A Chemical Method for the Quantitative Determination of Male Sperm Antagglutin

P. E. LINDAHL, J.-E. KIHLSTRÖM and S. ROSS

Institute of Zoophysiology, Uppsala, Sweden

A chemical method for the quantitative determination of male sperm antagglutin has been worked out, allowing determinations in the range of 0.5 to 3.5 μg antagglutin.

Since it had been understood that the agglutination of spermatozoa in mammals is prevented by certain substances, named sperm antagglutins, and produced in the male and female genitalia [1–5], the quantitative determination of these substances has been of great interest. For the male antagglutin a biological test method was elaborated [2], giving within certain limits and under favourable conditions certain rough quantitative values. Some variable and unknown factor, located probably in the spermatozoa used as test objects, limits, however, this method to be as yet a mere qualitative one. Still, it has the great advantage of permitting tests on very small samples (about 0.1 ml of normal sperm plasm), and making possible a differentiation between antagglutin in the reduced, biologically active and the oxidized, biologically inactive state. Because of the above mentioned disadvantages we have tried to develop a method, based only on chemical reactions and physical measurements, and rendering possible the determination of 2.0 μg of antagglutin with a reasonable error. Such a method would *e. g.*, allow a study of the physiological variation of the antagglutin content in sperm plasm, using only 0.1 ml samples.

The male sperm antagglutin is a complex, made up by protein, sugar, sulphuric acid residues, and a carbocyclic substance. After attempts to use colour reactions on protein or sugar for the quantitative determination of antagglutin in spots obtained by chromatography on different kinds of threads we intended to convert the antagglutin into a compound with a sufficiently high molar extinction to allow spectrophotometric determinations. It was found that heating of the antagglutin to 220°C with potassium bisulphate (melting point 210°C) results in the formation of a compound which is soluble in ethanol but not in ethyl ether, and which by oxidation with manganese dioxide is transformed into a substance with a high molar extinction in ultra-

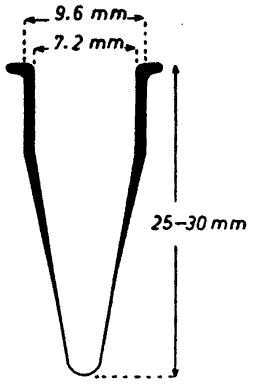

Fig. 1. Micro reaction tube. Note thickening of the edge supporting the tube in the centrifuge.

violet. The solubility of the intermediary product in ethanol but not in ethyl ether makes possible the removal of ether-soluble breakdown products which otherwise disturb the spectrophotometric determination. The extinction maximum disappears at further oxidation, *i. e.* aeration or prolonged standing in contact with air. This process, being slower in ethanol than in water, is, however, retarded by manganese ions. As the extinction of the end-product is much higher in water than in ethanol solution, the former solvent is preferred for the determination of the absorption.

Procedure. Of the sample to be analyzed * 0.1 ml is put into a pointed micro reaction tube (Fig. 1) of pyrex fitting into the micro-comb centrifuge (Laboratoriemaskiner Ltd, Stockholm). By addition of 0.03 ml saturated solution of potassium sulphate the antagglutin is precipitated, and spun down at 7 000 *g* for 5 min. The precipitate is dissolved in 0.1 ml distilled water, and the salting out repeated. The supernatant is removed, and the precipitate dissolved in 0.2 ml distilled water, occupying about two thirds of the height of the conical part of the tube. The water is evaporated at 40°C under vacuum whereby the antagglutin is deposited as a very thin film at the wall of the tube. The latter is then filled up with dry, powdered potassium bisulphate ** till slightly above the edge of the film, the powder pressed down tightly with a small glass pestle, and the filling completed if necessary. The reaction tube is then placed in a big test-tube (18 cm length) with a layer of glass beads at the bottom to keep the reaction tube upright, and the test tube immersed for one hour in an oil-bath of 220°C. Under these conditions the potassium bisulphate melts within 5 min.

After the reaction tube has cooled down it is taken out of the test-tube, its outside is cleaned with ethyl ether, and the tube with its hard content powdered in a mortar. The whole material is transferred to a centrifuge tube with a ground stopper, the mortar being washed out with 3 ml absolute ethanol ("Spectroscopically pure", Vin- och Sprit-centralen Ltd) which is then used for extraction of the salt powder. About 5 mg of manganese dioxide is added, and the closed centrifuge tube shaken vigorously lengthwise for 12 h. The solids are then brought down by centrifugation, and the supernatant poured into a 10 ml flask. The solids in the centrifuge tube are washed out with another half ml ethanol, which is added to the extract in the flask. From this the ethanol is driven off

* If the sample is semen the biologically active part of the antagglutin sticking to the surface of the spermatozoa (*cf.* Ref. [2]) is released by oxidation with 0.01 ml $8 \cdot 10^{-2}$ M hydrogen peroxide per 0.1 ml of semen, and the spermatozoa spun down.

** As commercial preparations of this salt often contain a surplus of sulphuric acid which is deleterious to the method, it is recommended to extract the potassium bisulphate for 12 h in a Soxhlet apparatus with dry freshly distilled ethyl ether.

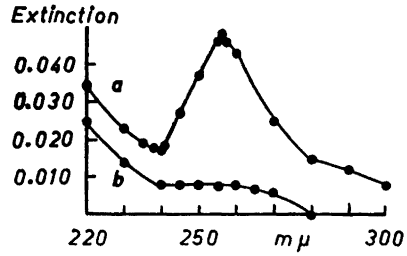

Fig. 2. Absorption curves: analytical procedure applied to *a* antagglutin containing sample, *b* to equal quantity distilled water.

under vacuum at 50°C. As soon as the liquid has disappeared 3 ml freshly distilled dry ethyl ether are poured into the flask which is then shaken for a moment, and left for 5—10 min. The ether is drawn off, and the rest of it quickly evaporated. The remainder in the flask is dissolved in 3.0 ml redistilled water. The UV-absorption of this extract should be read within one h with distilled water as a blank. This determination was carried out by means of a Beckman spectrophotometer, Model DU.

The absorption maximum of the product, obtained with the described procedure is at 256—257, the minimum at 240—242 mμ (Fig. 2a). A blank treated in the same way gives the extinction curve b (Fig. 2). Here the extinction values at 240—242 and 256—257 mμ do not differ significantly. The difference between the extinction maximum and minimum is 0.012 per μg bull antagglutin in the range 0.5 — 3.5 μg (Fig. 3). Above 3.5 μg this difference is not proportional to the amount of antagglutin treated, the straight line in Fig. 3 becoming parallel to the abscissa.

The standard deviation (s) calculated from 20 duplicate determinations on bull semen in the range 0.5 to 3.5 μg (*cf.* Hald [6], p. 244) is 0.103. The duplicate determinations with values below 1.0 μg give a somewhat higher standard deviation than those with values above 1.0 μg (*cf.* below).

Range μg antagglutin	Number of determinations	s
0.5—1.0	8	0.111
1.1—3.4	12	0.097

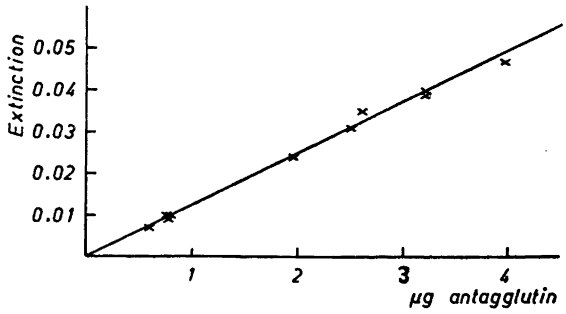

Fig. 3. Differences between extinction maximum at 256—257 mμ and extinction minimum at 240—242 mμ plotted against quantities of antagglutin.

It is essential that no other substances occurring in the sperm plasm give rise to an extinction maximum at 256—257 mμ when treated in the same way. This was controlled by performing the procedure of analysis on samples of sperm plasm from which the antagglutin had been removed by salting out. Further different appropriate quantities of antagglutin were added to equal samples of a sperm plasm with its original antagglutin, and the total antagglutin content analysed. The values obtained fell all on a straight line parallel with that in Fig. 3.

The reactions upon which the described method is based are being studied.

The financial support of the *Swedish Agricultural* and *Natural Science Research Councils*, the *Population Council*, Inc., New York, and *Pharmacia, Ltd.*, Uppsala, is gratefully acknowledged. We thank Mr. O. Heidenberger for valuable technical assistance.

On the Isomerism of Hydroxyurea

VIII. A Polarographic Study of the Formation Process in Aqueous Solution

HELMER KOFOD

Royal Danish School of Pharmacy, Dept. of Organic Chem. Copenhagen, Denmark

The formation of the isomeride, melting at 72°C, from hydroxylammonium chloride and potassium cyanate in aqueous solution, has been followed at 25°C and at 0°C by a polarographic method. The maximum wave height obtained corresponded to a mole fraction of approximately 0.6, not varying markedly with temperature. The rest of the stoichiometric yield — 0.4 in mole fraction — probably consists of the polarographically inactive higher melting isomeride. It is proposed that the isomerides are formed by a mechanism of concurrent reactions rather than by one of consecutive reactions.

In aqueous solution, buffered at pH 9.2, no formation of the lower melting isomeride was detectable. The preliminary results, reported in this paper, may be of interest in connection with the controversial views on the mechanism of the classical urea synthesis.

In the first paper in this series [1] the ionic reaction

$$HONH_3^+ + Cl^- + K^+ + {}^-OCN = \underset{\text{hydroxyurea isomerides}}{CH_4O_2N_2} + K^+ + Cl^- \qquad (1)$$

was subjected to a preliminary kinetic investigation at 0°C. The advancement of the reaction was followed conductometrically. The data indicated a bimolecular, second order process with a rate constant approximately 8 l mole^{-1} min^{-1}. The ultimate conductivity value, arrived at after 20 h, could be accounted for by the potassium ions alone, from which it may be inferred that the hydroxylammonium ion and the cyanate ion react practically completely to yield products, which are only slightly, if at all, ionized. This method obviously could provide no information on the relative amounts of hydroxyurea isomerides formed.

In a previous publication [2] it was shown that the lower melting hydroxyurea (72°C), which in the following will be denoted OU_{72}, is reduced at the dropping mercury electrode, whereas the higher melting one, OU_{140}, is not.

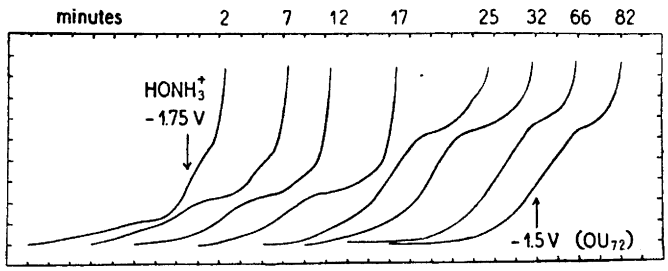

Fig. 1. Formation of hydroxyurea OU_{72} (reaction 1) at 25°C in aqueous solution. Initial concentration of reactants c_0 = 4.0 mM. Dilutions 1:10 with buffer at pH 9.2, polarographed at 25.0°C. Drop time 3.3 sec., height of mercury column 45 cm, rate of mercury outflow 2.66 mg/sec. One unit on the abscissa corresponds to 0.1 volt; the first four curves begin at −1.0 volt *vs.* SCE ("saturated calomel electrode"), one unit on the ordinate corresponds to 0.66 μA. The last four curves begin at −0.8 V *vs.* SCE and were recorded with a sensitivity, increased by a factor 2; one unit on the ordinate corresponds to 0.33 μA.

The polarographic method was worked out in detail for determination of OU_{72} in the presence of OU_{140}.

The present paper is devoted to a further investigation into reaction (1) by following the formation of OU_{72} polarographically.

As a supporting electrolyte potassium borate buffer at pH 9.2 was selected. In a more acid solution the hydroxylammonium wave would interfere severely, and in a more basic solution OU_{72} becomes increasingly unstable [2, Fig. 1].

THE FORMATION OF OU_{72} AT 25°C IN DILUTE AQUEOUS SOLUTION.

A 5 mM aqueous solution of hydroxylammonium chloride and a 20 mM aqueous solution of potassium cyanate, both freshly prepared, were separately equilibrated in a water-thermostat at 25.00±0.02 °C, dissolved oxygen being at the same time removed by passing a stream of moist, oxygen-free nitrogen through the solutions for five minutes. 40.00 ml of the hydroxylammonium solution and 10 ml of the cyanate solution were then rapidly mixed in a flask, which was kept in the thermostat during the reaction. The initial concentration of the reactants was thus 4 mM. 0.5 ml samples were withdrawn at intervals with a pipette, quickly mixed with 4.5 ml of previously deaerated buffer, and polarographed at 25.00°C. The recorded series of current-voltage curves is reproduced in Fig. 1. They clearly show the gradually vanishing hydroxylammonium wave at approximately —1.75 V and the growing hydroxyurea wave at about —1.5 V. The cyanate ion is polarographically inactive in this voltage region. The number appearing above each curve indicates the time in min from the mixing of the reactants and until the recording of the respective polarogram was begun. The wave height, produced by hydroxyurea has previously been demonstrated to be directly proportional to the concentration [2, Fig. 4]. The relation $i = 8.0\ c$ (i being the wave height in μA and c the concentration in mM) was found to apply also at pH 9.2, other conditions being identical. The observed maximum wave height of hydroxyurea OU_{72} is about

1.8 μA, and it corresponds to a concentration of 0.22 mM in the analytical dilution or 2.2 mM in the original reaction mixture. This is slightly more than half the total value, 4.0 mM, expected from stoichiometry, if OU_{72} were the only product. It corresponds to a mole fraction of OU_{72} of *ca.* 0.6; while a mole fraction of *ca.* 0.4 of the polarographically inactive OU_{140} has probably been formed simultaneously.

THE FORMATION OF OU_{72} AT 0°C IN DILUTE AQUEOUS SOLUTION

It was desirable to repeat the above experiment at 0°C. This is the most favourable reaction temperature for preparative work[3], and the data would be directly comparable with the conductometric data, reported earlier for the overall reaction [1], and finally, at the low temperature the slowed-down reaction would be better fit for the polarographic method of analysis.

A rapid withdrawal of well-defined sample-volumes from a reaction mixture at 0°C, followed by dilution and measurement at the standard temperature, 25°C, presented certain experimental difficulties, particularly with the available slow method of analysis. To overcome these obstacles it was first decided to carry out the reaction in the polarographic cell itself, properly thermostated at 0°C, and to work out a concentration-wave-height curve for this particular temperature. Since a pH of about 9.2 is the only region, in which the hydroxylammonium wave and the hydroxyurea wave may be independently and reproducibly measured [2, Fig. 3], the reaction had to be carried out in a buffer having this pH.

Introductory experiments of this kind showed, however, that at pH 9.2 and 0°C the reaction (1) is too slow for practical work. With an initial concentration of 10 mM of the reactants no hydroxyurea-wave was observable and no decrease in the height of the hydroxylammonium-wave was perceptible within 2 h. In unbuffered aqueous solution under otherwise identical conditions this space of time would correspond to more than 90 % reaction, as calculated [1] from $8\ t = \frac{1}{c} - \frac{1}{0.01}$. The temperature of the reaction mixture was raised to 25°C and polarographic measurements were carried out for another hour, still without detection of any hydroxyurea wave.

The failure of reaction (1) in the basic buffer unexpectedly solved the experimental difficulties, met with in the study of the reaction at low temperature, since it provided a convenient means of quenching the reaction in withdrawn samples for subsequent polarographic analysis at the standard temperature, 25°C. It was, therefore, decided to reproduce the experimental technique applied in the first experiment, except that the reaction was carried out at 0°C.

100 ml of an 8.0 mM aqueous solution of hydroxylammonium chloride and 100 ml of an 8.0 mM aqueous solution of potassium cyanate were freshly prepared and cooled separately to 0°C in an ice-water bath. During the temperature equilibration dissolved oxygen was removed in the way previously described. The cyanate solution was poured into the flask containing the hydroxylamine solution, and rapid mixing ensured ($t = 0$). The reaction mixture was maintained at 0°C during the experiment. From time to time 0.5 ml

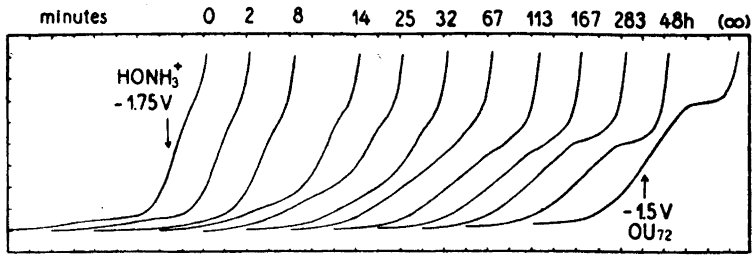

Fig. 2. Formation of hydroxyurea OU_{72} (reaction 1) at 0°C in aqueous solution. Initial concentration of reactants c_0 = 4.0 mM. Dilutions 1:10 with buffer of pH 9.2 polarographed at 25.0°C. Drop time 3.0 sec., height of mercury column 24 cm, rate of mercury outflow 3.02 mg/sec. One unit on the abscissa corresponds to 0.1 V. All curves begin at −1.0 volt *vs.* SCE. One unit on the ordinate represents 0.66 μA.

The first current-voltage curve, marked "0" was obtained with a 4.0 mM aqueous solution of hydroxylammonium chloride, without the addition of cyanate. The last curve ("∞") was obtained with a 4.0 mM aqueous solution of isolated hydroxyurea OU_{72}.

samples were withdrawn with a fast-draining pipette, quickly mixed with 4.5 ml of potassium borate buffer, pH 9.2, previously deaerated and equilibrated at 25.0°C in the polarographic cell. The analytical dilution was further deaerated, and proper mixing and temperature equilibration was ensured by passing a stream of nitrogen through the cell for another minute. The dilutions were then polarographed as previously described in detail [2].

The current-voltage curves are reproduced in Fig. 2. They present the same general picture as Fig. 1, deviating only in the reaction velocity. The initial concentration of the reactants is c_0 = 4.0 mM (0.4 mM in the dilutions). For comparison a 4.0 mM aqueous solution of hydroxylammonium chloride, denoted 0, has been recorded first in the same dilution 1:10. The hydroxylamine wave at −1.75 V is seen to decrease in height as the reaction proceeds, being replaced by a hydroxyurea wave at −1.5 V. The time for the maximum wave-height attained (curve "48 h") corresponds to almost 99 % reaction, as calculated from the conductometric rate constant k = 8 l · mole^{-1}min^{-1}, *vide* Ref. [1]. For comparison a 4.0 mM aqueous solution of authentic OU_{72} has been recorded (last curve in Fig. 2) under identical conditions (dilution 1:10). This curve represents the stoichiometric wave-height for 100 % reaction, if the lower melting hydroxyurea OU_{72} were the only product. We thus arrive at the same conclusion as from the experiment performed at 25°C, *i.e.* that somewhat more than half the reaction product is OU_{72}, mole fraction *ca.* 0.6, the rest being probably the polarographically inactive OU_{140}, in other words the ratio OU_{72}/OU_{140} is well over one. This agreement was to be expected. If follows from simple kinetic arguments that the ratio of isomeric products formed in a process should not vary markedly with temperature, provided the same reaction mechanism applies.

DISCUSSION

The above experimental material is not of sufficient accuracy to justify a detailed kinetic treatment. The individual wave heights, particularly those recorded for degrees of advancements round 50 %, can only be roughly estimated. In the experiment (Fig. 2) there has inevitably been a short rise of temperature during the transfer of samples to the arresting buffer solution. This error grows smaller as the reaction proceeds and becomes insignificant in the last curves. Frequent re-recording showed that the error due to undesired further reaction in the polarographic cell, during the recording of a curve (about 2 min), was negligible. The withdrawal of 0.5 ml samples was made with a fast-draining pipette, which was calibrated at 20°C as usual, and obviously no temperature equilibration could be permitted. The volume mixed with 4.5 ml buffer (measured out at 20°C), therefore, corresponded to slightly more than 0.5 ml at the standard temperature of measurement. Since, however, the same procedure was strictly adhered to, also in preparing the dilutions, recorded in curve 0 and ∞, this error does not invalidate the qualitative conclusions drawn in the following.

The actual mechanism of reaction (1) will be considered in a forthcoming publication, but it may be briefly mentioned here that *a priori* there seems to exist two possibilities, either a mechanism of concurrent reactions (Fig. 3 a) or one of consecutive reactions (Fig. 3b). In the figures 1 denotes the starting materials in reaction (1), 2 and 3 the isomeric hydroxyureas. According to the mechanism depicted in Fig. 3a the isomerides are formed simultaneously and side by side, whereas in Fig. 3b OU_{72} is the primary product, which is then partly isomerized to OU_{140}. Preliminary experiments [2, Fig. 1] have shown that in neutral aqueous solution at room temp. the isomerization 23 is incomparably slower than the formation 12, and this has been confirmed in unpublished work on the kinetics and mechanism of reaction 23 under various conditions. Under such circumstances the mechanism b would manifest itself as a polarographic hydroxyurea wave rapidly rising to almost the stoichiometric height and subsequently falling off very slowly. What actually was observed, however, (Figs. 1 and 2) was a maximum wave height slightly more than half the stoichiometric one, which seems to be in favour of mechanism a.

The apparent failure of reaction 12 in alkaline buffer pH 9.2 (*vide* p. 7) raises the question, as to whether the actual mechanism of the overall reaction (1) is ionic, as indicated in the stoichiometric equation, or rather involves free hydroxylamine and free cyanic acid. For the analogous process leading to

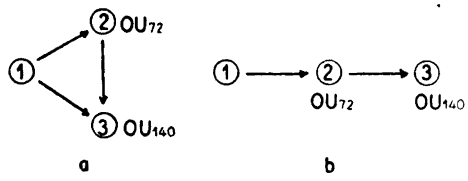

Fig. 3. Possible mechanisms of the formation of the hydroxyurea isomerides (reaction 1). 1 stands for the reactants; a. concurrent formation, b consecutive formation.

urea a non-ionic mechanism has recently been given priority [4] for steric reasons. Weil and Morris [5] have emphasized that the ionic and non-ionic mechanisms are kinetically indistinguishable, owing to the mobile equilibrium $NH_3 + HOCN \rightleftharpoons NH_4^+ + {}^-OCN$, and the same would probably apply to the reaction (1). It is, therefore, highly improbable that any useful information can be obtained from an examination of the pH-dependency of the rate constant of (1), and apart from that such measurements are impracticable with the polarographic method, because the hydroxylammonium wave and the hydrogen wave would interfere with the hydroxyurea wave in neutral and acid solution.

Materials, apparatus and general technique have been described in detail in previous publications [1,2].

Utilization of Doubly Labeled Pyrimidine Ribosides and Deoxyribosides by the Rat

PETER REICHARD

Biochemical Department, Karolinska Institutet, Stockholm, Sweden

Cytidine, uridine, deoxycytidine and thymidine were prepared from ^{14}C-labeled polynucleotides. The doubly labeled nucleosides were separately injected into partially hepatectomized rats and their incorporation into the pyrimidine part and the sugar moiety of polynucleotide pyrimidines was studied.

The intact incorporation of each administered labeled compound into the corresponding nucleoside was demonstrated. After injection of the labeled pyrimidine ribosides the ratio between the specific activities of pyrimidine and deoxyribose of the isolated deoxyribosides was very close to the corresponding pyrimidine/ribose ratio of the precursor, indicating a relatively direct conversion of the ribosides to deoxyribosides. No utilization of deoxyribosides for the synthesis of ribosides was observed.

In no case did the purine ribosides contain significant activity.

^{15}N-labeled pyrimidine ribosides and deoxyribosides are incorporated by the rat into polynucleotide pyrimidines [1,2]. Free pyrimidines, however, are very poorly or not at all utilized [3–7]. This was taken as evidence that the labeled nucleosides were incorporated as intact molecules into both pentose nucleic acid (PNA) and deoxypentose nucleic acid (DNA) [1,2]. Rose and Schweigert [8] subsequently demonstrated that the ribose and pyrimidine of doubly labeled cytidine-^{14}C were incorporated to the same extent into the pyrimidine and carbohydrate moiety of PNA and DNA pyrimidine nucleosides. This established that the postulated intact incorporation of the labeled nucleosides had taken place at least with cytidine.

In the present investigation cytidine, uridine, deoxycytidine and thymidine were prepared from over all ^{14}C-labeled polynucleotides. The nucleosides, which were accordingly labeled in both the pyrimidine ring and the carbohydrate moiety, were injected into partially hepatectomized rats, and their utilization for polynucleotide biosynthesis in the liver and the intestine was studied.

EXPERIMENTAL

Preparation of labeled ribosides. ^{14}C-yeast nucleic acid was purchased from Schwarz laboratories, Inc. After alkaline hydrolysis the labeled mononucleotides were prepared by gradient elution chromatography on a Dowex-2 formate column [9]. The pyrimidine nucleotides were dephosphorylated with prostatic phosphatase and the formed ribosides were then prepared by starch chromatography [10].

Preparation of labeled deoxyribosides. Labeled DNA was obtained by extraction [11] from *E. coli* grown in the presence of lactate-3-^{14}C *. Labeled deoxynucleotides were prepared by the combined action of deoxyribonuclease and snake venom diesterase [12]. After chromatography [9] the pyrimidine deoxynucleotides were dephosphorylated with snake venom monoesterase and the formed deoxycytidine and thymidine were chromatographed on starch [13].

The purity of all the labeled compounds used for the animal experiments was checked from light absorption data in the ultraviolet [14] and paper chromatography [15].

Before use each labeled compound was diluted with the corresponding nonlabeled riboside or deoxyriboside. The ratio between the specific activities of the pyrimidine ring and the carbohydrate was determined in duplicate experiments as described below.

Animal experiments. Rats weighing 150—200 g were subjected to partial hepatectomy according to the technique used in this laboratory [16]. Starting 20 h after the operation each nucleoside, dissolved in 0.9% NaCl, was injected into one rat at two hours interval. A total of five injections (0.5 ml each) was given to each rat. The rats were killed 42 h after the operation, the livers and the thoroughly washed small intestines were removed and separately placed in alcohol.

Isolation of polynucleotide compounds for ^{14}C-determinations. PNA and DNA were prepared and separated according to Hammarsten [11]. The ribosides and deoxyribosides, respectively, were obtained by a combination of ion exchange and starch chromatography as outlined above for the preparation of the isotopic compounds.

Degradation of nucleosides. In order to determine the ratio between the specific activities of the pyrimidine ring and of the sugar the following procedure was adopted:

Each nucleoside was dissolved in 5 ml of water. The amount of substance was measured by light absorption [14] after dilution of aliquots with 0.1 N HCl. Radioactivity was measured on infinitely thin samples (less than 0.2 μmoles/cm^2) in a Tracerlab Sc-18 windowless flow counter and the specific activity of the whole nucleoside was calculated.

The rest of the pyrimidine nucleoside containing solution was evaporated to dryness *in vacuo*. The residue was transferred to a bomb tube with a small amount of conc. formic acid (1—2 ml) and hydrolyzed at 175° [17], deoxyribosides for 1 h, ribosides for 3 h. This treatment liberated the free pyrimidines. The only nucleoside which was not quantitatively split was uridine. The formic acid was removed by repeated evaporation *in vacuo*, the residue was dissolved in butanol-water and chromatographed on starch [18].

The specific activities of the pyrimidines obtained in this way was calculated after light absorption measurements and determinations of radioactivity as described for the nucleosides.

This method gave the specific activity of the sugar moiety as the difference between that of the nucleoside and that of the pyrimidine ring.

RESULTS

Cytidine-^{14}C. Three different animal experiments were carried out and are recorded in Table 1. In accordance with earlier observations [1,8] cytidine was incorporated into all pyrimidines of both PNA and DNA. The ratios between the specific activities of the pyrimidine ring and of the carbohydrate moiety showed some variations for each nucleoside in the different experiments probably largely depending on the fact that the specific activity of the sugar was determined by difference. The average ratio for all cytidines from both

* I am much indebted to Dr. H. Palmstierna for a gift of the labeled bacteria.

Table 1. Incorporation of doubly labeled cytidine-^{14}C into polynucleotides of the rat.
The specific activity of the precursor was 172 000 ct/min/μmole. The ratio between the specific activities of ribose and cytosine was 1.85.
Each rat received a total of 10 μmoles of cytidine in expts. 1 and 2, 5 μmoles of cytidine in expt. 3.

liver and intestinal polynucleotides, however, was clearly very close to the corresponding value in the administered precursor.

The uracil/ribose ratios in the polynucleotide uridines were slightly lower than the corresponding values for cytidine. This was also true for the two deoxyribosides. The incorporation into the purine nucleosides is not recorded in the table, since it was insignificant in all cases (less than 10 counts/μmole).

Uridine-^{14}C. Relatively large amounts of the isotopic riboside were administered in order to obtain high enough counts in the isolated compounds (Table 2). In this experiment the pyrimidine/ribose ratios in the PNA ribosides were quite close to that of the administered precursor, and this was also true for the pyrimidine/deoxyribose ratios. Again only very low counts were found in the purine compounds.

Labeled deoxyribosides. The results of experiments with deoxycytidine-^{14}C and thymidine-^{14}C are demonstrated in Table 3. The former compound was incorporated into both deoxycytidine and thymidine of DNA, while the latter was utilized exclusively for thymidine synthesis. In no case was there significant incorporation into PNA pyrimidine ribosides or purine compounds.

Degradation of the isolated deoxyribosides showed that in all cases pyrimidine and deoxyribose were incorporated to about the same extent into DNA.

Table 2. Incorporation of doubly labeled uridine-^{14}C into polynucleotides of the rat. 100 μmoles of uridine (71 000 cts/min/μmole) were injected into one rat. The ratio between the specific activities of ribose and uracil was 1.46.

DISCUSSION

It is quite clear from the results that the rat has the capacity to incorporate pyrimidine ribosides and deoxyribosides into tissue polynucleotides without a more pronounced breakage of the pyrimidine-sugar bond.

Most experiments were carried out with labeled cytidine, since this compound, when administered in small amounts, was incorporated best into all pyrimidine ribosides and deoxyribosides. The fact that the ratio between the specific activities of cytosine and of ribose within experimental limits was the same in the injected precursor and in the isolated polynucleotide cytidine demonstrates the intact incorporation of the precursor. Such a finding would be extremely improbable if the glycoside linkage of the injected compound were first split and the split products were subsequently utilized for polynucleotide synthesis.

The uracil/ribose ratio was in all cases slightly lower than the cytosine/ribose ratio. Unless this finding depends on some unknown systematic experimental error, it might indicate that a small amount of pyrimidine was incorporated into uridine without being attached to ribose.

The pyrimidine/deoxyribose ratios in the isolated deoxycytidines and thymidines were on the average slightly lower than the pyrimidine/ribose ratios in the isolated ribosides. The difference was, however, not very significant. It is clear that the main route for the incorporation involved a reduction of the

Table 3. Incorporation of doubly labeled deoxyribosides into polynucleotides of the rat. In two experiments 25 μmoles of each deoxyriboside (deoxycytidine = 13 500 ct/min/μmole; thymidine = 13 200 ct/min/μmole) were injected into one rat. The ratios between the specific activities of pyrimidine and deoxyribose were for deoxycytidine 0.97 and for thymidine 0.99.

ribose of the *intact riboside* molecule or a derivative of it. The results definitely exclude a mechanism by which only a smaller part of the ribose molecule was attached to the pyrimidine during the reduction *, as might be visualized in analogy with known enzyme reactions [19]. Furthermore, transglycosidation mechanisms, as demonstrated for microorganisms [20], are also excluded. In this connection the absence of label from the purine bound ribose is of importance.

The data from the incorporation experiments with labeled uridine, deoxycytidine and thymidine all demonstrate the intact incorporation of the administered nucleosides.

Uridine-^{14}C behaved similar to cytidine-^{14}C and showed the transformation of the intact riboside to all polynucleotide pyrimidine nucleosides. Roll *et al.*[21] found some preferential incorporation of uracil from over all labeled uridylic acid-^{14}C into deoxycytidylic and thymidylic acids of the mixed internal organs of the rat. Our data do not show a more pronounced effect of this kind.

The results with the ^{14}C-labeled deoxyribosides confirm the conclusions drawn from earlier experiments with ^{15}N-labeled deoxyribosides that the conversion of ribosides to deoxyribosides *in vivo* is essentially irreversible.

* The loss of one carbon atom of the ribose chain during the reduction is not excluded from the results.

Formation of Uridine Phosphates from Uracil in Extracts of Ehrlich Ascites Tumor

PETER REICHARD and OLA SKÖLD

Biochemical Department, Karolinska Institutet, Stockholm, Sweden

The enzymic formation of uridine monophosphate from uracil in extracts from Ehrlich ascites tumor has been demonstrated to proceed according to two different mechanisms. The first involved the formation of uridine from uracil + ribose-1-phosphate by the action of nucleoside phosphorylase and the subsequent phosphorylation of uridine with ATP. This mechanism was by far the predominant one in the acetone powder extracts.

The second mechanism involved the direct condensation of uracil with phosphoribosyl pyrophosphate. In this case only very small amounts of UMP synthesis were observed.

The work of Plentl and Schoenheimer [1] originally demonstrated that uracil-^{15}N when injected into rats was not utilized for the biosynthesis of polynucleotide pyrimidines. Even though later work from different laboratories with uracil-^{14}C showed that there was a slight incorporation of the pyrimidine especially into fast growing organs [2,3], comparison of the incorporation data with results obtained with labeled nucleosides or orotic acid [4] demonstrated that the utilization of uracil was very much smaller than that of the other compounds. In the mouse, however, the incorporation of uracil and orotic acid was of the same order of magnitude [5].

The present investigation was started with the aim to investigate the pathway of uracil incorporation in the mouse. *In vivo* experiments demonstrated that labeled uridine phosphates appeared in the acid soluble fraction of mouse liver after injection of uracil-^{14}C in a similar manner as after injection [6] of orotic acid-^{14}C. It seemed justified to assume that the incorporation of uracil into polynucleotide pyrimidines proceeded *via* uridine phosphates. Our investigation was therefore confined to a study of the enzymic formation of uridine monophosphate (UMP)* from uracil.

* The following abbreviations are used throughout this paper: UMP = uridine-5′-phosphate, ATP = adenosine triphosphate, PGA = 3-phosphoglyceric acid, PCA = perchloric acid, PRPP = phosphoribosyl pyrophosphate.

EXPERIMENTAL

Uracil-^{14}C (80 000 ct/min/μmole) was synthesized according to Johnson and Flint [7]. Ribose-5-phosphate, ATP and PGA were commercial products (Schwarz Laboratories, Inc. and Sigma Chemical Company). *Ribose-1-phosphate* was a gift from Dr. H. Klenow, Copenhagen, for which we are very much indebted. *Phosphoribosyl pyrophosphate* was prepared enzymically as described earlier [8]. The preparation was 62 % pure judged from ribose analysis and had a ratio of ribose: acid labile phosphate of 1:1.96. It contained no ATP.

Preparation of enzyme extract. The ascites tumor was originally obtained through the courtesy of Dr. G. Klein, Institute of Cell Research, Karolinska Institutet. Routinely, it was kept by transfer of 0.1 ml of ascitic fluid 8—10 days after the previous inoculation. For the preparation of the acetone powder the ascitic fluid from 20—50 mice on the tenth day after inoculation was pooled and centrifuged cold at 1 000 *g* for 10 min. The sediment was washed twice with physiological sodium chloride and finally suspended in enough sodium chloride solution to give the original ascites volume. The solution was mixed in a Waring blendor with 10 volumes of acetone (−15°), filtered by suction and washed with cold acetone. The residue was dried in a desiccator and kept dehydrated at −15°. *Ca.* 4 g of acetone powder was obtained per 100 ml of ascites.

Immediately before use the powder was extracted with ice cold 0.05 M potassium phosphate buffer, pH 7.4 (10—50 ml per g powder) in a Potter-Elvehjem homogenizer. Three treatments were carried out at 10 min intervals. After centrifugation (15 000 *g* for 15 min) at 0° a clear red extract was obtained which was directly used for the experiments.

Assay of enzyme activity. The enzyme reaction was stopped by addition of 0.1 volume of 4.4 M PCA to the cold solution. The protein precipitate was centrifuged and washed once with 1 ml of 0.6 M PCA.

Two different methods were used after that. In *method 1* the combined supernatants were neutralized with 4 M KOH (phenol red) and the perchlorate was allowed to precipitate overnight in the refrigerator. The supernatant was then chromatographed on a Dowex-2 column according to Hurlbert *et al.*[9] Fractions within the different radioactive peaks were combined and the total radioactivity of each compound was determined on infinitely thin samples. This method gave the amount of the different radioactive uridine phosphates formed from uracil-^{14}C. The identity of the uridine phosphates was based on their localization on the chromatogram.

In *method 2* pyrophosphate linkages were hydrolyzed with acid so that all uridine phosphates were converted to UMP. This was achieved by heating the PCA supernatant at 100° for 1 h. Neutralization with KOH was then carried out as described above. The neutralized solution was then adsorbed on a Dowex-2-formate column (diameter 0.9 cm, length 5 cm). The column was washed with 50 ml of water which removed all uracil and uridine. Thereafter UMP was removed from the column with 60 ml of 6 N formic acid. The total radioactivity of the UMP fraction was determined and from this value and the specific activity of the uracil-^{14}C the amount of UMP formation could be calculated.

A blank which contained no enzyme was carried through the whole procedure and a small correction for "UMP formation" in the blank was applied.

Uracil and uridine could be separated and their specific activities determined by the following procedure: The first fraction from the Dowex-2 column was passed through a Dowex-50-H^+ column (0.9 cm diameter, 5 cm length). After washing with 30 ml of water the eluent was evaporated to dryness *in vacuo*. The dry residue was dissolved in butanol-water and chromatographed on a starch column (2 cm diameter, 20 cm length). The amount of the separated uracil and uridine was determined by light absorption and their specific activities were calculated after determination of radioactivities on infinitely thin samples.

Experiments with whole cells. (*cf.*[5]). In each of two 200 ml Erlenmeyer flasks 6 ml of ascites was mixed with 10 ml of Krebs-Henseleit substrate, from which $CaCl_2$ had been omitted. 50 μmoles of fructose diphosphate was added to each flask, and 25 μmoles of orotic acid-^{15}N to one vessel. The flasks were filled with an atmosphere of oxygen:carbon dioxide (95:5) and kept in an ice bath for 2 h in order to permit orotic acid to penetrate into the cells.[5] After that 25 μmoles of uracil-^{14}C was added and incubation carried out at 37° for another 2 h period.

The reaction was stopped by addition of 1.6 ml of 4.4 M PCA and the solution was mixed in a Waring blendor. The cell mass was filtered, washed with cold 0.2 M PCA and dried with alcohol and ether.

The PCA filtrate was neutralized with KOH and the acid soluble uridine phosphates were prepared from it as described above.

The polynucleotides from the ascites cells were prepared according to Hammarsten [10]. The pyrimidine ribosides were obtained by starch chromatography as described earlier [11]. The different compounds were analyzed for ^{15}N in the mass spectrometer and for ^{14}C in a Tracerlab SC-18 windowless flow counter (infinitely thin samples).

RESULTS

Extracts from acetone powder of Ehrlich ascites tumor showed a small but readily demonstrable capacity to form UMP from uracil in the presence of ribose-5-phosphate, ATP, Mg^{++} and an ATP regenerating system. The *same experimental conditions*, however, did not allow UMP synthesis in extracts from mouse liver acetone powder. All our subsequent experiments were carried out with the ascites tumor.

When starting our investigation we visualized three different pathways which might explain UMP formation: (1) Uracil might be carboxylated to orotic acid and orotic acid might subsequently by known enzymic pathways [12] be converted to UMP. (2) Uracil might replace orotic acid in the condensation with Kornberg's phosphoribosylpyrophosphate [12] and UMP be formed directly. (3) Uracil might react with ribose-1-phosphate [13] (formed from the added ribose-5-phosphate[14]) and form uridine. After that uridine might be phosphorylated by ATP with the formation of UMP, a reaction which we had earlier observed in rat liver extracts.

Formation of orotic acid

The influence of the presence of orotic acid-^{15}N on the formation of acid soluble uridine phosphates and polynucleotide pyrimidines from uracil^{14}-C is demonstrated in Table 1. Freshly obtained tumor cells were incubated with

Table 1. Non-involvement of orotic acid in UMP formation from uracil.

	Uracil + orotic acid			Uracil	
	μmoles formed	ct/min/μmole	atom per cent excess ^{15}N	μmoles formed	ct/min/μmole
Acid soluble fraction:					
UMP	0.12			0.15	
Uridine pyrophosphates	0.02			0.02	
Pentose nucleic acid:					
Uridine		1 290	0.252		1 330
Cytidine		410	0.063		570
Deoxypentose nucleic acid:					
Thymine		210	0.078		170
Cytosine		120	—		150

Ascites cells were incubated with uracil-^{14}C (80 000 ct/min/μmole) and orotic acid-^{15}N (16 atom per cent excess). For further explanation see text.

Krebs-Henseleit solution together with orotic acid. After 2 h at 0° uracil was added and incubation continued for two more hours. In the control vessel preincubation was carried out without orotic acid. The acid soluble nucleotides and the pyrimidines from polynucleotides were prepared in both experiments and the amount of ^{14}C in the different fractions was measured. Clearly the presence of orotic acid very little influenced the incorporation of uracil. The ^{15}N-data show that orotic acid did penetrate into the cells.

A similar experiment was carried out with an acetone powder extract from the tumor in a bicarbonate buffer. Again the presence of orotic acid did not influence the formation of radioactive uridine phosphates from uracil-^{14}C.

Reaction of uracil with phosphoribosyl pyrophosphate

The formation of UMP was greatly stimulated by the inclusion of ribose-5-phosphate and ATP in the medium (Table 2). Our experiments had to be carried out with an undialyzed extract since dialysis almost completely destroyed the ability of the system to synthesize UMP. It was conceivable that the requirement for ATP and ribose-5-phosphate indicated the intermediate formation of PRPP from these compounds. In Table 2 are also recorded two experiments, in which PRPP had been substituted for ATP and ribose-5-phosphate. More than six times the amount of "background synthesis" was observed. Inclusion of fluoride (to inhibit enzymic breakdown of PRPP) did not increase UMP synthesis.

Table 2. Involvement of PRPP.

Additions	μmoles UMP formed
Ribose-5-phosphate	0.007
ATP, PGA	0.007
Ribose-5-phosphate, ATP, PGA	0.092
PRPP	0.047
PRPP, NaF	0.037

Each vessel contained 75 μmoles of $MgCl_2$, 10 μmoles of uracil-^{14}C, 150 μmoles of phosphate buffer, pH 7.4 and enzyme (corresponding to 190 mg of acetone powder). Incubation 40 minutes at 37°. Final volume 4.5 ml.

Where indicated ribose-5-phosphate (40 μmoles), ATP (20 μmoles) PGA (60 μmoles), PRPP (17 μmoles) and NaF (200 μmoles) were added.

In these and the following experiments method 2 was used for enzyme assay. In order to ascertain the identity of the analyzed compound with UMP the radioactive fractions obtained by the acid washing from the PRPP experiments were combined and rechromatographed according to method 1. The main part of the radioactivity was localized in the UMP region of the chromatogram.

Intermediate formation of uridine

The possible participation of uridine during the reaction was tested in one experiment in which nonlabeled uridine was included during the incubation of the tumor extract with uracil-^{14}C, ribose-5-phosphate and ATP. With

method 2 it was found that a considerable increase of radioactivity appeared in the UMP fractions as compared to the control. The specific activity and the total amount of the formed UMP were determined after rechromatography. Uracil and uridine were purified by starch chromatography and the total amounts and specific activities of the two compounds were determined. The results (Table 3) show that a large amount of UMP had been formed, while most of the added uridine had disappeared. The specific activity of uracil had been lowered to about half of its original value. Uridine had received isotope during the incubation and its specific activity was between that of uracil and UMP.

Table 3. Uridine as intermediate in UMP formation.

Isolated after incubation	Addition		
	Uridine		None
	μmoles	ct/min/μmoles	μmoles
Uracil	9.0	49 000	*ca.* 7.5
Uridine	0.5	29 000	—
UMP	5.9	10 700	0.07

Each vessel contained 75 μmoles of $MgCl_2$, 20 μmoles of ATP, 60 μmoles of PGA, 40 μmoles of ribose-5-phosphate, 10 μmoles of uracil-^{14}C (80 000 ct/min/μmole) 150 μmoles of phosphate buffer, pH 7.4, and enzyme (corresponding to 190 mg acetone powder). Incubation 40 min at 37°. Volume = 4.5 ml.
Where indicated 10 μmoles of uridine was added.

This experiment gave strong support to the idea that uridine indeed was an intermediate in UMP formation. The fact that the *total amount* of ^{14}C in UMP was very much increased indicated that uridine was not only an intermediate in the formation of UMP from uracil but also had supplied the substrate for the conversion of uracil-^{14}C to uridine-^{14}C. In order to test this possibility inosine was substituted for ribose-5-phosphate in one experiment (Table 4). Good synthesis of UMP was obtained, but only in the presence of ATP.

Table 4 also includes results obtained with ribose-1-phosphate. Good synthesis of UMP was observed in the presence of ATP and Mg^{++}. When uracil and uridine were purified from the incubation mixture it was found that uridine was formed in the absence of ATP and Mg^{++}, while there was little nucleoside in the presence of these substances.

The localization of the phosphate group on the 5′-position of ribose was demonstrated by enzymic dephosphorylation of the formed UMP with snake venom (*Crotalus adamanteus*) 5′-nucleotidase. Complete liberation of the phosphate group was observed under conditions which allowed no dephosphorylation of the 2′- or 3′-phosphates of uridine.

Table 4. Formation of UMP and uridine from ribose-1-phosphate.

Additions	μmoles UMP formed from ^{14}C	μmoles uridine formed		μmoles uracil left	
		from light absorpt.	from ^{14}C	from light absorpt.	from ^{14}C
Inosine, ATP, PGA, Mg^{++}, phosphate	0.37				
Inosine, Mg^{++}, phosphate	0				
Ribose-1-phosphate, ATP, PGA, Mg^{++}	1.32	0		7.1	6.9
Ribose-1-phosphate, ATP, versene	0.05	2.6	2.4	5.0	4.8
Ribose-1-phosphate, versene	0	2.5	2.5	5.8	5.6

Each experiment contained enzyme (corresp. to 60 mg acetone powder), 10 μmoles of uracil-^{14}C and 150 μmoles of tris buffer, pH 7.4. Volume = 4.5 ml, incubation 40 min at 37°.

Where indicated ATP (20 μmoles), PGA (30 μmoles), inosine (10 μmoles), $MgSO_4$ (75 μmoles), versene (10 μmoles), ribose-1-phosphate (7 μmoles), and phosphate, (100 μmoles, pH 7,4) were added.

DISCUSSION

The results obtained by Hurlbert *et al.* [6] from *in vivo* experiments with orotic acid-^{14}C have made it very probable that uridine phosphates from the acid soluble fraction of cells are intermediates in the biosynthesis of polynucleotide pyrimidines. An investigation of the mechanism of uracil incorporation into polynucleotides in the Ehrlich ascites tumor should consequently start with the elucidation of uridine phosphate formation from uracil.

Three possibilities were from the beginning envisaged for the formation of uridine phosphate from uracil. Of these, transformation of uracil to orotic acid is clearly ruled out from our experiments, both with whole tumor cells and with extracts of acetone powder.

The results with acetone powder extracts demonstrated that UMP formation from uracil could take place in the presence of ATP and ribose-5-phosphate. The latter two compounds could be replaced by phosphoribosyl pyrophosphate, a compound which is an intermediate in UMP formation from orotic acid[12,8]. This resulted, however, in a lower synthesis of UMP than in the presence of ATP + ribose-5-phosphate. It seemed therefore unlikely that the function of these compounds was merely to form PRPP. We interpret the results to indicate that a quite low formation of UMP through direct condensation of uracil + PRPP did take place, though the reaction did only account for a fraction of the UMP formed. It is not probable that PRPP broke down to ribose-1-phosphate and that UMP was formed from this compound, since no ATP was added in these experiments and since UMP was not formed from ribose-1-phosphate in the absence of added ATP.

It is evident, however, that the main pathway of the reaction involved the intermediate formation of uridine. Uridine was formed either from uracil+ribose-1-phosphate or from uracil+inosine+phosphate. The enzyme for

uridine formation, pyrimidine nucleoside phosphorylase [13], is well known. In the presence of ATP, uridine was then phosphorylated and formed UMP. This second reaction required Mg^{++}. The reaction sequence is represented below:

$$\text{Uracil} + \text{ribose-1-phosphate} \xrightarrow[\text{phosphorylase}]{\text{nucleoside}} \text{uridine} + \text{phosphate}$$

$$\text{Uridine} + \text{ATP} \xrightarrow[\text{kinase, } Mg^{++}]{\text{nucleoside}} \text{uridine monophosphate} + (\text{ADP})$$

It is not quite clear why uracil is very poorly utilized for polynucleotide and UMP synthesis in many tissues, *e.g.* rat liver, while it is well utilized by the mouse. Nucleoside phosphorylase is a wide spread enzyme in rat tissues and also the kinase has been found by us in rat liver. Canellakis [15] has suggested that the enzymic reduction of uracil to dihydrouracil in rat liver proceeds at such a fast rate that very little uracil is available for synthetic reactions, unless large amounts are administered. Other explanations might also be considered, such as the availability of ribose-1-phosphate in the different tissues or the concentration of the nucleoside kinase.

Separation of Purines and Pyrimidines by Paper Electrophoresis

GIORGIO SEMENZA*

Institute of Biochemistry, Uppsala University, Uppsala, Sweden

An accurate and fairly rapid method has been worked out for the quantitative determination of purine and pyrimidine bases by paper electrophoresis.

Paper electrophoresis does not seem to have been widely used for the quantitative determination of purines and pyrimidines in nucleic acids hydrolysates. Dimroth *et al*[1]. have reported the separation of adenine from the mixture of the other purines and pyrimidines at pH 3.2, in acetate buffer. Burma [2] reported a successful separation of the four bases in nucleic acid hydrolysates at pH 2 (citrate-phosphate buffer), with 220 V, during 8 hours. Karyone and Inoue [3] also reported a separation of purines and pyrimidines, but no detailed data on their work are available.

In the following, a procedure for the quantitative estimation of purines and pyrimidines by paper electrophoresis is described. As it will be shown, it has some advantages, especially over paper chromatography, but also over other electrophoretic procedures, since it is both more rapid and more accurate, even with very little material.

Electrophoretic separation of the bases from a nucleic acid hydrolysate can only be performed at acidic pH's, because the low solubility of A and G ** leads to a considerable tailing at neutral and alkali pH's. Separation is possible at pH 3.8 (order of travelling towards the cathode: C, A, T+U, G) and at pH 3 (order of travelling: C, A, G, T+U). At intermediate pH values, a separation between G and U+T is not possible; at pH lower than 3, A and C tend to travel together.

---

* Fellow of the Lega Italiana per la Lotta contro i Tumori, Rome. Present address: Physiologisch-chemisches Institut, Zürichbergstrasse 4, Zürich (Switzerland).

** Abbreviations: A, Adenine; C, Cytosine; G, Guanine; T, Thymine; U, Uracil; WS, Levy and Snellbaker's substance [4]; DNA, deoxyribonucleic acid; RNA, ribonucleic acid.

pH 3 was chosen, because at pH 3.8 a certain tailing of G was often observed. Table 1 reports the pK's of dissociation of the amino groups of the bases and their percent dissociation at pH 3.

Table 1. Dissociation constants of the amino groups of the bases and their percent dissociation at pH 3.

	pK's of the amino groups [5]	Percent dissociation at pH 3
Cytosine	4.6	98
Adenine	4.1	92.5
Guanine	3.2	61.5
Thymine	—	—
Uracil	—	—

The relative electrophoretic mobilities, at pH 3, agree fairly well with those calculated from the figures of Table 1.

Although not tested, it is to be expected that 5-methylcytosine should travel with C.

When a hydrolysate of DNA (Wyatt method [6]) is separated by the method described here, a white-fluorescent spot travels with G. This contaminating substance is likely to be identified with the WS (white spot) described by Levy and Snellbaker [4], since the dissociation constants of its groups are very close to those of guanine. Moreover, the UV spectrum of G + WS eluted after paper electrophoresis, corresponds to that of a mixture of G + WS (*e. g.*, the E_{280}/E_{260} ratios are: for G[7], 0.84; for WS [4], about 0.40, and for the eluted mixed spot: 0.74). Since it has been shown [8] that WS is likely formed from G during the hydrolysis of DNA according to Wyatt, eluting and determining the WS together with its parent substance reduces this source of error.

A high electroosmotic flow was found, when Whatman paper No. 1 was used. This is an advantage, as it helps to avoid contamination of the T and U spots with the dark-coloured material formed during the hydrolysis, which remains at the starting point.

Citrate buffer was chosen, because of its low UV extinction.

PROCEDURE

DNA (prepared from calf thymus according to Kay *et al.*[11]) was hydrolysed according to Wyatt [6]. The hydrolysate was brought to dryness, and taken up in enough 1 N HCl, to have 5 to 50 μg of each base in 5 μl.

A humid chamber horizontal electrophoresis apparatus with Whatman No. 1 paper strips (10 cm wide and 42 cm long) and citrate-HCl buffer, pH 3 (Sørensen), diluted to an ionic strength of 0.02 ($\varkappa^{-1} = 0.175 \times 10^4$ ohms at 21° C) was used.

Samples of 5 μl were applied at the starting line, in a narrow zone, after the paper strips had been equilibrated in the apparatus. A part of the paper

Fig. 1. Separation of purines and pyrimidines from a DNA hydrolysate by paper electrophoresis (citrate-HCl buffer, pH 3, μ 0.02, 440 V, during 3 hours on Whatman No.1).

strip was left free for the blanks. A voltage of 440 V, 7—8 mA, was applied during about 3 h at room temperature. The paper was then dried in an oven at 100° C for 5 min. The spots were located with a UV television set [9] or according to Holiday and Johnson [10]. The spots were very compact, without any tailing, in all runs (see Fig. 1).

The spots were eluted overnight with 3.5 ml (or 1.2 ml; in this case, semi-micro cuvettes were used for UV readings) 0.1 N HCl (1 N HCl for G). Readings were taken against water at 250, 260, 280 and 290 mμ. A Beckman DU spectrophotometer was used; the values were corrected for the blanks of the paper (which ranged usually between 0.010 and 0.030).

The comparison between the ratios of the optical densities at these wavelenghts, and those reported by Volkin and Cohn [7] showed excellent agreement, except in the case of G, for the reasons reported above. The extinction coefficents at 260 (for A, G and T) or 280 mμ (for C) reported by Volkin and Cohn [7] were used.

As an example of determination of purine and pyrimidine composition of DNA, the following figures are reported (Table 2), dealing with calf thymus DNA. Ten separate runs were made from a single hydrolysate; each spot contained 5 to 10 μg of each base.

Table 2. Composition of calf thymus DNA, as determined by paper electrophoresis. The values ($\bar{x}$) are expressed as moles per 100 moles of total bases recovered, and represent the averages of ten determinations, on a single hydrolysate. The standard deviation (σ) are expressed as percent of $\bar{x}$.

	$\bar{x}$	σ
Adenine	29.0	± 1.67 %
Thymine	28.5	± 2.64 %
Guanine (+ WS)	21.2	± 3.75 %
Cytosine (+ 5-methyl-cyt.)	21.3	± 4.75 %

As it can be seen, the standard deviations σ in this method are very low. The $\frac{A+T}{G+C+5MeC}$ ratio is 1.35. It agrees fairly well with the figures reported in the literature: 1.20—1.22 [12]; 1.27 [13]; 1.28 [14]; 1.37 [15].

For quantitative purposes, the method described above seems to have some advantages over other methods:

1) It is quite accurate: in the author's hands no other method tested has given standard deviations $< 5\ \%$, when as little as 5—10 μg of each base were used. The method described here can therefore be recommended even when little material is available, as in column chromatography of DNA.

2) Levy and Snellbaker's substance (WS) [4] is determined with its parent substance, *i. e.* guanine [8]. In this way, too low guanine values, as well as too high values of other bases (contaminated by WS) are avoided.

3) Because of the high electroosmotic flow, contamination with the insoluble material formed during the hydrolysis (and not moving from the starting line) is also avoided.

4) It is quite rapid: a 3 hours' run gives a complete separation.

5) This procedure can also be used to separate the four bases (U, G, A, C) obtained from a strong acid hydrolysis of RNA.

I wish to express my sincere thanks to Prof. A. Tiselius and the members of his staff for working facilities, advice and stimulating discussions during the course of this work. I also want to thank Prof. E. Hammarsten for fruitful discussions.

This work was financially supported by the *Rockefeller Foundation* and the *Lega Italiana per la Lotta contro i Tumori*, to whom due thanks are expressed.

Studies on Rhenium Oxides

ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

The existence of the rhenium oxides ReO_3 and ReO_2 (MoO_2 type) has been confirmed. When rhenium metal and rhenium trioxide are heated together at 800° C only one intermediary phase forms, *viz.* an orthorhombic modification of the dioxide, which is the stable form of ReO_2 in the temperature interval 300° — 1 050° C.

The structure of orthorhombic ReO_2 has been studied by X-ray methods. The metal atom positions have been determined and a probable oxygen atom arrangement is proposed. The structure contains zigzag strings of ReO_6 octahedra joined by edges, the strings being mutually connected by octahedra sharing corners. The short Re-Re distance within the strings suggests the existence of covalent bonds between the metal atoms.

Rhenium trioxide was the first oxide of this metal to be studied by X-ray methods. Thus Meisel [1] found the crystal structure of this compound to be a cubic arrangement of ReO_6 octahedra joined by sharing corners (ReO_3-type structure). Rhenium dioxide, prepared by heating ammonium perrhenate at 500° C *in vacuo*, was investigated by Zachariasen [2], who was able to assign to this phase the MoO_2-structure type. Preliminary structural data on rhenium(VII) oxide have been reported by Wilhelmi [3].

The structural similarity between rhenium dioxide and wolfram dioxide (MoO_2 type) and between rhenium trioxide and wolfram trioxide (distorted ReO_3 type) made it of interest to find out if there exist intermediate oxides of rhenium as is the case with wolfram [4].

PHASE ANALYSIS

Starting materials were rhenium metal powder (Mackay, 99.9 % pure), rhenium trioxide and dirhenium heptoxide prepared from the metal according to Ref.[5] and ammonium perrhenate obtained by treating the latter oxide with ammonia.

Mixtures of rhenium metal and trioxide of gross compositions ranging from $ReO_{1.5}$ to $ReO_{2.5}$ were sealed in evacuated silica tubes and heated for a day at 300° C and then a day at 800° C. The results are summarized in Table 1.

Table 1. Results of the phase analysis.

Composition of the preparation	Appearance of the preparation	Evidence of X-ray powder pattern
Re	Dark, greyish powder	Re
$ReO_{1.50}$	» » »	X + Re
$ReO_{1.93}$	» » »	X + (Re)
$ReO_{2.00}$	» » »	X
$ReO_{2.14}$	» » » + small red grains	X + ReO_3
$ReO_{2.50}$	» » » »	X + ReO_3
ReO_3	Red powder	ReO_3

The only rhenium oxides that form under the conditions applied are the trioxide and the phase of composition close to $ReO_{2.0}$. The powder diagram of the latter is not in agreement with a MoO_2-type structure (*cf.* Table 2).

The powder patterns showed no displacements of the lines for samples of various compositions, which indicates that the ranges of homogeneity are narrow. The following unit cell dimensions were obtained *:

Re (hexagonal) $a = 2.762 \pm 0.001$ Å, $c = 4.457 \pm 0.001$ Å,
ReO_3 (cubic) $a = 3.7510 \pm 0.0005$ Å,

and for the new phase, the powder pattern of which could be indexed with an orthorhombic unit cell

$a = 4.8094 \pm 0.0005$ Å, $b = 5.6433 \pm 0.0005$ Å, $c = 4.6007 \pm 0.0005$ Å.

The density calculated for a cell content of four formula units of ReO_2 is 11.61 in excellent agreement with the density of 11.4 measured by Lehrer (in Biltz [7]) for a sample giving $ReO_{2.01}$ on analysis and prepared from rhenium and rhenium(VII) oxide at 600—650° C.

Rhenium dioxide evidently is dimorphic, forming a monoclinic and also an orthorhombic modification. Samples of the two phases, the former prepared according to Zachariasen [2], were sealed in evacuated silica tubes and heat-treated at various temperatures. While the orthorhombic form did not change within the interval 300—1 050° C, the monoclinic modification transformed into the former which is evidently the stable one in this region. At 300° C this reaction was almost completed in 3 days.

STRUCTURE OF ORTHORHOMBIC RHENIUM DIOXIDE

By heating rhenium dioxide at 1 050° C for a few weeks it was possible to grow crystals suitable for single crystal X-ray investigations. Rotation and Weissenberg photographs were taken with CuK radiation with [101] as rota-

* The X-ray powder data reported in this paper were obtained with a Guinier focusing camera of 80 mm diameter with strictly monochromatized CuKa_1 radiation. The temperature was about 20° C. Potassium chloride (Analar, British Drug Houses, $a = 6.2919$ Å) [6] was added to the specimens as an internal standard. Photographs of samples without admixture were used to reveal superpositions of lines.

tion axis. The intensities were estimated visually and the intensity scales of the various photographs were correlated by means of reflexions, equivalent on account of symmetry relations. The structure amplitudes were calculated using the nomograms given by Lu [8].

The following reflexions were found to be systematically missing:

$$\begin{array}{lll} 0kl & \text{for } k & = 2n + 1 \\ h0l & \text{for } l & = 2n + 1 \\ hk0 & \text{for } h + k & = 2n + 1 \end{array}$$

This is characteristic of the space group *Pbcn* (No. 60).

The linear Harker sections suggested by this symmetry were calculated and found to have the following appearance:

$$\begin{array}{lll} \mathrm{P}(u\tfrac{1}{2}0): & \text{maximum at } u & = \tfrac{1}{2} \\ \mathrm{P}(0v\tfrac{1}{2}): & \text{maximum at } v & = 0.220 \\ \mathrm{P}(\tfrac{1}{2}\tfrac{1}{2}w): & \text{maximum at } w & = 0 \end{array}$$

This locates the rhenium atoms at the point position 4(*c*) with $y = v/2 = 0.110$, which corresponds to an arrangement of zigzag chains of metal atoms running parallel to the *c* axis. The distance between rhenium atoms within the chain is 2.61 Å, while adjacent rhenium atoms of different chains are 3.68 and 3.71 Å apart.

It is of interest to compare the interatomic distances thus obtained with those present in monoclinic rhenium dioxide, the atomic parameters of which, however, have not been determined. The close similarity between the unit cell dimensions of this phase and molybdenum dioxide seem to justify the assumption that the parameter values of these compounds are approximately the same. This leads to Re-Re distances within the straight chains of 2.48 and 3.08 Å and Re-Re distances between neighbouring chains of 3.7 Å.

The similar metal-metal distances present in the two forms of rhenium dioxide suggest that the arrangement of the oxygen atoms around the rhenium atoms in the orthorhombic modification is essentially the same as in the MoO_2-type form, *viz.* in ReO_6 octahedra with shared edges corresponding to the shorter rhenium-rhenium distances and shared corners corresponding to the longer ones. These conditions are fullfilled by the following structure:

Space group: *Pbcn* (No. 60)

4 Re in 4(*c*): $0,y,\tfrac{1}{4}$; $0,\bar{y},\tfrac{3}{4}$; $\tfrac{1}{2},\tfrac{1}{2}+y,\tfrac{1}{4}$; $\tfrac{1}{2},\tfrac{1}{2}-y,\tfrac{3}{4}$. $y = 0.110$

8 O in 8(*d*): x,y,z; $\tfrac{1}{2}-x,\tfrac{1}{2}-y,\tfrac{1}{2}+z$; $\tfrac{1}{2}+x,\tfrac{1}{2}-y,\bar{z}$; $\bar{x},y,\tfrac{1}{2}-z$; $\bar{x},\bar{y},\bar{z}$; $\tfrac{1}{2}+x,\tfrac{1}{2}+y,\tfrac{1}{2}-z$; $\tfrac{1}{2}-x,\tfrac{1}{2}+y,z$; $x,\bar{y},\tfrac{1}{2}+z$. $x = 0.25$, $y = 0.36$, $z = 0.125$.

The interatomic distances have reasonable values throughout, *viz.* Re—O 1.95 and 2.1 Å and O—O 2.6—3.1 Å. The distance of 3.1 Å is that of edges shared by two ReO_6 octahedra.

The influence of the oxygen atoms on the intensities of the X-ray reflexions is very low compared with that of the rhenium atoms. However, for reflexions *hkl* with $h+k = 2n+1$, the contributions of the metal atoms cancel out. The proposed oxygen arrangement gives fair agreement between calculated and observed intensities for this type of reflexions (*cf.* Table 2). As these reflexions are very weak and rather few, it is not, however, possible to improve the oxygen parameters from the experimental data.

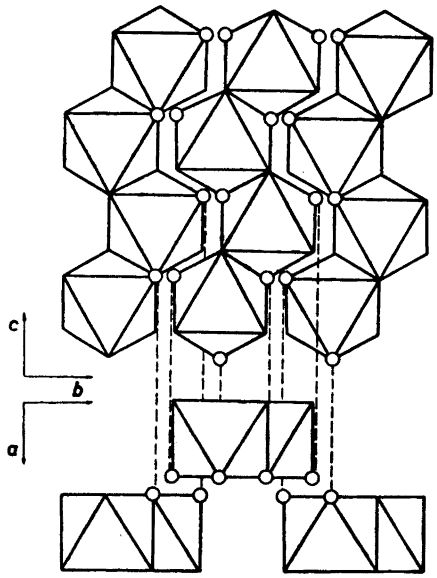

Fig. 1. The coupling of the ReO_6 octahedra of orthorhombic rhenium dioxide viewed along [100] and [001]. The strings of octahedra have been separated in order to reveal superimposed corners and edges. Corners shared by the strings are indicated by rings.

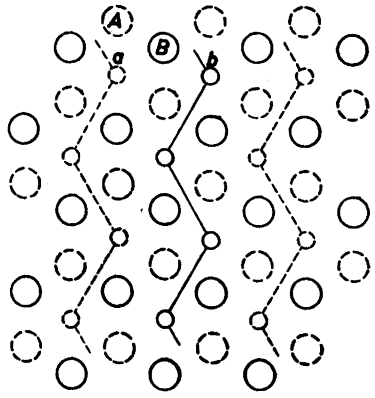

Fig. 2. The idealized structure of orthorhombic rhenium dioxide represented as hexagonal close-packing of the oxygen atoms (large circles). The rhenium atoms (small circles) are situated in octahedral holes. The sequence of the atoms normal to the plane of the figure is AaBbA.

The structure thus derived (*cf.* Fig. 1) has features in common with both the brookite and the rutile types. Thus both rhenium dioxide and brookite contain staggered strings formed by metal-oxygen octahedra having edges in common. While the strings of brookite are mutually connected by octahedra sharing edges and corners, those of rhenium dioxide are exclusively joined by corners as are the straight strings of rutile. No representative of this structure type seems to have been known before. However, as pointed out in a preliminary note [9] Pauling and Sturdivant [10] in connection with the determination of the brookite structure discussed a hypothetic structure, which is actually the same as the one now found for orthorhombic rhenium dioxide. The columbite structure is a superstructure of this type [11].

It is also possible to describe the structure as an hexagonal closepacking of oxygen atoms with rhenium atoms occupying certain of the octahedral interstices as illustrated in Fig. 2.

The pairwise arrangement of the metal atoms within the strings of the MoO_2 structure type has been ascribed to the existence of a homopolar bond between the metal atoms of the doublet [12]. In orthorhombic rhenium dioxide, the rhenium atoms within the staggered strings are uniformly distributed and at intervals (2.61 Å) which are longer than the short distance present in

Table 3. Metal-metal bond distances in some dioxides.

Compound	Structure type	Number of valence electrons available per metal-metal bond	Metal-metal distance Å
TiO_2	rutile	0	2.959
VO_2	MoO_2	2	2.65
ReO_2	ReO_2 (orthorhombic)	3	2.61
MoO_2	MoO_2	4	2.50
WO_2	MoO_2	4	2.49
TcO_2	MoO_2	6	(2.48)
ReO_2	MoO_2	6	(2.49)

the monoclinic rhenium dioxide (2.48 Å). However, if no intermetallic bond is present, the repulsion between the highly charged metal atoms would lead to metal-metal distances of octahedra sharing edges considerably longer than the ideal geometrical value (the normal oxygen-oxygen distance). This effect has actually been observed in several molybdenum and wolfram oxides, where distances of about 3.25 Å frequently occur [4]. Bonds are thus likely to be present also between the metal atoms of the strings of orthorhombic rhenium dioxide. Considering the fact that in this compound every metal atom is bound to two neighbours and the number of valence electrons per bond is thus only half that present in the MoO_2-type rhenium dioxide, the bond distance in the former compound fits in nicely in the qualitative relation between bond distance and number of valence electrons pointed out in a previous communication [13] (*cf.* Table 3).

The author is indebted to Mrs. Stina Nord for her valuable assistance in the experimental work.

These studies form part of a research program on metal oxides and related compounds financially supported by the *Swedish Natural Science Research Council.*

Determination of α-Tocopherol by Chromatography on Secondary Magnesium Phosphate

(With Collaborative Tests in Four Laboratories)

FINN BRO-RASMUSSEN and WILLY HJARDE

Statens Vitamin Laboratorium, Copenhagen, Denmark

A description is given of a method for quantitative determination of α-tocopherol in natural and enriched products. The method, which is generally applicable and suitable for routine examinations, consists in isolation of α-tocopherol by chromatography on secondary magnesium phosphate of the unsaponifiable fraction of the sample with subsequent Emmerie and Engel reaction in equal parts of alcohol and petroleum ether. The chromatography results in a complete separation in one step of α-tocopherol from other tocopherols as well as from carotinoids, vitamin A, sterols and other reducing substances without any time-consuming preliminary treatment. The results obtained by the described method are given and shown to be in close agreement with previously published results.

The chemical methods originally used for the estimation of the vitamin E content of a product aimed in principle at a determination of the total content of vitamin E active tocopherols. When it was found, however, that the biological potency of the individual tocopherols varied considerably, it was realized that methods of this nature were highly unsatisfactory. The vitamin E activity of most of the natural vitamin E sources is chiefly due to their content of α-tocopherol, since the vitamin E activity of some of the other tocopherols is so low that considerable amounts are required to make the activity comparable to that of α-tocopherol (this applies, *e.g.*, to γ- and δ-tocopherol), while in the case of others they occur very sparsely in nature (*e.g.* β-tocopherol, which has so far been found in wheat germ and wheat germ oil only). In practice the determination of the value of a certain product as a source of vitamin E must therefore take the form of a determination of its content of α-tocopherol. When further bearing in mind the growing appreciation of the importance of vitamin E, *e.g.* in feeding stuffs, which has led to the marketing of a steadily increasing number of products enriched with

synthetic α-tocopherol, it will be understood that there is an urgent need of a method for the determination of α-tocopherol for routine purposes.

In the course of time a number of attempts have been made in order to determine the proportion of individual tocopherols present. Hove and Hove [1] thus developed a method for the determination of the total content of tocopherols and the content of α-tocopherol based on the varying rates of reaction displayed by the individual tocopherols with Emmerie and Engel's reagent. Quaife [2] determines the content of α-tocopherol as the difference between the total content of tocopherols and the content of β-, γ- and δ-tocopherol on the basis of the conversion of the latter into nitroso derivatives which are chromatographed on zinc carbonate-Celite. Tosic and Moore [3] determine the content of α-tocopherol by chromatography on alumina of the unsaponifiable matter. By this chromatographic process α-tocopherol is collected together with carotene, however, necessitating a correction for the contribution to the $FeCl_3$-dipyridyl reaction provided by the latter substance. It is further stated that β-tocopherol is not separated completely, involving an overestimation of the content of α-tocopherol.

The best methods for the estimation of the individual tocopherols hitherto developed seem to be those based on paper chromatography which have recently found comparatively extensive application [4-7]. Most of these methods, however, require the removal of certain substances prior to the chromatography to prevent interference with the running of the tocopherols on the chromatogram. It is, *e.g.*, necessary to remove sterols by crystallization from methanol, while vitamin A and carotene are removed by adsorption to Floridin Earth. It seems, furthermore, that one-dimensional, reversed-phase chromatography involves certain losses. Brown [4] has thus ascertained recoveries of only about 80 % of tocopherols. Eggitt and Ward [5] state that the recoveries achieved by them by chromatography were about 95 %. Frequently, however, recoveries of only 90 % are obtainable [7]. A number of the difficulties mentioned above seem, however, to have been overcome by applying two-dimensional chromatography as devised by Green *et al.*[7] By subjecting the extract to initial chromatography on paper impregnated with zinc carbonate it will in many cases be possible to eliminate a number of the time-consuming preliminary treatments, and the duration of the subsequent reversed-phase chromatography may be cut down and the losses consequently diminished. Any statement of the total loss involved in this cromatographic determination is not given, however.

In the following a description will be given of a column chromatographic method for the determination of α-tocopherol in natural and enriched products. In principle the method is simple, and it is readily applicable in routine examinations. The chromatography, in which quantitative recovery of α-tocopherol (98—100 %) is obtained, serves to remove in one step both carotene and vitamin A as well as other tocopherols without any preceding reduction of the quantity of sterols present being required.

For special purposes the method can readily be modified so as to be applicable to the determination of the individual tocopherols. This will be accounted for elsewhere [8].

EXPERIMENTAL

The principle of the method. The material is saponified by means of alcoholic potassium hydroxide to which pyrogallol has been added to protect the tocopherols against oxidation. The saponified solution is extracted repeatedly with ether, and the combined ether extracts washed with water and subsequently dried with anhydrous sodium sulphate. The ether extract is now evaporated to dryness in a carbon dioxide atmosphere and the residue is dissolved in petroleum ether. From this solution α-tocopherol is isolated from the remaining reducing components by chromatography on secondary magnesium phosphate. The amount of α-tocopherol present is finally determined colorimetrically by means of ferric chloride and α,α-dipyridyl (Emmerie and Engel's reaction).

Equipment

Saponification flask with reflux condenser } size to be applied depends on the content of
Separatory funnels } tocopherol in the sample
Evaporation equipment arranged for connection to carbon dioxide supply.
Various volumetric flasks and pipettes.
Chromatographic tube (see Fig. 1).
Spectrophotometer.

Reagents

1. *Pyrogallol*
2. *Potassium hydroxide solution, about 60 %.* Dissolve 60 g potassium hydroxide pellets in 40 ml water.
3. *Absolute alcohol.*
4. *96 % alcohol.*
5. *Ethyl ether.* Render peroxide free by allowing to stand over potassium hydroxide pellets. Distill before use.
6. *About 0.5 N potassium hydroxide solution in about 30 % alcohol.* To 30 ml of potassium hydroxide solution, about 60 % (2) add 300 ml 96 % alcohol and water to make 1 l.
7. *Sodium sulphate.* Anhydrous.
8. *Petroleum ether.* Boiling point below 70°C.
9. *Secondary magnesium phosphate* for chromatography (Merck: Magnesium phosphoricum purum — *cf.* subsequent comments). The commercial product is activated as follows: Dry a quantity of magnesium phosphate corresponding to 200 g anhydrous substance for 24 h at not less than 176°C and cool over concentrated sulphuric acid. Boil the powder for 15 min with a solution of 20 g secondary sodium phosphate (Na_2HPO_4, $2H_2O$) in 1.6 l distilled water. Cool somewhat and separate on Büchner funnel, washing with about 1 l water. Dry the magnesium phosphate for not less than 48 h at not less than 176°C and cool to room temperature over concentrated sulphuric acid. Grind gently in a mortar and sieve through a 120 mesh sieve. Store in a dry place in a well-closed container.
10. *0.1 % ferric chloride solution in absolute alcohol* } store in brown bottles at room
11. *0.25 % alcoholic solution of α,α-dipyridyl* } temperature. Will keep for at least two months.

Procedure

Saponification and extraction. Weigh into the saponification flask a quantity of the sample equivalent to 0.4—4 mg α-tocopherol, but not less than 2 g. Add one fourth of the sample's weight of pyrogallol and as many ml of 60 % potassium hydroxide solution as denoted by the weight of the sample in g and four times its volume of 96 % alcohol.

Saponify by bringing to the boil on water bath and boiling for 10 min. Cool somewhat and add a volume of water equal to three times the volume of alcohol used. Transfer into a separatory funnel, rinsing the flask with ether, using 100—200 ml according to the volume of the sample. When working with larger quantities of feeding stuffs, the alcoholic saponification solution may be decanted into a separatory funnel into which the required volume of water has already been transferred. In this case wash the precipitate successively with all the ether used for the extraction. Shake or swirl the separatory funnel for

one minute, allow the layers to separate and run the aqueous phase into another separatory funnel in which extraction is performed by means of 50—100 ml fresh ether. After a third extraction process, transfer the three ether extracts into one separatory funnel and wash with 100 ml water, 100 ml 0.5 N potassium hydroxide in 30 % alcohol and finally with three 100—200 ml portions of water.

Dry the ether extract by filtering through a 2—3 cm thick layer of anhydrous sodium sulphate placed on a glass filter, and reduce the volume by evaporation in a carbon dioxide atmosphere on water bath until only a few ml remain. Remove the last traces of ether by means of a current of carbon dioxide, but do not heat.

By means of petroleum ether transfer the residue into a volumetric flask of suitable size and fill to volume with petroleum ether.

Chromatography. A column is prepared from the activated magnesium phosphate by suspending a suitable quantity in petroleum ether and running the mixture into a chromatographic tube, the effective length of which is 20 cm and the internal diameter 12 mm (Fig. 1). This tube is connected by means of a rubber tube to a nitrogen cylinder, the nitrogen pressure being regulated so as to provide a suitable rate of flow (2—4 ml per min). When the column of magnesium phosphate has settled, it is covered with a thin layer of anhydrous sodium sulphate. The petroleum ether level must never be allowed to fall below the top of the magnesium phosphate column.

An aliquot of the petroleum ether extract corresponding to about 0.4 mg α-tocopherol (quantities down to 0.1 mg may, however, be determined) is now transferred to the column.

After rinsing with 50 ml petroleum ether, the receiver is exchanged and α-tocopherol is eluted with altogether 150 ml 2 % ethyl ether in petroleum ether. Carotene will not be adsorbed to the column, but may be collected with the petroleum ether. β-, γ-, and δ-tocopherol as well as vitamin A are adsorbed, but require to be eluted an ether concentration higher than 2 % (*cf.* Bro-Rasmussen and Hjarde [8]).

The α-tocopherol fraction is evaporated on a water bath (30°C) until a residue of 5—10 ml remains. This residue is transferred into a volumetric flask (if the quantity of α-tocopherol chromatographed is 0.4 mg, a 30 ml volumetric flask will be suitable), several portions of absolute alcohol and petroleum ether are used for rinsing, the rinsings are added and the flask filled up with absolute alcohol and petroleum ether resulting in an α-tocopherol solution in a solvent consisting of equal parts of alcohol and petroleum ether.

To check the effectivity of the chromatography the last 5 ml petroleum ether eluate plus the first 5 ml petroleum ether-ethyl ether eluate are collected in a 20 ml volumetric flask with 10 ml absolute alcohol. Now the main fraction is collected as described above and, finally, 10 ml eluate likewise in a 20 ml volumetric flask with 10 ml absolute alcohol. Eluate collected in this way before and after the main fraction must not give any reaction for α-tocopherol (*cf.* the subsequent comments).

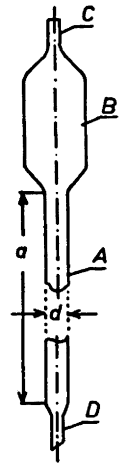

Fig. 1. Chromatographic column. A: column. B: reservoir for eluent. C: connection to pressure. D: outlet tube to retain plug of cottonwool at base of A.

The colorimetric measurement. To a 5 ml sample of the solution containing the isolated α-tocopherol are added 0.25 ml ferric chloride solution (reagent No. 10) and 0.25 ml α,α-dipyridyl solution (reagent No. 11).

The intensity of the colour is measured in a spectrophotometer (or suitable colorimeter) at 520 mμ exactly two min after the addition of the reagents, at which time the intensity must have reached a constant value.

A blank determination is run on 2.5 ml petroleum ether +2.5 ml absolute alcohol + 0.25 ml ferric chloride solution + 0.25 ml α,α-dipyridyl solution.

The value of $E^{1\%}_{1\,cm}$ 520 mμ for the sample can now be calculated and the content of α-tocopherol in the sample examined can be found. By measurements on spectrophotometer at 520 mμ the value of $E^{1\%}_{1\,cm}$ for pure α-tocopherol is taken to equal 400.

Comments

re secondary magnesium phosphate. It seems to be difficult to establish any certain criteria as regards the suitability of a commercial product for the purpose of chromatography. Examination of a number of products has shown that it is possible frequently, but not invariably from products of the above mentioned quality to obtain charges which can be activated. It appears to be necessary to test each charge directly by chromatographing pure α-tocopherol. In this process the α-tocopherol must not be eluted from a 20 cm column by means of 100 ml petroleum ether followed by 100 ml 0.5 % ethyl ether in petroleum ether, while elution should be quantitative when about 125 ml 2 % ethyl ether in petroleum ether is used. If α-tocopherol is eluted by means of petroleum ether or 0.5 % ethyl ether in petroleum ether, the charge of magnesium phosphate is unsuitable for the purpose, its activity being too low to allow for the adsorption of α-tocopherol from low-potency products with a large content of impurities.

re saponification. According to the method used in this case the sample to be tested is saponified directly without any preceding extraction of the fats. Pyrogallol is used to protect the tocopherol against oxidation in the alkaline solution. In agreement with previous investigations [3] pyrogallol was observed to have a marked effect, as will appear from Table 1.

However, even when using pyrogallol, it is not possible completely to eliminate losses in the α-tocopherol determination.

The losses involved in the analyses of individual products may be determined by parallel experiments in which known quantities of tocopherol corresponding to the contents in the products are added and recoveries determined. The following section on the results obtained by the present method gives examples of the losses involved in such determinations.

re chromatography. If the magnesium phosphate fulfills the above requirements, the efficiency of a chromatographic separation may be judged in the following way:

If the eluate collected before the main fraction gives reaction for reducing substances, this may be due either to a content in the extract of reducing substances which are eluted

Table 1. The protective effect of pyrogallol in the determination of α-tocopherol

	Quantity of α-tocopherol found (μg/g)		
	Butter	Wheat germ oil	Enriched fat emulsion
With pyrogallol	23.3	2 060	180
Without pyrogallol	21.5	1 570–1 720	139
Difference in %	8	17–24	20

immediately before α-tocopherol, or to an incomplete adsorption of α-tocopherol. If necessary, the identity of the reducing substances must be determined by chromatography of a parallel sample of the extract to which α-tocopherol has been added. According to the experiences gained hitherto it seems that in cases where this problem has been significant the reason has been an incomplete adsorption of α-tocopherol on account of extreme contents of impurities, chiefly sterols. In such cases a column of 5—10 cm greater length of the column is used.

If the fraction collected immediately after the main fraction displays a reducing action this indicates that tocopherol-like substances are eluted immediately after α-tocopherol.

The latter condition will generally manifest itself in the course of the colorimetric measurement in the form of an increase of the intensity of colour, since only α-tocopherol has been found to produce a colour of constant intensity in the course of 2 min in the mixture of alcohol and petroleum ether used here.

If it is not feasible in this way to eliminate the possibility that impurities have been collected together with α-tocopherol, the chromatography must be repeated, the eluate being collected in fractionation flasks half full of absolute alcohol. From each of the fractions which contain α-tocopherol an aliquot is drawn. These are combined and taken up with a suitable volume of equal parts of absolute alcohol and petroleum ether. If it is not immediately possible to ascertain which of the fractions contain α-tocopherol, parallel chromatography on part of the extract to which pure α-tocopherol has been added must, as referred to above, be resorted to.

RESULTS AND DISCUSSION

As mentioned above a number of determinations of the losses involved in the use of the method have been made in the course of the present work. Table 2 lists the total percentage recoveries for a number of samples with different α-tocopherol contents. It appears from this that the total recovery for the whole procedure decreases with decreasing content of α-tocopherol, the recovery in the case of wheat germ oil with a content of 2 100 μg/g being 98 %, while in the case of chicken feed containing 11 μg/g the loss is 15 %. It should be noted that the loss deriving from the chromatography only constitutes a small and constant part of the total loss (0—2 %), it having been endeavoured in all cases to use for the cromatography a quantity of the product containing about 0.4 mg α-tocopherol (in the case of chicken feed the quantity was only about 0.2 mg). The chief part of the losses in the case of the low-potency samples thus derive from the saponification and the extraction.

As already mentioned, the colorimetric measurement of the content of α-tocopherol is performed in solution in equal parts of alcohol and petroleum ether. For the purpose of the described method this solvent offers two advan-

Table 2. Total percentage recoveries in the α-tocopherol determination

Sample	α-Tocopherol found (μg/g)	Total recovery (%)	Corrected content (μg/g)
Wheat germ oil	2 060	98	2 100
Enriched feeding stuff	550	97	565
Enriched fat emulsion	180	95	189
Butter	23.5	90	26.1
Chicken feed	9.1	85	11

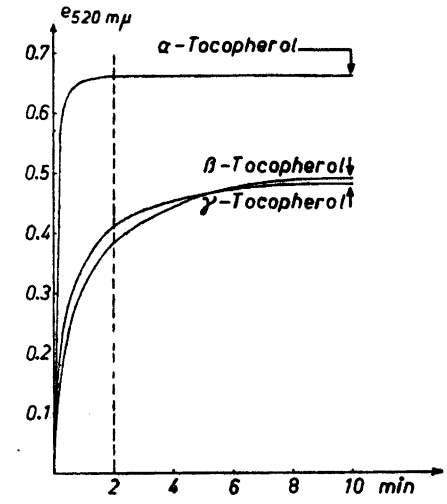

Fig. 2. The colour development at the Emmerie—Engel reaction for α-, β- and γ-tocopherol in petroleum ether/ethanol = 1/1.

tages above alcohol which is the solvent generally used. In the first place it is possible to use the eluate directly for the colorimetric measurement if it is collected in fractionation flasks half full of absolute alcohol, a procedure which is not feasible if petroleum ether only is used. This is of importance in cases when it proves to be necessary to perform a fractionate collection of α-tocopherol as mentioned above, and further in cases when a determination of the other tocopherols is required (*cf.* Bro-Rasmussen and Hjarde [8]). In the second place the use of this solvent gives a fairly certain criterion as to whether the reducing substance collected in the routine cromatography is identical with α-tocopherol, since, as already mentioned, it has been found that it is only the reduction by α-tocopherol of the ferric ions in Emmerie and Engel's reaction which is completed in less than 2 min. To illustrate this, Fig. 2 shows the relationship between colour intensity and time in the case of α-, β-, and γ-tocopherol. As it appears, most clearly in the case of β- and γ-tocopherol, the rate of reaction is reduced as compared to that prevailing in the case of corresponding measurements in alcohol. In the solvent used in this case full colour development is only obtained in the course of 7—10 min in the case of β- and γ-tocopherol, while in alcohol all the three tocopherols mentioned show full colour development in the course of less than 2 min [9].

The fact that the rate of reaction is thus less than when the reaction takes place in alcohol has no influence on the final colour intensity. In the case of synthetic α-, β-, and γ-tocopherol the $E^{1\%}_{1\,cm}$ 520 mμ values have thus in all cases been found to equal about 400 when measured after periods of 2, 10, and 10 min, *i.e.* the same value as that generally given for the reaction in alcohol. It should finally be mentioned that Lambert-Beer's law also applies unchanged when Emmerie and Engel's reaction is performed in a mixture of equal parts of alcohol and petroleum ether. δ-Tocopherol is the only tocopherol which does not show linear dependence on the concentration, for which reason a standard curve should be used in this case.

While the results of collaborative tests made in four laboratories to examine the reproducibility of the method are given in an addendum, a number of determinations of the α-tocopherol content of natural products will be given in the following (Table 3).

Table 3. Content of α-tocopherol in natural products (μg/g)

Material	Results obtained by present method	Results obtained by other workers
Wheat germ oil	2 100	1 680[4]
Wheat germ	220	—
Soybean oil	110	124[4]
Rapeseed oil	225	151[7]
Cottonseed oil	325	470[7]
Corn germ meal	73	—
Butter (summer)	26	24.8[10]
Lucerne	27	22—28[11]
Lucerne silage	36	30—31[11]
Chicken feed	11	—

Among the values given in the table only the determinations made on soybean oil and chicken feed have required additional chromatography with fractionate collection of α-tocopherol, since in these cases it has been found that α-tocopherol is followed immediately by a reducing substance which cannot be identified as a tocopherol [8]. In the case of all the other materials α-tocopherol has been collected directly in one fraction with 150 ml 2 % ether in petroleum ether.

With respect to some of the materials Table 3 lists α-tocopherol contents determined by other workers. A comparison shows that the values found in the present investigation agree well with those previously found.

The present method meets the demand for a simple and readily reproducible method for the determination of α-tocopherol independently of other tocopherols and other reducing constituents of natural and enriched products. The method has another advantage, *viz.* that it is generally applicable and at the same time provides a fairly good criterion as to the specificity of the method. Only in the case of products of very low potency will appreciable losses due to the saponification and extraction processes occur, necessitating parallel experiments with known α-tocopherol additions to correct for such losses. The chromatography, on the other hand, is practically quantitative.

Acknowledgements. We wish to express our thanks to Professor P. Karrer for a sample of synthetic β-tocopherol and to A/S Dansk Sojakagefabrik, Copenhagen, for the cottonseed oil and rapeseed oil used in the investigation.

Addendum

COLLABORATIVE EXAMINATIONS OF A METHOD FOR THE DETERMINATION OF α-TOCOPHEROL BY CHROMATOGRAPHY ON SECONDARY MAGNESIUM PHOSPHATE

K. Bondrup, A/S Ferrosan, Finn Bro-Rasmussen, Statens Vitamin Laboratorium, E. Jensen, F.D.B.'s centrallaboratorium, and E. Jespersen, Leo Pharmaceutical Products, Copenhagen, Denmark.

The method described above for the determination of α-tocopherol has been checked through collaborative examinations in four laboratories.

The examinations comprised two experimental series as difficulties were experienced as regards the acquisition of suitable magnesium phosphate for the first series. The difficulties manifested themselves in particular with regard to the results obtained in one of the laboratories, for which reason these results have been omitted from Table 4.

Table 4. Results of collaborative tests

Experimental series	Sample of	Calculated addition of α-tocopherol	Results of tests in μg α-tocopherol per g			
			Laboratory			
			A	B	C	D
1	Wheat germ oil	0	2 040	1 800	1 960	2 020
	Soybean oil	0	—	180	240	165
	Soybean oil with an addition of 0.469 mg α-tocopherol acetate per g	410	—	530	580	540
	Feeding stuff x	0	—	70	65	60
	Feeding stuff x with an addition of 0.624 mg α-tocopherol acetate per g	546	—	480	560	570
	Feeding stuff x with an addition of 4.61 per cent wheat germ oil	90	—	160	130	145
2	Feeding stuff y (chiefly ground cereals)	0	6	6	6.6	9
	Feeding stuff y with an addition of 0.0486 mg α-tocopherol acetate per g	42.5	36	44	47	46—38
	Feeding stuff y with an addition of 0.481 mg α-tocopherol acetate per g	420	350	460	440	430

The materials selected for the tests as well as the results of the latter appear from Table 4. As it will be seen, some of the samples have been given an addition of known quantities of tocopherol acetate. For this purpose a commercial, synthetic preparation has been used, analysis of which showed it to contain 875 mg tocopherol per g, corresponding to 96 % pure α-tocopherol acetate. The figures given in the table as regards quantities of tocopherol added have been calculated on the basis of this analysis.

Results of the examinations

Consideration of the results of series 1 shows that maximum deviation occurs in connection with the examination of soybean oil. The reason is that this oil contains reducing substances which are eluted with 2 % ether immediately after α-tocopherol [8] and thus give rise to results which are too high when, as done here, the α-tocopherol fraction is delimited by the collection of a stipulated quantity of eluate. As already mentioned, the presence of this impurity in the α-tocopherol fraction will disclose itself, in that the intensity of the colour does not reach a constant value in the course of 2 min and, further, in that the fraction collected immediately after the main fraction will give a colour reaction with ferric chloride-dipyridyl. If collection in small fractions, as described above, is applied, enabling a delimitation of the α-fraction in each individual case, this source of error will be eliminated.

The presence of the impurities does not make itself felt so much in soybean oil to which α-tocopherol has been added, *i.a.* because a smaller amount of extract is required on the column due to the greater content of α-tocopherol with a correspondingly smaller content of interfering reducing substances.

As regards the results of series 2 the agreement is better although the values obtained by Laboratory A are lower than those of the other laboratories. However, Laboratory A's examinations were made at a somewhat later time than those of the other three laboratories, and it is possible that the lower results are caused by storage losses. The examinations made by Laboratory D of one of the samples suggest that this may be the case, the two values having been obtained by examinations performed at an interval of three months.

It will be seen that it is possible to determine a content of α-tocopherol of less than 10 μg per g, but the accuracy of this determination would no doubt have been better if collection in small fractions had been used for the delimitation of the volume of the α-fraction.

It should be added that the results of repeated examinations of the same material in one laboratory show considerably smaller variations than might have been expected from the discrepancies between the examinations in the four laboratories as given in the table.

From the examinations made the conclusion must be drawn that complete agreement cannot always be obtained from determinations made according to the present method in different laboratories. In cases of doubt, and always when dealing with feeding stuffs with a low content of α-tocopherol, the chromatography should comprise collection in small fractions so as to make it possible to plot the fractionation curve.

ACTA CHEMICA SCANDINAVICA 11 (1957) 44—52

Quantitative Determination of the Individual Tocopherols by Chromatography on Secondary Magnesium Phosphate

FINN BRO-RASMUSSEN and W. HJARDE

Statens Vitamin Laboratorium, Copenhagen, Denmark

A method is given for the determination of the distribution of tocopherols in natural products. The method depends on columnar chromatographic separation of the natural tocopherols in three groups in which the chief components are α-, $\beta+\gamma$-, and δ-tocopherol.

With regard to the recently described and more rarely occurring tocopherols, ζ-tocopherol (5,7-dimethyltocol) will be found together with α-tocopherol, while ε-tocopherol (5-methyltocol) is estimated together with β- and γ-tocopherol.

The possibility of obtaining further separation of the individual tocopherols and the importance in practice of such a separation are discussed, both with a view to the vitamin E activity of the tocopherols and to their action as antioxidants.

Examples are mentioned and the results discussed.

For the majority of practical purposes, in estimating the vitamin E activity of natural products, the greatest significance will be attached to the contents of α-tocopherol. The reasons for this are the higher biological potency of α-tocopherol and the fact that it is the most abundant of the tocopherols. Likewise, in the case of enriched products the tocopherol used will generally be α-tocopherol.

In spite of these facts, the problem of determining the content of other tocopherols in a certain product will at times be of considerable interest. It is thus well-known that the content of α-tocopherol in certain vegetable oils is fairly low compared to their content of other tocopherols, so that to obtain a reliable estimate of the value of such a product as a vitamin E source the contribution to the activity due to each individual tocopherol should be taken into consideration.

The same applies to some extent to tocopherol determinations, the purpose of which is to establish the antioxidant activity of natural products. In this connection it should be noted, however, that it is not possible concerning the antioxidant activity to ascribe a predominating effect to any one of the tocopherols as is possible with respect to the vitamin E potency. When

determining the antioxidant activity of the tocopherols of a certain product, it will thus frequently be insufficient to account for the content of α-tocopherol only.

In such cases a method for the determination of the individual tocopherols is essential. The development of methods for this purpose has commanded great interest during recent years. So far the best results seem to have been obtained by the application of paper chromatography [1-3]. These methods have made it possible to make quantitative determinations of the tocopherols hitherto found (α, β-, γ-, and δ-tocopherol) and also to demonstrate the presence of two new natural tocopherols, *viz.* ε-tocopherol (5-methyltocol) and ζ-tocopherol (5,7-dimethyltocol). On the basis of experience drawn from the paper chomatographic methods Eggitt and Norris [4] have quite recently developed a method for the separation of tocopherol mixtures by means of partition chromatography on paraffin-impregnated kieselguhr columns. This reversed-phase technique allows a separation of the tocopherols into three groups of isomers, *i.e.* mono-, di-, and tri-methyltocols. The authors of the present article have, however, only learned of this method after the conclusion of the present work.

In the following a description will be given of a method for the determination of the individual tocopherols depending on cromatography on secondary magnesium phosphate. This method is a further development of a method for the determination of α-tocopherol published previously (Bro-Rasmussen and Hjarde [5]). When chromatographing tocopherol mixtures on secondary magnesium phosphate, the tocopherols are adsorbed from a solution in petroleum ether. Elution with ethyl ether in petroleum ether in concentrations increasing gradually from 2 % to 6—7 % will result in successive elution of the individual tocopherols in the following order: α-, $\beta+\gamma$-, δ-tocopherol. Any carotene present will not be adsorbed, but will pass through the column with the petroleum ether, while any vitamin A present will require an eluent containing 10—15 % ether, *i.e.* it will be eluted after δ-tocopherol.

EXPERIMENTAL

The present investigations have all been performed according to the technique used for the determination of α-tocopherol as previously described [5] with the exception that the chromatography of the unsaponifiable fraction of the sample has been continued beyond elution with 2 % ether, using gradually increasing ether concentrations as mentioned in connection with each individual experiment.

In certain cases it proved to be convenient, in order to obtain maximum separation, to use a column of greater length than 20 cm. In such cases a 30 cm column has generally been used. This means that α-tocopherol is only eluted quantitatively when slightly more than 150 ml eluent with 2 % ether has been used, but it does not give rise to greater losses in connection with the chromatography than the 0—2 % losses usually met with.

It should finally be stated that fractional collection has been applied in all cases. Fractions have been collected by volume in volumetric flasks half-full of absolute alcohol. The Emmerie-Engel reaction has subsequently been applied to each individual fraction, the measurement being made in the case of α-tocopherol after a 2 min interval, in the case of β- and γ-tocopherol after 10 min, and in the case of δ-tocopherol after 20 min.

The adsorption of α- and β-tocopherol. The unsaponifiable fraction of about 2.5 g wheat germ was chromatographed on a 20 cm column. Elution with 2—4 % ether in petroleum ether. Fig. 1 shows the fractionation curve, the extinction at 520 mμ after the reaction with ferric chloride and α,α-dipyridyl being plotted for each individual fraction.

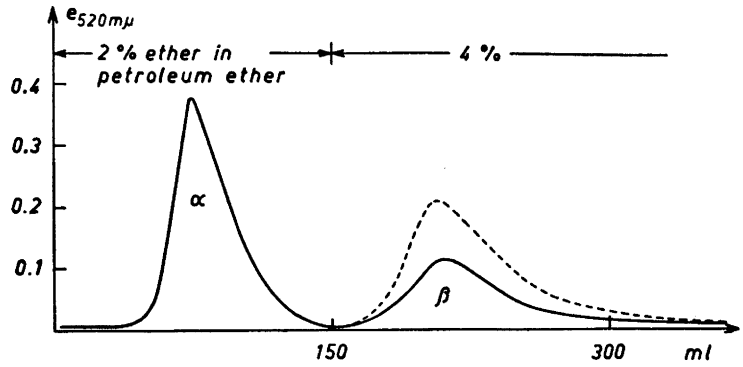

Fig. 1. Fractionation curve for wheat germ with a column 200 mm long. The dotted curve represents the result of addition of synthetic β-tocopherol.

It will be seen from the curve that the separation between the α- and β-tocopherol of wheat germ is complete, α-tocopherol being eluted with 2 % ether and β-tocopherol with about 4 % ether in petroleum ether. Summation shows the total contents in wheat germ to be:

α-tocopherol: 220 μg/g~66 %
β-tocopherol: 112 μg/g~34 %
Altogether: 332 μg/g~100 %

The identification of the two tocopherols of wheat germ was made by parallel runs with addition of the pure substances. To illustrate this the dotted curve in Fig. 1 represents the fractionation of wheat germ to which synthetic β-tocopherol (5,8-dimethyltocol) has been added.

The adsorption of γ-tocopherol. Experiments made with pure synthetic γ-tocopherol * show that this substance is adsorbed on secondary magnesium phosphate and that it is eluted with petroleum ether with about 4 % ether.

Chromatography on a 30 cm column of the unsaponifiable fraction of about 2.5 g wheat germ + about 0.5 mg γ-tocopherol was used to examine the adsorption of γ-toco-

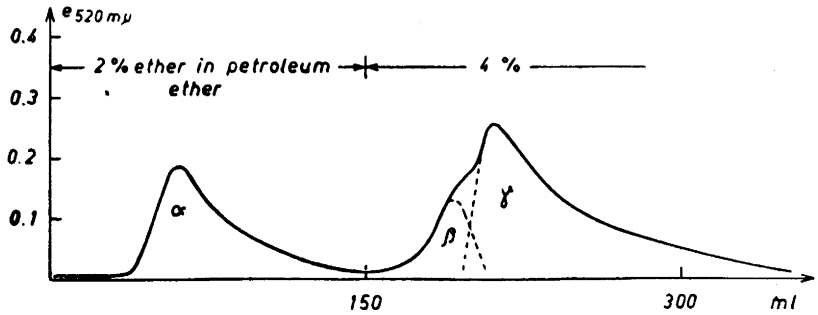

Fig. 2. Fractionation curve for wheat germ after addition of synthetic γ-tocopherol. Column 300 mm long.

* Bought from Distillation Products Industries.

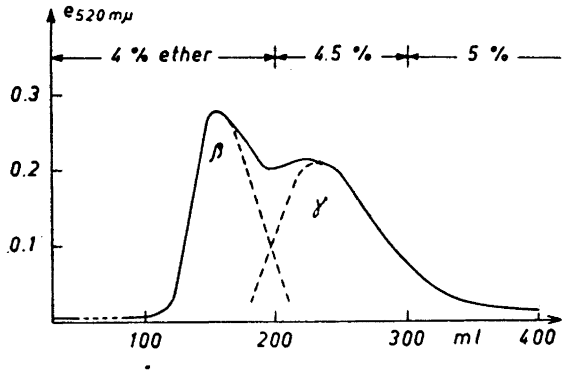

Fig. 3. Fractionation curve for mixture of synthetic β- and γ-tocopherol with a column 500 mm long.

pherol relative to that of β-tocopherol. Fig. 2 shows that β- and γ-tocopherol are on the whole eluted together by means of about 4 % ether. It appears from the figure, however, that there is a tendency towards separation, β-tocopherol being eluted together with the front of the γ-tocopherol zone.

That this tendency is an actual one appears more clearly from Fig. 3 which shows the fractionation curve obtained by chromatography of approximately equal quantities of pure β- and γ-tocopherol on a 50 cm column.

The adsorption of ζ-tocopherol. By means of two-dimensional paper chromatography Green *et al.*[3] have shown that 5,7-dimethyltocol is occasionally found in natural products, and they have given this substance the name of ζ-tocopherol. Since this tocopherol is known to possess a biological potency of the same order of magnitude as that of α-tocopherol (Jacob, Sutcliffe and Todd [6]), it is essential to examine the adsorption exhibited by this substance on chromatography with a view to vitamin E estimation.

By preliminary experiments it is found that synthetic 5,7-dimethyltocol is adsorbed on magnesium phosphate and eluted by means of 2 % ether in petroleum ether, *i.e.* as α-tocopherol. Chromatography on a 20 cm column together with α-tocopherol confirms

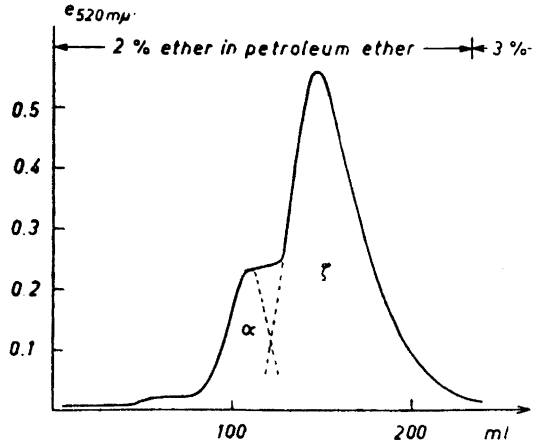

Fig. 4. Fractionation curve for mixture of synthetic α- and ζ-tocopherol with a column 300 mm long.

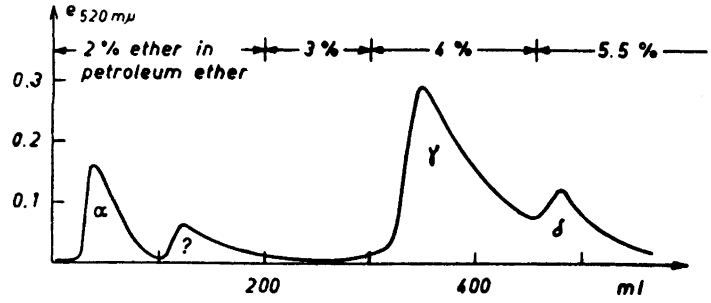

Fig. 5. Fractionation curve for unsaponifiable fraction of soybean oil with a column 300 mm long.

these results, α- as well as ζ-tocopherol being eluted quantitatively by means of 150 ml of 2 % ether in petroleum ether. In routine determinations of α-tocopherol any ζ-tocopherol present will thus be included in the estimate, a result which shows good agreement with the biological activities.

However, chromatography on a 30 cm column shows that there is a certain tendency towards separation between α- and ζ-tocopherol (Fig. 4), the adsorption of α-tocopherol being slightly weaker than that of ζ-tocopherol. Complete separation by this method does not seem to be possible, however.

δ-Tocopherol. Chromatography of soybean oil. To examine the asorption of δ-tocopherol the unsaponifiable fraction of about 2.5 g soybean oil was subjected to chromatography on a 30 cm column.

As appears from the fractionation curve (Fig. 5), a separation into four reducing substances is observed. Out of the four substances three may be identified as above in the case of β-tocopherol (Fig. 1) and are found to be α-, γ-, and δ-tocopherol, which may thus be separated completely, δ-tocopherol not being eluted until the ether concentration in the eluent has reached 6—7 %. The three tocopherols are found to be present in the following quantities:

α-tocopherol:	110 μg/g~13 %
γ-tocopherol:	430 μg/g~51.5 %
δ-tocopherol:	295 μg/g~35.5 %
Altogether:	835 μg/g~100 %

The possibility that the fourth reducing substance which is separated in the chromatography of soybean oil (marked with a ? in Fig. 5) is a tocopherol must apparently be ruled out. Judging from the course of the adsorption ζ-tocopherol is the only possibility, but chromatography of soybean oil with an addition of 5,7-dimethyltocol shows that the unknown substance is not identical with this substance. On the contrary, it appears from Fig. 6 that it is adsorbed between α-tocopherol and 5,7-dimethyltocol. By acting as "displacement carrier" the substance causes the above-mentioned, very incomplete separation between the two tocopherols to become complete. Thus there is no doubt that the unknown substance is not a tocopherol.

ε-Tocopherol. Chromatography of wheat bran. The last of the known natural tocopherols, 5-methyltocol, has hitherto been found in wheat bran and wheat germ only, in the former case in larger quantities, in the latter in small quantities [2,3]. It has been given the name ε-tocopherol.

Chromatography of the unsaponifiable fraction of about 10 g wheat bran showed that the total tocopherol content of 83 μg/g distributes itself between two elution peaks (Fig. 7), *viz*:

"α-tocopherol":	12.5 μg/g~15 %
"β-tocopherol":	70.5 μg/g~85 %
Altogether	83 μg/g~100 %

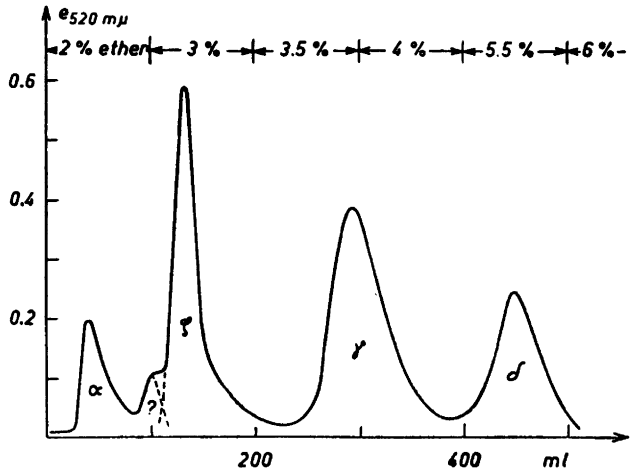

Fig. 6. Fractionation curve for soybean oil after addition of synthetic ζ-tocopherol. Column 300 mm long.

As previously shown, the "α-peak" may contain both α- and ζ-tocopherol. For the examination of the "β-peak" chromatography on paper impregnated with liquid paraffin was applied, the solvent used being 75 % alcohol. This showed that the "β-tocopherol" consisted of two components with $R_F = 0.55$ and $R_F = 0.75$, respectively. By means of parallel experiments in which pure β-tocopherol had been added the spot with $R_F = 0.55$ was identified as being due to β-tocopherol. The other spot ($R_F = 0.75$) thus seems to be identical with Brown's "fast spot" [1] as well as with the ε-tocopherol found by Eggitt and Ward [2] and by Green *et al.*[3]

The quantitative distribution of the components o f "β-tocopherol" was found to be as follows:

β-tocopherol: 11.5 μg/g~14 % of the total in wheat germ
ε-tocopherol: 59 μg/g~71 % » » » » » »

in good agreement with the results obtained by Green *et al.*[3]

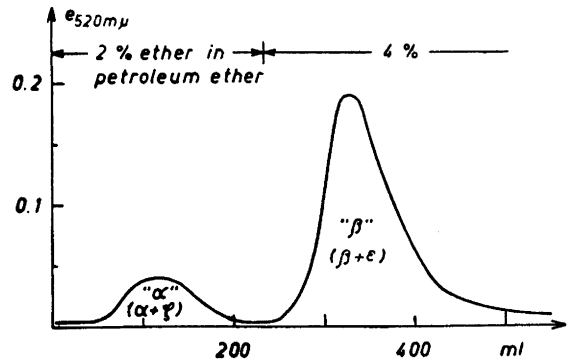

Fig. 7. Fractionation curve for wheat bran with a column 300 mm long.

DISCUSSION

The present experiments show that chromatography of mixtures of the known natural tocopherols on secondary magnesium phosphate results in a separation into three main groups, the number of methyl groups in *ortho* positions in relation to the 6-hydroxy group being the factor which chiefly determined the affinity to the adsorbent magnesium phosphate:

α-, and ζ-tocopherol are eluted with 2 % ether,
β-, γ-, and ε-tocopherol are eluted with 4 % ether,
δ-tocopherol is eluted with 6—7 % ether.

This separation is in perfect analogy with the conditions prevailing in chromatography on zinc carbonate-impregnated paper [3].

The possibility of obtaining further separation by means of the described chromatographic technique has been considered. The tendency, which is shown by Figs. 3 and 4, towards a separation of β- from γ-tocopherol and of α- from ζ-tocopherol suggests that the use of longer columns might enable further separation. In agreement with this attempts at a separation between β- and γ-tocopherol on a 50 cm column have shown improved separation as compared to that obtained on a 30 cm column. As, however, the separation on the 50 cm column is still very incomplete, the experiments have not so far been continued.

Another theoretical possibility of further separation has been demonstrated in connection with the chromatography of soybean oil. When, as shown in the case of α- and ζ-tocopherol there is a slight difference in the adsorption of the tocopherols, suitable substances may be used with success as "displacement carriers", causing a complete separation by being adsorbed between the two substances. The artefact found in soybean oil presents an example. Lacking knowledge of the chemical structure of this substance makes it impossible, however, at present to utilize this fact.

According to the technique used for the present investigations a more complete separation is apparently possible only when applying additional chromatography on paraffin-impregnated paper, as mentioned in connection with the adsorption of ε-tocopherol, a procedure which does not present any difficulties. In this connection it should be noted that by the chromatography on magnesium phosphate the sterols have been removed from the extract so that paper chromatography can be applied directly to the obtained tocopherol fractions. It should also be mentioned that a combination of the recently published reversed-phase partition chromatography on paraffin-impregnated kieselguhr [4] and chromatography on magnesium phosphate will give a separation corresponding to that obtained by two-dimensional paper chromatography. The determination might, *e.g.*, also be made by means of two parallel chromatographic separations of the unsaponifiable matter with subsequent calculation of the contents.

If the problem dealt with is the vitamin E activity of the tocopherols, it is a question, however, considering the biological activity of the individual tocopherols, whether there is any need of further differentiation beyond the three groups referred to above. As regards the biological activity of ζ-tocopherol it

is known that it is almost identical with that of α-tocopherol [6]. Even if the biological potency of ε-tocopherol has not as yet been determined, a consideration of its chemical structure will show that there is every reason to expect that it approximates that of γ- and β-tocopherol, which is generally stated to be 20—30 % of that of α-tocopherol [7]. Finally the biological potency of δ-tocopherol is taken to be 1 % (or less) of that of α-tocopherol. It will thus be seen that the separation obtained corresponds closely to the order of the biological potencies, so that when it is necessary to consider other tocopherols than α-tocopherol, a chromatographic separation on magnesium phosphate will be quite sufficient for most practical purposes.

Of course, it is not possible to apply these findings directly to the question of the antioxidant properties of the tocopherols. It cannot be excluded that for this purpose a complete elucidation of the composition of the tocopherol content may be of interest. In that case chromatography on magnesium phosphate may be combined with chromatography on paraffin-impregnated paper or reversed-phase partition chromatography on kieselguhr columns. It should be emphasized, however, in this connection that definite, quantitative figures for the relative antioxidant potencies of the tocopherols can hardly be given, since the values found depend to a great extent on methods of examination, temperature and criteria applied. [8,9] When taken together with our present lack of knowledge with regard to the antioxidant properties of the most recently described tocopherols, these circumstances tend to cause a determination of the content of each individual tocopherol to be rather illusory.

As mentioned previously in connection with the determination of α-tocopherol [5], column chromatography does not give rise to losses of any magnitude. Chromatography of a mixture of β- and γ-tocopherol on a 50 cm column and elution with 4—5 % ether in petroleum ether thus results in recoveries of 97—98 %.

Table 1. Distribution of tocopherols in natural products

Product	Total tocopherols (μg/g)	$\alpha+\zeta$ (%)	$\beta+\gamma+\varepsilon$ (%)	δ (%)
Wheat germ	332	66	34	
Wheat germ oil	2 300	91	9	
Wheat bran	83	15	85	
Corn germ meal	307	24	76	
Soybean oil	835	13	51.5	35.5
Rapeseed oil	691	32.5	68	
Cottonseed oil	888	36	64	
Mustard oil	525	16	84	

Table 1 lists the results of a number of examinations of natural products which are known to contain considerable quantities of the other tocopherols in addition to α-tocopherol.

Among the products mentioned in Table 1 both soybean oil and mustard oil contain artefacts which are eluted between α- and γ-tocopherol fractions. In soybean oil these substances occur in quantities corresponding to 8 % of

the total reducing power. Corresponding observations have been made by Green *et al.*[3] in twodimensional paper chromatography.

When considering the adsorption data, the artefacts observed in the course of the present investigation do not appear to be identical with those found by Green *et al.*, the latter authors stating that the reducing substances move beyond the α-tocopherol position on zinc carbonate paper, which should correspond to elution before α-tocopherol from the magnesium phosphate column.

The relative contents of α- and β-tocopherol in wheat germ correspond exactly to the values previously found [1,3]. It is remarkable, therefore, that the wheat germ oil examined displays such a low content of β-tocopherol, both as regards absolute and relative values. As the oil in question is a refined wheat germ oil, it cannot, of course, be excluded that the refining process has destroyed part of the β-tocopherol. Since, however, the content of α-tocopherol in the sample examined is slightly above the values usually found (values from 1 250 to 1 900 μg/g are given by Green *et al.*[3], Hove and Hove [10], Quaife [11], and Brown [1]), and since a *selective* destruction of β-tocopherol can hardly be expected to take place, it seems more probable that we are faced with individual variations in the tocopherol composition depending on the origin of the samples. This seems also to apply to cottonseed oil in the case of which Green *et al.*[3] find 58 % α-tocopherol (in the present investigation 36 %) and 42 % γ-tocopherol (in the present investigation 64 %).

Unlike previous researchers [3] the authors of the present work found no δ-tocopherol in mustard oil. It should be noted, however, that the present investigation has comprised one sample of mustard oil only.

Acknowledgements. We wish to express our thanks to Professor P. Karrer for samples of synthetic 5,7- and 5,8-dimethyltocol and to A/S Dansk Sojakagefabrik, Copenhagen, for the cottonseed oil, rapeseed oil and mustard oil used in the investigation.

Comparative Ligand Field Studies

III. The Decrease of the Integrals F^k for Manganese(II) Complexes as Evidence for Partly Covalent Bonding

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The relative energy differences between the terms of an electron configuration with a partly filled l-shell can be expressed as multipla of the integrals F^2, F^4, ...F^{2l}. Tanabe and Sugano, Owen, and Orgel pointed out that the ligand field theory agrees much better with absorption spectra of octahedral d^n-complexes, if the values of F^k are assumed to be only 40—90 % of the values found for gaseous ions. This decrease of F^k can have two causes: the central field is decreased by electrons, donated from the ligands, and the partly filled shell is partly present in the ligands. The latter effect is proven by the extrapolation from F^k to values of the average radius $r_0 \sim 0.8-2$ Å of the partly filled shell, which are larger than the ionic radii 0.5—0.8 Å. Manganese(II) complexes are especially discussed with respect to Schläfer's investigation.[34,41] The present author assumes (1) that chloro complexes are formed, (2) that the aquo ion is octahedral and not tetrahedral, (3) that Schläfer's matrix for $^4\Gamma_5$ is wrong, and (4) that the red shifts of the bands of strong $MnCl_2$-solutions only can be interpreted by partly covalent bonding. Generally, anion complexes are shown to have smaller values of F^k than complexes with neutral ligands. The principle of electroneutrality and the Pauling theory of covalent bonding are discussed. The explanation by Orgel of band widths is further discussed. The highly fluorescent tetraethylammonium manganese(II) bromide with tetrahedral environment of Mn(II) is described.

THE INTEGRALS F^k FOR PARTLY FILLED SHELLS

The ligand field theory for a regular octahedral complex describes the energy levels as function of one ligand field * parameter Δ and of linear combinations of the energy levels of the gaseous ion. The latter energy levels cor-

* Orgel, Nyholm, J. Bjerrum and the present author proposed at the Xth Solvay Conference, Bruxelles, May 1956, to use the word "ligand field theory" to denote the crystal field theory extended with the molecular orbital theory for partly intermixing with the orbitals of the ligands, when applied especially to the action of the first co-ordination sphere on the partly filled d-shell in a transition group complex.

† Further, it was proposed to denote the energy difference between the partly filled γ_3- and γ_5-orbitals in a regular octahedral complex by Δ (as proposed by Owen [1]) rather than 10 Dq (*cf.* Schlapp and Penney [2]) or $(E_1—E_2)$ (*cf.* Hartmann and Ilse [3]).

respond to more or less favourable average positions of the electrons, relative to each other, within the same shell. Slater, Condon, and Shortley [4] calculated the relative l^n-term energies as multipla

$$f_2F^2 + f_4F^4 + \ldots + f_{2l}F^{2l} \tag{1}$$

of the integrals

$$F^k = e^2\int_0^\infty \left[\int_0^{r_2} \frac{r_1^k}{r_2^{k+1}} R^2\, dr_1 + \int_{r_2}^\infty \frac{r_2^k}{r_1^{k+1}} R^2\, dr_1\right] R^2\, dr_2 \tag{2}$$

e is the electronic charge, R^2 the square of the radial function of the l-electron, and r_1 and r_2 are the variable distance of the electron from the nucleus.

For convenience, several linear combinations of the integrals F_k are used. For obtaining integral values of the coefficients f_k of eqn. 1, Condon and Shortley [4] defined for d-electrons:

$$F^2 = 49\ F_2 \text{ and } F^4 = 441\ F_4 \tag{3}$$

while Racah [5] later defined the linear combinations:

$$B = F_2 - 5\ F_4 \text{ and } C = 35\ F_4 \tag{4}$$

The energy differences between the terms with the maximum value of the total spin S (among which the term with the highest L is the lowest in the free ion, according to Hund's rule) are multipla of B alone.

When applying the matrices [6] for d^n-systems in ligand fields with the symmetry O_h, Tanabe and Sugano [6], Owen [1], and Orgel [7,8] reported the possibility of smaller values of the term distances (and thus of F^k) for complexes than for the gaseous ions. Fig. 1 is a plot of the ligand field parameter Δ as function of B for the complex divided by B for the gaseous ion. It is seen that a rough linear correlation exist for all the considered elements. However, for a given central ion, the complexes with anions, such as chloride, oxalate or cyanide, have much smaller values of B than complexes with neutral molecules, such as water or ammonia.

Thus, the Orgel diagram, *i. e.* the energy levels as function of Δ, will be partly distorted by the new variables F^k. For nickel(II) complexes, it has been demonstrated in the two earlier papers of this series [9,10] that the slopes of the lines in the Orgel diagram deviate rather much from the values, predicted from the simple ligand field theory [11]. This was originally [9,12] ascribed to the interaction with other electron configurations, *viz.* $3d^{n-1}4s$. The perturbation of the d^n-states of the gaseous ion, when imbedded in the complex, can formally be described as a complicated interaction with many other states with the same $^{2S+1}\Gamma_n$ of other electron configurations.* On the other

* The ligand field [44] can be expanded in a series of contributions: G_0, G_2, G_4. Two orbitals with defined values of l equal to l_1 and l_2 can only be intermixed by quantities F^k or G_k, where $|l_1 - l_2| \leqq k \leqq l_1 + l_2$ and k has the same parity as $l_1 + l_2$. Thus, the spherically symmetrical contribution G_0 can only intermix orbitals with the same l, but different n. As discussed elsewhere [57], this corresponds to a variation of the central field [4] and hence a decrease of F^k for the partly filled shell. It is not believed that the characteristic cubic contribution G_4 is so large that the physical significance of the treatment in terms of F^k-values is invalidated.

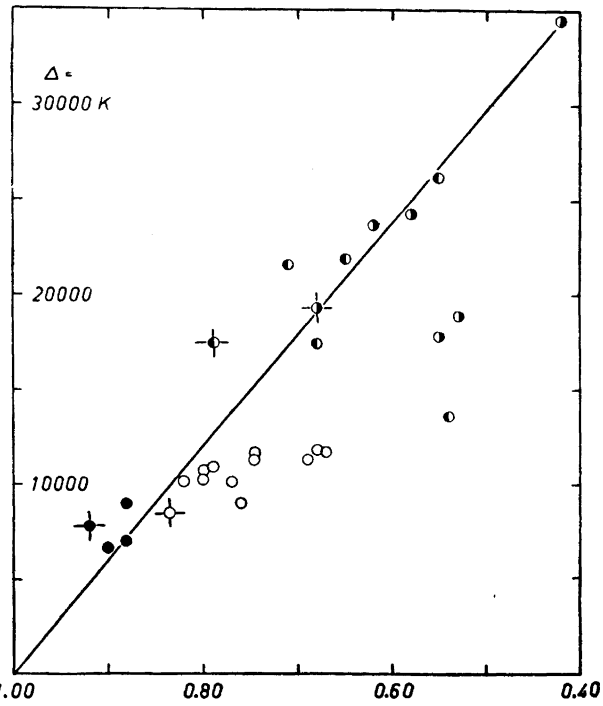

Fig. 1. The correlation between the ligand field parameter △ *and the ratio B in the complex: B in the gaseous ion. Filled circles correspond to manganese (II) complexes, empty circles to nickel (II),* ◐ *to chromium(III) and* ◑ *to cobalt(III). The hexaaquo ions, which have inter alia the highest values of* B, *i.e. the smallest decrease relative to the gaseous ion, are marked by a cross outside the circle.*

hand, it can also to a first-order approximation be described as an interaction between the *d*-orbitals and the other molecular orbitals with the same γ_n and parity, *i. e.* the even γ_3- and even γ_5-orbitals in octahedral complexes [1,13,14]. In the latter approximation, the effects of partly covalent bonding will only appear as a contribution to △ and as decreased values of F^k, as discussed below.

