of Fig. 2a:

$$A = \int_{x_m}^{x_c} y \mathrm{d}x \tag{7}$$

Insertion of expressions (3), (6) and (7) in eqn. (2) gives

$$\frac{S}{D} = \frac{k_1 y_m}{\omega^2 r_m \left(c_0 e^{-2\omega^2 St} - k_1 k_2 A\right)} \tag{8}$$

The first term in the denominator is determined in a separate experiment, II, a principle that was also used by Klainer and Kegeles [6]. The same synthetic boundary cell is used as in the previous experiment, and the equilibrated buffer is layered over the sample at a speed of 5 000—7 000 rpm. In all other details, such as acceleration time, rotational speed, temperature, phaseplate angle, exposure times and, if possible, exposure intervals, this experiment is an exact duplicate of the previous one. Fig. 1 d shows a typical exposure and Fig. 2 b the corresponding enlarged diagram. This time it is essential that there are two flat regions of the curve, one between the meniscus and the peak where the concentration is zero and one between the peak and the bottom with the concentration varying according to eqn. (4). In analogy with the previous discussion we now get the relation

$$c = c_0 e^{-2\omega^2 St} = k_1 k_2 \int_{x'_m}^{x'_c} y \mathrm{d}x = k_1 k_2 A_s \tag{9}$$

where A_s is the surface under the curve in Fig. 2 b. If expression (9) is inserted in (8) we obtain the simple relation

$$\frac{S}{D} = \frac{y_m}{\omega^2 r_m k_2 (A_s - A)} \tag{10}$$

y_m is the distance from the baseline to the intersection of the curve and the meniscus of the enlarged drawing of an exposure of experiment I and can be determined to better than $\pm$ 1 %. A is the surface between curve, baseline and meniscus of the same exposure, A_s the surface between the curve and the baseline in the corresponding exposure of experiment II. These surfaces are easily determined with a planimeter and the error in their difference is usually smaller than $\pm$ 1 %. The factor k_2 is suitably adjusted to 0.1000 $\pm$ 0.0002. The radius of the meniscus, r_m, is determined from the position of x_m relative to the two indices x_1 and x_2 on the drawing, the factor k_2, and the radius of the center of the cell. The latter is known to be better than $\pm$ 0.1 % at the moderate speeds used; at higher speeds, say exceeding 40 000 rpm, the accuracy is somewhat less due to elastic distortion of the rotor. This figure might be taken as an estimate of the error in r_m. ω is determined from the selected rotor speed which is kept constant to better than $\pm$ 0.5 % over any period of time. In ω^2, which enters in the expression (10), this means an error of $\pm$ 1 %. The temperature is kept constant within $\pm$ 0.1°C. As the viscosity effects S and D identically, the temperature error enters in S/D only because D is proportional to the absolute temperature. The error due to the temperature is thus about $\pm$ 0.04 %. All these contributions added together give a maximum error in a single determination of S/D of 3.4 %.

By means of a blank experiment with the buffer it is possible to evaluate a correction for gradients due to sedimenting salt and for curvature of the baseline. This correction was found to be negligible for rotor speeds below 20 000 rpm. Whenever such a correction is needed the maximum error is greater than 3.4 %. Other possible optical distortions or imperfections have not been considered.

Klainer and Kegeles [6] did not use the same cell in their experiments corresponding to I and II. This technique has been tried but found to be inferior since the two cells usually have slightly different depths and since the properties of the quartz windows might be slightly different.

The simple eqn. (10) can be used as long as the time schedules of experiments I and II are identical. If A_s can be determined only in an early period of experiment II, because of the diffusion which after some time violates the flat regions at both sides of the peak (Fig. 2 b), A_s in (10) has to be replaced by $A_{so} \cdot e^{-2\omega^2 S t_I} \approx A_{so}(1 - 2\ \omega^2\ S t_I)$, where the time t_I refers to experimet I. A_{so} is determined from experiment II as a mean of the values $A_s \cdot e^{2\omega^2 S t_{II}} \approx A_s (1 + 2\ \omega^2\ S t_{II})$. This means that a knowledge of S under the actual experimental conditions is necessary. If it is not known beforehand, it may be determined accurately enough at the end of experiment II. The rotor is then accelerated to a higher speed, and a few exposures are taken from which S can be calculated in the usual way. Because of the adiabatic cooling of the rotor this S-value corresponds to a slightly lower temperature than the orginal

and a proper correction has to be made before it is used in the calculation of S/D. If necessary a separate experiment has to be made in the synthetic boundary cell for the determination of S.

If the sedimentation constant is not known from the beginning and the wrong speed of rotation is chosen initially in experiment I, the rotor might be stopped, the cell taken out and shaken a little to make the solution homogeneous again. The experiment may then be started again and a more suitable speed of rotation selected. The two experiments I and II are usually performed within 6—8 h. All the calculations are made in 3 or 4 h by one person. If the plates instead were evaluated in a microcomparator and numerical integrations were made, the calculations were much more timeconsuming without much gain in accuracy.

The value of S/D thus obtained is used for the calculation of the molecular weight by insertion in the well known equation

$$M = \frac{S}{D} \cdot \frac{RT}{1 - V\varrho} \tag{11}$$

Here R is the gas constant and equal to 8.313×10^7 erg.mole^{-1}. degree^{-1}, T is the absolute temperature at which the experiment was performed, ϱ is the density of the buffer at that temperature and V is the partial specific volume of the solute at the same temperature.

The behaviour of a sample with several components of different S/D is easy to predict if it is permitted to superpose the systems. Each component, n, alone would give

$$\frac{S_n}{D_n} = K \frac{y_{mn}}{A_{sn} - A_n}$$

The observed ratio is

$$\frac{S}{D} = K \frac{y_m}{A_s - A}$$

where $y_m = \Sigma\, y_{mn}$ and $A_s - A = \Sigma\, (A_{sn} - A_n)$

Hence we obtain

$$\frac{S}{D} = \frac{\sum \frac{S_n}{D_n} (A_{sn} - A_n)}{\Sigma\, (A_{sn} - A_n)} \tag{12}$$

At time zero all the A_n are zero. If the specific refractive index increments are equal for all the components the value of S/D extrapolated to zero time is the mean of the different S_n/D_n weighted with their corresponding relative concentrations (the weight-average value). As the experiment goes on all the A_n values increase. Those corresponding to the higher S_n/D_n increase faster than the others and hence the contribution of these S_n/D_n in S/D will be relatively smaller and the observed S/D will decrease towards the lowest value S_n/D_n. The speed of this decrease depends on the ratio between the different values of S_n/D_n and on the rotor velocity. Only a solute that is

homogeneous with respect to the ratio S/D and for which this ratio is independent of the concentration will exhibit a value of S/D that does not change with time during the experiment.

A sample where the solute molecules are in a monomer-dimer equilibrium will also show a decrease with time in the ratio S/D or the proportional M. This decrease is due to the dilution of the solute close to the meniscus which favours the monomer.

DETERMINATION OF DIFFUSION COEFFICIENTS

The diffusion coefficients were determined from the exposures of the type II experiments in which a boundary between solution and solvent was formed in the centre of the cell. The data were evaluated in two different ways which both are easily derived from the solution of the differential equation of diffusion.

In the "maximum ordinate — area" method the following relationship is used:

$$\frac{A_s^2}{y_{max}^2} = 4\ k_2^2\ \pi\ D\ (t - t_0) \tag{13}$$

where A_s is the area between the gradient curve and the baseline at time t, measured from the instance when the synthetic boundary was formed. y_{max} is the maximum height of that curve (Fig. 2 b), k_2 is the magnification along the baseline and D is the diffusion coefficient.

According to the "maximum ordinate" method the relation

$$d_e^2 = 16\ k_2^2\ D\ (t - t_0) \tag{14}$$

is used. Here d_e is the distance along the baseline between the points on the gradient curve having $y = y_{max}/e$.

D is obtained from the slope of the line obtained by plotting either A_s^2/y_{max}^2 or d_e^2 *versus* t. Agreement between the two methods in combination with slightly negative values of t_0 has been taken as evidence of a successful experiment. Positive values of t_0 indicate that the boundary formation had been disturbed and made the results less reliable.

The right hand sides of eqns. (13) and (14) also should contain the factor $[1 + \frac{1}{2}\ \omega^2\ S(t - t_0)]$ corresponding to the correction factor given by Lamm [11]. The correction term, however, never caused a deviation of more than 0.5 % from the straight line.

MATERIALS

The old yellow enzyme, myoglobin I and apymyoglobin I were prepared by Theorell and Åkeson as they have recently described [12,13]. The rhodanese was prepared by Sörbo [14], the myeloperoxidase by Agner [15], and the liver alcohol dehydrogenase by Dalziel [16]. The growth hormone samples have been described elsewhere [17]. The bovine serum albumin was obtained from Armour Laboratories, lot No. J 10603.

The cytochrome c was prepared in the crystalline form from beef heart by Paléus and Theorell, and two different samples were used. One sample was prepared according to Hagihara *et al.*[18], had an iron content of 0.42 %, and was used for the centrifuge experi-

ments. The other sample was prepared according to Paléus and Theorell [19] and had an iron content of 0.46 %. It was used for the determination of the partial specific volume.

The pituitary growth hormones were dissolved in a 0.05 M borate buffer of pH 9.9. In all other cases a 0.05 M phosphate buffer of pH 7.0 was used. All the solutions contained 1 % NaCl.

In all cases the partial specific volume was assumed to depend on temperature in the same way as that of haemoglobin [10].

RESULTS AND DISCUSSION

A few proteins considered to be essentially pure and homogeneous have been investigated. The substances were chosen because of availability and because of possibility to compare with other data, especially analytical values. The main results have been collected in Table 1 and Fig. 3 a.

In spite of the fact that *bovine serum albumin* is known not to be completely homogeneous [20], it was subjected to several experiments because it has been so thoroughly investigated by many investigators and by means of many methods. The sedimentation coefficient of the sample was determined at a few concentrations and it was found to depend on the concentration according to the formula

$$S_{20}^{\circ} = 4.44\ (1 - 0.0060 \cdot a)\ S \qquad (15)$$

where a is the mean concentration in mg/ml. This concentration dependence agrees well with the data reported by Schulman [21]. A small fraction amounting to less than 5 % could be seen to move somewhat faster in the centrifuge.

In three experiments at a protein-concentration of 20 mg/ml the calculated M was found to increase with about 0.18 % in every period of 1 000 sec. No such increase could be identified in one experiment at half that protein

Table 1.

Protein	V_{sp}	S_{20}° (S-units)	D_{20}° (F-units)		M			
			in a diffusion cell	in the centrifuge	from S and D (diffusion cell)	from S and D (centrifuge)	from S/D at the meniscus	from analysis
Cytochrome c[18,19] (beef heart)	0.728	1.71 *	—	11.4	—	13 300	13 300	13 300
Apomyoglobin I[13]	0.743[26]	1.89	—	10.4	—	17 200	18 800	18 200[13]
CO-myoglobin I[13]	0.743[24]	2.01	—	10.3	—	18 500	18 300	18 800[13]
Rhodanese [14]	0.742[14]	3.03 *[14]	7.5 *[14]	8.2	38 000	35 600	36 300	—
Serum albumin (bovine)	0.7434[35]	4.44	5.805[20]	5.7	72 200	73 500	73 200	—

Old yellow enzyme [12]	0.753[12]	5.82	—	5.54	—	102 000	106 000	104 000[12]
Myeloperoxidase [15]	0.731[29]	7.93[29]	4.81 *[29]	4.9	149 000[29]	145 000	157 000	151 000[29]

1 S (Svedberg unit) = 10^{-13} s
1 F (Fick unit) = 10^{-7} cm^2 s^{-1}
* indicates that the value has not been extrapolated to infinite dilution. None of the diffusion coefficients determined in the centrifuge has been extrapolated in this way.

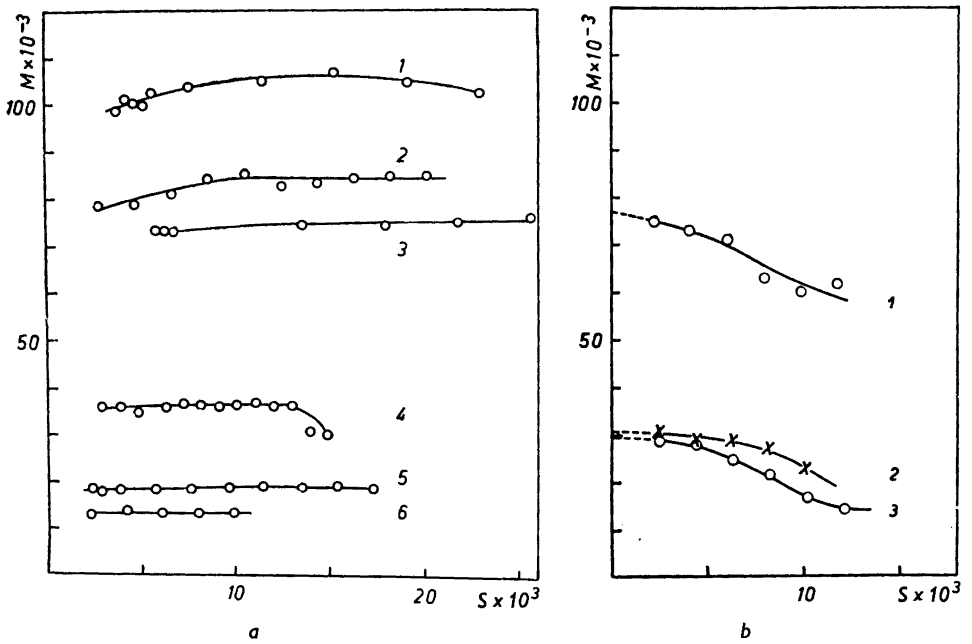

Fig. 3. Time dependence of the molecular weights of different proteins as evaluated from the boundary condition at the meniscus. The time is measured from the instance when the rotor attained equilibrium at the selected speed. a) Curve 1) old yellow enzyme (12 590 rpm); 2) liver alcohol dehydrogenase (12 590 rpm); 3) bovine serum albumin (12 590 rpm); 4) rhodanese (17 980 rpm); 5) apomyoglobin (23 150 rpm) and 6) cytochrome c (23 150 rpm). b) Curve 1) ox pituitary growth hormone (14 290 rpm); 2) human pituitary growth hormone (17 250 rpm) and 3) human pituitary growth hormone (23 150 rpm).

concentration. In the parts of these experiments later than 10 000 sec after the rotor had attained equilibrium speed the following mean molecular weights were ontained: 75 200, 69 900 and 72 700. One experiment at 10 mg/ml gave a value of 75 000. At concentrations of 5 mg/ml or lower the experiments were more difficult to evaluate and the results were no longer consistent.

The *Old yellow enzyme* was investigated because it was uncertain whether the molecule contained one or two prosthetic groups. The new analytical data [12] required a molecular weight of $n \times 52\,000$, while earlier studies [22] on a less pure preparation had given a value of 82 000, or 76 000 when corrected for the slightly elevated rotor temperature in the centrifuge used [2]. The partial specific volume of the crystallized enzyme was redetermined [12] and was found to be 0.753 at 25°C as compared with the previous value of 0.731 at 20°C. The difference accounts for an increase in M of 9 % which would bring it up to 83 000 again. Also the sedimentation coefficient has been redetermined. The concentration dependence was investigated and the following formula was found to be valid:

$$S_{20}^{\circ} = 5.82\ (1—0.0046 \cdot a)\ S \qquad (16)$$

where a is the concentration in mg/ml. The previously reported value [22] was 5.76 S, or 5.33 S, when corrected for the rotor temperature. The protein concentration in these experiments was not reported but must have been of the order of 10—20 mg/ml. Correction for this according to the formula (16) yields 5.5—5.7 S, which is only slightly lower than the present value. $S_{20}^{\circ} =$ 5.82 S instead of 5.33 S, however, adds another 8.5 % to M and brings it to 90 500.

The molecular weight has now been determined in one experiment at a protein concentration of 18.4 mg/ml. The calculated M appeared to increase in the first part of the experiment with about 0.45 %/1 000 s and to decrease in the later part having a maximum about 15 000 s after that the full speed had been reached. The maximum of 106 000 is taken as the best value of M.

The diffusion coefficient has been determined from two experiments with undisturbed synthetic boundary formation, one at 18.4 mg/ml and the other at 7.8 mg/ml. It was found to be 5.54 ($\pm$0.05) F, which is appreciably lower than the old value [13] of 6.3 F. Together with S_{20}° and V reported here it gives $M = 102\,000$.

These data definitely prove that there are two flavin mononucleotide molecules bound per molecule of the old yellow enzyme, for which case the M-value derived from analysis becomes 104 000. The great difference between the value of M determined now and the old value appears to be an unfortunate combination of errors in all the three quantities S, D and V.

The purified *myoglobin I* [13] has been investigated both in the form of apomyoglobin and in the form of CO-myoglobin. In both cases a partial specific volume of 0.743 has been used. This value has been determined [24] for ferri Mb and the same can be calculated for apo Mb on the basis of the amino acid analysis [25,26]. The sedimentation coefficient determined earlier [13] in the same centrifuge have been used. At that time the automatic temperature control had not yet been installed and no correction was made for the adiabatic cooling of the rotor. In a set of experiments this cooling has been found to be 0.87°C when the rotor is accelerated up to 59 780 rpm. A correction of 2.15 % had thus to be added to the previous data. Another small correction of 0.5 % has also been added according to Lamm's formula [11]. The data thus become:

$$S_{20}^{\circ} = 1.89\ (1-0.00682 \cdot a)\ S \text{ for apoMb I} \qquad (17)$$

and

$$S_{20}^{\circ} = 2.01\ (1-0.00642 \cdot a)\ S \text{ for Mb I} \qquad (18)$$

The colourless apo Mb I has been investigated in one experiment at a protein concentration of 12.5 mg/ml. Because of the high rotor speed of 23 150 rpm a minor correction had to be explored in a separate run on the buffer. Again M was found to increase slightly in the first part of the experiment (0.70 %/1 000 s). An asymptotic level of $M = 18\,800$ was reached.

A much less reliable experiment was conducted on a less concentrated sample of the carbon monoxide compound of Mb I. This derivative was used because of its low absorption above 600 mμ, and a red filter was used cutting off below this wavelength. The phaseplate, however, is manufactured for the green mercury line of 546 mμ, and long exposure times had to be used because

of the low efficiency of the lamp in the red region. Hence the pictures were not very sharp and the calculated molecular weight of 18 300 cannot be considered to be accurate to better than ± 4 %.

The diffusion coefficients of 10.4 and 10.3 F, respectively, are, as would be expected, rather smaller than the value of 11.25 F, that was earlier determined by Polsen [23] on an old preparation of Mb, which had an iron content 0.34 % as compared to 0.297 % for Mb I [13].

The M-values, as calculated from S/D or S and D, do not agree completely with the data obtained from iron-analysis of Mb I (Table 1). It is obvious that there might be an error in the determination of either $S_{20}°$ or $D_{20}°$ of apo Mb I. It is probable that $S_{20}°$ should be greater than 1.89 S, since the drop from 2.01 S for Mb I appears to be rather big, if not the removal of the haem is accompanied by a rather drastic change of molecular shape.

One experiment on *liver alcohol dehydrogenase* was performed at a protein concentration of 10 mg/ml. The M-value increased in the early part of the experiment but a level of 84 400 was reached before 10 000 s. This value is in good agreement with the other data discussed elsewhere [27] and referred to in Table 1, but it is considerably higher than the value of 67 500 (corrected for the rotor temperature [2]) that was determined on an earlier and less pure preparation of the enzyme [28].

Rhodanese was investigated at a protein concentration of 10 mg/ml. The M-value appeared to be practically constant until the decrease at the end due to back diffusion. The sedimentation constant of 2.97 S given by Sörbo [14] has in the table been corrected for the adiabatic cooling of the rotor. The present values of M are lower than the old one, which is also reflected in the greater diffusion constant obtained now. The absence of an initial increase in the calculated M-values might indicate the presence of some smaller molecular fragments, which would have caused an increase in D. The previous diffusion experiments [14] were made, however, under rather different conditions; the protein concentrations were low, the temperature was low and the observations were made over time periods of more than 30 h. The most likely explanation of the low diffusion coefficients obtained seems to be that some denaturation and aggregation occurred in the samples.

The partial specific volume of the *crystallized cytochrome c* was determined in a 10 ml pycnometer at 21.7°C as described elsewhere [29]. The protein concentration of the electrolyte free solution was 18.73 mg/ml. Two experiments gave $V = 0.728$ (mean of 0.7273 and 0.7282), which is appreciably higher than the old value 0.702—0.707 [30,31]. The new value implies that the sterical configuration of the helices in cytochrome c does not need to be as closely packed as was recently suggested [26].

The molecular weight was determined on cytochrome c in its reduced form at a concentration of 10 mg/ml, and the red filter cutting off below 600 mμ had to be used. The reduction was achieved by adding a small amount of ascorbic acid to the sample in the cellophane bag before starting the dialysis. This was made against a previously degassed buffer in a closed vessel filled with nitrogen. The calculated M did not change with time and it is in perfect agreement with the value obtained from the iron content.

The diffusion coefficient comes out rather close to the value 11,1 F determined by Theorell [31] on an old preparation of cytochrome c.

A few experiments have been performed with the crystallized *myeloperoxidase*. In spite of its green colour, the light absorption at 546 mμ made it impossible to work with concentrations higher than 5 mg/ml. In combination with the high sedimentation velocity this circumstance made the results rather unreliable. The mean M-value of three experiments, however, came out as 157 000, in rough agreement with the other data listed for this enzyme in Table 1 [29].

The slow increase of M with time in the early parts of the experiments, that has been observed for several of the proteins now discussed, might to a large extent have been caused by the concentration dependence of S. From eqns. (15)—(18) and the speed of dilution at the meniscus this effect can be calculated for serum albumin, old yellow enzyme and myoglobin. It amounts to about 0.3 %/1 000 s in the early part of the experiments and decreases to less than 0.1 %/1 000 s after 15 000 s. Part of the increase might, however, be an artefact due to difficulties in making the extrapolation to the meniscus from the first few photographs.

Some experiments have been made at pH 9.9 on *growth hormones* obtained from human and ox pituitaries, and the main results have already been reported [17]. The time dependence of the calculated M-values is seen from Fig. 3 b. The M-values decrease from the very beginning of the experiment instead of increasing slightly or remaining practically constant as observed for substances that are homogeneous. It has been shown in eqn. (13) that such a decrease of M is due to inhomogeneity with respect to S/D or the proportional M. In sedimentation studies at pH 9.9 the hormones seem to be quite homogeneous, but the sedimentation coefficients increase with increasing concentration [17,32]. These facts show that the hormone is in a state of equilibrium between molecules of different sizes, presumably a monomer-dimer equilibrium [17]. The M-values extrapolated to the time when the rotor obtained its equilibrium speed can thus be taken as a weight-average M of the sample, valid for the concentration used: M_{mean} = 30 000 for human hormone at 5—10 mg/ml and M_{mean} = = 75 000—80 000 for ox hormone at 10 mg/ml. The molecular weights extrapolated in the later part of the experiment would correspond to the monomeric molecules (or a mean of the smallest molecules): $M_{monomer}$ is hence approximately 15 000 and 50 000, respectively.

Similar more or less drastic decreases of M have been observed for impure protein preparations or for preparations known to be very inhomogeneous, *e.g.* cheese extracts [33] and stomach juice [34]. Also in these cases a mean value of M for the whole sample may be estimated as well as a mean M for the smaller molecules. If the components can be resolved by sedimentation analysis it is also possible to estimate M of the larger molecules.

CONCLUSIONS

The determination of molecular weights of homogeneous substances from the boundary condition at the meniscus appears to be quite accurate. The data generally agree within 2—3 % with those obtained from separate determina-

tions of sedimentation and diffusion coefficients or from analysis. As in case of sedimentation equilibrium the method is based on the balance between sedimentation and diffusion of the molecules, but the time requirement is much smaller. The diffusion coefficients are determined separately and appear to be reliable within a few percent. Only a small amount of material is needed, 15 mg is usually sufficient, and the method described here is simple and rapid to evaluate.

It is possible to investigate a rather wide range of molecular sizes. With a low speed attachment that makes it possible to run the centrifuge at a few thousands rpm molecular weights up to several hundred thousands might be determined. At the highest speed, 59 780 rpm, molecular weights as low as a few hundreds can be determined, as has been shown by Klainer and Kegeles [6].

By studying the time dependence of the ratio S/D or the proportional M the homogeneity of the sample might be explored. A constant or slightly increasing value indicates that the substance is homogeneous. A value that immediately starts to decrease shows that the sample is not monodisperse. Comparison with sedimentation analysis reveals the eventual presence of a reversible dimerization or polymerization.

Acknowledgements. The author wishes to thank all those who kindly put the various samples at his disposal. He also wishes to express his special gratitude to Professor H. Theorell for his interest and support in the work. Able technical assistance has been given by Mr. N. Ekman and Mr. K. Ingebrigtsen. Thanks are further due to the *Knut and Alice Wallenberg Foundation* for financial support.

Short Communications

The Magnetic Properties of the Elements Molybdenum and Tungsten

Studies in Magnetochemistry 17 *

R. W. ASMUSSEN and J. POTTS JENSEN

The Chemical Laboratory B, Technical University of Denmark, Copenhagen, Denmark

The first magnetic measurements concerning molybdenum and tungsten were published by Koenigsberger [1] in 1898. The author reports the χ_g-value 1.80×10^{-6} for molybdenum and 0.70×10^{-6} for tungsten. The susceptibility was dependent on the field strength. In 1899 Meyer [2] gave the χ_g-values 0.25×10^{-6} and 0.55×10^{-6}, respectively. The metal samples cannot be considered chemically and magnetically pure.

Magnetic measurements at different temperatures (room-temperature to 1 200°C) were published in 1910 by Honda [3]. For *molybdenum* a slight increase of χ_g with increasing temperature was observed; χ_g for *tungsten* was temperature independent. Mo: Metal lump (regulus) from Kahlbaum (nach Moissan), specific gravity 8.6 g/cm³. $\chi_g = 0.039 \times 10^{-6}$ is given as an average value. W: A metal lump and a powder sample both with a specific gravity 19.1 g/cm³ (from prof. Tammann); $\chi_g = 0.334 \times 10^{-6}$ and 0.336×10^{-6}, respectively.

In 1912 Owen [4] published the following results. *Molybdenum:* Powder specimen from Merck, the specific gravity 8.6 g/cm³ and $\chi_g = 0.603 \times 10^{-6}$ (0.558×10^{-6} for $H \rightarrow \infty$) at room-temperature and decreasing slightly with increasing temperature in the temperature range — 180°C to 20°C. *Tungsten:* Several samples with different (temperature independent but field strength dependent) χ_g-values. The author assumed the best value $\chi_g = 0.22 \times 10^{-6}$.

In 1933 de Haas and Alphen [5] published measurements on *molybdenum*, in which no impurities could be detected by chemical methods; spectroscopically, however, the presence of traces of certain metals were proved. Iron did not occur. The authors report $\chi_g = 0.949 \times 10^{-6}$ at 289°K. The susceptibility increases strongly with decreasing temperature. At 14.2°K, χ_g is 1.819×10^{-6}. For *tungsten* the following χ_g-values were found: 0.284×10^{-6}, 0.287×10^{-6} and 0.292×10^{-6} at the temperatures 289°K, 20.4°K and 14.2°K, respectively.

Finally Kriessman [6] in 1953 has published results of susceptibility measurements on molybdenum and tungsten. For *molybdenum:* $\chi_g = 0.93 \times 10^{-6}$ at 25°C increasing with increasing temperature being 1.11×10^{-6} at 1 825°C, (estimated from the χ_g, T-curve, no tables are published). The measurements on *tungsten* gave $\chi_g = 0.32 \times 10^{-6}$ at room-temperature; a slight increase in χ_g with increasing temperature was observed. The χ_g-value is 0.37×10^{-6} at 1 850°C. The samples used were spectroscopically pure metal-rods prepared by Johnson, Matthew and Co., London.

In this laboratory we have measured the magnetic susceptibility of molybdenum and tungsten at varying temperatures (80°K to 530°K) and at different values of the magnetic field strength.

The metal samples used for the measurements were spectroscopic standards prepared by Johnson, Matthew and Co., London. For *molybdenum* the specific gravity was determined to 10.3 g/cm³ (Landolt-Börnstein's tables give 10.2 g/cm³). The cylindrical rod had the dimensions: Diameter 4.98 mm and length 10.10 cm. In the spectra the sensitive

2 138	0.278	0.292	0.294	0.838	0.868	
2 657	0.278	0.292	0.294	0.839	0.875	0.875
3 040	0.278	0.293	0.296	0.839	0.874	0.874
3 346	0.281	0.293	0.296	0.839	0.837	0.872

lines of the elements Fe and Cu were barely visible and those of Ag, Al, As, Ca, Cd, Co, Cr, K, Li, Mn, Na, Nb, Ni, Pb, Rb, Sb, Sn, Si, Ta, Ti, V, W, Zn and Zr were not observed. The specific gravity of *tungsten* was determined to 19.1 g/cm³ (Landolt-Börnstein's tables give 19.1 g/cm³). The shape of the specimen was cylindrical (diameter 4.01 mm and length 10.10 cm). In the spectra the sensitive lines of the elements Fe and Si were very faint. No lines of the elements Ag, Al, Ca, Co, Cr, K, Li, Mg, Mn, Na, Ni, Pb, Sn, Ti, V, Zn, and Zr were observed.

The magnetic measurements were carried out as previously described [7].

The susceptibilities for both metals were measured at 2 138, 2 657, 3 040 and 3 346 Ørsteds at the temperatures 291, 198 and 80°K for molybdenum and at 294, 195 and 80°K for tungsten. The high-temperature measurements were carried out at 2 657, 3 040 and 3 346 Ørsteds, while in the temperature intervals: CO_2-temperature to liquid air temperature and CO_2-temperature to room-temperature, the susceptibilities were measured at 3 346 Ørsteds.

Our measurements of the gram susceptibilities are plotted against the temperature (°K) in Fig. 1. The straight lines have been determined by means of the method of least squares and have the equations:

$$\text{Mo: } \chi_g \times 10^6 = 0.8544 + 0.000053\ T$$
$$\text{W: } \chi_g \times 10^6 = 0.2798 + 0.000037\ T$$

For both metals there seems to be, at the lowest temperatures, a more rapid

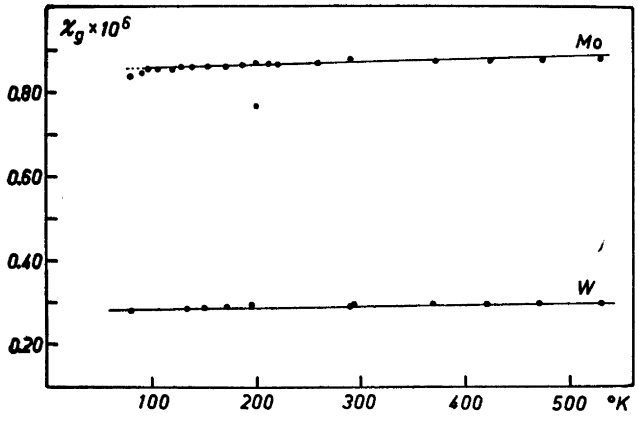

Fig. 1. Temperature dependence of the magnetic gram susceptibilities of molybdenum and tungsten.

decrease in χ_g with decreasing temperature, mostly pronounced in the case of molybdenum. Since we have no possibilities of carrying out magnetic measurements at lower temperatures than that of liquid air, we cannot decide, if this decrease in χ_g is a physical reality. Consequently the susceptibility of molybdenum at 80°K and 91°K have not been incorporated in the calculations mentioned above.

As average values for the specific magnetic susceptibilities in the temperature interval 97°K to 530°K for *molybdenum* and 80°K to 530°K for *tungsten* may be accepted the values 0.868×10^{-6} and 0.289×10^{-6}, respectively. The corresponding susceptibilities per gram-atom are 83.3×10^{-6} and 53.2×10^{-6}, respectively.

The susceptibilities were found to be independent of the field strength. The measurements arbitrarily selected for Table 1 exemplify this constancy.

The Structure of Ammines of Ammonium Halides

IVAR OLOVSSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

In a project covering structure investigations of ammines, formed with salts of alkali metal, alkaline earth metal and ammonium, the compounds $NH_4Cl \cdot 3NH_3$, $NH_4Br \cdot 3NH_3$, $NH_4I \cdot 3NH_3$ and $NH_4I \cdot 4NH_3$ have been studied. The structures of these are essentially solved but they will be further refined by least square methods. A full account of the structure determinations will be given after these refinements are finished. Some preliminary data are given below.

The crystal structure determinations are based on three-dimensional X-ray data taken in a low temperature Weissenberg camera. Exposures made at −35°, −80° and −140°C give identical photographs for each compound, apart from effects due to different temperature factors and cell dimensions.

$NH_4Cl \cdot 3NH_3$: The crystals (m.p. +10°C) are orthorhombic, space group $P\ 2_12_12_1$ with four formula units in a cell of dimensions $a = 8.795$, $b = 8.68$, $c = 8.989$ Å (at −35°C). The atomic coordinates for chlorine were obtained from Patterson-Harker sections $P(\frac{1}{2}; y; z)$, $P(x; \frac{1}{2}; z)$ and $P(x; y; \frac{1}{2})$ and the coordinates for the nitrogens thereafter from electron density projections and sections. The preliminary atomic coordinates are: Cl: (0.042; 0.000; 0.443); N_0: (0.477; 0.120; 0.284); N_1: (0.049; 0.106; 0.025); N_2: (0.232; 0.761; 0.191); N_3: (0.232; 0.342; 0.319). The ammonium ion (to which N_0 belongs) is tetrahedrally surrounded by three ammonia molecules (nitrogens N_1, N_2 and N_3) and one chloride ion; distances N−Cl: 3.26 Å; N−N: 2.83, 2.88 and 2.93 Å. The hydrogen atoms of the ammonium ions are evidently involved in these bonds.

The bromide and iodide compounds are isostructural with the chloride and possess the following cell dimensions:

$NH_4Br \cdot 3NH_3$: $a = 8.96$, $b = 8.996$, $c = 9.263$ Å (−35°C). (This work was done in collaboration with R. Liminga.)

$NH_4I \cdot 3NH_3$: $a = 8.32$, $b = 9.91$, $c = 9.96$ Å (−35°C). (The work was done together with G. Larsson.)

$NH_4I \cdot 4NH_3$: The work on this compound has been quite recently started and the structure is not yet completely elucidated. The crystals are probably tetragonal, space group $P\ 4/n$ with two formula units in a cell of dimensions $a = 8.94$, $c = 6.55$ Å (−140°C). (The work was done together with E. Hadler Vihovde, Oslo.)

Received August 31, 1957.

The Preparation of 3α,12α-Dihydroxy-25-methylcoprostane Bile Acids and Steroids 56

DEBABRATA SEN*

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The compound 3α,12α-dihydroxy-25-methyl-coprostan, which does not seem to have been described in literature before, was needed for metabolic studies. We have prepared it through anodic (Kolbe) synthesis from desoxycholic acid and *t*-butylacetic acid [1]. In order to promote mixed coupling, a 20 to 22 fold excess of *t*-butylacetic acid has been used resulting in a 17 % yield of the compound calculated on the basis of the bile acid used.

The pure substance was isolated from the neutral product of the electrolysis through chromatography on silicic acid. Reversed phase partition chromatography on hydrophobic Supercel according to the method of Danielsson [2] has also been used.

The molecular rotation of our compound has been found to be the same as that of coprostan-3α,12α-diol [3].

Experimental. All melting points were taken on electrically heated aluminium block and are corrected. Desoxycholic acid, crystallised from ethanol-water, was used without further drying.

A mixture of 504 mg of desoxycholic acid, 3 ml (23 mmole) of *t*-butylacetic acid [1] and 56 mg (2.42 mmole) of sodium was dissolved in 50 ml of methanol. This solution was electrolysed using the procedure reported before. Temperature of the electrolyte 25°–40°.

The solution was then taken to dryness in vacuum, water (40 ml) was added and it was extracted with ether (5 × 40 ml). The ethereal solution was washed with 10 % sodium hydroxide solution, water, 1 N hydrochloric acid and then water and then evaporated to dryness.

Adsorption chromatography on silicic acid. The residue (500 mg) was chromatographed on a column (i.d. of tube 24 mm) made with a mixture of silicic acid (16 g) (Silicic Acid powder, Baker-analysed-reagent; dried at 120° for 30 h) and Hyflo Supercel (8 g). Effluent-fractions 50 ml.

Fraction	*Eluent*	*Eluate*
1	methylenechloride	2 mg oil
2—5	Methylenechloride/ methanol (99:1 v/v)	0.5—2 mg oil in each;
6	—»—	74.0 mg, crystallised on addition of methanol
7	—»—	165.7 mg, crystallised on addition of methanol
8, 9, 10	—»—	20.2, 9.7 and 6 mg, respectively, oil, did not crystallise as above.

Several crystallisations from methanol and from acetone yielded 68 mg of white needles, m.p. 131.3°—132.3° from fractions 6 and 7.

Reversed phase partition chromatography. The combined mother liquors were taken to dryness and then crystallised once from methanol. The crystals (76 mg) were subjected to reversed phase partition chromatography [3] on hydrophobic Supercel (13.5 g) with 55 % *iso*propanol in water as moving phase and chloroform/heptane (1:4) (12 ml) as stationary phase. Fractions of about 3 ml were collected and the solvent was removed from them in a vacuum oven at about 55°.

The main band of crystalline material appeared in the fractions corresponding to 120—142 ml effluent. After two crystallisations of the material from these fractions from methanol 14 mg of white needles, m.p. 131.3°—132.3°, were obtained from them.

Total yield 82 mg (17 % calculated on the amount of bile acid used). Further crystallisations did not raise the melting point. (Found: C 80.2; H 12.1. Calc. for $C_{28}H_{50}O_2$: C 80.4; H 12.0).

$[\alpha]_D^{20} = +43.7° \pm 0.4°$ (in chloroform, $c = 0.0230$ g/ml solution). $M_D = +182$.

A Note on the Tritiation of Organic Compounds in Tritium Gas

SUNE BERGSTRÖM and SVEN LINDSTEDT

Department of Physiological Chemistry, University of Lund, Lund, Sweden

It was recently found by Wilzbach [1] that an exchange reaction occurs when organic compounds are exposed to tritium gas, resulting in the incorporation of tritium into stable positions. This important observation thus makes tritium labelled compounds easily available for purposes when a specific labelling is not required.

This communication describes a simple glass apparatus shown in Fig. 1 that we have used to carry out the tritiation on a milligram-scale. It was constructed from 8 mm Pyrex tubing except for the parts drawn with heavy lines in the figure which were made from 1 mm capillary tubing. At A the line was connected to a mercury diffusion pump through a ball joint. The tritium ampoule was connected at B. The substance to be exposed was put into a small glasstube which holds about 10 mg of material covered with a small plug of glass wool. Six of these tubes were placed in the reaction vessel (shown in scale), which was then connected at C. By this arrangement several substances can conveniently be exposed simultaneously.

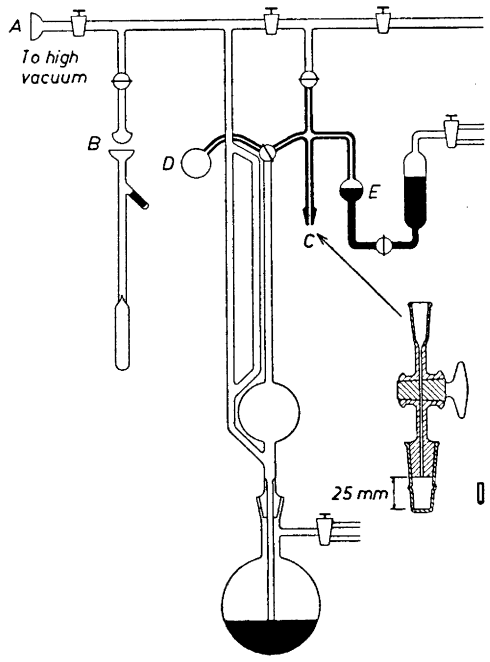

Fig. 1.

When the apparatus has been evacuated, the tritium is pumped into the reaction vessel with the Toepler pump. The pump is calibrated for volume measurements (10 μl—2 ml). After the desired time of exposure the Toepler pump is used to transfer the tritium gas to the glass bulb D (10 ml) where it is kept for further use.

As the apparatus is also used to carry out catalytic hydrogenations with tritium, it includes a device to alter the capacity of the reaction space, by varying the volume of the bulb E.

This apparatus has been used to label a large number of different compounds. As an example the labelling of cholic acid will be described. Six tubes loaded with 5 mg of crystalline cholic acid in each were kept for different times in 1 Curie of tritium gas (~80 % pure) at a pressure of approximately 100 mm Hg. The cholic acid was then purified by chromatography [2]. After 36 h the cholic acid had a specific activity of ~7 μC per mg that increased to ~3.2 mC per mg after 28 days. Less than 5 % of decomposition products had been formed.

The possibility of utilizing these high activities for analytical purposes is being investigated.

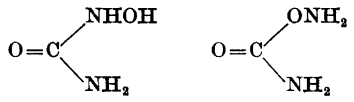
On the Isomerism of Hydroxyurea



IX. Absorption Spectra in the Infra-Red

HELMER KOFOD

Royal Danish School of Pharmacy, Dept. of Organic Chemistry, Copenhagen, Denmark

Absorption spectra in the frequency-region 3 600—600 cm^{-1} have been recorded of the two isomeric "oxyureas" melting at approximately 72°C (OU_{72}) and at approximately 140°C (OU_{140}), respectively [1].

The absorption spectrum of OU_{140} confirmed brief information previously published by other investigators [2]. It showed an intense, incompletely resolved pair of bands at about 1 650 cm^{-1}, similar to that produced by urea. It should undoubtedly, as also suggested by Runti and Deghenghi [2], be assigned to the carbonyl group.

(I) (II)

Urea as well as the two "oxyureas" showed an identical set of bands at 3 300 —3 400 cm^{-1}. These are tentatively assigned to N—H stretching vibrations. In the spectrum of OU_{140} there was observed an additional intense band at approximately 2 800 cm^{-1}, absent in the other two compounds. A possible assignment of this band to the (hydrogen-bonded) N—OH group would, together with the established carbonyl frequency, be in favour of formula (I) for OU_{140}. This structure can also account for most other physical and chemical properties (*vide, e. g.* previous publications in the present series) and may now be regarded as reasonably well established.

The IR-spectrum of OU_{72} has not previously been on record. In the region 1 500 —600 cm^{-1} it is much more complex than those of urea and OU_{140}. At higher frequencies it is similar to that of urea; it has, like urea, an intense absorption band in the carbonyl region (1 700 cm^{-1}). The strong absorption at 2 800 cm^{-1}, which was observed in OU_{140} is absent in OU_{72}. If the assignment of this frequency to the N—OH group is correct it follows that OU_{72} does not contain a hydroxy-group. Since, furthermore, there seems to be evidence for a carbonyl group, the absorption spectrum appears to support the formula (II) for OU_{72}; this was recently proposed on the basis of classical chemical arguments by Exner [3].

The structure (II) is one of more than twenty formally possible combinations of hydroxylamine and cyanic acid, considered by the present author [5]. It can account for a number of the observed properties, such as the solubility in ether, which is greater than that of the isomeride (I), the existence of only one methoxyurea [6, p. 491] corresponding to structure (I), the absence of a colour reaction with ferric chloride, and finally also for the basic properties [7] of OU_{72} (weak, though stronger than those of urea) contrary to the weak acidic properties of OU_{140}. Other observations are, however, difficult to explain on the basis of structure (II), *e. g.* the polarographic properties [8] and the relative amounts of the isomerides formed in different solvents [9] by the reaction of hydroxylamine with cyanic acid. In these experiments it was found possible to correlate the isomerism with well-established knowledge on the tautomerism of cyanic acid. Structure I/II on the other hand implies that the structural ambiguity of cyanic acid is unimportant, and that the isomerism arises from the hydroxylamine molecule being added in two different manners to cyanic acid. These are, however, formalistic arguments, which may be weakened by future knowledge of the true reaction mechanism of the formation (*cf.* Ref.[10]).

Although plausible the formula (II) cannot be regarded as definitely proved. The classical chemical arguments [3,4] have the usual weaknesses characteristic for structure determination on the basis of chemical reactivity, and the absorption spectra need expert interpretation. Since the pressed-plate technique was employed, the spectral data refer to the crystalline state only.

A more detailed account of the spectroscopic investigations and the results of a kinetic examination of the rearrangement $OU_{72} \rightarrow OU_{140}$ will be presented in forthcoming publications.

The assistance of Mr. Henry E. Andersen in recording the spectra is gratefully acknowledged. The instrument was a Perkin Elmer spectrophotometer, model 21.

Separation of Strontium-90 and Yttrium-90 and the Preparation of Carrier-free Yttrium-90

DAVID DYRSSEN

The Research Institute of National Defence, Dept. 1 (FOA 1), Sundbyberg 4, Sweden

In investigations with the radioactive isotope ^{90}Sr it is often valuable to have a simple and rapid method of separating ^{90}Sr and its daughter ^{90}Y. Methods that have been used for this separation include ion exchange [1-3], precipitation [4-6], electrolysis [7], and solvent extraction [8-10]. As solvent extraction procedures usually are very efficient and rapid, it seemed worth while to develop such a method. Previously the TTA-benzene [8,9] and the DBP-dibutyl ether [10] systems have been used. As DBP (dibutyl phosphoric acid) extracts metal ions at lower pH values than TTA (thenoyl trifluoroacetone), we preferred to work out a procedure using DBP as a complexing agent.

The extraction with DBP and chloroform can also be used for the preparation of carrier-free ^{90}Y which is a suitable isotope for tracer experiments. A 0.1 M nitric acid solution of the long-lived parent ^{90}Sr will constitute a continuous supply of ^{90}Y.

Reagents. The fission product ^{90}Sr was obtained in 1 M HNO_3 from AERE, Harwell, England. ^{89}Sr was also purchased from Harwell as neutron-irradiated $SrCO_3$. The chloroform (analytical grade) was washed with water to remove the alcohol present. The di-*n*-butyl phosphate (DBP) was kindly supplied by Albright & Wilson Ltd, London. Titration with alkali and analysis of C and H. (Found: C 45.0; H 8.7. Calc. for $C_8H_{19}PO_4$: C 45.7; H 9.1) showed the compound to be at least 99 % pure.

General procedure. The experiments were carried out at 25°C. The aqueous phase (5 ml) with 0.1 to 10 M HNO_3 and ^{90}Sr was shaken 3 to 5 minutes with an equal volume of 0.003 to 1 M DBP in chloroform. After centrifugation 0.1—0.5 ml of each phase was withdrawn. The dried samples were then counted with a total absorber thickness of 200 mg/cm². Corrections were made for counting efficiency, background, and the *bremsstrahlung* from ^{90}Sr.

0.1	48.3	7 154	+2.17	3.07
0.15	119	7 890	+1.82	3.25
0.2	180	7 634	+1.63	3.44
0.3	762	6 818	+0.95	3.28
0.5	2 310	5 120	+0.35	3.35
0.7	4 667	2 505	—0.27	3.17
1	6 544	1 134	—0.76	3.14
1.5	7 183	298	—1.38	3.05
2	6 952	180	—1.59	3.22
3	7 144	110	—1.81	(3.52)
5	7 292	53.4	—2.14	(3.86)
5	7 857	72.2	—2.04	(3.96)
7	7 630	20.4	—2.57	(3.87)
7	7 776	18.5	—2.62	(3.82)
10	7 132	89.2	—1.90	(5.00)
			Mean value:	3.22±0.13

Results. The results of the distribution experiments are given in Tables 1 and 2. It can be seen that ^{90}Y is more than 99 % extracted from 0.1 M HNO_3 with 0.1 M DBP in chloroform. Experiments with ^{89}Sr showed no activity in the organic phase under these conditions. However, with 1 M DBP small amounts of ^{89}Sr are extracted ($\log q = -2.216$). From this value we may calculate the extraction of ^{90}Sr to be less than 10^{-2} % ($\log q = -4.22$) with 0.1 M DBP.

Other measurements [11] have shown that DBP (HA) is highly dimerizised in chloroform. Within the concentration ranges of HNO_3 and DBP investigated here, the following equilibria may then explain the extraction of yttrium.

$$Y^{3+}\ (aq) + 3\ H_2A_2\ (org) \rightleftharpoons Y(HA_2)_3\ (org) + 3\ H^+\ (aq)$$

If the distribution of Y is given by

$$q = [Y(HA_2)_3]_{org}/[Y^{3+}]_{aq}$$

the equilibrium constant K will follow

$$\log K = \log q + 3 \log [H^+] - 3 \log C_A + 3 \log 2$$

where the DBP concentration in chloroform, $C_A = 2\ [H_2A_2]_{org}$.

The equilibrium constant K is calculated in the tables. The complex $Y(HA_2)_3$ is of a new type and will be further investigated. Other metal ions seem to form similar complexes [12].

Recommended procedure. a) Separation of ^{90}Sr and ^{90}Y. The sample is dissolved in 2—5 ml 0.1 M HNO_3 (HCl, $HClO_4$) and shaken with an equal volume of 0.1 M DBP in alcohol-free chloroform. The two phases are centrifuged and samples are withdrawn and evaporated to dryness. 80 % of the DBP in the chloroform sample may be removed at 190°C.

b) Preparation of carrier-free ^{90}Y. 5 ml of a 0.1 M HNO_3 solution with ^{90}Sr is shaken with 5 ml 0.1 M DBP in alcohol-free chloroform. The chloroform phase is then extracted with 5 ml of 5 M HNO_3. This nitric acid solution then contains 98 % of the ^{90}Y and 0.001 M of DBP. The DBP concentration can be lowered to 10^{-6} M, which is negligible for most purposes, by extraction first with 5 ml of chloroform and then twice with 5 ml of hexone (methyl *iso*butyl ketone). If carrier-free ^{90}Y is not wanted, inert yttrium may be added to the nitric acid solution and then precipitated with aqueous ammonia. This may be a convenient method of preparing an yttrium tracer, since neutron irradiated Y_2O_3 often contains some radioactive impurities.

The author wishes to thank the head of FOA 1, Professor Gustaf Ljunggren, for his kind interest and Mr. Bengt Carlsson and Mr. Ebbe Johansson for their technical assistance.

The Influence of Some Amino Acids on the Growth of and Vitamin B_{12} Production by *Streptomyces griseus* NzC5

W. KURZ and NIELS NIELSEN

Division of Food Chemistry, Royal Institute of Technology, Stockholm, and Research Department, AB Kabi, Stockholm, Sweden

The purpose of this investigation was to study the influence of different amino acids on both the growth and the vitamin B_{12} formation of *Streptomyces griseus*.

Methods. The organism used for this investigation was a strain of *Streptomyces*

griseus, NzC5, which gives low yields of vitamin B_{12} and streptomycin.

The nutrient solution had the following composition: 0.5 g K_2HPO_4, $3H_2O$ – 0.5 g $MgSO_4$, $7H_2O$ – 0.015 g $CuSO_4$, $5H_2O$ – 0.015 g $MnSO_4$, $4H_2O$ – 0.03 g $ZnSO_4$, $7H_2O$ – 0.025 g $FeSO_4$, $7H_2O$ – 0.05 g $CaCl_2$, $2H_2O$ – 0.005 g $Co(NO_3)_2$, $6H_2O$ and 20 g glucose made up to 1 000 ml with distilled water. Different amino acids were added to the solution as the nitrogen source so that the nitrogen content of the medium was 0.60 to 0.66 g per litre.

The experiments were made either with 50 ml of nutrient solution in 250 ml Ehrlenmeyer flasks, shaken continuosly at 25°, or with 3 litres of nutrient solution in 5 litre fermentors at the same temperature. The results of these two experiments were in good agreement. The amount of mycelium and vitamin B_{12} was determined daily; the former by weighing the washed and dried mycelium and the latter microbiologically using *Escherichia coli*. Vitamin B_{12} was determined both in the mycelium and in the nutrient solution; most of the vitamin B_{12} was found to be present in the nutrient solution. The amount of nitrogen was determined periodically to ensure that an excess of assimilable nitrogen was present. All experiments were performed in duplicate.

Results. A number of experiments were made in which the nutrient solution contained only one amino acid as the nitrogen source. The amino acids used in these experiments were: arginine, aspartic acid, cystine, glutamic acid, glycine, *iso*leucine, leucine, serine and valine. The amounts of the amino acids used corresponded to 0.60 g nitrogen per litre nutrient solution. The maximum values for mycelium and vitamin B_{12} content are given in Table 1 where the amino acids are tabulated according to the growth obtained. Maximum growth was obtained after 4 to 6 days and the maximum vitamin content somewhat later, after the commencement of autolysis.

Only three of the nine amino acids tried maintained good growth, *viz.* glutamic acid, glycine and aspartic acid. The vitamin B_{12} formation, however, was not proportional to the growth obtained. Whereas the growth obtained with aspartic acid was almost as vigorous as that obtained with glycine, the amount of vitamin B_{12} formed with aspartic acid was much smaller (See column 4 which gives the ratio μg B_{12} : g mycelium).

Table 1. Growth and vitamin B_{12} formation with different amino acids.

Nitrogen source	Mycelium max. amount, g dry weight per litre	Vitamin B max. amount, μg per litre	Ratio $\frac{\mu g \text{ vitamin } B_{12}}{g \text{ mycelium}}$
Glutamic acid	4.5	400	88
Glycine	3.1	360	116
Aspartic acid	2.6	60	23
Arginine	0.4	10	25
Leucine	0.4	7	18
Valine	0.4	20	50
Cystine	0.3	15	50
*Iso*leucine	0.3	6	20
Serine	0.3	5	17

With regard to the other six amino acids only slight growth occurred. The vitamin formation was accordingly low as the presence of a certain amount of mycelium is a necessary condition for good formation of the vitamin. Two of these six amino acids, *viz.* valine and cystine, produced higher amounts of vitamin B_{12} than the other four. From these experiments it appears that no strict proportionality exists between growth and vitamin B_{12} formation.