The analogous description of configuration interaction [4] by statistical methods in atomic spectroscopy was given by Trees [15], who added a correction term to the energies of d^n-terms:

$$f_2F^2 + f_4F^4 + \alpha L(L+1) \qquad (5)$$

and improved the agreement much by assuming values of $\alpha \sim 100$ K*. Racah [16] pointed out that this empirical correction corresponds to a mutual polarization of the *d*-orbitals by the electrons, which occupy them. It can be seen from eqn. 2 that isomorphous wavefunctions R^2, which are only differing by

* The unit cm^{-1} for wavenumber σ will now be called K = Kayser, as proposed by the Joint Committee for spectroscopy.

a multiplication factor in the distance r, correspond to values of F^k which are inversely proportional to r_{max} or another characteristic distance. Thus, the average distance of d-electrons from the nucleus must be larger in complexes than in the corresponding gaseous ions.

The perturbation theory states that the energy of two wavefunctions, totally imbedded in a sphere of negative charge, is increased by the same constant amount, thus not changing the energy difference [17]. If the excited wavefunction is partly present outside the sphere, the energy difference will be decreased. Thus, it must be assumed that a more negative charge is present in average between the central nucleus and the d-electron in the complexes than in the gaseous ion. This effect can be realized in two different ways:

I. Electrons from orbitals of arbitrary symmetry (*e. g.* the σ-bonding even γ_1 or odd γ_4) are donated from the ligands to the central ion, thus decreasing the effective charge by decreasing the central field in the theory of Condon and Shortley [4].

II. Linear combinations of atomic orbitals are formed with the symmetries γ_3 and γ_5 from d-electrons and respectively σ- and π-orbitals from the ligands. Orgel [7,8] discussed possibility I on the analogy of the influence of $4s$-electrons on the term distances of $3d^n$-configurations, while most authors have suggested II from Van Vleck's old discovery [18] that the molecular orbital theory and Bethe's electrostatic theory both lead to a considerable value of Δ, implying magnetically anomalous complexes when Δ in octahedral d^4- and d^7- or 2 Δ in d^5- and d^6-systems is larger than the necessary spin-pairing energy. The latter multipla of F^k, which are reported by Tanabe and Sugano [6], were discussed by Griffith [19]. The present author has found that the average spin-pairing energy (when the terms are weighted by factors $2L + 1$) to go from q to $q - 2$ spins is:

$$\begin{aligned} &q \cdot 15/4\ F_2 && \text{for } p^n\text{-systems} \\ &q\left(\frac{35}{12}\ F_2 + \frac{105}{4}\ F_4\right) && \text{for } d^n\text{-systems} \\ &q\left(\frac{35}{4}\ F_2 + \frac{231}{8}\ F_4 + \frac{1001}{4}\ F_6\right) && \text{for } f^n\text{-systems} \end{aligned} \qquad (6)$$

if no restriction is made on the seniority number [5]. These energies are multiplied by the factor $\frac{2l+2}{2l+3}$, if only the maximum values of the seniority numbers are considered. Thus, the average spin pairing energy is $q \cdot 0.15\ F^2$, $\sim q \cdot 0.10\ F^2$, and $\sim q \cdot 0.08\ F^2$ in the three cases.

Owen [1] has given experimental evidence for the possibility II from paramagnetic resonance, partly from hyperfine-structure*, due to the halogen nuclei and iridium nucleus in $IrCl_6^{--}$ and $IrBr_6^{--}$, and partly from the g-values in complexes, which can be written [1]

$$g = 2.00229 + \frac{k\zeta_{nd}}{\Delta} \qquad (7)$$

* Recently, Tinkham [54] reported similar evidence for partly covalent bonding to fluoride ligands of Mn(II), Fe(II), Co(II), and Cr(III) imbedded in ZnF_2. Tinkham proposes that both $2s$, $2p$, $3s$ and $3p$ orbitals of the fluoride ions are involved.

k is a constant, characteristic for the number of d-electrons, and ζ_{nd} is the Landé multiplet splitting factor. The measured g-values of complexes can be made compatible with eqn. 7 by assuming ζ_{nd} being between 10 and 40 % less in the aquo ions than in the gaseous ions of the first transition group. Owen [1] assumes that this can be directly translated to the partly filled shell containing 10—40 % of the ligands' orbitals in the squares of the wavefunction.

However, another evidence for partly covalent bonding can be obtained from the actual values of F^k of complexes. It is possible [17] to extrapolate from the values of F^k to the integral:

$$W = e^2 \int_0^\infty \frac{R^2}{r_i} \, dr \tag{8}$$

and to define an average radius of the partly filled shell:

$$r_0 = \frac{e^2}{W} \left(\text{in Å } r_0 = \frac{116\,000 \text{ K}}{W} \right) \tag{9}$$

If the partly filled shell was concentrated on a spherical surface, all the integrals W and F^k would be equal. For a broader radial function R^2 the inequalities

$$W > F^2 > F^4 > F^6 > \ldots \tag{10}$$

will be valid. For most actual ions [17], F^2 will be $\simeq \frac{1}{2} W$. The present author [17] calculated the values of W and F^k for a rectangular function

$$R^2 = \frac{1}{n-1} \text{ for } 1 \leq r \leq n \text{ and elsewhere } R^2 = 0 \tag{11}$$

Thus, if n is written $1 + \delta$, the series can be expanded:

$$\frac{F^k}{e^2} = \frac{1}{(n-1)^2} \left[\frac{2n}{k+1} - \frac{2}{k} + \frac{2}{n^k k(k+1)} \right] = \\ = 1 - \frac{k+2}{3} \delta + \frac{(k+2)(k+3)}{3 \cdot 4} \delta^2 - \ldots \tag{12}$$

while $$W = \frac{\ln n}{n-1} e^2$$

If R^2 is distributed on several peaks with the areas A_n, arranged according to increasing values of r_n, it is approximately valid [17]:

$$\frac{F^k}{e^2} \simeq \sum_n \frac{A_n^2}{r_n} \{1 - \frac{k+2}{3} \delta_n + \ldots\} + \sum_{m>n} \frac{2 A_n A_m r_n^k}{r_m^{k+1}} \tag{14}$$

Eqn. 14 is useful for anti-bonding combinations of atomic orbitals, which have at least two maxima of R^2, one in the central ion and one in the ligands.

Table 1 gives the values of r_0 for gaseous ions and complexes under the assumption $W = 2\ F^2$. While the analogous values [17] of r_0 for 4f-shells in trivalent lanthanide complexes vary between 0.80 Å for Pr^{+++} and 0.58

Å for Tm^{+++}, somewhat smaller than the ionic radii (and are increased slightly in anion complexes, at most to 0.84 Å in the *A*-form of Pr_2O_3), it is seen from Table 1 that the values of r_0 are distinctly larger than the ionic radii given by Goldschmidt [20].

Table 1.

Electron configuration		F^2 for the gaseous ion	Decrease of F^2 in complexes	r_0 of gaseous ion	r_0 of complexes	Ionic radius
3 d^3	Chromium(III)	74 000 K	21–47 %	0.78 Å	0.99–1.43 Å	0.55 Å
3 d^5	Manganese(II)	66 000	8–12	0.87	0.94–0.99	0.80
3 d^6	Cobalt(III)	~82 000	32–58	0.71	1.04–1.68	0.47
3 d^8	Nickel(II)	88 000	17–35	0.66	0.79–0.99	0.68
4 d^6	Rhodium(III)	~62 000	38–62	0.93	1.3–2.5	0.69

Thus, the gaseous ion will be strongly perturbed, if it is surrounded by other ligands in the distance ~ 2 Å known from crystallography. The maximum of the 3*d*-radial function will approximately be situated* on the boundary between the central ion and the ligand in the crystals. If the approximation of distinct molecular orbitals is assumed, the anti-bonding orbitals γ_3 and γ_5 (corresponding to the partly filled *d*-shell) will achieve a minimum of the square of the radial function between the ligand and the central ion, because the anti-bonding wavefunction will have one node more than the corresponding bonding wavefunction.

OVERLAP INTEGRALS BETWEEN ATOMIC ORBITALS OF THE LIGANDS AND THE CENTRAL ION

If the overlap integral is $S = \int \psi_1 \psi_2 \, d\tau$ between the two wavefunctions ψ_1 and ψ_2, their linear combinations can be written

$$\begin{aligned} \psi_b &= a\,\psi_1 + b\,\psi_2 \qquad & a^2 + b^2 + 2\,ab\,S &= 1 \\ \psi_a &= c\,\psi_1 - d\,\psi_2 \qquad & c^2 + d^2 - 2\,cd\,S &= 1 \end{aligned} \tag{15}$$

It must be realized that the orthogonalization condition

$$ac - db + (bc - ad)\,S = 0 \tag{16}$$

can be satisfied in infinitely many different ways. Thus, both functions do not need to differ from the unperturbed functions, *e. g.* ψ_1 and $\frac{1}{1-S}\psi_2 - \frac{S}{1-S}\psi_1$ are orthogonal. Only when the energy is minimized, the bonding orbital ψ_b with lowest energy may contain large coefficients *a* and *b* of eqn. 15.

* Recently, Hartree [55] has calculated the self-consistent 3*d*-wavefunctions in several divalent transition group ions in the gaseous state. The deviation of the radial functions from the hydrogen-like corresponds to higher electron densities both for small and large values of the distance *r* from the nucleus, while they are lower for intermediate values of *r*. Thus, the maximum occurs at a smaller value than at r_0 given above, while on the other hand, the tail for large *r* is very long. The conclusions on partly covalent bonding are not essentially altered from those presented above.

The secular determinant for wavefunctions with overlap integrals S_{mn} has the diagonal elements $E_{nn} - E$ and the symmetrical non-diagonal elements $E_{mn} - S_{mn}E$. For two levels, the eigenvalues of the energy will be given by the roots E of the equation

$$(E_{11}-E)\ (E_{22}-E) - (E_{12}-S_{12}E)^2 = 0 \tag{17}$$

It is often assumed [21,22] that

$$E_{12} = kS_{12} \cdot \frac{E_{11} + E_{22}}{2} \tag{18}$$

with k a constant between 1.6 and 2. The diagonal sum rule (which always is valid for $S_{mn} = 0$), *viz.*, that the sum of the roots of E is equal to the sum of E_{nn} is only valid, if $k = 1$.

The sum of the roots of eqn. 17 is:

$$E_a + E_b = (E_{11} + E_{22}) \cdot \frac{1 - kS_{12}^2}{1 - S_{12}^2} \tag{19}$$

Since $E_{11} + E_{22}$ generally is negative, $k > 1$ corresponds to relatively increased values of the average energy of the levels.

It is very difficult to derive quantitative information about the parameters S_{mn} and E_{nn} of eqns. 17—19. Many authors have discussed Slater's proposal [23]

$$R^2 = r^{2n} \exp\left(-\frac{2Z_* r}{n}\right) \tag{20}$$

which has the maximum value at

$$r_{max} = \frac{n^2}{Z_*} \text{ (in atomic units)} \tag{21}$$

If $r_0 \sim 1.5$ atomic unit ($= 1.5 \cdot 0.528$ Å) from Table 1 is identified with r_{max} of eqn. 21 with $n = 3$, then Z_* equals 6. (*Cf.* the foot-note p. 58).

Fig. 2 gives the two radial functions R_1 and R_2 from the central ion and the ligand under the assumption that R_2 has the same dependence on distance as R_1, but is distributed on two halves, one in the direction towards the central ion and one in the opposite direction. This is of course a rather rough approximation to the actual radial function. It is seen that the overlap between R_1 and the left-hand half part of R_2 is rather complete. While S_{12} in bi-nuclear complexes with a ligand between two metal ions might achieve large values near 1, S_{12} cannot exceed the upper limit $\sqrt{0.5}$ in mono-nuclear complexes as seen of Fig. 2, and will probably [24] be near 0.5. Fig. 2 gives further R_1^2 and the bonding orbital R_1^2 and anti-bonding orbital R_b^2, normalized to the same area. Due to the normalization factors, R_a^2 will contain most of the right-hand part of R_2, which does not overlap appreciably with R_1. Thus, F^k of R_a^2 (which is the partly filled shell of the complex) would be 20 % of the value for R_1^2, because only about a third of R_1^2 is refound as the first of the three maxima of R_a^2 (however, nearer to the central nucleus). This is not very different from the value 25—30 % implied by more simple reasoning on linear combination of atomic orbitals without consideration of overlap integrals.

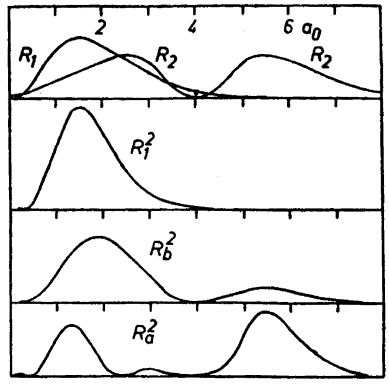

Fig. 2. The radial wavefunctions R_1 *and* R_2 *in a complex with the centres of the central ion at 0 and of the ligand at 4* a_0. *The squares of the bonding,* R_b^2, *and the anti-bonding radial function* R_a^2 *are given below after intermixing of* R_1 *and* R_2. *The partly filled* d-*shell in a complex near the Pauling case corresponds to* R_a^2 *on the figure, while a complex near the electrostatic limiting case has the partly filled shell nearly as* R_1^2.

Fig. 2 represents the Pauling hybridization case with equal energies of the two orbitals and equal radial dependences. Since F^k in complexes actually is decreased 8—62 % (Table 1) and not 80 %, all the complexes exemplify intermediate cases between the electrostatic model with pure d-wavefunctions and the Pauling case. This is the situation, described by Pauling [25] in the somewhat cumbersome language of valence-bond orbitals applied to the groundstates. Thus, Pauling [25] does not recognize the magnetic criterion as distinguishing ionic and covalent complexes, but rather between complexes, where the resistance towards spin-pairing of the d-electrons is larger or smaller than the tendency towards more favourable use of the orbitals for covalent bonding. This is described by the ligand field theory as the competition between spin-pairing energy, *i. e.* multipla of F^k-integrals, and ligand field strength Δ in the cases, where the slopes of the levels with low total spin are more negative in the Orgel diagram than the slope of the lowest level with the maximum spin [6,19,26].

It may be questioned, if σ-bonding is much more important than π-bonding in the d^n-complexes. Since the bond lengths [27,28] to the first approximation are an increasing linear function of the number of γ_3-electrons, the σ-anti-bonding character of these electrons seem well established. However, the F^k-integrals seem to be decreased by the same amount for the levels $^2\Gamma_3$ (G) of γ_5^3 in chromium(III) complexes * and $^1\Gamma_3$ (D) of $\gamma_5^6\,\gamma_3^2$ in nickel(II) complexes as for the levels $^4\Gamma_4$ and $^3\Gamma_4$, respectively, which contains in average 1.5 γ_3-electron more than the groundlevels. Thus, the delocalization of γ_5-electrons (which are π-anti-bonding with respect to filled molecular orbitals with less energy and π-bonding with respect to empty molecular orbitals with higher energy) does not seem to be less than of γ_3-electrons.

* as also Mo(III) and Re(IV). *Cf.* this journal **11** (1957) 82.

Probably, the large overlap integrals make π-bonding more important [24] than usually believed. Williams [29] assumes that the small values of Δ for iodo-, bromo, and chloro-complexes and high values of Δ for cyanide complexes are due to the influence of donation of π-electrons respectively, in the direction from the ligands to the central ion and in the opposite direction. Wolfsberg and Helmholz [21] assume so strong π-bonding in CrO_4^{--} and MnO_4^- that the negative sign of Δ for tetrahedral complexes, implied by both the electrostatic and the σ-bonding models, is reversed.

The experimental evidence from the absorption spectra that the degree of intermixing of d-electrons with γ_3- and γ_5-electrons of the ligands is 10—30 % rather than 50 % corresponds to higher energy of the unperturbed d-electrons than of the ligands' electrons. It can be estimated from Latimer's data [29] that the energy necessary for the reaction in aqueous solution

$$\tfrac{1}{2}\ H_2 \rightarrow H_3O^+\ aq + e^- \qquad (22)$$

is between 4.5 and 5 eV $\sim$ 40 000 K). Thus, it can be estimated from the oxidation potentials (when entropy effects are neglected) that the removal of a $3d$-electron from $Co(NH_3)_6^{++}$ demands $\sim$ 4eV and from $Co(H_2O)_6^{++}$ $\sim$ 6 eV. However, the optical transitions to states of a nearly free electron are not possible with so small an energy, because the ligands have not sufficient time for finding the new equilibrium positions, due to the Franck-Condon principle [28]. Further, it is only approximatively valid that the ionization potentials are equal to the energies of the orbitals, since the other orbitals rearrange slightly during the ionization process. The ionization potentials of most ligands will be $\sim$ 8 eV, but this value refers probably to π-electrons, while the σ-electrons have somewhat lower energies [14]. (1 eV = 8 067 K).

If complexes with $\sim$ 50 % intermixing of γ_3-electrons exist (*i. e.* the Pauling case), weak Laporte-forbidden electron transfer bands would be observed due to transition of bonding γ_3-electrons to γ_5 at nearly the same wavenumbers as the ligand field bands, which are caused by $\gamma_5 \rightarrow \gamma_3$ transitions within the partly filled shell. This case has not been observed, and only in systems, which have a strong tendency towards internal redox processes, such as [14] $IrBr_6^{--}$ or PtI_6^{--}, the electron transfer bands occur at lower wavenumber than the predicted ligand field bands.

The donation of electrons from the ligands, *e. g.* the σ-bonding γ_1- and odd γ_4-electrons, corresponding to the sp^3-part of the Pauling $d^2\,sp^3$-hybridization in octahedral complexes, decrease the effective charge on the central ion. Since the integrals F^k are roughly proportional to Z_0, where $Z_0 - 1$ is the external charge, this effect co-operates in decreasing F^k for complexes. The "principle of electroneutrality", as discussed by Pauling [25], seems to allow a residual charge between +1 and +2 in the domain of the central ion. Since the potential energy of a sphere with the electrical charge z and the radius r is proportional to z^2/r, one would expect small ions with high charges to be unstable. However, chemistry is remarkably unsymmetric with respect to the existence of cations and anions. While elementary anions are not easily provided with more negative charge than −2 (and even divalent anions seem to be highly polarized and only stable near cations), thorium(IV) aquo ions are definite entities. Since the ionic radius increases with negative charge and

decreases with positive charge, the effect can perhaps be described as the breakdown of highly negative anions with large radius, due to the presence of small cations with strong electrostatic fields. However, only the molecular orbital theory can explain the actual complicated behaviour of complexes, and recent investigations [25,27,30] have emphasized the importance of mutual donation of *e. g.* σ-electrons from the ligands and π-electrons to the ligands. That these subtle effects have strong influence on the chemistry of ions without inert gas configurations is evident from the highly different *cyclo*pentadienide complexes formed by thorium(IV) and uranium(IV) [31].

The increased acidity of water or ammonia, when bound to cations, might be taken as evidence for partly covalent bonding. However, pK of the complexes is probably not a linear function of the induced charge of the ligands, assuming *e. g.* the charge $+\frac{1}{2}$ on each water molecule of an aquo ion with p$K = 7$. It is necessary to consider the possibility of stronger covalent bonding of the hydroxo- or amido-group than of ammonia and water. Thus, the acidity [14] of $Pt(NH_3)_6^{+4}$, which is stronger than of NH_4^+, does not imply with certainty a charge above $+1$ of each ligand. Of purely electrostatic reasons, complex-bound H_2O and NH_3 would have the same energy of proton dissociation as H_3O^+ and NH_4^+, when the charge of the central ion is $\frac{3.3\ \text{Å}}{1.3\ \text{Å}} \sim 2.5$, since the distances from the proton to the hydroxyl group and the central ion are roughly 1.3 Å and 3.3 Å, respectively.

MANGANESE(II) COMPLEXES

The absorption spectra measured by Gielessen [32] of manganese(II) salt hydrates and by the present author [33] of the aqueous solution of $MnSO_4$ were interpreted by Orgel [8] on basis of the ligand field theory for an octahedral d^5-system [6,7] (*cf.* Fig. 3). Ten transitions from the groundstate $^6\Gamma_1$ (S) to quartet levels are predicted, and the present author [12] reported later the missing weak bands in the ultraviolet. Table 2 gives the bands with the identification of their excited levels of $MnCl_2$ and $MnSO_4$ in aqueous solution and the other complexes with ethylenediaminetetraacetate, ethylenediamine, and tartrate. The hexaaquo ion has nearly the same spectrum (found in dilute $MnCl_2$) as the un-ionized complex $MnSO_4(H_2O)_5$ probably occurring in strong sulfate solutions.

Schläfer [34] applied also the ligand field theory to the absorption spectra of $MnCl_2$, 4 H_2O and $NH_4Fe(SO_4)_2$, 12 H_2O, which were assumed to contain the ions $Mn(H_2O)_4^{++}$ and $Fe(H_2O)_6^{+++}$. Schläfer's assignment of levels deviate rather much from that of Orgel [8] and the present author [26]. The three levels $^4\Gamma_5$ seem to be shifted erroneously $\sim$ 6 000 K towards lower wavenumbers. The problem, whether the manganese(II) aquo ion is tetrahedral or octahedral, cannot be decided from the quantum numbers Γ_n, since the matrices for d^5-systems are symmetrical [6] with respect to a change of sign of Δ. However, the value of $\Delta = 7\,800$ K for manganese(II) suggests an octahedral co-ordination, when compared to $\Delta = 10\,400$ K for iron(II), 9 300 K for cobalt(II) and 8 500 K for nickel(II) hexaaquo ions. In a tetrahedral complex with purely electrostatic ligand fields, Δ would be [35] multiplied by

a factor $-\frac{4}{9}$. The molecular orbital theory may cause strong deviations from this ratio, as discussed p. 61, but the evidence from $CoCl_4^{--}$ suggests very low values of Δ in tetrahedral complexes. Hartmann and Fischer-Wasels [36] assume also tetrahedral co-ordination of paramagnetic nickel(II) complexes. However, the only certain case of this is found by Weyl [37] as a purple nickel glass in rubidium silicate. J. Bjerrum [38] demonstrated a regular development in the absorption spectra of Ni^{++} with from zero to six ammonia molecules. The latter type of argument can also be applied to manganese(II): as can be calculated from Table 2, $\Delta = 9\,100$ K of the tris(ethylenediamine) complex [38] is only 18 % larger than for the aquo ion, agreeing well with the usual effects of exchanging water and amines in octahedral complexes.

The terms of the gaseous Mn^{++} are known from atomic spectroscopy [39]:

^6S	0 K
^4G	26 800
^4P	29 200
^4D	32 300
^4F	43 600

The levels $^4\Gamma_1(G)$, $^4\Gamma_3(G)$ and $^4\Gamma_3(D)$ should have the same wavenumbers as ^4G and ^4D, respectively, if the integrals F^k and thus the term distances were not decreased in complexes. It is seen from Table 2 that these energy differences are decreased 8 % in $Mn(H_2O)_6^{++}$, 12 % in Mn enta^{--} and 12 % in Mn en_3^{++}.

Orgel [7,8] assumed that the presence of two 4*s*-electrons is sufficient to explain this effect, thus applying possibility I on p. 56. However, with the value of r_0 from Table 1, it is probable that ~5 % intermixing with the ligands' orbitals occur. The highest term ^4F seems more decreased, ~19 % in $Mn(H_2O)_6^{++}$. It seems generally valid that high terms are systematically depressed, thus the ratio between the wavenumbers of the spinforbidden transitions to $^2\Gamma_3$ and $^2\Gamma_5$ in chromium(III) complexes [40] is only ~1.5 rather than [6] 1.66 . . . This effect in Mn^{++} is perhaps caused by interaction with other electron configurations, which are situated above 50 000 K. It cannot be certainly decided, if an extra band does not occur of $Mn(H_2O)_6^{++}$ at 37 400 K. It may be due to a doublet level *, which is highly intermixed with the quartet levels. $^2\Gamma_5$ is predicted at 28 000 K of $Mn(H_2O)_6^{++}$ and at 23 000 K of Mn en_3^{++}, while the doublet levels of γ_5 $^4\gamma_3$ are distributed ~8 000 K above these wavenumbers.

Schläfer [41] studied the absorption spectra of crystalline $MnCl_2$, 4 H_2O and aqueous solutions between 1 M and 4.8 M $MnCl_2$. The bands separated in

* It will be a rather difficult task to observe the doublet levels of manganese(II) complexes, corresponding to bands with $\varepsilon \sim 10^{-4}$. Especially, the high overtones of vibration frequencies in the infra-red may produce similar bands. The intensity of quartet bands, even though only 1 % of spin-allowed bands of divalent $3d^n$-complexes, is rather high [26]. Since ζ_{3d} can be interpolated to 300 K, and the distances to the nearets sextet are ~ 20 000 K (either $^6\Gamma_1(S)$ or from other electron configurations), the spin intermixing would be expected to be only $\sim \left(\frac{300}{20\,000}\right)^2 \sim 2 \times 10^{-4}$. Probably, the intensity is borrowed from some other configuration, where the total spin is less strictly defined than in $[A]\ 3d^5$.

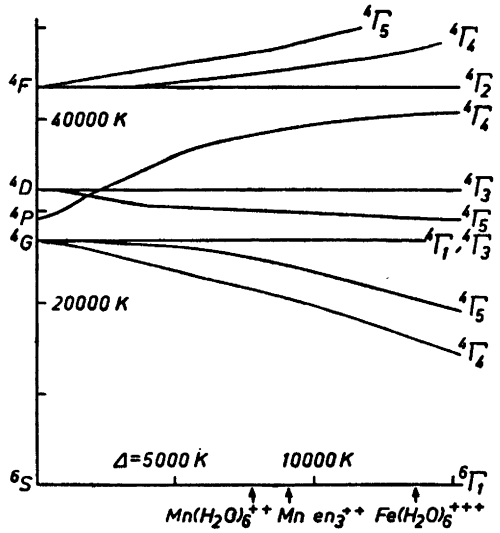

Fig. 3. The Orgel diagram of d^5*-systems, assuming no variation of the term distances* i.e. *the values of* B *and* C *from those of gaseous* Mn^{++}. *Since the term distances are decreased to the latter values in* $Fe(H_2O)_6^{+++}$, *this ion can also find a place in this diagram with* $\Delta =$ *13 700 K. The slopes of the levels can be compared with the observed band widths and with the variation of the wavenumbers of the individual bands as function of* Δ *in Table 2.*

several components, whose intensities change as function of the chloride concentration. The general result is a shift ~2 % towards lower wavenumbers, relative to the aquo ion. This was explained as a physical salt effect, caused by increasing concentration of the anion atmosphere around the manganese(II) ion. The present author believes that the spectral changes rather can be described to the consecutive formation of chloro complexes, and it is demonstrated [17] that Schläfer's electrostatic model for the red shift of the bands of strong salt solutions actually is a translation of partly covalent bonding (*cf.* p. 57). If the values of the molar extinction coefficient ε, reported by Schläfer [41] for the solid, which has a scattering back-ground, are decreased 0.04, the mani-fold of spectra can mainly be explained by the presence of two new complexes besides the hexaaquo ion:

Excited level	$MnCl(H_2O)_5^+$		$MnCl_2(H_2O)_4$

$^4\Gamma_3(D)$	339	0.023	343	0.06
$^4\Gamma_4(P)$	313	0.017	317	0.04

The two last bands have a minimum of ε in 2.5 M $MnCl_2$, where the monochloro complex probably is dominating. The absence of isosbestic points is not a strong argument against exchange of water with chloride in the first co-

ordination sphere, because the existence of three complexes and the small second-sphere effects probably will disturb the linear combinations of the absorption spectra.

While manganese(II) chloride solutions always will have $\bar{n}$ well below 2, due to the presence of free chloride, which determines the formation curve of mono-nuclear chloride complexes [38], strong hydrochloric acid can produce higher values of $\bar{n}$. Table 2 gives the spectra of $MnCl_2$ in 6 M HCl and in 9 M HCl. In these solutions the red shifts are stronger than in $MnCl_2$, 4 H_2O except when the decreasing value of Δ shifts the band, *e.g.* to ${}^4\Gamma_4(G)$ in the opposite direction. The present author assumes that these complexes are all octahedral. However, in anhydrous solutions, the tetrahedral $MnCl_4^{--}$ may perhaps occur. If $MnCl_2$ in 30 % ethanol +60 % *t*-butanol is treated with PCl_3, yellow solutions are obtained with higher bands at 440, 428, 424, 376 and 356 mμ, while the bands at 406 and 400 mμ reversibly re-appear by addition of a few per cent of water. The yellow solutions exhibit much smaller Δ than the aquo ion and the F^k-integrals are decreased ~13 %, resembling the conditions in $CoCl_4^{--}$. Mr. Palle Andersen [48] has kindly informed me that yellow-green Cs_3MnCl_5 probably has tetrahedral co-ordination of manganese, while the octahedrally co-ordinated double chlorides are pink.

Cs_3MnCl_5 fluoresces yellowish green in ultraviolet radiation, as also the yellow-green salt $[N(C_2H_5)_4]_2$ $MnBr_4$ described in the experimental section. The latter salt does not deliquesce in air and can be prepared from aqueous solution of the components. The intensity of the fluorescence light by 366 mμ excitation is higher than that of uranyl salts. The reflection spectrum corresponds closely to that predicted of Mn(II) in tetrahedral environment *. A narrow peak at 448 mμ, surrounded by a peak at 434 mμ and a shoulder at 476 mμ implies 17 % decrease of F^k, relative to gaseous Mn^{++}. The small value of Δ cannot be evaluated exactly, since the ligand field splitting is less conspicuous than the F^k-decrease. However, Δ seems to be between — 2 000 and — 3 000 K, when the hypothesis of negative sign is assumed. The fluorescent level is ${}^4\Gamma_4(G)$, as discussed by Orgel [28]. A band at 382 mμ and a shoulder at 365 mμ correspond probably to ${}^4\Gamma_4(P)$ and ${}^4\Gamma_4(D)$, while the measured reflectance increases above 100 % below 350 mμ (perhaps caused by the fluorescence). As discussed in the experimental section, a broad, low band ~560 mμ may be due to octahedrally co-ordinated impurities, and a narrow band at 905 mμ to the vibrational over-tone 4 σ(CH).

The decrease of F^k-integrals in anion complexes compared to aquo ions, was demonstrated for other manganese(II) complexes as seen from Table 2. Thus, 1.5 M KSCN produces 1.5 % smaller term distances, but the same Δ as the aquo ion, Mn ata_2^{-4} (these strong manganese solutions are only clear with a large excess of sodium nitrogentriacetate) resembles much Mn $enta^{--}$; tartrate in aqueous ammonia gives a rather strong red shift; etc. These effects resemble much the red shifts of lanthanide complexes [17] with citrate, tartrate,

* Similar arguments apply to $FeCl_4^-$ of which Schläfer [56] reports the reflection spectrum. The narrow band ~525 mμ implies ~40 % decrease of F^k, while the broader ${}^4\Gamma_5(G)$ at ~610 mμ and ${}^4\Gamma_4(G)$ at ~680 mμ implies Δ about —5 000 K. Cobalt-free $FeCl_3$ in 12 M HCl exhibit these bands at 600 and 684 mμ, while a broad shoulder ~740 mμ probably is caused by another iron(III) complex.

and ethylenediaminetetraacetate, which are ~1 % in Pr^{+++}, ~0.7 % in Nd^{+++} and Sm^{+++}, and ~0.3 % in Gd^{+++}, while they vanish in the heavy lanthanides.

Kleiner [42] abandoned the electrostatic ligand field theory, because the Hartree self-consistent field 3*d*-wavefunction for chromium [43] produces a very small and even negative value of Δ for Cr^{+++} in the alums. This is a translation of the large overlap between 3*d*-electrons and the ligands, as seen from Fig. 2. Thus, the electrostatic model of Ilse and Hartmann [44] can be shown to lead to a contradiction, caused by the spatial extensions of the hydrogen-like wavefunctions [12]. However, it is interesting to see that practically all information available on the energy levels of transition group complexes has been found by the electrostatic theory without taking partly covalent bonding into account (for a review, see Ref. [26]). This is due to several reasons of quantum-mechanical nature: (1) The number of levels with a given value of $^{2S+1}\Gamma_n$ is independent of the intermixing and can be found, *e.g.*, from the strong field sub-shell configurations [11]; (2) in complexes with high symmetry, such as O_h, the group-theoretical classification of levels and orbitals is very important; and (3) the molecular orbital theory without interaction of configurations is, contrary to the case of many simple molecules [45], able to predict the excited levels of transition group complexes with ~2 % uncertainty with Δ and the decreased F^k-integrals as the only parameters (*cf.* Fig. 3 and Table 2). The success of the electrostatic theory with Δ as empirical parameter cannot be found only in the general feature of the perturbation theory that the energy levels usually are predicted much better than the wavefunctions; even the squares of the wavefunctions must be highly intermixed in highly covalent complexes such as $Co(CN)_6^{-3}$ or $RhCl_6^{-3}$ with small F^k-integrals. The problem is rather connected with the nearly equal energies of the purely ionic and purely covalent (*i.e.* 50 % intermixing) limiting cases. It is very fortunate that complexes exist with partly filled shells, which can be in more than one state. It is possible in these cases to obtain much information from the excited levels, which is not available in general for closed shells. Especially, the absorption spectra can inform about the geometrical extension of partly filled shells. The only other type of experiment, which so far has presented such evidence, is the d-wavefunction, reported by Shull, Wollan, and Strausser [46] from neutron diffraction of manganese(II) salts. The maximum at 0.6 Å and the narrow half-width might suggest that the wavefunction is actually an anti-bonding combination of the type given in Fig. 2, but with a smaller density in the ligands, corresponding to much less than 50 % intermixing.

The molecular orbital theory gives a much more unified theory for all the energy levels of all the transition group complexes than might earlier have been predicted. The valence bond-theory, which is cumbersome [47] even for simple molecules such as CO or O_2, evolves extreme resonance possibilities for the groundstates of transition group complexes [25], and it is practically without value for the description of the excited levels. On the other hand, the electrostatic theory gives surprisingly good agreement with the observed energy levels, and the intermixing of the *d*-electrons with the ligands' orbitals can be said to be initiated by the perturbing effects of the ligands on the partly filled *d*-shell.

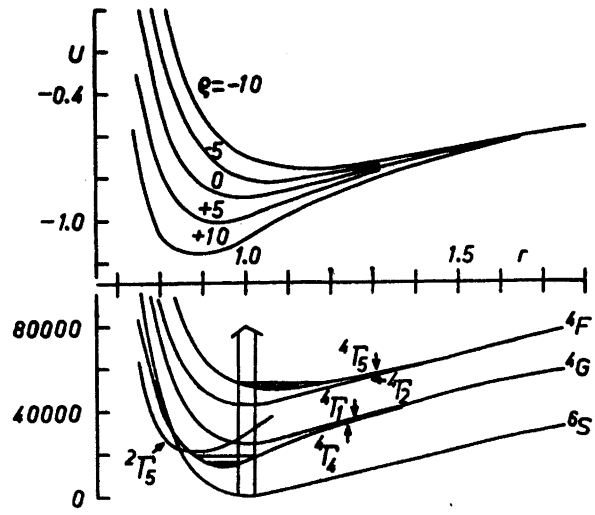

Fig. 4. The potential curve of eqn. (23) with different values of the ligand field stabilization parameter ϱ. The lowest part of the figure exhibits several levels of manganese (II) complexes under the assumption of the same form of potential curves as given above and with the terms of gaseous Mn^{++} at the dissociation limit. The mechanism of band-widths is indicated by the vertical projection of the vibration of the ground-level on the potential curves of the excited levels.

THE WIDTH OF MANGANESE(II) ABSORPTION BANDS AND VIBRATIONAL EXCITATION DUE TO THE FRANCK-CONDON PRINCIPLE

Orgel[8] pointed out that the width of absorption bands is roughly proportional to $\frac{d\sigma}{d\Delta}$, the difference in slope of the excited and the groundlevel in the Orgel diagram, using manganese(II) complexes [33] as examples. This effect is connected with the fact that the equilibrium distance between the central ion and the ligand increases regularly with the number of γ_3-electrons. Thus, a transition between two levels with a different number of γ_3-electrons corresponds to a broad absorption band, because the excited level will be vibrationally excited, since the Franck-Condon principle does not allow the complex to adjust itself to the new equilibrium distances during the very rapid optical excitation. Fig. 4 gives the potential curves $U(r)$ with the polynomial approximation in r^{-1}:

$$U = \frac{1}{9r^9} - \frac{0.02\,\varrho}{r^5} - \frac{1}{r} \qquad (23)$$

where the unit of r is chosen such that for $\varrho = 0$, the minimum of U occurs at $r = 1$. The first of the three parts of the expression represents the mutual repulsion between the closed shells, the second the ligand field effects (with the ligand field stabilization parameter $\varrho = 2n_5 - 3n_3$, n_3 and n_5 being the num-

ber of γ_3- and γ_5-electrons) and the third the electrostatic attraction of the ligand. The equilibrium distances r_L occur for:

ϱ	= +10	+5	0	—5	—10	
r_L	= 0.887	0.940	1.000	1.064	1.128	(24)

Thus, the present author is no longer inclined to assume, as earlier [50], that the equilibrium distances cannot increase ~6 % for each new γ_3-electron, even though the crystallographic distances suggest slightly smaller differences. The vibrational wavenumber 150 K found [50] of $ReCl_6^{--}$ cannot with certainty be identified with a definite one of the six fundamental frequencies of a regular octahedron. However, the order of magnitude of the frequencies is probably not very different from 200 K (*cf.* the recent results [51,52] for UF_6 and PuF_6), and the amplitude of the zero-point vibration thus ~0.08 Å, corresponding to 0.04 units on Fig. 4. Since the differential quotient of U (eqn. 23) at $r = 1$ is $0.1\,\varrho$ (while at $r = 0.9$, it is $-1.63+0.188\varrho$), the manganese(II) complexes are expected to exhibit bandwidths $\delta \sim 1\,500$ K for a difference in $\varrho = 5$.

Generally, the projection [53] of the lowest vibrational state of the ground-level on the potential curve U of the excited level is likely to produce an almost Gaussian-shaped absorption band

$$\varepsilon = \frac{\sigma}{\sigma_0} \cdot \varepsilon_0 \cdot 2^{-\frac{(\sigma_0-\sigma)^2}{\delta^2}} \tag{25}$$

with the half-width δ of the Gaussian part

$$\delta = 0.834\ x_c \cdot \frac{\mathrm{d}U}{\mathrm{d}r} \tag{26}$$

since the square of the wavefunction of the lowest level of a harmonic oscillator is a Gauss-curve with the half-width $x_c\sqrt{\ln 2}$, where x_c is the classical amplitude. If the difference between the potential curves of two levels with ϱ differing 5, *i.e.* Δ, is assumed to be proportional to r^{-5}, it will be valid for small values of x_c

$$\delta = 4.17\ \frac{x_c}{r_L}\ \Delta \tag{27}$$

Since x_c is proportional to $(k\mu)^{-\frac{1}{4}}$, k being the force constant $\frac{\mathrm{d}^2U}{\mathrm{d}r^2}$ of the ground-level, and μ the reduced mass (the existence of more vibrational quanta in molecules with more than two atoms necessitates a more detailed treatment), x_c is not expected to vary more than between 0.03—0.08 Å. Actually, manganese(II) and nickel(II) complexes have $\delta\sim0.15\ \Delta$, while [14] rhodium(III) has $\delta\sim0.09\ \Delta$ and iridium (III) $\delta\sim0.08\ \Delta$, corresponding to higher values of $k\mu$ in the platinum group complexes.

However, if the vibrational wavenumber

$$\sigma_c = \frac{1}{2\pi c}\sqrt{\frac{k}{\mu}} \tag{28}$$

is not much larger than 210 K (the mean Boltzmann energy at room temperature), transitions will occur from the n'th vibrational state of the groundlevel, which has two strong maxima near $r_L \pm x_c\sqrt{2n+1}$ for $n = 1, 2 \ldots$ The feet of the absorption bands will thus be too high and show a strong increase with the temperature T, while δ will be approximately proportional to $\sqrt{T}$ for small σ_c. On the other hand, all bands will vanish too quickly towards low wavenumbers, because $\frac{dU}{dr}$ of eqn. 26 is no constant, but approaches 0 in the bottom of the potential hole. Since no vibrational structure generally can be observed, all the excited states discussed here must be rather diffuse, at least $\sim 0.2\ \sigma_c$. It has earlier been discussed [50], if this broadening may be caused by collisions.

The lower part of Fig. 4 illustrates the potential curves of some manganese(II) levels with the assumption of eqn. 23. For decreasing values of r, corresponding to steeply increasing values of Δ, the levels with different values of ϱ cross each other in a rather complicated way, actually depicting an Orgel diagram such as Fig. 3. Especially, the groundstates of magnetically anomalous complexes (*viz.* $^2\Gamma_5$ in Fig. 4) have intrinsically small values of r_L and high values of Δ, as pointed out by Orgel [27]. The broad vertical arrow represents the possible transitions to excited levels, producing vibrational excitation of levels with r_L differing from that of the groundstate. Especially, excitations to $^4\Gamma_4(G)$, which may be fluorescent in manganese(II) complexes [28], correspond to a decreased value of r_L. The relatively long life of the excited state is made possible by this weak interaction with the environment, while excited states with increased values of r_L rapidly decay by transfer of energy to the thermal motion of other molecules.

EXPERIMENTAL

The stock solution of 2.3 M $MnCl_2$ was prepared from Merck's p.a., which was found to be free of iron. It was added to hydrochloric acid and to 3 M KSCN. Mn enta^{--} was prepared from $MnSO_4$, 4 H_2O (Merck's p.a.), 1.1 mole H_4 enta (Complexon II) and 2 moles Na_2CO_3. The chamois solution is not oxidized by air or H_2O_2, but turns brown (with a maximum at 450 and a narrow hump at 470 mμ) of Mn enta OH^{--} by addition of $KMnO_4$. This solution turns purple [49] (a maximum at 500 mμ) by addition of $HClO_4$ under formation of Mn enta H_2O^-. However, this colour disappears after some minutes.

On the other hand, it is difficult to prevent the oxidation of most other manganese(II) complexes in alkaline solution, thereby forming brown precipitates. The greyish green solution of Mn en_3^{++} (1 M Mn en_3^{++}, 1 M en H^+ and 3 M free en) can be protected against oxidation by a minute amount of ascorbic acid; however, especially in alkaline solution, this compound produces slowly a yellow decomposition product with a high maximum at 384 mμ. Also manganese(II) and ammonium tartrate dissolved in aqueous NH_3 is oxidized by air to a brown solution, which can be reduced by ascorbic acid.

Tetraethylammonium manganese(II) bromide can be prepared by evaporation of a solution of manganese(II) bromide with slightly more than two moles of tetraethylammonium bromide in aqueous hydrobromic acid. After cooling, yellowish green crystals separate, which are washed with ethanol on a glass-sintered funnel and dried, *e. g.* by heating with an ultraviolet "black" mercury lamp, causing a bright green illumination. The yield is $\sim$60 %. The analysis indicates the formula $[N(C_2H_5)_4]_2$ Mn Br_4:exp. 8.8 % Mn, 49.2 Br; theor. 8.7 % Mn, 50.4 % Br. In some cases, the content of Mn is higher, $\sim$10 %, and the reflection spectrum then exhibits a very broad band 560 mμ. It is

presumably caused by a complex with octahedral environment of Mn(II), either $[N(C_2H_5)_4]$ $MnBr_3$ or a solvate. In one sample containing 0.08 mole % cobalt, bands were observed at 645, 670, 705 and 720 mμ of $CoBr_4^{--}$. A narrow band at 900–910 mμ was found in all samples. It cannot be a Mn(II) ligand field band, but is rather four times the CH-stretching frequency, since it also appears in $N(C_2H_5)_4Br$.

The spectra of the solutions were measured in 10 cm silica cells on a Cary Recording Spectrophotometer, model 11 MS–50.

Acknowledgements. I am very much indebted to Professor Jannik Bjerrum for many interesting discussions.

Comparative Ligand Field Studies

IV. Vanadium(IV), Titanium(III), Molybdenum(V) and other Systems with one d-Electron

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The vanadium(IV) complexes can deviate so much from cubic symmetry that all the four possible bands are observed in the tartrate complex. The absorption spectra of VO enta^{--}, VO ox$_2^{--}$, VO^{++} and several other complexes suggest a tetragonal symmetry with stronger ligand field along one axis than along the two other axes. Thus, the oxygen atom is probably placed on the former axis and is not aquated to two hydroxyl ions. The titanium(III) complexes exhibit smaller deviations from octahedral symmetry, corresponding to shoulders on the principal band. The dark coloured binuclear complex, which is formed between Ti(III) and Ti(IV) in concentrated hydrochloric acid, is investigated. In strong HCl, molybdenum(V) occurs as $MoOCl_5^{--}$, which exhibits two ligand field bands, corresponding to levels analogous to those of VO^{++}. The behaviour of one d-electron in ligand fields and the Jahn-Teller effect is compared with the opposite tetragonality of copper(II) complexes. Other oxidation states of molybdenum, wolfram, and niobium, are shortly discussed.

Systems with only one d-electron do not exhibit levels with different values of the spin S, and thus, spin-forbidden bands do not occur as in d^2—d^8 systems. Further, the integrals F^k of electrostatic interaction between the electrons in the partly filled shell cannot be evaluated; only one multiplet term, ^2D, occurs in the gaseous ion. If the splitting between $^2D_3/_2$ and $^2D_5/_2$ is neglected (it amounts to 384 K in Ti^{+3} and 620 K in V^{+4}), only one absorption band is expected of an octahedral complex with the symmetry O_h. One of the historical foundations of the ligand field theory is that Ilse and Hartmann [1] interpreted the band 20 300 K of $Ti(H_2O)_6^{+++}$ as the transition of the d-electron from the state γ_5 to γ_3, thus exemplifying the parameter [2] Δ, also called $(E_1—E_2)$ or 10 Dq. However, if the ligand field has a symmetry lower than O_h, more than one absorption band is predicted. Kramers' degeneracy cannot allow more than five energy levels of a single d-electron, corresponding to four absorption bands caused by transitions from the groundstate. The low symmetry of the ligand field is not necessarily caused by differences among

Table 1. Absorption bands of vanadyl complexes. Wavelength λ_n in mμ, wavenumber σ_n in K (= cm^{-1}), and molar extinction coefficient ε_n of each maximum and the half-widths $\delta(-)$ and $\delta(+)$ in K towards lower and higher wavenumbers. Shoulders are given in parentheses. The ligands are abbreviated: $enta^{-4}$ = ethylenediaminetetraacetate, ox^{-2} = oxalate, aca^{-} = acetylacetonate, and $tart^{-4}$ = tartrate (with four protons removed from D-tartaric acid).

the six ligands of an octahedral complex; the Jahn-Teller effect produces a distortion to lower symmetry [3], when the cubic groundstate is either Γ_3, Γ_4, or Γ_5. The latter case of $Ti(H_2O)_6^{+++}$ was discussed by Van Vleck [4], who found that the absolute value of the distortion was not large. The present paper demonstrates that the effect is more important for vanadium(IV) complexes.

VANADIUM(IV)

The parameter Δ is 50—80 % larger for trivalent than for divalent ions of the first transition group. Since the pairs Cr(III)—Mn(IV)[5] and Ir(III)—Pt(IV)[6] demonstrate a further increase of Δ from trivalent to quadrivalent ions, Δ of a vanadium(IV) hexaaquo ion would be expected to be $\sim$ 25 000 K. However, VO^{++} in acidic aqueous solution exhibits a band at 13 100 K and a shoulder at 16 000 K, as seen from Fig. 1 and Table 1 and previously measured by Furman and Garner [7] and Rossotti [8].

The external charge + 2 of the vanadyl ion seems well established, *e. g.* by the potentiometric measurements by Ducret [9]. Since the equilibrium

$$O^{--} + H_2O \rightleftharpoons 2\ OH^-$$

is highly shifted towards the right-hand side, one might assume [65] that oxide and water cannot occur as ligands of a complex at the same time, but will exchange the hydrogen atom. Generally, the oxo-ions of the text-books seem to have seen their best time; the hydrolysis of uranium (IV)[10,11] does not produce UO^{++}, and CrO_2^- is undoubtedly $Cr(OH)_4(H_2O)_2^-$ or a polymer. However, the dioxo ions of quinquevalent and sexivalent actinides seem to retain their linear form in aqueous solution [12] and one must conclude that oxygen can be so strongly bound in a complex, probably by forming also π-bonds [13], that the proton affinity disappears.

A priori, one may consider three possibilities for the geometrical configuration of the vanadyl ion: tetrahedral (with two hydroxo- or one oxo-group), trigonal bipyramidic (with two *trans*-hydroxo groups or one perpendicular oxo group) and distorted octahedral (with two *trans*-hydroxo groups or one oxo group). The tetrahedral $V(OH)_2(H_2O)_2^{++}$ can be supported by many argu-

ments; Orgel [14] identified the band at 9 000 K of anhydrous VCl_4 as the transition from $^2\Gamma_3$ to $^2\Gamma_5$ of a tetrahedral complex. Eventhough the intermixing of molecular orbitals [15] can produce deviations from the ratio-4/9 predicted from the electrostatic model [16] between the values of Δ for tetrahedral and octahedral complexes, the absorption bands of the vanadyl ion resemble much those predicted of a split excited state $^2\Gamma_5$. The only known values of Δ for a tetrahedral complex [17], *viz.* those of $CoCl_4^{--}$ and the other cobalt(II) tetrahalides [14], are rather small.* The instantaneously reversible equilibrium between vanadium(IV) and vanadium(V), found by Ducret [9], might suggest the latter to occur in acidic solution as $V(OH)_4^+$. However, it is difficult to understand, why the $V(H_2O)_4^{+4}$ should be so acidic for the two first protons, while the third proton [8,18,19] has pK between 5 and 6, after which the polymerisation to brown hydroxides and anions soon follows. As seen from Fig. 1 and Table 1, a change in the absorption spectrum can actually be observed by going from 2 to 10 M $HClO_4$. However, the shift is so small that it might rather be ascribed to association with perchlorate ions than to a radical change of the first co-ordination sphere. Since the fourth excited level is reported below of VO enta^{--} and other complexes, these cannot be tetrahedral; however, it is not totally disproven that the vanadyl ion itself has a distorted tetrahedral structure. The trigonal bipyramidic structure would produce three levels of the d-electron [3], *i. e.* two absorption bands, and can at most be accepted for VO^{++}, but not for the complexes. Jones [20] discussed the possible equilibria between 5- and 6-co-ordinated vanadyl complexes. However, the X-ray structure [21] of VO_2 shows a distorted (hemiedric) octahedral environment and VO SO_4, 5 H_2O contains monomer vanadium, surrounded by six oxygen atoms [22]. Thus, the ionic radius of V^{+4} does not seem to be so small that the tetrahedral or trigonal bipyramidic configuration is more favoured **, except in the anhydrous VCl_4 and VBr_4.

As seen from Table 1 and Fig. 1, most vanadyl complexes exhibit the two absorption bands more clearly separated than VO^{++} itself, as already reported by Furman and Garner [24] for $VOSCN^+$. One of the most interesting spectra is found in the blue VO enta^{--}, discovered by Schwarzenbach [25]. It has the third band at 29 800 K, a wavenumber comparable to the expected Δ of a cubic vanadium(IV) complex. Thus, the two tetragonal components of $^2\Gamma_3$ in the ligand field of the distorted octahedron seem to be observed at 17 200 K and 29 800 K, a considerable distance. The second band of the complexes VO ox_2^{--}, VO aca_2, $VOSCN^+$, etc. must thus be considered as the first part of a tetragonal splitting of which the second part is hidden by the carboxylate band and other electron transfer bands in the ultraviolet. Actually, a shoulder was observed by Bürger [26] for VO $ox_2^{--} \sim 30\,000$ K besides the two bands at 12 600 and 16 200 K.

---

* *Cf.* the approximate values [2] of Δ in $MnBr_4^{--}$ (—2 000 K) and in $FeCl_4^-$ (—5 000 K).

** Even vanadium(V) appears to be hexa-coordinated in the black 8-hydroxyquinolinate [23] $(C_9H_6ON)_2VOOH$, which turns red with alcohols, yellow with amines, and which forms a blue $[(C_9H_6ON)_2V(OH)_2]Cl$ and a green dimeric anhydride. However, perhaps the nitrogen and the oxygen of the 8-hydroxyquinoline are not both co-ordinated as in other complexes.

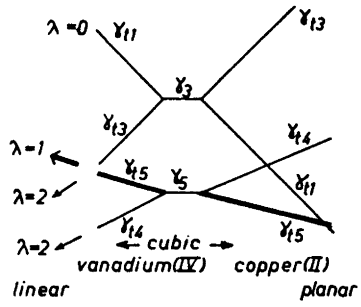

Fig. 2. The two opposite types of tetragonality. The behaviour of copper(II) and vanadium(IV) complexes is qualitatively described as a tetragonal distortion of the energy levels for ligand fields of exact cubic symmetry O_h. In the case of the vanadyl complexes, the energy levels can be extrapolated to those of a linear molecule with a negative value of $E\lambda$, as discussed in Ref. 29.

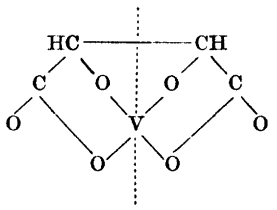
It is possible to determine the sign of the tetragonality by comparing the spectra of VO^{++} and the other complexes with four ligand atoms attached. Either the ligand field along two axes of a Cartesian co-ordinate is stronger than along the third axis (as is the case of copper(II) complexes [16,66]), or one axis has a stronger ligand field than the two others [27,3]. The latter seems distinctly to be the case; when enta^{-4} occupies the tetragonal plane, the tetragonal splitting is decreased. As seen from Fig. 2, the behaviour is opposite to that of the copper(II) complexes. When they have low tetragonality, two or three bands are observed in the near infra-red and in the visible [5,28] corresponding to transitions from $^2\Gamma_{t3}$ to $^2\Gamma_{t1}$, $^2\Gamma_{t4}$, and $^2\Gamma_{t5}$. When the tetragonality is very pronounced [5], such as in $Cu(NH_3)_4^{++}$ or $Cu\ en_2^{++}$, only one band is observed, probably due to superposition of the three excited levels.

This result supports strongly the classical composition VO^{++} of the vanadyl ion, with the oxygen on the tetragonal axis of strong ligand field. Even though O^{--} can occur on both sides of H_2O in the spectrochemical series (*cf.* the series green Cr_2O_3, violet $Cr(H_2O)_6^{+++}$, and red ruby), a similar strong ligand field would never be expected of two hydroxyl ions. As seen from Fig. 2, the strong bonding of the oxygen may be explained by the results for an electron in a linear ligand field [29]. If the influence of the ligands in the tetragonal plane vanished, $^2\Gamma_{t4}$ and $^2\Gamma_{t3}$ would correspond to the lowest energy level with $\lambda = 2$, $^2\Gamma_{t5}$ to $\lambda = 1$, and $^2\Gamma_{t1}$ of highest energy to $\lambda = 0$. Since the vanadyl ion contains only a single d-electron, it can remain in the groundstate in the level with $\lambda = 2$, while formation of both σ- and π-bonds, which increase the energy of the empty orbitals with $\lambda = 0$ and 1, respectively, does not destabilize the complex. Oxygen seem remarkably apt to π-bonding [13], which would explain the existence of oxo complexes with mainly linear ligand field in the beginning of the transition groups (VO^{++}, $MoOCl_5^{--}$ discussed below, UO_2^{++} etc.). The octahedral complexes in the middle of the transition groups (*e. g.* diamagnetic d^6) and the square-planar tetragonal d^9- and diamagnetic d^8-systems (which have high energy of the γ_{t3}-orbital) are more stable with σ-bonding ligands with high values of Δ, and in the case of low oxidation states, perhaps also by π-bonding in the direction from the central ion to the ligand. Thus, the general tendency to prefer oxygen in the beginning of a transition group (even though Δ is large and electrostatic effects does not dominate, as for Mn^{++} and Ca^{++}) and nitrogen in the end may have a profound connection

with the number of d-electrons, which are destabilized because they are in anti-bonding orbitals.

The transition of VO^{++} to $^2\Gamma_{t1}$ was expected $\sim$ 32 000 K. However, it seems to have a somewhat higher wavenumber and is masked by the broad band at 41 700 K ($\varepsilon = 240$) which was also reported by Furman and Garner [7]. The latter band is not due to hydrolysis, since it is the same in 0.1 M and 1 M $HClO_4$, nor to oxidation of VO^{++}, since it is not changed by addition of a small amount of V^{+++}. The intensity does not suggest that it is allowed; but it can hardly be the ligand field band sought for, since the other complexes do not have high intensity for their transitions to $^2\Gamma_{t1}$. Jones and Colvin [69] have shown by potentiometric measurements that VO^{++} is not more dimeric than V^{+++}; the band is thus not due to an oxygen bridge.

Jones [20] made a valuable contribution to the vanadyl problem by showing that VO aca_2 can be made anhydrous and is soluble as a monomer in benzene; and that the solvation with one molecule of H_2O, NH_3 etc. does not change the properties of VO aca_2 to such a degree that a di-hydroxo complex could be suggested.



The tetragonal splitting can be made even smaller than for VO $enta^{--}$, and a rhombic splitting, producing in total four ligand bands, seems probable: It has previously [30] been noted that tartrates and citrates in aqueous ammonia produce a purple colour with vanadium(IV). In weakly acidic solution, tartrates produce a dark blue solution, of which the spectrum resembles the other carboxylate complexes such as VO ox_2^{--} (Table 1), and a weak shoulder is observed $\sim$ 28 600 K. The complexes of VO^{++} with organic anions exhibit a different behaviour, according to whether they contain hydroxo (alcohol) functions or not. VO ox_2^{--} and the analogous dark blue complex with succinate decompose in aqueous ammonia to brown precipitates, while the malate with a single hydroxo function forms a violet solution at not too high a concentration of NH_3. Vanadyl tartrates, citrates, and gluconates are soluble even in concentrated NH_3. This suggests a Fehling's solution-type complex, where the metal ion is bound to alcoxo groups of the ligand which have released protons also from the alcohol functions.

Actually, Barbieri [62] prepared a solid purple salt $(NH_4)_2[VOC_4H_2O_6]$, 2 H_2O, which later was studied by Rosenheim and Yu-Mong [63], who also prepared $Ba[VOC_4H_2O_6]$, 5 H_2O, demonstrating that no ammonia of constitution occurs in the anion. The anion must have two carboxylate groups and two alcoxo groups bound to vanadium in the tetragonal plane with the vanadyl oxygen on the perpendicular axis. Ducret [9] reports two pK values = 6.85 and 2.8 for the consecutive uptake of two protons on VO $tart^{--}$. Mr. Kjeld Rasmussen has kindly titrated a sample of ammonium vanadyl tartrate *, prepared [63] by the author, and found the values of p$K \sim 6.1$ and ~ 2.9. It cannot easily be decided whether the protons go on the carboxyl or alcoxo groups; vanadyl ions seem to have a strong affinity to alcoxo and phenoxo groups analogous to

* However, this purple salt turns blue with an excess of tartrate, even in 1 M NH_3, suggesting the formation of a complex with two tartrates and high absorption in the range 800—600 mμ, analogous to $VOtartH^-$.

iron(III), as shown by the preparation of vanadyl bis(salicylates) * and bis(pyrocatechinates) [63].

The tetragonal splitting between the two highest levels ** of VO tart^{--} is decreased to 6 500 K, while the rhombic splitting of $^2\Gamma_{t5}$ amounts to 6 100 K (Table 1). This is rather remarkable, since if the complex had orthogonal axes, its symmetry would be tetragonal with two equivalent axes in the electrostatic perturbation model [3]. The complex can hardly lack a plane of symmetry, intersecting the plane of the paper along the dotted line:

However, the two lines OVO in the plane do not need to be orthogonal ***. The resulting low symmetry C_s no longer presents degenerate electronic levels, and all five possible energy levels are then separated. It must be emphasized that planar platinum(II) complexes, *trans*-Pt A_2B_2, generally exhibit a genuine rhombic splitting [64] which is not found in *cis*-Pt A_2B_2 in agreement with Ballhausen's and the author's predictions for complexes with orthogonal axes [3]. Actually, the d^1-systems such as vanadium(IV), and the d^9-systems, such as copper(II), seem much more liable to exhibit effects of low symmetry than the regular d^3-, paramagnetic d^8-, and diamagnetic d^6-systems, which maintain nearly the energy levels predicted for cubic symmetry O_h, even with sets of highly different ligands.

Small tetragonal splittings might also occur in vanadium(IV) complexes with six equal ligands. The dark red hexachlorides, *e. g.* $[N(CH_3)_4]_2VCl_6$ prepared by Gutmann [31], probably have electron transfer bands in the visible. The pink K_2VF_6 prepared by Hoppe [32] may have $^2\Gamma_{t3} \sim 20\,000$ K and $^2\Gamma_{t1}$ at slightly higher wavenumbers.

Vanadium(III) is also soluble in tartrate and aqueous ammonia with a dark green colour [30]. The solution has maxima at 612, 440 and 424 mμ, the latter forming a broad band. Vanadium(III) in 12 M HCl has the bands at 675 and 448 mμ, while they are situated at 588 and 396 mμ of the solution in 2 M HCl. There is no doubt that the pure hexaaquo ion is still more hypsochromic, resembling the values 562 and 389 mμ, found by Hartmann and Schläfer [33] for vanadium(III) alum crystals. The spectrum of V enta$^-$ is rather peculiar [5].

---

* The pale purplish pink ammonium vanadyl salicylate dissolves with dark green colour in water or ethanol and can be easily re-crystallized. It decomposes with aqueous ammonia, and thus, the purple complex cannot be measured in solution.

** an alternative possibility might be $^2\Gamma_{t5}$ at 17 100 and 18 800 K, thus implying the distance 14 300 K between $^2\Gamma_{t3}$ and $^2\Gamma_{t1}$.

*** Hartmann, Furlani and Bürger [67,68] have recently discussed the deviations from orthogonal axes. Their case, Vox_3^{-3}, exhibits surprisingly small deviations from the spectrum, predicted for an octahedral complex with the symmetry O_h.

TITANIUM(III)

Hartmann and Schläfer [34] observed strong variations in the absorption spectrum of titanium(III), which was ascribed to hydrolysis at low acid concentrations and formation of chloro complexes in strong hydrochloric acid. Recently, Hartmann, Schläfer, and Hansen [35] have investigated the spectrum of anhydrous $TiCl_3$ in different solvents in order to avoid some of these difficulties.

As previously discussed [36], the hexaaquo ion is the dominating species in the reddish purple solution in 2 M HCl. The band at 492 mμ is very broad and has a shoulder at 575 mμ, which was interpreted [3] as distortions caused by the Jahn-Teller effect. The large half-width may be connected with the large value of Δ and the large amplitude of the ligand's vibrations in the relatively weakly bound complex [2], where $\delta \sim 0.15\ \Delta$. However, with the picture given in Ref. 2, it is peculiar, why the bands with highest wavenumbers of the purple vanadyl tartrate and of $MoOCl_5^{--}$ are so narrow.

In stronger hydrochloric acid titanium(III) turns sky-blue with a shift of the double band to about 660 and 525 mμ. These spectra resemble much the spectra reported by Hartmann [35] of $TiCl_3$ in anhydrous alcohols. It may be questioned [37,38] whether these effects are caused solely by solvation or by the partial formation of chloro complexes in the first co-ordination sphere. The hexa(alcohol) solvates seem much more unstable towards uptake of anions than hexaaquo ions. In anhydrous ethanol (but not in 90 % C_2H_5OH), cerium(III) chloro complexes are formed at a chloride concentration $\sim$0.005 M, while 10 M HCl is necessary for the same effect in aqueous hydrochloric acid [39].

However, if the sky-blue solutions of titanium(III) in strong HCl are slightly oxidized, they turn much darker purplish black. This oxidation may be effected by, *e. g.*, a platinum wire, catalyzing the evolution of hydrogen. Table 2 gives the molar extinction coefficients at several wavelengths for mixtures of Ti(III) and Ti(IV) in 12 M HCl. The spectra are seen to be a linear combination of the sky-blue titanium(III) and the dark colour, which has a maximum at 482 mμ and a shoulder at 670 mμ. Further, a strong absorption in the ultraviolet appears, which is absent in pure Ti(III) (which has $\varepsilon = 8$ at 310 mμ).

The dark-coloured complex is similar to the "interaction colours" found in the pair of oxidation states: copper(I, II)[40], tin(II, IV) [41] and antimony-

Table 2. Molar extinction coefficients of titanium(III) and (IV) in 12 M HCl. For mixtures, ε is calculated solely with respect to the total concentration C_{Ti+3} of trivalent titanium. Wavelengths in mμ.

(III, V) [42] in concentrated HCl. Thus, from the variation of ε in Table 2, the existence of a bi-nuclear complex containing equal amounts of Ti(III) and Ti(IV) is demonstrated. The formation constant of this complex in 12 M HCl, relative to the concentrations [III], [IV], and [III, IV], having the ε values of pure Ti(III), pure Ti(IV) and the limiting value of ε for mixtures and with the known concentrations $C\mathrm{Ti}^{+3} = [\mathrm{III}] + [\mathrm{III, IV}]$ and $C\mathrm{Ti}^{+4} = [\mathrm{IV}] + [\mathrm{III, IV}]$, can be inferred from Table 2 to

$$\frac{[\mathrm{III, IV}]}{[\mathrm{III}]\ [\mathrm{IV}]} = 12$$

Since the pure oxidation states probably occur mainly as $TiCl^{++}$ and $TiCl_6^{--}$ in concentrated HCl, (*cf.* Ref. 61) the composition of the mixed complex [III, IV] may perhaps be rather near to the neutral form Ti_2Cl_7.

The interaction colours, due to titanium in both oxidation states (analogous to molybdenum blue, ferroferricyanides etc.) occur probably also in the black precipitate of $Ti(OH)_3$ from $Ti(H_2O)_6^{+++}$ and alkali. The precipitate is probably oxidized by a spontaneous evolution of hydrogen, analogous to the air oxidation of white $Fe(OH)_2$ to greenish black forms. Also titanium(III, IV) solutions in strong sulphuric acid are black, while the similar phenomenon is not observed in phosphoric acid. Neither do Zr^{+4}, Th^{+4} or U^{+4} interact visibly with Ti^{+3} in strong HCl. It may be remarked that while the pale green $U(OH)_4$ on partial oxidation produces dark brown intermediates, it does not interact with U^{+3}. If the red solution * in HCl is added to aqueous ammonia, a pale orange-red precipitate of $U(OH)_3$ can be observed one second before the evolution of H_2 and the change to pale green.

Titanium (IV) complexes have a strong electron transfer band in the ultraviolet. Thus, TiO_2 is much more absorbing [43] than ZrO_2. Even while the liquid $TiCl_4$ is free of iron (the absorption band of the vapour has recently been measured [44]), its solution in 12 M HCl is pale yellow. Much more conspicuous is the reaction with thiocyanate. While a yellow solution is obtained with this reagent in water, a dark red-brown compound (probably un-ionized $Ti(SCN)_4$) can be extracted with diethyl ether. If titanium(III) is free from impurities of (IV), thiocyanate produces a clear purple colour (the maximum at 528 mμ has $\varepsilon_n = 12$ and $\delta = 3\,000$ K) which is not shifted by extraction with diethyl ether and thus probably is caused by $Ti(SCN)_3(H_2O)_3$.

The purple Ti enta$^-$ has been made several times by cautious addition of Na_4enta and NaOH to Ti(III) in 2 M HCl. Besides the broad maximum at the rather large wavelength 543 mμ, a band one-fourth as strong is observed $\sim$760 mμ, thus corresponding to large deviations from the cubic symmetry O_h.

These examples show that titanium(III) has by no means the strong tendency to form regular octahedral complexes as have d^3-, d^8- and diamagnetic d^6-systems. Thus, no Ti ox_3^{-3} is known; the brown [45] Ti ox_2^- has a strong absorption band $\sim$405 mμ. However, these bands are often electron transfer bands (perhaps also causing the strong colour of violet $TiCl_3$, which was rather expected to have $\Delta \sim 15\,000$ K) rather than ligand field bands.

* of chloro complexes.[70] Below a HCl-concentration 6 M, or in $HClO_4$, uranium(III) is grey.

MOLYBDENUM(V)

When molybdenum(VI) is reduced with zinc in strong HCl, a green colour is observed, which can be ascribed to $MoOCl_5^{--}$, of which Klason [46] and Nordenskjöld [47] prepared several salts, among those some anhydrous. Further reduction yields a red solution of Mo(III), which probably contains $MoCl_6^{-3}$ and $MoCl_5(H_2O)^{--}$. Chilesotti [48] proved by potentiometric measurements that Mo(IV) is not formed in 9 M HCl, while the reduction in more dilute acid may yield all three consecutive oxidation states +5, +4 and +3.

The behaviour seems less complicated in HCl than in other acids. In dilute sulphuric acid, molybdenum(V, VI) blue is invariably formed, and the reduction proceeds with formation of brownish black solutions. Even dilute HCl is highly different from strong HCl in respect to the colour of molybdenum(V). Hiskey, Meloche, and Springer [49,50] studied spectrophotometrically the change of colour from pale green in 8 M HCl to strong amber yellow in 2 M HCl. Table 3 gives the absorption bands of $MoOCl_5^{--}$. Even though the second narrow

Table 3. Absorption bands of $MoOCl_5^{--}$ in 9—12 M HCl. Notation as in Table 1.

λ_n	σ_n	ε_n	$\delta(-)$	$\delta(+)$
712	14 050	16	1 500	1 900
445	22 500	14	1 100	—
355	28 200	500	1 400	—
310.5	32 200	4 400	1 600	1 700
240	40 700	5 500	2 100	—

band has nearly the same position as the much higher, but broader, band which appears in the brown solutions by dilution with water, the present author is inclined to believe that it actually belongs to the undecomposed $MoOCl_5^{--}$. Thus, the intensity ratio between the two first bands is constant in the range 9 M—12 M HCl. Analogous to the levels of VO^{++} (see Fig. 2), the excited level of the band at 14 050 K is $^2\Gamma_{t5}$, while the band at 22 600 K is $^2\Gamma_{t3}$. The cubic contribution $\triangle$ predicted of the hypothetical $MoCl_6^-$ is ~30 000 K. If the spontaneous Jahn-Teller distortion is not very large, the latter ion will be nearly colourless. The second band of $MoOCl_5^{--}$ is much narrower than the first; this may be explained by the influence of intermediate coupling, splitting $^2\Gamma_{t5}$ in the two levels $^2\Gamma_{t6}$ and $^2\Gamma_{t7}$.

The third band of $MoOCl_5^{--}$ is much higher ($\varepsilon = 500$) than the first two ($\varepsilon = 16$ and 14). It is probably a relatively weak electron transfer band. When molybdenum(III) in HCl is slightly oxidized, the third band of this impurity appears strongly. Thus, it can be applied as an indicator for the presence of +5, proving that the broad shoulder at 728 mμ on the red side of the sharp maximum at 673 mμ ($\varepsilon = 1.7$)* is not caused by molybdenum(III). Schmidt [26] observed the behaviour of molybdenum(III) in strong

* The present author [15] has previously identified the excited doublet levels as $^2\Gamma_3$ and $^2\Gamma_4$. However, the absence of $^2\Gamma_5$ is so surprising that it might be assigned to these levels in the red, implying B ~450 K as also the quartet levels do. Actually, the reflection spectrum of $(NH_4)_2[MoCl_5(H_2O)]$ exhibits low bands at 1 050,678 and a shoulder at 652 mμ, while the high bands occur at 506 and 406 mμ. The solution in 12 M HCl shows a band at 1 035 mμ ($\varepsilon = 0.5$). Professor R. W. Asmussen and Mr. Potts Jensen have previously measured a band at 1 100 mμ of solid K_2ReCl_6.

and dilute HCl, which resembles much that of rhodium(III) [6], except that the equilibria are established rapidly. Thus, the bands at 522 and 418 mμ ($\varepsilon = 25$ and 35) are shifted towards 475 and 385 mμ by dilution with water.

The brown solutions of molybdenum(V) in 6 M HCl have $\varepsilon \sim 20$ at 720 mμ and $\varepsilon \sim 150$ at 445 mμ, while the shoulder at 352 mμ is blurred out. There is some evidence that the brown hydrolysis product is more easily formed at high Mo concentrations, indicating at least two Mo atoms per complex. Sacconi and Cini [51] have found that the paramagnetism, corresponding to $S = \frac{1}{2}$ of $MoOCl_5^{--}$, is changed to diamagnetism of Mo(V) in dilute HCl, probably due to formation of oxygen bridges of the type [52] encountered in $Cl_5RuORuCl_5^{-4}$ and $Cl_5ReOReCl_5^{-4}$, of which the latter is in equilibrium [53] with the monomer $ReCl_5(OH)^{--}$.

WOLFRAM(V)

When tungstates(VI) are dissolved in very strong HCl, they can be reduced by amalgamated zinc at first to a blue solution, which perhaps contains the monomer $WOCl_5^{-}$ together with some tungsten(V, VI) blue. It has a maximum (655 mμ, $\varepsilon \sim 7$). By further reduction, a purple solution of tungsten(IV) with $\varepsilon \sim 600$ in a maximum at 19 100 K, is formed. After some time, the more robust yellow-green $W_2Cl_9^{-3}$ are formed (they are oxidized by air much more slowly than W(IV)). The spectrum of this does not exhibit two spin-allowed ligand field transitions to $^4\Gamma_5$ and $^4\Gamma_4$ such as the monomeric Mo(III) does. The first two bands (at 13 200 K, $\varepsilon \sim 25$ and at 16 300 K, $\varepsilon \sim 40$) are probably the spin-forbidden transitions to $^2\Gamma_3$ and $^2\Gamma_5$ with the high intensity perhaps caused by the absence of a centre of inversion in each tungsten atom. Further, a high band occurs at 22 200 K ($\varepsilon \sim 1\,200$). Laudise and Young [54] recognize further a pale red form of tungsten(III) in addition to $W_2Cl_9^{-3}$.

NIOBIUM(IV)

Cozzi and Vivarelli [55] investigated the absorption spectra of niobium(IV), (III) and (II) in hydrochloric acid of different concentrations. Thus, the red-orange niobium(IV) complex in 13 M HCl has a maximum at 478 mμ ($\varepsilon \sim 120$), while the blue Nb(IV) solution in 8—9 M HCl has a broad band ~ 700 mμ ($\varepsilon \sim 150$). It is assumed [55] that these complexes are analogous to VO^{++}, $VOCl_4^{--}$ and VCl_6^{--}. However, it is doubtful whether VO^{++} takes many chloride ligands up in HCl (see Table 1), since the maximum is only slightly shifted. *Cf.* the ion exchange measurements by Kraus, Moore and Nelson [61].

GENERAL REMARKS

Even though the d^1-systems in some cases (VO^{++}, $MoOCl_5^{--}$) exhibit the opposite sign of tetragonality to that of the d^9-systems (*e. g.* Cu^{++}), it is only in a limited range of oxidation states that the typically linear molecules occur. While titanium(III) does not deviate so much from the cubic symmetry as vanadium(IV), the higher oxidation states assume tetrahedral configuration with the necessary Jahn-Teller distortion. Thus, MnO_4^{--} has three bands of nearly equal intensity at 605, 435 and 355 mμ, which must be caused by transfer of π-electrons from the oxygen atoms, analogous to the two strong bands [13]

of MnO_4^-. With the larger ionic radii of the 4d-elements, it has become possible for molybdenum(V) to retain hexa-coordination in $MoOCl_5^{--}$, while ruthenium(VII) in RuO_4^- is tetrahedral with electron transfer bands [56] at 385 and 310 mμ.

It is interesting to see how much more important inherent Jahn-Teller distortion is for the development of typical tetragonal symmetry of titanium(III), vanadium(IV), molybdenum(V) and copper(II) complexes than the tetragonality of mixed complexes, *e. g.* of chromium(III) [57], cobalt(III) [57], nickel(II)[5,58], rhodium(III)[6,59] and iridium(III)[6,59] which often is difficult to detect.

EXPERIMENTAL

The spectra were measured in the range 800—210 mμ on a Cary recording spectrophotometer, Model 11-MS-50, and above 800 mμ on a Beckman DU.

Vanadium solutions. AnalaR NH_4VO_3 was directly, or after ignition to V_2O_5, dissolved in 2 M $HClO_4$ and reduced electrolytically to VO^{++}, or in 10 M HCl and reduced with amalgamated zinc to a mixture of V^{++} and V^{+++}. A 0.5 M solution of the latter kind was diluted with water to 0.1 M and used directly for vanadium(III) measurements and after spontaneous oxidation by air for vanadium(IV) measurements.

0.1 M Na_4enta, 0.6 M $(NH_4)_2$ox, 1 M tartaric acid, 1 M citric acid, 12 M aqueous ammonia etc. were made from analytical or C. P. reagents, and added to vanadium and titanium solutions in measuring flasks.

Solid $(NH_4)_2[VO\ C_4H_2O_6]$, $2H_2O$ and $VO\ aca_2$, H_2O were prepared according to Rosenheim and Yu-Mong [63].

Titanium solutions. Colourless $TiCl_4$ was mixed with 12 M HCl giving a 2 M solution. This solution was diluted to 0.2 M or 0.1 M $TiCl_4$ with different concentrations of HCl and reduced to the clearest shade of purple titanium(III) with zinc.

Molybdenum solutions. Merck's $(NH_4)_6Mo_7O_{24}$ was dissolved in 6 M HCl giving a 0.5 M solution. This was diluted with HCl to 0.1 M or lower concentrations and reduced with amalgamated zinc. Solid K_3MoCl_6 and $(NH_4)_2MoCl_5(H_2O)$[60] were also used for some experiments.

Acknowledgments. I thank Professor Jannik Bjerrum for his kind interest in the investigations.

Studies on the Extraction of Metal Complexes

XXVII. The Distribution of Some Actinides and Fission Products between Methyl *Iso*butyl Ketone and Aqueous Solutions of HNO_3 and $Ca(NO_3)_2$

JAN RYDBERG and BRITA BERNSTRÖM

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The distribution ratios of U(VI), Pu(VI), Pu(IV), Th(IV), Zr(IV), La(III), Ca(II), Na(I) and HNO_3 between methyl *iso*butyl ketone (hexone) and aqueous solutions of varying HNO_3 and $Ca(NO_3)_2$ concentrations have been determined and are given in Figs. 2—10. Some possible methods of separating uranium and plutonium from certain fission products are discussed.

Recently, a considerable number of papers [1] have been released on the separation of uranium, plutonium and mixed fission products from each other by means of different liquid-liquid extraction methods. The two most used organic solvents seem to be hexone (methyl *iso*butyl ketone) and TBP (tributyl phosphate), both of which are used for the extraction of the metal nitrates.

The present work * deals with the extraction of U(VI), Pu(VI), Pu(IV), Th(IV), Zr(IV), La(III), Ca(II), and Na(I) nitrates from aqueous solutions with various concentrations of HNO_3 and $Ca(NO_3)_2$ as salting-out agents. The elements studied represent about 90 % of the β- and γ-activity from the fission products of natural uranium ** which has been irradiated in a pile for several months and cooled for about the same time; the rest of the radioactivity is mainly due to Ru-Rh, which elements are not considered here.

In the present study, distribution experiments were run with each metal separately. The metal concentration of each phase was determined after equilibration. The ratio of the metal concentration in the organic phase to that in the aqueous phase gives the distribution ratio q of the metal. It was

* Based on Report FOA1, No. H 1149—8509, 1954.

** Cs and Rb are assumed to accompany Na, Sr and Ba to accompany Ca while all the rare earths resemble La. Nb is assumed to follow Zr.

generally found that q increases with the HNO_3 or $Ca(NO_3)_2$ concentration of the aqueous phase. Since very little $Ca(NO_3)_2$ dissolves in the organic phase, the variation of q with increasing HNO_3 concentration has been determined at a constant $Ca(NO_3)_2$ concentration in the aqueous phase. In the following, q_{Ca}, q_{La}, etc. will be used as abbreviations for the distribution ratios of the metals given by the subscripts.

EXPERIMENTAL

Chemicals. Hexone (methyl *iso*butyl ketone, $C_4H_9COCH_3$) of technical quality was purchased from the Svenska Shell AB; after filtration it was washed with $NaHCO_3$ and water to remove acid and water-soluble impurities and to saturate it with water.

^{234}Th was prepared according to Dyrssen [4].

^{140}La was obtained as the neutron-irradiated oxide, which was dissolved in HNO_3.

U(VI) solutions were prepared by dissolving UO_3 of high purity in HNO_3.

Zirconium nitrate of puriss. quality was dissolved in 1 M HNO_3. The solution was filtered and standardized by weighing the ignited oxide.

$Ca(NO_3)_2$ and $NaNO_3$ were of analytical grade.

General procedure. All distribution experiments were carried out at room temperature (20 ± 2° C). The metal nitrate and $Ca(NO_3)_2$ were mixed with varying amounts of HNO_3 and shaken with an equal volume of hexone. In all systems, equilibrium was established within 5 min. At high HNO_3 concentrations, the phases were found to undergo large volume changes. This is due to an appreciable extraction of HNO_3 into hexone whereas only negligible amounts of $Ca(NO_3)_2$ are extracted. In order to maintain the $Ca(NO_3)_2$ concentration of the aqueous phase constant throughout a series of distribution experiments, distilled water was added with repeated shaking up to the original volume of the aqueous phase. The two phases were then separated by centrifuging and samples were withdrawn for metal analysis and the titration of nitric acid.

Solubility of $Ca(NO_3)_2$ in HNO_3—H_2O. The addition of HNO_3 to concentrated $Ca(NO_3)_2$ solutions causes $Ca(NO_3)_2$ to crystallize out because its solubility product is exceeded. Solutions of varying HNO_3 content were saturated with $Ca(NO_3)_2$ and allowed to stand for a couple of days to attain equilibrium. Calcium was determined by weighing the ignited oxide after careful evaporation of a definite volume. The acid concentration was determined by titration. Fig. 1 shows the solubility of $Ca(NO_3)_2$ in water solutions as a function of the HNO_3 concentration. As a consequence, the distribution experiments are limited to a smaller acid concentration range at high $Ca(NO_3)_2$ concentrations.

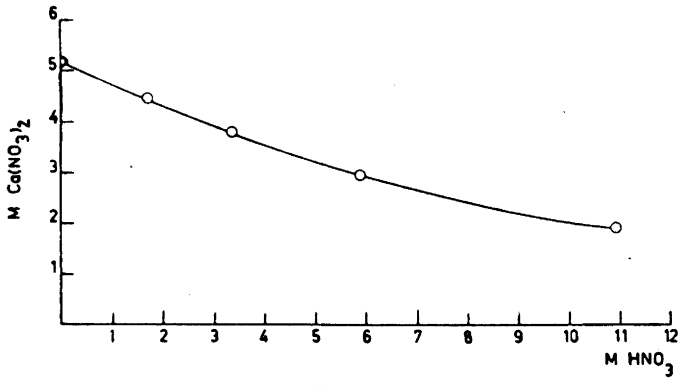

Fig. 1. The solubility of $Ca(NO_3)_2$ in HNO_3 solutions.

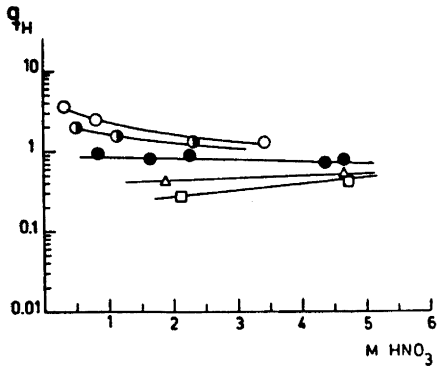

Fig. 2. The distribution ratio q_H of HNO_3 as a function of the equilibrium concentration of HNO_3 in the aqueous phase. Concentrations of $Ca(NO_3)_2$: ○ 4—3.8 M*, ◑ 3 M, ● 2 M, △ 1 M, □ no $Ca(NO_3)_2$ present.

The molal solubility of $Ca(NO_3)_2$ in solutions of varying HNO_3 content has been investigated by Basset and Taylor [5]. By determining the density of the aqueous solutions, a check was made that our results were in agreement with those obtained by Basset and Taylor.

The distribution ratio of HNO_3, q_H. The distribution ratio q_H of HNO_3 between the organic and aqueous phases was determined by titration of the acid in each phase with NaOH. In Fig. 2, q_H is plotted against the equilibrium concentration of HNO_3 in the aqueous phase for different $Ca(NO_3)_2$ concentrations *.

The distribution ratio of sodium, q_{Na}. A gravimetrical determination of the distribution of $NaNO_3$ gave an upper limit of $q_{Na} \leqq 10^{-3}$.

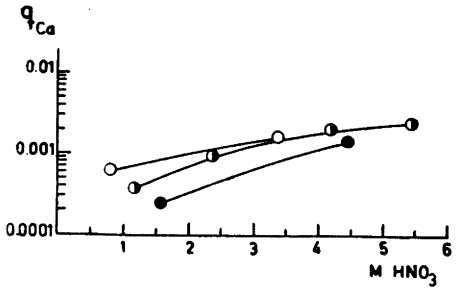

Fig. 3. The distribution ratio q_{Ca} of calcium as a function of the equilibrium concentration of HNO_3 in the aqueous phase. Total concentrations of $Ca(NO_3)_2$: ○ 4—3.8 M*, ◑ 3 M, ● 2 M.

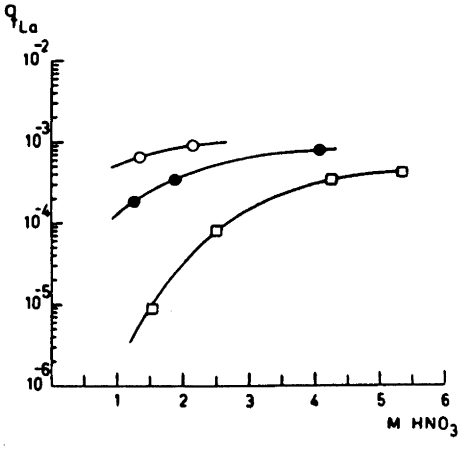

Fig. 4. The distribution ratio q_{La} of lanthanum as a function of the equilibrium concentration of HNO_3 in the aqueous phase. Concentrations of $Ca(NO_3)_2$: ○ 4—3.8 M*, ● 2 M, □ no $Ca(NO_3)_2$ present.

* The $Ca(NO_3)_2$ concentration can be kept constant at 4 M only for acid concentrations $\leqq$ 1 M. To obtain a higher acidity one is forced to start the distribution experiment with an initially acid hexone phase. After equilibrium the aqueous phase has increased in volume due to the distribution of HNO_3, thus causing a decrease of the $Ca(NO_3)_2$ concentration.

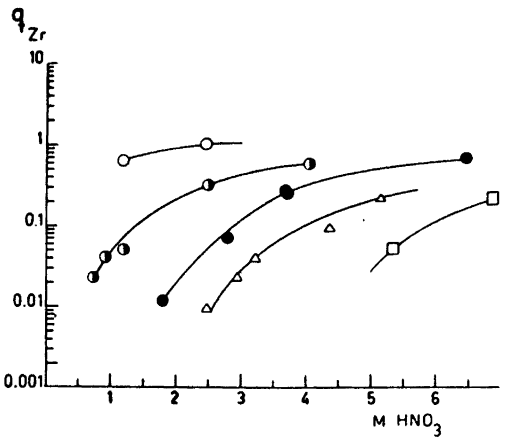

Fig. 5. The distribution ratio q_{Zr} of zirconium as a function of the equilibrium concentration of HNO_3 in the aqueous phase. Concentrations of $Ca(NO_3)_2$: ○ 4—3.7 M*, ◑ 3 M, ◉ 2 M, △ 1 M, □ no $Ca(NO_3)_2$ present.

The distribution ratio of calcium, q_{Ca}. The distribution ratio of Ca between hexone and water is very low. In order to determine the Ca concentration of the hexone phase, a known volume of the phase was taken and evaporated to dryness, whereupon the residue was dissolved in distilled water. Ca was determined by a substitution titration with EDTA (ethylenediamine tetraacetic acid) at pH = 10 using Eriochrome Black T as indicator [6,7]. Blanks were run in the same way. The distribution data obtained are plotted in Fig. 3.

The distribution ratio of lanthanum, q_{La}. The distribution was followed by means of ^{140}La as a tracer. Dry samples of each phase were counted. The La solution used was of very high specific activity, which made it possible to count the aqueous phase after a 100-fold dilution thus avoiding vitiating salt residues of $Ca(NO_3)_2$. In Fig. 4, q_{La} is plotted versus the equilibrium HNO_3 concentration of the aqueous phase.

The distribution ratio of zirconium, q_{Zr}. With an original zirconium concentration of 0.1 M in the aqueous phase, it was possible to determine the distribution of zirconium by gravimetrical analysis. Since $Ca(NO_3)_2$ was present in the aqueous phase, only samples of the hexone phase were weighed after the evaporation and ignition to the oxide. The weights were corrected for the small amounts of calcium coextracted into the hexone phase according to Fig. 3. The phase volumes were measured after equilibrium so that the zirconium content of the aqueous phase could be calculated from the difference between the total amount of zirconium added and that found in the organic phase. The data are given in Fig. 5.

The distribution ratio of thorium, q_{Th}. By means of ^{234}Th (UX_1), the distribution of thorium was followed radiometrically. The thorium concentration in these experiments was $\leq 10^{-5}$.

Liquid counting was used, which involved corrections due to the different absorptions of the radiation in the hexone phase and in the aqueous phases of varying $Ca(NO_3)_2$ concentrations. Using the same liquid counter, these corrections were measured experimentally in the following manner:

a) the counting rate of a definite amount of ^{234}Th was measured in 1 M HNO_3 and in 1 M HNO_3 solutions containing 1, 2, 3 and 4 M $Ca(NO_3)_2$.

b) the counting rate of the same amount of ^{234}Th was measured in hexone after an extraction with 0.2 M TTA (thenoyltrifluoroacetone) in hexone from a 0.05 M $HClO_4$ phase; in this case $q_{Th} > 500$.

The results for q_{Th} are plotted in Fig. 6.

The distribution ratio of hexavalent uranium, q_U, *at* U *concentrations* ≤ 0.1 *M*. After equilibration, samples were withdrawn and evaporated to dryness whereupon the residues were dissolved in 0.1 M $HClO_4$. The uranium content was determined colorimetrically by means of the thiocyanate method [8]. The residues sometimes contained appreciable amounts of Ca but it was found that this did not interfere with the method.

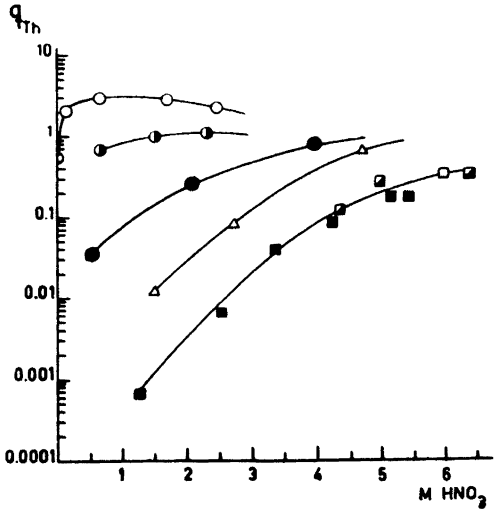

Fig. 6. The distribution ratio q_{Th} of thorium as a function of the equilibrium concentration of HNO_3 in the aqueous phase. Initial concentration of Th $\leq 10^{-5}$ M, except for ◪ where Th concentration is 0.1 M. Concentrations of $Ca(NO_3)_2$: ○ 4—3.7 M*, ◑ 3 M, ● 2 M, △ 1 M, □ ◪ ■ no $Ca(NO_3)_2$ present. (□ radiometrical, ◪ gravimetrical, ■ radiometrical with 0.1 M U present).

The titration of HNO_3 was carried out with methyl orange as indicator in order to avoid titration errors due to the uranium present. The curves for different $Ca(NO_3)_2$ concentrations are found in Fig. 7.

The distribution ratio of thorium and hexavalent uranium at U *concentrations between 0.1 and 1 M.* The experiments were carried out with uranium (UI) in radioactive equilibrium with ^{234}Th (UX_1). It was then possible to determine the distribution of the two

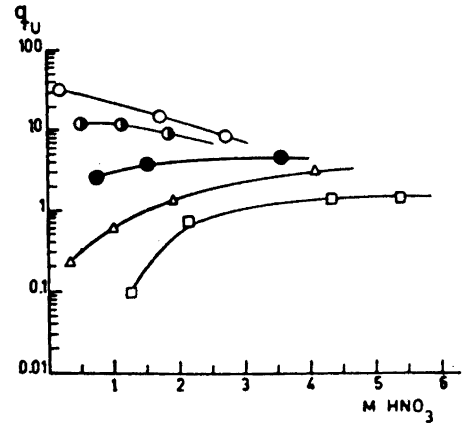

Fig. 7. The distribution ratio q_U of hexavalent uranium as a function of the equilibrium concentration of HNO_3 in the aqueous phase. Concentration of $Ca(NO_3)_2$: ○ 4—3.6 M*, ◑ 3 M, ● 2 M, △ 1 M, □ no $Ca(NO_3)_2$ present.

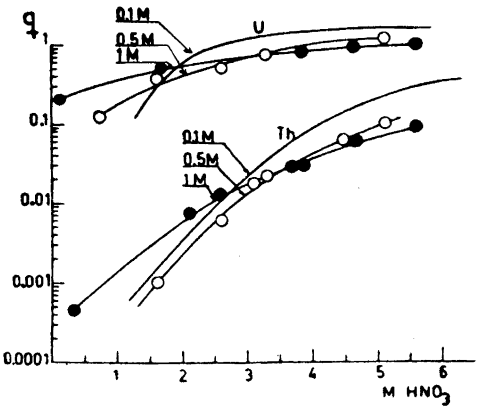

Fig. 8. The distribution ratios q_U of hexavalent uranium and q_{Th} of thorium as functions of the equilibrium concentration of HNO_3 in the aqueous phase. No $Ca(NO_3)_2$ added. Total concentration of U(VI): ● 1 M, ○ 0.5 M. For comparison the curves for 0.1 M U are drawn.

* See footnote, p. 88.

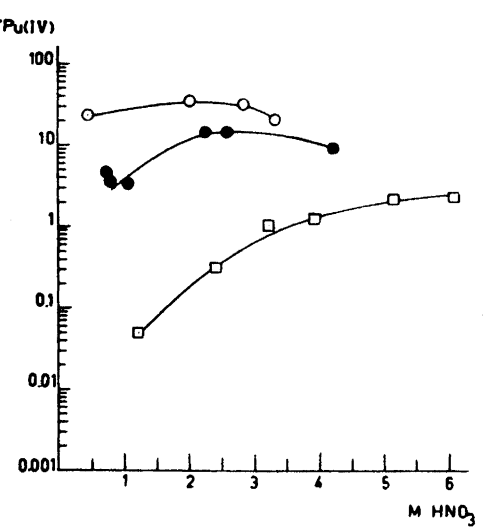

Fig. 9. The distribution ratio $q_{Pu(IV)}$ of Pu(IV) as a function of the equilibrium concentration of HNO_3 in the aqueous phase. Concentrations of $Ca(NO_3)_2$: ○ 4—3.5 M*, ● 2 M, □ no $Ca(NO_3)_2$ present.

metals separately in the solutions using the same analytical procedures as before. The HNO_3 concentration of the aqueous phase was determined by a NaOH titration after removing the uranyl ions by running the sample through the hydrogen form of a cation exchange column (Dowex 50). It is noted that for each UO_2^{2+} that is adsorbed 2 H^+ are removed and must be subtracted in the NaOH titration. The data are given in Fig. 8 where q_U and q_{Th} have been plotted against the HNO_3 concentration of the aqueous phase at equilibrium.

The distribution of tetravalent plutonium, $q_{Pu(IV)}$. A solution of Pu(IV) in 10 M HNO_3 (3×10^{-3} mg Pu/ml) was available. A TTA extraction was employed to confirm the tetrapositive state of plutonium [13].

In the distribution experiments with Pu(IV), 1 ml of this solution was added to a 4 ml aqueous phase of varying HNO_3 content and the resulting solution was then mixed with an equal volume of hexone. After the separation of the phases by centrifugation, samples of 0.1 ml were taken from the two phases and evaporated on Pt-dishes. The pipets were rinsed with 1 M HNO_3 solutions and the washings were also added to the dishes. The dry samples were measured internally in an argon-methane proportional counter. With $Ca(NO_3)_2$ present in the aqueous phase, direct radiochemical analysis of the aqueous phase was not possible. The procedure used was therefore to extract plutonium from the $Ca(NO_3)_2$ solution with a 0.05 M solution of dibutyl phosphate in $CHCl_3$. Tests were made to show that plutonium(IV) was extracted quantitatively under the conditions in question, *i. e.* from acid solutions of 2 M and 4 M $Ca(NO_3)_2$. The results are plotted in Fig. 9.

The distribution of hexavalent plutonium, $q_{Pu(VI)}$. To obtain Pu(VI), different oxidizing agents can be used, *cf.* Refs.[2,11]. The symbols in Fig. 10 represent the following procedures:

◑. A plutonium solution kept in 5 M HNO_3 was treated for 5 min with solid $NaBiO_3$; the excess bismuthate was removed by centrifugation. The oxidized plutonium solution was then immediately used in distribution experiments with hexone, pretreated only as described under "Chemicals".

□. The plutonium solution was treated with 0.001 M $Cr_2O_7^{2-}$ in 1 M HNO_3 with Co^{2+} as catalyst for 10 min at 90° C. The hexone used in the distribution experiments was pretreated with dichromate solutions in the same way but at room temperature. Dry, thin samples could not be obtained in the distribution experiments when more concentrated dichromate solutions were used.

* See footnote, p. 88.

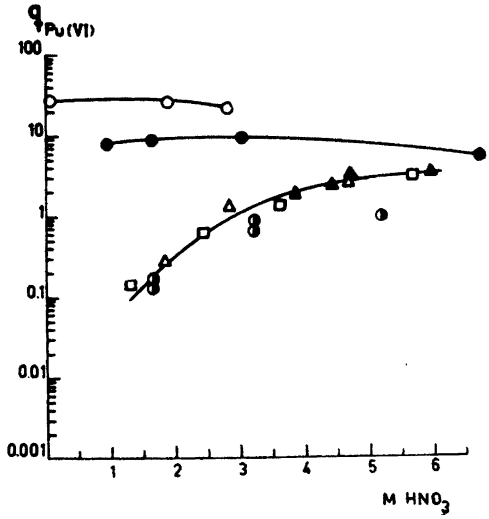

Fig. 10. The distribution ratio $q_{Pu(VI)}$ of Pu(VI) as a function of the equilibrium concentration of HNO_3 in the aqueous phase. Concentrations of $Ca(NO_3)_2$: O 4—3.6 M *, ● 2 M, □ ◑ △ ▲ no $Ca(NO_3)_2$ present (for explanation of symbols see text).

▲. The plutonium solution was made 10 M in HNO_3 and 0.67 M in $KBrO_3$; the hexone was shaken immediately before the distribution experiments with an equal volume of 10 M HNO_3 and 0.1 M $KBrO_3$.

△. The plutonium solution was made 1 M in HNO_3 and 0.2 M in $KBrO_3$ and kept at 95° C for 30 min; the hexone was pretreated with 0.1 M $Cr_2O_7^{=}$ in 1 M HNO_3 followed by washing with sodium hydroxide and finally steam distilliaton of the hexone (*cf.* Ref.[1] Paper 541, Vol. 9).

For the curves with 2 M (symbol ●) and 4 M (symbol O) $Ca(NO_3)_2$, 0.2 M $KBrO_3$ was used as oxidant. The plutonium analysis of the two phases was performed in the following manner: a) a dry, thin sample of the hexone phase could be obtained directly by evaporation, b) when no $Ca(NO_3)_2$ was present, 0.1 ml of the aqueous phase was evaporated and counted; when $Ca(NO_3)_2$ was present, 3 ml of the aqueous phase was adjusted to approximately 0.05 M in H^+ by adding concentrated NH_3 and then shaken with 2 ml hexone 0.05 M in dibutyl phosphate; preliminary tests showed that plutonium(VI) is extracted quantitatively under these conditions. The results are found in Fig. 10.

DISCUSSION OF RESULTS

The results obtained above are collected in Figs. 11—15, from which it is possible to choose conditions for separating the different metals from each other.

When uranium and plutonium are dissolved in hot, concentrated HNO_3, one gets mainly U(VI), Pu(IV) and Pu(VI). Now it can be seen from Figs. 11, 13 and 15 that the distribution ratios of these species are close together, which makes it difficult to separate them from each other. If it is desired to separate uranium from plutonium, one should make use of the facts that plutonium can be reduced to Pu(III) without the reduction of U(VI) [1,2] and that Pu(III) behaves much similar to La(III) [3], which is easily separated from U(VI) [1,2].

The following discussion will only deal with the separation of uranium together with plutonium from the other metals, which represent most of the

* See footnote, p. 88.

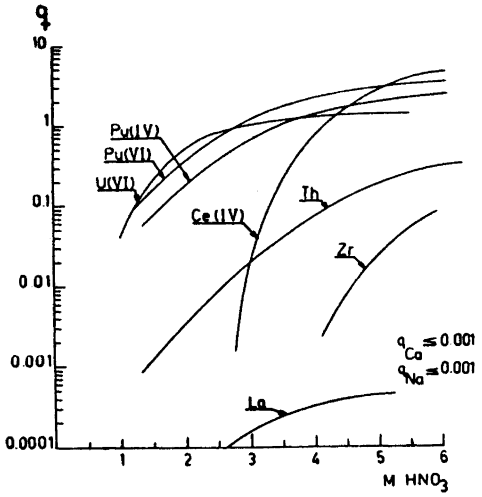

Fig. 11. The distribution ratios of U, Pu(IV) and Pu(VI), Th, Zr, Ce(IV) and La as functions of the equilibrium concentration of HNO_3 in the aqueous phase. No $Ca(NO_3)_2$ added. The Ce(IV) curve is taken from Glendenin *et al.*[12].

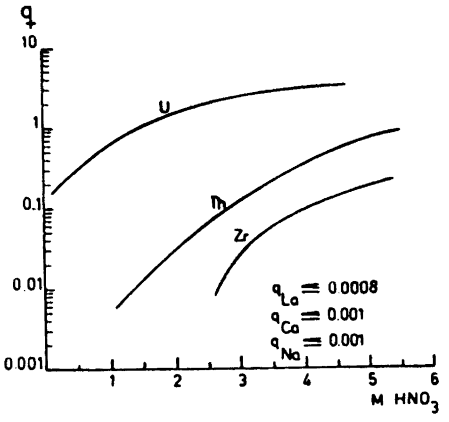

Fig. 12. The distribution ratios of U, Th and Zr as functions of the equilibrium concentration of HNO_3 in the aqueous phase. Concentration of $Ca(NO_3)_2$ 1 M.

undesired impurities in pile irradiated uranium. In order to avoid complications due to hydrolyses of some of the metals, the discussion will be limited to acidities ≤ 1 M in H^+.

Extraction formulas and definition of the decontamination factor

For batchwise extractions of a single (stationary) aqueous phase with fresh organic solvent (also called "multiple extraction"), the equation

$$P = 100 \cdot q \cdot r_v \sum_{1}^{n} (1 + q \cdot r_v)^{-n} \qquad (1)$$

gives the percentage P of the metal obtained in the combined organic phases after n extractions when the ratio between the volumes of the organic and aqueous phases is r_v. It is seen that the larger $q \cdot r_v$ is, the more complete will the extraction be.

For counter-current extractions (batchwise or continuous) with n extracting and m stripping stages and introduction of the feed at the stage $m = n = 1$, the ratio R of the amount of the metal leaving in the organic phase to that leaving in the aqueous phase is given by

$$R = \frac{E^m(E^n - 1)}{E^m - 1} \qquad (2)$$

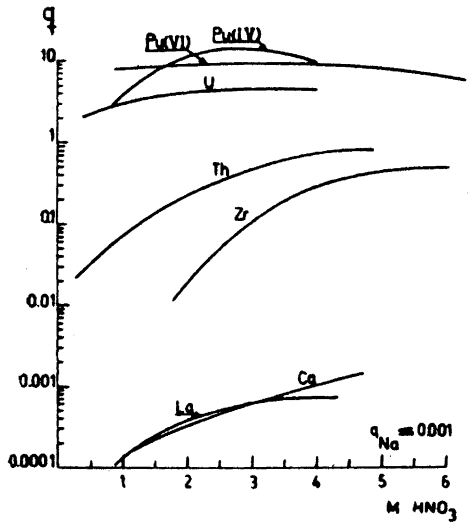

Fig. 13. The distribution ratios of U, Pu(IV) and Pu(VI), Th, Zr, La and Ca as functions of the equilibrium concentration of HNO_3 in the aqueous phase. Concentration of $Ca(NO_3)_2$ 2 M.

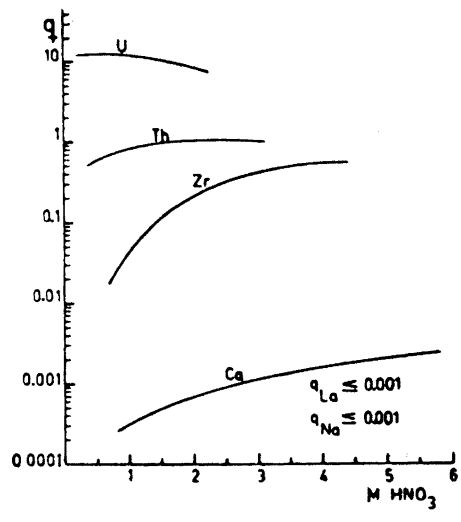

Fig. 14. The distribution ratios of U, Th, Zr and Ca as functions of the equilibrium concentration of HNO_3 in the aqueous phase. Concentration of $Ca(NO_3)_2$ 3 M.

where $E = q \cdot r_v$ (E is called extraction factor). Eqn. 2 is valid provided r_v is constant throughout all stages, which implies that the volume of the feed is negligible. Convenient graphs of this equation have been given by Bartels and Kleiman [9].

The decontamination factor (*D. F.*) is here defined as the ratio of the desired product (A) to the contaminants (B) in the organic phase at the n:th stage divided by the corresponding ratio in the original aqueous phase (= feed),

$$D.\,F. = \frac{(A)_n/(B)_n}{(A)_0/(B)_0} \qquad (3)$$

The extraction of uranium and plutonium into hexone without the addition of $Ca(NO_3)_2$

In Fig. 11, the distribution ratios q of the different metals are compared for the case where no $Ca(NO_3)_2$ is added. Since the distribution ratios are fairly low for uranium and plutonium, the ratio r_v of the volume of the organic phase to that of the aqueous phase must be considerably greater than 1 in order that a good yield of these ions shall be obtained in the combined organic phases for a reasonably small number of extraction stages.

As an example, a multiple extraction using a HNO_3 equilibrium concentration of 2 M, where the decontamination factor is large, will be described. (*Cf.* Fig. 16 which illustrates how the separation factor between U and Th (*i.e.* q_U/q_{Th}) varies with the HNO_3 and $Ca(NO_3)_2$ concentration). Let us assume according to Fig. 11 that $q_{Pu(IV)} \approx q_{Pu(VI)} \approx q_{U(VI)} \geq 0.2$ at 2 M HNO_3. If $r_v = 5$, then

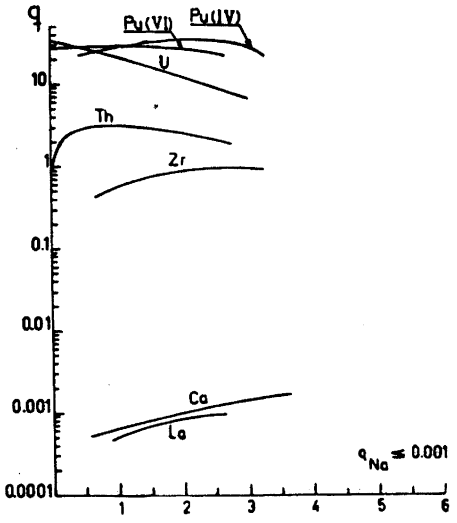

Fig. 15. The distribution ratios of U, Pu(IV) and Pu(VI), Th, Zr, La and Ca as functions of the equilibrium concentration of HNO_3 in the aqueous phase. Concentration of $Ca(NO_3)_2$ 4—3.5 M *.

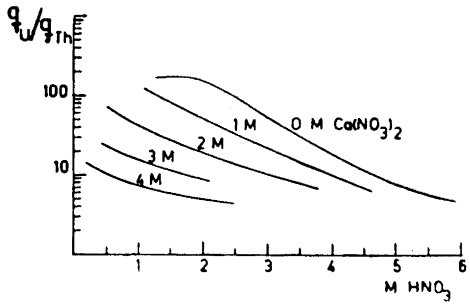

Fig. 16. The separation factor q_U/q_{Th} as a function of the equilibrium concentration of HNO_3 in the aqueous phase at varying $Ca(NO_3)_2$ concentrations.

eqn. 1 indicates that, with 6 extractions ($n = 6$), more than 98 % of U(VI), Pu(IV) and Pu(VI) is extracted. The decontamination factor will be > 8 with respect to thorium and $> 10^3$ with respect to La and probably also to the other elements in Fig. 11 (Ce, Zr, Ca and Na).

In a counter-current extraction, E in eqn. 2 must be > 1 in order to get any appreciable extraction of an element. Thus either q or r_v must be increased compared to the multiple extraction above. Since $r_v = 5$ is about the practical upper limit with hexone, q must be increased, which is possible by going to higher HNO_3-concentrations. Let us assume that $q_{U(VI)} \approx q_{Pu(IV)} \approx q_{Pu(VI)} \geq 0.6$ in 3 M HNO_3 while, for the other elements in Fig. 11, $q \leq 0.02$. For $n = 4$ and $m = 3$ (*i. e.* 6 stages altogether since $m = 1$ and $n = 1$ is the feed stage) and $r_v = 5$, it is found that more than 99 % of U(VI), Pu(IV) and Pu(VI) will be extracted with a decontamination factor $> 10^3$.

This shows that with a counter-current technique it is feasible to get a good separation of uranium and plutonium from fission products. However, a drawback of these extractions is the large volumes of organic solvent needed.

The extraction of uranium and plutonium into hexone from $Ca(NO_3)_2$ solution

By comparing Figs. 12—15, where 1, 2, 3 and 4 M $Ca(NO_3)_2$ was present in the aqueous phase, it is seen that the distribution ratios of all metals increase with the $Ca(NO_3)_2$ concentration. This makes it possible to use $r_v \approx 1$ at high

* See footnote, p. 88.

$Ca(NO_3)_2$ concentrations. It is also noted that the curves for the different metals become closer to each other which means that the separation between the elements becomes less efficient (*cf.* Fig. 16). For the separation of U(VI), Pu(IV) and Pu(VI) from the fission products, it is necessary to consider primarily the decontamination due to zirconium.

Let us assume that a multiple extraction is carried out at 1.5 M HNO_3 and with 3 M $Ca(NO_3)_2$, where we estimate from Figs. 13 and 15 that $q_{Pu(IV)} \approx \approx q_{Pu(VI)} > q_{U(VI)} = 10$ (Fig. 14). It can be calculated from eqn. 1 with $r_v = 1$ that 3 multiple extractions will yield 99.9 % U(VI), Pu(IV) and Pu(VI) in the hexone phase. However, at the same time about 25 % of the zirconium present will go into the hexone phase ($q_{Zr} = 0.1$).

If the extractions instead are carried out in a counter-current manner with $n = 3$, $m = 3$, one can calculate, using eqn. 2, that > 99 % of U(VI), Pu(IV) and Pu(VI) will be extracted with < 1 % zirconium.

The advantage of using high salt concentrations is that the ratio r_v of the volume of the organic phase to that of the aqueous phase can be kept ≈ 1. An easier separation of the hexone and aqueous phase with high salt concentration is also obtained due to the increased density of the aqueous phase. A drawback of the method is that more difficulties are in general encountered in taking care of salt-rich radioactive wastes.

The extraction of uranium and thorium at higher uranium concentrations

In most practical separation processes, one has to start with a high concentration of uranium. Since uranium nitrate will act as a salting-out agent and increase the distribution ratios, a separate investigation was made in which the initial uranium concentration was increased to 1 M and q_U and q_{Th} were determined (Fig. 8). In agreement with the results obtained with $Ca(NO_3)_2$, an increased uranium concentration increases the distribution ratios most at HNO_3 concentrations < 1 M. At high acidities, the distribution ratios q_U and q_{Th} show a tendency to decrease with increasing uranium concentration.

However, for the case discussed above where the extraction is made from a $Ca(NO_3)_2$-free solution at 3 M HNO_3, one can assume that the same separation of uranium and plutonium from the bulk of the fission products will be obtained when starting with higher initial uranium concentrations.

Acknowledgements. The authors wish to thank the head of this institute, Professor G. Ljunggren, for his continuous interest and support of this work. We also wish to thank Professor L. G. Sillén and Dr. D. Dyrssen for valuable discussions and Miss V. Dahlberg for generous experimental assistance. The English in this paper has been revised by Dr. D. Gillam.

The Non-occurrence of Cedrene and Cedrol in *Juniperus communis* L.

JOHAN B-SON BREDENBERG

Department of Chemistry, Institute of Technology, Helsingfors, Finland

It is proposed that the presence or absence of cedrene and cedrol can be used to differentiate between the sections *Sabina* and *Oxycedrus* in the genus *Juniperus*. Neither cedrene nor cedrol have been detected in the ethereal oil from the wood of *Juniperus communis* L., which belongs to the section *Oxycedrus*.

The genus *Juniperus*, which comprises about 60 species, is divided into three sections: *Caryocedrus*, *Oxycedrus* and *Sabina* [1]. No investigation of the extraneous matter of the monotypic section *Caryocedrus* has been made. Most of the investigations of the species belonging to *Oxycedrus* and *Sabina* have been concentrated on the ethereal oil. Erdtman [2] quotes cedrene and cedrol as typical constituents of the wood of junipers. It was of interest to check this statement in the case of the ethereal oil from the wood of *Juniperus communis* L. The oil was fractionally distilled. From the fraction (No. 3, Table 2) corresponding to the boiling point of cedrene no cedrene glycol could be obtained. An infrared spectrum of the fraction showed that it did not contain cedrene. From a higher boiling fraction (No. 10, Table 2) crystals, m.p. 75—76°, were slowly deposited. The infrared spectrum of this compound was not identical with the spectrum of cedrol. No additional crystalline substances could be obtained in spite of prolonged cooling or storage at room temperature (two years). As cedrol crystallizes well, these results are taken as evidence of the absence of cedrene and cedrol from the oil.

In the light of this discovery a closer scrutiny of the literature was made, with interesting results (Table 1).

It has been claimed that cedrene occurs in *J. oxycedrus* L.[19]. The constants given for this cedrene, however, show such a great divergence from those for natural cedrene that this claim is not worthy of consideration. It must be remarked that a negative sign does not necessarily exclude the presence of the substances, since the investigations are far from complete. This is especially true of cedrene, a liquid hydrocarbon. Nevertheless it seems possible to differentiate the sections *Sabina* and *Oxycedrus* by the presence or absence of cedrene and cedrol in the ethereal oil from the wood.

EXPERIMENTAL

The ethereal oil was obtained, in connection with other work [20], by extraction of wood meal (13 kg) with ether, separation of the acidic components, and steam distillation of the neutral oil. The steam distillate (234 g, 1.8 % of the air-dried wood) had the following constants: d_{15}^{15} 0.937, n_D^{20} 1.507, α_D^{20} −24°, E. No. 7.2. It was fractionated in a 1 m spinning band column, giving the fractions in Table 2.

Table 2. Fractional distillation of 234 g of ethereal oil. Yield 185 g, 79 %.

Distillate,	g	B.p. °C,	mm Hg	d_4^{20}	n_D^{20}	α_D^{18}
1.	5.4	116–26	14	0.9172	1.4980	−27.7
2.	14.1	126–27	14	9238	5014	−44.8
3.	52.8	127–28	14	9273	5031	−62.3
4.	19.6	128–38	14	9207	5074	−34.0
5.	16.3	138–40	14	9250	5125	+3.0
6.	25.8	140–42	14	9252	5143	+2.3
7.	7.9	130–32	9	9259	5154	−1.5
8.	9.4	132–43	9	9498	5135	−4.1
9.	7.7	143–45	9	9737	5069	−7.3
10.	7.4	145–47	9	9779	5068	−7.7
11.	8.8	147–54	9	9815	5102	−10.2
12.	4.1	154–58	9	9870	5138	−8.3
13.	3.7	158–68	9	9970	5197	−21.1
14.	2.1	168–72	9	9972	5235	+0.7

The constants of the fraction No. 3 corresponded fairly well with those reported for natural cedrene [21]. Five grams of this fraction were oxidized with $KMnO_4$ according to a method described in the literature [22]. No cedrene glycol could be found. Comparison of the infrared spectrum of the fraction with a spectrum given by Plattner *et al.*[23] showed that no cedrene was present.

After two months, crystals were slowly formed in fraction No. 10. Four months later the crystals were filtered (yield 90 mg, m.p. 70—75°). Recrystallisation from methanol-water raised the melting point to 75—76°. An infrared spectrum established that the compound was not cedrol.

All attempts to obtain additional crystalline substances by prolonged cooling or storage of the fractions at room temperature for a long time (two years) failed.

The author is indebted to Professor H. Erdtman, who has supplied the IR-spectrum of authentic cedrol and to Mr. B. C. Fogelberg, Centrallaboratorium Ab., Helsingfors, who has taken the other IR-spectra.

On the Occurrence of Folic Acid, Folic Acid Conjugates and Folic Acid Conjugases in Pollen

NIELS NIELSEN and BJÖRN HOLMSTRÖM

Research Department, AB Kabi, Stockholm, Sweden

The contents of folic acid and folic acid conjugates of 10 different pollen samples were determined. The folic acid content ranged between 0.42 and 2.2 μg per g pollen. The amount of folic acid conjugates was in most cases considerably higher — 4 to 12 times as high. In two samples of pollen from grasses, *viz. Zea mays* and *Secale cereale*, the content of folic acid and of folic acid conjugates was of the same magnitude. Compared to other vegetable materials the pollen is relatively rich in folic acid and folic acid conjugates.

The presence of conjugases was established for pollen from *Pinus montana*, *Zea mays*, *Phleum pratense* and *Secale cereale*. For pollen from *Zea mays* the conjugase(s) was found to have its pH-optimum at 4.5 being active between pH 4 and 6. This conjugase must therefore be different from the conjugases in chicken pancreas. The effect obtained is stronger than that obtained with hog kidney and for this reason the conjugase in pollen can hardly be the same as in hog kidney. The content of conjugase in pollen is sufficient to convert all the conjugates in the pollen.

Continuing previous studies on the vitamin content of different pollen samples[1] we have studied the occurrence of folic acid. Very little is known regarding the presence of this vitamin in pollen. As folic acid is believed to be an important component of the so called vitamin T [2] which is reported to be an important growth factor for insects [3], investigations on the occurrence of this vitamin in pollen seemed of *a priori* interest.

In this investigation we wanted to determine both the amount of folic acid * and the amount of folic acid conjugates. As considerable amounts of folic acid conjugates were found (in most pollen samples the content of folic acid conjugates was much greater than the content of folic acid) we also studied the occurrence of folic acid conjugases in the pollen.

* In accordance with Welch and Nichol [4] we understand by folic acid the compounds able to promote the growth of *Streptococcus faecalis* and *Lactobacillus casei, viz.* pteroyl glutamic acid and pteroyl diglutamic acid.

Table 1. The occurrence of folic acid and folic acid conjugates in pollen.

Source of pollen	Folic acid µg/g pollen dry weight	Folic acid + folic acid conjugates	Folic acid in percentage of folic acid + conjugates
Pinus contorta	0.74	3.1	24
Pinus montana	0.42	2.5	17
Picea canadensis	1.4	12.8	11
Alnus glutinosa	0.53	4.3	12
Alnus incana	0.84	10.1	8
Betula alba	1.1	4.3	26
Fagus silvatica	1.9	7.3	26
Zea mays	2.2	4.5	49
Phleum pratense	1.1	5.6	20
Secale cereale	1.1	2.3	48

For the determination of folic acid, 5 g of pollen was suspended in 30 ml of water and heated to 120° for 5 min. Due to this heating the conjugases which might be present in the pollen are inactivated [5]. After heating, the suspension was centrifuged and the pollen residue washed twice with 20 ml of water. The combined extracts were made up to 100 ml for assay.

For the determination of the total content of folic acid plus folic acid conjugates the samples were treated with chicken pancreas conjugase according to the method described by Teply and Elvehjem [6]. The treatment with hog kidney or almond conjugases [7] was also tried, but the values obtained with chicken pancreas conjugase were found to be somewhat higher and this method was therefore preferred. For the assay, *Streptococcus faecalis* ATCC 8043 was used applying the paper-disc method.

Ten pollen samples were analyzed. The samples were collected directly from the plants. The purity of the samples was high, the amount of foreign pollen not exceeding 1 %. The pollen samples were collected in 1955 and stored in a cool and dry place until they were analyzed.

As can be seen from Table 1 the sum of folic acid and folic acid conjugates varied between 2.3 and 12.8 µg per g dry material. These values are relatively high in comparison with those of other vegetable materials [8]. No connection can be seen between the folic acid content and the systematic position of the plant from which the pollen was derived. The pollen samples from the closely related species *Alnus glutinosa* and *A. incana* show a marked deviation in their contents of folic acid and folic acid conjugates. Earlier it was found that the content of six other B-vitamins in pollen from these two species was rather similar [1].

The content of folic acid calculated as per cent of the sum of the contents of folic acid and folic acid conjugates varies considerably. For most of the pollen samples it varied between 10 and 25 %, *i.e.* the folic acid conjugates were present in considerably higher amounts than was folic acid. For two of the samples, however, the relative amounts of folic acid were very high. In the pollen from the two grasses *Zea mays* and *Secale cereale* the folic acid content was as high as that of the folic acid conjugates. In the third sample of grass-pollen investigated, *i.e.* pollen from *Phleum pratense*, the amount of folic acid

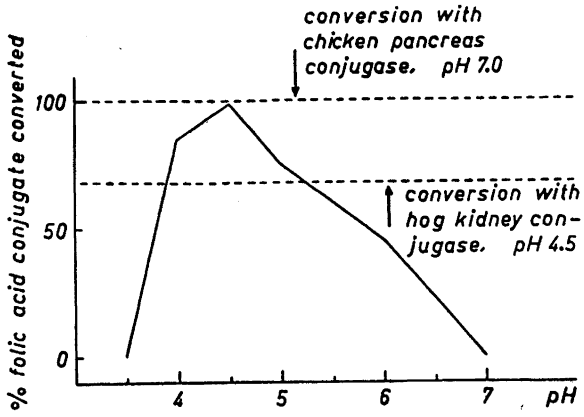

Fig. 1. Conversion of folic acid conjugates.

was low compared to the value for the folic acid conjugates. The number of pollen samples investigated was to small to justify any conclusion as to whether pollen from grasses have a tendency to be relatively rich in folic acid compared to folic acid conjugates.

Weygand and Hofmann [9] studied the content of folic acid in some pollen samples and found the amount to vary between 3.4 and 6.4 μg per g pollen. It is uncertain whether the folic acid conjugates are included.

As the content of folic acid conjugates appeared to be high in pollen it was of interest to investigate the presence of conjugates in the pollen. Since conjugases are widely distributed in nature [7] their occurrence in pollen was to be expected.

The investigation of pollen conjugases was performed mainly with pollen from *Zea mays*. A number of samples were prepared, each containing 5 g pollen in 25 ml of water. One of the samples was heated to 100° immediately in order to inactivate the conjugases, and was then used to determine the amount of folic acid present. One other sample was similarly heated and chicken pancreas conjugase added to determine the total content of folic acid and folic acid conjugates. Other samples were kept for 18 h at 25° at different pH values.

As can be seen from Fig. 1, the amount of folic acid was unaltered in the samples kept at pH 3.5 and 7.0 whereas there was an increase in the folic acid activity of the other samples. This indicates that the pollen contains conjugase (or conjugases) active between approximately pH 4.0 and pH 6.0, the optimum being about pH 4.5.

The conjugase present in the pollen from *Zea mays* differs from the conjugase in chicken pancreas in having the optimum at pH 4.5. The chicken pancreas conjugase has the optimum at pH 7-8 [5]. Although the conjugase extracted from hog kidney has its optimum at pH 4.5 [7,10] it can, however, hardly be the same conjugase as that in pollen. Our experiments showed that the hog kidney conjugase cannot split the conjugates in pollen to the same extent as

can the pollen conjugase. Thus the conjugase found in pollen must differ from both the conjugase in chicken pancreas and that in hog kidney.

It is seeen from Fig. 1 that at pH 4.5 the same amount of folic acid was obtained with pollen conjugases as with chicken pancreas conjugase. If it be assumed that chicken pancreas conjugase can split all the conjugates, then the amount of conjugase present in the pollen would suffice to convert all the conjugates of the pollen into folic acid.

It is of interest that pollen conjugase has its optimum at a pH not naturally occurring in pollen.

Experiments with other pollen samples, *viz.* pollen from *Pinus montana*, *Phleum pratense* and *Secale cereale*, demonstrated that the content of folic acid increased and that the content of folic acid conjugates decreased when the pollen was incubated in water at 25° and at pH 5. This indicates that conjugases are also present in these pollen samples.

An Investigation of Conditions for Precipitation of Uranium(IV) Orthophosphate

ERIK STRANDELL

Department of Applied Inorganic Chemistry, Royal Institute of Technology, Stockholm, Sweden

The precipitation of uranium as uranium(IV) orthophosphate from low concentrated acid solutions depends greatly on the possible presence of aluminium salts in the solutions. At high concentrations of aluminium ion, no precipitation is obtained. In chloride solutions consisting of uranium(IV) chloride, aluminium chloride, orthophosphoric and hydrochloric acids, the precipitation is prevented due to the formation of soluble double complexes between uranium, aluminium and phosphate ions. In sulfate solutions consisting of uranium(IV) sulfate, aluminium sulfate, orthophosphoric and sulfuric acids, the precipitate is formed only within a relatively narrow pH range around pH 1. At higher pH values, precipitation is prevented probably by the same double complexes as in chloride solutions. At lower pH values, precipitation is prevented mainly by soluble complexes between uranium and sulfate.

Some investigations were performed in order to clarify the conditions for the precipitation of uranium(IV) orthophosphate from low concentrated acid solutions. It was then proved that the presence of aluminium salts in the solutions has a great effect.

PRECIPITATION EXPERIMENTS

To perform the precipitation experiments, solutions were prepared containing 0.0017 M uranyl chloride, 0.042 M orthophosphoric acid and various amounts of aluminium chloride. The pH was adjusted to various values using hydrochloric acid. Analogous sulfate solutions were prepared from uranyl sulfate, orthophosphoric acid, aluminium sulfate and sulfuric acid. The solutions were heated to 35° C and reduced with a suitable reducing agent. The solutions were kept under slight stirring at 35° C for about 24 h. The time elapsing before a precipitate could be clearly seen was noted. After 24 h, the solutions were filtered and the amounts of uranium in the mother liquors were determined by analysis.

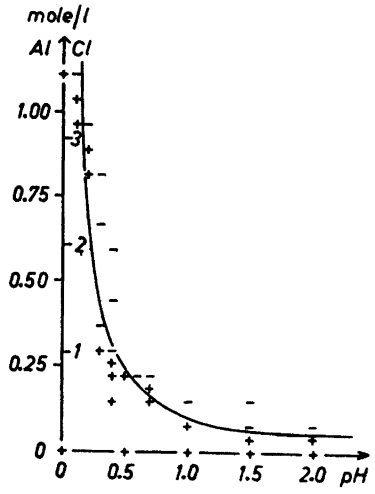

Fig. 1. Precipitation of uranium(IV) phosphate from chloride solutions with various concentrations of $AlCl_3$. + indicates precipitation, — no precipitation.

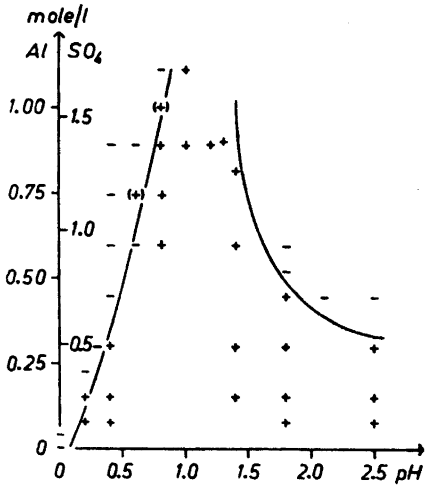

Fig. 2. Precipitation of uranium(IV) phosphate from sulfate solutions with various concentrations of $Al_2(SO_4)_3$. (+) indicates precipitation after 5 h.

In Figs. 1 and 2, where the axes are the concentration of aluminium in the various solutions and pH, the precipitation experiments on the above mentioned chloride and sulfate solutions have been plotted. Cases where a precipitate is obtained within 5 h have been marked with + on the figures. If precipitation occurs after 5 h, this is marked with (+). Cases where no precipitation occurs within 24 h have been marked with — on the figures. The approximate boundary between precipitation and no precipitation is drawn.

Figs. 1 and 2 show that no uranium(IV) phosphate precipitates from low concentrated solutions at high aluminium concentrations. Fig. 1 shows that, in chloride solutions, the boundary between precipitation and no precipitation decreases with increasing pH. Gelin [1] has in an unpublished article given an account of precipitation experiments with uranium chloride solutions with various concentrations of aluminium chloride and phosphoric acid. In diagrams with the aluminium concentration plotted against the phosphate concentration, Gelin obtained precipitation boundaries similar to those of Fig. 1. According to Fig. 2, a boundary with a pronounced peak within pH interval 0.7—1.2 is obtained in sulfate solutions.

Precipitation experiments have been performed on sulfate solutions with an addition of sodium, magnesium or iron(II) sulfate as ionic medium, Figs. 3, 4 and 5. These additions were so calculated that, at various concentrations of aluminium sulfate, the total concentration of sulfate in the different solutions remained constant = 1.4 mole/l. The experiments were carried out as before.

Figs. 2—5 show that the area for precipitation of uranium(IV) phosphate in sulfate solutions depends greatly on the ionic medium. The difference between sodium and magnesium sulfate as ionic medium is especially remarkable.

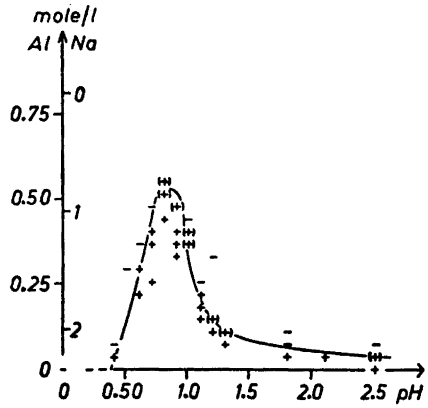

Fig. 3. Precipitation of uranium(IV) phosphate from sulfate solutions at various concentrations of aluminium. Sulfate concentration kept at 1.4 mole/l using Na_2SO_4.

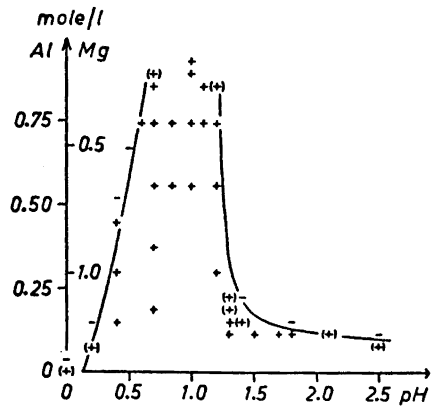

Fig. 4. Precipitation of uranium(IV) phosphate from sulfate solutions at various concentrations of aluminium. Sulfate concentration kept at 1.4 mole/l using $MgSO_4$.

PRECIPITATION YIELDS

In the above mentioned chloride solutions, the yield of precipitate is over 90 % in the greater part of the region where a precipitate is obtained. Not until the precipitation boundary is reached does the yield quickly decrease to zero. Corresponding conditions are obtained with sulfate solutions, with sodium, magnesium or iron(II) sulfate as ionic medium, on the right hand side of the peak. With magnesium sulfate as ionic medium, the following yields at pH 1.3, 1.8 and 2.5 were obtained, corresponding to the precipitation experiments shown in Fig. 4:

Al	Yield, %		
mole/l	pH 1.3	pH 1.8	pH 2.5
0.07			93
0.11	97	94	0
0.15	72	0	
0.19	90		
0.22	35		

In sulfate solutions without an extra addition of sulphate salt, the yields of uranium decrease more slowly with increasing concentration of aluminium. The corresponding precipitation experiments are shown in Fig. 2.

Al	Yield, %	
mole/l	pH 1.8	pH 2.5
0.07	97	96
0.15	95	66
0.30	85	40
0.45	30	
0.52	0	

On the left side of the peak in Figs. 2—5, the yields decrease slowly with increasing concentration of aluminium. In solutions without an extra addition of sulfate salt and also in solutions with magnesium sulfate, the following yields were obtained at pH 0.4. The corresponding points are found in Figs. 2 and 4.

Al mole/l	Yield, % No extra addition of sulfate	With $MgSO_4$ as ionic medium
0.07	94	
0.15	75	92
0.30	15	45
0.45		15

PRECIPITATE ANALYSES

Examinations in a Norelco Geiger-Counter X-Ray Diffractometer and in an electron microscope (10 000 ×) showed the precipitate to be amorphous.

A number of precipitates deposited from solutions at pH 0.4 have been analysed. The results are shown in Figs. 6—9. By means of the chloride analyses of the precipitates and the mother liquors, the compositions of the precipitates have been corrected for the amount of enclosed mother liquor using the rough assumption that Cl^- was not adsorbed on the precipitates to any appreciable extent. In chloride solutions containing 0.0025 M uranium(IV) chloride, 2.8 M sodium chloride, orthophosphoric and hydrochloric acids, the uranium phosphate precipitates with a composition of 2.1 mole phosphate/mole

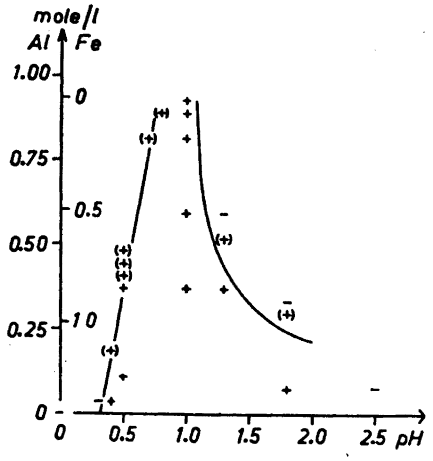

Fig. 5. Precipitation of uranium(IV) phosphate from sulfate solutions at various concentrations of aluminium. Sulfate concentration kept at 1.4 mole/l using $FeSO_4$.

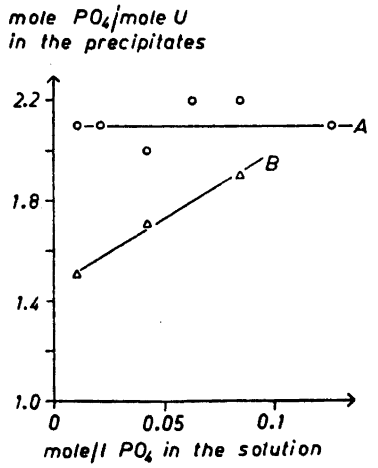

Fig. 6. Composition of uranium precipitates: A) The ratio PO_4:U in precipitates from solutions of uranium chloride with 2.8 M NaCl and various proportions of H_3PO_4. pH 0.4. B) The same solutions with an addition of 0.7 M $FeSO_4$.

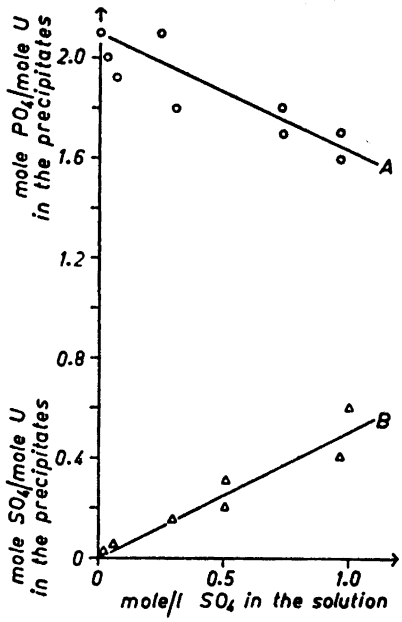

Fig. 7. The compositions of precipitates from solutions containing 0.0025 M UCl_4, 2.8 M NaCl, 0.04 M H_3PO_4 and various concentrations of sulfate. pH 0.4. A) The ratio PO_4:U in the precipitates. B) The ratio SO_4:U.

uranium irrespective of the phosphoric acid concentration in the solution (*cf.* Fig. 6). From the same chloride solutions but with an addition of *ca.* 0.7 M iron(II) sulfate, precipitates are obtained with a phosphate/uranium ratio which decreases as the phosphate concentration in the solution decreases. In solutions with the same phosphate concentration but with different sulfate concentrations, the precipitates according to Fig. 7 deposit, where the ratio mole phosphate/mole uranium decreases with increasing amount of sulfate in the solution. However, the ratio sulfate/uranium increases to the same extent so that the ratio (phosphate + sulfate)/uranium remains constant at 2.1.

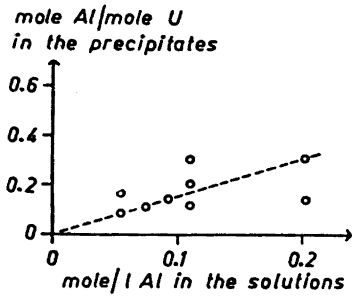

Fig. 8. The ratio Al:U in the precipitates from uranium chloride solutions with 2.8 M NaCl, 0.04 M H_3PO_4, various concentrations of $AlCl_3$ and pH 0.4.

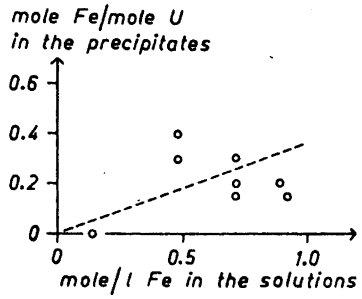

Fig. 9. The ratio Fe:U in the precipitates from solutions of uranium chloride with 2.8 M NaCl, 0.04 M H_3PO_4, various concentrations of $FeSO_4$ and pH 0.4.

According to Fig. 8, a larger amount of aluminium is obtained in the precipitate as the concentration of aluminium in the solution increases. With iron(II) sulfate in the solution, iron is also found in the precipitates. A comparison between washed and unwashed precipitates showed that the iron, but not the aluminium, can be removed by water.

EXTINCTIOMETRIC MEASUREMENTS

It was found that, in the greater part of the precipitation regions in Figs. 1—5, an initial opalescence or precipitation develops to complete visibility within 0.5—1.5 h. The time required has been measured from the moment when the reducing agent was added. In the chloride solutions, the precipitate shows a tendency to develop more rapidly than in the corresponding sulfate solutions. In the vicinity of the precipitation boundary, the precipitates do not become visible until after *ca.* 1.5—3.5 h.

Some preliminary complex investigations and measurements of reduction speed have been performed to find the reason for these long precipitation times. The experiments were performed in a Beckman spectrophotometer, model DU. The concentrations of the solutions were selected so that no precipitation was obtained during the reduction.

First, the extinction was measured at various wave-lengths on unreduced as well as reduced solutions containing 0.0075 M uranium chloride or uranium sulfate dissolved in 0.4 N hydrochloric acid or sulfuric acid respectively. Then the extinction was measured on the same solutions after the addition of the remaining components. The state of reduction and complexity for uranium were estimated by comparing the extinction curves obtained. These experiments were supplemented by a few measurements of the reduction speed, where the extinction was measured at 649 mμ as a function of the time elapsed from the addition of the reducing agent. In Fig. 10, where a few of the extinction curves obtained are shown, the curves A and B refer to the above mentioned reduced solutions containing uranium chloride and sulfate, respectively. Curve C is the extinction curve for the same reduced uranium chloride solution as in curve A but with an addition of 0.5 M aluminium chloride and 0.1 M orthophosphoric acid.

According to Rodden [4], curve A is typical for the extinction of uranium(IV) chloride in strong hydrochloric acid solutions. Not only are the extinction peaks at 429.5 mμ, 549 mμ and 649 mμ characteristic but also the shape of the peak at 485—495 mμ and the small extra peak at 672 mμ. The same curves are obtained with uranium(IV) perchlorate. This indicates that uranium(IV) is present mainly as free ions in the solutions.

According to Betts and Leigh [2], uranium(IV) forms very strong complexes with sulfate. Curve B is characteristic for these complexes. The shape of the peak at 485—495 mμ is especially remarkable. In addition, the highest peak is lower than that for the chloride solutions and moved from 649 mμ to 651 mμ. The small peak at 672 mμ was not found.

During measurements on 0.0075 M uranium(IV) chloride solutions containing 2.8 M sodium chloride, it was proved that the extinction curve typical for sulfate solutions was obtained on the addition of 0.1 M sodium sulfate. This is also evidence for no, or only weak, complexes between uranium(IV) and chloride.

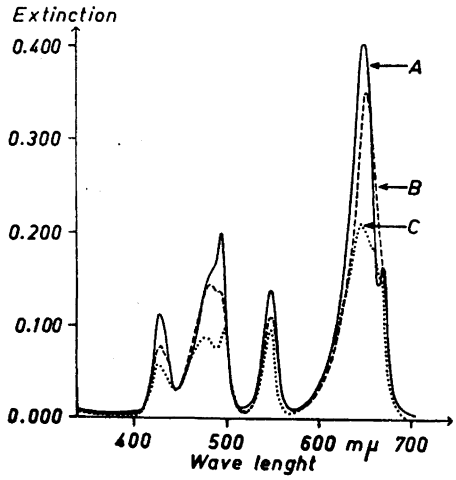

Fig. 10. Extinction curves of a few uranium(IV) solutions. A) 0.0075 M UCl_4 in 0.4 N HCl. B) 0.0075 M $U(SO_4)_2$ in 0.4 N H_2SO_4. C) 0.0075 M UCl_4, 0.5 M $AlCl_3$, 0.1 M H_3PO_4 and HCl to pH 0.4. The measurements were performed in 10 mm cuvettes.

Curve C, Fig. 10 is characteristic for the soluble uranium(IV) phosphate complexes that were obtained in connection with the precipitation experiments. Especially notable is the double peak at 479 and 498 mμ and the great decrease in the peak at 650 mμ. In those cases where it was impossible to determine whether the change in the extinction curves was due to incomplete reduction or complex formation, measurements were performed on solutions where the uranium was reduced before as well as after the addition of the remaining components. If the extinction curves from solutions reduced *before* the addition of remaining components agree with those from solutions reduced *after* the addition, then any differences between these extinction curves and the corresponding curves from solutions *without* addition cannot be caused by incomplete reduction. The difference must then be due to complex formation in the solutions.

The important results from experiments on precipitation of uranium as uranium(IV) orthophosphate from acid solution can be summed up as follows:

a) In the solutions used for precipitation experiments according to Figs. 1—5, uranium(IV) is reduced completely or almost completely to uranium(IV) even in the cases where no precipitate is obtained.

b) The long times for precipitation are due not to the rate of reduction but to difficulties of precipitate development.

c) In chloride solutions, the extinction curves typical for the actual uranium(IV) phosphate complexes are found in the region where, according to Fig. 1, no precipitate is formed.

d) In sulfate solutions, the uranium is complex-bound in the region for no precipitation on the right hand side of the peak in Figs. 2—5, in the same way as in chloride solutions. However, on the left hand side of the peak, the uranium in sulfate solutions mainly exists as soluble uranium(IV) sulfate complexes.

CALCULATION OF THE PRECIPITATION BOUNDARY IN FIG. 1 VALID FOR CHLORIDE SOLUTIONS

Figs. 1 and 2 show that the precipitation conditions are simpler in chloride solutions than in corresponding sulfate solutions. The extinction curves obtained do not indicate that uranium(IV) forms complexes with chloride. However, uranium does form very strong complexes with sulfate [2]. When calculating the complex ratio of uranium in chloride solutions, the possible presence of uranium(IV) chloride complexes may therefore be disregarded, whereas the complexes between uranium(IV) and sulfate must be considered when calculating the ratio in sulfate solutions. Only the conditions in chloride solutions are discussed here. The calculations below should give an explanation of the form of the precipitation boundary in Fig. 1 as well as of the precipitation yield, which is over 90 % within the whole precipitation region except for a small section near the precipitation boundary where the yield quickly decreases to zero.

The calculations have been based upon the assumption that soluble double complexes between uranium(IV), aluminium and phosphate prevent the uranium phosphate from precipitating.

In the calculations, consideration has been taken only of possible complexes between uranium, aluminium and phosphate, while all the possible complexes with remaining ions are neglected. No consideration has been taken of activity factors, hydrolysis (the actual pH-range is below 2) or of the fact that the salt concentrations have not been kept constant in the experiments in Fig. 1 with which the calculated precipitation boundaries are compared.

The following complexes between uranium and phosphate are conceivable: With one uranium ion in each complex, such as $U(H_2PO_4)_n$, $U(HPO_4)_n$ and $U(PO_4)_n$, with several uranium ions such as $U_m(H_2PO_4)_n$, $U_m(HPO_4)_n$ and $U_m(PO_4)_n$ or mixed complexes such as $U_m(H_2PO_4)_n(HPO_4)_{n'}(PO_4)_{n''}$. The complexes found in the solutions can be designated by the formula $U_m(H_pPO_4)_n$ where $m = 1, 2, 3, \ldots$, $n = 1, 2, 3, \ldots$ and p is continuously variable between 0 and 2. The total concentration is denoted here by $\Sigma[U_m(H_pPO_4)_n]$.

The corresponding complexes between aluminium and phosphate are conceivable and may be collected together in the general formula $Al_q(H_tPO_4)_r$. The total concentration of these complexes is written $\Sigma[Al_q(H_tPO_4)_r]$.

Conceivable complexes between uranium, aluminium and phosphate may be collected together in the general formula:

$$U_xAl_y(H_zPO_4)_w^{+4x+3y+wz-3w},$$

which is shortened below to $U-Al-PO_4$. The total concentration of these complexes is written $\Sigma[U-Al-PO_4]$. The complexity constants are obtained from the formula:

$$[U-Al-PO_4] \,/\, [U^{4+}]^x \cdot [Al^{3+}]^y \cdot [H_zPO_4^{-3+z}]^w = K_{x,y,w} \qquad (1)$$

According to Fig. 6, uranium(IV) precipitates from a chloride solution as phosphate with a composition approximately corresponding to the formula $U(HPO_4)_2$. Hence we obtain the following equation for the solubility product L:

$$[U^{4+}] \cdot [HPO_4^{2-}]^2 = L \qquad (2)$$

If the complexity constants for the aluminium phosphate complexes are denoted by $k_{q,r}$, the following equation is obtained:

$$[Al_q(H_tPO_4)_r] = k_{q,r} \cdot [Al^{3+}]^q \cdot [H_tPO_4^{-3+t}]^r \qquad (3)$$

If the total concentrations of uranium, aluminium and phosphoric acid are written C_U, C_{Al} and C_{PO_4}, respectively, the following formulas are obtained:

$$C_U = [U^{4+}] + \Sigma m[U_m(H_pPO_4)_n] + \Sigma x[U-Al-PO_4] \quad (4)$$

$$C_{Al} = [Al^{3+}] + \Sigma q[Al_q(H_tPO_4)_r] + \Sigma y[U-Al-PO_4] \quad (5)$$

$$C_{PO_4} = [H_3PO_4] + [H_2PO_4^-] + [HPO_4^{2-}] + [PO_4^{3-}] + \\ + \Sigma r[Al_q(H_tPO_4)_r] + \Sigma n[U_m(H_pPO_4)_n] + \Sigma w[U-Al-PO_4] \quad (6)$$

In uranium(IV) chloride solutions not containing aluminium, the uranium phosphate precipitates almost to 100 %. In sulfate solutions not containing aluminium, a complete yield is also obtained within a favourable pH range. According to Betts and Leigh [2], uranium(IV) forms very strong complexes with sulfate. Consequently the solubility product must be very small and the concentration of soluble uranium phosphate complexes must be low. In eqn. (4), $[U^{4+}]$ and $\Sigma m[U_m(H_pPO_4)_n]$ may be disregarded in comparison with the double complexes. Since it cannot be determined from the empirically found precipitation boundary whether one or several uranium ions are found in each double complex, it may be assumed that only one uranium ion is present in each complex, consequently $x = 1$. The low uranium concentrations in the solutions are in evidence for this assumption. It may further be assumed that one of the double complexes present is so dominant that the remainder can be overlooked. On applying these simplifications we obtain:

$$C_U \approx [U-Al-PO_4] \quad (7)$$

Similarly, one of the aluminium phosphate complexes present in the solutions may be assumed so dominant that the remainder can be neglected. This complex is assumed as simple as possible, *i. e.* $AlHPO_4^+$. Eqn. (3) is then:

$$\Sigma[Al_q(H_tPO_4)_r] \approx [AlHPO_4^+] = k_{1,1} \cdot [Al^{3+}] \cdot [HPO_4^{2-}] \quad (8)$$

In eqn. (6), $[HPO_4^{2-}]$ and $[PO_4^{3-}]$ may be neglected since the pH range is below 2.5. The uranium phosphate complexes may be neglected for the same reason as in eqn. (3). On applying these simplifications the following equations are obtained:

1) For soluble complexes of the type $UAl_y(PO_4)_w^{+4+3y-3w}$:

$$C_{Al} = \left(\frac{C_U}{K_{1,y,w} \cdot L}\right)^{\frac{1}{y}} \cdot [HPO_4^{2-}]^{\frac{2-w}{y}} \cdot (1 + k_{1,1} \cdot [HPO_4^{2-}]) \cdot \left(\frac{k_s'''}{\{H^+\}}\right)^{\frac{y}{w}} + yC_U \quad (9)$$

2) For soluble complexes of the type $UAl_y(HPO_4)_w^{+4+3y-2w}$:

$$C_{Al} = \left(\frac{C_U}{K_{1,y,w} \cdot L}\right)^{\frac{1}{y}} \cdot [HPO_4^{2-}]^{\frac{2-w}{y}} \cdot (1 + k_{1,1} \cdot [HPO_4^{2-}]) + yC_U \quad (10)$$

3) For soluble complexes of the type $UAl_y(H_2PO_4)_w^{+4+3y-w}$:

$$C_{Al} = \left(\frac{C_U}{K_{1,y,w} \cdot L}\right)^{\frac{1}{y}} \cdot [HPO_4^{2-}]^{\frac{2-w}{y}} \cdot (1 + k_{1,1} \cdot [HPO_4^{2-}]) \cdot \left(\frac{k_s''}{\{H^+\}}\right)^{\frac{w}{y}} + yC_U \quad (11)$$

$[HPO_4^{2-}]$ is obtained from the equation:

$$k_{1,1} \cdot \left(\frac{\{H^+\}^2}{k_s' \cdot k_s''} + \frac{\{H^+\}}{k_s''}\right) \cdot [HPO_4^{2-}]^2 + \\ + \left(\frac{\{H^+\}^2}{k_s' \cdot k_s''} + \frac{\{H^+\}}{k_s''} + k_{1,1} \cdot (C_{Al} - C_{PO_4} + wC_U - yC_U)\right) \cdot [HPO_4^{2-}] = C_{PO_4} - wC_U \quad (12)$$

where $k_s' = \{H^+\} \cdot [H_2PO_4^-]/[H_3PO_4]$, $k_s'' = \{H^+\} \cdot [HPO_4^{2-}] / [H_2PO_4^-]$,

$k_s''' = \{H^+\} \cdot [PO_4^{3-}] / [HPO_4^{2-}]$ and $-\log\{H^+\} = pH$.

From eqns. (9)—(12), $C_{Al} = f(\{H^+\})$ is obtained by inserting various values for y and w at constant concentrations of uranium and phosphate. In Figs. 13—15, precipitation boundaries with 0% yields are shown, calculated with $C_U = 0.0017$ mole/l and $C_{PO_4} = 0.042$ mole/l. In eqns. (9)—(12), the complexity constant for aluminium phosphate is included. Bjerrum and Dahm [3] have examined complex formations in acid solutions with low concentrations of aluminium, an excess of phosphate and low salt concentrations. From the complexity constants obtained, $k_{1,1}$ is calculated to be 7.2×10^7 l/mole. A determination in solutions containing 2.8 M sodium chloride as ionic medium, made for the calculations mentioned below, gave $k_{1,1} = 3.3 \times 10^7$ l/mole. In the precipitation experiments according to Fig. 1, the salt concentrations in the solutions varied between the concentrations used in the two determinations of $k_{1,1}$ mentioned above. Thus the average value 5×10^7 l/mole is used here.

The dissociation constant of the orthophosphoric acid k_s' was taken to be 8×10^{-2} l/mole, k_s'' to be 6×10^{-8} l/mole and k_s''' to be 5×10^{-13} l/mole.

In eqn. (12), the factors wC_U and $(w-y) \cdot k_{1,1} \cdot C_U$ can be neglected. In this equation, C_{Al} is included as a correction factor. These values of C_{Al} at various pH values are taken from Fig. 1. Such a correction is not accurate in cases where the calculated precipitation boundary does not agree with the experimental one but this is of course of no importance here.

The factor $(C_U/K_{1,y,w}.L)^{\frac{1}{y}} = a_{y,w}$ included in eqns. (9)—(11) is calculated from these equations at $C_{Al} = 0.31$ mole/l, $C_{PO_4} = 0.042$ mole/l and pH = 0.4 corresponding to point A in Figs. 13—15.

In Fig. 11, some precipitation boundaries for uranium(IV) orthophosphate, based on point A and under the assumption of a few simple soluble double complexes of the type $UAl_y(HPO_4)_w^{+4+3y-2w}$, are found. The figure shows that soluble complexes of this type give a boundary close to the experimental one

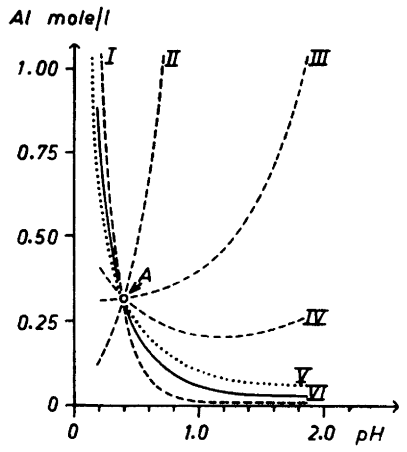

Fig. 11. A few calculated precipitation boundaries under assumption of soluble complexes of the type $UAl_y(HPO_4)_w^{+4+3y-2w}$. I) $UAl(HPO_4)_4^-$; II) $UAlHPO_4^{5+}$; III) $UAl_2(HPO_4)_2^{6+}$; $UAl(HPO_4)_2^{3+}$; IV) $UAl_3(HPO_4)_3^{7+}$; V) By Fig. 1; VI) $UAl(HPO_4)_3^+$, $UAl_y(HPO_4)_{y+2}^{+y}$.

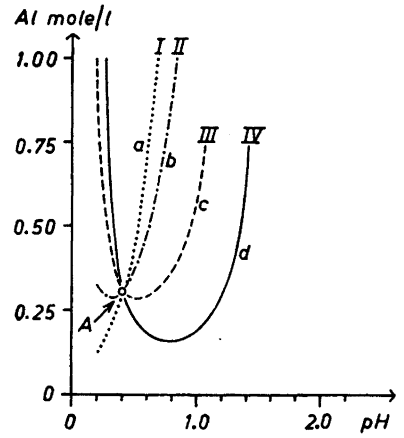

Fig. 13. A few precipitation boundaries calculated under the assumption of soluble complexes of the type $UAl_y(H_2PO_4)_w^{+4+3y-w}$. I) $UAl(H_2PO_4)_2^{5+}$; II) $UAl(H_2PO_4)_4^{3+}$, III) $UAl(H_2PO_4)_6^{+}$; IV) $UAl(H_2PO_4)_8^{-}$.

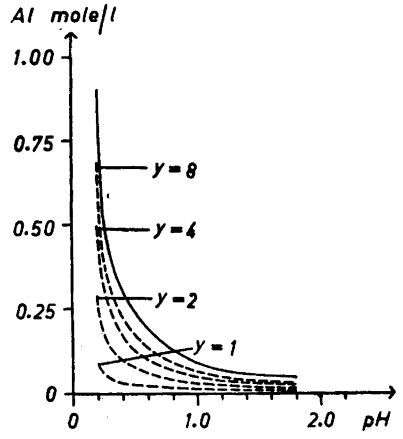

Fig. 14. A few calculated boundaries for 90 % precipitate yield (dashed curves). The continuous line is the experimentally found boundary for a 0 % yield.

if $w \approx y + 2$, *i. e.* the following complex: $UAl_y(HPO_4)_{y+2}^{+y}$. If $w > y + 2$, the curve increases too rapidly with decreasing pH compared with the experimental one while, if $w < y + 2$, it increases too slowly.

If a different point than point A in Figs. 11—13 is chosen as basis for the calculations, only a parallel shift of the calculated precipitation boundary is obtained.

In Fig. 12, the precipitation boundaries for uranium phosphate have been calculated under the assumption of a few soluble complexes of the type $UAl_y(PO_4)_w^{+4+3y-3w}$. The figure shows, that complexes of this type give a precipitation boundary close to the experimental one for the following cases: a) when $y = 1$, $w = 1$, *i. e.* $UAl(PO_4)_2^{+}$, b) when $y = w \geqq 3$ and c) for higher values of y and w when $y \approx w$, *i. e.* the following complexes: $UAl_y(PO_4)_y^{4+}$.

According to eqn. (11), the following equation applies for soluble complexes of the type $UAl_y(H_2PO_4)_w^{+4+3y-w}$:

$$C_{Al} = \beta_{y,w}\,[HPO_4^{2-}]^2 \cdot (1 + k_{1,1}\,[HPO_4^{2-}]) \cdot ([HPO_4^{2-}] \cdot \{H^+\})^{-\frac{w}{y}} + yC_U \quad (13)$$

$$\text{where } \beta_{y,w} = (C_U/K_{1,y,w} \cdot L)^{\frac{w}{y}} = \text{a constant.}$$

In eqn. (13), the expression $[HPO_4^{2-}]^2 \cdot (1 + k_{1,1} \cdot [HPO_4^{2-}])$ increases rapidly with increasing pH. However, the expression $([HPO_4^{2-}] \cdot \{H^+\})$ increases slowly with pH. In order that C_{Al} in eqn. (13) shall decrease with increasing pH, it is necessary that quotient w/y should be large. In Fig. 13, curve a shows the calculated precipitation boundary for $w/y = 2$, curve b for $w/y = 4$, curve c

for $w/y = 6$ and curve d for $w/y = 8$. It is seen that soluble complexes of the type $UAl_y(H_2PO_4)_w^{+4+3y-w}$ cannot give a precipitation boundary similar to the experimental one.

In Figs. 11—13, the precipitation boundaries are calculated so that precipitation just begins for the appropriate solution or *i. e.* so that the yield is 0 %. In the following, the boundary is calculated on the basis of a yield of 90 %.

In Fig. 1, the yield is more than 90 % for the precipitation region and decreases rapidly near the boundary to zero. When calculating the HPO_4^{2-} concentration at various pH, C_{Al} is included only as a term of correction. Hence, during the calculation of the precipitation boundary, the same HPO_4^{2-} concentrations can be used in eqns. (9)—(11) independent of the yield.

If the total uranium(IV) concentration in the solutions at a certain precipitate yield is denoted by C'_U, the corresponding a-value by $a'_{y,w}$ and the corresponding values at 0 % yield by C_U^{tot} and a_U^{tot}, respectively, the following equation is obtained from the relation $a_{y,w} = (C_U/K_{1,y,w} \cdot L)^{\frac{1}{y}}$:

$$a'_{y,w} = \left(\frac{C'_U}{C_U^{tot}}\right)^{\frac{1}{y}} \cdot a_{y,w}^{tot} \tag{14}$$

The precipitation boundary at a certain yield is obtained from eqn. (10):

$$C'_{Al} = a'_{y,w} \, [HPO_4^{2-}]^{\frac{2-w}{y}} (1 + k_{1,1} \cdot [HPO_4^{2-}]) + yC'_U \tag{15}$$

If the aluminium concentration in the solutions at 0 % yield is denoted by C_{Al}^{tot}, one obtains:

$$C_{Al}^{tot} = a_{y,w}^{tot} \cdot [HPO_4^{2-}]^{\frac{2-w}{y}} \cdot (1 + k_{1,1} \cdot [HPO_4^{2-}]) + yC_U^{tot} \tag{16}$$

From eqns. (14), (15) and (16) one obtains the expression:

$$C'_{Al} = (C_{Al}^{tot} - y \cdot C_U^{tot}) \cdot \left(\frac{C'_U}{C_U^{tot}}\right)^{\frac{1}{y}} + yC'_U \tag{17}$$

If eqn. (9) or (11) is used instead of eqn. (10), it is seen that eqn. (17) is true for the three complex types $UAl_y(PO_4)_w^{+4+3y-3w}$, $UAl_y(HPO_4)_w^{+4+3y-2w}$ and $UAl_y(H_2PO_4)_w^{+4+3y-w}$.

At a 90 % precipitation yield the following values apply at the concentrations used in the experiments: $C_U^{tot} = 0.0017$ mole/l and $C'_U = 0.00017$ mole/l. C_{Al}^{tot} at various pH values is obtained from Fig. 1.

Eqn. (17) shows that the greater the number of aluminium ions in the double complexes the closer the boundary for 90 % precipitate yield approaches the boundary for 0 % yield. In Fig. 14 the boundary for a 90 % yield is calculated for complexes with 1, 2, 4 and 8 aluminium ions. Complexes with 6—8 aluminium or more correspond best with the experimentally found precipitate yields.

According to Figs. 11 and 12, both $UAl_y(HPO_4)_w^{+4+3y-2w}$ and $UAl_y(PO_4)_w^{+4+3y-3w}$ can be used to explain the precipitation boundary in chloride solutions. The main part of the double complexes is probably of the type $UAl_y(HPO_4)_w^{+4+3y-2w}$ since the actual pH range is 0.1—2.5. The precipitate yields obtained indicate indirectly a maximum number of phosphate around each

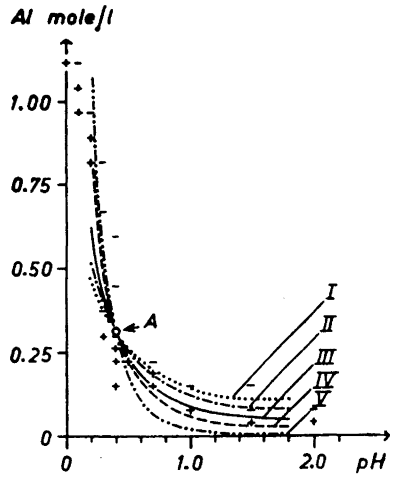

Fig. 15. Calculated precipitation boundaries under assumption of soluble complexes of the type $UAl_y(HPO_4)_8^{+3y-12}$. I) $UAl_{12}(HPO_4)_8^{24+}$; II) $UAl_{10}(HPO_4)_8^{18+}$; III) $UAl_8(HPO_4)_8^{12+}$; IV) $UAl_6(HPO_4)_8^{6+}$; V) $UAl_4(HPO_4)_8$.

uranium atom. The distance U—O in uranium dioxide [5] is 2.34 Å and distance P—O in phosphate [6] 1.56—1.69 Å. This shows that around each uranium(IV), there is sufficient space for a maximum of 8 phosphate groups. This would correspond to complexes of the type $UAl_y(HPO_4)_8^{+3y-12}$. Fig. 15 shows a few precipitation boundaries calculated using complexes of this type. The figure shows that the formulas $UAl_6(HPO_4)_8^{6+}$ and $UAl_8(HPO_4)_8^{12+}$ give the best fit with the experimentally found precipitation boundary.

The distances between the aluminium ions and the phosphate groups in the above mentioned complexes are too great for a stable complex to be formed. According to tests with models on the other hand, a stable complex with the formula $UAl_8(HPO_4)_8(H_2O)_{12}^{12+}$ is possible, where each aluminium is surrounded octahedrally by 2 water units and 4 oxygens from 2 phosphate groups.

In a solution with 0.0025 M uranium(IV)sulfate, 0.8 M sodium sulfate and sulfuric acid to pH 0.4, no precipitate was obtained with a concentration of 0.0105 M phosphoric acid, with 0.046 M 86 % yield and with 0.084 M phosphoric acid 96 %. If the complexity constant for $[USO_4^{2+}] / [U^{4+}] . [SO_4^{2-}] =$ 1 740 l/mole (Betts and Leigh [2]) and the dissociation constant for $HSO_4^- = 10^{-2}$ l/mole and the dissociation constant for $H_3PO_4 = 7.5 \times 10^{-3}$ l/mole and that for $H_2PO_4^- = 6.2 \times 10^{-8}$, then the solubility product may be estimated from the above mentioned precipitation yields:

$$L = [U^{4+}] . [HPO_4^{2-}]^2 \approx 10^{-25} \text{ (mole/l)}^3$$

If the complex $UAl_8(HPO_4)_8^{12+}$ represents all the forms of double complexes that may give an explanation of the precipitation boundary obtained in chloride solutions, then the complexity constant for this complex may be estimated to be:

$$K_{1,8,8} = \frac{[UAl_8(HPO_4)_8^{12+}]}{[U^{4+}] . [Al^{3+}]^8 . [HPO_4^{2-}]^8} \approx 10^{82} \text{ (l/mole)}^{16}$$

CONCLUSIONS

In acid *chloride* solutions containing 0.0017 M uranium(IV) chloride and 0.042 M orthophosphoric acid but different concentrations of aluminium chloride and different pH values, it was found that uranium phosphate precipitates only within an area marked with + in Fig. 1. Within the greater part of this area, the precipitate yield is over 90 %. The precipitates are amorphous with a somewhat variable composition, corresponding approximately to the formula $U(HPO_4)_2$. According to certain extinction measurements, the uranium phosphate is prevented from precipitating by some soluble uranium(IV) phosphate complexes. A plausible explanation of the precipitation boundary in Fig. 1 is that these complexes are double complexes of uranium, aluminium and phosphate. Calculations show that the following types of complexes give a precipitation boundary corresponding well with the experimental one, considering the conditions under which this boundary was obtained:

a) $UAl_y(HPO_4)_w^{+4+3y-2w}$ where $\frac{2-w}{y} = -0.9 \pm 0.3$

b) $UAl_y(PO_4)_w^{+4+3y-3w}$ where $w/y = -1 \pm 0.3$

Complexes of the type $UAl_y(H_2PO_4)_w^{+4+3y-w}$ cannot give a precipitation boundary similar to the experimental one.

Since the actual pH range is 0.1—2.5 the double complexes are probably mainly of the type $UAl_y(HPO_4)_w^{+4+3y-2w}$. The more aluminium ions there are in the complex, the smaller is that region in the neighbourhood of the precipitation boundary where the precipitation yield falls from over 90 % to zero. Thus, in order to correspond to the precipitation yields obtained, the number of aluminium ions in the complex and hence also the number of phosphate groups must be considered to be as large as possible. Since 8 phosphate groups is the maximum number which can be accommodated around each uranium(IV) ion, this indicates that complexes of the type $UAl_y(HPO_4)_8^{+3y-12}$. Of these complexes, $UAl_6(HPO_4)_8^{6+}$ and $UAl_8(HPO_4)_8^{12+}$ fit in best with the experimentally determined precipitation boundary in acid chloride solutions.

From *sulfate* solutions containing 0.0017 M uranium(IV) sulfate and 0.042 M orthophosphoric acid but different concentrations of aluminium sulfate and different pH values, it was found that there exists a boundary (*cf.* Fig. 2) for the precipitation of uranium phosphate which has a pronounced peak at pH 0.7—1.2. Corresponding precipitation boundaries were found on adding sodium, magnesium or iron(II) sulfate as ionic medium.

A plausible explanation of the precipitation boundary in Figs. 2—5 is that, at pH values to the *right* of the peak, the uranium is prevented from precipitating because of the same soluble double complexes between uranium(IV), aluminium and phosphate as those in the chloride solutions. The shape of the curve, the precipitate yields and the extinction measurements are all in favour of this. A calculation on this part of the boundary may however be more complicated than for chloride solutions since, besides allowing for the presence of uranium and aluminium sulfate complexes, it must also be considered that the uranium does not precipitate as pure phosphate but as phosphate-sulfate: $U(HPO_4,SO_4)_2$.

At pH values to the *left* of the peak, the uranium is prevented from precipitating by uranium(IV) complexes with sulfate. With decreasing pH, the HPO_4^{2-} content decreases faster than the SO_4^{2-} content, for which reason the possibility of reaching the solubility product of the uranium(IV) phosphate decreases quicker than that for forming soluble uranium sulfate complexes. From Figs. 2—5, it is clear that, even in this part of the pH range other factors must play a part, *inter alia* the double complexes mentioned above.

The author wishes to thank the head of the Department, Professor Otto Stelling, for suggesting this topic of research, for his encouraging help and advice during the investigations and for his kind permission to publish this article. Thanks are also due to Professor Arne Ölander for many helpful discussions. Financial aid for this investigation has been provided by *A/B Atomenergi*, Stockholm. Tekn. lic. Erik Svenke is thanked for his kind help with the application for A/B Atomenergi's authorization for publication.

Haemoglobin Present in the Nuclear Fraction of the Liver

R. BONNICHSEN, G. EHRENSTEIN, G. HEVESY and J. SCHLIACK

Institute for Organic Chemistry and Biochemistry, University of Stockholm, Sweden

The nuclear fraction of 1 g of rat and rabbit liver contains 0.34 and 0.58 mg of in aqueous medium non-extractable haemoglobin. The corresponding figure for the nuclei of the red corpuscles of 1 ml of hen's blood is 0.9 mg.

The haemoglobin content of the nuclear fraction of 1 g of foetal rabbit liver is 100 times as large as that of 1 g of maternal liver. The ratio of their ^{59}Fe content 11 to 17 h after labelling the maternal plasma iron, works out to be 100.

One day or more after exposure of the rat to 500 r, incorporation of ^{59}Fe into the non-extractable haemoglobin of the liver nucleus fraction is strongly depressed.

As mentioned in a previous note (Bonnichsen *et al.*[1]) the nuclear fraction of the liver of the guinea-pig contains small amounts of haemoglobin not extractable by saline or other aqueous solutions. This paper contains data on the incorporation of ^{59}Fe into this fraction isolated from the liver of adult rats and rabbits and of that of the rabbit embryo. This fraction was furthermore located in the nuclei of the erythrocytes of the hen.

That in the basophilic erythroblasts of human and rat bone marrow the site of haemoglobin synthesis is primarily the nucleus, was repeatedly suggested. The methods applied in these investigations were ultraviolet absorption microspectroscopy and cytochemical staining procedures [2–9].

EXPERIMENTAL

In 15 experiments with male rats an aggregate number of 173 animals, weighing between 150—280 g were injected intraperitoneally with 0.25 ml of a 3.8 % ammonium-citrate solution containing 0.5—12 μg of with ^{59}Fe labelled iron of 0.1—12 μC activity. Half the number of rats was exposed to 150 *r* — 500 *r* of X-rays. Injection took place 15 min to 5 days after exposure.

The animals were killed from 2 to 48 h after injection. The livers were perfused first with 0.145 M NaCl and then with 0.25 M sucrose containing 0.018 m $CaCl_2$. The weighed livers were homogenized in 9 vols. of 0.25 M sucrose — 0.0018 M $CaCl_2$. The further procedure was carried out according to Hogeboom *et al.*[10]

The nuclear fraction isolated by this procedure was cytologically inhomogeneous. The fraction contained about 60—80 % of the cell nuclei, it also contained erythrocytes, connective tissue, residual intact cells and free mitochondria.

In order to haemolyze the erythrocytes, the fraction was homogenized with 10 vols. distilled water and allowed to stand several hours. This last step was repeated at least three times more.

After clearing the suspension of nuclei obtained in this way by adding 3 % of deoxycholate, the haemoglobin bands were steadily visible in the handspectroscope. The CO-band was that of haemoglobin. The pyridine-haemochromogen band was located at 557 mμ.

The haemin was extracted with a mixture of acetone and HCl (10 ml 20 % HCl in 1 l of acetone). After filtration, the acetone was evaporated *in vacuo*. The haemin was crystallized twice from conc. acetic acid, and the crystals washed with 1 N HCl. The haemin was then combusted and the solution analyzed as described by Bonnichsen *et al.*[11]

In order to know in which part of the above nuclear fraction the non-extractable haemoglobin is located, we separated the fraction, prior to haemolyzing the red cells with distilled water, in the counter-streaming centrifuge of Lindahl [12] in five fractions containing particles of different size and different specific gravity. The fractions were examined with the phase-contrast microscope and with the handspectroscope. Thereafter, the specific activity of their haemin was determined. The result of one of these experiments is seen in Fig. 1.

In five of the above experiments of the liver nuclei have been isolated both in aqueous medium and in organic solvents of low polarity according to the methods described by Dounce *et al.*[13] and Allfrey *et al.*[14] The nuclear preparations obtained in this way were treated and analysed as described above. No difference was found in the properties of the non-extractable haemoglobin of the nuclear fraction prepared either in aqueous or in organic medium.

The liver ferritin was prepared as previously described by Loftfield *et al.*[15]

In experiments with 2—3 kg rabbits 8 animals were investigated. Their plasma was labelled with ^{59}Fe as described by Ehrenstein *et al.*[16] and reinjected. The animals were killed 3—24 h after injection.

Simultaneously, in all our experiments haemin of the circulating haemoglobin was analysed as well.

In two experiments with hens 100 ml of hen blood were incubated *in vitro* for 3 h at 37° C with 2 ml of 3.8 % ammonium citrate solution containing 2 μg labelled iron of 25 μC activity. The plasma was centrifuged off and the red cells washed four times with 5 vols. or more of isotonic saline.

The erythrocyte nuclei were prepared according to Hogeboom *et al.*[10] However, as the red cells are not sufficiently broken down by the homogenization procedure usually employed for the disintegration of other tissues, we haemolyzed the cells by freezing at —20° C and thawing them three times or more, suspended in a mixture of 0.25 M sucrose — 0.00018 m $CaCl_2$. The nuclei were then centrifuged down (International Refrigerated centrifuge head No. 269) for 10 min at 2 000 r.p.m. Thereafter, the procedure of Hogeboom *et al.*[10] was applied. Samples were taken from the whole washed red cells, the stroma-free haemolysate and from the final nucleus preparation. The haemin was extracted as described above.

RESULTS AND DISCUSSION

a) *Experiments with rats.*

The amount of ^{59}Fe present in one μg of iron of the nuclear haemoglobin fraction of the liver varied in experiments on rats between 0.6×10^{-4} and 10×10^{-4} % of that injected.

The liver of our rats contained 10 μg of nuclear haemin iron out of 2.5 mg of total iron present in the liver. This fraction makes out 0.4 % of its total iron content.

In the course of the purification process in aqueous medium extractable haemoglobin may have been removed. However, the non-extractable haemoglobin content of the nuclei was not found to be larger when the nuclei were

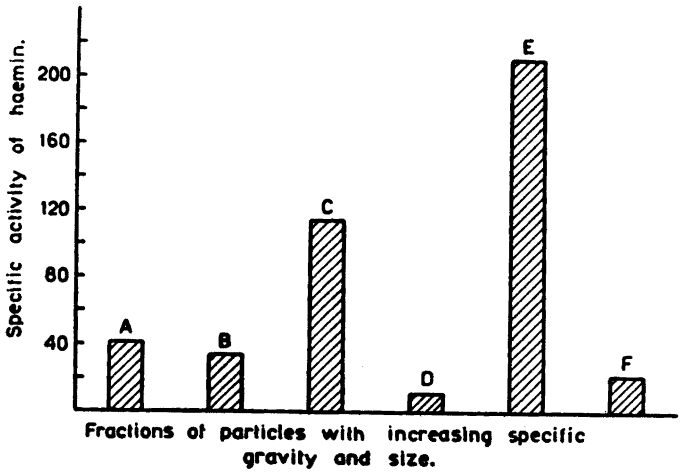

Fig. 1. Results of separation of nuclear components of the liver cells of the rat in Lindahls counter-streaming centrifuge.

E = Small nuclei.
F = Large nuclei.

isolated after lyophilisation in organic medium. In the haemoglobin content of the nuclear fraction of the red cells of the hen, when these were isolated in an organic medium, Stern *et al.*[17] found a haemoglobin-iron content of 19 % of that of the total red corpuscle, while we find after isolation of the nuclei in an aqueous medium 1 % of the total haemoglobin-iron content to be non-extractable. This 1 % compares with 0.4 % found by us in the liver nuclei of rats and 2 % in those of the rabbit.

We compared also the effect of irradiation with 500 *r* of X-rays on rats on the incorporation of ^{59}Fe into the liver nuclear haemoglobin fraction. As seen in Table 1 the X-ray effect is shortly after exposure a very restricted one for both haemoglobin fractions. The X-ray effect as seen in Fig. 2 doesn't seem as pronounced as that on the circulating haemoglobin. If we, however, take into account the enhanced activity of the liver of the exposed animal, this difference is strongly reduced.

b) *Experiments with rabbits.*

The amount of ^{59}Fe present 4 h after injection in one μg iron of the non-extractable haemoglobin of the nuclear fraction of the rabbit liver varied between 2×10^{-4} and 6×10^{-4} % of that injected.

The iron content of the non-extractable liver nucleus fraction haemoglobin varied between 0.5 and 3.8 μg with a mean value of 1.9 μg per one g liver.

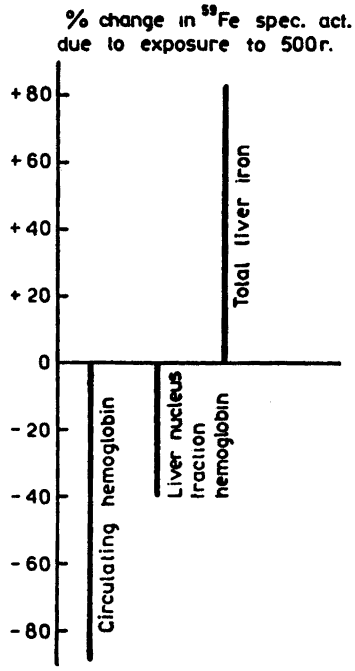

Fig. 2. Effect of exposure of the rat to whole body irradiation on the incorporation of intraperitoneally injected ^{59}Fe as citrate into liver fractions and the circulating haemoglobin.

For the nuclear haemoglobin content of 1 g of rat and rabbit liver the corresponding figures are 0.38 mg and 0.56 mg.

We also carried out experiments with pregnant rabbits 21 days after mating. A plasma sample of the mother was labelled as described by Ehrenstein *et al.*[16] The livers of the mothers and foetuses were investigated 11 to 17 h after labelling the maternal plasma. The results are seen in Table 2.

Table 1. Ratio of specific activities of iron fractions of to 500 *r* exposed and control rats.

Injected with ^{59}Fe shortly after exposure			Injected with ^{59}Fe 1 day or more after exposure		
Liver nucleus fraction haemoglobin	Circulating haemoglobin	Total liver iron	Liver nucleus fraction haemoglobin	Circulating haemoglobin	Total liver iron
1.16	0.53	1.60	0.915	0.161	1.15
0.97	1.04	1.41	0.503	0.063	2.48
1.15	0.84	0.93	0.570	0.238	1.72
0.78	0.46	1.27	0.727	0.072	1.92
			0.318	0.029	2.44
Mean value 1.01	0.72	1.30	0.605	0.112	1.94

Table 2.

	Mother	Foetus
Total liver iron	13.9 mg	1.5 mg
Total non-extractable liver nuclear haemoglobin iron	24 μg	41 μg
Total liver activity in % of that injected	8	20
Total non-extractable liver nuclear haemoglobin activity in % of that injected	3.4×10^{-3}	3.4×10^{-1}

Both the iron content of the nuclear fraction and its specific activity is much higher in the foetus than in the mother.

Three of the pregnant rabbits were exposed 1 day prior to injecting them with ^{59}Fe to an X-ray dose of 500 *r*. The effect of the radiation on the incorporation of ^{59}Fe into the liver nuclear fraction is discussed in a paper by Ehrenstein *et al.*[16]

The generous support to this investigation by *Riksföreningen för kräftsjukdomarnas bekämpande*, *Cancernämnden* and the *Alice och Knut Wallenbergs Stiftelse* is gratefully acknowledged. We are also much indebted to Professor P. E. Lindahl for kindly putting his centrifuge at our disposal.

The Acidity Function in Solutions of Hydrogen Chloride in Methanol-Water Mixtures

PENTTI SALOMAA

Department of Chemistry, University of Turku, Turku, Finland

Values of Hammett's acidity function H_0 for solutions of hydrogen chloride in water and methanol and in their binary mixtures have been measured spectrophotometrically for the concentration range from 0.08 to 0.8 N. The proton-donating power of the solution decreases at first with increasing methanol content, passes through a minimum when the mole fraction of methanol is approximately 0.5, and then increases as pure methanol is approached. The acidic properties of the solutions are more pronounced in anhydrous methanol than in water, but the addition of even relatively small amounts of water to methanol is able to lower appreciably the proton-availability. The value of the equilibrium constant for the distribution of protons between methanol and water calculated from the values of the acidity function in methanol solutions containing low concentrations of water has been found to be in agreement with the value derived from kinetic data.

The acidity function H_0 introduced by Hammett and co-workers [1,2] makes possible a comparison of the protolytic properties of a wide range of acid solutions. Values of this quantity have already been determined for aqueous solutions of several inorganic acids [1-6] and for solutions of hydrogen chloride in dioxan, ethanol and acetone [7], and in their binary mixtures with water [8]. The values of the acidity function for solutions of hydrogen chloride in water-methanol mixtures presented in this paper have been measured for use in connection with kinetic data [9].

RESULTS AND DISCUSSION

The measurement of Hammett's acidity function H_0 involves the determination of the ratio of the concentration of a suitably chosen uncharged indicator base to that of its conjugate acid in the acid solution under study. If B denotes the indicator base and BH^+ its conjugate acid, the thermodynamic constant of the equilibrium

$$B + H^+ \rightleftharpoons BH^+ \qquad (I)$$

is given by the mass-law expression:

$$\frac{[BH^+]\, f_{BH^+}}{[B]\, [H^+]\, f_B\, f_{H^+}} = K_B \qquad (1)$$

in which the f's are the respective activity coefficients. The acidity function H_0 is defined by

$$H_0 = \log K_B - \log \frac{[BH^+]}{[B]} = - \log \frac{f_B\, f_{H^+}}{f_{BH^+}} [H^+] \qquad (2)$$

In order to obtain a common basis for the comparison of the proton-availabilities in different solvents, pure water can be taken as the reference solvent, in which case K_B is the constant for the indicator equilibrium in dilute aqueous acid.

The acidities of the solutions examined in the present study were such that only one indicator, *p*-nitroaniline, was required, since the ratio of concentrations of the base and conjugate acid forms of the indicator could be spectrophotometrically measured with sufficient accuracy in all cases. Measurements of the equilibrium ratio for *p*-nitroaniline in dilute aqueous hydrochloric acid solutions gave the value 1.02 for log K_B. This value is intermediate between the value 1.11 obtained by Hammett and Paul [2] and the value 0.95 reported by Braude [7] for the same indicator. The slight differences between the values for the indicator constant which may be due to differences in apparatus and technique are of no practical significance when the data for a given binary solvent system are compared, as even the selection of the reference solvent is in principle arbitrary.

The recorded values of the indicator ratio in water-methanol mixtures of varying hydrogen chloride content are presented in Table 1. The values λ are the wavelengths of the absorption maxima and ε the corresponding molar extinction coefficients. The indicator ratio has been computed by the equation

$$\frac{[BH^+]}{[B]} = \frac{\varepsilon_N - \varepsilon_A}{\varepsilon_A - \varepsilon_s} \qquad (3)$$

where ε_N and ε_A are the extinction coefficients of the indicator solutions at the wavelengths of maximum absorption in the neutral solvent and in the acid solution in question, respectively, and ε_s is a small correction term which denotes the extinction coefficient of the conjugate acid of *p*-nitroaniline in the acid solution. For estimating ε_s, which cannot be measured directly, Braude and Stern [7,8] took advantage of the fact that in the near ultraviolet region the absorption of the conjugate acid of an aromatic amine is of the same order of magnitude as that of the corresponding hydrocarbon lacking the amino group, and substituted the extinction coefficients of nitrobenzene for those of the conjugate acid of *p*-nitroaniline. The molar extinction coefficients of nitrobenzene varied from 20 to 90 in ethanol-water mixtures in the wavelength range in question. Since the values of ε_s are evidently of the same order of magnitude also in methanol-water mixtures, and since the experimental errors when measuring ε_A were approximately of the same order of magnitude, a

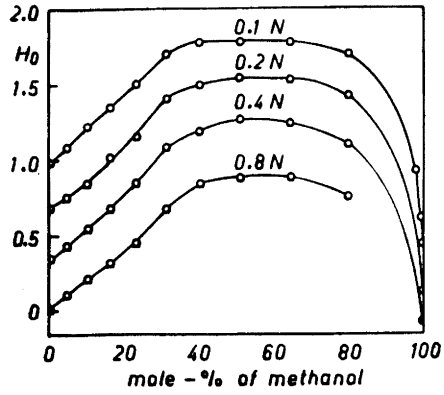

Fig. 1. The variation of H_0 with solvent composition in solutions of hydrogen chloride in methanol-water mixtures.

mean value $\varepsilon_s = 60$ was used in all cases to correct for the absorption by the conjugate acid when calculating the indicator ratio by eqn. (3).

The values of the acidity function H_0 calculated by substituting in eqn. (2) the measured values of the indicator ratio and the value 1.02 given above for log K_B were found to vary approximately linearly with the logarithm of the hydrogen chloride concentration in each solvent mixture. In order to facilitate the calculation of H_0-values for different acid concentrations by interpolation, the slopes of the plots of H_0 against log[HCl] for the different solvents are included in Table 1.

In Fig. 1 H_0 is plotted against the solvent composition in methanol-water mixtures for hydrogen chloride concentrations of 0.1, 0.2, 0.4 and 0.8 N. From the curves it is seen that H_0 increases at first and hence the proton-donating power of the solution decreases when methanol is added to water. The acidity function has its highest values when the mole fraction of methanol is between 0.4—0.7 and remains practically constant over this range. When pure methanol is approached, H_0 decreases rapidly and in anhydrous methanol its values are smaller than in water solution at the same hydrogen chloride concentrations. The variation of H_0 with solvent composition is similar in methanol-water as in ethanol-water mixtures, investigated by Braude and Stern [8], but is not quite so marked in the former mixtures, which is natural since methanol resembles water more closely in its properties. In the methanol-water mixtures at 0.1 N hydrogen chloride concentration the maximum value of H_0 is by 0.79 unit higher than in water, whereas in the ethanol-water mixtures the corresponding increase is 1.24 units [8]. The value of the acidity function for 0.1 N hydrogen chloride in anhydrous methanol, +0.47, is slightly smaller than the value, +0.61, in anhydrous ethanol. Thus the proton-availability is somewhat higher in methanol than in ethanol solution, which is in accordance with the greater basicity of ethanol as compared with methanol [10].

The data in Table 2 illustrate the effect of small additions of water to methanol on the value of H_0. Owing to the method of preparing the solutions, the hydrogen chloride concentrations varied slightly for different additions of water, and the indicator ratios have been corrected to apply to the same

concentration, 0.1 N, of hydrogen chloride that was present in anhydrous methanol by taking into account that the indicator ratio is approximately proportional to the acid concentration, at least in the narrow concentration range in question. The values with subscript 0.1 are the corrected values. The data in Table 2 show that small additions of water to methanol effect a pronounced increase in H_0, *i.e.* the proton-availability is appreciably reduced by the additions. This result is in accordance with the observations of Goldschmidt and Thuesen [11] who found that the equivalent conductance of hydrogen chloride falls rapidly when small quantities of water are added to methanol.

As Braude and Stern [8] have shown, the values of the indicator ratio determined for acid solutions in alcohol containing small amounts of water can be employed in a study of the alkoxonium-hydroxonium ion equilibrium. If a proton solvated by methanol is denoted by (mMeOH ,H^+) (m, the number of methanol molecules in the complex) and a proton solvated by water by ($n H_2O$, H^+) (n, the number of water molecules in the complex), the following equilibrium may be written:

$$(m\text{MeOH},H^+) + n\,H_2O \rightleftharpoons (nH_2O,H^+) + m\ \text{MeOH} \qquad \text{(II)}$$

The equilibrium constant for the reaction is given by

$$K_{H_2O}^{MeOH} = \frac{[nH_2O,H^+]}{[m\text{MeOH},H^+]\,[H_2O]^n} \qquad (4)$$

when the methanol concentration is taken to be constant. If hydrogen chloride can be assumed to be completely dissociated in methanol and in methanol-water mixtures, and it is written

$$x = \frac{[nH_2O,\ H^+]}{[m\text{MeOH},H^+]} \qquad (5)$$

eqn. (4) takes the form

$$K_{H_2O}^{MeOH} = \frac{x\ (1+x)^n}{\{(1+x)\ [H_2O]_{tot.} - nx[HCl]\}^n} \qquad (6)$$

In this equation, $[H_2O]_{tot.}$ denotes the total concentration of water present. The values of x can be computed if it is assumed that the minimum value of the indicator ratio $[BH^+]/[B]$ occurs in methanol-water mixtures in a region where the hydrogen ions have been completely transferred from methanol molecules to water molecules. The values of x can then be calculated by the equation

$$x = \frac{I_0 - I}{I - I_{min.}} \tag{7}$$

where I_0, I and $I_{min.}$ are the indicator ratios for the same concentration of acid in pure methanol, in the methanol solution containing a small amount of added water under study, and in the mixture where it has a minimum value, respectively. By interpolation from the data in Table 1, the value of $I_{min.}$ for 0.1 N hydrogen chloride is found to be 0.17, while the value of I_0 given in Table 2 is 3.55. Using these values, and the indicator ratios for 0.1 N hydrogen chloride solutions in methanol-water mixtures of low water content, the values of x given in Table 2 are obtained by eqn. (7).

The number of water molecules, n, which participate in the solvation of proton (eqn. II) in methanol-water mixtures of low water content can be determined by eqn. (6). For the mixtures studied, it is found that n is equal to unity as the values of the equilibrium constant computed by eqn. (6), by substituting $n = 1$, remain constant within the limits of experimental error, as shown by the figures in the last column of Table 2. The value of n was found to be unity also for ethanol-water mixtures of low water content, investigated by Braude and Stern [8].

The average value of $K_{H_2O}^{MeOH}$, 4.5 l mole^{-1}, in Table 2 is in excellent agreement with the value 4.8 l mole^{-1} derived by Goldschmidt and Thuesen [11] from their kinetic data on the effect of small water concentrations on the rate of esterification in methanol.

EXPERIMENTAL

Chemicals. Methanol, *pro analysi* from E. Merck, Darmstadt, was dried with magnesium according to Lund and Bjerrum [12], refluxed over anhydrous cupric sulphate, and distilled. The *p*-nitroaniline, of *purum* grade from E. Merck, was crystallised twice from anhydrous ethanol; it melted at 149°C.

Solutions. The solutions, which contained 20 moles per cent or more water were prepared by mixing measured volumes of water, aqueous hydrochloric acid and methanol to which the indicator had been dissolved to give the chosen concentration. When calculating the concentrations of indicator and hydrogen chloride in the mixed solutions, the data for the contraction of methanol-water mixtures given in the International Critical Tables [13] were employed. In a few cases the hydrogen chloride concentrations were checked also by titration, whereupon values in agreement with those calculated were obtained. The indicator concentration was varied from 1.5×10^{-5} M to 1.5×10^{-4} M depending upon the acidity of the solution. The solutions in pure methanol were prepared by passing carefully dried hydrogen chloride into anhydrous methanol. The methanol-water mixtures of low water content were prepared by mixing anhydrous methanol and methanol containing 5 moles per liter of water. The measurements on the solutions were made immediately after their preparation, in order that the slow reaction between hydrogen chloride and methanol could not influence the results.

Spectrophotometric measurements. The absorptions of the solutions required for the calculation of the indicator ratios were measured at 25±2°C with a Beckman Model DU

Quartz Spectrophotometer. The solutions containing *p*-nitroaniline exhibited maximum absorptions at wavelengths close to 380 mμ. A slit width of 0.15 mm was employed in the measurements; in the spectral range in question this corresponds to a half-intensity band width of about 1.3 mμ. The absorbance of the indicator solution was in each case measured against the same solution without added indicator because the solvents were found to differ appreciably in their absorption in the wavelength range where the measurements were made.

The value of the indicator constant K_B of *p*-nitroaniline in water which was used for the calculation of the values of the acidity function was determined by measuring the indicator ratio in dilute aqueous hydrochloric acid solutions by the method described above. Table 3 gives the results from which the values of the indicator constants have been calculated according to eqn. (1) by taking into account that the activity coefficient ratio remains practically unity in dilute aqueous solutions.

The Acid-Catalysed Solvolysis of Alkoxymethyl Esters. Part I. The Relation between the Rate of Hydrolysis and the Acidity Function

PENTTI SALOMAA

Department of Chemistry, University of Turku, Turku, Finland

Kinetic measurements are made of the rate of hydrolysis of methoxymethyl acetate, ethoxymethyl acetate and methoxymethyl formate in different aqueous acids up to 5 N acid concentration. In all cases, the velocity of hydrolysis is more closely related to the acidity function H_0 of the solution than to its acid concentration, thus indicating that the critical complex behaves like the conjugate acid of the ester and does not contain a water molecule. The plots of the logarithms of the first-order rate constants against $-H_0$ give straight lines with slopes varying between 1.00 and 1.15. The results suggest that the reactions take place predominantly according to a mechanism, which in the rate-determining reaction stage involves the formation of an alkoxymethyl cation from the conjugate acid of the ester. This mechanism is identical with the unimolecular alkyl-oxygen fission mechanism of acid-catalysed ester hydrolysis, designated $A_{AL}1$ by Ingold.

The acid-catalysed hydrolysis reaction of alkoxymethyl esters

$$RCOOCH_2OR' + H_2O \xrightarrow{H^+} RCOOH + HCHO + R'OH \qquad (I)$$

provides an interesting problem for kinetic investigations. Owing to the fact that these compounds are as well esters as acetals, various reaction mechanisms may be expected to be involved. The hydrolysis by dilute aqueous hydrochloric acid has been previously investigated by Palomaa and co-workers [1-3] and by Salmi [4]. As the temperature dependence of the rate of hydrolysis was more closely related to that of dialkyl formals than to that of simple alkyl esters, the latter author suggested that the point of initial rupture was on the alkoxyl side of the ester.

The acidity function H_0, first introduced by Hammett and co-workers [5,6], has furnished a criterion which has been frequently used to obtain information about the mechanisms of acid-catalysed hydrolysis reactions[e.g.7-11]. Its use

necessarily involves the extension of the rate measurements up to relatively high acid concentrations in which the difference between the values of H_0 and pH becomes significant. The present paper describes the results obtained for the hydrolysis of some constitutionally simple alkoxymethyl esters in different aqueous acids.

RESULTS AND DISCUSSION

The basic idea about the application of the acidity function H_0 to acid-catalysed hydrolysis reactions originates from Zucker and Hammett [7]. The authors showed that if the critical complex contains only a proton in addition to the substrate molecule, there exist a linear relation between the logarithm of the first-order rate constant and $-H_0$ with a slope of nearly unity. On the other hand, if the critical complex contains also a water molecule, such a dependence of the reaction rate on the acidity function is not to be expected. In the latter case, the reaction velocity is more closely related to the acid concentration of the solution. The former type of mechanism is to be termed unimolecular, because only one reacting species, the conjugate acid of the substrate, is undergoing a change of covalency in the rate-determining reaction stage, whereas the latter mechanism is bimolecular, two molecular species being involved in the rate-determining reaction [12].

Our kinetic method to follow reactions (I) was based on the determination of formaldehyde produced at various reaction times. The experimental results are given in Tables 1, 2 and 3. In the tables, k denotes the first-order rate constant, and k_c the rate constant reduced to 1 N catalyst concentration by dividing k by the normality of the acid. The tables also include the values of the Hammett acidity function H_0 for the solutions used. The latter values have been obtained by interpolation from the data given by Hammett and Deyrup [5] and by Bell, Dowling and Noble [10] for aqueous hydrochloric acid, and by Hammett and Paul [6] for aqueous sulphuric acid, and by Harbottle [13] for aqueous perchloric acid containing added sodium perchlorate, respectively. Since the values given by Hammett and co-workers refer to molal concentrations of the solute, the corresponding molar concentrations were calculated from the data given by Harned and Ehlers [14] and in the International Critical Tables [15].

The values obtained for k_c at relatively low acid concentrations show but slight differences from the corresponding values determined earlier by Palomaa and co-workers [2,3]. These authors measured the velocity of reaction (I) by a titrimetrical determination of the acid produced, and found for k_c at 25°C the values: 0.00247 l mole^{-1}sec.$^{-1}$ for methoxymethyl acetate, 0.00875 l mole^{-1}sec.$^{-1}$ for ethoxymethyl acetate, and 0.00918 l mole^{-1}sec.$^{-1}$ for methoxymethyl formate, respectively. In the present case, the determination of the rate constants by an alkalimetric titration was not possible, because the concentration of the catalyst acid was usually relatively high in comparison to that of the acid formed during the reaction. In addition, the formaldehyde analysis allowed to bring the reactions to stop, and the end points of the titrations were sharp, whereas in the alkalimetric titration the rapidity of the alkaline hydrolysis of alkoxymethyl esters is a source of error in analysis. In the

case of methoxymethyl acetate, the present method allowed an accurate determination of rate constants up to nearly 5 N hydrochloric acid concentration, whereas the rapidity of the reactions of ethoxymethyl acetate and methoxymethyl formate limited the measurements to a narrower range of concentrations.

The values of k_c given in Tables 1, 2 and 3 show that the rate of hydrolysis increases much more rapidly than the acid concentration of the solution. For instance, in the case of methoxymethyl acetate, the value of k_c increases by a factor of about 25 when the hydrochloric acid concentration is increased from 0.1 N to 5 N. In the case of ethoxymethyl acetate, the relative increase in the values of k_c with hydrochloric acid concentration is nearly of the same order of magnitude, whereas the increase is less pronounced in the hydrolysis of methoxymethyl formate.

Like the hydrolysis reactions of methylal [8] and trioxan [11], the hydrolysis of alkoxymethyl esters shows a close relation between the reaction velocity and the acidity function of the solution. This is seen from Figs. 1 and 2 in which the values of log k are plotted against the Hammett acidity function. The plots follow an approximately linear course as shown by the straight lines drawn in the diagrams which have slopes of 1.15 in the cases of methoxymethyl acetate and ethoxymethyl acetate, and a slope of 1.00 in the case of methoxymethyl formate, respectively. In the hydrolysis of methoxymethyl acetate (Fig. 1), the points corresponding to hydrochloric and sulphuric acids lie approximately on the same straight line, whereas the points referring to perchloric acid solutions containing added sodium perchlorate show systematic deviations from the former solutions. This may be due to small systematic differences between the values of H_0 determined by different authors, and to the limitations involved in assuming that the ratio of the activity coefficients of the substrate ester and the critical complex would vary with the solvent composition in an exactly similar way as the activity coefficient ratio of the indicator base and its conjugate acid, which have been used in the determination of H_0 [cf.8,13,16]. Systematic deviations between the results for different acids were also observed in the hydrolysis of trioxan, investigated by Bell, Bascombe and McCoubrey [11].

From the relationship between the hydrolysis rate of alkoxymethyl esters and the acidity function it may be concluded that the reactions take place by a mechanism, in which no water molecule is undergoing a change of covalency on the attainment of the transition state, *i.e.* the slow, rate-determining stage of the reaction is unimolecular and involves the formation of a carbonium ion from the conjugate acid of the ester. Similar conclusions were reached by McIntyre and Long [8] for the hydrolysis of methylal, and by Bell, Bascombe and McCoubrey [11] for the hydrolysis of trioxan. The plots corresponding to those of Figs. 1 and 2 gave a slope of 1.15 for methylal, and a slope of 1.2 for trioxan. In the case of acetal hydrolysis, the unimolecular mechanism has been also supported by other lines of experimental evidence [17,18].

The similarity of alkoxymethyl ester hydrolysis to acetal hydrolysis is not confined to a similar dependence of the reaction rate on the acidity function of the solution. In addition, it is most probable that the carbonium ion produced in the rate-determining stage of the hydrolysis of alkoxymethyl esters is structurally similar to that postulated for the hydrolysis of acetals [8,11,17,18],

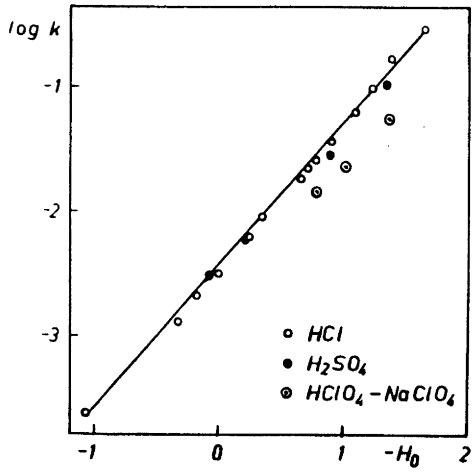

Fig. 1. Plot of log k against $-H_0$ for the hydrolysis of methoxymethyl acetate at 25°C.

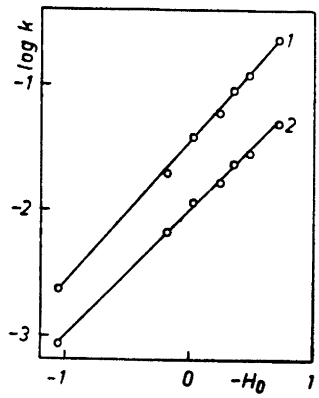

Fig. 2. 1. Plot of log $k+0.40$ against $-H_0$ for the hydrolysis of ethoxymethyl acetate. 2. Plot of log k against $-H_0$ for the hydrolysis of methoxymethyl formate. Hydrochloric acid solutions, 25°C.

i.e. the intermediate ion is a mesomeric alkoxymethyl cation. For that case, the rate-determining reaction stage which follows the preliminary proton uptake can be represented as follows:

$$RC(=O)-\overset{+}{O}H-CH_2OR' \xrightarrow[\text{slow}]{} RCOOH + CH_2=\overset{+}{O}R' \qquad \text{(II)}$$

Reaction (II) is then followed by the rapid subsequent reactions:

$$CH_2=\overset{+}{O}R' + H_2O \xrightarrow[\text{fast}]{} H^+ + HOCH_2OR' \xrightarrow[\text{fast}]{} H^+ + HCHO + HOR' \qquad \text{(III)}$$

which lead to the final products. In the present case, there are no structural factors to favour the formation of cations such as R^+, R'^+ or RCO^+ in the rate-determining reaction stage, whereas the production of an alkoxymethyl cation according to eqn. (II) is greatly facilitated by its mesomeric structure *cf.*[19-21]. The only alternative unimolecular mechanism, which were conceivable, would involve the formation of an acyloxymethyl cation in the rate-determining reaction stage:

$$RC(=O)-O-CH_2-\overset{+}{O}H-R' \xrightarrow[\text{slow}]{} RC(=\overset{+}{O})-O=CH_2 + HOR' \qquad \text{(IV)}$$

Also in this case, the formation of the cation is facilitated, although to a minor extent, by its possibility to resonate between different valence bond structures. Owing to the influence of the carbonyl group which is directly attached to the

ether oxygen atom, the resonance energy of this cation is materially reduced, and the conditions for its formation are thus less favourable. This is clearly illustrated by the results obtained for the solvolysis of chlorine in alkoxymethyl chlorides [19–21], $ROCH_2Cl$, when compared with those obtained for the corresponding reaction of acyloxymethyl chlorides, $RCOOCH_2Cl$, investigated by Euranto [22]. The former reaction takes place very rapidly with the unimolecular S_N1 mechanism involving the production of the alkoxymethyl cation in the rate-determining reaction stage, whereas the latter reaction is relatively slow and does not produce an intermediate carbonium cation, the reaction mechanism being S_N2. We must therefore conclude that the unimolecular hydrolysis of alkoxymethyl esters by aqueous acids takes place by the mechanism represented by eqns. (II) and (III). Our results thus provide an illustration for an acid-catalysed ester hydrolysis involving unimolecular alkyl-oxygen fission, designated $A_{AL}1$ by Ingold [23].

The application of the Hammett acidity function to relatively complicated reactions, where different points for initial rupture are conceivable as in the present case, does not give an information about the possible side mechanisms. Suppose, for instance, that a reaction in dilute acid solutions occurs by two simultaneous mechanisms, a unimolecular mechanism the rate of which follows the acidity function, and a bimolecular mechanism the rate of which depends primarily on the acid concentration. When passing to relatively concentrated acid solutions, the contribution of the latter reaction from the total reaction rate falls gradually off, and its presence cannot be clearly shown by the plot of log k against the acidity function. On view of the structural factors, discussed below, it is very probable that, at least in the case of methoxymethyl formate, the unimolecular reaction is at low acid concentrations accompanied to a certain extent by a bimolecular reaction, the mechanism of which is that of acid-catalysed ester hydrolysis involving bimolecular acyl-oxygen fission [23]. As shown by Bell, Dowling and Noble [10], the velocity of the latter type of reaction is more closely related to the acid concentration than to the acidity function of the solution.

The value of k_c (Table 3) determined for methoxymethyl formate in 0.1 N hydrochloric acid at 25°C, 0.00859 l mole^{-1}sec.$^{-1}$, is only 3.5-fold in comparison to the corresponding value for methyl formate, 0.00247 l mole^{-1}sec.$^{-1}$,determined by Salmi [4]. Owing to the fact that the rate of bimolecular acid-catalysed ester hydrolysis taking place with acyl-oxygen fission is but slightly influenced by changes in the alkyl part of the ester [23], it is reasonable to assume that the rate constant determined for methoxymethyl formate includes a contribution resulting from its hydrolysis by the acyl-oxygen fission mechanism, in addition to that which results from the unimolecular mechanism. Euranto [22] found that the rate constant for acid-catalysed ester hydrolysis at 25°C was reduced by a factor of about 3, when passing from methyl acetate to chloromethyl acetate, and a similar, although probably a smaller decrease is to be expected in the velocity of the bimolecular ester hydrolysis, when passing from methyl formate to methoxymethyl formate. On the contrary, in the cases of methoxymethyl acetate and ethoxymethyl acetate, the contribution from the bimolecular mechanism to the total hydrolysis rate is probably too small to be of practical importance. Tommila and Hella [24] determined for the rate constant

of methyl acetate in dilute aqueous acid at 25°C the value 0.000109 l mole^{-1} sec.$^{-1}$, whereas the corresponding values for methoxymethyl acetate and ethoxymethyl acetate (Tables 1 and 2) are considerably higher, 0.00237 l mole^{-1} sec.$^{-1}$ and 0.00871 l mole^{-1}sec.$^{-1}$, respectively. The smaller slope, 1.00, obtained for methoxymethyl formate by the plot of log k against $-H_0$, as compared with the slopes of 1.15 obtained for methoxymethyl acetate and ethoxymethyl acetate, is readily understood if it is assumed that in the former case the reaction rate involves a contribution from an accompanying bimolecular mechanism.

EXPERIMENTAL

Materials. Methoxymethyl acetate, $CH_3COOCH_2OCH_3$, and ethoxymethyl acetate, $CH_3COOCH_2OC_2H_5$, were prepared from the corresponding alkoxymethyl chlorides and potassium acetate according to Palomaa [1]. After fractionation, the products were found to be free from chlorine. The boiling points were: 118.6—118.8°C/766 mm Hg for methoxymethyl acetate, and 132.5—133.0°C/762 mm Hg for ethoxymethyl acetate. The purity of the products was controlled by hydrolysing weighed samples in dilute acid solutions and determining both the acetic acid and formaldehyde produced at the end of hydrolysis, the former by titrating against a standard sodium hydroxide solution, the latter using the modified bisulphite method described earlier by the author [19,25]. In the analysis, 59.9 mg of methoxymethyl acetate was found to be equivalent to 11.21 ml of 0.0519 N sodium hydroxide (*calc.* 11.09 ml), and to 16.64 ml of 0.0688 N iodine (*calc.* 16.73 ml). Ethoxymethyl acetate (78.3 mg) was equivalent to 12.58 ml of 0.0519 N sodium hydroxide (*calc.* 12.77 ml), and to 19.12 ml of 0.0688 N iodine (*calc.* 19.27 ml). Methoxymethyl formate, $HCOOCH_2OCH_3$, was prepared from methoxymethyl chloride and lead formate as described by Palomaa and Herna [2]. The boiling point was 103.6°C/762 mm Hg. In the analysis, 51.7 mg of the compound was equivalent to 11.24 ml of 0.0519 N sodium hydroxide (*calc.* 11.06 ml), and to 16.58 ml of 0.0688 N iodine (*calc.* 16.68 ml).

The acidic reaction solutions were prepared by diluting the corresponding concentrated acids, and their concentrations were determined by titrating against standard alkali solutions. Commercial acids of highest grade of purity were employed.

Kinetic measurements. The thermostat used in kinetic measurements and the technique of sampling were the same as described earlier [19,20]. The samples withdrawn from the reaction mixture at different time intervals were run into conical flasks, which contained 10 ml of the phosphate buffer solution (pH 7.3) which was employed for the formaldehyde determinations [19,25], and an amount of 0.5—5 N sodium hydroxide solution, which was calculated to neutralise the catalyst acid present in the sample. In the experiments, in which the concentration of the catalyst acid was relatively high, an amount of crushed ice was added, in order to avoid the considerable warming up of the mixture as a result of the heat of neutralisation. Particular experiments indicated that the velocities of alkaline hydrolysis of methoxymethyl acetate and ethoxymethyl acetate in the phosphate buffer were sufficiently small and did not cause an error in analysis. However, in the case of methoxymethyl formate it was established that an error in analysis resulted from a delayed analysis of the sample. The observed formaldehyde content increased slightly with time. The effect of this source of error was eliminated by performing the analysis immediately after taking the samples and by using a constant standing period (three minutes) for the bisulphite-formaldehyde addition reaction *cf.* [19]. In this case the small error resulting from the additional formaldehyde (estimated to be less than 5 % of the amount of remaining ester) did not affect the values of the rate constants as they were calculated by the first-order equation.

Zero time was the time of taking of the first sample. In addition, 6—8 samples were taken during the reaction. The concentration of formaldehyde formed after infinite time (over ten-fold period of the half-life) was checked by several parallel determinations. The initial concentration of the ester varied between 0.03—0.06 M. The volumes of the samples withdrawn from the reaction mixtures were 5 ml or 10 ml, and the concentration of the standard iodine solution used in the formaldehyde determinations was 0.06—0.07 N. The details for some typical runs are given in Tables 4, 5 and 6. In the tables, a denotes the

concentration of the ester at zero time, x the concentration of formaldehyde produced during time t, and k the first-order rate constant. The values of the rate constants were calculated by the usual equation for first-order reactions.

The Acid-Catalysed Solvolysis of Alkoxymethyl Esters. Part II. Reaction Rates and Products in the Solvolysis of Methoxymethyl Esters in Methanol-Water Mixtures

PENTTI SALOMAA

Department of Chemistry, University of Turku, Turku, Finland

The acid-catalysed solvolysis reactions of methoxymethyl formate and methoxymethyl acetate have been investigated kinetically in methanol-water mixtures containing 30—65 moles per cent of methanol. A method has been developed to determine the reaction mechanisms which takes advantage of analysis of the different solvolysis products. The results indicate that the reactions of the esters take place involving two simultaneous mechanisms in the solvents under study. One mechanism is unimolecular and leads to the formation of methoxymethyl cation in the rate-determining stage. The second mechanism is bimolecular and takes place with an acyl-oxygen fission. The contribution of the bimolecular mechanism to the total solvolysis rate is more notable with methoxymethyl formate than with methoxymethyl acetate. Approximate calculations are made by Hammett's acidity function to elucidate the reaction mechanisms in pure water solution, the results suggesting that methoxymethyl acetate hydrolyses in this medium almost exclusively by the unimolecular mechanism, whereas in the case of methoxymethyl formate the unimolecular reaction is accompanied by a contribution from the bimolecular reaction.

In the first part of the present study [1] it was established that the acid-catalysed solvolysis of simple alkoxymethyl esters in water solution takes place predominantly according to a unimolecular mechanism involving the production of an intermediate alkoxymethyl cation. However, it was considered as being probable that, at least in the case of methoxymethyl formate, an alternative reaction mechanism of a normal type of acid-catalysed ester hydrolysis might play some role in the hydrolysis by dilute aqueous acids. The purpose of the present work is to furnish additional evidence for the reaction mechanisms suggested for the solvolysis of alkoxymethyl esters in hydroxylic media.

METHOD OF DETECTING THE MECHANISMS

In an earlier study [2] the author determined the values of Hammett's acidity function H_0 for solutions of hydrogen chloride in methanol-water mixtures and found the values to increase by 0.7—0.8 units when passing from water to media containing 30—65 moles per cent of methanol. The theory suggested *cf.* [1] that the logarithm of the rate constant for the unimolecular mechanism should decrease by an amount of nearly this order of magnitude when passing from water to the water-methanol mixtures, whereas such a decrease would not be probable for the postulated bimolecular mechanism. The change in solvent composition was thus expected to facilitate the detection of the possible bimolecular mechanism.

The investigation of reaction mechanisms in alcohol-water mixtures may be based on the following considerations. Let us assume that the alkoxyl group of the alkoxymethyl ester is the same as that of the alcohol in the water-alcohol mixture under study. Let it be at first presupposed that the reaction mechanism is unimolecular. The rate-determining stage which follows the initial proton uptake leads to the formation of an alkoxymethyl cation:

$$\mathrm{RC(=O)-O^{+}H-CH_2OR' \xrightarrow[\text{slow}]{} RCOOH + CH_2{=}\overset{+}{O}R'} \qquad \text{(I)}$$

The fast, product-forming reactions of the unstable cation are those given by eqns. (II):

$$\begin{aligned} &\mathrm{CH_2{=}\overset{+}{O}R' + H_2O \xrightarrow[\text{fast}]{} H^+ + HOCH_2OR' \xrightarrow[\text{fast}]{} H^+ + HCHO + HOR'} \\ &\mathrm{CH_2{=}\overset{+}{O}R' + R'OH \xrightarrow[\text{fast}]{} H^+ + CH_2(OR')_2} \end{aligned} \qquad \text{(II)}$$

The intermediate mesomeric ion is exactly the same, which is formed in the solvolysis reaction of the corresponding alkoxymethyl chloride. The latter reaction has been shown to take place by the S_N1 mechanism involving the ionisation reaction (III) as the rate-determining stage[3]:

$$\mathrm{ClCH_2OR' \xrightarrow[\text{slow}]{} Cl^- + CH_2{=}\overset{+}{O}R'} \qquad \text{(III)}$$

When the solvolysis of an alkoxymethyl ester in an alcohol-water mixture takes place exclusively by the mechanism represented by eqns. (I) and (II), that implies that the relative amounts of formaldehyde and formal produced at the end of reaction are the same as in the solvolysis reaction of the corresponding alkoxymethyl chloride under the same external conditions, because the product-forming reactions are identical in both cases.

Let us now suppose that the solvolysis occurs by a bimolecular mechanism, which involves an acyl-oxygen fission. In that case, the rate-determining, slow reactions which follow the preliminary proton uptake are those given by eqns. (IV) *cf.* [4]:

$$\begin{array}{l} \mathrm{RC(=O)—O^{+}(H)—CH_2OR' + H—OH \xrightarrow[\text{slow}]{} RCOOH_2^{+} + HOCH_2OR'} \\ \mathrm{RC(=O)—O^{+}(H)—CH_2OR' + H—OR' \xrightarrow[\text{slow}]{} RCOO^{+}(H)R' + HOCH_2OR'} \end{array} \qquad \text{(IV)}$$

Both of the possible reactions, the reaction with water and that with alcohol, give no formal, formaldehyde being one of the reaction products in both cases. Actually, the formaldehyde formed in the alcoholic media may be present, at least partly, in the form of semiacetal, but that is of no importance from the analytical viewpoint.

It thus appears that the relative amount of formaldehyde formed furnishes a criterion for the reaction mechanism. The unimolecular mechanism yields both formaldehyde and formal in a molar ratio, which is equal to that by the solvolysis of the corresponding alkoxymethyl chloride under the same conditions, whereas the bimolecular mechanism gives an amount of formaldehyde, which is equivalent to the amount of the ester initially present. It is seen that an assumption of alternative, less probable reaction mechanisms *cf.* [1] would not essentially alter the method of revealing the different mechanisms by the reaction products. If the mechanism (IV) were replaced by a unimolecular acyl-oxygen fission mechanism [4], the reaction would similarly produce quantitatively formaldehyde. The same situation prevails when the solvolysis would occur on the alkoxyl side of the ester molecule, the reaction with water giving formaldehyde and that with alcohol regenerating the ester, the observed net change thus being formaldehyde formation. Hence the contributions of these less probable mechanisms would be included in the observed net rate of formaldehyde production. The only alternative mechanism, which could produce formal in addition to formaldehyde, were bimolecular nucleophilic substitution at the carbon atom of the methylene group. This carbon atom is, however, much less electrophilic than that present in the carbonyl group, and actually, a bimolecular alkyl-oxygen fission mechanism has never been established in acid-catalysed ester hydrolysis [4].

The subsequent reactions, the esterification of the carboxylic acid formed and its reverse reaction, which followed the solvolysis of alkoxymethyl esters in methanol-water mixtures, did not affect our method as it took advantage only of the amounts of formaldehyde and methylal produced by the reactions. On the contrary, the rates of the subsequent acetalisation of formaldehyde and its reverse methylal hydrolysis were of such an order of magnitude, that these reactions must be taken into account in order to obtain reliable results.

METHOD OF CALCULATION

As shown experimentally, the acid-catalysed solvolysis of methoxymethyl esters in methanol-water mixtures under study proceeds to completion and yields both formaldehyde and methylal. The sum of the concentrations of

formaldehyde and methylal formed is equivalent to the amount of methoxymethyl ester reacted. Formaldehyde and methylal are converted to each other in a slow, subsequent equilibrium reaction. At a given acid concentration, all of these reactions are of the first order. Let the respective first-order rate constants be denoted as follows: k' for the formation of formaldehyde from the ester, k'' for the formation of methylal from the ester, k_a for the acetalisation of formaldehyde, and k_h for the hydrolysis of methylal. Independently of the reaction mechanisms involved, we thus have the following simplified reaction-scheme:

$$\begin{array}{l} \overset{k'}{\nearrow}\ \mathrm{HCHO} \\ \mathrm{RCOOCH_2OCH_3} \overset{k_a}{\underset{k_h}{\rightleftarrows}} \\ \underset{k''}{\searrow}\ \mathrm{CH_2(OCH_3)_2} \end{array} \qquad \text{(V)}$$

Making use of the known values of k_a and k_h which can be measured separately, we wish to calculate the values of k' and k'' from the experimental data.

If a denotes the initial ester concentration, and x and y are the concentrations of formaldehyde and methylal present at time t, respectively, we obtain eqns. (1) which express the rates of increase in formaldehyde and methylal concentrations:

$$\begin{aligned} \frac{\mathrm{d}x}{\mathrm{d}t} &= k'(a-x-y)-k_a x+k_h y \\ \frac{\mathrm{d}y}{\mathrm{d}t} &= k''(a-x-y)+k_a x-k_h y \end{aligned} \qquad (1)$$

By applying the initial conditions, $x = 0$ and $y = 0$, when $t = 0$, eqns. (1) may be integrated to give

$$\frac{x}{a} = \frac{k_h}{k_a+k_h}\left(1-\mathrm{e}^{-(k_a+k_h)t}\right) + \alpha\left(\mathrm{e}^{-(k_a+k_h)t} - \mathrm{e}^{-(k'+k'')t}\right) \qquad (2)$$

in which

$$\alpha = \frac{k'-k_h}{(k'+k'')-(k_a+k_h)} \qquad (3)$$

Taking advantage of the fact that the value of $(k'+k'')$ is large in comparison to that of (k_a+k_h), the last exponential of eqn. (2) can be neglected for large values of t, *i.e.* when practically all of the ester present initially has been converted to the final products, formaldehyde and methylal. We thus obtain from eqn. (2) the following expression which is valid for sufficiently long reaction times:

$$\alpha = \frac{x}{a}\,\mathrm{e}^{(k_a+k_h)t} - \frac{k_h}{k_a+k_h}\left(\mathrm{e}^{(k_a+k_h)t}-1\right) \qquad (4)$$

By this equation, the value of α can be calculated, and using the value found, values of $(k'+k'')$ can be calculated from the data referring to the earlier stages of the reaction by the following equation which is readily obtained from eqn. (2):

$$k'+k'' = \frac{1}{t}\ln\frac{\alpha a}{\alpha a\mathrm{e}^{-(k_a+k_h)t}-x+\dfrac{k_h a}{k_a+k_h}\left(1-\mathrm{e}^{-(k_a+k_h)t}\right)} \qquad (5)$$

From the known values of a, $(k'+k'')$, k_a and k_h, the values for k' and k'' can be calculated separately by eqn. (3).

The above calculation implies that the zero time is to be chosen at that time when no reaction has occurred. In actual measurements, some formaldehyde had been already formed at the time of taking of the first sample. The real zero time was hence determined by taking several samples with short time intervals at the initial phase of the reaction and by extrapolating to zero formaldehyde concentration. Table 1 shows a typical example of the individual experimental runs. Eqns. (3), (4) and (5) have been used in the calculations. The time interval passed from the time of taking of the first sample has been denoted by $(t—t_0)$, t being the actual reaction time which is found by a short extrapolation. As shown by the last column of the table, the values of $(k'+k'')$ remain practically constant at the different time intervals when the subsequent reactions have been taken into account. The effect of the subsequent reactions is clearly illustrated by the fact that the formaldehyde concentration which increases at first, reaches a maximum value, and then begins slowly to decrease, as shown by the values given in the second column of the table.

The solvolysis of methoxymethyl formate in methanol-water mixtures was so rapid in comparison to the subsequent reactions that their influence could be neglected, except in order to correct the final concentration of formaldehyde formed. In this case, the exponentials in eqn. (5) were practically unity, and the equation could be replaced by

$$k'+k'' = \frac{1}{t—t_0} \ln \frac{\alpha a—x_0}{\alpha a—x} \qquad (5\ a)$$

Table 1. The calculation of the constants k' and k'' for the solvolysis of methoxymethyl acetate in 47.2 moles per cent methanol at 25°C at 0.1182 N hydrogen chloride concentration. $a = 0.0658$. $k_a+k_h = 2.92 \times 10^{-6}$ sec.$^{-1}$, $k_h/(k_a+k_h) = 0.155$.

in which x_0 denotes the formaldehyde concentration present at the time (t_0) of taking of the first sample. Table 2 shows an example of experimental runs illustrating this case. The value of a has been calculated as above from the data referring to long reaction times, taking into account that for these times (t-t_0) becomes practically equal to t.

RESULTS AND DISCUSSION

Table 3 gives the experimental results for the solvolysis of methoxymethyl formate and methoxymethyl acetate in methanol-water mixtures. The rate constants for the subsequent reactions which were necessary for the calculation of the values of k' and k'' were estimated simultaneously by determining both the rate of formation of methylal from formaldehyde and the rate of methylal hydrolysis, as described in the experimental part which also contains the values observed. Although it was verified that the values of k' and k'' were proportional to the acid concentration when it was varied but slightly, all of the values included in Table 3 were determined at the same concentration, 0.1182 N, of hydrogen chloride.

Table 4 gives the average values determined for the molar ratios of formaldehyde and methylal formed in the solvolysis of methoxymethyl chloride in the methanol-water mixtures. Also in this case it was established that the

$[HCHO]/]CH_2(OCH_3)_2]$	1.538	0.681	0.348

product ratio was not affected by small variations in the initial hydrogen chloride concentration. The solvolysis of methoxymethyl chloride in these solvents took place much too rapidly to permit of kinetic measurements; still the composition of the final product could be easily determined. In this case, the slow, subsequent reactions of formaldehyde and methylal did not affect the results, the product analysis being performed almost immediately after mixing the components.

As shown above, the bimolecular solvolysis mechanism (IV) could produce no methylal, *i.e.* the value of k'' would be zero. This is not the case here, as indicated by the values determined for k'' (Table 3). On the other hand, the unimolecular mechanism which is presented by eqns. (I) and (II) would give formaldehyde and methylal in a molar ratio, which were exactly the same as in the solvolysis of methoxymethyl chloride under the same conditions, *i.e.* the value of the ratio k'/k'' would be identical with the molar ratio of formaldehyde and methylal, which is given in Table 4 for the solvent in question. A comparison between the values of Tables 3 and 4 shows that in all cases the values of k'/k'' are higher than the respective molar ratios of formaldehyde and methylal produced in the unimolecular solvolysis of methoxymethyl chloride. This indicates that the both reaction mechanisms occur simultaneously. The respective contributions of the mechanisms to the total rate of solvolysis may be evaluated as shown below.

Let k_1 denote the first-order rate constant for the solvolysis by the unimolecular mechanism. The first-order rate constants for the formation of formaldehyde and methylal by this mechanism are then given by *cf.* [3] $r\,k_1/(1+r)$ and $k_1/(1+r)$, respectively, in which r denotes the molar ratio of formaldehyde and methylal formed in the rapid, product-forming reactions (II) of the intermediate methoxymethyl cation. The values of r are identical with the ratios of formaldehyde and methylal concentrations, which are determined for the solvolysis of methoxymethyl chloride (Table 4). Let k_2 denote the first-order rate constant for the production of formaldehyde by the bimolecular mechanism (IV), the rate of methylal formation by this mechanism being zero. It is to be noted that in the case of bimolecular mechanism there are two different reactions, hydrolysis and alcoholysis, which both lead to the formation of formaldehyde, and k_2 thus represents the sum of the rate constants of these two reactions. Altogether, we obtain for the first-order rate constants of the formation of formaldehyde (k') and methylal (k'') the following expressions:

$$\begin{aligned} k' &= r\,k_1/(1+r)+k_2 \\ k'' &= k_1/(1+r) \end{aligned} \qquad (6)$$

by which, using the known values of k', k'' and r (Tables 3 and 4), the values of k_1 and k_2 can be readily calculated. The results of such calculations are given in Table 5 which also includes the values of the Hammett acidity function H_0 for the solutions under study [2].

A comparison between the values of k_1 and k_2 indicates that in the case of methoxymethyl formate, the contribution of the bimolecular mechanism is more pronounced than that of the unimolecular mechanism in the media under study, whereas the opposite situation prevails in the solvolysis of methoxy-

Table 5. The first-order rate constants (in sec.$^{-1}$) for the unimolecular (k_1) and bimolecular (k_2) solvolysis of methoxymethyl esters in methanol-water mixtures at 25°C at 0.1182 N hydrogen chloride concentration.

Moles % of MeOH		0	30.9	47.2	64.2
H_0		+0.91	+1.62	+1.69	+1.69
$HCOOCH_2OCH_3$	k_1		0.00016	0.00014	0.00015
	k_2		0.00087	0.00086	0.00101
	$\log k_1+H_0$		−2.18	−2.16	−2.13
$CH_3COOCH_2OCH_3$	k_1		0.000109	0.000082	0.000077
	k_2		0.000032	0.000031	0.000034
	$\log k_1+H_0$		−2.34	−2.40	−2.42

methyl acetate. This is in good accord with the previous results [1]. In addition, the values of the rate constants k_1 and k_2 are approximately of those orders of magnitude, which are to be expected in view of the reaction mechanisms involved (see below).

The unimolecular mechanism presupposes a linear relation between the logarithm of the first-order rate constant and $-H_0$ with a slope of close to unity. If the slope would be exactly unity, $\log k_1 + H_0$ would be constant for different media. In this case, the values of $\log k + H_0$ (k, the first-order rate constant in water solution) determined in water solution would be equal or higher in comparison to the respective values of $\log k_1 + H_0$ in methanol-water mixtures depending as the reaction mechanism in water solution were purely unimolecular or, if the unimolecular mechanism were accompanied by a contribution from the bimolecular mechanism. According to the previously determined values [1], the first-order rate constants for 0.1182 N aqueous hydrochloric acid at 25°C are: 0.00102 sec.$^{-1}$ for methoxymethyl formate, and 0.000281 sec.$^{-1}$ for methoxymethyl acetate; from these we obtain for the respective values of $\log k + H_0$ in water solution: −2.08 for methoxymethyl formate, and −2.64 for methoxymethyl acetate. The value for methoxymethyl formate is somewhat higher than the corresponding values of $\log k_1 + H_0$ determined in methanol-water mixtures (Table 5), whereas the opposite situation prevails in the case of methoxymethyl acetate. In view of the limitations involved in the calculation, this is in accord with the difference in mechanisms assumed for the hydrolysis of these compounds by aqueous acids [1]. The actual dependence of $\log k_1$ on H_0 in methanol-water mixtures remains obscure owing to the difficulties encountered in the determination of the values for k_1 in solvents of lower methanol content in which the changes in H_0 were more significant than in the present solvents [2]. In solvents of relatively low methanol content the determination of k_1 was found to be very inaccurate. This is also seen from the latter of eqns. (6) according to which the value of k_1 in water solution takes the indefinite form $0 \cdot \infty$.

The values of k_2 determined for methoxymethyl formate and methoxymethyl acetate in methanol-water mixtures (Table 5) are approximately threefold as compared with the respective rate constants for the hydrolysis of methyl formate and methyl acetate in aqueous acid (see *ref.* 1). This is in accord with the relatively small constitutional effect of the alkyl group of an ester,

which undergoes acid-catalysed solvolysis by the bimolecular acyl-oxygen fission mechanism [4], and to the relatively slight solvent influence. A comparison between the values determined by Salmi [5] and by Tommila and Hella [6] for the rate constants of acid-catalysed hydrolysis of methyl formate and methyl acetate in water, and the respective values for the hydrolysis in 50 moles per cent methanol, determined by Palomaa and Siitonen [7], shows the rate constants to decrease by 30—40 % when passing from water to the methanol solution. However, in the reactions of simple alkyl esters in alcoholic media, in which the alkyl group of the alcohol is the same as that present in the esters in question, the hydrolysis reactions of the esters and their reverse reactions are the only measurable processes, the reactions with alcohol molecules remaining obscure because they regenerate the esters present initially. Such a situation does not prevail in the solvolysis of methoxymethyl esters in methanol-water mixtures, the sum of the rates of the hydrolysis and alcoholysis reactions (IV) being that which is measured, and the somewhat higher values of k_2 as compared with the corresponding rate constants of the hydrolysis of alkyl esters may be primarily ascribed to the competing alcoholysis reactions.

EXPERIMENTAL

Materials. The methoxymethyl esters were prepared as described in the first part of the present study [1]. Methylal, which was used in the determination of the rates of its reversible hydrolysis reaction, was prepared from paraformaldehyde and methanol with hydrogen chloride as the catalyst. The raw product was refluxed over sodium and fractionated, b.p. 44°C/755 mm Hg. The degree of purity of the product was found to be over 99 % by formaldehyde analysis which followed the hydrolysis of a weighed sample by 2 N hydrochloric acid. Methanol, *pro analysi* from E. Merck, Darmstadt, was purified as described earlier [2]. The methanol-water mixtures employed for the kinetic measurements were prepared by weighing, after which carefully dried hydrogen chloride gas was passed in, and the solutions were diluted to give the hydrogen chloride concentration desired. All of the solutions were made up freshly before the experiments.

Kinetic measurements. The method of analysis used in following the solvolysis of methoxymethyl esters in methanol-water mixtures was essentially the same as in the first part of the present study [1]. In the kinetic experiments, a weighed sample of the ester which was sealed in a small glass bulb was brought into a measured volume of the reaction solvent, and after attainment of the thermostat temperature, the bulb was broken and the components were mixed by vigorous shaking to start the reaction. The value of the initial ester concentration was calculated from the amount of ester weighed, taking into account a small correction which was due to the deviation of the degree of purity of the ester from 100 % [1]. Particular experiments indicated that the solvolysis of the esters which produced both formaldehyde and methylal proceeded to completion, no methoxymethyl ester being present in the reaction mixture after sufficiently long reaction time. This was seen by running the samples into a large excess of 1 N sodium hydroxide solution, and after a standing period of 1 h, analysing the samples for formaldehyde. No increase in the formaldehyde content was observed during this time, which is sufficient to the quantitative hydrolysis of the methoxymethyl esters by the alkaline solution.

The method of determining the product composition for the solvolysis of methoxymethyl chloride in methanol-water mixtures was that described earlier by the author [3]. In all solvents investigated, several parallel determinations were conducted. In the solvolysis in 64.2 moles per cent methanol at 25°C, for instance, the following values were found for the molar percentage of formaldehyde in the product: 25.8, 26.6, 25.8, 25.4 and 25.6 (*average* 25.8). From the average value, the value 0.348 is obtained for the molar ratio of formaldehyde and methylal.

Table 6. The values of k_a and k_h (in sec.$^{-1}$) for the reversible acetalisation of formaldehyde in methanol-water mixtures at 25°C at 0.1182 N hydrogen chloride concentration. A. Measured by following the acetalisation of formaldehyde. B. Measured by following the hydrolysis of methylal.

$10^6 \cdot (k_h+k_a)$		3.17	3.24	3.12	3.28	2.99	3.11	3.10	2.99	

average $k_h+k_a = 0.00000312$ sec.$^{-1}$

$k_h/(k_h+k_a) = 1.41/5.34 = 0.264$

The determination of the rate constants for the hydrolysis of methylal (k_h) and the acetalisation of formaldehyde (k_a) took place by two different ways. In the first method, the acetalisation of formaldehyde was followed until the attainment of the equilibrium, in the second method the initial reactant was methylal. Both methods gave nearly identical results, as indicated by the values given in Table 6. Formaldehyde analysis was used for the rate measurements. In the second method, weighed samples of methylal were dissolved in measured volumes of the solvent, in order to calculate the initial concentration of methylal. In both methods, the first samples were taken almost immediately after mixing the components. Zero time was the time of taking of the first sample. Owing to the slowness of the reactions, practically no reaction had occurred at the zero time. The rate constants were calculated by the usual formulas for reversible first-order reactions [8]. Table 7 gives the details for one of the individual runs.

Complexes of the 4d- and 5d-Groups

III. Absorption Spectra of Marcel Delépine's Rhodium(III) and Iridium(III) Complexes

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

Professor M. Delépine has kindly furnished the octahedral complexes of rhodium(III) and iridium(III) with pyridine, oxalate, chloride, bromide, ammonia and water. In the *cis*-isomers of rhodium(III), the first transition to a singlet level is observed approximately at the position interpolated from the complexes with six equal ligands, while the first strong band is split into two bands of *trans*-isomers. However, it is difficult to describe this behaviour quantitatively by the ligand field theory for tetragonal symmetry without assuming interaction with higher $^1\Gamma_{t_5}$ levels. In iridium(III), the electron transfer bands of oxalate groups and the ultraviolet absorption of pyridine render the observation of singlet bands difficult, while the triplet bands are rather strong due to the intermediate coupling. The *trans*-isomer of Ir $py_2Cl_4^-$, but not of Ir $ox_2Cl_2^{-3}$, has the triplet band at a lower wavenumber than the *cis*-isomer. The acidity of water in iridium(III) complexes is remarkably low, thus $pK = 5.1$ of *trans*-Ir $py_2(NH_3)_3H_2O^{+3}$, 6.7 of *cis*-Ir $py_2Cl_3(H_2O)$ and ~10.1 of Ir $Cl_5(H_2O)^{--}$.

In the first paper of this series [1], the absorption spectra of several rhodium(III) and iridium(III) complexes were interpreted as transitions to one of the two triplet levels $^3\Gamma_4$ and $^3\Gamma_5$ and to the two singlet levels $^1\Gamma_4$ and $^1\Gamma_5$ of the excited configuration $\gamma_5^5\gamma_3$ while the groundstate is $^1\Gamma_1$ of γ_5^6. This notation [2] is only meaningful for complexes of perfect cubic symmetry, *e.g.* with six equal ligands in equal distances from the central ion. Most complexes MA_nB_{6-n} with two different ligands A and B arranged in a regular octahedron have tetragonal symmetry [3], of these *trans*-MA_4B_2 has a centre of inversion as also MA_6, while the other complexes have no centre of inversion. In some cases, the Jahn-Teller effect produces tetragonal symmetry by distortion of MA_6, *e.g.* copper(II)[4–7]. While these effects are conspicuous in the absorption spectra, the regular octahedral d^3-, d^8- and diamagnetic d^6-systems without Jahn-Teller effect [3,8,9] exhibit only small effects of tetragonal splitting with mixed sets of ligands, *e.g.* nickel(II) complexes [10–12]. Mr. C. E. Schäffer will later demonstrate that the absorption bands of chromium(III) complexes of tetra-

gonal symmetry generally are only slightly widened, but do not always exhibit the splitting, predicted from the ligand field theory by Hartmann and Kruse [13]; Linhard and Weigel [14] found that pentamine complexes of cobalt(III) in most cases exhibit a broadening or a splitting of the first singlet band, which is even more evident in *trans*-substituted cobalt(III) tetramine ions [15]. This led Orgel [16] to apply the ligand field theory on the case, and Basolo, Ballhausen and Bjerrum [17] have later given more evidence, while Yamada, Nakahara, Shimura and Tsuchida [18] investigated the dichroism* of *trans*-Co $en_2Cl_2^+$ and *trans*-Co $en_2Br_2^+$ in crystals.

Professor Marcel Delépine of Collège de France has kindly placed at my disposal samples of the highly robust *cis*- and *trans*-isomers of rhodium(III) and iridium(III) complexes, which allow a comparison with the behaviour of cobalt(III).

Table 1. Absorption bands of M. Delépine's rhodium(III) complexes. λ_n is the wavelength, σ_n the wavenumber, ε_n the molar extinction coefficient of each maximum. $\delta(-)$ is the halfwidth towards smaller and $\delta(+)$ towards larger wavenumbers. The ligand field quantum numbers of the excited levels are discussed in the text.

DICHLORO BIS(OXALATO)RHODIUM(III) IONS

Fig. 1 and Table 1 give the absorption spectra of *cis*- and *trans*-Rh $ox_2Cl_2^{---}$ prepared by Delépine [19]. The two bands of the *cis*-isomer are situated nearly as interpolated between the cubic Rh Cl_6^{---} and Rh ox_3^{---}, given in Ref. 1:

* Recently, Ballhausen and Moffitt [38] applied the selection rules for transitions, coupled with one quantum of odd vibration, to these dichroitic effects, supporting the identification of the first band as $^1\Gamma_{t_1} \rightarrow {}^1\Gamma_{t_2}$.

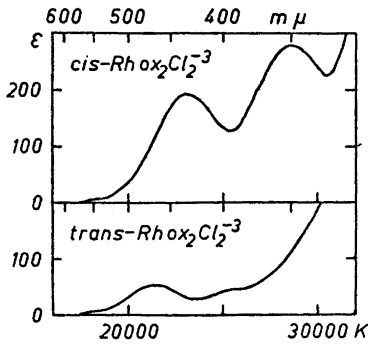

Fig. 1. Absorption spectra of rhodium(III) dichlorodioxalate complexes. 0.006 M *trans*-$K_3[Rhox_2Cl_2]$,$4H_2O$ and 0.005 M *cis*-$K_3[Rhox_2Cl_2]$, H_2O in aqueous solution.

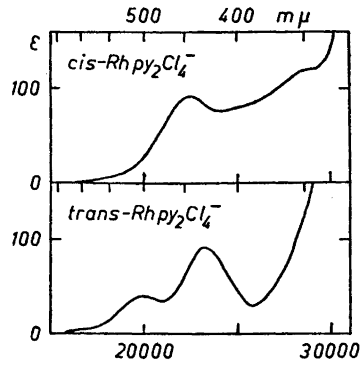

Fig. 2. Absorption spectra of rhodium(III) dipyridinotetrachloro complexes. 0.014 M *cis*-$K[Rhpy_2Cl_4]$, H_2O and 0.016 M *trans*-$K_3[Rhpy_2Cl_4]$, H_2O in aqueous solution.

	σ_1	σ_2
Rh Cl_6^{---}	19 300 K	24 300 K
Rh ox_3^{---}	25 100	30 000
cis-Rh $ox_2Cl_2^{---}$	23 000	28 400
$\frac{1}{3}\,\sigma_n(RhCl_6^{---}) + \frac{2}{3}\,\sigma_n(Rh\,ox_3^{---})$	23 170	28 100

In the place of σ_1, the *trans*-isomer gives two weak bands at 21 300 and 25 100 K. These bands [17] are caused by transitions to the levels $^1\Gamma_{t_5}$ and $^1\Gamma_{t_2}$, which have the degeneracy numbers 2 and 1, respectively. The weighted average of the two wavenumbers is then 22 600 K.

DIPYRIDINE TETRACHLORO RHODIUM(III) IONS

Fig. 2 and Table 1 give the absorption spectra of *cis*- and *trans*-Rh $py_2Cl_4^-$ studied by Delépine [20]. While *trans*-Rh $ox_2Cl_2^{---}$ is tetragonal in the same way as copper(II) complexes, *viz.* with less crystal field strength along one axis than along the two equivalent axes in a plane, *trans*-Rh $py_2Cl_2^-$ is »compressed« tetragonal [3], since the order in the spectrochemical series is:

$$Br^- < Cl^- < ox^{--} < H_2O < py < NH_3 < en.$$

The Rh py_6^{+++} is regrettably not known, but its first singlet band can be assumed [1] to be ~30 000 K. The cubic contribution [3] of Rh $py_2Cl_4^-$ is thus 22 900 K. *cis*-Rh $py_2Cl_4^-$ has the first singlet band at 22 400 K. In *trans*-Rh $py_2Cl_4^-$, two bands are observed at 20 000 and 23 200 K. In this case the second band is stronger than the first, agreeing with the degeneracy numbers 1 and 2. The weighted average is 22 200 K.

DICHLORO TETRAPYRIDINE RHODIUM(III) IONS

The pale yellow Rh $py_4Cl_2^+$ was first prepared by S. M. Jørgensen [21]. Recently, Delépine [22] discovered the strong catalytic influence of even 1 % of alcohols on the reaction between pyridine and a concentrated aqueous solution of Na_3RhCl_6, forming [Rh py_4Cl_2] Cl,6 H_2O.

The spectrum (Table 1) has a band at 24 400 K, which is so low a wavenumber that it presumably is due to ${}^1\Gamma_{t5}$ of a *trans*-complex, which here is analogous to copper(II). The *trans*-configuration is also supported by the formation [21] of [Rh py_4Cl_2]Cl,HCl, 2 H_2O analogous to the similar *trans*-[Co en_2Cl_2]Cl,HCl, 2 H_2O. Steric reasons seem to prevent pyridine from using the two perpendicular places.

When Rh $py_4Cl_2^+$ is boiled for some minutes with dilute Na_2CO_3, the band is shifted to 358 mμ (28 000 K) and by acidification with $HClO_4$, it is shifted to 384 mμ (26 000 K). This behaviour can be interpreted by the formation of hydroxo- and aquo-complexes, of which the spectra are analogous to Co $en_2(OH)_2^+$ and *trans*-Co $en_2(H_2O)_2^{+3}$ studied by Bjerrum and Rasmussen [23]. Analogously when *cis*-Rh $py_2Cl_4^-$ is boiled with water, or with Na_2CO_3 and subsequently with $HClO_4$, the first maximum is shifted to 421 mμ (23 700 K) corresponding to *cis*-Rh $py_2Cl_3(H_2O)$. If *trans*-Rh $py_2Cl_4^-$ is analogously treated, an orange precipitate [20], *trans*-Rh $py_2Cl_3(H_2O)$,H_2O is formed, which on heating polymerizes [20] to a completely insoluble pink product, Rh py_2Cl_3. Only one ligand field band has been observed of 1,2,6-Rh py_3Cl_3 (dissolved in $CHCl_3$) at 23 700 K. This seems somewhat less than the probable cubic contribution ~24 600 K and may be ascribed to rhombic splitting of ${}^1\Gamma_4$. However, the larger number of interactions possible between levels in low symmetry may systematically depress the wavenumber of the first band.

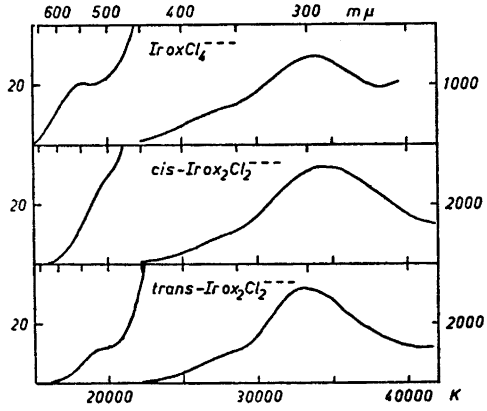

Fig. 3. Absorption spectra of iridium(III) chloro-oxalate complexes. 0.001 M to 0.014 M $K_3[Ir\,ox Cl_4]$, H_2O, 0.0006 M to 0.011 M *cis*-$K_3[Ir\,ox_2Cl_2]$, H_2O (racemic form), and 0.0006 M to 0.011 M *trans*-$K_3[Ir\,ox_2Cl_2]$,5 H_2O in aqueous solution.

Table 2. Absorption bands of M. Delépine's iridium(III) complexes. Notation as in Table 1. In the column "Excited level", triplet and singlet denote ligand field levels, Ir py the transition of an electron from the central ion to pyridine, redox the usual electron transfer spectra in the opposite direction, and py 0, py 1, . . . the vibrational structure of the pyridine band (py broad denotes the actual maximum, when this structure is blurred out), while "oxalate" denotes the ligand transition, polarized by the iridium ion.