The experiments summarized in Table 1 show that aspartic acid promotes good growth whereas the vitamin B_{12} production is small, calculated on g mycelium formed. Other amino acids maintain only weak growth, but the vitamin B_{12} formation is relatively high. In a series of experiments it was investigated whether aspartic acid together with the last mentioned amino acids would result in an increased vitamin B_{12} formation. In each experiment to one litre of nutrient solution 0.60 g nitrogen as aspartic acid and 0.06 g as one of the other amino acids was added. The total amount of nitrogen thus amounted to 0.66 g per litre. The fact that this increased amount of nitrogen is of no importance *per se* was demonstrated in an experiment in which the amount of aspartic acid was increased by 10 %.

While the addition of the amino acids had no marked effect on growth there was in most cases an increase in the vitamin B_{12} formation. In all cases except when β-alanine, arginine and leucine were used, the vitamin formation was increased by about

Table 2. Growth and vitamin B_{12} formation with aspartic acid + one of the following amino acids.

Amino acids added	Mycelium max. amount, g dry weight per litre	Vitamin B_{12} max. amount, μg per litre	Ratio $\frac{\mu g \text{ vitamin } B_{12}}{g \text{ mycelium}}$
β-alanine	3.3	60	18
Arginine	2.2	70	32
Glutamic acid	2.9	95	33
Glycine	3.0	100	33
Histidine	2.7	100	37
Leucine	2.9	80	28
Lysine	2.6	100	38
Proline	3.3	100	30
Serine	2.8	130	46
Tryptophane	2.7	95	35
Valine	2.4	100	42
No addition	2.6	60	23

50 %. Column 4, Table 2, shows that the greatest stimulation of the vitamin production was obtained with serine and valine (in the presence of aspartic acid). In the case of valine this is in good agreement with the experiments given in Table 1. Serine, however, when being the sole nitrogen source, was found to give a very low vitamin formation. The reason for this must be, that if serine is the only nitrogen source such a small amount of mycelium is formed that a high vitamin formation is impossible.

Glutamic acid and glycine have, when added in small amounts, a less marked effect on the vitamin B_{12} production than would be expected from Table 1 (if these amino acids constitute the sole nitrogen source they give rise to vigorous growth and vitamin production). The reason for this peculiar behaviour (Table 2) is probably that these amino acids, when added in small amounts, are used for the nitrogen assimilation and accordingly hardly anything remains for the formation of vitamin B_{12} which, as mentioned above, mainly takes place after the cessation of the growth. Serine and valine, on the other hand, are very bad nitrogen sources for growth and are thus not used during the growth phase but are left over to the vitamin forming phase.

An Efficient Method for the Separation and Identification of Alkaloids in Biological Material

R. BONNICHSEN, A. C. MAEHLY and S. NORDLANDER

Statens Rättskemiska Laboratorium, Stockholm, Sweden*

The detection of alkaloids in biological material has long been based largely on colorreactions and crystal precipitation methods under the microscope. In recent years, paper chromatography has been employed to an increasing degree, pioneered by Munier *et al.*[1] and used by Jatzkewitz [2,3], Vidic [4] and others.

Buffered paper was employed by Carless and Woodhead [5], Goldbaum and Kazyak [6] and others. Schmall *et al.*[7] refined this technique by buffering zones to different pH values on the same paper. We have modified their technique for toxicological work and extended it to the identification of more than 30 compounds mainly of the alkaloid group. Quantitative estimation by spectrophotometry has also been worked out for many alkaloids. The basic principle of the method is as follows:

The tissue (whenever possible urine is employed, otherwise kidney, liver or blood) is heated with hydrochloric acid for 1 h for hydrolytic cleavage of adducts with glucuronic acid etc., and extracted in the usual way *via* amylacetate, 0.1 N HCl and chloroform.

The chloroform extract is dried, and evaporated to dryness. The residue is dissolved in hot 75 % ethanol and the ethanolic solution applied to a filter paper.

The migration and efficient separation of alkaloids and some other toxicologically important compounds on filter paper is achieved only if the free base is allowed to migrate in the direction of descending pH values and depends on the pH of the buffered zones as well as on the partition coefficients between the buffers and the mobile organic phase. The most efficient way to prepare the filter paper was the subject of extensive experimentation.

Ni Nicotine
Nk Nikethamide (nicamide)
Pa Phenacetin
Pc Paracodin (dihydrocodeine)
Pe Percaine (dibucaine)
Pi Piperine
Pp Papaverin
Pr Promethazine
Qu Quinine
Sa Santonin
Sc Scopolamine
St Strychnine
Th Thebaine

Compounds that are not clearly resolved from all others are indicated in groups (A—F).

The following symbols are used for the individual spots:

⊙ colored by Dragendorff's reagent and absorbing ultraviolet light.
○ colored by Dragendorff's reagent but not absorbing ultraviolet light.
● colored by Dragendorff's reagent and fluorescing in ultraviolet light.
× ⊙ not colored by Dragendorff's reagent but absorbing ultraviolet light.

The pH values finally adopted for ether and chloroform respectively as the mobile phases are shown in Figs. 1 and 2.

Fig. 1 shows the distribution on the chromatography sheat of 33 standard substances. The positions of spots are averaged from a number of runs on different days and with somewhat varying amounts of material (10—50 μg of each compound). The solvent was *ether* and the descending method was used at room temperature and in the dark. The buffer

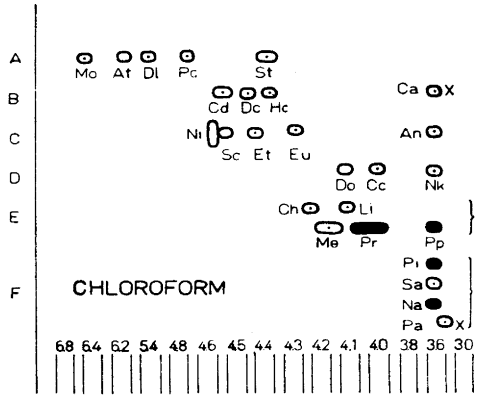

Fig. 2. Those compounds that are not cleary resolved when using ether as the mobile phase are here shown on a chromatogram where chloroform is the moving solvent. Groups A to F of Fig. 1 are each shown on 1 or 2 horizontal lines. The symbols used are the same as in Fig. 1.

Table 1. Buffer solutions employed. The amounts of 0.10 M citric acid and 0.20 M disodium phosphate listed were diluted to a final volume of 100 ml with distilled water.

pH	X ml 0.1 M citric acid	Y ml 0.2 M Na_2HPO_4	pH	X ml 0.1 M citric acid	Y ml 0.2 M Na_2HPO_4
3.0	39.3	10.2	4.8	25.2	24.8
3.6	33.9	16.1	5.0	24.3	25.7
3.8	32.3	17.7	5.4	22.2	27.8
4.0	30.7	19.3	6.2	16.9	33.1
4.1	30.0	20.0	6.3	16.2	33.8
4.2	29.4	20.6	6.4	15.4	34.6
4.3	28.6	21.4	6.6	13.6	36.4
4.4	27.8	22.2	6.8	9.1	40.9
4.5	27.2	22.8	7.0	6.5	43.6
4.6	26.7	23.3	—	—	—

composition as it is presently employed is listed in Table 1. Only disodium phosphate and citric acid are needed. The compounds are quite evenly distributed over the whole paper and some of them show distinct R_F values or "pH values", a term better suited for this technique. However, most of them appear in groups marked A to F in Fig. 1. Fortunately these groups are almost all clearly separated with *chloroform* as the mobile phase (Fig. 2).

Exceptions are chloro-promazin, methadone and phenbenzamine in group E and also all of group F. In the latter case, optical properties help in identification: piperine and narcotine show a blue fluorescence and the former also gives a distinct yellow color with Dragendorff's spraying reagent. Santonine and phenacetine both absorb ultraviolet light (UV-lamp in conjunction with fluorescein treated paper) but only the former reacts with Dragendorff's reagent.

The position of a spot (R_F or pH value) is never regarded as an absolute invariable and standards of known purity and concentration are always run on the same sheet of paper. Qualitative identification was sometimes aided by cutting the spot into a narrow rectangle, wetting it with liquid paraffin oil and measuring its spectrum *vs.* a blank treated in the identical way. If the paper had been sprayed with Dragendorff's reagent, a short treatment with ammonia vapour to restore the free base preceded the oiling.

Semi-quantitative evaluation was usually possible by extracting the spot with dilute ammonia and chloroform, evaporating and dissolving the residue in 75 % ethanol for spectrophotometric analysis. In cases where the spectrum did not show any characteristic bands or where the amount of material was insufficient, known amounts of standard solutions were run simultaneously on the same paper as the unknown, and the amount of the unknown estimated by matching spot sizes.

Transfers of individual "spots" to another paper for re-chromatography proved to be a useful and often indispensible means for separation and purification. If sufficient amounts of material were present, elution and evaporation were used. In other cases, a simple transfer could be achieved by sandwiching the cut-out spot between a new filter paper and a small glassplate with the help of paper clips and running the paper in the usual manner.

Some of the main advantages of the method for the toxicologist are: The need of only very small amounts of material (10 μg for qualitative identification is usually the lower limit), the relative speed of the process and the possibilities for purifying individual compounds from an often complex array of "spots" from tissue extracts.

A detailed report together with application of the method to actual toxicological cases will be published later.

Isotope Effect in the Methanolysis of Grignard Compounds

LARS OLOF ASSARSSON

Nobel Institute of Chemistry, Stockholm 50, Sweden

Measurements of the hydrogen isotope effect in the hydrolysis of methylmagnesium iodide, phenylmagnesium iodide and phenylmagnesium bromide in different solvents, *i. e.* anisole-pyridine and anisole-tetrahydrofuran, have been reported in previous preliminary papers [1,2].

Decomposition of Grignard compounds by tritiated methanol has now been carried out under the same or similar conditions. The reactions investigated are the methanolysis of methylmagnesium iodide in anisole-tetrahydrofuran and in *n*-butyl ether and that of dimethylmagnesium, *n*-butylmagnesium bromide, and phenylmagnesium bromide in *n*-butyl ether. Determination of the deuterium isotope effect in the methanolysis of a number of organometallic compounds has earlier been carried out by Wiberg [3], who found a small inversed isotope effect.

The methanolysis of dimethylmagnesium was done in an attempt to throw some light upon the reaction mechanism. It has been found [4], for instance, that acetone reacts about 50 times faster with dimethylmagnesium than with methylmagnesium iodide, and it has been concluded that dimethylmagnesium is probably the reactive component of the Grignard solution, the reaction rate of the ordinary reagent being determined by that of the generation of dimethylmagnesium by the well-known Schlenk-disproportionation.

If in the present experiments with methylmagnesium iodide and dimethylmagnesium, the methanolysis takes place with the dimethylmagnesium in both cases, then it could be expected that the mechanism of the decomposition, and hence the isotope effect, should be independent of the origin of the dimethylmagnesium. The results do not confirm such an expectation, as they do not confirm any hypothesis of a reactive species common to both reagents, *e. g.* the methyl carbanion. The mechanisms might be analogous but not identical, the difference being at least some kind of interaction with the mother reagent.

It has further been found [5] that diethylmagnesium reacts about 3 times faster with 1-alkynes than does ethylmagnesium bromide and that the isotope effect deuterium-protium is of considerable magnitude but not equal in the two cases. The isotope effect has its largest value with ethylmagnesium bromide. Since the isotope effect is large, the C—H bond concerned is believed to be cleaved in the rate-determining step. The reaction with ethylmagnesium bromide was shown to be a simple reaction of the second-order, and the kinetics of that with diethylmagnesium could be explained by the assumption of a competitive, consecutive, second-order reaction.

An analogous reaction scheme might be assumed for the methanolysis of dimethylmagnesium and methylmagnesium iodide, but the cleavage of the O—H bond has to take place in a step which is kinetically nearly insignificant, since the isotope effect is small, although not equal for the two compounds. Another, less likely alternative would be that the cleavage from oxygen is part of the rate-determining step but involves almost no loss of zero-point energy.

The methylmagnesium iodide reagent used was a solution of the compound in anisole-tetrahydrofuran and in *n*-butyl ether. The *n*-butyl ether solutions are known to contain practically no dimethylmagnesium [4,6]. This was confirmed in the present investigation by precipitating a solution of methylmagnesium iodide in *n*-butyl ether with a large excess of dioxan, *i. e.* 4 moles per g-ion of halogen [6]. The supernatant when tested both directly, as well as after vigorous shaking for 175 h (in order to reach equilibrium), evolved no appreciable amount of gas on hydrolysis.

The dimethylmagnesium reagent was prepared by precipitating a boiling ethyl ether solution of methylmagnesium iodide with dioxan in the excess mentioned above and boiling the mixture. The hot mixture was centrifuged to separate the precipitate from the clear supernatant, which was transferred into *n*-butyl ether. The ethyl ether and dioxan were distilled off in an argon atmosphere at reduced pressure from the *n*-butyl ether solution of dimethylmagnesium. Possible traces of dioxan in the solution are probably without significance, because it has been shown [7], that the presence of dioxan in dialkylmagnesium solutions is generally without influence on the reaction kinetics.

After the preparation of *n*-butylmagnesium bromide and phenylmagnesium bro-

Table 1. Results in the decomposition of Grignard compounds with methanol at 20°C

Grignard compound	Reaction medium	k_T/k_H	Number of parallel determinations of tritium in combustion water	Mean value (including error in determination of tritium in combustion water from the methanol)
CH_3MgI	Anisole-tetrahydrofuran	0.823 0.827 0.843 0.810	1 1 1 1	0.83 ± 0.02
CH_3MgI	*n*-butyl ether	0.953 0.938 0.950	2 1 2	0.95 ± 0.02
$(CH_3)_2Mg$	—»—	0.802 0.864 0.868	1 1 1	0.84 ± 0.04
n-C_4H_9MgBr	—»—	0.979 0.916 0.848	2 1 1	
C_6H_5MgBr	—»—	0.857 0.843	2 four different 2 combustions	0.85 ± 0.02

mide, a fraction of the solvent was distilled off at reduced pressure in order to eliminate hydrocarbons formed by moisture or other side reactions.

The technique of the decompositions was the same as the one used earlier, *i. e.* the Grignard reagent was added by means of an injection syringe or a dropping funnel into a solution of tritiated methanol. The methanol was present in at least 8-fold excess over the Grignard compound.

The anisole and the *n*-butyl ether were dried by refluxing over and distilling from metallic sodium, while the dioxan was dried in the same manner after standing for some weeks over anhydrous calcium chloride. The tetrahydrofuran was dried by shaking it with anhydrous calcium chloride, thereafter with metallic sodium and finally distilling it from methylmagnesium iodide. The ethyl ether was made absolute according to current methods.

The tritiated methanol (CH_3OT + CH_3OH) was made by addition of tritiated water to dry methanol, drying the mixture with gypsum, decanting and distilling.

The hydrocarbons formed in the methanolysis as well as the methanol were burnt over cupric oxide, and the radioactivity of the water of combustion was determined by means of a Geiger-Müller counter after reduction to hydrogen.

The results, all obtained at 20°C, are given in Table 1. The reported values have not been corrected for the small change in the specific activity of the methanol occurring during the reaction. The decreasing values of the ratio k_T/k_H in the *n*-butylmagnesium bromide methanolysis are probably due to small amounts of moisture gradually entering the flask containing the Grignard reagent.

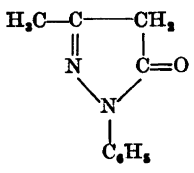
Studies on Pyrazolones

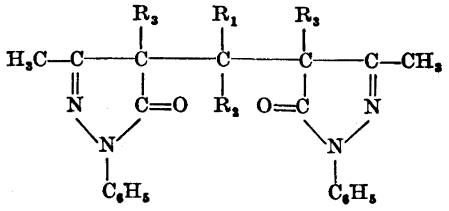
XI. Reactions between 1-Phenyl-3-methyl-2-pyrazolin-5-one and Some Aliphatic Carbonyl Compounds

GUNNEL WESTÖÖ



Institute of Organic Chemistry, University of Lund, Lund, Sweden

Aliphatic aldehydes and 1-phenyl-3-methyl-2-pyrazolin-5-one (I) react with the formation of 4,4′-alkylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-ones] (II a—e). No 1-phenyl-3-methyl-4-alkylidene-2-pyrazolin-5-ones (III a) could be isolated.



Methylalkyl ketones and I yield 1-phenyl-3-methyl-4-(1-methylalkylidene)-2-pyrazolin-5-ones (III b, c) and 4,4′-(1-methylalkylidene)-bis[1-phenyl-3-methyl-2-pyrazolin-5-ones] (II f, g). In solution II f and g — contrary to II a—e — are strongly dissociated into I and III (b, c).

1-Phenyl-3-methyl-2-pyrazolin-5-one (I) reacts rapidly at room temperature with aliphatic aldehydes, colourless, crystalline, stable acids, 4,4′-alkylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-ones] (II a—e) being formed. In anhydrous 1,2-diaminoethane they can be titrated as dibasic acids with sodium methoxide in benzene-methanol solution using *o*-nitroaniline as indicator [1,2], but under ordinary conditions — in ethanol - water using phenolphthalein as indicator — they are titrated as monobasic acids. They form 4,4′-dibromo compounds, *e.g.*, II h. Only one alkylidene compound, preparable from an aliphatic aldehyde and I, has been described in the literature before, *viz.* the methylene compound [3-5].

A comparison between the acidic properties of II a—e and 1,1′,1″-triphenyl-3,3′,3″-trimethyl-4,4′,4″-ter-[2-pyrazoline-5,5′,5″-trione] [IV][6] shows a great difference in the dissociability of the second 4-H atom, caused by the different electron affinity of the alkylidene and pyrazolonylidene groups, the electron donating alkylidene groups weakening the acidic strength, the electron attracting pyrazolonylidene group increasing the acidity remarkably. Thus IV is titrated as a dibasic acid in aqueous ethanol with barium hydroxide using phenolphthalein as indicator, whereas even on titration in dimethylformamide solution with sodium methoxide in benzene-methanol using azo violet as indicator [7], II a—e turn out as monobasic acids.

IV

From reactions between acetone and I Knorr [8], with excess of acetone, isolated 1-phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one (III b) and, with equivalent amounts of reactants, an acid for which he proposed the structure 4,4′-*iso*propylidenebis [1-phenyl-3-methyl-2-pyrazolin-5-one] (II f), though without proof.

A closer investigation of the reaction showed that I rapidly adds to III b with formation of a bispyrazolone. Accordingly, even with great excess of acetone, bispyrazolone is formed in the beginning of the reaction when the concentration of I is large. However, there exists an equilibrium *

$$PyH_2 + Py{=}C(CH_3)_2 \rightleftharpoons PyHC(CH_3)_2PyH$$

* Py represents the group  and tautomeric forms.

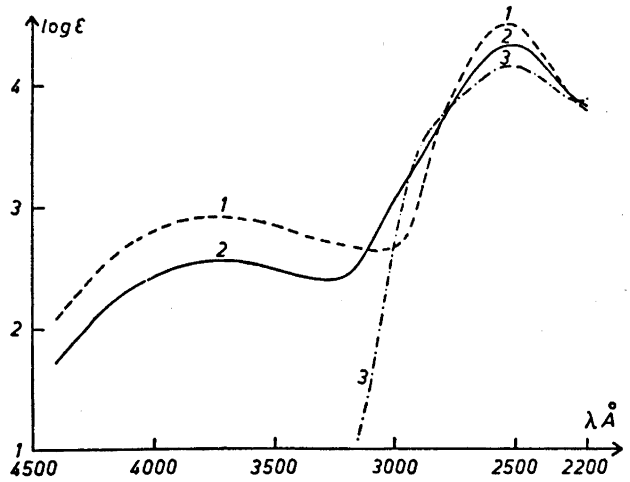

Fig. 1. UV absorption curves of 1) 1-phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one (III b), 2) 4,4′-*iso*propylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (II f) and 3) 4,4′-propylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (II b), showing the stability of II b and the dissociation of II f.

and on prolonged boiling with acetone all pyrazolone is therefore transformed into III b.

The structure of the bispyrazolone is difficult to settle by direct study on account of its strong dissociation into I and III b in solution. But the analogy to the corresponding compounds (II a—e) obtained from aldehydes and the plausibility that a Michael addition takes place between I and III b are in favour of the structure II f. The equivalent weight of II f cannot be determined, for both I and III b consume alkali, III b probably mainly by addition of the ethanol used as solvent to form a salt of the unstable acid 1-phenyl-3-methyl-4-(1-ethoxy-1-methylethyl)-2-pyrazolin-5-one (*cf.* Westöö [9]).

Methylethylketone reacts with I analogously to acetone, 1-phenyl-3-methyl-4-*sec*-butylidene-2-pyrazolin-5-one (III c) and 4,4′-*sec*-butylidenebis-[1-phenyl-3-methyl-2-pyrazolin-5-one] (II g) being formed. III c is rather unstable at room temperature. The corresponding diethyl compound, III d, is still more unstable and could not be isolated from the reaction between diethylketone and I. Similar to II f, but contrary to II a—e, II g is strongly dissociated into I and III c in solution. The difference in stability between the alkylidene and 1-methylalkylidene compounds (see Fig. 1), may be caused by III a being less stabilized by hyperconjugation and presenting less hindrance towards addition than III b or c (steric and inductive effects).

EXPERIMENTAL

4,4'-Ethylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (II a). Finely divided 1-phenyl-3-methyl-2-pyrazolin-5-one (I), recrystallized from ethyl acetate, (10 g) was dissolved in acetaldehyde (30 ml). On scratching colourless crystals separated. They were collected by filtration and washed with light petroleum. The product was purified by solution in benzene and precipitation with light petroleum, yield 9.3 g. After recrystallization from ethanol (solution in 15 ml at room temperature, crystallization on scratching, yield 8.4 g) it melted at 173° (decomp.). (Found: C 70.3; H 5.9; N 14.9; equiv. wt. 372 on titration in aqueous ethanol with barium hydroxide using phenolphthalein as indicator, 185 on titration in 1,2-diaminoethane with sodium methoxide in benzene-methanol using *o*-nitroaniline as indicator. Calc. for $C_{22}H_{22}N_4O_2$: C 70.6; H 5.9; N 15.0; equiv. wt. 374.4 or 187.)

4,4'-Ethylidenebis[1-phenyl-3-methyl-4-bromo-2-pyrazolin-5-one] (II h). II a (0.97 g) was dissolved in acetic acid, a few pieces of ice were added, and bromine (0.83 g) in acetic acid was poured into the solution. More ice and water precipitated the bromo compound, which was filtered, washed with water and air-dried. Yield: 1.47 g. After one crystallization from ethanol it melted at 119—120° (decomp.). The bromine was split off quantitatively at room temperature by dilute sodium hydroxide solution. (Found: C 49.4; H 3.8; N 10.6; Br 29.9; mol.wt. 520. Calc. for $C_{22}H_{20}N_4O_2Br_2$: C 49.6; H 3.8; N 10.5; Br 30.0; mol.wt. 532.)

4,4'-Propylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (II b). A mixture of 1-phenyl-3-methyl-2-pyrazolin-5-one (6 g) and propionaldehyde (15 ml) was stirred until an almost clear solution was obtained. After filtration the aldehyde was evaporated under reduced pressure and the residue was recrystallized from ether. Yield of colourless crystals: 5.3 g. After recrystallization from ethanol the product melted at 152° (decomp.). (Found: C 71.1; H 6.3; N 14.4; equiv. wt. 386 on titration in ethanol — water with barium hydroxide using phenolphthalein as indicator, 197 on titration in 1,2-diaminoethane with sodium methoxide in benzene-methanol solution using *o*-nitroaniline as indicator. Calc. for $C_{23}H_{24}N_4O_2$: C 71.1; H 6.2; N 14.4; equiv. wt. 388.5 or 194.)

4,4'-Butylidenebis [1-phenyl-3-methyl-2-pyrazolin-5-one] (II c). A mixture of I (6 g) and *n*-butyraldehyde (15 ml) was shaken until an almost clear solution was obtained and was then filtered after addition of ether. In the filtrate colourless crystals separated. More ether was added and the crystals were collected by filtration and washed with ether, yield 5.5 g. After recrystallization from ethanol, the product melted at 145° (decomp.). (Found: C 71.4; H 6.5; N 13.9; equiv. wt. 398 on titration with barium hydroxide using phenolphthalein as indicator. $C_{24}H_{26}N_4O_2$ requires: C 71.6; H 6.5; N 13.9; equiv. wt. 402.5.)

*4,4'-*Iso*butylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (II d)* was prepared from I (6 g) and *iso*butyraldehyde (15 ml) analogously to II c, yield 5.4 g, m.p. 210° (decomp.). (Found: C 71.4; H 6.7 ;N 14.0; equiv. wt. 398 on titration with barium hydroxide solution using phenolphthalein as indicator. $C_{24}H_{26}N_4O_2$ requires: C 71.6; H 6.5; N 13.9; equiv. wt. 402.5.)

4,4'-Heptylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (II e). Heptanal (10.3 g) and I (15.1 g) were stirred overnight. The following day the excess of aldehyde and impurities were extracted with light petroleum. Colourless crystals (19 g) remained. They were recrystallized from ethanol, m.p. 134—135° (decomp.). (Found: C 72.8; H 7.2; N 12.5; equiv. wt. 439 on titration in aqueous ethanol with barium hydroxide (phenolphthalein) and 219 on titration in 1,2-diaminoethane with sodium methoxide in benzene-methanol solution (*o*-nitroaniline). Calc. for $C_{27}H_{32}N_4O_2$: C 72.9; H 7.3; N 12.6; equiv. wt. 445 or 222.)

*1-Phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one (III b).* This compound has been prepared by a modification of the method of Knorr [8]. Acetone (30 ml) and I (5.0 g) were refluxed overnight. The acetone was then evaporated under reduced pressure, and the 1-phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one left was recrystallized once from ethanol. Yield: 4.2 g; m.p. 116°. If the product obtained contains traces of II f, it can be purified by extraction with ether at room temperature, filtration of the extract and evaporation of the solvent at reduced pressure.

*1-Phenyl-3-methyl-4-*sec*-butylidene-2-pyrazolin-5-one (III c).* III c was prepared from methylethylketone (35 ml) and I (5.0 g) analogously to III b. Yield: 3.9 g; m.p.

88—89°. (Found: C 73.5; H 7.0; N 12.3. Calc. for $C_{14}H_{16}N_2O$: C 73.7; H 7.1; N 12.3.) The product should be stored in an ice-box.

4,4'-sec-Butylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (II g). I (10 g) was refluxed in methylethylketone (40 ml) for 3 h. The ketone was evaporated under reduced pressure, and the III c formed was extracted with small amounts of ether. The colourless residue (II g) was crystallized once from ethanol, m.p. 106°. Michaelis and Zilg [10] give quite a different m.p., 248°, which is, however, surprisingly high compared to the m.p. of the corresponding *iso*propylidene compound, 138° (Knorr [8]). (Found: C 71.4; H 6.5; N 13.9; O 8.0. Calc. for $C_{24}H_{26}N_4O_2$: C 71.6; H 6.5; N 13.9; O 8.0.)

The analyses were performed by the Department of Analytical Chemistry, University of Lund, or by Mikroanalytisches Laboratorium im Max-Planck-Institut für Kohlenforschung, Mülheim, Germany.

The financial support of *Statens naturvetenskapliga forskningsråd* is gratefully acknowledged.

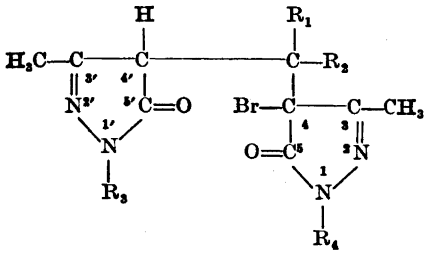
Studies on *Cyclo*propanes

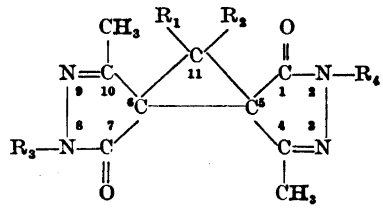
I. Preparation and Properties of Some Hexasubstituted *Cyclo*propanes

GUNNEL WESTÖÖ



Institute of Organic Chemistry, University of Lund, Lund, Sweden

Alkali salts of 4-bromo-4,4′-*iso*propylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (I a) and related compounds, *e.g.*, I b—f, in solution are rapidly converted to hexasubstituted *cyclo*propanes, II a—f. These *cyclo*propane derivatives under proper conditions isomerize quantitatively to bispyrazolones of the structure III a, b or substituted III a, b, cleavage of the *cyclo*propane ring with migration of a hydrogen atom from a methyl group taking place.



In a preceding paper [1] it was shown that 1,1′,1″-triphenyl-3,3′,3″-trimethyl-4-bromo-[4,4′,4″-ter-2-pyrazoline]-5,5′,5″-trione (IV) splits off hydrogen bromide with formation of furlone yellow (V) in good yield. The isomeric *cyclo*propane derivative was not detected among the reaction products and could only have been formed in a small amount, in spite of the fact that the analogous reaction between *e.g.*, 1-phenyl-3,4-dimethyl-4-bromo-2-pyrazolin-5-one and 1-phenyl-3,4-dimethyl-2-pyrazolin-5-one takes place with formation of a C—C bond, 1,1′-diphenyl-3,3′-dimethyl-[4,4′-bi-2-pyrazoline]-5,5′-dione being formed [2]. Besides for steric reasons, the non-appearance of a carbon-carbon coupling in the case of IV may be caused by a lack of electrons in the 4 and 4″ positions.

Experiments have now been performed to investigate whether an exchange of the second pyrazolonylidene group in IV for small, electron-releasing groups will cause formation of substituted *cyclo*-alkanes. Preparations of *cyclo*propane derivatives by ring closure of halogen compounds having an active hydrogen atom in the γ-position of the halogen atom have been described by several authors [3-5].

The sodium salt of 4-bromo-4,4′-*iso*propylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (I a) could be prepared by a Michael addition of the sodium salt of 1-phenyl-3-methyl-4-bromo-2-pyrazolin-5-one to 1-phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one (VI a) in ethanol solution (equilibrium reaction, *cf.* Westöö [1, 6, 7]). The addition compound rapidly splits off sodium bromide with formation of a neutral product of the empirical formula $C_{23}H_{22}N_4O_2$.

(VII)

From the two possible structures of $C_{23}H_{22}N_4O_2$, II a and VII, VII may be excluded, for after addition of hydrogen chloride to a benzene solution of the product, 1,1′-diphenyl-3,3′-dimethyl-4-(1-chloro-1-methylethyl)-[4,4′-bi-2-pyrazoline]-5,5′-dione (III c) could be isolated in good yield. The dissociation products of 4-chloro-4,4′-*iso*propylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (IX), *viz.* VI a and VIII, were also formed. Dilute alkali splits off hydrogen chloride from III c, the main reaction being ring closure with reformation of II a (Scheme 1). Thus the structure of $C_{23}H_{22}N_4O_2$ is 2,8-diphenyl-4,10,11,11-tetramethyl-2,3,8,9-tetrazadispiro[4.0.4.1]undeca-3,9-diene-1,7-dione (II a). The formation of the *trans* isomer is most probable, but the existence of the *cis* isomer cannot be excluded.

Scheme 1.

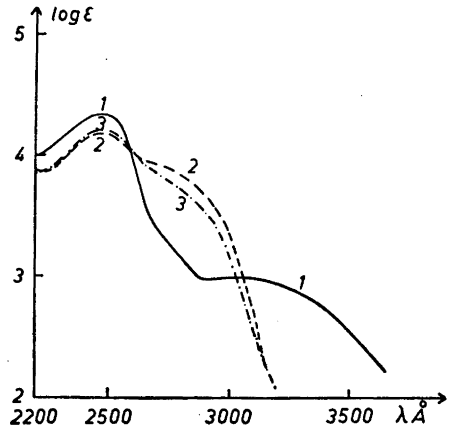

Fig. 1. UV absorption in ethanol of 1) II a, 2) III a, 3) III c.

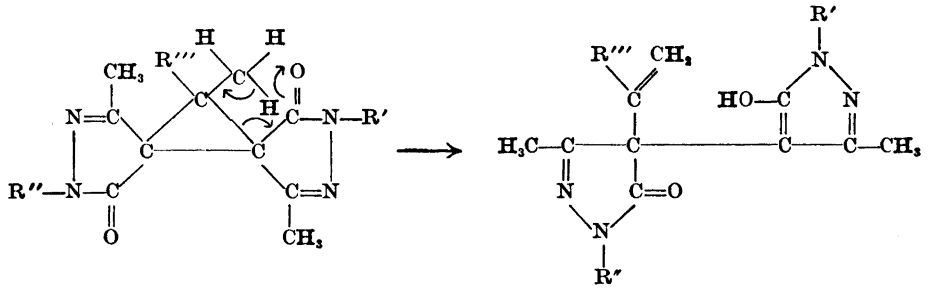
A bromo derivative of II a, II c, has been prepared in two different ways a) by addition of the sodium salt of 1-*p*-bromophenyl-3-methyl-4-bromo-2-pyrazolin-5-one to 1-phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one (VI a) and b) by addition of the sodium salt of 1-phenyl-3-methyl-4-bromo-2-pyrazolin-5-one to 1-*p*-bromophenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one (VI b). The identity of the compounds obtained was demonstrated by UV and IR absorption measurements and affords another indication of the *cyclo*propane structure of II.

When boiled with ethanol for a few minutes or when left in acetone or alcohol solution at room temperature for some days, II a is quantitatively isomerized to a monobasic acid, for which the structure 1,1′-diphenyl-3,3′-dimethyl-4-*iso*propenyl-[4,4′-bi-2-pyrazoline]-5,5′-dione (III a) is proposed. The acid is stable towards hydrogen chloride and presents an UV absorption curve similar to the corresponding curve of 1,1′-diphenyl-3,3′-dimethyl-[4,4′-bi-2-pyrazoline]-5,5′-dione [2]. The existence of a $CH_2{=}C$ group in the acidic isomer was demonstrated by the method of Bricker and Roberts [8].

A total of five derivatives of II a have been synthesized, *viz.* II b—f. Their UV absorption curves are almost identical with the curve of II a. According to various authors [9–13] the IR spectra of *cyclo*propane derivatives contain a ring deformation band at 1 000—1 050 cm^{-1}. The spectra of II a—f show absorption at the long wave limit of this region. The steric arrangement of the groups in II b-f has not been investigated.



II b and c, like II a, when heated in dry state or in solution for a short time or when kept in solution at room temperature for some days, undergo ring cleavage with a hydrogen shift from one of the methyl groups attached to the *cyclo*propane ring to the 4 position of one of the pyrazolone rings. The para substituents do not appreciably affect the rate of isomerization. In acetone-ethanol solution (1:1, v/v) at 25° the monomolecular rate constants were found to be for II a 9.8×10^{-4}, for II b 9.6×10^{-4} and for II c 9.95×10^{-4}. In the case of II b and c two isomeric acids, e.g., 1-phenyl-1′-*p*-tolyl-3,3′-dimethyl-4-*iso*propenyl-[4,4′-bi-2-pyrazoline]-5,5′-dione and 1-phenyl-1′-*p*-tolyl-3,3′-di-

methyl-4′-*iso*propenyl-[4,4′-bi-2-pyrazoline]-5,5′-dione, can be formed. The rate constants indicate that about equal amounts of the two isomers are obtained. The mixtures have not been resolved.

2,8-Diphenyl-11-ethyl-4,10,11-trimethyl-2,3,8,9-tetrazadispiro[4.0.4.1]undeca-3,9-diene-1,7-dione, II d, and its *p*-methyl and *p*-bromo derivatives, II e and f, isomerize with formation of acids under the same conditions as II a—c, though with greater ease. The monomolecular rate constants of the isomerization in acetone-ethanol solution (1:1, v/v) at 25° are for II d 1.36×10^{-3}, for II e 1.25×10^{-3} and for II f 1.35×10^{-3}.

For the isomerization product of II d there are two possible structures, III b and d. A test of end unsaturation [8] was positive. A determination of the amount of C-methyl gave the same value as for III a. Accordingly 1,1′-diphenyl-3,3′-dimethyl-4-(1-ethylvinyl)-[4,4′-bi-2-pyrazoline]-5,5′-dione, III b, is the correct structure of the acid.

The isomerizations take place also in solvents like benzene which cannot supply protons for addition to the carbonyl groups. The acids formed during the reactions have no influence on the rates. An intramolecular rearrangement seems plausible (Scheme 2).

Scheme 2.

EXPERIMENTAL

1-p-Bromophenyl-3-methyl-4-isopropylidene-2-pyrazolin-5-one (VI b). This product was prepared in the same way as 1-phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one (VI a) (Westöö [7]). M.p. 155° (decomp.). (Found: C 53.3; H 4.5; Br 27.21; N 9.6; O 5.6. Calc. for $C_{13}H_{13}BrN_2O$: C 53.3; H 4.5; Br 27.26; N 9.6; O 5.5.)

2,8-Diphenyl-4,10,11,11-tetramethyl-2,3,8,9-tetrazadispiro[4.0.4.1]undeca-3,9-diene-1,7-dione (II a). 1-Phenyl-3-methyl-4-bromo-2-pyrazolin-5-one (2.16 g) was dissolved in an equivalent amount of N sodium hydroxide solution (7.2 ml) and ethanol (25 ml) at room temperature and immediately poured into a solution of 1.83 g of 1-phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one (VI a) in ethanol (100 ml). Almost colourless crystals of II a separated. After 3—4 h the precipitate (2.32 g) was filtered, washed with ethanol and water and air-dried. The combined filtrate and washings were left overnight when another 0.51 g of II a separated. Both products were pure, yield 2.83 g. (Found: C 71.4; H 5.8; N 14.5; mol.wt. 379 (freezing point depression of benzene solutions). Calc. for $C_{23}H_{22}N_4O_2$: C 71.5; H 5.7; N 14.5; mol.wt. 386.) No sharp melting point was obtained because the compound isomerized into III a on heating. The solid product is stable at room temperature. For UV absorption curve, see Fig. 1.

2-p-Bromophenyl-8-phenyl-4,10,11,11-tetramethyl-2,3,8,9-tetrazadispiro[4.0.4.1]undeca-3,9-diene-1,7-dione (II c). a) 1-*p*-Bromophenyl-3-methyl-4-bromo-2-pyrazolin-5-one (crude product) was dissolved in ethanol (25 ml) and the equivalent amount of 2.5 N sodium hydroxide solution, and was then immediately poured into a solution of 1.81 g

of 1-phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one (VI a) in ethanol (125 ml). After a few minutes II c started separating. When the separation was complete, the crystals were filtered and washed with ethanol and water, yield 4.42 g. (Found: C 59.2; H 4.55; Br 17.26; N 12.0; O 7.0. Calc. for $C_{23}H_{21}BrN_4O_2$: C 59.4; H 4.55; Br 17.17; N 12.0; O 6.9.)

b) II c was also prepared from 1-phenyl-3-methyl-4-bromo-2-pyrazolin-5-one and 1-*p*-bromophenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one (VI b) in the same way as described above. Analyses, UV and IR absorption curves were identical for the product obtained here and the one obtained according to a).

2-Phenyl-8-p-tolyl-4,10,11,11-tetramethyl-2,3,8,9-tetrazadispiro[4.0.4.1]undeca-3,9-diene-1,7-dione (II b). 1-Phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one (8.32 g) was dissolved in ethanol (600 ml). Hydrobromide of 1-*p*-tolyl-3-methyl-4-bromo-2-pyrazolin-5-one (13.55 g of crude product) in ethanol (30 ml) was neutralized with 2.5 N sodium hydroxide solution using thymolphthalein as indicator and immediately poured into the above solution. The II b formed was filtered and washed with ethanol and water, yield 13.4 g, m.p. about 125° (decomp.). (Found: C 72.0; H 6.0; N 13.9. Calc. for $C_{24}H_{24}N_4O_2$: C 72.0; H 6.0; N 14.0.)

2,8-Diphenyl-11-ethyl-4,10,11-trimethyl-2,3,8,9-tetrazadispiro[4.0.4.1]undeca-3,9-diene-1,7-dione (II d). 1-Phenyl-3-methyl-4-bromo-2-pyrazolin-5-one (9.7 g) was dissolved in the equivalent amount of 1.63 N ethanolic piperidine (23.6 ml). The solution was immediately poured into a solution of 1-phenyl-3-methyl-4-*sec*-butylidene-2-pyrazolin-5-one [7] (VI c) (10 g) in ethanol (125 ml). On scratching II d started separating. After 4 h the precipitate was filtered and washed with ethanol and water, yield 7.5 g. (Found: C 71.9; H 6.1; N 14.1. Calc. for $C_{24}H_{24}N_4O_2$: C 72.0; H 6.0; N 14.0.)

2-Phenyl-8-p-tolyl-11-ethyl-4,10,11-trimethyl-2,3,8,9-tetrazadispiro[4.0.4.1]undeca-3,9-diene-1,7-dione (II e) and 2-p-bromophenyl-8-phenyl-11-ethyl-4,10,11-trimethyl-2,3,8,9-tetrazadispiro[4.0.4.1]undeca-3,9-diene-1,7-dione (II f). II e and f were prepared analogously to II d from 1-phenyl-3-methyl-4-*sec*-butylidene-2-pyrazolin-5-one and 1-*p*-tolyl-3-methyl-4-bromo-2-pyrazolin-5-one or 1-*p*-bromophenyl-3-methyl-4-bromo-2-pyrazolin-5-one. (Found for II e: C 72.2; H 6.3; N 13.6. Calc. for $C_{25}H_{26}N_4O_2$: C 72.4; H 6.3; N 13.5. Found for II f: C 60.0; H 5.0; Br 16.65; N 11.7. Calc. for $C_{24}H_{23}BrN_4O_2$: C 60.1; H 4.8; Br 16.67; N 11.7.)

Addition of hydrogen chloride to $C_{23}H_{22}N_4O_2$ (neutral isomer). A solution of $C_{23}H_{22}N_4O_2$ in benzene was cooled in ice, and dry hydrogen chloride was passed into the solution for 15 min. After removal of the benzene under reduced pressure, the residue was dissolved in ethanol and precipitated with water, filtered, washed with water and air-dried. A yellow product was obtained.

When sodium acetate solution and a small amount of cupric sulphate were added to the filtrate, pyrazole blue precipitated, indicating the presence of 1-phenyl-3-methyl-4-chloro-2-pyrazolin-5-one.

With light petroleum at room temperature 1-phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one could be extracted from the yellow, solid mixture. After recrystallization from ethanol, it melted at 116° alone and mixed with authentic 1-phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one.

It is evident that a hydrochloride of 4-chloro-4,4'-*iso*propylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one] is primarily formed from part of the $C_{23}H_{22}N_4O_2$, and that it is decomposed into hydrogen chloride, 1-phenyl-3-methyl-4-chloro-2-pyrazolin-5-one and 1-phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one on addition of ethanol and water. As this chlorobispyrazolone is a minor part of the addition product, VII can not be the structure of $C_{23}H_{22}N_4O_2$. (According to light absorption measurements the mixture obtained contained about 20 % of 1-phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one, corresponding to about 35 % cleavage of the C_5-C_6 bond of II a).

The main addition compound, which was not extracted by the light petroleum, was an almost colourless, acidic product. For UV curve see Fig. 1. (Found: C 65.3; H 5.6; Cl 8.29; N 13.15. Calc. for $C_{23}H_{23}ClN_4O_2$: C 65.3; H 5.5; Cl 8.38; N 13.25.) On addition of dilute alkali, the product split off hydrogen chloride with formation of the original 3-ring in about 75 % yield. The acidity of the addition product, its slight solubility in light petroleum and easy ring closure together with the lack of oxidative power (*cf.* Westöö [14]) show that the product is 1,1'-diphenyl-3,3'-dimethyl-4-(1-chloro-1-methylethyl)-[4,4'-bi-2-pyrazoline]-5,5'-dione (III c).

Isomerization of II a into 1,1'-diphenyl-3,3'-dimethyl-4-isopropenyl-[4,4'-bi-2-pyrazoline]-5,5'-dione (III a). II a (1.35 g) was boiled in ethanol (30 ml) until about 15 ml remained (30 min). On cooling colourless crystals separated (1.20 g). They were filtered, washed with cold ethanol and air-dried, m.p. 201° (decomp.). (Found: C 71.5; H 5.7; N 14.6; O 8.3; equiv.wt. 384. Calc. for $C_{23}H_{22}N_4O_2$: C 71.5; H 5.7; N 14.5; O 8.3; equiv.wt. 386). The existence of $CH_2=$ in the molecule was demonstrated by the method of Bricker and Roberts [8], though only qualitatively. A quantitative determination did not succeed. For UV absorption curve, see Fig. 1.

When a weighed amount of II a was boiled in excess of ethanol for 5 min, cooled and titrated with barium hydroxide solution using thymolphthalein as indicator, the consumption of base corresponded to a quantitative isomerization into 1,1'-diphenyl-3,3'-dimethyl-4-*iso*propenyl-[4,4'-bi-2-pyrazoline]-5,5'-dione (III a). The same isomerization took place in a couple of days at room temperature in acetone or acetone-ethanol solution. Heating of solid II a at 140° for one hour also gave III a together with degradation products.

1,1'-Diphenyl-3,3'-dimethyl-4-isopropenyl-4'-bromo-[4,4'-bi-2-pyrazoline]-5,5'-dione. Because the mol.wt. of III a could not be determined on account of the slight solubility in benzene and glacial acetic acid of the product, the 4-bromo derivative was prepared for mol.wt. determination.

III a (0.80 g) was dissolved in acetic acid. A few pieces of ice were added, and bromine (0.34 g) in acetic acid was dropped into the solution. More ice and water precipitated the reaction product, which was filtered, washed with water and air-dried. The 4-bromobispyrazolone was isolated by solution of the mixture obtained in acetic acid and dropwise addition of water until yellow crystals started separating. The solution was then cooled in ice and the crystals formed were filtered and washed with dilute acetic acid and water. The product could be recrystallized from acetic acid. (Found: C 59.1; H 4.6; Br 17.3; N 11.9; mol.wt. 455. Calc. for $C_{23}H_{21}BrN_4O_2$: C 59.35; H 4.6; Br 17.2; N 12.0; mol.wt. 465.)

Isomerization of II d to form 1,1'-diphenyl-3,3'-dimethyl-4-(1-ethylvinyl)-[4,4'-bi-2-pyrazoline]-5,5'-dione (III b). II d (1.18 g) was refluxed in ethanol (10 ml) for 15 min. On cooling and scratching colourless crystals separated (0.92 g), m.p. 188° (decomp.). (Found: C 72.0; H 6.0; N 14.0; equiv.wt. 400. Calc. for $C_{24}H_{24}N_4O_2$: C 72.0; H 6.0; N 14.0; equiv.wt. 400.)

For the acid formed there are two possible structures, III b and d. A qualitative test of end unsaturation according to Bricker and Roberts [8] was positive, thus supporting the formula III b. Furthermore, a determination of C-methyl on this product and on III a gave in both cases 10.1 %. III a requires 11.7 %, III b 11.3 % and III d 15.0 %. Accordingly III b must be the structure of the acid.

Isomerization of II b, c, e and f. The mono-*p*-methyl and mono-*p*-bromo derivatives, II b, c, e and f, could be isomerized by boiling them in ethanol or by keeping their solutions in acetone or acetone-ethanol at room temperature for some days. Two isomeric acids can be formed in each case, *e.g.*, from II c 1-phenyl-1'-*p*-bromophenyl-3,3'-dimethyl-4-*iso*propenyl-[4,4'-bi-2-pyrazoline]-5,5'-dione and 1-phenyl-1'-*p*-bromophenyl-3,3'-dimethyl-4'-*iso*propenyl-[4,4'-bi-2-pyrazoline]-5,5'-dione. They have not been separated.

Reaction rates of the isomerizations. About 2 g of the *cyclo*propane derivatives were dissolved in 250 ml of acetone (25 ml) and so much commercial, anhydrous ethanol (warmed to 39° to compensate the decrease of temperature when the solvents are mixed) was added that the total volumes were 500 ml at 25.0°. The solutions were placed in a thermostat at 25.00°±0.05°. At intervals samples of 50.0 ml were titrated with barium hydroxide solution using thymophthalein as indicator. The constants were calculated from the moment when the first sample was titrated.

The analyses were performed by the Department of Analytical Chemistry, University of Lund, or by Mikroanalytisches Laboratorium im Max-Planck-Institut für Kohlenforschung, Mülheim, Germany.

The financial support of *Statens naturvetenskapliga forskningsråd* is gratefully acknowledged.

*iso*Thiocyanates XXVI*. Straight-Chain ω-Methylthioalkyl *iso*Thiocyanates and some Derivatives

ANDERS KJÆR and BO CHRISTENSEN

Chemical Laboratory of the University of Copenhagen, Denmark

The occurrence in plants of straight-chain compounds, containing a methylthio-grouping in terminal position, is briefly surveyed. Special attention is given to a number of *iso*thiocyanates of this general type encountered in Nature.

The preparation as well as properties of the homologous series, $CH_3S(CH_2)_nNCS$, with values of n ranging from two to nine, are reported, together with the corresponding thiourea-derivatives resulting from interaction of the *iso*thiocyanates with ammonia and benzylamine (Tables 1, 2 and 3).

The ω-methylthioalkylamines, (XXI), serving as intermediates in the syntheses of the mustard oils, are produced by varying methods and characterized as crystalline thiourea-derivatives formed upon reaction with phenyl *iso*thiocyanate (Table 4).

Comparison of a synthetic specimen of 1-benzyl-3-(9-methylthiononyl)-urea, (XXIII), with a product directly derivable from the *Arabis* mustard oil, on which we recently reported [16], establishes beyond doubt the proposed structure of the latter as (−)-9-methylsulphinylnonyl *iso*thiocyanate (XI).

The biosynthetic origin of the methylthio-grouping in natural products is briefly discussed.

About fifty years ago, Schneider isolated the *iso*thiocyanates cheirolin [1] (I) and erysolin [2] (II) from seeds of the crucifers *Cheiranthus cheiri* L. and *Erysimum Perofskianum* Fisch. *et* M.**, respectively. The structural analogy of cheirolin and methionine was commented upon by Barger and Coyne [3] in 1928 when these authors first announced the structure and synthesis of the new amino acid. Since then, an additional number of straight-chain compounds, having a terminally located methylthio-grouping in common, has been recognized in Nature. Thus, 3-methylthiopropanol (III), a constituent of soya-sauce [4], methyl 3-methylthiopropionate (IV), present in the essential oil of pineapple [5], and the adenylthiomethylpentose recognized in yeast many years ago (*cf.* Ref.[6]), all belong to this structural type.

* Part XXV of this series: *Acta Chem.Scand.* 11 (1957) 577.

** Thus far, it has not been possible in this laboratory to confirm the occurrence of an erysoline glucoside in this or other botanical species.

$CH_3S(O)(CH_2)_nNCS$

II: n = 4

$CH_3SCH_2CH_2CH_2OH$ III

$CH_3SCH_2CH_2COOCH_3$ IV

$CH_3S(O)CH_2CH(NH_2)COOH$ V

$CH_3SCH_2CH(NH_2)COOH$ VI

$CH_3SCH=CHCOOH$ VII

Other examples can be adduced from more recent work. Independently, Synge and Wood [7] and Morris and Thompson [8] announced the discovery of (+)-S-methyl-L-cysteine sulphoxide (V) in various crucifers, a finding recently supplemented by the discovery also of the corresponding S-methyl-L-cysteine (VI) as a constituent of higher plants [9]. The stereoisomeric 3-methylthioacrylic acids (VII), demonstrated by Stoll *et al.* [9a] to occur as the acid moieties of two esters present in rhizomes of *Petasites officinalis* Moench, also deserve attention in this connexion.

Besides (I) and (II), a number of straight-chain *iso*thiocyanates, carrying a terminal methylthio grouping as such or oxidized to the sulphoxide stage, has been encountered in various members of the family *Cruciferae*. Thus, Schmid and Karrer [10] established the structure (VIII) for sulphoraphene, derivable from a glucoside in radish seeds, whereas Schultz and Gmelin [11] assigned the formula (IX) to a mustard oil enzymically liberated from an analogous glucoside in seeds of *Iberis amara* L. In this laboratory, 3-methylthiopropyl [12] (XIII), 4-methylthiobutyl [13] (XIV) and 5-methylthiopentyl [14] (XV) *iso*thiocyanates have been established as products of enzymic hydrolysis of glucosides present, *inter alia*, in seeds of *Iberis sempervirens* L., *Eruca sativa* Mill. and *Berteroa incana* (L.) DC., respectively. More recently, we have proved also the existence in Nature of glucosides corresponding to the *levo*rotatory sulphoxide *iso*thiocyanates, (X)—(XII), *viz.* in seeds of *Alyssum argenteum* Vitm.[15], *Arabis alpina* L.[16] and *Camelina sativa* (L.) Crantz [17], respectively. It appears likely that these sulphoxides should be regarded as secondary products, biogenetically deriving from the corresponding 5-methylthiopentyl (XV), 9-methylthiononyl (XIX) and 10-methylthiodecyl (XX) *iso*thiocyanates.