OXALATO- AND CHLORO-IRIDIUM(III) COMPLEXES

Vèzes and Duffour [24] studied the mixed chloro-oxalato complexes of iridium(III), and Delépine [25] later investigated the exact conditions for formation of Ir $oxCl_4^{-3}$, *cis*- and *trans*-Ir $ox_2Cl_2^{-3}$. In these complexes, the triplet band [1] of $IrCl_6^{-3}$ can be seen (Table 2 and Fig. 3) to be regularly shifted towards the higher wavenumbers with increasing number of oxalate groups, while the two singlet bands are hidden by the electron transfer band in the ultraviolet. This band has been found by Babaeva and Mosyagina [26] in all oxalate complexes. In iridium(III), the ε_n of the maximum is 1 600 per oxalate group.

In Ir ox_3^{---}, all the crystal field bands are hidden [1]. The differences between *cis*- and *trans*-Ir $ox_2Cl_2^{---}$ are the intensity of the triplet band (which have the same position in the two complexes) and 3 % different wavenumbers of the electron transfer band (which perhaps is an internal transition in the oxalate group, analogous to the acetylacetonate [7] absorption.)

PYRIDINE- AND CHLORO-IRIDIUM(III) COMPLEXES

Delépine [27] prepared the red-brown Ir $py Cl_5^{--}$, and [28] the pink *trans*-Ir $py_2Cl_2^-$ and orange *cis*-Ir $py_2Cl_4^-$, and the two yellow compounds [25] 1,2,3-Ir py_3Cl_3 and 1,2,6-Ir py_3Cl_3. Finally, Professor M. Delépine has sent me the chloride of Ir $py_4Cl_2^+$, which is not yet described in the literature, but is made by heating *cis*-Py H[Ir py_2Cl_4] with pyridine 1.5 h to 130°C.

As seen from Fig. 4 and Table 2, the triplet band is also here shifted from the place in $IrCl_6^{---}$ towards higher wavenumbers. But the triplet band of *trans*-Ir $py_2Cl_4^-$ is shifted 2 200 K towards the red and is less intense, compared to the band of the *cis*-form. It might be argued that the weak band observed in Ir $py_4Cl_2^+$ is the first singlet band as in the corresponding rhodium complex discussed above, but the extreme hypsochromy [1] of Mathieu's $Ir(NH_3)_5Cl^{++}$ and Ir en_3^{+++} makes the triplet assignment more probable.

The pyridine-complexes of iridium(III) all have a broad band in the range 30 000—34 000 cm^{-1} and a set of narrow bands, often four members of a vibrational structure 37 000—41 000 cm^{-1} (*cf.* Fig. 5). The latter bands are nearly equal in different complexes and can be ascribed to the π-electron system of the heterocyclic pyridine-ring. The broad band at lower wavenumber is not observed in free pyridine or pyridinium salts with a comparable intensity. Further, Rh $py_2Cl_4^-$ and Rh $py_4Cl_2^+$ do not either exhibit this band, which must be due to some electron transfer process in iridium(III) which is not observed in pyridine-free complexes [1].

In the fourth paper of the series, the latter band will be discussed. Its position is dependent on the other ligands and seems to follow the spectrochemical series. Actually, it has nearly the same wavenumber as predicted of the ligand field transition to the second singlet level $^1\Gamma_5$. However, it is not very likely that it is strongly intermixed with this Laporte-forbidden band, or that it is a triplet or weak singlet band elsewise known of pyridine: rather, it is probably due to transition of a γ_5-electron from iridium(III) to a π-antibonding orbital of pyridine.

THE THREE ISOMERS OF DIPYRIDINO TRICHLORO AQUO IRIDIUM(III)

Delépine [29,39] has prepared three isomers of Ir $py_2Cl_3(H_2O)$: one with the pyridines in *trans*-position, and the two possible monomers with pyridine in *cis*-position and the water in *trans*-position to either pyridine or chloride. The two latter isomers can be made from an aqueous solution of *cis*-Ir $py_2Cl_4^-$ by a photochemical reaction with sunlight, producing a relatively more water-soluble form, and by heating in an autoclave to 130°C, where polymerized by-products and a less soluble monomer is produced. The geometrical configuration of the "sun" and the "autoclave" isomer is not yet elucidated. *Cf.* the seven publications by Delépine [29].

It is seen in Table 2 that while the absorption spectra of the three isomers of Ir $py_2Cl_3(H_2O)$ are not very different, the alkaline solutions, forming Ir $py_2Cl_3(OH)^-$, have, *e.g.*, the iridium-pyridine band mentioned above at highly different wavenumbers. It is remarkable that the water group can be revers-

ibly titrated without appreciable loss of chloride in alkaline solution for many hours at room temperature. Even the least robust iridium(III) pyridine complex with the highest number of chloride groups, Ir $pyCl_5^{--}$, aquates during several days with the result that the Ir-py band shifts monotonously towards higher wavenumbers of the aquo forms and towards lower wavenumbers of the hydroxo forms, as discussed in the next paper. It is necessary to boil the alkaline solution of Ir $pyCl_5^{--}$ to efficiently destroy the binding between iridium and pyridine.

trans- and *cis*-(autoclave) Ir $py_2Cl_3(H_2O)$ are so weakly soluble in water that it is difficult to observe the ligand field triplet transition. Similar remarks apply to the 1,2,3-isomers of Ir py_3Cl_3 and Ir py_3Br_3, of which the best solvent known, chloroform, only dissolves a very small amount.

PYRIDINE-, AMMONIA-, CHLORO-, AQUO-COMPLEXES OF IRIDIUM(III)

Delépine [28] has prepared yellow Ir $py_2(NH_3)_2Cl_2^+$, pale yellow Ir $py_2(NH_3)_3Cl^{++}$, and white Ir $py_2(NH_3)_3H_2O^{+++}$, all with the pyridines in *trans*-position, and Delépine and Pineau [30] the pale yellow Ir $py(NH_3)_4Cl^{++}$. In the chloro complexes, there are very weak traces of a shoulder corresponding to the triplet band at 360 mμ of $Ir(NH_3)_5Cl^{++}$. The wavenumber of the broad and strong Ir-py band increases with a decreasing number of chloride groups, but seems still to subsist in Ir $py_2(NH_3)_3H_2O^{+++}$ superposed upon the narrow pyridine bands, while it is very evident in Ir $py_2(NH_3)_3OH^{++}$ (see Fig. 5).

THE ACIDITY OF WATER IN IRIDIUM(III) COMPLEXES

Reversible titration curves have been made with a glass electrode pH-meter of the following of Delépine's compounds:

cis-Ir $py_2Cl_3(H_2O)$ (sun) has $pK = 6.7$
trans-Ir $py_2(NH_3)_3H_2O^{+++}$ has $pK = 5.1$
Ir $Cl_5(H_2O)^{--}$ has $pK \sim 10.1$. however with some decomposition in alkaline solution.

Thus, the acidity of water increases with the positive external charge, but not to a larger extent than known of aquo complexes of cobalt(III) or chromium(III).

A sample of what was assumed to be Ir $py_2(NH_3)_3NH_2^{++}$ exhibited the same absorption spectrum as Ir $py_2(NH_3)_3OH^{++}$, and by titration of a sample of assumed Ir $py_2(NH_3)_4Cl_3$, 80 % of the calculated stoichiometric amount titrated with a fine one-proton curve, corresponding to $pK = 5.2$. Thus, the latter sample contains at most 20 % Ir $py_2(NH_3)_4^{+++}$, and its acidity cannot be ascribed to formation of amido complexes. This is not in disagreement with the analyses of Delépine [28], who determined only iridium and chloride but not nitrogen.

PYRIDINE- AND BROMO-IRIDIUM(III) COMPLEXES

Ir Br_6^{---} and Ir $Br_5(H_2O)^{--}$ have not very different spectra in aqueous solution, as seen from Table 2. The former ion aquates probably rather quickly in aqueous solution, explaining the slight deviation from the solution in HBr, described previously [1]. While most other iridium(III) complexes do not exhibit maxima of the electron transfer bands in the accessible range above 205 mμ Ir Br_6^{---} and Ir $Br_5(H_2O)^{--}$ have a double band with $\varepsilon_n \sim 11\,000$ and 20 000, resembling much the isoelectronic [32] Pt Br_6^{--}. The doublet structure and energy levels of halide complexes will be discussed in the fourth paper of this series.

In dilute solution, both $IrBr_6^{---}$ and $IrBr_5(H_2O)^{--}$ form the same $IrBr_6^{--}$ by addition of bromine:

$$IrBr_5(H_2O)^{--} + 1/2\ Br_2 = IrBr_6^{--} + H_2O$$

the total reaction thus being an addition of a bromine atom and not a simple electron transfer.

Madame Delépine-Tard [37] prepared dark red Ir $py_2Br_4^-$, which has the triplet at so high a wavenumber (compared to Ir $py_2Cl_4^-$) that the *cis*-structure is most probable. Besides the Ir-py and the py-bands, this ion exhibits also a genuine redox band at a much higher wavenumber than $IrBr_6^{---}$, as usually found for a decreasing number of halide ligands.

1,2,6-Ir py_3Br_3 is sufficiently soluble [29] in $CHCl_3$ to show the triplet band. The Ir-py band has a larger wavenumber in this isomer than in 1,2,3, as is also found for Ir py_3Cl_3.

Table 3. Absorption bands of iridium(IV) pyridine pentachloro complex.

PYRIDINE- AND CHLORO-IRIDIUM(IV) COMPLEXES

Delépine [27,33] oxidized Ir $pyCl_5^{--}$, *cis*- and *trans*-Ir $py_2Cl_4^-$ to the corresponding iridium(IV) complexes Ir $pyCl_5^-$ and *cis*- and *trans*-Ir py_2Cl_4. The two latter neutral compounds are nearly insoluble in any solvent. Ir $pyCl_5^-$ and *trans*-Ir py_2Cl_4 are even stronger oxidizing agents than bromine [27]. Inamura and Kondo [34] have measured the spectrum of Ir $pyCl_5^-$, which is also given in Table 3 and can be compared with [32] Ir Cl_6^{--}. While the maximum in the blue-green is nearly identical except for a shoulder at 502 mμ of Ir $pyCl_5^-$, the double maximum at 431 and 414 mμ of $IrCl_6^{--}$ is here shifted to 405 mμ and is single. Further, Ir $pyCl_5^-$ has the first shoulder at 625 rather than at 575 mμ. Presumably, all the bands are mainly due to transfer of π-electrons [32]. If the band at 625 mμ of Ir $pyCl_5^-$ was a ligand field band, it would probably be shifted towards the blue; it has rather another, mainly even excited state.

Table 4. Absorption bands of pyridine and pyridinium ion in aqueous solution. Notation as in Table 1.

THE PYRIDINE BANDS AND S.M. JØRGENSEN'S PYRIDINO PLATINUM(II) COMPLEXES

Table 4 gives the absorption bands of pyridine, which are very narrow (δ = 300 K) and are nearly equidistant with σ_c = 920 K. This is evidently a vibrational structure, which is excited by a Franck-Condon mechanism. There is no sign of transitions from vibrationally excited levels of the electronic groundstate, and the bands can thus be numbered 0, 1, ... according to the vibrational quantum number of the excited electronic state. In aqueous solution, there is no sign of weaker bands at smaller wavenumbers than those of the vibrational structure. Thus, the values of ε are:

270	275	280	285	290	300 mμ
150	27	3	0.5	0.1	0.02

The pyridinium ion pyH^+ has bands at nearly the same wavenumbers as py, but they are blurred out ($\delta \sim 500$ K) and have ~70 % higher intensity. In rhodium(III) pyridine complexes, the bands have not much smaller wavenumbers than of py, and nearly the same intensity per pyridine molecule, as seen above. Some iridium(III) complexes have not very much larger bathochromic shifts of the py-bands, while other have very broad py-bands with vanishing vibrational structure at relatively low wavenumbers, σ ~4 000 K below the centre of the bands of py (*cf.* Fig. 5). The latter behaviour of iridium(III) is enhanced by the presence of many anions (Cl^-, Br^-, OH^-) among the ligands and a low number of pyridine molecules, suggesting an especially strong bonding of the pyridine with larger change of the π-electron system of this molecule than in most other complexes.

As discussed in the next paper, the electron transfer, producing the new Ir-py band may be expected to occur also in pyridine complexes of other metals with low oxidation states. Platinum(II) should have possibilities for exhibiting this effect, and therefore the absorption spectra were measured of

some of the pyridine complexes, prepared by S. M. Jørgensen [35]. As seen from Table 5, the py-bands are shifted towards lower wavenumbers to a remarkably low extent, and there is no sign of a Pt-py band in the complexes with neutral ligands, such as py and NH_3. In the chloro complex, there may be distinguished an increasing background, but no certain conclusion can be drawn.

LIGAND FIELD QUANTUM NUMBERS IN COMPLEXES OF TETRAGONAL SYMMETRY

Qualitatively, the order of tetragonal levels [3,16,17] are supported by the measurements of *cis*- and *trans*-isomers of Rh $ox_2Cl_2^{-3}$ and Rh $py_2Cl_4^-$:

$$^1\Gamma_5 \rightarrow {}^1\Gamma_{t_4},\ {}^1\Gamma_{t_5}$$
$$^1\Gamma_4 \nearrow\ {}^1\Gamma_{t_2}$$
$$\qquad\ \searrow\ {}^1\Gamma_{t_5}$$

"copper(II)-like" tetragonality

$$^1\Gamma_5 \rightarrow {}^1\Gamma_{t_4},\ {}^1\Gamma_{t_5}$$
$$^1\Gamma_4 \nearrow\ {}^1\Gamma_{t_5}$$
$$\qquad\ \searrow\ {}^1\Gamma_{t_2}$$

"compressed" tetragonality

The result, derived by Tanabe and Sugano [36] for an electrostatic ligand field acting on pure d^n-configurations, *viz.* that $^1\Gamma_4$ is lower than $^1\Gamma_5$ of $\gamma_5^5\gamma_3$, is highly supported, since $^1\Gamma_{t_4}$ could hardly [3] take the place of $^1\Gamma_{t_2}$ in the left-hand set of levels. But quantitatively, the results reported here cannot be explained without strong interactions between the electron configurations of tetragonal orbitals.

Thus, the ratio between the splitting of $^1\Gamma_{t_2}$ and $^1\Gamma_{t_5}$ and the differences of the cubic ligand field strength of the purely hexa-coordinated complexes should be a constant number [3]. However, this ratio is 0.65 for *trans*-Rh $ox_2Cl_2^{-3}$, but only 0.32 for *trans*-Rh $py_2Cl_4^-$. This is a more fundamental difficulty than the problem of the value [3] of B_2/B_4, which may be solved by use of other d-wavefunctions than the hydrogen-like ones, *e.g.* the Hartree model discussed by Linn Belford [7], and by consideration of the much stronger influence of charge distributions near to the surface of the central ion than the point charges and point dipoles assumed in early electrostatic theory [6]. According to calculations on strong tetragonal fields [3], it is an almost paradoxical fact that $^1\Gamma_{t_4}$ does not decrease much in energy, producing a larger splitting of the second band, if this is caused by $^1\Gamma_5$ (the energy difference between $^1\Gamma_4$ and $^1\Gamma_5$ is explained as the correlation energy between d-electrons expressed in the Racah parameters B and C). An interaction between the two $^1\Gamma_{t_5}$, useful for explaining a part of the splitting of the first band, will further increase the distance between $^1\Gamma_{t_4}$ and the second $^1\Gamma_{t_5}$, which actually have nearly the same energy. Among the tetragonal levels of $\gamma_5^4\gamma_3^2$, the lowest energy will probably be represented by $\gamma^3{}_{t_5}\gamma_{t_4}\gamma^2{}_{t_1}$ in *trans*-Rh $ox_2Cl_2^{-3}$ and $\gamma^3{}_{t_5}\gamma_{t_4}\gamma_{t_3}{}^2$ in *trans*-Rh $py_2Cl_4^-$, both composed of $^1\Gamma_{t_5}$ and $^3\Gamma_{t_5}$. Thus, the second $^1\Gamma_{t_5}$ may be held in place besides $^1\Gamma_{t_4}$ by the interaction from opposite directions. This can also explain, why the second cubic band in some few cases capriciously exhibits tetragonal splitting, *e.g.*[11] Co enta OH^{--}. It may be noticed that the non-diagonal elements of energy between the two $^1\Gamma_5$ of

$\gamma_5^4\gamma_3^2$ and the one $^1\Gamma_5$ of $\gamma_5^5\gamma_3$ are rather important [36], explaining the decrease of the distance between $^1\Gamma_4$ and $^1\Gamma_5$ from the asymptotical strong-field value 16 B to 10—12 B.

In the case of the first tetragonal level $^1\Gamma_{t5}$ the configurations $\gamma_{t5}^3\gamma_{t4}^2\gamma_{t1}$ and $\gamma_{t5}^3\gamma_{t4}^2\gamma_{t3}$ must be highly intermixed [3] at low values of the tetragonality. Actually, the intermixing does not need to produce a splitting, proportional to the tetragonality, but rather to the square. This would explain why the splitting of the first band of *cis*-complexes is not always half as large as in the corresponding *trans*-complex [3]. Figs. 1 and 2 show that the first band of *cis*-Rh $ox_2Cl_2^{-3}$ and *cis*-Rh $py_2Cl_4^-$ definitely do not exhibit splittings amounting to 1 900 and 1 600 K, respectively. Analogously, the first band [1] of $Rh(NH_3)_5I^{++}$ is only split 1 700 K, while the difference between the first band of $Rh(NH_3)_6^{+++}$ and the hypothetical RhI_6^{-3} must be over 15 000 K ($Rh(NH_3)_5I^{++}$ is remarkable by having a negative cubic contribution [3] of the iodide, since the wavenumber of the first band is less than 5/6 of that of $Rh(NH_3)_6^{+++}$). The tetragonality effect, calculated for *trans*-M A_4B_2 is thus only $\lesssim 0.22$ for $Rh(NH_3)_5I^{++}$ and 0.32 for *trans*-Rh $py_2Cl_4^-$ multiplied by the differences in cubic ligand field strengths, while most electrostatic models would have presumed this ratio near to or above 1.

EXPERIMENTAL

The absorption spectra were measured at 25°C on a Cary recording spectrophotometer 11 MS—50. Since many of the measured compounds are so rare, several samples were weighed and transferred to the 1 cm absorption cell, which by weighing was found to contain 3.1 ml. Subsequent dilutions were performed with A. Krogh's syringe-pipettes. The high absorption bands ($\varepsilon_n \sim 10\,000$) were redetermined with solutions of weighed portions ~5 mg in 50 ml or 250 ml measuring flasks.

The ligand field bands ($\varepsilon_n = 10-200$) were measured with solutions, 0.01—0.03 M. The aqueous solutions of chloro-complexes were measured twice within 10 min (as the other complexes) and one and four days later. Only during at least several days were aquation effects observed of complexes with at most four chloride ligands. The complexes Ir $py_2(NH_3)_2Cl_2^+$, Ir $py_2(NH_3)_2Cl^{++}$ and Ir $py(NH_3)_4Cl^{++}$ were measured in 2 M NH_3 without showing changes of spectra, which might be caused by acidity of the amine groups. The titration curves were measured on a Radiometer glass-electrode pH-meter M 22.

It was assumed that the crystalline compounds have the compositions, indicated by M. Delépine:

cis-$K_3[Rh\ ox_2Cl_2],H_2O$
trans-$K_3[Rh\ ox_2Cl_2],4H_2O$
cis-$K[Rh\ py_2Cl_4],H_2O$
trans-$K[Rh\ py_2Cl_4],H_2O$
1,2,6-$Rh\ py_3Cl_3$
$[Rh\ py_2Cl_4]Cl,6H_2O$
$K_3[Ir\ oxCl_4],H_2O$

Acknowledgements. I am very much indebted to Marcel Delépine, Professor of Collège de France for his generous present of the rhodium and iridium complexes, which he has investigated for so many years, and which are so valuable for theoretical reasons because of the robustness of their geometrical isomers. I express also my gratitude to Madame Madeleine Delépine-Tard for the bromo- and bromo-pyridine iridium(III) complexes. Finally, I thank Professor Jannik Bjerrum and Mr. Claus E. Schäffer for valuable discussions, and Mr. Kjeld Rasmussen for assistance with some of the measurements.

Complexes of the 4d- and 5d-Groups

IV. Electron Transfer Bands with Special Application to M. Delépine's Complexes and a Transition from Iridium(III) to Pyridine, with some Remarks about Intermediate Coupling in Halide Complexes and the Uranyl Ion

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

In addition to the narrow pyridine-bands, which are only moderately shifted towards lower wavenumbers in complexes, the twenty iridium(III) pyridine complexes prepared by M. Delépine exhibit a new, broad band in the range 29 000—35 000 K. The qualitative molecular orbital diagrams are related to energy levels of the complexes and it is suggested that the broad band is caused by an electron transfer from iridium(III) to the π^*-orbitals of pyridine. The "redox" bands, caused by electron transfer from reducing halide ions to the central ion are discussed. The doublet structure, which Scheibe and Katzin ascribe to the two possible values of J of a free halogen atom, is related to the energy levels of a single electron in a linear ligand field with intermediate coupling. The influence of non-diagonal elements of energy between two levels with the same Ω is emphasized, *e.g.* of a 5f-electron in a linear dioxo complex. Finally, the absorption spectra of α,α'-dipyridyl and o-phenanthroline complexes are investigated; the bands at low wavenumbers of complexes with low oxidation state of the central ion seem analogous to the Ir-py band.

The preceding paper [1] of this series considered the iridium(III) complexes, presented by Professor M. Delépine. In addition to the ligand field transitions (singlet → triplet bands with $\varepsilon \sim 10$ and singlet → singlet bands with $\varepsilon \sim 100$), and the narrow pyridine bands (which are part of a vibrational structure with $\sigma_c \sim 1\,000$ K and $\varepsilon_n \sim 4\,000$ per pyridine molecule), the pyridine complexes exhibit a broad band (with $\varepsilon_n \sim 2\,000$ per pyridine molecule) at lower wavenumber than the genuine pyridine bands. Since neither pyridine-free iridium complexes [2] such as $Ir(NH_3)_5Cl^{++}$ and Ir en_3^{+++}, nor rhodium(III) and platinum(II) pyridine complexes exhibit such a band, it may be denoted by the Ir-py band. Table 1 gives the wavenumbers in Kayser, K = cm^{-1}, of this band and the vibrational structure py 0, py 1, ... of the

Table 1. Wavenumbers of the iridium(III) pyridine electron transfer band Ir py and the pyridine bands py 0, py 1, etc. "b" denotes broad maximum without vibrational structure.

* 0.0004 M $KIrpyCl_5$ in aqueous solution kept at ~25°C. After each measurement, the aquated ions were transformed into the hydroxo forms by making the solution 0.1 M in Na_2CO_3. The reversibility of the aquo-hydroxo equilibria were proven by addition of $HClO_4$, producing 0.2 M free H_3O^+. After 14 days, this reaction was not completely reversible.

** Recently, M. Delépine has sent me two different isomers of KIr py $Cl_4(H_2O)$, prepared from the action of sun-light and by warming of K_2Ir py Cl_5 in aqueous solution.

iridium(III) complexes and of py itself. In some cases of strong bathochromy, the vibrational structure is blurred out to a broad band, denoted by "b" in the Table.

It might be assumed that the Ir-py band is actually some feature of the absorption spectrum of pyridine itself, which has obtained better possibilities of observation in the complexes. Rush and Sponer [3] observed two excited electronic states in gaseous py with 0-vibrational levels at 34 769 K and 38 350 K. Stephenson [4] assumes that ~90 % of the oscillator strength (0.04) of the pyridine bands in a non-polar solvent such as *iso*-octane is due to the 38 350 K-state, but that ~10 % is concentrated in a weaker band towards lower wavenumbers nearer 34 769 K. The latter band is hidden by the higher band near 38 350 K in solvents such as ethanol [4]. This is also the case in

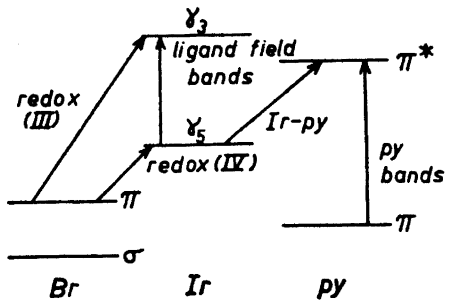

Fig. 1. Relative positions of molecular orbitals in an iridium complex with bromide and pyridine among the ligands. The disagreement of this qualitative picture with the observed energy differences is discussed p. 169. The four types of transitions are indicated:
1. Ligand field transitions within the d-shell (which is, however, intermixed with the orbitals of the ligands by partly covalent bonding).
2. Redox bands, caused by the transfer of an electron from the ligands to the central ion (having smaller wavenumbers in iridium(IV) than in iridium(III) complexes).
3. Ir-py bands, caused by the transfer of an electron from the d-shell to the empty π^*-orbitals of the ligands.
4. py bands, characteristic for the aromatic ligands, caused by internal transitions from π to π^*-orbitals.

aqueous solution [1]. The hypsochromic effect of polar solvents is explained by Stephenson [4] by the interpretation of the weak band as a transfer of a non-bonding electron mainly concentrated on the nitrogen atom, to the anti-bonding π^* orbitals of the heterocyclic ring. When hydrogen bonds stabilize the non-bonding electron, the wavenumber of the transition is increased. The influence of positive central ions will probably be much larger and thus, the Ir-py band can hardly be identified with this transition. Reid [5] has reported triplet levels of gaseous pyridine at 30 876 K (and also at 31 459 and 32 538 K) corresponding to $\varepsilon = 0.10$. The aqueous solution seem less absorbing at these wavenumbers [1]. Reid [5] reported also dubious bands with $\varepsilon \sim 10^{-4}$ of liquid py near 25 500, 26 490, and 27 500 K. However, the presence of other heterocyclic compounds *, overtones of infra-red bands etc. may explain this observation. It might be argued that the large extent of intermediate coupling in iridium(III) [2] ($k\zeta_{5d} = 2\,000$ K) may explain a high intensity of singlet-triplet transitions in pyridine by intermixing with the orbitals of the central ion. However, the present author believes that the observed effect is too strong for this type of explanation, and that its absence in platinum(II) complexes, where the intensity ratios in $PtCl_4^{--}$ and $PtBr_4^{--}$ also imply $k\zeta_{5d} = 2\,000$ K, is pertinent.

Thus, the Ir-py band must rather be ascribed to an electron transfer process. Since pyridine is not so reducing as Br^-, and since the "redox" bands of $IrBr_6^{-3}$ occur at 37 000 and 41 500 K and of $IrCl_6^{-3}$ at 48 500 K (see Table 2), while the Ir-py bands are situated in the range 29 000—35 000 K, it can be concluded

* Recently, Brealey [27] has demonstrated that the bands 29 000—33 000 K are caused by one part in 150 000 of pyrazine, and thus, no triplet levels are known of pyridine.

that the electron is transferred from the central ion to the pyridine ligand, the opposite direction of the usual redox bands. This might be visualized in a diagram of the relative energy of molecular orbitals such as Fig. 1. However, this diagram leads to a paradoxical contradiction, if applied to the energy difference between the ground level and the excited level of the Ir-py band. If a complex with pyridine and bromide among the ligands is considered with an energy difference Δ (also called $(E_1—E_2)$ or 10 Dq) between the γ_3- and γ_5-orbital of the 5d-shell equal to 25 000 K, it is concluded from the redox bands (Table 2) of both $IrBr_6^{--}$ (where the electron is excited to fill the γ_5-hole) and $IrBr_6^{-3}$ (where the electron is excited to the γ_3-orbital) that the highest orbital of Br^- is $\sim$ 15 000 K below γ_5. It is easily recognized that the highest filled π-orbital of py must have an energy at least 15 000 K below Br^- (*cf.* the redox spectrum [1] of Rh $py_2Cl_4^-$). Thus, the excited π^*-orbital of py, which is 38 000 K above the groundlevel, will be only $\sim$8 000 K above γ_5 of the central ion, *i.e.* the Ir-py band should have a wavenumber at least 20 000 K below the observed. This trend of thought leads generally to difficulties for all complexes of ligands, which have empty orbitals not much more than 50 000 K above their highest occupied orbital. While the high ultraviolet absorption [6] of most *o*-phenanthroline complexes undoubtedly represents a bathochromic shift of the aromatic absorption bands of the free ligand (*cf.* Table 1) the high band of Fe $phen_3^{++}$ at 19 600 K is perhaps analogous to the Ir-py band, as discussed in the last section. However, these cases do not seem very common; in contrast to $Fe(CN)_6^{-3}$, which may have redox bands [7] at 23 900 and 32 900 K, $Fe(CN)_6^{-4}$ does not exhibit such strong bands below 40 000 K. It may be questioned, if CN^- (which is itself practically non-absorbing [7] below 50 000 K) actually has π^*-orbitals at much lower energies than CO or N_2.

The failure of the qualitative diagram of molecular orbitals, Fig. 1, is of course that it does not take into account the change of equilibria positions of the ligands in the excited levels and the reciprocal influence of the energies of the molecular orbitals. Actually, only energy levels of the total system have physical significance; the distribution of the energy on the single orbitals is a matter of choice, if it cannot be assumed that the ionization potentials are a first order approximation to the negative orbital energies, *i.e.* that the other orbitals re-arrange but slightly during the ionization process. In the case of the Ir-py band, it must not be presumed that the energy of π^* in pyridine is independent of the existence of a hole in the elsewise filled π-orbitals. For this reason, the Ir-py band has higher wavenumber than implied from the energy levels of pyridine.

The former difficulty, the excitation according to the Franck-Condon principle [8] of vibrations, is probably even more important. Thus, an electron transfer process necessitates often supply of energy in both directions, which act as an activation energy to counteract the unfavourable interatomic distances of the excited system, compared to the vibrational groundstate of the excited system [9]. The reactions

$$Ir^{III}py\ Cl_5^{--} + 30\,400\ K \rightarrow Ir^{IV}py^*Cl_5^{--}$$
$$Ir^{IV}py\ Cl_5^{-} + 20\,000\ K \rightarrow Ir^{III}pyCl^*Cl_4^{-}$$

do not give any immediate evidence on the relative stability of the oxidation states +3 and +4 of iridium. They may suggest Franck-Condon activations of the order of magnitude 10 000 K.

REDOX BANDS OF METAL HALIDE COMPLEXES

Scheibe [10,11] assumed that the strong absorption bands in the far ultraviolet of Cl^-, Br^-, and I^- in aqueous solution is due to the photochemical reaction *e.g.*

$$Br_{aq}^- + 54\,000\ K \rightarrow Br_{aq} + e_{aq}^-$$

where the solvated electron of course is unstable towards formation of molecular hydrogen etc. Since the corresponding reaction *in vacuo* necessitates [12]

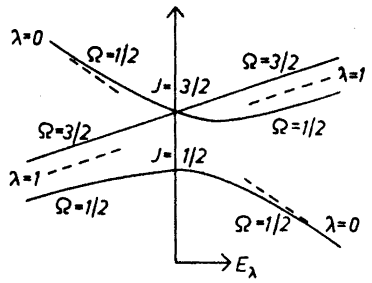

Fig. 2. The energy levels of a p-electron in a linear ligand field as function of the parameter E_λ. The intermediate coupling splits the levels with definite values of λ into two (for $\lambda > 0$) with different values of Ω (analogous to J of the gaseous ion). Levels with the same Ω interact, forming hyperbolic curves in the diagram.

only 3.56 eV, *i.e.* 27 700 K, Br^- must be stabilized considerably better by solvation than e^-.

If the halide ion is near a metal ion with larger electron affinity than water, it is natural to assume a smaller energy necessary for the transfer of an electron to the metal ion. Thus, the strong absorption will be shifted more towards lower wavenumbers, the more oxidizing the metal ion. This assumption was applied by Linhard and Weigel [13,14] to the halide pentammine cobalt(III) and chromium(III) complexes. If the electron shall penetrate the first coordination sphere, then the bathochromic shift of the electron transfer band will be smaller, as found for the ion pairs [15] of halide and $Co(NH_3)_6^{+++}$, even though the effect is stronger [16] in solid $Co(NH_3)_6I_3$, where the second ligand field band is masked.

Scheibe [10,11] found further that the absorption band of I^-_{aq} is double with maxima at 44 500 K and 52 000 K, while the splitting is smaller in Br^-_{aq} and not detectable in Cl^-_{aq}. This was ascribed to the two possible states $^2P_{3/2}$ of lowest and $^2P_{1/2}$ of higher energy of the free halogen atom with the outer electron configuration s^2p^5. This energy difference is for the gaseous atoms 881 K for Cl, 3 685 K for Br and 7 603 K for I, corresponding to increasing values of $3/2\ \zeta_{np}$ for n = 3, 4, 5. Katzin [17] has recently continued this study and found that a large number of iodide complexes have two absorption bands in the near ultraviolet with a wavenumber difference 6 000—8 000 K, while the similar values for bromide complexes are 3 000—7 000 K.

The present author does not doubt that most of these splitting effects* are caused by intermediate coupling. However, it is not very probable that the excited levels resemble the states with $J = 3/2$ and $1/2$ of the atomic spectroscopy very much. It is seen from Table 2 that only one broad redox band is observed of $IrCl_6^{-3}$ and $PtCl_6^{-2}$, while two bands are observed of $IrBr_6^{-3}$ and $PtBr_6^{-2}$ with the intensity ratio $\sim 1:2$, arranged according to increasing wavenumber. This is not quite expected in Scheibe's theory, since the de-

* However, most crystalline alkali metal halides [36] have from four to six absorption bands in the range 45—90 000 K and hence, the nature of the electronic states is not easily recognized.

generacy numbers of the levels are 4 and 2. Generally, the first band of bromide and iodide complexes is often remarkably weak.

However, it can be theoretically justified that the degeneracy numbers of the two first levels may be 2 and 2, while a third level, also with 2, may give rise to an even stronger absorption band at higher wavenumbers than usually observed. If the six halide ions are not very strongly perturbed by the central ion, they can be treated as independent of each other, placed in a linear ligand field from the positive central ion. If the ligand contains an electron with the angular momentum quantum number l, and if the effects of intermediate coupling are neglected, $l+1$ equidistant energy levels occur with the quantum number $\lambda = l, l-1, l-2, \ldots, 0$. The first-order effect of intermediate coupling will be to split all the levels with $\lambda > 0$ in two with the quantum number $\Omega = \lambda + \frac{1}{2}$ and $\lambda - \frac{1}{2}$ and with the energy difference $\lambda\zeta_{nl}$.

If we denote the energy difference between the levels $\lambda+1$ and λ by E_λ, E_λ will be positive when the linear field is caused by a positive charge and negative, when the linear field is supplied by negative ligands. For a p-electron with $l = 1$, this has a simple physical explanation: If the charge is placed on the z-axis of a Cartesian co-ordinate system, $\lambda = 0$ is represented by the p_z orbital (of which the potential energy is decreased by a positive charge) and $\lambda = 1$ is represented by the two equivalent orbitals p_x and p_y, concentrated in the plane perpendicular to the linear field. In a ligand field of tetragonal symmetry, supplied by four square-planar ligands, the opposite behaviour of p_z will occur.

If E_λ is not much larger than ζ_{nl}, the two levels with equal values of Ω (if less than $l + \frac{1}{2}$) will interact, forming a hyperbola in the energy diagram as function of E_λ. Fig. 2 gives the result for a p-electron and Fig. 3 for a f-electron. In the former case, the diagonal elements of energy, corresponding to the asymptotes of the hyperbolae, are:

$$\begin{aligned} &\lambda = 1,\ \Omega = 3/2: \quad 1/3\, E_\lambda + 1/2\zeta_{np} \\ &\lambda = 1,\ \Omega = 1/2: \quad 1/3\, E_\lambda - 1/2\zeta_{np} \\ &\lambda = 0,\ \Omega = 1/2: -2/3\, E_\lambda \end{aligned} \tag{1}$$

while the square of the non-diagonal element between the two latter levels is $1/2\ \zeta_{np}^2$. Thus the two levels with $\Omega = \frac{1}{2}$ cannot have a smaller distance than two times the non-diagonal element, *viz.* $\sqrt{2}\,\zeta_{np}$. In the general case, the diagonal elements of energy will be

$$\begin{aligned} &\Omega = \lambda + \tfrac{1}{2}: \left(\lambda - \frac{l(l+1)}{2l+1}\right) E_\lambda + \frac{\lambda}{2}\,\zeta_{nl} \\ &\Omega = \lambda - \tfrac{1}{2}: \left(\lambda - \frac{l(l+1)}{2l+1}\right) E_\lambda - \frac{\lambda}{2}\,\zeta_{nl} \end{aligned} \tag{2}$$

while the square of the non-diagonal element between two levels with the same Ω will be

$$\tfrac{1}{4}(l + \tfrac{1}{2} + \Omega)\ (l + \tfrac{1}{2} - \Omega)\ \zeta_{nl}^2 \tag{3}$$

The slopes of the lines in the energy diagram (Figs. 2 and 3) for $E_\lambda \to 0$ are a linear function of Ω. For the upper level with $J = l + \frac{1}{2}$ are the first-order splittings

$$E = \frac{2l}{2l+1}\left(\Omega - \frac{l+1}{2}\right) E_\lambda + \frac{l}{2}\zeta_{nl} \tag{4}$$

while for the lower atomic level with $J = l - \frac{1}{2}$, the first-order energies are

$$E = \frac{2l+2}{2l+1}\left(\Omega - \frac{l}{2}\right) E_\lambda - \frac{l+1}{2}\zeta_{nl} \tag{5}$$

In the case of an electron transfer, where a hole is created in a p-shell, and only one significant energy level occurs in the system which has accepted the electron, one would thus expect three absorption bands, arranged according to increasing wavenumbers:

$$(\lambda = 1, \Omega = 3/2) \quad (\lambda = 1, \Omega = \tfrac{1}{2}) \quad (\lambda = 0, \Omega = \tfrac{1}{2}).$$

The distance between the two first bands will be somewhat less than ζ_{nl}, while the distance between the two last bands will be slightly larger than $E_\lambda - \frac{1}{2}\zeta_{nl}$. The two first bands are due to transfer of π-electrons ($\lambda = 1$), if the intermixing of the two levels with $\Omega = \frac{1}{2}$ is neglected, and the last band is due to transfer of a σ-electron ($\lambda = 0$).

Orgel [9] assumes that the two bands, observed of halide pentammine cobalt(III) complexes [13,14], which have highly different intensities (*cf.* Table 2) are due to transfer of π- and σ-electrons, respectively. These bands are also observed of $Rh(NH_3)_5Br^{++}$ and $Rh(NH_3)_5I^{++}$ by the present author, but are perhaps a special feature of d^6-systems, since they seem to be absent in halide chromium(III) pentammines. The weak bands might be introduced by intermixing with ligand field bands by vibrational interaction with odd electron transfer states *. However, it is also possible that they actually represent the $\Omega = 3/2$ bands with accidentally low intensity. The similar problem has been treated by Mulliken [18,19] for halogen compounds and the halogen molecules [20]. Mulliken [19] found the distance between the two bands $^2\Pi_{3/2}$ and $^2\Pi_{1/2}$ (highest) equal to 5 570 K in HI, 4 915 K in CH_3I, 4 650 K in C_2H_5I, 3 457 K in HBr, and 3 070 K in CH_3Br. The intensity ratios were > 10 in the chlorides, ~4 in the bromides and ~2 in the iodides in favour of the second band, resembling the behaviour of halide pentammine-d^6-complexes. The partly σ-character of the second band might have been used as an argument for increased intensity, if it was higher for iodide than for chloride complexes.

* The effective value E_{af} of the non-diagonal element of energy between even and odd levels, to which the forbidden (with the oscillator strength P_f and wavenumber σ_f) and allowed (P_a,σ_a) transitions occur, can be defined:

$$\frac{P_f}{P_a} = \frac{\sigma_f}{\sigma_a} \cdot \frac{E_{af}^2}{(\sigma_f - \sigma_a)^2}.$$

For a large number of $3d^n$-, $4d^n$-, $5d^n$-, and $5f^n$-transitions, E_{af} is remarkably invariant in the range 1 500—2 500 K. The physical significance of E_{af} is the product of the amplitude of the odd vibrations in atomic units (~0.1) and an electrostatic interaction energy of the order of magnitude 20 000 K, as discussed for the case of benzene by Murrell and Pople [35].

The present author is not inclined to believe that the σ-band can occur at lower wavenumbers than the absorption band of the free halide ion in aqueous solution. Even though the strongest band of $Rh(NH_3)_5I^{++}$ has nearly the same wavenumber as the first band of I^- (Table 2), it cannot simply be argued that the transfer of electrons will occur to the solvent, if the metal ion has no larger electron affinity than water. The iodide ion must be stabilized by its bonding to the rhodium ion (even though the partial contribution to the ligand field strength is remarkably negative [1]) while the excited state, the free I, hardly can be so much stabilized. Thus, the anti-bonding character of the excited state will tend to increase the wavenumber of the σ-band in all cases.

From group-theoretical reasons, it is difficult to understand, why the redox spectra of hexahalide complexes do not contain much more than two bands. The 36 states of the resonance structure of five halide ions and one halogen atom (s^2p^5) might give 18 levels, if only one state is possible of the central ion + the added electron. If q states are possible in the latter system, 18 q levels are expected, if the Kramers' degeneracy does not allow 36 q levels (as is the case, if an even number of electrons occur in totality). Even though $ReCl_6^{--}$ exhibits [21,22] three bands and $ReBr_6^{--}$ six bands, such a complicated behaviour has never been reported. However, the "one-ligand excitation" model of the linear ligand field above seems to develop splittings for very large electron affinities of the central ion, *e.g.* the visible redox spectra of $IrCl_6^{--}$ and $IrBr_6^{--}$, which exhibit, respectively, four and six bands (Table 2) while in this case, q = 1 for the excited central ion configuration γ_5^6. If the symmetry of the complex is restricted to the cubic O_h, only four π-levels and three σ-levels are predicted [2]. If the Laporte-forbidden transitions to even levels are neglected, only two π- and one σ-absorption bands are expected of a d^5-system, while a d^6-system with q = 4 ($\gamma_5^6\gamma_3$) should exhibit the double number each of singlet and triplet levels. However, when intermediate coupling is considered, more bands are predicted. Thus, eight odd levels ($2\Gamma_6$, $2\Gamma_7$ and $4\Gamma_8$, of which the last four may be split by ligand fields of lower symmetry) occur, when a π-electron is transferred to the empty γ_3-shell of a d^6-system. It may be reasonable to conclude that the "one-ligand excitation" model seems satisfactory for redox spectra at not too low wavenumbers, *e.g.* of $IrBr_6^{-3}$ or $PtBr_6^{--}$, while systems with a large tendency of the electron transfer, *e.g.* PtI_6^{--}, may begin to exhibit some of the many bands predicted from group theory, *i.e.* the exchange integrals between different halide ligands begin to be important.

THE DIOXO ACTINIDE IONS AND 5f-ELECTRONS IN LINEAR LIGAND FIELDS

The uranyl ion UO_2^{++} has no partly filled shell, and thus all electronic absorption bands must be due to electron transfer. Besides the well known group of bands in the range 20 500—26 300 K, a similar group with vibrational structure is observed in the range 28 500—32 200 K (see Table 3). The molar extinction coefficients ε_n of these bands are remarkably low, ~6 and ~10 (when corrected for the raising background). Besides the two band groups, there is only a monotoneously increasing absorption in the ultraviolet ($\varepsilon = 60$ at 300, 135 at 280, 300 at 260, 720 at 240 and 1 300 at 220 mμ).

The two band-groups are undoubtedly Laporte-forbidden and can be ascribed [23] to the transfer of an odd electron (*e.g.* with $\lambda = 1$, which is not σ-bonding as those with $\lambda = 0$) from the ligands to the empty 5f-shell of the central ion. Eisenstein and Pryce [24] investigate the dioxo actinide ions with one 5f-electron, *viz.* UO_2^{+} and NpO_2^{++}, and assume a large value of $E_\lambda \sim -15\,000$ K of eqn. 2. These authors did not discuss the influence of the non-diagonal elements of intermediate coupling (eqn. 3), which is rather conspicuous (*cf.* Fig. 3). While ζ_{5f} in trivalent and quadrivalent uranium [23] is ~1 600 K, it cannot easily be decided, if ζ_{5f} of UO_2^{++} has the value ~3 000 K expected [25] for gaseous U^{6+}, or if the partly covalent bonding [26] has decreased the value much.* Generally, it cannot be expected that the intermixing with the orbitals of the ligands conserves the equidistant splitting of the λ-levels, as expressed in eqn. 2. Rather, the distance between $\lambda = 0$ and $\lambda = 1$ may be much lar-

* Professor B. Weinstock, Argonne, has kindly informed me that NpF_6 exhibits a group of bands at 7 300—9 500 K and hence the ligand field splittings are small compared to $\zeta_{5f} \approx 2\,400$ K. Weinstock will later discuss the absorption spectrum of PuF_6, which has a sub-level $\Gamma_J = \Gamma_1$ as a rather isolated groundstate [27], corresponding to $^3H_4$ as weak field asymptote and γ_3^3 as strong field asymptote.

ger than between $\lambda = 2$ and $\lambda = 3$. In the latter case, Fig. 3 will be distorted (the left-hand side with negative E_λ applies to UO_2^{++}) such that the three lowest levels would have $\Omega = 5/2$, 3/2, and 7/2, with the subsequent distances $\sim 1/2$ and $\sim 5/2\ \zeta_{nf}$.

Since neither E_λ nor ζ_{5f} is known *a priori* for UO_2^{++}, Fig. 3 allows many possible explanations of the existence of the two electronic states with a distance ~7 900 K (Table 3). If E_λ is small, then the observed distance is simply the atomic splitting $\frac{7}{2}\ \zeta_{5f}$. This cannot be excluded, if 5f-electrons actually do not take any part in the covalent bonding.* However, it is more probable that E_λ is larger, and that the lowest level (which is fluorescent) is that with $\Omega = 5/2$. Then, the next electronic level might either have $\Omega = 7/2$ (with less than 3 ζ_{5f} higher energy) or $\Omega = 3/2$ (the energy difference then mainly being composed of E_λ).

Eisenstein and Pryce [24] assume that the weak bands of NpO_2^{++} with vibrational structure in the range 15 400—23 800 K are caused by an internal 5f-transition from $\Omega = 5/2$ to the two levels of $\lambda = 2$. However, the present author assumes as an alternative possibility that the weak vibrational bands of UO_2^{++}, NpO_2^{++}, PuO_2^{++}, and AmO_2^{++} (which must not be confused with the high, extremely narrow bands occurring in systems with at least two 5f-electrons in the groundstate [23]) have a common cause, *viz.* the transfer of an electron to the 5f-shell of the central ion. The wavenumbers decrease with increasing electron affinity of the central ion, analogous to the ordinary redox bands, and seem very high in the species MO_2^+.

ABSORPTION SPECTRA OF α,α'-DIPYRIDYL AND o-PHENANTHROLINE COMPLEXES

The complexes of α,α'-dipyridyl and o-phenanthroline have much more complicated absorption spectra than the pyridine iridium(III) complexes discussed above. Especially, low oxidation states of metals seem stabilized and form strongly coloured complexes with the heterocyclic diimines: red iron(II), red ruthenium(II), brown copper(I)[28], black vanadium(—I)[29], blue vanadium(0)[30], purple vanadium(I)[30], green vanadium(II)[30], blue chromium(I)[31] and purple chromium(II)[31].

Presumably, these strong absorption bands in the visible are caused by electron transfer from the central ion to the ligand, analogous to the Ir-py band studied here. The ground-state of the purplish red Fe dip_3^{++} and red-orange Fe $phen_3^{++}$ has been described [32] in terms of Pauling's directed valence bonds as a resonance of three π-bonds (in the direction towards the ligands) besides the usual d^2sp^3-hybridization. As discussed by Orgel [9], this is more adequately described by the molecular orbital theory, assuming increased

* Recently, Coulson and Lester [38] proposed that 6f-rather than 5f-electrons are involved in the partly covalent bonding of actinide complexes. Generally, the group-theoretical requirements of molecular orbitals (given for f-electrons by Eisenstein [39]) refer to the angular part of the wave-function only, while the radial function can be chosen rather arbitrarily. Hence, the partly covalent bonding can often be described by a complicated intermixing of empty and filled orbitals from the central ion and the ligands, resulting in the current reconciliation of ligand field and molecular orbital theory [40].

energy of the empty γ_3-sub-shell by formation of π-antibonding linear combinations with the empty orbitals of the ligands. Recently, Schläfer [33] has applied an electrostatic perturbation calculation to the energy levels of α,α'-dipyridyl, analogous to the considerations of Belford [34] for acetylacetonate. Even though it is interesting to note that a certain group of bands are identically shifted for all mono- and tris-dipyridyl complexes of divalent metal ions, Schläfer's theory [33] appears somewhat too simplified in the case of *o*-phenanthroline. These compounds have a very irregular vibrational structure of the bands, indicating strong coupling between electronic and vibrational states. Furthermore, while the pyridine complexes have only one conspicuous σ_c, several of the 60 characteristic frequencies seem to occur in *o*-phenanthroline, since no equidistant band groups can be observed.

The following bands are observed of some representative complexes in the range 12 500—50 000 K, with approximative values of ε_n, and shoulders in parenthesis.

dip		dip H^+		Fe dip_3^{++}		Ni dip_3^{++}	
(31 100)	1 000	33 200	15 700	19 100	8 600	24—30 000 increase	
35 600	12 800	(37 000)	4 000	(20 200)	7 800	32 400	40 000
42 900	10 700	41 600	8 000	(24 100)	2 400	33 800	42 000
				(25 800)	3 700	40 800	32 000
				28 500	6 500		
				33 500	70 000		
				(34 500)	60 000		
				40 500	32 000		
phen		phen H^+		Fe $phen_3^{++}$		Ni $phen_3^{++}$	
30 900	750	(33 300)	7 000	19 600	11 200	24—28 000 increase	
(32 300)	1 200	36 200	29 000	(21 000)	9 500	29 100	1 500
(34 600)	9 200	36 800	31 000	(22 800)	7 300	30 600	2 400]
37 800	28 000	45 500	36 000	31 200	3 300	(32 000)	3 300
44 000	40 000	48 700	38 000	(34 400)	20 000	34 000	28 000
				37 600	67 000	37 100	78 000
				44 400	64 000	44 000	93 000

The first five bands * of Fe dip_3^{++} and at least the three first bands of Fe $phen_3^{++}$ can thus be ascribed to a Laporte-allowed electron transfer from the γ_5-orbitals of iron(II) to the heterocyclic π^*-orbitals. They are very far removed from being internal d^n-transitions in the central ion, as also contradicted by the highly different band structure of the dip and the phen complex. The other bands can mainly be identified as bands of the free ligand, which are shifted and partly split during the influence of H^+, Fe^{++}, and Ni^{++}. However, many remarkable features are still unexplained: the slowly increasing absorption in the near ultraviolet of the nickel(II) complexes may be interpreted as a similar electron transfer or as a shift of the first shoulder of dip, not mentioned by Schläfer [33]. The narrow bands of moderate intensity of Ni $phen_3^{++}$ were found by Roberts and Field [6], who reported too many bands, because the absorption of an aqueous solution of 3 phen was subtracted from

* Busch and Bailar [32] prepared the diamagnetic tris (biacetylbismethylimine)iron(II) iodide $Fe(C_6H_{12}N_2)_3I_2$, which contains no heterocyclic rings. The bands reported at 17 600 K (ε=10 700) and 29 000 K (ε = 1 200) are undoubtedly of the Ir-py type, while the band at 44 000 K (E = 38 100) is under suspicion for being simply the iodide band.

that of Ni $phen_3^{++}$. They seem to be a general feature of all phen-complexes, comparable to the first, weak band of benzene [35]. The higher oxidation state iron(III) has in the blue Fe $phen_3^{++}$ (a band at 16 800 K, $\varepsilon = 750$) and Fe dip_3^{++} (16 300 K) much less colour. The broad band may be due to electron transfer from the ligands to the central ion, and may be compared to the relatively weak first band [7] of $IrCl_6^{--}$.

Acknowledgements. I am very much indebted to Professor Marcel Delépine of Collège de France for the valuable samples of iridium(III) and rhodium(III) complexes, which have made the observation of the Ir-py band possible. Further, I thank Professor Jannik Bjerrum for his kind interest in the work.

Short Communications

Ion Exchange of Quaternary Salts

A. BERGGREN and C. O. BJÖRLING

Laboratories of Pharmacia Ltd., Uppsala, Sweden

It is well known that organic ions of a high molecular weight are difficult to elute once they are taken up by a cation exchange resin containing a "normal" network. The ion exchange process seems not to be totally reversible (*e. g.* Refs.[1-4]). Lately, several authors have used cation exchange resins with a low percentage of crosslinking, (*e. g.* Refs.[5-7]). They could elute tertiary alkaloidal cations from the resins with alcoholic ammonia. Büchi and Furrer [5] also tried 10 % hydrochloric acid for the elution of quinine, but very large eluates were necessary.

We have repeated their experiments, using Dowex 50-X1, a cation exchange resin with 1 % crosslinking. 200—300 mg of quinine sulphate was applied to a column (10 × 150 mm). All the quinine was taken up and could be quantitatively eluted with 25 ml of 10 % ammonia in 60 % alcohol. However, a full recovery was also obtained with 75 ml of 2 N hydrochloric acid in 70 % alcohol.

On account of this very interesting result we tried to elute quaternary cations from Dowex 50-X1 with alcoholic media.

Method. Suitable quantities, usually 1—2 mg, of the compounds dissolved in water or alcohol of various strengths were run through a column, 4 × 30 mm, of Dowex 50-X1 (200—400 mesh) in its hydrogen form. The column was washed with the solvent. The bases were completely adsorbed. After elution, usually with 25 ml of the elutriant, the bases were determined by means of their ultraviolet spectra. Benzethonium chloride was titrated by Carkhuff and Boyd's method [8].

Results: 9-(4-Dimethylaminobenzylidene)-fluorene ethyltosylate. Aqueous mineral acids up to 2 N were without effect. 50 % alcoholic solution of mineral acids gave total yields if the acid was 1—2 N. Further, at this alcohol level there is a difference between perchloric, hydrochloric, and sulphuric acids as 0.2 N perchloric acid gave a full yield in contrast to hydrochloric which gave 60 % and sulphuric acid 20 % yields. 70 % alcoholic solution of mineral acids gave total yields if the acid was 0.5—2 N.

Experiments with aqueous and alcoholic potassium hydroxide were unsuccessful. 5 % sodium bromide in 70 % alcohol gave 95 % yield in 50 ml eluate.

Hyoscine methylnitrate. Of this alkaloid 10—15 mg was taken and was quantitatively eluted by 20 ml of 1 N hydrochloric acid in 50 % alcohol.

Codeine ethyliodide. The positive ion was eluted to 85—95 % by aqueous 1 N hydrochloric acid and totally by the same acid in 50 % alcohol. 0.5 N potassium hydroxide in 70 % alcohol gave 100 % recovery.

Papaverine ethyltosylate. 15—25 ml of 1 N hydrochloric acid in 50 % alcohol gave 100 % recovery.

Berberine sulphate. 1 N hydrochloric acid in 70 % alcohol gave a quantitative yield.

Strychnine ethyliodide. 1 N hydrochloric acid in water gave 75—80 %, in 50 % alcohol 85 %, and in 90 % alcohol 100 % recovery.

Benzethonium chloride. 100 % recovery was obtained with 10 ml of 1 N sulphuric acid in 90 % alcohol.

A full report will be given in a later publication.

Thanks are due to Mrs. Barbro Willman-Johnson who performed most of the experimental work.

Mass Spectrometric Determination of the Structure of Phthiocerol

RAGNAR RYHAGE

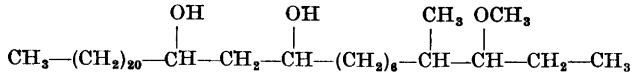
The position of the methoxyl group in phthiocerol previously inferred from mass-spectrometric and X-ray data [1] has now been confirmed by a mass-spectrometric study of synthetic 3-methoxy-4-methylheptene-6. The spectrum of this molecule, like that of phthiocerol, shows an intense peak at $m/e = 73$, arising from cleavage between carbon atoms 3 and 4.

A similar study of the parent hydrocarbon, phthiocerane [2], definitely settles the structure of this hydrocarbon in favour of 4-methyltetratriacontane and not 4-methyltritriacontane, which previously appeared more likely [3-5]. The mass-spectrum shows a small parent peak at $m/e = 492$ corresponding to $C^{35}H^{72}+$ (ionized unfragmented molecule), and very strong peaks at $m/e = 449$ and $m/e = 421$ corresponding to $C_{32}H_{65}+$ and $C_{30}H_{61}+$, respectively, arising from cleavage on both sides of the tertiary carbon atom in position 4.



Parts of the mass-spectra of phthiocerol, 16,17-dihydroxydotriacontane, and 2,4-dihydroxyeicosane are shown in Fig. 1. A comparison between the spectrum of phthiocerol and those of the two synthetic glycols shows that phthiocerol is an 1,3-glycol as previously demonstrated by Demarteau-Ginsburg and Lederer [6] and excludes the possibility that phthiocerol is an 1,2-glycol. In the spectrum of 17,19-dihydroxyeicosane (2,4-dihydroxyeicosane) the C_{15}-alkene peaks $C_{15}H_{30}+$ and $C_{15}H_{28}+$ are considerably stronger than the corresponding peaks in the C_{14}- and C_{16}-groups. In the phthiocerol spectrum the $C_{20}H_{40}+$ and $C_{20}H_{38}+$ peaks are similarly increased, indicating the presence of a hydroxyl group in position 22. In phthiocerol the C_{27}- and C_{28}-groups of peaks are very weak, but a comparison with 17,19-dihydroxyeicosane is of course not possible as this molecule is too short. A comparison with the spectrum of 16,17-dihydroxydotriacontane, where the C_{20}- and C_{21}-groups of peaks are weak, does indicate, however, that phthiocerol has no hydroxyl group in position 25 or 26 from the normal chain end of the molecule.

Through the kind co-operation of Professor E. Lederer we have been able to make mass-spectrometric and monolayer studies of the acidic long-chain product obtained by Mme Demarteau-Ginsburg by oxidation of phthiocerol. The sample was found to consist of a mixture of about equal amounts of n-C_{22}- and n-C_{24}-acid together with smaller amounts of n-C_{21}- and n-C_{23}-acid. The presence of behenic acid supports the conclusion that phthiocerol has a hydroxyl group in position 22.

The presence of n-tetracosanoic acid appears more difficult to explain. This acid might arise from elimination of the hydroxyl group in position 22 before cleavage of the chain between the 24th and 25th carbon atom. It is hoped to settle this question by the study of oxidation products of a suitable synthetic 1,3-glycol.

Phthiocerol would thus have the empirical formula $C_{35}H_{69}(OH)_2OCH_3$ and be one of the sixteen theoretically possible stereoisomers of 3-methoxy-4-methyl-11,13-dihydroxytetratriacontane.

The mass-spectra of phthiocerol preparations from a virulent human strain of

Dihydroxyglutamic Acid in Plants

ARTTURI I. VIRTANEN and
TERTTU ETTALA

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In an earlier paper [1] we reported the discovery of dihydroxyglutamic acid in the seeds of *Lepidium sativum* and in the green parts of *Rheum rhaponticum*.

On the two-dimensional paper chromatogram (solvents: butanol-acetic acid-water and phenol-water in NH_3-atmosphere) of 70 % ethanol extracts of the seeds of *Lepidium*, and of many plants later on, a spot could be detected after ninhydrin spraying which moved much slower than aspartic, γ- and β-hydroxyglutamic acids [2] in both solvents (Fig. 1). In butanol-acetic acid it moved somewhat slower than hydroxyaspartic acid. The colour of the spot was at first weak but turned stronger and violet later on. The substance was unaffected by mild (1 N HCl, 20 h, 108° C) as well as strong (6 N HCl, 20 h, 108° C) acid hydrolysis. The colour became even more intense when the ethanol extract was hydrolyzed before paper chromatography. When separating basic and neutral amino acids in an Amberlite IR-4B column the new amino acid remained in the fraction with acidic amino acids. In paper electrophoresis 2 000 V, 18 mA Na-acetate buffer, pH 3.2) it proved to be more strongly acid than any other known natural aminodicarboxylic acid.

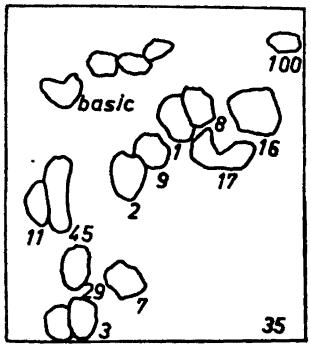

Fig. 1. Two-dimensional paper chromatogram of a 70 % ethanol extract (hydrolyzed with 6 N HCl) of the seeds of *Lepidium sativum*. Solvents: phenol-NH_3 and butanol-acetic acid. 100 = the new acidic amino acid (dihydroxyglutamic acid), 1 = gly, 2 = ala, 3 = val, 7 = tyr, 8 = ser, 9 = threo, 11 = pro, 16 = asp, 17 = glu, 29 = γ-aminobutyric acid, 45 = ethanolamine.

Isolation of the new amino acid from Rheum and the seeds of Lepidium. The amino acids in a 70 % ethanol extract were separated in an Amberlite IR-120 column. The eluate (1 N ammonia) was evaporated *in vacuo* and the extract hydrolyzed with 6 N HCl in order to split eventual peptides. Since the new amino acid moved slower in phenol than all other known natural amino acids, it was separated in a cellulose powder column using phenol as eluant. Before the run the cellulose powder column was washed with 1 % acetic acid and afterwards thoroughly with hot water. The fractions containing only the new amino acid were evaporated to dryness.

The structure of the new amino acid. The light coloured, slightly yellowish preparation obtained was on the basis of a two-dimensional paper chromatogram free from other amino acids. It did not contain sulphur or phosphorus. An aminodicarboxylic acid was thus obviously in question. An OH group in α-position to the NH_2 group was established with periodic acid and Nessler's reagent. On reduction with 66 % HI (d 1.96) and red phosphorus (4 mg substance + 18 μl HI + 3 mg P) at 140° C for 4 h mostly glutamic acid was found to be formed (Fig. 2). Small amounts of serine and glycine, and traces of threonine and alanine could also be found on the paper chromatogram. In some experiments a very faint spot was observed also in the position of β-hydroxyglutamic acid, but the substance could not be identified.

Using both phenol and butanol-acetic acid as solvents, the position of the new amino acid on the paper chromatogram (R_F values 0.05 and 0.04, respectively) showed that it was not β- or γ-hydroxyglutamic acid. Dihydroxyglutamic acid seemed thus probable. The amino acid contained 7.88 % N, calc. for dihydroxyglutamic acid $C_5H_9O_6N$, 7.85 % N.

Upon heating the amino acid at pH 3.3 at 125° C for 4 h the amino acid was transformed into the corresponding pyrroli-donecarboxylic acid to about 90 %. This compound was established by paper chromatography, treating the paper first with chlorine and then with a solution of 1 %

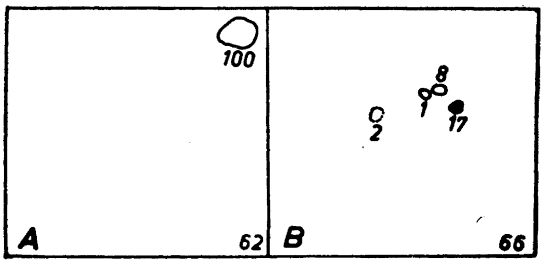

Fig. 2 A. Two-dimensional paper chromatogram of pure dihydroxyglutamic acid isolated from the seeds of *Lepidium sativum*. B. After reduction with HI and red P.

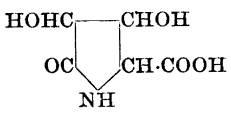

starch-KI, upon which the spot changed into bluish black [3]. The substance was isolated in a cellulose powder column using phenol-water as eluant. The fractions giving this colour reaction were evaporated to dryness *in vacuo* and extracted with ethyl-acetate, in which the pyrrolidonecarboxylic acid was difficult to dissolve. The substance was white, became darker upon heating at 235° C and decomposed at about 250° C. It contained 8.61 % N, calc. for $C_5H_7O_5N$, 8.70 % N.

The splitting of the carboxyl group as CO_2 by the effect of ninhydrin was determined according to Linko [4]. 0.269 mg of CO_2, or 26.4 %, were formed from 1.018 mg of the substance. Calc. for dihydroxypyrrolidonecarboxylic acid 27.3 %. Only little ammonia was formed, 27 % NH_3-N of total N. The determination, made for comparison, with pyrrolidonecarboxylic acid prepared from glutamic acid gave similar results: CO_2 formation 30.4 %, calc. 34.1 %, NH_3-N formation 22.1 % of total N.

The R_F value of the isolated dihydroxypyrrolidonecarboxylic acid was 0.33 in phenol-water. On hydrolysis with 6 N HCl the original aminodicarboxylic acid was re-formed.

The new amino acid had thus been established as dihydroxyglutamic acid,

The chromatographical and chemical properties of the new amino acid are compatible with the formula HOOC · CHOH · CHOH · $CHNH_2$ · COOH. The corresponding dihydroxypyrrolidonecarboxylic acid

seems not to be an artificial product only but also a very probable compound in fresh plants, because in the plant extract the amount of dihydroxyglutamic acid rises after strong acid hydrolysis. The increase is strongest in *Rheum* (pH of the sap 3.5—3.8) but can be noticed also in other plants (pH of the sap about 6.5).

The N-content of dihydroxyglutamic acid in the seeds of *Lepidium* is about 0.2 % of soluble N. On the whole the content of this amino acid is small in all the plants investigated. There is no experimental information yet about its biosynthesis. Hypothetically it can be assumed to be formed *via* transamination from the corresponding keto acid. The keto acid may be formed as an oxidation product of a ketopentose or also of γ-hydroxyglutamic acid.

Dihydroxyglutamic acid is comparatively common as a free amino acid in plants, and is to be found in all parts of the plants. By paper chromatography we have found it in the following plants: (The part of the plant in which the amino acid has been found is mentioned in parenthesis. Other parts have not been investigated. When both fruits and green parts have been investigated the amino acid has been found in both.)

Flowering plants. *Aesculus hippocastanum* (leaves and fruits), *Alchemilla vulgaris* (leaves and stem), *Angelica archangelica* (leaves), *Arctostaphylos uva-ursi* (leaves, stem and berries), *Brassica napa* (seeds), *Cornus alba* (berries), *Daucus carota* (stem and root), *Digitalis lanata* (leaves), *Lactuca sativa* (seeds), *Lepidium sativum* (seeds and sprouts), *Lilium bulbiferum* (leaves and stem), *Parthenocissus vitacea* (leaves), *Polygonum amphibium* (leaves and stem), *Polygonum aviculare* (leaves and stem), *Rheum rhaponticum* (leaves and stem), *Ribes alpinum*

(leaves), *Ribes grossularia* (leaves), *Ribes nigrum* (leaves and berries), *Ribes rubrum* (berries), *Spinacia oleracea* (leaves).

*iso*Thiocyanates XXIV*. (+)-, (—) and (±)-α-Methylbenzyl *iso*Thiocyanate

ANDERS KJÆR

Chemical Laboratory of the University of Copenhagen, Denmark

In connexion with other work in this laboratory pure specimens of the enantiomeric α-methylbenzyl *iso*thiocyanates became desirable. The racemic mustard oil has been described by Dyson and George [1] as a slightly yellow liquid, b.p. 240—244°, without presentation, however, of additional physical constants or analytical data. Recently, Luskin *et al.*[2] reported the preparation of (±)-α-methylbenzyl *iso*thiocyanate from α-methylstyrene and *iso*thiocyanic acid, as well as from α-methylbenzylamine by the customary decomposition of its dithiocarbamate.

In the present work the method of Schmidt *et al.*[3], involving hypochlorite oxidation of dithiocarbamates, was utilized for the synthesis of the racemic mustard oil, further characterized as its benzylthiourea-derivative. The pure, optically active α-methylbenzyl *iso*thiocyanates, (I) and (II), were produced on reaction of the corresponding amines with thiocarbonyl chloride by a slightly modified variation of the described procedure [1]. Again, the benzylthiourea-derivatives were synthesized for the purpose of characterization. Attempts to prepare the simple thioureas by reaction of the mustard oils with ammonia did not result in crystalline products.

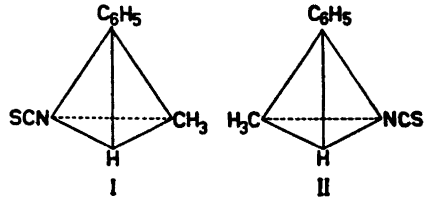

Fig. 1.

The symbols (I) and (II) are considered to represent the absolute configurations of (+)- and (—)-α-methylbenzyl *iso*thiocyanate, respectively. The former derives from (—)-α-methylbenzylamine, the transformation of which into (+)-alanine has been effected previously [4]. The configurational relationship of this amino acid with (—)-glyceraldehyde has been established by Wolfrom *et al.*[5] A unique three-dimensional representation of such molecules is required in consequence of the experimentally established absolute configuration of appropriate optically active molecules [6]. Adopting the recently proposed system for specification of absolute configuration [7] the sequence of transformations mentioned above is: *S*(—)-glyceraldehyde → *S*(+)-alanine → *S*(—)-α-methylbenzylamine → *S*(+)-α-methylbenzyl *iso*thiocyanate (I).

Experimental. Melting points are uncorrected and determined in capillary tubes in a slowly heated bath. Rotations are measured in a 1 dm tube.

S(+)-α-Methylbenzyl isothiocyanate (I). To (—)-α-methylbenzylamine (2.02 g, $[\alpha]_D^{24}$ —39.2° (neat)), dissolved in water, was added a chloroform solution of thiocarbonyl chloride (1.91 g). A total of 33.4 ml of 1 N NaOH was added in small portions to the vigorously stirred mixture. The organic layer was separated, the aqueous phase extracted twice with fresh portions of chloroform and the combined organic extracts dried over sodium sulphate. After removal of the solvent, the *iso*thiocyanate (1.12 g) distilled as a colourless oil, b.p. 126° at 16 mm, n_D^{25} 1.5802; $[\alpha]_D^{24}$ +17.5° (*c* 9.8, $CHCl_3$). (Found: C 66.50; H 5.52; N 8.91. Calc. for C_9H_9NS: C 66.24; H 5.56; N 8.59).

*iso*Thiocyanates XXIV*. (+)-, (—) and (±)-α-Methylbenzyl *iso*Thiocyanate

ANDERS KJÆR

Chemical Laboratory of the University of Copenhagen, Denmark

In connexion with other work in this laboratory pure specimens of the enantiomeric α-methylbenzyl *iso*thiocyanates became desirable. The racemic mustard oil has been described by Dyson and George [1] as a slightly yellow liquid, b.p. 240—244°, without presentation, however, of additional physical constants or analytical data. Recently, Luskin *et al.*[2] reported the preparation of (±)-α-methylbenzyl *iso*thiocyanate from α-methylstyrene and *iso*thiocyanic acid, as well as from α-methylbenzylamine by the customary decomposition of its dithiocarbamate.

In the present work the method of Schmidt *et al.*[3], involving hypochlorite oxidation of dithiocarbamates, was utilized for the synthesis of the racemic mustard oil, further characterized as its benzylthiourea-derivative. The pure, optically active α-methylbenzyl *iso*thiocyanates, (I) and (II), were produced on reaction of the corresponding amines with thiocarbonyl chloride by a slightly modified variation of the described procedure [1]. Again, the benzylthiourea-derivatives were synthesized for the purpose of characterization. Attempts to prepare the simple thioureas by reaction of the mustard oils with ammonia did not result in crystalline products.

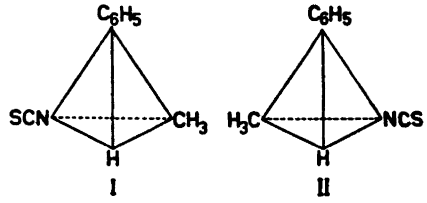

Fig. 1.

The symbols (I) and (II) are considered to represent the absolute configurations of (+)- and (—)-α-methylbenzyl *iso*thiocyanate, respectively. The former derives from (—)-α-methylbenzylamine, the transformation of which into (+)-alanine has been effected previously [4]. The configurational relationship of this amino acid with (—)-glyceraldehyde has been established by Wolfrom *et al.*[5] A unique three-dimensional representation of such molecules is required in consequence of the experimentally established absolute configuration of appropriate optically active molecules [6]. Adopting the recently proposed system for specification of absolute configuration [7] the sequence of transformations mentioned above is: *S*(—)-glyceraldehyde → *S*(+)-alanine → *S*(—)-α-methylbenzylamine → *S*(+)-α-methylbenzyl *iso*thiocyanate (I).

Experimental. Melting points are uncorrected and determined in capillary tubes in a slowly heated bath. Rotations are measured in a 1 dm tube.

S(+)-α-Methylbenzyl isothiocyanate (I). To (—)-α-methylbenzylamine (2.02 g, $[\alpha]_D^{24}$ —39.2° (neat)), dissolved in water, was added a chloroform solution of thiocarbonyl chloride (1.91 g). A total of 33.4 ml of 1 N NaOH was added in small portions to the vigorously stirred mixture. The organic layer was separated, the aqueous phase extracted twice with fresh portions of chloroform and the combined organic extracts dried over sodium sulphate. After removal of the solvent, the *iso*thiocyanate (1.12 g) distilled as a colourless oil, b.p. 126° at 16 mm, n_D^{25} 1.5802; $[\alpha]_D^{24}$ +17.5° (*c* 9.8, $CHCl_3$). (Found: C 66.50; H 5.52; N 8.91. Calc. for C_9H_9NS: C 66.24; H 5.56; N 8.59).

* Part XXIII of this series: *Acta Chem. Scand.* **10** (1956) 1358.

A solution of the *iso*thiocyanate (250 mg) and benzylamine (400 mg) in ether (5 ml) rapidly deposited the crystalline (*S*)-1-benzyl-3-(α-methylbenzyl)-thiourea. Two recrystallizations from aqueous ethanol afforded colourless needles (267 mg), m. p. 82.5°, $[\alpha]_D^{24}$ + 22.8° (*c* 2.4, 96 % EtOH). (Found: C 71.40; H 6.71; N 10.20. Calc. for $C_{16}H_{18}N_2S$: C 71.09; H 6.71; N 10.36). The UV-spectrum in ethanol displayed a maximum at 243 mμ (ε 14 800), a minimum at 238 mμ (ε 14 100), and strong end-absorption towards the short wave-length region.

R *(—)-α-Methylbenzyl* i*sothiocyanate* (II). This mustard oil was prepared from (+)-α-methylbenzylamine ($[\alpha]_D^{24}$ +38.9° (neat)) in exactly the same way, b. p. 121° at 10 mm, n_D^{25} 1.5801; $[\alpha]_D^{24}$ —17.3° (*c* 10.0, $CHCl_3$). (Found: C 66.15; H 5.44; N 8.68. Calc. for C_9H_9NS: C 66.24; H 5.56; N 8.59).

Upon reaction of the mustard oil with benzylamine the (*R*)-1-benzyl-3-(α-methylbenzyl)-thiourea was obtained, m. p. 82.5°, $[\alpha]_D^{24}$ —23.4° (*c* 2.3, 96 % EtOH). (Found: C 71.05; H 6.63; N 10.36. Calc. for $C_{16}H_{18}N_2S$: C 71.09; H 6.71; N 10.36).

(±)-α-Methylbenzyl i*sothiocyanate.* Racemic α-methylbenzylamine was transformed into the corresponding *iso*thiocyanate according to the directions given by Schmidt *et al.*[3] for the preparation of analogous compounds. The yield of pure mustard oil, b. p. 122—123° at 12 mm, was 55 %; n_D^{25} 1.5801. (Ref.[2]: b. p. 135-137°/23 mm, 133-134°/20 mm; n_D^{25} 1.5784, 1.5780).

The racemic 1-benzyl-3-(α-methylbenzyl)-thiourea separated in colourless needles from aqueous ethanol, m. p. 100°. (Found: C 71.35; H 6.62; N 9.98. Calc. for $C_{16}H_{18}N_2S$: C 71.09; H 6.71; N 10.36).

The oily thiourea, resulting from the reaction of the *iso*thiocyanate with ammonia, was subjected to paper chromatography in water-saturated chloroform according to our usual method [8]. An R_{Ph}-value of 1.15 was determined, *i. e.* the compound migrates at a rate definitely higher than that of control spots of benzyl- (R_{Ph} 0.93) and the isomeric β-phenylethyl-thiourea (R_{Ph} 1.08).

Microanalyses were made in this laboratory by Mr. P. Hansen. The experimental assistance of Mr. R. Boe Jensen is acknowledged. Dr. Egelund Pedersen of this laboratory kindly furnished the optically pure α-methylbenzylamines employed in the present work, which is part of investigations supported by *Statens Almindelige Videnskabsfond (The Danish State Research Foundation)* and *Carlsbergfondet (The Carlsberg Foundation)*.

A Rapid Method to Determine Sulphur

ROLF OTTOSSON and
OLLE SNELLMAN

Institute of Biochemistry, University of Uppsala, Uppsala, Sweden

In the method of determining sulphur in organic compounds used earlier here and described by Paulson [1], there were certain difficulties inherent in the combustion of the material. To facilitate the measurements and to obtain a better accuracy some modifications have been introduced in the measuring device and the oxidation of the material has been performed according to a modification of a method described by Schöniger [2]. With this method, sulphur determinations have been performed during the last year and the reproducibility has been very good. The method seems to be both rapid and accurate.

Apparatus. For burning the material a 500 ml bottle with a ground stopper is used. A platinum wire is sealed into the stopper. The wire is 10 cm long and has a diameter of 1 mm. A loop is made on the wire according to Fig. 1.

The same kind of measuring apparatus is used as described by Paulson. The milliam-

A Rapid Method to Determine Sulphur

ROLF OTTOSSON and
OLLE SNELLMAN

Institute of Biochemistry, University of Uppsala, Uppsala, Sweden

In the method of determining sulphur in organic compounds used earlier here and described by Paulson [1], there were certain difficulties inherent in the combustion of the material. To facilitate the measurements and to obtain a better accuracy some modifications have been introduced in the measuring device and the oxidation of the material has been performed according to a modification of a method described by Schöniger [2]. With this method, sulphur determinations have been performed during the last year and the reproducibility has been very good. The method seems to be both rapid and accurate.

Apparatus. For burning the material a 500 ml bottle with a ground stopper is used. A platinum wire is sealed into the stopper. The wire is 10 cm long and has a diameter of 1 mm. A loop is made on the wire according to Fig. 1.

The same kind of measuring apparatus is used as described by Paulson. The milliam-

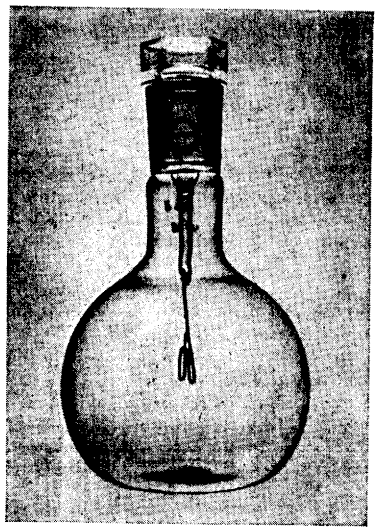

Fig. 1. The burning bottle.

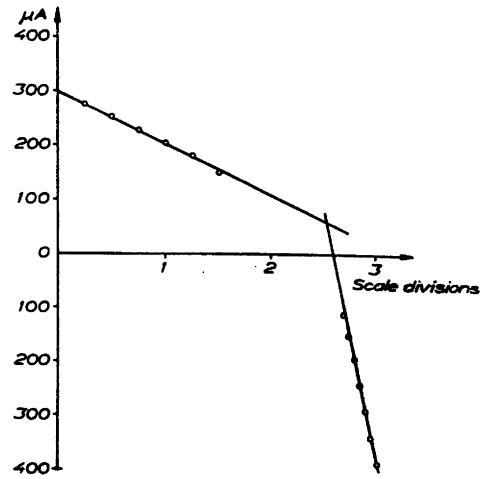

Fig. 2. Example of an analysis curve. The displacement of the micrometer screw is plotted as abscissa and the ammeter reading as ordinate.

meter (Philips mA) is used in such a range that a shift of about 40 Ω in the 1 000 Ω region on the bridge will cause a deflection of the whole scale on the ammeter (0—500 mA).

Method. The sample is burnt according to the method proposed by Schöniger [2], but without using the sodium hydroxide. 10 ml distilled water and 2 ml perhydrol are pipetted in the bottle. The last drop of the water in the pipette is used to make a wet zone around the ground stopper. Oxygen is let into the bottle from an oxygen cylinder for about 20 sec. The substance to be tested is wrapped in a filter paper strip and put into the loop in the platinum wire. The end of the strip is lighted and quickly put in the bottle where the substance is burnt in the oxygen. The bottle is left for 30 min. After this time, the ground surfaces are washed with the contents in the bottle, in case the drop on the stopper has absorbed any sulphur dioxide. Of the reaction mixture, 10 ml is transferred to the conductivity cell.

To the 10 ml reaction mixture in the conductivity cell, one drop of 20 % acetic acid and 1 ml of a barium sulphate suspension in distilled water are added. The content of the cell is then vigourously stirred with a rotating glass rod. It is important that the glass rod is not inserted between the platinum electrodes, as this causes variations in the conductivity and the capacitance of the circuit and hence the needle of the ammeter will not be stable. The apparatus is left for about 10 min for stabilization.

After this time, the apparatus is adjusted to zero deflection and then the resistance is lowered about 40 Ω. The barium chloride solution used for the titration is about 0.5 M. It is added in 0.002 ml portions and the readings after every addition are plotted against the total displacement of the micrometer screw.

The points on the steep line are taken after the zero point on the ammeter is passed and the same region of the scale is reached in which the first series of points was taken. The last points are plotted on the negative side of the diagram (Fig. 2). By these symmetric readings the non-linear sensitivity in the system is cancelled.

A calibration curve is given in Fig. 3, where the scission points of the lines are plotted against a known amount of sulphur. Using the same solution we have not detected any shift in the calibration curve over a period of six months. The substance used for calibration was sulfanilamide (Eastman Kodak).

Tests. Cystein hydrochloride (Merck) analytical reagent gave the following values

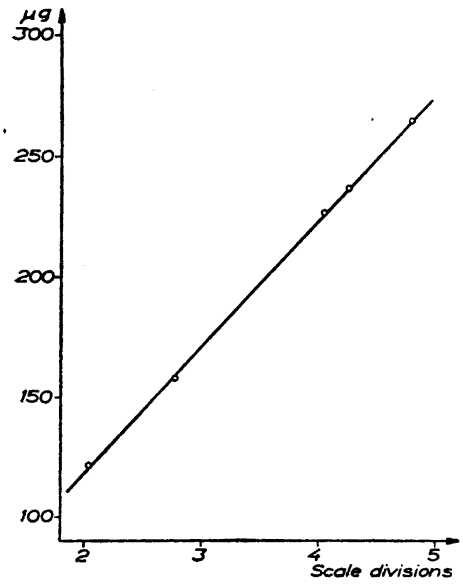

Fig. 3. Calibration curve in the region 100—250 µg. The displacement of the micrometer screw is plotted as abscissa and the sulphur amount as ordinate.

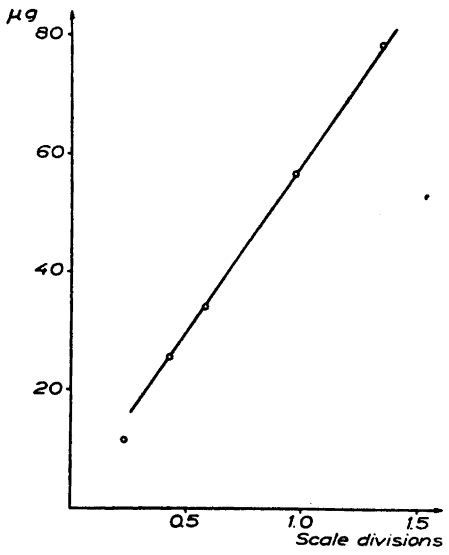

Fig. 4. Calibration curves in the region 20—80 µg. The same abscissa and ordinate as in Fig. 3. The lowest point on the line is not reliable.

Amount	5 per cent		
2.57 mg	18.11		
2.32	18.20		
2.52	18.00		
2.04	18.02		
	Mean 18.08	Calculated	18.32

Methionine (Merck)

Amount	5 per cent		
2.08	21.50		
1.57	21.80		
1.01	21.25		
	Mean 21.51	Calculated	21.48

The standard error is 0.4 %. In this error is included the error from the weighing of the sample. We used a balance which was graduated in 0.05 mg.

In the region 20—80 µg S, we got the calibration curve Fig. 4 by taking parts of the absorption fluid from different burnings, diluting to 6 ml in the conductivity cell and adding 1 drop 20 % acetic acid and ½ ml barium sulphate suspension. However, in this case it was very difficult to draw the lines in the diagram as one could get only few points in a narrow interval before the equivalence point was reached.

As the conductimetric titration takes about 5 min and the burning can be done in two bottles alternately, the method is not at all time consuming.

The investigation has been financially supported by a grant from Eli Lilly and Company, Indianapolis, U.S.A.

The Structure of Crystalline Cytidylic Acid b

E. ALVER and S. FURBERG

Chemical Institute, University of Bergen, Bergen, Norway

The crystal and molecular structure of cytidylic acid b is being investigated by X-ray diffraction methods. So far the main features of the structure have been established.

The crystal symmetry and the dimensions of the unit cell were derived from oscillation and Weissenberg photographs, taken with filtered copper radiation (λ = 1.542 Å). The crystals are orthorhombic, with space group $P2_12_12$, and unit cell dimensions [1]: a = 8.74 Å, b = 21.4 Å, c = 6.82 Å. The unit cell contains four molecules $C_9H_{14}N_3O_8P$. Weissenberg diagrams of the zones $hk0$-$hk4$ and $0kl$-$5kl$ were taken, and about 1 300 reflexes were recorded. The intensities were estimated visually.

Patterson projections along the two shortest axes indicated several possibilities for the position of the phosphorus atom. By the aid of three Harker sections and vector convergence maps [2] all of these except one were ruled out as improbable. The c-projection was very difficult to attack directly, as few unitary structure factors are larger than 0.15, and several attempts failed. It was then decided to try the a-projection, as the distribution of intensities in the $0kl$ zone seemed more favourable, though serious overlapping of atoms had to be expected.

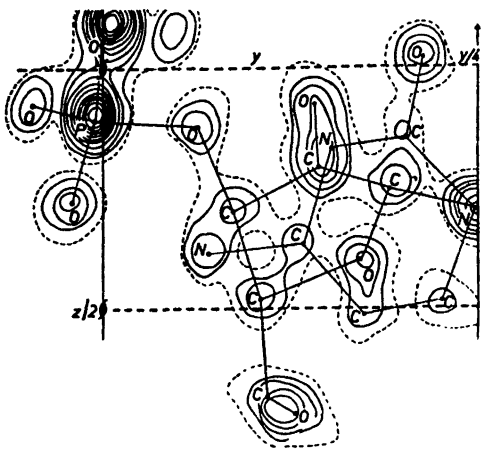

Fig. 1. Electron density projection along the a axis, showing one asymmetric unit. Plane group *pgm*. Contours at arbitrary but equal intervals.

It was found possible to derive the probable phases of four reflexes from an analysis of the distribution of vectors along the lines $x = 1/2$ and $z = 0$ in the two Patterson projections. From the distribution of positive and negative areas in the vector convergence map of the a-projection it could be concluded that the two largest structure factors should probably have opposite signs. One of these and one sign more could be chosen arbitrarily.

With these seven phases as a starting point a set of 22 probable phases was found by Harker-Kasper inequalities, using a high artificial temperature factor. The corresponding Fourier map was unclear, but indicated the positions of the oxygen atoms of the phosphate group. These were confirmed by the three-dimensional Patterson function. The rest of the molecule was then placed roughly by trial and error, and the structure refined by F_o and $(F_o - F_c)$ syntheses.

At the present stage the electron density map of the a-projection shows no false maxima, and the reliability index R is 0.30. We hope to be able to publish a full report on the work and a detailed discussion of the structure in the near future. So far it can only be said with a high degree of certainty that the phosphate group is bound to the ribose ring in the 3′ position, as should be expected [3].

We want to express our thanks to *Norges Almenvitenskapelige Forskningsråd*, whose financial support made this work possible.

Structure of Formamidine Disulphide

OLAV FOSS and JONAS JOHNSEN

Chemical Institute, University of Bergen, Bergen, Norway

Salts of formamidine disulphide result on oxidation of thiourea with halogens or other oxidizing agents [1-3]. Although the disulphide nature of the salts appears to be fairly well established, *e. g.*, from the careful study by Preisler and Berger [4] of the oxidation-reduction potential of the reversible thiourea-formamidine disulphide system, it has been claimed [5] that they are not disulphides, but monomeric compounds containing one thiourea unit only in the molecule.

The crystal structure of the diiodide of formamidine disulphide has now been determined. The results indicate the presence of an S—S bond and the correctness of the formamidine disulphide structure.

Formamidine disulphide diiodide, $[(H_2N)_2CS]_2I_2 \cdot H_2O$, was prepared from iodine and thiourea as described by Marshall [2]. The colourless salt, which turned out to be a monohydrate, was obtained as plates {100}, or as flat prisms bounded by {100} and, less developed, {001}. The axial lengths are, $a = 5.15$ Å, $b = 16.52$ Å, $c = 13.39$ Å ($\pm$ 0.5 %). There are four formula units per unit cell; density, calc. 2.47, found 2.47 g/cm³. The space group, from systematic absences, is D_{2h}^{10}—*Pccn*, which has eightfold general positions, and centres of symmetry and twofold axes as special, fourfold positions.

Intensities of the 0*kl* and *hk*0 reflections were estimated visually from Weissenberg photographs taken with copper radiation, using crystals with cross-sections of 0.04 × 0.05 mm and 0.07 × 0.05 mm, respectively, in the case of the *a* and *c* axis photographs. Patterson, Fourier and Fourier difference projections along these axes, refined to reliability factors of $R = 8.8$ % and 9.7 %, respectively, for the 0*kl* and *hk*0 reflections, have led to the atomic coordinates given in Table 1.

Table 1. Atomic coordinates, in fractions of cell edges. Origin at a centre of symmetry.

	x	*y*	*z*
I	0.072	0.0783	—0.1453
S	0.578	0.2192	—0.008
C	0.665	0.141	0.071
N_1	0.481	0.080	0.076
N_2	0.850	0.142	0.136
H_2O	0.250	0.250	0.214

The data of Table 1 give a length of 2.04 Å for the S—S bond, across the twofold axis at ($\frac{1}{4}$, $\frac{1}{4}$, *z*). The C—S—S bond angles are 98°, and the C—S—S/S—S—C dihedral angle, 104°. The disulphide group has thus normal dimensions. The shortest I—I approaches are 4.60 Å and 4.73 Å, across a twofold screw axis and a centre of symmetry, respectively, and the shortest I—S approaches are 3.91 Å and 3.95 Å.

Details of the structure of the diiodide will be published later.

The crystal structure of the corresponding dibromide [1], $[(H_2N)_2CS]_2Br_2 \cdot H_2O$, is being studied [6]. This salt is monoclinic, with $a = 8.61$ Å, $b = 5.12$ Å, $c = 12.40$ Å, $\beta = 99\frac{1}{2}°$, and two formula units per unit cell. The probable space group is C_{2h}^4—*P*2/*c*.

Small-Angle Scattering of X-Rays in Aqueous Solutions of Sodium Salts of Conjugated and Unconjugated Bile Acids

PER EKWALL, KRISTER FONTELL and ARNE NORMAN*

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

We have previously shown that aqueous sodium desoxycholate and cholate solutions produce a small angle X-ray pattern [1,2]. Using the same apparatus and technique we have now investigated solutions of sodium salts of a number of conjugated and unconjugated bile acids, which we have found to give rise to similar X-ray patterns. The salts studied are: sodium cholate, desoxycholate, chenodesoxycholate, dehydrocholate, taurocholate, taurodesoxycholate, taurochenodesoxycholate, glycocholate, glycodesoxycholate and glycochenodesoxycholate. The chenodesoxycholic acid and all the conjugated bile acids were synthesized by one of us (A.N.)[3]. The other acids were samples from Hoffmann-La Roche A. G., Basle, which were recrystallized several times before use. Their melting points were: cholic acid, 197° C, desoxycholic acid, 174—175° C, dehydrocholic acid 237° C.

The sodium dehydrocholate solutions (up to 0.4 molal) gave only a dark background; no intensity maximum was evident on the photometer curve. All the other bile salts, however, yielded pronounced intensity maxima, as seen in Figs. 1 and 2, where photometer recordings of the X-ray films obtained with 0.4 molal solutions of the salts are reproduced. It is immediately noted that the three cholates as a group and also the three desoxycholates and the three chenodesoxycholates exhibit closely similar X-ray patterns. Conjugation does not appear to have any greater influence on the location of the intensity maxima. Also the photometric curves for the desoxycholates and chenodesoxycholates are very similar, which indicates that the positions of the hydroxyl groups (3,12 and 3,7) do not exert any significant effect. The number of hydroxyl groups does, however, influence the scattering since marked differences are noted between the photometric curves of the cholate series (3 hydroxyl groups), on one hand, and those of the desoxy- and chenodesoxycholate series (2 hydroxyl groups), on the other.

* Present address: Department of Physiological Chemistry, University of Lund, Lund, Sweden.

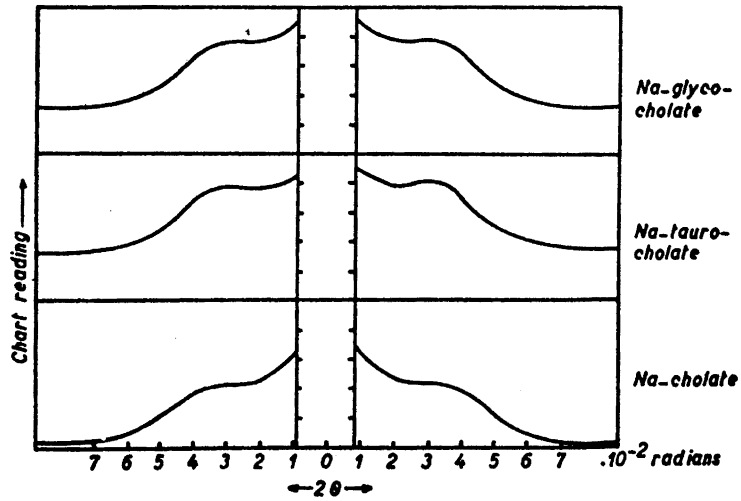

Fig. 1. Photometer recordings of the small angle scattering by 0.4 M aqueous solutions of sodium cholate, taurocholate and glycocholate.

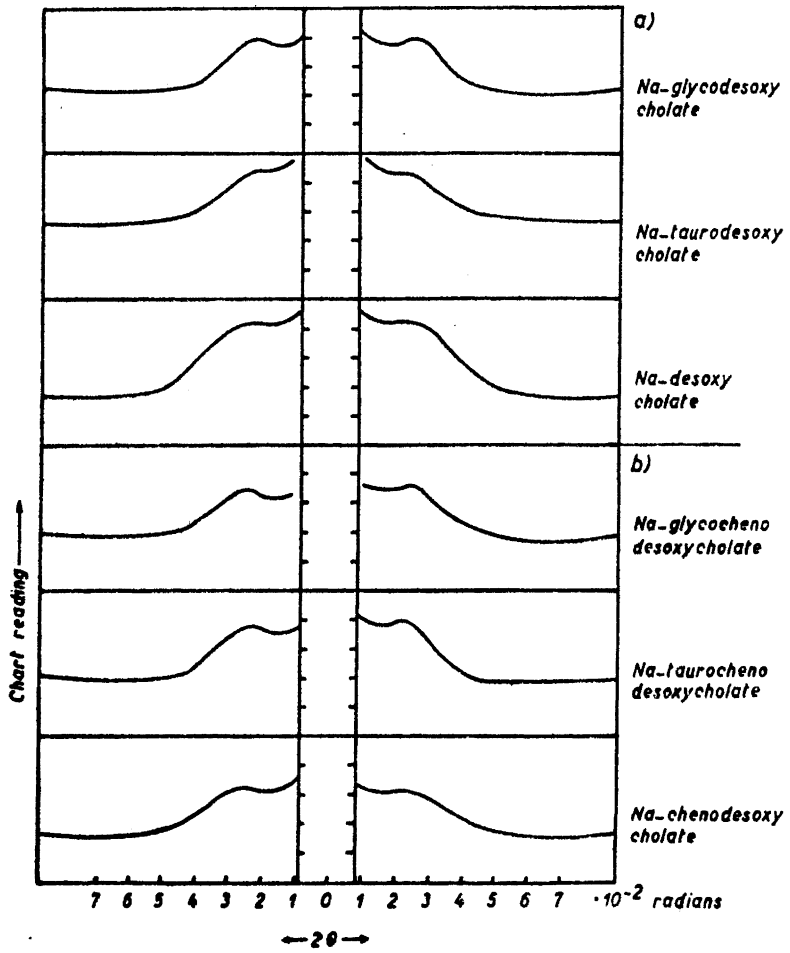

Fig. 2. Photometer recordings of the small angle scattering by 0.4 M aqueous solutions of

a) sodium desoxycholate, taurodesoxycholate and glycodesoxycholate.

b) sodium chenodesoxycholate, taurochenodesoxycholate and glycochenodesoxycholate.

The fact that the bile salt solutions yield small-angle X-ray scattering patterns shows that an association of the ions to colloidal aggregates, micelles, occurs in their solutions. This result is in agreement with earlier conclusions drawn on the basis of studies in which other methods have been employed [4,5]. Also the finding that conjugation does not greatly influence the micelle formation is in accordance with our previous experience [4,5]. The fact that sodium dehydrocholate solutions do not give rise to an intensity maximum in the small angle X-ray pattern agrees with the results of other physicochemical measurements which indicate that association in these solutions sets in only after a very high concentration, about 0.12 M, has been reached, *i. e.* the tendency of these anions to form micelles is weak [4].

Fractionation of Methyl Cellulose Hydrolysate

INGEMAR CROON and BENGT LINDBERG

Institutionen för Träkemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

The distribution of substituents in cellulose derivatives has previously been studied by indirect analytical methods (*cf.* Ref.[1]), the results of which may be rather uncertain and open to some doubt. Spurlin [1] suggested that cellulose ethers should be studied by a different method, involving hydrolysis to glucose and glucose ethers and the fractionation of these by some chromatographic technique. The actual isolation and identification of these products would offer a more reliable basis for calculations. Several authors [2-5] have reported partial fractionations of the products obtained by hydrolysis of methyl cellulose, *e. g.* the fractionation of the three monomethylated glucoses or the fractionation of glucose, mono-, di- and trimethyl ethers. In the present paper the complete fractionation of the eight products in such a hydrolysate is reported. The fractionation was performed on a carbon column using the gradient elution technique. Lindberg and Wickberg[6] separated some methylated sugars by this method and we have recently reported a similar fractionation of the hydrolysate from a hydroxyethyl cellulose[7]. Two components, 6- and 3-*O*-methyl-D-glucose, did not separate by this method but were easily separated by paper chromatography. All components were obtained in a state of purity and identified by their behaviour in paper chromatography and paper electrophoresis, by comparison with authentic samples and by determination of m.p. and optical rotation. Some of them crystallised (see Table 1) and the values for their melting points and specific rotations were in good agreement with those previously recorded.

Experimental. The methyl cellulose investigated was prepared from cotton linters and had a D.S. of 0.90 (OCH_3 15.85, 15.91, 15.97). A sample (1.5 g) was treated with cold 72 % sulphuric acid (16.7 ml). After 30 min at 0° the sample had dissolved completely. It was then diluted with water to 150 ml and heated under nitrogen, first overnight at 60° and finally for 3 h at 100°. The sulphuric acid was neutralised with barium carbonate, the salts removed by filtration and the solution concentrated to dryness (1.460 g). No cellobiose could be detected in the hydrolysate. An aqueous solution of the hydrolysate (50 ml) was added to the top of a carbon column (43 × 3.5 cm) which was then eluted with the following solvents.

Water		1 000 ml
Aqueous ethanol	0 — 8 %	5 000 »
» »	8 — 25 »	2 500 »
» »	25 — 50 »	3 000 »

Fractions (26 ml) were collected and investigated by paper chromatography, paper electrophoresis and determination of the optical rotation (2 dm tube). The result of the fractionation is given in Fig. 1. The 6- and 3-*O*-methyl ethers did not separate well, the former is eluted very slightly faster, and they both contribute to the third peak in Fig. 1, which has a somewhat irregular shape. A small part of the 2-*O*-methyl-D-glucose (second peak) was mixed with the 6-*O*-methyl-D-glucose. Fractions containing s_0 (glucose), s_2(2-*O*-methyl-D-glucose), s_2+s_6, s_6+s_3, s_{26}, s_{36}, s_{23} and s_{236} respectively, were combined, taken to dryness and weighed. In the mixed fraction s_2+s_6, the rather small amount of s_2 was estimated from the shape of the curves. In the mixed fraction s_6+s_3, the proportion between the components was determined by paper chromatography, using methyl ethyl ketone-water (15:1) as solvent. An analytical determination, following the procedure of Hirst, Hough and Jones [8] and a preparative separation on thick filter paper, gave figures in reasonably good agreement, 2.32, 2.43 and 2.26:1, respectively. The yields of each component together with characterising data are given in Table 1.

In a preliminary experiment a larger amount (3.0 g) of methyl cellulose was hydrolysed in the same way and the components fractionated on the same column. A steeper gradient was

The Determination of N-terminal Amino Acids during the Conversion of Fibrinogen to Fibrin

BIRGER BLOMBACK and IKUO YAMASHINA

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

It has been suggested by earlier workers that the conversion of fibrinogen to fibrin is the result of a proteolytic reaction. Actually, in 1951, Lorand, Bettelheim and Bailey [1] showed by means of Sanger's method, differences in the N-terminal amino acids of fibrinogen and of fibrin. They also found "fibrinopeptides" in the supernatant of a fibrin clot produced by the action of thrombin [2-5]. However, due to the difficulties of determining the N-terminal amino acids quantitatively, no conclusive figures as to the number of polypeptide chains in either fibrinogen or in fibrin have been obtained [6]. Moreover, the doubtful purity of the fibrinogen preparations, used by earlier workers, might result in the release of contaminating substances from the fibrinogen preparation into the supernatant during the formation of fibrin.

Recently, a highly purified preparation of bovine fibrinogen has become available in our laboratory [7]. At least 99 % of the protein in this preparation is coagulable with thrombin, indicating that the fibrinopeptides make up only a very small part of fibrinogen. By applying Edman's method to this preparation, we reinvestigated the N-terminal amino acids both in fibrinogen and in fibrin. Determinations were also performed at different times during the conversion of fibrinogen to fibrin by thrombin.

The results show the presence of glutamine, glutamic acid and tyrosine as N-terminal amino acids in fibrinogen and the presence of glycine and tyrosine in fibrin. One glutamyl residue (amide plus acid) and one tyrosyl residue are present in about 1.7×10^5 g of fibrinogen and two glycyl residues and one tyrosyl residue in the corresponding amount of fibrin. Since the molecular weight of fibrinogen has been estimated to be $3.4 \times 100\,000$ [8,9], two glutamyl residues in the fibrinogen molecule seem to be replaced by four glycyl residues by the action of thrombin.

We have found that fibrin formed by means of papain or an enzyme extracted from snake venom has the same N-terminal amino acids as the normal fibrin. However, only two glycyl residues were found in those fibrins instead of four in the normal, thus indicating that there are differences in the mode of action among these three enzymes.

We have followed the proteolysis caused by thrombin in low concentration. The reaction was followed also by determining light-scattering [10]. During the action of thrombin on fibrinogen there is a time lag before polymerization and the subsequent coagulation occur. Glycine appeared as N-terminal amino acid immediately after the addition of thrombin to the fibrinogen solution, showing that there is a formation of an intermediary product, soluble fibrin, during this lag (Fig. 1). The amount of glycine released reaches a maximum value, about 40 % of the total, before any coagulation occurs.

During the coagulation the glycine in the supernatant decreases as shown in Fig. 2.

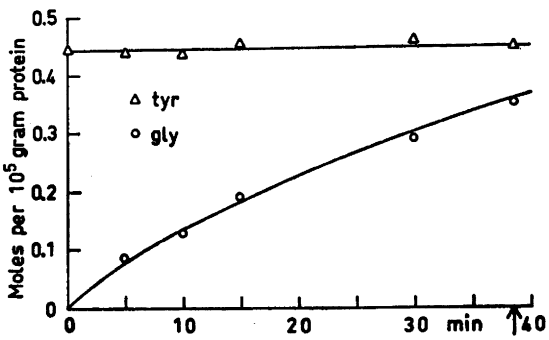

Fig. 1. The appearance of N-terminal glycine in the fibrinogen solution after addition of thrombin. The arrow indicates the coagulation-time.

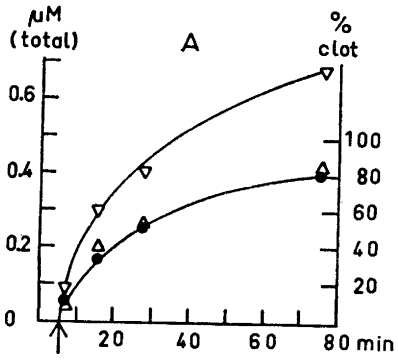

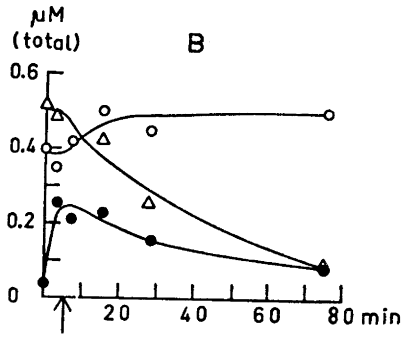

Fig. 2. A. N-Terminal amino acids and protein content of clots collected at different times. The arrow indicates the coagulation-time. ▽ gly; △ tyr; ● coagulated protein in per cent of total.

B. N-Terminal amino acids in the supernatant after removal of the clot. The arrow indicates the coagulation-time. △ tyr; ○ glu; ● gly.

Glutamic acid present originally as an N-terminal amino acid of fibrinogen remained in the supernatant throughout the reaction. The low figure found for glutamic acid in the early stage of the transformation is due to the lower yield of the phenylthiohydantoin amino acid in the presence of high concentrations of protein.

The total amount of tyrosine in fibrinogen and in fibrin was constant.

Judging from these experimental results, it is quite evident that the conversion of fibrinogen to fibrin includes the formation of soluble fibrin, and the subsequent polymerization of soluble fibrin to insoluble fibrin.

The complete paper will be published in Arkiv för Kemi in 1957.

Mass spectra of methyl esters of normal, long-chain fatty acids exhibit a series of peaks corresponding to ionized fragments of the general type $-(CH_2)_n-COOCH_3^+$ with intact methoxycarbonyl group.

The intensity distribution among this group of peaks in the case of methyl *n*-hexacosanoate is shown in Fig. 1 a. The spectrum also shows a large peak at $m/e = 74$, corresponding to an ionized molecule of methyl acetate formed by re-arrangement. This is analogous to the $m/e = 60$ peak found for *n*-carboxylic acids [1]. If the carbon atom in α-position to the methoxycarbonyl group carries one or two alkyl substituents these are included in the re-arranged fragment. A large peak thus appears at $m/e = 88$ for methyl 2-methylhexacosanoate (Fig. 1 b) and at $m/e = 116$ for methyl 2-methyl-2-ethyleicosanoate (Fig. 1 c).

Methyl 3-methyleicosanoate shows a large $m/e = 74$ peak, but the peak at $m/e = 87$ ($n = 2$) is comparatively low because the corresponding fragment can only be formed by the simultaneous breaking of two bonds and rearrangement of one hydrogen atom. On the other hand, $m/e = 101$ is large owing to easy cleavage of the bonds attached to the tertiary carbon atom in position 3.

Methyl 3,5-dimethyltricosanoate (Fig. 1 d) shows for $n = 1$—3 a behaviour very similar to that of the 3-methyl substituted ester just mentioned. The peak for $n = 4$ ($m/e = 129$) is small, as the corresponding fragment, like that of $m/e = 87$, can be formed only by the breaking of two bonds with simultaneous rearrangement.

Two stereo-isomers of methyl 3,4-dimethyldocosanoate have been studied. These give practically identical mass spectra, which show a strong $m/e = 74$ peak and a very large peak at $m/e = 101$. The latter corresponds to the fragment obtained by cleavage between the two tertiary carbon atoms in positions 3 and 4.

Methyl 2,4-dimethylheneicosanoate (Fig. 1 e) shows a weak peak at $m/e = 73$ and a strong one at $m/e = 88$, characteristic of a 2-methyl substituted ester. The peaks at $m/e = 101$ ($n = 3$) and 129 ($n = 5$) are strong, as they arise from cleavage of the bonds on both sides of the tertiary carbon atom in position 4. The peak at $m/e = 115$ is weak, as expected.

The methyl esters all give very strong parent peaks corresponding to the ionized unfragmented molecule. The mass-spectrum thus gives the exact molecular weight.

We have used the mass-spectrometric method to determine the molecular weight and structure of mycocerosic acid isolated from *M. tuberculosis* (human strain H-37) by Anderson and collaborators [2-4]. Ginger and Anderson [4] fractionated the methyl ester by distillation at low pressure. The highest-boiling fraction had m. p. 25°, $[\alpha]_D^{24}$—7.6° (chloroform), d_4^{30} 0.8541, n_D^{30} 1.4509. The analytical data for the acid agreed [4] best with $C_{30}H_{60}O_2$. Analogous or identical acids were later isolated by Chanley and Polgar [5] from a human strain of the bacillus, and by Asselineau [6] from the avirulent strain H 37 Ra. Polgar [7] subjected his compound, called mycoceranic acid, to stepwise degradation, and his results indicated the presence of methyl groups in positions 2, 4, and 6. The acid was considered probably to have 31 carbon atoms.

Cason and Fonken [8] have recently described a similar compound called C_{31}-mycosanoic acid. They report the following analytical data: C 79.89; H 13.50 %, equiv. wt. by titration 475. These data are, however, in better accord with the C_{32} formula (calc. for $C_{32}H_{64}O_2$: C 79.93; H 13.42 %; mol. wt. 480.8) than the C_{31} formula (calc. for $C_{31}H_{62}O_2$: C 79.76; H 13.39 %; mol. wt. 466.8).

The specimen of methyl mycocerosate used in the present work was prepared from a specimen of the acid obtained from Professor R. J. Anderson several years ago. A C-methyl

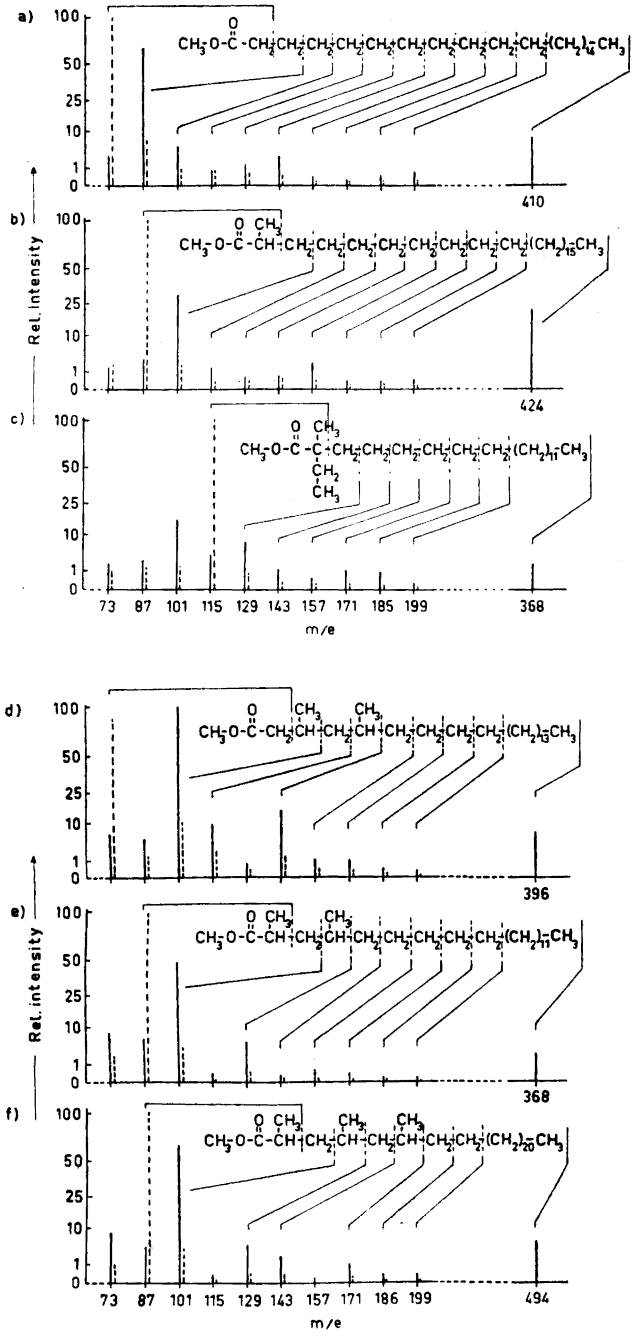

Fig. 1. Schematic diagram showing relative intensities of peaks corresponding to fragments containing an intact methoxycarbonyl group in mass-spectra of long-chain methyl esters. The heights of the vertical lines are proportional to the square root of the observed intensity, with the intensity of the strongest peak arbitrarily set at 100. Unbroken vertical lines represent normal fragments, and dotted lines re-arranged fragments in which the m/e is equal to m/e of the normal fragments plus one unit.
a) Methyl *n*-hexacosanoate b) Methyl 2-methylhexacosanoate c) Methyl 2-methyl-2-ethyleicosanoate d) Methyl 3,5-dimethyltricosanoate e) Methyl 2,4-dimethylheneicosanoate f) Methyl mycocerosate

group determination by a modified Kuhn-Roth method on the acid as received gave 3.33 equiv. of acetic acid, indicating the presence of four methyl groups [9]. The acid (887 mg) was converted into methyl ester by means of diazomethane, and the ester purified by chromatography on neutralized and slightly deactivated aluminium oxide. The ester fractions with the same refractive index (n_D^{25} 1.4520) were combined (589 mg), and distilled at 0.2 mm pressure: b. p. (air-bath temp.) 220—225°. The distilled methyl ester had m. p. 20.8—21.4°, $[\alpha]_D^{21.5}$ —7.8° (chloroform; *c*, 7.7); $n_D^{21.5}$ 1.4535; $d_4^{21.5}$ 0.8550.

The infra-red spectrum in the sodium chloride region was identical with that of methyl mycoceranate recently isolated by one of us (J.A.) from the *Test* strain of *M. tuberculosis* and with that of a specimen of methyl mycoceranate obtained from Dr. N. Polgar, Dyson Perrins Laboratory, Oxford, in 1953.

The purified methyl mycocerosate gave an excellent mass spectrum with a parent peak at $m/e = 494$ corresponding to the empirical formula $C_{33}H_{66}O_2$. There was no indication of the presence of homologous impurity. The empirical formula of the acid is thus $C_{32}H_{64}O_2$. In order to determine the nature and positions of the side chains the relevant parts of the mass spectrum were examined (Fig. 1 f). The low peak at $m/e = 74$ and strong peak at $m/e = 88$ show the presence of a methyl group in position 2. The low peak at $m/e = 115$ and the strong peaks at $m/e = 101$ and 129 indicate a further methyl side-chain in position 4 (*cf.* Fig. 1 e). Finally, the peak at $m/e = 157$ is very weak compared with those at $m/e = 143$ and 171, indicating the presence of a third methyl group in position 6. The methyl group positions derived for mycocerosic acid are thus the same as found for mycoceranic acid by Polgar [6].

A direct comparison with methyl mycoceranate from the *Test* strain was unfortunately not possible as the original sample had been converted into alcohol ("mycoceranol", m. p. 35.3—36.0°, $[\alpha]_D^{17}$ + 3.5° (chloroform)) before we had found that the methyl esters were especially suited to structure analysis. A mass-spectrometric study of the alcohol indicates the empirical formula $C_{32}H_{66}O$, and a comparison with the spectra of synthetic alcohols, including 2,4-dimethyleicosanol-1, shows that mycoceranol has methyl side-chains in positions 2, 4, and 6.

The results reported above make us believe that, apart from possible stereochemical differences (which cannot be studied by mass-spectrometric methods), mycocerosic, mycoceranic, and C_{31}-mycosanoic acids have the same structure, *viz.* that of 2,4,6-trimethylnonacosanoic acid.

We are indebted to Professor R. J. Anderson, Yale University, for the specimen of mycocerosic acid, and to Mrs. Stina Ställberg-Stenhagen for synthetic branched-chain acids. We also wish to thank Professor Einar Hammarsten for making possible the construction of a mass-spectrometer suitable for the study of structure problems in organic chemistry. Details of the instrument and details of the methyl ester and alcohol spectra will be given in forthcoming papers. The expenses of this work have been defrayed in part by grants from the *Swedish Medical Research Council.*

Gradient Elution Analysis of Hop Bitter Substances

L. O. SPETSIG and MAJ STENINGER

Forskningslaboratoriet LKB, Äppelviken, Sweden

Studies in this laboratory [1] have shown recently that the humulones may be separated by reversed-phase partition chromatography with carbon tetrachloride as the stationary phase and 61 % (w/w) aqueous methanol as eluant. In the same manner the lupulones were resolved using 69 % (w/w) methanol as the moving phase.

Subsequent work has shown that both humulones and lupulones can be separated

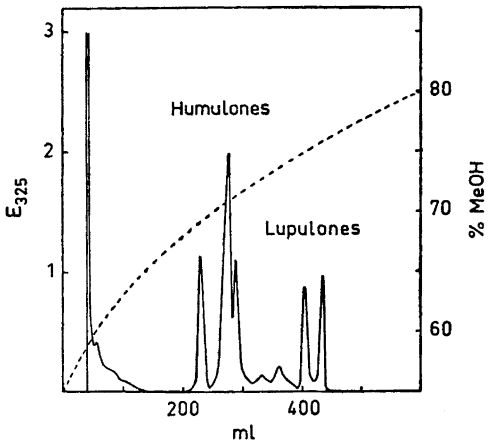

Fig. 1. Gradient elution analysis of humulones and lupulones from Hallertau hops. Column 800 × 8 mm.

in one single operation by means of gradient elution. If the analysis of the eluate is performed spectrophotometrically at 325 mμ, where the contributions from other hop substances is small, a solvent extract of hops can be used without purification. Fig. 1 shows the result of an analysis of the humulone and lupulone groups of Hallertau hops. The concentration gradient of the eluant was accomplished by letting 90 % (w/w) methanol flow into a constant volume mixing chamber loaded with 55 % (w/w) methanol, the effluent of which was fed to the column. The resolution was satisfactory but somewhat less complete than with normal elution. Thus lupulone and adlupulone were not separated.

In other experiments it has been possible to vary the methanol concentration over still wider ranges. Carbon tetrachloride extracts of hops have been shown to be very heterogeneous mixtures containing substances which may be eluted at methanol percentages varying from 0 to 85 % or still higher.

The collection of eluate fractions from a chromatographic column and the determination of the ultraviolet absorption of each fraction are inherently subject to systematic errors, which may be of a considerable magnitude, especially when working with substances which are unstable to air. The column effluent was therefore passed through a 5 mm absorption cell in a Hilger Uvispek spectrophotometer and the optical density at 280 or 325 mμ recorded automatically by a Brown recorder.

On the Production of Magnetic Centres in Glycine by X-Rays

A. EHRENBERG, L. EHRENBERG and K. G. ZIMMER

Biochemical Department, Nobel Medical Institute; Institute for Organic Chemistry and Biochemistry, University; and Genetics Department, Forest Research Institute, Stockholm, Sweden

The demonstration of the production of magnetic centres in a variety of chemicals by ionizing radiation might well lead to a better understanding of the mechanisms by which a relatively small amount of energy absorbed in the form of radiation causes marked biological effects [1-4]. The paramagnetic resonance spectra obtained have been tentatively explained by assuming that organic free radicals constitute the magnetic centres [5-8]. These results are of great interest to radiation biology when considered in relation to other evidence concerning aftereffects of irradiation and protection against radiation damage [9]. We thought it worth while to try and obtain data in order to evaluate, more quantitatively, the importance of the earlier observations for radiation biology. As a first step we investigated the relation between the dose of radiation administered and the number of magnetic centres produced in an amino acid, glycine.

For irradiation we used X-rays produced at 175 kV and filtered by 2 mm of aluminium (about 800 $r \cdot min^{-1}$). The dose was measured during the irradiation by means of a wavelength independent thimble chamber connected to a valve electrometer and integrating counter *(Duplex-Dosemeter)* carefully calibrated in Roentgens. The glycine, in amounts of about 150 mg, in the form of small crystals, was irradiated in evacuated and sealed quartz tubes, which were only half-filled. This en-

b. Paramagnetic resonance spectrum of glycine, —·— immediately and ····· 12 days after irradiation (integrated derivative curves).

abled one half of the tubes to be shielded from irradiation, and, after shaking the glycine into the unirradiated part of the tube, the measurement of paramagnetic resonance was conducted excluding completely the well known effects of radiation on quartz. The unirradiated quartz did not show any detectable signal. The spectrometer [10] used contained a simple microwave bridge operating at a frequency of 9 400 Mc. The signal reflected from the cavity could be recorded as an absorption curve on an oscillograph or as a derivative curve by means of a pen recorder. Irradiation and magnetic measurements were conducted at room temperature.

The spectra observed immediately after the irradiation (Fig. 1 a) showed a central peak at a g-value of 2.004 (± 0.001) and two satellites at ± 22.4 gauss. On keeping the material *in vacuo* and repeating the measurements the shape of the spectrum was found to change slowly (Fig. 1 b), though the area under the absorption curves remained essentially constant. This may be taken to indicate a constant number of magnetic centres. The decay, if any, is less than 1 % per day at about 20° C.

Spectra of identical shape could be recorded in the range from 2 kr to 350 kr, thus including much of the region of biological interest. Since the shape of the curves is independent of dosage, the linear rise in amplitude with dosage, shown in Fig. 2, indicates a corresponding increase in the number of magnetic centres.

Intensity, shape, and time dependence of the recorded spectra were not changed by the presence of air, neither during nor after irradiation, contrasting with results published for some other substances [5].

By comparing the areas under the absorption spectra of irradiated glycine and of a known amount of free radicals (diphenylpicryl hydrazyl) a rough estimate of the concentration of free radicals produced per unit dose in glycine could be obtained. The yield was found to be of the order of magnitude of 1 radical per 10 eV of radiation energy absorbed, *i. e.*, much higher than the values reported for plastics [11].

Another series of experiments was conducted with living material. Embryos cut from resting barley seeds yielded a resonance peak at a g-value characteristic of free radicals, when irradiated in air or in nitrogen. A more detailed account of these studies will appear elsewhere.

The Reduction of Plutonium by Tetravalent Uranium

JAN RYDBERG

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

In the search for substances to reduce small amounts of plutonium of higher oxidation states to Pu(III) in the presence of large amounts of U(VI), U(IV) has been tested under a number of various conditions. The use of U(IV) for reducing plutonium does not seem not to have been described previously [1].

Tetravalent uranium at concentrations $\gtrsim 0.01$ M has been found to be stable in solutions of most acids for weeks or months if air is excluded. However, the stability in HNO_3 is poor, but increases with the U(IV) concentration. Maximum stability in HNO_3 seems to be obtained around 1 M HNO_3, where about 50 % of originally 0.1 M U(IV) is reduced in a little more than an hour at room temperature. Thus U(IV) can be used as a reducing agent even in HNO_3 solutions, provided the time of the experiments does not much exceed an hour.

In 1 M HNO_3, Pu(IV) and Pu(VI) are quantitatively (>99 %) reduced to Pu(III) by 0.1 M U(IV) within 5 min at room temperature. This effect can theoretically be used for separating uranium from plutonium in liquid-liquid extractions, if U(VI), U(IV), Pu(VI) and Pu(IV) prefer the organic phase and Pu(III) only prefers the aqueous phase [2]. The practical usefulness of this was tested in two sets of experiments.

In the first set of experiments two solutions were prepared. The organic solution consisted of methyl *iso*butyl ketone, which was 1.0 M in HNO_3 and contained Pu(IV) and Pu(VI); the aqueous solution was 0.7 M in HNO_3, 3 M in $Ca(NO_3)_2$ and contained a reductant. When these two phases are equilibrated with each other, the distribution ratio of the metals between the organic and the aqueous phases is for U(VI) 12, U(IV) $\sim$ 10, Pu(VI) 13, Pu(IV) 9, and Pu(III) $\lesssim 0.001$[3]; of these species thus only Pu(III) prefers the aqueous phase, and can easily be separated from the other metal ions. After the two phases had been shaken together, the amount of reduced plutonium (*i. e.* Pu(III)) was determined. Some of the results obtained with different reductants are given in the table for 5 min equilibration time.

Reducing agent	% Pu reduced
0.05 M $NH_2OH \cdot HCl$ + 0.005 M Fe^{2+}	65±8
0.05 M $H_4NOSO_2NH_2$ + 0.005 M Fe^{2+}	65±10
0.05 M U^{4+} in air	70±10
0.05 M U^{4+} in N_2	95±3

It is seen that U(IV) is equally or more effective than iron(II) plus hydroxylamine or sulfamate.

In the second set of experiments, the organic phase contained Pu(IV) as the uncharged TTA complex in 0.1 M TTA (thenoyltrifluoroacetone) in benzene, while the aqueous phase was 0.33 M in $HClO_4$ and contained U(IV). For 0.010 M U(IV), 14 % Pu had been reduced in 30 min, and 60 % in 20 h.

These experiments show the usefulness of U(IV) as a reducing agent for plutonium, either in aqueous solution or in two-phase

The Reduction of Plutonium by Tetravalent Uranium

JAN RYDBERG

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

In the search for substances to reduce small amounts of plutonium of higher oxidation states to Pu(III) in the presence of large amounts of U(VI), U(IV) has been tested under a number of various conditions. The use of U(IV) for reducing plutonium does not seem not to have been described previously [1].

Tetravalent uranium at concentrations $\gtrsim 0.01$ M has been found to be stable in solutions of most acids for weeks or months if air is excluded. However, the stability in HNO_3 is poor, but increases with the U(IV) concentration. Maximum stability in HNO_3 seems to be obtained around 1 M HNO_3, where about 50 % of originally 0.1 M U(IV) is reduced in a little more than an hour at room temperature. Thus U(IV) can be used as a reducing agent even in HNO_3 solutions, provided the time of the experiments does not much exceed an hour.

In 1 M HNO_3, Pu(IV) and Pu(VI) are quantitatively (>99 %) reduced to Pu(III) by 0.1 M U(IV) within 5 min at room temperature. This effect can theoretically be used for separating uranium from plutonium in liquid-liquid extractions, if U(VI), U(IV), Pu(VI) and Pu(IV) prefer the organic phase and Pu(III) only prefers the aqueous phase [2]. The practical usefulness of this was tested in two sets of experiments.

In the first set of experiments two solutions were prepared. The organic solution consisted of methyl *iso*butyl ketone, which was 1.0 M in HNO_3 and contained Pu(IV) and Pu(VI); the aqueous solution was 0.7 M in HNO_3, 3 M in $Ca(NO_3)_2$ and contained a reductant. When these two phases are equilibrated with each other, the distribution ratio of the metals between the organic and the aqueous phases is for U(VI) 12, U(IV) $\sim$ 10, Pu(VI) 13, Pu(IV) 9, and Pu(III) $\lesssim 0.001$[3]; of these species thus only Pu(III) prefers the aqueous phase, and can easily be separated from the other metal ions. After the two phases had been shaken together, the amount of reduced plutonium (*i. e.* Pu(III)) was determined. Some of the results obtained with different reductants are given in the table for 5 min equilibration time.

Reducing agent	% Pu reduced
0.05 M $NH_2OH \cdot HCl$ + 0.005 M Fe^{2+}	65±8
0.05 M $H_4NOSO_2NH_2$ + 0.005 M Fe^{2+}	65±10
0.05 M U^{4+} in air	70±10
0.05 M U^{4+} in N_2	95±3

It is seen that U(IV) is equally or more effective than iron(II) plus hydroxylamine or sulfamate.

In the second set of experiments, the organic phase contained Pu(IV) as the uncharged TTA complex in 0.1 M TTA (thenoyltrifluoroacetone) in benzene, while the aqueous phase was 0.33 M in $HClO_4$ and contained U(IV). For 0.010 M U(IV), 14 % Pu had been reduced in 30 min, and 60 % in 20 h.

These experiments show the usefulness of U(IV) as a reducing agent for plutonium, either in aqueous solution or in two-phase

liquid-liquid extraction; however, in the presence of strong complexing agents for tetravalent actinides, the reduction is very slow. A more detailed account of the experiments will soon be given.

Tritium Labelling of *p*-Aminosalicylic Acid (PAS)

ÅKE HANNGREN and JAN RYDBERG

Söderby Hospital, Uttran, and Pharm. Dept., Kgl. Veterinärhögskolan, Stockholm; Chem. Dept., Univ. of Stockholm, Stockholm, Sweden

For the study of the metabolic properties of the tuberculostatic agent *p*-aminosalicylic acid* (PAS) [1], it was of importance to obtain tritium labelled PAS. In order to avoid cumbersome syntheses, the possibility of using recoil tritons for the labelling [2] was investigated.

In this method the organic compound to be labelled is mixed with a lithium salt, and the mixture is irradiated with slow neutrons. From nuclear reactions between these neutrons and ^{6}Li, tritium atoms with a kinetic energy of 2.7 MeV** are produced. These fast tritons are successively slowed down by collisions with surrounding atoms, which cause heavy destruction along the path of the triton, until it is finally trapped in some molecule. Since the neutron irradiation usually is carried out in a nuclear reactor, considerable destruction of the organic compound is also caused by other high energy particles present (neutrons, γ-quanta, *etc.*). The irradiated mixture will therefore contain a number of decomposition products of the original compounds, which all may be labelled with tritons. As has been pointed out [3], the difficulty lies not in the labelling, but in the isolation of a pure product.

In our experiment, 6.0 g PAS was mixed with 0.6 g Li_2CO_3 and irradiated with a slow neutron flux of 1.4×10^{12} n/cm^2/sec for 120 h (temperature ~40° C) in the reactor at A. B. Atomenergi in Stockholm. The isolation of pure PAS from the product, which had slightly darkened during the irradiation, was made in the following manner.

The product was mixed with amyl alcohol, which dissolves PAS as well as some of the organic decomposition products but not the Li_2CO_3. After solid substances had been filtered off, the solution was shaken with an equal volume of 0.1 M $NaHCO_3$ in water.

The distribution ratio q of PAS between the two solvents is given by the equation

$$q = \frac{k_d}{1 + k_a [H^+]}$$

at pH > 3 (at lower pH another term has to be added in the denominator to correct for the amphoteric character of PAS). Since the dissociation constant [4] k_a of the carboxylic hydrogen in PAS is $10^{-4.08}$, and the distribution constant k_d of undissociated PAS between amyl alcohol and water was determined to be 36 ± 3, it is easily calculated that about 95 % of PAS goes down into the aqueous phase when this is 0.1 M in $NaHCO_3$ (pH ~ 7).

The aqueous solution thus obtained was washed five times with equal portions of amyl alcohol. Since the equation above is generally valid for monobasic acids, these washings with amyl alcohol remove all organic decomposition products with $k_a < 10^{-7}$ and $k_d > 1$ (including the probable decomposition product *m*-aminophenol (MAP) with [5] $k_a = 1.3 \times 10^{-10}$ and $k_d \sim 2$). The aqueous solution was then treated in two different ways.

In *procedure A*, 0.1 M HCl was added until pH 3.8 was reached. The solution was then shaken with an equal volume of amyl alcohol. From the equation above, it can be calculated that at pH 3.8 about 95 % of PAS will be obtained in the organic phase, while a number of organic impurities are left in the aqueous phase. By this procedure all substances are removed which do not have k_a and k_d close to that of PAS.

In *procedure B*, the aqueous phase was cooled in ice, and HCl was added until a

Tritium Labelling of *p*-Aminosalicylic Acid (PAS)

ÅKE HANNGREN and JAN RYDBERG

Söderby Hospital, Uttran, and Pharm. Dept., Kgl. Veterinärhögskolan, Stockholm; Chem. Dept., Univ. of Stockholm, Stockholm, Sweden

For the study of the metabolic properties of the tuberculostatic agent *p*-aminosalicylic acid* (PAS) [1], it was of importance to obtain tritium labelled PAS. In order to avoid cumbersome syntheses, the possibility of using recoil tritons for the labelling [2] was investigated.

In this method the organic compound to be labelled is mixed with a lithium salt, and the mixture is irradiated with slow neutrons. From nuclear reactions between these neutrons and ^{6}Li, tritium atoms with a kinetic energy of 2.7 MeV** are produced. These fast tritons are successively slowed down by collisions with surrounding atoms, which cause heavy destruction along the path of the triton, until it is finally trapped in some molecule. Since the neutron irradiation usually is carried out in a nuclear reactor, considerable destruction of the organic compound is also caused by other high energy particles present (neutrons, γ-quanta, *etc.*). The irradiated mixture will therefore contain a number of decomposition products of the original compounds, which all may be labelled with tritons. As has been pointed out [3], the difficulty lies not in the labelling, but in the isolation of a pure product.

In our experiment, 6.0 g PAS was mixed with 0.6 g Li_2CO_3 and irradiated with a slow neutron flux of 1.4×10^{12} n/cm^2/sec for 120 h (temperature ~40° C) in the reactor at A. B. Atomenergi in Stockholm. The isolation of pure PAS from the product, which had slightly darkened during the irradiation, was made in the following manner.

The product was mixed with amyl alcohol, which dissolves PAS as well as some of the organic decomposition products but not the Li_2CO_3. After solid substances had been filtered off, the solution was shaken with an equal volume of 0.1 M $NaHCO_3$ in water.

The distribution ratio q of PAS between the two solvents is given by the equation

$$q = \frac{k_d}{1 + k_a [H^+]}$$

at pH > 3 (at lower pH another term has to be added in the denominator to correct for the amphoteric character of PAS). Since the dissociation constant [4] k_a of the carboxylic hydrogen in PAS is $10^{-4.08}$, and the distribution constant k_d of undissociated PAS between amyl alcohol and water was determined to be 36 ± 3, it is easily calculated that about 95 % of PAS goes down into the aqueous phase when this is 0.1 M in $NaHCO_3$ (pH ~ 7).

The aqueous solution thus obtained was washed five times with equal portions of amyl alcohol. Since the equation above is generally valid for monobasic acids, these washings with amyl alcohol remove all organic decomposition products with $k_a < 10^{-7}$ and $k_d > 1$ (including the probable decomposition product *m*-aminophenol (MAP) with [5] $k_a = 1.3 \times 10^{-10}$ and $k_d \sim 2$). The aqueous solution was then treated in two different ways.

In *procedure A*, 0.1 M HCl was added until pH 3.8 was reached. The solution was then shaken with an equal volume of amyl alcohol. From the equation above, it can be calculated that at pH 3.8 about 95 % of PAS will be obtained in the organic phase, while a number of organic impurities are left in the aqueous phase. By this procedure all substances are removed which do not have k_a and k_d close to that of PAS.

In *procedure B*, the aqueous phase was cooled in ice, and HCl was added until a

** MeV = million electron volts.

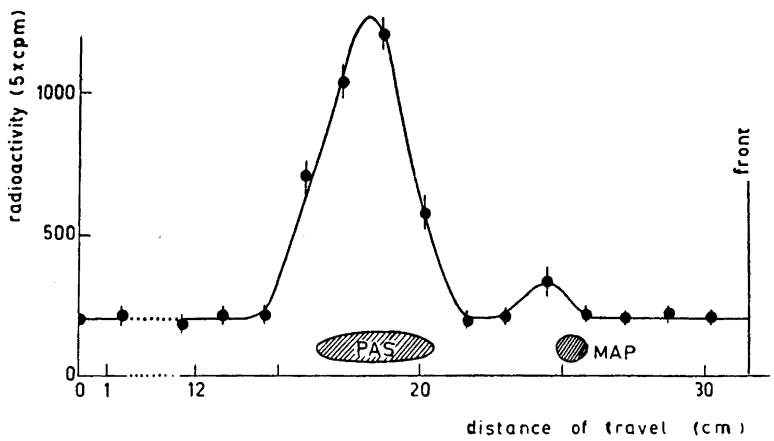

Fig. 1. Paper chromatogram of PAS purified according to method B. For comparison spots obtained with pure PAS and MAP are also shown.

pH around 3 was reached, when PAS precipitates. Now it is known that at this acidity PAS may decompose to MAP[6]; however, under the conditions used not more than a few percent was decomposed (see further below). The advantage of this procedure is that it leads to a solid PAS compound somewhat more rapidly than procedure A.

In both procedures tritium, which is unstably bound in the pH range 4—7 (as *e. g.* carboxylic hydrogen), is removed.

In order to test the purity of the products, paper chromatograms were run on Whatman No. 4 papers using a mixture of 40 % methyl alcohol, 20 % amyl alcohol, 20 % benzene, and 20 % water[7]. Due to the low energy of the β-radiation from tritium (0.018 MeV, corresponding to a maximum range of about 0.7 mg/cm^2), the radioactivity from tritium could not be measured directly on the paper chromatograms. These were therefore cut in pieces, and the activity eluted by several washings with the solvent mixture. The eluates were collected in aluminum dishes and evaporated, and the activity of the samples was measured in an internal proportional counter.

Fig. 1 shows the results obtained with PAS purified according to method B. As a comparison, parallel runs were made with ordinary PAS and MAP; these spots were determined either in ultraviolet light or developed with Ehrlich reagent. It is believed that the activity found is only due to tritium in PAS and MAP. The MAP may originate from the decomposition of some PAS at the high acidity used in the final step. By integrating the areas under the peaks in Fig. 1, after the back ground has been subtracted, it is found that 4 ± 2 % of the total tritium activity is due to tritium is bound in MAP; the rest of the activity to PAS.

The specific activity of the product was determined in the same counting arrangement, which had an efficiency of about 60 % for the β-radiation from tritium. This value includes geometry factors and back-scattering but excludes self-absorption. Since the self-absorption in the samples is very high, successive dilutions were made with ethyl alcohol, and the activity of aliquotes measured after each dilution. The following results were obtained:

μg PAS in sample	cpm	cpm/μg PAS
278	43 000	155
22.2	6 100	274
1.78	1 000$\pm$40	561
0.143	120$\pm$12	840
0.0114	11$\pm$5	970

The specific activity approaches a constant value, which is estimated to 1 500 ± 500 cpm/μg PAS. With this value and knowing the efficiency of the counter, the yield in the tritium labelling of PAS is calculated to 1.5 ± 0.5 mC/g PAS.

Preparation of 2-Methyl[1-^{14}C]-octadecanoic Acid

GUNNEL WESTÖÖ

*Department of Physiological Chemistry *, University of Lund, Lund, Sweden*

2-Methyloctadecanoic acid has been prepared by several investigators, *e. g.* by Schneider and Spielman [1] from diethyl methylmalonate and hexadecyliodide and by Morgan and Holmes [2] from methylmagnesiumiodide and 2-bromooctadecanoic acid.

For the preparation of [carboxy-^{14}C] 2-methyloctadecanoic acid a Kolbe electrolysis of hexadecanoic acid and sodium 3-[^{14}C]cyanobutyrate and subsequent hydrolysis of the cyano group seemed more suitable and was found to be convenient. The cyanobutyrate (previously prepared in a different way by Widequist [3]) was easily obtained in comparatively good yield from ethyl crotonate and sodium [^{14}C]cyanide (*cf.* the preparation of methylsuccinic acid by Higginbotham and Lapworth [4]).

Experimental. Sodium 3-[^{14}C]cyanobutyrate (I). A solution of ethyl crotonate (0.91 g) in ethanol (3.6 ml) was mixed with 0.41 g of sodium [^{14}C]cyanide dissolved in 1.0 ml of water and the mixture refluxed on a water bath for 5 h. The solvents were removed by distillation and the residue extracted with boiling acetone. The insoluble fraction was filtered off. On cooling the filtrate, colourless crystals of I (0.72 g, 67 %) separated. They were dried at 0.4 mm Hg, 78°. (Found: C 44.0; H 4.7; N 10.1. Calc. for $C_5H_6NO_2Na$: C 44.4; H 4.5; N 10.4.)

2-Methyl[1-^{14}C]octadecanoic acid (III). A solution of I (0.64 g of crude product) and hexadecanoic acid (7.0 g) in methanol (75 ml) was electrolysed between platinum electrodes as described by Stenhagen [5]. The precipitate (triacontane and a small amount of 2-methyloctadecanenitrile, II) was filtered off at room temperature and dissolved in boiling methanol. The solution was cooled to 20° and the precipitate again removed by filtration. The combined methanol solutions were evaporated and the residue extracted with ether, saturated with water. After removal of free acids from the ether solution by the ion exchanger Amberlite IRA 400, the ether was evaporated and the product hydrolysed by refluxing with ethanolic potassium hydroxide solution. Water was added to the hydrolysate, and hydrocarbons were removed by extraction with ligroin. Acidification of the alcohol-water layer and extraction of the 2-methyl[1-^{14}C]octadecanoic acid with ether, yielded 0.65 g (46 %) of crude III. After recrystallization from methanol and ligroin, 0.36 g of pure acid, m.p. 54.5—55.0°, remained. Schneider and Spielman [1] give m.p. 54.5°, Cason, Wolfhagen, Tarpey and Adams [6] 54.6—55.1° and Morgan and Holmes 58°.

* Now Institute of Organic Chemistry.

$$CH_3CH{=}CHCOOC_2H_5 + Na^{14}CN + H_2O \rightarrow \underset{\text{I}}{CH_3CH(^{14}CN)CH_2COONa} + C_2H_5OH.$$

The Paramagnetic Resonance Absorption of a Semiquinone of FMN

ANDERS EHRENBERG

Biochemical Department, Nobel Medical Institute, Stockholm, Sweden

Recently Beinert [1] has presented strong evidence for the existence of a semiquinoid compound appearing as an intermediate in the oxidation-reduction reactions of flavinmononucleotide (FMN). In collaboration with Gutowsky and Rutledge he succeeded in obtaining a paramagnetic resonance signal characteristic of a free radical from FMN reduced by Zn in an acid 50 % aqueous ethanol solution [1]. They failed to obtain any signal with a pure aqueous solution *, because of the high dielectric losses in liquid water. It is, however, of the greatest importance to be able to investigate the paramagnetic resonance of this and similar substances as the postulated semiquinones of FAD, DPN and TPN when they are dissolved in water, the milieu of the enzymatic reactions in which they are supposed to take part [2,3].

By freezing the samples, which diminishes the dielectric losses greatly, and working at liquid N_2 temperatures, which improved the sensitivity, it has now been possible to record intense resonance signals from the semiquinone of FMN in dilute solutions. The FMN was dissolved in 1 N HCl and reduced by metallic Zn, until the color was brownish. A 0.20 ml sample was transferred to a small quartz tube, which immediately was dipped into liquid N_2. The solution rapidly solidified and was cooled down to 80° K. The sample was then transferred into the precooled high-Q cavity of the spectrometer [4] operated at 9 400 Mc and the spectrum was recorded (Fig. 1). It did not change over a period of 30 min at liquid N_2 temperature. No signal could be obtained from FMN before adding Zn or after reoxidation in air, nor from a sample without FMN but reacted with Zn. The g-value of the resonance is practically identical with that of the free radical diphenylpicryl hydrazyl. No further signals could be seen in the region 2 600 to 3 900 gauss and no hyperfine structure has thus far been resolved.

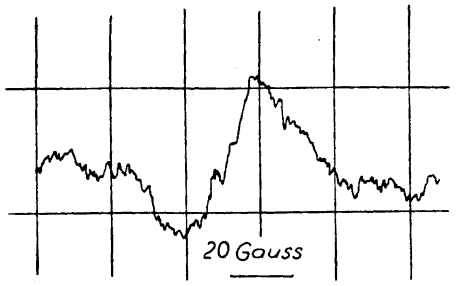

Fig. 1. Derivative of paramagnetic resonance absorption of 160 μM FMN in 1 N HCl after reduction by solid Zn for 8 min and subsequent rapid cooling to about 80° K.

Comparison of the surfaces under the absorption curve obtained by integration of Fig. 1 and that of a known amount of diphenylpicryl hydrazyl reveals that the concentration of free radicals is roughly half the initial concentration of FMN. This would appear to dispel any doubt that a semiquinone intermediate of FMN is really formed under the conditions described.

The technique used here will be of great value in cases when the intermediate is shortlived, since the low temperature will practically lock the reaction at a desired

The Paramagnetic Resonance Absorption of a Semiquinone of FMN

ANDERS EHRENBERG

Biochemical Department, Nobel Medical Institute, Stockholm, Sweden

Recently Beinert [1] has presented strong evidence for the existence of a semiquinoid compound appearing as an intermediate in the oxidation-reduction reactions of flavinmononucleotide (FMN). In collaboration with Gutowsky and Rutledge he succeeded in obtaining a paramagnetic resonance signal characteristic of a free radical from FMN reduced by Zn in an acid 50 % aqueous ethanol solution [1]. They failed to obtain any signal with a pure aqueous solution *, because of the high dielectric losses in liquid water. It is, however, of the greatest importance to be able to investigate the paramagnetic resonance of this and similar substances as the postulated semiquinones of FAD, DPN and TPN when they are dissolved in water, the milieu of the enzymatic reactions in which they are supposed to take part [2,3].

By freezing the samples, which diminishes the dielectric losses greatly, and working at liquid N_2 temperatures, which improved the sensitivity, it has now been possible to record intense resonance signals from the semiquinone of FMN in dilute solutions. The FMN was dissolved in 1 N HCl and reduced by metallic Zn, until the color was brownish. A 0.20 ml sample was transferred to a small quartz tube, which immediately was dipped into liquid N_2. The solution rapidly solidified and was cooled down to 80° K. The sample was then transferred into the precooled high-Q cavity of the spectrometer [4] operated at 9 400 Mc and the spectrum was recorded (Fig. 1). It did not change over a period of 30 min at liquid N_2 temperature. No signal could be obtained from FMN before adding Zn or after reoxidation in air, nor from a sample without FMN but reacted with Zn. The g-value of the resonance is practically identical with that of the free radical diphenylpicryl hydrazyl. No further signals could be seen in the region 2 600 to 3 900 gauss and no hyperfine structure has thus far been resolved.

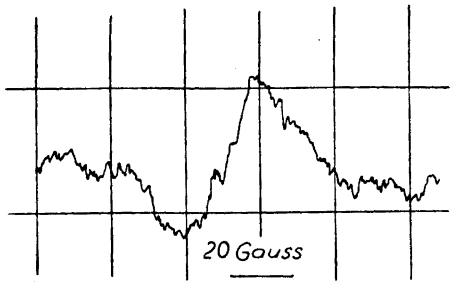

Fig. 1. Derivative of paramagnetic resonance absorption of 160 μM FMN in 1 N HCl after reduction by solid Zn for 8 min and subsequent rapid cooling to about 80° K.

Comparison of the surfaces under the absorption curve obtained by integration of Fig. 1 and that of a known amount of diphenylpicryl hydrazyl reveals that the concentration of free radicals is roughly half the initial concentration of FMN. This would appear to dispel any doubt that a semiquinone intermediate of FMN is really formed under the conditions described.

The technique used here will be of great value in cases when the intermediate is shortlived, since the low temperature will practically lock the reaction at a desired

* Personal communication.

stage. Work is in progress to correlate the amount of FMN-semiquinone to the absorption curves of the reaction mixture in the visible region under various conditions and to investigate whether the semiquinone can be formed from FMN, when it is bound to the apoprotein of the old yellow enzyme.

Electronic Structure of Metal Aromatic Complexes

A. D. LIEHR* and C. J. BALLHAUSEN**

Mallinckrodt Laboratory, Harvard University, Cambridge, Massachusetts, U.S.A.

A semi-quantitative theory of the electronic structure of aromatic complexes formed by the *cyclo*pentadienyl radical and by benzene is presented. The theory utilizes the wavefunctions given by the molecular-orbital theory, and on the basis of a simple scheme for evaluating the necessary integrals gives an internally consistent treatment of the bonding in metal aromatic complexes. The magnetic properties of these compounds are correlated by means of the given theory. A comparison between the treatment here presented and those of previous authors is given.

All of the theories of "sandwich" bonding thus far proposed have made use of the molecular orbital theory of valence.[1-4] The various treatments differ solely in the methods of determining the relative locations of the sundry molecular energy levels.

The most general mixing of the available *cyclo*pentadienyl radical and metal orbitals to form appropriate molecular orbitals has been performed by Jaffé [1] and by Ruch [4]. The approach of both of these authors is open to some criticism. Whereas Jaffé's treatment is too indefinite as to the relative positions of the molecular energy levels, Ruch's treatment is governed too much by a predisposition to obtain a rare gas configuration about the metal atom. Because of these objections neither Jaffé nor Ruch is able to give a satisfactory physical picture of the bonding in di-π-*cyclo*pentadienyl compounds.

The first physically appealing treatment of the problem was given by Dunitz and Orgel [2a]. These authors assumed that the *cyclo*pentadienyl orbital $\psi_{cp}(a_{1g})$ was too tightly bound to mix with any of the available metal orbitals of symmetry a_{1g}, such as $3d(a_{1g})$ and $4s(a_{1g})$. They likewise assumed that the empty 4p levels of the metal atom were too far removed energetically to interact with the filled *cyclo*pentadienyl orbitals $\psi_{cp}(a_{1u})$ and $\psi_{cp}(e_{1u})$. Further, they proposed that the bonding consisted mainly of two "covalent-ionic" bonds between the half-filled *cyclo*pentadienyl orbitals $\psi_{cp}(e_{1g})$ and the metal orbitals $3d(e_{1g})$. It was also supposed that the bonding could take place *via*

* National Science Foundation Post-doctoral Fellow, 1955—56. Now at Bell Telephone Laboratories, Murray Hill, New Jersey, U.S.A.

** On leave of absence from the Technical University of Denmark, Chemical Laboratory A, Copenhagen, Denmark.

two "donor" bonds formed by the mixing of the empty *cyclo*pentadienyl orbitals $\psi_{cp}(e_{2g})$ with the metal orbitals $3d(e_{2g})$.

However, as more experimental data became available, it was found that the bonding scheme as first proposed by Dunitz and Orgel was not adequate to explain the magnetic properties of all the newly prepared *cyclo*pentadienyl-metal compounds. This led Moffitt [3] to propose a modification of the Dunitz and Orgel model. He assumed that the large difference in energy between the $3d(e_{2g})$ and the $\psi_{cp}(e_{2g})$ orbitals precluded any interaction of these orbitals, and thus eliminated the "donor" bonds of Dunitz and Orgel. He also assumed that the $4s(a_{1g})$ and $3d(a_{1g})$ metal orbitals interact under the molecular force fields to produce one orbital lying in the vicinity of the 4p metal orbitals, and one in the vicinity of the $3d(e_{2g})$ orbitals. Moreover, he placed the antibonding orbital of symmetry e_{1g} above the 4p metal orbitals. This model will explain satisfactorily the magnetic properties of the di-π-*cyclo*pentadienyl compounds, but is admittedly of a qualitative nature.

The first and only other semi-quantitative treatment has been recently published by Dunitz and Orgel [2b]. They have retained the major portion of their own previous theory [2a], but have also included some of the modifications given by Moffitt. They differ from Moffitt in placing the antibonding levels of symmetry e_{1g} below the 4p levels of the metal. This calculation of Dunitz and Orgel is based on the heuristic principle which states that the interaction energy is proportional to the overlap, the overlap being computed according to the prescriptions of Craig, Maccoll, Nyholm, Orgel and Sutton [5]. This means of evaluating the molecular integrals seems to the present authors to be less satisfactory than that utilized in this paper.

1. ENERGY LEVELS FOR THE DI-π-*CYCLO*PENTADIENYL COMPOUNDS

The di-π-*cyclo*pentadienyl compounds have the structure depicted in Fig. 1[2a]. Thus, calling one *cyclo*pentadienyl ring CpA and the other CpB, we have the following wave functions for the *cyclo*pentadienyl ring systems [3],

$$\begin{aligned}
&\mathrm{Cp}S(a_2'') = (5)^{-\frac{1}{2}}\sum_r \varphi_r^{(s)} && (S = \mathrm{A, B}).\\
&\mathrm{Cp}S(e_{1\pm}'') = (5)^{-\frac{1}{2}}\sum_r (\omega^{\pm 1})^r \varphi_r^{(s)} && \omega = \exp(2\pi i/5)\\
&\mathrm{Cp}S(e_{2\pm}'') = (5)^{-\frac{1}{2}}\sum_r (\omega^{\pm 2})^r \varphi_r^{(s)}. && (1)
\end{aligned}$$

In eqn (1) we have given in parenthesis the symmetry designations of the wave functions CpS (S = A, B) in the point group D_{5h}. Combining the wave functions given in (1) to form molecular orbitals of symmetry D_{5d} we have

$$\begin{aligned}
\psi_{cp}(a_{1g}) &= (2)^{-\frac{1}{2}}\{\mathrm{CpA}(a_2'') - \mathrm{CpB}(a_2'')\}\\
\psi_{cp}(a_{1u}) &= (2)^{-\frac{1}{2}}\{\mathrm{CpA}(a_2'') + \mathrm{CpB}(a_2'')\}\\
\psi_{cp}(e_{1g}^{\pm}) &= (2)^{-\frac{1}{2}}\{\mathrm{CpA}(e_{1\pm}'') - \mathrm{CpB}(e_{1\pm}'')\}\\
\psi_{cp}(e_{1u}^{\pm}) &= (2)^{-\frac{1}{2}}\{\mathrm{CpA}(e_{1\pm}'') + \mathrm{CpB}(e_{1\pm}'')\}\\
\psi_{cp}(e_{2g}^{\pm}) &= (2)^{-\frac{1}{2}}\{\mathrm{CpA}(e_{2\pm}'') - \mathrm{CpB}(e_{2\pm}'')\}\\
\psi_{cp}(e_{2u}^{\pm}) &= (2)^{-\frac{1}{2}}\{\mathrm{CpA}(e_{2\pm}'') + \mathrm{CpB}(e_{2\pm}'')\} \quad . \qquad (2)
\end{aligned}$$

The wave functions of eqn. (2) represent the appropriate molecular orbitals for the di-π-*cyclo*pentadienyl ring system.

We must now construct wave functions for the metal atoms having the proper symmetry in D_{5d}. We shall assume that only the 3d and 4s orbitals of the metal are significantly involved in the bonding. In section 5 we shall discuss the validity of this assumption. Thus, the appropriate wave functions are *

$$\begin{aligned} \mathrm{s}(a_{1g}) &= R_{4s}(r)\Theta_{00}\,(2\pi)^{-\frac{1}{2}} \\ \mathrm{d}(a_{1g}) &= R_{3d}(r)\Theta_{20}\,(2\pi)^{-\frac{1}{2}} \\ \mathrm{d}(e^{\pm}_{1g}) &= R_{3d}(r)\Theta_{2\pm1}\,(2\pi)^{-\frac{1}{2}}\,\exp\,(\pm i\varphi) \\ \mathrm{d}(e^{\pm}_{2g}) &= R_{3d}(r)\Theta_{2\pm2}\,(2\pi)^{-\frac{1}{2}}\,\exp\,(\pm 2i\varphi) \end{aligned} \tag{3}$$

The molecular orbitals for the entire molecule are then formed by functions of the type

$$\chi(e^{\pm}_{1g}) = \sin\xi\cdot\psi_{cp}(e^{\pm}_{1g}) + \cos\xi\ \mathrm{d}\ (e^{\pm}_{1g}). \tag{4}$$

Following Moffitt [3], we shall assume that the bonding takes place primarily through the $e^{\pm}_{1g}$ orbitals, the remaining molecular orbitals being of the non-bonding variety. To determine the energies of these orbitals, we shall employ a new type of approximation scheme which combines the most appealing parts of the molecular orbital and crystal field theories of chemical valence.

Under the assumptions mentioned above, we may write the single electron *molecular orbitals* for the valence electrons as

$$\begin{aligned} \chi(e^{\pm}_{1g}) &= \sin\xi\cdot\psi_{cp}(e^{\pm}_{1g}) + \cos\xi\,\mathrm{d}(e^{\pm}_{1g}) \\ \check{\mathrm{d}}(a_{1g}) &= \cos\eta\ \mathrm{d}(a_{1g}) + \sin\eta\ \mathrm{s}(a_{1g}) \\ \check{\mathrm{s}}(a_{1g}) &= \sin\eta\ \mathrm{d}(a_{1g}) - \cos\eta\ \mathrm{s}(a_{1g}) \\ \check{\mathrm{d}}(e_{2g}) &= \mathrm{d}(e_{2g}) \end{aligned} \tag{5}$$

And, according to molecular orbital theory, we may determine the corresponding single electron energies as

$$\begin{aligned} \mathrm{h}(e_{1g})\chi(e^{\pm}_{1g}) &= E[\chi(e^{\pm}_{1g})]\chi(e^{\pm}_{1g}) \\ \mathrm{h}(a_{1g})\check{\mathrm{d}}(a_{1g}) &= E[\check{\mathrm{d}}(a_{1g})]\check{\mathrm{d}}(a_{1g}) \\ \mathrm{h}(a_{1g})\check{\mathrm{s}}(a_{1g}) &= E[\check{\mathrm{s}}(a_{1g})]\check{\mathrm{s}}(a_{1g}) \\ \mathrm{h}(e_{2g})\check{\mathrm{d}}(e^{\pm}_{2g}) &= E[\check{\mathrm{d}}(e^{\pm}_{2g})]\check{\mathrm{d}}(e^{\pm}_{2g})\ , \end{aligned} \tag{6}$$

where h is the appropriate single electron Hamiltonian.

Substituting eqns. (5) into eqns. (6), and performing the usual variational treatment, we obtain the following results:

* For the definition of $R_{3d}(r)$, $R_{4s}(r)$, and Θ_{lm} see Pauling, L. and Wilson, E. B. *Introduction to Quantum Mechanics*, McGraw-Hill, 1935, pp. 132–9.

$$E[\chi(e_{1g}^{\pm})] = \tfrac{1}{2}\{E[\psi_{cp}(e_{1g}^{\pm})] + E[d(e_{1g}^{\pm})]\} \pm \tfrac{1}{2}\{(E[\psi_{cp}(e_{1g}^{\pm})] - E[d(e_{1g}^{\pm})])^2 + 4(\mathrm{Rl.}\int \psi_{cp}^{*}(e_{1g}^{\pm})h(e_{1g})d(e_{1g}^{\pm}))^2\}^{\frac{1}{2}}$$

$$E[\tilde{d}(a_{1g})] = \tfrac{1}{2}\{E[d(a_{1g})] + E[s(a_{1g})]\} + \tfrac{1}{2}\{(E[d(a_{1g})] - E[s(a_{1g})])^2 + 4(\int d^{*}(a_{1g})h(a_{1g})s(a_{1g}))^2\}^{\frac{1}{2}}$$

$$E[\tilde{s}(a_{1g})] = \tfrac{1}{2}\{E[d(a_{1g})] + E[s(a_{1g})]\} - \tfrac{1}{2}\{(E[d(a_{1g})] - E[s(a_{1g})])^2 + 4(\int d^{*}(a_{1g})h(a_{1g})s(a_{1g}))^2\}^{\frac{1}{2}}$$

$$E[\tilde{d}(e_{2g})] = \int d^{*}(e_{2g}^{\pm})h(e_{2g})d(e_{2g}^{\pm})$$

$$\tan 2\xi = \frac{2\ \mathrm{Rl.}\{\int \psi_{cp}^{*}(e_{1g}^{\pm})h(e_{1g})d(e_{1g}^{\pm})\}}{E[d(e_{1g}^{\pm})] - E[\psi_{cp}(e_{1g}^{\pm})]}$$

$$\tan 2\eta = \frac{2\int d^{*}(a_{1g})h(a_{1g})s(a_{1g})}{E[d(a_{1g})] - E[s(a_{1g})]} \quad , \tag{7}$$

where Rl. = "real part of".
For convenience, we have set the overlap integral between the metal orbitals and the ring orbitals equal to zero in eqn. (7).

Since it is observed that the di-π-*cyclo*pentadienyl compounds are fairly stable, one would naturally wish to maximize the binding strength of the $\chi(e_{1g}^{\pm})$ orbitals. To accomplish this, we assume that the $\psi_{cp}(e_{1g}^{\pm})$ and $d(e_{1g}^{\pm})$ electrons have approximately the same energy. That is, we set

$$E[\psi_{cp}(e_{1g}^{\pm})] = E[d(e_{1g}^{\pm})]. \tag{8}$$

From (7) we see that the $\chi(e_{1g}^{\pm})$ energy is then given by (since this condition makes $2\xi = \pm\frac{\pi}{2}$)

$$E[\chi(e_{1g}^{\pm})] = E[d(e_{1g}^{\pm})] \pm \mathrm{Rl.}\{\int \psi_{cp}^{*}(e_{1g}^{\pm})h(e_{1g})d(e_{1g}^{\pm})\} \quad , \tag{9}$$

and the corresponding wave functions are

$$\chi_b(e_{1g}^{\pm}) = (2)^{-\frac{1}{2}}\{d(e_{1g}^{\pm}) + \psi_{cp}(e_{1g}^{\pm})\}$$
$$\chi_a(e_{1g}^{\pm}) = (2)^{-\frac{1}{2}}\{d(e_{1g}^{\pm}) - \psi_{cp}(e_{1g}^{\pm})\}. \tag{10}$$

In (9) and (10) the plus sign corresponds to the bonding orbital and the minus sign to the antibonding orbital.

We have yet to evaluate the integrals occurring in eqns. (7) and (9). In general, the evaluation of such integrals involves insuperable difficulties. However, there does exist a consistent approximation scheme for evaluating them. The procedure is the following:

For the electrons involved primarily in the bonding, the $e_{1g}^{\pm}$ electrons, we shall consider the effect of compound formation to be a strong attraction of the $d(e_{1g}^{\pm})$ electrons of the metal to the rings, with a similar attraction of the ring electrons to the metal atom. Thus, we *replace* the true expression for the energy of the $\chi_b(e_{1g}^{\pm})$ state, $E[\chi_b(e_{1g}^{\pm})]$, by an *estimate* obtained by considering the energy of attraction to be given by a set of *positive* point charges, $+qe_{1g}$,

situated on the carbon atoms of the two *cyclo*pentadienyl rings and interacting with the electrons, metal plus ring, which are moving in $d(e_{1g}^{\pm})$ orbitals. We hence assume that the energy of the *bonding* $e_{1g}^{\pm}$ orbitals is given by

$$E[\chi_b(e_{1g}^{\pm})] = E_d^0 + \int d(e_{1g}^{\pm})^* V_c(+ qe_{1g}) d(e_{1g}^{\pm}) \quad , \tag{11}$$

where E_d^0 is the energy of a d-electron in the normal atom and $V_c(+ qe_{1g})$ is the crystal field potential produced by the ten point charges $+ qe_{1g}$ of the two *cyclo*pentadienyl rings.

For the *antibonding* $\chi_a(e_{1g}^{\pm})$ electrons we replace the true $\chi_a(e_{1g}^{\pm})$ energy, $E[\chi_a(e_{1g}^{\pm})]$, by an estimate obtained by considering the energy of repulsion to be given by a set of *negative* point charges, $-qe_{1g}$, situated on the carbon atoms of the two *cyclo*pentadienyl rings and interacting with the electrons, metal plus ring, which are moving in $d(e_{1g}^{\pm})$ orbitals. That is,

$$E[\chi_a(e_{1g}^{\pm})] = E_d^0 + \int d(e_{1g}^{\pm})^* V_c(-qe_{1g}) d(e_{1g}^{\pm}) \tag{12}$$

For the *nonbonding* electrons, *i.e.*, those not primarily involved in the bonding, such as the $\tilde{d}(e_{2g}^{\pm})$, $\tilde{d}(a_{1g})$, and $\tilde{s}(a_{1g})$ electrons, the situation is conceptually simpler. Here we assume that the sole effect of compound formation is to *repel* these electrons from the region of the *cyclo*pentadienyl rings. We shall consider this repulsion to be represented by the effect of a set of ten negative point charges, $-qe_{2g}$ or $-qa_{1g}$, situated on the carbon atoms and interacting with the electrons moving in $d(a_{1g})$, $s(a_{1g})$, and $d(e_{2g}^{\pm})$ orbitals. Thus we can finally write

$$\begin{aligned}
&E[\chi_{(b)}^{(a)}(e_{1g}^{\pm})] \approx E_d^0 \pm \int d(e_{1g}^{\pm})^* V_c(qe_{1g})\, d(e_{1g}^{\pm}) \\
&E[\tilde{d}(e_{2g}^{\pm})] \approx E_d^0 + \int d(e_{2g}^{\pm})^* V_c(-qe_{2g}) d(e_{2g}^{\pm}) \\
&E[d(a_{1g})] \approx E_d^0 + \int d(a_{1g})^* V_c(-qa_{1g}) d(a_{1g}) \\
&E[s(a_{1g})] \approx E_s^0 + \int s(a_{1g})^* V_c(-qa_{1g}) s(a_{1g}) \\
&\int d(a_{1g})^* h(a_{1g}) s(a_{1g}) \approx \int d(a_{1g})^* V_c(-qa_{1g}) s(a_{1g})
\end{aligned} \tag{13}$$

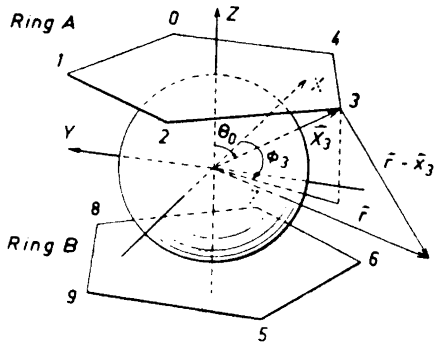

Fig. 1. Model of the compounds.

We next wish to consider the explicit evaluation of the integrals occurring in eqn. (13). Now by making use of Fig. 1, we see

$$V_c(\pm q) = \pm \frac{(-e)q}{a_0} \sum_{j=0}^{9} \frac{1}{|\vec{r}-\vec{x}_j|} \tag{14}$$

In eqn. (14) $\vec{r}$ and $\vec{x}_j$ are measured in units of the Bohr radius a_0. Expanding $|\vec{r}-\vec{x}_j|^{-1}$ in terms of the associated Legendre polynomials of the first kind and carrying out the sum over all the atoms occurring in (14) we obtain

$$V_c(\pm q) = \frac{\mp 10qe}{a_0 r_>} \sum_{l \geq 5m}^{\infty} \left(\frac{r_<}{r_>}\right)^l \sum_{5m=-l}^{l} \frac{(l-|m|)!}{(l+|m|)!} P_l^{|m|}(\cos\vartheta) P_l^{|m|}(\cos\vartheta_0) \exp.[5im(\varphi-\varphi_0)] \tag{15}$$

Substituting the wave functions of eqn. (3) together with the expansion of $V_c(\pm q)$ of eqn. (15) into eqn. (13) we have

$$\begin{aligned}
E[\chi_{(a)}^{(b)}(e_{1g}^{\pm})] &\approx E_d^0 \mp 10qe_{1g} \cdot e\{G_{0d} + \frac{1}{7} P_2(\cos\vartheta_0)\, G_{2d} - \frac{4}{21} P_4(\cos\vartheta_0)\, G_{4d}\} \\
E[\tilde{d}(e_{2g}^{\pm})] &\approx E_d^0 + 10qe_{1g} \cdot e\{G_{0d} - \frac{2}{7} P_2(\cos\vartheta_0) G_{2d} + \frac{1}{21} P_4(\cos\vartheta_0) G_{4d}\} \\
E[d(a_{1g})] &\approx E_d^0 + 10qa_{1g} \cdot e\{G_{0d} + \frac{2}{7} P_2(\cos\vartheta_0) G_{2d} + \frac{2}{7} P_4(\cos\vartheta_0) G_{4d}\} \\
E[s(a_{1g})] &\approx E_s^0 + 10qa_{1g} \cdot eG_{0s},
\end{aligned} \tag{16}$$

where

$$\begin{aligned}
G_{kd}(x) &= \frac{1}{a_0} \int_0^x \frac{r^k}{x^{k+1}} R_{3d}^2(r) r^2 dr + \frac{1}{a_0} \int_x^{\infty} \frac{x^k}{r^{k+1}} R_{3d}^2(r) r^2 dr \\
G_{ks}(x) &= \frac{1}{a_0} \int_0^x \frac{r^k}{x^{k+1}} R_{4s}^2(r) r^2 dr + \frac{1}{a_0} \int_x^{\infty} \frac{x^k}{r^{k+1}} R_{4s}^2(r) r^2 dr
\end{aligned} \tag{17}$$

Using [6-8] a carbon-carbon distance equal to 1.41 Å, a metal carbon distance of 2 Å, and the angle ϑ_0 equal to arc cos (0.80338) in the formulae given above we obtain the results tabulated in Tables 1 and 2. These results are also plotted

in Figure 2a. Since the computations for a wide range of values of Z_{3d} and Z_{4s} showed that the interaction integral, $\int d(a_{1g})^* h(a_{1g}) s(a_{1g})$, is only of the order of 10^{-2} times the diagonal terms $E[d(a_{1g})]$ and $E[s(a_{1g})]$, this term was neglected in computing the values given in Tables 1 and 2.

In the following section we shall use Tables 1 and 2 as well as Figures 2a and 2b to explain the magnetic properties of the di-π-*cyclo*pentadienyl compounds.

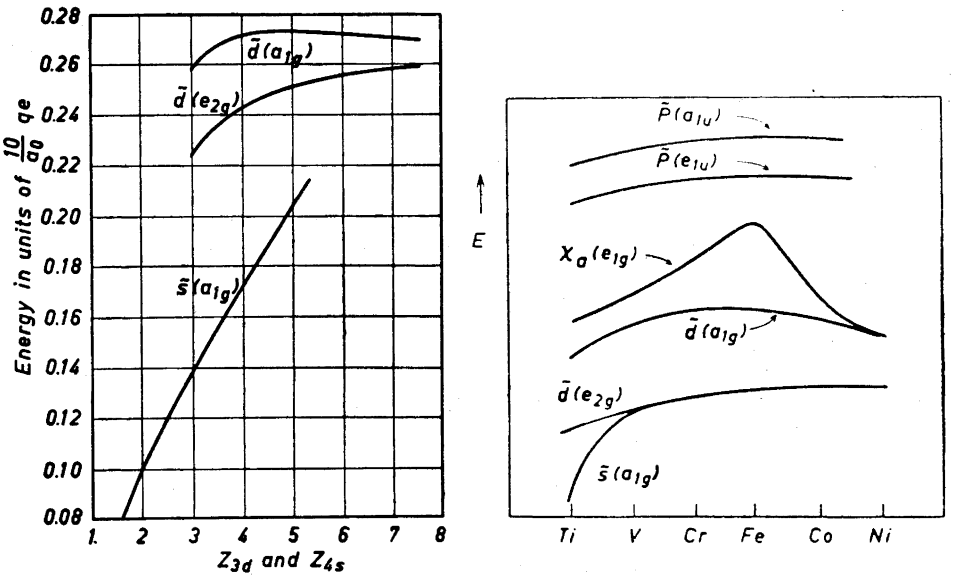

Fig. 2 a, b. A qualitative plot of the energy levels for the di-π-*cyclo*pentadienyl compounds of the first transition series. The energy spacings are distorted for illustrative clarity. Manganese is omitted from the plot for reasons stated in the text.

2. DISCUSSION OF THE MAGNETIC PROPERTIES OF THE DI-π-*CYCLO*-PENTADIENYL COMPOUNDS

Titanium. The compound $(C_5H_5)_2Ti$ is diamagnetic [9]. Hence, on our energy level diagram we must have the electronic structure * $[A]cp(a_{1g})^2cp(a_{1u})^2cp(e_{1u})^4 \chi_b(e_{1g})^4\tilde{s}(a_{1g})^2$. Since $E_s^0-E_d^0$ for Ti(II) is about $9\times10^{-2}\times\frac{10}{a_0}qa_{1g}e$, we see from Figure 2a that any value of $Z_{4s}\sim2.5$ and $Z_{3d}\sim4.5$ will ensure that the $\tilde{s}(a_{1g})$ level is well below the $\tilde{d}(e_{2g})$ level (if $qa_{1g}=1/5\ e$ it is $\sim16\ 000\ cm^{-1}$ below it) [10]. These values, in addition to yielding a diamagnetic molecule, are very reasonable physically for the $\tilde{s}(a_{1g})$ and $\tilde{d}(e_{2g})$ *molecular orbitals* of the *molecule* $(C_5H_5)_2Ti$. Ionization of the *molecule* to form $[(C_5H_5)_2Ti]^{+1}$ and $[(C_5H_5)_2Ti]^{+2}$ then takes place by the removal of first one and then the other $\tilde{s}(a_{1g})$ electron. This makes $[(C_5H_5)_2Ti]^{+1}$ paramagnetic with one unpaired electron and makes $[(C_5H_5)_2Ti]^{+2}$ diamagnetic.

Vanadium. The compound $(C_5H_5)_2V$ is paramagnetic with three unpaired electrons [11,12]. This implies that the $\tilde{s}(a_{1g})$ and $\tilde{d}(e_{2g})$ levels must be nearly degenerate. Thus the electronic structure is $[A]cp(a_{1g})^2cp(a_{1u})^2cp(e_{1u})^4 \chi_b(e_{1g})^4\tilde{s}(a_{1g})^1\tilde{d}(e_{2g})^2$. This will be the case if $Z_{4s}\sim3.3$ and $Z_{3d}\sim4.8$ for then the observed value of $E_s^0-E_d^0$ for V (II) will bring the $\tilde{s}(a_{1g})$ and $\tilde{d}(e_{2g})$ levels into near degeneracy (if $qa_{1g}=qe_{2g}\sim\frac{1}{5}e$ then $E_s^0-E_d^0=1\times10^{-1}\times\frac{10}{a_0}qa_{1g}e$). *The above choices of Z_{4s} and Z_{3d} are not critical. All that is required is that they be slightly higher than those occurring in $(C_5H_5)_2Ti$, as they must be on physical grounds.* Having determined the best values of Z to use for the $\tilde{s}(a_{1g})$ and $\tilde{d}(e_{2g})$ *molecular orbitals*, we would predict that $[(C_5H_5)_2V]^{+1}$ and $[(C_5H_5)_2V]^{+2}$ would be paramagnetic with two unpaired and one unpaired electrons, respectively.

Chromium. The additional electron introduced into the *cyclo*pentadienyl-metal electronic system upon replacement of vanadium by chromium will probably not introduce too great a change in the energy level scheme present in vanadium. Thus we might expect chromium to have the electronic structure:

$$[A]cp(a_{1g})^2cp(a_{1u})^2cp(e_{1u})^4\chi_b(e_{1g})^4[\tilde{s}(a_{1g})\tilde{d}(e_{2g})]^4.$$

This structure predicts that $(C_5H_5)_2Cr$ is paramagnetic with two unpaired electrons. The energy level scheme $(\tilde{d}(e_{2g}))^4(\tilde{s}(a_{1g}))^0$ is eliminated on the grounds that it would require larger values of Z_{4s} than are reasonable. We therefore have two possibilities: (a) The $\tilde{s}(a_{1g})$ and $\tilde{d}(e_{2g})$ levels are nearly degenerate as in vanadium, so that $[(C_5H_5)_2Cr]^{+1}$ and $[(C_5H_5)_2Cr]^{+2}$ are paramagnetic with three and two unpaired electrons, respectively; (b) the $\tilde{s}(a_{1g})$ level is lower than the $\tilde{d}(e_{2g})$ level as in titanium, so that $[(C_5H_5)_2Cr]^{+1}$ is paramagnetic with one unpaired electron and $[(C_5H_5)_2Cr)]^{+2}$ is diamagnetic. The investigations of the German school [13–15] indicate that $[(C_5H_5)_2Cr)^{+1}$ has three unpaired electrons

* The symbol [A] is used to designate the Argon core which is common to all of the metals of the first transition series.

and thus case (a) is the one actually occurring. The relative instability of $(C_5H_5)_2Cr$ indicates [16] that the binding parameter of qe_{1g} is not very large.

Manganese. The compound $(C_5H_5)_2Mn$ is known from experiment to be "ionic", and therefore has no $\chi_b(e_{1g})$ bonding orbital. In the crystal the ions $C_5H_5^-$ Mn^{++} $C_5H_5^-$ are probably arranged in a lattice having D_{5d} symmetry at the manganese sites.[16,17] Hence, the energy levels are given by a pure crystal field perturbation of the Mn^{+2} ion by the $C_5H_5^-$ rings. Since the ground state of Mn^{+2} is a ^6S state, which will not be split by a crystal field, the $(C_5H_5)_2Mn$ molecule will have five unpaired electrons [unless the crystal field is strong enough to depress one of the higher states, such as ^4G, ^4P, etc., below the ^6S state). Since it is observed that $(C_5H_5)_2Mn$ has five unpaired electrons [16], we see that the latter possibility is not realized.*

Iron. Here we have an extremely stable covalent compound having the formula $(C_5H_5)_2Fe$. Since iron has enough electrons to fill both the $\tilde{s}(a_{1g})$ and $\tilde{d}(e_{2g})$ shells, the relative location of these shells with respect to one another is immaterial from the magnetic viewpoint. Since the $\tilde{d}(a_{2g})$ level is significantly higher than the $\tilde{s}(a_{1g})$ and $\tilde{d}(e_{2g})$ levels, all possible assignments of the electrons will yield a diamagnetic $(C_5H_5)_2Fe$ molecule and a paramagnetic $[(C_5H_5)_2Fe]^{+1}$ ion having one unpaired electron. The degree of stability of this compound indicates a large positive value for qe_{1g}. The $\tilde{s}(a_{1g})$ and $\tilde{d}(e_{2g})$ levels are probably equi-energetic as in the case of vanadium.

Cobalt. It is likely that for $(C_5H_5)_2Co$, the $\tilde{s}(a_{1g})$ and $d(e_{2g})$ levels are, as in vanadium, nearly degenerate. The electrons are then placed in the molecule as $[A]cp(a_{1g})^2cp(a_{1u})^2cp(e_{1u})^4\chi_b(e_{1g})^4[\tilde{s}(a_{1g})\tilde{d}(e_{2g})]^6(\tilde{d}(a_{1g}))^1$, yielding a paramagnetic molecule with one unpaired electron. The cobalticinium ion, $[(C_5H_5)_2Co]^{+1}$, is then diamagnetic.

Nickel. This compound is relatively unstable thermally, in contrast to ferrocene.[18] Hence, we expect that qe_{1g} is not too large. This is further confirmed by the fact that the molecule is paramagnetic with two unpaired electrons. This paramagnetism implies that the antibonding orbital, $\chi_a(e_{1g})$, is nearly degenerate with the $\tilde{d}(a_{1g})$ nonbonding orbital. We see from Table 1 that the choice $q_{e_{1g}} = q_{a_{1g}}$ will bring about this degeneracy. Hence, we may assign to nickelocene the following electronic structure:

$$[A]cp(a_{1g})^2cp(a_{1u})^2cp(e_{1u})^4\chi_b(e_{1g})^4[\tilde{s}(a_{1g})\tilde{d}(e_{2g})]^6[\tilde{d}(a_{1g})\chi_a(e_{1g})]^2.$$

This structure gives nickelocene two unpaired electrons. We also see that this electronic assignment for $(C_5H_5)_2Ni$ implies that the nickelocinium ion is paramagnetic with one unpaired electron.

Miscellaneous Di-π-cyclopentadienyl Compounds. A number of other di-π-*cyclo*pentadienyl compounds have also been prepared, and a discussion of these follows much the same pattern as that given for the first transition series. For example, $[(C_5H_5)_2Zr]^{+2}$, $[(C_5H_5)_2Nb]^{+3}$, and $[(C_5H_5)_2Ta]^{+3}$ are formed exactly as is $[(C_5H_5)_2Ti]^{+2}$; $(C_5H_5)_2Ru$, $[(C_5H_5)_2Rh]^{+1}$, and $[(C_5H_5)_2Ir]^{+1}$ are similar to ferrocene; $[(C_5H_5)_2Ru]^{+1}$ is analogous to the ferricinium ion.

* In the solid state the five unpaired electrons interact to form an antiferromagnetic crystal. See Ref.[16]

The compounds $[(C_5H_5)_2Mo]^{+3}$ and $[(C_5H_5)_2W]^{+3}$ are completely analogous to the similar electronic systems $[(C_5H_5)_2V]^{+2}$ and $[(C_5H_5)_2Ti]^{+1}$. Preliminary investigations by Piper and Wilkinson [19] indicate that $(C_5H_5)_2Mo$ is analogous to $(C_5H_5)_2Cr$. However, $[(C_5H_5)_2Mo]^{+2}$ behaves quite differently from $[(C_5H_5)_2Cr]^{+2}$, being diamagnetic instead of paramagnetic [20]. Reference to the discussion of $(C_5H_5)_2Cr$ shows that for molybdenum we must thus have the $\tilde{s}(a_{1g})$ level below the $\tilde{d}(e_{2g})$ level. Hence, $[(C_5H_5)_2Mo]^{+2}$ resembles its neutral titanium analogue rather than its chromium and vanadium analogues.*

3. DISCUSSION OF THE MAGNETIC PROPERTIES OF THE *CYCLO*PENTADIENIDES OF THE GROUP III METALS AND THE ACTINIDES.

The group III metals form ionic compounds of the general formula $(C_5H_5)_3M$ (M = Sc, Y, and the rare earths).[21] Both the spectra and the magnetic properties are very similar to those of the normal triply ionized metals in solution. Thus, one is led to assume that, as in the case of manganese, the crystal field acting on the trivalent metal ions is of the same order of magnitude as that found in the normal salts of these metals. One then has the ordinary weak crystal field splitting of the trivalent ion which gives rise to the well-known magnetic properties of these ions [22].

Recently there have been reported [23] the stable ions $[(C_5H_5)_3U]^{+1}$ and $[(C_5H_5)_2Th]^{+2}$ (the latter ion has not as yet been fully characterized). The bonding in these ions would involve, in general, the low lying 5f, 6d, and 7s orbitals. A treatment similar to that given in sections 1 and 2 for the first series of transition elements could also be applied here. However, the uncertainty in geometry and the intrinsic complexity of the atomic systems involved makes a treatment of this sort impracticable.

4. DISCUSSION OF THE MAGNETIC PROPERTIES OF THE DI-π-BENZENE CHROMIUM COMPOUNDS

Fischer and Hafner [24] have recently reported the covalent diamagnetic compound $(C_6H_6)_2Cr$, and have, because of its great similarity to ferrocene, proposed a "sandwich" type bonding. ** They have also reported the stable ion $[(C_6H_6)_2Cr]^{+1}$ which they found to be chemically analogous to the ferricinium ion. As the theory of section 1 is completely general, it applies equally well to these di-π-benzene systems. To adapt section 2 to the di-π-benzene chromium compounds all one need to do is alter the geometrical parameters slightly and run all summations over twelve point charges rather than ten. Hence one would obtain exactly the same results for $(C_6H_6)_2Cr$ and $[(C_6H_6)_2Cr]^{+1}$ as were obtained for the isoelectronic systems $(C_5H_5)_2Fe$ and $[(C_5H_5)_2Fe]^{+1}$. These conclusions agree with the experimental findings [24].

---

* In an earlier paragraph we have shown that the hypothetical $[(C_5H_5)_2Cr]^{+2}$ ion must be paramagnetic.

** Previously Zeiss and Tsutsui had proposed a "sandwich" type bonding for several of the polyphenyl chromium compounds. See the review article by Cotton [25].

5. DISCUSSION

On the basis of a simple scheme for evaluating the necessary interaction integrals, we have been able to give an internally consistent semi-quantitative treatment of the bonding in metal aromatic complexes. This treatment has preserved those parts of the previous theories of Jaffé, Dunitz and Orgel, Moffitt, and Ruch which are most appealing physically. For example, we have followed Moffitt [3] in assuming that the only *cyclo*pentadienyl orbitals intimately involved in the bonding are the $\psi_{cp}(e_{1g})$ orbitals. However, as a calculation based on the *molecular orbital-crystal field* formalism employed in this paper shows that the p levels lie higher than the antibonding levels $\chi_a(e_{1g})$, we have followed Dunitz and Orgel [2b] rather than Moffitt in the ordering of these levels.

Of course, the explanation of the magnetic properties of the metal aromatic complexes is not alone sufficient proof of the validity of any given energy level scheme. A further test of the various theories concerning the electronic structure of these compounds could be obtained by a study of their absorption spectra. However, considerations of this kind have so far only been presented by Jaffé. In view of these facts, we plan next to apply the theory set forth in this paper to the problem of explaining the visible spectrum of the metal aromatic complexes.*

We wish to thank Professor G. Wilkinson for stimulating our interest in this problem and for many illuminating discussions. We also wish to express thanks to Drs. J. M. Birmingham, F. A. Cotton, and T. S. Piper and Mr. L. T. Reynolds for helpful discussions in connection with this work.

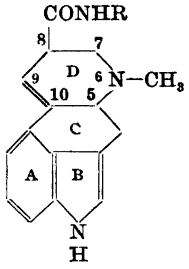
On the Photo-transformation of Ergot Alkaloids

HANS HELLBERG

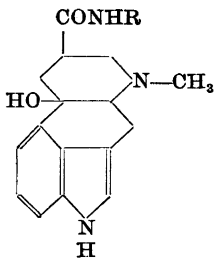
Chemical Department, State Pharmaceutical Laboratory, Stockholm, Sweden

The photo-catalyzed transformation of ergot alkaloids has been investigated. The results conform with the conclusion of Stoll and Schlientz that in aqueous solutions the reaction is an addition of water to the double bond of ring D. It is shown here that a prerequisite for the reaction is that the solution contains suitable, strongly polar constituents in sufficient quantities. In water solution hydrogen ions, primary phosphate ions and to a less extent acetate ions are highly active.



Paper chromatography is suggested as a new means for the assignment of configurational relationships within the lumialkaloids. The order of migration on paper is the reverse of that on alumina within every pair of lumialkaloids investigated. Theoretically, identification of the lumilysergic acid obtained on cleavage of a lumialkaloid should be the best way of establishing the connexions between lumi-derivatives from different alkaloid series. Such identifications have been approached here by paper chromatography of the products of alkaline hydrolysis of lumialkaloids and have led to certain conclusions. The spots can be tentatively assigned to the four possible lumilysergic acids.

The fact that the pK_a-values of the lumi-derivatives of ergometrine and ergometrinine are considerably higher than those of the dihydroalkaloids may be explained by axial conformation of the hydroxyl group at C_{10}.



The preparation of lumi-derivatives of ergometrinine, ergocristine and ergocristinine is reported. Physical and chemical data of the new substances are given together with some supplementary findings on the lumi-derivatives of ergometrine, ergotamine and ergotaminine.

It is well known that ergot alkaloids are sensitive to light. This instability is of great importance in alkaloid chemistry and in pharmacy, but until recently it has not been studied in any detail. In this laboratory the subject had been treated for some time [1], when Stoll and Schlientz [2] gave an account of their work in that domain. They concluded that, on illuminating genuine ergot alkaloids in acid water solutions, a molecule of water is added to the double bond in ring D of the lysergic or *iso*lysergic acid, forming new series of alkaloids analogous to the dihydroalkaloids. They distinguished the new derivatives with the prefix lumi-, and in order to indicate the stereoisomeric connexions with corresponding dihydroalkaloids they added the figure I or

II to the names. The preparation of lumi-derivatives of ergometrine, ergotamine and ergotaminine, was described and the usual physical and chemical data of the substances were given.

Genuine alkaloid

Lumialkaloid

The results obtained in this laboratory confirm and enlarge the work of Stoll and Schlientz. Moreover, to some extent the problem has been attacked by us in another way.

I. ON THE EXTERNAL PREREQUISITES FOR THE TRANSFORMATION

Having noticed by chance that transformation occurred very easily in phosphate buffers we studied the influence of different electrolytes on the velocity of the transformation. The results are reported in Figs. 1—4. Practically no transformation occurs in water or in solutions of neutral salts, *e. g.* sodium chloride (Figs. 1 and 3). In acid solutions, however, transformation takes place, and its considerable rate increase in the series of tartaric, phosphoric, hydrochloric acid solutions (Fig. 1) and in the series of phosphate buffers with decreasing pH (Fig. 2) shows that the hydrogen ion activity has an important effect. This conclusion conforms with the extensively accepted theories on the addition to double bonds of for instance hydrogen halides directly or of water by acid catalysis. The electrophilic hydronium ions are thought to be able to attack the electron excess of the double bond [3].

However, certain anions, especially primary phosphate ions and to some extent acetate ions, promote the photo-transformation (Figs. 1, 2 and 4). On the other hand chloride, methanesulphonate and primary tartrate ions seem to have little or no effect. The rate variation in the series of phosphate buffers (Fig. 2) is interesting. The effect of the decreasing hydrogen ion concentration is compensated for by the increasing concentration of primary phosphate ions. Not until these begin to disappear above pH 6 does the transformation velocity diminish considerably. Moreover Fig. 3 shows that an increase of primary phosphate concentration enhances the transformation velocity appreciably. No satisfactory theoretical explanation of the influence of the anions has been found.

On irradiating glacial acetic acid solutions of ergot alkaloids we obtained rapid transformations with spectrophotometric characteristics similar to those in aqueous solutions. Judging from paper chromatography (see Section III A)

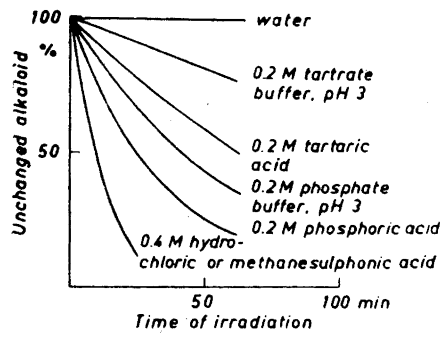


Fig. 1. Photo-transformation of ergotamine (tartrate) in water solutions of the composition stated in the figure. Irradiation with U.V.-light (max = 366 mμ) at standard distance. Room temperature. The content of unchanged alkaloid was followed spectrophotometrically at 315 mμ.

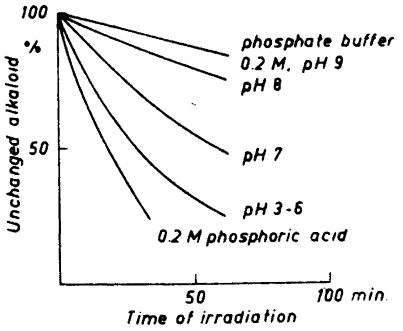

Fig. 2. Photo-transformation of ergometrine(maleate) in water solutions of the composition stated in the figure. Experimental conditions as in Fig. 1.

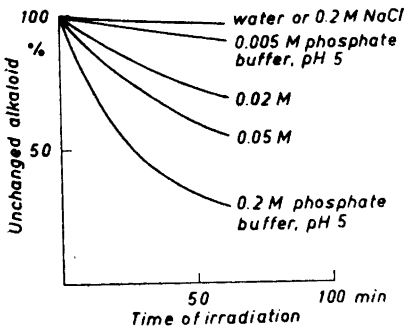

Fig. 3. Photo-transformation of ergometrine(maleate) in water solutions of the composition stated in the figure. Experimental conditions as in Fig. 1.

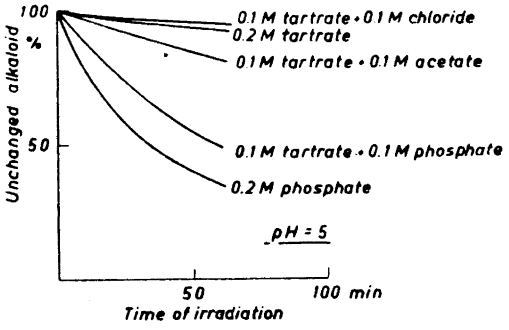

Fig. 4. Photo-transformation of ergometrine(maleate) in water solutions of the composition stated in the figure. Experimental conditions as in Fig. 1.

the transformation products were mainly the same as those obtained in water solutions *. Diluting the acetic acid with water or ether, respectively, we found that the transformation was much faster in the aqueous solution than in the ether solution.

From the above-mentioned facts it is possible to conclude that illumination is only one prerequisite for the transformation; another is that the solution contains suitable, strongly polar constituents in sufficient quantity. Thus in water solutions hydrogen ions, primary phosphate ions and to a less extent acetate ions are highly active.

* In the chromatographic process the transformation products came into contact with water.

II. ON THE PROPERTIES OF THE LUMIALKALOIDS

There are good theoretical and experimental reasons for the opinion that on the addition of water to the double bond of ring D the hydroxyl group goes to C_{10}, thus creating an asymmetric carbon atom. Like the dihydroalkaloids the lumialkaloids should exist in four series, deriving from four stereoisomeric lumilysergic acids, namely, according to Stoll's nomenclature, lumilysergic acid I, and II, lumi*iso*lysergic acid I and II. The derivatives of lysergic acid differ from those of *iso*lysergic acid by different configuration at C_8, and the substances designated I from those designated II by different configuration at C_{10}.

For the assignment of configurational relationships within the lumialkaloids as well as between the groups of dihydro- and lumialkaloids Stoll and Schlientz[2] used primarily the following indirect methods: 1) Comparison of the magnitude of the yields, 2) The order of adsorption on alumina, 3) Comparison of the specific optical rotations. In this work also paper chromatography of the lumialkaloids and of the lumilysergic acids obtained from them has been used for the same purposes.

From the beginning of our work we designated the lumialkaloids — regularly appearing in pairs — with the Greek letters α and β after their order of migration on paper chromatograms, the α-component moving more slowly than the β-component. This notation has been extensively used in this paper especially in the experimental part. However, the nomenclature of Stoll and Schlientz [2] seems more fundamental, and therefore later in this section a key will be given for the translation of our names into that nomenclature.

Already at the beginning of this work paper chromatography revealed that on illuminating a lysergic acid alkaloid only one transformation product appeared in quantities great enough to produce a spot while an *iso*lysergic acid alkaloid always caused two spots [1]. Working on a preparative scale with chromatography on alumina, however, new small fractions appeared as reported in the experimental section.

Comparing the R_F-values of Tables 2 and 3 with the order of migration on alumina (experimental part of this paper and Ref.[2]) it is found that the two lumi-derivatives of a certain alkaloid migrate on paper in an order which is the reverse of that on alumina. Paper chromatography seems to be an equally good method for classifying lumialkaloids as chromatography on alumina.

Experimental evidence obtained by Stoll and Schlientz supported the assumption that the substitution of the C_{10}-hydrogen of a pair of dihydroalkaloids for hydroxyl in the corresponding lumialkaloids did not affect the order of migration on alumina. It would have been interesting to investigate if this rule holds true also in paper chromatography but unfortunately the dihydroalkaloids necessary were not available. Stoll and his collaborators [4] used the different adsorbability on alumina as an argument for assigning definite conformations at C_8 to the different dihydroalkaloids. The paper chromatography of the lumialkaloids shows, however, the uncertainty of such conclusions.

As is well known, epimerization at C_8 takes place easily in the genuine alkaloids but much more slowly after saturation of the double bond of ring D.

It was therefore hoped that alkaline hydrolysis of the lumialkaloids would give the corresponding lumilysergic acids in fairly pure form, serving as a new means for the study of the mutual configurative connexions between the lumialkaloids. Paper chromatography of the lumilysergic acids obtained by alkaline hydrolysis of pure lumialkaloids (see Section III A) showed, however, that matters were not so simple. Thus double spots were obtained from all lumialkaloids tried. As is seen from Fig. 5 the chromatograms were of two different types, β-lumi-ins and α-lumi-inins giving type I (two spots near each other) α-lumi-ins and β-lumi-inins type II (two spots more widely separated). The most reasonable explanation of the two spots is that after all an epimerization at C_8 takes place, this reaction having several parallels in the chemistry of alkaloids [6,7]. This prompts to caution in the interpretation of experiments in preparing lumilysergic acids from lumialkaloids by alkaline hydrolysis. The results, however, constitute a proof that the α-lumi-ins and the β-lumi-inins have the same configuration at C_{10}, while β-lumi-ins and α-lumi-inins have the other. Desiring to relate these two groups to the configuration of dihydroalkaloids at C_{10} we established that the criteria magnitude of yields, and order of migration on alumina lead to the same conclusion within the lumiergometrine series and lumiergocristine series as Stoll and Schlientz [2] came to within the lumiergotamine series. Comparison of specific rotations lead to agreement with the other criteria in the ergocristine series, the ergometrine derivatives, however, giving inconsistant results; though of course this criterion is not to be trusted in the face of all other evidence.

The regularly recurring properties in each of the three series of lumialkaloids show the mutual connexions between the members, clearly reflected and confirmed also by the paper chromatograms, thus giving us a key to the configuration of the lumialkaloids hitherto investigated *.

α-lumi-in	= lumi-in II
β-lumi-in	= lumi-in I
α-lumi-inin	= lumi-inin I
β-lumi-inin	= lumi-inin II

In the light of this the paper chromatograms of the lumilysergic acids obtained on alkaline hydrolysis acquire renewed interest. In most cases the spots were unequal in magnitude, and if it is postulated that the bigger spot of a pair derives from the acid not rearranged at C_8 during hydrolysis it is possible to assign the spots to the four possible lumilysergic acids. This has been done at the bottom of Fig. 5, the perspicuousness of which is diminished by the fact that lumilysergic acid II and lumi*iso*lysergic acid I do not separate on the paper chromatograms. The interpretation in Fig. 5 is still to be considered as hypothetical but it is supported by the fact that irradiated lysergic acid gives practically only one spot, namely, the one assigned to lumilysergic acid I.

* The key is probably valid also for the lumialkaloids not yet investigated.

In the discussion of the configurations and conformations of ergot alkaloids the pK_a-values have played a certain rôle. Therefore an approach to these constants was made for the fairly watersoluble lumi-derivatives of ergometrine and ergometrinine. In the course of the potentiometric titrations of the equivalent weights (molecular weights), more closely described in the experimental part, we noted the pH's, at which the alkaloids were half-neutralized. These pH-values can be regarded as relative pK_a-values for the acid in the equation $HN^{+}CH_3 \rightleftharpoons H^+ + NCH_3$. The figures obtained are recorded in Table 1 together with some values for comparison, partly taken from literature [8,9].

Table 1. Estimated pK_a-values for ergometrine and derivatives. The figures obtained in this work refer to solutions containing 20 % ethanol.

** Ref.[8]; water solution.

Obviously the lumialkaloids are stronger bases than both genuine alkaloids and dihydroalkaloids. This is surprising at first sight because the inductive effect of an OH-group in C_{10} ought to be a weakening of the basicity of the nitrogen atom [3]. However, Stenlake [10] has emphasized the purely electrostatic effect, which negative substituents under favourable steric conditions can exert on the amino-nitrogen of lysergic acid. Stoll and collaborators [4], accepting this opinion, have shown that 6-methyl-8-*iso*hydroxyergoline I is a considerably stronger base than 6-methyl-8-hydroxyergoline I, concluding that the hydroxyl group is axial in the first-mentioned substance. C_8 and C_{10} are both equidistant from N_6 in ring D, and therefore the same substituent may have approximately the same influence on N_6, whether it is situated at C_8 or at C_{10}. Now according to the theories on the conformation of the dihydroalkaloids developed by Cookson [5] and by Stoll and his collaborators [4] the hydrogen of C_{10} is axial in relation to ring D. Probably the hydroxyl of the lumialkaloids takes the same position, and that explains the comparatively strong basicity of these substances.

III. EXPERIMENTAL

A. Paper chromatography

We used the descending technique, performed at 20—22° C in glass tanks of 22 × 32 × 61 cm with Whatman No. 1 paper in pieces of 54 × 23 cm. Papers with four applications each were kept over-night in the atmosphere of the water-rich phase. To

facilitate equilibration a filter paper moistened with the liquid was fixed in the middle of the container. The pre-treatment of the papers and the development of the chromatograms are described below for the different groups of substances. To visualize the spots after the evaporation of the solvent we used a reagent described by Berg [11], containing 0.5 g of *p*-dimetylaminobenzaldehyde in 5 ml of conc. HCl and 95 ml of ethanol. Fluorescent alkaloids could also be indicated by the U.V.-lamp.

Modifying the solvents suggested by Foster and collaborators [12] for the separation of ergometrine and ergometrinine, we used benzene, butanol, acetic acid and water in the proportions 2.5:2.5:1:4 for the lumi-derivatives of ergometrine, ergometrinine, lysergic and *iso*lysergic acid. At first considerable tailing was obtained. Shute [13] and Munier *et al.*[14], however, have suggested pretreatment of the papers with neutral salts. In our case a normalization of the spots was achieved by moistening the papers with 0.2 M NaCl and subsequent air-drying.

For paper chromatography of the peptide alkaloids of ergot many procedures have been suggested in recent years *e.g.* [11,12,15,16]. From our own investigations on counter current distribution [17,18] and from those of Berg on paper chromatography [11] it was known that benzene displays good separating properties on peptide alkaloids. Starting from this fact we found the following combination of solvents useful for the lumi-derivatives of ergotamine, ergotaminine, ergocristine and ergocristinine: benzene, butanol, acetic acid and water (9:1:2:8). The papers were impregnated with sodium chloride as above. Some precautions were necessary because of the great volatility of the solvents. Thus one of the papers in the tank was always run empty, starting 1.5 h before the real chromatogram in order to keep the atmosphere saturated with the solvents.

In Tables 2 and 3 the results of the paper chromatography have been summarized and given as average R_F-values. The R_F-values were not very well reproducible probably because of the high volatility of the solvents. This disadvantage could as usual be overcome by running standard substances for comparison parallel to the test substances.

Alkaline hydrolysis of lumialkaloids was performed on the pattern given in Ref.[6]. Protected from light about 1 mg of the substance was refluxed for 2 h with 1 ml of a 20 % solution of KOH in 50 % ethanol. After saturation with CO_2 (pH < 7) the solution was quickly evaporated to dryness on the water bath and the residue extracted with a few small portions of absolute ethanol. The filtered ethanol solution was directly applied to the chromatographic paper.

The chromatographic procedure was the same as for the lumiergometrins. Average R_F-values for the lumilysergic acids are given in Fig. 5.

B. The preparation of some lumialkaloids; their physical and chemical properties

For the preparation of lumialkaloids we had comparatively small quantities of genuine alkaloids at our disposal, and therefore some derivatives forming only in minor quantities have not been characterized completely.

Owing to experiences in the transformation velocity, reported in Section I of this paper, the alkaloids were illuminated in water solutions containing a strong acid (hydrochloric or methanesulphonic). For the separation of the reaction mixtures we applied chromatography on alumina, this method having been extensively used by Stoll and his collaborators [2,6].

The elementary analyses have been performed under the direction of Dr. K. J. Karrman in the Analytical Department of the Chemical Institute, University of Lund. The paper chromatographic methods have been described in Section III A of this paper.

Transformation products of ergometrine

A solution of 0.25 g of ergometrine maleate in 10 ml of M/10 HCl was irradiated in a quartz flask under N_2 atmosphere, until the transformation had almost ceased as judged from spectrophotometric measurements of samples drawn; time: *ca.* 8 h; light-source: "Mineralight" U.V.-lamp, the radiation of which was limited to the region of 366 mμ. Some sodium phosphate and 2.5 g of NaCl were added to the liquid, and after adjusting

Table 2. R_F-values for ergometrine alkaloids and lumi-derivatives. The chromatographic procedure is described in the text (Section III A).

Ergometrine	0.57	Ergometrinine	0.68
α-Lumiergometrine	0.29	α-Lumiergometrinine	0.37
β-Lumiergometrine	0.36	β-Lumiergometrinine	0.54

Table 3. R_F-values for ergotamine and ergocristine alkaloids and lumi-derivatives. The chromatographic procedure is described in the text (Section III A).

Ergotamine	0.85	Ergocristine	>0.90
α-Lumiergotamine	0.25	α-Lumiergocristine	0.59
β-Lumiergotamine	0.54	β-Lumiergocristine	0.79
Ergotaminine	0.69	Ergocristinine	0.89
α-Lumiergotaminine	0.23	α-Lumiergocristinine	0.49
β-Lumiergotaminine	0.68	β-Lumiergocristinine	0.88

the pH to 9 it was extracted with 3 × 20 ml of a mixture of ethanol and ether (1:2). The extract was evaporated to dryness in a vacuum (N_2 atmosphere). The residue, dissolved in 1 ml of ethanol and 100 ml of absolute chloroform, was transferred to the top of a column of alumina (10—20 g), and gradually eluted with chloroform (*ca.* 500 ml) containing increasing amounts of ethanol (1—7 %). First a small fraction of unchanged ergometrine was obtained and then two fractions of transformed alkaloid, the first one very small, the second one strongly dominating. Their paper chromatographic properties showed them to be α-lumiergometrine and β-lumiergometrine, respectively.

α-Lumiergometrine was obtained in a quantity of only a few mg of raw product, which showed, however, a pure lumialkaloid absorption spectrum and gave a single spot on the paper chromatogram (Table 2).

β-Lumiergometrine. The dominating second fraction was dissolved in some absolute methanol and diluted with 5—7 volumes of ether. On scratching the walls of the vessel needle-shaped crystals were formed. Yield: 90 mg (air-dry). On the Kofler block the crystals gave off their solvent of crystallization at about 110° C, transforming into an apparently amorphous modification with a very diffuse melting point (about 146°—150° C). The material was uniform on paper chromatograms (Table 2).

After drying the substance in a high vacuum at 130° C the following constants were obtained: *Light absorption:* E (1 %, 1 cm) = 196 at 283 mμ (max.) in M/10 HCl. *Optical rotation:* $[\alpha]_D^{20°} = -27°$ (pyridine, $c = 1$). *Molecular weight:* acidimetric equiv.wt. = 347* (calc. for ergometrine + 1 H_2O : 343). *Elementary analysis:* Found: C 64.9; H 7.40; O 14.3; N 12.9. Calc. for $C_{19}H_{25}O_3N_3$ (343.4): C 66.45; H 7.34; O 13.98; N 12.24.

The properties of β-lumiergometrine are chiefly the same as reported by Stoll and Schlientz [3] for lumiergobasine.

Transformation products of ergometrinine

The same preparation procedure was used as for ergometrine. We obtained three fractions of non-fluorescent alkaloid, all with a maximum of light absorption at 283 mμ. The first and the last of these were the main fractions and according to their paper-chromatographic properties they were called α-lumiergometrinine and β-lumiergometrinine, respectively. The very small intermediate fraction, which differed from the other two even paper chromatographically, was not examined any more.

α-Lumiergometrinine crystallized from absolute methanol as needles. Yield: 30 mg of air-dry crystals from 150 mg of ergometrinine. On the Kofler block the crystals were transformed into an apparently amorphous modification at about 135° C and melted diffusely and under decomposition at 193°—197° C. The material was uniform on the paper chromatogram (Table 2).

* Obtained by titrating potentiometrically *ca.* 2 mg of substance, dissolved in 0.15 ml of ethanol and 0.50 ml of water, with 0.02 N HCl.

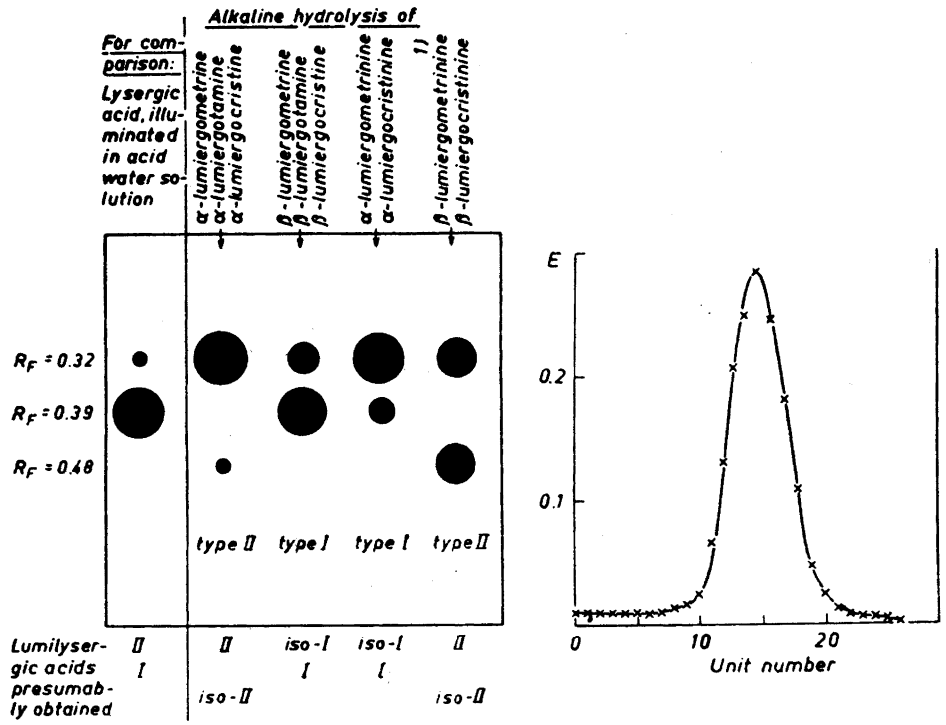

Fig. 5. Paper chromatography of lumilysergic acids obtained by alkaline hydrolysis of lumialkaloids (idealized picture).

Fig. 6. Counter current distribution of β-lumiergocristinine. Benzene/0.2 M phosphate buffer pH 5.9 (Photometric determination by *p*-dimethylaminobenzaldehyde).

After drying in a high vacuum at 130° C the substance showed the following properties: *Light absorption:* E (1 %, 1 cm) = 193 at 283 mμ (max.) in M/10 HCl. *Optical rotation:* $[\alpha]_D^{20°}$ = + 24° (pyridine, c = 1). *Molecular weight:* acidimetric equiv.wt. = **341** (calc. for ergometrinine + 1 H_2O: 343). *Elementary analysis:* Found: C 66.5; H 7.57; O 14.1; N 11.7. Calc. for $C_{19}H_{25}O_3N_3$ (343.4): C 66.45; H 7.34; O 13.98; N 12.24.

β-Lumiergometrinine crystallized on evaporation of a solution in little ethanol and much chloroform. Yield: 55 mg of air-dry crystals from 150 mg of ergometrinine. All attempts failed to crystallize the substance from solvents usually applied to ergot alkaloids as methanol, ethyl acetate or acetone. From warm benzene solutions it was precipitated as an apparently amorphous modification. On the Kofler block the crystalline β-lumiergometrinine at 105° C gave off its solvent of crystallization, changing into an apparently amorphous modification, the melting point of which (*ca.* 125° – 135° C) was very difficult to observe. The product was uniform on paper chromatogram (Table 2).

After drying the substance in a high vacuum at 120° C we obtained the following constants: *Light absorption:* E (1 %, 1 cm) = 188 at 283 mμ (max.) in M/10 HCl. *Optical rotation:** $[\alpha]_D^{30°}$ = + 18° (pyridine, c = 1). *Molecular weight:* acidimetric equiv.wt. = 356

* Based on one single experiment.

(calc. for ergometrinine + 1 H_2O: 343). *Elementary analysis:* Found: C ...; H 7.30; O 14.2; N 12.0. Calc. for $C_{19}H_{25}O_3N_3$ (343.4): C 66.45; H 7.34; O 13.98; N 12.24.

Transformation products of ergocristine

0.25 g of ergocristine was dissolved in 50 ml of M/10 methanesulphonic acid. In order to give the same effect on the peptide alkaloids as on ergometrine the irradiation had to be more powerful and therefore a strong mercury-lamp without a filter was used in this case, completing the transformation in 1—2 h. The products were extracted with absolute chloroform after alkalinizing the reaction mixture with ammonia. The chloroform extract was dried over anhydrous sodium sulphate and poured onto a column of alumina (20—40 g). The elution was made step by step, first with chloroform containing 1 % ethanol until the small fraction of α-lumiergocristine had been obtained and then with chloroform containing 3 % ethanol until the dominating fraction of β-lumiergocristine had come out. The fractions were as soon as possible evaporated in a vacuum to dryness.

α-Lumiergocristine was formed only in minor quantities. The top fractions from several preparations — strongly contaminated with coloured substance — were collected and distributed between a large quantity of diluted hydrochloric acid (about M/20) and a small quantity of chloroform. The nearly colourless aqueous solution was alkalinized with ammonia and extracted with chloroform. From this solution a small quantity of substance (*ca.* 10 mg) could be obtained but we did not succeed in crystallizing it. However, it was uniform on paper chromatogram (Table 3).

β-Lumiergocristine was purified from colouring matter in the same way as the α-product and could be crystallized from methanol in short, thick prisms. Yield: 90 mg of air-dry crystals from 200 mg of ergocristine. Melt.p. on the Kofler block: 179°—181° (decomp.). It was uniform on the paper chromatogram (Table 3).

After drying in a high vacuum at 130° C the substance showed the following properties: *Light absorption:* E (1 %, 1 cm) = 109 at 283 mμ (max.) in M/10 HCl. *Optical rotation:* $[\alpha]_D^{20°}$ = + 17° (pyridine; c = 1). *Molecular weight:* acidimetric equiv.wt.: 641 * (calc. for ergocristine + 1 H_2O: 628). *Elementary analysis:* Found: C 65.6; H 6.62; O 15.4; N 10.9. Calc. for $C_{35}H_{41}O_6N_5$ (627.7); C 66.96; H 6.58; O 15.29; N 11.16.

Transformation products of ergocristinine

The ergocristinine had to be dissolved in glacial acetic acid, the solution diluted with water to the strength of about 5 % acetic acid and finally made M/10 in respect of methanesulphonic acid. The irradiation and the extraction were made as described for ergocristine. For the separation gradient elution was used again. The transformation products were very sensitive to the ethanol percentage of the elutrient and therefore this was allowed to increase only slowly (0—1 % in 500 ml of elutrient). The main products were the α-lumiergocristinine and the β-lumiergocristinine. Between them small fractions with variable paper chromatographic properties appeared. These were not further examined.

α-Lumiergocristinine crystallized from methanol as needles. The yield was remarkably small. From 300 mg of ergocristinine only 33 mg of air-dried crystals were obtained. M.p. on the Kofler block: 234—236° C. It was uniform on paper chromatogram (Table 3).

Dried in a high vacuum at 130° C the α-lumiergocristinine showed the following properties. *Light absorption:* E (1 %, 1 cm) = 107 at 283 mμ (max.) in M/10 Hcl. *Optical rotation* **: $[\alpha]_D^{20°}$ = +116° (pyridine, c = 0.6). *Molecular weight:* acidimetric equiv.wt.: 638 (calc. for ergocristinine + 1 H_2O: 628). *Elementary analysis:* Found: C 66.6; H 6.71; O 15.7; N 11.0. Calc. for $C_{35}H_{41}O_6N_5$ (627.7): C 66.96; H 6.58; O 15.29; N 11.16.

β-Lumiergocristinine. The raw product was purified from most of the coloured material as described for α-lumiergocristine. It was dissolved in much boiling benzene from which it precipitated on cooling in an apparently non-crystalline form. The yield of this product

* Obtained for the petide alkaloids by titrating potentiometrically *ca.* 3 mg of substance, dissolved in 0.50 ml of glacial acetic acid, with 0.02 N perchloric acid.

** Based on one single experiment.

was 150—200 mg from 300 mg of ergocristinine. The material could not be brought to crystallization even after further chromatographic purifications. However, the substance obtained was uniform on paper chromatogram and gave a single top on counter current distribution (Fig. 6). On the Kofler block it had a reproducible and comparatively good melting point at 171—172° C (decomp.). Thus there are good reasons to believe that the substance was pure.

After drying in a high vacuum at 130° C the substance showed the following properties: *Light absorption:* E (1 %, 1 cm) = 107 at 283 mμ (max.) in M/10 HCl. *Optical rotation:* $[\alpha]_D^{20°} = \pm 0°$ (pyridine, $c = 1$). *Molecular weight:* acidimetric equiv.wt.: 650 (calc. for ergocristinine + 1 H_2O: 628). *Elementary analysis:* Found: C 66.5; H 6.57; O 15.6; N 11.0. Calc. for $C_{35}H_{41}O_6N_5$ (627.7): C 66.96; H 6.58; O 15.29; N 11.16.

Transformation products of ergotamine and ergotaminine

The lumi-derivatives from these alkaloids have been prepared and described by Stoll and Schlientz [2]. The β-lumiergotamine had been made by us before we were aware of the Swiss paper. The main properties of our product were the following: It crystallized from methanol in short, thick prisms. M.p. on the Kofler block: 248° C (decomp.); $[\alpha]_D^{20°} = +12°$ (pyridine; $c = 1$) E (1 %, 1 cm) = 115 at 283 mμ (max.) in M/10 HCl. Acidimetric equiv. wt. (mol. wt.) = 605 (calc. for ergotamine + 1 H_2O: 600). Found: C 66.1; H 6.38; O 16.15; N 11.55. Calc. for $C_{33}H_{37}O_6N_5$ (599.7): C 66.09; H 6.22; O 16.01; N 11.68.

β-Lumiergotamine gave a slightly soluble hydrochloride and could be almost totally precipitated from its aqueous solution by an excess of hydrochloric acid. The paper chromatographic properties of the lumiergotamines and lumiergotaminines are reported in section III A of this paper (Table 3, Fig. 5).

Acknowledgements. I wish to thank Dr. K. J. Karrman of the University of Lund for the elementary analyses and Mrs. Ingegerd Dinnetz of this laboratory for technical assistance. My thanks are also due to Mrs. M. Spilsbury, who revised the English.

The Effect of Volatile Substances on the Chemical Activity of Ultrasonic Cavitation

NILS ELLFOLK and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

The effect of volatile substances on the reactions in ultrasonic-treated water was investigated. It was found that butanol, propanol *etc.* are able to inhibit practically all reactions, the oxidation of luminol being, however, unchanged. The sonoluminescence of pure distilled water could not be observed in the presence of these substances.

In an earlier paper [1] we reported that different volatile substances such as fatty acids, alcohols, *etc.* are able to inhibit nitrogen fixation in water treated with ultrasonics In the homologous series the inhibition was observed to increase with the length of the carbon chain. When trying to explain this inhibition it seemed at least apparent that the vapour pressure of the substances was not the cause of the inhibitory effect. Since the inhibition generally increased with the length of the carbon chain it seemed reasonable to suppose that the substances caused the inhibition of the reactions by lowering the surface tension of the solution. It is, however, to be observed that other properties also change with the lengthening of the carbon chain.

In the present work attempts were made to elucidate this problem by observing the effect of volatile substances on the oxidation of compounds like luminol during the ultrasonic treatment of distilled water.

EXPERIMENTAL

Ultrasonic vibrations were produced as described previously [1]. A sensitive photometer was used for the measuring of the luminescence produced by ultrasonics in distilled water with or without the addition of luminol. The photoelectric cell (RCA 931 A) and the amplifying system were enclosed in a light-tight metal box with a window for the light to be measured. Fig. 1 shows a schematic diagram of the complete electronic circuit [2]. The weak electric current was measured with a sensitive galvanometer (Lange) having a current sensitivity of 3.5×10^{-9} amp/mm.

In the experiments with luminol the following solution was used: 100 ml of the test solution, 0.01 % luminol (5-amino-2,3-dihydro-1,4-phthalazinedione) in 0.05 % Na_2CO_3. The light emitted was measured after it had reached its maximum. Table 1 shows the influence of different substances on the chemiluminescence of luminol.

Toluene	0.2	150

These experiments show that alcohols are hardly competing for oxygen with nitrogen because practically no decrease in light intensity can be observed in the presence of luminol. On the other hand we have previously found that nitrogen fixation does not take place in the presence of alcohol [1]. This question will be reverted to below.

To elucidate the interrelationship between the chemiluminescence of luminol and the luminescence of distilled water, treated with ultrasonics, experiments were made with pure distilled water in the same way as with luminol, *i. e.* measuring luminescence after the maximum had been developed. Table 2 shows the influence of different substances on luminescence.

Table 2. Luminescence of water with volatile substances without luminol.

Propanol	1	0

A KI solution was treated in the ultrasonic field (100 ml of a solution made up of 50 ml of 1 % KI, 45 ml of 1 % H_2SO_4, and 5 ml of 0.1 % starch solution). The liberated iodine was titrated with thiosulphate. It can be seen in Fig. 2 that no oxidizing substances are produced in the solution in presence of *n*-butanol.

When 1 ml of chloroform is added to this solution some oxidizing substances are still produced in the presence of *n*-butanol as can be seen from the liberation of iodine (Fig. 3). An experiment was made to find out if a change in the physical structure of water possibly causes changes in the chemical activity of cavitation. No effect was observed in 1 M NaCl solution.

DISCUSSION

If oxygen containing water with or without luminol is treated with ultrasonics, molecular nitrogen is fixed under the formation of nitrite, but if for instance 1 % butanol is added nitrogen fixation is completely inhibited. So is also the formation of hydrogen peroxide. Butanol does not, however, notably decrease the chemiluminescence of luminol, a fact which shows that easier

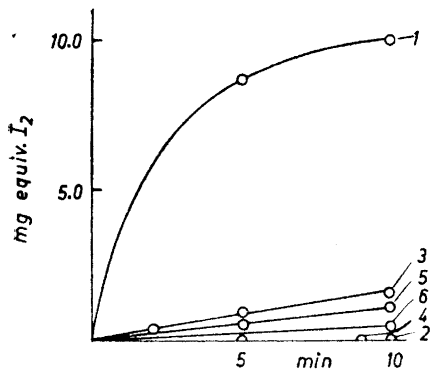

Fig. 2. Inhibitory effect of volatile substances on liberation of iodine from KI. 1) Control without *n*-butanol addition, 2) addition of 1 % *n*-butanol, 3) 1 % butyric acid, 4) 0.2 % toluene, 5) 0.25 % caproic acid, 6) 0.5 % *iso*-amylalcohol.

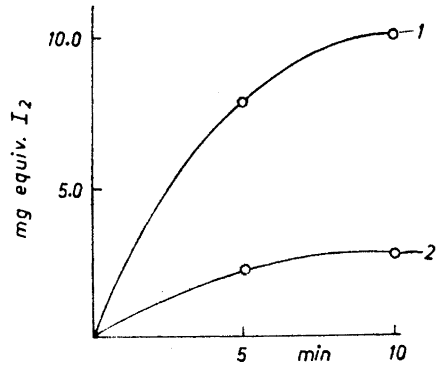

Fig. 3. 1) Control without butanol addition, 2) addition of 1 % *n*-butanol.

occurring oxidation reactions still take place and that cavitation occurs in the presence of this alcohol, since substances with a high vapour pressure such as ether *etc.* completely extinguish the light given by luminol. Due to the addition of alcohol, however, radical changes have taken place in the system. The hypothesis that alcohols should act as acceptors for oxidizing agents is not well-founded because no liberation of iodine from KI was observed in a 1 % butanol solution. Since the changes caused by alcohol cannot be due to the ability of the substances to compete for oxygen with nitrogen, nor to the destruction of cavitation because of the vapour pressure, it seems reasonable to suppose that the substances which lower the surface tension decrease the energetic state of cavitation, so that for merely energetic reasons some reactions do not take place. As to the mechanism of the decrease of the energy level at least two possible ways had to be observed.

In the first case the mechanism of the lowering of the energy level is assumed to be connected with the mechanism of cavity formation. According to Lindström [3] cavitation is preceded by the nucleation process during which separate gas bubbles dissolved in the liquid combine, and a germ consisting of six gas molecules is built up. Through the formation of this germ, or box, the great cohesive forces in water are overcome and cavitation is initiated. Earlier we assumed it hardly likely that surface active substances should accumulate on the inside surface of the cavitation bubble because of its short duration, but if the nucleation process precedes cavitation it may be assumed that during this lag period surface active substances are mobilized in the vicinity of the box. On this account it can perhaps be understood why there is a difference in regard to inhibition between dissociated and undissociated fatty acids. The dissociated carboxyl group is surrounded by such a large amount of water molecules that, contrary to the undissociated group, its

mobility is hampered. From this the observed difference between neutralized and unneutralized valeric acid arises, *i. e.* the former is able to inhibit nitrogen fixation by only 30 or 40 % whereas the latter inhibits it completely.

Lindström assumes further that the chemical reactions in cavitation are due to the fact that the water surface around a gas bubble is negatively charged, the surface charge acquiring rather high values (0.08 e.s.u./cm^2). When the surface of the cavity is formed the surface charge must be established by transport of electricity, by which process the gas molecules in the cavity will be ionized. In such a case it is evident that if surface active substances have been accumulated in the surface of the gas bubble the surface charge per cm^2 should be lower than in a solution without surface active substances for the very reason that the number of water molecules per cm^2 of the surface of the bubble has decreased.

In this case the explanation of the changes in the chemical activity of cavitation is assumed to be connected with the drastic changes in the physical structure of water caused by addition of different alcohols.

According to Bernal and Fowler [4] water may be regarded as a partially broken down ice structure, tridymite-like, with each oxygen atom surrounded tetrahedrally by four other oxygen atoms, the structure being held together by hydrogen bonds. When a molecule of solute is introduced into the water structure a cavity can first be formed in this by taking away a given number of water molecules. Hereby a number of hydrogen bonds have to be broken proportional to the size of the molecule. This breaking of hydrogen bonds is reflected in changes in compressibility, viscosity and surface tension. A decrease in compressibility means a closer packing of the water molecules with increased cohesive forces. It could therefore be assumed that the formation of cavity is prevented because of the depolymerization of the association of water.

It should, however, be observed that no inhibition of nitrogen fixation was observed in a solution in which a depolymerization of water had been produced by sodium chloride. It is therefore suggested that changes in the physical structure of water is not responsible for changes in the chemical activity of the cavitation.

The Acid-Catalysed Solvolysis of Alkoxymethyl Esters. Part III. Reaction Rates and Products in the Solvolysis of Ethoxymethyl Acetate in Ethanol-Water Mixtures

PENTTI SALOMAA

Department of Chemistry, University of Turku, Turku, Finland

The kinetics of the acid-catalysed solvolysis of ethoxymethyl acetate have been investigated in six ethanol-water mixtures containing 35—78 moles per cent of ethanol. By the composition of the solvolysis product it has been established that the reaction takes place in these media by two simultaneously occurring mechanisms: a unimolecular mechanism which involves an intermediate formation of ethoxymethyl cation, and a bimolecular mechanism which is identical with the acyl-oxygen fission mechanism of the acid-catalysed solvolysis of simple alkyl esters. The contribution of the unimolecular mechanism has been found to be more marked than that of the bimolecular mechanism in the solvents investigated. The results have been discussed and compared to earlier observations made on the hydrolysis of ethoxymethyl acetate in water solution.

In extension of the earlier study on the mechanisms of acid-catalysed solvolysis reactions of alkoxymethyl esters [1,2], the present paper deals with results obtained for the solvolysis of ethoxymethyl acetate in ethanol-water mixtures of a sufficiently low proton-availability, in which an experimental distinction could be made between the two different mechanisms of the solvolysis.

Table 1. The first-order rate constants (in sec.$^{-1}$) for the formation of formaldehyde (k') and ethylal (k'') from ethoxymethyl acetate in ethanol-water mixtures at 25° C at 0.1 N hydrogen chloride concentration.

The method of measuring the rates of the solvolysis reactions and that of estimating the rate constants referring to the different mechanisms were those described in the second part of the present study [2]. The results are given in Tables 1, 2 and 3, the meaning of the symbols being the same as before. Table 1 also includes the value of k' in water solution which has been taken from the results of the previous measurements [1], and the values of the Hammett acidity function H_0 for the reaction solutions employed. The latter values have been obtained by interpolation from the data given by Braude and Stern [3] for ethanol-water mixtures. The rate constants of the slow, subsequent reactions, the hydrolysis of ethylal and its reverse reaction, which were used for the calculation of the values of k' and k'' are given in the experimental part.

The results of the present study show a close similarity to the corresponding values determined for the solvolysis of methoxymethyl acetate in methanol-water mixtures [2]. As indicated by the values of Table 3, the contribution of the unimolecular mechanism is about 60—80 % of the total rate of solvolysis in the media investigated. Although the resolution of the solvolysis rate into the two parts which correspond to the different mechanisms is remarkably susceptible to the influence of experimental errors, the values of k_1 are seen, as expected by the theory, to pass through a minimum at approximately the same alcohol contents of the solvent at which the solutions have their lowest proton-availabilities, as measured by the Hammett acidity function.

The value of H_0 decreases by about one unit, when passing from a solution containing 34.9 moles per cent of ethanol to water solution. The theory suggests that the rate constant of the unimolecular reaction will be increased by a factor of about 10 by this change of medium, whereas a decrease of the value of k_2 is to be expected, *cf.* Ref.[2] Thus the fact that in 34.9 moles per cent ethanol approximately 80 % of the total solvolysis reaction does occur by the unimolecular mechanism furnishes an additional evidence for the suggestion made [1], according to which the hydrolysis of ethoxymethyl acetate by aqueous acid takes place almost exclusively by the unimolecular mechanism.

Table 4. The values of k_a and k_h (in sec.$^{-1}$) determined for the reversible acetalisation of formaldehyde in ethanol-water mixtures at 25° C at 0.1 N hydrogen chloride concentration.

275	0.0271	276		0.0000860
1 505	0.0296	1 506	0.611	
2 030	0.0279	2 031	0.623	
2 210	0.0271	2 211	0.620	

Averages: $a = 0.618$, $k' + k'' = 0.0000883$ sec.$^{-1}$
$k' = 0.0000529$ sec.$^{-1}$, $k'' = 0.0000354$ sec.$^{-1}$

The values of k_1 determined in ethanol-water mixtures (Table 3) are nearly of that order of magnitude which is to be expected for the unimolecular mechanism. From the first-order rate constant of the hydrolysis of ethoxymethyl acetate in water at 25° C at 0.1 N hydrogen chloride concentration, 0.000871 sec.$^{-1}$, and from the corresponding value of the acidity function, +1.01, it is obtained: $\log k + H_0 = -2.05$. This value shows a satisfactory agreement with the values calculated for $\log k_1 + H_0$ for ethanol-water mixtures (Table 3), in view of the difficulties encountered in revealing the actual dependence of $\log k_1$ on the acidity function in ethanol-water mixtures, *cf.* Ref.[2]

EXPERIMENTAL

The methods of preparing and purifying the materials used were those described earlier [1,4]. The technique of the kinetic measurements and the methods of calculation were the same as those applied to the solvolysis of methoxymethyl esters in methanol-water mixtures [2]. Table 4 gives the rate constants measured for the hydrolysis of ethylal and its reverse reaction, the acetalisation of formaldehyde, Table 5 illustrating one of the individual measurements. Table 6 gives the details for a typical example of the experimental runs in which the solvolysis of ethoxymethyl acetate was investigated. The meaning of the symbols is the same as previously [2].

The Acid-Catalysed Solvolysis of Alkoxymethyl Esters. Part IV. The Temperature Dependence of the Hydrolysis Rate

PENTTI SALOMAA

Department of Chemistry, University of Turku, Turku, Finland

The kinetics of the hydrolysis of methoxymethyl acetate, ethoxymethyl acetate and methoxymethyl formate by dilute hydrochloric acid have been investigated over a temperature range from 0°C to 60°C. The reactions of the two former compounds show a linear relationship between the logarithm of the rate constant and $1/T$, in a satisfactory agreement with the Arrhenius equation, over the whole temperature range investigated. By methoxymethyl formate, on the contrary, an apparent deviation from the Arrhenius equation is notable especially at relatively low temperatures, the logarithm of the rate constant increasing more rapidly than as proportional to $-1/T$. This deviation can be interpreted in terms of the previous observations according to which the hydrolysis of this compound by dilute aqueous acid occurs by two simultaneous mechanisms, a unimolecular and a bimolecular mechanism, the unimolecular mechanism involving a considerably higher activation energy. By assuming the Arrhenius equation to be well obeyed by the two reactions involving the different mechanisms, the respective activation energies and frequency factors have been estimated from the experimental rate constants and found to be in agreement with the mechanisms suggested. The factors determining the mechanism of the acid-catalysed solvolysis of alkoxymethyl esters have been generally discussed.

In the previous kinetic study on the acid-catalysed solvolysis of alkoxymethyl esters in water [1] and in water-alcohol mixtures [2,3] it was established that these reactions can take place by two different mechanisms. The former mechanism involves a unimolecular formation of an alkoxymethyl cation in the rate-determining reaction stage, whereas the latter mechanism is bimolecular and consists of an acyl-oxygen bond fission. In the solvolysis by dilute aqueous acids at 25°C, it was found that the bimolecular mechanism is insignificant except the reaction of methoxymethyl formate.

In view of the relatively large differences between the activation energies involved in the two different reaction mechanisms, it was expected that these differences might be revealed by deviations from the Arrhenius equation, thus furnishing an additional criterion for the simultaneous occurrence of the two mechanisms. The present paper gives the results obtained for the hydrolysis of methoxymethyl acetate, ethoxymethyl acetate and methoxymethyl formate by dilute hydrochloric acid solutions over a wide temperature range. The kinetics of the hydrolysis of these compounds have been previously investigated by Palomaa and co-workers [4,5] at three temperatures from 15°C to 35°C, but this temperature range is too limited to allow a reliable experimental verification as to the validity of the Arrhenius equation for the reactions investigated.

RESULTS AND DISCUSSION

At relatively low acid concentrations the first-order rate constants of the hydrolysis of alkoxymethyl esters are directly proportional to the concentration of the catalyst acid, the values of pH and the acidity function H_0 becoming practically identical, *cf.* Refs.[1,6]. For these solutions the second-order rate constant which is obtained by dividing the experimental first-order constant by the catalyst concentration is thus independent of the latter. The concentration of the catalyst hydrochloric acid used in the present study was about 0.1 N, except in the measurements carried out at 45°C and at 60°C, at which temperatures, owing to the rapidity of the reactions, lower catalyst concentrations, *viz.* about 0.025 N, were chosen. The results obtained in the rate measurements are given in Table 1. In the table, k denotes the second-order rate constant.

35	83.3	302	254
45	270	954	794
60	1 360	4 300	3 480

As shown by the values of Table 1, the effect of structure on the velocity of hydrolysis is notably dependent on the temperature. At relatively low temperatures methoxymethyl formate is hydrolysed more rapidly than methoxymethyl acetate and ethoxymethyl acetate, whereas at higher temperatures its hydrolysis rate is between those of the two latter compounds.

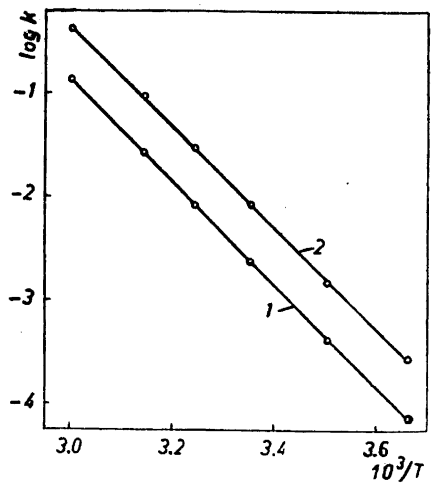

Fig. 1. The plot of log k against $1/T$ for the hydrolysis of methoxymethyl acetate (1) and ethoxymethyl acetate (2).

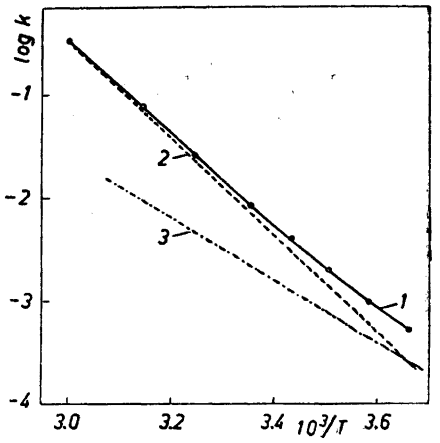

Fig. 2. The plot of log k against $1/T$ for the hydrolysis of methoxymethyl formate. 1. The experimental values. 2. The values calculated for the unimolecular mechanism. 3. The values calculated for the bimolecular mechanism.

In Figs. 1 and 2 the values of log k are plotted against $1/T$ for the hydrolysis of the different alkoxymethyl esters investigated. By methoxymethyl acetate and by ethoxymethyl acetate the plots show a linear course over the whole temperature range investigated, in accord with the Arrhenius equation. In the case of methoxymethyl formate, on the contrary, the logarithm of the rate constant decreases somewhat less rapidly than as directly proportional to $1/T$. This apparent deviation from the Arrhenius equation is most material at relatively low temperatures. The difference in the temperature dependence of the hydrolysis rates of the different alkoxymethyl esters is also seen, although to a more limited extent, from the values determined by Palomaa and co-workers [4,5]; the relative increases in the rate constants of methoxymethyl acetate and ethoxymethyl acetate are seen to be slightly higher, when passing from 15°C to 25°C, than when passing from 25°C to 35°C, in accordance with the Arrhenius equation, whereas the opposite situation is found to prevail in the hydrolysis of methoxymethyl formate.

From the plots of Fig. 1, the following values can be calculated for the parameters of the Arrhenius equation: log $A = 13.97$, $E = 22\,600$ cal/mole for methoxymethyl acetate, and log $A = 14.19$, $E = 22\,150$ cal/mole for ethoxymethyl acetate, respectively. Thus the frequency factor of the former compound is slightly lower than that of the latter, the activation energy of the former compound being somewhat higher. Both of these factors act in the same direction and increase the hydrolysis rate, when passing from the methoxymethyl ester to the corresponding ethoxymethyl ester.

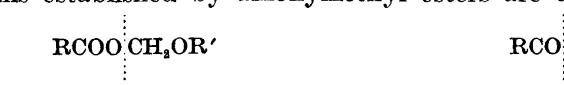
In the case of methoxymethyl formate, a calculation of the parameters of the Arrhenius equation by a similar method is not possible over the whole temperature range. However, the satisfactory validity of the Arrhenius equation for the acetates, and the previous results [1,2], allow it to be presumed that the apparent deviation is in the present case due to two simultaneously occurring reaction mechanisms. The Arrhenius parameters for both the reactions concerned can be, at least approximately, evaluated from the experimental data by the method described below.

Let A_1 and E_1 denote the frequency factor and the activation energy of the one reaction, and A_2 and E_2 the corresponding parameters of the other reaction, respectively. If the Arrhenius equation can be assumed to be obeyed by both the reactions separately, and if the respective rate constants are denoted by k_1 and k_2, we have the following expression for the experimentally determined rate constant k:

$$k = k_1 + k_2 = A_1 \, e^{-E_1/RT} + A_2 \, e^{-E_2/RT}$$

The values of E_1 and E_2 must necessarily differ essentially, in order to give rise to such an apparent deviation from the Arrhenius equation, that can be experimentally detected at the temperatures investigated. Let the value of E_1 be higher than that of E_2. That implies that the relative contribution of k_1 to the experimentally measured rate constant k increases with temperature, and if the rate determinations have been extended up to sufficiently high temperatures the total reaction rate is practically determined by the values of k_1. In this case the plot of log k against $1/T$ at high temperatures gives the parameters A_1 and E_1 as a first approximation. From these values the values of k_1 can be calculated for the lowest temperatures, and the values of $k-k_1$ thus give the first approximations for the values of k_2 at these temperatures. A plot of the values of log k_2 thus found against $1/T$ gives approximations for the values of A_2 and E_2 from which, in turn, the values of k_2 and $k_1 = k - k_2$ can be calculated for the higher temperatures. From the values of log k_1 thus obtained, the second approximations for E_1 and A_1 can be determined. Similar successive approximations are reiterated until both the sets of values for the parameters of the Arrhenius equation remain practically constant over the whole temperature range investigated.

The application of the above method of successive approximations to the rate constants of the hydrolysis of methoxymethyl formate at various temperatures (Table 1) gave the following values for the parameters of the Arrhenius equation: log $A_1 = 13.82$, $E_1 = 21\,790$ cal/mole, and log $A_2 = 7.6$, $E_2 = 14\,000$ cal/mole, respectively. It is to be noted that the above values are influenced by experimental errors much more significantly than such, in which only one reaction is involved, because the errors are here absorbed into four parameters instead of two. In addition, small genuine deviations from the Arrhenius equation which are conceivable, will be included in the values calculated for the two sets of parameters. However, owing to the fact that the hydrolysis rates of methoxymethyl and ethoxymethyl acetates are satisfactorily expressed in terms of the Arrhenius equation, we have no reason to assume that this would not be the case for that reaction of methoxymethyl formate, the values of which have been denoted by the subscript 1, these values being similar to those determined for the acetates, and thus obviously referring to the same reaction mechanism. Because this reaction of methoxymethyl formate was the dominating over nearly the whole temperature range investigated, its Arrhenius parameters could be calculated relatively accurately, whereas the corresponding values for that reaction, the constants of which have been denoted by the subscript 2, were found to be relatively inaccurate (*e. g.* it could



be estimated that the value of E_2 is accurate only within ± 2 000 cal/mole). Table 2 gives the values of k_1 and k_2 for the hydrolysis of methoxymethyl formate at various temperatures which have been calculated from the above values for the respective activation energies and frequency factors. It is seen that the contributions of both the reactions are nearly equal at 0°C, but at higher temperatures the contribution of k_2 to the total hydrolysis rate is rapidly decreased with temperature. Thus a more accurate determination of the parameters of the Arrhenius equation for the latter reaction would necessarily involve an extension of the rate measurements down to very low temperatures. The contributions estimated for the two different reactions are also illustrated by the straight lines drawn in Fig. 2.

Table 2. The values of k_1 and k_2 (in l mole^{-1} sec.$^{-1}$) for the hydrolysis of methoxymethyl formate at various temperatures.

°C	0	6	12	18	25	35	45	60
$10^3 . k_1$	0.238	0.564	1.29	2.85	6.90	22.8	69.7	329
$10^3 . k_2$	0.25	0.43	0.73	1.2	2.1	4.6	9.5	26

The values of log A_1 and E_1 calculated for methoxymethyl formate which are close to the corresponding values of log A and E determined for methoxymethyl and ethoxymethyl acetates are in good agreement with the assumption that all of the respective reactions take place by the same mechanism, *i. e.* by the unimolecular mechanism involving an alkoxymethyl cation as a reaction intermediate [1–3]. On the other hand, those values for methoxymethyl formate which have been denoted by the subscript 2, show, in spite of the approximativeness of their determination, a close similarity to the corresponding values of the acid-catalysed hydrolysis of simple alkyl formates. The value of k_2 estimated for methoxymethyl formate at 25°C, 0.0021 l mole^{-1} sec.$^{-1}$, is of the same order of magnitude as the corresponding values for methyl formate and ethyl formate, 0.00247 l mole^{-1}sec.$^{-1}$ and 0.00307 l mole^{-1}sec.$^{-1}$, determined by Salmi [7] and by Tommila and Hella [8], respectively. The activation energies calculated for the hydrolysis of methyl and ethyl formates are 14 500 and 15 770 cal/mole correspondingly, which are of that order of magnitude than the approximate value of E_2, 14 000 cal/mole, estimated for methoxymethyl formate.

Although the experimental material presented in this and in the three preceding papers [1–3] has so far been confined to the acid-catalysed solvolysis reactions of relatively few, constitutionally simple alkoxymethyl esters, some characteristic features of the different solvolysis mechanisms of these compounds may be presented, in accordance with the general theory on the acid-catalysed ester hydrolysis, extensively discussed by Ingold [9]. The two mechanisms established by alkoxymethyl esters are the following:

Unimolecular alkyl-oxygen fission $A_{AL}1$

Bimolecular acyl-oxygen fission $A_{AC}2$

In the first place, the above mechanisms are differently influenced by the external conditions, the reaction medium and temperature. The unimolecular mechanism is much more dependent on the proton-availability of the reaction solution than is the bimolecular mechanism. Thus the contribution of the bimolecular mechanism becomes more significant in solutions of low proton-donating power, whereas the unimolecular mechanism is greatly favoured by solvents of high proton-availability, in particular by concentrated, strong aqueous acids. As to the effect of temperature, the bimolecular mechanism involving a lower activation energy is more favoured by low temperatures.

From the constitutional point, the bimolecular mechanism is more notably dependent on the structure of the acyl group of the ester than is the unimolecular mechanism. In the case of the latter mechanism, changes of the acyl part of the ester do not materially influence the reaction velocity, as shown by the rate constants of the solvolysis of methoxymethyl formate and methoxymethyl acetate, the values for the former compound being only about 1.5—3 times larger than those of the latter compound in the solvolysis in water and in methanol-water mixtures. In the case of the bimolecular mechanism, the effect of the structure of the acyl group is much more significant. Alkyl formates are hydrolysed much more rapidly than the corresponding acetates by the bimolecular acyl-oxygen fission mechanism. The same structural effect is clearly illustrated also by alkoxymethyl esters. In water-methanol mixtures, the solvolysis rate constants of methoxymethyl formate which referred to the bimolecular mechanism, were observed to be about 30 times higher than the corresponding values for methoxymethyl acetate [2]. The fact that in the hydrolysis in water, the bimolecular mechanism has a significant contribution only for methoxymethyl formate, but not for methoxymethyl and ethoxymethyl acetates, is also well understood in terms of these structural effects.

In addition, the polar effects in the alkoxyl group of the ester are much more significant for the unimolecular mechanism which involves a production of an alkoxymethyl cation in the rate-determining reaction stage. Electron-releasing substituents are able greatly to stabilise the mesomeric cation, and thus favour the unimolecular mechanism, whereas electron-attracting substituents effect a material decrease of the velocity of the unimolecular reaction, thus favouring the bimolecular mechanism. The extent of this influence of a substituent depends primarily on the distance between the substituent and the point of the reaction, *i. e.* the carbon atom of the methylene group which acquires a positive charge on the attainment of the transition state. The retarding influence of an electron-attracting substituent on the velocity of the unimolecular reaction is clearly illustrated by the rate constants, determined by Palomaa and Herna [4] for the hydrolysis of 2-chloro-ethoxymethyl formate, $HCOOCH_2OCH_2CH_2Cl$. The value of the rate constant at 25°C, 0.00187 l mole^{-1}sec.$^{-1}$, as well as the value for the activation energy, 15 200 cal/mole, which can be calculated from the rate constants given by these authors for different temperatures, show such a close similarity to the corresponding values for simple alkyl formates (see above) that one can rather safely presume that in this case, the rate of the unimolecular reaction is effectively suppressed by the negative chlorine as a substituent, and hence the bimolecular mechanism is the dominating. Palomaa and Herna also

suggested that the hydrolysis mechanism of this compound will resemble most closely that of simple alkyl formates, thus differing from the behaviour of the other alkoxymethyl esters investigated, although the actual nature of the different mechanisms could not be elucidated by the observations thus far made.