On this background, and for various other reasons, it became desirable to have at disposal the individual mustard oils of the general series $CH_3S(CH_2)_n$-NCS, with values of *n* ranging from two to nine. The present paper records the

[a] Apparently, Weller *et al.*[17] synthesized this compound, yet without presenting any physical or analytical data for the mustard oil. [b] *cf.* Ref.[13]. [c] *cf.* Ref.[13]. [d] Reported b.p. 130–140°/9 mm[26]. [e] *cf.* Ref.[14].

preparation and properties of these *iso*thiocyanates, together with data for the thiourea-derivatives formed upon their reactions with ammonia and benzylamine. For particular reasons, the symmetric *bis*-(ω-methylthioalkyl)-thioureas, wherein the alkyl represents hexyl, heptyl, octyl, and nonyl, have also been synthesized. In general, the *iso*thiocyanates, (XIII)–(XIX), were produced from the corresponding amines by reaction with thiocarbonyl chloride in a slightly modified version of the traditional reaction. They all distilled as colourless, pungent oils possessing a characteristic taste and odour, reminiscent

[a] Crystallization of this previously described derivative[27] could be induced only after seeding with crystalline material (m.p. 58°), kindly placed at our disposal by Dr. H. M. Sell. [b] *cf.* Ref.[13]. [c] Recrystallized from a mixture of ethyl acetate and pentane. [d] *cf.* Ref.[15]. [e] *cf.* Ref.[17].

of those of fresh radish root. Physical and analytical data for the mustard oils are presented in Table 1, whereas the two series of thioureas are summarized in Tables 2 and 3. For the sake of completeness a few compounds, recorded in previous papers in this series, are included.

The requisite ω-methylthioalkylamines (XXI), whence the mustard oils derive, were synthesized by a number of different routes as briefly outlined in the sequel. 2-Methylthioethylamine (XXI, n = 2), the lowest member of the series, was obtained from ethyleneimine and methanethiol according to Wie-

[a] Reported as an oil by Schmid and Karrer [26].

land *et al.*[18] The synthesis of the following two homologues, (XXI, n = 3 and 4) was accomplished by lithium aluminium hydride reduction of the corresponding nitriles, as described in earlier papers from this laboratory [19, 20]. Again, details on the preparation of 5-methylthiopentylamine (XXI, n = 5) were presented in a previous memoir [14] of this series *. 6-Chlorohexanol was readily transformed into 6-methylthiohexanol, and the latter, in turn, into 6-chlorohexyl methyl sulphide which served as a common intermediate for the syntheses of 6-methylthiohexylamine (XXI, n = 6), *via* N-(6-methylthiohexyl)-phthalimide, and 7-methylthioheptylamine (XXI, n = 7), the latter resulting from lithium aluminium hydride reduction of 7-methylthioheptanenitrile. This, in turn, was accessible from the above chlorosulphide by employing the general conditions developed by Brändström [22] for the synthesis of organic cyanides. 1,8-Octanediol was converted into its chlorohydrin as described elsewhere [23, 24]. Again, the further transformations into 8-methylthiooctanol and 8-chloro-octyl methyl sulphide were accomplished according to established methods [25]. The latter intermediate was processed to N-(8-methylthiooctyl)-phthalimide and 8-methylthiooctylamine (XXI, n = 8) in straight-forward reactions. Essentially the same procedure was employed in the preparation of 9-methylthiononylamine (XXI, n = 9), characterized as its N-benzoyl derivative, from N-(9-methylthiononyl)-phthalimide and the previously known 9-chlorononyl methyl sulphide [25]. For the purpose of characterization, the whole series of amines was converted into crystalline phenylthioureas upon reaction with phenyl *iso*thiocyanate. The properties of these derivatives are recorded in Table 4.

$CH_3S(CH_2)_nNH_2$ XXI

$CH_3S(CH_2)_9NHCXNHCH_2C_6H_5$ XXII : X = S; XXIII: X = O

The preparation of the thioureas, summarized in Tables 2 and 3, calls for no comments. It is of interest, however, that the synthetic preparation of 1-benzyl-3-(9-methylthiononyl)-thiourea, (XXII), permitted the unequivocal structure determination of the *levo*rotatory mustard oil which we recently demonstrated to be liberated on enzymic hydrolysis of a glucoside in seeds of *Arabis alpina* L., and to which we assigned the structure (XI) on strong, though admittedly inconclusive, evidence [16]. On treatment of (XXII) with a solution of silver nitrate in dilute ethanol 1-benzyl-3-(9-methylthiononyl)-urea (XXIII) resulted. Its identity with the product of m.p. 99.5°, formerly attained by stepwise degradation of the natural mustard oil [16], was established by mixed melting point determination and coinciding infra-red spectra. Hence, there remains no uncertainty as to the mustard oil, derivable from glucoarabin, being (−)-9-methylsulphinylnonyl *iso*thiocyanate (XI).

The numerous and diverse plant constituents, containing a terminal methylthio-grouping, raise the question as to a possible common biogenetic origin of

* Professor P. Karrer kindly informed us that analyses and physical constants for this amine have been recorded in 1950 from his laboratory in a thesis [21] the existence of which we regret not to have known at the time our manuscript was submitted for publication.

the latter. Positive evidence in favour of any general pathway is lacking. It rather appears that more than one route is needed in order to account for the biosynthesis of these compounds. Thus, very little is known about methionine formation in higher plants, but in *E. coli* and *Neurospora* strains it proceeds, according to general belief, from cysteine and *homo*serine, *via* cystathionine, to *homo*cysteine, followed by S-methylation of the latter (*cf.* Ref.[28]). The recent observation by Wolff *et al.*[29], that an extract of yeast can accomplish an enzymic synthesis of S-methyl-L-cysteine from L-serine and methanethiol, indicates an alternative mode of introduction of the CH_3S-moiety, involving again, however, the exchange of a terminal hydroxy-grouping with a sulphur-containing fragment. In principle, the newly reported cysteine synthesis in yeast from serine and hydrogen sulphide [30] also fits this general scheme. Hence, the function of ω-hydroxyalkyl chains as intermediate stages in the biosynthesis of the various natural ω-methylthioalkyl *iso*thiocyanates, or rather their glucosides, is an attractive possibility. The hypothesis further accomodates the appearance in Nature of several terminally unsaturated *iso*thiocyanates, as well as of masked hydroxyalkyl species such as the 3-benzoyloxypropyl mustard oil lately recognized in this laboratory as a constituent arising from a glucoside in seeds of *Malcolmia maritima* (L.) R. Br [31]. The investigations on the occurrence and biogenesis of *iso*thiocyanates in higher plants are being continued in this laboratory.

EXPERIMENTAL

All melting points are uncorrected and determined in capillary tubes (soft glass) in a slowly heated bath.

Hexamethylene series

6-Methylthiohexanol. Methanethiol (27 g) was introduced into a solution of sodium (13 g) in methanol (350 ml). 6-Chlorohexanol [32] (75 g) was slowly added to this solution, and the stirred reaction mixture was refluxed for 3 h. The salt was then filtered off, the methanol removed by distillation, and water was added to the residue to cause the alcohol to separate. After extraction with ether, it distilled as a colourless, hygroscopic oil, b.p. 125°/9 mm, n_D^{25} 1.4821 (Found: C 56.15; H 10.98; S 21.70. Calc. for $C_7H_{16}OS$: C 56.71; H 10.88; S 21.63). Yield: 71 g.

6-Chlorohexyl methyl sulphide. In a three-necked flask, provided with a sealed stirrer, reflux condenser and dropping funnel, was placed a solution of 6-methylthiohexanol (69 g) in dry chloroform (40 ml). Purified thionyl chloride (58 g) was added at such a rate as to maintain a steady reflux (about 2 h). Towards the end of the reaction occasional heating was needed to keep the desired refluxing rate. After removal of the solvent, the chlorosulphide was distilled *in vacuo*, b.p. 72–74°/0.3 mm (63 g, 81 %). Redistillation furnished a colourless specimen for analysis, b.p. 103–104°/9 mm, n_D^{25} 1.4818 (Found: C 50.60; H 9.08; S 19.39. Calc. for $C_7H_{15}SCl$: C 50.42; H 9.07; S 19.23).

N-(6-Methylthiohexyl)-phthalimide. A solution of 6-chlorohexyl methyl sulphide (30 g) and potassium phthalimide (36.5 g) in dimethylformamide (310 ml) was heated and stirred at 100° for 5 h. After cooling, ice water (300 ml) was added and the solution extracted thrice with 250 ml portions of ether. The combined ether extracts were washed with 0.5 N NaOH (300 ml), 0.5 N HCl (300 ml) and water (300 ml). On removal of the solvent from the dried extract a crystalline mass remained. Recrystallization from aqueous ethanol furnished essentially pure material (42 g, 84 %). An analytical specimen separated from pentane as colourless plates, m.p. 51° (Found: C 64.85; H 6.83; N 5.06. Calc. for $C_{15}H_{19}NO_2S$: C 64.95; H 6.90; N 5.05).

6-Methylthiohexylamine (XXI, n = 6). A solution of the phthalimide (39 g) in 96 % ethanol (250 ml) was refluxed for 1 h with 90 % hydrazine hydrate (7.8 g). After being digested with 7 N HCl (400 ml) for another hour the separated phthalhydrazide was removed by filtration. The filtrate was made alkaline with strong NaOH and the amine was extracted with ether (3 × 200 ml). The combined extracts were dried over solid KOH, the ether removed over a small column, and the 6-methylthiohexylamine distilled *in vacuo* care being taken to minimize its exposure to the atmosphere. The colourless amine was obtained in analytically pure form after one redistillation, b.p. 104—105°/10 mm, n_D^{25} 1.4814 (Found: C 56.85; H 11.58; N 9.40. Calc. for $C_7H_{17}NS$: C 57.08; H 11.64; N 9.51).

1,3-bis-(6-Methylthiohexyl)-thiourea. A solution of 6-methylthiohexyl *iso*thiocyanate, prepared according to the general directions given below, and 6-methylthiohexylamine (1.5 mole) in ether, deposited on standing the symmetric thiourea as crystalline material, which was recrystallized thrice from aqueous ethanol before analysis, m.p. 41° (Found: C 53.60; H 9.51; N 8.31. Calc. for $C_{15}H_{32}N_2S_3$: C 53.55; H 9.59; N 8.33).

Heptamethylene series

7-Methylthioheptanenitrile. The reaction between 6-chlorohexyl methyl sulphide (16 g) and NaCN (7 g) was performed in polyethylene glycol (35 ml), essentially following the directions given by Brändström for analogous reactions [22]. The reflux temperature gradually rose from 180° to about 210° within half an hour, when it remained constant, indicating that the reaction had gone to an end. The organic cyanide was removed in a vacuum and redistilled to furnish 9.5 g (68 %) of a product, b.p. 135—137°/10 mm, n_D^{25} 1.4755, which, according to analyses, may have contained traces of the solvent (Found: C 60.30; H 9.68; N 8.00. Calc for $C_8H_{15}NS$: C 61.09; H 9.61; N 8.91).

7-Methylthioheptylamine (XXI, n = 7). In a three-necked flask, equipped with a Hershberg-stirrer, reflux condenser, dropping funnel and nitrogen inlet, was placed a solution of $LiAlH_4$ (5.0 g) in anhydrous ether (100 ml). In nitrogen atmosphere, a solution of 7-methylthioheptanenitrile (9.8 g) in an equal volume of ether, was added at such a rate as to maintain a steady reflux. The reaction was completed by heating for an hour on the water bath. After cooling, water (6 ml) and 15 % NaOH (6 ml) were carefully added, the precipitate filtered off and thoroughly washed with liberal amounts of ether. The combined filtrates were dried over KOH pellets, the solvent removed over a small column, and the amine distilled. The colourless oil had b.p. 118°/10 mm, n_D^{25} 1.4799, (7.5 g, 75 %) (Found: C 59.30; H 12.12; N 8.68. Calc. for $C_8H_{19}NS$: C 59.59; H 11.88; N 8.69).

1,3-bis-(7-Methylthioheptyl)-thiourea. A pure specimen of this derivative, prepared exactly as described above for the lower homologue, was secured by repeated crystallizations from aqueous ethanol, m.p. 45° (Found: C 56.25; H 9.89; N 7.70. Calc. for $C_{17}H_{36}N_2S_3$: C 56.00; H 9.95; N 7.69).

Octamethylene series

8-Methylthiooctanol. This was prepared, essentially as described above for 6-methylthiohexanol, in 80 % yield from 8-chlorooctanol [23, 24] and sodium methyl mercaptide. The alcohol distilled as a colourless oil, b.p. 143—145°/10 mm, n_D^{25} 1.4788 (Found: C 61.30; H 11.26; S 17.85. Calc. for $C_9H_{20}OS$: C 61.33; H 11.44; S 18.19). Previously recorded [25]: b.p. 135—138°/10 mm.

8-Chlorooctyl methyl sulphide. 8-Methylthiooctanol was converted in 73 % yield into the chlorosulphide following the directions given above for the production of 6-chlorohexyl methyl sulphide. The colourless chloride distilled at 86°/0.2 mm, n_D^{25} 1.4783 (Found: C 55.50; H 9.83. Calc. for $C_9H_{19}ClS$: C 55.50; H 9.83). Ref.[25] reports: b.p. 113—116°/3 mm, n_D^{20} 1.4821.

N-(8-Methylthiooctyl)-phthalimide. This intermediate was prepared in 90 % yield from the chlorosulphide as described above for the analogous 6-methylthiohexyl-derivative. It separated from hexane in nacreous plates, m.p. 46° (Found: C 66.95; H 7.44; N 4.62. Calc. for $C_{17}H_{23}NO_2S$: C 66.86; H 7.59; N 4.59).

8-Methylthiooctylamine (XXI, n = 8). The amine resulted from hydrazinolysis of the phthalimide-derivative performed exactly as reported above for the hexamethylene compound. It distilled as a colourless oil, b.p. 133°/10 mm, n_D^{25} 1.4780 (Found: C 61.30; H 12.06; N 8.24. Calc. for $C_9H_{21}NS$: C 61.66; H 12.07; N 7.99).

1,3-bis-*(8-Methylthiooctyl)-thiourea.* This was prepared in the usual way and separated from aqueous ethanol in colourless needles, m.p. 52° (Found: C 58.30; H 10.21; N 7.06. Calc. for $C_{19}H_{40}N_2S_3$: C 58.10; H 10.27; N 7.14).

Nonamethylene series

9-Methylthiononanol. The preparation of a correctly analyzing specimen of this compound was performed from 9-chlorononanol [24] and methanethiol according to the established procedure [25], b.p. 161°/12 mm, m.p. 17°, n_D^{25} 1.4783. Yield: 82 %. Ref.[25] reports: b.p. 138—142°/9 mm, m.p. 22°.

9-Chlorononyl methyl sulphide. Upon reaction with thionyl chloride in the usual way, the foregoing alcohol furnished the chlorosulphide in satisfactory yield as a colourless liquid, b.p. 96°/0.1 mm, n_D^{25} 1.4775. Previously reported [25]: b.p. 118—124°/2 mm, n_D^{25} 1.4811.

N-(9-Methylthiononyl)-phthalimide. This resulted in almost quantitative yield from the usual reaction of the chlorosulphide with potassium phthalimide. An analytical specimen separated from dilute ethanol in colourless plates, m.p. 69° (Found: C 67.60; H 7.61; N 4.29. Calc. for $C_{18}H_{25}NO_2S$: C 67.69; H 7.89; N 4.39).

9-Methylthiononylamine (XXI, n = 9). Hydrazinolysis in the usual way afforded an 80 % yield of 9-methylthiononylamine from the phthalimide-derivative, b.p. 145°/11 mm. Because of the extreme readiness of the amine to take up carbon dioxide from the atmosphere, it was preferred to perform the analyses on the crystalline *N-(9-methylthiononyl)-benzamide,* produced under ordinary Schotten-Baumann conditions. It separated from dilute ethanol as colourless needles, m.p. 50° (Found: C. 69.20; H 9.12; N 4.70. Calc. for $C_{17}H_{27}NOS$: C 69.59; H 9.28; N 4.77).

1,3-bis-*(9-Methylthiononyl)-thiourea.* This derivative crystallized in colourless needles from dilute ethanol, m.p. 60° (Found: C 60.20; H 10.60; N 6.42. Calc. for $C_{21}H_{44}N_2S_3$: C 59.94; H 10.54; N 6.66).

1-Benzyl-3-(9-methylthiononyl)-urea (XXIII). An ethanolic solution of 1-benzyl-3-(9-methylthiononyl)-thiourea (*cf.* Table 3) (581 mg) was treated on the steam bath with another solution, containing silver nitrate (585 mg) in 50 % ethanol. Gradually, enough 1 N NaOH was added to keep the mixture at pH 7. After filtering off precipitated silver sulphide, water was added to the filtrate resulting in precipitation of the urea, which was collected and recrystallized twice from ethyl acetate (Found: C 66.95; H 9.47; N 8.53. Calc. for $C_{18}H_{30}N_2OS$: C 67.02; H 9.38; N 8.68). The colourless product had the m.p. 99.5°, alone or in admixture with a specimen obtained by step-wise degradation of the *Arabis* mustard oil derivative [16]. Coinciding infra-red spectra further served to establish the identity of the two specimens.

General synthetic methods

*iso*Thiocyanates $CH_3S(CH_2)_nNCS$ (n = 2—9). The following procedure was adopted as a standard method of converting the ω-methylthioalkyl amines into the corresponding mustard oils.

To a solution of thiocarbonyl chloride (0.02 mole) in chloroform (20 ml) was added the appropriate amine (0.02 mole) and 12 ml of a 5 % solution of sodium bicarbonate. An exothermic reaction set in upon mixing the components and the flask was thoroughly shaken until all thiophosgene had disappeared (about 10 min). The yellow chloroform layer was separated and the aqueous phase extracted with two additional portions of chloroform. After removal of the solvent, distillation *in vacuo* furnished the mustard oil as a colourless or slightly yellow liquid. In all preparations, considerable quantities of dark-brown by-products were formed, accounting for the fact that yields never exceeded 50 %. Most likely, however, runs on a larger scale would proceed in more satisfactory yields. The physical and analytical data of the individual *iso*thiocyanates are summarized in Table 1.

Thioureas. All mono-substituted thioureas (Table 2) were obtained in practically quantitative yields by keeping the *iso*thiocyanates overnight at room temperature in methanol, saturated with ammonia. The mostly oily products, remaining upon removal of the solvent, crystallized on chilling and scratching. The thioureas were recrystallized to constant melting points from aqueous ethanol, when not otherwise indicated. Their properties are presented in Table 2.

Similarly, reaction of the *iso*thiocyanates in anhydrous ether with 1.5 molecular proportion of benzylamine at room temperature furnished the benzylthioureas in high yields. Analytical specimens, produced by repeated recrystallizations from aqueous ethanol, possessed the properties recorded in Table 3.

The phenylthioureas, summarized in Table 4, were obtained by reaction of the ω-methylthioalkylamines (XXI) with slightly less than one equivalent of phenyl *iso*thiocyanate in ether solution at reflux temperature for 2 h. The mostly oily, crude products crystallized usually in contact with a few drops of dilute HCl. Some of the products, however, needed cooling to $-80°$ for crystallization to commence. Again, aqueous ethanol was the preferred solvent for recrystallization of the derivatives to constant melting points.

Paper chromatography. The mono-substituted thioureas (Table 2) could be chromatographed on paper according to our previously published method [33], yet modified to the descending technique. Using Whatman paper No. 1, and water-saturated chloroform as the mobile phase, the thioureas, containing 2, 3, 4, 5 and 6 methylene-groupings, could be clearly distinguished, possessing the R_{Ph}-values [33]: 0.58, 0.83, 0.99, 1.12 and 1.15, respectively. The higher members of the series travelled too near the solvent front to make a clean separation possible in this solvent system. It was found, however, that on paper chromatography with formamide as the stationary and chloroform as the mobile phase, a complete and satisfactory separation of even the long-chain thioureas was easily achieved.

Microanalyses were performed in this laboratory by Mr. P. Hansen. The work is part of investigations supported by *Statens Almindelige Videnskabsfond (The Danish State Research Foundation)* and *Carlsbergfondet (The Carlsberg Foundation)*. A special grant from *Kai Hansen's Fond* is gratefully acknowledged.

Studies on the Stability of Aluminium Chelates of Catecholdisulphonic Acid in Aqueous Solutions

REINO NÄSÄNEN

Institute of Chemistry, University of Helsinki, Finland

The complex formation between the aluminium ion and catecholdisulphonic acid (H_4A) has been investigated. The stability constant of AlA^- was determined. The effect of some added electrolytes on the stabilities of AlA^- and AlA_2^{5-} has been studied. The effects of potassium chloride and nitrate on the stability of AlA_2^{5-} were nearly equal. The effects of sodium perchlorate, chloride and nitrate were mutually nearly equal but differed considerably from the effect of potassium salts. The effect of one pentavalent ion (AlA_2^{5-}) appeared to be nearly equal to that of five monovalent ions.

In a recent paper from this laboratory [1], it was concluded that the types of the complexes formed between the aluminium ion and catecholdisulphonic acid (H_4A) are AlA^-, AlA_2^{5-} and AlA_3^{9-}. At that time the equilibrium

$$Al^{3+} + H_2A^{2-} = AlA^- + 2H^+ \quad (1)$$

was not investigated in detail. Data concerning equilibrium (1) are now presented.

The previous potentiometric method was used and the equilibrium constant

$$K_I = [AlA^-][H^+]^2 / [Al^{3+}][H_2A^{2-}] \quad (2)$$

was calculated from the equations

$$[H_2A^{2-}] = (c - 0.5c_B - 0.5[H^+]) / (1 + 0.5K_3 / [H^+])] \quad (3)$$

$$c' = c - [H_2A^{2-}](1 + K_3 / [H^+]) \quad (4)$$

$$x = [H_2A^{2-}] / [H^+]^2 \quad (5)$$

$$K_I = c' / x(c_{Al} - c') \quad (6)$$

where c, c_B and c_{Al} are the total molar concentrations of tiron, sodium hydroxide and aluminium perchlorate, respectively.

1.333	0.077	2.63	3.999	1.333	0.172	2.84				

In Table 1 the results of some titrations for the determination of the constant K_I are presented. The ionic strength is calculated from $I = \frac{1}{2}\Sigma z_i^2 c_i$. The constant K_I is seen to vary in a way to be expected from the Debye-Hückel equation, which in this case has the form

$$pK_I = pK_I^\circ + \frac{5.09\sqrt{I}}{1 + a\sqrt{I}} - BI. \qquad (7)$$

The results do not suggest the formation of the complex AlHA, a type which is found among the Fe(III) complexes of tiron [2]. The effect of addition of potassium chloride on the constant K_I was also investigated and the results are presented in Table 2. These results can be represented satisfactorily by the equation

$$pK_I = 2.32 + \frac{5.09\sqrt{I}}{1 + 2.35\sqrt{I}} + 0.06I \qquad (8)$$

On comparing the values in Tables 1 and 2, one sees they differ at higher ionic strengths, as would be expected from the differences in ionic medium.

The equilibrium constant of the reaction

$$AlA^- + H_2A^{2-} = AlA_2^{5-} + 2H^+ \qquad (9)$$

defined by

$$K_{II} = [AlA_2^{5-}][H^+]^2 / [AlA^-][H_2A^{2-}] \qquad (10)$$

has been determined previously by Näsänen and Veivo [1]. They became aware that the points of both the second and the third buffer ranges of the titration curve give almost constant values for K_{II} and K_{III}, respectively,

55.6	3.55	1.78	4.522	0.580	0.421	6.68

although the increase in the concentrations of the ions AlA_2^{5-} and AlA_3^{9-} during the titrations causes a considerable change in ionic strength as calculated from $I = \frac{1}{2}\Sigma z_i^2 \cdot c_i$. More complete measurements have since been carried out by the present author in the case of AlA_2^{5-}. In Table 3 some titrations with the ratio $c / c_{Al} = 3$ but with different total concentrations are recorded. The results are in agreement with Brönsted's theory of specific ionic interaction [3] in the sense that one pentavalent negative ion has nearly the same effect on K_{II} as five univalent negative ions. The quantity $\frac{1}{2}\Sigma z_i c_i$ also varies during the titration but much less than $\frac{1}{2}\Sigma z_i^2 \cdot c_i$ and obviously the variation of K_{II} with $\frac{1}{2}\Sigma z_i c_i$ is of the same order of magnitude as the accuracy reached in the case in question.

The specific ionic interaction in the case of equilibrium (9) was further investigated by means of some neutral salts. These results are presented in Table 4. From this table and from Fig. 1 one can see that sodium chloride, nitrate and perchlorate have a nearly equal effect. The effects of potassium chloride and nitrate are also mutually nearly equal but differ considerably from the effect of sodium salts. Thus these results are also in accordance with the theory of specific ionic interaction.

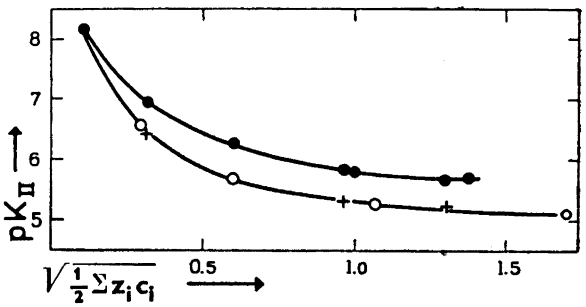

Fig. 1. The effect of some salts on the constant K_{II}. ● NaCl, $NaNO_3$, $NaClO_4$. ○ KCl, +KNO_3.

Besides concentrations of negative ions, eqn. (10) also contains the concentration of hydrogen ion. The change in the activity coefficient of hydrogen ion with ionic medium is small compared with the respective changes of the activity coefficients of the high valent ions and obviously does not much influence the results.

For the calculation of the stability constants

$$k_\nu = [AlA_\nu^{(4\nu-3)-}] / [Al^{3+}][A^{4-}]^\nu, \qquad (11)$$

the ionisation constants

$$K_3 = [H^+]\,[HA^{3-}] / [H_2A^{2-}] \text{ and } K_4 = [H^+]\,[A^{4-}] / [HA^{3-}] \qquad (12)$$

Table 5. Some values of the stability constants of aluminium chelates of catecholdisulphonic acid in potassium chloride solutions at 25°C.

$\sqrt{\frac{1}{2}\Sigma z_i c_i}$	$\log k_1$	$\log k_2$
0.1	16.6	30.0
1.0	14.9	28.4
2.0	14.6	28.1

are needed. One obtains

$$k_1 = K_I/K_3K_4\,; \quad k_2 = K_IK_{II}/K_3^2K_4^2 \text{ and } k_3 = K_IK_{II}K_{III}/K_3^3K_4^3 \quad (13)$$

The third and fourth ionisation constants have been determined recently by the present author [4]. The values of k_1 and k_2 at various ionic strength in potassium chloride solutions are given in Table 5.

1 : 1 Complexes of Acid Chromate Ion with Alcohols or Acetaldehyde

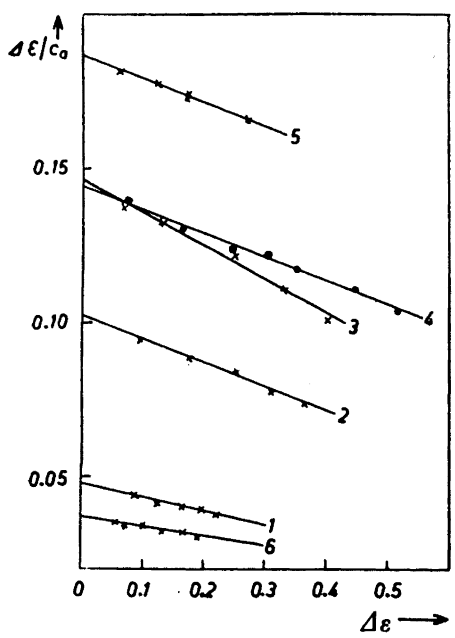
ULRIK KLÄNING

Laboratoriet for Fotokemi, Fotografi og Reproduktionsteknik, Polyteknisk Læreanstalt, Copenhagen, Denmark

Evidence for 1:1 complexes of acid chromate ion with some aliphatic alcohols or acetaldehyde is presented. The stability constants and spectra have been measured, and the heat of formation of one of the complexes (the 2-propanol complex) has been determined. In view of these complexes, the light sensitiveness of the acid chromate-alcohol solutions will be discussed.

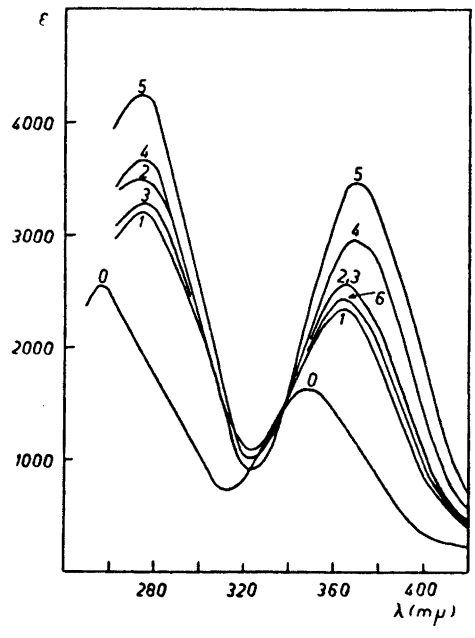
Westheimer *et al.* [1-3] have investigated the kinetics of the oxidation of 2-propanol to acetone by acid chromate ions in aqueous solution, and have shown that the primary step in the reaction is the formation of a complex (an ester)

$$CH_3CHOHCH_3 + HCrO_4^- + H^+ = H_2CrO_4 \cdot CH_3CHOHCH_3$$



Edwards has postulated the existence of a similar complex [4].

At low acidities, 10^{-2} M to 10^{-3} M, and temperatures below 40°C, the above mentioned oxidation is extremely slow. Under these conditions the present author has found evidence for an equilibrium of the type:



$$X + HCrO_4^- = X \cdot HCrO_4^-$$

where X stands for an alcohol or acetaldehyde. In more acid solutions these complexes (probably esters) may react with a proton to form unstable complexes (esters) similar to those proposed by Westheimer.

Measurements were made of the difference in extinction $\Delta\varepsilon$ of two solutions, both containing 10^{-4} M acid chromate and 10^{-3} M perchloric acid, one of them, furthermore, an alcohol or acetaldehyde. Under these conditions less than 1 % of the acid chromate is present as dichromate. For constant alcohol concentration $\Delta\varepsilon$ was measured at wavelengths between 260 mμ and 420 mμ; at 375 mμ $\Delta\varepsilon$ was measured at various concentrations of alcohol or acetaldehyde.

Figur 1. $\Delta\varepsilon/c_a$ *versus* $\Delta\varepsilon$ for acid chromate solutions containing 1) methanol, 2) ethanol, 3) *n*-propanol, 4) 2-propanol, 5) 2-butanol and 6) acetaldehyde.

Figur 2. The absorption spectrum of the acid chromate ion 0), and the absorption spectra of the complexes of acid chromate with 1) methanol, 2) ethanol, 3) *n*-propanol, 4) 2-propanol, 5) 2-butanol and 6) acetaldehyde.

The following relation was established, indicating the existence of a 1:1 complex:

$$\frac{\Delta\varepsilon}{c_a} = K \cdot \Delta\varepsilon_{K1} \cdot l \cdot c_0 - K \cdot \Delta\varepsilon$$

where K is the stability constant, l the length of the optical path in cm, c_a the concentration of alcohol or acetaldehyde, c_0 the concentration of acid chromate, and $\Delta\varepsilon_{K1}$ the difference between the extinction coefficient of the complex and that of the acid chromate ion at 375 mμ.

From the straight line representing $\Delta\varepsilon/c_a$ as a function of $\Delta\varepsilon$, K and $\Delta\varepsilon_{K1}$ were calculated for methanol, ethanol, *n*-propanol, 2-propanol, 2-butanol and acetaldehyde (Fig. 1). The stability constants in litre · mole^{-1} at 25°C were, for methanol 0.043, ethanol 0.077, *n*-propanol 0.109, 2-propanol 0.078, 2-butanol 0.082 and for acetaldehyde 0.034. The spectra were obtained from measurements of $\Delta\varepsilon$ at varying wavelengths, knowing the absorption spectrum of the acid chromate ion [5]. The spectra of the complexes are shown in Fig. 2.

The equilibrium constant for 2-propanol was measured also at 11°C, 0.0884, and at 35°C, 0.0746, giving a value for the heat of formation of $-\Delta H$ = 1.31 kcal/mole.

Furthermore it was found that $\Delta\varepsilon$ is independent of the concentration of perchloric acid in the interval 2×10^{-4} — 0.2 M, indicating that the complexes, like the acid chromate ion, are weak both as acids and as bases. At the highest acidities the oxidation is rather fast, $\Delta\varepsilon$ therefore was found by extrapolating log ε to zero time, assuming a first order reaction rate.

Westheimer [1] has found that the dichromate ion is inactive in the above mentioned oxidation. In agreement with this, measurements of the extinction per cm, ε, at 366 mμ of solutions containing dichromate and 2-propanol indicated that the interaction between 2-propanol and dichromate ions is weak. In these experiments the concentration of 2-propanol was 3 M, the ionic strength was 10^{-2} and the total chromium concentration c_0 was varied between 5×10^{-4} M and 1.5×10^{-3} M. Assuming that the dichromate ion does not form a complex with 2-propanol, we may write for the extinction ε:

$$\varepsilon = \varepsilon_1 \cdot c_0 + 2c_2\Delta\varepsilon_{21} + c_K\Delta\varepsilon_{K1}$$

where ε_1 is the extinction coefficient of acid chromate and $\Delta\varepsilon_{21}$ the difference between the extinction coefficient of dichromate and that of acid chromate. c_2 and c_K are concentrations of dichromate and of the complex, respectively. c_K is given by:

$$2c_K^2K_2 + c_K(K \cdot c_a + K^2c_a^2) - K^2c_a^2c_0 = 0$$

c_2 is given by

$$4K_2c_2^2 - (1 + 4K_2(c_0 - c_K))c_2 + (c_0 - c_K)^2K_2 = 0$$

where K_2 is the constant for the equilibrium between acid chromate and dichromate. From these equations ε has been calculated. For $\Delta\varepsilon_{K1}$ and K the values at $c_0 = 10^{-4}$ M have been used. $\Delta\varepsilon_{21}$ is known [6], 873 litre·mole^{-2} cm^{-2}. K_2 has been determined by Tong and King [7], $K_2 = 45$ litre·mole^{-1}. Table 1 shows the calculated and the measured values of ε at various concentration c_0.

Table 1. 25.0°C

c_0 mole/litre	ε measured	ε calculated
1.5×10^{-3}	2.445	2.462
1.0×10^{-3}	1.632	1.623
7.5×10^{-4}	1.210	1.215
5.0×10^{-4}	0.805	0.807

We introduce the coefficient $\gamma_0 = \dfrac{c_a \cdot K \cdot \varepsilon_K}{c_a \cdot K \cdot \varepsilon_K + \varepsilon_1}$, where ε_K is the extinction coefficient of a complex. γ_0 is that fraction of the absorbed photons, which are absorbed by the complexes. At small values for c_a, γ_0 becomes $\dfrac{c_a \cdot K \cdot \varepsilon_K}{\varepsilon_1}$

In Table 2 the γ_0/c_a values at 366 mμ are given for the 5 alcohols and acetaldehyde. The quantum yields for the photochemically induced oxidation of some of the above mentioned alcohols and acetaldehyde by acid chromate at 366 mμ have been determined by Bowen and Chatwin [8]. Their values for the quantum yields

Table 2. 25.0°C

Complex	γ_0/c_a	γ/c_a
Acetaldehyde-	0.065	0.0396
Methanol-	0.079	0.0130
Ethanol-	0.155	0.0416
n-Propanol-	0.217	0.0470
2-Propanol-	0.179	0.0470
n-Butanol-	—	0.081
2-Butanol-	0.220	—
*Iso*butanol-	—	0.0775

in dilute solutions divided by the alcohol or acetaldehyde concentrations, γ/c_a, are also given in Table 2. We note that γ_0/c_a varies parallel to γ/c_a (except for acetaldehyde), suggesting that it is the complexes, which are photochemically active.

EXPERIMENTAL

Acetaldehyde was distilled just before use. The alcohols were purified by distillation. The normal alcohols were distilled over NaOH and $Pb(CH_3COO)_2$ to remove aldehydes. The solutions were made with redistilled water.

The extinction measurements were made with a Beckman DU spectrophotometer. The temperature was held within 0.2°C by circulating thermostated water through the Beckman Thermospacer.

Fractionation of Casein by Distribution in a Liquid Two-Phase System

NILS ELLFOLK

Laboratory of Valio, Biochemical Institute, Helsinki, Finland

The distribution of casein between a two-phase system of collidine, ethanol, and water has been studied. α-Casein was found to distribute in favour of the water-rich phase and β- and γ-casein in favour of the collidine-rich. Electrophoretically pure α-casein was prepared by extracting a neutralized casein solution with the collidine-rich phase of the collidine-ethanol-water system.

Until recently it has generally been assumed that casein is a pure protein, although there was some evidence to the contrary. Linderstrøm-Lang [1] first demonstrated that casein was a mixture of several distinct proteins. Later on Mellander [2] showed that casein is composed of at least three components which he denoted α-, β-, and γ-casein in order of decreasing mobility.

It was apparent from previous attempts to fractionate casein that the separation of the different electrophoretic components would be difficult. Warner [3] devised the first chemical method for the separation of α- and β-casein, a repeated isoelectric precipitation at low temperature. This technique was further developed by Cherbuliez and Baudet [4]. Hipp *et al.*[5] separated the different electrophoretic fractions of casein by precipitation from 50 % alcohol by means of variations in temperature, pH, and ionic strength. Another method, developed by the same authors, was based on the solubility of the different casein components in aqueous urea. Walter [6] succeeded in fractionating α- and β-casein between a liquid two-phase system containing phenol. This system was found to be highly specific to casein.

Fractionation of casein by means of distribution in a two-phase system containing collidine is studied in the present paper.

METHODS

Description of the three-component system of collidine-ethanol-water (C-E-W). A three-component system is usually described in a triangular diagram. The composition of any ternary system can be represented by a point in the diagram, when the side of the equi-

lateral triangle is taken as unity and the amounts of the three components are expressed as fractions of the whole. The corners of the triangle represent the pure component. The distance from one point to any side, measured parallel to either of the others, gives the proportion of the component occupying the opposite corner. Any point within the triangle represents three components, but a point situated on one of the sides indicates two components only.

To determine the diagram, 10 g of collidine were titrated in an Erlenmayer flask with distilled water under thorough mixing to a permanent turbidity showing the presence of two phases. 1 ml of ethanol (96 %) was then added, and the titration was again carried out with water to slight turbidity. By repeating this procedure the ascending part of the curve could be constructed to its vertex. The descending part of the curve was determined in a similar way by titrating 10 g of distilled water with collidine and adding ethanol after the endpoint of the titration was shown by a slight turbidity. Any point outside the constructed curve represents one liquid layer only. Inside the curve two liquid layers are in equilibrium, the components being given by the appropriate points on the curve. One known concentration term allows the position of one layer to be fixed on the constructed curve and defines the system completely. In order to determine the composition of the layers an analysis of collidine was made.

Determination of collidine. Collidine was determined on the basis of the absorption at 280 mμ, using a Beckman spectrophotometer. For the analysis the samples were diluted with distilled water. The amount of collidine was read from a curve constructed by diluting a known amount of collidine with distilled water.

Electrophoresis. Moving boundary electrophoresis was carried out with a Klett electrophoresis apparatus. The optical system was that of Philpot-Svensson. In the runs a 15 ml analytical cell was used. All samples were diluted with veronal buffer of pH 8.6 and of ionic strength 0.12 and dialyzed against 2 l of the same buffer for a week. In all experiments so much buffer was added to the samples as to make the total protein concentration 1.0 %. The runs were carried out with a potential gradient of 9 volt/cm at 4°C.

Since the area enclosed by the electrophoresis curve of the gradient and the basis line is proportional to the concentration of the gradient, the relative amounts of the different protein components can be determined by calculating their corresponding areas. This was done by enlarging the films on millimeter paper and drawing the diagrams on the paper. From the drawings the areas were easily determined by means of a planimeter.

Determination of the pH. The pH of the solutions was measured with a glass electrode (Beckman).

RESULTS AND DISCUSSION

Preliminary experiments were carried out with the phase-pair collidine-water. When casein solutions of different concentrations, neutralized to a pH of about 7, were mixed with an equal volume of collidine, stable milk-white emulsions were formed. It is well known that proteins act as emulsifying agents. In order to prevent the formation of these emulsions, some lower alcohols were tested as de-emulsifying agents. Methanol as well as ethanol were found to have strong de-emulsifying effects. A diagram of the three-component system C-E-W can be seen in Fig. 1. The phases obtained at both temperatures are extremely temperature-labile. A mere warming with the hand caused turbidity. In the following experiments the two-phase system was obtained by mixing the three components at 20°C in the following proportion: 30 ml of collidine, 16.5 ml of ethanol, and 60 ml of distilled water. The pH of the mixture was 9.5. The pH value as measured with a glass electrode is not exact beacuse of the high content of organic solvents.

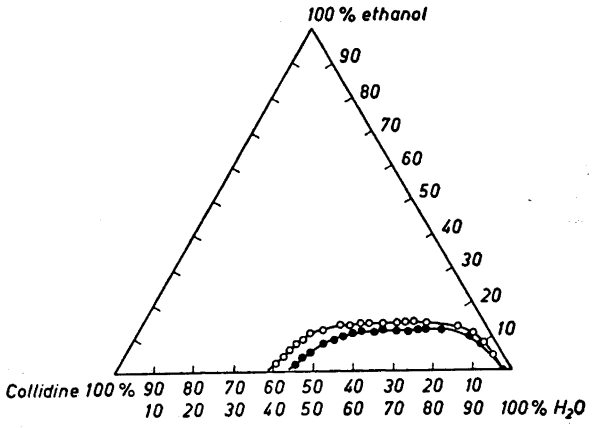

Fig. 1. Phase diagrams of the C-E-W system at 15°C (●) and at 20°C (○).

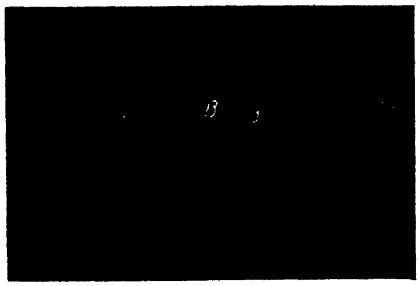
When the bottom and the top phase had separated completely, their composition was determined and found to be as follows:



Collidine phase (top phase)	Water phase (bottom phase)
41.9 % collidine	13.7 % collidine
46.1 % water	72.3 % water
12.0 % ethanol	14.0 % ethanol

It can be seen from Fig. 1 that these points are situated in the homogenous part of the diagram when the temperature is 15°C.

Acid Hammarsten's casein (Merck) was found to be easily soluble in the top phase without any neutralizing. When in a two-phase system in equilibrium different columes of the top phase were replaced by the corresponding volume of the top phase containing casein, and the two phases were mixed, no separation in two phases occurred, but the solution was completely clear and homogeneous. When, however, the casein in the top phase was neutralized with NaOH, dissolved in the top phase, a separation again occurred. It is evident that casein neutralized by collidine functioned as a homogenizing agent in the liquid two-phase system. In order to avoid this, the casein solutions in the following experiments were neutralized to a slight alkalinity.

Fractionation of casein in the C-E-W system. 1 g of Hammarsten's casein (Merck) was dissolved in water by neutralizing it to pH 8.7 and made up to 60 ml. 30 ml of collidine and 16.5 ml of ethanol were added to this solution, well mixed and kept at room temperature (20°C) until both phases had separated completely. Samples of the two phases were taken and evaporated to dryness *in vacuo*, the temperature of the bath not rising over 45°C. Both these dried fractions were dissolved in veronal buffer, dialyzed against the same buffer and analyzed by electrophoresis. The diagrams of the ascending limbs of the different preparations can be seen in Figs. 2—4.

Fig. 2. Electrophoresis diagram of Hammarsten's casein.

Fig. 3. Electrophoresis diagram of casein isolated from the collidine-rich phase after distribution in the C-E-W system.

Fig. 4. Electrophoresis diagram of casein isolated from the water-rich phase after distribution in the C-E-W system. (Ascending boundaries, pH 8.6, $\mu = 0.12$, $F = 9$ Volt/cm, $t = 90-120$ min, α, β, and γ denote the different casein fractions and B the buffer peak.)

It is apparent from these diagrams that α-, β-, and γ-casein vary considerably, and that a distinct enrichment of the β-component occurs in the collidine phase after only one distribution. By quantitative evaluation of the electrophoretic diagrams the following values were obtained for α-, β-, and γ-casein (Table 1). The diagrams of the ascending limbs were used in the calculations, because it was found that the ascending limbs showed values for β-casein more closely to the real value of 25 % than those of the descending limbs. Nitschmann and Zürcher [7] have shown that the concentration of β-casein, shown in electrophoresis diagrams of descending limbs, decreases, continuously with increasing casein concentration, a fact which is due to a formation of a reversible complex or association between α- and β-casein. At infinite dilution the complex was found to be completely dissociated, the amount of

Fraction	Relative amount present in %		
	α-	β-	γ-casein
Hammarsten's casein	76	22	2
Collidine phase	46	37	17
Water phase	91.5	8.5	—

Table 2. Concentrations and distribution constants of α- and β-casein in the C-E-W system at 20°C.

Fraction	Collidine phase c_{coll} %	Water phase c_w. %	Distribution factor $K = c_w/c_{coll}$
α-Casein	0.294	1.35	$K_\alpha = 4.6$
β-Casein	0.236	0.117	$K_\beta = 0.5$

β-casein being 25 %, whereas in a 1 % casein solution the amount of β-casein was 18 % and in a 2 % solution only 14 %.

In order to evaluate the distribution constants of α- and β-casein, the protein concentrations of the two phases were determined on a dry weight basis. It was found that the protein concentration of the collidine-rich phase was 0.64 % and that of the water-rich phase 1.48 %. Compared with the amount of casein added, the sum of the protein concentrations in the two phases was a little too high, but, owing to the semiquantitative nature of the calculation, it was assumed to be satisfactory. The α- and β-casein concentrations of the two phases, calculated from the electrophoretic diagrams, and the distribution constants of the two casein fractions in the C-E-W system can be seen in Table 2. The distribution coefficient of α-casein is high compared with that of β-casein. The separation factor, β, defined as the ratio of the partition coefficients, was found to be:

$$\beta = K\beta/K_\alpha = 9.2$$

Preparation of electrophoretically pure α-casein. On the basis of the above findings electrophoretically pure α-casein was prepared in the following way: 1 g of casein was dissolved in 60 ml as earlier, and the same amounts of collidine and ethanol were added, mixed and kept at room temperature until both phases separated completely, after which the top phase was carefully removed. The remaining bottom phase was now treated three times with fresh top phase (50 ml each time), the top phase being removed after each treatment. At the end of the experiment the bottom phase was evaporated to dryness

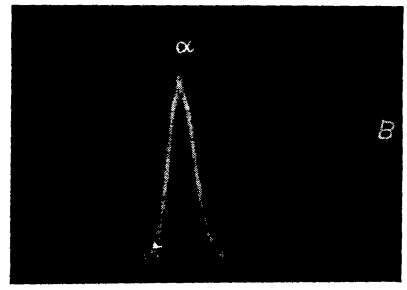

Fig. 5. Electrophoresis diagram of the bottom fraction from a four step distribution of casein in the C-E-W system at 20°C. (Conditions as in Figs. 2—4).

in vacuo, dissolved in veronal buffer as earlier and analyzed by electrophoresis in the usual way. The diagrams of the ascending and descending limbs can be seen in Fig. 5. Since both boundaries are completely symmetric it is assumed that the concentration of β-casein is very low. It is, however, to be assumed that the tendency for complex formation between α- and β-casein is greater at a low β-casein concentration when the concentration of α-casein is high.

I am deeply indebted to Professor Eero Uroma, head of the State Serum Institute, for his kindness in letting me use the electrophoresis equipment of his institute, and to Mr. Antti Louhivuori, M.A., for valuable advice.

Electroorganic Preparations

IV. Oxidation of Aromatic Hydrocarbons

HENNING LUND

Leo Pharmaceutical Products, Copenhagen, Denmark

It is shown that aromatic hydrocarbons can be oxidized at a platinum electrode in acetonitrile containing sodium perchlorate. The half-wave potentials of the voltammetric curves are found to be directly related to the wave numbers of the *p*-bands in the ultraviolet absorption spectra of the hydrocarbons. The reaction product of the controlled potential oxidation of anthracene in acetonitrile containing pyridine and sodium perchlorate is shown to be 9,10-dihydroanthraquinyldipyridinium diperchlorate.

Electrolytic oxidation of aromatic hydrocarbons [1] yields mostly a mixture of hydroquinones, quinones, and acids, when the current density is used as the controlling factor. No controlled potential oxidations of aromatic hydrocarbons have been reported.

In the second part of this series [2] it was shown that some aromatic alcohols by controlled potential oxidation in acetonitrile containing sodium perchlorate and pyridine could be oxidized to the aldehydes and it was postulated that the first step of the oxidation in this inert medium was a loss of electrons from the aromatic sytem.

This investigation is concerned with the controlled potential oxidation of some aromatic hydrocarbons and their derivatives. The technique used to determine the optimal potential for the oxidation is the same as that used in Part II [2]. The current-potential curve of the compound in acetonitrile is determined with a platinum microelectrode and the oxidation is performed at a potential about 0.15 V more positive than the half-wave potential of the compound in the medium used.

VOLTAMMETRIC INVESTIGATION

In Table 1 are compiled the results of the voltammetric investigation. In column 1 are given the compounds, in column 2 the wave numbers of the first *p*-band in their ultraviolet spectrum as defined by Clar [3]. The wave numbers were obtained from Clar [3]. Most of the spectra have been

* The spectrum measured in benzene solution.

measured in alcohol, but those marked with an asterisk were measured in benzene. The wave numbers used in Fig. 1 were, for comparative purposes, corrected to ethanol by the relationship: ν (ethanol)= ν (benzene) + 300 cm^{-1}, which is characteristic of *p*-bands. In column 3 are compiled the anodic half-wave potentials corrected for iR-drop in the solution measured against the 0.1 N silver ion/silver electrode, and in column 4 the shape of the voltammetric curve.

As the half-wave potentials of the compounds depend upon the surface of the microelectrode and the reaction products often alter the surface slightly

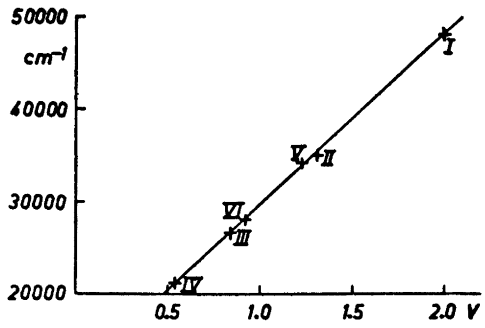

Fig. 1. The anodic half-wave potentials of some acenes and phenes plotted against the wave number of the first *p*-band in their ultraviolet absorption spectrum in alcohol. Benzene (I), naphthalene (II), anthracene (III), tetracene (IV), phenanthrene (V), 1,2-benzanthracene (VI).

the half-wave potentials are only reproducible within about 0.03 V although a standard procedure of wiping off the electrode before the measurement was used.

DISCUSSION

The cathodic half-wave potentials at the dropping mercury electrode of aromatic hydrocarbons [4-8] have been related to wave-mechanical calculations [5,8] and to absorption spectra [4,6,7]. It has been shown [6] that in a series of related hydrocarbons the half-wave potentials are proportional to the wave number of the first *p*-band as defined by Clar [3] in the ultraviolet absorption spectrum of the hydrocarbon following the equation $E_{\frac{1}{2}} = a + b\,\nu$, where a and b are constants and ν the wave number of the first *p*-band. When the wave numbers are replaced by the corresponding energies in electron volts, the slope ($\Delta E_\nu / \Delta E_{\frac{1}{2}}$) has been predicted [4] to be two.

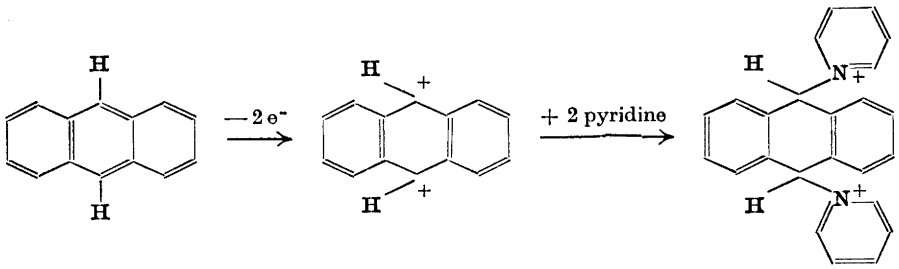
As shown in Fig. 1 a similar relation is found between the wave number of the first *p*-band and the anodic half-wave potential at a platinum microelectrode, $E_{\frac{1}{2}} = 0.543 \times 10^{-4}\nu - 0.61$, and it seems reasonable to expect that there in a series of related hydrocarbons would be a relation between the energy required to exite an electron corresponding to a defined band in the spectrum and the energy necessary to remove an electron completely from the aromatic system.

It was attempted to correlate the anodic half-wave potentials of a series of acenes with their *para*-localization energy as computed by Brown [9], but only a semi-quantitative accordance was found.

When the resonance system of a benzene ring in a polynuclear aromatic hydrocarbon loses two electrons the system acts as if the loss is restricted to a single benzene ring and the remaining separated resonance systems are apparently only affected to a minor degree. Thus tetracene yields a second wave at about the same potential as does 5,12-dihydrotetracene and both potentials are of the value which would be expected for a 2,3-dialkyl naphthalene.

The qualitative influence of a substituent on the half-wave potential can be predicted from its electron-attracting or electron-releasing properties as long as the steric circumstances permit the expected interaction between the substituent and the nucleus. An electron-releasing group as the methoxy

group or the amino group lowers the half-wave potential whereas an electron-attracting group as the nitro group or the quaternary ammonium group raises the half-wave potential in comparison with the unsubstituted hydrocarbon. A qualitative connection between the influence of a substituent on the half-wave potential and its σ-value as defined by Hammett was found, but no quantitative connection was detected.