EXPERIMENTAL

The preparation and purification of the materials used and the technique of kinetic measurements have been described in the first part of the present study [1]. The thermostat which was employed for measurements below room temperature, was situated in a room the temperature of which was refrigerated to −2°C, and the thermostat was filled with sodium chloride solution to allow the measurements at 0°C. The electrical heating and controlling system of this thermostat was the same as that used for measurements at the higher temperatures.

The concentration of the catalyst hydrochloric acid in the reaction solutions was 0.1 N or 0.025 N, measured at 20°C. The corresponding concentrations at the temperatures of the rate measurements were calculated from the values of the density of water at different temperatures, using the data given in the *International Critical Tables* [10]. Tables 3, 4 and 5 give the details for three typical individual runs. In the tables, a denotes the ester concentration at zero time (at the time of taking of the first sample), $a-x$ the ester concentration remaining after time t, and $\bar{k}$ the first-order rate constant.

The Hydrolysis of Methylene Diacetate and Ethylidene Diacetate in Concentrated Hydrochloric Acid Solutions

PENTTI SALOMAA

Department of Chemistry, University of Turku, Turku, Finland

Kinetic measurements have been made of the hydrolysis of methylene diacetate and ethylidene diacetate at 25°C in aqueous hydrochloric acid solutions at acid concentrations varying from 0.1 N up to 8 N. The results show that the velocity of the hydrolysis is more closely related to the acid concentration than to the acidity function of the reaction solution, thus indicating, in accord with the constitutional effects observed, that the hydrolysis of these esters takes place by a bimolecular mechanism, the transition state of which contains a water molecule in addition to the conjugate acid of the ester. No change of the reaction mechanism was observed even at the highest acid concentrations investigated.

In the previous study [1–4] the author established that the hydrolysis of simple alkoxymethyl esters, $RCOOCH_2OR'$, in aqueous acids takes place preferably by a unimolecular mechanism involving an intermediate formation of an alkoxymethyl cation, although under certain conditions a bimolecular mechanism which was considered to be essentially the same as that of simple alkyl esters, was also found to contribute to the reaction rate. The present paper gives the results of a kinetic study on the hydrolysis of constitutionally closely related compounds, methylene diacetate and ethylidene diacetate. Hammett's acidity function has been applied as a kinetic criterion of the molecularity of the rate-determining stage of the reaction, and for this the rate measurements have been extended up to high acid concentrations. The kinetics of the hydrolysis of these compounds by dilute aqueous acid solutions have been previously investigated by Skrabal and Schiffrer [5] and by Salmi [6].

RESULTS AND DISCUSSION

The method of following the rates of the hydrolysis reactions (R = H, Me)

$$(CH_3COO)_2CHR + H_2O \xrightarrow{H^+} RCHO + 2\ CH_3COOH$$

at various acid concentrations was based on the determination of formaldehyde or acetaldehyde produced during different reaction times. By this method it

was possible to extend the rate measurements up to about 8 N hydrochloric acid concentration. The results of the kinetic measurements are given in Tables 1 and 2. In the tables the values of $\bar{k}$ denote the first-order rate constants directly measured, the values of k giving the second-order rate constants which have been obtained by dividing the first-order rate constants by the concentrations of the catalyst hydrochloric acid. The tables also include the values of the Hammett acidity function H_0 for the solutions employed. These values have been obtained by interpolation from the data given by Hammett and Deyrup [7] and by Bell, Dowling and Noble [8].

The values obtained for the rate constants at relatively low acid concentrations are in good agreement with the corresponding values determined earlier by Skrabal and Schiffrer [5] and by Salmi [6]. The first authors found for the second-order rate constants at 25°C the following values: 0.000134 l mole^{-1}

Table 1. The hydrolysis of methylene diacetate by aqueous hydrochloric acid at 25 °C.

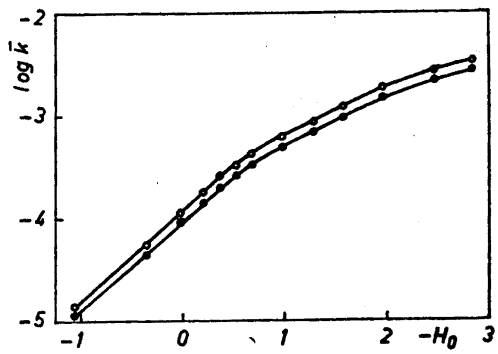

Fig. 1. The plots of the logarithms of the first-order rate constants against $-H_0$. Aqueous hydrochloric acid, 25°C. Upper curve, the hydrolysis of methylene diacetate; lower curve, the hydrolysis of ethylidene diacetate.

sec.$^{-1}$ for methylene diacetate, and 0.000108 l mole^{-1}sec.$^{-1}$ for ethylidene diacetate, respectively. Salmi determined the value 0.000144 l mole^{-1}sec.$^{-1}$ for the hydrolysis of methylene diacetate at 25°C.

A comparison between the values of Tables 1 and 2 shows that the hydrolysis rates of methylene diacetate and ethylidene diacetate are similarly influenced by the acid concentration of the solution, the rate constants of the former compound being slightly higher than those of the latter at the same acid concentrations. In both cases the second-order rate constants increase slightly when passing over to higher acid concentrations, the relative increases being, however, of a much lower order of magnitude than those observed by alkoxymethyl esters [1].

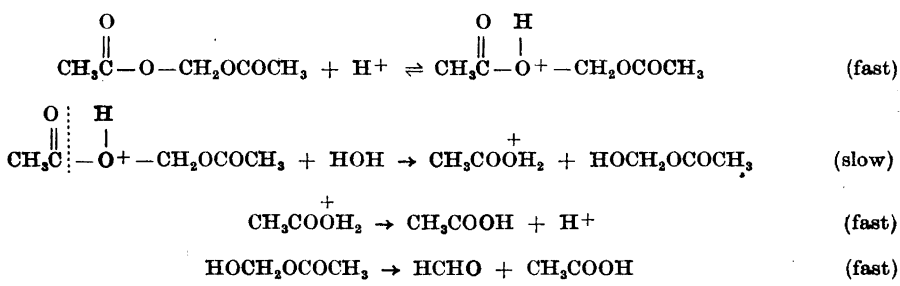

Fig. 1 gives the plots of the logarithms of the first-order rate constants against the Hammett acidity function. The plots show that the values of log $\bar{k}$ increase much less rapidly than the values of $-H_0$, when passing up to higher acid concentrations, thus considerably differing from the behaviour observed by alkoxymethyl esters [1]. *E. g.*, in the case of methylene diacetate, a linear relation between log $\bar{k}$ and $-H_0$ with a slope of unity would imply an about 8 000-fold increase in the first-order rate constant, when passing from 0.1020 N up to 7.92 N hydrochloric acid, and even a larger increase were to be expected, if the dependence of log $\bar{k}$ on the acidity function were similar to that observed by methoxymethyl and ethoxymethyl acetates. The actual increase in the value of $\bar{k}$ is, however, much lower in magnitude, *viz.* 240-fold (Table 1).

On the contrary, the results for the diacetates show a close similarity to the observations made by Bell, Dowling and Noble [8] of the hydrolysis of methyl formate and ethyl acetate by concentrated hydrochloric acid solutions. These authors found the first-order rate constants to increase slightly more rapidly than the acid concentration of the solution. The increase was, however, too small to be interpreted in terms of the acidity function of the solution. It was considered that the results are in a satisfactory agreement

with the bimolecular mechanism of the acid-catalysed ester hydrolysis, in view of the fact that there is no reason to assume that the hydrolysis velocity would remain strictly proportional to the acid concentration, when going up to relatively high acid concentrations.

The fact that the esters investigated here are affected by the acid concentration of the reaction solution similarly as the simple alkyl esters indicates that both the reactions take place by an essentially similar mechanism. As the hydrolysis velocity of the diacetates is also more closely related to the acid concentration than to the value of H_0 of the reaction solution, it implies that the reaction is bimolecular, *i. e.* the critical complex contains a water molecule which is undergoing a change of covalency, in addition to the conjugate acid of the substrate, *cf.* Ref.[1]

Although the rate measurements at high acid concentrations furnish only a criterion of molecularity of the rate-determining reaction stage, and do not allow a distinction as to the point of the initial bond rupture, there are no reasons to support an assumption that this point would not be the same here as in the acid-catalysed hydrolysis of simple alkyl esters, *i. e.* the acyl-oxygen bond [9]. Owing to the less electrophilic character of the carbon atom of the methylene or ethylidene group, in comparison to that of the carbonyl group, a bimolecular alkyl-oxygen fission mechanism would be less probable, as also shown by the fact that this type of mechanism has never been established in acid-catalysed ester hydrolysis. The bimolecular acyl-oxygen fission mechanism [9], as particularised to the hydrolysis of methylene diacetate

is also in accord with the constitutional effects. The values of k determined for the hydrolysis of methylene diacetate and ethylidene diacetate at relatively low acid concentrations at 25°C (Tables 1 and 2) are of the same order of magnitude as the corresponding value for methyl acetate, 0.000109 l mole^{-1}sec.$^{-1}$, determined by Tommila and Hella [10]. This is well understood in view of the fact that the velocity of the acid-catalysed ester hydrolysis by the bimolecular mechanism is but slightly influenced by substituents on the alkyl group of the ester.

It might be suggested that the small increase in the values of the second-order rate constants with acid concentration (Tables 1 and 2) is due, at least partly, to a simultaneous unimolecular mechanism which is greatly favoured by the high proton-availability of the concentrated acid solutions, *cf.* Ref.[4] This assumption is, however, rendered doubtful by the following reasons. The

cation formed in the rate-determining unimolecular reaction stage could be presented as (*cf.* Ref.[1]) $CH_3COO\overset{+}{C}HR$ (R = H, Me). The unimolecular reaction would be greatly accelerated by an electron-releasing substituent directly attached to the site of reaction, *i. e.* that carbon atom, which acquires a positive charge on the attainment of the transition state. The influence of this effect is illustrated, for instance, by the unimolecular solvolysis of 1-chloroethers where it was established [11] that the rate-determining formation of the cation $CH_3O\overset{+}{C}HCH_3$ is greatly more rapid than that of the cation $CH_3O\overset{+}{C}H_2$. Thus the conditions for the unimolecular mechanism are much more favourable in the hydrolysis of ethylidene diacetate than in that of methylene diacetate, and hence a change of the reaction mechanism, when passing up to higher acid concentrations, would occur by the former compound earlier than by the latter. If such a change of mechanism were actually present here, the values of the rate constants of ethylidene diacetate would increase in comparison to the corresponding values of methylene diacetate, when higher acid concentrations are approached. As shown by Fig. 1, however, the relative hydrolysis velocities of both the diacetates remain practically unaffected by the acid concentration of the reaction solution, thus indicating that the reaction mechanisms remain bimolecular even at the highest acid concentrations investigated.

EXPERIMENTAL

Materials. Methylene diacetate, $(CH_3COO)_2CH_2$, and ethylidene diacetate, $(CH_3COO)_2CHCH_3$, were prepared by the method described by Knoevenagel [12]. The raw products were purified by repeated fractional distillations. The boiling points were: 88.5°C/40 mm Hg for methylene diacetate, and 166.5–167.0°C/752 mm Hg for ethylidene diacetate, respectively. The purity of the products was controlled by hydrolysing weighed samples by alkali (one minute was found to be sufficient for a quantitative hydrolysis of the esters by a large excess of 0.25 N sodium hydroxide solution), and after neutralisation, by determining the aldehyde formed using the previous method [11,13]. The standard iodine solution used for the aldehyde determinations was 0.0688 N. In the analysis of formaldehyde formed by the hydrolysis of methylene diacetate, a sample of 45.6 mg of the ester was equivalent to 10.17 ml of the standard iodine solution (calc. 10.03 ml), and a sample of 66.2 mg was equivalent to 14.70 ml of the iodine solution (calc. 14.57 ml). In the analysis of acetaldehyde formed by the hydrolysis of weighed samples of ethylidene diacetate, respectively, 43.5 mg of the ester was equivalent to 8.76 ml of the standard iodine solution (calc. 8.65 ml), and 60.7 mg was equivalent to 12.16 ml of the standard solution (calc. 12.07 ml).

Kinetic measurements. The preparation of the reaction solutions and the method of kinetic measurements were similar to those described in connection with the earlier work on the hydrolysis of alkoxymethyl esters [1]. In all cases the first-order kinetics were well obeyed. Tables 3 and 4 give the details for two typical examples of the individual rate

Table 3. The hydrolysis of methylene diacetate in 7.92 N hydrochloric acid at 25°C. $a = 0.0440$.

t (in minutes)	1	2	3	4	5	6	8	10

Kinetics of the Alcoholysis of Hydroxymethylacetamide and Proton Transfer Equilibria in Methanol, Ethanol and *iso*Propanol

JOUKO KOSKIKALLIO

Institute of Chemistry, University of Helsinki, Helsinki, Finland

In a previous study [1] the kinetics of formation and hydrolysis of hydroxymethylacetamide were studied in alkaline aqueous solutions. The analogous alcoholysis reactions in a number of alcohols have now been investigated. In the alcoholysis of hydroxymethylacetamide in methanol, ethanol and *iso*propanol, similarly as in the hydrolysis, the role of a base is to produce the hydroxymethylacetamide anion which reacts with the solvent molecule to give acetamide and monoformal anion. The rate constant for the reaction between hydroxymethylacetamide anion and the solvent has been calculated in each case from the kinetic data obtained by varying the concentration of alcoholate. Also the equilibrium constants of the alcoholysis reactions were determined. The equilibrium is shifted further towards hydroxymethylacetamide in different alcohols in the following order: methanol, ethanol, *iso*propanol and *tert.*-butanol. Values of the equilibrium constants for the proton transfer between alcoholate ions and hydroxymethylacetamide were also derived from the kinetic data. The acidities of the various alcohols relative to that of the hydroxymethylacetamide anion were found to decrease in the order: methanol, ethanol, *iso*propanol. The heat of the proton transfer reaction was found to vary considerably in the different alcohols.

Similarly as the hydrolysis [1], the alcoholysis of hydroxymethylacetamide is a three-step process:

$$CH_3CONHCH_2OH + RO^- \rightleftharpoons CH_3CONHCH_2O^- + ROH \quad (1)$$
$$CH_3CONHCH_2O^- + ROH \rightleftharpoons CH_3CONH_2 + ROCH_2O^- \quad (2)$$
$$ROCH_2O^- + ROH \rightleftharpoons ROCH_2OH + RO^- \quad (3)$$

The proton transfer reactions (1) and (3) are fast, the alcoholysis reaction (2) being the slow, rate-determining step. The reaction product monoformal is believed to be stable in the alcohol solutions used, but if free formaldehyde (CH_2O) is formed, it will influence only the calculation of the equilibrium constant of reaction (3).

Fortunately the acidity of hydroxymethylacetamide does not differ very much from the acidities of the alcohols used as solvents, so that by varying the concentration of alcoholate ion (RO^-) the amount of ionized hydroxymethylacetamide can be altered, this will effect a change in the reaction rate

$$-\frac{dc_{CH_3CONHCH_2O^-}}{dt} = k_1\ c_{CH_3CONHCH_2O^-} - k_2\ c_{CH_3CONH_2}\ c_{ROCH_2O^-} \qquad (4)$$

where k_1 is the first-order rate constant of the alcoholysis reaction and k_2 the second-order rate constant of the reverse reaction 2.

EXPERIMENTAL

Materials. Methanol, ethanol and *iso*propanol, all of the highest purity obtainable, were dried by adding the corresponding aluminium alcoholate [2] and distilling. Usually only about 0.1 g of water per liter was found to be present in the dried alcohols by the Fischer titration. *Tert.*-butanol was purified by crystallisation. The other compounds were prepared as described earlier [1].

Analytical. The kinetic measurements were performed as described in the previous paper [1]. The amount of formaldehyde liberated during the reaction was analysed by the sulphite method [1] used previously except that phosphate buffer solution (0.5 M NaH_2PO_4, 0.125 M K_2HPO_4) was added to the sample in order to reduce the standing period required after the addition of bisulphite solution [3], since the reaction between bisulphite and formaldehyde is retarded by alcohols.

Calculations. The alcoholysis of hydroxymethylacetamide did not go to completion in the solvents studied. The rate eqn. (4) yields on integration

$$k_1 = \frac{2.303}{t} \cdot \frac{A_{eq} \cdot F_{eq}}{(M_0+A)\,(M_0+F_0)} \log \left[\frac{M_0 - M_{eq}}{M_t - M_{eq}} \cdot \frac{(M_0+A_0)\ (M_0+F_0) - M_tM_{eq}}{(M_0+A_0)\ (M_0+A_0) - M_0M_{eq}} \right] \qquad (5)$$

Table 1. Rate constants for the ethanolysis of hydroxymethylacetamide at 20° (eqn. (5). Initial concentrations: hydroxymethylacetamide 0.0196 mole/l (which corresponds to 9.57 ml of 0.0246 N iodine solution), acetamide 0.200 mole/l and sodium ethylate 0.0482 mole/l.

* Calculated using eqns. (7) and (8) with $K_1 = 7.84$, 3.16 and 1.68 at 0°, 20° and 40°, respectively.

where M, A and F denote the concentrations of hydroxymethylacetamide, acetamide and formaldehyde, respectively, and subscripts o, t and eq referring to times $t = 0$, t and infinity, and k_1 is the first-order rate constant of the alcoholysis reaction. The rate constant of the reverse reaction is computed in the usual way from $k_2 = k_1 K$, where K is the equilibrium constant of the reaction 2

$$K = \frac{M_{eq}}{F_{eq}\ A_{eq}} = \frac{k_2}{k_1} \tag{6}$$

The rate constants were usually calculated from data for 15–90 % reaction. The first-order rate constant showed a slight tendency to decrease as the reaction proceeded. A typical run is shown in Table 1. The variation in the rate constant may be due to the incorrect substitution of total concentrations of hydroxymethylacetamide and formaldehyde for the concentrations of the respective ions in eqn. (5). The concentrations of the ionic forms could be obtained from eqns. (7) if the respective equilibrium constants of the proton transfer reactions (1) and (3), K_1 and K_3, were known.

$$K_1 = \frac{c_{MH}\ c_{RO^-}}{c_{M^-}} \text{ and } K_3 = \frac{c_{FH}\ c_{RO^-}}{c_{F^-}} \tag{7}$$

MH and M^- denote hydroxymethylacetamide and its anion, FH and F^- monoformal and its anion and RO^- the alcoholate anion. Because the values of K_1 and K_3 were not known, it was assumed that the decrease of the alcoholate ion concentration in reactions (1) and (3) can be neglected, *i. e.* $c_{RO^-} \gg c_{M^-}$ and c_{F^-}. This assumption proved to be a good approximation for methanol and ethanol but only approximately valid for *iso*propanol. The error can be diminished further by extrapolating rate constants obtained at a con-

stant alcoholate concentration to zero hydroxymethylacetamide concentration. The rate constant k_1 is obtained by extrapolating the experimental k_1' values to infinite alcoholate concentration by the method described in the previous paper [1]. Using the extrapolated value k_1 together with the different k_1' values c_{M^-} is calculated from

$$c_{M^-} = \frac{k_1'}{k_1} \cdot c_{M_{total}} \qquad (8)$$

and K_1 from eqn. (7). The constancy of the K_1 values gives evidence for the validity of the assumptions made in the calculations. The mean value of K_1 was used to recalculate k_1, but the latter was not found to be altered. Tables 2, 3 and 4 give the experimental first-order rate constants, the extrapolated values of the first-order rate constants, and the rate constants calculated using the values of k_1 and K_1 obtained by extrapolation (eqns. (7) and (8)). The agreement between the experimental and calculated values are satisfactory in methanol and ethanol, but in *iso*propanol only when the alcoholate concentration is greater than the concentration of hydroxymethylacetamide.

When total concentrations of hydroxymethylacetamide and formaldehyde are used in the calculations of the equilibrium constant K of reaction 2 (eqn. (6)), a considerable change in the values of K are obtained as the alcoholate concentration is altered. This

implies that $K_1 \neq K_2$. By making the simplifying assumption, $c_{RO^-} \gg c_{M^-}$ and c_{F^-}, which was previously found to be a good approximation, the equation

$$K_2 = K_{tot} \frac{K_1 + c_{RO^-}}{K_1 + c_{RO^-}} \qquad (9)$$

used previously [1] is obtained. K_2 is the equilibrium constant for reaction (2) and K_{tot} the equilibrium constant for the same reaction when total concentrations of hydroxymethylacetamide and formaldehyde are substituted in eqn. (6). K_2 and K_3 both can be determined, as K_1 is previously known from kinetic experiments, from the slope and intercept of the straight line plotting $K_{tot} / (K_1 + c_{RO^-})$ *versus* $K_{tot} c_{RO^-} / K_1 + c_{RO^-})$. The values of K_{tot} and K_2 are given in Tables 2, 3 and 4. The constancy of calculated K_2 values illustrate the validity of the approximations made in the calculations.

RESULTS AND DISCUSSION

The values of the rate and equilibrium constants of reaction (2) and the equilibrium constants of the proton transfer reactions (1) and (3) calculated from the kinetic experiments by the methods described are summarized in Tables 5 and 6. For comparison, also values obtained previously [1] are included. Because of the poor reproducibility of the experiments made in *tert.*-butanol due to the high rate of the reaction and to the great sensitivity of the alcoholate

solution to traces of water, only approximate values were obtained; these are included in Table 5 to illustrate the order of magnitude.

The values obtained for the proton transfer constants K_1 and K_3 given in Table 6 show that the acidities of the hydroxylic solvents decrease in the order methanol, water, ethanol, *iso*propanol. Similar results were obtained by Koivisto [4], Calding [5], and Hine [6]. Formaldehyde is known to exist practically entirely in the hydrated form $HOCH_2OH$ in dilute aqueous solutions and thus contains two hydroxyl groups (for references see Ref.[1]) whereas the monoformal $ROCH_2OH$ present in alcohol solutions contains only one hydroxyl. In order to get comparable values, the value of K_3 obtained in water should be multiplied by two; for example at 20° $K_3 = 2 \times 0.11 = 0.22$. After this correction, the formaldehyde-solvent addition product is found to be an about 1.5 times stronger acid than hydroxymethylacetamide in all the solvents studied. Compared with the solvents, hydroxymethylacetamide and formaldehyde monoformals at first seem to be of the same order of strength as acids, but according to the reaction $FH + RO^- = F^- + ROH$, the concentrations of the solvent molecules should be included in eqns. (7). Thus the hyd-

i-PrOH	0.006	0.006		0.010	0.011		0	0.5

roxymethylacetamide and formaldehyde monoformals are much stronger acids than the alcohols used as solvents.

Great differences were found in the heats of proton transfer reactions (1) and (3) in the solvents studied. Although the values obtained by extrapolation in methanol are not very accurate, the values of ΔH of proton transfer equilibria in methanol and water were found to differ by about 7.8 kcal. It is of the same order of magnitude as found by other methods. Koivisto [4] found calorimetrically when neutralizing phenol or acetic acid with sodium alcoholate in methanol and sodium hydroxide in water, a difference $\Delta H_w - \Delta H_m = 7.2$ kcal. In ethanol and *iso*propanol the values of ΔH are 3.4 and 1.3 kcal. greater than the value of ΔH in water for the proton transfer reaction (1), whereas the calorimetric values obtained by Koivisto using carboxylic acids and phenol gave a difference of about 6 and 4 kcal in ΔH in the corresponding solvents.

At low alcoholate concentrations the experimental rate constant k_1' is approximately proportional to the alcoholate concentration. When $c_{RO^-} \gg c_{M^-}$ and $c_{MH} \gg c_{M^-}$, $k' = k_1 c_{RO^-} / K_1$ (eqns. (7) and (8).

The experimental activation energy should approach the value $E' = E - \Delta H_1$ at low alcoholate concentrations. From the last column in Tables 2, 3 and 4 it will be seen that the change in the calculated activation energy is of the same order of magnitude as ΔH_1 in Table 6, which gives further evidence that the method of extrapolation used gives correct values.

When comparing the rate constants of reaction 2 (Table 5), it must be remembered that as the group R in the reactant is altered, also the solvent is changed. Thus both the solvent and substituent effects are superimposed in the change in the reaction rate. The rates of solvolysis of hydroxymethylacetamide anion in water, methanol and ethanol are approximately equal. It seems that the solvent effects are of minor importance as the rate is not much altered in spite of a considerable change in the nature of the solvent. The observed difference in the reaction rates in *iso*propanol and *tert.*-butanol is evidently mainly due to substituent effects. For the two reactions:

	Values of ΔH (kcal) when R is H	CH_3	CH_3CH_2	$(CH_3)_2C$	
$ROH + CH_3CONHCH_2O^- \rightarrow RO^- + CH_3CONHCH_2OH$	−1.3	6.5	2.1	0	(10)
$ROH + CH_3CONHCH_2O^- \rightarrow ROCH_2O^- + CH_3CONH_2$	−4.3	−3.1	−2.1	−4.9	(11)

the heats of the proton transfer and solvolysis reactions change in the same direction when R is altered. The equilibria of both reactions (10) and (11) are shifted towards the left in the series R = CH_3, CH_3CH_2, $(CH_3)_2CH$, the equilibrium values found in water (R = H) being exceptional in that they are intermediate between those in methanol and ethanol for reaction (10) and between those in ethanol and *iso*propanol for reaction (11). Both reactions involve a proton transfer. A proton is donated by ROH to an oxygen atom in reaction (10) and to a nitrogen atom of the amide in reaction (11). In the latter reaction there occurs in addition a breaking-up of the formaldehyde-amide bond and the formation of the formaldehyde-alcohol bond. These latter changes are the reason for the smaller changes observed in the heats and rates

of reaction as compared with those of the proton exchange. In accordance with the above discussion, the following mechanism is proposed for reaction (2):

$$CH_3CONHCH_2O^- + ROH \rightleftharpoons \begin{matrix} CH_3CONH...CH_2O^- \\ \vdots \quad \vdots \\ H...OR \end{matrix} \rightleftharpoons CH_3CONH_2 + ROCH_2O^- \qquad (12)$$

The hydrogen of ROH can become bonded ("hydrogen bond") to the nitrogen of hydroxymethylacetamide before the molecule reaches the energy level necessary for reaction and only a part of the energy of proton transfer is included in the activation energy. The formation of two bonds and the breaking of two other bonds in the transition complex probably occurs in one step simply by a simultaneous shift of the electron pairs forming the four reacting bonds.

Note on the Chloride Content of the Mineral Constituents of the Skeleton

G. HEVESY

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

By adding ^{36}Cl to the diet of pregnant mice and to their offspring until they are outgrown uniformly labelled animals are obtained. Prior to administering non-labelled diet to the outgrown labelled mice the total activity of the body of one member of the litter is determined. All ^{36}Cl with the exception of that sequestered in the skeleton is then removed by keeping the mice for 6 months on non-radioactive diet. After that date the skeleton is found to contain 0.73 % of the total activity which the sister mouse had prior to removal of the radioactive diet. From this figure and the chloride content of the mouse the chloride sequestered in the skeleton of a 35 g mouse is calculated to amount to 0.35 mg. While almost 90 % of the bone sodium is excess sodium, the corresponding figure for chloride is about 10 only.

In view of the only slightly differing size of the hydroxyl and fluoride ion, the hydroxyl ions of the bone apatite can be replaced by fluoride ions. Furthermore some of the fluoride may be present in the bone mineral as calcium fluoride.

The fluoride content of the bone apatite is determined by that of the plasma, which in turn depends on the fluoride content of the food. The fluoride content of the earth's crust is much lower than that of the seawater, the mineral constituents of the skeleton of mammals living in the sea is, correspondingly, very much, about eleven times, larger than that of mammals living on land, which contain 0.05 % fluoride only. The skeleton of fish living in the Baltic, which has a low fluoride content, have a much lower fluoride percentage (0,06 %) than the skeleton of fish living in the Atlantic (0.43 %). Incorporation of fluoride into the mineral constituents of the bone was in recent years much investigated, mainly in connection with the observation that the presence of fluoride in the mineral constituents of teeth increases their resistance to caries.

The radius of the chloride ion is much larger (1.81 Å) than that of the fluoride ion (1.33 Å) and calcium chloride being very soluble we can expect to find slight amounts of chloride in the mineral constituents of the bone. While the

X-ray diagram of fluoroapatite is almost identical with that of hydroxyapatite that is far from being the case for chloroapatite[9]. The fluids circulating in the bone tissue having a high chloride content (about 300 mg/100 ml); this has to be quantitatively removed prior to the determination of the amount of chloride incorporated into the mineral constituents. Such removal by chemical treatment of the bone encounters great difficulties. However, when labelling the skeleton all through with radiochloride and then placing the animal, *e. g.* the mouse, on diet containing non-radioactive chloride for several months, all exchangeable radiochloride will be removed and excreted, the radiochloride fixed in the mineral constituents alone remaining in the skeleton.

In the human half of the exchangeable chloride is removed in the course of 14 days [1] and replaced by chloride of the food and after 6 months, *i. e.* after 12 periods, all exchangeable chloride initially present will be practically absent. In the mouse, with its high metabolic rate, the removal rate of chloride can be expected to be still higher than in man. The removal can be accelerated by increased chloride feeding. Besides the chloride present in the standard biscuits fed we added 0.2 % NaCl to the water the mice were drinking after they were put on non-radioactive diet. To the water administered to the mice in the first phase of the experiment ^{36}Cl of 0.67 μ C activity per liter was added as sodium chloride weighing 9.3 mg. The labelled chloride was administered to pregnant mice about 2 weeks prior to gestation. After gestation the administration of labelled chloride was continued for 4 months when the animals were fully grown. One member of each litter was then killed and its total ^{36}Cl content and that of its skeleton determined. The remaining members of the litters were investigated 6 months later.

The bone was ashed in the presence of sodium carbonate. The activity of 100 mg, thus of an infinite thick layer of the samples obtained was determined, the counts registered being multiplied by the total weight of the ash-sodium carbonate mixture.

The total ash of the first member of the litter of the mice investigated had a total activity of 2 780 counts per min, mean value 2 910 $\pm$ 452 counts, that of the mineral constituents of the skeleton of the first investigated offspring 56.6 counts. This was prior to biological removal of all exchangeable chloride from the skeleton but after the removal of some of the latter in the course of the isolation of the mineral constituents.

By keeping the mice on an activity-free diet for 6 months the activity of the mineral constituents declined in the average to 21.2 counts (*cf.* Table 1).

The total chloride content of a 35 g mouse taken to be 48 mg, the activity of 1 mg of the body chloride prior to removal of the active food was 60.6 counts per min. As the total skeleton after biological removal of all exchangeable chloride had an activity of 21.2 counts per min the sequestered chloride content of the bone mineral amounted to 0.35 mg or 0.73 % of the total body chloride.

The sequestered fraction of the bone calcium of the mouse, that non-replaceable by circulating calcium, was found [2] to be 67.2 $\pm$ 7.9 %. The corresponding figure for bone sodium is stated to be 60—70 [3], 65 [4], 60 [5] and 69 [6]

Table 1. Counts per min. ^{36}Cl activity of the skeleton of 33—36 g mice after keeping on non-active diet, thus after biological removal of exchangeable radiochloride, for 6 months

by different authors. Thus about a similar percentage of excess sodium and of excess calcium is prevented from interchanging with their circulating atoms. The sequestration of bone constituents is presumably due to the fact that a contact between these constituents and the circulating body fluids is obstructed. To arrive at the total excess chloride content of the bone of the mouse we correspondingly have to multiply the figure of 0.35 mg found for the non-exchangeable bone chloride by about 1.5, thus arriving at the result that the total excess bone chloride content of our 35 g mice amounts to about 0.53 mg.

In contrast to the bone sodium which is to a large extent present as excess sodium in the skeleton it can be shown that the chloride present as excess chloride makes out 1/10 only of the total bone chloride.

From 234 meqiv sodium present in 1 kg of dry human bone 84.9 %, thus 46 g, was found by Edelman *et al.*[5] to be excess sodium in a 70 kg man. For the dog Edelman and associates found 89.5 % of the bone sodium to be excess sodium and a similar figure is stated by Miller and associates [7]. 1 kg of rat bone was found to contain 125 meqiv excess sodium [8]. As to the total chloride content of 1 kg fat free bone this was found to amount to 19 meqiv only [5], thus to less than the extracellular bone sodium which makes out 25 meqiv. While excess bone sodium is to a marked extent responsible for the difference between total and extracellular body sodium, for chloride this difference is almost entirely due to the presence of intracellular chloride in the soft tissues.

The author's thanks are due to Miss Jutta Schliack for her very effective assistance and to *Statens Naturvetenskapliga Forskningsråd* for the support of this investigation.

The Free-Electron Model, "Overtone" Bands, and Vibrational Structure in Absorption Spectra of Polyenes and Polyenynes

JOHANNES DALE

Forsvarets Forskningsinstitutt, Kjeller, Norway

An analysis of the free-electron model for polyenes has provided theoretical justification for the empirical spectral rule correlating electronic "overtone" bands with the main band of shorter polyenes of lengths equal to integral fractions of the polyene considered. It is further shown how the vibrational structure of the various bands of polyenynes can be predicted by considering the detailed π-electron density displacement pattern along the chain during the transition. The relative intensities of the short wave length bands of polyenynes, in particular of dehydro-carotenoids, indicate that these bands are never due to independent partial chromophores, but must be regarded as overtone transitions. It is also concluded that the most stable configuration around an acetylenic (or odd-cumulenic) link in a polyene chain must be the planar *trans*-configuration.

In an earlier paper [1] it was shown that the minor bands, or "overtone" bands, of polyenes with n conjugated double bonds correspond in wave length location to the main band of polyenes with n/s conjugated bonds, where s is the band order (= 1 for the main band, 2 for the first overtone, and so on). The experimental data available at that time, and, in addition, numerous recently published spectra, fully confirmed the general validity of this rule. However, no theoretical interpretation was attempted.

The success of the free-electron gas model in making spectral predictions for conjugated systems would indicate that it might be of promise when trying to put the rule on a theoretical basis. A comparison of absolute transition energies is of little interest, since Bayliss [2], and Kuhn [3], have shown that simple quantum mechanical calculations based on this crude model, with the assumption of a uniform potential well with infinitely high walls, give fair results only for the main band of short polyenes. For longer chains, and quite generally for overtone bands, the agreement is very poor. However, as Bayliss has emphasized [4], it is the number and position of the orbital nodes of π-electrons confined to a given space, and not the detailed shape of the force field that

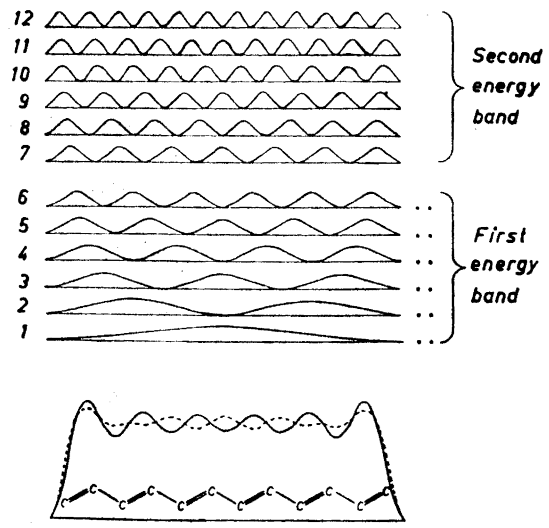

Fig. 1. Top: π-electron density (φ_n^2) along the chain for free-electron orbitals (φ_n) of the hexaene chromophore. Energy scale is arbitrary.
Bottom: Total π-electron density for the ground state (full line) and the first excited state (dashed line). (*Cf.* Bayliss [4].)

keeps the electrons within that space, which are of prime importance in determining the character (polarization, selection rules, intensities, *etc.*) of the electronic transitions as well as the distribution of π-electron charge density, and in this respect the free-electron model, even in its crude shape, is a good approximation.

A qualitative examination of this simple model leads to results in accordance with the observed empirical rule, but it also raises an important question.

As an illustration the hexaene chromophore has been chosen to enable a direct comparison of its first two overtones with the main bands of the triene and diene chromophores. In Fig. 1 the 12 lowest free-electron molecular orbitals (corresponding to all the possible LCAO molecular orbitals) have been represented in their squared form, which is a measure of the π-electron density along the chain. The energy of each orbital is given by $E = \frac{h^2 n^2}{8 m L^2} = k \frac{n^2}{L^2}$ where n is now the quantum number. The length L of the potential well has for simplicity been set equal to 12 times the average C—C distance since there is no more theoretical justification for other choices made by Bayliss and by Kuhn. The orbitals have been split into two groups, or energy bands, corresponding to the introduction of a Kuhn's periodic potential with minima at each formal double bond [3]. In the ground state the lowest energy band is completely filled by the 12 electrons. Summation gives the total electron density distribution given in Fig. 1 (full line) which is seen to correspond roughly

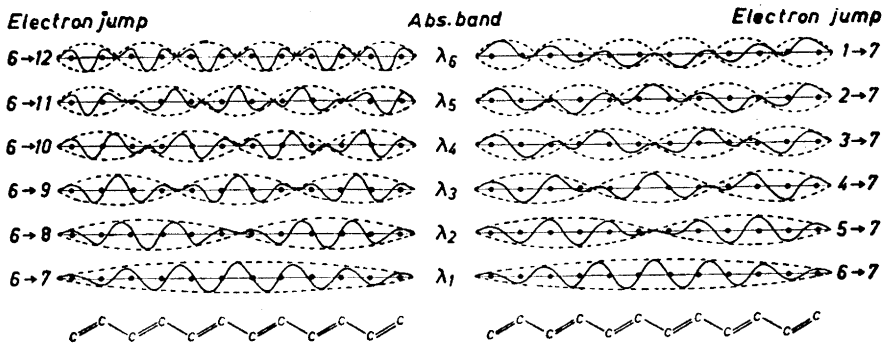

Fig. 2. Differential curves illustrating the displacement of electron density during transitions from the highest filled orbital (left), and similar transitions to the lowest vacant orbital (right). Electronic charge moves from regions where the curve is below the zero line to regions where it is above.

to the classical chemical formula [4,5]. Transfer of one electron from level 6 to level 7 ($\Delta n = s = 1$) gives the first excited state (dashed line) which is seen to correspond to a tendency towards the classical structures

$$\overset{\pm}{\mathrm{C}}-\mathrm{C}=\mathrm{C}-\mathrm{C}=\mathrm{C}-\mathrm{C}=\mathrm{C}-\mathrm{C}=\mathrm{C}-\mathrm{C}=\mathrm{C}-\overset{\mp}{\mathrm{C}}.$$

The displacement of electron density that takes place during a transition is more conveniently represented by the differential curves shown in Fig. 2. It is clearly seen that for the 6—7 transition, or in general: *f*—*g* transition according to Platt's notation [6], most of the excitation resides in the middle of the chain (*cf.* results from LCAO calculations for stilbene by Coulson and Jacobs [7]), the envelope of the displacement curve ("beat" curve) resembling the fundamental tone of a vibrating string.

OVERTONE BANDS

When the quantum number changes by more than one unit, there will, for a certain change *s*, be *s* different transitions; for example, *f*—*h* and *e*—*g* for $s = 2$; *f*—*i*, *e*—*h* and *d*—*g* for $s = 3$; and so on. Now the experimental data indicate that we have to do in each case with only one electronic transition. Thus, overtone bands show just as distinct vibrational structure as the main band of other polyenes that fall in the same wave length region. That all quasi-degenerate transitions within a group should coincide so perfectly, would only be possible if the energy levels were equidistant (with the exception of the *f*—*g* interval), and this possibility can be safely excluded since it conflicts with the convergence of the overtone bands, presumably towards an ionization limit, that is observed in all known spectra. The two remaining possibilities would then be that the transitions are either all from the highest occupied energy level or they are all to the lowest empty level. The pertinent differential curves are given in Fig. 2.

It is at once seen that the envelope of the displacement curves for overtone transitions are identical in both series and resemble the corresponding overtones of a vibrating string. However, the detailed displacement patterns differ more and more with increasing s. For transitions from the highest filled level they are in good accordance with chemical intuition; thus, the structures given below for various values of s are good representations for the corresponding excited states:

$s = 2$ $\overset{\pm}{C}-C=C-C=C-\overset{\mp}{C}-\overset{\mp}{C}-C=C-C=C-\overset{\pm}{C}$

$s = 3$ $\overset{\pm}{C}-C=C-\overset{\mp}{C}-\overset{\mp}{C}-C=C-\overset{\pm}{C}-\overset{\pm}{C}-C=C-\overset{\mp}{C}$

$s = 4$ $\overset{\pm}{C}-\overset{\mp}{C}-C=C-\overset{\mp}{C}-\overset{\pm}{C}-\overset{\pm}{C}-\overset{\mp}{C}-C=C-\overset{\mp}{C}-\overset{\pm}{C}$

$s = 5$ $\overset{\pm}{C}-\overset{\mp}{C}-\overset{\mp}{C}-\overset{\pm}{C}-\overset{\pm}{C}-C=C-\overset{\mp}{C}-\overset{\mp}{C}-\overset{\pm}{C}-\overset{\pm}{C}-\overset{\mp}{C}$

$s = 6$ $\overset{\pm}{C}-\overset{\mp}{C}-\overset{\mp}{C}-\overset{\pm}{C}-\overset{\pm}{C}-\overset{\mp}{C}-\overset{\mp}{C}-\overset{\pm}{C}-\overset{\pm}{C}-\overset{\mp}{C}-\overset{\mp}{C}-\overset{\pm}{C}$

We see from the left side of Fig. 2 that the electrons are mainly displaced from regions with high density ("double bonds") to regions with low density ("single bonds"). In contrast, overtone transitions to the lowest vacant level (right side of Fig. 2) must also involve displacement of electrons from regions with low density to regions with high density.

Furthermore, only transitions from the highest filled level will give the same displacement pattern for each half of the hexaene chromophore when $s = 2$ as for the triene chromophore when $s = 1$, and for each third of the hexaene chromophore when $s = 3$ as for the diene chromophore when $s = 1$, etc., which might be expected from the empirical rule.

It has also been empirically established [1] that steric prevention of coplanarity at certain points, as with *cis*-bonds, both "hindered" and "unhindered", decreases the intensity of bands for which the excitation, as deduced from Fig. 2, is considerable in the part of the molecule where the hindrance is located, but enhances the intensity of bands for which the displacement curve envelope (Fig. 2) is zero at the hindrance. It might therefore be expected that electronic charge transfer is negligible through these zero points, or nodes of the "beat" curve. From Fig. 2 it will be seen that transitions from the highest filled level satisfy this requirement, whereas for overtone transitions to the lowest vacant level electronic charge will have to be transferred through the "nodes". The extreme case is the 1—7 transition where the charge has moved from the double bonds in the middle to the double bonds at both ends.

It is also interesting to observe that if the free-electron expression for the excitation energies [2,3] is developed in a more general form to include also overtones, the following expression is obtained for transitions from the highest filled level:

$$\Delta E_{\frac{N}{2} \rightarrow \frac{N}{2}+s} = \frac{h^2}{2\,m\,a_0^2}\left[\frac{s}{N} + \frac{s^2}{N^2}\right]$$

Here N is the number of π-electrons in a polyene with $N/2$ double bonds, and s the change in quantum number ($\Delta\, n$) (which is equal to the band order). The length of the chromophore has been set equal to $\frac{N}{2} \cdot a_0$, where a_0 is the length of one single bond plus one

double bond. The only variables are N and s which occur here as the ratio s/N as would be required in order to satisfy the empirical rule. In contrast, the analogous general expression for transitions to the lowest unfilled orbital

$$\Delta E_{\frac{N}{2}+1-s \rightarrow \frac{N}{2}+1} = \frac{h^2}{2\,m\,a_0^2}\left[\frac{s}{N} + \frac{s(2-s)}{N^2}\right]$$

also contains the variables in the ratio $(2-s)/N$ in conflict with the requirements.

If Kuhn's sine curve potential [3] is introduced we get in both cases the additional energy term $V_0(1-\frac{s}{N})$, where V_0 is the amplitude of the potential energy variation along the chain (period $= a_0$). This term contains the variables only as the ratio s/N.

It is not easy to explain theoretically why only electrons of the outermost π-electron shell should be excited by light. Neither the LCAO nor the free-electron approximation lead to any such selection rule *.

VIBRATIONAL STRUCTURE IN POLYENE SPECTRA

From Fig. 2 we have seen that the excitation responsible for the main band in polyene spectra is concentrated mainly in the middle of the chain. Now from the Franck-Condon principle one should expect that the stretching frequency of the bonds that receive the greatest change in bond order should be coupled most strongly with the electronic transition and thus contribute most to the vibrational structure of the absorption band. It is therefore not surprising that even in α,ω-diphenylpolyenes [8] it is the polyene frequencies 1 570 cm^{-1} and 1 230 cm^{-1} (in average about 1 400 cm^{-1}) that build up the structure, not only for the long chains, but also in stilbene.

As to the distribution of intensity among the vibrational peaks in the absorption bands of polyenes it is clear that as the number of conjugated double bonds increases, a one-electron jump from a bonding π-orbital to an antibonding π-orbital will have proportionately less and less effect on the binding force, so that the change in bond order decreases and the first peak (vibrationless transition) will have to gain intensity. This is in accord with observations in the unsubstituted polyene series [9] as well as in the diphenylpolyene series [8]. However, with increasing length *cis*-isomerization will often complicate this behaviour of the main band. It may therefore be more illustrating to compare bands in the same wave length region, that is, overtones of long polyenes with main bands of short polyenes. Numerous examples can be found where the first peak is the strongest in the λ_2-band, although λ_1-bands of comparable chromophores with half the length usually have the second peak the strongest. In the λ_3-band of very long chromophores practically all the intensity may be concentrated in the first peak, as can be seen in the spectrum of lycopene [10]. That the vibrationless transition is by far the strongest in the main band of the spectra of similar ionic compounds, such as the cya-

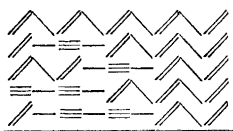
* A solution of this problem has been proposed to the writer by Prof. J. R. Platt, who thinks that the observed "selection rule" is only apparent and that the s quasi-degenerate transitions of a group mix to give one with strong transition moment and $s-1$ transitions with zero moment (*cf.* his recent paper on configuration interaction [42]).

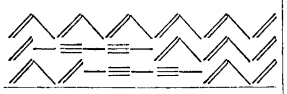
nine dyes [11], can also be explained by using the free electron model, from which it is seen that very little change of bond order will occur during excitation, since bonds have now taken the positions occupied by the atoms of polyenes, and *vice versa* [4]. The same deduction has also been made by Platt in his recent paper [42].

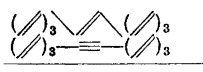
VIBRATIONAL STRUCTURE IN POLYENYNE SPECTRA

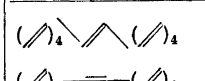
Since the excitation for the various bands in polyene spectra is located in different parts of the chromophore, it should be possible to predict the vibrational structure of these absorption bands if some of the ethylenic bonds are exchanged with acetylenic bonds. Thus, one acetylenic bond in the middle of a polyene chain should be sufficient to give the λ_1-band acetylenic spacing ($\sim$ 2 000 cm^{-1}) if the chain is very short, as in divinylacetylene [12]. In longer chains both acetylenic and ethylenic spacings should occur and the result may be a smearing out of the structure, especially on the short wave length side of the band, since the number of possible combinations of the vibrational quanta will increase rapidly as more quanta are excited. A greater number of acetylenic bonds are therefore needed to give the band clear acetylenic spacing. However, the λ_2-band should be unaffected and show ethylenic spacing ($\sim$ 1 400 cm^{-1}).

If now the acetylenic bonds are instead at the end, the λ_1-band will remain ethylenic, but it will probably be necessary to have acetylenic bonds located in both halves in order to give clear acetylenic structure to the λ_2-band.









Available experimental data for polyenynes and corresponding polyenes have been compiled in Table 1. It is seen that to the extent that the vibrational structure is resolved, the observed spacings agree well with the spacings that would be expected from the geometry of the chromophores. Compounds in which the acetylenic portion constitutes more than half the chromophore have not been included, since they show the spectral anomalies typical for polyacetylenes. Unfortunately, no examples of chromophores consisting of a polyacetylene chain with a few ethylenic bonds in the middle are known.*

WAVELENGTH SHIFTS AND INTENSITY RELATIONSHIPS IN POLYENYNE SPECTRA

In Table 1 the substitution patterns on the chromophores have not been included. But when substances with equal substitution are compared, it is always found that there is an intensity reduction and a blue-shift of the λ_1-band as compared with polyenes (*cf.* Inhoffen and Bohlmann [13]). This may be connected with the stronger binding of π-electrons to *sp*-hybridized carbon

* *Note added in proof:* Very recently Bohlmann and Politt (*Chem. Ber.* **90**(1957)130) have synthesized compounds with the following chromophores: ≡–≡–⟋⟍⟋⟍≡, ≡–≡–⟋⟍⟋≡–≡, and ≡–≡–⟋⟍⟋⟍≡–≡–⟋⟍⟋⟍≡–≡. The main bands show the vibrational spacings which can be predicted from the arguments given above. As expected, the overtone bands of the second compound have acetylenic structure, but position and intensity are apparently complicated by interaction between the two short π-electron components of the acetylenic portions and the polyene-like "hexaene" component. The overtone bands of the last compound do not show resolved structure.

Table 1. Predicted and observed vibrational structure in spectra of polyenynes (and corresponding polyenes).

atoms [14]. The effect should be particularly pronounced when the acetylenic bonds are in the middle of the chain where most of the excitation occurs. The λ_2-band may then be wholly unaffected and even undergo a red-shift since the excitation is made easier by the attraction of π-electrons by *sp*-carbons. Similar observations have been made on replacement of carbon by nitrogen, in a comparison of diphenylpolyenes with diphenylpolyenalazines [1]. Alternatively, these phenomena can be discussed in terms of energy changes of the orbitals

involved as Kuhn has shown for polymethine dyes in which carbon has been replaced by nitrogen [5].

Most of the published spectra of polyenynes show rather weak λ_2-bands except when the acetylenic section is not centrally located. If there were free rotation around the acetylenic bonds one should expect strong λ_2-bands in all cases, so that one is led to conclude that the planar *trans*-configuration, for which λ_2-transitions are forbidden, must be the most stable one. For the very few symmetrical polyenynes which show strong λ_2-bands, the explanation may be that some of the double bonds have a *cis*-configuration or that geometrical isomerism occurs around the acetylene system, so that there can exist also a planar "*cis*-isomer", if both ethylenic π-electron systems remain conjugated with the same component of the acetylenic π-electron system, and a non-planar isomer if they do not conjugate with the same component. According to calculations by Dunitz and Orgel [15] energy differences between such isomers would be small and are further decreased with increasing length of the acetylenic system.

Another effect, which has been observed for *cis*-polyenes, is also encountered in polyenynes. Like *cis*-bonds, acetylenic and cumulenic bonds apparently have a blocking effect for transitions for which there will be excitation in these bonds, but enhance the intensity of transitions for which the bonds are in regions where no excitation occurs ("nodes" of the "beat curve"). Thus, some bisdehydro-lycopenes [16], in which the acetylenic or cumulenic hindrances have divided the chromophore into three roughly equal sections, show degraded λ_1-bands and only weak λ_2-bands, since the chain is essentially straight, but the λ_3-bands at about 300 mμ, the same location as λ_3-bands in the corresponding hindered di-*cis*-lycopenes, have become exceptionally intense, since they have to take over the intensity of the hindered transitions. Even more illustrative material is afforded by the closely related lycopene analogues bis-dehydro-diphenyl-tetramethyl-octadecanonaenes (Fig. 3) synthesized by Karrer and coworkers [17]. It is evident from the spectra that the cumulene system $\rangle C{=}C{=}C{=}C\langle$ represents a more severe hindrance in a polyene chain than the $-C{\equiv}C-$ system. Thus, the dicumulene has a much more degraded λ_1-band and a correspondingly stronger λ_3-band than the diacetylene. The acetylene-cumulene has an intermediate λ_1-band, but the λ_3-band is lower, since because of the unsymmetry (Fig. 3) the λ_2-band (at 360 mμ) and the λ_4-band (at 265 mμ) become allowed and take over much of the intensity. The λ_5-band (at 240 mμ) is also quite distinct in these compounds and its intensity variation can likewise be predicted.

The corresponding unsymmetric monocumulene and monoacetylene have also been obtained [18], and their spectra can be interpreted by similar considerations. The λ_2-bands are here relatively weak since the chains are approximately linear. It is then very interesting to observe that upon *cis*-isomerization of the ethylenic bonds, the λ_2-, λ_4-, and λ_5-bands increase in intensity, while the λ_1- and λ_3-bands decrease correspondingly.

An analogous diacetylenic bisdehydro-methylbixin has been prepared [19]. It shows no λ_2-band but a very strong λ_3-band.

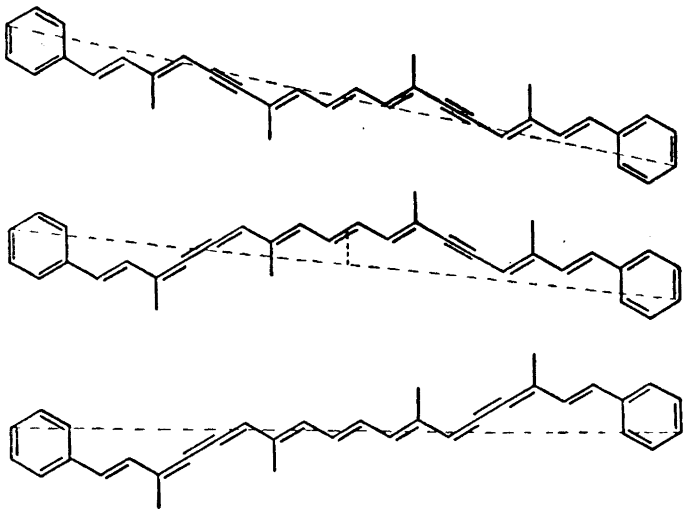

Fig. 3. Skeleton models of bisdehydro-diphenyl-tetramethyl-octadecanonaenes. Planar *trans*-configuration around the linear C_4-sections has to be assumed to account for the absorption spectra. Top, diacetylene; middle, acetylene-cumulene; and bottom, dicumulene.

That the spectra of the numerous dehydro-carotenoids with one (or two) centrally located acetylenic bonds prepared by Inhoffen and coworkers [13,20-25] show no correspondingly intense band in the λ_2-band region (forbidden by symmetry), and only moderate λ_3-bands, is a very strong support for the idea that in polyenynes, as well as in polyenes, the minor bands are always to be regarded as overtones and never as due to independent partial chromophores as has been suggested by Oroshnik and Mebane [26] for these polyenynes, and earlier by Heilbron *et al.*[27] for polyenynes containing the diacetylene grouping. The present interpretation implies that the planar *trans*-configuration is the most stable one around an acetylenic (or odd-cumulenic) link. The same configuration has been established earlier for a few compounds in the crystalline state by X-ray diffraction [28-32], but these results have not, of course, allowed any conclusion to be drawn as to the configuration of free molecules, since packing effects may come into play in the crystal lattice.

The Biochemical Evaluation of Paper Chromatograms of Parathion, its Isomers and Analogues

KLAS-BERTIL AUGUSTINSSON and GUNNEL JONSSON

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

Parathion, its analogues and isomers were separated from mixtures by paper chromatography. The chromatograms were evaluated biochemically by dividing the chromatogram into sections, the cholinesterase inhibiting effects of which were measured against a system of acetylcholine and purified enzyme. The enzyme inhibiting power of several pure *p*-nitrophenyl esters of phosphoric and thiophosphoric acids was determined and the biochemical evaluation of the chromatograms was carried out with four samples (pure compound, heterogeneous technical grade compound, 96.5 % technical grade parathion, and a commercial formulation for insecticidal use). The various derivatives formed by heating parathion and methyl-parathion, can be demonstrated with the new technique.

In connection with the testing of various methods for the chemical assay of parathion, including the chromatographic separation on paper of the different constituents present in technical grade preparations [1], certain biochemical studies were made, and these results are the basis of the present paper.

Methods for paper chromatography of parathion (O,O-diethyl-O-*p*-nitrophenyl thiophosphate) and related compounds have been described in recent publications. A variety of solvents and stationary phases have been tested but the most convenient technique reported so far is that described by Metcalf and March [2]. This method gives the best results according to the experience of our laboratory and has therefore been used, partly modified throughout the present investigation. Other methods use ethanol-ammonia-water [3,4] as solvent or ethyl ether in water-saturated petroleum ether [5]. The detection of parathion and its degradation product (*p*-nitrophenol) in these methods is based either upon ultraviolet absorption [3,5] or upon spraying with Millon's reagent [4].

In the biochemical analysis of paper chromatograms such as that described below, the enzyme (cholinesterase) inhibition by various sections or spots of the chromatograms was measured. The technique used is suggested as a valuable complement for the evaluation of paper chromatograms of organophosphorus compounds.

METHODS AND MATERIAL

Paper chromatography. Filter paper (Munktell OB) was impregnated with silicone (MS 550) from a 5 % hexane solution and air dried. The phosphate esters (ethanol solutions) were applied to the paper and chromatographed using the ascending technique. The solvent used was the upper phase from a mixture containing water-ethanol-chloroform (6 : 10 : 10). The paper was afterwards dried in an air stream, sprayed with 5 % alcoholic potassium hydroxide solution, and finally kept for some minutes in steam over boiling water. The various components were visible as yellow spots (*p*-nitrophenolate).

Measurement of enzyme inhibition. Undeveloped chromatograms, *i. e.*, those not treated with alcoholic potassium hydroxide solution, were used to study the cholinesterase inhibition by separated phosphate and thiophosphate esters. The chromatogram was cut into sections of the same size, usually 20 sections from the starting point to the solvent front and extracts of each section were made in a bicarbonate buffer solution. Cholinesterase inhibition by these extracts was assayed, using a technique described previously [6], with acetylcholine chloride as substrate and a purified preparation from human blood serum as enzyme source. Before the addition of substrate the enzyme was incubated for 50 min with the extract. The location of the active constituents thus obtained, evaluated as per cent enzyme inhibition, was compared with a chromatogram developed with the technique described above.

Phosphate and thiophosphate esters. Most compounds (see Table 1) used in the present study were kindly supplied by Dr. Gerhard Schrader [7]. Gifts of pure parathion were made by Plant Protection (England) and the American Cyanamid Co. (USA).

RESULTS

Paper chromatograms. The results obtained on analysing the various phosphate and thiophosphate esters by the paper chromatographic technique are summarised in Table 1. It gives the R_F values of all the pure grade compounds tested and, in addition, the values for three unknown constituents which were traced in a parathion preparation heated for 40 h at 140° C. Some of these unknown compounds were also found in some technical preparations. The *o*- and *m*-nitrophenyl esters had the same R_F values as the corresponding *p*-nitrophenyl ester, as demonstrated with the S-phenyl isomers of parathion and methyl-parathion.

Cholinesterase inhibiting effect. The I_{50} values (*i. e.*, molar inhibitor concentration giving 50 % enzyme inhibition) are recorded in Table 1. These values were obtained by incubating a cholinesterase preparation for 50 min at 25° C with various concentrations of the inhibitor prior to the addition of substrate (acetylcholine). The most active inhibitor of cholinesterase was found to be the S-phenyl isomer of parathion, confirming a recent observation made by Hecht and Wirth [9] with horse serum as an enzyme source. The bis-(*p*-nitrophenyl) ethyl ester of phosphoric acid came next, and then paraoxon and methyl-paraoxon. The inhibiting power of parathion was relatively low. The least active inhibitors in this series were methyl-parathion and bis-(*p*-nitrophenyl) ethyl thiophosphate. Amongst the three unknown compounds traced on the chromatograms, the two slow running esters had no measurable inhibiting effect on cholinesterase activity. The compound with R_F 0.90, on the other hand, did inhibit the enzyme, but its nature could not be determined. Double spotting cannot be excluded, however, in these cases.

Table 1. R_F values and cholinesterase inhibiting power of various *p*-nitrophenyl esters of phosphoric and thiophosphoric acids. pI_{50} = negative logarithm of molar inhibitor concentration (during enzyme incubation) giving 50 % inhibition.

R_F at 22° C	Formula	Code name	pI_{50}
0.01	$(C_2H_5O)_2P(S)-O-C_6H_4-NO_2$	Bis-nitrophenyl thioester *	<2.3
0.03	$(C_2H_5O)_2P(S)-O-C_6H_4-NO_2$	Parathion, E 605	< 4
0.06	$(CH_3O)_2P(S)-O-C_6H_3-NO_2Cl(m)$	Chlorthion	— **
0.11	$(CH_3O)_2P(S)-O-C_6H_4-NO_2$	Methyl-parathion	< 2
0.12	Unknown	—	No inhibitor
0.17	Unknown	—	No inhibitor
0.22	$(C_2H_5O)_2P(O)-O-C_6H_4-NO_2$	Bis-nitrophenyl ester *	8.2
0.40	$C_2H_5O(C_2H_5S)P(O)-O-C_6H_4-NO_2$	S-ethyl isomer	~ 6
0.51	$(C_2H_5O)_2P-S-C_6H_4-NO_2$	S-phenyl isomer of parathion	8.55
0.60	$CH_3O(CH_3S)P(O)-O-C_6H_4-NO_2$	S-methyl isomer	— **
0.70	$(C_2H_5O)_2P(O)-O-C_6H_4-NO_2$	Paraoxon, E 600	8.18
0.72	$(CH_3O)_2P-S-C_6H_4-NO_2$	S-phenyl isomer of methyl-parathion	6.5
0.79	$HO-C_6H_4-NO_2$	pNP	No inhibitor
0.84	$(CH_3O)_2P(O)-O-C_6H_4-NO_2$	Methyl-paraoxon	6.0
0.90	Unknown	—	Inhibitor

* The corresponding methyl ester probably has an R_F close to this.

** Pure compound not available. DuBois *et al.*[8] give for chlorthion a pI_{50} of 4.4 (rat serum; compound "more than 95 % pure"), Hecht and Wirth [9] for the S-methyl isomer a pI_{50} of 5.55 (horse serum).

The I_{50} values, as shown in Table 1, do not always give the correct measure of the inhibitory effects of a compound. This is especially true for parathion and its analogues because they are mostly very difficult to obtain in a pure state and the presence of an impurity may not be detected in a simple determination of the 50 % inhibition concentration (I_{50}). A better technique was introduced by Aldridge and Davison [10], who used bimolecular rate constants (for reaction of inhibitor with cholinesterase) instead of I_{50}. Despite this criticism of a comparison of the inhibitory power based upon I_{50} values, we believe the values of Table 1 to be of value for the technique described in the present paper. In fact, the 50 % inhibition concentration is a useful property of a preparation, pure or not, in deciding the amount to be applied to the filter paper for chromatography with subsequent enzymic evaluation.

The effect of solvent and silicone treated filter paper on the inhibitory effect. Before measuring the cholinesterase inhibition by various sections of paper chromatograms, the effects on enzyme inhibition by the solvent and the silicone treated paper were studied. There is a possibility that a compound may

Table 2. Change of cholinesterase inhibiting power of parathion and methyl-parathion applied on filter paper. Samples kept at room temperature for various periods of time before testing.

Compound	Days	% Inhibition		
		Untreated paper	Paper treated with silicone	Paper treated with silicone + solvent
Parathion	0	29	14.5	15

	8	28	13.5	17.5
	15	32.5	16	17.5

undergo isomerisation or oxidation during chromatography or spontaneous reactions may take place on a chromatogram kept for some time before biochemical evaluation.

The following experiments were made. Ethanol solutions of parathion and methyl-parathion respectively were placed on chromatographic paper

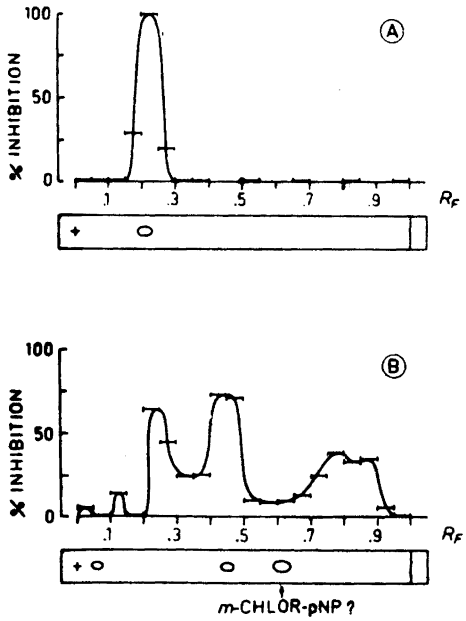

Fig. 1. Inhibition of cholinesterase by various sections of the paper chromatograms of bis- (*p*-nitrophenyl) ethyl phosphate (A), and a chlorthion preparation ("Chlorthion-Forte, Bayer") (B).

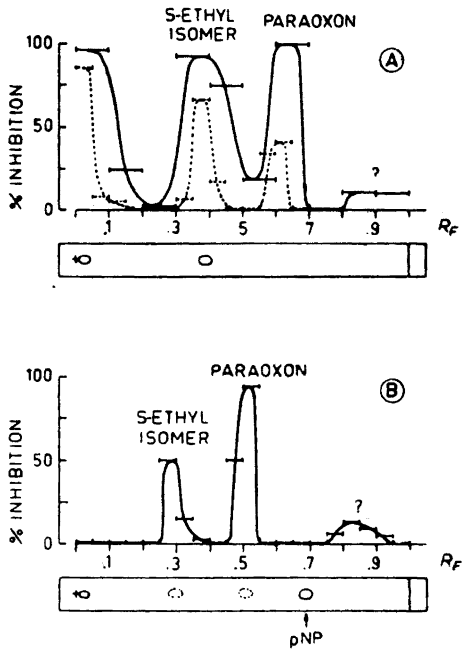

Fig. 2. Inhibition of cholinesterase by various sections of the paper chromatograms of a 96.5 % parathion preparation (American Cyanamid Co.) (A) (two separate experiments with various amounts applied on the paper), and a commercial formulation ("Ara-Parathion 35") for insecticidal use containing 35 % parathion (B).

(untreated, treated with silicone, and with silicone + solvent). After varying times, extracts of the spots were made in bicarbonate buffer and the cholinesterase inhibitory effect tested in the usual way. Table 2, recording the results, shows that both compounds studied underwent transformations to more active cholinesterase inhibitors, parathion more rapidly than its methyl analogue. It will be noted that the inhibitory effect of the samples on the silicone treated paper was about 50 % lower than the effect shown by the samples on untreated paper, except for very high inhibition values. The derivatives produced in these reactions are most probably the oxygen analogues (paraoxon and methyl-paraoxon) and the S-ethyl and S-methyl isomers which are known to be formed rather easily under a variety of experimental conditions. It is therefore to be expected that the section of a chromatogram containing parathion will show enzyme inhibition if it is not tested immediately after chromatographic separation, although parathion itself should not show this property (*cf.* Table 1). This is in accord with the experimental results (see Fig. 2 A).

The biochemical evaluation of chromatograms of pure and "pseudo pure" compounds. The results obtained in the biochemical evaluation of paper chromatograms are exemplified by four analyses. Fig. 1 A illustrates the

results obtained with bis-(*p*-nitrophenyl) ethyl phosphate. This highly active cholinesterase inhibitor gave only a single spot on the developed chromatogram and the biochemical results confirmed the purity of the preparation used. Fig. 1 B illustrates the chromatographic and biochemical results obtained with a technical grade preparation of chlorthion. Pure chlorthion is probably a weak enzyme inhibitor and it would therefore be expected that biochemical means would not be able to detect it on the chromatogram. The heterogeneity of the preparation used in this case was clear from the developed chromatogram but was still more pronounced when the various sections of the chromatogram were tested against a cholinesterase preparation. No efforts were made in the present investigation to identify the various constituents shown in the diagram, because pure preparations of chlorthion, its isomers and analogues were not available.

The chromatogram (Fig. 2 A) of a 96.5 % parathion preparation showed, in addition to the parathion area, an area of R_F 0.40 represented by the S-ethyl isomer. The biochemical results demonstrated the presence of a third constituent identified as the oxygen analogue of parathion (paraoxon). The results shown are from two separate experiments in which various amounts of the preparation were applied on the filter paper. The weak inhibitory effect of the area with R_F 0.9 was due to an unknown constituent demonstrated in several other parathion preparations analysed. It will be noted that the parathion section inhibited cholinesterase, an effect which would not be expected from the known weak inhibiting effect of this compound. The chromatograms in this case were kept for several days at room temperature before being analysed biochemically and during this period more active enzyme inhibitors (S-ethyl isomer and paraoxon) had been produced by spontaneous reactions (see above for proof of this explanation).

The next example is given in Fig. 2 B which illustrates the results obtained with a commercial parathion formulation. The lower R_F values obtained for the four visible constituents on the chromatogram (parathion, S-ethyl isomer, paraoxon, and *p*-nitrophenol) were most probably due to the disturbing effects of other unknown constituents (65 %) in this mixture. The biochemical analysis confirmed the presence of the S-ethyl isomer and paraoxon; in addition, the typical (for many technical grade parathion preparations) but unknown derivative with R_F 0.9 was present.

Isomerisation of parathion and methyl-parathion at high temperature. It is known from previous investigations [7,11,12] that parathion isomerises on heating, one of the products being the S-ethyl isomer. The strong cholinesterase inhibitor derived from parathion *in vivo*, on the other hand, is paraoxon [13]. After heating pure parathion for 40 h in a sealed tube at 140° C, chromatographic analysis of the mixture revealed the presence of eight constituents (Fig. 3 B). Four of these could be seen without difficulty on the developed chromatogram, *i. e.*, the bis-nitrophenyl ester, the S-ethyl isomer, paraoxon and *p*-nitrophenol. The other four (parathion and the three unknown constituents with R_F 0.12, 0.17 and 0.90) were visible when a greater amount of the heated mixture was chromatographed. Amongst these eight constituents, four were known to be highly active cholinesterase inhibitors and they were demonstrated clearly in the biochemical analysis (Fig. 3 B).

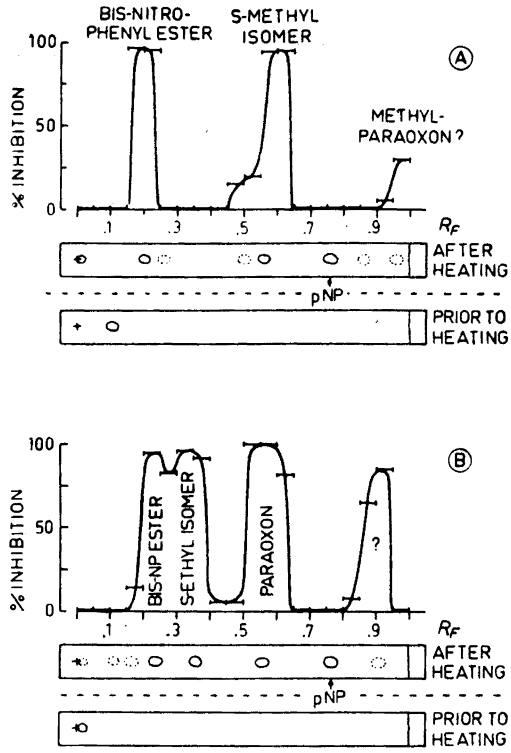

Fig. 3. Inhibition of cholinesterase by various sections of the paper chromatograms of methyl-parathion (A) and parathion (B); both preparations heated at 140° C for 40 hours.

The various constituents present in a methyl-parathion preparation heated in the same way were not as easily identified (Fig. 3 A). Eight constituents were present in this mixture also, some of which were traced from known R_F values. The slow running compound (R_F 0.02) was probably bis-(*p*-nitrophenyl) methyl thiophosphate. Two constituents were found to be strong cholinesterase inhibitors and they were almost certainly identical with bis-(*p*-nitrophenyl) methyl phosphate (R_F 0.20) and the S-methyl isomer (R_F 0.60), respectively. Except for *p*-nitrophenol the remaining constituents were unknown; one of the two fast running constituents was presumably identical with methyl-paraoxon.

DISCUSSION

Paper chromatography has been a valuable tool in analysing organophosphorus insecticides, especially technical grade parathion preparations [1]. It is proposed that this technique should be combined with a biochemical evaluation of the chromatograms as described in the present paper. Many parathion

preparations are more or less heterogeneous. The toxicity of these preparations is greatly dependent on the amounts of S-ethyl isomer, bis-(*p*-nitrophenyl) ethyl phosphate, and paraoxon present. These derivatives, especially in small amounts, are difficult to assay by available chemical methods. Paper chromatography alone is not sufficient in many cases, as its sensitivity is not high enough. A knowledge of the presence of these highly active constituents is important since otherwise misleading values may be obtained for toxicity, cholinesterase inhibitory power, hydrolysis rates, and insecticidal usefulness. These highly toxic isomers and analogues of parathion are formed spontaneously under various conditions and are especially important in the case of preparations which have been stored under uncontrolled conditions.

The technique described should be valuable in studying the metabolism of parathion, methyl-parathion, *etc.* in animals and plants as well as the mode of action of such compounds in mammals and insects and its usefulness may be extended to other organophosphorus compounds, many of which are highly active cholinesterase inhibitors. For parathion, and several related compounds, the toxicity and other properties are dependent on the presence of trace amounts of isomers or analogues which may give misleading results in pharmacological, biochemical and chemical studies. The homogeneity of preparations under examination can be tested easily by the technique as described in the present paper for a few compounds, the biochemical properties of which are characteristic of a larger group of toxic agents.

This investigation has been supported by grants from *Jordbrukets Forskningsråd (Swedish Agricultural Research Council)* and *Statens Institut för Folkhälsan (National Institute for Public Health*, Sweden). The kind interest shown by Professor Ernst Abramson is gratefully acknowledged.

I wish to express my sincere gratitude to Dr. Gerhard Schrader, Farbenfabriken Bayer, Wupperthal-Elberfeld (Germany) for his generous gift of the pure grade phosphorus compounds.

Electroorganic Preparations 1. Reduction of Steroid Ketones

HENNING LUND

Leo Pharmaceutical Products, Copenhagen, Denmark

It is shown that Δ^4-keto-3-steroids and $\Delta^{1,4}$-keto-3-steroids can be reduced at a mercury cathode at controlled cathode potential to pinacols, whereas saturated keto groups are not reduced at the potential used. The stereochemistry of the pinacols is discussed. The formation and a subsequent oxidation of the pinacols with a 1,2-glycol splitting reagent as lead tetraacetate or periodic acid is proposed as a method for protection of the reactive unsaturated keto group in the presence of saturated keto groups.

Δ^4-Unsaturated steroid ketones are known to be reducible at the dropping mercury electrode [1–4], but no conclusive evidence of the electrode reaction has been presented. The purpose of the present work is to examine the electrode reaction and its use in preparative chemistry. The investigation consists of a polarographic examination of the compounds under different conditions and controlled potential electrolysis under similar conditions.

POLAROGRAPHIC INVESTIGATIONS

The half-wave potentials of progesterone and androsta-1,4-diene-17β-ol-3-one in 75 % methanol—25 % water containing 0.5 M LiCl and 0.05 M buffer are listed in Table 1. The compounds showed only one wave when the solutions had been deaerated for half an hour. The slope of $E_{\frac{1}{2}}$ *vs* pH is near the value 0.059 required for reversible reactions [5].

The height of the wave varies only slightly with pH indicating that the same number of electrons participate in the electrode reaction in acid and alkaline solution. The reduction of an $\alpha,\beta,\alpha',\beta'$-unsaturated ketone must take place at the carbonyl group as the reduction of a double bond would yield an α,β-unsaturated ketone that would show a reduction wave.

The diffusion coefficients D are calculated from the diffusion currents by means of the Ilkovic equation [5]. As the product of D and the molecular weight M is the same for the two compounds it is likely that they use the same number of electrons in the electrode reaction.

The pH-values are measured with a glass electrode, but it was felt necessary to control the found values in the medium used by measuring the half-

wave potentials of anthraquinone-2-sulfonate in the same solutions. By assuming a linear connection between $E_{\frac{1}{2}}$ for anthraquinone-2-sulfonate and pH, the pH of the solution used was found as the abscissa-value corresponding to the measured $E_{\frac{1}{2}}$-ordinate. The two methods gave identical results from pH 1 to pH 11.

The polarographic results can be accounted for by the following assumptions. The potential determining step of the electrode reaction is reversible in the examined pH-interval. The number of electrons in the electrode reactions for α,β-unsaturated and $\alpha,\beta,\alpha',\beta'$-unsaturated steroid ketones is the same and probably one from pH 1 to 11. The similarity of the polarographic behaviour of an α,β- and an $\alpha,\beta,\alpha',\beta'$-unsaturated steroid ketone makes it likely that an α,β-unsaturated steroid ketone also is reduced at the carbonyl group. The polarographic behaviour of an α,β-unsaturated steroid ketone is thus different from that of the simple α,β-unsaturated ketones [6].

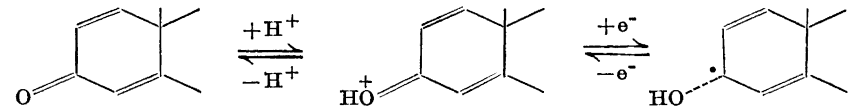

Table 1. **Half-wave potential (*vs.* saturated silver/silver chloride electrode) and diffusion current at different pH's for progesterone and androsta-1,4-diene-17β-ol-3-one. Drop time t measured at $E_{\frac{1}{2}}$.**

PREPARATIVE REDUCTIONS

The controlled potential electrolysis showed that α,β-unsaturated and $\alpha,\beta,\alpha',\beta'$-unsaturated steroid ketones yielded pinacols both in acid and alkaline solution and are thus different from the simple α,β-unsaturated ketones which dimerise at the β-carbon atom [6]. The reaction path of the reduction of an $\alpha,\beta,\alpha',\beta'$-unsaturated steroid ketone may be formulated as follows:

Acid solution:

Alkaline solution:

The radical formed dimerises slowly and irreversibly thus forming a pinacol. The products were proved to be pinacols by their ability to form the original ketones on oxidation with lead tetraacetate. The dimerisation takes place at carbon atom number 3 rather than at 1 or 5, as a dimerisation at one of the latter carbon atoms would be subject to severe steric hindrance.

The polarographic reduction is not the only reduction in which the α,β-unsaturated steroid ketones behave in another way than the simple unsaturated ketones. Windaus [7] found that cholestenone yielded a pinacol by reduction with sodium amalgam, and as he expected to get a saturated dimerised ketone from an α,β-unsaturated ketone he concluded that cholestenone was not an α,β-unsaturated ketone.

The reduction of a Δ^4-3-keto-steroid to a pinacol gives rise to the formation of two asymmetric carbon atoms and there is thus the possibility of formation of three compounds, one with both hydroxyl groups α, one with both hydroxyl groups β and one with one α and one β hydroxyl group.

An investigation of a model shows that in the compound where both hydroxyl groups are α the ring A will be in the 'half-chair' conformation and the bonding between the two dimerised radicals 'quasi-equatorial'. When the hydroxyl groups are β it is likely that the ring A adopts the 'half-boat' conformation and the hydroxyl groups are thus 'quasi-flagpole' and the carbon-carbon bond 'quasi-bowsprit'. In that case there will be free rotation of the carbon-carbon bond and the hydroxyl groups would then have the possibility of being *cis* which would facilitate the oxidation of the glycol with lead tetraacetate.

The relative amounts of the possible isomers depend among other things upon pH. Thus androsta-1,4-diene-17β-ol-3-one yields at pH 5 almost exclusively a pinacol with the rotation $[\alpha]_D^{23} = +277°$, whereas it in alkaline solution nearly quantitatively yields a pinacol with the rotation $[\alpha]_D^{23} = +8°$. The pinacol formed in acid solution dehydrates very easily by treatment with acid, whereas the one formed in alkaline solution requires more drastic conditions for the dehydration.

It is tempting to explain this by assuming that in acid solution it is the protonated ketone which is reduced, whereas the free ketone is reduced in alkaline solution. The most likely way for a steroid molecule to get the con-

jugated ketone system in contact with the cathode is by approaching the cathode with the methyl groups in the positions 10 and 13 pointing away from the electrode. In acid solution the positive protonated carbonyl oxygen would be attracted by the negative cathode, and the formed pinacol would thus have the hydroxyl group α. In alkaline solution the negative carbonyl oxygen would be repulsed from the cathode to the β configuration, where it also has the best chance of extracting a proton from a solvent molecule.

The proposed configurations are consistent with the difference found in the rate of dehydration. It has been shown [8] that divinyl carbinols very easily by an allylic rearrangement form a carbinol with the double bonds conjugated. According to Stork and White [9] there is a *cis* relation between the departing and the entering group in a S_N2' allylic rearrangement. A S_N1' mechanism must be rejected as it does not distinguish between the two isomers. The α-hydroxyl pinacol would thus yield a 5-α-carbinol, where the hydroxyl group is axial. As the 6-β-hydrogen is axial too, the 5-α-carbinol would dehydrate smoothly on treatment with acid. The β-hydroxyl pinacol would not have the same chance for dehydration as there is less tendency to form a 5-β-carbinol and no axial α-hydrogen in position 6 or 10.

It has furthermore been pointed out [10] that there is a difference in rotation from 200° to 300° between the α-hydroxy and the β-hydroxy isomer of unsaturated 3-hydroxy steroids as Δ^4-cholestenol ($\alpha-\beta = +297°$) and cholesta-4,7-dien-3-ol ($\alpha-\beta = +269°$). The difference in rotation between the proposed α-hydroxyl pinacol and the β-hydroxyl pinacol is $+269°$.

For the Δ^4-steroid ketones the difference in the composition of the mixture of pinacol isomers formed in acid and alkaline solution is not as pronounced as in the case of $\Delta^{1,4}$-steroid ketones. This is probably due to the fact that whereas in the latter the ring A is planar or nearly planar the former has the possibility of existing in a 'half-chair' or a 'half-boat' conformation. Etiocholane-3,17-dione exists partly with ring A in the boat form [11] and if it is assumed that the same is the case for the unsaturated 3-ketones, this explains the formation of a mixture of the pinacol isomers, as the reduction of the 'half-chair' and the 'half-boat' may result in the formation of different isomers. The isomer with the hydroxyl groups in the β-configuration probably has the ring A in the 'half-boat' conformation and it may, therefore, be impossible to deduce anything concerning the configuration from the rotations.

Like other 1,2-glycols the pinacols are quantitatively oxidized at room temperature by lead tetraacetate to carbonyl compounds the carbon-carbon bond being cleaved, thus forming the original α,β-unsaturated ketones. This reaction has been used to prove the reduction products to be 1,2-glycols.

The reduction of an α,β-unsaturated keto group to a pinacol and the subsequent oxidation of the pinacol to an α,β-unsaturated carbonyl group may be used to protect the more reactive conjugated carbonyl group, while the less reactive saturated keto group is brought to reaction with some other reagent, which does not attack the pinacol system. After the reactions the pinacol is oxidized with lead tetraacetate or periodic acid to the α,β-unsaturated carbonyl group.

The pinacols are slowly, but well crystallizing compounds which mostly are less soluble than the ketones from which they are formed. Sometimes a

pinacol crystallizes in two forms with different solubilities and it is not always easy to get the more soluble form to crystallize in the less soluble form [12]. The solubilities of the isomers are qualitatively the same but quantitatively there may be quite a difference. They are all soluble in tetrahydrofuran, soluble or recrystallizable from amyl acetate, toluene and ethyl alcohol and slightly soluble in water and hexane. The pinacols are stable in alkaline solution, whereas in acid solution they more or less rapidly lose water thus forming a compound with four (for the diene six) conjugated double bonds [13]. Dilute acetic acid affects the pinacols very slowly, whereas hydrochloric acid acts very quickly as dehydrating agent. Even the small amount of hydrochloric acid present in ordinary chloroform makes it impossible to use chloroform as a solvent for the pinacols for more than a short period. That is the reason why tetrahydrofuran has been used as solvent in the measurements of the rotation of the compounds. The pinacols themselves are also dehydrated at elevated temperatures, a fact which makes the melting point of minor importance as a physical constant of the compound.

EXPERIMENTAL

Apparatus. To the polarographic investigation were used a Sargent-Heyrovsky Model XII photographically recording polarograph and a recording polarograph Radiometer Type PO 3 a; the reported results are obtained with the latter. The capillary delivered 2.346 mg of mercury per second at an effective column height of 48 cm. The drop times reported were measured in the test solutions at the half-wave potential of the reducible compound.

All potentials are measured against a silver/silver chloride electrode in an aqueous saturated potassium chloride solution separated from the test solution with an agar plug and fritted glass diaphragm.

The potentiostat was a Lingane-Jones potentiostat [14]. For manual control a circuit adapted from Lingane [15] was used, in which the D.C. source was a 12 volts accumulator, the voltage adjuster a variable resistance (50 Ω) and the potential measuring device a "Polymeter" manufactured by Radiometer, Copenhagen, which had a resistance of 12×10^6 Ω.

The cell for the preparative reduction is adapted from Pasternak [6]. It consists of two conical 200 ml flasks which are connected through two fritted glass diaphragms 30 mm in diameter. In the cathode chamber is placed the mercury cathode (34 cm^2) which is connected through a platinum wire through the bottom of the flask to the outer circuit, the silver/silver chloride reference electrode, which has the fritted glass diaphragm just above the cathode, and a dropping mercury electrode. Further there are a stirrer (a uniform stirring is important) and an inlet for purified [16] nitrogen. Between the diaphragms agar containing potassium chloride or some other suitable salt is placed, and in the anode chamber is the platinum anode (15 cm^2). When the cell contains a 2 M salt solution the resistance is about 10 Ω.

Materials. The buffer solutions were made according to Ref.[17]. The materials were analytical grade. The steroids were recrystallized to constant properties.

Procedure. The controlled-potential electrolysis were performed in the following way. In the cathode chamber is placed 150 ml of the reaction medium (aqueous buffer solution and methanolic lithium chloride solution) and the anode chamber is filled with aqueous, alkaline sodium nitrite. The cathode chamber is deaerated with purified nitrogen [16] and reducible impurities are removed by electrolysis by keeping the cathode potential 0.3—0.4 volts more negative than the half-wave potential of the compound to be reduced. When the current has reached a stationary value, the reducible compound is added. By use of a potentiostat or by manual control the cathode potential is kept 0.1—0.2 volt more negative than the half-wave potential of the compound in the medium used. The current

drops from an initial value of 0.5—0.3 A to about 5 mA during 3—4 h. The reduction is followed polarographically with the dropping mercury electrode in the reaction medium whereby it is ensured that the reduction is undertaken at the right potential and the progress of the reduction can be followed. When the polarogram shows that the reduction is complete, the process is discontinued.

ISOLATION OF THE PINACOLS

The cathode chamber is emptied, the reaction medium is diluted with 200 ml water and made alkaline, if that does not affect the side chain of the steroid. The pinacols are extracted with a mixture of tetrahydrofuran and ether. After washing the organic layer with a bicarbonate solution and water, the solvents are evaporated at temperatures not exceeding 40°.

Androstenedione pinacol (1). 1.00 g of androstenedione was reduced at pH = 5 at —1.30 V. The pinacol residue was refluxed half an hour with 20 ml ethanol until a uniform suspension was obtained. After cooling for two days 690 mg (compound A) were filtered off, which after recrystallization from 25 ml toluene yielded 600 mg. $[\alpha]_D^{23} = +153° \pm 2°$ (tetrahydrofuran, $c = 0.438$, $a = 1.34°$, $l = 2$ dm). The compound dehydrates before melting. The dehydrated compound decomposes at about 305°. (Found: C 79.45; H 9.45. Calc. for $C_{38}H_{54}O_4$: C 79.47; H 9.47). The infra-red and ultra-violet spectrum and polarographic data show that no conjugated carbonyl group is present and the ability to form a semicarbazone and the infra-red spectrum show the presence of a keto group. The compound yields a yellow compound on treatment with acid and it yields quantitatively androstenedione by oxidation with lead tetraacetate in dry benzene at room temperature. From these pieces of evidence it is concluded that the compound A is one of the possible isomers of androstenedione pinacol.

The mother liquor was evaporated and the residue recrystallized from 3 ml ethanol. There was obtained 80 mg of compound A identified by its rotation and its ability to form androstenedione by oxidation with lead tetraacetate.

Androstenedione pinacol (2). 1.00 g of androstenedione was reduced at pH about 12.5 at —1.70 V. The pinacol residue was boiled with 20 ml 96 % ethanol until a uniform suspension was obtained. After cooling for two days 420 mg was filtered off, which after recrystallization from 15 ml toluene (360 mg) had a rotation of $[\alpha]_D^{23} = +152° \pm 2°$ (tetrahydrofuran, $c = 0.558$, $a = 1.70°$, $l = 2$ dm) (Found: C 79.43; H 9.40. Calc. for $C_{38}H_{54}O_4$: C 79.47; H 9.47). As all the chemical and physical data are indistinguishable from those of androstenedione pinacol A it was concluded that the isolated compound was the same isomer of androstenedione pinacol. The mother liquor was evaporated and the residue dissolved in benzene. On addition of hexane a component is obtained (410 mg) which after recrystallization from alcohol-water (340 mg) has a rotation of $[\alpha]_D^{23} = +174° \pm 2°$ (tetrahydrofuran, $c = 0.705$, $a = 2.45°$, $l = 2$ dm). The compound shrinks about 160° and dehydrates. The dehydrated compound decomposes at about 300°. (Found: C 79.45; H 9.48. Calc. for $C_{38}H_{54}O_4$: C 79.47; H 9.47). This compound had an infra-red spectrum very similar to that of compound A, and as it yielded androstenedione by oxidation with lead tetraacetate it was concluded, that this compound B was another isomer of androstenedione pinacol.

Progesterone pinacol (1). 1.00 g of progesterone was reduced at pH = 5 at —1.30 V. The pinacol residue was boiled with 20 ml ethanol until a uniform suspension was obtained. After cooling for two days 650 mg (compound PA) were filtered off. It was recrystallized from 20 ml acid-free amyl acetate. Rotation $[\alpha]_D^{23} = +162° \pm 2°$ (tetrahydrofuran, $c = 1.27$, $a = 4.10°$, $l = 2$ dm). The compound dehydrates before melting. The dehydrated product decomposes at about 290°. (Found: C 79.68; H 10.05. Calc. for $C_{42}H_{62}O_4$: C 79.94; H 9.91). The compound is soluble in tetrahydrofuran, less soluble in ethanol and benzene and insoluble in water and hexane. The infra-red spectrum shows the presence of an unconjugated carbonyl group and the absence of a conjugated ketone. This is confirmed by polarographic data and ability to form a semicarbazone. The compound PA yields a yellow compound on treatment with acid or heating to about 190°. It gives by oxidation with lead tetraacetate at room temperature in dry benzene quanti-

tatively progesterone. It is, therefore, concluded that the compound PA is one of the possible isomers of progesterone pinacol.

The mother liquor was evaporated and the residue dissolved in 4 ml ethanol. On standing was obtained 65 mg of a compound which was identified as compound PA by its rotation and ability to form progesterone by oxidation with lead tetraacetate.

Progesterone pinacol (2). 1.00 g of progesterone was reduced at pH 12.5 at −1.70 V. The pinacol residue was refluxed with 20 ml ethanol for half an hour. After cooling for two days a compound (560 mg) was filtered off. The rotation was not changed by recrystallization from amyl acetate. $[\alpha]_D^{23} = +163° \pm 2°$ (tetrahydrofuran, $c = 0.675$, $a = 2.20°$, $l = 2$ dm). M. p. (after dehydration) 285−290° (decomp.) (Found: C 79.80; H 9.79. Calc. for $C_{42}H_{62}O_4$: C 79.94; H 9.91). As all the physical and chemical data for the compound are indistinguishable from those of progesterone pinacol PA it was concluded that the isolated compound was the same isomer of progesterone pinacol.

The filtrate from compound PA was evaporated and the residue dissolved in hot benzene. On addition of hexane a compound is obtained (280 mg) which after recrystallization from ethanol-water yields 190 mg. $[\alpha]_D^{23} = +186° \pm 2°$ (tetrahydrofuran, $c = 0.536$, $a = 1.99°$, $l = 2$ dm). M. p. 165°. On further heating it dehydrates and solidifies at about 180° and the dehydrated compound decomposes at about 285°. (Found: C 79.43; H 9.84. Calc. for $C_{42}H_{62}O_4$: C 79.94; H 9.91). The compound has an infra-red spectrum very similar to that of compound PA and as it yielded progesterone by oxidation with lead tetraacetate it was concluded that the compound PB was an isomer of progesterone pinacol.

Androstadieneolone pinacol (1). 1.00 g of androsta-1,4-diene-17β-ol-3-one was reduced at pH=5 at −1.20 V. The pinacol residue was dissolved in benzene. On addition of hexane a compound is obtained (850 mg) with a rotation of $[\alpha]_D^{23} = +277° \pm 2°$ (tetrahydrofuran, $c = 0.542$, $a = 3.11°$, $l = 2$ dm). M. p. after dehydration 208−211° (decomp.). (Found: C 79.10; H 9.49. Calc. for $C_{38}H_{54}O_4$: C 79.47; H 9.47). The compound is very easily dehydrated under influence of acid, light or heat and yields a yellow compound. The infra-red spectrum shows absence of a carbonyl group. By oxidation with lead tetraacetate in dry benzene androstadieneolone is the main product, but a minor part of the compound is dehydrated by the acetic acid. All the data are consistent with the assumption that the isolated compound is one of the isomers of androstadieneolone pinacol.

The mother liquor was evaporated and evidence of a compound with lower rotation was found, but the compound was not isolated.

Androstadieneolone pinacol (2). 0.620 g of androstadieneolone was reduced at pH = 12.5 at −1.60 V. The pinacol residue was recrystallized from benzene yielding 510 mg of a compound with a rotation of $[\alpha]_D^{23} = +8° \pm 2°$ (tetrahydrofuran, $c = 0.683$, $a = 0.11°$, $l = 2$ dm). M. p. 180−182° (decomp.). (Found: C 79.63; H 9.30. Calc. for $C_{38}H_{54}O_4$: C 79.47; H 9.47). This compound is not dehydrated as easily as the above mentioned isomer of androstadieneolone pinacol, but can be dehydrated by heating to about 200° or by treatment with hydrochloric acid. It is quantitatively oxidized by lead tetraacetate at room temperature to androstadieneolone. It contains no carbonyl absorption in the infra-red spectrum. From the evidence it is concluded that the compound is a second isomer of androstadieneolone pinacol.

The mother liquor was evaporated and evidence of a compound with higher rotation was found, but the compound was not isolated.

Cholestenone pinacol. 1.00 g of cholestenone was reduced at pH = 5 at −1.30 V. The pinacol residue was refluxed with 25 ml ethanol for two hours. After cooling a compound (850 mg) was obtained, which after recrystallization from amyl acetate has a rotation of $[\alpha]_D^{23} = +92° \pm 2°$ (tetrahydrofuran, $c = 3.052$, $a = 5.65°$, $l = 2$ dm). Dolou *et al.*[13] report $[\alpha]_D^{23} = 85°$, but a recalculation of their data gives 92°. (Found: C 84.12; H 11.72. Calc. for $C_{54}H_{90}O_2$: C 84.08; H 11.77). The compound has physical and chemical data consistent with the data reported [12,13] for cholestenone pinacol. The compound yields quantitatively cholestenone by oxidation with lead tetraacetate.

Testosterone propionate pinacol. 1.00 g of testosterone propionate was reduced at pH = 5 at −1.30 V. The pinacol residue was recrystallized from ethanol giving 700 mg of a compound with a rotation of $[\alpha]_D^{23} = +76° \pm 2°$ (tetrahydrofuran, $c = 0.586$,

$a = 0.90°$, $l = 2$ dm). (Found: C 76.68; H 9.46. Calc. for $C_{44}H_{66}O_6$: C 76.46; H 9.63). The found data are consistent with the data reported [12] for testosterone propionate pinacol. It possesses no androgenic activity.

Part of this investigation was carried out at the Chemistry Department of Harvard University 1954—1955. The author wishes to express his thanks to Dr. L. F. Fieser and Dr. J. J. Lingane for their kind interest and for many facilities which have been put at his disposal.

Insulin Crystals

III. Determination of the Rhombohedral Zinc-Insulin Unit-Cell by Combined Microscopical and Chemical Examinations

JØRGEN SCHLICHTKRULL

NOVO Terapeutisk Laboratorium, Copenhagen, Denmark

Cattle insulin is recrystallized by a method yielding perfectly shaped rhombohedral zinc-insulin crystals. During crystallization, samples are taken in which the process of crystallization is arrested by adding zinc ions.

The crystalline fractions in the samples are separated from non-crystalline insulin and determined quantitatively.

The volumes of insulin crystals in the stabilized suspensions as well as the size distributions are determined by a special microscopical counting procedure. Ordinary microscope equipment is used.

From the ratio between the volume of crystals and their content of nitrogen, the dimensions of the unit-cell are calculated to be $a = 50.7 \pm 0.7$ Å ($P = 0.95$). The volume of crystals containing 1 g of protein (water and salt-free) is calculated to be 1.35 ml. The possible causes of the significant difference between the estimate $a = 50.7$ Å and the X-ray estimate $a = 49.4$ Å are discussed.

Crowfoot and Riley [1] in 1939, by means of X-ray analyses, measured the dimensions of the unit-cell of wet zinc-insulin crystals lying in their mother-liquid. The length of the edge of the unit-cell rhombohedron is called a and the obtuse angle of the rhomb is α. They found that $a = 49.4$ Å (with 0.5 % accuracy) and $\alpha = 114° 16'$.

On a 1.3 mm large perfect zinc-insulin crystal the angle, α, has already been estimated by goniometric measurement [2] as $\alpha = 114° 22'$. The purpose of the present investigation is to determine the dimension a by a combined chemical and microscopical examination.

THE PRINCIPLE OF INVESTIGATION

It is assumed that the unit-cell contains 6 of the smallest molecular units, the structure of which was established by Sanger and coworkers [3]. Thus, the insulin content of the unit-cell is M = 34 400 and the nitrogen content is $6 \times 65 = 390$ atoms.

The number of unit-cells, n, present in the rhombohedral crystal is proportional to the volume and hence to the cubes of the edges, l_a (Å), *i. e.*

$$l_a^3 = n \cdot a^3.$$

Thus the nitrogen content, m_N, of a crystal is

$$m_N = \frac{n}{N} \times 390 \times 14.008 \text{ g, where } N = 6.02 \times 10^{23}.$$

Hence,

$$a = 2.086 \times 10^{-7} \left(\frac{l_a^3}{m_N}\right)^{\frac{1}{3}} \text{ Å}.$$

When a drop of an insulin crystal suspension is placed on a slide on the microscope stage, the crystals settle down on their faces. Therefore the greatest diagonal, l, in the crystal projection on the horizontal plane is used as a convenient measure of the crystal size. It follows that

$$l = l_a \times \sec \frac{\alpha}{2}$$

and

$$a = 1.130 \times 10^{-7} \left(\frac{l^3}{m_N}\right)^{\frac{1}{3}} \text{ Å}$$

Consider a suspension of insulin crystals containing c_N g/ml nitrogen belonging to the crystals. The cumulative distribution of crystal sizes, $P(l)$, *i. e.* the number of crystals per ml greater than l, is determined in a counting chamber using a calibrated eye-piece scale for measuring l. Using the volume of a rhombohedron with $l = 1$ Å as volume unit for the crystals, the volume, V, of crystals per ml of suspension is

$$V = \int_0^{l_{max}} p(l) l^3 \, dl$$

where

$$p(l) = -\frac{dP(l)}{dl}$$

thence,

$$a = 1.130 \times 10^{-7} \left(\frac{V}{c_N}\right)^{\frac{1}{3}} \text{ Å} \qquad (1)$$

When V and c_N are known, a can be calculated from eqn. (1). In the following the methods used for the determination of V and c_N are described.

METHODS

The perfect rhombohedral shape which is essential for the investigation is ensured by adding halogen ions to the medium of crystallization [2]. In order to get several estimates of a, samples are taken at different times during the crystallization. The crystallization process in the samples is immediately arrested

by diluting with a zinc salt solution. The crystals in the stabilized suspension are measured and counted, and the amount of nitrogen in the crystals is determined by Kjeldahl analyses on the isolated crystals.

Determination of V

About 0.1 ml of the stabilized suspension is drawn up into a narrow pipette and let out into the chamber (Fuchs-Rosenthal) which is 0.200 mm deep. (Verified by check-up). The 2 great squares (4 × 4 mm each) are both divided into 256 small squares each corresponding to c ml of the crystallization mixture, $c = 1.25 \times 10^{-6}$ ml. The crystals are measured and classified. Class limits $l_1 = 0$, l_2, l_3, *etc.* are devised, $l_i - l_{i-1} = 3-6$ μ. The inspection may begin in one corner and proceed as when reading a page. In A_i small squares, n_i crystals are found to be greater than l_i. A_i and n_i are counted simultaneously. The areas inspected within the large squares are not chosen at random as this process is very time consuming. As no significant differences have been observed when changing the system of inspection, it is believed that systematic errors are unimportant. About 30 crystals are counted per class limit, but not more than one large square is generally inspected per class. When the area is insufficient, the chamber is refilled. Two determinations of V are made for each suspension.

The number of crystals per square unit, n_i', belonging to the class $l_i < l < l_{i+1}$ is

$$n_i' = \frac{n_i}{A_i} - \frac{n_{i+1}}{A_{i+1}}$$

The volume V_i of these crystals is calculated from the assumption that $p(l_i)$ is constant in the intervals.

It follows that

$$V_i = \int_{l_i}^{l_{i+1}} p(l) l^3 \, dl = p(l) \, (l_{i+1} - l_i) \, \frac{l^4_{i+1} - l_i^4}{4(l_{i+1} - l_i)} \qquad (2)$$

Since

$$p(l) \, (l_{i+1} - l_i) = n_i'/c$$

then, estimates of V_i may be obtained from

$$V_i = f_i \, n_i'; \; f_i = \frac{m_i^3 + m_i d_i^2}{8c} \qquad (3)$$

where

$$m_i = l_{i+1} + l_i; \; d_i = l_{i+1} - l_i.$$

The distribution of particles according to weight may be obtained from eqn. (3). The volume per ml of all the crystals is then obtained by summation of V_i,

$$V = \sum_{i=1}^{i=i_{max}} V_i$$

The limit i_{max} is the smallest limit above which no crystals are found.

Error: As $p(l)$ is not strictly constant within the classes, a systematical error is introduced by eqn. (2). The error is estimated from an examination of the size distributions. It can be shown that

$$P(l) = c_1 \cdot \exp.\ (-\ c_2 l);\ c_1,\ c_2 > 0;\ l_i < l < l_{i+1}$$

or

$$p(l) = c_1 \cdot c_2 \cdot \exp.\ (-\ c_2 l).$$

This relation is observed when the logarithms of the numbers in column (4) are plotted against the class limits (1) in Table 1. Deviations which are insignificant in this connection occur in the outer regions of the distributions [5].

Hence, the actual volume of crystals within the size interval $(l_i,\ l_{i+1})$ is

$$V_i = c_1 \cdot c_2 \int_{l_i}^{l_{i+1}} l^3 \exp.\ (-c_2 l)\mathrm{d}l = c_1\ [\mathrm{F}(l_i) - \mathrm{F}(l_{i+1})] \qquad (4)$$

where

$$\mathrm{F}(l) = (l^3 + 3l^2 c_2^{-1} + 6l c_2^{-2} + 6c_2^{-3}) \exp.\ (-c_2 l)$$

Table 1. Determination of crystal volume (V) by the counting procedure.

						Total:	67	150

(1) $10^{-4} \cdot l_i$ (l_i in Å)
(2) n_i (number of crystals greater than l_i)
(3) A_i (number of squares in which n_i are counted)
(4) n_i/A_i
(5) $n_i' = n_i/A_i - n_{i+1} / A_{i+1}$
(6) $10^{-21} \times f_i$; $f_i = (m_i^3 + m_i d_i^2) / 8c$; $c = 1.25 \times 10^{-6}$ ml
(7) $10^{-21} \times f_i n_i'$
(8) $10^{-42} \times n_i\ (f_i^2 + f_{i-1}^2) / A_i^2$

$V = 67 \times 10^{21}$; $\sigma_V^2 = 150 \times 10^{42}$

The volume calculated from eqn. (3) is

$$V_i = \frac{m_i^3 + m_i d_i^2}{8c} [P(l_i) - P(l_{i+1})] \cdot c$$

or

$$V_i = \frac{m_i^3 + m_i d_i^2}{8} \cdot c_1 [\text{exp. } (-c_2 l_i) - \text{exp. } (-c_2 l_{i+1})]$$

Hence, the ratio between this volume and that from eqn. (4) is

$$r = \frac{[\text{exp. } (-c_2 l_i) - \text{exp. } (-c_2 l_{i+1})] (m_i^3 + m_i d_i^2)}{8 [F(l_i) - F(l_{i+1})]} \quad (5)$$

It is found that $r = 1.00—1.02$ so that this error can be neglected.

The variance of V is the sum of the variances of V_i.

$$\sigma_V^2 = \sum_{i=1}^{i=i_{max}} \sigma_{V_i}^2$$

where

$$\sigma_{V_i}^2 = f_i^2 \sigma_{n_i'}^2$$

The error of A_i is considered negligible, then

$$\sigma_{n_i'}^2 \approx \frac{\sigma_{n_i}^2}{A_i^2} + \frac{\sigma_{n_{i+1}}^2}{A_{i+1}^2}$$

If it is further assumed that the crystals are classified without error and that they are distributed in the chamber according to the Poisson distribution, it follows that

$$\sigma_{n_i}^2 \approx n_i$$

and

$$\sigma_V^2 \approx \sum_{i=1}^{i=i_{max}} n_i \cdot \frac{f_{i-1}^2 + f_i^2}{A_i^2}, \quad (f_0 = 0) \quad (6)$$

In order to keep σ_V^2 within reasonable limits, the terms in the last equation must not be allowed to increase too much with l_i. Aiming at constant terms it follows from eqn. (6) that the area of inspection shall be

$$A_i = \text{const.} \cdot P(l_i) \cdot l_i^6$$

The specific feature of this counting method is that both the particles and the squares are counted; the latter increase with the particle size.

Determination of c_N

The isolation of insulin crystals from the stabilized suspensions is achieved by extracting the amorphous particles.

Solvent:
8.15 g CH_3COONa, $3H_2O$
42.0 g NaCl
150 ml acetone
+ water to make 500 ml.

15 ml of the stabilized suspension are centrifuged and the supernatant liquid is discarded. The precipitate is resuspended in 5 ml of distilled water, 10 ml of the solvent are added and mixed with the suspension. The suspension is centrifuged and the supernatant liquid containing the dissolved amorphous fraction is discarded. The crystals are suspended in 10 ml of 60 % (v/v) acetone, centrifuged and the acetone is discarded. The nitrogen content of the remaining crystals is determined by semi-micro Kjeldahl analysis. The result is expressed in g of nitrogen per ml of the original crystallization medium. The test has been included in the British Pharmacopoeia [6].

Error: Mixed suspensions containing amorphous and crystalline insulin in different proportions have been analyzed. The results of analyses were in agreement with the values of c_N predicted from analyses of the original suspensions used for the mixing. A small systematical error is caused by the fact that a part of the amorphous particles is denatured and heavily soluble, which causes overestimation of the crystal fraction. This error which amounts to 2—3 % of the total insulin-nitrogen, is corrected by making analyses of the crystallization mixture before crystals are formed.

The standard deviation of a single determination has been estimated from double analyses as 1.0×10^{-5} g N/ml.

EXPERIMENTAL

Composition of crystallization mixture: 2.42 mg/ml insulin-nitrogen (equiv. to 1.7 % insulin)
155 µg/ml Zn++, as chloride (including the Zn++ from the insulin)
7 % NaCl
0.1 M CH_3COONa
+ HCl to pH = 5.45—5.55.

Solutions: (I). 68 g recrystallized insulin from beef pancreas, containing 9.68 g insulin-nitrogen were dissolved in water containing 80 ml 1 N HCl and so much $ZnCl_2$ that the final solution contained a total of 0.62 g Zn++. The solution was sterilized by filtering through an asbestos filter previously rinsed with diluted HCl. The filtered solution was diluted with water to 3 000 ml.

(II). 54.4 g CH_3COONa, $3H_2O$ + 280 g NaCl + 44 ml 1 N NaOH + water to make 1 000 ml.

The crystallization: The solutions (I) and (II) were poured simultaneously into an 8-litre glass beaker placed in a water thermostat at 25° C. The beaker was covered with a glass lid. Slow, continuous stirring was provided with a glass propeller through a hole in the lid.

Initially about 95 % of the insulin was precipitated as amorphous particles. During the first 30 min between one fourth and one third of the amorphous insulin was dissolved but only a few crystals were formed. After a further 30 min the crystallization became

rapid, but soon slowed down again and was practically finished within 12 h. At that time approximately 92 % of the insulin was crystalline, 3 % was still in solution and the rest was in the amorphous state.

The stabilized samples: The process of crystallization was arrested by combining the insulin with zinc ions at neutral reaction [4]. A 10 ml sample was added to 90 ml of a neutral solution of zinc chloride containing 7.2 mg Zn^{++}, 100 mg methyl-*p*-hydroxybenzoate and 2.75 ml 0.1 N NaOH. The total volume was adjusted to 100 ml. The insulin thereby immediately combined with some of the zinc ions. The crystals and the amorphous particles were not visibly altered, whereas the dissolved insulin from the samples was precipitated as stable amorphous particles.

RESULTS

Two crystallizations were made and analyzed with an interval of 19 months. Fourteen samples were taken during the first crystallization and seventeen in the second experiment. Each sample was subjected to counts twice. The results of the 62 countings are too numerous to be compiled in a table, but for the purpose of illustration the result from one of them is presented in Table 1. The volume V is estimated from this counting to be 67×10^{21}. The systematical error is calculated by means of eqn. (5) using $c_2 = 0.18$. When $l_i = 50$ and $l_{i+1} = 55$, it is found that $r = 1.021$ and likewise for $l_i = 22$, $l_{i+1} = 25$, $r = 1.017$. This error is considered insignificant. The standard deviation of the V estimate is calculated by means of eqn. (6) and found to be 12×10^{21}.

Table 2 contains all the condensed data. The two rectangular parts correspond to the two crystallizations and each row represents a sample. As crystallization proceeds, both V and c_N increase, while a remains constant except for casual variations. The systematical error of V has been calculated for the samples in Table 2. In the first crystallization it is found to be 2 % or less and in the second where $c_2 = 0.07$ it is less than 1 %. Hence, this error is neglected. The standard deviation of the V estimate from a counting has been calculated from eqn. (6) to be 12×10^{21} (Table 1). As two countings are made on each of the samples it is also possible to calculate s_V from the double determinations. However, as V increases, s_V increases also as seen from the ranges in column (3), but in spite of this a pooled estimate of the standard deviation has been calculated in the usual way. It is found that $s_V = 13 \times 10^{21}$, with 14 and 17 d.f. from each of the two experiments, in close agreement with the result, 12×10^{21}, from Table 1.

The standard deviation of a is calculated from the variation of a between the 14 resp. 17 samples taken during each of the two crystallizations.

The estimates of a from I and II are pooled as their difference is insignificant. $a = 50.7$ Å with confidence limits $\pm$ 0.7 Å (P = 0.95). The volume of the unit-cell is calculated from the values $a = 50.7$ Å and $\alpha = 114° 22'$ using the formula

$$\text{Volume} = 2 \cdot \sin^2\left(\frac{\alpha}{2}\right) \cdot \sqrt{1 + 2\cos\alpha} \cdot a^3$$

The volume is $0.591 \times 50.7^3 = 7.70 \times 10^4$ Å^3. The weight of insulin within the unit-cell is $6 \times 5\,734 / 6{,}02 \times 10^{23} = 5.71 \times 10^{-20}$ g. Hence the volume of crystals containing 1 g of insulin is 1.35 ml.

						221	208	13	215	227	51.5
						242	203	39	223	226	52.2

(1) $10^{-21} \times V$ from first counting;
(2) $10^{-21} \times V$ from a second counting;
(3) The range between (1) and (2);
(4) The average of (1) and (2);
(5) $10^5 \times c_N$;
(6) $a = 1.130 \times 10^{-7}\left(\frac{V}{c_N}\right)^{\frac{1}{3}}$ Å.

I. $s_V = 13 \times 10^{21}$ with 14 d.f. II. $s_V = 13 \times 10^{21}$ with 17 d.f.
$a = 50.8 \pm 0.4$ Å (S.E.) $a = 50.6 \pm 0.5$ Å (S.E.)
$a_{I,II} = 50.7 \pm 0.7$ Å (confidence limits, P = 0.95)

DISCUSSION

The estimate $a = 50.7$ Å differs significantly from the X-ray value $a = 49.4$ Å and it may be due to an overestimate of V by 8 %. In that case a systematical error is present in the counting method, but this possibility cannot be verified from the present data. However, the crystals examined by X-ray were lying in their mother-liquid of crystallization while in the present investigation the crystals were actually insulin-zinc crystals containing approximately 2.3 % zinc calculated on dry weight [4]. It appears possible that the stabilization with zinc causes the lattice to expand, just as drying causes it to shrink. Thus experimental conditions may be responsible for the difference observed in a.

Insulin Crystals

IV. The Preparation of Nuclei, Seeds and Monodisperse Insulin Crystal Suspensions

JØRGEN SCHLICHTKRULL

Novo Terapeutisk Laboratorium, Copenhagen, Denmark

Nuclei were formed by freeze-drying a crystallization mixture containing dissolved insulin. The freeze-dried insulin was suspended in a buffered insulin solution whereupon the nuclei grew up to 1—2 μ crystals which were used as seeds for the preparation of monodisperse insulin crystal suspensions with different crystal sizes (5, 25 and 40 μ)

It is the purpose of the present investigation to demonstrate the effect of seeding with a large number of small seed crystals on insulin crystallization.

The size of a rhombohedral insulin crystal has been defined [1] as the greatest diagonal in the projection of the crystal on a plane through a face. An amount of seed-crystals weighing w_s g contains n seeds of almost uniform size, l_s μ. Hence,

$$w_s = knl_s^3$$

where k is a constant. The total weight of insulin gained as crystals after seeding is w_i. Assuming that the crystals grow with identical rates of linear growth, it follows that

$$\alpha w_i = knl^3$$

where (1—α) is the fraction of spontaneously formed crystals, and l is the size of the grown up seeds. Hence,

$$l = l_s \sqrt[3]{\frac{\alpha}{r}} \tag{1}$$

or

$$\alpha = r\left(\frac{l}{l_s}\right)^3 \tag{2}$$

where r is the ratio w_s/w_i between weight of seeds and total insulin gained as crystals. The fraction, α, of uniform crystals depends on the conditions of crystallization as well as on l_s and r. When the conditions and the size of seeds are fixed, a decrease in r causes α to decrease.

When seeding is employed immediately after mixing the components for crystallization, it follows from the assumption and eqn. (1) that the upper limit of crystal size is

$$l_u = l_s \sqrt[3]{\frac{1}{r}}$$

PREPARATION OF SEED-CRYSTALS

Solutions: (1). 5 g beef insulin, recrystallized from a citrate buffer [2] + 42.5 ml 0.1 N HCl + water to make 500 ml; (2). 500 mg citric acid + 20 mg Zn^{++} (as chloride) + 800 mg methyl-*p*-hydroxybenzoate + 11.2 ml 1 N NaOH + water to make 500 ml.

Freeze-drying: To 100 ml of sol. (1) were added 100 ml (2) and 1 N NaOH to pH = 6.7. The solution was frozen at once and freeze-dried.

Crystallization: The freeze-dried insulin was suspended in 400 ml of the alkaline (pH 8.5) solution (2) and immediately thereafter 400 ml of sol. (1) were added. The mixture (pH = 6.2—6.5) was shaken over night at room temperature. The crystals which developed were 1 μ large.

CRYSTALLIZATION WITH AND WITHOUT SEEDS

The first experiment is a comparison between crystallizations with and without seeding.

The crystallization mixture had the following composition [3]:

1.7 % beef insulin, 155 μg/ml Zn^{++} (as chloride, including the zinc from the insulin), 7 % NaCl, 0.1 M CH_3COONa + HCl to pH = 5.45 to 5.55.

One ml of the 1 μ-seed crystal suspension containing 6 mg insulin was diluted with water to 20 ml and added to 4 litres of crystallization mixture containing 68 g insulin. The final distribution of crystal sizes was determined by the technique described earlier [1]. The cumulative distribution of insulin units was calculated and presented in a graph, Fig. 1, in which can be seen that 90 % of the weight was concentrated in the size range 20—30 μ.

In the control, which was not seeded, 90 % of the insulin was found in the much greater interval 25—100 μ. It is concluded that seed crystals grow with identical rates of linear growth in accordance with the assumption for eqn. (1).

VARIATION OF THE AMOUNT OF SEED-CRYSTALS

The dependence of α on r is illustrated by an experiment in which the conditions of crystallization remain as in the previous experiment while r is varied. The size of seeds was 2—3 μ. The resulting cumulative distributions of units (or weight) on crystal size are shown in Fig. 2. The median size is taken as

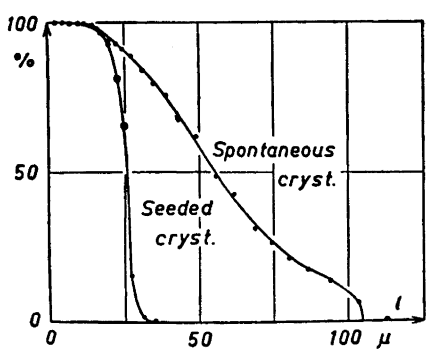

Fig. 1. Cumulative distribution of insulin units.

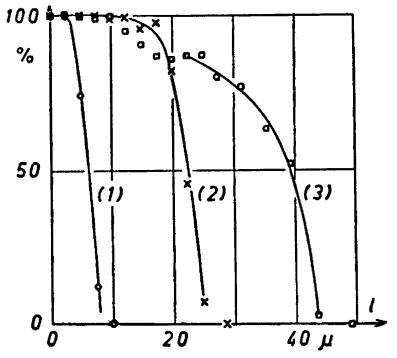

Fig. 2. Cumulative distribution of insulin units. The suspensions were prepared with different amounts of seeds (see Table 1).

representative of l, the size of grown up seeds. The results from 3 crystallizations are presented in Table 1. It is assumed that spontaneous crystallization is negligible ($\alpha = 1$) in the first case where r is relatively large. Hence, by inserting l_{50}, r and $\alpha = 1$ in eqn. (1) it is calculated that $l_s = 3.0\ \mu$. When eqn. (2) is employed in case 2 and case 3, α is found to be 0.9 and 0.7, respectively. These values of α are confirmed by Fig. 2 as they are found to be the ordinates corresponding to deflections of the curves. These points presumably divide the distributions in the two parts containing, respectively, spontaneously formed crystals and grown up seeds.

Table 1. Variation of the amount of seed-crystals.

No.	r	l_{50}	$\alpha = r\left(\frac{l}{3}\right)^3$
(1)	12×10^{-2}	6 μ	1.0
(2)	21×10^{-4}	23 μ	0.9
(3)	30×10^{-5}	39 μ	0.7

Legend: r, The ratio between weight of seed-insulin and total insulin.
l_{50}, The median size in the distribution of insulin units.
α, The weight of spontaneously formed crystals is $(1-\alpha)w_i$, where w_i is the total weight of insulin gained as crystals.

DISCUSSION

The freeze-drying method originated from the incidental observation that crystallization yielded smaller crystals when using glass apparatus which had not been cleansed after a previous crystallization process. The small amounts of dried-in insulin on the propeller rod and in the beaker were apparently responsible. The number of crystals was further increased hundredfold when freeze-dried insulin was added.

When suspended in the alkaline (pH = 8.5) solution (2), the freeze-dried insulin is partially dissolved. The pH may even be increased to 11 (glass-electrode). In this case the insulin disappears into solution, apart from a great number of particles which are visible in the dark field microscope. The seeding properties of the colloidal solution vanish within one hour together with the small particles.

The faces of the seed-crystals do not grow with equal growth rate upon seeding. Thus the seed-bodies from 3—5 μ seeds are finally found in the obtuse vertices of the crystals. Smaller seeds are barely or not at all visible in the final crystal suspension.

Die Verteilung von Äthylalkohol und Wasser bei Ionenaustauschern auf Harzbasis

HEINZ RÜCKERT und OLOF SAMUELSON

Institut für Technische Chemie, Chalmers Technische Hochschule, Göteborg, Schweden

Die Verteilung von Äthylalkohol und Wasser wurde für Kationenaustauscher und Anionenaustauscher in verschiedenen Ionenformen bestimmt. Die Alkoholkonzentration der Harzphase ist im allgemeinen kleiner als in der Aussenlösung (Aussalzen). Je höher die Ionenkonzentration der Austauscherphase ist (kleine Quellung), umso mehr wird der Alkohol ausgesalzt. Unter gewissen Umständen kann man aber auch ein Einsalzen erhalten. Die Quellung der Austauscher nimmt, je nach Beladungszustand und Vernetzungsgrad, entweder mit steigender Alkoholkonzentration kontinuierlich ab oder durchläuft ein Maximum.

Es ist bekannt, dass sich organische Moleküle in wässeriger Lösung ungleichmässig zwischen einem Ionenaustauscher und der ihn umgebenden Lösung (Aussenlösung) verteilen. Das System Äthylalkohol-Wasser ist früher von Gregor und Mitarbeitern [1] untersucht worden und diese Untersuchungen zeigten, dass der Alkoholgehalt der Harzphase (Innenlösung) niedriger ist als in der Aussenlösung.

In einer früheren Arbeit [2] wurde gezeigt, dass Ionenaustauscher zur Adsorption von Zuckerarten aus Mischungen von Wasser und Alkohol verwendet werden können und dass diese Adsorption von der Art der Gegenionen stark abhängig ist. Um die Grundlagen einer Diskussion über die Zuckeradsorption zu schaffen, wird in der vorliegenden Arbeit über die Verteilung von Wasser und Äthylalkohol berichtet und zwar für Austauscher in denselben Ionenformen, wie sie bei den Zuckeruntersuchungen verwendet wurden.

EXPERIMENTELLER TEIL

Prinzip der Versuche. Um die Verteilung von Alkohol und Wasser zwischen den beiden Phasen zu studieren, wird eine bestimmte Austauschermenge mit einer Alkohol-Wasserlösung bis zur Erreichung des Gleichgewichtes geschüttelt. Die Zusammensetzung der Innenlösung kann auf zwei verschiedene Arten bestimmt werden. Entweder berechnet man aus der Konzentrationsänderung der Aussenlösung die Zusammensetzung der Innenlösung, oder jede Phase wird für sich analysiert. Die erste Methode führt schneller zum

Resultat, jedoch auf Kosten der Genauigkeit und bei sehr kleinen Konzentrationsänderungen ist diese Methode unbrauchbar. Daher wurde bei allen Versuchen sowohl die Innenlösung als auch die Aussenlösung auf ihre Zusammensetzung analysiert. Die beiden Phasen wurden durch Abzentrifugieren der Aussenlösung von einander getrennt. Diese Methode ist für wässerige Lösungen von Gregor [3] und Pepper [4] eingehend studiert worden. Durch das Zentrifugieren erhielt man das feuchte Gewicht des Austauschers. Das Gewicht der Innenlösung konnte somit durch Subtrahieren des Trockengewichtes ermittelt werden. Um die Zusammensetzung der Innenlösung festzustellen, wurde diese entweder mit Wasser oder Methylalkohol verdrängt. Der Wassergehalt wurde im allgemeinen aus der Differenz zwischen dem Gewicht der Innenlösung und dem titrimetrisch bestimmten Gewicht des Alkohols berechnet. Bei Alkoholgehalten von über 50 Mol % liess sich die Zusammensetzung der Innenlösung genauer durch Bestimmung des Wassergehaltes ermitteln. Für den Kationenaustauscher ergaben beide Methoden übereinstimmende Werte. Beim Anionenaustauscher hingegen erhielt man mit der Wasserbestimmungsmethode stets einen höheren Alkoholgehalt in der Innenlösung als bei jenen Versuchen, wo der Alkohol direkt bestimmt wurde. In den Tabellen ist das arithmetische Mittel von den nach beiden Methoden bestimmten Werten angegeben.

Die verwendeten Ionenaustauscher. Als Ionenaustauscher dienten der Kationenaustauscher Dowex 50 und der Anionenaustauscher Dowex 2. Aus den handelsüblichen Produkten wurde im lufttrockenen Zustand eine Fraktion von 0,2—0,4 mm Korndurchmesser herausgesiebt. Für die Untersuchungen mit schwach vernetzten Austauschern (1 % Divinylbenzen) wurden die vom Hersteller mit 0,15—0,30 mm Korndurchmesser gelieferten Austauscher Dowex 50 X1 und Dowex 2 X1 ohne weiteres Sieben verwendet. Alle Austauscher wurden in der üblichen Weise konditioniert [5] und in die entsprechenden Ionenformen übergeführt, an der Luft bei Zimmertemperatur getrocknet, und in diesem Zustand in dicht verschlossenen Gefässen verwahrt. Die Feuchtigkeit wurde durch Trocknen im Vakuum über Magnesiumperchlorat bei 50—60° C ermittelt. Konstantes Gewicht stellte sich nach drei bis vier Tagen ein. Die Kapazität der Austauscher wurde auf folgende Weise bestimmt. 1 g des Austauschers wurde in Wasser gequollen und in eine Austauschersäule von etwa 4 ml gefüllt. Durch 50 ml 3 M Salzsäure (für ClO_4^- - Anionenaustauscher 100 ml) wurde der Austauscher in die H^+- bzw. Cl^--Form übergeführt. Nach Auswaschen mit entionisiertem Wasser wurden die Wasserstoffionen des Kationenaustauschers mit 25 ml 1 M Natriumchloridlösung aus der Säule verdrängt und das Eluat mit 0,1 N Natronlauge titriert. Der in die Chloridform übergeführte Anionenaustauscher wurde mittels 3 M Natronlauge mit Hydroxylionen beladen und die letzteren nach Auswaschen mit entionisiertem Wasser mit einem Überschuss an 0,1 N Salzsäure aus der Säule verdrängt. Der Säureüberschuss im Eluat wurde dann mit 0,1 N Natronlauge zurücktitriert. In Tabelle 1 sind die gefundenen Werte für die Kapazität zusammengestellt, ausgedrückt in Milliäq. pro g Trockensubstanz in der entsprechenden Ionenform.

Tabelle 1. Kapazität der verwendeten Ionenaustauscher.

Austauscherharz	Kapazität Milliäq. / g Trockensubstanz
Dowex 50 Li^+	4,91
Na^+	4,50
K^+	4,34
Dowex 50 X1 Li^+	5,00
K^+	4,41
Dowex 2 ClO_4^-	2,27
Cl^-	2,71
SO_4^{2-}	2,60
Dowex 2 X1 ClO_4^-	3,03
SO_4^{2-}	3,58

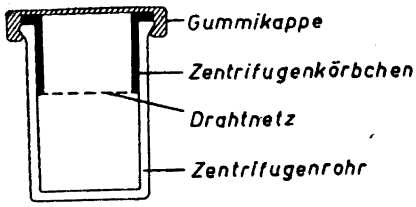

Abb. 1. Zentrifugenkörbchen im Zentrifugenrohr.

Einstellung des Gleichgewichtes. Etwa 1 g des an der Luft getrockneten Austauscherharzes samt 40 ml der alkoholischen Lösung wurden in ein 50 ml Reagenzglas eingeführt. Das Reagenzglas wurde dann mit einem Glasstopfen verschlossen und an einer sich langsam drehenden Scheibe befestigt. Ein Luftthermostat sorgte für die Konstanthaltung der Temperatur auf 25 ± 0,1° C. Alle Verteilungsversuche liefen mindestens 3 Tage. Innerhalb dieser Zeit stellte sich für alle Alkoholkonzentrationen das Gleichgewicht ein.

Die Abtrennung des Austauschers. Nach Einstellung des Gleichgewichts wurde das Reagenzglas von der Scheibe abgenommen und das Austauscherharz durch ein siebartiges Zentrifugenkörbchen aus rostfreiem Stahl (Abb. 1) von der Aussenlösung abfiltriert. Das Zentrifugenkörbchen befand sich dabei in einem kleinen Trichter, durch den die Aussenlösung in einen verschliessbaren Messkolben rann. Die Entleerung des Reagenzglases geschah mit einer besonderen Vorrichtung, um Konzentrationsänderungen wegen der Hygroskopizität bzw. Flüchtigkeit des Alkohols möglichst zu vermeiden. Das eine Ansatzrohr eines grossen Einweghahnes war mit einem Normalschliff versehen, sodass der Hahn anstelle des Glasstopfens auf das Reagenzglas aufgesetzt werden konnte. Der Innendurchmesser der Ansatzrohre betrug 1 cm. Das Reagenzglas mit aufgesetztem Hahn wurde nun umgedreht und senkrecht mit dem freien Ansatzrohr in das Zentrifugenkörbchen hineingehalten und der Hahn geöffnet. Auf diese Weise konnte der Austauscher in kürzester Zeit und beinahe quantitativ im Zentrifugenkörbchen aufgesammelt werden.

Als nächstes wurde die am Austauscher haftende Aussenlösung bei einer Umdrehungszahl entsprechend 600 g während 40 Min. abzentrifugiert. Abb. 1 zeigt das Körbchen im Zentrifugenrohr. Eine dichtschliessende Gummikappe verhinderte das Verdunsten des Alkohols. Um das Erwärmen der Zentrifuge zu vermeiden, blieb der Deckel während des Zentrifugierens offen. Die Temperaturerhöhung betrug dadurch nur 1° C. Nach dem Zentrifugieren wurde das Körbchen zum Wiegen in ein Wägeglas mit eingeschliffenem Stopfen gestellt. Der vom Austauscher verdunstende Alkohol kondensierte an den Glaswänden des Wägeglases und konnte nachher abgespült werden und ging somit der Analyse nicht verloren.

Die Reproduzierbarkeit der erhaltenen Werte für das Gewicht der Austauscherphase war zufriedenstellend. Bei 4 parallelen Zentrifugierungen betrug der mittlere Fehler 0,4 %.

In Vorversuchen wurde der Einfluss der Zentrifugierungszeit und der Umdrehungsgeschwindigkeit studiert. Ein in 73 Mol% Äthylalkohol gequollener Austauscher wurde verschieden lange bei bestimmten Umdrehungsgeschwindigkeiten zentrifugiert. Bei allen Umdrehungsgeschwindigkeiten fiel das Gewicht der Austauscherphase innerhalb der ersten 5 Min. stark ab. Bis zu 40 Min. wurde die Abnahme schwächer und über 40 Min. war diese proportional der Zentrifugierungszeit (1 % für die darauffolgende Stunde). Die letzte Gewichtsabnahme kann auf der langsamen Erwärmung der Zentrifuge beruhen. Als Zentrifugierungszeit wurden daher 40 Min. gewählt. Die Änderung der Umdrehungsgeschwindigkeit zeigte, dass das Gewicht der Innenlösung innerhalb des untersuchten Umdrehungsbereiches (300—1 000 g) mit der relativen Zentrifugalkraft linear abnahm. Die Gewichtsabnahme der Austauscherphase betrug 1 % zwischen 600 und 800 g.

Bestimmung des Äthylalkohols in der Innenlösung. Zur Bestimmung des Alkohols in der Innenlösung wurde der Austauscher mit destilliertem Wasser aus dem Zentrifugenkörbchen in einen Messkolben hineingespült und bis zur Marke aufgefüllt. Das Volumen des Messkolbens richtete sich nach der aufgenommenen Alkoholmenge und variierte zwischen 100 und 5 000 ml. Eine Verdünnung der Aussenlösung auf 100 ml kann schon

als genügend betrachtet werden. Unter diesen Bedingungen ist der Fehler, der von der ungleichmässigen Verteilung des Alkohols herrührt, sehr klein.

In dieser Lösung wurde der Äthylalkohol durch Oxydation mit schwefelsaurer Bichromatlösung bestimmt. Danach wurde das Austauscherharz quantitativ in einen gewogenen Glasfiltertiegel übergeführt und im Vakuum bei 50—60° C über Magnesiumperchlorat bis zum konstanten Gewicht getrocknet. Die Oxydation wurde nach den Methoden von Neish [6] und Nogare [7] mit kleinen Änderungen ausgeführt. In einen 200 ml Erlenmeyerkolben wurden 20 ml 0,04 N $K_2Cr_2O_7$, gelöst in 18 N H_2SO_4, und 10 ml der Probelösung eingeführt. Der Kolben wurde mit einem Gummistopfen schnell verschlossen und mehrere Male kräftig geschüttelt. Die Oxydation war nach 30 Min. beendet und der Inhalt des Kolbens wurde mit 100 ml destilliertem Wasser und 10 ml Kaliumjodidlösung (300 g/l) versetzt und schliesslich mit 0,05 N $Na_2S_2O_3$ aus einer 10 ml Bürette, die durch eine aufgeschmolzene 10 ml Pipette verlängert war, titriert. Ein Blindversuch unter denselben Bedingungen nur mit Wasser anstelle der Probelösung wurde ausgeführt. Aus der Differenz des Thiosulfatverbrauches errechnete sich der Alkoholgehalt unter Berücksichtigung, dass einem Mol Äthylalkohol vier Äquivalente $K_2Cr_2O_7$ entsprechen.

Bestimmung des Wassers. Die Bestimmung des Wassergehaltes der Aussenlösung erfolgte mit dem Reagenz nach Karl Fischer. In einem 25 ml Messkolben wurde eine bestimmte Menge der Aussenlösung entsprechend 75—150 mg Wasser eingewogen und mit wasserfreiem Methylalkohol bis zur Marke aufgefüllt. Davon gelangten 5 ml zu der von Johansson [8] modifizierten Wassergehaltsbestimmung.

Wie schon oben erwähnt, wurde bei hohen Alkoholgehalten die Innenlösung auf ihren Wassergehalt analysiert. Zu diesem Zwecke wurde nach dem Zentrifugieren das Zentrifugenkörbchen in einen besonders konstruierten Extraktor gestellt, der Austauscher unter Ausschluss der Luftfeuchtigkeit mit 25 ml wasserfreiem Methylalkohol eine Stunde extrahiert und darin das Wasser nach obiger Methode bestimmt.

RESULTATE UND DISKUSSION

Das ganze Versuchsmaterial ist in Tabelle 2 und Tabelle 3 zusammengestellt. Für jede Alkoholkonzentration der Aussenlösung, ausgedrückt durch den Molenbruch (x), sind die entsprechenden Werte der Innenlösung angegeben. Bei der Berechnung des Molenbruches der Innenlösung (x_r) wurde der Austauscher nicht berücksichtigt sondern nur Wasser und Alkohol. Ferner sind in den Tabellen die Quellung der Austauscher, ausgedrückt in g Innenlösung pro Äquivalent Austauscher, und die absoluten Mengen an Wasser bzw. Äthylalkohol in der Innenlösung, ausgedrückt in Mol pro Äquivalent Austauscher, wiedergegeben.

Die Quellung der Austauscher kann sowohl als Funktion der Alkoholkonzentration der Aussenlösung als auch der Innenlösung studiert werden. Um Zusammenhänge zwischen der Alkoholkonzentration und der Quellung näher zu betrachten, ist es zweckmässiger, die Alkoholkonzentration der Innenlösung als Vergleichsbasis zu wählen. Dies ermöglicht einen leichten Vergleich der Quellung bei verschiedenen Gegenionen, denn das Volumen der Innenlösung ist bei gleicher Alkoholkonzentration dem Gewicht proportional, wenn man von etwaigen Änderungen der partiellen Molvolumina durch die Gegenwart der betreffenden Ionen absieht.

Wie man aus Tabelle 2 sieht, nimmt für den normal vernetzten Kationenaustauscher das Gewicht der Innenlösung mit steigender Alkoholkonzentration ab. Die individuellen Eigenschaften der Gegenionen haben einen starken Einfluss auf die Quellung. Unabhängig davon, ob man die Quellung durch das Gewicht oder Volumen ausdrückt, nimmt diese mit dem Gegenion nach folgender Reihe ab: $Li^+ > Na^+ > K^+$.

Tabelle 2. Alkohol-Wasserverteilung und Quellung bei dem Kationenaustauscher Dowex 50.

Austauscherharz	x	x_r	Quellung Gramm / Äq. Austauscher	Mol H_2O / Äq. Austauscher	Mol C_2H_5OH / Äq. Austauscher

Die Quellung des normal vernetzten Anionenaustauschers weist für alle untersuchten Ionenformen ein Maximum auf (vgl.[1]). Dies ist besonders auffallend für die ClO_4^--Form, die auch, verglichen mit anderen Ionenformen, sehr wenig Lösung absorbiert. Bei niedriger Alkoholkonzentration ist die Quellung für die SO_4^{2-}-Form grösser als für die Cl^--Form. Bei höherer Alkoholkonzentration ergeben die Gegenionen bezüglich der Quellung folgende Reihe: $Cl^- > SO_4^{2-} > ClO_4^-$.

Für den Anionenaustauscher mit geringem Vernetzungsgrad zeigt die ClO_4^--Form sowohl in Wasser als auch in Alkohol eine geringere Quellung. Bei steigender Alkoholkonzentration durchläuft die Quellungskurve ebenfalls ein Maximum. Die SO_4^{2-}-Form desselben Austauschers quillt in Wasser mehr als der normal vernetzte. Mit steigender Alkoholkonzentration gleicht sich für Sulfat die Verschiedenheit in der Quellung aus, und bei höherer Alkoholkonzentration ist die Quellung auch hier kleiner als beim Anionenaustauscher mit normaler Vernetzung.

Als allgemeine Regel hat man bekanntlich gefunden, dass schwach vernetzte Austauscher mehr quellen als Austauscher mit dichterer Vernetzung [5]. Dies wurde dadurch erklärt, dass die Querbindungen die fortschreitende Quellung hindern. Aus den Versuchen mit Anionenaustauschern geht hervor,

dass bei der ClO_4^--Form entgegengesetzte Verhältnisse herrschen sowohl in Wasser als auch in Alkohol-Wasserlösungen. Auch die SO_4^{2-}-Form nimmt eine Ausnahmestellung ein, aber nur bei höherer Alkoholkonzentration. In Systemen, bei denen das Quellungsvermögen niedrig ist, können die Querbindungen im Harzskelett das Schrumpfen behindern. Den Molekülketten wird es somit erschwert, sich so dicht wie möglich zu packen. Weitere Versuche mit gut

definierten Ionenaustauschern und mit anderen Lösungsmittelsystemen sind wünschenswert, um die hierher gehörenden interessanten Erscheinungen näher zu klären.

In Abb. 2 und Abb. 3 sind die absoluten Mengen an Wasser bzw. Alkohol der Innenlösung, ausgedrückt in Mol pro Äquivalent Austauscher, gegen den Molenbruch des Alkohols der Innenlösung aufgetragen. Man erhält für jede Ionenform Kurven gleicher Art, wie es hier für den Kationenaustauscher gezeigt ist. Die Kurven für die Wassermengen fallen erst linear mit der Alkoholkonzentration ab, um dann langsam gegen Null abzuflachen. Für den Alkohol zeigen die Kurven einen umgekehrten Verlauf. Für die vom Austauscher aufgenommenen Wassermengen ergibt sich eine offensichtliche Parallelität mit der Hydratation der Gegenionen. Bei den Systemen Azeton-Wasser und Dioxan-Wasser erhielten Davies und Owen [9] den gleichen Kurventypus für die absorbierten Wassermengen. Es sei aber darauf aufmerksam gemacht, dass bei diesen Systemen die Kurve einen markanten Knick aufweist, während bei Äthylalkohol-Wasser die beiden Kurventeile allmählich ineinander übergehen. Die erwähnte Parallelität zwischen der Hydratation und der Wasserabsorption scheint daher nicht für eine quantitative Bestimmung der Hydratation geeignet zu sein.

Die ungleichmässige Verteilung des Alkohols zwischen Harzphase und Aussenlösung kommt am besten zum Ausdruck, wenn man die Versuchsresultate in Form von Verteilungskurven wiedergibt. Abb. 4 zeigt solche Verteilungskurven für den Kationenaustauscher in verschiedenen Ionenformen. Die Zusammensetzung ist durch den Molenbruch Äthylalkohol sowohl für die Aussenlösung (x) als auch für die Innenlösung (x_r) angegeben. Alle Kurven zeigen einen S-förmigen Verlauf und in allen Fällen ist der Alkoholgehalt in

der Harzphase kleiner als in der Aussenlösung. Die verschiedenen Gegenionen im Austauscher beeinflussen die Verteilung mehr oder weniger stark. Qualitativ können die erhaltenen Effekte durch einen Aussalzeffekt erklärt werden, d.h. die Ionen des Austauschers wirken auf den Alkohol aussalzend. Beim Kationenaustauscher nimmt der Aussalzeffekt in der Reihenfolge $Li^+ < K^+ < Na^+$ zu. Es sei darauf aufmerksam gemacht, dass sich ein grösserer Aussalzeffekt beim Natriumion bemerkbar macht im Vergleich zum Kaliumion, obwohl der Austauscher in der Na^+-Form mehr quillt als in der K^+-Form, oder mit anderen Worten, dass die Natriumionenkonzentration in der Harzphase kleiner ist. Zu dem geringen Aussalzeffekt bei Lithium trägt wahrscheinlich die Tatsache dazu bei, dass die Quellung hier grösser ist als bei Natrium und Kalium.

Versuche wurden auch ausgeführt mit dem schwach vernetzten Kationenaustauscher (Dowex 50 X1) in Li^+- und K^+-Form. Die Quellung war hier grösser als bei normalem Vernetzungsgrad und es zeigte sich auch eindeutig, dass der Aussalzeffekt kleiner war, was durch die niedrigere Ionenkonzentration in der Innenlösung erklärt werden kann. Da es sich als sehr schwierig erwies bei dem schwach vernetzten Kationenaustauscher reproduzierbare Resultate zu erhalten, wurden diese in den Tabellen nicht wiedergegeben.

Ein eindeutiger Zusammenhang zwischen dem Aussalzeffekt bei den verschiedenen Kationen und der Hydratation liegt in diesem Falle nicht vor. Von anderen Systemen ist es jedoch auch bekannt, dass das Lithiumion eine Ausnahme von den Alkalimetallen macht und dass die Salzeffekte in derselben Reihenfolge zunehmen, wie sie hier beim Kationenaustauscher beobachtet wurden [10].

In Abb. 5 sind die entsprechenden Kurven für den Anionenaustauscher in verschiedenen Ionenformen wiedergegeben. Die Kurven sind symmetrischer

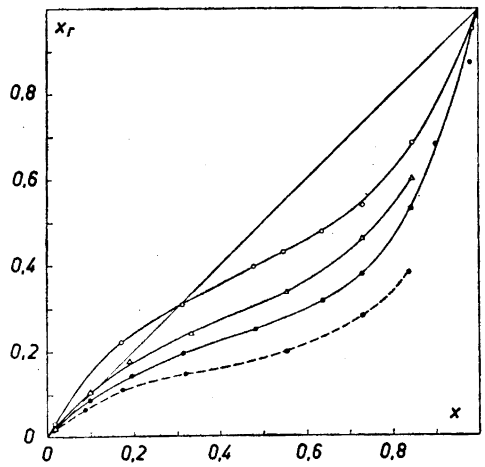

Abb. 5. Äthylalkohol-Wasserverteilungskurven für Dowex 2 (————) und Dowex 2 X1 (– – – –) in verschiedenen Ionenformen. Molenbruch für Äthylalkohol der Innenlösung x_r als Funktion des Molenbruches für Äthylalkohol der Aussenlösung x. Ionenform: O ClO_4^- △ Cl^- ● SO_4^{2-}

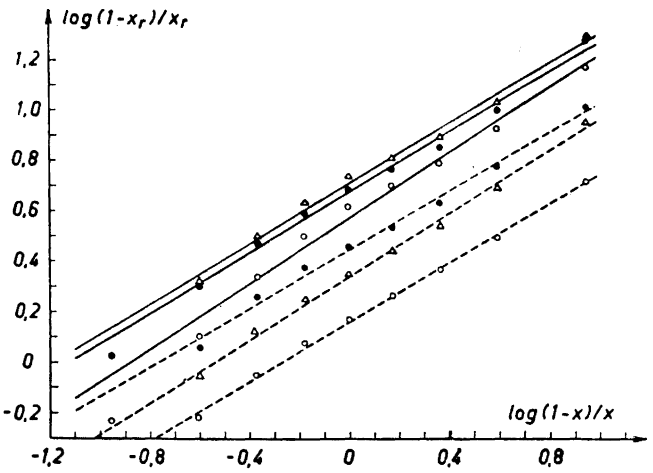

Abb. 6. log $(1-x_r)/x_r$ als Funktion von log $(1-x)/x$ für Dowex 50 (– – – –) und Dowex 2 (————) in verschiedenen Ionenformen.
Ionenform: ○ Li^+ ○ ClO_4^-
△ Na^+ △ Cl^-
● K^+ ● SO_4^{2-}

als beim Kationenaustauscher und unterscheiden sich in einer wichtigen Beziehung von den Kurven des Kationenaustauschers. Bei niedrigen Alkoholkonzentrationen schneiden nämlich die Kurven die Diagonale. Dies bedeutet, dass man bei niedrigen Alkoholkonzentrationen ein Einsalzen des Alkohols erhält, d.h., der Alkoholgehalt in der Innenlösung ist grösser als in der Aussenlösung. Besonders deutlich tritt diese Erscheinung bei der ClO_4^--Form zu Tage. Die Kurven für die verschiedenen Ionenformen schneiden einander nicht. Der Alkoholgehalt der Innenlösung nimmt im ganzen Konzentrationsbereich nach folgender Reihe ab: $ClO_4^- > Cl^- > SO_4^{2-}$. Innerhalb des Bereiches, wo ein Aussalzen stattfindet, steigt dieses also in der Reihenfolge $ClO_4^- < Cl^- < SO_4^{2-}$ an. In diesem Falle herrscht eine Parallelität zwischen der Alkohol-Wasserverteilung und der Hydratation der Ionen dahingehend, dass eine zunehmende Hydratation zu einer steigenden Wasserabsorption beiträgt (steigender Aussalzeffekt). Dies ist im allgemeinen der Fall, wenn es sich um das Aussalzen von Nichtelektrolyten handelt [10], aber, wie schon oben erwähnt, gibt es auch Ausnahmen von dieser Regel.

Wenn die Ionenkonzentration in der Harzphase geändert wird, ergibt sich für den Anionenaustauscher eine analoge Änderung des Aussalzeffektes wie beim Kationenaustauscher. Dies zeigen die Versuche mit der ClO_4^-- und SO_4^{2-}-Form. Da schwach vernetzte Anionenaustauscher bei höherer Alkoholkonzentration weniger quellen als die normal vernetzten und folgedessen die Ionenkonzentration grösser ist, wirken schwach vernetzte Anionenaustauscher auch stärker aussalzend für Äthylalkohol.

Bei den Versuchen, wo die Alkohol-Wasserverteilungskurven die Diagonale schneiden, haben die Austauscher ihr Quellungsmaximum bei der gleichen Alkoholkonzentration. Diese Erscheinung kann mit der azeotropen Destillation verglichen werden.

Es wurde versucht, eine einfache empirische Gleichung zu finden, die die erhaltenen Resultate bezüglich der Verteilung von Alkohol und Wasser wiedergeben kann. Zu diesem Zwecke wurden aus den in Abb. 4 und Abb. 5 wiedergegebenen Verteilungskurven für bestimmte x-Werte die entsprechenden x_r-Werte entnommen. In Abb. 6 sind $\log (1-x_r) / x_r$ gegen $\log (1-x) / x$ aufgetragen. Man erhält bis zu $x = 0{,}8$ eine lineare Beziehung. Somit gilt die Gleichung

$$\frac{1-x_r}{x_r} = k \left(\frac{1-x}{x} \right)^p \qquad (1)$$

in der k und p Parameter bedeuten.

Die beste Gerade innerhalb dieses Konzentrationsbereiches wurde nach der Methode der kleinsten Quadrate errechnet. In Tabelle 4 sind die gefundenen Parameter p und k zusammengestellt. Der Parameter p besitzt für alle Ionen fast den gleichen Wert. Als Mittelwert erhält man $p = 0{,}6$, welcher als charakteristischer Wert für das hier untersuchte System Äthylalkohol-Wasser angesehen werden kann. Daher wurde durch die aus den Verteilungskurven entnommenen Punkten für jede Ionenform die beste Gerade mit dem Winkelkoeffizienten 0,6 gelegt und der Parameter k berechnet. In Tabelle 4 sind auch die gefundenen Werte für k mit $p = 0{,}6$ zusammengestellt. Mit Hilfe obiger empirischer Gleichung und den zuletztgenannten Parametern wurden die Äthylalkohol-Wasserverteilungskurven berechnet und mit den experimentellen erhaltenen Kurven verglichen. Es zeigte sich, dass bis zu einem Molenbruch von 0,8 Äthylalkohol in der Aussenlösung die experimentellen und berechneten Kurven sehr gut übereinstimmen. Auf Grund der hier gemachten Beobachtungen, dürfte also Gleichung (1) dazu geeignet sein, die ganze Alkohol-Wasserverteilungskurve aus wenigen experimentellen Punkten berechnen zu können. Will man nur durch einen einzigen Versuch die Verteilungskurve bestimmen, so nimmt man $p = 0{,}6$ und für die Ermittlung des Parameters k wählt man am besten als Alkoholkonzentration der Aussenlösung $x = 0{,}5$.

Tabelle 4. Parameter für die Gleichung (1).

Austauscher	p	k	k für $p = 0{,}6$
Dowex 50 Li^+	0,647	3,68	3,89
Na^+	0,596	5,08	5,20
K^+	0,594	4,67	4,73
Dowex 2 ClO_4^-	0,582	1,44	1,44
Cl^-	0,621	2,18	2,24
SO_4^{2-}	0,578	2,78	2,82

In diesem Punkte gibt dann der Bruch $1-x_r / x_r$ direkt den Parameter k an. Gleichung (1) ist vom gleichen Typus, wie die Gleichung von Rothmund und Kornfeld [11], die sich als sehr verwendungsfähig erwies, um Ionenaustauschergleichgewichte quantitativ wiederzugeben. Es sei jedoch an dieser Stelle hervorgehoben, dass der Austausch von Ionen in äquivalenten Mengen erfolgt, während dies bei der Verteilung von Nichtelektrolyten nicht der Fall ist.

Wir danken dem *Schwedischen Technischen Forschungsrat* für die Bereitstellung von Mitteln.

Die Verteilung von Glukose bei Ionenaustauschern auf Harzbasis in Äthylalkohol-Wassergemischen

HEINZ RÜCKERT und OLOF SAMUELSON

Institut für Technische Chemie, Chalmers Technische Hochschule, Göteborg, Schweden

Die Sorption von Glukose an Ionenaustauscher aus Äthylalkohol-Wasserlösungen wurde für Kationenaustauscher und Anionenaustauscher studiert. Die vom Austauscher aufgenommene Glukosemenge ist sowohl von der Ionenform als auch der Alkoholkonzentration abhängig. Eine gewisse Parallelität zwischen der Verteilung von Äthylalkohol und Wasser und der Glukosesorption wurde festgestellt dahingehend, dass eine hohe Wasserkonzentration in der Austauscherphase eine hohe Glukosesorption begünstigt. Der direkte Salzeffekt der Ionen auf die Glukosemoleküle kann jedoch nicht vernachlässigt werden.

In einer früheren Arbeit [1] wurde gezeigt, dass Ionenaustauscher zur Sorption von Zuckerarten befähigt sind, wenn man als Lösungsmittel Äthylalkohol-Wassergemische verwendet. Die vom Austauscher aufgenommene Zuckermenge kann sehr beträchtlich sein. So werden z.B. von einem Kationenaustauscher in K^+-Form etwa 200 mg Glukose pro Gramm Austauscher aus 73 mol %iger Alkohollösung bei einer Gleichgewichtskonzentration von 10 g Glukose pro Liter aufgenommen. Diese ungleichmässige Verteilung ist in hohem Grade von der Kapazität des Austauschers und der Art der Gegenionen abhängig. Es konnte somit gezeigt werden, dass die Ionen direkt oder indirekt für die Zuckersorption verantwortlich sind. In der vorliegenden Arbeit wurden die Versuche mit Glukose auf andere Alkoholkonzentrationen ausgedehnt, um die Ursachen der Glukoseverteilung näher zu studieren.

EXPERIMENTELLER TEIL

Bezüglich der verwendeten Austauscherharze und des Arbeitsganges für die Bestimmung der Alkoholsorption sei auf eine Arbeit über die Verteilung von Wasser und Äthylalkohol bei Ionenaustauschern auf Harzbasis verwiesen [2]. Hier werden im folgenden nur die fehlenden und geänderten Bestimmungsmethoden, bedingt durch die Gegenwart der Glukose, behandelt. In der früheren Arbeit über die Zuckersorption wurde die vom Austauscher aufgenommene Zuckermenge durch die Konzentrationsänderung der Aussenlösung bestimmt. Bei den hier beschriebenen Versuchen sollte aber neben der Glukose

auch gleichzeitig der Alkohol in der Innenlösung bestimmt werden, was sich nur dann durchführen lässt, wenn sowohl die Aussenlösung als auch die Innenlösung für sich auf ihre Zusammensetzung analysiert werden. Aus diesem Grunde wurden die beiden Phasen durch Zentrifugieren von einander abgetrennt.

Bestimmung des Äthylalkohols in der Austauscherphase. Da bei der Alkoholbestimmung durch Oxydation mit schwefelsaurer Bichromatlösung auch Glukose oxydiert wird, musste der Alkohol durch Destillation von der Glukose getrennt werden. Zu diesem Zwecke wurde nach der Extraktion des Austauscherharzes mit Wasser 50 ml von dieser Lösung destilliert und das Destillat in einem 100 ml Messkolben aufgefangen. Die Destillationsapparatur wurde im Hinblick auf die geringen Alkoholmengen so klein wie möglich gehalten und bestand aus Normalschliffteilen. Bei allen Versuchen wurden 30 ml Destillat gesammelt, der Messkolben bis zur Marke mit Wasser aufgefüllt und der Alkohol darin bestimmt.

Bestimmung der Glukose in der Austauscherphase. Nach der Extraktion des Austauschers mit Wasser wurde die Glukose mit dem Anthronreagenz [3] colorimetrisch bestimmt.

Bestimmung der Glukose in der Aussenlösung. Eine gewogene Menge der Aussenlösung entsprechend 25—60 mg Glukose wurde auf dem Wasserbad eingedampft und der Rückstand in 20 ml destilliertem Wasser gelöst. Davon gelangten 10 ml zur Glukosebestimmung nach Schoorl [4]. Bei der hier verwendeten modifizierten Methode hat es sich als vorteilhaft erwiesen, zur jodometrischen Titration des Kupferüberschusses eine erheblich grössere Menge an Kaliumjodid zu nehmen, als die CCA-Methode vorschreibt. Der Endpunkt der Titration konnte wesentlich leichter erfasst werden, wenn für jede Titration etwa 10 g Kaliumjodid zugesetzt wurden [5]. Das Eindampfen der alkoholischen Glukoselösung war aus dem Grunde erforderlich, weil der Alkohol den Siedepunkt bei der Reduktion herabsetzte und somit die empirischen Umrechnungsfaktoren ungültig wurden. Ein separater Versuch zeigte, dass sich die Glukose durch das Eindampfen nicht zersetzte.

Einstellung des Gleichgewichtes. Die Einstellung des Gleichgewichtes für die Glukosesorption war sowohl von der Äthylalkoholkonzentration als auch von der Ionenform des Austauschers abhängig. Separate Untersuchungen haben ergeben, dass sich beim Lithiumion das Gleichgewicht bei allen Alkoholkonzentrationen schon innerhalb 50—100 Std. eingestellt hatte und ebenso für den Anionenaustauscher in den untersuchten Ionenformen. Beim Kaliumion hingegen wurde das Gleichgewicht bei 73 Mol % Äthylalkohol nach etwa 200 Std. erreicht. Alle Glukosesorptionsversuche liefen zur Sicherheit 500—1 000 Std.

RESULTATE UND DISKUSSION

Die Resultate der Glukoseverteilung bei verschiedenen Alkoholkonzentrationen sind in Tabelle 1 für den Kationenaustauscher und in Tabelle 2 für den Anionenaustauscher zusammengestellt. Für jede Alkoholkonzentration der Aussenlösung (x) sind die entsprechenden Werte für die Alkoholkonzentrationen der Innenlösung (x_r) angegeben. In die Berechnung des Molenbruches (x_r) wurden nur Alkohol, Wasser und Glukose einbezogen. Die Änderung von x_r mit der Glukosekonzentration lag innerhalb des experimentellen Fehlers. Daher ist für x_r nur jeweils der Mittelwert angegeben. Für jede Alkoholkonzentration wurde die Glukoseverteilung für mindestens zwei verschiedene Glukosekonzentrationen bestimmt. Die Glukosekonzentrationen der Aussen- und Innenlösung sind ebenfalls durch den Molenbruch (x_G bzw. x_{G_r}) ausgedrückt. Da der Molenbruch nur ein relatives Mass darstellt, eignet sich dieser sehr gut dafür, die Konzentration der Innenlösung unabhängig von der Quellung des Austauschers auszudrücken. Vom praktischen Standpunkt aus kann es jedoch von grösserem Interesse sein, ein absolutes Mass für die vom Austauscher aufgenommenen Glukosemengen zu haben. Daher sind auch die Werte für die pro Äquivalent Austauscher absorbierte Anzahl Mol Glukose tabelliert.

Tabelle 1. Glukoseverteilung bei dem Kationenaustauscher Dowex 50.

In Abb. 1 sind die von dem normal vernetzten Kationenaustauscher Dowex 50 in Li^+-Form aufgenommenen Glukosemengen gegen die Glukosekonzentration der Aussenlösung aufgetragen. Die einzelnen Geraden entsprechen verschiedenen Alkoholkonzentrationen der Aussenlösung. Man sieht, wie die Glukosesorption mit der Alkoholkonzentration kräftig ansteigt. Aus 90 mol %igem Äthylalkohol nimmt dieser Austauscher ungefähr das 20-fache an Glukose auf als aus wässeriger Lösung. Zum Vergleich sind die entsprechenden Kurven für die K^+-Form desselben Austauschers in Abb. 2 wiedergegeben. Auch hier findet man eine mit der Alkoholkonzentration steigende Glukosesorption, die bei allen Alkoholkonzentrationen grösser ist als für Lithium. Bei niedriger Alkoholkonzentration ist die aufgenommene Glukosemenge der Glukosekonzentration der Aussenlösung proportional, bei höheren Alkoholkonzentrationen sind die Kurven gebogen.

Über die Abhängigkeit der Glukosesorption sowohl von der Alkoholkonzentration als auch von der Ionenform des Austauschers gibt am besten der Verteilungskoeffizient K^* Auskunft. Der Verteilungskoeffizient ist durch die

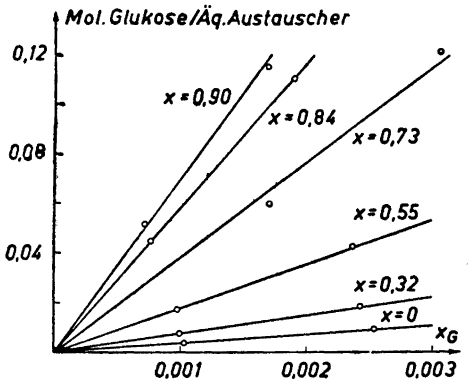

Abb. 1. Aufgenommene Glukosemenge in Mol Glukose/Äq. Austauscher als Funktion des Molenbruches für Glukose der Aussenlösung x_G bei verschiedenen Äthylalkoholkonzentrationen für Dowex 50 Li^+. Die Äthylalkoholkonzentration der Aussenlösung ist durch den Molenbruch x ausgedrückt.

Gleichung $K^* = x_{G_r}/x_G$ definiert. Innerhalb des untersuchten Konzentrationsbereiches ($x_G = 0 - 0{,}0025$) sind in den Fällen, wo die Sorption niedrig ist, die K^*-Werte von der Glukosekonzentration unabhängig. Bei hoher Sorption nehmen die K^*-Werte mit der Glukosekonzentration ab. Für die Versuchsreihen, bei denen K^* innerhalb der Grenzen des experimentellen Fehlers konstant ist, sind in den Tabellen die Mittelwerte für K^* angegeben, anderenfalls für jede Glukosekonzentration der entsprechende K^*-Wert.

Wie man aus den Tabellen ersieht, steigen die K^*-Werte mit der Alkoholkonzentration. Die Gegenionen lassen sich bezüglich ihres Einflusses auf den Verteilungskoeffizienten bei allen Alkoholkonzentrationen und jedem Austauscher in folgende Reihe für steigendes K^* einordnen: $Li^+ < Na^+ < K^+$ bzw. $ClO_4^- < Cl^- < SO_4^{2-}$. Es wurde versucht, K^* als Funktion der Alkoholkonzentration der Aussenlösung durch die empirische Gleichung

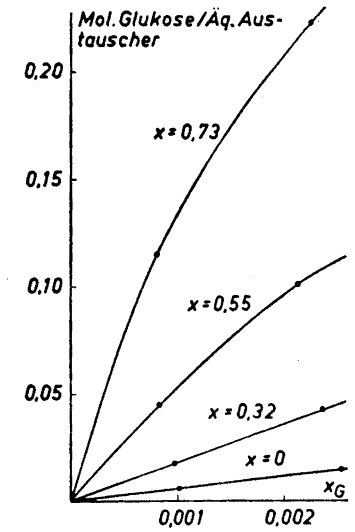

Abb. 2. Aufgenommene Glukosemenge in Mol Glukose/Äq. Austauscher als Funktion des Molenbruches für Glukose der Aussenlösung x_G bei verschiedenen Äthylalkoholkonzentrationen für Dowex 50 K^+. Die Äthylalkoholkonzentration der Aussenlösung ist durch den Molenbruch x ausgedrückt.

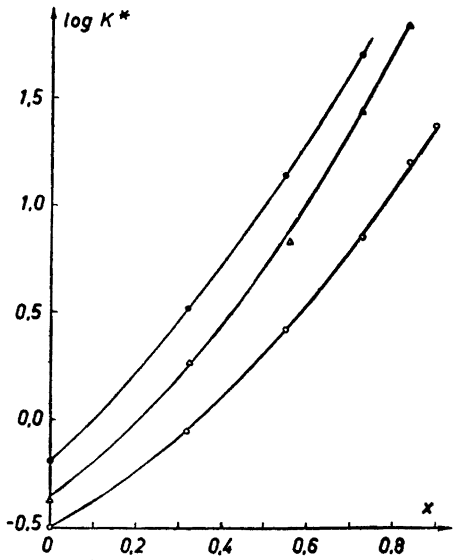

Abb. 3. log K^* als Funktion des Molenbruches für Äthylalkohol der Aussenlösung x für Dowex 50 in verschiedenen Ionenformen.
Ionenform: ○ Li^+, △ Na^+, ● K^+.

$$\log K^* = \log K^*_W + ax + bx^2$$

auszudrücken. In dieser Gleichung sind a und b empirische Konstante und K^*_W bedeutet die Verteilungskonstante in wässeriger Lösung. In Tabelle 3 sind die nach der Methode der kleinsten Quadrate berechneten Konstanten für den normal vernetzten Kationenaustauscher in Li^+-, Na^+- und K^+-Form zusammengestellt. Da, wie schon erwähnt, K^* auch von der Glukosekonzentration abhängig sein kann, wurden die Berechnungen für eine Glukosekonzentration der Aussenlösung von $x_G = 0{,}001$ durchgeführt. Abb. 3 zeigt den empirisch gefundenen Zusammenhang zwischen log K^* und x entsprechend obiger Gleichung mit den Konstanten aus Tabelle 3. Zum Vergleich sind auch in demselben Diagramm die experimentellen Punkte eingezeichnet.

In der Praxis wird man im allgemeinen daran interessiert sein, die pro Austauschereinheit aufgenommenen Glukosemengen berechnen zu können. Da diese auch von der Quellung des Austauschers abhängen, eignet sich obige empirische Gleichung nicht unmittelbar für so eine Berechnung. Die Quellung des Austauschers in Alkohol-Wassergemischen wurde in einer früheren Arbeit [2] behandelt, aus der die Summe der pro Äquivalent Austauscher aufgenommenen Mole Wasser und Alkohol zu entnehmen ist. Wenn zu der Innenlösung auch

Tabelle 3. Konstanten der Gleichung log $K^* = \log K^*_W + ax + bx^2$.

Austauscher	log K^*_W	a	b
Dowex 50 Li^+	−0,501	1,08	1,09
Na^+	−0,356	1,42	1,45
K^+	−0,196	1,91	0,96

die sorbierte Glukose hinzukommt, zeigte es sich, dass diese Summe innerhalb der Grenzen des experimentellen Fehlers unverändert blieb. Man kann also für die Glukosesorption mit hinreichender Genauigkeit die gleichen Quellungswerte wie für das System Äthylalkohol-Wasser verwenden. Mit Hilfe der K^*- und Quellungswerte lassen sich dann auch für jede Alkoholkonzentration die pro Austauschereinheit aufgenommenen Glukosemengen berechnen.

Bei hohen Alkoholkonzentrationen ($x = 0{,}84$ und $x = 0{,}90$) wurde für die K^+-Form das Gleichgewicht noch nicht nach 2 000 Std. erreicht und dasselbe ergab sich für die Na^+-Form bei $x = 0{,}90$. Diese Versuche sind daher auch nicht in den Tabellen verzeichnet. Die lange Dauer für die Einstellung des Gleichgewichtes bei hohen Alkoholkonzentrationen kann in der Schrumpfung des Austauschers seine Erklärung finden. Wenn der Austauscher mit zunehmendem Alkoholgehalt schrumpft, kann bei einer bestimmten Alkoholkonzentration die Maschenweite des Harzskelettes so eng werden, dass die im Verhältnis zu Alkohol und Wasser grossen Glukosemoleküle nur mehr schwer in den Austauscher eindringen können. Dieser beginnende Sperreffekt für Glukosemoleküle tritt für die K^+-Form bei einer Alkoholkonzentration in der Aussenlösung zwischen $x = 0{,}73$ und $x = 0{,}84$ ein. Untersuchungen über die Quellung in Äthylalkohol-Wassergemischen [2] zeigten, dass das Volumen der Na^+-Form bei $x = 0{,}9$ kleiner ist als das der K^+-Form bei $x = 0{,}73$. Der Sperreffekt ist also für die Na^+-Form bei etwa $x = 0{,}9$ zu erwarten, während die Li^+-Form auf Grund der grösseren Quellung bei allen Alkoholkonzentrationen zur ungehinderten Glukosesorption befähigt sein müsste.

Die ungleichmässige Verteilung von Alkohol und Wasser wurde qualitativ durch einen Aussalzeffekt bzw. Einsalzeffekt erklärt [2]. Die Verhältnisse bei der Glukoseverteilung werden dadurch noch komplizierter, weil hier nicht nur die Ionen sondern auch die Alkoholkonzentration die Verteilung beeinflussen. Man könnte sich als Grenzfall denken, dass die Ionen auf die Glukosemoleküle gar nicht einwirken und dass die Glukosesorption eine direkte Folge der ungleichmässigen Verteilung von Wasser und Alkohol zwischen der Aussen- und Innenlösung wäre. Da die Alkoholkonzentration in der Austauscherphase meistens kleiner ist als in der Aussenlösung und die Löslichkeit der Glukose mit steigender Alkoholkonzentration abnimmt, könnte man die Glukosesorption qualitativ als eine Verteilung zwischen zwei Phasen mit verschiedenen Lösungsmitteln erklären, d.h., die Glukose dringt vorzugsweise in die Phase mit dem besseren Lösungsmittel ein, also in die wasserreichere Innenlösung.

Auf Grund von Löslichkeitsbestimmungen für Glukose in Alkohol-Wassergemischen und der Verteilung von Alkohol und Wasser kann eine theoretische Glukoseverteilung berechnet werden. Hierbei wird also angenommen, dass die direkte Einwirkung der Ionen auf die Glukosemoleküle vernachlässigt werden kann. Ein Vergleich dieser berechneten Verteilung mit der experimentell gefundenen zeigte, dass eine solche Approximation unzulässig ist. Bedeutende Abweichungen ergaben sich und zwar in der Richtung, dass man bei niedriger Alkoholkonzentration einen deutlichen Aussalzeffekt für Glukose erhält und bei höherer Alkoholkonzentration statt dessen einen Einsalzeffekt. Der Aussalzeffekt im niedrigen Konzentrationsbereich kann übrigens direkt aus den Tabellen entnommen werden. Die Tatsache, dass in wässeriger Lösung Glukose ausgesalzt wird, ist schon früher bekannt [6].

Tabelle 4. Vergleich des Verteilungskoeffizienten für Glukose K^* mit der Alkoholkonzentration der Innenlösung x_r.

Austauscher	x_r	K^* bei $x = 0{,}73$ und $x_G = 0{,}001$
Dowex 50 Li^+	0,32	7,2
Na^+	0,24	27,5
K^+	0,25	50,8
Dowex 50 X1 Li^+	0,57	3,4
K^+	0,34	36,3
Dowex 2 ClO_4^-	0,53	1,1
Cl^-	0,44	8,2
SO_4^{2-}	0,35	31,2
Dowex 2 X1 ClO_4^-	0,43	1,3
SO_4^{2-}	0,25	46,3

Ohne irgend welche anderen theoretischen Berechnungen heranziehen zu müssen, kann man mit dem hier gesammelten experimentellen Material zeigen, dass die Wechselwirkung zwischen den Ionen und Glukosemolekülen nicht vernachlässigt werden kann. In Tabelle 4 sind die K^*-Werte für die untersuchten Austauscher bei einer konstanten Zusammensetzung der Aussenlösung [$x = 0{,}73$ und $x_G = 0{,}001$] zusammengestellt. Die Alkoholkonzentration der Innenlösung x_r ist dann für jeden Austauscher verschieden und ebenfalls in der Tabelle verzeichnet. Es soll nun die Alkoholkonzentration der Innenlösung mit K^* verglichen werden. Beim normal vernetzten Anionenaustauscher Dowex 2 findet man eine Parallelität zwischen dem Verteilungskoeffizienten und der Alkoholkonzentration. Wie erwartet steigt die Glukosesorption, wenn die Alkoholkonzentration der Innenlösung abnimmt, d.h. wenn das Lösungsmittel in der Harzphase für Glukose besser wird. Dasselbe ergibt sich für den schwach vernetzten Anionenaustauscher Dowex 2 X1. Vergleicht man diesen bei gleichem Gegenion mit dem normal vernetzten Anionenaustauscher, so nimmt hier auch die Glukosesorption mit fallendem Alkoholgehalt der Innenlösung zu. Für den Kationenaustauscher findet man ebenfalls eine gewisse Parallelität aber auch das Gegenteil. Die Alkoholkonzentration der Na^+-Form des normal vernetzten Kationenaustauschers ist z.B. niedriger als die der K^+-Form. Trotzdem wird von der Na^+-Form viel weniger Glukose aufgenommen als von der K^+-Form. Überhaupt lässt sich eine allgemeine Parallelität zwischen der Alkohol-Wasserverteilung und der Glukosesorption nicht aufstellen. Wenn diese Parallelität vorhanden wäre, müssten alle in Tabelle 4 angeführten Alkoholkonzentrationen die gleiche Reihenfolge für die entsprechenden Verteilungskonstanten geben, was aber nicht zutrifft. Dies zeigt deutlich, dass die Verschiedenheit der Alkoholkonzentration der Innen- und Aussenlösung eine zufriedenstellende Erklärung für die Glukosesorption nicht gibt, sondern dass man ebenfalls auf den Salzeffekt Rücksicht nehmen muss, der auf die Glukosemoleküle ausgeübt wird.

Wir danken dem *Schwedischen Naturwissenschaftlichen Forschungsrat* für die Bereitstellung von Mitteln.

Thermodynamic Dissociation Constants of 2,4-Dichlorophenoxyacetic Acid (2,4-D) and Some Related Plant Growth Regulators

MAGNUS MATELL* and SVEN LINDENFORS

Institute of Organic Chemistry, Royal Agricultural College, Uppsala, and Department of Organic Chemistry, University of Uppsala, Sweden

The dissociation constants of four substituted aryloxyacetic acids in water at 25° C have been determined by the conductivity method. The acids belong to the group of plant growth regulators.

The biological activity of weak acids and bases is strongly influenced by the pH of the medium in which the activity is measured. In many cases it has been found that the activity of weak acids is independent of the acidity at pH levels below pK but decreases rapidly when the pH is raised above pK [1]. The aryloxyacetic acids, to which 2,4-D, 2,4,5-T and MCPA belong, is an important type of biologically active, weak acids for which similar relations have been found. It has been assumed that only the undissociated molecule is active in bringing about a physiological response [2]. This view is supported by the fact that undissociated organic acids appear to penetrate the plasma membranes more easily than their anions [3]. In contrast to this some cases have been reported where the physiological response appeared to be determined by the concentration of the anion [4,5].

In spite of these conflicting conclusions it is obvious that the degree of dissociation is of great importance for the growth regulating properties of weak acids. For a quantitative discussion of the influence of pH on the activity of 2,4-D and related growth regulators, the dissociation constants must be known with some accuracy. An examination of the literature has displayed that several determinations of dissociation constants of these compounds have been carried out (Table 1). Most of these refer to classical dissociation constants calculated from the pH of aqueous solutions of the acids, free or neutralized to 50 %. Such methods are only approximate, especially when the solubility of the acid investigated is small. Thus the discrepancies between values given by different authors are not surprising.

* Present address: Research Laboratory, Mo & Domsjö AB, Örnsköldsvik, Sweden.

Because of this need for more dependable data we have calculated thermodynamic dissociation constants from conductivity measurements of the phenoxyacetic acids recorded in Table 1.

Table 1.

		11.4	»	13
		12.0	»	14
	12.8—13.2	12.6	»	This investig.

The measurements were performed with a conductivity bridge, built according to the principles of Jones and Josephs [15]. The acids examined are rather strong and therefore the limiting conductivity at infinite dilution was not determined by the sodium salt method but from the conductivity of the aqueous acid solutions by the extrapolation method of Fuoss [16].

In order to test the bridge and the procedure, the dissociation constant of 2-chlorobenzoic acid was determined too. As seen from Table 1 the result is in fairly good agreement with data obtained from the literature.

The phenoxyacetic acids now studied, are rather strong, and their dissociation constants do not differ very much. This is a general feature of substituted phenoxyacetic acids as pointed out by Hayes and Branch [7]. The unusual strength is probably due to resonance structures of type I. In the phenoxyacetic acids there is no conjugation between the carboxylic group and the aromatic nucleus. Consequently, substituents will not affect the carboxyl group to the same extent as in the benzoic acids with resonance structures of type II.

I II

It was found by Hayes and Branch that the strength of phenoxyacetic acid was decreased by a methyl group in the nucleus but increased by a chlorine

atom [7]. These rules were derived for monosubstituted acids but they seem to be valid also for the acids investigated here. However, the material is too small to permit a general statement.

EXPERIMENTAL

Materials. 2-Chlorobenzoic acid, recrystallized three times from conductivity water, m. p. 140—141°.

4-Chlorophenoxyacetic acid, recrystallized twice from conductivity water, m. p. 157.2 —157.9°.

2-Methyl-4-chlorophenoxyacetic acid, recrystallized three times from toluene, m. p. 119.0—119.8°.

2,4-Dichlorophenoxyacetic acid, recrystallized once from formic acid and twice from toluene, m. p. 139.0—139.8°.

2,4,5-Trichlorophenoxyacetic acid, recrystallized once from formic acid, once from toluene and twice from benzene, m. p. 155.0—155.8°.

Potassium chloride (p. a.), recrystallized twice from conductivity water and fused in a platinum dish.

Melting points (corrected) were determined with a hot stage microscope. The conductivity water, which had a specific conductance of $0.8—0.9 \times 10^{-6}$ ohm^{-1} cm^{-1}, was obtained by aeration of the distillate from a two-stage, all quartz still.

Conductivity measurements. The bridge network was based essentially on the bridge described by Jones and Josephs [15]. The ratio arms of the bridge were two equal, 1 000 Ω, low-inductance resistances. The variable resistance was a calibrated, low-inductance, five-decade box of total resistance 11 111 Ω, with a variable resistance, adjustable to 0.001 Ω (Leeds and Northrup, Cat. No. 43 256). The capacitances in the bridge were as follows: a variable capacitance (0—500 pF) across earth and either end of the bridge, a capacitance (200 pF) across the conductivity cell, two capacitances (500 pF, 1 000 pF) and a variable capacitance (0—500 pF) across the decade box. The detector was a high-resistance (2 000 ohms) telephone without amplifier. The earphone was covered with sheetmetal, connected to earth. The oscillator was an audion tube oscillator giving 4 V at 1 000 cycles per sec (Philips type GM 4260). The conductivity cells, of the type described by Jones *et al.*[17], had greyed platinum electrodes. During measurements the cells were immersed in a thermostat filled with oil and controlled within 0.005 °C. The whole assembly was placed in a constant temperature room at 20.0 ± 0.1 °C.

One of the conductivity cells was directly calibrated against M/100 potassium chloride solution, using the conductance data of Jones and Bradshaw [18]. This cell (constant 1.315) was used for calibration of the other (constant 0.3483).

The conductance at 25 °C of the pure acids dissolved in conductivity water was measured at different concentrations in the range 0.0003—0.003 M. The conductance of the acid solutions was not corrected for water conductance. All solutions were prepared by weighing and the weighings were corrected to *vacuo*.

The results of the conductivity measurements are found in Tables 2—6. The following symbols are used.

C	total concentration of acid
Λ_0	equivalent conductance at infinite dilution
Λc	equivalent conductance at concentration C
K_0	thermodynamic dissociation constant
K	classical dissociation constant.

Mercury(II) Halide Mixed Complexes in Solution

I. The Experimental Method and the Distribution of the Neutral Complex

Y. MARCUS*

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Experimental details are described for a study of the formation of mixed mercury(II) halide complexes. The distribution coefficients log λ° of HgX_2 between benzene and water, obtained both directly and from the solubilities, are: $HgCl_2$ — 1.06 ± 0.01; $HgBr_2$ 0.05±0.01; HgI_2 1.66 ± 0.01. The coefficients for benzene — 0.5 M perchlorate ionic medium were also obtained. The solubilities of HgX_2 in benzene are: $HgCl_2$ (1.92±0.01) × 10^{-2} M; $HgBr_2$ (1.90 ± 0.01) × 10^{-3} M; HgI_2 (4.78 ± 0.05) × 10^{-3} M. Literature values for the solubilities and the distribution coefficients are reviewed. The salting-out effect of up to 2 M $NaClO_4$ on HgX_2 was studied, and the same salting-out coefficient k_c = 0.14 was found for all three halides. This value agrees with McDevit and Long's compression theory, although equations of other authors also fit the data.

1. INTRODUCTION

The careful study of metal complex formation in solution has mainly been confined, until recently, to systems of one metal and one ligand, which we shall call binary systems. Although practically no systematic investigation of complex systems between a metal and two ligands — which might be called ternary systems — has taken place, such cases have already been mentioned in passing, and sometimes complexity constants have been assigned to them. For instance Lister and Rivington [1] report the species $FeClCNS^+$, $FeBrCNS^+$, $FeCl_2CNS$ and $FeSO_4CNS$, while Newman [2] in his recent thesis studied complexes of the type $BiCl_nBr_{5-n}^{2-}$.

It was felt that a more systematic work on ternary systems was desirable, in particular in order to find whether their formation obeys the statistical rules or is favoured or obstructed by the intra-molecular forces.

A convenient system to study was found in the mercury(II) halide complexes. These have been thoroughly studied before [3], and accurate constants for the binary complexes are available. Furthermore, a convenient method of

* Permanent address: Israel Atomic Energy Commission, Hakiryah, Tel-Aviv, Israel.

solvent distribution can be applied to the system, which has the advantage that the distribution of one of the mixed complexes, the neutral one, may be studied almost directly (part III).

a) Plan of work

The experimental study of mixed halide complexes of mercury included also a restudy of the binary complexes, the data for which are important in subsequent calculations. First the distribution of the neutral complex (*e. g.* $HgCl_2$) was studied, in the range of concentrations where it is stable, and its distribution coefficient was determined for all the halide ligands as a function of the ionic medium concentration (part I). The stepwise complexity constants of the binary complexes were then studied under the same conditions as formerly applied [3], in order to check the constants against the earlier potentiometric values (part II). Later, mixed complexes were considered, where the ligand number is two, *i. e.* only the neutral species exist. Two such binary complexes (*e. g.* $HgCl_2$ and $HgBr_2$) may interact to give a ternary one ($HgClBr$) (part III). In the next paper the system mercury(II)-bromide-iodide is completely worked out, by both central group (Hg) and ligand (I) solvent distribution methods. The latter, incidentally, does not seem to have been used before (part IV). Finally, a literature survey of mixed complex formation is presented and commented on, and the question of ternary complex formation is discussed against the background of complex formation in general (part V).

b) Symbols

The following symbols apply in all the papers of this series:

A, B	two different ligands, for instance two halide ions, where B applies to the heavier of the two.
A, B	analytical (total) concentrations of A and B present in both the phases.
a, b	concentrations of free A and B in the aqueous phase.
D	gross distribution of M between the organic solvent and the aqueous solution, *i. e.* the ratio of concentrations, organic to aqueous, for equal volumes of the phases. (In part IV it denotes also distribution of B in the section devoted to it.)
i, j	indices, integers or zero (for mercury always $i + j \leq 4$). i usually applies to A, j to B.
K	disproportionation constant, for $M + MX_2 \rightleftharpoons 2\ MX$ in part II, and for $MA_2 + MB_2 \rightleftharpoons 2\ MAB$ in part III.
k_n	successive equilibrium constant for $MX_{n-1} + X \rightleftharpoons MX_n$.
$k_{i,j}$	equilibrium constant for $MA_{i-1}B_j + A \rightleftharpoons MA_iB_j$.
$k_{i',j}$	equilibrium constant for $M_iAB_{j-1} + B \rightleftharpoons MA_iB_j$.
M	complex-forming central group, for instance Hg^{2+}.
M	analytical (total) concentration of M present in both phases.
m	concentration of free M in the aqueous phase.
$\bar{n}$	ligand number for the binary complexes M—X.
$\bar{n}_{A,B}$	total ligand number for the ternary system M—A—B (*i. e.* the sum $\bar{n}_A + \bar{n}_B$).
$)_{or}$	subscript, the organic solvent phase (no subscript — the aqueous phase).
R	ratio B/A.
r	ratio b/a.
$s_{solvent}$	molar solubility in solvent stated.
u	concentration $[MA_2]$ in part IV.
X	general ligand, for instance halide.
X	analytical (total) concentration of X in both phases.

x concentration of free X in the aqueous phase.
$\beta_{i,j}$ overall complexity constant for $M + iA + jB \rightleftharpoons MA_iB_j$.
β_n overall complexity constant for $M + nX \rightleftharpoons MX_n$.
λ distribution coefficient of MX_2 between organic solvent and aqueous solution.
λ^0 distribution coefficient at zero ionic medium concentration (*i. e.* distribution benzene — pure water).
$\lambda_{i,j}$ distribution coefficient of MA_iB_j $(i + j = 2)$.
[ ] molar concentration of the species within the brackets.

Further symbols may be introduced and defined for occasional use in the appropriate places.

Charges are omitted in the mathematical equations and in reactions generally.

Concentrations and constants are given on the molar (moles per liter solution) scale, denoted by M.

2. EXPERIMENTAL METHOD

The description in this section applies to all the papers in this series (parts I—V).

a) Conditions of study

The complexes were studied in aqueous solutions of 0.50 M (ClO_4^- + X^-) *ionic medium*, which was made up from 0.010 M hydrogen ions, M M mercury(II) ions, 0.490—2M M sodium ions, $A + B$ M halide and 0.500—$(A+B)$ M perchlorate. The function of the hydrogen ions was to repress hydrolysis, although this was actually unnecessary, since the complexing by halide is very strong. Nevertheless, this acidity was retained so that the conditions would be the same as in the earlier potentiometric study [3].

The *temperature* of equilibration was kept fixed at 25.0 ± 0.2 °C, again the same as in the earlier study. This was achieved by equilibrating the solutions in a thermostated room.

The *method* of study consisted of measuring the gross distribution of the central group (mercury), or of a ligand (iodine), between an organic solvent phase (benzene) and the immiscible aqueous solution described above, by measuring the distribution of the radioactivity of ^{203}Hg or ^{131}I. The amount of benzene introduced into the ionic medium (0.036 mole %, calculated from McDevit and Long's data [4]) is quite negligible.

b) Materials

The *sodium perchlorate* used for the ionic medium was made by neutralizing perchloric acid with sodium carbonate to the extent of 98 %, boiling off the carbon dioxide, and making up to volume with distilled water. Sometimes a slight adjustment of acidity to exactly 0.010 ± 0.001 M was made after titration. The perchlorate concentration was checked by passing the solution through a cation exchange column in the hydrogen form and titrating the total acid. It always corresponded to 0.500 ± 0.005 M. The solution was checked from time to time for presence of halide, but always with negative results.

Stock solutions of *sodium halides* were prepared, about 0.49 M in halide and 0.010 M in perchloric acid, except the iodide, which was kept neutral in concentrated solutions, and was acidified only when [I] was below 0.001 M. The halide concentration was measured by Volhard titration of the stock solutions.

A 0.0440 M *mercury(II) perchlorate* stock solution was prepared by dissolving mercury(II) oxide in a calculated amount of perchloric acid, so that after dilution by sodium perchlorate solution and water the final acidity would be 0.010 M, and the final perchlorate concentration 0.50 M. The mercury(II) oxide, in its turn, was prepared by precipitation

from mercury(II) sulphate solution by sodium hydroxide, filtration and thorough washing. The mercury concentration was measured by titration with standard thiocyanate.

Benzene was equilibrated with sodium perchlorate ionic medium prior to use. The benzene then contained 0.26 mole % water [5], but only 0.01 % material not volatile at 5° C. Apart from the water, the only species which benzene extracts from the aqueous solutions seems to be the neutral mercury halides.

Radioactive mercury(II) oxide, containing the ^{203}Hg isotope (half-life 47.9 days, the characteristic radiation being 0.21 MeV β-rays and 0.28 MeV γ-rays) was obtained from A.E.R.E., Harwell, England, and was used after the decay of the 65 hour ^{197}Hg produced together with it. It was "specpure" and had an activity of about 26 mC/g. A weighed amount of it was dissolved in the minimum amount of 1.0 M perchloric acid and diluted with sodium perchlorate solution to a known volume. The stock solution was 0.00117 M in mercury.

A *radioactive* carrier-free *iodide* solution containing the ^{131}I isotope (half-life 8.0 days, characteristic radiation 0.61 MeV β-rays and 0.36 MeV γ-rays) was obtained from J.E.N. E.R., Kjeller, Norway. Its activity was initially 2 mC/ml, it contained less than 1 μg/ml iodide and less than 0.05 M reducing substances. It was added to known amounts of iodide solution before use, giving a negligible contribution to the total iodine concentration, and diluting the solutions by no more than 1 %, for which, however, no correction was made.

All the *reagents* used were of analytical quality grade, in particular the benzene was thiophene-free, according to the A.C.S. standard.

c) Equilibration and radioactive assay

Equilibration of the phases was effected by shaking together equal volumes (10.00 $\pm$ 0.05 ml) of aqueous solution and benzene in 40 ml glass stoppered bottles by a mechanical shaker rotating at 24 r.p.m.

The time of contact was in the large majority of cases 17 $\pm$ 1 h (overnight). In a few instances it was as short as 5 $\pm$ 1 h or as long as 43 $\pm$ 1 h. A number of experiments were made to determine the time needed for equilibrium to be reached. A small difference was sometimes found between the distribution values for 0.5 h and 1.5 h, but the latter value agreed with those for 5, 17 and 42 h, within the experimental errors.

When the shaking ended the phases separated cleanly, and were pipetted each in its turn up to a fixed height into the G.-M. tube. This was a "20th Century Electronics" M6 concentric-tubes liquid counter, containing about 9.5 ml. All measurements of radioactivity were relative, *i. e.* only ratios were obtained (usually between the activities in the two phases, in part III also between stock solutions of mercury(II) halides in benzene). Moreover, the activities making up the ratio were measured on the same day, so that no correction for decay was necessary.

Since there is a difference between the absorption of radioactive rays in the benzene and aqueous solutions, a correction must be applied. From radioactivity balance it was found that the value for the activity of Hg in benzene must be multiplied by 0.89 and that of I by 0.85 to make them comparable with those in aqueous solutions. In practice, 0.050 log units were subtracted from the log D values for radioactive Hg, and 0.070 log units for I.

d) Representation of results and errors

Primary data will usually appear as graphs of log D *vs* a suitable variable. Sometimes, however, they will appear in tabular form.

The experimental errors may be divided into two groups: analytical and volumetric errors on the one hand and counting errors on the other. Results of titrations are usually accurate to within $\pm$0.7 %. The error in the relative volumes of the phases might have come to $\pm$1.0 %. The errors in the counting varied, as it was necessary sometimes to count values not much above the

background. Usually the statistical error was within ±1.5 %, and thus the total error of an individual determination was about ±2.5 % or 0.010 log units in log *D*. The reproducibility was quite good, even experiments made several months apart with different stock solutions usually showed results not deviating by more than the sum of the experimental errors.

In the calculation of the equilibrium constants from the data, such limits of error were assigned to them, that at least 90 % of the experimental points fell between curves calculated with the extreme values of the constants.

3. THE DISTRIBUTION COEFFICIENTS

a) Experimental results

The distribution of mercury(II) halides between an organic and an aqueous phase was studied by two approaches. One was to measure the distribution directly, at very low mercury concentrations — of the order of 10^{-5} M—using radioactive mercury. The other approach was to measure the solubility of the mercury halide in each phase separately, and to take the ratio as representing the distribution coefficient, according to Nernst's law. This is permissible, provided there is only negligible intersolubility of the phases and no association, dissociation or solvation of the solute occurs. This seems to be the case with the mercury(II) halides (except for $HgCl_2$, see discusssion below).

The solubility of HgX_2 in water saturated benzene was measured by shaking excess HgX_2 with the benzene in a thermostated room at 25.0 ± 0.2°C for 42 h, allowing the solid to settle for half an hour, taking an aliquot with a calibrated pipette from the clear supernatant liquid, evaporating the benzene at room temperature in a current of air and weighing the residue. In separate experiments it was checked that no HgX_2 volatilized with the benzene by the above procedure.

The values of the benzene solubility of the mercury(II) halides $s_{C_6H_6}$ are given in Table 1 and also in Table 2.

Distribution coefficients were calculated as the ratio of the benzene solubility to the aqueous solubility, using the average of the values that are not in parenthesis in Table 2. (Column "Solubility" in Table 1).

Table 1. Experimental distribution coefficients of mercury(II) halides, log λ.

Molar Solubility $s_{C_6H_6}$	"Solubility" log λ°	Distribution coefficients "Direct determination" log λ°	"Direct determination" log λ	"Extrapolation" log λ
$HgCl_2$ $(1.92\pm0.01)10^{-2}$	$\left\{\begin{matrix}(-1.142\ \ )\text{a)}\\ -1.084\pm0.003\end{matrix}\right\}$	-1.057 ± 0.007	-0.965 ± 0.010	-0.960 ± 0.015

Table 2 (Contd.)

a) Extrapolated to zero concentration.
b) From ratio of solubilities.
c) Interpolated, though with little accuracy, from values at several temperatures between 6.5° and 54°.
d) Additional, less reliable, values are: Benrath [31] −0.59, and Benrath and Ammer [32] −0.58.
e) Extrapolated linearily from values at 15°: −2.37 and at 23°: −2.32.
f) The authors give a critical discussion on the solubility of HgI_2 in water, and also a value for the solubility in the 0.50 M $NaClO_4$ ionic medium: -4.13 ± 0.02.
g) Brown's values apply to 24°.
h) Author gives solubility as 0.00218 n, but, apparently this should read M.
i) A misquotation, *via* Comey and Hahn's "Dictionary" [33] value of 0.0063 g/100 g solution, which is Grossmann's value.
j) This is the value obtained experimentally by Tananaev and Pilipenko, but with only 10 minutes' shaking. Garrett [21] misquoted them, the value he reports in their name is what they think is Sherrill's figure, and actually is Morse's.

The column "Direct determination" in Table 1 gives the values found by determination of the distribution of HgX_2 between benzene and water (λ^0), and between benzene and 0.50 M sodium perchlorate ionic medium λ, starting with a benzene solution of HgX_2 to ensure having only the neutral complex.

Finally, the column "Extrapolation" gives the values found by extrapolation of distribution data of HgX_2 between benzene and excess halide X^- in the ionic medium (described in detail in part II) to zero excess halide.

In addition, a few experiments were made to see if $Hg(CNS)_2$ could also be extracted by benzene. Owing to the extremely small solubility in benzene, the distribution coefficient between benzene and the ionic medium could be obtained only very roughly. The best estimates are $\log \lambda = -2.2 \pm 0.1$. The values for solutions where excess thiocyanate was present also extrapolate roughly to the same value:

$[CNS^-]$ M:	0.015	0.019	0.027
log D:	-2.4 ± 0.2	-2.4 ± 0.2	-2.5 ± 0.3

The aqueous solubility of $Hg(CNS)_2$ does not seem to have been determined since 1905 (see Table 2), and no experimental details were given for the reported figures. The solubility was therefore determined anew. Mercury(II) thiocyanate was precipitated from a solution of radioactive mercury, and the precipitate washed well with water and dried. A portion of 0.360 g was weighed out and dissolved in 25.00 ml 0.1 M NaCNS solution, which became thus 0.00454 M in mercury, and its activity a_0 was counted. Water and 0.50 M $NaClO_4$ ionic medium were then shaken for 72 h at 25° with excess radioactive mercury(II) thiocyanate, and the activities a_w and a_m of the filtered solutions determined. The concentrations (*i. e.* solubilities) are then $a_w a_0^{-1}$ 0.00454 and $a_m a_0^{-1}$ 0.00454 M, respectively. The averages of two determinations are:

water solubility:	$(2.20 \pm 0.03)10^{-3}$ M and
ionic medium solubility:	$(1.34 \pm 0.03)10^{-3}$ M.

From the ionic medium solubility and the coefficient log $\lambda = -2.2 \pm 0.1$, the benzene solubility log $s_{C_6H_6} = -5.1 \pm 0.1$ was calculated, and from the latter and the water solubility, the coefficient log $\lambda^\circ = -2.5 \pm 0.1$ was obtained.

b) Previous results

Literature values, which are mostly rather old and sometimes conflicting, are summarized in Table 2.

c) Discussion

Table 1 shows very good agreement between log λ and log λ° values found by two different methods. Of the two values of log λ° reported for $HgCl_2$ in column 3, —1.142 is the value obtained directly from the solubilities. This value must be corrected for dimerization. According to Linhart [6a] $[Hg_2Cl_4] = 0.3\,[HgCl_2]^2$. If this is correct, then in a saturated solution (total concentration of mercury chloride 0.265 M), there is 0.233 M free $HgCl_2$ and 0.016 M Hg_2Cl_4. The same equilibrium constant applies also to the benzene phase, according to Linhart, but because of the low solubility the necessary correction is negligible. If now the corrected water solubility of $HgCl_2$ is used, the value log $\lambda^\circ = -1.084$ is obtained, which is nearer to the value obtained from the distribution. Moreover, as will be shown below, the salting out effect on the distribution is independent of the particular halide used, so that there is a constant difference of (approximately) 0.11 log units between log λ for 0.50 M $NaClO_4$ ionic medium and log λ° (this may be seen also in Table 1). If 0.11 is subtracted from the average log λ for $HgCl_2$ in Table 1, the value —1.07 is obtained, agreeing with the value obtained from the distribution and the corrected solubility.

The values found in this work may now be compared with those reported in literature (Table 2). Regarding the aqueous solubility of $HgCl_2$, an average value of the more modern figures, log $s_{H_2O} = -0.575 \pm 0.002$ might be a fair approximation to the truth. Very good agreement is observed among the various determinations of the aqueous solubility of $HgBr_2$. Of the two groups of values for the aqueous solubility of HgI_2, the more recent one (DeBruijn and Sillén and Biedermann), combined with the benzene solubility gives a distribution coefficient log λ° about 1.68, in agreement with the directly determined value 1.66, and therefore seems to be better than the older one, yielding a coefficient of only 1.58. The aqueous solubility of $Hg(CNS)_2$ is seen to be in very good agreement with the previously reported values.

Considering the benzene solubilities, there seems to be good agreement with the few reported values, apart from $HgCl_2$, where the reported data are conflicting. The directly determined distribution coefficients of $HgCl_2$ (Linhart [6]) and $HgBr_2$ (Sherrill [7]) are quite near those obtained in this work. The salting-out of HgI_2 by 0.50 M $NaClO_4$ observed by Sillén and Biedermann [27] — a difference of 0.15 ± 0.03 log units in the solubilities — is quite near the value obtained here, 0.11 ± 0.01 log units.

4. EFFECT OF IONIC MEDIUM CONCENTRATION

a) Experimental results

The effect of the sodium perchlorate ionic medium on the distribution was studied further. Experiments were made where the distribution was measured as function of the ionic medium concentration, called C below, up to 2 M. All solutions more concentrated than 0.01 M contained 0.01 M perchloric acid, the remainder being sodium perchlorate, while more dilute solutions contained only perchloric acid. The data are summarized in Fig. 1 as plots of log λ—log λ° *vs* C.

As may be seen in Fig. 1, the values for all three halides lie on a single curve, with only slight random deviations.

b) Discussion

Many approaches have been proposed to describe and explain the salting-out effect, but none has found complete quantitative success. (See Ref.[34] for a modern review.) Empirically, salting-out data may be described by the Setchenov equation:

$$\log \lambda - \log \lambda^\circ = \log f_c = k_c C \qquad (1)$$

where f_c is the activity coefficient of the non-electrolyte in the ionic medium of concentration C and k_c is the salting-out constant, and where all the symbols refer to a very dilute solution of the non-electrolyte.

When eqn. (1) is applied to the data in Fig. 1, it is seen that it described them well at the lower concentrations, with the parameter $k_c = 0.14$. However, at concentrations C above about 1.5 M a curvature upwards occurs.

Various non-linear equations have been proposed to account for this. The simplest empirical one is due to Morrison [35]:

$$\log \lambda - \log \lambda^\circ = \log f_c = k_c C^{k_p} \qquad (2)$$

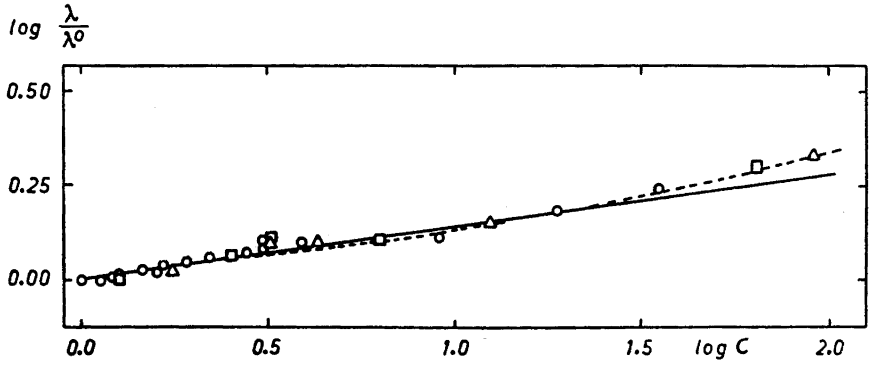

Fig. 1. Salting-out mercury(II) halides as function of ionic medium concentration. ○ Hg(II) chloride, □ Hg(II) bromide, △ Hg(II) iodide. ——— equation (1), $k_c = 0.14$, ····· equations (2), (3) and (4).

where k_p is an empirical constant. A curve with $k_c = 0.14$ and $k_p = 1.3$ expresses the data fairly well.

Of the more fundamental approaches, Debye's electrostatic theory [36] has won recognition as being able to explain the effects at least qualitatively for an electrolyte of the type of sodium perchlorate. It should be possible, in principle, to calculate the parameter J in eqn. (3) below for any pair of electrolyte- non-electrolyte, provided the ionic radii of the ions and the dielectric decrement of the non-electrolyte solutions are known.

$$\log \lambda - \log \lambda^\circ = \log f_c = -\log (1-JC) \qquad (3)$$

Eqn. (3) fits the data quite well with the parameter $J = 0.27$.

Finally, a recent equation proposed by Nakajima [37] can be rewritten in the form:

$$\log \lambda - \log \lambda^\circ = \log f_c = -\log (1-\mu C(1+\nu\sqrt{C})\ (1+0.707\sqrt{C})^{-1}) \qquad (4)$$

which is, again, a two parameter equation, and gives with $\mu = 0.18$ and $\nu = \sqrt{2}$ a very good fit with the data.

Eqns. (2), (3) and (4) give such similar results that they are incorporated into one curve in Fig. 1.

Although the one-parameter eqn. (1) fails at higher concentrations, it is possible to calculate the expected k_c from compressibility and volume data. According to McDevit and Long [4] k_c is given by:

$$k_c = \lim_{C \to 0} \mathrm{d}(\log \lambda - \log \lambda^\circ) / \mathrm{d}C = \overline{V}_n^\circ\ (V_e - \overline{V}_e^\circ)\ (2.3\beta_0 RT)^{-1} \qquad (5)$$

where $\overline{V}_n^\circ$ is the partial molar volume of the non-electrolyte, $\overline{V}_e^\circ$ that of the electrolyte — both at infinite dilution — and β_0 is the compressibility of water. Inserting the values $\beta_0 = 4.56.10^{-5}$ bar $^{-1}$, R = gas constant = 83.11 ml bar deg^{-1} mole^{-1}, $T = 298$ deg, $\overline{V}_n^\circ = 49$ ml mole^{-1} (given by Linhart [6a], p. 273) for $HgCl_2$, $(V_e - \overline{V}_e^\circ) = 7.5$ ml^{-1} mole (Mc Devit and Long [4]), the value $k_c = 0.141$ is obtained, in very good agreement with the observed value.

This good agreement might, however, be only fortuitious. For instance, the theory assumes that the radius of the non-electrolyte molecules is much smaller than the radii of the ions, whereas they are really comparable. Moreover, the variability of $\overline{V}_n^\circ$ with the various halides was neglected here.

The author wishes to thank the Israel Atomic Energy Commission for a research grant abroad, Professor Lars Gunnar Sillén for the facilities provided, and particularly for his advice, comments and criticism, and Dr. Helen S. Dunsmore for improving the English presentation.

Diffusion from a Bottom Layer; Diffusion with Moving Boundaries

STIG LJUNGGREN and OLE LAMM

The Royal Institute of Technology, Division of Physical Chemistry, Stockholm 70, Sweden

A new method of carrying out diffusion experiments is outlined, the initial condition being that the whole quantity of diffusing substance is concentrated in a thin layer at the bottom of the cell at zero time. Ideal equations are derived for uniform and non-uniform substances and a normalization procedure is described. The diffusion curves theoretically calculated for various binary mixtures of solutes are discussed and it is pointed out that in this type of diffusion the distortion of the curves due to non-uniformity is usually greater than that which occurs in ordinary diffusion. The apparatus and mode of operation are described in detail and a few experiments with uniform and non-uniform substances are related. In particular, mixtures of partially hydrolyzed dextran and sodium chloride were investigated.

I. INTRODUCTION

If pure solvent or a dilute solution of a single substance is levelled above a more concentrated solution of the same substance, so that the initial concentration difference equals Δc° (Fig. 1), the resulting one-dimensional diffusion process will under ideal conditions be governed by the following equation [2,3]

$$\frac{\partial c}{\partial x} = \frac{\Delta c^\circ}{2\sqrt{\pi D t}} e^{-x^2/4Dt},$$

where x denotes the position coordinate with reference to the original boundary surface, D the diffusion coefficient and t the diffusion time. If a linear relation is assumed between the concentration and the refractive index of the solution (which holds fairly accurately in most cases), the concentration gradient can be measured, using, *e. g.*, the scale method.

For non-uniform diffusion, *i. e.* if there are two or more components with different diffusion coefficients present, this equation is not valid. This fact may be utilized as an indication of non-uniformity. Thus it was shown by Lamm [1] that in normal coordinates the curve of a non-uniform diffusion

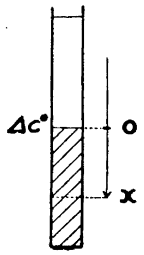

Fig. 1. Principle of "ordinary" diffusion.

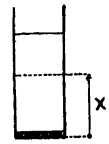

Fig. 2. Principle of bottom layer diffusion.

process will always have a positive excess at the axis of symmetry as compared to the curve of uniform diffusion. Theoretically the shape of an experimentally obtained curve would even permit the distribution function of diffusion coefficients to be calculated using numerical methods, although the experimental accuracy is as a rule too low for this to be practical.

It was pointed out by Lamm [2] that ordinary diffusion is by no means the ideal process for indicating non-uniformity. The uniform diffusion curves of the single components, which combine to give the resulting compound curve, will all have a mutual axis of symmetry at the position of the original boundary. This results in rather a close amalgamation of the curves.

It seems, therefore, that if the diffusion could be arranged with a different initial condition so that the resulting uniform diffusion curve was non-symmetrical, non-uniformity would be more clearly displayed. Such a possibility is offered by diffusion from a bottom layer, where the diffusion starts out from a very thin layer of relatively concentrated solution at the bottom of the cell, levelled below pure solvent (Fig. 2). If the bottom layer is infinitely thin and if the influence of the concentration on the diffusion coefficient is neglected, the equation of uniform diffusion from bottom layer can be written [3]

$$\frac{\partial c}{\partial x} = -\frac{Ax}{2\sqrt{\pi}\, D^{3/2} t^{3/2}} e^{-x^2/4Dt}$$

where x is the height above the bottom of the cell. This function is the first derivative with respect to x of the above function for "ordinary" diffusion and it is non-symmetrical, as is seen from Fig. 3. Further it is easily seen that the abscissa of the maximum point depends on D and t. Some elementary properties of the function will be given for convenience in the theoretical section below. In cases, however, where non-uniformity is not very pronounced, a direct comparison with the ideal curve suggests itself. In order that this be possible, the curve must be plotted in normal coordinates independent of time and other general experimental conditions. The normalization procedure, analogous to that applied in connection with "ordinary" diffusion, rests on the calculation of moments and it will be shown that the first moment can advantageously be used for the normalization.

In this connection it may be worth mentioning that the first "absolute" moment can also be used for the normalization of "ordinary" diffusion curves in place of the second moment ordinarily used.

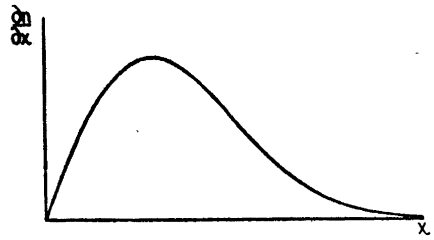

Fig. 3. Ideal curve for uniform bottom layer diffusion, according to eqn. (4).

II. THEORETICAL

a) Elementary properties of the uniform curve

If A moles per cm² are concentrated to $x = 0$ at the time $t = 0$ (Fig. 2), the following equation will now hold for the concentration (compare above)

$$\bar{c} = \frac{A}{\sqrt{\pi Dt}} e^{-x^2/4Dt} \tag{1}$$

The bar above c denotes that we are dealing with a uniform case. This mode of notation will be generally adopted in the subsequent discussion. Derivation with respect to x yields

$$\frac{\partial \bar{c}}{\partial x} = -\frac{Ax}{2\sqrt{\pi} D^{3/2} t^{3/2}} e^{-x^2/4Dt} \tag{2}$$

If a linear relation is assumed between refractive index and concentration [4],

$$n = n^0 + Rc \tag{3}$$

we obtain for the refractive index gradient

$$-X = \frac{\partial \bar{n}}{\partial x} = -\frac{RAx}{2\sqrt{\pi} D^{3/2} t^{3/2}} e^{-x^2/4Dt} \tag{4}$$

For the abscissa of the maximum point we get

$$\bar{x}_m^2 = 2Dt \tag{5}$$

and for the abscissa of the point of inflexion

$$\bar{x}_i^2 = 6Dt \tag{6}$$

Thus

$$\bar{x}_i/\bar{x}_m = \sqrt{3} \tag{7}$$

The area of the curve is

$$\Phi = -\int_0^\infty \frac{\partial \bar{n}}{\partial x} dx = \int_0^\infty \bar{X} dx = \frac{RA}{\sqrt{\pi Dt}} \tag{8}$$

and the maximum ordinate is obtained if x_m is inserted into (4):

$$\bar{X}_m = \frac{RA}{\sqrt{2\pi e Dt}} \tag{9}$$

Hence

$$\frac{\Phi^2}{\bar{X}_m^2} = 2eDt \tag{10}$$

The ordinate of the point of inflexion is

$$\bar{X}_i = \frac{RA\sqrt{6}}{2e\sqrt{\pi eDt}} \tag{11}$$

Thus

$$\frac{\bar{X}_i}{\bar{X}_m} = \frac{\sqrt{3}}{e} \tag{12}$$

The slope of the curve at the point of inflexion is

$$\left(\frac{\partial \bar{X}}{\partial x}\right)_i = \frac{-RA}{\sqrt{\pi e^3 D^3 t^3}} \tag{13}$$

But the slope at $x = 0$ is

$$\left(\frac{\partial \bar{X}}{\partial x}\right)_{x=0} = \frac{RA}{2\sqrt{\pi D^3 t^3}} \tag{14}$$

Hence

$$\left(\frac{\partial \bar{X}}{\partial x}\right)_{x=0} = -\frac{e^{3/2}}{2}\left(\frac{\partial \bar{X}}{\partial x}\right)_i$$

The slope of a line combining the maximum point with the origin is

$$\frac{\bar{X}_m}{x_m} = \frac{RA}{2\sqrt{\pi eD^3 t^3}} \tag{15}$$

Thus

$$\frac{\bar{X}_m}{x_m} = \frac{1}{\sqrt{e}}\left(\frac{\partial \bar{X}}{\partial x}\right)_{x=0} = -\frac{e}{2}\left(\frac{\partial \bar{X}}{\partial x}\right)_i \qquad \text{(Fig. 5)} \tag{16}$$

A combination of some of the foregoing expressions yields

$$\frac{\bar{x}_i \bar{X}_m}{\left(\frac{\partial \bar{X}}{\partial x}\right)_i} = Dt\ e\sqrt{3} \tag{17}$$

In case it should be difficult to find the exact position of the origin, the width of the curve, δ, at the ordinate of the inflexion point (Fig. 4) may be used. By the use of the tables of Jahnke and Emde it is found that

$$\delta \approx 1.852\sqrt{Dt} \tag{18}$$

Hence

$$Dt \approx \frac{\delta^2}{3.43} \tag{19}$$

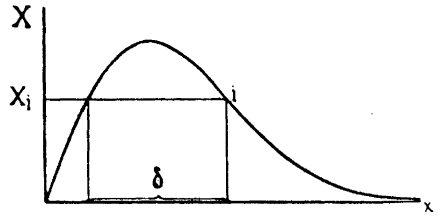

Fig. 4. "Width" of ideal curve.

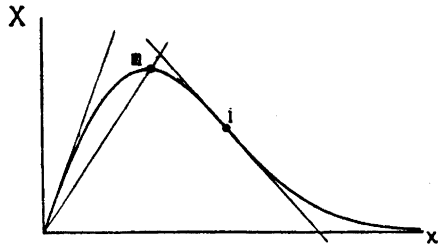

Fig. 5. Elementary properties of bottom layer diffusion curves.

For the calculation of the diffusion coefficient, relations (5), (6), (10), (17) and (19) may be used.

b) Relations for non-uniform curves

We will now assume that there are several components present, each of which diffuses independently of the others, *i. e.* the Arrhenius-Thovert effect is neglected. Then

$$-X = \frac{\partial n}{\partial x} = \sum_{i=1}^{q} \frac{\partial n_i}{\partial x} = -\sum_{i=1}^{q} \frac{R_i A_i x}{2\sqrt{\pi}\, D_i^{3/2} t^{3/2}}\, e^{-x^2/4D_i t} \qquad (20)$$

owing to the additive property of the refractive index contributions. If the number of substances were increased infinitely, the sum of eqn. (20) would go over into an integral. For the sake of generality we define a distribution function, $f(D)$, such that

$$d(RA) = f(D)\, dD$$

The expression equivalent to eqn. (20) will then be

$$-X = \frac{\partial n}{\partial x} = -\frac{1}{2\sqrt{\pi}} \int_0^\infty \frac{x}{D^{3/2} t^{3/2}}\, e^{-x^2/4Dt}\, f(D)\, dD \qquad (21)$$

A discontinuous distribution case cannot be described exactly by eqn. (21) but it can be approximated with any desired degree of accuracy. The calculation of the maximum and inflexion point coordinates of a non-uniform curve does not give any simple explicit result. From a practical point of view, however, it is obvious that at least in cases of pronounced non-uniformity there will be a deviation from the conditions of eqn. (16).

c) Moment expressions

The r:th moment of the refractive index gradient curve is defined in the following way

$$m_r = \int_0^\infty x^r X dx = -\int_0^\infty x^r \frac{\partial n}{\partial x}\, dx \qquad (22)$$

Obviously the moment of order zero is identical with the area of the curve, previously denoted by Φ:

$$m_0 = \Phi$$

Substituting for X the expression of eqn. (21) we obtain

$$m_r = \frac{1}{2\sqrt{\pi}} \int_0^\infty x^r \mathrm{d}x \int_0^\infty \frac{x}{D^{3/2} t^{3/2}} \mathrm{e}^{-x^2/4Dt} f(D)\, dD \tag{23}$$

By the substitution

$$\zeta = x / 2\sqrt{Dt}$$

(23) is transformed into

$$m_r = \frac{2^{r+1} t^{(r-1)/2}}{\sqrt{\pi}} \int_0^\infty f(D)\, D^{(r-1)/2}\, \mathrm{d}D \int_0^\infty \zeta^{r+1} \mathrm{e}^{-\zeta^2} \mathrm{d}\zeta$$

We will abbreviate

$$\mu_r = \int_0^\infty f(D)\, D^{(r-1)/2}\, \mathrm{d}D \tag{24}$$

Hence

$$m_r = \frac{2^r t^{(r-1)/2}}{\sqrt{\pi}} \Gamma\left(\frac{r+2}{2}\right) \mu_r = \alpha \cdot \mu_r \tag{25}$$

since

$$\int_0^\infty \zeta^{r+1} \mathrm{e}^{-\zeta^2} \mathrm{d}\zeta = \frac{1}{2} \Gamma\left(\frac{r+2}{2}\right)$$

provided that $r + 2 > 0$, or $r > -2$.

For convenience the factor, $\alpha = \frac{1}{\sqrt{\pi}} 2^r t^{(r-1)/2} \Gamma\left(\frac{r+2}{2}\right)$, is listed in Table 1 for some values of r.

Table 1.

r	α
0	$1/\sqrt{\pi t}$
1	1
2	$4\sqrt{t}/\sqrt{\pi}$
3	$6t$
4	$32t^{3/2}/\sqrt{\pi}$

The reduced moments of the distribution function are defined as follows:

$$\mathcal{D}_{rm}^{r/2} = \frac{\mu_r}{\mu_0}; \qquad \mathcal{D}_{rm} = \left(\frac{\mu_r}{\mu_0}\right)^{2/r} \tag{26}$$

In the uniform case, (24) reduces to

$$\bar{\mu}_r = RAD^{(r-1):2} \tag{27}$$

Hence

$$\bar{\mathcal{D}}_{rm} = D \tag{28}$$

Relation (28) provides a method for obtaining the diffusion coefficient from an experimental curve. For the calculation of moments the use of Simpson's formula is recommended.

If the error in a moment computed from an experimental curve is $\delta\, m_r$, then the error in the reduced moment calculated according to eqn. (26) will be

$$\left| \frac{\delta\, \mathcal{D}_{rm}}{\mathcal{D}_{rm}} \right| = \left| \delta \ln \mathcal{D}_{rm} \right| = \frac{2}{r} \cdot \left| \delta \ln \frac{\mu_r}{\mu_0} \right|$$

or

$$\frac{\delta\, \mathcal{D}_{rm}}{\mathcal{D}_{rm}} = \frac{2}{r} \left| \frac{\delta\, m_r}{m_r} \right| + \frac{2}{r} \left| \frac{\delta\, m_0}{m_0} \right| \tag{29}$$

Since the error in a moment calculated from an experimental curve increases greatly with increasing r, it should be possible to find an optimum value of r, depending on the experimental degree of accuracy, which gives $|\delta\, \mathcal{D}_{rm} / \mathcal{D}_{rm}|$ a minimum value. For practical purposes it seems reasonable to use the first moment.

d. Normalization

By the linear transformations

$$\Xi = -\frac{\sqrt{\mathcal{D}_{rm} t}}{m_0} \frac{\partial\, n}{\partial\, x} \tag{30}$$

$$\xi = x/2\sqrt{\mathcal{D}_{rm} t}$$

the equation of uniform diffusion is transformed into

$$\Xi = \xi \cdot e^{-\xi^2} \tag{31}$$

since, in the uniform case,

$$\bar{m}_0 = RA/\sqrt{\pi D t}$$

$$\bar{\mathcal{D}}_{rm} = D$$

The normalized curve is independent of time. In the discussion below it will be assumed that $\mathcal{D}_{1m}$ has been used for the normalization. In non-uniform cases, the normalized curve will deviate from the curve of eqn. (31). The applied mode of normalization implies that the first and zero moments will always be identical with those of the ideal curve, *i. e.* the area and the ξ-coordinate of the point of gravity of all normalized curves will have fixed values.

e. Recognition of non-uniformity

From the foregoing we recall that

$$\mu_r = \int_0^\infty f(D)\ D^{(r-1)/2}\ \mathrm{d}D \tag{24}$$

and

$$\bar{\mu}_r = RAD^{(r-1)/2} \tag{27}$$

Hence

$$\bar{\mu}_p = \bar{\mu}_r^\alpha \bar{\mu}_s^\beta \tag{32}$$

if

$$p = \alpha r + \beta s; \quad \alpha + \beta = 1$$

By a simple application of the Hölder inequality it can be shown that

$$\mu_p < \mu_r^\alpha \mu_s^\beta \tag{33}$$

if $p = \alpha r + \beta s$, $\alpha,\beta > 0$, $\alpha + \beta = 1$
From (32) and (33) it follows that for $\mu_r = \bar{\mu}_r$ and $\mu_s = \bar{\mu}_s$

$$\mu_p < \bar{\mu}_p \tag{34}$$

if

$$r < p < s$$

In a similar manner we find that

$$\mu_p > \bar{\mu}_p \tag{35}$$

if

$$p < r \text{ or } p > s,\ r < s$$

These relations can be applied to show that the slope at $\xi = 0$ of a non-uniform curve in normal coordinates is always greater than that of the uniform curve.

Other elementary methods for recognizing non-uniformity rest on a comparison of the values of the diffusion coefficient obtained by different methods (5), (6), (10), (17) and (19). As already mentioned, there will also be a deviation from eqn. (16) in non-uniform cases. Depending on the nature and degree of non-uniformity present, the eye will be more or less sensitive to the deviation from the shape of the ideal curve.

f. Non-uniformity in two-component cases

The simplest non-uniform cases are those where there are only two diffusing components present, denoted by the respective indices 1 and 2. If the following two parameters are introduced

$$\beta = R_1A_1 / R_2A_2 \tag{36}$$

$$\gamma = \sqrt{D_1 / D_2}$$

the compound curve in its normalized form can be written

$$\Xi = \Xi_1 + \Xi_2 \tag{37}$$

where

$$\Xi_1 = \frac{\beta(\beta+1)}{(\beta+\gamma)^2} e^{-\xi_1} \xi_1; \quad \xi_1 = \frac{\beta+1}{\beta+\gamma} \xi \tag{38}$$

$$\Xi_2 = \frac{\gamma^2(\beta+1)}{(\beta+\gamma)^2} e^{-\xi_2} \xi_2, \quad \xi_2 = \frac{\gamma(\beta+1)}{\beta+\gamma} \xi \tag{39}$$

Here Ξ_1 and Ξ_2 are the respective contributions from the two components. In the case of "ordinary" diffusion, the corresponding equations are

$$\Xi_1 = \frac{2}{\sqrt{\pi}} \frac{\beta(\beta\gamma+1)}{\gamma(\beta+1)^2} e^{-\xi_1}; \quad \xi_1 = \frac{\beta\gamma+1}{\gamma(\beta+1)} \xi \tag{40}$$

$$\Xi_2 = \frac{2}{\sqrt{\pi}} \frac{\beta\gamma+1}{(\beta+1)^2} e^{-\xi_2}; \quad \xi_2 = \frac{\beta\gamma+1}{\beta+1} \xi \tag{41}$$

For a comparison between the two methods, the following six cases are reproduced in normal coordinates along with the uniform curve, denoted by index zero

Curve No.	β	γ
1	5	2
2	1	2
3	10	4
4	1	4
5	100	4
6	1/100	4

in Figs 6, 7 and 8 for diffusion from a bottom layer and in Figs 9, 10 and 11 for "ordinary" diffusion. Especially important from the point of view of judging the relative merits of the two methods are cases 5 and 6, where one of the components is present only in minute amounts, *i. e.* may be regarded as a

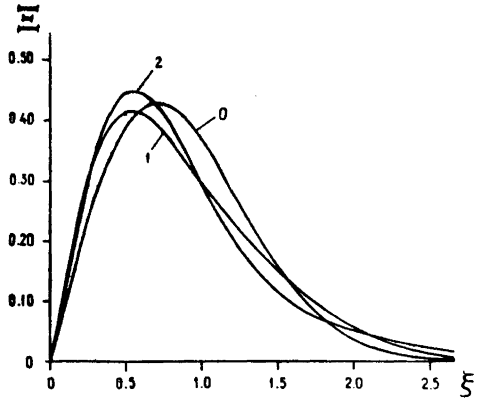

Fig. 6. Normalized curves for two-component cases. Bottom layer diffusion. 0, Ideal curve; 1, $\beta = 5$, $\gamma = 2$; 2, $\beta = 1$, $\gamma = 2$.

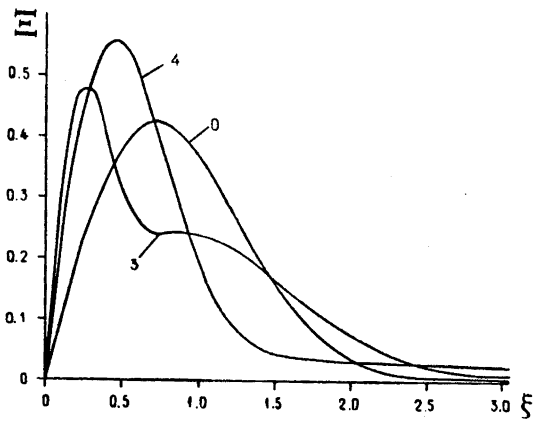

Fig. 7. Normalized curves for two-component cases. Bottom layer diffusion. 0, Ideal curve; 3, $\beta = 10$, $\gamma = 4$; 4, $\beta = 1$, $\gamma = 4$.

contamination. As appears from the figures, the assymmetrical character of the curves for bottom layer diffusion will generally cause a considerable deviation from the ideal curve to occur over a greater range of abscissa values. Further it is seen that the bottom layer method is particularly favourable when the "contamination" has a lower diffusion coefficient than the main component (Fig. 8). From the equations above, it is found that if

$$\eta = \frac{(\Xi \text{ contaminant})_{max}}{(\Xi \text{ main.comp.})_{max}}; \qquad \gamma > 1 \tag{42}$$

then

$$\text{for } \beta > 1;\ \eta' = \frac{(\Xi_2)_{max}}{(\Xi_1)_{max}} = \frac{\gamma^2}{\beta} \tag{43}$$

and

$$\text{for } \beta < 1;\ \eta'' = \frac{(\Xi_1)_{max}}{(\Xi_2)_{max}} = \frac{\beta}{\gamma^2} \tag{44}$$

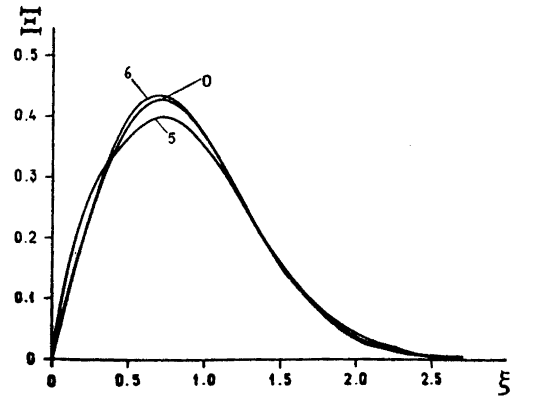

Fig. 8. Normalized curves for two-component cases. Bottom layer diffusion. 0, Ideal curve; 5, $\beta = 100$, $\gamma = 4$; 6, $\beta = 1/100$, $\gamma = 4$.

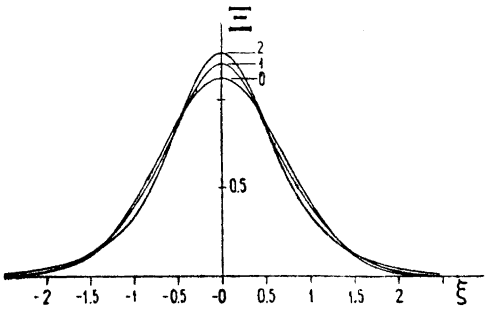

Fig. 9. Normalized curves for two-component cases. "Ordinary" diffusion. 0, Ideal curve; 1, $\beta = 5$, $\gamma = 2$; 2, $\beta = 1$, $\gamma = 2$.

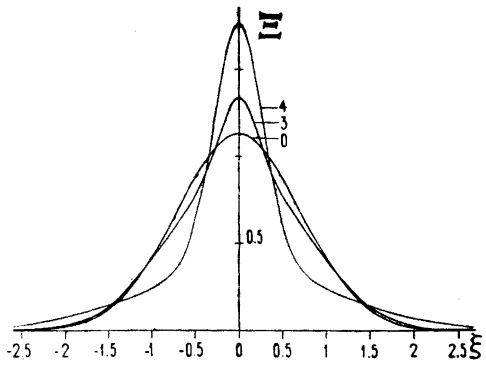

Fig. 10. Normalized curves for two-component cases. "Ordinary" diffusion. 0, Ideal curve; 3, $\beta = 10$, $\gamma = 4$; 4, $\beta = 1$, $\gamma = 4$.

Thus

$$\eta' / \eta'' = \gamma^4 \tag{45}$$

i. e. the former case is greatly favoured. For "ordinary" diffusion we have

$$\eta' = \frac{\gamma}{\beta}, \quad \eta'' = \frac{\beta}{\gamma} \tag{46}$$

Hence

$$\eta' / \eta'' = \gamma^2 \tag{47}$$

Further it can be shown that the excess,

$$\Delta = \Xi_{max} - \bar{\Xi}_{max} = \frac{\beta}{\gamma} \frac{(\gamma - 1)^2}{(\beta + 1)^2} \tag{48}$$

Thus

$$\Delta(\beta) = \Delta(1 / \beta) \tag{49}$$

i. e. the excess is independent of whether the "contamination" has a greater or smaller diffusion coefficient than the main component, although in the former case the excess will occur over a greater range of abscissa values.

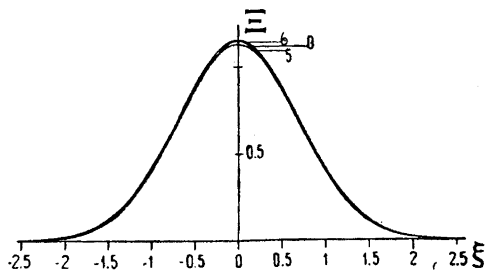

Fig. 11. Normalized curves for two-component cases. -'Ordinary" diffusion. 0, Ideal curve; 5, $\beta - 100$, $\gamma - 4$; 6, $\beta - 1/100$, $\gamma - 4$.

From the above arguments it is concluded that in cases of very low β and large γ, the "ordinary" diffusion method would be favoured in comparison with diffusion from bottom layer from the point of view of recognizing non-uniformity. This is evidently true, but rather extreme conditions are probably required to outweigh the advantages of the bottom layer method. As is seen in case 6, the two methods are practically equal even for $\beta = \frac{1}{100}$, $\gamma = 4$. Thus it is concluded that, for most practical purposes, diffusion from a bottom layer is a more sensitive means of detecting non-uniformity.

Note: In eqns. (38), (39) and (40), (41) the "ordinary" diffusion curves are assumed to have been normalized using the first absolute moment. Some words on this method may therefore be apposite.

If the moments are defined in the usual way

$$m_r = \int_{-\infty}^{+\infty} x^r X \mathrm{d}x \tag{50}$$

it is obvious that all moments of odd order will disappear, due to the symmetrical shape of the curves. This fact may even be utilized to find the position of the axis of symmetry. For this reason, the second moment has usually been employed for the normalization.

If we instead introduce the "absolute" moments

$$M_r = \int_{-\infty}^{+\infty} |x|^r X \mathrm{d}x \tag{51}$$

which can be readily calculated from an experimental curve, it can be shown that

$$M_r = \alpha' \mu_{r+1} \tag{52}$$

where u_{r+1} is defined according to eqn. (24) and

$$\alpha' = \frac{1}{\sqrt{\pi}} 2^r t'^{/2} \Gamma\left(\frac{r+1}{2}\right) \tag{53}$$

The reduced moments are then defined by

$$\mathscr{D}_{rM} = \left(\frac{\mu_{r+1}}{\mu_1}\right)^{2/r} \tag{54}$$

and normalization is effected by the transformations

$$\Xi = \frac{4\sqrt{\mathscr{D}_{rM} t}}{M_0} X \tag{55}$$

$$\xi = x / 2\sqrt{\mathscr{D}_{rM} t}$$

III. EQUIPMENT AND OPERATION

a. *The thermostat.* The thermostat, shown in Fig. 12, had the outside dimensions, 31 × 36 × 33 cm. It was insulated by 3 cm thick insulating cork, C, painted black, and protected from radiation losses by aluminium foil. The distilled water serving as thermostat liquid was stirred by a propeller stirrer driven by an almost vibrationless electric motor, B. The temperature control system was the usual one, including a contact thermometer, D, a relay and a dip-heater, E. A precision thermometer F enabled temperature fluctuations of 0.002 °C to be measured. The cell was placed between two brass blocks in position A. Slits in the brass blocks and a tube passing through the thermostat gave free passage to the light beam. The thermostat was mounted on a rider of a very stable (lathe type) optical bench, which in turn rested on a solid foundation.

The temperature fluctuations of the thermostat liquid never exceeded ± 0.002° C during the experiments.

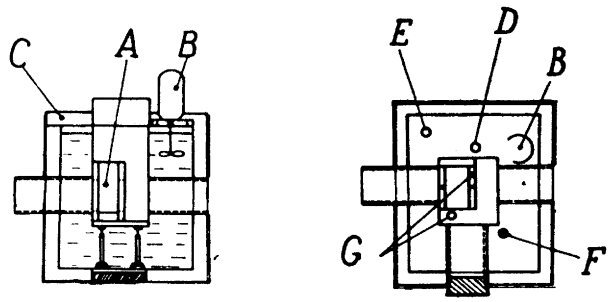

Fig. 12. Thermostat. A, cell position; B, electric stirrer motor; C, cork insolation; D, position for contact thermometer; E, Immersion heater; F, position for precision thermometer; G, position for thermometers for air and brass-block temperatures.

b. *The diffusion cell.* In the construction of the cell and the levelling arrangement the greatest possible simplicity was aimed at, simultaneously as the risk of convection and leakage had to be duly considered.

The cell was composed of plane parallel glass plates as shown in Fig. 13, the inner dimensions being: height 7.9 cm, bottom area 3 × 3 cm^2. At the center of the bottom plate there was a small hole filled with mercury into which the cannula of a tuberculine syringe dipped. The mercury served the double purpose of preventing the syringe leaking and of preventing cascade formation on injection of the bottom layer. The plexi-glas cover of the cell was provided with two holes, one for the cannula and one for the introduction of the solvent. To enable a slow and vibrationless operation of the syringe, a simple device was constructed, which included a micrometer screw acting directly upon the piston, Fig. 14. One turn of the screw corresponded to an injected volume of 0.008 ml.

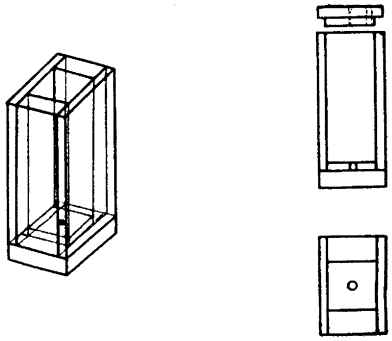

Fig. 13. Diffusion cell with plexi-glas cover.

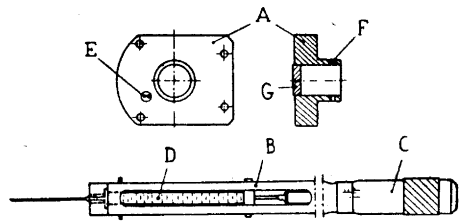

Fig. 14. Injection device. A, holder; B, syringe holder; C, micrometer screw, D, syringe; E, hole for the introduction of solvent; F, socket for B; G, rubber washer.

The cell fitted precisely into the space between two brass blocks in the thermostat, A, Fig. 12, and the holder of the injection device was screwed fast to the brass blocks. Fig. 15 shows the final arrangement with the cell in position in the thermostat.

c. *The optical arrangement.* The optical arrangement, schematically shown in Fig. 16, was based on the Svensson short focus modification of the scale method [5]. As suggested by Lamm [6], the diffusion cell was placed on the "plate" side of the lens system. The Svensson modification claims the advantage of reducing the length of optical bench required, without neglecting the

demand for parallel or nearly parallel light through the cell. The condition is, however, that the focal distances of the lenses chosen should be sufficiently small. With focal distances of around 120 cm as used in our experiments, the necessity of using the Svensson method is debatable; it also limits the non-distorted part of the image. The diaphragm diameter used was 1.4 cm, which corresponds to an aperture of approx. 1 : 86. A precision glass scale with a scale constant of 0.399 mm was used. Fig. 17 shows the actual arrangement. During the experiments, however, the injection device was insulated by a tube of aluminium foil, lined with cotton.

The adjustment of the optical system was carried out by means of a telescope provided with cross-hairs adjusted for infinity. An illuminated scale was observed through the telescope and one of the lenses of the optical system and the position of the scale adjusted until no parallax between the cross-hairs and the scale remained. The scale was then assumed to be in the focal plane of the lens.

d. *Mode of operation.* The carefully cleaned and dried cell was then inserted in the thermostat. The syringe was filled with the solution to be injected and the top of the piston was greased to prevent vibrations while the micrometer screw was being turned. The syringe was placed in its holder, and the cannula carefully wiped. The injection device was then placed in position in the thermostat and screwed fast. Through the hole in the glass and plexi-glas covers, 50 ml of freshly boiled distilled water of a temperature slightly exceeding that of the thermostat was introduced by means of a cannula, connected with a separatory funnel by a polythene tube. After the introduction of the water the hole was plugged with cotton wool and the cork cover of the thermostat was put on. The thermostat was left for temperature equilibration, the mercury preventing the syringe from leaking. The bottom layer was then injected by slowly turning the micrometer screw at a uniform rate. The process could be followed on the ground glass plate. The time required for injection was 3—4 min, which, of course, introduces a small time-dependent non-uniformity since the diffusion constant always appears in eqn. (4) in connection with the time. The height of the injected layer was approx. 0.4 mm. Obviously it is desirable that the height of the bottom layer should be as small as possible, if the simple eqn. (4) is to be valid. This, however, requires that the bottom of the cell should be nearly perfectly horizontal.

The scale pictures were recorded on 6 × 9 process plates with one exposure per hour during the first 6 h of the experiment. The best exposures were obtain-

ed several hours (3 or 4 h with KCl) after the experiment had been started. During the first few hours, while the concentration gradient was still very high, the effective part of the scale was considerably blurred, owing to the defocussing effect of the gradient. This is, however, not serious for the accuracy of the measurement [1].

IV. EXPERIMENTS

A. Experiments with uniform substances

Experiment 1. In order to test the method, experiments with uniform substances were first conducted. 0.4 ml of 0.5 N KCl (analytical reagent) was injected. The thermostat temperature was 24.78 °C. Exposures were taken before the beginning of the levelling and after 2, 3, 4, 5 and 6 h. The scale photographs were comparated in the usual manner and the corresponding curves drawn, Fig. 18. The parts of the scales corresponding to low values of x were rather diffuse, due to the cutting-off effect of the cell bottom. For this reason it was difficult to find the exact Z-value corresponding to $x = 0$. By a consideration of various elementary properties of shape (rel. (20)), however, the position of the origin was estimated.

The curve taken after 4 h was normalized in the way described above and the ideal curve was drawn for comparison, Fig. 19. As appears from the diagram, the experimental difficulties have not yet been overcome. At present, however, it is difficult to judge whether the deviation is due to the systematic short-comings of the method of levelling or to other experimental circumstances.

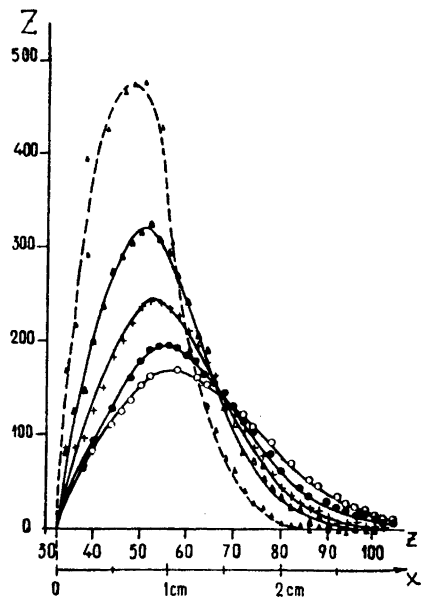

Fig. 18. Experimental (z, Z)-curves for the diffusion of potassium chloride in water at 24.78°C. Expt. 1.

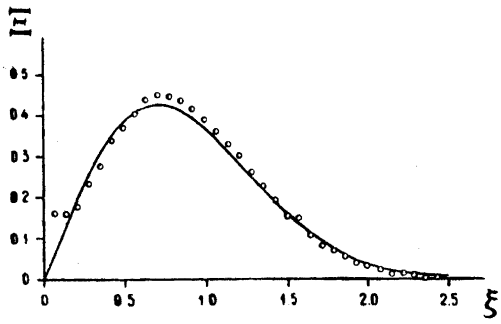

Fig. 19. Points of normalized 4-h curve of expt. 1 together with normal ideal curve.

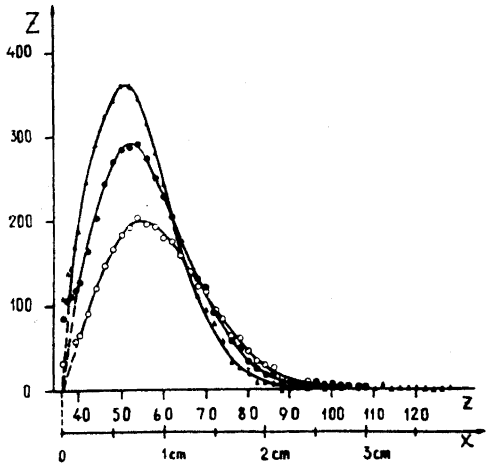

Fig. 20. Experimental curves from expt. 2. NaCl in water at 24.77°C. Filled triangles, 3-h curve; filled circles, 4-h curve; empty circles, 5-h curve. The deviation from the ideal shape of the curve for low values of x is probably due to minute amounts of high-molecular impurities.

Experiment 2. 0.4 ml of a 3 % NaCl solution was injected. Curves analogous to those for KCl were obtained.

In expt. 2 as in expt. 1, it was noted that the deviation from the ideal shape of curve for low x is not altogether irregular but exhibits a positive tendency. This is probably due to the presence of quite minute amounts of high-molecular impurities, which will cause, even at very low concentrations, an appreciable deviation from the ideal curve (compare Fig. 8).

The diffusion coefficient was calculated according to the maximum point, the inflexion point and the "width" methods, Table 2 and Figs. 21, 22 and 23.

Table 2.

t	x_m	x_i	δ
3	0.599	1.002	0.794
4	0.656	1.107	0.840
5	0.761	1.286	0.938

The diffusion coefficient was recalculated for 25 °C using the viscosity ratio, giving the following result.

Inflexion point method:

$$D_{25°} = 1.29 \text{ cm}^2/\text{day}$$

"Width" method:

$$D_{25°} = 1.30 \text{ cm}^2/\text{day}$$

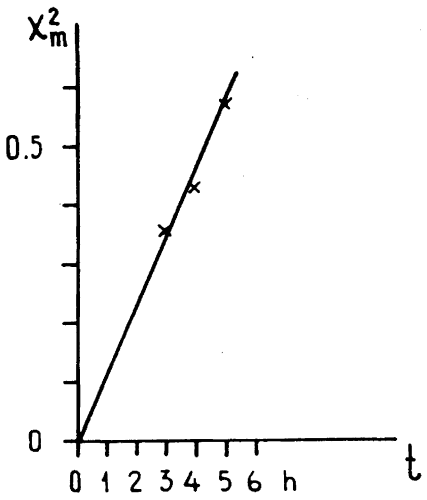

Fig. 21. Maximum point method for the determination of the diffusion coefficient of NaCl. Expt. 2.

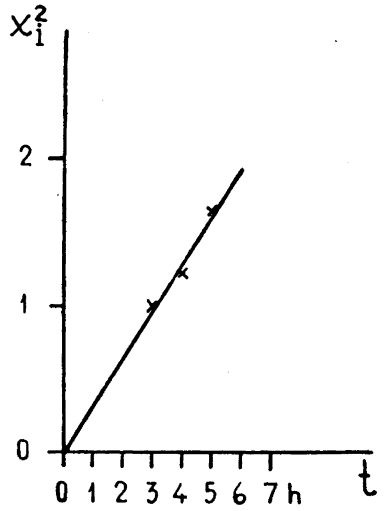

Fig. 22. Inflexion point method. Expt. 2.

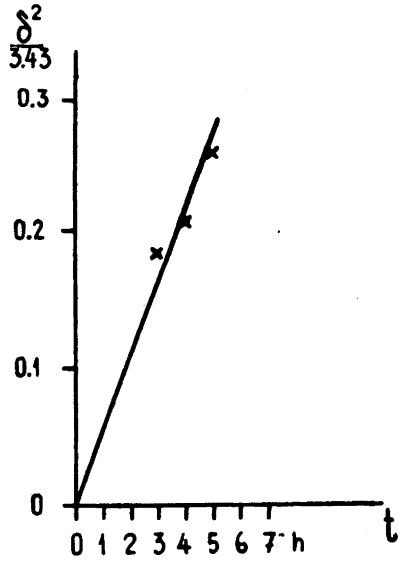

Fig. 23. "Width" method. Expt. 2.

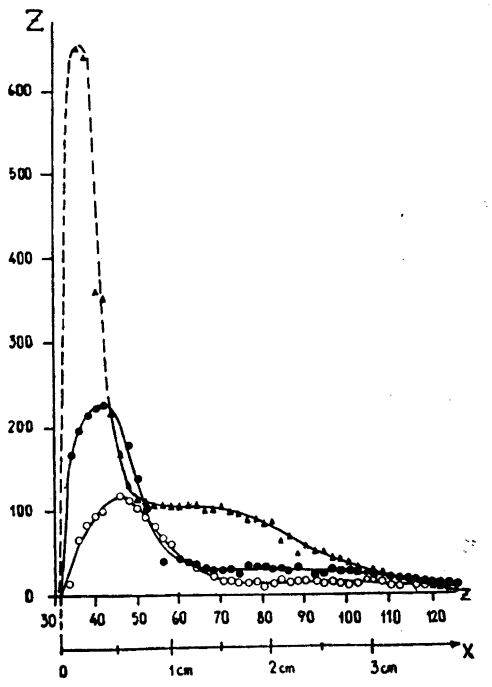

Fig. 24. Expt. 3. 0.6 % dextran + 2.4 % NaCl at 24.77°. Filled triangles, 12-h curve; filled circles, 35.3-h curve; empty circles, 71-h curve.

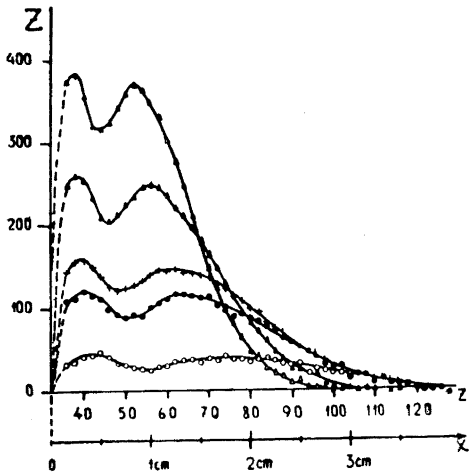

Fig. 25. Expt. 4. 0.1 % dextran + 2.9 % NaCl at 24.77°. Empty triangles, 4-h curve; filled triangles, 6-h curve; crosses, 10-h curve; filled circles, 12-h curve; empty circles, 24.5-h curve.

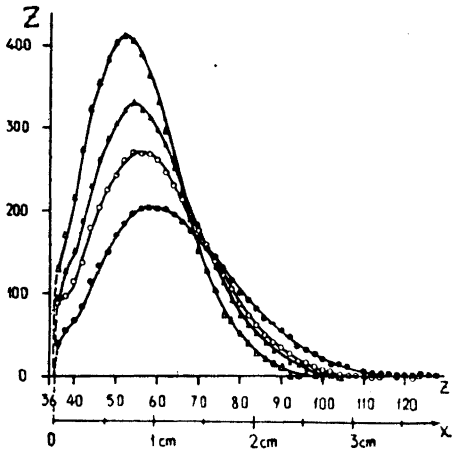

Fig. 26. Expt. 5. 0.03 % dextran + 3 % NaCl at 24.78°. Empty triangles, 4-h curve; filled triangles, 5-h curve; empty circles, 6-h curve; filled circles, 8-h curve.

Maximum point method:

$$D_{25°} = 1.38 \text{ cm}^2/\text{day}$$

illustrative of the fact that the maximum point abscissae are less accurately read from the curve diagram than the widths and the influxion point abscissae.