In an attempt to find the reason why some compounds yield deformed waves whereas other produce normal waves it is interesting to note the difference between indene and fluorene as indene yields a normal wave whereas fluorene produces a pronounced deformed wave. As will be shown in the preparative oxidation, anthracene yields in the presence of pyridine a product which is a derivative of dihydroanthracene. Assuming a similar reaction path in the oxidation of indene and fluorene the analogous oxidation product of indene would be a derivative of indane and would very likely be a stable compound, whereas a derivative of dihydrofluorene would be expected to be very unstable and to polymerize to a more or less defined product, in agreement with the fact that the reaction product covers the electrode with a black, insoluble layer which insulates the electrode from the solution.

The same considerations can be applied to other compounds giving deformed waves as benzene, diphenyl, fluoranthene and benzpyrene. In all cases the dihydro derivatives are unstable compounds. Naphthalene gives a slightly deformed wave and correspondingly dihydronaphthalene is only moderately stable.

The hydrocarbons which give a Diels-Alder adduct produce normal waves and there is a qualitative connection between the rate of formation of such adducts and the anodic half-wave potentials in such a way that the hydrocarbons having the lowest half-wave potential react most readily with maleic anhydride [9]. The presence of methyl substituents in the meso positions of anthracene lowers the half-wave potential and increases the rate of the addition of maleic anhydride whereas it decreases the percentage adduct in the equilibrium mixture of anthracene derivative and maleic anhydride [10].

As may be expected, there is a qualitative connection between the anodic half-wave potentials of the acenes and the tendency to form photo oxides. The influence of substituents is mostly the same in both cases, meso methyl groups greatly facilitate the photochemical addition of oxygen and lowers the half-wave potential. 9,9'-Bianthryl, however, forms no photo oxide, whereas it is oxidized at the anode. The half-wave potential is not, however, as low as might be expected from the analogy between benzene-diphenyl and anthracene-9, 9'-bianthryl substantiating the assumption that the plane of one of the anthracene molecules forms an angle of nearly 90° with the plane of the other anthracene molecule in 9,9'-bianthryl [11].

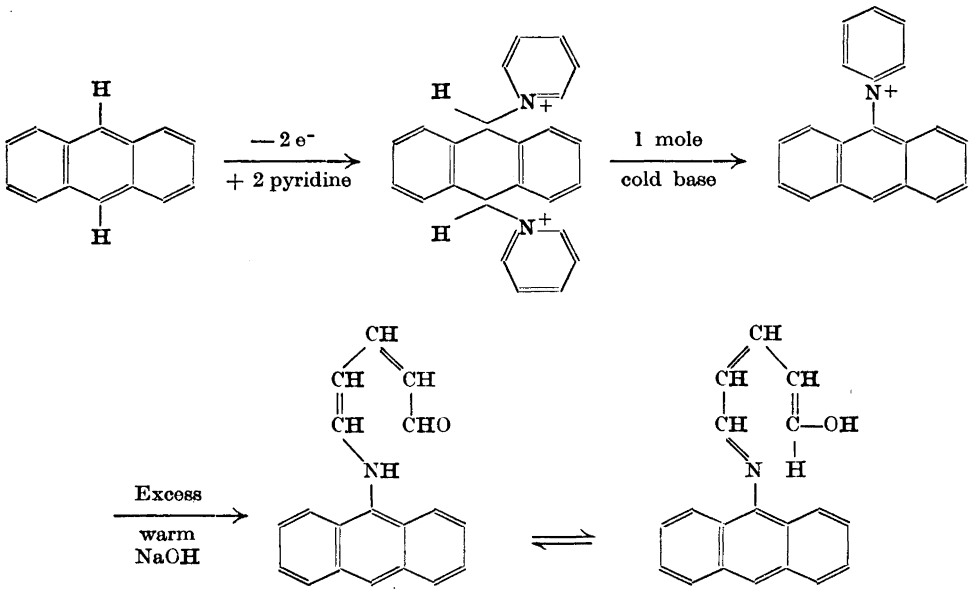
The first step in the oxidation is probably a localization of two π-electrons either at the same carbon atom or at two carbon atoms due to the attraction of the positive electrode. In either case they are extracted from the aromatic resonance system leaving a divalent carbonium ion. In the case of anthracene the electron deficiency is localized most of the time in the 9 and 10 positions. In presence of an electron donor as pyridine the pyridine donates its unpaired electrons to the carbonium ion thus forming a pyridinium ion:

The compound thus formed contains only isolated benzene rings which further are somewhat deactivated by the presence of the pyridinium groups and the compound is therefore not further attacked anodically at the potential used for the oxidation of anthracene. If the oxidation had consisted of a dimerization to 9,9'-bianthryl a further oxidation of the reaction product would be expected.

The addition of anhydrous perchloric acid in acetonitrile does not change the anodic half-wave potentials of the hydrocarbons, whereas the presence of pyridine lowers the half-wave potentials from 0.05—0.1 V. This can be explained by assuming the electron transfer to be a reversible reaction. In the presence of pyridine the concentration of the carbonium ion would be very much lower than in the absence of an electron donor, and the measured half-wave potential is, therefore, lowered. As hydrogen ions are not involved in the oxidation the addition of hydrogen ions is of no effect.

In view of the fact that the anodic half-wave potentials of the aromatic carbinols mostly differ only about 0.1 V from the half-wave potentials of their parent compounds (α-naphthyl carbinol 1.25 V, naphthalene 1.31 V; anisyl alcohol 1.22 V. anisol 1.35 V; cinnamyl alcohol 1.36 V, methyl styrene 1.47 V) it seems likely to assume that the first step in this case also is a loss of two electrons from the resonance system as postulated in Part II [2].

PREPARATIVE OXIDATION



The controlled potential oxidations were performed in anhydrous acetonitrile or acetone containing sodium perchlorate and pyridine. It was found that the oxidation of anthracene at an anode potential of + 0.95 V *vs* the 0.1 N silver ion/ silver electrode yielded a watersoluble ionic compound which was identified as 9,10-dihydroanthranyldipyridinium diperchlorate by analysis of the diperchlorate, the diiodide and the dipicrate, m.p. 169.5°—171° (168.5°—170°, Barnett and Cook [12]) and by its infrared and ultraviolet spectrum. The ultraviolet spectrum showed only a very slight absorption at wave lengths above 280 mμ indicating that the compound did not contain the anthracene resonance system.

The 9,10-dihydroanthranyldipyridinium diperchlorate was also formed by addition of sodium perchlorate to an aqueous solution of the dibromide prepared according to Barnett and Cook [12], and the compounds were found to be identical.

As 9,10-dihydroanthracene is not planar three isomers (two *cis* and one *trans* isomer) of the 9,10-dihydroanthranyldipyridinium diperchlorate are theoretically possible, but only one has been isolated. The configuration of the isolated isomer is not known.

As described for the dibromide [12] the diperchlorate yielded on addition of a little less than 1 equiv. cold base or contact with an ion exchange resin IRC-50 9-anthrylpyridinum perchlorate. This conversion could be detected simply on heating the diperchlorate with water and it also proceeded to a certain degree during the electrolytic oxidation in the presence of the excess of pyridine giving the reaction mixture a yellow colour.

Barnett and Cook [12] treated 9,10-dihydroanthranyldipyridinium dibromide with excess of warm sodium hydroxide and isolated in a yield of 3.5 % a chocolate-brown compound to which they suggested the formula $C_{14}H_9$-NH-CH=CH-CH=CH-CH=O. The 9,10-dihydroanthranyldipyridinium diperchlorate was treated with excess of warm sodium hydroxide and there was isolated in a yield of 55 % a chocolate-brown compound with an analysis close to that found by Barnett and Cook. The infrared spectrum of the compound (in chloroform solution) showed a band at 1 648 cm^{-1}. As 2,4-hexadienal [13] shows a band (in chloroform solution) at 1 642 cm^{-1} the infrared spectrum of the compound supports the proposed formula containing a dienal. The band did not, however, possess the intensity to be expected of a dienal, but this can be explained by a strong enolisation. By enolisation the unsaturation of the side chain comes into conjugation with the anthracene resonance system. A high degree of enolisation is also suggested by the strong dark-red colour of the solution in chloroform, as a solution of the pure dienal would be expected to give a faint, yellow solution.

The oxidation of 9,10-dibromoanthracene in the presence of pyridine followed the same reaction path as the oxidation of anthracene, but only (9-bromo-10-anthranyl)pyridinium perchlorate was isolated probably due to instability of the analogous product 9,10-dibromo-9,10-dihydroanthranyldipyridinium diperchlorate. In this connection it is interesting to note that the half-wave potential of the second wave of 9-bromoanthracene (1.48 V) and that of 9,10-dibromoanthracene (1.47 V) is close to the half-wave potential of (9-bromo-10-anthryl)pyridinium perchlorate (1.47 V).

EXPERIMENTAL

The apparatus used for the voltammetric investigation and the preparative oxidations was the same as described in Part I[14], II[2], and III[15].

The acetonitrile, sodium perchlorate and silver perchlorate were purified in the same manner as described in Part II[2]. The acetone was Riedel-de-Haën analytical grade.

The following compounds were prepared according to the given references: anthracene [16], 9,9'-bianthryl [17], 9-nitroanthracene [18], 9-bromoanthracene [19], 9,10-dibromoanthracene [20], and 9,10-dimethylanthracene [21].

The other compounds investigated were commercially available or were obtained from Dr. L. F. Fieser, Dr. Hakon Lund or Mr. F. Lund. The author wishes to acknowledge with thanks the receipt of these hydrocarbon samples.

Oxidation of anthracene. In 150 ml of a deaerated solution of 15 g anhydrous sodium perchlorate and 4 ml pyridine in acetonitrile was suspended 1.00 g of anthracene, and the anthracene was oxidized at an anode potential of +0.90 – +0.95 V *vs* the 0.1 N silver ion/silver electrode. The anolyte was stirred with a magnetic stirrer and purified nitrogen was bubbled through the solution during the oxidation. As the oxidation proceeded the anthracene gradually dissolved. The amount of electricity required for the oxidation corresponded to a two-electron oxidation. After completion of the reaction the acetonitrile was evaporated *in vacuo* at temperatures not exceeding 30°. To the dry residue were added 40 ml of water, the precipitate was filtered off and washed with small portions of cold water. After drying the precipitate was dissolved in acetonitrile and precipitated with dry ether. One further recrystallization from acetonitrile/ether yielded a white compound (1.35 g). The compound turns yellow at about 170° and decomposes at about 215°. (Found: C 53.71; H 3.70; N 5.17; Cl 13.30. Calc. for $C_{24}H_{20}O_8N_2Cl_2$: C 53.72; H 3.76; N 5.24; Cl 13.41.) The compound had an absorption maximum at 251 mμ and showed only a very faint absorption at wave lengths above 280 mμ. Its infrared spectrum contained no carbonyl absorption. The compound was readily soluble in acetonitrile and acetone, soluble in 50 % aqueous alcohol, but less soluble in absolute alcohol and water and insoluble in benzene and ether. The compound formed a picrate, m. p. 169.5–171°. (Found: C 54.47; H 2.94; N 14.03. Calc. for $C_{36}H_{24}O_{14}N_8$: C 54.55; H 3.05; N 14.14). By adding an excess of sodium iodide in acetone to a solution of the compound in acetone an iodide was obtained, m. p. 143° (decomp.). (Found: C 49.17; H 3.27; N 4.80; I 43.19. Calc. for $C_{24}H_{20}N_2I_2$: C 48.86; H 3.41; N 4.75; I 42.98). The compound was identified as 9,10-dihydroanthranyldipyridinium diperchlorate.

Analogous to the preparation of 9-anthrylpyridinium bromide [12] the 9-anthrylpyridinium perchlorate was obtained by adding a little less than one equivalent of sodium hydroxide to a 50 % aqueous alcoholic solution of the diperchlorate and evaporating part of the solvent after the reaction was completed. M. p. 269–272°. (Found: C 64.28; H 4.14; N 3.90; Cl 10.03. Calc. for $C_{19}H_{14}O_4NCl$: C 64.13; H 3.97; N 3.94; N 9.97). On addition of excess of sodium iodide in acetone to a solution of the compound in acetone the iodide was obtained, m. p. 260–64°. (Found: C 59.67; H 3.83; N 3.44; I 33.25. Calc. for $C_{19}H_{14}NI$: C 59.55; H 3.68; N 3.65; I 33.12). The 9-anthrylpyridinium perchlorate had maxima (in alcohol) at 389, 369, and 352 mμ.

Treatment of 9,10-dihydroanthranyldipyridinium diperchlorate with excess of sodium hydroxide. To 1.0 g of the diperchlorate were added 50 ml 1 N sodium hydroxide and 50 ml chloroform. The mixture was refluxed for 1 h and cooled. The dark-purple chloroform layer was separated from the aqueous layer, to which were added 25 ml 1 N sodium

hydroxide and 50 ml chloroform. The mixture was again refluxed for 1 h, cooled and the layers were separated. The pooled chloroform layers were washed with water and most of the chloroform evaporated *in vacuo*. On addition of ether a chocolate-brown compound was obtained, 290 mg (55 %). (Found: C 80.85; H 5.30; N 4.88. Calc. for $C_{19}H_{15}ON$, $\frac{1}{2}H_2O$: C 80.83; H 5.71; N 4.96). The infrared spectrum of the compound showed a relatively weak carbonyl band at 1 648 cm^{-1} (in chloroform solution).

Oxidation of 9,10-dibromoanthracene. A suspension of 2.0 g 9,10-dibromoanthracene in 150 ml of a solution of 15 g sodium perchlorate and 4 ml pyridine in acetone was oxidized at an anode potential of +1.2 V *vs* the 0.1 N silver ion/silver electrode in acetone. The oxidation was not run to completion, but was stopped after a consumption of electricity of 910 coulomb (80 % of the theoretical amount). The current was rather low as it was governed by the rate of dissolving the 9,10-dibromoanthracene. The undissolved, unreacted dibromoanthracene was filtered off, part of the solvent was evaporated *in vacuo* and the residue diluted with water. The precipitate was filtered off, dried and extracted in a Soxhlet extractor with carbon tetrachloride, which dissolved unreacted dibromoanthracene. The residue, 1.3 g, was dissolved in hot acetone. On addition of carbon tetrachloride a precipitate, 0.95 g, was obtained. M. p. 270–272°. (Found: C 52.18; H 3.05; N 3.24; Br 18.75; Cl 8.51. Calc. for $C_{19}H_{13}O_4NBrCl$: C 52.50; H 3.02; N 3.22; Br 18.38; Cl 8.16). The compound formed a picrate, m. p. 237–240°. (Found: C 52.90; H 2.53; N 9.93; Br 14.18. Calc. for $C_{25}H_{15}O_7N_4Br$: C 53.35; H 2.68; N 9.94; Br 14.17). The compound showed maxima (in 50 % aqueous ethanol) at 399, 378 and 359 mμ. The compound was identified as (9-bromo-10-anthryl)pyridinium perchlorate.

Oxidation of naphthalene. 1.0 g of naphthalene was dissolved in 150 ml of a solution of 15 g sodium perchlorate and 4 ml pyridine in acetonitrile. The naphthalene was oxidized at an anode potential of +1.4 V *vs* the 0.1 N silver ion/silver electrode. The current decreased rapidly from 0.2 A to about 5 mA. No visible layer covered the electrode, but after the electrode had been wiped off the current again started at about 0.2 A. The current decreased, however, rapidly to a negligible value. The amount of electricity consumed was less than 5 % of the theoretical amount and no oxidation products could be isolated from the reaction mixture.

The Magnetic Properties of Manganous Complexes

Studies in Magnetochemistry 18 *

R. W. ASMUSSEN and H. SOLING

The Chemical Laboratory B, Technical University of Denmark, Copenhagen, Denmark

The effective magnetic moments at room temperature of representative manganous complexes are reported. The temperature dependence of the susceptibility in the interval 85—295°K is studied for Mn(II)-bis-salicylaldehyde, Mn(II)-bis-salicylaldehyde-ethylenediimine and Mn(II)-bis-salicylaldehyde-*o*-phenylenediimine. Preparative details are given for these chelates. The magnetic moments found are compared with the predictions of the valence bond theory and the ligand field theory. A qualitative explanation of the apparent non-existence of planar manganous complexes with magnetic moment 3.87 μ_B is suggested. A slight discontinuity in the χ^{-1}, T-diagram of Mn(II)-bis-salicylaldehyde-ethylenediimine is reported. The reflection spectrum of the pink $Mnpy_2Cl_2$ is interpreted as originating in a halogenbridged polymeric structure. Evidences for the non-existence of Reitzenstein's brown "isomer" $Mnpy_2Cl_2$ are given.

The ground level of the $3d^5$ electron system of the free Mn^{+2} ion is ^6S. Assuming ideal Russell-Saunders coupling the magnetic moment of the free manganous ion is 5.92 μ_B. When the manganous ion is the central-ion in complexes more or less pronounced deviations from the ideal free ion value of the magnetic moment may be expected according to the type of bond and the spatial arrangement of the ligands. The valence bond theory thus predicts three different magnetic moments, *viz.* 5.92 μ_B, 3.87 μ_B, and 1.73 μ_B. In the two last mentioned cases, with reduced spin multiplicity, the bonding electrons are supposed to utilize the planar dsp^2-hybrid and the octahedral d^2sp^3-hybrid, respectively.

The magnetic moments actually found in manganous complexes are almost invariably about 5.9 μ_B corresponding to the sextet ground level. A slightly higher value, 6.2 μ_B is reported by Wiley, Tyson, and Stellar [1] in the case of the manganous-kojate. However, only the manganous hexacyanides exemplify the case of the lowest spin multiplicity, while no certain instances of compounds with a quartet ground level are reported. As an illustration of the

* No. 17 of this series is published in *Acta Chem. Scand.* 11 (1957) 1271.

Table 1. Effective magnetic moments in Bohr magnetons of complex manganous compounds.

	Temp. °C	μ_{eff}/μ_B
$MnSO_4$	19	5.85
$[Mn(OH_2)_4]SO_4$	19	5.96
$[Mn(C_2O_4)_2](NH_4)_2$, $2H_2O$	17	5.84
$Mnpy_2Cl_2$ I brown	17	5.67
$Mnpy_2Cl_2$ II pink	18	5.89
$Mnpy_2Cl_2$ III pink	18	5.96
$Mnpy_2Br_2$	18	5.96
$Mnpy_6Br_2$	18	6.00
$[Mn(SCN)_6]K_4$, $3H_2O$	18	6.06
$[Mn(CN)_6]K_4$, $3H_2O$	17	2.13

experimental results some manganous complexes earlier prepared and measured magnetically by one of us [2] are stated in Table 1.

The magnetic results mentioned in Table 1 are equally well described by the theory of crystalline field potential (v. Vleck and his school [3]). According to this theory the electric field from the ligands causes a sort of intramolecular Stark splitting of the energy levels of the central ion. In case of the manganous ion the Stark splitting leaves a sextet level lowest in octahedral and tetrahedral ligand fields of weak and intermediate strength, while at strong ligand fields a doublet becomes the ground level, and a reduction of the magnetic moment occurs as observed for $K_4Mn(CN)_6$.

The value of the magnetic moment of $K_4Mn(CN)_6$ stated in Table 1 is somewhat higher than the "spin only" value 1.73 μ_B of one unpaired electron. It is rather difficult to prepare this substance of a sufficient purity as the presence of even minute amounts of other manganese compounds may increase the susceptibility considerably. The rather large range of moments quoted in the literature reflects this. However, it is interesting that the deviation from the value 1.73 μ_B may also be explained theoretically. A quantum mechanical calculation by Kotani [4], taking into account the spin-orbit interaction, leads to an effective magnetic moment of about 2.5 μ_B at room temperature. According to Kotani's calculations the effective magnetic moment decreases slowly when the temperature is lowered and converges against the "spin only" value when the temperature approaches the absolute zero. A study of the temperature dependence of the susceptibility of this and a few other manganous-cyano-complexes is being carried out in this laboratory at present.

Particular interest is connected to the measurements of the three preparates $Mnpy_2Cl_2$ I, II and III. Reitzenstein [5] prepared a pink compound of this composition and furthermore a brown substance of apparently the same composition, which have been considered as *cis-trans* isomers. The magnetic moment of the brown preparation I is lesser than the moment of the pink preparation III, which may be due to the presence of higher oxidation states of manganese. This assumption is supported by the fact that preparation I becomes darker brown when exposed to the air for some time. After recrystalli-

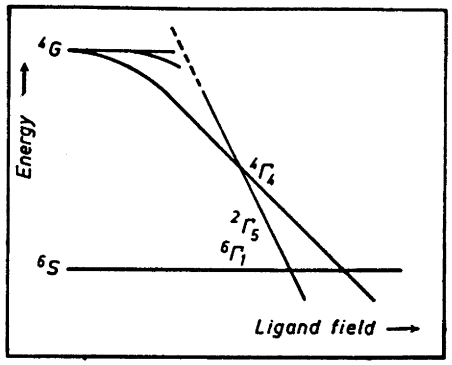

Fig. 1. Theoretical Orgel diagram for octahedral manganous complexes. (For explanation of terms see Ref. 7).

zation of I from ethanol the pink preparation II was obtained having nearly the theoretical value 5.92 μ_B for the magnetic moment (compare also the results of the Cl-determinations in the three cases). The brown "isomer" is probably not a chemically pure substance. Neither the directions given by Reitzenstein nor systematic variations of the experimental conditions yielded well defined products. In one of the more or less brownish powders now obtained, the presence of higher oxidation states of manganese could be demonstrated. X-Ray powder photograms (19 cm Bradley camera) supplied by P. F. Andersen M.sc. of this laboratory prove that all the lines in the powder-photogram of the pink compound appear in the powder photos of the brownish products with identical Bragg-angles and intensities. The powder photos of the brown products contain besides these lines a few foreign lines. In our opinion the only existing compound of the composition $Mnpy_2Cl_2$ is the pink crystalline com-

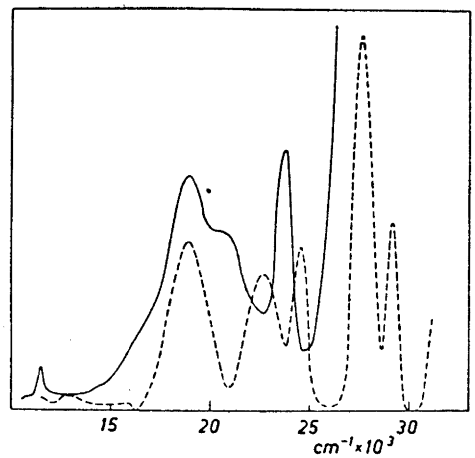

Fig. 2. Reflectionspectra of $MnCl_2 \cdot 4\,H_2O$ (punctuated) and $Mnpy_2Cl_2$ (full drawn) measured with a Beckman spectrophotometer model DU. Ordinate in arbitrary units. Abscissae frequencies in Kayser-units = cm^{-1}.

pound with the magnetic moment 5.96 μ_B which moment, according to the valence bond theory, excludes a planar configuration.

Concerning the non-existence of planar manganous complexes with magnetic moment 3.87 μ_B Dr. Klixbüll Jørgensen has kindly pointed out to us that referring to the energy level diagram in Fig. 1 the following arguments might be given, (for further details and explanation of the terms used compare for instance Ref.[7]).

In octahedral complexes the $^2\Gamma_5$-level crosses the $^6\Gamma_1$-level at a smaller ligand field strength than is the case with $^4\Gamma_4$. When the octahedron of 6 ligands are tetragonally deformed the quartet and the doublet levels are further split, but in view of the relative slopes of the $^2\Gamma_5$ and $^4\Gamma_4$-lines it seems rather improbable that this splitting should cause an interchange of the sequence of the crossing points with the $^6\Gamma_1$-level. Thus one may conclude that provided the intramolecular Stark-pattern caused by four co-planar ligands is comparable with that caused by a tetragonally deformed octahedral arrangement of 6 ligands, the existence of planar manganous-complexes with the magnetic moment 3.87 μ_B seems energetically less probable.

In the particular case of $Mnpy_2Cl_2$ the results of the magnetic measurements are in conformity with the formula

$$[Mnpy_4][MnCl_4]$$

and with a halogenbridged chain-like structure as well. In view of the reflection spectrum discussed below we prefer the latter possibility.

The reflection spectra of $Mnpy_2Cl_2$ and of $MnCl_2,4H_2O$ are shown in Fig. 2. Following the arguments of Orgel [6] the bands of the latter are identified as follows (frequencies in Kayser units = cm^{-1}).

18 800 $^4\Gamma_4$ (G)	22 700 $^4\Gamma_5$ (G)	24 600 $^4\Gamma_1$ (G) and $^4\Gamma_3$ (G)
27 600 $^4\Gamma_5$ (D)	29 200 $^4\Gamma_3$ (D)	

By analogy the spectrum of $Mnpy_2Cl_2$ is interpreted in the following way: The narrow band at 23 800 K is due to the transition $^6\Gamma_1$ (S)$\rightarrow$$^4\Gamma_1$ (G) and $^4\Gamma_3$ (G). The red shift of this band gives evidence for an increased anionic character of the complex [7]. The broad band in the region 15 000 K to 23 000 K shows two maxima and a shoulder towards the red. The maximum with the highest wavenumber, being due to the transition $^6\Gamma_1$ (S)$\rightarrow$$^4\Gamma_5$ (G), is also shifted towards the red. This red shift is at least partly a consequence of the former, but an increased ligand field strength probably also contributes. The last maximum together with the shoulder is believed to originate in a tetragonal splitting of the $^4\Gamma_4$ (G) level. This interpretation suggests that $Mnpy_2Cl_2$ has a halogen-bridged polymeric structure *i.e.* octahedra sharing 2 Cl^- and with 2 pyridine molecules in *trans* position analogous to that found by X-ray analysis of the violet $Copy_2Cl_2$[8].

From the magnetochemistry of nickel(II)-complexes several planar, diamagnetic chelates with tetradentate Shiff-base ligands of the type salicylaldehyde-ethylenediimine are well known. In the light of the above discussion it was therefore considered worth while to study the magnetic behaviour of similar manganous compounds. We have prepared and studied the magnetic properties of manganous-bis-salicylaldehyde-ethylenediimine and manganous-

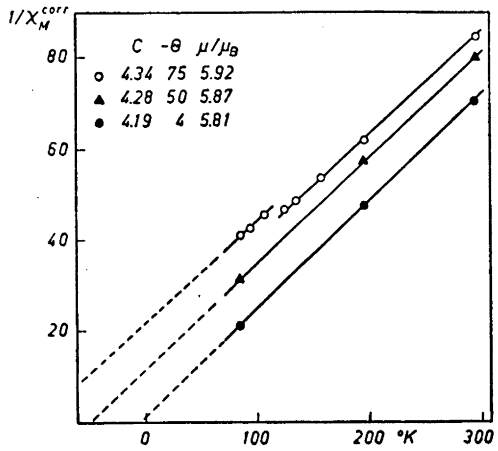

Fig. 3. Reciprocal corr. molar susceptibility of manganous-bis-salicylaldehyde ▲, manganous-bis-salicylaldehyde-ethylenediimine O, and manganous-bis-salicylaldehyde-o-phenylenediimine ● plotted against the abs. temperature.

bis-salicylaldehyde-*o*-phenylene-diimine and for comparison also manganous-bis-salicylaldehyde, although this latter compound could not be obtained in a quite satisfactory purity.

Fig. 3 illustrates the results of the magnetic measurements over a range of temperatures. The reciprocal molar susceptibility corrected for the diamagnetism of the ligands and the diamagnetism of the electron system of the manganous ion is plotted against the absolute temperature. The straight lines, representing the Curie-Weiss relation, are fixed by means of a least square analysis of the data. In the figure is also stated the values of the Curie constant C, the Weiss-correction Θ and the mean magnetic moment calculated from the formula $\mu = 2.84 \sqrt{\chi_M^{cor}(T-\Theta)}\mu_B$. The magnetic moments are only a little smaller than the "spin only" value of five unpaired electrons, thus indicating a sextet ground level clearly.

It is noteworthy that while the Weiss correction for the salicylaldehyde-*o*-phenylenediimine-compound is only $-4°$, this constant has a considerably higher value for the salicylaldehyde- and the salicylaldehyde-ethylenediimine-compounds *viz.* $-50°$ and $-75°$, respectively. Since a residual orbital contribution and anisotropy effects are not expected for manganous compounds the Θ-values may be ascribed to exchange interactions. It is in accordance with this point of view that the presumably most diluted *o*-phenylene-diimine-compound has the smallest Θ-value.

In the temperature range 85—107°K the susceptibilities of the salicylaldehyde-ethylenediimine-complex are from 8 to 10 % lower than calculated from the Curie-Weiss line based upon the susceptibilities measured between 125 and 295°K. A rough estimate of the values gives the relation $\chi_M^{cor} = \frac{4.48}{T+99}$

for $85 < T < 107$°K. In this temperature interval obviously a change in the crystals occurs, which increases the exchange forces (Θ). A decrease in the atomic distances explains this effect; however, since no X-ray information is available this question cannot be settled for the present.

EXPERIMENTAL

Preparation and analysis of the compounds

The materials used for the preparation of the compounds were the tetrahydrates of manganous chloride and manganous sulphate, anhydrous manganous bromide prepared from the oxide and hydrogen bromide, potassium cyanide, potassium thiocyanate and furthermore pyridine, salicylaldehyde, ethylenediamine and *o*-phenylenediamine. The potassium cyanide was the purest product available. The other substances were c.p. chemicals. The Schiff-bases prepared from salicylaldehyde and the amines were recrystallized from 96 % ethanol.

Manganese was determined as manganous sulphate or potentiometrically according to *Lingane* and *Karplus* [9] after destruction of the complexes and chelates with concentrated sulphuric acid to which was added a small amount of concentrated nitric acid. Chloride was determined argentometrically after Volhard.

Anhydrous manganous sulphate was obtained by dehydration of the tetrahydrate (constant weight).

Manganous sulphate tetrahydrate. Some of the most well developed and apparently not dehydrated crystals were selected for the magnetic measurement. The evidence for the composition of this salt is of course not entirely satisfactory. A slight deviation in the water content has, however, no significant influence upon the value of $\mu_{eff.}$

Ammonium manganous dioxalate dihydrate. This compound was prepared after the method of Sonchay and Lenssen [10]. No higher hydrates were isolated. (Found: Mn 18.30, Calc.: Mn 18.13).

Potassium manganous thiocyanate trihydrate. The method used to prepare the complex is essentially that of Walden [11]. Only red crystals were used for the analysis and the magnetic measurement. Brownish crystals were discarded. (Found: Mn 9.04. Calc. Mn 8.95).

Potassium manganous hexa-cyanide trihydrate. The procedure given by Christensen [12] was followed. (Found: Mn 13.14. Calc.: Mn 13.04).

Dipyridinomanganous chloride. Preparation No. I, brown powder, was obtained as described in the paper of Reitzenstein [5]. (No. I. Found: Cl. 24.65. Calc. Cl 24.98). The preparation of this brown substance was carried out with success only once.

A portion of No. I was recrystallized from ethanol. The pink crystals were washed with ether and dried in vacuum; thus we obtained preparate No. II, the composition of which also is $Mnpy_2Cl_2$. (No. II. Found: Cl 24.61. Calc. Cl 24.98).

The third specimen, preparation No. III, was produced by addition of pyridine to a solution of manganous chloride in ethanol. Further treatment as in the case of No. II. (No. III. Found: Cl 24.88. Calc. Cl 24.98).

It seems to be a mere accident if Reitzenstein's "kaffeebraune" compound is precipitated. If the aqueous solution of manganous chloride is saturated with oxygen, one obtains a substance of a light brown colour. In other experiments oxygen was continuously passed through the solution during the preparation. In these cases deeper brown solids were precipitated. Specimens selected for analysis gave 24.26 % Cl and 24.87 % Cl. However, the substance was not homogeneous. The total yield was ground in a mortar and the content of Cl was now 26.85 % and 26.95 %. In another series of experiments the ratio of the concentration of manganous chloride to pyridine was varied from 1 : 4 to 1:20. The colour of the precipitates became deeper brown when decreasing this ratio. One of the deepest brown products gave evolution of chlorine when boiled with hydrochloric acid (potassium iodide paper).

These evidences, the X-ray results above mentioned, and the magnetic measurements on preparations I, II, and III discussed above indicate that the existence of a well defined brown or darkbrown compound of the composition $Mnpy_2Cl_2$ is doubtful. The reason for

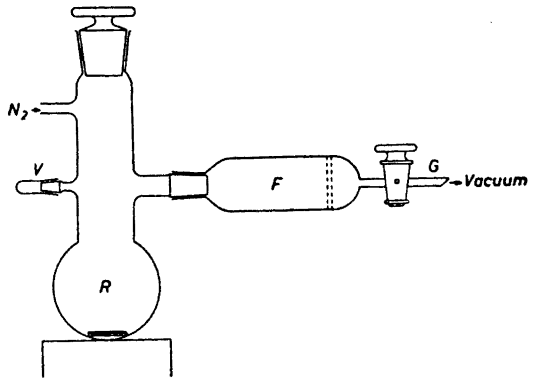

Fig. 4. Apparatus for preparation of manganous-bis-salicylaldehyde.

the brown colour may be that the pink compound is contaminated with a manganese compound in which the oxidation state of manganese is higher than 2. In our opinion the pink, crystalline substance above described as II or III is the only existing defined compound of the composition $Mnpy_2Cl_2$.

Dipyridinomanganous bromide. This complex was prepared following the method of Grossmann [13]. (Found: Mn 14.89. Calc. Mn 14.73).

Hexapyridinomanganous bromide. Crystals of this compound were obtained by cooling a boiling solution of anhydrous manganous bromide in pyridine (Grossmann [13]). The substance gives off pyridine easily at room temperature. (Found: Mn 7.87. Calc. Mn 7.97).

Manganous-bis-salicylaldehyde. Emmert, Gsottschneider and Stanger [14] prepared a hydrate containing $1\frac{1}{2}$ H_2O from manganous chloride and salicylaldehyde in aqueous ammonia (Found for C and H respectively, 51.84 % and 4.01 % calc 51.83 % and 3.81 %, respectively). Ray and Mukherjee [15] in a similar way prepared a dihydrate (Found: Mn 16.68. Calc. Mn 16.51). Our preparation was carried out as follows: The apparatus shown in Fig. 4 was evacuated and a current of nitrogen passed through. This operation was repeated several times. The following reagents were introduced into the reaction bulb *R* while a continuous stream of nitrogen was passed through: 1.0 g $MnCl_2 \cdot 4H_2O$ was dissolved in 40 ml 50 % aqueous acetone (oxygen-free), 1.5 ml salicylaldehyde was added and furthermore drop by drop 10 ml water-acetone mixture +5 ml conc. ammonia while stirring the mixture.

The apparatus was closed and the reaction mixture vigorously stirred for half an hour (magnetic stirrer). The liquid and the strawcoloured crystals were transferred to the filterbulb *F*. The crystals were filtered off by suction through *G* and washed with aqueous acetone and next with acetone, which was introduced through *V* by means of a long funnel. The washing operation was carried out in an atmosphere of nitrogen.

The apparatus was again closed and the precipitate was dried by pumping through *G* for some hours. The substance was finally dried in a high vacuum over P_2O_5 at 110 – 120°C until the weight was constant. The dry compound does not become darker when exposed to the atmosphere. Seven different preparates were produced. (No. 1: Mn 19.42. No. 2: Mn 19.47; No. 3: Mn 19.15. Calc. Mn 18.49).

These particular 3 compounds were applied for the magnetic measurement in spite of their manganese content being too high. The magnetic moments of these substances are practically identical and equal to 5.87 μ_B and the Curie-Weiss line is nearly *parallel* to that of manganous-bis-salicylaldehyde-*o*-phenylenediimine. The surplus of manganese does not increase the magnetic moment more than 1 % of the theoretical value for ionic- or sp^3-bonds (5.92 μ_B). The main point is that the presence of the impurity does not make our statement concerning the non-planar configuration doubtful.

Manganous-bis-salicylaldehyde-ethylenediimine. 750 ml redistilled ethanol was placed in a 1 000 ml round-bottomed flask fitted with a mechanical stirrer and a fractionating column with condenser. A current of nitrogen was passed through the system and 100 ml ethanol was distilled over. Together with 3.0 g $MnCl_2 \cdot 4H_2O$ this distillate was returned to the remanens. 100 ml ethanol were again distilled off and returned to the flask together with 4.0 g salicylaldehyde-ethylenediimine. 100 ml ethanol was distilled over and 0.9 g solid NaOH was added to the reaction mixture. The column was adjusted so that the destillation was now very slow. Red crystals separated after 45 min, and after 4—5 h 2—3 g of red crystals were formed, which were filtered off (glassfilter-crucible) and washed with ethanol, acetone, and ether. These operations were all carried out in an atmosphere of nitrogen. Sometimes the red crystals were contaminated with a yellow precipitate, which was easily eliminated by washing with 0.04 M acetic acid.

Three independent specimens were prepared for the magnetic measurement. (No. 1: Mn 17.14; No. 2: Mn 17.19; No. 3: Mn 17.03. Calc. Mn 17.10).

Manganous-bis-salicylaldehyde-o-phenylenediimine. This substance was obtained by a method similar to the preceding. The reaction-mixture turned strongly red after half an hour. After one hour the precipitate was so dense that the preparation had to be interrupted. A dark yellow spongy mass of 1 cm long crystals was obtained.

Two independent preparates were produced for the magnetic measurement. (No. 1: Mn 14.80; No. 2: Mn 15.02. Calc. Mn 14.88).

In a previous publication by Asmussen [2] it was pointed out that it is very difficult to prepare manganous chelates by means of Schiff-bases as chelating agents in so well defined composition that a magnetic measurement has any sense. The preparation methods here described seem to give compounds for which the magnetic susceptibilities are sufficiently reproducible. However, it must be admitted that we have not succeeded in preparing the analoguous chelates with bis-salicylaldehyde-putrescine and bis-salicylaldehyde-cadaverine. Manganous-bis-salicylaldehyde could not be prepared following the method described above for manganous-bis-salicylaldehyde-ethylenediimine.

Magnetic measurements

The determination of the magnetic susceptibilities were carried out by the Gouy-method as described by Asmussen and Soling [16]. The susceptibilities were measured at room temperature, then at 195°K and at 85°K and finally for control again at room temperature. Manganous-bis-salicylaldehyde-ethylenediimine No. 3 was measured at 5 temperatures between 85°K and 195°K. These temperatures were realized by means of a brass block which fitted in the Dewar vessel. The amounts of liquid air were so adjusted that the different temperatures were fixed within 5° intervals. At all temperatures except room temperature the measurements were performed 20—30 min after the specimen tube had been suspended in the cooling system. The measurement was repeated after 20—30 min. In some cases a third measurement was performed after another 20—30 min interval. The agreement between the results was in general excellent. The temperature dependence of the susceptibility for the preparate mentioned is illustrated by the data given in Table 2.

Table 2. Temperature dependence of χ_M (corr) and μ_{eff} for manganous-bis-salicylaldehyde-ethylenediimine No. 3.

°K	$\chi_M^{cor} \times 10^6$	μ_{eff}/μ_B	°K	$\chi_M^{cor} \times 10^6$	μ_{eff}/μ_B
290	11 965	5.29	125	21 374	4.64
195	16 157	5.04	107	21 949	4.35
157	18 634	4.88	94	23 488	4.22
135	20 529	4.73	85	24 416	4.09

Table 3. Susceptibilities and μ_{eff} values for the 3 different manganous-bis-salicylaldehyde-ethylenediimine preparates.

Preparation number	°K	$\chi_g \times 10^6$	$\chi_M \times 10^6$	$\chi_M^{cor} \times 10^6$	$1{:}\chi_M^{cor}$	μ_{eff}/μ_B
1	291	36.11	11 600	11 760	85.03	5.25
2	294	36.10	11 596	11 756	85.06	5.28
3	294	36.20	11 629	11 789	84.82	5.29
1	195	49.58	15 927	16 087	62.15	5.03
2	195	49.63	15 943	16 103	62.11	5.03
3	195	49.96	16 047	16 207	61.69	5.05

The values for χ_M^{corr} are calculated from χ_M by means of the corrections for the diamagnetism of the ligands and the diamagnetism of the electron system of the Mn^{+2} ion. The values used for these corrections are -122×10^{-6} and -160×10^{-6} and -175×10^{-6} for the bis-salicylaldehyde, the bis-salicylaldehyde-ethylenediimine and the bis-salicylaldehyde-*o*-phenylenediimine chelates, respectively. These corrections were calculated from Pascal's constants and the experimental value $\chi_M = -64.4 \times 10^{-6}$ for salicylaldehyde measured by Rumpf and Leguin [17]. The diamagnetism of the Mn^{+2} ion was calculated [2] to $-21 \cdot 10^{-6}$.

The results of the measurements are shown in Fig. 3. We point out that the "points" in the diagram at each temperature are mean values of all measurements on different preparations of the compound in question. The data in Table 3 give an impression of the reproducibility of the measurements of the 3 different preparates of manganous-bis-salicylaldehyde-ethylenediimine.

The field strength dependence was investigated at room temperature. The susceptibilities of all compounds were field strength independent in the interval 700 to 8 000 Ørsted.

Dialkoxy-phosphorylthiocholines, Alkoxy-methyl-phosphorylthiocholines and Analogous Choline Esters.

Syntheses, pK_a of Tertiary Homologues and Cholinesterase Inhibition

L-E. TAMMELIN

Research Institute of National Defence Dept. 1, Sundbyberg 4, Sweden

The syntheses of S,ω-dimethylaminoethyl-dialkylthiophosphate, ω-dimethylaminoeththio-alkoxy-methyl-phosphine oxide and their corresponding oxygen phosphates are described. These tertiary amino esters have been quaternized with methyl iodide, yielding esters of thiocholine and choline. The alkoxy groups were ethoxy and *iso*-propoxy groups. The protolytic dissociation constants in water $(pK)_a$ at 25°C of the dimethylaminoethyl esters have been determined and results obtained have been used in a discussion of the properties of the substituted phosphoryl groups. Compounds with sulfur-phosphoryl groups have significantly lower pK_a values than other analogous compounds investigated. The cholinesterase inhibiting properties of the compounds have been determined as pI_{50}. The esterase preparations were human plasma and hemolysate of human red cells. Thio derivatives are potent inhibitors and about 10^4 times as potent as their oxygen analogues. The chemical structures of the inhibitors in relation to their cholinesterase-inhibiting properties are discussed.

Choline esters of the aliphatic carboxylic acids, as *e.g.* acetylcholine, are considered to form addition compounds with cholinesterases as a first step in the sequence of reactions which lead to enzymic hydrolysis. The anchor points of the substrate are considered to be the carbonyl-ester and the ammonium parts of the molecule [1]. It has been shown that methyl-fluoro-phosphorylcholines are potent inhibitors of cholinesterases and it has been pointed out that phosphorylcholines are likely to react with the enzyme, as the first step in inhibition, in qualitatively the same way as substrates [2,3] do. The phosphoryl group in the inhibitors resembles the carbonyl group in substrates.

A new group of compounds related to choline esters has been introduced by Gosh and Newman [4]. It has been shown that S, ω-dialkyl-aminoethyl-dialkyl-thiophosphates are insecticides and methods for their syntheses are

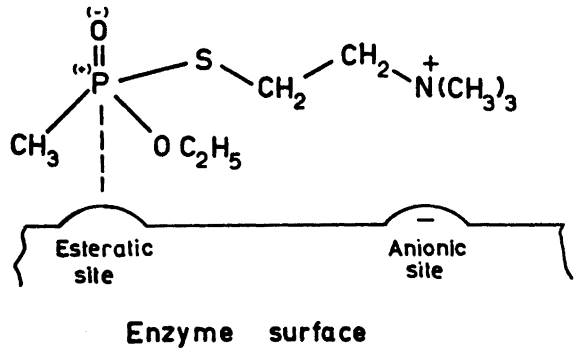

Fig. 1. Hypothetical model of the enzyme inhibitor complex formed during the inhibition of acetylcholinesterase by organophosphorylcholines.

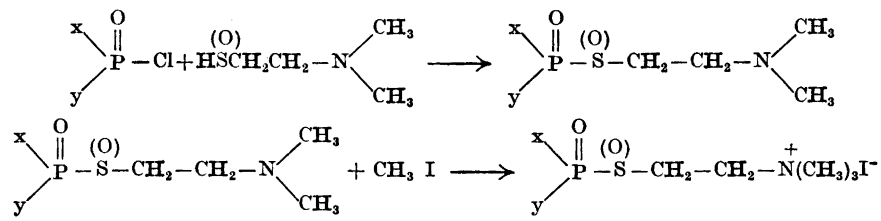
given [5]. Diethoxy-phosphorylthiocholine and S, ω-dimethylaminoethyl-diethylthiophosphate have been shown to be potent cholinesterase inhibitors [6].

The present work deals with the syntheses and description of thio compounds of the types mentioned above, their oxygen analogues and alkoxymethyl-phosphorylthiocholines (See Fig. 1.), their tertiary homologues and corresponding oxygen compounds.

The earlier described dialkoxy-phosphorylthiocholines, and the alkoxymethyl-phosphorylthiocholines described in this paper, do presumably react with the cholinesterases as described above. (See Fig. 1.)



The bond energy between the esteratic site of the enzyme and the phosphoryl group is part of the total affinity to the enzyme. The degree of polarity in insecticides has been correlated to the toxicity by Perkow [7] and his general view can be applicated to the organo-phosphorylcholines. In the following an attempt will be made to use K_a values of the acid base equilibrium

$$RCH_2—CH_2—NH(CH_3)_2^+ = RCH_2—CH_2—N(CH_3)_2 + H^+$$

where R is the organophosphorus residue, for a discussion of the electronic distribution in the phosphoryl part of the inhibitor molecules. Through determinations of K_a values and inhibiting properties it is thus possible to discuss the affinity to cholinesterases in relation to the polarity.

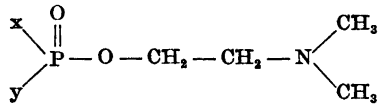
EXPERIMENTAL

The phosphorylcholine and phosphoryl-thio-choline esters were synthesized according to the scheme [5]

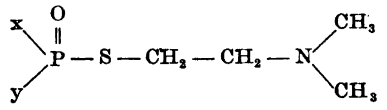
Two series were synthesized 1) x = y = C_2H_5O or *iso*-C_3H_7O and 2) x = CH_3 and y = C_2H_5O or *iso*-C_3H_7O.

The thio compounds (tertiary or quaternary) are extremely toxic and care must be taken while handling them to avoid direct contact with, or inhaling of, the compounds.

The free amino bases. One mole of dialkoxyphosphoryl chloride or alkoxy-methylphosphoryl chloride and one mole of dimethylaminoethanol or dimethylaminoethanthiol were mixed in 400 ml of ether with 1.05 moles of triethylamine. The reaction mixture was refluxed for one hour. Triethylammonium chloride was filtered off and the filtrate fractionated by distillation at reduced pressure. Yield ~60 %.



Hydrogen oxalates. One mole of the amino base (25 % solution in methanol) and 1.05 moles of oxalic acid (10 % solution in methanol) were mixed. The hydrogen oxalate which was precipitated by evaporation of the methanol is recrystallized from acetone to constant melting point (as a rule only once). Yield ~70 %.



Choline and thiocholine esters. One mole of the tertiary amino base and 1.5 moles of methyl iodide were refluxed in 2.5 l of ether. The methiodides precipitate in 5 h and were filtered off. Yield ~85 %.

Verification of the composition. The boiling points were rather approximately determined by the distillation by means of an ordinary thermometer and a McLeod manometer and shall not be considered as characteristic physical constants though reproducible in our distillation set up. Densities were determined by a pycnometer and the refractive index in an Abbe refractometer. Molar refractions were calculated from group and atomic refractions given by Vogel [8] and Holmstedt [9]. Melting points were determined on a Kofler Heizbank. Carbon and hydrogen contents were determined in an ordinary combustion oven which is possible if the sample is mixed with the double amount of vanadium pentoxide. Nitrogen content was determined according to Kjeldahl and sulfur content was determined by combustion with sodium peroxide in a Parr bomb and precipitation as barium sulfate. The content of oxalic acid was determined by permanganate titration at 60°C. The end point is rather vague but after some exercise reproducible results were obtained. (For data see Table 2). Finally the number of acid protons per molecule were determined by means of sodium hydroxide titration. (See determination of pK_a and Fig. 2).

The choline and thiocholine esters were prepared as iodides. The iodine content was determined by directly applied potentiometric argentometric titration. For data see Table 3.

Determination of the acid equilibrium constants, pK_a, of the ω-dimethylaminoesters

When hydrogen oxalates of the amino esters, *i.e.* BHOxH (see also heads of Tables 2 and 3) are dissolved in water, BH^+ and HOx^- are formed. Both ions show protolysis. The values of pK_a for the equilibrium, $BH^+ = B + H^+$, were determined at 25°C with an automatic recording titrator as described by Larsson and Hansen [10]. Hydrogen oxalates (BHOxH) of the compounds (B) were dissolved in 0.100 M potassium chloride (yielding $10^{-2.4}$ M solutions) and titrated with 0.1000 M sodium hydroxide. All solutions were kept carbon dioxide free. The titration curves were recorded and showed pH as a function of the amount of sodium hydroxide added. The pH scale of the equipment was standardized against two buffer solutions, 0.05 M potassium hydrogen phtalate, pH = 4.01, and 0.01 M borax, pH = 9.18.

For evaluation of pK_a the curves were converted to curves where the number of protons split off per BHOxH, Z, was shown as a function of pH [11] (Fig. 2). At every point of the recorded curve Z can be calculated from the equation:

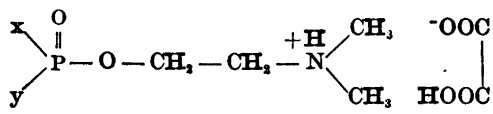
$$Z = \frac{[H^+] + [Na^+] - [OH^-]}{[B] + [BH^+]}$$

where $[H^+]$ and $[OH^-]$ were computed from pH and $[Na^+]$ from the added amount of sodium hydroxide, and $[B]+[BH^+]$ is the total concentration of B or oxalate, that is $[B]+[BH^+] = [H_2Ox]+[HOx^-]+[Ox^{2-}]$. Using the law of electro-neutrality and the following relationships:

$$K_1' = \frac{a_{H^+}[HOx^-]}{[H_2Ox]} \; ; \; K_2' = \frac{a_{H^+}[Ox^{2-}]}{[HOx^-]} \; ; \; K_a' = \frac{a_{H^+}[B]}{[BH^+]}$$

Z may be expressed as

$$Z = \frac{\dfrac{a_{H^+}}{K_2'} + 2}{\dfrac{a_{H^+}^2}{K_1'K_2'} + \dfrac{a_{H^+}}{K_2'} + 1} - \frac{\dfrac{a_{H^+}}{K_a'}}{\dfrac{a_{H^+}}{K_a'} + 1}$$



Evaluation of the mixed diss. const. K_2' and K_a'. The curves in Fig 2 show that pK_2' and pK_a' are rather well apart and it was decided to use the preceding expression of Z to test if A—B and B—C in Fig 2 could be treated as separate titration curves. In this case pH at $Z = 0.5$ gives pK_2' and pH at $Z = 1.5$ gives pK_a'. Using the approximate values $K_2' = 10^{-4}$; $K_a' = 10^{-8}$ and $K_1' = 6.5 \times 10^{-2}$, Z was calculated at $a_{H^+} = K_2'$ giving $Z = 0.4995$ and at $a_{H^+} = K_a'$ giving $Z = 1.5001$. This shows that $pK_2' =$ pH at $Z = 0.5$ and $pK_a' =$ pH at $Z = 1.5$ with satisfactory accuracy. Moreover the experimental pH/Z curves have been shown to follow the theoretical curve, yielding equivalence points at $Z = 1$ and $Z = 2$. Errors in analysis, impurities in the substanses or simultaneous hydrolysis of the esters are easily recognized as deviations from the theoretical curves [11].

Evaluation of the second thermodynamic diss. const. K_2 of oxalic acid. The eight pH/Z curves at $Z = 0.5$ (part A—B, Fig. 2) showed pH = 3.93 ± 0.01. Thus $pK_2 = 3.93 \pm 0.01$

$pK_2 = pK_2' + \log \frac{f_{HOx^-}}{f_{Ox^{2-}}}$ where f is the activity factor of the ion indicated. The ionic strength was 0.10. Values of f are from Bates [12]. $pK_2 = pK_2' + 0.324 = 4.25$.

Evaluation of the thermodynamic diss. const. K_a of the ammonium ions. The titration curves of the eight different substances showed at $Z = 1.5$ different pH values between the

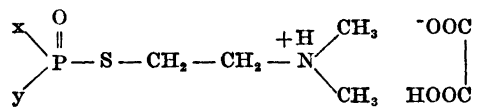
limits indicated in Fig. 2 part B—C. The pK'_a values found were converted to pK_a as follows:

$$pK_a = pK'_a + \log f_{BH^+} = pK'_a - 0.08$$

f_{BH^+} is the activity factor of the ammonium ions. The ionic strength was 0.10. The value of f_{BH^+} was estimated from values given by Kielland[13]. The pK_a values of the organophosphorus ammonium esters are shown in Table 5.

Determination of the cholinesterase inhibiting effect, pI_{50}.



The ability to inhibit cholinesterase was determined by means of an electrometric method[14]. The enzyme preparations were erythrocyte hemolysate and plasma from human blood. Hemolysate diluted 1/30 and plasma diluted 1/20 in a Michel buffer solution (pH = 8) were incubated at 25°C with the inhibitor and thereafter acetylcholine was added to a final concentration of $10^{-2.3}$ M. Two compounds, methyl-etoxy-phosphoryl thiocholine and the corresponding dimethylaminoethanthiol ester were tested on enzyme preparations free from phosphorylphosphatases, the plasma fraction IV. 6 and a homogenate of the electric organ from *Torpedo*. In both cases I_{50}-values were obtained which were in good agreement with those obtained from human blood.

The results from preliminary tests with varying incubation time indicated that two hours are sufficient to obtain maximum inhibition at 25° with the actual concentrations of enzymes and inhibitors. The enzyme activity (v) was measured at various inhibitor concentrations (I) and pI_{50} determined by plotting v/v' against pI (v' = uninhibited enzymic activity) and taking the pI value at $v/v' = 0.5$ as pI_{50}[15]. The results are given in Table 6. Inhibitor solutions stored overnight gave the same results as those freshly prepared. Reproducibility of the pI_{50} values is shown by the maximum deviations in series of three determinations being ± 0.2.

RESULTS

S,ω-Dimethylaminoethyl-O,O′-dialkylthiophosphates, ω-dimethylaminoeththio-alkoxy-methyl-phosphine oxides and the corresponding compounds with oxygen instead of sulfur have been prepared as free amines, hydrogen oxalates

and methiodides (see Tables 1, 2, 3 and 4). The methiodides are choline or thiocholine ester iodides.

The dimethylaminoethyl-phosphoryl esters are water soluble colorless liquid compounds which are faintly discolored by storage in closed bottles at room temperature. The S,ω-dimethyl aminoethyl-diethylthiophosphate is not quite stable and preparations solidify after some months of storage. The hydrogen oxalates and methiodides are water soluble colorless crystalline compounds. It is apparent that the compounds hydrolyse very slowly because there is no effect on pK_a determinations nor on the cholinesterase inhibition studies if the experiments are performed within a few hours after preparation of solutions.

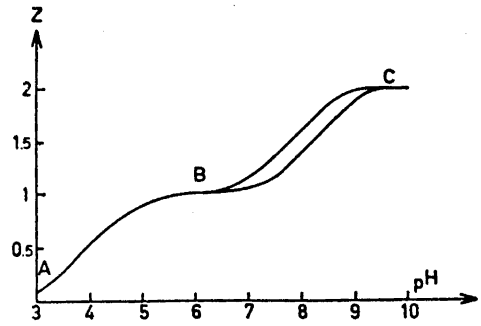

Fig. 2. Titration curves obtained with hydrogen oxalates of ω-dimethylaminoethyl-organo-phosphoryl esters (BHOxH) as titrand and sodium hydroxide as titrator. Z is the number of protons split off per mole BHOxH. A—B shows titration of OxH^- and B—C of BH^+. The two B—C curves limits the family of curves obtained from different B shown together with pK_a in Table 5.

Hydrogen oxalates of dimethylaminoethyl esters can be prepared in a pure state, as has been shown in the preparative part of this paper and confirmed by the titration curves (Fig. 2). The pH-scale was fixed by means of two buffer solutions. In determinations of the thermodynamic equilibrium constants pK_a, pH at $Z = 0.5$ offers a third possibility in controlling the pH-scale. The obtained value of the second dissociation constant (pK_2) of oxalic acid is well in accordance with earlier determinations. (Found 4.25, earlier values 4.22 and 4.29)[16]. The pH-scale is thus satisfactorily fixed and the reproducability of the ammonium pK_a determinations can be controlled by the A-B part of the (Z/pH) diagram (Fig 2). This part of the titration curve, which admittedly could be considered to be a complication, has thus been shown to be of value in checking the reliability of the experiments. Hydrogen oxalates of amines are therefore suitable for determinations of ammonium pK_a. The pK_a values of the compounds investigated in this paper are shown in Table 5.

It has been confirmed that the *dialkoxy-phosphorylthiocholines* and tertiary homologues are potent inhibitors of acetylcholinesterase. Koelle [6] used rabbit

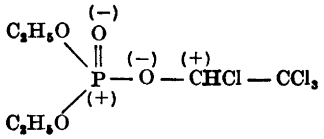
brain and rabbit erythrocytes as enzyme sources. In the present experiments human erythrocytes were used. Moreover, it has been shown that these organophosphorus compounds are equally or more potent inhibitors of the cholinesterase from human plasma than of the cholinesterase from human erythrocytes.

It has been shown that *alkoxy-methyl-phosphorylthiocholines* and tertiary homologues are more potent inhibitors than the dialkoxy derivatives of the acetylcholinesterase from human erythrocytes. The alkoxy-methyl-phosphoryl compounds are however less potent as inhibitors of human blood plasma cholinesterase.

It has been found that the dialkoxy-phosphorylcholines, alkoxy-methyl-phosphorylcholines and tertiary homologues are weak inhibitors of cholinesterases.

It was found that complete reaction between cholinesterases and the inhibitors is obtained in two hours. The pI_{50} values obtained after two hours incubation time are summarized in Table 6.

DISCUSSION



A question of importance in syntheses of the thio compounds is the position of the sulfur atom. The method of synthesis results in compounds where the sulfur is genetically situated between the dimethylaminoethyl and phosphoryl groups. A subsequent isomerisation is not probable since it has been made probable that

$$=\overset{\overset{S}{\|}}{P}-O-CH_2-CH_2-N(CH_3)_2 \text{ yields } =\overset{\overset{O}{\|}}{P}-S-CH_2-CH_2-N(CH_3)_2$$

when heated [5,20]. Moreover the Z/pH diagrams show that the products obtained are homogeneous, which would be improbable if rearrangements occurred. The distillates described in Table 1 are rather crude due to difficulties in the dis-

tillation of the compounds which combine high boiling points with thermolability. However, the molar refractions show that the distillates on the whole have the predicted composition.

According to Perkow [7] the electronic distribution in organophosphorus insecticides can be described by the following formula:

which seems rather probable. The same author has shown that a fewer number of chlorine atoms in the chloroethyl group gives less potent insecticides. This is interpreted as being due to a decreased polarity in the organophosphorus residue. It is also pointed out that the reaction with proteins is favored by a high polarity in cases where the reaction is an addition of the insecticide or if it is a phosphorylation as in cholinesterase. In the last case the increased polarity is said to cause a weakening of the $\overset{(+)}{P}-\overset{(-)}{O}-\overset{(+)}{C}$ bridge with consequently enhanced phosphorylation.

The thio compounds show as a group considerably higher cholinesterase inhibiting properties than corresponding oxygen compounds. The present data are not sufficient to make it possible to judge definitely whether the present organophosphorus compounds phosphorylate cholinesterases, or are added as such or as metabolites although the first alternative seems probable for the thio inhibitors. However, a difference might be that the oxygen compounds are added as such and the thio compounds phosphorylate through breakage of the P—S bond. The relatively high hydrolysability of compounds containing the P-S-C group [17] supports the hypothesis of phosphorylation.

The thio compounds show also as a group lower pK_a values than the oxygen compounds. If the viewpoints of Eucken [18] on chloroacetic acid are applied qualitatively on these admittedly more complicated compounds the low pK_a values in the organophosphorus compounds can be understood as follows. The dipole resulting from the formal charges of atoms in the sphere around the phosphoryl group has, because of the found low pK_a values, a repellent effect on the proton added to the amino group and is, due to asymmetry, more efficient in the thio compounds. The difference in polarity indicated by the pK_a values in oxygen and thio compounds seems, however, too small to explain the relatively high cholinesterase inhibiting potency of the thio compounds as being due only to an increased dipole-dipole attraction between inhibitor and enzyme. A comparison between the pK_a values in phosphoryl esters [19] (*e.g.*, ω-dimethylaminoethhyl acetate)

$$-\overset{\overset{O}{\|}}{C}-S-C$$

indicates that the polarity of the system is lower than of the

$$=\overset{\overset{O}{\|}}{P}-S-C$$

system.

Steric effects of the alkoxy groups in the thio compounds on the affinity for cholinesterases has been demonstrated in two ways. Di*iso*propoxy-phosphorylthiocholine is less active an inhibitor than the diethoxy compound and the same difference is shown by the tertiary homologues although the pK_a values and thus the reactivities should be similar. Moreover, dialkoxy and alkoxy-methyl compounds showed different patterns in affinity for acetylcholinesterase and serum esterase, effects which should be contributed to steric phenomena. The relatively high affinity for acetylcholinesterase compared to that for serum esterases of the alkoxy-methyl-phosphoryl compounds is unique among organophosphorus esters.

It seems probable that the compounds studied in this paper will become valuable tools in pharmacological studies of cholinergic effects due to their stability and interesting relations to cholinesterases. The comparison between thiocholine and dimethylaminoethanthiol diethoxy-phosphoryl esters made by Koelle and Steiner [6] is already one excellent example.

My thanks are due to the Director of this Institute, Professor G. Ljunggren, for his kind interest in this work.

Further Studies on Amino Esters of Substituted Phenylcarbamic Acids

RICHARD DAHLBOM and ALFONS MISIORNY

Research Laboratories, AB Astra, Södertälje, Sweden

The synthesis of some amino esters of 2,6-dimethylphenylcarbamic acid substituted in the *para* position with an amino group or substituted amino group is described. Two amino esters of 2-chloro-6-methylphenylcarbamic acid were also prepared. The new compounds have been tested for local anesthetic activity.

In a previous paper the synthesis of some esters and amides of 2,6-dimethyl and 2,4,6-trimethylphenylcarbamic acids with basic substituents was described [1]. As an extension of these investigations a number of related compounds of the following type were prepared, R being H, n-C_4H_9 or an acyl group.

The starting material for these syntheses was ethyl 2,6-dimethyl-4-nitrophenylcarbamate (I) which could be prepared from 2,6-dimethyl-4-nitroaniline and ethyl chloroformate. It could also be obtained in good yield by nitration of ethyl 2,6-dimethylphenylcarbamate. The smooth formation of the 4-nitro compound in this case is rather interesting since the nitration of 2,6-dimethylacetanilide and 2,6-dimethylformanilide mainly gives the 3-nitro derivatives [2]. As ethyl 2,6-dimethyl-4-nitrophenylcarbamate is easily hydrolysed to 2,6-dimethyl-4-nitroaniline in almost quantitative yield, this method opens a new satisfactory route to this amine in addition to the method devised by Wepster [2]. The different steps involved in the synthesis of the amino esters (V, VI) and their alkyl and acyl derivatives (VIII-XI) are shown in Fig. 1.

In addition, the β-diethylaminoethyl and β-piperidinoethyl esters of 2-chloro-6-methylphenylcarbamic acid were prepared (XIII, XIV).

Fig. 1.

The new compounds were tested for local anesthetic action on the rabbit cornea and compared with Xylocaine *. The *p*-amino derivatives V and VI were devoid of anesthetic activity. The *n*-butylamino derivate VIII had an effect comparable with that of Xylocaine but had a longer latency time, low frequency of anesthesia and more than twice the toxicity. The acyl derivate IX was inactive, and X was only slightly active but XI had a strong anesthetic effect. It was, however, irritating to the rabbit eye and had a long latency time and a low frequency of anesthesia. Strong activity was also displayed by the amino esters of 2-chloro-6-methylphenylcarbamic acid (XIII, XIV), but they were too toxic to be of any clinical value.

EXPERIMENTAL

Ethyl 2,6-dimethyl-4-nitrophenylcarbamate (I). (*a*) 2,6-Dimethyl-4-nitroaniline (8.3 g, 0.05 mole), prepared by hydrolysis of 2,6-dimethyl-4-nitro-1-(*p*-toluenesulfonyl)-aniline according to the method of Wepster [3], and pyridine (5.15 g, 0.065 mole) were dissolved in benzene (600 ml) and ethyl chloroformate (7.0 g, 0.065 mole) was added dropwise with mechanical stirring. The mixture was refluxed for 2.5 h and then filtered hot. The benzene was evaporated and the residue dissolved in ether (800 ml) and extracted with conc. hydrochloric acid (150 + 100 ml) in order to remove unreacted starting material. The ether solution was washed with water, dried over sodium sulphate and the solvent was then evaporated. The crystalline residue (6.9 g, 58 %) melted at 165—168°; recrystallisation from ethanol yielded pale yellow crystals of m.p. 172—173°. (Found: C 55.3; H 5.95; N 11.8. Calc. for $C_{11}H_{14}N_2O_4$: C 55.45; H 5.92; N 11.8).

(*b*) To a solution of nitric acid (76 ml, 2 moles; *d* 1.50) in water (600 ml) were added successively ethyl 2,6-dimethylphenylcarbamate [1] (58 g, 0.3 mole), glacial acetic acid (600 ml) and sodium nitrite (2.1 g, 0.03 mole). The mixture was refluxed for 1.5 h and after cooling to room temperature it was poured into water (1.2 l). The crude nitro compound (56 g, 78 %) of m.p. 169—171° was recrystallised from ethanol giving yellow crystals melting at 172—173°. A mixed m.p. with the product prepared by procedure (*a*) showed no depression.

Hydrolysis of ethyl 2,6-dimethyl-4-nitrophenylcarbamate (I) to 2,6-dimethyl-4-nitroaniline. A mixture of compound I (2.4 g, 0.01 mole) and 85 % sulphuric acid (25 ml) was heated in an oil bath at 140—150°. Evolution of carbon dioxide began at once and had subsided after 45 min. The reaction mixture was then poured into ice water (200 ml) and made alkaline with 5 N sodium hydroxide. The light yellow product (1.55 g, 94 %) melted at 163—164° alone or in admixture with a sample of 2,6-dimethyl-4-nitroaniline prepared according to the method of Wepster [3]. Recrystallisation from aqueous ethanol did not raise the m.p.

Ethyl 4-amino-2,6-dimethylphenylcarbamate (II). Ethyl 2,6-dimethyl-4-nitrophenylcarbamate (14.3 g), dissolved in ethanol (125 ml), was hydrogenated at about 50° and normal pressure with Raney nickel as catalyst. The calculated amount of hydrogen was consumed after 4 h. The solution was filtered and the solvent evaporated. The crystalline residue (12.5 g, 100 %) was recrystallised from benzene giving a product (10.0 g) of m.p. 107—108°. (Found: C 63.9; H 8.01; N 13.1. Calc. for $C_{11}H_{16}N_2O_2$: C 63.4; H 7.74; N 13.4).

β-Diethylaminoethyl 2,6-dimethyl-4-nitrophenylcarbamate (III). A mixture of ethyl 2,6-dimethyl-4-nitrophenylcarbamate (71.4 g, 0.3 mole) and β-diethylaminoethanol (195 g, 1.65 mole) in which a piece of sodium (1.5 g) had been dissolved was heated at 75—80° for 3 h at a pressure of 80—100 mm/Hg. The excess of the amino alcohol was evaporated off and the residue washed with water and extracted with 2 N hydrochloric acid. The acid solution was extracted with ether and made alkaline with dilute sodium hydroxide. The precipitated, semisolid base was extracted with ether. Evaporation of the ether yielded a crystalline residue (75.0 g, 81 %) of m.p. 46—48°. Since further purification of the base proved to be difficult, it was converted to the *hydrochloride* which was recrystallised

* Acknowledgement is made to Dr. S. Wiedling for performing these tests.

from ethanol-ether; m.p. 164—165°. (Found: C 51.9; H 6.94; Cl 10.4. Calc. for $C_{15}H_{21}ClN_2O_4$: C 52.1; H 6.99; Cl 10.25).

β-Piperidinoethyl 2,6-dimethyl-4-nitrophenylcarbamate (IV). This compound was prepared in 90 % yield from ethyl 2,6-dimethyl-4-nitrophenylcarbamate and β-piperidinoethanol by the same method as that described for III. The amino ester base was recrystallised from methanol-water; m.p. 139—140°. (Found: C 60.0; H 7.52; N 12.7. Calc. for $C_{16}H_{23}N_3O_4$: C 59.8; H 7.21; N 13.1).

β-Diethylaminoethyl 4-amino-2,6-dimethylphenylcarbamate (V). (*a*) The nitro compound III (4.2 g) was dissolved in ethanol (50 ml) and hydrogenated at about 50° and normal pressure with Raney nickel as catalyst. The calculated amount of hydrogen was consumed in 2 h. The catalyst was removed by filtration and the solvent evaporated. The colourless oily residue (3.6 g, 95 %) was converted to the *dihydrochloride;* m.p. 299—301° after recrystallisation from ethanol-ether. (Found: C 51.3; H 7.85; Cl 20.4. Calc. for $C_{15}H_{27}Cl_2N_3O_2$: C 51.1; H 7.72; Cl 20.1).

(*b*) Transesterification of ethyl 4-amino-2,6-dimethylphenylcarbamate with diethylaminoethanol as described for III yielded the *dihydrochloride* of V in 50 % yield. M.p. after recrystallisation from ethanol-ether 300—302°.

β-Piperidinoethyl 4-amino-2,6-dimethylphenylcarbamate (VI). The nitro compound IV was hydrogenated as described above for V (*a*) and the piperidino ester was isolated as the *dihydrochloride* in 80 % yield. M.p. 291—293° (decomp.) after recrystallisation from ethanol-ether. (Found: C 52.55; H 7.54; N 11.3. Calc. for $C_{16}H_{27}Cl_2N_3O_2$: C 52.7; H 7.47; N 11.5).

Ethyl 4-n-butylamino-2,6,dimethylphenylcarbamate (VII). (*a*) A solution of ethyl 4-amino-2,6-dimethylphenylcarbamate (4.15 g, 0.02 mole), *n*-butyraldehyde (0.04 mole) and fused sodium acetate (1 g) in ethanol (50 ml) was hydrogenated with Raney nickel as catalyst at normal pressure and room temperature for one hour. The catalyst was removed by filtration and the solvent evaporated. The residue was dissolved in 2 N hydrochloric acid, the acid solution was extracted with ether and then made alkaline with dil. sodium hydroxide. The precipitate was extracted with ether and the solvent was evaporated yielding a crystalline residue (4.7 g, 90 %) of m.p. 73—74°. Recrystallisation from aqueous methanol raised the m.p. to 76—77°. (Found: C 68.15; H 9.01; N 10.5. Calc. for $C_{15}H_{24}N_2O_2$: C 68.15; H 9.15; N 10.6).

(*b*) This compound could also be prepared in 82 % yield by using ethyl 2,6-dimethyl-4-nitrophenylcarbamate (I) as starting material in the reductive alkylation described above (*a*). The reaction was, however, rather sluggish; the calculated amount of hydrogen was consumed after 6 h.

β-Diethylaminoethyl 4-n-butylamino-2,6-dimethylphenylcarbamate (VIII). (*a*) A solution of β-diethylaminoethyl 4-amino-2,6-dimethylphenylcarbamate (3.9 g, 0.014 mole), *n*-butyraldehyde (1.3 g, 0.018 mole) and sodium acetate (1.0 g) in ethanol (50 ml) was hydrogenated at normal pressure and room temperature over Raney nickel for one hour. The reaction mixture was worked up as described above for compound VII (*a*). The product was isolated as the *dihydrochloride* (3.6 g, 62 %); m.p. 236—237° (decomp.) after recrystallisation from ethanol-ether. (Found: C 55.6; H 8.72; N 9.93. Calc. for $C_{19}H_{35}Cl_2N_3O_2$: C 55.9; H 8.64; N 10.3).

(*b*) This compound was also obtained by transesterification of ethyl 4-*n*-butylamino-2,6-dimethylphenylcarbamate with β-diethylaminoethanol according to the procedure described for compound III. The yield of the *dihydrochloride* was 63 %.

β-Diethylaminoethyl 4-acetamido-2,6-dimethylphenylcarbamate (IX). A suspension of compound V (2.8 g free base, 0.01 mole) in acetic anhydride (10 ml) was heated to 60° for 30 min and was then poured into water (100 ml). The mixture was made alkaline and extracted with ether. The ether solution was filtered through a short column of aluminium oxide and evaporated. The solid residue (1.7 g, 53 %) was recrystallised from benzene; m.p. 122—123°. (Found: C 63.0; H 8.45; N 13.1. Calc. for $C_{17}H_{27}N_3O_3$: C 63.5; H 8.47; N 13.1).

β-Diethylaminoethyl 4-benzamido-2,6-dimethylphenylcarbamate (X). Compound V was treated with benzoyl chloride in pyridine-benzene. A heavy precipitate consisting of the hydrochloride of X was formed. The salt was suspended in water, the suspension made alkaline and the base extracted with ether. Evaporation of the ether yielded a crystalline residue which was recrystallised from benzene; m.p. 144—145°. (Found: 69.4; H 7.65; N 10.8. Calc. for $C_{22}H_{29}N_3O_3$: C 68.9; H 7.62; N 11.0).

β-Diethylaminoethyl 4-(β-cyclopentylpropionamido)-2,6-dimethylphenylcarbamate (XI) was prepared similarly in 71 % yield from V and *β-cyclo*pentylpropionyl chloride; m.p. 115—116° after recrystallisation from benzene-light petroleum. (Found: C 68.4; H 9.19; N 10.45. Calc. for $C_{23}H_{37}N_3O_3$: C 68.45; H 9.24; N 10.4).

Ethyl 2-chloro-6-methylphenylcarbamate (XII). To a stirred solution of 2-chloro-6-methylaniline (28.3 g, 0.2 mole) and pyridine (20 g, 0.25 mole) in benzene (200 ml), ethyl chloroformate (27.1 g, 0.25 mole) was added dropwise over a period of one hour. The temperature gradually rose to 45°. The stirring was then continued for one hour and the pyridine hydrochloride formed was removed by filtration. The benzene solution was washed successively with water, 2 N hydrochloric acid and water and was then evaporated to dryness. The residue (38.5 g, 90 %) melted at 75—77° and was recrystallised from aqueous methanol; m.p. 76—77°. (Found: C 56.3; H 5.69; N 6.62. Calc. for $C_{10}H_{12}ClNO_2$: C 56.2; H 5.66; N 6.56).

β-Diethylaminoethyl 2-chloro-6-methylphenylcarbamate (XIII). This compound was prepared by transesterification of the ethyl ester XII with β-diethylaminoethanol by the method described for compound III. The oily base was converted to the *oxalate*. Yield 51 %; m.p. 127—128° after recrystallisation from 80 % ethanol. (Found: C 51.7; H 6.51; N 7.35. Calc. for $C_{16}H_{23}ClN_2O_2$: C 51.3; H 6.18; N 7.48).

β-Piperidinoethyl 2-chloro-6-methylphenylcarbamate (XIV) was prepared similarly from β-piperidinoethanol and XII. The oily base was isolated as the *hydrochloride*. Yield 87 %; m.p. 172—173° after recrystallisation from ethanol-ether. (Found: C 54.1; H 6.47; N 8.39: Calc. for $C_{15}H_{22}Cl_2N_2O_2$: C 54.05; H 6.66; N 8.41).

The Occurrence of 3-Oxoglucose Units in Oxidised Cellulose

BENGT LINDBERG and OLOF THEANDER

Institutionen för träkemi, Kungl. Tekniska Högskolan, and Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

D-Allose has been isolated from the hydrolysate of a cellulose which was first oxidised with chromate and subsequently reduced with borohydride. The mannose content was roughly the same as found in the hydrolysate of an unmodified cellulose. These results strongly indicate that most of the keto-groups in the oxidised cellulose are present as 3-oxoglucose units and that the contribution from 2-oxoglucose units is rather insignificant.

The oxidation of cellulose is technically an important although usually most undesirable reaction, which takes place during the bleaching of pulp, aging of paper etc. The alcoholic hydroxyl groups of the cellulose are converted to oxo or carboxyl groups, and more drastic oxidation also cleaves carbon-carbon linkages. Fairly satisfactory methods are available for the analytical determinations of these groups, but these are complicated by the heterogeneous nature of the reactions upon which they are based. Meesook and Purves [1] have also developed methods which distinguish between aldo and keto groups. The assignment of definite structures to different oxidised units in the modified celluloses is, with few exceptions, based upon assumptions only. The structure of periodate oxidised cellulose, however, has been proved both by further oxidation and by reduction of the material and subsequent identification of the products of hydrolysis [2]. The isolation of 3,5-dioxo-tetrahydro-4-pyrone [3] after acid hydrolysis of a cellulose oxidised with nitrogen dioxide, indicated the presence of 2,3-dioxoglucose units.

Whistler *et al.*[4] have recently studied a hypochlorite oxidised starch; after hydrolysis they isolated glyoxylic acid and D-erythronic acid, which demonstrates that the link between $C_{(2)}$ and $C_{(3)}$ in the glucose units has been broken. Purves *et al.*[5,6] have investigated chromate and hypochlorite oxidised starch. The modified polysaccharides were first subjected to a cyanohydrin synthesis and then to hydrolysis and reduction with hydrogen iodide. 4-Hydroxy-2-methylhexanoic acid was isolated from the reaction product and is obviously formed from 2-oxoglucose units. As no products derived from

potential 3-oxoglucose units were obtained, they draw the conclusion that the main part of the keto-groups in these modified starches were due to 2-oxoglucose units.

When methyl β-D-glucopyranoside was oxidised with chromate, the 6-oxoglucoside was the dominating oxo-derivative, follwed by the 3-oxoglucoside [7]. We have since found that the 2-oxoglucoside is also formed, but in a much lower yield [8]. From these results one would, by analogy, expect to find more 3- than 2-oxoglucose units in chromate oxidised cellulose.

The present paper describes an investigation of cellulose, cotton linters, oxidised with chromate; the modified product contained 6.9 oxo groups per 100 glucose units, as determined by the borohydride method [9]. The oxidised cellulose was reduced with borohydride. By reduction under similar conditions [8] methyl β-D-2-oxoglucoside yielded glucoside and mannoside in the proportions 41:59 and methyl β-D-3-oxoglucoside yielded glucoside and alloside in the proportions 48:52. In neither case were other sugars formed in detectable amounts, which indicates that no isomerisations took place. It is reasonable to assume that the reduction of potential 2- and 3-oxoglucose units in the cellulose should follow a similar course. The reduced polysaccharide was then hydrolysed to a mixture of glucose and other sugars, and the glucose was selectively removed by enzymatic oxidation to gluconic acid with the aid of notatin and subsequent treatment with ion exchange resins. In the residue, the presence of mannose, xylose, allose and traces of glucose could be demonstrated by paper chromatography and by paper electrophoresis in borate buffer. Glucose and xylose, however, were not separated by the last method. A weak spot, probable due to arabinose, was also obtained both in the modified and unmodified sample. Mannose and xylose were also found in the hydrolysate of the unmodified cellulose. The quantitative determination of the sugars was complicated by the presence of unknown material, possibly proteins or peptides from the enzyme preparation which interfered with various reactions tried. These difficulties were finally overcome by estimating the sugars from the sizes of the spots in comparison with those of reference spots, using anisidine hydrogen chloride as spraying reagent. Fairly reproducible results were obtained and the agreement between the values determined by paper chromatography and by paper electrophoresis was satisfactory (Table 1). The analytical figures were corrected for sugar decomposition during the acid hydrolysis and also for the formation of 1,6-anhydro-D-allose [10]. Losses during the manipulations were also corrected for by adding a known amount of rhamnose to the hydrolysate and determining rhamnose in the final sugar mixture. The oxidation of sugars other than glucose by notatin was considered insignificant and was not corrected for (*cf.* Ref.[11]) In a separate experiment, the losses of mannose during this treatment were found to be less than 1 % of the total amount.

The figures in Table 1 show that the cellulose contained small but detectable amounts of mannose and xylose. The modified cellulose contained comparable amounts of these sugars, and no increase in the mannose content was observed. Allose, which of course was not present in the linters, was found in the modified cellulose. In a separate and essentially analogous experiment, crystalline D-allose was isolated from an oxidised and reduced cellulose and

Table 1. Sugars other than glucose, before and after oxidation reduction of the cellulose. E and C, determined by paper electrophoresis and paper chromatography, respectively.

Sample	Mannose %		Xylose %		Allose %	
	E	C	E	C	E	C
Cotton linters,	0.18	0.13	—	0.26	0	0
» » modified	0.16	0.14	—	0.24	0.17	0.17

proved to be identical with an authentic sample. These results, which are in agreement with our earlier model experiments, demonstrate the presence of 3-oxoglucose units in chromate oxidised cellulose. There may be 2-oxogroups also present, but to a much lesser extent. If practically no mannose is formed by the reduction of the 2-oxoglucose units, the percentage of the latter could of course be quite high, but the results of model experiments [8] make this assumption improbable. It is also possible that the original mannose in the sample, as present in the form of a highly accessible hemicellulose, was destroyed during the oxidation and that the mannose found in the modified cellulose should come from 2-oxoglucose units. This assumption, however, seems highly improbable as the xylose content is the same in both samples, and xylose units, by the same argument, should also be preferentially oxidised. Thus, of the oxogroups present, 6.9 in 100 glucose units, only 0.34 or 5 % should be in 3-oxoglucose units. This, of course, is a very crude estimation, which is valid only for the actual sample investigated, since the proportions between different groups may vary considerably with the conditions of preparation.

EXPERIMENTAL

Preparation of the modified cellulose. Cotton linters (20 g) was treated with a solution of potassium dichromate (7.86 g) in 0.4 N sulphuric acid (1 600 ml) at 25° for 120 h and was then carefully washed with water and dried in air. The oxogroups were determined by the borohydride method as 6.9 groups in 100 glucose units. The copper number, determined according to Hägglund [12], was 18.9. The modified cellulose (10 g), reduced by treatment for 6 hours at 25° with an aqueous solution (400 ml) containing potassium borohydride (0.56 g), buffered to pH 9.6 by boric acid (3.70 g) and sodium hydroxide (1.60 g) was filtered off, washed and air-dried.

Hydrolysis and enzymatic oxidation of the hydrolysate. Unmodified or modified cellulose (3 g) was treated with 72 % sulphuric acid (7.5 ml), a vacuum being applied and released a number of times to obtain a better contact with the solvent. After 17 h at room temperature the solution was diluted with water (105 ml) and refluxed 3 h. The cooled solution was then neutralised with barium carbonate using vigorous agitation and keeping the temperature below 15°. After filtering and washing, the solution was deionised, using the ion exchange resins Amberlite IR 120 and IR 4B and concentrated under reduced pressure to an almost colourless syrup (3.5 g). The syrup was dissolved in 0.5 M acetate buffer (90 ml) at pH 5.5 and the enzyme preparation (Dee 0 Takamine Laboratory) (30 mg) was added. Oxygen was bubbled through the solution, which was kept at 35° and vigorously agitated. At intervals the pH was adjusted to 5.5 by addition of solid sodium hydrogen carbonate. After one day further enzyme preparation (30 mg) was added and after 2 ½ days the oxidation was stopped. Rhamnose monohydrate (30 mg) was added and the solution was deionised as above and concentrated to a syrup under reduced pressure.

Analysis of the hydrolysate. The syrup above was dissolved in water and the volume adjusted to 5 ml. A qualitative chromatographic analysis revealed the presence of significant amounts of rhamnose, xylose, mannose and allose, the latter, however, only in the hydrolysate from the modified cellulose. Smaller amounts of glucose and arabinose were also found together with some substances that were obviously oligosaccharides, since they gave spots with low R_F-values and positive reactions with anisidine hydrogen chloride. A fast spot, which gave a weak reaction with the silver nitrate-sodium ethoxide reagent, and which had the R_F-value of 1,6-anhydroallose, was also obtained from the hydrolysate of the modified cellulose.

For the quantitative estimations, aliquot amounts of the hydrolysate were spotted on sheets of Whatman No. 1 filter papers, together with varying amounts of reference substances (5—75 μg). The chromatograms were run, first with solvent A, ethyl acetate-acetic acid-water, 3:1:3 (upper phase), for 16 h, dried and then run with solvent B, butanol-pyridine-water, 3:1:1.5, for 24 h. The spots were developed with the anisidine hydrogen chloride reagent, the areas of the reference spots were plotted against the amounts of sugars and the amounts of sugars in the hydrolysates determined by interpolation. The electrophoretic separations were carried out on Whatman No. 3 filter paper in a 0.1 M borate buffer at pH 10 for 2 h at 1 500 V. The quantitative estimations were made as described above. The results of analyses are given in Table 1.

Isolation of D-*allose.* A sample of the modified cellulose (10 g) was hydrolysed, enzymatically oxidised and worked up as described above. A rather large amount of enzyme preparation, 0.50 g, was used. The syrup (525 mg) was fractionated as above on ten sheets of Whatman No. 3 filter paper (width 23 cm), which had previously been carefully washed with water. The bands containing the allose, mixed with mannose, were cut out, the sugars were eluted and the solution concentrated to a syrup (70 mg) under reduced pressure. This syrup was now fractionated on three sheets of the same paper, run for 24 h with solvent B. A fraction (42 mg) containing allose as the only sugar was obtained. The syrup was extracted with boiling 75 % aqueous ethanol, and the extract was concentrated to dryness, dissolved in water, decolourised with carbon, deionised and concentrated again. When anhydrous ethanol was added to the syrup, it crystallised. The crystals (8 mg) were recrystallised from ethanol, yielding pure D-allose (4.2 mg) m. p. 127—128°, undepressed on admixture with authentic material. In its behaviour on paper chromatography in various solvents and in paper electrophoresis, the substance was undistinguishable from authentic D-allose.

The authors wish to thank Mrs. S. Lidman-Safwat for her skilful assistance.

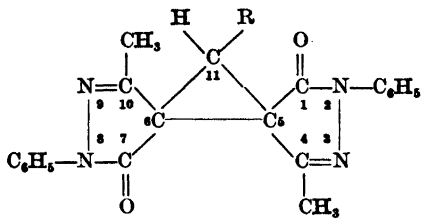
Studies on *Cyclo*propanes

II. Preparation and Properties of Some Penta- and Tetrasubstituted *Cyclo*propanes

GUNNEL WESTÖÖ

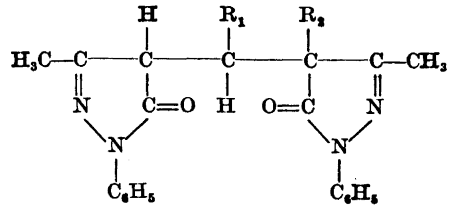
Institute of Organic Chemistry, University of Lund, Lund, Sweden



The pentasubstituted *cyclo*propanes, I b—e, and the tetrasubstituted one, I a, have been prepared. They are more stable towards isomerization than the hexasubstituted *cyclo*propane derivatives described in a previous paper [1]. On heating I a and I e are transformed into III a and III b.

2,8,11-Triphenyl-4,10-dimethyl-2,3,8,9-tetrazadispiro[4.0.4.1]undeca-3,9-diene-1,7-dione, I e, could be prepared from 1-phenyl-3-methyl-4-benzylidene-2-pyrazolin-5-one and 1-phenyl-3-methyl-4-bromo-2-pyrazolin-5-one analogously to the hexasubstituted products [1]. For the preparation of I a—d the corresponding 4,4′-alkylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-ones] [2] (II a—d) were used as starting materials. When their sodium salts were brominated or iodinated to form II h or II i, ring closure took place immediately at room temperature, I a—d precipitating in good yields (>90 %). The bromination was performed with a bromopyrazolone, *e.g.*, 1-phenyl-3-methyl-4-bromo-2-pyrazolin-5-one or preferably 1-phenyl-3-methyl-4,4-dibromo-2-pyrazolin-5-one [3].

Analogous ring closures have been made with alkylidenebis[indanedione] and 2,2′-methylenebis[5,5-dimethyl-1,3-*cyclo*hexanedione] by Radulescu and Georgescu [4] and with methyl β-phenyl-γ-bromo-γ-benzoyl-ethylmalonate by Kohler and Conant [5].



Good support for the *cyclo*propane structure of the reaction products is afforded by the UV curves (Fig. 1), which are almost identical with the corresponding curves of the hexasubstituted *cyclo*propanes described earlier [1]. The IR spectra [1,6,7] show absorption at 1 000—1 010 cm^{-1}. — The steric arrangement of the groups in I a—e has not been studied.

Hydrogen chloride adds to the compounds I a, b or c with formation of 4-chloro-4,4′-alkylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-ones], II e, f or g, as proved by the following facts. The products obtained are acids which in

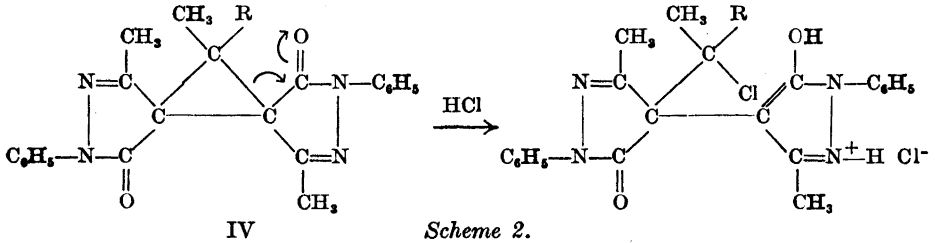
acetate-buffered solution split off hydrogen chloride with reformation of I a, b or c. They oxidize iodides almost quantitatively to iodine at room temperature according to the equation (*cf.* Westöö [8]):



$$PyClCHRPyH\,{}^{*}+2KI \rightarrow PyHCHRPyK+I_2+KCl.$$

Contrary to 4-chloro-4,4′-*iso*propylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one] [1] and 1,1′,1″-triphenyl-3,3′,3″-trimethyl-4-bromo-[4,4′,4″-ter-2-pyrazoline]-5,5′,5″-trione [9], II e, f and g do not dissociate into 1-phenyl-3-methyl-4-halogeno-2-pyrazolin-5-one and an α,β-unsaturated carbonyl compound.

The opening of the *cyclo*propane ring by hydrogen chloride is probably started by the addition of a proton to a carbonyl group, followed by an electron transfer from a *cyclo*propane bond to the pyrazolone ring and the uptake of a chloride ion by the most positive carbon atom. When C_{11} carries one methyl or ethyl group only, it is too electron-deficient to allow a displacement of the $C_5—C_{11}$ bonding electrons to the pyrazolone, and the $C_5—C_6$ bond breaks exclusively (Scheme 1). However, when C_{11} has two electron-releasing groups, a cleavage of the $C_5—C_{11}$ bond is instead the main reaction [1] (Scheme 2). Under the conditions described in the experimental part only about 20 % of the $C_5—C_6$ bonds were cleaved in the 11,11-dimethyl compound (IV a), 5 % in the 11-ethyl-11-methyl compound (IV b) in accordance with the increased inductive effect on C_{11}.

* Py represents the group

The quantitative rearrangement, which was found in solution even at room temperature with the hexasubstituted *cyclo*propanes (cleavage of the *cyclo*propane ring with migration of a hydrogen atom from an 11-methyl group), has no analogue with the pentasubstituted products I b—d. These are quite stable at room temperature and are markedly more resistant towards heat than are the hexasubstituted ones. On prolonged heating of I b or c in dioxan-water at 95°, amorphous products were obtained. Besides degradation products the isomer Py = C(CH_2R)PyH has probably been formed, but it has not been isolated. I d is even more stable than I b and c and could be recovered to 90 % after heating at 95° for 24 h in dioxan-water solution.

Heating in solid form or in solution of the phenyl compound, I e, yielded 4,4'-benzylidynebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (III b)[10]. The same form of isomerization was found with the tetrasubstituted product I a, methylidynebis[1-phenyl-3-methyl-2-pyrazolin-5-one][11] (III a) being formed.

EXPERIMENTAL

2,8-Diphenyl-4,10-dimethyl-2,3,8,9-tetrazadispiro[4.0.4.1]undeca-3,9-diene-1,7-dione (I a). 4,4'-Methylenebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (II a) (2.5 g of crude product, obtained from the reaction of 1-phenyl-3-methyl-2-pyrazolin-5-one in benzene solution with formaldehyde at room temperature) was dissolved in ethanol (50 ml) and poured into a neutralized solution of 1-phenyl-3-methyl-4-bromo-2-pyrazolin-5-one (1.5 g) in ethanol (15 ml). I a (2.0 g) separated immediately. It was collected by filtration and washed with ethanol and water. M.p. after crystallization from ethanol 162° (decomp.). (Found: C 70.5; H 5.0; N 15.7; mol.wt. 350 *. Calc. for $C_{21}H_{18}N_4O_2$: C 70.4; H 5.1; N 15.6; mol.wt. 358.)

2,8-Diphenyl-4,10,11-trimethyl-2,3,8,9-tetrazadispiro[4.0.4.1]undeca-3,9-diene-1,7-dione (I b). a) 4,4'-Ethylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one][3] (II b) (1.53 g) in ethanol (5 ml) was neutralized with 2.5 N sodium hydroxide solution using phenolphthalein as indicator. Excess of 1-phenyl-3-methyl-4,4-dibromo-2-pyrazolin-5-one (1.36 g) dissolved in ethanol (20 ml) was added. I b separated at once as a soft mass which on scratching was transformed into crystals. The product was filtered, washed with ethanol, dilute sodium hydroxide solution and water. Yield: 1.40 g of crude product, m.p. 130—131° (decomp.). After one crystallization from ethanol it melted at 131—132° (decomp.). (Found: C 71.0; H 5.4; N 15.1; mol.wt. 370 *. Calc. for $C_{22}H_{20}N_4O_2$: C 70.95; H 5.4; N 15.05; mol.wt. 372.) b) 4,4'-Ethylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (II b) (2.60 g) was dissolved in ethanolic sodium hydroxide solution (10 ml of ethanol + 5.65 ml of 2.46 N aqueous NaOH solution). Iodine (1.76 g) dissolved in ethanol (25 ml) was added with stirring. Crystals of I b separated. They were filtered and washed with 50 % ethanol. Yield: 2.35 g, m.p. of crude product 131° (decomp.).

2,8-Diphenyl-4,10-dimethyl-11-ethyl-2,3,8,9-tetrazadispiro[4.0.4.1]undeca-3,9-diene-1,7-dione (I c) and 2,8-diphenyl-4,10-dimethyl-11-isopropyl-2,3,8,9-tetrazadispiro[4.0.4.1]-undeca-3,9-diene-1,7-dione (I d). These compounds were prepared from equimolar amounts of the sodium salts of the corresponding alkylidenebis[1-phenyl-3-methyl-2-pyrazolin-5-one][3] (II c and d) and 1-phenyl-3-methyl-4,4-dibromo-2-pyrazolin-5-one or iodine in the way described for I b. The yields were 90—95 % of the theoretical amounts. The m.p. of I c was 110° and of I d 163—164° (decomp.). (Found for I c: C 71.4; H 5.7; N 14.6. Calc. for $C_{23}H_{22}N_4O_2$: C 71.5; H 5.7; N 14.5. Found for I d: C 71.6; H 6.0; N 13.9. Calc. for $C_{24}H_{24}N_4O_2$: C 72.0; H 6.0; N 14.0.)

2,8,11-Triphenyl-4,10-dimethyl-2,3,8,9-tetrazadispiro[4.0.4.1] undeca-3,9-diene-1,7-dione (I e). 1-Phenyl-3-methyl-4-benzylidene-2-pyrazolin-5-one[12] (1.93 g) was dissolved in ether (80 ml) and ethanol (40 ml) and mixed with a neutralized solution (phenolphthalein) of 1-phenyl-3-methyl-4-bromo-2-pyrazolin-5-one (1.87 g) in ethanol (40 ml). When the

* determined by measurements of the freezing-point depressions of benzene solutions.

mixture had been decolorized, the ether was evaporated under reduced pressure. The precipitate was filtered and washed with ethanol and water. Yield: 3.10 g, m.p. 132°. (Found: C 74.5; H 5.1; N 12.8. Calc. for $C_{27}H_{22}N_4O_2$: C 74.6; H 5.1; N 12.9.)

Cleavage of the cyclopropane ring of I c with hydrogen chloride. I c (0.55 g) was dissolved in benzene, and dry hydrogen chloride was introduced with ice-cooling until the solution was saturated. After one hour the solvent was removed under reduced pressure; the solid residue was dissolved in ethanol, precipitated with water, filtered and washed with water. Yield: 0.48 g. (Found: C 65.0; H 5.5; Cl 8.5; N 13.0. Calc. for $C_{23}H_{23}ClN_4O_2$: C 65.3; H 5.5; Cl 8.4; N 13.25.)

When a buffered ethanol solution (50 ml of 1.8 N aqueous sodium acetate solution + ethanol to 500 ml) of the acid obtained was left for a few hours, hydrogen chloride was split off, and the three-ring was reformed quantitatively, as could be shown by UV measurement.

The chloro compound oxidized hydrogen iodide to iodine rapidly at room temperature.

0.0984 g of the addition product was dissolved in ethanol (10 ml) and mixed with an excess of potassium iodide dissolved in water (3 ml). After 3 min 5 N hydrochloric acid (3 ml) was added and the solution was titrated with 0.0998 N sodium thiosulphate solution. 4.65 ml was consumed. This corresponds to pure $PyClCH(C_2H_5)PyH$, II g. Another sample gave 97 % of $PyClCH(C_2H_5)PyH$.

Cleavage of the cyclopropane ring of I b with hydrogen chloride. I b (1.00 g) was dissolved in benzene (10 ml). Dry hydrogen chloride was introduced for 15 min into the ice-cooled solution, which was then kept in the ice bath for 2 h. The benzene was evaporated under reduced pressure, the solid residue was dissolved in ethanol (25 ml) and the solution was poured into water (200 ml) with stirring. The precipitate formed (II f) was filtered and washed with water. Yield: 1.02 g of almost colourless acid. It was purified by solution in ether and precipitation with light petroleum. (Found: C 64.5; H 5.3; Cl 8.6; N 13.6; O 7.7. Calc. for $C_{22}H_{21}ClN_4O_2$: C 64.6; H 5.2; Cl 8.7; N 13.7; O 7.8.)

Ring closure and oxidation of iodide were performed as for II g and with the same results.

Cleavage of I a by hydrogen chloride. I a was cleaved with hydrogen chloride in the same way as described for I b and c, II e being the main product formed. (Found: C 63.7; H 5.0; Cl 9.0; N 14.1; O 8.2. Calc. for $C_{21}H_{19}ClN_4O_2$: C 63.9; H 4.85; Cl 9.0; N 14.2; O 8.1.)

The addition product oxidized hydrogen iodide to iodine in about 90 % yield according to the procedure described for II g (time of reaction 1 min instead of 3). The low iodine yield may be caused by some hydrogen iodide splitting off from $PyICH_2PyH$.

When an ethanol solution of the product was titrated with barium hydroxide solution, I a (identified by its m.p. 162° (decomp.), UV curve and neutrality) separated during the titration. In acetate-buffered solution ring closure also took place as could be shown by UV measurements. When a concentrated ethanol solution of the addition product was left for some weeks, methylidynebis[1-phenyl-3-methyl-2-pyrazolin 5-one][11] (III a) separated, m.p. alone and mixed with an authentic sample 182.5°.

Cleavage of 2,8-diphenyl-11-ethyl-4,10,11-trimethyl-2,3,8,9-tetrazadispiro[4.0.4.1]undeca-3,9-diene-1,7-dione (IV b) by hydrogen chloride [1]. IV b (0.25 g) was dissolved in ice-cooled benzene [20 ml) saturated with hydrogen chloride. After 15 min the solvent was removed under reduced pressure, the residue was dissolved in ethanol (5 ml) and poured into water (50 ml) with stirring. The precipitate formed was filtered and washed with water. Yield: 0.25 g of faintly yellow product. According to light absorption measurements less than 3 % of 1-phenyl-3-methyl-4-*sec*-butylidene-2-pyrazolin-5-one was present in the mixture, indicating that the C_5-C_6 bond had been cleaved to about 5 %.

When 2,8-diphenyl-4,10,11,11-tetramethyl-2,3,8,9-tetrazadispiro[4.0.4.1]undeca-3,9-diene-1,7-dione (IV a) was treated in the way described above, about 12 % of the reaction product was 1-phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one.

Bromination of $C_{23}H_{23}ClN_4O$. The chloro compound II g (0.19 g) was dissolved in acetic acid, and the equimolar amount of bromine (0.07 g) in acetic acid and a few pieces of ice were added. The product formed was precipitated with more ice and water, filtered, washed with water and air-dried. Yield: 0.22 g of yellow crystals, m.p. 123° (decomp.). Recrystallization from ethanol did not change the m.p. (Found: C 55.2; H 4.5; Br 16.1; Cl 7.2. Calc. for $C_{23}H_{22}BrClN_4O_2$: C 55.0; H 4.4; Br 15.9; Cl 7.1.)

Isomerization of I e to form 4,4'-benzylidynebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (III b). I e was heated in an oil bath at 135° for two hours or in dioxan-water (10:1)

solution at 95° for 20 h. Recrystallization from ethanol gave orange crystals, which melted at 240–241.5° (decomp.). Michaelis and Zilg [10] give m.p. 242° for III b. (Found: C 74.8; H 5.1; N 12.9. Calc. for $C_{27}H_{22}N_4O_2$: C 74.6; H 5.1; N 12.9.)

Isomerization of I a to form 4,4'-methylidynebis[1-phenyl-3-methyl-2-pyrazolin-5-one] (III a). I a (0.50 g) in ethanol (30 ml) was refluxed for 24 h. On cooling orange crystals (0.43 g) separated. After crystallization from ethanol they melted at 183°. According to Ionescu and Georgescu [11] III a melts at 180°. (Found: C 70.1; H 5.2; N 15.6; equiv.wt. 354. Calc. for $C_{21}H_{18}N_4O_2$: C 70.4; H 5.1; N 15.6; equiv.wt. 358.)

Attempts to isomerize I b, I c, and I d. Boiling of I b or I c in ethanol solution overnight was not sufficient to decompose the *cyclo*propane rings completely. More than 25 % of unaltered I b or c could be isolated from the orange-red products.

Heating at 95° in dioxan-water (10:1, v:v) for 24 h destroyed the three-rings of I b and c. However, when I d was heated in the same way, about 90 % of the starting material could be recovered unchanged.

The analyses were performed by the Department of Analytical Chemistry, University of Lund, or by Mikroanalytisches Laboratorium im Max-Planck-Institut für Kohlenforschung, Mülheim.

Isolation of Disaccharides from Golden Apple Gum

BENGT O. LINDGREN*

Queen's University, Kingston, Ontario, Canada

The structure of Golden Apple gum has been studied by the method of partial hydrolysis. After a mild acid treatment 3-*O*-α-[4(?)-*O*-methyl-D-glucuronopyranosyl]-L-arabinose was obtained. This acid thus is an integral part of the easily split side-chains of the gum molecule. The partially hydrolysed material yielded after further hydrolysis the following three disaccharides: 3-*O*-β-D-galactopyranosyl-D-galactose, 6-*O*-β-D-galactopyranosyl-D-galactose, and 6-*O*-β-[4(?)-*O*-methyl-D-glucuronopyranosyl]-D-galactose. Consequently, these acids are parts of the more resistant, pyranoside framework of the gum.

A previous investigation [1] of the gum exuded from Golden Apple tree (*Spondias cytheria* Sonner; family *Anacardiaceae*) showed that it was composed of residues of arabinose, galactose, a uronic acid (probably 4-*O*-methyl-D-glucuronic acid), xylose, and traces of rhamnose and fucose. The isolation of 3-*O*-β L-arabopyranosyl-L-arabinose from a hydrolysate of the gum showed that some of the arabinose units were present in the pyranose form. At least some of the xylose units must be linked to arabinose since 3-*O*-α-D-xylopyranosyl-L-arabinose was also obtained from the hydrolysate.

This paper reports a further study of the gum. The sample examined contained 51 % of pentose anhydride units and 15 % of uronic anhydride units. Its equivalent weight was 1 070. $[\alpha]_D$ — 5° (*c* 1.1; water).

Many gums are considered to be built up of a framework of galactopyranose units to which are attached side chains, composed largely of arabofuranose residues. The gum was therefore first hydrolysed under conditions such that practically all of the furanoside bonds, but only a small part of the pyranoside ones should be split. This was done in the usual way by heating a solution of the gum in its acidic form (autohydrolysis) until the reducing power did not further increase (80 h at 98°C).

The hydrolysate obtained was divided by conventional methods into i) the acidic mono- and oligosaccharides, ii) the neutral mono- and oligosaccharides, and iii) the degraded gum which constituted the pyranoside framework of the gum.

* Present address: Swedish Forest Products Research Laboratory, Stockholm, Sweden.

i) The weight of the acidic sugars was 13 % of that of the gum. The main component was an aldobiuronic acid, which is called acid A in the following. If formed about a third of the fraction. The rest was composed mainly of higher oligosaccharides, as revealed by paper chromatography of the fraction.

The hydrolysate of acid A showed on a paper chromatogram spots of arabinose and of a monomethyl-uronic acid, which probably was 4-*O*-methyl-D-glucuronic acid. The high positive rotation of A, $[\alpha]_D$ + 123°, suggested that its components were linked by an *alpha*-glycosidic bond.

The structure of A was determined by degradation in the following steps: complete methylation, reduction of the ester group to a carbinol group, methylation of the carbinol group, and hydrolysis of the glucosidic bond. A paper chromatogram of the hydrolysate obtained showed three spots. Two of the components were isolated in pure form by paper sheet chromatography. One of them was identified as 2,4-di-*O*-methyl-L-arabinose by conversion into the corresponding *N*-phenyl-glycosyl amine. The other was shown to be 2, 3, 4, 6-tetra-*O*-methyl-D-glucose by comparing its infra-red spectrum with that of an authentic sample.

The third component did not move when subjected to paper electrophoresis using a borate buffer. This implied that the hydroxyl group on C_2 was methylated since the α-glycol group on C_1 and C_2 should otherwise form a borate complex. (For instance, the rate of movement of 3, 4-di-*O*-methyl-L-arabinose was found to be 40 % of that of glucose.)

On paper chromatograms, the component gave a brown spot with *p*-anisidine hydrochloride, and had an R_F greater than that of 2, 4-dimethyl-arabinose. Two of the dimethyl-arabinoses, 2, 3- and 2, 5-dimethyl-arabinose, move faster than the 2, 4-derivative [1]. Only the 2, 5-derivative, however, gives a brown spot with anisidine; that of the other is coloured red [1]. The third component was therefore probably 2,5-di-*O*-methyl-L-arabinose.

From this followed that acid A should be 3-*O*-α-(4-*O*-methyl-D-glucurono-pyranosyl)-L-arabinose, which has not earlier been reported as having been isolated from a polysaccharide. The fact that *two* arabinose methyl ethers were obtained obviously indicated that the completely methylated disaccharide contained both arabopyranose and arabofuranose residues.

The identification of 4-*O*-methyl-glucuronic acid as the acidic component of A was, however, made only by paper chromatography. As the rates of the movement of the other monomethyl-glucuronic acids are not known, the position of the methoxyl group in acid A is not definitely established. 4-*O*-Methyl-D-glucuronic acid is, however, a common component in polysaccharides while the other monomethyl-glucuronic acids are comperatively rare in nature.

ii) The weight of the neutral sugars was 59 % of that of the gum. The fraction was composed mainly of arabinose (about 58 %). The other constituents were xylose (7 %), oligosaccharides (32 %) and small amounts of galactose and rhamnose (1—2 % each). This fraction had already been examined in the earlier investigation [1], which led to the isolation of 3-*O*-β-L-arabopyranosyl-L-arabinose and 3-*O*-α-D-xylopyranosyl-L-arabinose, and was therefore not examined further.

iii) The degraded gum constituted 28 % of the total gum. It contained 30.5 % of pentose anhydride units and 20 % of uronic anhydride units. $[\alpha]_D$—41° (*c* 1.0; water).

Its hydrolysate contained mainly galactose, arabinose, and an aldobiuronic acid, which is called acid B in the following. Acid A was not present.

From the hydrolysate of another sample of degraded gum, acid A was isolated (see experiment B in the experimental part). This sample of degraded gum had not been prepared by such a prolonged hydrolysis as the above mentioned sample and was obtained in a higher yield. It was therefore probable that it still contained considerable amounts of arabofuranose residues.

The difficulty of removing all of the arabinose units from the gum by autohydrolysis has already been pointed out[1]. It follows from the above that practically all of the remaining arabinose units in the degraded gum most probably are in the pyranose form.

The aldobiuronic acid isolated from the degraded gum, acid B, was built up of galactose and monomethyl-uronic acid, probably 4-*O*-methyl-D-glucuronic acid. It yielded, on methylation, the crystalline methyl ester of hepta-*O*-methyl-6-*O*-*β*-D-glucuronopyranosyl-D-galactose. Consequently, B should be 6-*O*-*β*-(4-*O*-methyl-D-glucuronopyranosyl)-D-galactose, which has previously been isolated from gum myrrh [2]. As in the case of acid A, the position of the methyl group in acid B is not definitely established. The rate of movement of B on a paper chromatogram and its $[\alpha]_D$ value agreed, however, with the corresponding figures for the acid from gum myrrh.

From the hydrolysate of the degraded gum small amounts of two disaccharides were isolated. They crystallised readily from methanol. One of them, disaccharide C, had m.p. 156—159 °C. The crystals of the other, disaccharide D, rapidly liquefied when kept in air. They probably contained methanol of crystallisation, which easily evaporated causing the destruction of the crystal lattice. Both disaccharides on hydrolysis gave only galactose, which was identified by paper chromatography.

Disaccharide C was found to be identical with 3-*O*-*β*-D-galactopyranosyl-D-galactose, which has been isolated from *Acacia pycnantha* gum[3].

Disaccharide D yielded no formaldehyde on periodate oxidation in slightly alkaline solution, which is characteristic for hexose containing disaccharides with 1,5 or 1,6-linkages [4]. The low positive optical rotation, $[\alpha]_D$ + 30°, indicated a *beta*-glucosidic link between the sugar units. D should accordingly be 6-*O*-*β*-D-galactopyranosyl-D-galactose, and this was confirmed by a comparison of the infra-red spectrum of D with that of a synthetic sample. This disaccharide has recently been obtained from the water-soluble arabogalactan which is present in the wood of *Larix occidentalis* [5].

EXPERIMENTAL

Analyses etc.

Paper chromatography. Solvents:

a. Ethyl acetate:acetic acid-formic acid:water (18:3:1:4 v/v).
b. Ethyl acetate:acetic acid:water (7:2:1: v/v) .
c. *n*-Butanol:ethanol:water:conc. ammonia (200:50:244:5 v/v, the top layer).

d. *n*-Butanol:pyridine:water (10:3:3 v/v).
Paper: Whatman No. 1.
Spray: *p*-Anisidine hydrochloride dissolved in butanol.
R_{gal}: the rate of movement relative to galactose.
R_G: the rate relative to 2,3,4,6-tetra-*O*-methyl-D-glucose.

Paper electrophoresis. The experiment was performed according to Foster [6]. The pH of the borate buffer was 10. Voltage 900 V. Time 2 h. The correction for electroendosmosis was determined by running parallel tests with 2,3,4,6-tetra-*O*-methyl-D-glucose.

M_G: the rate of movement relative to glucose.

Infra-red spectra. If not otherwise stated, they were determined on potassium bromide pellets with a Perkin-Elmer double beam spectrophotometer. The maxima in the most characteristic part of the spectra, the region 700 – 1 000 cm^{-1}, are recorded in this paper.

Pentose anhydride. This analysis was carried out according to a Tappi standard method [7], by which the amount of furfural formed is determined by oxidation with bromate-bromide solution. As the predominant pentose sugar in the gum was arabinose, the yield of furfural was assumed to be 74 %, which is the yield obtained from arabinose [7]. The correction for the amount of furfural formed from the uronic acid units was applied by assuming that the yield was one half of that from arabinose [8]. No correction was made for the small amount of hydroxymethylfurfural formed from the galactose units.

Uronic anhydride. The determinations were carried out according to Browning [9].

Reducing power. This was determined iodometrically according to Ingles and Israel [10]. The oxidation was carried out at pH 11.5.

Hydrolysis

Autohydrolysis. An aqueous solution of the gum (5.00 g) was passed through a column of a cation exchanger (Amberlite IR-120) saturated with hydrogen ions. The eluate (150 ml) was heated in a water bath at 98°C, The consumption of 0.1 N iodine solution per ml of the solution was after 0 h, 0.04 ml; after 3 h, 0.74 ml; after 9 h, 1.25 ml; after 21 h, 1.57 ml; after 45 h, 1.77 ml; after 68 h, 1.79 ml, and after 75 h, 1.75 ml.

After 80 hours' heating a part of the solution (78 ml) was passed through a column (diameter 4.5, height 7.5 cm) of a "weak" anion exchanger (Amberlite IR-4B) saturated with acetate ions. The column was then washed with water until the water gave a negative Molisch test.

The column was eluted with N formic acid. The residue after evaporation of the eluate (334 mg, corresponding to 13 % of the weight of the gum) showed on a paper chromatogram (solvent a) a faint, red spot at R_{gal} = 2.70 (probably 4-methyl-glucuronic acid), a strong, red spot at R_{gal} = 1.3 (acid A), and a series of spots having lower R_{gal} values (different oligosaccharides).

The residue (38 mg) was separated on a paper sheet using solvent a. The strip containing acid A was extracted with water. Evaporation of the extract yielded 12 mg of acid A.

The solution which passed directly through the anion exchanger column was neutralised with barium carbonate and concentrated to 20 ml. Ethanol (100 ml) was added and the precipitate of degraded gum (728 mg, corresponding to 28 % of the weight of the gum) was removed by centrifugation.

The residue on evaporation of the alcohol-water solution weighed 1 525 mg (corresponding to 59 % of the weight of the gum). A part of the residue (124 mg) was separated on paper sheets using solvent a. The strips containing the different components were extracted with water and the extracts were evaporated to dryness. The weight of the residue from the arabinose strips was 71 mg; from the xylose strips, 8 mg; from the rhamnose and galactose strips, 2 mg each; from the strips with 3-xylopyranosyl-arabinose, 9 mg; from the strips with 3-arabopyranosyl-arabinose, 15 mg; and from the strips containing the remaining oligosaccharides, 15 mg. Total 122 mg.

Hydrolysis of degraded gum. Experiment A. The degraded gum (681 mg obtained from the experiment described above) dissolved in N sulphuric acid (10 ml) was heated on a water bath for 5 h. The solution was neutralised with barium carbonate, passed through a column of a cation exhanger (Amberlite IR-120) saturated with hydrogen ions, and

evaporated to dryness. The weight of the residue was 480 mg. A paper chromatogram (solvent a) showed at R_{gal} = 2.70 a red, faint spot (probably 4-methyl-glucuronic acid), at R_{gal} = 1.63 a strong, red spot (arabinose), at R_{gal} = 1.00 a strong, brown spot (galactose), and at R_{gal} = 0.58 a strong, brown spot (acid B). No spot was observed at R_{gal} = 1.3 (which would be due to acid A). With solvent d spots were obtained at R_{gal} = 1.53 (arabinose), at R_{gal} = 1.00 (galactose), and at low R_{gal} values (acidic components).

Experiment B. The degraded gum for this experiment was obtained by heating an aqueous solution (2 000 ml) of the acidic gum (38.4 g) at 83°C for 24 h. The product (15.3 g, 40 % of the weight of the gum) was precipitated from the neutral part of the hydrolysate by addition of alcohol as described above.

The degraded gum (15.0 g) dissolved in 2 N sulphuric acid (200 ml) was heated at 53°C for 8 days. The solution was neutralised with barium hydroxide, and passed through a column of a cation excanger (Amberlite IR-120) saturated with hydrogen ions. The components of the solution were fractionated into *a*) neutral and *β*) acidic compounds by passing the solution through a column (diameter 4.5, height 11 cm) of a "weak" anion exchanger (Amberlite IR-4B) in its acetate form.

a) Evaporation of the solution which passed through the column yielded a syrup of the neutral components (4.9 g). The syrup was passed through a carbon-Celite column 1:1 w/w, diameter 3, height 27 cm). The column was eluted with water containing stepwise increasing amounts of ethanol in the usual way. The fractions obtained were examined by paper chromatography.

0 % ethanol. Weight 3.65 g. Contained: galactose, arabinose, and traces of rhamnose.

2 % ethanol. Weight 0.02 g. Contained: galactose, arabinose, 3-xylopyranosyl-arabinose (?), and traces of rhamnose.

5 % ethanol. Weight 0.18 g. Contained: 3-xylopyranosyl-arabinose (?), 3-arabopyranosyl-arabinose (?), disaccharides C and D.

The last fraction was chromatographed on paper sheets using solvent a. C (39 mg) and D (16 mg) were obtained.

b) The acidic fraction absorbed on the column was eluted with N formic acid. The eluate was continuously extracted with ether for 24 h (to remove formic acid), then evaporated to dryness, residue 6.1 g.

The residue (3.0 g) was fractionated on a cellulose column using solvent b. The following fractions were collected and examined by paper chromatography.

Fraction a) contained 4-methyl-glucuronic acid (?); weight, 67 mg. b) contained acid A; weight, 165 mg. c) contained acid B; weight 402 mg.

Structures of the disaccharides

Acid A. R_{gal} = 1.3 (solvent a). $[\alpha]_D$ +123° (*c* 1.0; water). Paper chromatograms of the hydrolysate of A showed three spots: i) unchanged A, ii) arabinose, and iii) a sugar, which moved at the same rate as 4-methyl-glucuronic acid in solvents a and d.

A (300 mg) was methylated with dimethyl sulphate and sodium hydroxide, and then with Purdie reagent. The infra-red absorption curve of the product (in carbon tetrachloride solution) showed no maximum in the vicinity of 3 400 cm^{-1} indicating the absence of hydroxyl groups.

The completely methylated A was then dissolved in ether (about 5 ml, distilled from lithium aluminium hydride). Lithium aluminium hydride (0.5 g) was added to the solution and the mixture was left at room temperature for 24 h. After addition of ice and water, the solution was continuously extracted with chloroform.

The extract was dried (Drierite) and evaporated to dryness. After methylation with Purdie reagent the product was hydrolysed (N hydrochloric acid, steam bath, 20 h). The hydrolysate was neutralised with silver carbonate, filtered, and evaporated to dryness. Residue 140 mg.

Paper chromatograms of the residue showed three spots with the R_G values (solvent c): 0.63 (red), 0.86 (brown), and 1.00 (red). Paper electrophoresis showed only one spot: M_g = 0.0.

The components of the hydrolysate were separated on paper sheets. By a mishap most of the components were lost during the separation. Only about 5 mg each of the fastest moving and the slowest moving components were obtained. The fast moving component

crystallised, m.p. 60—70°C. Its infra-red spectrum and that of 2,3,4-6-tetra-*O*-methyl-D-glucose were identical. They showed maxima at 700, 768 (broad), 853 (strong), 887 (weak), 905 (weak), 917 (weak), 964, and 990 (strong) cm^{-1}.

The slow moving component (5 mg), aniline (5 mg), and methanol (0.5 ml) were heated together on a water bath for 2 h. Evaporation of the solvent yielded crystals, m.p. 128—130°C. The infra-red spectrum of the crystals and that of *N*-phenyl-2,4-di-*O*-methyl-L-arabinosyl amine were identical. In the region 600—1 100 cm^{-1} they showed maxima at: 660, 695 (strong), 746 (strong), 760 (strong), 820, 825 (masked), 860, 880, 900, 928 (strong), 973, 990, 1 037 (strong), 1 055, 1 080 (strong, broad) cm^{-1}.

Acid B. R_{gal} = 0.58 (solvent a). $[\alpha]_D$ −1° (*c* 0.4; water). Paper chromatograms of the hydrolysate of B gave three spots; i) unchanged B, ii) galactose, and iii) a sugar which moved with the same rate as 4-methyl-glucuronic acid in solvents a and d.

Methylation of B (380 mg) with dimethyl sulphate and sodium hydroxide, and after that with Purdie reagent yielded the crystalline methyl ester of hepta-*O*-methyl-6-β-D-glucuronopyranosyl-D-galactose (195 mg). After recrystallisation from light petroleum, the compound had m.p. 92—93°C, undepressed on admixture with an authentic sample. (Found: C 51.2; H 7.8; OCH_3 52.8. Calc. for $C_{20}H_{36}O_{12}$: C 51.2; H 7.7; OCH_3 52.8.)

Disaccharide C. R_{gal} = 0.27 (solvent a), and 0.25 (solvent d). Paper chromatograms of the hydrolysate showed only one spot, that of galactose. C crystallised readily from methanol, m.p. 156—159°C, undepressed by addition of 3-β-D-galactopyranosyl-D-galactose. The behaviour of C with lead-tetracetate [11] and its X-ray powder diagram were identical with those of this disaccharide. (The oxidation and the determination of the X-ray diagram were kindly carried out by Dr. A. S. Perlin.)

Disaccharide D. R_{gal} = 0.16 (solvent a), and 0.11 (solvent d). $[\alpha]_D$ +30° (*c* 1.2; water). Paper chromatograms of the hydrolysate showed only one spot, that of galactose. D crystallised in needles from methanol. If kept in a dessiccator or in air, the crystals decomposed.

The periodate oxidation in slightly alkaline solution was carried out as described by Hough and Perry [4]. The pH of the periodate solution was 8. Oxidation time, 24 h. Formaldehyde was determined colorimetrically using the chromotropic acid method. In the test D gave the same reading as a blank. (This experiment was kindly performed by Mr. M. B. Perry.)

6-β-D-galactopyranosyl-D-galactose was synthesised according to Freudenberg and co-workers [12]. Its infra-red spectrum had maxima at 703, 775, 790 807, 876, 894, 916, 950, 973, 998 cm^{-1} in the region 700—1 000 cm^{-1}. Outside this region the spectrum had distinct maxima at 1 150, 1 213, and 1 248—1 252 (broad) cm^{-1}.

Since there was insufficient amount of D available the distinct maxima only showed up in the comparison diagram for D. They were at 703, 775, about 890, 916, 950, 1150, 1 213, and about 1 250 cm^{-1}.

Acknowledgement. I would like to express my thanks to Dr. J. K. N. Jones for suggesting this subject and for his kind interest. I am also indebted to the *Swedish America Foundation* for a fellowship.

Enzymatic Hydrolysis of Organophosphorus Compounds

VII. The Stereospecificity of Phosphorylphosphatases

KLAS-BERTIL AUGUSTINSSON

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

The enzymatic hydrolysis of dimethylamido-ethoxyphosphoryl cyanide (tabun) by purified phosphorylphosphatase preparations from human blood plasma, swine kidney and liver, and by the plasma of rabbit and rat was studied from a kinetic point of view. The hydrolysis was a first-order reaction for the human plasma enzyme. When the kidney and liver enzymes were used, the reactions were composed of two simultaneous first-order reactions; the numerical values of the rate constants for the kidney enzyme were 5.70 h^{-1} and 0.39 h^{-1}. The results were interpreted as being due to stereospecificity for the kidney and liver enzymes, the stereoisomers of tabun being hydrolysed at two different rates by these enzymes. In studies with mixed enzymes it was demonstrated that the isomer of tabun, being slowly hydrolysed by the kidney enzyme, was readily hydrolysed by both the human plasma phosphorylphosphatase and the rabbit plasma enzyme. Both the rat and rabbit plasma phosphorylphosphatases also showed stereospecificity, but to a lower degree compared with the kidney enzyme.

The existence and properties of phosphorylphosphatases have recently been reported by this [1] and other laboratories [2-4]. In most of our studies, tabun (dimethylamido-ethoxyphosphoryl cyanide) was used as substrate. From the reaction curves (see paper I of the present series of reports [1]) for the system tabun-phosphorylphosphatase using various animal tissues as enzyme sources, it can be concluded that the reaction, in certain cases at least, might be composed of two different hydrolysis rates. Hoskin and Trick [5] recently obtained experimental evidence for this proposal and suggested that tabun, containing an asymmetric phosphorus atom, exists in two optically active forms which are enzymatically hydrolysed at different rates. Rat serum was employed in their experiments, and polarimetric determinations indicated that the dextrorotatory form of tabun is more rapidly hydrolysed. Similar experiments have been performed in this laboratory, and extended to a variety of enzyme preparations. The present report deals with the results obtained.

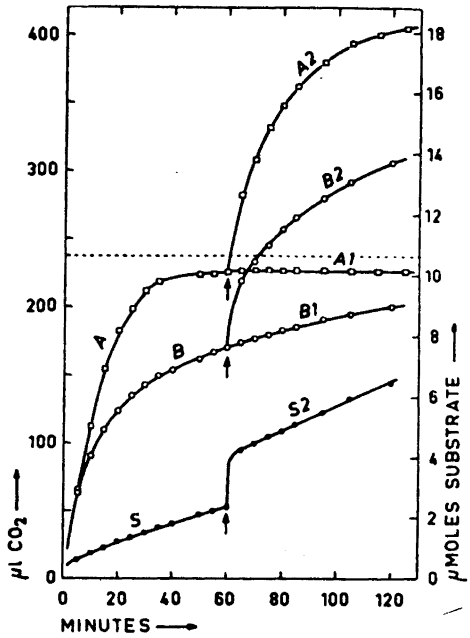

Fig. 1. Enzymatic hydrolysis of tabun by purified phosphorylphosphatase preparations from human serum (A) and swine kidney, and the effects of the addition (indicated by an arrow) of a second portion of enzyme (1) and substrate (2) respectively. S, spontaneous substrate hydrolysis. Dotted line refers to total substrate hydrolysis (273.5 µl CO_2 or 10.6 µmoles).

METHODS AND MATERIAL

Enzyme activity was measured by the Warburg manometric technique at 25°C using flasks with two side bulbs [1]. All determinations were carried out in 0.040 M sodium bicarbonate solution of pH 7.6 (equilibrated with a mixture of 95 % N_2 and 5 % CO_2) and tabun, dissolved in water immediately before use, was used as substrate throughout. The total volume of the reaction mixture was 2.00 ml after adding the first portion of substrate from one of the side bulbs. In most experiments, 1.60 ml of the enzyme solution was placed in the main compartment, and 0.40 ml of the substrate or enzyme solution in each of the two side bulbs. The amount of substrate added to the enzyme from the beginning was 10.6 µmoles of tabun, and this amount was also used when a second portion of substrate was added to the reaction mixture.

Human plasma enzyme was prepared from postpartum serum according to a partly modified method No. 6 of Cohn *et al.*[6]. It was identical with Fraction IV−1 used in previous investigations of this series.

Rabbit plasma enzyme and *rat plasma enzyme.* Fresh plasma was used as such without any treatment.

Kidney and *liver enzymes* were prepared from fresh swine organs, the first part of the method being similar to that described by Mounter *et al.*[2] for DFPase, and continued with ammonium sulphate fractionation according to a procedure to be described in a following report.

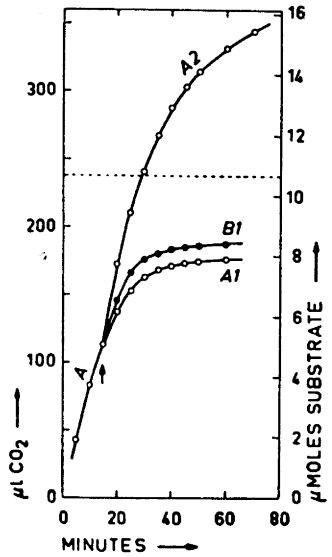

Fig. 2. Enzymatic hydrolysis of tabun by rat plasma (A), and the effects of the addition of a second portion of enzyme (rat plasma, A1; purified kidney enzyme, B1) and substrate (2). *Cf.* Fig. 1.

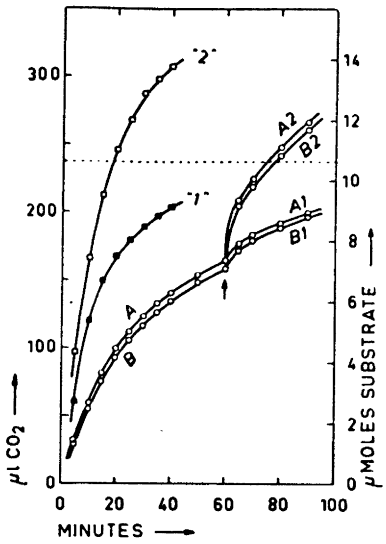

Fig. 3. Enzymatic hydrolysis of tabun by two purified preparations (A and B) of swine liver phosphorylphosphatase, and the effects of the addition of a second portion of enzyme (1) and substrate (2); prepn. A purer than prepn. B. Curves "1" and "2" refer to systems where the concentrations of enzyme and substrate respectively were doubled from the beginning of the reaction. *Cf.* Fig. 1.

RESULTS

Human plasma phosphorylphosphatase. The hydrolysis curve (Fig. 1) showed that tabun was hydrolysed to almost 100 %, suggesting that both the optical isomers of the substrate were split by this preparation. Two identical reaction mixtures were used, and after 60 min when the reaction had come to completion, the same amounts of substrate and enzyme, respectively, as present from the beginning of the experiment were added in order to double the concentration of the two constituents. The addition of more enzyme had no effect, confirming that all the substrate had been used up. After adding the second portion of substrate, on the other hand, the hydrolysis reaction started again with a rate somewhat lower than was observed with untreated enzyme. The lower reaction rate was probably due to enzyme inhibition by the degradation product(s) of tabun.

It will be noted in Fig. 1 and also in the following figures that the theoretical 100 % hydrolysis of the substrate was never reached. This was due to the spontaneous hydrolysis of tabun, *i.e.*, the substrate concentration at the moment of mixing enzyme and substrate is lower than the actual amount of substrate dissolved; it is impossible to avoid such spontaneous hydrolysis

of the substrate solution before use, for practical reasons. The spontaneous hydrolysis curve is inserted in Fig. 1, and was obtained by replacing the enzyme solution with the bicarbonate solution. The acid degradation product of tabun formed (dimethylamido-ethoxy-hydroxy-phosphine oxide) gives rise to an instantaneous production of CO_2, when the substrate solution is mixed with the bicarbonate containing enzyme solution.

Rat plasma phosphorylphosphatase. Rat plasma splits tabun at about the same rate as human plasma. In the experiment shown in Fig. 2 the second portion of substrate and enzyme, respectively, were added before the reaction had come to completion. The rat plasma enzyme seems to split one of the stereoisomers at higher rate than the other isomer. This result confirms the observation reported previously by Hoskin and Trick [3].

With the *rabbit plasma phosphorylphosphatase* similar results were obtained, but the stereospecificity of this enzyme is less pronounced than that of the rat plasma enzyme. This was obvious from an experiment where the rabbit plasma was added to a mixture in which one of the isomers of tabun had been split completely by the kidney phosphorylphosphatase (Fig. 4).

Swine kidney phosphorylphosphatase. The hydrolysis of tabun by purified enzyme of swine kidney (Figs. 1 and 4) is readily interpreted on the basis of enzyme stereospecificity with respect to the substrate. After the gas evolution during the first minutes due to the decomposition of tabun before the addition of the substrate solution to the bicarbonate system, a rapid hydrolysis was observed which came to completion when about one-half (120 μl) of the theoretical yield of gas was evolved. Then the reaction rate became relatively low; this slow reaction was partly due to the spontaneous (non-enzymatic) hydrolysis of the other stereoisomer of tabun and partly to the enzymatic hydrolysis of that isomer. The addition of a second portion of enzyme did not change the reaction rate; after adding a second portion of substrate, on the other hand, the reaction started again with a rate which was lower than following the addition of the first portion of substrate. It is suggested that the phosphorus containing reaction product inhibits the enzymatic hydrolysis, thus explaining the lower reaction rate.

The composition of the reaction curve by two hydrolysis rates are further illustrated in Fig. 5.

Swine liver phosphorylphosphatase. A purified preparation of this enzyme behaved similarly to the kidney enzyme, but the difference between the hydrolysis rates of the two stereoisomers was less pronounced for the former enzyme (Fig. 3).

Studies with mixed enzymes. In order to find confirmation for the suggestion put forward above that human plasma phosphorylphosphatase splits both the stereoisomers of tabun, the following experiment was performed (Fig. 4). The substrate was hydrolysed by the kidney enzyme, and when the enzymatic hydrolysis had come to completion a purified preparation of human plasma enzyme was added to the reaction mixture. It was found that the plasma enzyme split that isomer of the substrate which had not been attacked by the kidney enzyme. A similar result was obtained when the rabbit phosphorylphosphatase was added to the reaction mixture. The same amount

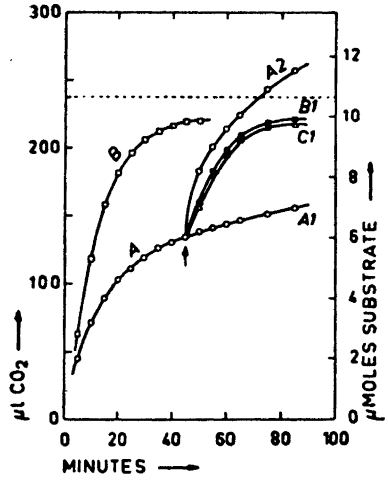

Fig. 4. Enzymatic hydrolysis of tabun by a purified phosphorylphosphatase preparation from swine kidney (A) and the effect of purified phosphorylphosphatase from human serum (B1) and of rabbit plasma (C1) on the reaction mixture. The hydrolysis curve for the purified enzyme from human serum (B) is inserted for comparison. *Cf.* Fig. 1.

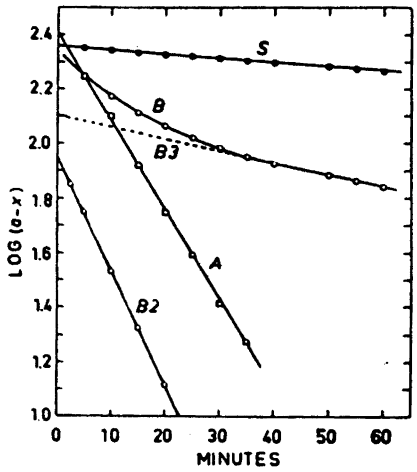

Fig. 5. Graphical evaluation of first-order reaction constants for the enzymatic hydrolysis of tabun by purified phosphorylphosphatase preparations from human serum (A) and swine kidney (B) and the spontaneous (non-enzymatic) hydrolysis of the substrate (S). B3, extrapolated line to estimate k_3 (actually $k_1 + k_3$), and to obtain B2, the line necessary for the estimation of k_2. Experimental values taken from Fig. 1. *Cf.* text.

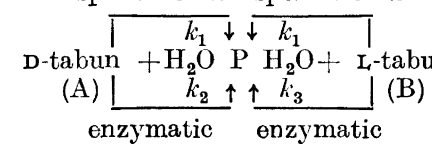

of gas was finally evolved as when the human plasma enzyme hydrolysed the substrate alone from the beginning.

Rat plasma behaved differently in these experiments compared with human and rabbit plasma: it was not found possible to hydrolyse the "non-attacked" isomer. In a similar experiment performed, the result of which is shown in Fig. 2, it was likewise demonstrated that the rat plasma enzyme split the same isomer of tabun as did the kidney enzyme.

DISCUSSION

The results reported above show that the enzymatic hydrolysis of tabun by certain enzyme preparations (especially those from the kidney and liver) is composed of at least two simultaneous reactions. The explanation, is, most probably, that tabun contains an asymmetric phosphorus atom and thus exists in two optically active isomers which are hydrolysed enzymatically at different rates. This idea, first pointed out by Hoskin and Trick [5], is clearly demostrated by a purified enzyme preparation from swine kidney (Fig. 1). The data obtained in this experiment were used to calculate the reaction constants according to a classical graphical technique, and the results are recorded in Fig. 5.

When a racemic mixture of tabun is used as substrate for this particular enzyme (kidney phosphorylphosphatase), the following four first-order reactions are suggested to take place simultaneously (rate constants in brackets): the spontaneous hydrolysis (k_1 which is the same for the two isomers), the enzymatic hydrolysis of the D-isomer (k_2) and the enzymatic hydrolysis of the L-isomer (k_3). Whether the reaction products (P) contain dimethylamido-ethoxy-hydroxy-phosphine oxide in an optically active form or as a racemic mixture has not been investigated:

The four reactions are represented by the following differential equations:

Spontaneous:	Enzymatic + spontaneous:
$-\frac{d(A)}{dt} = k_1(A)$	$-\frac{d(A)}{dt} = k_1(A) + k_2(A)$
$-\frac{d(B)}{dt} = k_1(B)$	$-\frac{d(B)}{dt} = k_1(B) + k_3(B)$

If $\log (a - x)$ (a = original amount of substrate, x = amount of substrate hydrolysed spontaneously and/or enzymatically after t min) is plotted against t, a straight line is obtained for the spontaneous hydrolysis, and from the slope of the line the rate constant, k_1, was found to be 0.21 h^{-1}. The curved line (B) representing the enzymatic hydrolysis by the kidney enzyme (*cf.* Fig. 1, B) indicates that this reaction can be resolved into two first-order reactions, represented by the line B3 (extrapolation of line B to the ordinate) and the line B2 (obtained by subtracting line B3 from B) (Fig. 5). The line B3 in its turn is composed of the spontaneous (k_1) substrate hydrolysis and the enzymatic (k_3) hydrolysis of the slow reacting stereoisomer. The numerical values of k_3 and k_2 obtained were 0.39 h^{-1} (= 0.60 — 0.21) and 5.71 h^{-1}.

The enzymatic hydrolysis of tabun by the purified human plasma phosphorylphosphatase is a first-order reaction, indicated by the straight line obtained when the experimental values from Fig. 1 are analysed according to the same graphical method. The numerical value of the reaction constant in this case was 4.45 h^{-1}. This enzyme, therefore, split both the stereoisomers of tabun at the same rate.

It will be noted that the hydrolysis reaction proceeded in a medium of pH 7.6 at which pH the P-CN is the only linkage broken, both spontaneously [7] and enzymatically [1].

In the experiments reported by Hoskin and Trick [5], using rat serum as the enzyme source, the reaction constant for the spontaneous hydrolysis of tabun was found to be approximately five times greater than that for the slow reaction observed during the enzymatic hydrolysis. It is difficult to

find a plausible explanation for this observation. Such an unexpected difference between the two rate constants has not been found in any of our experiments.

It has not been possible to supplement this investigation by observing changes in optical rotation during the reactions. This is mainly due to technical reasons: a comparatively high tabun concentration is necessary for polarimetric determination, and there are difficulties in getting the enzyme solutions clear enough to make observations of optical rotation possible. Using rat serum, Hoskin and Trick [5] reported some data from polarimetric determinations which indicated that the dextrorotatory isomer of tabun is more rapidly hydrolysed enzymatically. It is likely that this isomer also is the form of tabun which is more readily attacked, for example, by the kidney phosphorylphosphatase.

The results obtained in the present investigation with various enzyme preparations support the idea that there exists a variety of phosphorylphosphatases. The enzyme present in human plasma differs from those present in the kidney and liver by not showing stereospecificity. Furthermore, the enzymes of rat and rabbit plasmas behave differently in this respect both from the human plasma enzyme and the enzymes present in the organs studied. In a report to be published in due course, further support for the complexity of phosphorylphosphatases will be discussed.

The author wishes to express his sincere thanks to Professor Gustaf Ljunggren, Chief of the Research Institute of National Defence, Department 1, for his continual interest in these investigations. He is greatly indebted to Miss Toril Isachsen for skilful technical accistance.

On the Synthesis of Protein and Polynucleotides in Spores of *Penicillium brevicompactum*

E. HAMMARSTEN and H. PALMSTIERNA

Department of Bacteriology, Karolinska Institutet, Stockholm, Sweden

Spores of *Penicillium brevicompactum* have been cultivated in submerged cultures, until, after 10 hours, the very first morphological signs showed a beginning development of mycelia.

In this system the net synthesis of ribonucleic acid (RNA) started during the first 30 minutes of cultivation and preceded the net synthesis of protein.

No measurable net synthesis of desoxyribonucleic acid (DNA) was found before 8 to 10 hours of cultivation. The amounts of DNA present in the spores is very low compared to animal and bacterial cells.

The net syntheses were determined by direct measurements of amounts and were investigated by tracer methods.

EXPERIMENTAL

Microbiological methods. Spores of *P. brevicompactum* were spread on Czapek-Dox maltose agar plates and grown two weeks at 25°C. After this period the plates were placed at room temperature for another three weeks. The spores were then removed by a soft sterilized brush. The pooled material was freed from contaminating mycelia by filtering a suspension in glass-distilled water at 0°C through Pyrex glass wool. No mycelia were found in the filtrate, as checked by means of phase contrast microscopy. In order to reduce the culture volume and to ascertain a rapid growth of the spores, the cells were kept submerged by continuous shaking and aeration. The medium used was the salt-glucose medium devised by Czapek-Dox. The glucose concentration, however, was only one tenth (0.4 %) of the one commonly used in their medium. The glucose was labeled in all carbon atoms with ^{14}C. The specific activity was 190 c.p.m. per μg of glucose carbon.

The culture volume was 10 litres. Inoculation was made with approximately 5 g of spores calculated as dry weight. The culture was aerated at a rate of 1.5 litres per min and litre of medium. The air was dispersed by a sintered glass filter.

In order to check if the spores would develop into mycelia in this medium, a 1 litre culture had previously been inoculated with about 5 mg of spores. After 3 days 700 mg of dry mycelium were harvested. The first sign of morphological changes were found between 10 and 12 h after inoculation in the form of a small bud on some cells. The spores in the main experiment were controlled in this way too, and the buds after 10 h were found to be extremely rare.

Chemical methods. The cells were disintegrated in a Griffith shaker with glass beads (0.28 mm in diameter) in 30 % ethanol (v/v) at 0°C. After 24 h no spores remained, and the disintegration seemed to be complete as checked by phase contrast microscopy. The poly-

nucleotides were isolated from samples of about 500 to 800 mg of dry spores according to Hammarsten [1]. RNA was degraded to mononucleotides by alkaline hydrolysis. The hydrolysates of RNA were chromatographed on Dowex 2 resin according to Cohn [2] and Hurlbert *et al.*[3] with 4 N formic acid-0.2 M ammoniumformate for elution. DNA was degraded enzymatically according to the method of Hurst *et al.*[4] as modified by Cohn [5]. Elution from Dowex 2 resin was accomplished according to Hurlbert and Potter [3] with 1 M ammonium formate-formic acid (pH = 4.8). Guanine was isolated after acid hydrolysis of guanylic acid (Dowex 50). Adenine from RNA and the pyrimidine nucleotides from RNA and DNA were only so far purified that it could be shown that their labeling did not significantly deviate from that of guanine. Adenine from DNA could not be isolated on account of the minute amounts of DNA in our material. The labeling of purines and polynucleotides followed the pattern found for *Escherichia coli B* in the lag-phase [6].

The activity of guanine was determined by measuring the activity at "infinite" thinness on lead planchets in a windowless gas flow counter. The amount of guanine was estimated from spectrophotometric data.

The protein fraction was isolated by the trichloracetic acid method of Schneider after mechanical disintegration of the cells in the way mentioned. The precipitate was boiled in 6 N hydrochloric acid for 18 h. The hydrolysate was filtered through Pyrex glass wool and the hydrochloric acid removed *in vacuo*. The nitrogen to carbon ratio was determined in four samples and found to be 0.26 ± 0.03.

All samples with a low labeling were counted to an accuracy of 10 % and the others to 5 %.

RESULTS AND DISCUSSION

It is shown in Table 1 that the RNA-phosphorus increased rapidly during the first half hour after inoculation. Since there was no corresponding high activity in the RNA-guanine, it is possible that the net synthesis to a large part derived from unlabeled procursors within the cells and only to a smaller part from the medium. Another possibility is the formation of phosphopentose backbone before incorporation of guanine. In recent work on *E. coli* in the lagphase [6] the cells had been labeled with ^{13}C before the actual culti-

Table 1.

Cultivation time, h	mg dry spores per litre of culture	mg phosphorus in RNA per litre of culture	mg phosphorus in DNA per litre of culture	mg nitrogen in protein per litre of culture	Counts per min per μg carbon in:		
					RNA guanine	DNA guanine	Protein
0	598	1.78	0.010	28.1	—	—	—
1/2	596	2.47	0.010	33.4	0.7	0.4	0

8	801	4.43	0.016	46.2	43.2	0.5	21.5
10	944	5.41	0.015	61.0	68.5	6.8	38.1

vation experiment. It was found in that work that the syntheses of polynucleotides and also of proteins used material from cell precursors in the earliest stages of growth in the lagphase.

During the period that followed, the increase per hour in RNA-phosphorus in the spores was between 7 and 12 %. Owing to the very small amounts of DNA present in the spores no very exact estimates could be made of the DNA-phosphorus. In contrast to the rapid incorporation of ^{14}C into RNA, the DNA did not show any appreciable incorporation.

The proteins did not incorporate ^{14}C during the first hour of growth. Compared to the RNA the specific activity of the protein carbon remains at low values during the first 4 to 5 h. Thereafter the incorporation of ^{14}C had still a lower gradient than the incorporation into RNA. In view of the incorporation and protein synthesis from labeled precursors within the cells found in *E. coli* [6] it is quite probable that some protein in the spores has been synthesized from precursors within the cells during the period when proteins remain unlabeled. If the protein had derived all its carbon from medium carbon exclusively, the specific activity of the protein carbon at 10 h after inoculation would have been approximately half that of the carbon in the medium glucose. It is, however, only 20 % of the specific activity of the medium glucose. This probably means that a large part of the protein carbon was derived from cellular carbon sources present at the moment of inoculation (or partly from CO_2). The figures for protein net synthesis are irregular owing to technical difficulties arising from the capsular substances.

Studies on *Escherichia coli* B in the Lag Phase of Growth

N. A. ELIASSON, E. HAMMARSTEN, H. PALMSTIERNA and S. ÅQVIST

Karolinska Institutet, Departments of Chemistry and Bacteriology, Stockholm, Sweden
and

L. REIO

Wenner-Gren Institute, Department of Physiological Chemistry, Stockholm, Sweden

The growth of *E. coli* B in the lag-phase of growth was investigated by analysis of the amounts of proteins, RNA, DNA and glycogen. The cells had been labeled with ^{13}C in a preculture running into the stationery phase, and were then cultivated in a medium labeled with ^{14}C and ^{15}N.

The relative increase in amount per litre culture followed the sequence: Glycogen>RNA>DNA>protein.

The role of cell precursors relative to that of the medium is discussed.

Previous work [1,2] led us to investigate some processes during the lag phase that starts when *E. coli* B cells, harvested from a culture in the stationary phase, are incubated in a fresh medium and prepare themselves for fission. Preliminary experiments with cells labeled with ^{15}N had shown that a redistribution of the nitrogen in the cells occurred simultaneously with an incorporation of nitrogen from the medium. This implies a very complex metabolic pattern in the lag-phase which may correspond to similar stages of growth in other cells. In spite of this anticipated complexity we have tried the method of prelabeling the cells and then cultivating them in a fresh medium labeled in another way. The cells were prelabeled with ^{13}C. The new medium contained lactate ($^{14}CH_3CH(OH)COO^-$) as the only carbon source and ^{15}N-labeled ammonium chloride as the only nitrogen source. Samples were taken at zero time and after 5, 25, 50 and 80 min of cultivation.

The rates of relative increase in amounts were found to be: Glycogen > RNA > DNA > Proteins (Fig. 1.). This is in accordance with earlier findings [1,2]. No carbon, once incorporated, disappeared from the cells. The proteins incorporated carbon from cell sources during the first 50 min. The same was the case

with glycogen during the first 50 min. The proteins incorporated practically all their nitrogen from the medium but RNA and DNA used rather much nitrogen, that was present in the cells at the moment of inoculation.

EXPERIMENTAL

E. coli B was grown in Friedleins salt-sodium lactate medium. The lactate was labeled with ^{13}C in the methyl group. The atom per cent excess ^{13}C in the medium was 5.45 at zero time and 2.35 after 18 h cultivations. The cells were harvested and washed in tracer-free medium and then inoculated into fresh medium with ^{14}C label in carbon 3 of the lactate and ^{15}N label in the ammonium chloride. The cultivation was carried out in four 30 litres pyrex flasks in a waterbath at 37°C. The culture volume was 20 litres. The cultures were aerated at a rate of 1 litre per min and litre of medium. The flasks were arranged around a vertical axis and were driven back and forth by a compressed-air motor. The flasks were emptied at appropriate times and the cultures cooled with a cooling coil. The taking of a sample and its cooling to +3° to +4°C took 3,5—4 min. A small sample was taken for counting the number of cells under the phase contrast microscope in a Bürker chamber and the rest of the culture was centrifuged at 0°C at 2 500 × *g* for 2 h in stainless steel tubes fitted with baffles and a netting of stainless steel at the bottoms of the tubes to prevent the cells from whirling up during the retardation of the centrifuge. The number of cells remaining in the supernatant was determined by counting the number of colonies produced on endo agar plates. Less than 1.5×10^4 cells/ml were left in the supernatant. Tests on blood and endo agar plates did not show any contamination with foreign cells. The sediment was washed 3 times at 0°C with tracer-free medium in a centrifuge at 25 000 × *g*. The harvesting of the cells and the centrifuging were carried out on a quantitative basis in order to ensure the calculation of the number of cells per unit final dry weight.

Previously we had tried to calculate the number of cells in a freeze-dried sample by resuspending part of the sample and counting the cells. No accurate estimate could be made in this way, since part of the cells disappeared, possibly due to a fragility induced by the freeze-drying process. For this reason the cell concentration in the culture was estimated and the cells harvested and lyophilized in a quantitative way. The dry weight was estimated by weighing a small part of the lyophilized material and drying it to constant weight (90°C, P_2O_5 vacuum). The figures listed in Table 1 are calculated on dry weight and this weight is corrected for the amount of medium solids enclosed in the sample (about 5 % of the dry weight). It was assumed that the loss in weight during the drying procedure corresponded to water from a solution with the same content of solute as the medium. This approximation may be justified, especially as the corrections were too small to affect the main conclusions.

The extractions of DNA and RNA were carried out on 400 to 500 mg dry cells. The cells were mixed with 10 ml of pyrex beads (0.28 mm diam.) and 30 ml of 30 % (v/v) cold ethanol and disintegrated by shaking them at high rates in a Griffith shaker at — 15°C. The contents remained in the same tube through all manipulations. After freeze-drying and extraction with boiling ethanol-ethylether (3:1) the lipidfree cells were extracted for DNA and RNA according to Hammarsten [8]. The hot TCA-extractable phosphorus in the undissolved residue was determined after combustion. The following values were obtained and are expressed as per cent of the total phosphorus in the extracted polynucleotides:

Cultivation times in min	0	5	25	50	80
Phosphorus in per cent of phosphorus in polynucleotides	7.1	9.0	8.3	6.6	7.6

Over 90 % of the polynucleotides were thus extracted.

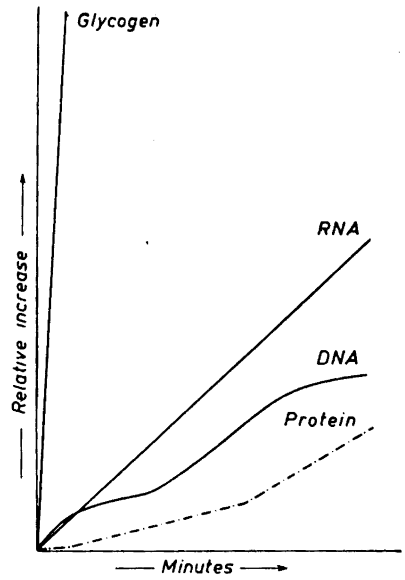

Fig. 1. (From Table 2.)

After hydrolysis with alkali the mononucleotides of RNA were separated [4] on Dowex 2 (elution with formic acid). Cytidylic and adenylic acids were further purified on Dowex 2 (elution with 0.01 N HCl). These two fractions and uridylic and guanylic acids from the formic acid elution were separated together on Dowex 50 in the H^+ form, previously washed with water until the eluate was neutral. Uridylic acid was eluted with water, cytidylic acid with 0.01 N HCl, guanylic and adenylic acids (well separated from each other) with 0.02 N HCl.

Uridylic and cytidylic acids were analysed for tracer content without any further purification. Parts of the guanylic and adenylic acids were analysed in the same way and the rest hydrolysed (1 h, 100°C, N HCl). The products of each nucleotide were separated on Dowex 50 as above. By elution with water the first few tubes showed a very weak light absorption at 260 mμ. This fraction was considered as ribose. Guanine and adenine

80	2.44	2.33	19.1	2.16	4.05	2.72	1.13

were then eluted with 2 N HCl. The bases were mixed and run on a Dowex 50 column (6 × 0.6 cm) and eluted again with 2 N HCl. They were obtained in very small volumes. The different fractions were evaporated and dissolved in water. The amounts of nucleotide carbon were calculated from the determinations of phosphorus. The amounts of purine carbon were calculated from determinations of nitrogen. In both cases (nucleotides and purines) samples were combusted (dry) and total carbon determined as barium carbonate. The amounts of "ribose" were calculated from combustion. The measurements of the radioactivity were performed in a windowless gas flow counter with less than 20 μg of material per cm^2. The corrections for foreign carbon (total carbon by combustion divided by the carbon calculated from determinations of P and N) ranged from 1.2 – 3.0 but was in most cases 1.2 – 2.0. No correction could be made in the case of ribose.

The degradation of DNA was carried out according to Hurst *et al.*[5]. The chromatographic separations were in all essentials the same as for the nucleotides from RNA. The correction terms for foreign carbon were within the same limits as those for the RNA-products.

The protein fractions were determined in separately weighed samples of lyophilized cells. These were disintegrated in the way described above, lyophilized and treated accord-

ing to Schneider. The protein precipitate was hydrolysed for 18 h in 6 N HCl. The hydrolysate was carefully washed out from the glass beads, evaporated and dissolved to a suitable volume. Protein carbon was directly determined by combustion. No correction was made for foreign carbon. The part that was not used for analyses (Tables 1 and 3) was separated on Dowex 50 and starch [6] and 11 of the amino acids were isolated (the two leucines as one fraction). The individual amino acids were run again on very small columns. Total carbon was determined as for the RNA derivatives and amino carbon was calculated from determinations of nitrogen. The quotients for correction varied between 1.1 and 2.0. Most of the amino acids, however, did not contain over 30 % foreign carbon.

The lactates labeled with ^{13}C and ^{14}C in β-position were synthesized according to Reio [7]. Isotopic barium carbonate (^{13}C and ^{14}C labeled) was reduced in two different batches with lithium aluminium hydride into methanol, which in turn was converted to methyl iodide and condensed with acetamino-malonic ester. After hydrolysis alanine was isolated and treated with sodium nitrite yielding sodium DL-lactate. The synthesis of ^{14}C-labeled compounds from barium carbonate to alanine was carried out in a closed apparatus-system, whereby all reaction steps were performed in a short time with a minimum loss of activity. The lactic acids were purified from remaining alanine and salts by passing them through Dowex 50 columns. The determinations of specific activity in the medium at different times were based on direct determinations of lactic acid [8] and countings of 8—4 μg lactic acid before and after a second separation on Dowex 2 and stepwise elution with water to 0.4 N HCl.

DISCUSSION AND RESULTS

The values for the atom per cent excess ^{13}C depend on the rather high corrections for foreign carbon. The determination of carbon as barium carbonate after dry combustion is admittedly not a very exact method. This has certainly

Table 4a. Isotopic data on the components in the protein and nucleic acid and glycogen fractions.

to be considered when using the labeling of carbon for calculations. ^{14}C was determined on plates at "infinite" thinness. The lactates used as substrates were racemic. It was still racemic after the harvesting of the cells. In experiments in which the amount of new synthesized glycogen could be determined accurately and in which probably no "old glycogen" was degraded, this new synthesized glycogen had the same specific activity as the medium glucose, when totally labeled glucose was used. This was certainly not the case when β-labeled lactate was used, as in the present experiments. The specific activity in glycogen was only 30 % of the specific activity of the medium lactate. In recent work[10] on spores from *Penicillium brevicompactum* with ^{14}C-labeled glucose as carbon source it was shown that RNA in the lag phase incorporated considerable amounts of cellular carbon. It seems also that the methyl carbon in lactate has not been used to the same extent as carbon atoms 1 and 2.

Table 5, col. 4, demonstrates that the product of ^{13}C in total cells and their dry weight per litre was constant. The variations are irregularly distributed. This indicates that little if any carbon had left the cells during the cultivation time. The assumption is made that all carbon-containing substances in the cells from the stationary phase of preculture were labeled with ^{13}C. The same calculation for RNA, protein and glycogen show greater irregularities which could be expected on account of the difficulties of the tracer analyses in the purified substances. Still, the figures show that there cannot be any considerable exchange of the carbon present in RNA at zero time with other cellular components during the 80 min incubation (Table 6).

The protein fraction incorporated carbon from other cellular sources during the first 5 min of incubation which is indicated by the rise in ^{13}C content (Table 7, col. 4) and by the rise in ^{13}C-labeling in several amino acids during the same period (Table 4). During the following period from 5 to 80 min after incubation the product of protein carbon per litre and atom per cent excess ^{13}C remains fairly constant, demonstrating that the original carbon in proteins was not, or only to a small extent exchanged during this period. Glycogen had incorporated carbon from other cellular sources during the first 50 min (Table 7, col. 7). Protein carbon was higher labeled than glycogen and the amount of this was not more than 1 to 15 % of the protein carbon. The incorporation of carbon from the medium into glycogen starts during the first 5 min (Table 3, col. 8). It may well be that cell carbon, incorporated into glycogen, is derived from remaining ^{13}C-lactate or other low molecular precursors. A small part may have been derived from broken-down protein.

In Table 8 the quotients are given between the increases from zero time at each investigated cultivation time in amounts per litre found by direct analysis (numerator) and the same amounts (denominator) calculated from the labeling. In this calculation the total amount per litre at each investigated cultivation time was multiplied with the labeling at the corresponding time in relation to the labeling in the medium.

The net synthesis of protein in 80 min, determined by nitrogen analysis (54 %) agrees well with the synthesis as calculated from the labeling with ^{15}N (53 %). This shows that the incorporation of ^{15}N into protein may be

taken as a measure of the net synthesis of protein during active growth in bacterial cells at least when the sole source of nitrogen is NH_4Cl.

The quotients (Table 8) calculated for protein at 5 min are probably not significant, since the figure for net synthesis is too near the limits of the analytical error. Otherwise the quotients both for total cells and for proteins show no systematical variation. Thus the protein incorporated its nitrogen

exclusively or nearly so from the medium. The quotients from the calculation from ^{14}C increase with the cultivation time. As protein incorporates very little if any carbon from the cell carbon between 5 and 80 min, the possibility is not excluded that during this period of carbon incorporation some change in selectivity occurs in the use of the three lactate carbons. The same relative decrease of the incorporation of labeled carbon from the lactates in the medium turns up in the quotients for glycogen, though less marked. The quotients for RNA as calculated from the content of ^{15}N go in opposite way from 2.30 to 1.21, showing that RNA in earlier stages incorporates comparatively much nitrogen from the cells, whilst the medium as time passes on is furnishing more and more of the nitrogen. The quotients calculated from ^{14}C are probably too inaccurate for being safely interpreted. It was shown (Table 6) that RNA does not change its total ^{13}C-content much. The fact that the quotients (Table 8) are high may signify that carbon atoms 1 and 2 in the medium-lactate are more extensively used than carbon 3. The quotients for DNA are even more erratic than those for RNA but show the same general tendency. The most rapidly formed of the four components investigated, glycogen, was using cell carbon proportionally more than any of the others, and RNA (and DNA) acted in a similar way in respect to nitrogen in early stages of synthesis. Except for a small uptake of cellular carbon during the first 5 min protein was mainly synthesized from the medium.

The very first part of the lag-phase seems thus to be characterized by a redistribution of the cellular carbon. This redistribution still operates later on in the lag-phase, but to a smaller extent. In the later part of the lag-phase the synthesis from medium constituents dominates.

The Infra-Red Absorption Spectra of Some Amide- and Dipeptide-Metal Chelates

ANDREAS ROSENBERG

Institute of Biochemistry, University of Uppsala, Uppsala, Sweden

Changes in the infra-red absorption spectra of amino acid amides and dipeptides after chelate formation with Cu(II) are interpreted as a result of the shift in the resonance equilibrium of the peptide group. The magnitude of these changes for chelates of Cu(II), Ni(II) and Zn(II) has been used as a measure for the interaction of metal ions with the peptide group.

The behaviour of the infra-red (IR) absorption frequencies of $-NH_2$ and -COOH groups in amino acid-metal chelates was examined in a previous publication.[1] In the present investigation the behaviour of the amide group, as represented by its IR absorption spectra, is studied in some amide- and dipeptide-metal chelates. The chelation of peptides and amides by metal ions has mainly been studied in solutions, by methods aimed at the determination of complex constants.[2-4] A number of crystalline chelates has been prepared and analyzed and the ratio of metal to ligand thus determined.[5,6] The need for a better elucidation of metal-peptide bond interaction has arisen from studies of metal-activated enzymes. Smith and Spackman [7], for example, explain the role of metal ions in proteolytic enzyme systems by assuming a metal chelate bridge between the enzyme and the substrate molecule. The interaction of the peptide group with the metal ion is viewed as resulting in an electron displacement rendering the bond susceptible to nucleophilic attack by hydroxyl ions. If this were the case, the IR frequencies of the amide linkage should be considerably influenced by the metal ion. An IR study of chelate formation between metals and peptides has been published by Chouteau [8]. Since Chouteau's main interest was the investigation of the biuret reaction, the solid chelate compounds were precipitated or evaporated at extremely high pH values. Working at the pH values of 12—13, Chouteau found that the frequencies ascribed to the amide group did change considerably. The behaviour of the amide group at such extreme pH values has probably no direct bearing on the biological role of the metal ions. The solid chelates of peptides used in the present examination are all of neutral character, isolated from aqueous solutions where the pH value never exceeded 9.

PREPARATIONS

Bis-glycinamido-Cu(II)monohydrate, $(GA)_2Cu,H_2O$, Bis-L-leucinamido-Cu(II), $(La)_2Cu$, and Bis-L-leucinmethylamido-Cu(II) trihydrate, $(LMA)_2Cu,3H_2O$, were prepared from the corresponding amides with Cu(II) acetate as described by Rising and Yang [9] with the modification that the volume of the reaction mixture was increased to prevent an instantaneous precipitation. The solution was then slowly evaporated until the reddish-blue crystals appeared. The crystals were dried over P_2O_5 and analyzed . The $(LMA)_2$-Cu(II) showed a tendency to crystallize with varying numbers of water molecules. These differences were not essential for the IR investigation, as the different species showed only changes in the diffuse background absorption.

Glycylglycino-Cu(II) trihydrate, GG-Cu,$3H_2O$, DL-alanylglycino-Cu(II) dihydrate, AG-Cu,$2H_2O$, DL-leucylglycino-Cu(II) hydrate, LG-Cu,H_2O and Glycyl-L-leucino-Cu(II) hydrate GL-Cu, H_2O were prepared from commercial dipeptides and $CuCO_3$ according to Tomita *et al.*[5]. The crystalline chelates were recrystallized from water and washed with alcohol. When dried over P_2O_5, the dark blue trihydrate of glycylglycine is converted to a blue monohydrate. The monohydrate of GG-Cu(II) can be obtained directly when the chelate is precipitated from aqueous solution by ethanol.

The Bis-glycylglycino-Ni(II) didhydrate, $(GG)_2Ni,2H_2O$, was obtained as pale blue crystals. An aqueous solution of GG was vigorously shaken with an excess of freshly precipitated Ni(II) hydroxide. The pH of the suspension was adjusted to approx. 8. The residual Ni(II) hydroxide was removed by filtration. The volume of the blue solution was reduced and ethanol added. The chelate crystallized even from a solution of GG and $NiCl_2$ in proportions 2 to 1 when the pH of the solution was adjusted to 8 and ethanol added.

Bis-glycylglycino-Zn(II) dihydrate, $(GG)_2Zn,2H_2O$, was prepared from $Zn(OH)_2$ and GG. An excess of freshly precipitated and washed $Zn(OH)_2$ was added to an aqueous solution of GG. The pH of the suspension was adjusted approx. to 8 and the suspension shaken vigorously before filtration. The chelate crystallized as white needles upon addition of ethanol. Bis DL-alanylglycino-Zn(II) dihydrate was obtained by the same method.

Table 1. Analyses.*

* N was determined according to Dumas and the metals titrated with EDTA.

Glycinamide-hydrochloride, GA, HCl, was prepared according to Bergell and Wülfing [10]. Mp. for hydrochloride: 185—187° and for free glycinamide 64—65°.

L-Leucinamide, LA, was prepared from L-leucine ethyl ester according to Yang and Rising [11]. The L-leucine ester used was obtained according to Fischer [12] M.p. found for L-leucinamide hydrochloride 235°. L-Leucine methylamide, LMA, was prepared from

L-leucine ethyl ester. The ester was cooled with dry CO_2 in ethanol and an equal volume of liquid methyl amine was added. The glass tube containing the mixture was sealed and kept at 50° for 3 days. The amide was then distilled *in vacuo*; bp/9 mm Hg 139°C. (Found: N 19.17. Calc. 19.46).

Glycylglycine ethyl ester, GGet, was obtained by the same method as L-leucine ester. (Found: N 14.30. Calc. 14.25).

A Perkin-Elmer model 21 spectrophotometer equipped with CaF_2 and NaCl prisms was used for the IR-absorption measurements. The chelates were pressed into transparent KBr discs as described by Schiedt and Reinwein [13]. Ir order to achieve the best resolution possible, the IR absorption of the chelates was generally measured at low temperature. The low-temperature cell and the effects of low temperature have been described previously [1]. The values obtained at normal temperatures are directly compared with those obtained at low temperatures only when the temperature change has no effect on the position of the absorption bands.

The deuterium exchange was obtained by recrystallizing the substance under investigation from 99.7 % D_2O.

RESULTS OF THE ABSORPTION MEASUREMENTS

The first chelates investigated were the Cu(II)-amide chelates. Fig. 1—3 show the IR-absorption in the 3 μ region for 3 pairs of substances. GA and $(GA)_2$ Cu, H_2O, LA and $(LA)_2$ Cu, LMA and $(LMA)_2$ Cu, $3H_2O$. All the absorption curves except that for the pure LMA were obtained at low temperatures. The spectra of LMA can still be compared with the spectra of its Cu(II) chelate as the positions of the chelate frequencies were not influenced by a change of temperature.

The positions of the absorption bands due to N-H or O-H stretching frequencies are compiled in Table 2.

Table 2.

	Stretching frequencies in the 3 μ region		
GA	3 347	3 279	3 137, 3 084
$(GA)_2,Cu,H_2O$	3 329	3 218	3 106
LA	3 349	3 279	3 096
$(LA)_2Cu$	3 323	3 202	3 112
LMA	3 312		3 086
$(LMA)_2Cu,3H_2O$	3 232		3 117

Figs. 4—6 show the 6 μ region of the same chelates.

The amides themselves show, in this region, two well-known bands produced by the amide group frequencies. In the following these bands are referred to as the amide I and amide II bands.

The dashed curves in Figs. 4—6 represent the absorption of the deuterated compounds.

Deuterization removes from this region the possible amide II band and all the bands due to N-H bending movements. The frequencies of the free amides and amide hydrochlorides are presented in Table 3 together with the corresponding values for Cu-amide chelates.

Table 3.

	Solid		Solution	
	Amide I	Amide II	Amide I	Amide II
GA	1 695	1 608	1 686	1 553
GA, HCl	1 709	1 597		
$(GA)_2Cu,H_2O$	1 570			
LA	1 664 1 681	1 600	1 678	1 548
LA, HCl	1 678 1 686	1 618		
$(LA)_2Cu$	1 588 1 554			
LMA	1 658	1 541	1 678	1 520
LMA, HCl	1 675	1 572		
$(LMA)_2 Cu,3H_2O$	1 567			

The next group of substances examined, were the metal chelates of simple dipeptides. Fig. 7 shows the 3 μ region of GG and GG-Cu(II) trihydrate.

Fig. 8 shows the same spectral region of three further dipeptide-Cu(II) chelates. The AG-Cu(II) has two molecules of water attached to the chelate molecule, the other two LG-Cu(II) and GL-Cu(II) posess only one molecule of water each. The next two figures (9 and 10) show the IR absorption of the chelates in the 6 μ region. Fig. 9 represents the absorption of GG-Cu, H_2O.

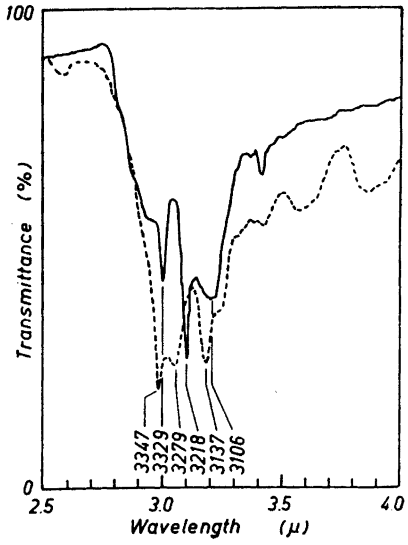

Fig. 1. IR absorption of glycinamide, GA, ---------- and of $(GA)_2Cu,H_2O$ ————

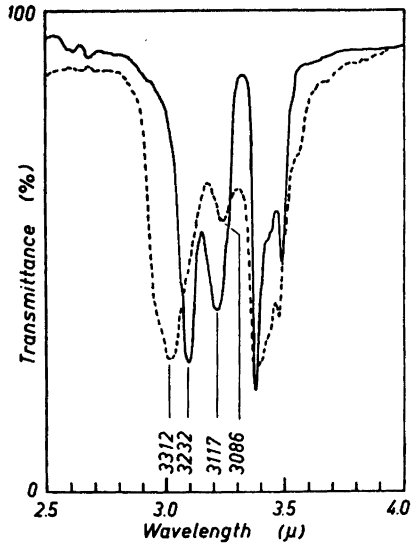

Fig. 3. IR absorption of L-leucinmethylamide, LMA, ---------- and of $(LMA)_2Cu,3H_2O$ ————

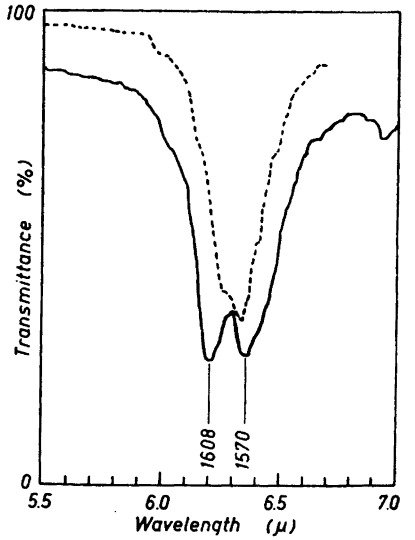

Fig. 4. IR absorption of $(GA)_2Cu,H_2O$ ———— and of the deuterated compound ----------

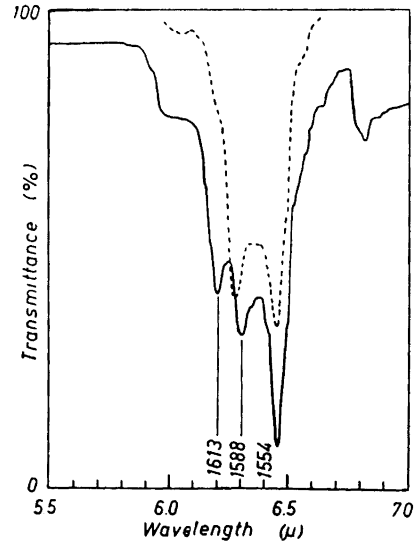

Fig. 5. IR absorption of $(LA)_2Cu$ ———— and of the deuterated compound ----------

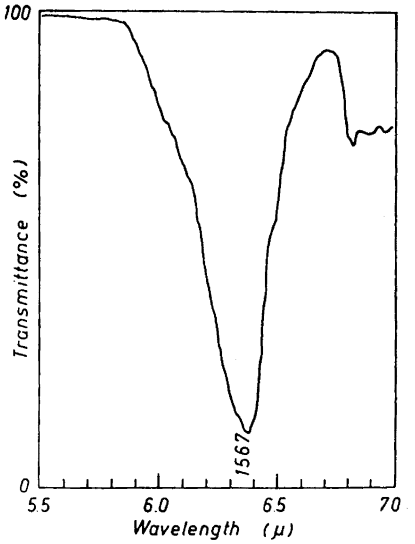

Fig. 6. IR absorption of $(LMA)_2Cu,3H_2O$

The spectrum of the trihydrate shown in Fig. 11 is complicated due to the three water molecules. In order to simplify the picture the chelate was recrystallized from D_2O. The IR absorption of the deuterated compound is represented by the broken curve in Fig. 9. The absorption spectra of the deuterated products of GG-Cu, H_2O and GG-Cu, $3H_2O$ were identical in this wavelength region.

Fig. 10 shows the 6 μ region for three further dipeptide chelates. The values of the two main bands, ν (COO^-) and ν ($-C\overset{O}{\underset{N-}{\ll}}$), are collected in Table 4. The extra bands visible in the figure are due to N-H or O-H bendings as they all vanish after deuterization.

Table 4.

	ν (COO^-)	ν ($-C\overset{O}{\underset{N-}{\ll}}$)
GG-Cu,H_2O	1 592	1 541
AG-Cu,$2H_2O$	1 587	1 548

GL-Cu,H_2O	1 595	1 524

Fig. 11 represents the IR absorption of Cu(II), Ni (II) and Zn(II) chelates of glycylglycine (GG). The absorption in wavelength regions between 2.5-4 μ and 5.5-7.0 μ was measured with a CaF_2 prism, for the region from 7 to 14 μ a NaCl prism was utilized. Low temperature has been used for all of the measurements. As the absorption from water molecules conceals most of the absorption bands of GG-Cu, $3H_2O$ in the 6 μ region, the absorption of the monohydrate, represented by the broken curve, was added to the original spectrum.

The frequencies of the peptide and carboxyl groups for the different forms of GG are collected in Table 5.

Table 5.

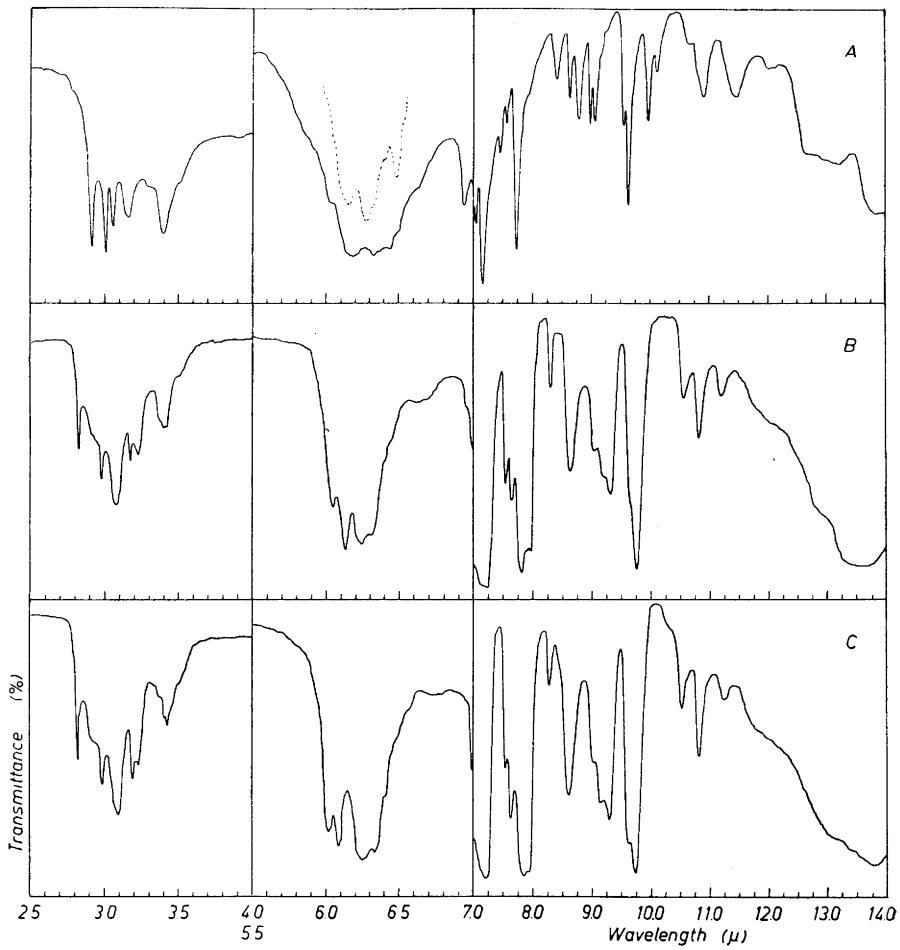

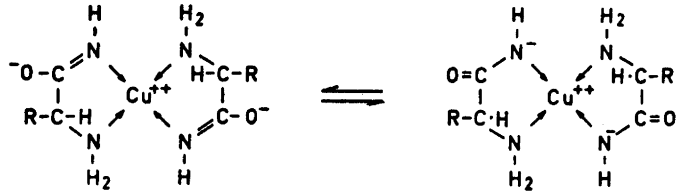

Fig. 11. IR absorption of GG-Cu,$3H_2O$ curve A, of $(GG)_2Ni,2H_2O$ curve B and of $(GG)_2Zn,2H_2O$ curve C.

In order to check the assignments of absorption frequencies in the Zn(II) chelates, the Zn(II) chelates of DL-alanylglycine and glycyl-L-leucine were prepared. $(AG)_2Zn,2H_2O$ crystallized beautifully and showed an IR spectrum in the 6 μ region that was almost identical with the spectrum of $(GG)_2Zn,2H_2O$. The amide I doublet was found at 1 658 and 1 639 cm^{-1}, the absorption of the carboxyl group appearing at 1 600 cm^{-1}. The Zn(II) chelate with glycyl-L-leucine is not included in the experimental part because a chelate with a definite number of water molecules could not be isolated. The product with an undefined number of water molecules exhibited broad absorption bands in the same region as $(GG)_2Zn,2H_2O$ and $(AG)_2Zn,2H_2O$, no absorption being visible below 1 580 cm^{-1}.

DISCUSSION

Amide-Cu(II) chelates. The interpretation of the observed changes in the IR absorption spectra of amide molecules after chelate formation is comparatively simple. The red Cu(II) chelates of DL-leucinamide and glycinamide have previously been isolated and analyzed by Rising and Yang [9]. They found that two amide molecules combine with one Cu(II) ion to form a neutral chelate. $(GA)_2Cu(II)$ crystallizes with one molecule of water whereas $(LA)_2$ Cu(II) lacks water of crystallization. This eliminates the possibility that the neutral molecule is formed by dissociation of hydrogen ions from coordinatively bound water molecules. The results of analyses of the amide chelates prepared for this investigation are in accordance with the values given by Rising and Yang. Potentiometric measurements, recently described by Datta and Rabin [16], confirm the assumption that, in each of the two amide molecules, one hydrogen is ionized from the amide nitrogen so that the chelate formed carries no net charge. The structure of the Cu(II) chelates with amino acid amides can be represented by Fig. 12.

I II

Fig. 12.

These changes in the amide molecule ought to be accompanied by changes in the IR absorption due to hydrogen stretching movements in amino and amide groups and in the intense vibration bands of the amide group in the neighbourhood of 6 μ.

The chelate formation results in a shift of the N-H bond stretching frequencies of amides towards lower wavenumbers. The shift is generally exhibited by amino groups when the free electron pair of the nitrogen is used for bond formation [1,17]. The behaviour of the N-H frequencies observed follows this rule. The spectrum of amides in the 3 μ region is rather complicated as the unsubstituted amides exhibit at least four N-H absorption bands in this region, some of these being certainly influenced by hydrogen bonds with the oxygen of the peptide group. The band structure of the Cu(II) chelates seems to be somewhat simpler. The amino group contributes with two frequencies and the remaining amide N-H with one frequency. It can be inferred from studies of the metal chelates of amino acids [1] that amino frequencies appear at slightly lower wavenumbers than the N-H frequencies in free amides. The Cu(II) chelate of leucine, for example, has its main amino frequencies at 3 308 and 3 240 cm^{-1}. The Cu(II) chelates of GA and LA show 3 frequencies in this region. The band, at 3 106 cm^{-1} for $(GA)_2Cu$ and at 3 112 cm^{-1} for $(LA)_2Cu$,

can thus tentatively be ascribed to the N-H stretching of the amide group. The Cu(II) chelate of LMA shows as expected only two absorption bands in this region. The interpretation of the absorption data of N-H stretchings is not entirely unambiguous as some of the bands are broad enough so that the possibility of two overlapping frequencies is not excluded. At the same time some of these frequencies might be split into two bands due to crystal effects. It must be stressed that, owing to above mentioned difficulties, the position or absence of the amide N-H frequency can scarcely be used as a general indication of the influence of the metal ion on the peptide linkage.

The region of 6 μ is far more suitable for this purpose as the intense amide I frequency can easily be identified. The amide I, at approx. 6 μ, is usually considered to be a stretching frequency of the amide carbonyl in resonance with the C-N bond. Amide I is only slightly influenced by deuterization. The amide II, at approx. 6.2—6.4 μ, is a combination band where the N-H bending movement participates. It is strongly influenced by deuterization. These assignments have recently been reviewed and discussed by Miyazawa *et al.*[14] in connection with the calculation of frequencies for monosubstituted amides. The frequencies of the chelates show a vastly changed picture. The region for amide I is devoid of any absorption, the band structure being markedly shifted towards lower wavenumbers. The picture is further completed by the deuterized compounds, where the absorption due to hydrogen bending movements is removed from this wavelength region. The band remaining must be the stretching frequency of the resonating structure corresponding to the amide I band ($-C\begin{matrix}O\\ \diagdown N-\end{matrix}$). The only deviation from the simple picture expected is the split of this band for $(LA)_2$ Cu. When interpreting these changes, the influence of the hydrogen bonds on the amide I frequency ought to be considered. The positions of the frequencies of free amides in the solid state and in dilute $CHCl_3$ solutions can be compared in Table 3. The frequency changes do not exceed the value of approx. 20 cm^{-1}.

Further, the effect of metal ion-amino group interaction on the amide frequency ought to be considered.

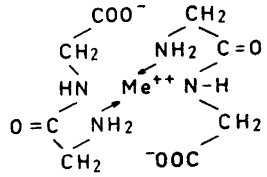
A comparison between the free amide and its hydrochloride can be considered as relevant, the hydrogen ion taking the place of the metal ion. The observed shift of the amide I frequency is at its height approximately 20 cm^{-1} towards higher wavenumbers. The difference between the normal amide I frequency and the frequency observed in Cu(II) chelates is of the order 90—100 cm^{-1}. This can hardly be due to other effects than to the definite shift of the resonance equilibrium of the amide group towards the canonical form (I) in Fig. 12. From his IR studies of the biuret reaction of amides at high pH values, Chouteau [8] puts forth the same explanation.

Dipeptide-Cu(II) chelates. The next step is to compare these results with the IR-absorption of dipeptide-metal chelates. GG-Cu, $3H_2O$ and LG-Cu, H_2O have been crystallized and analyzed by Tomita *et al.*[5] and GG-Cu,H_2O by Manyak *et al.*[6] In all these chelates one dipeptide molecule combines with one Cu(II) ion, Manyak *et al.* proposed the structure III in Fig. 13 for the glycylglycine chelate.

III IV

Fig. 13.

The neutral chelate is formed either by the dissociation of the amide hydrogen or by dissociation from the coordinatively bound water molecule. From titrimetric and spectrometric data Dobbie and Kermack [2], and later Datta and Rabin [4,16], arrive at the conclusion that the dissociation takes place from the peptide group.



The IR absorption of Cu dipeptides in the 3 μ region is exemplified by Figs. 7 and 8. The absorption of amide chelates, and especially that of the secondary amide $(LMA)_2Cu$, indicates that GG-Cu is liable to exhibit two N-H frequencies in the neighbourhood of 3 200—3 300 cm^{-1}. Of the 4 possible absorption bands in Fig. 7, those at 3 331 and 3 282 cm^{-1} are most likely to belong to the N-H stretching frequencies. When the two other peaks present are considered it must be borne in mind that OH frequencies can appear in this wavelength region originating from the three molecules of water attached to the chelate. It is evident from a comparision with the N-H bands of the amide-Cu(II) chelates that the band at 3 435 cm^{-1} in GG-Cu(II),$3H_2O$ appears at a wavenumber too high for the N-H stretching frequency; it must be assigned to an OH stretching frequency. The band at 3 173 cm^{-1} is possibly the other OH frequency of the coordinated water molecule. It is obvious from Fig. 8 that the 4 main bands found in GG-Cu(II),$3H_2O$ dominate also the spectra of Cu dipeptide chelates with only one water of crystallization as LG-Cu (II),H_2O. This indicates that the OH bands originate from the water molecule bound to the metal ion as a fourth ligand (Fig. 13). The other two water molecules in GG-Cu(II),$3H_2O$ contribute presumably only with broad and undefined absorption. The special position of one water molecule is even emphasized by the fact that whereas it is easy to remove two molecules of water from GG-Cu (II),$3H_2O$ the third molecule is retained even at high temperatures.

The OH absorption and the fact that some of the absorption bands are not sharp enough to exclude an overlapping of frequencies, are the reasons why the IR-absorption in the 3 μ region does not give a conclusive answer to the question of metal ion influence on the peptide linkage. We have, as in the case of amide-Cu(II) chelates, to rely mainly on the results obtained in the double bond region. The IR absorption of dipeptide-Cu (II) chelates in the 6 μ region is characterized by two strong bands unaffected by deuterization. The frequency due to the stretching of the carboxyl group is generally found [15] in the neighbourhood of 1 590 cm^{-1}. When the carboxyl group participates in some kind of covalent bound formation with the metal ion, the stretching frequency shifts to higher wavenumbers as observed for Pt(II) chelates of glycine and, to a certain extent, for the water-free Cu(II) chelates

of some amino acids [1]. Table 4 summarizes the behaviour of the carboxyl frequency for Cu-dipeptide chelates. The COO^- frequencies show no appreciable trend towards higher wavenumbers so that the interaction between the carboxyl group and the metal ion ought to be of the same kind as in alkali salts of carboxylic acids. The only change in the position of the carboxyl frequency is displayed by the deuterization product of GG-Cu(II) as shown by Fig. 9. The position of similar bands in other dipeptide-Cu chelates, uninfluenced by deuterization, indicates that of the two bands remaining after deuterization, the carboxyl frequency at 1 613 cm^{-1} is represented in the monohydrate by the band at 1 592 cm^{-1} and not by the band at 1 624 cm^{-1}.

The band at 1 541 cm^{-1} in GG-Cu(II),H_2O must be ascribed to the amide I frequency, representing the same mode of vibration of the peptide group as observed in the Cu(II) chelates of amino acid amides. The position of this band in different Cu(II) dipeptides is fairly constant. The wavenumbers of these bands are gathered in Table 4. The observed shift of the amide I band, due to chelate formation, is for the peptides examined, approx. 100 cm^{-1}, which is in close agreement with the values observed for amide-Cu(II) chelates. The frequency is thus found at a considerably lower wavenumber than the normal peptide group vibration or a conjugated C = N bond frequency, indicating that the resonance structure of the peptide group is preserved but the equilibrium shifted towards the canonical structure III in Fig. 13.

Dipeptide chelates with Ni(II) and Zn(II). Manyak *et al.*[6] presume that the chelates formed by dipeptides with Ni(II) and Zn(II) are of the same type as the corresponding Cu(II) chelates. The Ni(II) and Zn(II) chelates isolated for this investigation are, as the analysis results show, neutral compounds consisting of two dipeptide molecules and one metal ion. These proportions and the absence of alkali ions rule out the possibility of further hydrogen ionisation in addition to the carboxyl group dissociation. The structure can be represented by *V* in Fig. 14.

V

Fig. 14.

A comparison of the IR curves in Fig. 11 reveals that the IR spectra of Ni(II) and Zn(II) chelates are almost identical and of another type than that of the Cu(II) chelate. The difference between Ni(II) and Zn(II) chelates lies in the position of the amide I band. This suggests a difference in the influence of metal ions on the peptide link. A second more prominent feature, common for both Ni(II) and Zn(II) chelates, is the splitting of the amide I frequency. Such splitting is frequently observed in crystalline peptides. Glycylglycine

itself, for example, shows a similar double peak. It is presumably due to hydrogen bond effects between the peptide groups in the crystal lattice.

Table 5 summarizes the behaviour of the important frequencies of GG under different conditions. We choose the value of the amide I band of GG-ester at 1 672 cm^{-1} measured in dilute $CHCl_3$ solution, as a standard for the uninfluenced peptide group. When the solution of the GG-ester is evaporated to dryness, the remaining film of liquid ester shows a shift of the amide I band by 8 cm^{-1} towards lower wavenumbers. The effect is undoubtedly due to hydrogen bond formation. The same kind of shift is observed when the GG-ester is compared with free GG. The shift of the mean of two amide I frequencies is in this case 5 cm^{-1}. That the shift is so small is probably due to the fact that the GG molecule exists in the solid state as a "zwitterion" where the extra hydrogen at the amino group shifts the amide frequency in the opposite direction. This kind of influence was observed in the hydrochlorides of amides and is also exhibited by the hydrochloride of GG, where the shift of the amide I frequency is 14 cm^{-1} towards higher wavenumbers. The hydrochloride of the GG-ester, when compared to the free ester, shows a similar shift of 14 cm^{-1} in the same direction.

Thus the shifts of the amide I band due to changes in hydrogen bond structure and bond formation at the amino group do not exceed the value of 20 cm^{-1}.

The amide I band of the Cu(II) chelate of GG shows, as previously demonstrated, a shift of 131 cm^{-1} towards lower wavenumbers. The Ni(II) chelate displays a similar shift of 32 cm^{-1} and the Zn(II) chelate a shift of 20 cm^{-1} in the same direction. The mean value of the two amide I frequencies has been used for the Ni(II) and Zn(II) chelates. The shift in Ni(II) chelates is big enough to permit the conclusion that the metal ion has an influence on the resonance of the peptide bond. The influence of the Zn(II) ion is smaller and the shift of the amide I band exceeds only with 12 cm^{-1} the value shown by the free GG. The position of the amide I band in $(GG)_2Zn(II)$, $2H_2O$ at 1 653 cm^{-1} lies in a region where the normal amid I frequencies of secondary amides are due to appear [18]. For example the methylamide of L-leucine (Table 1) has its amide I band as near as at 1 658 cm^{-1}. The influence of the Ni(II) ion is not unexpected as Maynak *et al*[6]. have isolated, from a more alkaline solution, a chelate of the same proportions as the neutral compound investigated here, but with two Na ions attached. The presence of the Na ions indicates that the chelate formed has lost two protons in analogy to the GG-Cu(II) chelate. The observation that Ni(II) forms, at high pH values, a chelate of the same character as the Cu(II) ion can also be inferred from the titration curves [6,16]. The existence of such a chelate with Zn(II) ions has not been demostrated.

These differences observed for the chelates of different metal ions lead to the conclusion that, although Cu(II), Ni(II) and Zn(II) all form chelate structures with the amino group of the GG molecule, differences between the various ions are large enough, so that, for example, the neutral chelate of GG with Cu(II) isolated at pH 8, shows a major change in the peptide group resonance, whereas the neutral chelate with Zn(II) scarcely shows any change in the peptide group.

The question whether the neutral chelate with Cu(II) is formed by proton dissociation from the amide nitrogen or from the coordinatively bound water molecule cannot be solved directly from changes in hydrogen stretching frequencies due to the complexity of the absorption band structure in the 3 μ region. However, as the changes in the 6 μ region for GG-Cu(II)H_2O are of the same type as for $(LA)_2$Cu(II), where the existence of two OH groups is excluded by the analysis results, the IR-investigation strongly supports the view that the proton dissociation takes place from the peptide group. The proton dissociation is also essential for the interpretation of the resonance shift in the peptide group, as in a chelate where the nitrogen binds both a proton and a metal ion, the peptide group resonance is blocked and the carbonyl frequency (amide 1) shifted towards higher wavenumbers. This kind of behaviour has been observed by Penland *et al.*[19] for different metal chelates of urea. The evidence that the metal ion-peptide group interaction in Cu(II) chelates is characterized by the substitution of the amide hydrogen with a metal ion does not imply that the observed interaction of Ni(II) with the peptide group does involve the nitrogen atom. On the contrary, the conclusions from urea chelates when applied to dipeptide chelates indicate that in case the amide hydrogen is retained after chelate formation and the amide I frequency still shows a shift towards lower wavenumbers, as in $(GG)_2$-Ni (II), the interaction between the metal ion and the peptide group probably takes place through the oxygen of the peptide link.

Although it is not quite correct to apply results obtained with solid chelates to aqueous solutions, it is interesting to note that the Zn(II) ion, which activates several proteolytic enzymes, shows practically no tendency to interact with the peptide group. This means that if chelate formation with the peptide group of the substrate molecule with a resulting electron displacement is a necessary step in the mechanism of metal activated enzymes, the role of the metal ion must be considerably influenced by the protein molecule [20].

Acknowledgements. The author wants to express his gratitude to Professor Arne Tiselius for encouraging interest and to make grateful acknowledgement to Mr. Stig Bergwall for able technical assistance. This investigation is a part of a program of infrared research financially supported by grants from the *Royal Swedish Academy of Sciences*, the *State Technical Research Council* and the *Rockefeller Foundation.*

Studies on Cobaltammines

I. Equilibrium Measurements of Inner-Sphere Thiocyanato- and Nitro-Complexes

RAGNAR LARSSON

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The exchange of ammonia in the hexammine cobalt(III) ion for one and two thiocyanate ions or one nitrite ion has been achieved by the use of active carbon as a catalyst. By measurement of the total cobalt concentration in solutions saturated with hexammine cobalt (III) perchlorate, the equilibrium constants at ionic strength 1 M have been calculated. The influence of outer-sphere complexes has been considered.

Ever since the beginning of coordination chemistry in the days of Jørgensen and Werner the ammino compounds of tervalent cobalt have been intensely studied. Little has been known, however, about the equilibrium constants of reactions between these compounds. This situation is obviously related to those properties that made Co(III) complexes so suitable for preparative work; the low solubility of many of them and — above all — their sluggish reaction.

Until the work of J. Bjerrum [1], no reactions had been quantitatively studied, involving an ammonia displacement from the hexammine cobalt(III) ion. In the present paper, equilibrium measurements of the reaction of the hexammine cobalt(III) ion with thiocyanate and nitrite ions, respectively, will be presented.

METHOD OF INVESTIGATION

To overcome the slow attainment of equilibrium J. Bjerrum [1,2] has used active carbon as a catalyst. Other workers have also studied this catalytic effect.[3,4] They agree that the efficiency of the carbon is gradually decreased as time progresses. The probable explanation is that the carbon is poisoned by a layer of cobalt(III) hydroxide; a proposal strengthened by the observation of Bjerrum [1, p. 255], that there is a decrease in the total concentration of cobalt when equilibrium has been attained. Though experiments of the

present author have shown platinum black and finely dispersed silver to be catalysts as well, active carbon has been used in this investigation because of its cheapness and (compared to silver) greater inertness.

The measurements should be performed in a medium of high and constant ionic strength in order to justify the assumption that the coefficients of activity are constant, so that the law of mass action may be expressed in concentration units instead of activities.

Furthermore, the concentration of ammonium ions should be as great as possible in order to suppress the hydrolysis:

$$Co(NH_3)_6^{3+} + H_2O \rightleftharpoons Co(NH_3)_5OH^{2+} + NH_4^+$$

As the neutral salt, therefore, 1 M NH_4ClO_4 has been used. At the temperature of measurement, 20°C, the solubility of $Co(NH_3)_6(ClO_4)_3$ in 1 M NH_4ClO_4 is 0.21 mM.

It therefore seemed natural to measure the degree of complex formation from the increase in solubility of this rather sparingly soluble salt.

For easy concentration determinations the hexammine cobalt(III) salt was labelled with radioactive ^{60}Co.

NOTATIONS AND GENERAL FORMULAE

The notations used and methods of calculation will conform as closely as possible to those used by Fronæus [5].

In formulae M will stand for Co, A for ammonia and B for thiocyanate or nitrite.

C_A will mean the total and [A] the free concentration of A. Equivalent notations apply to other molecular species.

The equilibrium constant for the reaction

$$MA_6 + nB \rightleftharpoons MA_{6-n}B_n + nA$$

will be denoted by γ_n

$$\gamma_n = \frac{[MA_{6-n}B_n][A]^n}{[MA_6][B]^n} \tag{1}$$

In recent years the conception of "outer-sphere complexes" has been used in connection with the explanation of kinetical data on cobalt(III) complexes [6–8]. The eventual formation of such outer-sphere complexes will be duly accounted for in this investigation.

An outer-sphere coordination of the ligand B to the unsubstituted ion MA_6 may be written:

$$MA_6 + B \rightleftharpoons (MA_6)B$$

The equilibrium constant is denoted

$$\beta^o_{B,1} = \frac{[(MA_6)B]}{[MA_6][B]} \tag{2a}$$

In the general case, with n ligands B in the inner (hexacoordination-) sphere and m ligands B in the outer sphere we write:

$$MA_{6-n}B_n + mB \rightleftharpoons (MA_{6-n}B_n)B_m$$

$$\beta^{(n)}_{B,m} = \frac{[(MA_{6-n}B_n)B_m]}{[MA_{6-n}B_n][B]^m} \tag{2b}$$

Analogously, with ammonia in the outer coordination sphere we write in the general case

$$MA_{6-n}B_n + mA \rightleftharpoons (MA_{6-n}B_n)A_m$$

$$\beta^{(n)}_{A,m} = \frac{[(MA_{6-n}B_n)A_m]}{[MA_{6-n}B_n][A]^m} \tag{2c}$$

It is further defined:

$$X^{(n)}_A = \sum_{m=1}^{M} \beta^{(n)}_{A,m}[A]^m \tag{3a}$$

$$X^{(n)}_B = \sum_{m=1}^{M} \beta^{(n)}_{B,m}[B]^m \tag{3b}$$

Combining the expressions (1), (2 b), (2 c), (3 a) and (3 b) we may write the total metal concentration C_M

$$C_M = [MA_6]\Big[1 + X^{\circ}_A + X^{\circ}_B + \gamma_1 \frac{[B]}{[A]}(1 + X^{(1)}_A + X^{(1)}_B) + \cdots + \gamma_n \frac{[B]}{[A]}(1 + X^{(n)}_A + X^{(n)}_B)\Big] \tag{4}$$

For the sake of simplicity in writing, we denote the expression inside the large brackets as Y.

Thus $$C_M = [MA_6]Y \tag{5}$$

Though the concentration of ammonium ions is kept high, the hydrolytic reactions may still be of significance.

For the first step of hydrolysis

$$MA_6 + H_2O \rightleftharpoons MA_5OH + HA$$

we put $$k_{\overline{OH}} = \frac{[MA_5OH][HA]}{[MA_6]}$$

Now $$[HA] = C_{NH_4} = 1 \text{ M}$$

Thus $$[MA_5OH] = [MA_6]k_{\overline{OH}} \tag{6}$$

From the value of the second constant of hydrolysis reported by Bjerrum [1, p. 272] (for another temperature and another ionic medium) it may be inferred that the second hydrolytic step

$$MA_5OH + H_2O \rightleftharpoons MA_4(OH)_2 + HA$$

will not contribute to an appreciable amount.

Adding eqn. (6) to the expression (5) for the total metal concentration we finally get

$$C_M = [MA_6](Y + k_{OH}) \tag{7}$$

As the solution is saturated with $MA_6(ClO_4)_3$ we have

$$[MA_6][ClO_4]^3 = l \tag{8}$$

where l is the solubility product of $MA_6(ClO_4)_3$ in the actual solution. When $C_B = C_A = 0$ we write

$$[MA_6]_0[ClO_4]_0^3 = l_0 \tag{9}$$

By dividing eqn. (8) with eqn. (9) we get

$$[MA_6] = [MA_6]_0 \cdot \frac{[ClO_4]_0^3}{[ClO_4]^3} \cdot \frac{l}{l_0} \tag{10}$$

Inserting eqn. (10) in eqn. (7) we get

$$C_M = (Y+k_{OH}) \cdot [MA_6]_0 \cdot \frac{[ClO_4]_0^3}{[ClO_4]_3} \cdot \frac{l}{l_0} \tag{11}$$

As previously mentioned the cobalt determination was a radiometric one. The counting intensity for a given volume of the suturated solution (I cpm) is proportional to C_M.

Thus

$$I = \text{const.}C_M \tag{12 a}$$

$$I_0 = \text{const.}[MA_6]_0 \tag{12 b}$$

Combining eqns. (11), (12 a) and (12 b) we get

$$Y + k_{OH} = \frac{I}{I_0} \cdot \frac{[ClO_4]^3}{[ClO_4]_0^3} \cdot \frac{l_0}{l} \tag{13}$$

The above deduction is made under the assumption that no polynuclear complexes are formed. This may be regarded as reasonable, because of the small value of C_M. Furthermore, as it is known that most polynuclear Co(III) complexes involve the formation of OH or NH_2 bridges [9], and only a small contribution to C_M is due to hydrolytic products, the assumption made is so much more plausible.

EXPERIMENTAL

Chemicals used. Unlabelled $Co(NH_3)_6Cl_3$ was prepared from analytical grade $CoCl_2$ aq, following the prescriptions of Bjerrum [1, p. 241].

$Co(NH_3)_6(ClO_4)_3$, *labelled with* ^{60}Co, was prepared from neutron irradiated metallic cobalt (from AERE, Harwell) which was dissolved in dilute hydrochloric acid, some platinum black acting as a catalyst. Thereafter $Co(NH_3)_6Cl_3$ was prepared as above, and the perchlorate was precipitated with concentrated perchloric acid, filtered and washed with alcohol and ether.

From these two preparations a stock solution was made containing 5 mM $Co^*(NH_3)_6(ClO_4)_3$ and 55 mM $Co(NH_3)_6Cl_3$.

Ammonium thiocyanate and *sodium nitrite.* Analytical grade reagents were used and the stock solutions were checked by titration according to Volhard and by cerimetric titration, respectively.

Ammonium perchlorate was of analytical grade. The concentration of the stock solution was checked by evaporation of a sample on the steam bath. No loss of weight could be detected on prolonged heating at this temperature.

Sodium perchlorate. A *purum* quality preparation was recrystallized once from hot water and dried at 110°.

Carbon dioxide-free *ammonia* was used together with ammonium perchlorate to make buffer solutions (C_{NH_4}:C_{NH_3} = 1 : 5, 1 : 0.5 and 1 : 0.05), the ammonia content of which was determined by acidimetric titration using bromocresol green as indicator.

Active carbon. A gas adsorption carbon was used. Once every month it was heated in an oven to 150 °C to increase the acurate attainment of equilibrium. (*Cf.* Fig. 1 and the foot-note on p. 217 of Ref.[10])

Procedure. In 100 ml flasks with ground glass stoppers 30 ml aliquots of solutions of the following general composition were mixed from stock solutions:

C_B M ammonium thiocyanate (or sodium nitrite)
C_A M ammonia
1.000 − C_B M ammonium perchlorate
2.0 mM $Co^*(NH_3)_6^{3+}$

The amount of $Co(NH_3)_6(ClO_4)_3$ will then be about ten times that of a saturated solution. After a while a precipitation takes place. In the experiments aiming at an inner-sphere equilibration, weighed amounts of active carbon were added. Three (or sometimes four) flasks were charged with solution of the same composition, each flask being charged with different amounts of active carbon, approximately 25, 40 and 70 mg. The flasks, with the stoppers shielded and kept in place by a rubber nipple, were placed in a shaker and vigorously shaken for some days.

Thereafter a 10 ml sample was withdrawn from each flask, using a pipette with two small disks of filter paper kept in place at the tip of the pipette by means of a set of small cut rubber tubings. The samples were poured into small Petri dishes and the activity was measured with a Tracerlab P-20 QG Scintillation Counter, combined with a Tracerlab SC-18 Superscaler. The Petri dishes used were internally calibrated with an equal amount of a solution of known activity.

At no time less then 10 000 counts, more often 20 000 counts, were registered. Thus the error of counting was always less than 1 %.

Using the value of 5.3 years for the half-life of ^{60}Co, the measured intensities (I cpm) have been corrected to a common time.

Sodium nitrite was chosen instead of ammonium nitrite because of its easy availability. This choice does not invalidate the assumptions made on the constancy of the ammonium ion concentration, as the concentration of sodium nitrite will in no case be more than 3 % of the total salt concentration. Furthermore, an extrapolation to $C_{NO_2^-} = 0$ is undertaken in the course of calculation, thus completely eliminating any errors introduced.

Temperature control. The shaking of the flasks and the separation of aliquots to be measured, were made in a thermostatically controlled room, the temperature of which was 20.0°±0.2°. The pipettes used had been stored in the same room and had thus attained the same temperature.

The temperature dependency of the solubility of $Co(NH_3)_6(ClO_4)_3$ was determined by raising the temperature of the room to 22.9°. The increase in the solubility was then 25 %, corresponding to 0.9 % for every tenth of a degree.

Calculation of the concentration of perchlorate ions. As seen from the composition of the solutions examined and the stock solution of hexammine cobalt(III) salts, the perchlorate concentration will depend on C_B and on the amount of cobalt complexes formed. The following formula may be derived:

$$[ClO_4] = 1000 - 5.5 - C_B + 3 \times 0.21 \times I/I_0 = 994.5 - C_B + 0.63 \times I/I_0 \text{ mM}$$

The second term on the right side of the formula corresponds to the chloride ions brought into the solution from the cobalt stock solution. The fourth term represents the increase in $[ClO_4]$ as the solubility rises.

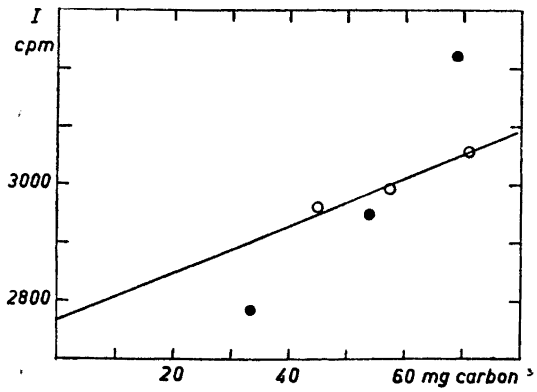

Fig. 1. The dependency of the equilibration on the amount of carbon in the thiocyanate measurements. Filled circles denote experiments with carbon that had long been exposed to air, unfilled circles denote experiments with carbon heated to 150° for several hours.

The solubility of $Co(NH_3)_6(ClO_4)_3$ in pure 1 M NH_4ClO_4 was determined by radiometric isotope dilution analysis to be 0.21 mM.

On the action of carbon. The criterion that equilibrium has been reached should be that the intensities of the solutions equilibrated by different amounts of carbon are the same. As long as the solution is saturated with respect to $Co(NH_3)_6(ClO_4)_3$, any adsorption of cobalt on the carbon would not affect this result. As a matter of fact this criterion has been found to be fulfilled in the measurements on the nitrite-substitution and the hydrolysis. In these cases the value of I, recorded in the following, is the mean value of the measurements with different amounts of carbon.

In the case of the thiocyanate-substitution, however, it was found that I increased as the carbon amount was increased. This effect was most prominent in experiments with low ammonia concentration. Those values of I reported in this system and denoted by an asterisk are attained by a linear extrapolation to zero amount of carbon. For series, notably those at high ammonia concentration, where the spreading is $< \pm 2$ %, the mean values have been reported. In Fig. 1 this effect is illustrated together with the effect of heating the carbon.

The nature of this effect is rather dubious. A probable explanation is perhaps that there occurs a catalytic decomposition of the thiocyanate ions on carbon, yielding cyanide ions, which react with the cobaltammine ions. This reaction may well be favoured by a decrease in the pH, as it is known that the thiocyanic acid is not stable in acid solution. It is strengthened by the fact that the slope of the line I *versus* the amount of carbon is increased on prolonged shaking, indicating the occurrence of a time reaction.

RESULTS

In order to obtain information on the hypothetic existence of outer-sphere complexes of the hexammine cobalt(III) ion, measurements were made of the solubility of the perchlorate at varying concentrations of thiocyanate or nitrite ions and of ammonia, *without any addition of carbon.* For the two first-mentioned ligands the value of $\frac{I}{I_0} \cdot \frac{[ClO_4]^3}{[ClO_4]_0^3}$ are reported in Figs. 2 and 3. Within the limits of experimental error the quotient is found to have a constant

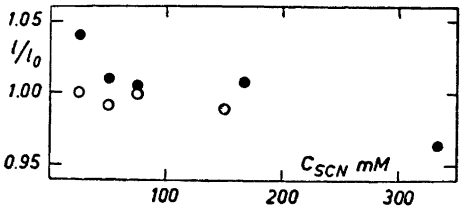

Fig. 2. The function l/l_0 plotted against C_{SCN^-}. Filled circles correspond to C_{NH_3} = 194 mM, unfilled circles to $C_{NH_3} = 0$.

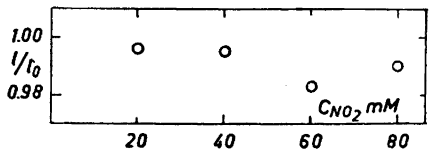

Fig. 3. The function l/l_0 plotted against $C_{NO_2^-} \cdot C_{NH_3} = 69$ mM.

value of 1. Thus it might be concluded that no outer-sphere complexes with charged ligands are formed and secondly that there is no medium effect affecting the solubility product l. However, the possibility of these two factors just compensating each other over the rather small concentration range used, must still be kept in mind. Two facts favour such an explanation.

Firstly, there has been observed quite distinct changes of the absorption spectrum of the hexammine cobalt(III) perchlorate, when part of the perchlorate ions is exchanged for halide or azide ions (Ref. [12,13]) and also for thiocyanate ions (Sonesson [14]).

Secondly, it is seen from Table 1, that an exchange of one fifth of the ammonium perchlorate for sodium perchlorate effects a distinct change of the solubility of $Co(NH_3)_6(ClO_4)_3$. As thiocyanate and nitrite ions are more unequally shaped compared to perchlorate ions than sodium ions are compared to ammonium ions, the change in solubility in the cases considered might be expected to be at least as large as that indicated in Table 1.

In the case of ammonia, conditions are quite different. The measurements are recorded in Table 1, showing a steady increase of solubility as C_{NH_3}

Table 1. The influence of the ammonia concentration on the solubility of $Co(NH_3)_6(ClO_4)_3$.

$C_{NH_4ClO_4} = 1$ M						$C_{NH_4ClO_4} = 0.8$ M $C_{NaClO_4} = 0.2$ M

1.770	1 815	0.31	3.94	2 903	1.09			

increases. This effect may be due to any of two causes; an increase in the solubility product of $Co(NH_3)_6(ClO_4)_3$ as the solvent dielectric constant is changed with increasing ammonia, or an outersphere complex formation with one or more molecules of ammonia. As no value of the dielectric constant of ammonia water solutions has been found in literature, we are not able to tell the direction of such a change of solubility. However, some data of J. Bjerrum [11] on the solubility of $Ba(IO_3)_2$ in 2 M NH_4NO_3 and varying C_{NH_3} suggests that this medium effect should be one to decrease the solubility, not to increase it. The possibility of outer-sphere ammine complexes has then been accepted as a working-hypothesis.* In the third column of Table 1 the function x_A° is recorded.

$$x_A^\circ = \frac{I}{I_0} - 1$$

This notation is chosen to distinguish the thus defined quantity from the quantity X_A° defined by eqn. (3 a). X_A° might be calculated from x_A°, if the dependency of the solubility product on C_{NH_3} was known. Then, however, this correction would have to be used also when calculating Y in the inner-sphere equilibration measurements.

In the following the quantity $Y - x_A^\circ$ is used in calculation, Y being formed under the assumption that $l/l_0 = 1$, *i.e.* is independent of C_{NH_3}. The measurements recorded in Table 1 with the ionic medium 0.2 M $NaClO_4$, 0.8 M NH_4ClO_4 show that the increase in solubility is independent of the pH, thus there is (at this pH) no reaction like $Co(NH_3)_6^{3+} \rightleftharpoons Co(NH_3)_5NH_2^{2+} + H^+$.

THE HYDROLYTIC EQUILIBRIUM

By adding active carbon to an ammonium perchlorate solution with $C_B = 0$ we can get an estimation of the constant of hydrolysis, defined by eqn. (6). As this constant will be obtained at a difference of two almost equal quantities, the random error will be consequently large. The values reported in Fig. 4 are mean values of five or more independent determinations. It is seen that there is a slight increase in the values as C_{NH_3} increases. However, it is uncertain if this is a real effect or follows from experimental error. If the change is significant, it is of interest to note that the trend is the inverse to that found by Bjerrum [1, p. 257]. This might be seen as a support of the hypothesis of outersphere ammonia complexes.

THE THIOCYANATE SYSTEM

Measurements were made at the thiocyanate concentrations 25.0, 75.0 and 166.7 mM. The results are tabulated in Table 2. The values of x_A° are obtained by a graphical interpolation of the data given in Table 1, and those of k_{OH} from the line drawn in Fig. 4.

* Light absorption measurements of the present author, the results of which are soon to be published, strengthen this view.

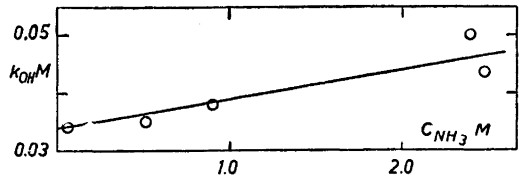

Fig. 4. The experimentally determined values of k_{OH} plotted against C_{NH_3}. The line is drawn to fit the points as closely as possible.

In Fig. 5 the quantity $Y-x_A^0$ is plotted against C_B/C_A. Actually the quotient [B]/[A] should be used in the subsequent calculations, but for small values of C_B/C_A the number of B bound per metal atom, $\bar{n}$, is small and thus $[B] = C_B - \bar{n}\ C_M$ is almost equal to C_B. (Analogous reasoning, of course, is to be applied to C_A and [A].) For greater values of C_B/C_A where $\bar{n}$ is rather large and a distinct difference exists between [B] and C_B, the degree of reproducibility of measurements is rather low, so there is no point in making extra corrections of the quotient C_B/C_A. Thus C_B/C_A will be used as the ligand quotient throughout the calculations.

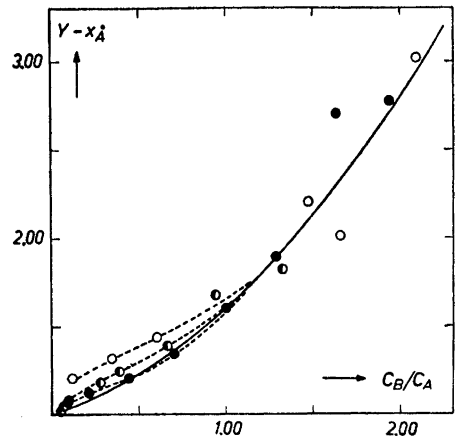

Fig. 5. The thiocyanate system. $Y-x_A^\circ$ as a function of C_B/C_A. Filled, half-filled and unfilled circles correspond to C_B = 25.0, 75.0 and 167 mM, respectively. The dotted lines are those used for the extrapolation of Table 3. The full-drawn curve is obtained from the reported constants.

However, there is no difficulty in calculating $\bar{n}$, and for systems where greater accuracy might be obtained, this correction may be worth while.

Applying the method of calculation used by Fronaeus [5], we get

$$\bar{n} \approx \frac{[B]}{[A]} \cdot \frac{1}{Y} \cdot \frac{dY}{d([B]/[A])}$$

From graphical estimation on the curve $Y-C_B/C_A$ we can get an approximate value of $\frac{dY}{d([B]/[A])}$ and of [B]/[A] and thus the more correct expression:

$$\frac{[B]}{[A]} = \frac{C_B - \bar{n}C_M}{C_A + \bar{n}C_M}$$

It is seen in Fig. 5 that we obtain different curves for the different values of C_B. At about $C_B/C_A = 1.3$ they seem to coalesce. This means that in the expression Y of eqn. (4) *either* we have still some terms dependent on [A] or [B] only and not on [B]/[A], *i.e.* the correction with x_A° corresponding to outer-sphere ammonia attachment to the MA_6^{3+} ion has not made account for all possible outer-sphere complexes, so that there may also exist, *e.g.*, $(MA_6)B$- and $(MA_5B)A$-complexes, *or*, and this is as plausible an explanation as the preceding one, the equilibrium constants γ_n will be effected by the change in the dielectric constant of the solvent as C_{NH_4} increases. Such an effect is well known for dissociation constants of weak acids [15], and has also been observed in studies on complex formation [16,17].

Both these effects may be thought to combine to give the effect of Fig. 5. Whatever the cause, however, an extrapolation to $C_A = C_B = 0$ for constant values of C_B/C_A will make all these effects vanish, *i.e.* the function Y will transform to

$$Y_0 = 1 + \gamma_1 \frac{C_B}{C_A} + \gamma_2 \left(\frac{C_B}{C_A}\right)^2 + \text{----}$$

where the constants γ are valid in 1 M NH_4ClO_4.

Table 3. The thiocyanate system. Extrapolation to $C_B = 0$ and calculation of equilibrium constants.

$\gamma_1 = 0.3 \pm 0.1$ $\gamma_2 = 0.3 \pm 0.1$

$\frac{C_B}{C_A}$	$Y - x_A^0$			Y_0	$\frac{C_A}{C_B}(Y_0 - 1)$
	$C_B = 167$ mM	$C_B = 75.0$ mM	$C_B = 25.0$ mM		
0.100	1.182	1.091	1.063	1.037	0.37
0.250	1.265	1.179	1.131	1.106	0.42
0.400	1.337	1.245	1.186	1.160	0.40
0.600	1.432	1.348	1.277	1.254	0.42
0.900	1.592	1.538	1.490	1.477	0.53
1.300	1.89	1.88	1.88	1.88	0.67
1.47	2.21			2.21	0.82
1.63			2.7	2.7	1.04
1.66	2.0			2.0	0.61
1.94			2.8	2.8	0.93
2.09	3.0			3.0	0.96

In Table 3 such an extrapolation is performed for $C_B/C_A \leq 1.3$, above this region of coalescence the experimental Y-x_A^0 values have been used. The function $\frac{C_A}{C_B}(Y_0 - 1)$ are, within the limits of the rather large experimental errors, linear, showing the existence of the first and second substituted complex to be formed for these values of the ligand quotient.

THE NITRITE SYSTEM

As the nitro-ligand was found to be more strongly attached to the Co(III) nucleus, much smaller values of the ligand quotient had to be used than was the case in the preceding investigation on the thiocyanate system. The nitrite concentrations used were 9.00, 18.00 and 27.00 mM. In Table 4 the experimental results are recorded. As before, C_B/C_A is used instead of [B]/[A]. In Fig. 6 a line with the slope 43 has been drawn through the upper points.

The points corresponding to $(Y$-$x_A^0)$-values less than about 2.5 are found to lie above that line and the ones corresponding to $C_B = 27$ mM and $C_B = 18$ mM are lying progressively higher than those corresponding to $C_B = 9$ mM. An extrapolation to $C_B = 0$ would, within the limits of experimental error, bring about a complete coincidence with the above-mentioned line. Thus it may be concluded that at these values of the ligand quotient only the first substitution complex exists, γ_1 being 43 ± 2. The colour of the solutions when the carbon had been filtered off was clear yellow. Thus the nitropentammine complex is formed and not the nitritopentammine one.

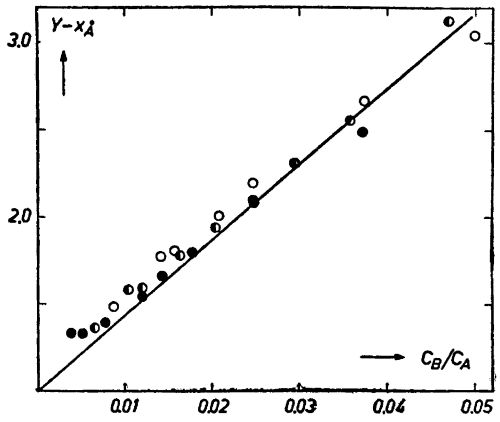

Fig. 6. The nitrite system. $Y-x_A^\circ$ as a function of C_B/C_A. Filled, half-filled and unfilled circles correspond to C_B = 9.00, 18.00 and 27.0 mM, respectively.

My sincere appreciation is due to Professor S. Bodforss for his having awakened my interest in the chemistry of cobaltammines and having kindly placed at my disposal the facilities of this laboratory.

The helpful interest of Dr. S. Ahrland and Dr. S. Fronaeus is also acknowledged.

Short Communications

Tocopherol Levels in Normal Pigs and in Pigs with Waxy Muscle Degeneration and *Hepatosis diaetetica*

HANS WANNTORP and ANNA-LISA OBEL

Departments of Chemistry and Pathology, State Veterinary Medical Institute, Stockholm, Sweden

Vitamin E or tocopherol was first considered to be a fertility or antisterility vitamin on the basis of early experiments with rats. Numerous investigations have since demonstrated, however, that this vitamin has a much wider range of activity. In animals other than rats including domestic animals, the major activity seems to be as an antioxidant in metabolic processes.

The most commonly used pig feeds are relatively deficient in vitamin E. It is, therefore, to be expected that lesions often occur in pigs which may be the expression of a deficiency of this vitamin. Many of the changes which can be observed in experimental vitamin E deficiency in the rat such as waxy degeneration of the muscles, ulceration in the cutaneous partition of the mucous membrane of the stomach, and so-called yellow fat can also be seen in many pig autopsies. Vitamin E deficiency is also an aetiological factor contributing towards the production of the hepatosis diaetetica syndrome. Obel [1] was able to produce this disease experimentally through a deficiency of vitamin E and sulphur-containing amino acids.

In order to establish whether or not the tocopherol level in the tissues of pigs with waxy degeneration of the muscles and *hepatosis diaetetica* is lower than is the case for healthy animals, determinations were carried out for various groups of animals. The tocopherol content of the heart, liver, and spleen was determined by the method of Wanntorp and Nordlund [2].

The average values for tocopherol in the heart, liver, and spleen of normal slaughter pigs (group 1) was 1.42, 0.96, and 0.59 mg/100 g, respectively. Group 2 consisted of pigs submitted for autopsy and which were affected by diseases other than those which could be associated with vitamin E deficiency. Average values for the hearts, livers, and spleens from this group were 1.07, 0.67, and 0.45 mg/100 g, respectively. Both these groups can be taken as comparison material for the other groups which consisted of animals probably deficient in vitamin E, *i. e.*, pigs with waxy degeneration of the skeletal musculature, group 3, pigs with *hepatosis diaetetica*, group 4, and pigs with experimental vitamin E deficienty, group 5. The average values obtained for tocopherol in group 3 were 0.76, 0.52, and 0.34 mg/100 g, respectively, in group 4, 0.59, 0.38, and 0.24 mg/100 g, respectively, and in group 5, 0.65, 0.44, and 0.26 mg/100 g, respectively.

Statistical treatment of the results showed that pigs with *hepatosis diaetetica* and the animals in group 5 which had received a diet deficient in vitamin E had significantly lower tocopherol levels in the heart, liver, and spleen than the pigs in group 2 which represent the normal levels for autopsy material.

The tocopherol levels in the heart and spleen of pigs with waxy muscle degeneration may possibly be significantly lower than the normal levels in group 2.

In order to study more closely the relationships between the tocopherol levels in different organs, an analysis of covariance was made using the tocopherol values for heart and liver as one variant pair and the values for heart and spleen as another. If, in a coordinate system, the x-axis repre-

sents the tocopherol level for heart and the y-axis the tocopherol level for liver and spleen, respectively, the regression lines for the averages of the groups will pass through zero and they are significantly straight lines. This indicates that the relationship between the tocopherol levels in heart, liver, and spleen are linear. From the angle of the regression lines for the average values of the groups, it is possible to state the general relationship between the tocopherol content of heart, liver, and spleen to be about 8: 5: 3. This relationship applies to all groups, fresh normal material, autopsy material in which the tocopherol level may sink after death, and material from animals with vitamin E deficiency.

Metal Ammine Formation in Solution

XI. Stability of Ethylenediamine Complexes and the Coordination Number of Chromium(II)

R. L. PECSOK* and JANNIK BJERRUM

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The coordination compounds of chromium(II) have been studied for many years; however, no stability constants have been reported for any of its complexes, nor has any experimental evidence been given of its coordination number. The difficulty of preparing chromium(II) solutions free from other metals (or acetate), the instability of chromium(II) toward oxidation, and the strong tendency of chromium(II) to form insoluble basic salts are serious obstacles to such an investigation. From the ligand field theory it is postulated [1] that chromium(II) complexes should show similarity with copper(II) complexes, *i. e.* have a tetragonal bipyramidal configuration and the metal ion a characteristic coordination number of four. This has been verified by establishing the formation curve for the chromium(II) ethylenediamine complexes. Studies with other amines are in progress and will be reported elsewhere.

Solutions containing *ca.* 0.04 M chromous chloride, 0.35 M hydrochloric acid, and 1 M potassium chloride were titrated with concentrated solutions of ethylenediamine (*ca.* 5 M, and 1 M KCl), the hydrogen ion concentration being determined with the glass electrode. It was shown spectrophotometrically that below 6 M chloride ion, chloro complexes are insignificant. The formation curves giving the average ligand number as function of the exponent of the free ethylenediamine concentration were calculated according to Bjerrum [2]. Three independent titrations are represented in Fig. 1. The fulldrawn curve is the theoretical formation curve calculated from the stability constants obtained. With a concentration of free amine higher than *ca.* 0.1 M, there is a considerable scatter in the experimental points because of the high initial acid concentration required to prevent precipitation of hydroxy compounds during the course of the titration. However, it is evident that the formation function of Cr(II)-en levels off at $\bar{n} = 2$. Preliminary spectrophotometric measurements show qualitatively that the bis(ethylenediamine) chromous ion has only a very slight tendency to take up more ethylenediamine. Further it is interesting to see that there is a distinct "pentammine" effect in the spectra just as in the corresponding cupric systems [3,4] (see Table 1).

Table 1. Data for the absorption maximum of the aquo chromous ion and two chromium (II) ethylenediamine solutions.

$C_{Cr(II)}$	C_{en}	λ_{max}	$1/\lambda_{max}$	ε_{max}
mole/l	mole/l	mμ	cm^{-1}	
0.212	0	714	14 000	4.7
0.0375	0.57	547	18 300	25.1
0.0351	10.8	571	17 500	17.1

The consecutive formation constants were calculated in the usual way [2,5], and found to be $\log K_1 = 5.145$, $\log K_2 = 4.035$ at 25°. In Table 2 these values are compared with the earlier determined constants for the other divalent transition group

* Guggenheim Fellow 1956—57, on leave from the University of California, Los Angeles.

sents the tocopherol level for heart and the y-axis the tocopherol level for liver and spleen, respectively, the regression lines for the averages of the groups will pass through zero and they are significantly straight lines. This indicates that the relationship between the tocopherol levels in heart, liver, and spleen are linear. From the angle of the regression lines for the average values of the groups, it is possible to state the general relationship between the tocopherol content of heart, liver, and spleen to be about 8: 5: 3. This relationship applies to all groups, fresh normal material, autopsy material in which the tocopherol level may sink after death, and material from animals with vitamin E deficiency.

metals under similar conditions (25°, $\mu \sim 1.4$) *.

The crystal field stabilization is calculated as previously described [1,7], and the data show that chromium(II) has a rather high stabilization compared to the other transition group metals. From Table 1 it is seen that the bis(ethylenediamine)-chromium(II) ion is displaced 18 300—14 000 = 4 300 cm^{-1} relative to the aquo ion. The corresponding displacement of the planar bis(ethylenediamine)copper(II) ion is not much higher, 18 200—12 600 = 5 600 cm^{-1}. This shows that the tetragonal distortion is of the same order of magnitude in the two cases, and considering that the

* See Refs. [2,4-6]. The manganous constants are converted from 30° to 25° by addition of 0.04 to log K_n, the ferrous constants by addition of 0.06, and the cobaltous constants by addition of 0.08.

complexity constants are much higher in the copper than in the chromium system, it can be concluded that the 3rd formation constant must be exceedingly small in the last mentioned case. Also the relatively small "pentammine" effect in the chromous system gives evidence for this.

Experimental. Chromous solutions were prepared by dissolving electrolytically purified chromium metal (kindly furnished by E. I. du Pont de Nemours and Co.) in hot oxygenfree hydrochloric acid to give solutions containing *ca.* 0.2 M chromous chloride and 0.2 M hydrochloric acid. Chromium(II) was determined by titration with potassium iodate [8], hydrochloric acid by potentiometric titration with sodium hydroxide, and chromium(III) spectrophotometrically. The solution used contained less than 2 % of the chromium as chromic ion which was ignored. The chromium(II) solution was always under a positive pressure of nitrogen, and all other solutions were made oxygenfree by bubbling with nitrogen. The ethylenediamine hydrate was specially purified by Carbide and Carbon Chemicals Company and distilled through a column. It was diluted with an equal volume of 2 M potassium chloride and swept with nitrogen before use.

The titrations were performed under nitrogen in a thermostated cell at 25°C. The cell E.M.F. was measured with a Radiometer pH meter, model PHM 3, using a glass electrode which had been tested for linear response to pH. The acidity constants of the ethylenediamine ($pK_{enH_2} = 7.44$, $pK_{enH} = 10.06$) were determined by titrating solutions of the same composition as for the complexity titrations, replacing the chromous chloride with an equivalent amount of barium chloride [2].

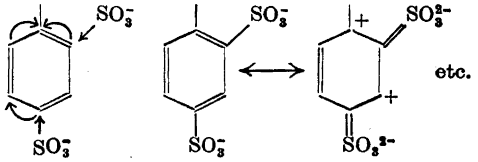
The Preparation of Benzene-1,2,4-trisulphonic Acid



ROLF LUNDQVIST

Chemical Institute, University of Uppsala, Uppsala, Sweden

As a part of the preliminaries for an investigation on the adsorption of benzene sulphonic acids and naphtalene sulphonic acids on aluminium oxide, asymmetrical benzene trisulphonic acid has been prepared.

After unsuccessful experiments with the method of Gattermann [1,2], involving the use of aniline-2,4-disulphonic acid, and after attempts to develop sulphonation products of thiophenyl derivatives, refluxing [3] a solution of the sodium salt of bromobenzene-2,4-disulphonic acid [4-7] and sodium sulphite for 6 h in the presence of some cupric sulphate turned out to be a simple and successful method. [8] Benzene-1,4-disulphonic acid [8] was prepared from bromobenzene-4-sulphonic acid [9] as a preparatory study of this method.

Compared with the preparation of benzene sulphonic acid from bromobenzene, which is achieved by heating bromobenzene with a solution of sodium sulphite and cupric sulphate at 180—200°C for 7 h, the displacement of bromine from bromobenzene-2,4-disulphonic acid is clearly facilitated. As the reaction is carried out in a neutral solution, it gives some valuable information on the relative strengths of the inductive and mesomeric effects operating from the two sulphonate groups. The inductive effect (I) is opposite to the mesomeric effect (II).

I. + I effect II. — M effect

The displacement of bromine is a nucleophilic reaction:

complexity constants are much higher in the copper than in the chromium system, it can be concluded that the 3rd formation constant must be exceedingly small in the last mentioned case. Also the relatively small "pentammine" effect in the chromous system gives evidence for this.

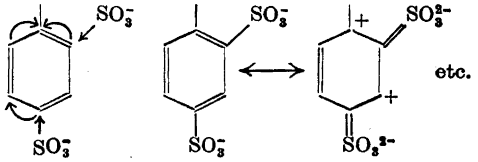
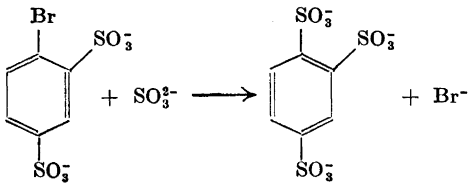
The Preparation of Benzene-1,2,4-trisulphonic Acid



ROLF LUNDQVIST

Chemical Institute, University of Uppsala, Uppsala, Sweden

As a part of the preliminaries for an investigation on the adsorption of benzene sulphonic acids and naphtalene sulphonic acids on aluminium oxide, asymmetrical benzene trisulphonic acid has been prepared.



After unsuccessful experiments with the method of Gattermann [1,2], involving the use of aniline-2,4-disulphonic acid, and after attempts to develop sulphonation products of thiophenyl derivatives, refluxing [3] a solution of the sodium salt of bromobenzene-2,4-disulphonic acid [4-7] and sodium sulphite for 6 h in the presence of some cupric sulphate turned out to be a simple and successful method. [8] Benzene-1,4-disulphonic acid [8] was prepared from bromobenzene-4-sulphonic acid [9] as a preparatory study of this method.

Compared with the preparation of benzene sulphonic acid from bromobenzene, which is achieved by heating bromobenzene with a solution of sodium sulphite and cupric sulphate at 180—200°C for 7 h, the displacement of bromine from bromobenzene-2,4-disulphonic acid is clearly facilitated. As the reaction is carried out in a neutral solution, it gives some valuable information on the relative strengths of the inductive and mesomeric effects operating from the two sulphonate groups. The inductive effect (I) is opposite to the mesomeric effect (II).

I. + I effect II. — M effect

The displacement of bromine is a nucleophilic reaction:

and thus the statement is justified that the mesomeric effect of the two sulphonate groups in the bromobenzene-2,4-disulphonate ion is stronger than the corresponding inductive effect.

The common method of isolating and characterizing the sulphonic acid as the sulphonyl chloride was found not to be the proper way in this case due to the formation of chlorobenzene-2,4-disulphonyl chloride[10] (m. p. 88—89°C, diamide m. p. 205—208°C) in most experiments, and so the S-benzyl*iso*thiouronium salt was chosen for this purpose. — The benzene-1,2,4-trisulphonyl chloride was prepared afterwards using mild conditions during the treatment with phosphorus pentachloride.

A convenient method of preparing bromobenzene-2,4-disulphonic acid has also been developed.

Experimental. Bromobenzene - 2,4 - disulphonic acid: A mixture of 76 g of bromobenzene and 260 ml of chlorosulphonic acid was heated at 145°C on an oil bath for 4 h with stirring. After cooling the excess of chlorosulphonic acid was carefully hydrolysed on ice. A substance insoluble in water was obtained and was thoroughly washed with 1 500 ml of ether in small portions. The volume of the ether solution was reduced to 100 ml by evaporating and after adding 200 ml of light petrol 41 g of bromobenzene-2,4-disulphonyl chloride crystallized out on cooling at 0°C (m.p. 102—104°C, diamide m.p. 241—242°C). The yield corresponds to 24 % of the theoretical amount. — The sodium salt was prepared by hydrolysing the dimethyl ester with boiling water and neutralizing with NaOH.

Benzene-1,2,4-trisulphonic acid: 25.6 g of the sodium salt of bromobenzene-2,4-disulphonic acid was refluxed for 6 h with a solution of 13.4 g (= 3 equiv.) of sodium sulphite and 1.3 g of cupric sulphate in 190 ml of water. During the reaction a red coating of Cu_2O was formed on the walls of the vessel. After cooling the solution was acidified with hydrochloric acid and air was passed through to displace the SO_2 until the odor of the gas abated. The solution was freed from precipitated CuCl by filtering, cooled in an ice bath and poured with stirring into an ice cooled solution of 44.5 g of S-benzyl*iso*thiouronium chloride in 200 ml of water. A pale yellow precipitate was at once obtained and after a few hours' cooling on ice a white substance crystallized out. Both substances were recrystallized from 50 % alcohol and yielded 30.7 g of rectangular prisms, m. p. 240—241°C (decomp.). Another 7.5 g of the same substance was obtained from the mother liquors by evaporating and cooling.

Analysis: Found H 4.57; C 44.03; N 10.15; S 23.87. Calculated for $C_6H_3[SO_3 \cdot (NH_2)_2 C \cdot S \cdot CH_2 \cdot C_6H_5]_3$: H 4.44; C 44.11; N 10.29; S 23.55. The equivalent weight of the substance was obtained by passing it through a cation exchanger (Amberlite IR-100) and titrating with NaOH. Found 272.3, calc. 272.3. Infrared spectra showed the presence of a 1,2,4-trisubstituted benzene nucleus.

The yield of S-benzyl*iso*thiouronium benzene-1,2,4-trisulphonate, 38.2 g, was 66 % of the theoretical amount, calculated on sodium bromobenzene-2,4-disulphonate.

The sodium salt was prepared by passing a 50 % alcoholic solution of the S-benzyl*iso*-thiouronium salt through a cation exchanger and neutralizing the eluate with NaOH. After evaporating the solvent the sodium salt was crystallized from 70 % alcohol and was obtained as a white powder.

Benzene-1,2,4-trisulphonyl chloride was prepared by heating the sodium salt with excess of phosphorus pentachloride at 110°C for 5 min with stirring. The reaction mixture was hydrolysed with ice water and the sulphonyl chloride was dissolved in ether and crystallized twice from light petrol; irregularly shaped crystals, m. p. 114—116°C. (Found: C 19.39. Calc. for $C_6H_3(SO_2Cl)_3$: C 19.29).

*iso*Thiocyanates XXIX* Separation of Volatile *iso*Thiocyanates by Gas Chromatography

ANDERS KJÆR and AAGE JART

Chemical Laboratory of the University of Copenhagen, Denmark

The frequent occurrence in crucifers and certain other higher plants of mixtures of mustard oil glucosides (*cf. e. g.* Ref.[1]), enzymically hydrolyzed to corresponding mixtures of *iso*thiocyanates, renders the analytical separation of the latter a matter of considerable interest. Although liquid partition chromatography, on paper as well as columns, has served this purpose extensively, alternative methods of separation have occasionally been felt desirable. The present communication records preliminary results of an investigation, undertaken in order to study the applicability of gas chromatography for the separation of volatile *iso*thiocyanates.

All separations were performed in a 2 m column at various, but closely controlled and constant temperatures. Dixon helices served as support for the stationary phase, consisting of silicon grease, and nitrogen was used throughout as a carrier gas at a rate of 10 mg per min. The output pressure was 20 mm, and the total pressure drop through the entire column about 4 mm.

A typical separation of a five-component system, with a total weight of 6.7 mg, is reproduced in Fig. 1, A. The mixture had the composition:

Methyl *iso*thiocyanate	14	%
Ethyl *iso*thiocyanate	18	»
*iso*Propyl *iso*thiocyanate	17	»
n-Butyl *iso*thiocyanate	18.5	»
*iso*Pentyl *iso*thiocyanate	32.5	»

and a temperature of 68.5° was selected. Under these conditions the components emerged from the column in the above order, yet with the ethyl and *iso*propyl bands unresolved. However, some separation of these was achieved at 50°, and in an experiment conducted at 30.5° the two *iso*thiocyanates were recognizable as distinct bands (Fig. 1, B). Separate runs on the individual compounds indicated that the small peaks appearing briefly after the start, and the slight inflexion just ahead of the butyl derivative (Fig. 1, A), could be attributed to unknown impurities in the specimens of *iso*pentyl and *iso*propyl *iso*thiocyanates employed, respectively. Preliminary runs at fixed temperatures in the range 40° – 50° have further provided satisfactory separations of 3-butenyl and allyl *iso*thiocyanate, as well as of the latter and *iso*propyl *iso*thiocyanate.

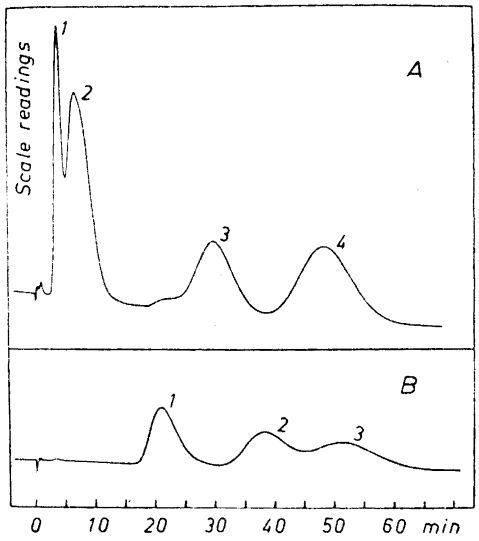

Fig. 1. A: Separation by gas chromatography of: 1. methyl, 2. ethyl and *iso*propyl, 3. *n*-butyl, and 4. *iso*pentyl *iso*thiocyanates. Total weight: 6.7 mg. Column temperature: 68.5°. *B:* Separation of: 1. methyl, 2. ethyl, and 3. *iso*propyl *iso*thiocyanate. Total weight: 4.4 mg. Column temperature: 30.5°.

Gas chromatography thus appears to be a method of great promise for the separation, analysis and identification of volatile *iso*thiocyanates, including those of natural provenance. Further work along this line is in progress and a more detailed account will appear at a later date.

The work is part of investigations supported by *Statens Almindelige Videnskabsfond (The Danish State Research Foundation)* and *Carlsbergfondet (The Carlsberg Foundation)*. A special grant to one of us (A.K.) from *Kai Hansen's Fond* is gratefully acknowledged.

Unit Cells and Space Groups of Some Carboxylic Acid Derivatives of 1,2-Dithiolane, 1,2-Dithiane, 1,2-Diselenane and 1,2-Dithiepane

OLAV FOSS and LENNART SCHOTTE

Chemical Institute, University of Bergen, Bergen, Norway, and Chemical Institute, University of Uppsala, Uppsala, Sweden

The X-ray crystallographic survey of saturated cyclic disulphides reported below serves as a preliminary to attempts at complete crystal structure determinations of suitable representatives. Of special interest is the stereochemistry of the disulphide group, particularly in five-membered rings where the CSS/SSC dihedral angle is expected to be considerably smaller than the normal value of about 90°.

The data were obtained from oscillation and Weissenberg photographs of single-crystal specimens, using Cu$K\alpha$ radiation, $\lambda = 1.542$ Å. Axial lengths are believed to be accurate to within 0.5 %. Densities were determined by flotation in suitable solvent mixtures.

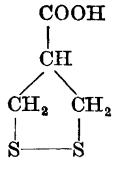
1,2-Dithiolane-4-carboxylic acid [1-3] (I). Triclinic, irregularly shaped crystals, with $a = 5.34$ Å, $b = 5.85$ Å, $c = 10.75$ Å, $\alpha = 93\frac{1}{2}°$, $\beta = 89\frac{1}{2}°$, $\gamma = 109\frac{1}{2}°$. There are two molecules per unit cell; density, calc. 1.58, found 1.54 g/cm³. The space group is $C_i^1-P\bar{1}$.

The projection of the structure along the a axis has been solved [4], and the complete structure will be worked out. The a-axis projection indicates that the dithiolane ring is not planar, the CSS/SSC dihedral angle being different from 0°.

Racem - *1,2 - dithiolane - 3,5 - dicarboxylic acid* [2,5-7] (II). Monoclinic prismatic, $a = 8.47$ Å, $b = 18.20$ Å, $c = 10.14$ Å, $\beta = 98°$. Eight molecules per unit cell; density, calc. 1.67, found 1.67 g/cm³. The space group, from systematic absences, is $C_{2h}^5-P2_1/c$, from which follows that the asymmetric unit consists of two molecules.

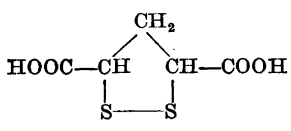
The crystals were plates {010} sometimes elongated along the c axis.

Racem - *1,2-dithiane - 3,6-dicarboxylic acid* [2,6,8,9] (III). Monoclinic prismatic, $a = 9.62$ Å, $b = 9.26$ Å, $c = 9.70$ Å, $\beta = 102\frac{1}{2}°$. There are four molecules per unit cell; density, calc. 1.64, found 1.65 g/cm³. The space group, from systematic absences and from Patterson and Fourier projections along the b axis, is C_{2h}^6-I2/c. In the conventional $C2/c$ setting, $a = 12.09$ Å, $\beta = 129°$, otherwise as above.



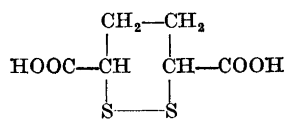
The crystals occurred as thick prisms {110}.

With four molecules per unit cell, each molecule must possess twofold symmetry in the crystals, and were found to lie on twofold axes. The dithiane ring has the chair form, with the substituents in equatorial positions. A detailed structure determination is being made [10].



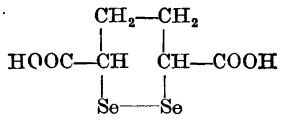
Meso - *1,2 - dithiane - 3,6 - dicarboxylic acid* [2,6,8,9]. Monoclinic prismatic, $a = 6.36$ Å, $b = 13.63$ Å, $c = 10.31$ Å, $\beta = 110°$. Four molecules per unit cell; density, calc. 1.65, found 1.64 g/cm³. The space group, from systematic absences, is $C_{2h}^5-P2_1/c$.

The crystal studied was a thick prism extended along the a axis, bounded by {010}, {001} and {011}, and terminated by {100}.



The *meso* acid, granted that its disulphide group is non-planar. will in the crystals occur in two equivalent mirror image forms, since the space group is not enantiomorphous. In solution, conversion of the dithiane ring, *i. e.*, of one enantiomorph of the *meso* acid into the other, takes place. In view of the relatively high barrier, 10—14 kcal/mole [11], towards rotation through the planar *cis* form of a disulphide group, it may be expected that conversion of the 1,2-dithiane ring takes place less rapidly than the conversion of *cyclo*hexane itself and its derivatives.

(I)



(II)

(III)

Racem - *1,2 - diselenane - 3,6 - dicarboxylic acid* [12,13] (IV). Monoclinic, probably prismatic, $a = 9.97$ Å, $b = 9.43$ Å, $c = 9.78$ Å, $\beta = 105°$. There are four molecules per unit cell; density, calc. 2.26, found 2.27 g/cm³. Systematic absences, *hkl* when $h + k$ is odd, *h0l* when *l* is odd. Similarities with the dithiane analogue, particularly of the *h0l* zones of reflections, indicate that the space group is the centrosymmetric one, C_{2h}^6-C2/c. In the *I2/c* setting, $a = 12.01$ Å, $\beta = 127°$. As in the case of the dithiane analogue, the crystals occur as prisms {110}.

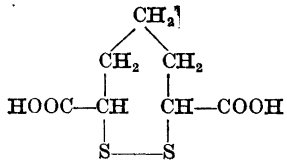
The *racem* 1,2-dithiane- and 1,2-diselenane-3,6-dicarboxylic acids thus crystallize in the same space group, with very similar unit cell dimensions, but, once the *a* axes and β angles are chosen so as to conform dimensionally, the *C*- and *I*-centered settings are interchanged in the two crystals. Thus, the photographs of the 0*kl* zones of reflections have different symmetries, corresponding to the plane groups *cmm* and *pmg*, respectively. The difference corresponds to interchange of locations of twofold screw axes and symmetry centres at $x = \frac{1}{4}$ and $\frac{3}{4}$, and to different arrangements of the molecules relatively to each other as seen along the *a* axes. Otherwise, the two structures should be very similar.

(IV)

(+) - *1,2 - diselenane - 3,6 - dicarboxylic acid* [12,13]. Orthorhombic sphenoidal, $a = 9.57$ Å, $b = 9.91$ Å, $c = 9.50$ Å. Four molecules per unit cell; density, calc. 2.23, found 2.21 g/cm³. The systematic absences are those of the space group $D_2^4-P2_12_12_1$.

The crystals occurred as flat prisms extended along the *c* axis, with {100} dominant. {110} and {101} were also observed. There is a pronounced tendency of cleavage along the *c* plane.

Racem - *1,2-dithiepane - 3,7 - dicarboxylic acid* [2,14,15] (V). Monoclinic prismatic, $a = 12.97$ Å, $b = 8.20$ Å, $c = 8.90$ Å, $\beta = 96°$. There are four molecules per unit cell; density, calc. 1.57, found 1.57 g/cm³. The space group is $C_{2h}^5-P2_1/c$, from systematic absences.



The crystals were mostly poorly developed; the one studied was a prism extended along the *b* axis.

Meso - *1,2 - dithiepane - 3,7 - dicarboxylic acid* [2,14,15]. Monoclinic, $a = 25.91$ Å, $b = 5.82$ Å, $c = 13.21$ Å, $\beta = 91\frac{1}{2}°$. Eight molecules per unit cell; density, calc. 1.48, found 1.49 g/cm³. Systematic absences, *hkl* when $h + k$ is odd, *h0l* when *l* is odd. The morphology of the crystals indicates that a twofold axis is present, and thus that the space group is the centrosymmetric one, C_{2h}^6-C2/c.

The sample consisted of prisms elongated along the *b* axis and bounded by {100} and {201}.

The disulphide group of the 1,2-dithiepane ring almost certainly being non-planar, two enantiomorphous forms of the *meso* acid occur in the crystals. Analogous considerations as to interconversion of the enantiomorphs in solution should apply as indicated above for *meso*-1,2-dithiane-3,6-dicarboxylic acid.

In the course of the work, data were obtained also for meso-*α,α'-dibromo-adipic acid* (m. p. 193 °C). The crystals were monoclinic prismatic, and occurred as prisms {011} terminated by {101}, with $a = 5.00$ Å, $b = 10.42$ Å, $c = 9.78$ Å, $\beta = 111°$. There are two molecules per unit cell; density, calc. 2.12, found 2.12 g/cm³. The space group from systematic absences, is $C_{2h}^5-P2_1/c$, from which follows that the molecules are centrosymmetric in the crystals.

Structure of Crystalline 1,2-Dithiolane-4-carboxylic Acid

OLAV FOSS and OLAV TJOMSLAND

Chemical Institute, University of Bergen, Bergen, Norway

As part of a program for the study of crystal structures of five-, six- and seven-membered cyclic disulphides, with the view of obtaining information about the stereochemistry of the disulphide group in the rings, unit cell and space group determinations have recently been made of some 1,2,4-dithiazolidine derivatives [1] and of some 1,2-dithiolane-, 1,2-dithiane-, 1,2-diselenane- and 1,2-dithiepane-carboxylic acids [2]. Also, the detailed structure of thiuret (3,5-diimino-1,2,4-dithiazolidine) hydroiodide has been worked out [3,4]. The present note gives the preliminary results of a crystal structure determination of 1,2-dithiolane-4-carboxylic acid [5,6].

The crystals are triclinic, with the unit cell dimensions [2], $a = 5.34$ Å, $b = 5.85$ Å, $c = 10.75$ Å, $\alpha = 93\frac{1}{2}°$, $\beta = 89\frac{1}{2}°$, $\gamma = 109\frac{1}{2}°$. The space group is $C_i^1 - P\bar{1}$, and there are two molecules per unit cell. The intensities of the $0kl$ reflections were estimated visually from Weissenberg photographs taken with CuK radiation, and were converted to relative structure factors in the usual way. The positions of the two sulphur atoms were found from a F_0^2 synthesis of the $0kl$ data, and a subsequent F_0 synthesis with signs based on the sulphur contributions showed the outline of the molecule and gave approximate coordinates for the carbon and oxygen atoms. After a few F_0 and $(F_0 - F_c)$ refinements the $0kl$ electron density map is as shown in Fig. 1, and the y and z coordinates as listed in Table 1. The reliability index R is at this stage 15.7 %.

Provided that the chemically equivalent S_1-C_5 and S_2-C_3 bonds and $S_1-S_2-C_3$ and $S_2-S_1-C_5$ bond angles do not have too different dimensions, the a-axis projection shows that the disulphide group of the 1,2-dithiolane ring is not planar. If, pending the determination of the x coordinates through a projection along another axis, the assumption is made that the S—C bond lengths are equal and approximately 1.81 Å, and that the S—S—C bond angles are equal, the y and z coordinates of the sulphur atoms and the C_3 and C_5 atoms lead to a disulphide group with dimensions approximately as follows: S—S bond length = 2.09 Å, S—S—C bond angles = 95°, and CSS/SSC dihedral angle = 20°.

The carboxyl groups of different molecules appear to be arranged around symmetry centres at $z = \frac{1}{2}$, and non-bonded S—S contacts only to occur across the c plane at $z = 0$.

Structure of Crystalline *Racem*-1,2-dithiane-3,6-dicarboxylic Acid

OLAV FOSS and TORBJØRN REISTAD

Chemical Institute, University of Bergen, Bergen, Norway

In two preceding notes [1,2], crystal data on some carboxylic acid derivatives of five-, six- and seven-membered cyclic disulphides, and preliminary results of a crystal structure determination of the five-membered one, 1,2-dithiolane-4-carboxylic acid, have been reported. A corresponding study of a six-membered representative, *racem*-1,2-dithiane-3,6-dicarboxylic acid[3-6], has so far given the following results.

The crystals are monoclinic prismatic, with a four-molecule unit cell based on the space group C_{2h}^6-I2/c, and with the unit cell dimensions [1], $a = 9.62$ Å, $b = 9.26$ Å, $c = 9.70$ Å, $\beta = 102\frac{1}{2}°$. The correctness of the centrosymmetric space group was first assumed, and confirmed through the subsequent work. The intensities of the *h0l* reflections were estimated visually from Weissenberg photographs taken with Cu*K* radiation; 51 reflections out of 57 attainable were recorded with measurable intensities. The position of the one sulphur atom of the asymmetric unit was derived

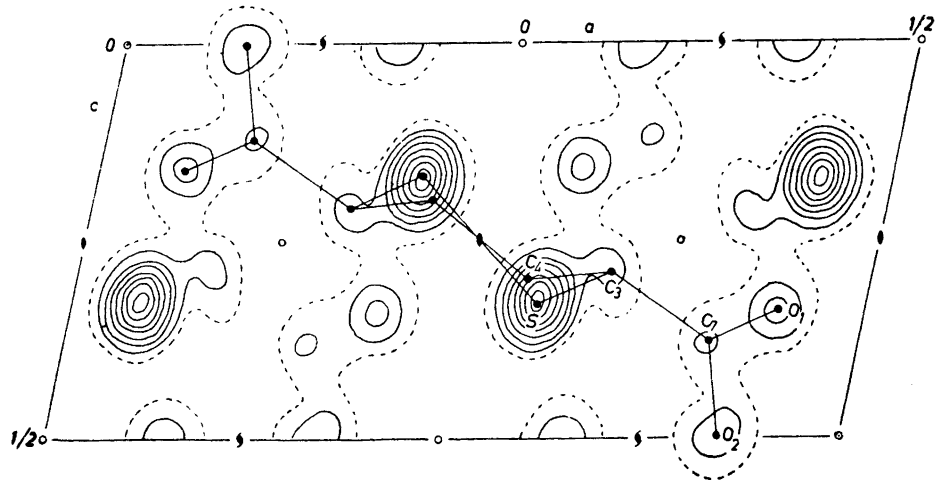

Fig. 1. Electron density projection of *racem*-1,2-dithiane-3,6-dicarboxylic acid along the *b* axis. Four asymmetric units (half a unit cell) are shown, and lines are drawn to indicate the outline of one molecule. Contours at intervals of 3 e · Å^{-2}, beginning with 4 e · Å^{-2} (dashed).

Structure of Crystalline *Racem*-1,2-dithiane-3,6-dicarboxylic Acid

OLAV FOSS and TORBJØRN REISTAD

Chemical Institute, University of Bergen, Bergen, Norway

In two preceding notes [1,2], crystal data on some carboxylic acid derivatives of five-, six- and seven-membered cyclic disulphides, and preliminary results of a crystal structure determination of the five-membered one, 1,2-dithiolane-4-carboxylic acid, have been reported. A corresponding study of a six-membered representative, *racem*-1,2-dithiane-3,6-dicarboxylic acid[3-6], has so far given the following results.

The crystals are monoclinic prismatic, with a four-molecule unit cell based on the space group C_{2h}^6-I2/c, and with the unit cell dimensions [1], $a = 9.62$ Å, $b = 9.26$ Å, $c = 9.70$ Å, $\beta = 102\frac{1}{2}°$. The correctness of the centrosymmetric space group was first assumed, and confirmed through the subsequent work. The intensities of the *h0l* reflections were estimated visually from Weissenberg photographs taken with Cu*K* radiation; 51 reflections out of 57 attainable were recorded with measurable intensities. The position of the one sulphur atom of the asymmetric unit was derived

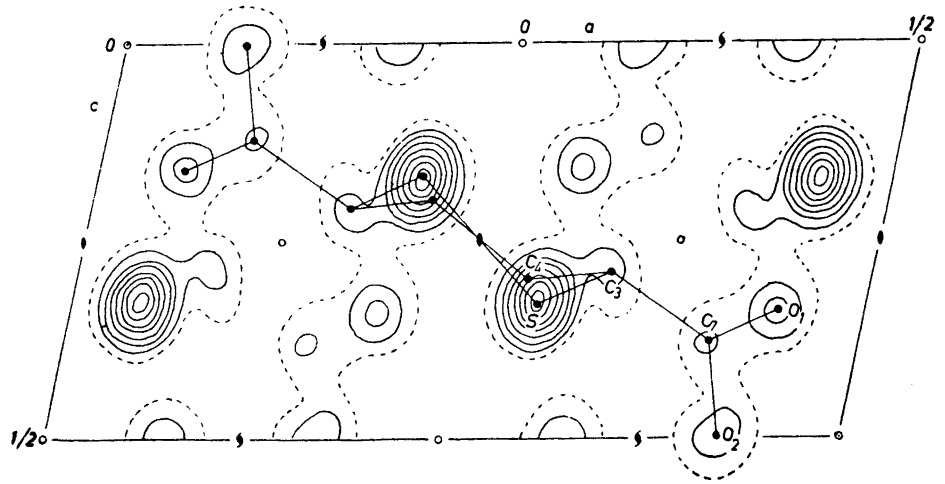

Fig. 1. Electron density projection of *racem*-1,2-dithiane-3,6-dicarboxylic acid along the *b* axis. Four asymmetric units (half a unit cell) are shown, and lines are drawn to indicate the outline of one molecule. Contours at intervals of 3 e · Å^{-2}, beginning with 4 e · Å^{-2} (dashed).

from a F_0^2 synthesis of the *h0l* data, and the sulphur atom then served as a heavy atom for the determination of the carbon and oxygen positions through F_0 syntheses. Refinement was carried out by means of successive (F_0-F_c) syntheses, and led to a standard deviation in electron density of about 0.45 e · Å^{-2} for the *h0l* zone, and a corresponding reliability index R of 10.4 %.

The *h0l* electron density map is shown in Fig. 1, and the x and z coordinates are listed in Table 1. They give a S—S bond length of 2.069 Å across the twofold axis, with an estimated standard deviation of about 0.014 Å.

Table 1. Atomic coordinates, in fractions of monoclinic cell edges. Origin at a centre of symmetry.

	x	z
S	0.0885	0.3325
C_3	0.173	0.292

O_1	0.393	0.342
O_2	0.348	0.499

The molecule possesses, by space group requirements, a twofold axis of symmetry. The 1,2-dithiane ring occurs in the chair form, and has the substituents in equatorial positions. The difference maps indicated a pronounced anisotropic thermal vibration for the sulphur atom. In the temperature factor $\exp[-B(\sin^2\Theta/\lambda^2)]$ finally chosen B was 4.0 Å^2 for the carbon and oxygen atoms and $(6.5-4.0\sin^2\varphi)$ Å^2 for the sulphur atom, where φ is the angle between the normal of the reflecting plane and the direction of maximum vibration of the atom. This direction lies about 16° from c in the acute angle, and is very close to the axial direction of the 1,2-dithiane ring, *i. e.*, to the direction of movement of the atom for conversion of the ring.

The work will be continued, and details published later.

Aberrations Chromosomiques Produites dans des Graines par de Hautes Pressions d'Oxygène

L. EHRENBERG, J. MOUTSCHEN-DAHMEN * et M. MOUTSCHEN-DAHMEN **

Institut de chimie organique et de biochimie, Université de Stockholm; Institut de recherche forestière, Département de génétique, Stockholm 51, Suède

En 1951, Conger et Fairchild ont trouvé que l'oxygène pur produit des aberrations chromosomiques dans les microspores de *Tradescantia* [1].

Dans d'autres expériences, des résultats contradictoires ont été obtenus [2]. Ceci peut indiquer que, alors que l'oxygène, sous certaines conditions, est capable de casser les chromosomes, le matériel biologique change dans son aptitude à résister à cet effet.

Dans une étude biochimique des mutations spontanées et de leurs mécanismes, nous nous sommes posé la question de savoir si l'oxygène peut produire des aberrations chromosomiques dans les graines de plantes supérieures.

Méthodes. Des graines sèches d'orge var. *Bonus*, dont la teneur en eau est de 11 %, ont été traitées pendant une ou deux semaines, respectivement, dans une bombe de fer sous 60 atmosphères de pression d'oxygène. Dans le but d'étudier l'effet d'une haute pression, *per se*, une expérience parallèle fût réalisée avec 60 atmosphères d'azote. Lors de ces traitements, on a pris soin de changer la pression très lentement afin d'éviter les effets thermiques.

Après une semaine de traitement, les graines sons mises à germer. Les pointes de racines sont fixées 30 à 90 h après la fin du traitement afin de pouvoir observer les successions des trois premières mitoses consécutives au traitement.

Après le traitement de deux semaines, nous avons attendu un délai de trois semaines avant de les mettre à germer.

En 1951, Conger et Fairchild ont trouvé que l'oxygène pur produit des aberrations chromosomiques dans les microspores de *Tradescantia* [1].

Dans d'autres expériences, des résultats contradictoires ont été obtenus [2]. Ceci peut indiquer que, alors que l'oxygène, sous certaines conditions, est capable de casser les chromosomes, le matériel biologique change dans son aptitude à résister à cet effet.

Dans une étude biochimique des mutations spontanées et de leurs mécanismes, nous nous sommes posé la question de savoir si l'oxygène peut produire des aberrations chromosomiques dans les graines de plantes supérieures.

Méthodes. Des graines sèches d'orge var. *Bonus*, dont la teneur en eau est de 11 %, ont été traitées pendant une ou deux semaines, respectivement, dans une bombe de fer sous 60 atmosphères de pression d'oxygène. Dans le but d'étudier l'effet d'une haute pression, *per se*, une expérience parallèle fût réalisée avec 60 atmosphères d'azote. Lors de ces traitements, on a pris soin de changer la pression très lentement afin d'éviter les effets thermiques.

Après une semaine de traitement, les graines sons mises à germer. Les pointes de racines sont fixées 30 à 90 h après la fin du traitement afin de pouvoir observer les successions des trois premières mitoses consécutives au traitement.

Après le traitement de deux semaines, nous avons attendu un délai de trois semaines avant de les mettre à germer.

Tableau 1.

Traitement		Cassures par métaphase	Cassures par anaphase	Ponts par anaphase	Nombre de cellules en méta- ou anaphase
O_2	1 semaine	0.102	0.021	0	600
	2 semaines	0.213	0.041	0.03	600
N_2	2 semaines	0	0	0	600

Le fixateur utilisé est le mélange de Çarnoy et les observations sont effectuées en "Feulgen-squashes".

Résultats. Nous avons observé les effets suivants:

Après une semaine de traitement par O_2, la première mitose consécutive au traitement montre une profusion d'effets primaires fortement marqués. De l'érosion chromosomique parfois discrète mais plus fréquemment généralisée se présente dans environ 45 % des anaphases et des métaphases. Du collage "stickiness" des chromosomes est observé en métaphases et en anaphases et les "pseudo-ponts" sont très peu abondants (0.12 % des anaphases sticky).

Dans les figures mitotiques perturbées, les chromosomes sont souvent effilochés et fréquemment hyper-colorés et montrent dès lors, une structure en "lamp-brush"[3]. Cet effet fréquemment considéré comme étant nécrotique s'est néanmoins montré réversible et labile. Lors de la première mitose, les effets primaires sont donc présents dans environ 90 % des mitoses. Lors de la seconde mitose après le traitement, on ne note plus de l'érosion que dans environ 30 % des métaphases et anaphases.

Pour le traitement pendant 2 semaines, aucun phénomène précédemment décrit n'a pu être observé lors de la première mitose à l'exception de l'érosion chromosomique présente dans 45 % des cas. Nous avons attribué cette absence au temps de latence entre la fin du traitement et la mise en germination. Pour les deux temps de traitement, lors de la seconde mitose consécutive à ces traitements, nous avons observé des effets radio-mimétiques résumés dans le Tableau 1.

Ce tableau montre que les effets radiomimétiques (cassures métaphasiques et anaphasiques avec quelques ponts vrais) ont augmenté avec le temps de traitement. Aucun effet analogue n'a été observé chez le témoin sous N_2. Chez celui-ci, la première mitose montre seulement une certaine fréquence (40—50 %) d'érosion chromosomique parfois assez marquée. Il est donc probable qu'une partie au moins des perturbations cellulaires conduisant à des modifications matricielles soient imputables à un effet de pression mais il n'en est pas de même en ce qui concerne les effets radio-mimétiques.

Il est donc démontré qu'un traitement par l'oxygène à de très hautes pressions (60 atmosphères étant 300 fois la pression du milieu normal) produit un nombre d'aberrations appréciable: 0.1 des secondes métaphases perturbées correspond à l'effet d'une dose de rayons X d'environ 1 000 r appliquée à des graines ayant la même teneur en eau. L'effet semble d'autant plus remarquable que la fréquence d'aberrations spontanées chez l'orge est extrêmement basse. L'effet semble plutôt général étant donné que, après des traitements similaires sur des graines de légumineuses (*Pisum sativum* et *Vicia faba*), les feuilles de ces plantes montrent des fréquences accrues des types de panachures qui pourraient être imputées à des aberrations chromosomiques [4,5].

Preparation of the Laevorotatory Enantiomer of Methylallylacetic Acid

GUNNEL STÄLLBERG

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

The dextrorotatory form of methylallylacetic acid ((+)-2L-methyl-$\Delta^{4:5}$-pentenoic acid) was first obtained by Ställberg-Stenhagen [1] by resolution of the racemic acid *via* the quinine salt. The configuration was determined by Ställberg-Stenhagen and Stenhagen [2], who oxidized the (+)-acid to (−)-methylsuccinic acid. The laevorotatory enantiomer has so far not been reported in the literature. In connection with work on the synthesis of phthiocerol in this laboratory, both enantiomers were needed for the synthesis of the different stereoisomeric forms of the 3-methoxy-4-methyl-grouping of the phthiocerol molecule [3]. It has now been found that the laevorotatory enantiomer of methylallylacetic acid ((−)-2D-methyl-$\Delta^{4:5}$-pentenoic acid) can be obtained *via* the (+)-1-phenylethylamine salt. The optical rotation found was numerically equal to that reported for the dextrorotatory enantiomer [4,5].

Experimental. (−)-2D-*Methyl-*$\Delta^{4:5}$*-pentenoic acid.* Partially resolved laevorotatory acid (43 g, a_D^{25} −5.3° (undiluted, *l* 1)), obtained from the mother liquor of the first crystallization of the quinine salt of the dextrorotatory enantiomer, was dissolved in ether (700 ml) and a solution of (+)-phenylethylamine (44.5 g) in ether (800 ml) was added cautiously (heat is evolved during the formation of the salt). Crystallization was allowed to take place overnight at a temperature of −15°. The salt crystallized in the form of long thin needles. Acid isolated from the mother liquor of this crystallization had an optical rotation of a_D^{25} −2.2° (undiluted, *l* 1). The salt was recrystallized from successively smaller volumes of ether and the course of the resolution followed by measuring the rotation of acid isolated from the mother liquors. Nine crystallizations were needed before the rotation attained the constant value a_D^{25} −7.80° (undiluted, *l* 1). Decomposition of the salt gave 6.6 g of (−)-methylallylacetic acid of b.p. 87−88° at 12 mm; n_D^{25} 1.4275, n_D^{18} 1.4305; d_4^{25} 0.946; R_D calcd. 31.02, found 31.01.

Optical rotation: a_D^{25} −7.80° (undiluted, *l* 1); $[\alpha]_D^{25}$ −8.25°; $[M]_D^{25}$ −9.41°.

The specimen of the dextrorotatory enantiomer, prepared in the course of the present work had $[\alpha]_D^{25}$ +8.25°. Ställberg-Stenhagen [4] gives a_D^{20} +7.88° (undiluted, *l* 1), which corresponds to $[\alpha]_D^{20}$ +8.28°. Fray and Polgar [5] give $[\alpha]_D^{19}$ +8.24°.