These values can be compared with the following values given by Kortüm and Bockris, *Textbook of Electrochemistry* for the diffusion coefficient of NaCl:

at $c = 0$ $D_{25°} = 1.39$ cm²/day

$c = 0.5$ $D_{25°} = 1.27$ cm²/day

in fair agreement with the above results. It should, however, be mentioned that the precision determinations of diffusion coefficients approach or attain an accuracy of 0.1 %.

B. Experiments with non-uniform substances

Native dextran as produced by *Leuconostoc mesenterioides* is a polydisperse polysaccharide with molecular weight ranging from 14 000 to 40 000 000. A partially hydrolyzed form with molecular weight of 20 000—200 000 has gained use as a plasma substitute. A commercial preparation, "Macrodex", manufactured by the Pharmacia company, Uppsala, Sweden, contains 6 % partially hydrolyzed dextran and 0.9 % NaCl. The solutions used in the experiments described below were prepared by diluting "Macrodex" and adding the required amount of sodium chloride.

Experiment 3. 0.4 ml of a solution containing 0.6 % dextran and 2.4 % NaCl was injected. The diffusion curves obtained are reproduced in Fig. 24. In this case the dextran gives by far the greatest contribution to the refractive index gradient, which illustrates the facts already pointed out in the theoretical section.

Experiment 4. 0.4 ml of a solution of 0.1 % dextran and 2.9 % NaCl was injected. The diffusion curves are reproduced in Fig. 25. If we assume $R_1 = R_2$ we get

$$\beta = A_1 / A_2 = 2.9/0.1 = 29$$

It is remarkable, and in conformity with the foregoing discussion, how much this small amount of dextran contributes to the refractive index gradient. In fact two distinct peaks in the curve are obtained, the relative positions of which agree fairly well with the relation between the diffusion coefficients.

Experiment 5. 0.4 ml of 0.03 % dextran and 3 % NaCl was injected. The diffusion curves are reproduced in Fig. 26. If $R_1 = R_2$ we have $\beta = A_1/A_2 = 100$. A definite deviation from the curve for pure sodium chloride is seen to occur for low values of x. However, this probably represents the limiting case unless high-molecular impurities can be wholly avoided. In fact, the quantity of dextran injected in this case is only $0.4 \times 0.03 \times 10^{-2}$ g $= 0.12$ mg.

An Analytical Treatment of a Reference Coordinate for the Diffusion and Sedimentation Processes

OLE LAMM

The Royal Institute of Technology, Division of Physical Chemistry, Stockholm 70, Sweden

In order to ensure a clear significance of a reference equation, which is used in certain theories of the diffusion and sedimentation processes, a general derivation and discussion of this equation is developed.

At least in fluid systems, the diffusion and sedimentation processes are generally studied under such conditions that there is no, or only a negligibly small, "bulk displacement" or flow of the mixture as a whole. Here, we will stick to the typical case of a mixture in which the *partial volumes* of the different components are practically independent of the time and the distance coordinates, either owing to very small concentration differences (differential diffusion) or due to the use of nearly ideal mixtures. Absence of flow then simply means that the system is enclosed in a diffusion or sedimentation cell.

The fundamental equations in the diffusion and sedimentation theories (*cf.* Refs.[1–3]) need a complementary equation which defines a reference frame for the flows. In this respect, an equation proposed by Onsager [4]

$$\sum \bar{v}_i J_i = \sum \bar{v}_i C_i c_i = 0 \qquad (1)$$

has been used. J is the flow in moles/cm^2 sec, C the linear velocity of the component, c mole/cm^3 the concentration of the component and $\bar{v}$ its partial molar volume. The sums in these equations have the dimension of velocity and represent the flow in bulk of the mixture. Eqn. (1) has never been deduced analytically and the underlying facts have been explained only for *two* components [5,6]. It is felt that this is disadvantageous at least from an elementary point of view, especially in a case like the sedimentation diffusion process in a centrifugal field. This proceeds in a cell of sector shape and there should be no doubt as to the applicability of eqn. (1) also in this case.

The procedure is to combine the equation of continuity with the general expression $\sum \bar{v}_i dc_i = 0$, known from the treatment of partial quantities in thermodynamics. The former gives for the (trivial) case of parallel flow

$$\frac{\partial c_i}{\partial t} = -\frac{\partial J_i}{\partial x} \tag{2a}$$

and for the cylindrical flow in a parallel-walled cell of sector shape

$$\frac{\partial c_i}{\partial t} = -\frac{1}{x}\frac{\partial xJ_i}{\partial x} \tag{3a}$$

Combining these equations with $\sum \bar{v} \frac{\partial c_i}{\partial t} = 0$ gives

$$\sum \bar{v}_i \partial J_i = 0 \tag{2b}$$

and

$$\sum \bar{v}_i \partial J_i / \sum \bar{v}_i J_i = -\partial x/x \tag{3b}$$

or by integration

$$\sum \bar{v}_i J_i = C' \tag{2c}$$

and

$$\sum \bar{v}_i J_i = \frac{D'}{x} \tag{3c}$$

Owing to $\sum \bar{v}_i (C_i + C)c_i = \sum \bar{v}_i C_i c_i + C$, to give a certain value to the integration contants C' or D' is to define a coordinate for the velocities which is common to all the components. In eqn. (1) these constants are put equal to zero.

In order to see that $C' = 0$ and $D' = 0$ correspond to the case of a closed cell, *i. e.* absence of flow in bulk, we simply have to consider the volume change caused by the transports of ∂n_i mole in the time ∂t per cm² through a certain x-level. This is $\partial V = \sum \bar{v}_i \partial n_i = \sum \bar{v}_i J_i \partial t = \partial t \sum \bar{v}_i J_i$. Hence, $\partial V = 0$ corresponds to the validity of eqn. (1) and *vice versa*.

That $\sum \bar{v}_i J_i$ represents the velocity of the flow in bulk of the mixture is illustrated by eqn. (3c) since, in the sector shaped cell, the velocity of a flow in bulk is inversely proportional to the radius x. It is seen that $D' = 0$ is the only assumption which gives a *fixed* coordinate for the diffusion sedimentation process in a sector-shaped cell. Any other assumption defines a *local* frame, varying with x. This fixed coordinate evidently also holds for the cell itself and the measuring arrangement as a whole.

The Force and Friction Conception in the Diffusion of Multicomponent Systems

OLE LAMM

The Royal Institute of Technology, Division of Physical Chemistry, Stockholm 70, Sweden

The reciprocal relations of irreversible thermodynamics have been examined from the standpoint of the force and friction theory of pure diffusion. In cases where this theory is practicable, it gives a complete description in the sense that the reciprocal relations are dispensable. These latter are shown to be valid for relative flows, whereas the introduction of a special reference frame for the flows gives equations for which the reciprocal relations are not valid. — The force and friction theory contains throughout magnitudes of a direct physical significance, *e.g.* frictional coefficients of a uniform character. The latter coefficients are compared with those occurring in Onsagers theory of diffusion.

According to the force and friction conception, the dynamics [1] of pure diffusion in multicomponent systems is described by [2,8]

$$-c_i \frac{\partial \mu_i}{\partial x} = \sum_{j=1}^{k} (C_i - C_j) \varphi_{ij} \qquad (i = 1 \ldots . k) \tag{1}$$

These equations equalize, for each component i, the forces per unit volume; on the left hand side we have the driving force and on the right hand side the frictional forces for component i. The equations are written here for one-dimensional diffusion (in the x direction); c is the concentration in mole/cm^3, μ the chemical potential, C the component velocity (the flow J_i divided by c_i), φ the friction/cm^3 and k the number of components. The equations refer to the conditions in a volume element (dx).

In Onsagers system of description, the flows are written [3]

$$J_i = - \sum_{j=1}^{k} D_{ij} \frac{\partial c_i}{\partial x} \tag{2}$$

In addition to this we have [2] (*cf.* Refs.[4,5])

$$J_i = - \sum_{j=1}^{k} \Omega_{ij} \frac{\partial \mu_i}{\partial x} \tag{3}$$

According to eqn. (1), the coefficients of eqn. (2) may be expressed in terms of frictions, thermodynamic factors, and concentrations. This will be treated in detail elsewhere [7]. We are, for the present, more interested in eqn. (3), in order to study the reciprocal relations $\Omega_{ij} = \Omega_{ji}$. The coefficients Ω may, according to eqn. (1) be expressed in terms of concentrations and frictions. For this purpose we must, however, have an additional condition for the flows, since otherwise the coefficients Ω are indeterminate. We may define the flows relative to a certain component (= the solvent as "macro-component" in Refs. [4,5]), say component l, by the condition $J_l = 0$. It is, then, an easy matrix calculation to show that, if (as is physically self-evident) $\varphi_{ij} = \varphi_{ji}$, we must also have $\Omega_{ij} = \Omega_{ji}$ and *vice versa*. In view of this, it is difficult to see that the reciprocal relations of pure diffusion are, on principle, capable of giving any new information regarding the process.

The process is completely described in terms of concentrations, frictions and thermodynamic factors, and it can be stated *a priori* that the reciprocal relations can only, at most, yield relations between these magnitudes which are already known.

If, instead of reckoning the flows relative to a component l (see above), we prefer to define a reference frame for the flows [3] by means of the equation $\Sigma J\bar{v}_i = 0$ ($\bar{v}$ = partial molar volume), which has proved very useful in other connections, the coefficients no longer fulfil the condition $\Omega_{ij} = \Omega_{ji}$. Thus it seems that the conditions for a proper choice of fluxes and forces in Onsagers theory have to contain some restrictions regarding the reference frame for the fluxes, especially as the coefficients Ω are always indeterminate (0/0) if *no* additional condition for the flows is introduced.

It should be pointed out that if the force and friction conception is not used and the interpretation (as in the current treatment of the diffusion of gases) is directly concerned with the diffusion coefficients, the reciprocal relations are profitable in giving connections between these coefficients, see Ref.[6].

In addition to eqn. (2), Onsagers system also contains the equations [3].

$$\frac{\partial \mu_i}{\partial x} = -\sum_j R_{ij} J_j \qquad (i = 1 \ldots . k) \tag{4}$$

If $c_i R_{ij}$ are denoted by Φ_{ij}, eqn. (4) may be written

$$\frac{\partial \mu_i}{\partial x} = -\sum_j \Phi_{ij} C_j \tag{5}$$

It is of interest to compare this with eqn. (1), now in the form

$$\frac{\partial \mu_i}{\partial x} = -\sum_j (C_i - C_j) \Phi_{i(j)} \tag{6}$$

where $\Phi_{i(j)}$ is the coefficient of *molar* friction of component i in relation to component j, *i. e.* the friction between the components i and j in a volume, containing one mole of i. It is seen that the two equations, (5) and (6), are identical if

$$\text{a) } \Phi_{ii} = \sum_{\substack{j \\ j \neq i}} \Phi_{i(j)} \quad \text{and b) } \Phi_{ij} = -\Phi_{i(j)} \qquad (j \neq i) \tag{7}$$

Owing to $c_i c_j R_{ij} = -\varphi_{ij}$ $(j \neq i)$, the symmetry of φ_{ij} automatically also leads to symmetry of the R_{ij} coefficients. Whereas the $\Phi_{i(i)}$ evidently do not exist, $\Phi_{ii} = 0$ or $R_{ii} = 0$ are physically unallowable assumptions.

The final aim for the diffusion measurements is to determine the φ-values of eqn. (1) through a solution of the corresponding differential equations [7]. — As the diffusion theory can be outlined in different ways, it is appropriate to make reference also to the well-known work of de Groot [8] for other sides of the problem.

The author's thanks are due to Mr. O. Persson, Civ.Eng., of the Institute of Applied Mathematics (Professor C. G. Esseen), for very valuable help with the matrix calculations, the routine character of which made their reproduction unnecessary.

Investigations on σ-FeCrSi

BERTIL ARONSSON and TORSTEN LUNDSTRÖM

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The solubility of Si in σ-FeCr at 690° and the lattice dimensions of the sigma-phase as functions of the Si-content have been determined.

The distribution of the Si-atoms in σ-FeCrSi is discussed in comparison with some common transition metal silicide structures.

The brittle non-magnetic FeCr sigma phase was first reported by Bain and Griffiths [1] and Chevenard [2] in 1927. In the following years it was discussed whether this phase existed in the *pure* binary system or not. That the sigma phase did exist also when only very small amounts of impurities were present, was shown in 1936 by Jette and Foote [3], who pointed out the accelerating effect of Si and of cold work on sigma phase formation. In the same year, Andersen and Jette [4] investigated the Fe-Cr-Si system (mainly the Fe-rich corner). These authors found that considerable amounts of Si were dissolved in the sigma phase and they outlined the sigma phase region in the ternary system.

In connection with studies of transition metal silicides at this institute we decided to investigate more closely the solubility of Si in the sigma phase. The investigation was limited to the FeCr-Si section of the ternary system. Our results are presented in two parts — the first dealing with the lattice dimensions and the determination of the solubility limit, and the second dealing with our ideas of the distribution of Si-atoms in σ-FeCrSi. In the latter part, some aspects on the relation between the sigma phase structure and some common silicide structures are given.

I. THE SOLUBILITY OF Si IN σ-FeCr

(T. Lundström and B. Aronsson)

Experimental

Electrolytic Cr-powder and Baker's Fe (> 99.8 %) were used. The silicon was analysed and found to contain 98.92 % Si with iron as main impurity. The alloys were prepared by melting in an arc furnace. After annealing at the relevant temperature in evacuated silica tubes they were quenched in oil. The following annealing times were used: 690°,

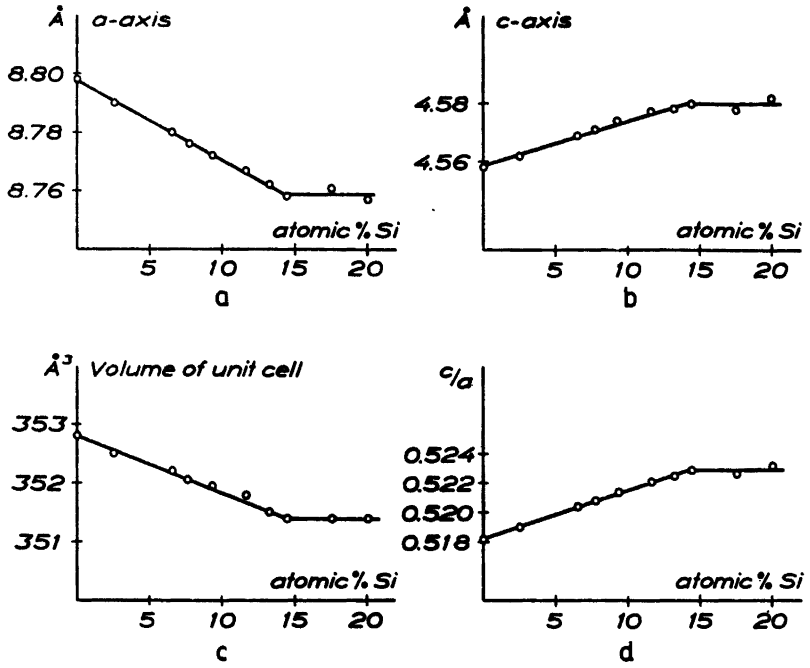

Fig. 1. Lattice parameters of σ-FeCrSi as functions of Si-content at 690°.

22—26 days; 950°, 7 days; 1 200°, 48 hours. All alloys containing less than 15 atomic % Si were analysed for Si and some alloys also for Fe and Cr. It was found that the atomic quotient Fe/Cr was constant = 1.01 with variations less than one per cent. This variation should not affect the lattice parameters more than within the experimental errors. Powder photographs were obtained in a Guinier type focusing camera, using Cr*Ka*-radiation. All specimens were mixed with some NaCl before the exposure and the camera constant was evaluated for each film, assuming the cube edge of NaCl to be 5.6394 Å (18° C) [5]. The agreement between observed and calculated $\sin^2\Theta$-values was ± 0.03 % and the lattice parameters were considered to be accurate to about 0.02 %. Because of the impurities present and a possible error in a_{NaCl}, all values may be subject to a small systematic error. These sources of error are, however, not likely to influence the changes of the lattice parameters.

Results

Alloys, annealed at 690°, showed only the sigma phase lines up to 14.4 atomic % Si. In the 17 % alloy the *110*-line of the α-phase could be observed. The changes of the lattice dimensions with Si-concentration are given in Fig. 1. The figure shows that σ-FeCr dissolves 14.2 % Si at 690° (estimated error about ± 0.5 %). Annealing of the 20 % alloy at 950° and 1 175° has shown that the upper solubility limit varies little with temperature (Fig. 2). At the lower solubility limit no two-phase range was observed between σ and α and for this reason the lower limit, outlined in Fig. 2, is only very approximate. In alloys, containing about 10 atomic % Si, the sigma phase is evidently

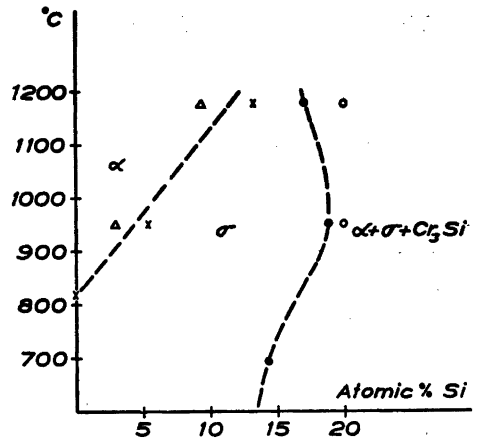

Fig. 2. Sigma region in the section FeCr-Si of the Fe-Cr-Si system.

● Solubility limit of sigma phase, determined from lattice dimensions.

stable up to near the melting point, since around this composition, this phase is the only one found even in the unannealed melts.

The changes of the lattice parameters with variation of the Si-concentration are small (Fig. 1 c). The unit cell volume decreases only 0.03 % per atomic % Si, which is about half the decrease when small amounts of Si (< 10 atomic %) are dissolved in iron [6]. The axial ratio increases from 0.5181 to 0.5229 (Fig. 1 d) when the Si concentration is increased from 0 to 14 atomic % and the highest value of c/a which we have observed is 0.5246 (in an alloy annealed at 950°). The axial ratio is evidently very critical for the sigma structure. It is almost the same for all known sigma phases [7,7a] and the highest value hitherto reported is 0.5237 for σ-MoFe [8] which is only stable in a small temperature interval. It seems probable that when c/a exceeds 0.524 the sigma phase structure becomes energetically unfavourable and is not likely to be formed.

The influence of Si on FeCr-sigma phase formation is quite different from that of carbon [9] and nitrogen [10]. (Recent investigations at this institute indicate that boron behaves similarly to these elements.) When these small non-metals are present, Cr-rich carbides and nitrides are formed, thereby lowering the amount of Cr, available for sigma formation. Silicon, on the other hand, is dissolved in the sigma phase and expands its region of existence appreciably. When the solubility limit is exceeded we have found — confirming the results of Andersen and Jette [4] — that Cr-rich Cr_3Si and Fe-rich α-phase with about the same Si-content are formed. Thus, the equilibria in this part of the Fe-Cr-Si system indicate that Fe and Cr have about the same "affinity" towards Si.

The stabilizing effect of Si on the sigma phase is also revealed in the Cr-Ni-Si system, where this phase is easily formed when small amounts of Si are present but has not been found in the binary Cr-Ni system.

II. THE STRUCTURE OF σ-FeCrSi AND ITS RELATION TO SOME SILICIDE STRUCTURES

(B. Aronsson)

The crystal structure of the sigma phase has been determined by Bergman and Shoemaker [8] and by Dickins, Douglas and Taylor [11]. The unit cell is tetragonal and the space group is D_{4h}^{14}—$P4/m\,n\,m$. The atomic parameters of FeCr, according to B. and S., are given in Table 1 together with the coordination numbers (C.N.) and the number of electrons which these authors have found in the different maxima of the electron density function. As pointed out in Refs.[8,11] the structure resembles that of β—U [12]. (The details of this structure are still under discussion [13].)

Following the nomenclature of Tucker [12], the structure can be described as built up of *main layers*, pseudohexagonal layers from which some atoms have dropped out. Between these are the *subsidiary layers*, the atoms of which are placed above and beneath the holes of the main layers. Atoms of successive subsidiary layers have close contact with each other and form straight rows, perpendicular to the layers.

The ordering in the sigma phase has been discussed in Refs.[8,11]. More definite results on this point have been obtained by Kasper and Waterstrat [14], who investigated the sigma phases, appearing in the Ni-V, Fe-V and Cr-Mn systems, using neutron diffraction. The conclusions of the latter authors are, that V, Cr and Mo (A metals) prefer the positions with the highest C. N. (II, III and V), while Fe, Co and Ni (B metals) prefer the positions with the lowest C. N. (I and IV). Mn can behave both as an A- and a B-metal. The sigma phase appears at different compositions in different systems. Of course, this affects the distribution of the atoms so that III and V may be more or less mixed positions. We have tried to determine if Si behaves as an A-metal, as a B-metal or as Mn.

Experimental

Powder photographs of alloys containing 0, 9.3 and 14.4 atomic % Si were microphotometered and the intensities determined. It was found that the intensity of the *002* powder line of the sigma phase decreased 33 ($\sim \pm 10$) % when its Si concentration increased from 0 to 14.4 %. This shows that the Si-atoms chiefly substitute atoms in the main layers. This is also to be expected from the lattice spacing relations. In order to get some information of the substitution within the main layers a single crystal investigation was undertaken.

A small crystal fragment was picked out of the 11.6 % alloy. When a narrow collimator was used the spots were split into triplets at high glancing angles. This did not affect the intensity measurements appreciably but made an accurate determination of the composition from its lattice parameters difficult. With a method described by Weisz, Cochran and Cole [15] (Θ-method) the a-axis of the crystal was found to be 8.758 Å ($\sim \pm 0.010$ Å), corresponding to a composition of 12—14 atomic % Si or 3.5—4 Si-atoms per unit cell. In this determination Cu$K\alpha$-radiation and the reflexion *11, 1, 0* were used. Efforts to get a better crystal were unsuccessful.

Weissenberg photographs were taken around the c-axis, using Mo$K\alpha$-radiation. The layer lines 0—4 were recorded. The multiple film method was used and the intensities of 110 nonequivalent reflexions were visually estimated. No deviation in the linear dependence of $\log \frac{I_{obs}}{I_{calc}}$ on $\left(\frac{\sin\Theta}{\lambda}\right)^2$ was observed. The temperature constant B was found to be

0.77 Å². Using the structure of Bergman and Shoemaker [8], the observed F-values were put on an absolute scale. The temperature factors were divided out and a threedimensional Fourier-synthesis $\left(\frac{x}{60}\frac{y}{60}\frac{z}{24}\right)$ was made with the aid of the Hägg-Laurent [16] machine. The number of electrons in the different maxima of the electron density function were summed. With these atomic numbers and the parameters of Bergman and Shoemaker a three-dimensional $F_o - F_c$ synthesis was worked out in the section $xy0$. Small maxima of nearly the same height were found at the assumed atomic positions — confirming that the result of the electron counts fitted well to the intensity data. The atomic coordinates, determined from the difference synthesis, were not significantly different from those of Bergman and Shoemaker. The background indicated that a standard deviation in number of electrons of 0.5 e for the atoms II, III and IV and of 1.0 e for the atom I was reasonable. The same value was obtained with a formula given by Cruickshank [17].

The distribution of Si-atoms may, of course, vary with annealing temperature and Si-content. It should be emphasized that the results of this investigation have been obtained from a 12 % alloy, annealed 22 days at 690°.

Results and discussion

The result of the electron counts is given in Table 1, column 5. The number of electrons found in position IV is about 10 % lower than the numbers found in the other positions. The considerations of the preceding paragraph indicate that this difference is significant. Certainly there are many factors which may influence the result of electron counts, but the most reasonable interpretation

Table 1.

	Position [8]	Parameters [8]	C.N. [8]	Atomic number in σ-FeCr [8]	Atomic number in σ-FeCrSi$_{0.25}$
I	2(*a*)		12	28.1	26.0
II	4(*f*)	$x = 0.3981$	15	23.8	23.8
III	8(*i*)	$x = 0.4632$, $y = 0.1316$	14	25.8	24.2
IV	8(*i*)	$x = 0.7376$, $y = 0.0653$	12	25.8	21.6
V	8(*j*)	$x = 0.1823$, $z = 0.2524$	14	23.3	24.1

of the above mentioned result is that the Si-atoms mainly occupy IV-positions. That is, Si behaves as a B metal. If the metal atoms are ordered as Kasper and Waterstrat [14] suggest, the approximate distribution of atoms in σ-FeCrSi— should be: mainly Fe in I, mainly Cr in II, about 3 Si- and 5 Fe-atoms in IV and a mixture of Fe and Cr (and perhaps a little Si) in the III- and V-positions.

That silicon behaves as a B-metal in σ-FeCr is in accordance with the facts that the solubility of Si is greater in Fe (26 atomic %)[6] than in Cr (< 14 %) [18] and that the highest coordination number of Si in any known silicide structure is 12. At first glance, it seems curious that no Si-atoms are found in I-positions. Inspecting Fig. 3 a more closely we see, however, that if more than two Si atoms shall be placed in the unit cell the IV-positions alone permit a more even distribution of the Si-atoms in the structure, than does a combination of I- and IV-positions. If Si-Si contacts are to be avoided, a maximum of four Si-atoms per unit cell can occupy the positions, having 12 coordination, and this can only be achieved if IV-positions alone are occupied. It must be mentioned that the solubility limit corresponds to about four Si-atoms per unit cell.

There are some interesting common features in the sigma- and the cubic *A* 15-(or W_3O-[19]) structures in both of which straight rows of metal atoms with close contact are found. Inspecting Figs. 3 a and 3 d and Table 2, we see that the III-atoms of the sigma phase have two close and eight remote A-metal neighbours as well as four B-metal neighbours at "normal" distances, while the Cr-atoms of Cr_3Si [18] (W_3O-type) are surrounded by 2 + 8 Cr-atoms and 4 Si-atoms at similar distances. The figures further show that the spatial arrangements of atoms around the III- and V-atoms are roughly the same as around the Cr-atoms of Cr_3Si. On the other hand, the I- and IV-atoms have environments, similar to that of the Si-atom of Cr_3Si. These similarities are only qualitative, but it is interesting to note that — following the nomenclature of Kasper and Waterstrat [14] — all the hitherto reported phase of W_3O-type [20,20a,20b,31] can be written A_3B, where we have to add Ti, Zr, Nb, Ta and W to the A-metals and Ru, Rh, Os, Ir, Pt, Au, Hg, Ga, Sn, Si, As and

Sb to the B-metals given by these authors. Perhaps, some general principle accounts for the structural similarities between V_3Ni [21] (W_3O-type) and σ-NiV [14] as well as between Cr_3Si and σ-FeCrSi.

As seen from Figs. 3 b and 3 e, the concepts of main and subsidiary layers are also very suitable for the description of two other silicide structures, namely the W_5Si_3—[22,23] ($T1$-) [24] and $D8_8$[25]-structures. The main layers are more irregular than in the sigma phase, but the short distances between atoms of successive subsidiary layers and the characteristic 14-coordination around these atoms are also found here. In W_5Si_3, the structure of which can be described as a combination of the sigma- and the $CuAl_2$-structures, both Me- and Si-rows are found. In order to be stable such a structure probably demands shorter distances in the rows than do structures which contain only Me-rows (*e. g.*, $D8_8$). The discussion of the sigma- and W_3O-structures has shown that rows with the closest interatomic contact are most easily formed by the metals

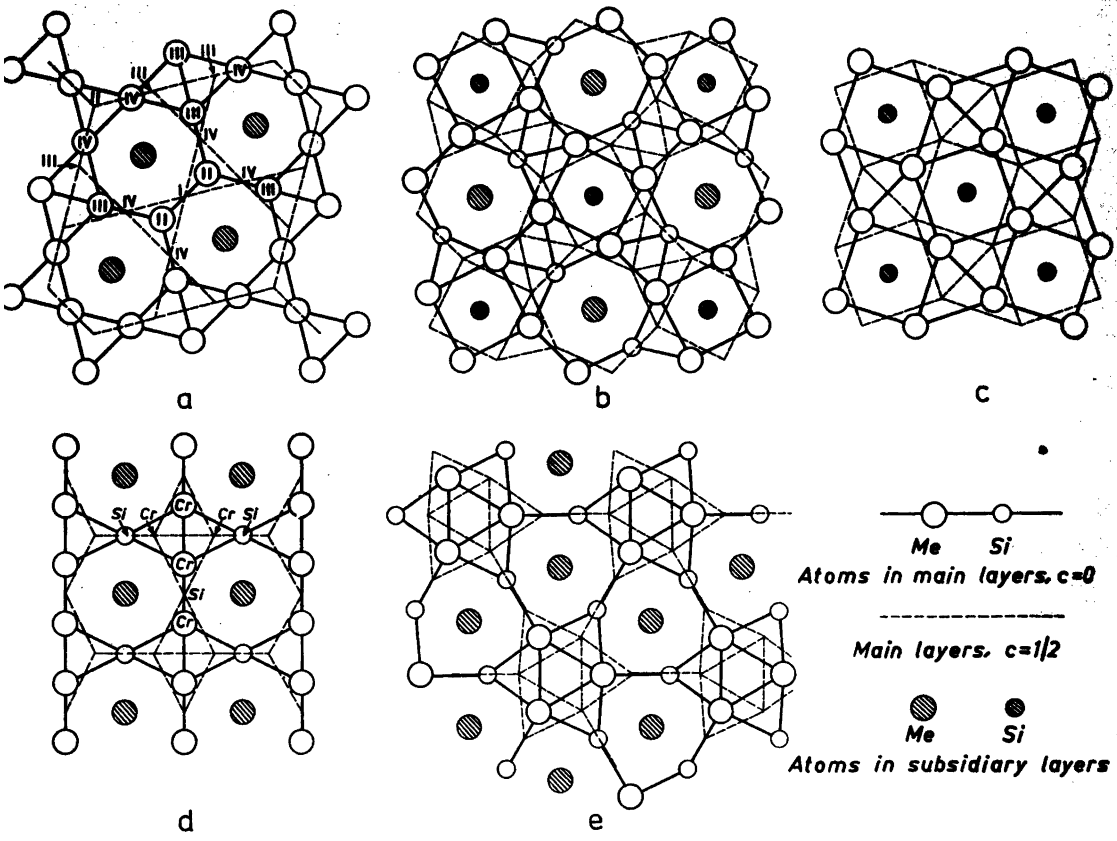

Fig. 3. The sigma structure and some silicide structures. a. σ -FeCr [8]. b. W_5Si_3 [22,23]. c. Ta_2Si [30] ($CuAl_2$-type). d. Cr_3Si [18]. e. Mn_5Si_3 [25]. The layers are parallel to the plane of the paper. (In $D8_8$ the main layers are found in the planes $c = 1/4$ and $c = 3/4$.)

of the Va and VIa groups. This may be part of the explanation of the curious morphotropy among the Me_5Si_3-phases: Ti_5Si_3 [26] ($D8_8$), V_5Si_3 [27] ($T1$), Cr_5Si_3 [22] ($T1$), Mn_5Si_3 [25] ($D8_8$) and Fe_5Si_3 [6] ($D8_8$) with the following interatomic distances in the metal rows: 2.58 Å, 2.37 Å, 2.30 Å, 2.40 Å and 2.36 Å. Recently these phases have been comprehensively discussed by Nowotny and his school [24,28].

As pointed out by Bergman and Shoemaker [8], Fe_7W_6 is structurally related to the sigma phases. In the rhombohedral Fe_7W_6 [25]-structure, groups of four W-atoms are found on the trigonal axis. The distances between adjacent atoms of such a group are less than in elementary W.

The most conspicuous structural feature of all these metallic phases are the straight rows of atoms with close contact. These rows are most easily formed by the transition metals of the Va- and VIa-groups. They are found in a number of common silicide structures, which indicates that silicon has

some beneficial effect on the stability of these rows. As long as so little is known about the electronic structures of the transition elements, it is probably meaningless to try to give a more fundamental explanation of the mentioned facts.

Acknowledgements. We want to express our gratitude to Professor G. Hägg and Dr. I. Lindqvist for their kind interest in this work and for all the facilities they have put at our disposal.

The chemical analyses were carried out at the analytical department of this institute. We wish to thank the Head of this department, Dr. F. Nydahl, as well as Dr. Lilly Gustafsson and Mr. L. Bergin for their excellent assistance.

Thanks are also due to Mrs. B. Flemström, who has prepared the manuscript and to Mr. S. Wahlgren and J. Åselius for technical assistance.

This investigation has been supported by the *Swedish State Council for Technical Research*, whose aid is gratefully acknowledged.

On the Hydrolysis of Trialkylphenoxysilanes. II

EVERT ÅKERMAN

Department of Organic Chemistry, University of Lund, Lund, Sweden

The hydrolysis of twelve substituted triethylphenoxysilanes in aqueous ethanol has been studied spectrophotometrically. The reaction is catalysed by both acid and alkali. The catalytic constants for the *meta*- and *para*-substituted compounds agree well with the Hammet equation. Dimethyl-*t*-butylphenoxysilane has been prepared and its hydrolysis studied. The mechanisms of the reactions are discussed and the ultraviolet spectra are described.

In a previous paper [1] the preparation and hydrolysis of five trialkylphenoxysilanes was described, the alkyl groups being methyl, ethyl, *n*-propyl, *n*-butyl and *n*-amyl. The specific rate of the reaction was found to be proportional to the hydrogen ion concentration in acid solution and the sum of hydroxide and ethoxide ion concentrations in alkaline solution and to diminish with increasing length of the alkyl groups. The investigation has now been extended to phenoxysilanes with substituents in the phenoxy group in order to acquire better knowledge of the mechanism of the reactions and, if possible, to obtain a quantitative relationship between rate constants and substituents according to Hammet's equation [2]. Some reactions of substituted aryl- and benzylsilanes have been reported, where the rate constants satisfy the Hammet equation. Gilman and Dunn [3] investigated the hydrolysis of six triarylsilanes in wet piperidine and found a reaction constant $\varrho = 3.09$, but the rate constant for one of the substituents, the *para*-dimethylamino group, did not satisfy the equation when the σ-value from Hammet's table was used. Eaborn and Parker [4] studied spectrophotometrically the alkali-catalysed cleavage of seventeen substituted benzyltrimethylsilanes in aqueous methanol. They found the substituent effects to agree well with Hammet's σ constants and they calculated a reaction constant $\varrho = 4.88$.

The reaction now examined is described by the over-all reaction formula

$$(C_2H_5)_3SiOC_6H_4R + H_2O \longrightarrow (C_2H_5)_3SiOH + HOC_6H_4R$$

From the five trialkylphenoxysilanes previously measured triethylphenoxysilane was chosen as the unsubstituted compound, as it has the most convenient rate of reaction. The corresponding trimethyl compound was not chosen, as its rate constants are much too great to be measured with accuracy. The

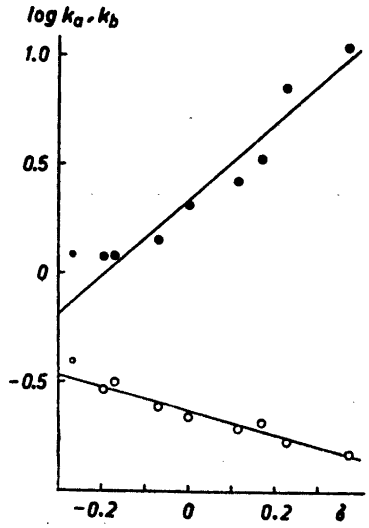

Fig. 1. Catalytic constants *versus* Hammet's σ-constants.
● Alkaline hydrolysis of triethylphenoxysilanes.
O Acid » » »

following twelve substituents have been introduced in the phenoxy group: *o*-CH_3, *m*-CH_3, *p*-CH_3, *p*-*t*-C_4H_9, *o*-CH_3O, *m*-CH_3O, *p*-CH_3O, *o*-Cl, *m*-Cl, *p*-Cl, 1,3$(CH)_4$ (*α*-naphthyl) and 2,4$(CH)_4$ (*β*-naphthyl). The rate constants k were determined for at least five different concentrations of hydrogen ions and five concentrations of hydroxyl ions. The catalytic constants $k_a = k/[\text{acid}]$ and $k_b = k/[\text{base}]$ were calculated and were found to be reasonably constant for each compound. Consequently none of the compounds have any spontaneous hydrolysis rapid enough to be noticed at the actual concentrations. These results are collected in Table 1.

According to Hammet [2] the quantitative relationship between the rate constants k' for the reaction of a *meta*- or *para*-substituted benzene derivative and the so called substituent constant σ is expressed by the formula

$$\log k' - \log k_0' = \varrho\,\sigma$$

where k'_0 is the rate constant of the unsubstituted compound, ϱ is a constant, the reaction constant, and σ is defined from the equation

$$\sigma = \log K - \log K_0$$

K and K_0 being the dissociation constants of the benzoic acid with the same substituent and that of unsubstituted benzoic acid, respectively. A plot of the catalytic constants k_a and k_b of the *meta*- and *para*-substituted phenoxysilanes in Table 1 against σ is shown in Fig. 1. (The two small circles at $\sigma = -0.27$ refer to the *para*-methoxy group, *cf* below). The σ values are taken from Jaffé's review on the Hammet equation[5]. The plot shows that the expected

a α-naphthyl, b β-naphthyl, c from Ref[1].

linear relationship between log k and σ is rather well satisfied. One of the points, *viz* that for the *para*-methoxy group, has an obviously greater deviation than the others from the best straight line. This is, however, not uncommon (*cf* Ref. 5. p. 230), and so it seems reasonable to exclude this point when calculating the reaction constant. This constant ϱ and the calculated catalytic constant for the unsubstituted compound k_0 were obtained according to the method of least squares. The results together with the standard deviation s and the correlation coefficient r (calculated in the same way as in Jaffé's review [5]) are given in Table 2. The figures in parenthesis are the values obtained when the rate constants for the *para*-methoxy group are included.

Attempts have been made to extend the Hammet equation to other reactions than those of *meta*- and *para*-substituted benzene derivatives. Thus Taft [6–8] succeeded in modifying the equation by introducing a steric term E_s in such a way that the equation became valid also for *ortho* substituents:

$$\log k - \log k_0 = \varrho\sigma^* + E_s \qquad (1)$$

Table 2. Reaction constant ϱ, log k_0, standard deviation s and correlation coefficient r for the acid and base catalysed hydrolysis of triethylphenoxysilanes.

Catalysis	ϱ	log k_0	s	r
Acid	−0.533 (−0.600)	−0.632 (−0.621)	0.030 (0.038)	0.968 (0.964)
Base	1.742 (1.575)	0.337 (0.364)	0.094 (0.109)	0.970 (0.958)

The polar substituent in this equation was originally indicated by E_σ, but this was later [7] changed to σ^*. The substituent constants are evaluated by assuming that ϱ has the same value as for *meta-para*-substituted derivatives and that E_s has the same value in alkaline as in acid hydrolysis. The agreement between Taft's values and those that can be calculated from the rate constants in Table 1 are, however, only qualitative. This is not unexpected as the validity of eqn. (1) is much more limited than that of the Hammet equation. Thus all the reactions investigated by Taft are of one single type, *viz.* esterification and ester hydrolysis.

It is still less probable that the hydrolysis of trialkylphenoxysilanes with different alkyl groups should fit eqn. (1). It is possible in the case of substituted acetates as shown by Taft [6-8], but here only *one* substituent is changed and in the compounds described in Part I [1] of this work *three* substituents are changed. Even if polar effects might be additive as in the case of *meta-para*-substituted benzene derivatives, this is probably not true for steric effects.

In addition to the five compounds previously described, dimethyl-*t*-butylphenoxysilane has been prepared and its hydrolysis studied (Table 3). The rate constants of these six compounds cannot - as expected - be correlated with Taft's σ^* and E_s constants according to eqn. (1). It is interesting, however, to compare the specific rate constants of dimethyl-*t*-butylphenoxysilane with those of triethylphenoxysilane ($k_a = 0.219$, $k_b = 2.05$) and trimethylphenoxysilane ($k_a = 10.4$, $k_b \approx 330$). The substitution of a *t*-butyl group for a methyl group lowers the catalytic constants by a factor of 10^{-5}. But even in comparison with triethylphenoxysilane, dimethyl-*t*-butylphenoxysilane is hydrolysed very slowly, the ratio between the catalytic constants being less than 10^{-2}. If the polar effects in these two compounds are assumed to be of the same order of magnitude (the numbers of carbon atoms in α- and β-position to the silicon atom are the same, and according to Taft [7], σ^* for three ethyl groups is —0.72, σ^* for two methyl groups plus one *t*-butyl group is —0.84), the low rate constants can at least to a large extent be ascribed to the steric influence of the *t*-butyl group.

From these facts several mechanisms of the reactions can be formulated. As the reaction constant for the alkaline hydrolysis has a rather high positive value, this reaction is obviously facilitated by a low electron density at the

reaction centre. The simplest mechanism consistent with this is an S_N2 mechanism:

$$RO^- + Et_3SiOC_6H_4R' \rightarrow \overset{\delta^-}{RO} \ldots Et_3Si \ldots \overset{\delta^-}{OC_6H_4R'} \rightarrow ROSiEt_3 + {}^-OC_6H_4R'$$

followed by the equilibrium

$$R'C_6H_4O^- + ROH \rightleftharpoons R'C_6H_4OH + RO^-$$

where R is H or Et.

The acid hydrolysis has a negative value of the reaction constant, so it must be facilitated by a high electron density at the reaction centre. A simple mechanism involves a fast proton transfer and a slow reaction between a charged complex and a solvent molecule:

$$ROH_2^+ + Et_3SiOC_6H_4R' \rightarrow ROH + Et_3\overset{H}{\underset{+}{Si}}OC_6H_4R'$$

$$Et_3\overset{H}{\underset{+}{Si}}OC_6H_4R' + ROH \rightarrow Et_3\overset{H}{\underset{+}{Si}}OR + HOC_6H_4R'$$

$$Et_3\overset{H}{\underset{+}{Si}}OR + ROH \rightarrow Et_3SiOR + ROH_2^+$$

However, the first step can also be rate determining and the second one rapid. R is also here H or Et.

In either case it is possible to formulate a mechanism involving a pentacovalent silicon atom. Eaborn and Parker [4] did not exclude this possibility in the alkaline hydrolysis of benzyltrimethylsilanes, and Swain, Esteve and Jones [9] made such an intermediate probable in the reaction between water and triphenylsilylfluoride. According to this mechanism the alkaline hydrolysis could be represented by the formula

$$RO^- + Et_3SiOC_6H_4R' \overset{\text{fast}}{\rightleftharpoons} Et_3(RO)\overset{-}{Si}OC_6H_4R' \overset{\text{slow}}{\rightarrow} Et_3SiOR + R'C_6H_4O^-$$

if the last step is assumed to be rate determining as in the hydrolysis of triphenylsilylfluoride. A similar mechanism - with a positive intermediate - can be formulated for the acid hydrolysis.

In addition to these mechanisms there are also other possibilities where the carbon-oxygen bond is broken, but there is some indication that the cleavage of silicon-oxygen bond is favoured at least in the case of alkoxysilanes [10]. The stability of aryl ethers against hydrolysis at room temperature also indicates a cleavage of the silicon-oxygen bond. It is true that *t*-butyl phenyl ether - the carbon analogue of trimethylphenoxysilane - is less stable than *n*-alkyl phenyl ethers, but the ease with which it is cleaved by mineral acids depends on the formation of *i*-butylene and phenol [11].

EXPERIMENTAL

The phenoxysilanes were prepared from triethylchlorosilane and the corresponding phenol according to the formula

$$(C_2H_5)_3SiCl + HOC_6H_4R \rightarrow (C_2H_5)_3SiOC_6H_4R + HCl$$

as previously described [1]. If the evolution of hydrochloric acid was very slow, as in the case of dimethyl-*t*-butylphenoxysilane, the reaction was carried out in pyridine.

Dimethyl-t-butylphenoxysilane. To 6.6 g (0.07 mole) of phenol in 5 g of pyridine were added 10.6 g (0.07 mole) of dimethyl-*t*-butylchlorosilane prepared according to Sommer and Tyler [12] dissolved in 15 g of pyridine, and the mixture was refluxed for half an hour. The precipitated pyridine hydrochloride (6.0 g, calc. 8.1 g) was filtered off and washed with dry ether. The ether and pyridine was distilled off and the residue distilled *in vacuo*. 3.0 g = 45 % of phenol were recovered and the yield of the silane was 6.8 g = 48 %. B. p. 100–101°/15 mm, $n_D^{20} = 1.4812$, $d^{20} = 0.9127$, $MR_D = 64.97$. (Found: C 69.3; H 9.7; Si 13.6; Calc. for $C_{12}H_{20}OSi$: C 69.2; H 9.7; Si 13.5). Analyses and physical constants for the other compounds are found in Table 4. The agreement between the found and calculated molecular refractivity is not very good, the found value being on the average 0.2 ml too high, but it is known that the phenoxy group attached to silicon has no constant group refractivity as shown by Smith [13] in the case of mixed alkoxy-phenoxysilanes.

The rate constants were determined as in Ref.[1] and thus the temperature was 25.0°C, the ionic strength 0.05 M and the solvent 51.4 wt-% ethanol. As examples of buffers used in the alkaline hydrolysis at low hydroxyl ion concentrations can be mentioned: in 0.013 M glycinate + 0.003 M glycine [OH^-] is equal to 3×10^{-5} M, in 0.012 M $NaHCO_3$ + 0.006 M Na_2CO_3 [OH^-] is equal to 3×10^{-4} and in 0.005 M $NaHCO_3$ + 0.010 M Na_2CO_3 [OH^-] is equal to 10^{-3} M.

The ultraviolet spectra were determined and are generally similar to those of unsubstituted phenoxysilane in having only one maximum in the region 250–320 mμ, but five of the compounds have a secondary maximum. The wavelengths and extinction coefficients of these maxima are given in Table 5 together with the wavelengths used for the kinetics. The spectra of the naphthoxysilanes are more complicated (Fig. 2). The rate of hydrolysis for the α-naphthoxycompound was determined at 325 mμ and that for the β-naphthoxycompound at 335 mμ in acid and 340 mμ in alkaline solution.

The author is indebted to Professor Erik Larsson for his kind interest in this work.

ACTA CHEMICA SCANDINAVICA 11 (1957) 382—390

Recommendations by the Commission on Physico-Chemical Symbols and Terminology under the International Union of Pure and Applied Chemistry (IUPAC), 1955

The following pages contain a reprinted edition of the recommendations by the above mentioned Commission from its meeting in Zürich 1955. It has been submitted to this journal by its chairman J. A. Christiansen, who has also read the proofs.

RECOMMENDATIONS ON MATTERS OF DETAIL

The recommendations on the following pages are mainly those agreed upon in Amsterdam (1949), with modifications which subsequent discussions in the commission have made desirable. The commission refers to the report of 1949 concerning the history and concerning the agreement with recommendations from related bodies, especially the S. U. N. commission of I. U. P. A. P.

Referring to section III below the commission has found it desirable however to quote two paragraphs from the introduction to the report of 1949.

"It is recognised that recommendations by an international body must involve compromises and will sometimes have to include alternative usages for particular quantities from which the various national organisations can select those most closely in accord with their established practices. The proposals now made are not therefore intended to prescribe rigidly usages that should be universally adopted, but to give guidance in seeking a wider measure of international agreement and warning of instances where existing diversities may cause misunderstandings."

"Even among chemists in different countries, or belonging to different schools, complete agreement has not been attained on the use of symbols for certain quantities and in a few instances it may be necessary, at least temporarily, to agree to disagree and to say so."

I. NUMBERS AND MATHEMATICAL OPERATIONS

Numbers should be printed in upright figures, using a comma or point only to separate whole numbers from the decimals. To facilitate reading of long numbers the figures may be grouped together in threes without using commas or points to separate the groups.

Symbols for mathematical operations should be printed in roman (upright) type.

II. ABBREVIATIONS FOR WORDS

To be printed in upright type.

A. ABBREVIATIONS FOR THE NAMES OF UNITS

Abbreviations for units named after persons begin with a capital letter. Single capital letters used as abbreviations may be printed in smaller type than is used in the body of the text, but practice in this varies and no recommendation is made.

metre	m	degree Celsius (1)	°C
micron	μ	degree Fahrenheit (1)	°F
ångström	Å	degree Kelvin (1)	°K
litre	l	lumen	lm
second	s	lux	lx
minute	min	stilb	sb
hour	h	candela	cd
hertz	Hz	coulomb	C
gramme	g	ampère	A
tonne	t	volt	V
dyne	dyn	ohm	Ω
newton	N	farad	F
bar	b	henry	H
poise	P	molal (concentration) (2)	m
joule	J	molar (concentration) (2)	M
watt	W	normal (concentration) (2)	N
calorie	cal	formal (concentration) (2)	F

Prefixes to abbreviations for the names of units indicating:

Multiples			Sub-multiples		
tera	10^{12}	T	deci	10^{-1}	d
giga	10^{9}	G	centi	10^{-2}	c
mega	10^{6}	M	milli	10^{-3}	m
kilo	10^{3}	k	micro	10^{-6}	μ
			nano	10^{-9}	n
			pico	10^{-12}	p

(1) The °sign and the letter following form *one symbol* and there should be no space between them *e. g.* 25 °C or 25°C but *not* 25° C.

(2) Used only when preceded by numerals to indicate the magnitude of a concentration in the specified terms and not as symbols for concentrations in equations.

B. ABBREVIATIONS FOR OTHER WORDS

These will vary with the language used and no attempt is therefore made to secure uniformity of practice at an international level.

A full point is sometimes used after abbreviations but this practice is not recommended except when required to avoid confusion.

III. SYMBOLS FOR PHYSICAL AND CHEMICAL QUANTITIES

Symbols for physical and chemical quantities, in contrast to abbreviations for units, should be printed in sloping (italic) type whenever these symbols are letters of the latin alphabet and if practicable when they are letters of the greek alphabet. A bold face italic type may be used to represent certain specified physical constants or conversion factors.

Symbols separated by commas represent equivalent recommendations.

Symbols preceded by three dots are alternatives to be used only when there is some reason for not using a symbol before the three dots.

Space, time, mass and related quantities

Chemical Reactions

	Quantity	Symbol
401	stoichiometric number of molecules (negative for reactants, positive for products)	ν
402	standard equation of chemical reaction	$\Sigma \nu_B B = 0$
403	affinity ($-\Sigma \nu_B \mu_B$) of a reaction	A
404	equilibrium constant	K
405	equilibrium quotient or equilibrium product (of molalities)	Q
406	extent of reaction ($dn_B = \nu_B d\xi$)	ξ
407	degree of reaction (*e.g.* degree of dissociation)	α
408	rate constant	k
409	collision number (collisions per unit volume and unit time)	Z

Light

	Quantity	Symbol
501	Planck's constant	h, $\boldsymbol{h}$
502	» » divided by 2π	$\frac{1}{2}\boldsymbol{h}$
503	quantity of light	Q
504	radiant power, flux of light ($\mathrm{d}Q/\mathrm{d}t$)	Φ
505	luminous intensity ($\mathrm{d}\Phi/\mathrm{d}\omega$)	I
506	illumination ($\mathrm{d}\Phi/\mathrm{d}S$)	E
507	luminance	L, B
508	luminous emittance	H
509	absorption factor (fraction of incident radiant power which is absorbed)	α
510	reflection factor (fraction of incident radiant power which is reflected)	ϱ
511	transmission factor (fraction of incident radiant power which is transmitted)	τ
512	transmittance ($T = I/I_0$)	T
513	absorption (extinction) coefficient ($\varkappa lc = \ln(1/T)$	$\varkappa$
514	absorbance (extinction) ($A = \log_{10}(1/T)$)	$A...E$
515	absorptivity (specific absorbance) (decadic absorption or extinction coefficient)	a
516	molar absorptivity (molar decadic absorption or extinction coefficient) ($\varepsilon lc = A$)	ε
517	refraction index	n
518	refractivity	r
519	angle of optical rotation	α

Electricity and magnetism

703	degree of electrolytic dissociation	α
704	ionic strength	$I...\mu$
705	electrolytic conductivity (specific conductance)	$\varkappa$
706	equivalent or molar conductance of electrolyte or ion	Λ
707	transport number	t, T
708	electromotive force	E
709	overpotential	η

SYMBOLS FOR SUBSIDIARY QUANTITIES

It is much more difficult to make detailed recommendations on symbols for subsidiary quantities than on symbols for the principal quantities. The reason is the incompatibility between the need for specifying numerous details and the need for keeping the printing reasonably simple. Among the most awkward things to print are superscripts to subscripts and subscripts to subscripts. Examples of symbols to be avoided are

$$\Lambda_{NO_3^-} \text{ and } H_{25°C}$$

The problem is vastly reduced if it is recognized that two different kinds of notation are required for two different purposes. In the formulations of general fundamental relations the most important requirement is a notation easy to understand and easy to remember. In applications to particular cases, in quoting numerical values and in tabulation the most important requirement is complete elimination of any possible ambiguity even at the cost of an elaborate notation.

The advantage of a dual notation is already to some extent accepted in the case of concentration. The best notation for formulating the laws of homogeneous chemical equilibrium is something such as

$$\mathrm{A} + ... \rightleftharpoons \mathrm{L} + ...$$

$$\frac{c_{\mathrm{L}...}}{c_{\mathrm{A}...}} = K_c$$

$$\frac{m_{\mathrm{L}...}}{m_{\mathrm{A}...}} = K_m$$

but when we turn to a particular example it is better to use a notation such as

$$Br_2 + H_2O \rightleftharpoons HOBr + H^+ + Br^-$$
$$\frac{[HOBr]\,[H^+]\,[Br^-]}{[Br_2]} = K_c$$
$$K_c(25\,^\circ C) = 6 \times 10^{-9}\ \text{mole}^2\,\text{l}^{-2}$$

Once the principle of dual notation is accepted, its adaptibility and usefulness become manifest in all fields of physical chemistry. It will here be illustrated by just a few examples.

The general relation between the equivalent conductance of an electrolyte and the equivalent conductance of the two ions is written most simply and most clearly as

$$\Lambda = \Lambda^+ + \Lambda^-$$

but when it comes to giving values in particular cases a much more appropriate notation is

$$\begin{aligned}
\Lambda(\tfrac{1}{2}\,Mg^{++}) &= 53\ \Omega^{-1}\,\text{cm}^2\,\text{equiv}^{-1}\ \text{at}\ 25\,^\circ C\\
\Lambda(Cl^-) &= 76\ \Omega^{-1}\,\text{cm}^2\,\text{equiv}^{-1}\ \text{at}\ 25\,^\circ C\\
\Lambda(\tfrac{1}{2}\,MgCl_2) &= 129\ \Omega^{-1}\,\text{cm}^2\,\text{equiv}^{-1}\ \text{at}\ 25\,^\circ C\\
\Lambda(MgCl_2) &= 258\ \Omega^{-1}\,\text{cm}^2\,\text{mole}^{-1}\ \text{at}\ 25\,^\circ C
\end{aligned}$$

In both notations the meaning of the symbols is so obvious and so well suited to the purpose that it is hardly necessary even to define them.

Again partial quantities are most simply denoted by the use of a subscript, for example V for partial volume and the general relation between the partial volumes of the two components of a binary system is written most simply

$$n_1 \mathrm{d}V_1 + n_2 \mathrm{d}V_2 = 0 \qquad (T,\ P\ \text{const.})$$

and this relation holds whether the partial volumes V_1, V_2 are expressed per mole or per gram or per kilogram according as the quantities n_1, n_2 are measured in moles or grams or kilograms. When it is desired to emphasize the contrast between partial quantities, which are intensive, and the extensive properties from which they are derived, this may be achieved either by use of a bar over the symbol or by use of the corresponding lower case letter. Thus in these notations

$$n_1 \mathrm{d}\overline{V}_1 + n_2 \mathrm{d}\overline{V}_2 = 0 \qquad (T,\ P\ \text{const.})$$
$$n_1 \mathrm{d}v_1 + n_2 \mathrm{d}v_2 = 0 \qquad (T,\ P\ \text{const.})$$

But when it comes to specifying values a completely different notation is called for such as

$$\begin{aligned}
V\,(K_2SO_4,\ \text{aq.},\ 0.1\ \text{M},\ 25\,^\circ C) &= 48\ \text{ml mole}^{-1}\\
&= 24\ \text{ml equiv}^{-1}\\
&= 0.27\ \text{ml g}^{-1}
\end{aligned}$$

Each kind of notation is appropriate to its purpose.

Incidentally the notation for extensive and partial quantities need not be restricted to purely thermodynamic quantities but is also appropriate to such quantities as refractions. Thus if we define the refraction R (an extensive property) by

$$R = \frac{n^2-1}{n^2+2} V$$

then it becomes natural to denote the derived partial refractivity by R_i or $\overline{R}_i$ or r_i.*

Short Communications

Δ^3-Carene and (+)-Limonene Mixtures

GUNNAR WIDMARK

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Sweden

In a previous communication, Widmark and Blohm [1] have demonstrated the usefulness of an analytical micro-sorption method devised by Blohm [2], when studying terpene mixtures. In the above mentioned paper [1] it was shown that the refractive indices of Δ^3-carene and (+)-limonene, n_D^{25} = 1.4700 and 1.4703, respectively, were too close to allow good readings of the sorptograms of mixtures of these two pure terpenes.

This paper demonstrates that this limitation of the sorption method can be overcome by measuring in a microtube the optical rotations of 0.4 ml ethanolic solutions made up from the 5 μl fractions obtained from the sorption. This method is of course limited to compounds possessing marked differences in their optical activities, *e.g.* (+)-limonene, $[\alpha]_D^{25}$ = +123, and Δ-carene, $[\alpha]_D^{25}$ = +17, and is found to be less accurate and much more laborious than the ordinary way of reading the refractive indices.

Experimental part. The Δ^3-carene and (+)-limonene were purified to index homogeneity according to Widmark [3,4]. The mixtures were prepared by weighing *ca.* 0.4 g samples to form five solutions containing 5, 10, 50, 75 and 90 % (+)-limonene in Δ^3-carene. 40 μl lots of these solutions were pipetted into the top of a 250 mm high column (i Ø 1.4 mm) of activated silica gel [2]. The samples were displaced with ethanol at 1 atm. pressure in the ordinary way [2,1] and eight 5.0 μl fractions were collected in capillaries. The fractions were transferred to 0.40 ml quantities of ethanol in small test tubes. The capillaries were rinsed by sucking the solutions up and down several times. The optical rotations of the solutions were measured in a 5 cm microtube (Hilger Co., M 289, volume 0.35 ml) and the mean value of 10 readings was taken. The results are given in Fig. 1.

A Comparative Study of the Autoxidation of Δ^3-Carene, α-Pinene, β-Pinene and (+)-Limonene

GUNNAR WIDMARK and
SVEN-GÖSTA BLOHM

Institute of Organic Chemistry and Biochemistry, University of Stockholm, and Department of Dermatology, Karolinska Institutet, Stockholm, Sweden

A comparison of the rates of autoxidation of the four most commonly occurring terpenes in technical turpentine is a question of technical interest, but as oxidized turpentine is aggressive to sensitive human skin [1], the oxidation rates are of importance for dermatological research. In a preceding series of communications, the present authors have given the experimental conditions for this investigation. These necessitate having a method to investigate the homogeneity [2,3] and a way to purify [4,5] the individual terpenes. However, the inhibiting or accelerating influence of minimum impurities, which cannot be detected by the sorption method has not of course been taken into consideration.

The four terpenes, freshly distilled, were prepared in a state of index homogeneity giving the sorptograms; Δ^3-carene $n_D^{25} =$ 1.4700US, 1–7, α-pinene 1.4632US, 1–7, β-pinene 1.4762US, 1–7 and (+)-limonene 1.4703US, 1–7. Twenty-gram samples were added to four oxidation apparatus assembled side by side on a wooden stand (*cf.* Blohm and Widmark [6]) which were kept at room temperature (22±2°C) and in diffuse daylight *. The consumption of oxygen was measured daily, and at the same time the oxidation vessels were removed and weighed. The samples were analysed by sorption and iodine titration, and the viscosity,

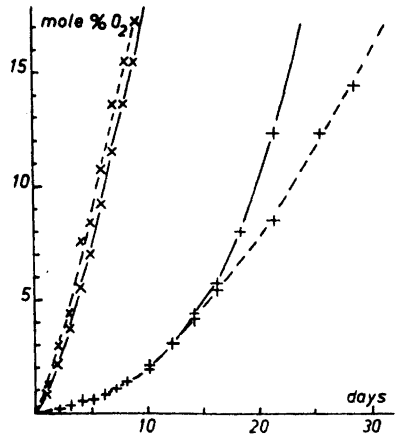

Fig. 1. Rates of oxidation of Δ^3-carene (×) and (+)-limonene (+) and peroxide content from iodine titration (broken lines).

the density and the optical rotation were determined. (In order to save material, these determinations were not made every day.) A small sample was saved for medical investigations. After the determinations, the liquids were replaced in the oxidation vessels which were reweighed, usually indicating a loss of 0.1 g *. The vessels were reconnected to the oxidation apparatus which were totally refilled with oxygen, *cf.* Lombard [7]. Care was taken to prevent contaminations within the four terpenes and separate sets of glass apparatus were used for analysis.

The results of the oxidation series are given in Figs. 1–5 and by the sorptograms, Figs 6–8. Sorptograms of oxidized Δ^3-carene have been published earlier [6] and therefore have been excluded here. It is seen that Δ^3-carene is by far the most easily oxidized, α-pinene and (+)-limonene follow, with very similar behaviour, whereas β-pinene is very slowly oxidized and remains an easily flowing liquid when the others have become yellow resins. There is a relationship between the sorptograms due to degree of oxidation. The medical investigations show that the der-

* The oxidation series was performed in the period February to March, whereas the earlier reported [6] oxidation of Δ^3-carene was made during June and July. It is very likely that the slower rate in the present oxidation experiments is explained by the difference in illumination.

* The rate of oxidation has been corrected for this loss and the mole percent oxygen consumed has been calculated on the hydrocarbon remaining, assuming a monoreaction.

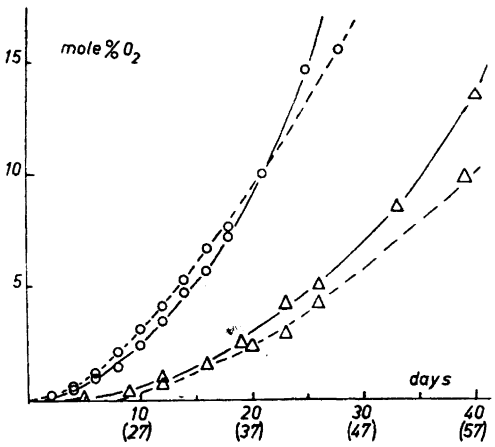

Fig. 2. Rates of oxidation of α-pinene (O) and β-pinene (△) and peroxide content. (β-pinene 18 to 50 days.)

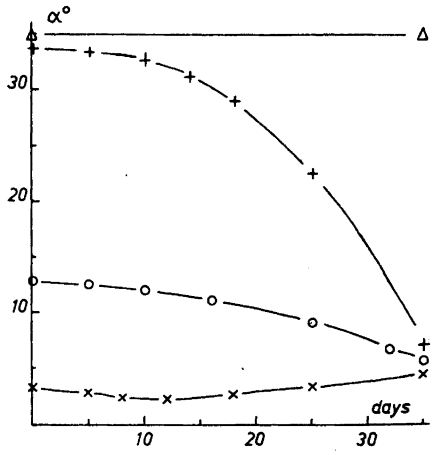

Fig. 4. Changes in optical rotations ($\alpha_{10\ cm}$); Δ^3-carene (pure) 15.°2, after 32 days 16.°4; α-pinene 29.°4 and 22.°8; β-pinene −18.°5 and −18.°5; (+)-limonene 102° and 70°, resp.

matologically active compounds are enriched in the "peaks" of the sorptograms. In the case of (+)-limonene a lift of the "plateau" in a sorptogram is observed.

This paper reports only the figures from the consumption of up to 20 mole percent of oxygen which from a dermatological and chemical point of view is the most interesting part. For the higher stages, the measurements become less accurate due to the marked increase in viscosity, and the curves are similar to that of Δ^3-carene previously reported by the present authors [6]. Furthermore, a detailed report together with the results of the medical investigation will be given elsewhere [8].

Experimental. The oxidation apparatus and the sorption equipment are similar to the ones used previously [6], but the surfaces of the oxidation vessels were made larger = 8.7—9.2 cm².

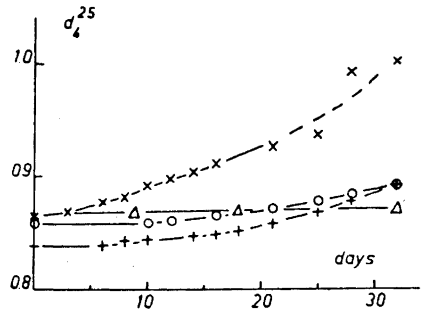

Fig. 3. Changes in densities during the oxidation. × = Δ^3-carene. O = α-pinene. △ = β-pinene. + = (+)-limonene. (The same marks are valid for Figs. 1—5.)

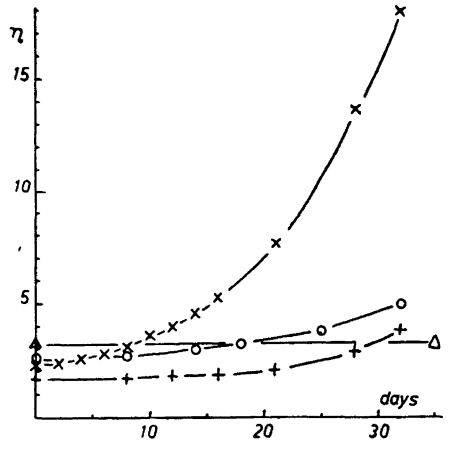

Fig. 5. Changes in viscosities, centipoises.

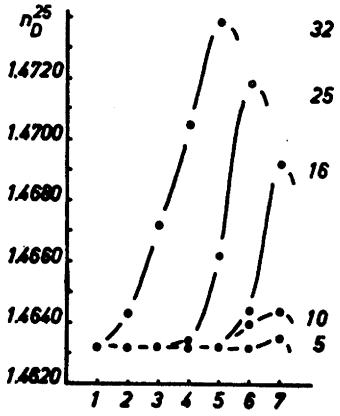

Fig. 6. Sorptograms of oxidized α-pinene. The number of days of reaction is given to the right.

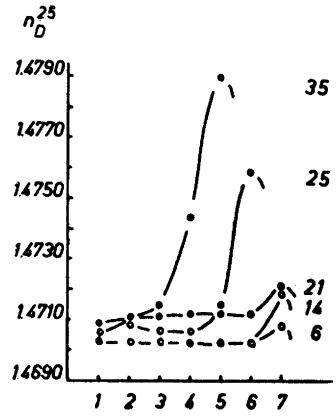

Fig. 8. Sorptograms of oxidized(+)-limonene.

The four viscometers, type Ostwald, volumes 3 ml, had the flow times for water at 25°C 16.9, 18.0, 15.3 and 15.2 sec. and the flow times of the pure terpenes (in the order given in the title) 24.1, 29.8, 30.6 and 16.4 sec., which gave 2.34, 2.66, 3.22 and 1.71 centipoises, respectively. The optical rotations were measured in four 10 cm tubes (volume 6 ml) which also have been used as containers when determining the densities by the aid of a Mohr's balance. In this case, a fall in the temperature of one degree was unavoidable. The iodine titrations were performed as before [6], but the time was increased to 12 min.

On Anti-Fungal Factors in Potato Leaves

EERO VALLE

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

There are considerable varietal differences in the damage of potato (*Solanum tuberosum*) leaves caused by late blight (*Phytophora infestans* de By). Anti-fungal factors have been demonstrated in all cultivated plants so far investigated in this laboratory [1] and new light has thus been thrown on the nature of the resistance of these plants to pathogenic fungi. Attention was also paid to corresponding factors against *Phytophthora infestans* in potato leaves. *Phytophthora infestans* and *Fusarium nivale* have been used as test organisms in these experiments. The latter fungus was used because its cultivation on an entirely synthetic medium was easy and results were soon obtained. *Phytophthora infestans* was cultivated on pea-agar, on which its growth was good.

The leaf material used in the experiments was taken at various stages of development from potato plants grown under natural conditions in the field. A highly active extract was obtained when the leaves were macerated in 96 % ethanol for 5 min. The leaf material was taken from Aquila, a variety highly resistant to late blight. Ethanol was evaporated before biological activity estimations. The ethanol residue of 0.5 g fresh leaf material in 1 ml synthetic medium totally inhibited the mycelial growth of *Fusarium nivale*. On pea-agar the inhibition limit was 0.7 g fresh wt/1 ml medium. The growth of *Phytophthora infestans* on pea-agar was inhibited when the concentration exceeded 1 g fresh wt/1 ml medium. An anti-fungal effect was also observed in an extremely late blight-susceptible variety, Sieglinde, but the inhibition limits were considerably higher.

For the investigation of the active factor, 3.8 kg of sound leaves of Aquila were taken on August 30, and homogenised by grinding. 96 % ethanol was added immediately, until there was 70 % alcohol in the whole homogenate. The homogenate was kept for 2 days at +5°C and then filtered under pressure through filter paper. No activity was observed in the compact residue. The filtrate was concentrated *in vacuo* at 30°C to 350 ml; the pH of this press juice was 4.7. It was extracted with equal amounts of ether ten times. From each fraction both a biological activity determination and a one-dimensional paper chromatogram using acetic acid-water (15:85) as solvent was made. The highest activity was found in fractions 1 and 2. In fractions 3—10 an activity, though considerably weaker than in the first two fractions, was still observed.

Three fluorescent spots with the R_F-values ~0.02, ~0.50, and ~0.70 were found in fractions 1 and 2 in chromatograms exposed to ultraviolet radiation. In fractions 3—10 only the last spot was found. The blue fluorescence of the first two spots was unchanged in NH_3 vapour, the light blue fluorescence of the last changed into yellowgreen. The spots with R_F ~0.50 and 0.70 were eluted with 96 % ethanol and the ultraviolet absorption spectrum of the two solutions was determined. The spectra were much alike, the spot with R_F ~0.70 having a maximum at 245 and 330 mμ and a minimum at 266 mμ, the spot with R_F ~0.50 a maximum at 237 and 325 mμ and a minimum at 264 mμ in ethanol. (Fig. 1.) These results suggested chlorogenic and caffeic acids. The spectra and the corresponding fluorescence of the pure preparations of these acids supported this view. Chromatograms of a mixture of caffeic acid and the spot with R_F ~0.50 gave only one spot when different solvents were used and this was also the case with a mixture of chlorogenic acid and the spot with R_F ~0.70. The following solvent-systems were used: methanol-water (1:2), *iso*propanol-ammonia (25 %)-water (8:1:1), butanol-acetic acid-water (6.3:2.7:1) and (5:4:1), butanol saturated with water, benzene, chloroform, dist. water.

A very strong blue fluorescence was still found in the press juice of Aquila after the ether extractions. The pH of the juice was lowered with phosphoric acid to 3 and immediately extracted with ether. The ether extract was active, the extract from 5 g fresh wt in 1 ml medium totally inhibiting the growth of *Fusarium nivale*. The spectrum of this fraction, measured in ethanol, was exactly the same as that of pure chlorogenic acid. The calculated content of chlorogenic acid ($E^{1\%}_{1cm}$ = 526)[2] in this fraction was 480 μg fresh wt.

The pH of the press juice was further lowered to 1 and the juice extracted with ether. A weak activity was found in the ether extract, 10 g fresh wt/1 ml medium had a clearly inhibiting effect on the growth of *Fusarium nivale*. A light blue fluorescence was found in the chromato-

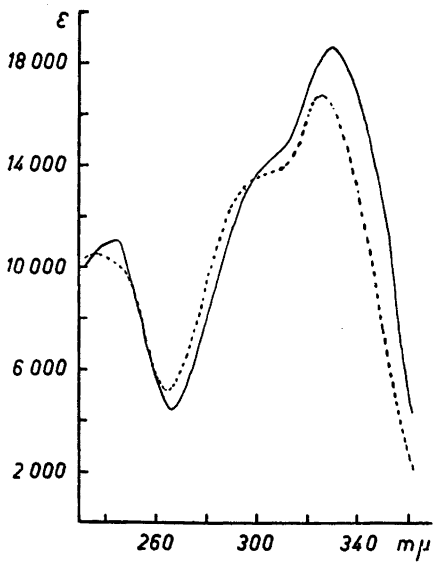

Fig. 1. The molar absorption spectra of chlorogenic (———) and caffeic (·····)acids.

gram from the starting point to the liquid front, the strongest fluorescence, however, in the region of chlorogenic acid (R_F 0.65—0.75). The calculated content of chlorogenic acid amounted to 60 μg/g fresh wt. The press juice, which had now lost its fluorescence, was allowed to stand at —10°C for 7 days and was then extracted with ether. Even this extract had a weak activity and the chromatogram of the extract was about the same as above. It is probable that chlorogenic acid was slowly liberated through hydrolysis at pH 1. On stronger hydrolysis (2 h at 100°C in bomb in 1 % HCl) a very weak light blue fluorescence all over the chromatogram was obtained from the press juice. After hydrolysis the spectrum of the juice was very uncharacthristic, bearing no relation to those of the above-mentioned acids.

The author tried to isolate chlorogenic acid from the ether fraction, which was obtained after lowering the pH to 3. The ether was evaporated *in vacuo* and the residue carefully washed with chloroform and small amounts of cold dist. water. The residue was dissolved in 50 % ethanol and kept at room temperature until crystals began to form. Ethanol was added and the solution cooled to —10°C. The crystals were washed with 50 % ethanol and dried in a vacuum desiccator above P_2O_5 at room temperature. The m.p. of the crystals obtained was 207—209°C, which is in agreement with that given for chlorogenic acid [2]. The mixed m.p. with pure chlorogenic acid was 206—209°C.

For biological activity tests with pure substances, a preparation of chlorogenic acid (m.p. 206—209°C) was obtained from the Laboratory of Biochemistry, University of Helsinki. A commercial product of caffeic acid (Light & Co.) was used. Because chlorogenic acid is composed of one caffeic and one quinic acid molecule [3], the activity of quinic acid was also investigated. On a synthetic medium, chlorogenic acid totally inhibited the growth of *Fusarium nivale* in a concentration of ~1 mg/ml medium, on pea-agar in a concentration of ~1.5 mg/ml.

The anti-fungal effect of caffeic acid was considerably higher, the corresponding inhibition limits being ~0.5 mg/ml and ~0.8 mg/ml. The very weak solubility of caffeic acid in water made the determination of the inhibition limit more difficult. Quinic acid had no inhibiting effect on the growth of *Fusarium nivale* in corresponding concentrations. The growth of *Phytophthora infestans* was inhibited on pea-agar when the amount of caffeic acid exceeded 1 mg/ml and that of chlorogenic acid 2 mg/ml. Quinic acid had no effect.

The quantitative determinations of chlorogenic and caffeic acids in potato leaves show that the amount of free chlorogenic acid is often sufficient to inhibit the mycelial growth of various fungi, since determinations with various potato varieties indicated 0.5—4 mg free chlorogenic acid in one g fresh leaves. Because it is evident that considerable amounts of chlorogenic acid may be bound in complex form, the anti-fungal effect of leaves improves when the complex is disorganized. It is possible that such a defence mechanism begins to function chiefly after infection. The amount of free caffeic acid in potato leaves is so insignificant that only a minor part of the plant's resistance can be due to it.

Among the above mentioned fluorescent spots on the paper chromatogram, of which the spot with R_F ~0.70 contained chlorogenic acid, the spot with R_F ~0.02 was also found to have an anti-fungal effect. The substance has absorption maxima at 272 and 310 mμ in ethanol and it appears to be comparatively unstable. Its chemical nature is not established yet. The substance is found both in leaves, stems and tubers although in so small amounts that

its effect is of no importance. Chlorogenic and caffeic acids are thus not the only anti-fungal factors in the potato plant.

Acknowledgments. The author is deeply indebted to Professor A. I. Virtanen for his valuable advice and for the facilities put at the author's disposal. Thanks are also due to the Laboratory of Biochemistry, University of Helsinki, for the supply of chlorogenic acid. A grant from the *Finnish Cultural Fund*, which has made possible this investigation, is gratefully acknowledged.

The Assay and Specific Activity of Crystalline Alcohol Dehydrogenase of Horse Liver

KEITH DALZIEL *

Biochemical Department, Nobel Medical Institute, Stockholm, Sweden

Crystalline alcohol dehydrogenase was first prepared from horse liver by Bonnichsen and Wassén [1]. Modifications of the procedure were reported by Bonnichsen [2] and Bonnichsen and Brink [3]. Assay of the enzyme, based on spectrophotometric measurements of the reduction of diphosphopyridine nucleotide (DPN) coenzyme by excess ethanol substrate at alkaline pH, was described by Theorell and Bonnichsen [4,3]. A modification of this assay method is described below.

Reagents. 0.1 M glycine-NaOH buffer, pH 10.0. DPN solution 0.83 mg/ml (1 mg/ml »cozymase 90», Sigma Chemical Co.). Ethanol solution, 1 ml 96 % to 100 ml with water.

Procedure. The reagents and the cell compartment of the spectrophotometer are kept at 23.0°. 1.85 ml buffer, 1.0 ml DPN solution and 0.15 ml ethanol solution are mixed in a cuvette of 1 cm optical depth, and the extinction at 340 mμ (E_{340}) is measured. A small volume (1 to 10 μl) of enzyme solution is introduced into the reaction mixture on a stirrer, and the time ($t_{0.2}$) required for an increase of 0.200 in E_{340} (λ_{max}DPNH) is measured.

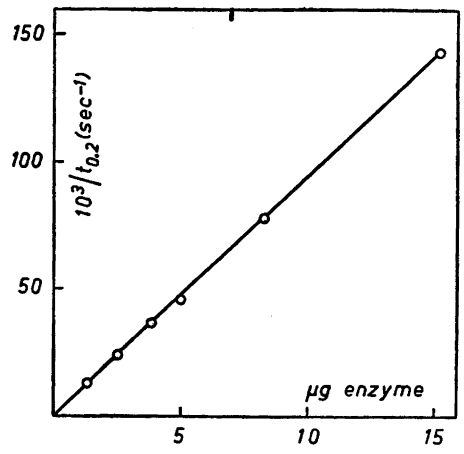

Fig. 1.

Theoretically, the enzyme concentration should be more closely proportional to the reciprocal of $t_{0.2}$, the time required for the reduction of a definite fraction of the DPN, than to the amount of DPN reduced in a fixed time (E_{340} in 3 min) measured in the earlier method [3], provided that the enzyme is stable in the test mixture [5]. This was found to be the case, as shown in Fig. 1 by a plot of measured values of $1/t_{0.2}$ against the weight of enzyme used in the test, obtained by adding different volumes (0.9 to 10 μl) of the same enzyme solution. The plot is a satisfactory straight line passing through the origin, *i.e.* the product, $t_{0.2} \times$ amount of enzyme, is constant to within 2 %. The method has proved consistently reproducible to this extent.

The ethanol concentration (9 mM) is the optimum value [6]; the concentration of 300 mM used originally causes considerable inhibition. Neither the ethanol nor the DPN concentration (0.42 mM) is critical, variations of 50 % in either causing only 10 % variation in the results. Semicarbazide has no effect, as at pH 10.0 the reduction of DPN goes practically to completion with these reactant concentrations [4].

Specific Activity. The enzyme used for the assays of Fig. 1 had been recrystallized with ethanol to constant activity/E_{280} ratio. The enzyme was prepared as described by Bonnichsen and Brink [3]; after removal of the haemoglobin, the enzyme

The Assay and Specific Activity of Crystalline Alcohol Dehydrogenase of Horse Liver

KEITH DALZIEL *

Biochemical Department, Nobel Medical Institute, Stockholm, Sweden

Crystalline alcohol dehydrogenase was first prepared from horse liver by Bonnichsen and Wassén [1]. Modifications of the procedure were reported by Bonnichsen [2] and Bonnichsen and Brink [3]. Assay of the enzyme, based on spectrophotometric measurements of the reduction of diphosphopyridine nucleotide (DPN) coenzyme by excess ethanol substrate at alkaline pH, was described by Theorell and Bonnichsen [4,3]. A modification of this assay method is described below.

Reagents. 0.1 M glycine-NaOH buffer, pH 10.0. DPN solution 0.83 mg/ml (1 mg/ml »cozymase 90», Sigma Chemical Co.). Ethanol solution, 1 ml 96 % to 100 ml with water.

Procedure. The reagents and the cell compartment of the spectrophotometer are kept at 23.0°. 1.85 ml buffer, 1.0 ml DPN solution and 0.15 ml ethanol solution are mixed in a cuvette of 1 cm optical depth, and the extinction at 340 mμ (E_{340}) is measured. A small volume (1 to 10 μl) of enzyme solution is introduced into the reaction mixture on a stirrer, and the time ($t_{0.2}$) required for an increase of 0.200 in E_{340} (λ_{max}DPNH) is measured.

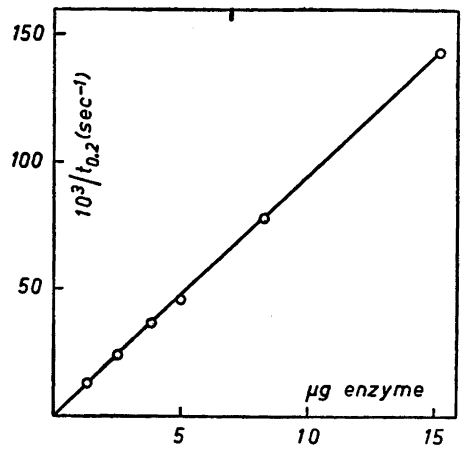

Fig. 1.

Theoretically, the enzyme concentration should be more closely proportional to the reciprocal of $t_{0.2}$, the time required for the reduction of a definite fraction of the DPN, than to the amount of DPN reduced in a fixed time (E_{340} in 3 min) measured in the earlier method [3], provided that the enzyme is stable in the test mixture [5]. This was found to be the case, as shown in Fig. 1 by a plot of measured values of $1/t_{0.2}$ against the weight of enzyme used in the test, obtained by adding different volumes (0.9 to 10 μl) of the same enzyme solution. The plot is a satisfactory straight line passing through the origin, *i.e.* the product, $t_{0.2} \times$ amount of enzyme, is constant to within 2 %. The method has proved consistently reproducible to this extent.

The ethanol concentration (9 mM) is the optimum value [6]; the concentration of 300 mM used originally causes considerable inhibition. Neither the ethanol nor the DPN concentration (0.42 mM) is critical, variations of 50 % in either causing only 10 % variation in the results. Semicarbazide has no effect, as at pH 10.0 the reduction of DPN goes practically to completion with these reactant concentrations [4].

Specific Activity. The enzyme used for the assays of Fig. 1 had been recrystallized with ethanol to constant activity/E_{280} ratio. The enzyme was prepared as described by Bonnichsen and Brink [3]; after removal of the haemoglobin, the enzyme

* Rockefeller Fellow, 1955—7.

was precipitated twice with 30 % (v/v) ethanol and then recrystallized 5 times with 7—10 % ethanol. The relative values of the activity/E_{280} ratio obtained for the 5 crystalline products were, successively, 0.80, 0.89, 0.97, 1.00, 0.98 and 0.99.

A solution of the final product, after thorough dialysis against 0.01 M phosphate, pH 7.3, was found by dry weight to contain 15.5 mg protein/ml, and was diluted 10 fold for activity and E_{280} measurements. From the latter a value of 0.450 was obtained for the extinction of 1 mg/ml in 1 cm optical depth, in good agreement with Bonnichsen's [2,3] value of 0.455. From the activity measurements (Fig. 1) the relationship between the volume in ml (v) of an enzyme solution used in the assay, the value of $t_{0.2}$ in seconds, and the concentration of the enzyme solution is mg/ml $= 1.05/(t_{0.2} \times v)$. If E_{280} is measured on the same solution in 1 cm optical depth, the % purity of the sample relative to the above preparation will be $0.47/(E_{280} \times t_{0.2} \times v)$. These data have been reproduced to within a few per cent with many other crystalline preparations.

In the activity test of Theorell and Bonnichsen [4], our enzyme preparations gave an increase of E_{340} of 0.058 in 3 min per μg enzyme per ml, which is significantly higher than values previously reported (0.036[4], 0.045[5]). The corresponding value of the maximum initial rate of the reaction of ethanol and DPN at pH 10.0 was $k_2 = 8.0$ sec^{-1}, compared with 5.5 sec^{-1} obtained by Theorell and Bonnichsen [4]. In spite of the high activity, evidence of inhomogeneity in the present preparations was obtained in prolonged electrophoresis, indicating the presence of about 10 % of a second component. Further work on the preparation and properties of the enzyme is in progress.

The author is grateful to Professor Hugo Theorell and Dr. Roger Bonnichsen for guidance and helpful criticism.

The Sedimentation Constant of Crystalline Horse Liver Alcohol Dehydrogenase

ANDERS EHRENBERG and KEITH DALZIEL*

Biochemical Department, Nobel Medical Institute, Stockholm, Sweden

The sedimentation constant of crystalline alcohol dehydrogenase (ADH) prepared from horse liver [1,2] was found by Pedersen to be $S^0_{20} = 4.9$ S as the mean of two runs in the oil driven ultracentrifuge at Uppsala, with *ca.* 10 mg protein/ml at pH 7.8 [3]. This gives 4.5 S after correction as suggested by Pedersen [4]. In connection with the interpretation of marked effects of pH and chloride ion concentration on the kinetics of the enzyme reaction, DPNH + acetaldehyde + H$^+$ $\rightleftharpoons$ DPN + ethanol, reported by Theorell and his collaborators [3,5], it is of interest to test the possibility that the enzyme itself undergoes some change, such as dissociation or polymerisation, with change of ionic milieu. Such changes might be revealed by variations of the sedimentation constant.

Table 1. Sedimentation constants of liver alcohol dehydrogenase.

ADH mg/ml	NaCl M	Buffer (ionic strength = 0.1)	pH	S^0_{20} Svedberg units

* Rockefeller Fellow, 1955—7.

Alcohol dehydrogenase was prepared by the method of Bonnichsen and Brink [6] and recrystallized 5 times to constant activity/protein ratio, as described earlier [7]. The sedimentation constant was measured in the Spinco ultracentrifuge at 59 780 r.p.m. and 20°C with various protein, chloride and hydrogen ion concentrations. The results are shown in Table. 1. There is no evidence of any significant effect of chloride or hydrogen ion concentration on the sedimentation constant. Extrapolation to infinite dilution of the protein gives $S^0_{20} = 5.1\ S$.

These data give a value of 4.8 S at a protein concentration of 10 mg/ml, slightly greater than Pedersen's value. The difference is probably to be ascribed to the greater purity of our material indicated by higher specific activity [7]. More complete data on the molecular weight will be reported shortly.

The Equilibrium Between Yellow and Blue Nickel(II) Triethylenetetramine Ions in Strong Salt Solutions

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

Lifschitz *et al.*[1,2] prepared solid nickel(II)bis(stilbenediamine) complexes in two isomers, one yellow, diamagnetic, and one blue, paramagnetic. The equilibrium between two such forms in solution has not yet been studied by means of the absorption spectra. Jonassen and Douglas [3] investigated nickel(II) complexes of triethylenetetramine (= trien) and prepared solid salts of $Ni_2trien_3^{+3}$, but not of Ni trien++. The latter violet-blue ion turns brownish yellow in strong salt solutions. Fig. 1 gives the absorption spectra at 19°C in different concentrations of sodium perchlorate. The absorption band at 443 mμ, which increases in the yellow solutions, corresponds to the planar, diamagnetic complex. Basolo *et al.*[4] prepared the yellow Nitemeen$_2$++ (temeen = C, C, C′, C′ tetramethyl-ethylenediamine) which has a Gaussian shaped band at 433 mμ with $\varepsilon = 67$. It is interesting that Ni temeen$_2$++ does not exhibit other spin-allowed, Laporte-forbidden ligand field bands below the ultra-violet absorption limit ($\varepsilon = 8$ at 260 mμ), since the ligand field theory [5] would predict three transitions at not very different wavenumbers (the analogous difficulty * occurs in Cu en$_2$++). The two

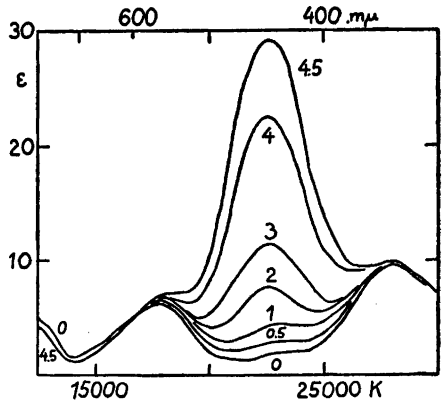

Fig. 1. The absorption spectra of 0.1 M Ni trien$(NO_3)_2$ in water and aqueous solutions of sodium perchlorate. The numbers on the curves indicate the molarity of $NaClO_4$. The spectra were measured at 19°C on a Cary spectrophotometer.

* However, the band at 422 mμ of Ni(II) in ethanolic sodio-succinimide has a shoulder at 470 mμ, and the band at 440 mμ of Ni(II) in 1 M NaOH with caseine has a shoulder at 510 mμ. These orange solutions do not seem to contain paramagnetic nickel, according to the spectra. Sodium caseinate is very effective for formation of tetragonal complexes; its biuret reaction with Cu(II) has the band maximum at 547 mμ.

Alcohol dehydrogenase was prepared by the method of Bonnichsen and Brink [6] and recrystallized 5 times to constant activity/protein ratio, as described earlier [7]. The sedimentation constant was measured in the Spinco ultracentrifuge at 59 780 r.p.m. and 20°C with various protein, chloride and hydrogen ion concentrations. The results are shown in Table. 1. The Equilibrium Between Yellow and Blue Nickel(II) Triethylenetetramine Ions in Strong Salt Solutions

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

Lifschitz *et al.*[1,2] prepared solid nickel(II)bis(stilbenediamine) complexes in two isomers, one yellow, diamagnetic, and one blue, paramagnetic. The equilibrium between two such forms in solution has not yet been studied by means of the absorption spectra. Jonassen and Douglas [3] investigated nickel(II) complexes of triethylenetetramine (= trien) and prepared solid salts of $Ni_2trien_3^{+3}$, but not of Ni trien++. The latter violet-blue ion turns brownish yellow in strong salt solutions. Fig. 1 gives the absorption spectra at 19°C in different concentrations of sodium perchlorate. The absorption band at 443 mμ, which increases in the yellow solutions, corresponds to the planar, diamagnetic complex. Basolo *et al.*[4] prepared the yellow Nitemeen$_2$++ (temeen = C, C, C′, C′ tetramethyl-ethylenediamine) which has a Gaussian shaped band at 433 mμ with $\varepsilon = 67$. It is interesting that Ni temeen$_2$++ does not exhibit other spin-allowed, Laporte-forbidden ligand field bands below the ultra-violet absorption limit ($\varepsilon = 8$ at 260 mμ), since the ligand field theory [5] would predict three transitions at not very different wavenumbers (the analogous difficulty * occurs in Cu en$_2$++). The two

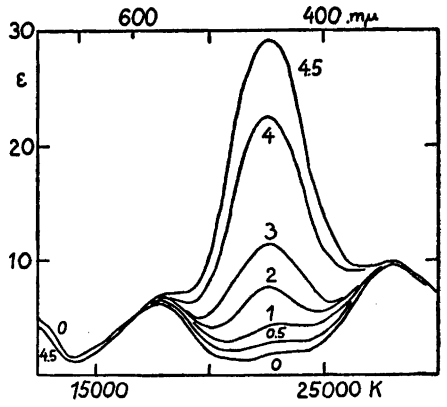

Fig. 1. The absorption spectra of 0.1 M Ni trien$(NO_3)_2$ in water and aqueous solutions of sodium perchlorate. The numbers on the curves indicate the molarity of $NaClO_4$. The spectra were measured at 19°C on a Cary spectrophotometer.

* However, the band at 422 mμ of Ni(II) in ethanolic sodio-succinimide has a shoulder at 470 mμ, and the band at 440 mμ of Ni(II) in 1 M NaOH with caseine has a shoulder at 510 mμ. These orange solutions do not seem to contain paramagnetic nickel, according to the spectra. Sodium caseinate is very effective for formation of tetragonal complexes; its biuret reaction with Cu(II) has the band maximum at 547 mμ.

equally strong bands of $PtCl_4^{--}$ may be caused by effects of intermediate coupling [6].

However, the height of the new band of yellow Nitrien++ cannot be implied with certainty from the Figure, since the decrease of the concentration of the blue form cannot be determined, due to salt effects. However, ε seems to be between 50 and 80, as expected. The formation of the yellow isomer is endothermic; a boiling solution of 0.1 M Ni trien$(NO_3)_2$ alone turns reversibly yellowish. Some salt solutions, such as nine-tenths-saturated $CaCl_2$ ($\varepsilon = 27$ at 443 mμ and the same shape of the band as in 4.5 M $NaClO_4$) and molten $Mg(NO_3)_2$, 6 H_2O, are equally effective for forming the yellow colour, while saturated NaBr and molten Na_2SO_4, 10 H_2O produce only a brownish purple mixture. Since Ni temeen$_2$++ neither solvates nor takes up chloride ions [7], it is not believed that ClO_4^- or Cl^- directly participate in the first coordination sphere of the yellow Ni trien++, even though a general effect of ion-pair formation cannot be excluded. However, a special de-hydration effect does not seem to occur in aqueous ethanol, compared to an aqueous solution with identical salt content. Actually, Lifschitz *et al.*[1] observed blue solutions in chloroform and other non-polar solvents of salts, which are yellow in aqueous solution. Thus an equilibrium may be postulated between blue *cis*-NiA_4X_2, blue *trans*-NiA_4X_2 and yellow *trans*-NiA_4, where X are water, alcohol, anions, etc., which are more strongly bound in solutions with low dielectric constant than in water. It is a necessary condition [5] for diamagnetism in d^8-systems to have a much weaker ligand field along the tetragonal axis than in the plane of the four strongly bound ligands.

The blue isomer is not tetrahedrally coordinated, but is rather *cis*-octahedral. Thus, the water can be exchanged by other ligands, and the absorption spectra greatly resemble those of the corresponding tren- (= β, β', β'' tris(ethylamino)amine)nickel (II) complexes [7]. The spin-allowed transitions from $^3\Gamma_2$ (F) to $^3\Gamma_4$ (F) and $^3\Gamma_4$ (P) are situated at:

Ni trien $(H_2O)_2$++	564 mμ	358 mμ
Ni_2 trien$_3$+4	539	346
Ni trien $(NH_3)_2$++	546	350
Ni trien en++	538	344
Ni trien gly+	550	352

The last glycinate complex resembles more Ni en$_2$gly+ than Ni tren gly+, which [7] has the bands at 532 and 354 mμ. It is not easily decided whether *trans*-Ni trien++ also exists as a blue diaquo complex in equilibrium with the anhydrous yellow form. At most 2 % of the yellow form occurs in the most dilute solution of the Figure (a spin-forbidden band may be the cause of the weak shoulder ~443 mμ). If all the *trans*-isomer is diamagnetic, this would correspond to a similar deviation from the statistical *cis*/*trans* equilibrium constant [8] as in the case of Coen$_2(H_2O)_2$+++. J. Bjerrum and Poulsen [9] have reported yellow Nien$_2$++ as an intermediate by low-temperature kinetic studies. Even though Cutrien++ has mainly the *trans*-configuration, it has only been possible [10] to prepare *cis*-Co trienCl_2+. Mr. Kjeld Rasmussen and the present author will later discuss a possible blue *trans*-isomer of the latter ion.

Analogous [5] to the behaviour of Nien$_2$++, it is possible to precipitate yellowish pink [Ni trien] $[AgBrI]_2$. Most other salts of Ni trien++ seem to be paramagnetic. Thus, thiocyanates produce a copious precipitate of pale blue Ni trien$(SCN)_2$, which is soluble in excess of trien. If a solution of $NiBr_2$ and trien is evaporated to dryness, a dark purple salt results, which deliquesces to a brown solution. $Ni(ClO_4)_2$ and trien produces a sticky reddish brown syrup. On inflaming some mg of this material, it explodes violently. Yellow colour of the commercial trien can be removed by treating the 1 M aqueous solution with norite carbon for several weeks.

The Infrared Absorption of Rosin Acids in Tall Oil Rosin

HENRIK H. BRUUN and PENTTI JALAVA

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden, and The Institute of Wood Chemistry, Åbo Akademi, Åbo, Finland

The tall oil rosin produced in Northern Europe is composed of 90—95 % rosin acids, 5—10 % fatty acids and 0.3—2 % unsaponifiables [1,2]. Sandermann [3] studied the rosin acid fraction of tall oil rosin using chemical methods and found it to contain about 50 % abietic acid, up to 25 % dextropimaric acid, and up to 25 % pyroabietic acids which represent a mixture of dehydro-, dihydro- and tetrahydroabietic acids [4]. Later spectrophotometric studies [5,6] of the rosin acids of tall oil rosin have shown the abietic acid content to vary from 23 to 52 % and that of dehydroabietic acid [5] from 30 to 45 %.

The present paper deals with an investigation of the infrared absorption of two samples of the rosin acid fraction of tall oil rosin. The purpose of the study was to utilize previously recorded infrared absorption spectra for individual rosin acids [7,8] to obtain information about the composition of the rosin acid fraction in tall oil rosin. The isolation of the rosin acids from tall oil rosin which was a crystalline, batch-distilled quality (a commercial product of Enso-Gutzeit Oy, Kotka, Finland) was in one case performed using the customary method of extracting the esterified fatty acids and unsaponifiables and in the other by precipitating the rosin acids with *cyclo*hexylamine from the solution of tall oil rosin in acetone [9]. Both rosin acid fractions were recrystallized from methanol and acetone.

The infrared absorption curves recorded for the two samples are reproduced in Figs. 1 and 2, respectively. The curves are seen to be identical. All the bands in one can be distinguished in the other and corresponding bands are almost equal in height. (Absorption curves similar to these were also recorded for rosin acid samples isolated by *cyclo*hexylamine preci-

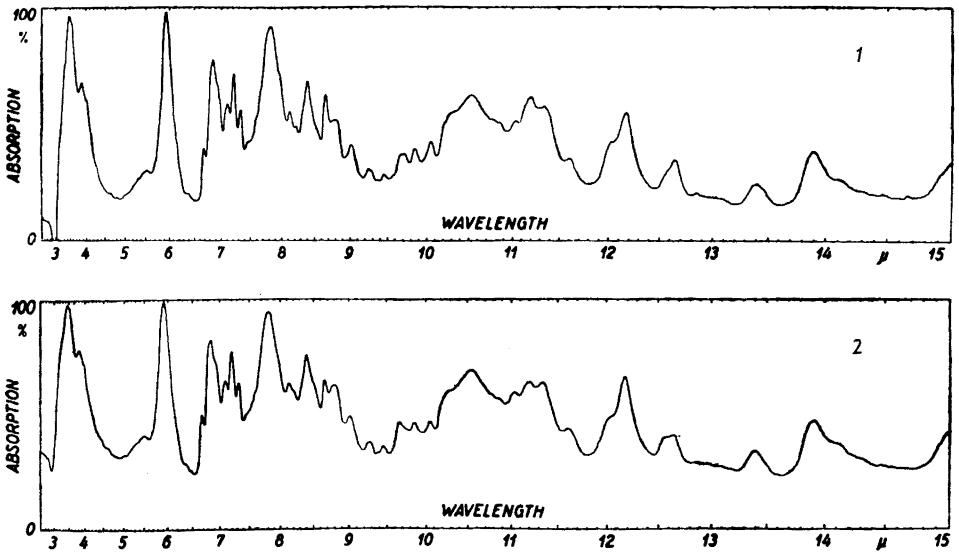

Fig. 1 and *Fig. 2.* Infrared absorption spectra of the rosin acid fraction of tall oil rosin: 1) Rosin acid fraction isolated from tall oil rosin by removing esterified fatty acids and unsaponifiables by solvent extraction. 2) Fraction isolated by precipitating the rosin acids with *cyclo*hexylamine.

pitation from amorphous tall oil rosin (also a product of the above-mentioned company) and from a crystalline, continuously distilled product of Oulu Oy, Oulu). Bands typical of abietic acid occur at 8.66, 11.21, 12.65 and 13.87 μ and bands typical of dehydroabietic acid at 6.68, 8.82, 9.65, 12.20 and 13.89 μ. No bands are observed which would indicate the presence of tetrahydroabietic acid (characteristic bands at 8.47, 8.61 and 14.27 μ), dihydroabietic acid (bands at 11.53 + 11.68 and 14.12 μ; the shoulder at 14.12 μ results from the combined medium strong absorptions of abietic and dehydroabietic acids), dextropimaric acid (bands at 6.97, 11.75, 14.00 and 14.61 μ), and *iso*dextropimaric acid (bands at 8.00, 8.68 + 8.75, 11.00, 13.67 and 13.99 μ). The rosin acid mixture isolated from tall oil rosin thus seems to consist solely of abietic and dehydroabietic acids. No signs indicating the presence of other acids of the abietic series or of pimaric acids are evident (if these do exist in the mixture, their contents amount to a few per cent at the most).

Absorption spectra * recorded for binary mixtures of abietic and dehydroabietic acid suggested that the batch-distilled rosin acid samples studied contained about 55 % abietic acid and about 45 % dehydroabietic acid.

Absorption spectra * recorded for rosin acid mixtures isolated by *cyclo*hexylamine precipitation from crystalline tall oil rosin samples which were heated at 300°C for periods of different length revealed that the content of dehydroabietic acid in the mixtures increased with the time of heating. The rosin acid mixture precipitated with *cyclo*hexylamine from a tall oil rosin sample that had been heated three hours at 300°C was found to consist almost solely of dehydroabietic acid. A similar observation concerning American tall oil rosin has been previously reported by Hasselström [10].

The observation that the rosin acid mixture isolated from tall oil rosin does not contain pimaric acids is somewhat surprising and does not conform with the analytical data of Sandermann or with the general opinion of the composition of the rosin acid fraction of tall oil rosin. However, the somewhat erroneous conclusions that were drawn on the basis of the very extensive work that was done after the turn of the century to determine the structure of pinabietic acid is now easily understood when one realizes that this rosin acid mixture primarily consisted of only two abietic acids.

We wish to express our sincere gratitude to Dr. Ingrid Fischmeister of the Department of Medical Biochemistry for the spectrophotometric measurements. One of us (H.H.B.) is indebted to Professor Einar Stenhagen for placing the facilities of the Department at his disposal and to the *Natural Science Council of Finland* for a grant which made possible a study visit to Uppsala.

Association of Crystallized Bovine Plasma Albumin

J. A. CHRISTIANSEN, C. E. JENSEN and K. MARCKER

Universitetets fysisk-kemiske institut, Copenhagen, Denmark

Many investigators have found that the molecular weight of bovine plasma albumin (B.P.A.) is about 70×10^3. This figure has been obtained from osmotic measurements (see, *e. g.*, Scatchard

et al.[1], and Adair and Robinson [2]). We have tried to reproduce these results by means of the osmometer described previously by two of the present authors [3]. By means of this apparatus it is possible to measure the osmotic pressure of the solution about one hour after it has been placed in the osmotic cell.

The preparation used was Armour crystallized B.P.A. The substance was dissolved in acetate buffer (M = 0.2; pH = 4.64, the isoelectric point of B.P.A.) and put into the osmometer immediately after dissolution. Under these conditions we observed that solutions of B.P.A. showed an osmotic pressure corresponding to a molecular weight of 270×10^3. This result may be interpreted as an aggregation of four molecules of B.P.A.

In order to explain the disagreement between our results and those obtained by other workers it should be noticed that the experiments described by other investigators have been performed on stock solutions or by means of static-elevation cells, which require several days for the attainment of equilibrium. We suspected therefore that the disagreement was due to a gradual depolymerization of a tetramer. To verify this assumption the following experiments were performed. Two stock solutions of B.P.A. were prepared and placed at 20° C and 30° C, respectively. At certain intervals of time aliquots were withdrawn and their osmotic pressures determined at 20° C. The aliquot at 30° C was first cooled to 0° C to delay the reaction before the measurement. The results are in Fig. 1. It is seen that the molecular weight decreases with time, and that the rate of the decrease increases with temperature. These facts strongly indicate a gradual depolymerization.

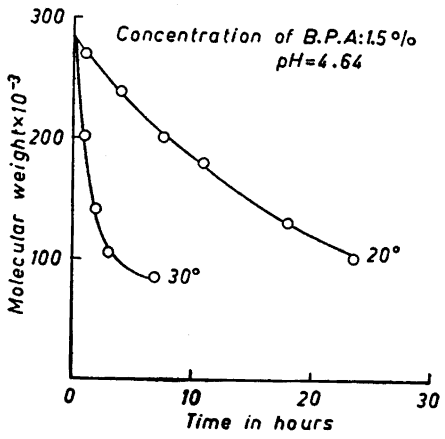

Fig. 1. Decrease in molecular weight with time at 20° C and 30° C.

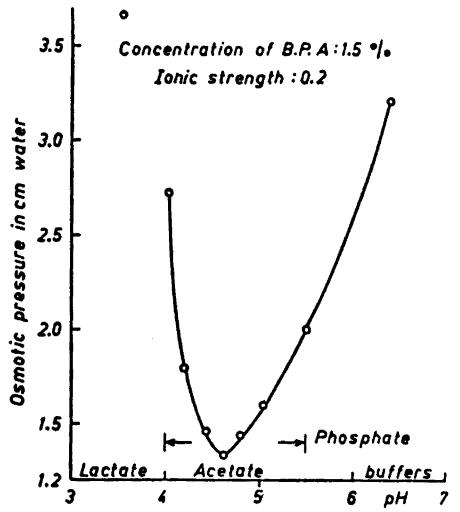

Fig. 2. Relation between osmotic pressure and pH.

Experiments have been carried out which show that the osmotic pressure, measured one hour after dissolution, is dependent on the pH. A minimum is found at the isoelectric point (Fig. 2).

It was further observed that the acidity of unbuffered solutions of B.P.A. increased with time. This phenomenon has been found previously by Tanford [4].

One of us (C.E.J.) wishes to thank *Købmand i Odense Johann og Hanne Weimann født Seedorffs legat* for financial support.

We are grateful to mag.scient. Mogens Lassen of this institute for valuable discussions.

Darstellung langkettiger Alkylborsäuren

KURT TORSSELL und ERIK N. V. LARSSON

Institut für organische Chemie und Biochemie der Universität, Stockholm, Schweden

Im Verhältnis zu den Arylborsäuren sind die Alkylborsäuren viel unbeständiger. Sie zersetzen sich langsam an der Luft unter Bildung von Borsäure und Alkohol [1]. In feuchtem Zustand sind sie stabiler und beim Aufbewahren unter Stickstoff sind sie unbegrenzt haltbar. Veresterung mit Diäthanolamin hat sich auch gut bewährt um die Säuren in stabile und handliche Derivate zu überführen [2]. Bis jetzt sind nur die niedrigeren Glieder der Alkylborsäuren — Methyl- bis Hexylborsäure — dargestellt worden [1,3]. Es wäre aber denkbar, dass die langkettigeren Alkylborsäuren eine höhere Stabilität besitzen, da die Umhüllung der B—C-Bindung mit einem grösseren Alkylrest eine Schutzwirkung bedingen könnte. Dies scheint auch tatsächlich der Fall zu sein. Die Stabilität erlaubt jedoch kein unbegrenztes Aufbewahren an der Luft. Nach einiger Zeit bemerkt man den Geruch des Alkohols, und die Verbindung, die zuerst in unpolaren Lösungsmitteln, z.B. in Benzol leicht löslich ist, ergibt eine schwache Trübung von freigesetzter Borsäure.

Die langkettigen Alkylborsäuren bilden farblose, niedrig (bei etwa 70—80°) schmelzende und in reinem Zustand geruchlose Substanzen, die in den gebräuchlichsten organischen Lösungsmitteln löslich, in Wasser aber fast unlöslich sind. Infolge weitgehender Hydrolyse lösen sie sich auch nicht in Lauge:

$$RB(OH)_3^- K^+ \overset{H_2O}{\rightleftharpoons} RB(OH)_2 + KOH$$

Es ist zu erwarten, dass langkettige Verbindungen dieser Art oberflächenaktiv sind. Wegen ihrer Schwerlöslichkeit und geringen Beständigkeit besitzen sie jedoch kein Interesse in diesem Zusammenhang.

Alkylborsäuren mit einer geraden Anzahl von Kohlenstoffatomen, C_8 bis C_{18}, sind durch Umsetzung der Grignardverbindungen mit Tributylborat dargestellt worden. Bei der Darstellung von den langkettigeren *n*-Alkylmagnesiumverbindungen entstanden beträchtliche Mengen von Kohlenwasserstoffen (Paraffinen), die schwierig von den Alkylborsäuren zu trennen waren.

$$2\ RX + Mg \rightarrow R—R + MgX_2$$

Diese Nebenreaktion konnte durch vorsichtiges Zusammenbringen der Reaktionspartner teilweise unterdrückt werden. Nach dem Zusatz des Alkylhalogenids wurde die Ätherlösung auf dem Wasserbad unter Rückfluss 5 Min. gekocht, wonach die Grignardlösung sofort verwendet wurde. Die höheren Kohlenwasserstoffe, die in Äther ziemlich schwerlöslich waren, fielen bei der Reaktion in Form von blättrigen Kristallen aus.

Die C—H-Analysen zeigten besonders bei den langkettigeren Alkylborsäuren einen etwas zu hohen C-Wert, was auf eine geringe Verunreinigung mit Kohlenwasserstoff hindeutete.

Experimenteller Teil. n-*Oktylborsäure.* Die Grignardlösung, aus 10 g *n*-Oktylchlorid und 1,9 g Magnesium in 80 ml Äther dargestellt, wurde tropfenweise unter Stickstoff und Umrühren zu einer auf —70° gekühlten Lösung von 18,4 g Tri-*n*-butylborat in 30 ml Äther zugegeben. Die Reaktionstemperatur wurde während der Umsetzung bei —65 bis —70° gehalten. Die Lösung durfte dann langsam Zimmertemperatur erreichen und wurde in einem Scheidetrichter in 100 ml Eiswasser + 5 ml konz. Schwefelsäure hydrolysiert. Die wässrige Schicht wurde von der ätherischen getrennt und zweimal mit je 30 ml Äther extrahiert. Von den vereinigten Ätherlösungen wurde die Hauptmenge des Äthers bei gewöhnlichem Druck abdestilliert. Der Rückstand wurde stark alkalisch gemacht worauf das Butanol-Wasser-Gemisch im Vakuum abgetrieben wurde. Wasser wurde gelegentlich während der Destillation zugesetzt um die Wassermenge einigermassen konstant zu halten ($\sim$ 100 ml). Inzwischen hatte sich ein weisser Niederschlag gebildet, der abgenutscht, auf dem Filter mit einem Glasstopfen zusammengepresst, mit Wasser gewaschen und an der Luft getrocknet wurde. Das Filtrat enthielt ein Öl, das zum grössten Teil aus Hexakosan bestand. Oktylborsäure lässt sich aus Nitromethan oder Toluol umkristallisieren; Rohausbeute 6,3 g oder 59 %. Sintert leicht bei 70°. Zersp. 77—78°. Sie zerfällt langsam an der Luft unter Bildung von Borsäure und Oktylalkohol. Wenig löslich in Wasser, löslich in Lauge ($C_8H_{19}O_2B$ (158,1): Ber. C 60,77; H 12,11. Gef. C 60,09; H 12,57).

n-*Heptylborsäure* und n-*Decylborsäure* wurden in ähnlicher Weise dargestellt. Die beiden Substanzen zersetzen sich langsam an der Luft. *Heptylborsäure* ist schwerlöslich in Wasser.

Sie lässt sich aus Nitromethan oder Toluol umkristallisieren. Zersp. 81—83°. Sintert bei etwa 70°. Rohausbeute 43 %. *Decylborsäure* ist fast unlöslich in Wasser und Lauge. Sie wurde aus Nitromethan-Äthylacetat (1:1) umkristallisiert. Zersp. 76—78°. Ausbeute 44 %. ($C_{10}H_{23}O_2B$ (186,1): Ber. C 64,54; H 12,46. Gef. C 64,82; H 13,07).

Bei der Darstellung der *Lauryl-*, *Myristyl-*, *Cetyl-* und *Stearyl*-borsäuren wurden den Vorschriften für *Oktylborsäure* bis auf die Aufarbeitung des Reaktionsguts gefolgt. Wegen der Schwerlöslichkeit der Produkte in Wasser ist es nicht notwendig die wässrige Schicht mit Äther zu extrahieren.

Laurylborsäure. Die bei der Aufarbeitung erhaltene ätherische Schicht wurde einige Stunden in den Kühlschrank gestellt, um den gebildeten Kohlenwasserstoff möglichst zum Ausfällen zu bringen, wonach dieser abfiltriert wurde. Diese Fraktion bestand aus fast reinem Tetrakosan. Schmp. 56,0—56,5°. ($C_{24}H_{50}$(338,6) Ber. C 85,12; H 14,88. Gef. C 84,70; H 15,23). Die Ätherlösung wurde dann wie oben eingedampft. Der Niederschlag wurde wiederholt aus Toluol umkristallisiert, wobei die Lösung nur auf Zimmertemperatur gekühlt wurde, um Mitfällung von Kohlenwasserstoff zu vermeiden. Zersp. 70—75°. ($C_{12}H_{27}O_2B$(214,2): Ber. C 67,30; H 12,71. Gef.C 68,03; H 12,54). Die Ausbeute war gering.

Myristylborsäure wurde ähnlich wie Laurylborsäure dargestellt. Ausbeute 24 %. Zersp. 74—76°. ($C_{14}H_{31}O_2B$ (242,2): Ber. C 69,41; H 12,90. Gef. C 70,38; H 12,89).

Cetylborsäure. Es wurde von 20 g Cetylbromid + 1,9 g Magnesium in 90 ml Äther und 18 g Tributylborat in 40 ml Äther ausgegangen. Die bei der Hydrolyse gewonnene Ätherlösung wurde über Nacht sich selbst überlassen. Nach Abfiltrieren des Niederschlags (Dotriakontan) wurde die Lösung einige Stunden auf —10° abgekühlt. Die gebildeten Kristalle, 3 g, die etwas mit Kohlenwasserstoff verunreinigt waren, wurden wiederholt aus Toluol umkristallisiert. Beim Eindampfen der Ätherlösung konnte noch etwas von der Substanz erhalten werden. Zersp. 78—79°. ($C_{16}H_{35}O_2B$ (270,3): Ber. C 71,08; H 13,06. Gef. C 72,52; H 13,38).

Stearylborsäure wurde aus Stearylmagnesiumbromid und Tributylborat nach den Vorschriften für Oktyl- und Cetylborsäure dargestellt. Ausbeute 33 %. Zersp. 82—84°. ($C_{18}H_{39}O_2B$ (298,3): Ber. C 72,51; H 13,18. Gef. C 73,45; H 13,41).

Synthesis of the *cis*- and *trans*-Isomers of Methyl 2,4L,21,21-tetramethyl- L$\Delta^{2:3}$-docosenoate

INGRID HEDLUND-STOLTZ and EINAR STENHAGEN

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

In the course of work on the synthesis of compounds structurally related to C_{27}-phthienoic acid from virulent tubercle bacilli [1], Ställberg-Stenhagen [2] prepared the *trans*-isomer of 2,4D-dimethyl-$\Delta^{2:3}$-heneicosenoic acid. This acid and its ethyl ester were strongly laevorotatory. The corresponding *cis*-compound and the isomer with α-methylene structure were not isolated in pure form, but both appeared to be dextrorotatory.

The *cis*- and *trans*-isomers of methyl 2,4L,21,21-tetramethyl-$\Delta^{2:3}$-docosenoate have now been prepared in order to study the biological properties of fatty acids related to the phthienoic acid type but possessing a neopentyl group in ω-position, the presence of which renders biological ω-oxidation difficult. The *trans*-ester is strongly dextrorotatory, whereas the *cis*-ester is laevorotatory, the molecular rotations being +69° and −40°, respectively. The geometrical arrangement of the substituent groups attached to the carbon atoms forming the α,β-double bond has thus a very marked effect on the optical rotation of the asymmetric carbon atom in γ-position.

The synthesis follows that of racemic methyl phthienoate described by Asselineau *et al.*[3]

Experimental. Methyl 17,17-dimethyloctadecanoate was prepared from *tert*-butylacetic acid and methyl hydrogen tetradecane-1,14-dioate *via* the Kolbe reaction. Hydrolysis gave

Synthesis of the *cis*- and *trans*-Isomers of Methyl 2,4L,21,21-tetramethyl- L$\Delta^{2:3}$-docosenoate

INGRID HEDLUND-STOLTZ and EINAR STENHAGEN

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

In the course of work on the synthesis of compounds structurally related to C_{27}-phthienoic acid from virulent tubercle bacilli [1], Ställberg-Stenhagen [2] prepared the *trans*-isomer of 2,4D-dimethyl-$\Delta^{2:3}$-heneicosenoic acid. This acid and its ethyl ester were strongly laevorotatory. The corresponding *cis*-compound and the isomer with α-methylene structure were not isolated in pure form, but both appeared to be dextrorotatory.

The *cis*- and *trans*-isomers of methyl 2,4L,21,21-tetramethyl-$\Delta^{2:3}$-docosenoate have now been prepared in order to study the biological properties of fatty acids related to the phthienoic acid type but possessing a neopentyl group in ω-position, the presence of which renders biological ω-oxidation difficult. The *trans*-ester is strongly dextrorotatory, whereas the *cis*-ester is laevorotatory, the molecular rotations being +69° and −40°, respectively. The geometrical arrangement of the substituent groups attached to the carbon atoms forming the α,β-double bond has thus a very marked effect on the optical rotation of the asymmetric carbon atom in γ-position.

The synthesis follows that of racemic methyl phthienoate described by Asselineau *et al.*[3]

Experimental. Methyl 17,17-dimethyloctadecanoate was prepared from *tert*-butylacetic acid and methyl hydrogen tetradecane-1,14-dioate *via* the Kolbe reaction. Hydrolysis gave

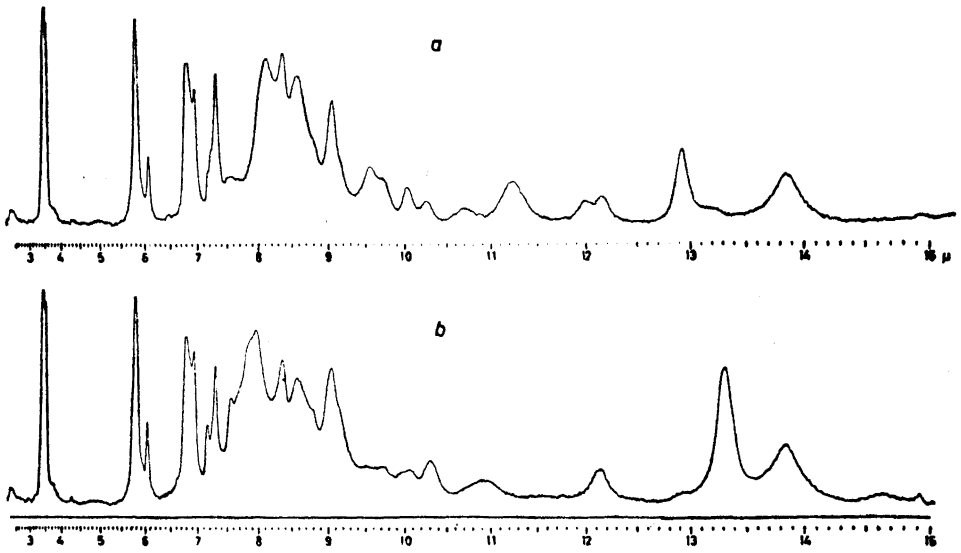

Fig. 1. Infra-red absorption spectra in the liquid state: a) (—)-methyl *cis*-2,4L,21,21 tetramethyl-$\Delta^{2:3}$-docosenoate; b) (+)-methyl *trans*-2,4L,21,21-tetramethyl-$\Delta^{2:3}$-docosenoate Cell thickness 0.02 mm.

17,17-dimethyloctadecanoic acid of m. p. 56.7 —57.2° (Sobotka and Stynler [4] give m. p. 57.2 —57.7°), which, *via* a second mixed Kolbe reaction with (—)-methyl hydrogen β-methylglutarate [5], followed by hydrolysis, gave (—)-3L, 20,20-trimethylheneicosanoic acid (m. p. 43.5—43.9°, $[M]_D^{27}$ — 12.6° (chloroform; *c*, 14.5), amide m. p. 91.7—91.9°). Reaction of the acid chloride of this acid with methyl cadmium [6] gave (—)-2-oxo-4L, 21,21-trimethyldocosane. After purification by chromatography on aluminium oxide the ketone had n_D^{30} 1.4477, $[\alpha]_D^{22}$ — 4.6° (chloroform, *c*, 10.4). It was converted into cyanhydrin by means of hydrogen cyanide, and the crude cyanhydrin was hydrolysed by hydrochloric acid in glacial acetic acid to a mixture of stereoisomeric hydroxy-acids melting at 83.8—85.1°. This mixture was pyrolysed by heating to 206° for one hour, followed by half an hour at 215°. After treatment with diazomethane in ether solution the resulting mixture of methyl esters was separated by chromatography on aluminium oxide. (—)-Methyl *cis*-2,4L,21,21-tetramethyl-$\Delta^{2:3}$-docosenoate, m.p. 25.5—25.8°; n_D^{25} 1.4572; $d_4^{24.5}$ 0.869; $[\alpha]_D^{24.5}$ —9.87° ± 0.27° (chloroform; *c*, 7.6); $[M]_D^{24.5}$ —40°, was followed by (+)-methyl *trans*-2,4L, 21,21-tetramethyl- $\Delta^{2:3}$ -decosenoate, m. p. 27.1—27.5°, n_D^{25} 1.4588 (supercooled liquid); $[\alpha]_D^{26}$ + 16.9° ± 1.0° (chloroform; *c*, 1.95); $[M]_D^{26}$ + 69°. Ultra-violet spectrum: *cis*-isomer λ_{max} 216 mμ, ε = 10.200; *trans*-isomer λ_{max} 215 mμ, ε = 13.500 (hexane).

The infra-red spectra are shown in Fig. 1. The strong absorption band at 750 cm^{-1} (13.33 μ) of the *trans*-isomer is observed also in the spectra of racemic methyl phthienoate [2] and methyl *trans*-2,4D-dimethyl-$\Delta^{2:3}$-heneicosenoate [2], and thus appears characteristic for methyl esters of acids having the 2,4-diMe-2-enoic structure. In methyl *trans*-2,5D-dimethyl-$\Delta^{2:3}$-heneicosenoate the frequency is shifted to 740 cm^{-1} (13.51 μ).

In the spectra of *cis*-forms of the 2,4-diMe-2-enoate structure, represented by the *cis*-ester now described and by the *cis*-isomer of racemic methyl phthienoate, a corresponding absorption occurs at 773 cm^{-1} (12.93 μ).

Details of this work will be published later.

Acknowledgements. We wish to thank Professor Arne Fredga for his interest in the work, and Dr. Ingrid Fischmeister for the infra-red absorption spectra. The financial support of the *Swedish Medical Research Council* is gratefully acknowledged.

On the Effect of Organic Mercury Compounds and Copper Salts on Catalase Cyanide

BO SÖRBO

Research Institute of National Defence, Dept. 1, Sundbyberg 4, and Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

In connection with studies of different antidotes in cyanide poisoning it became of interest to investigate the action of certain heavy metal compounds on cyanide inhibited heme enzymes. The toxicity of cyanide is attributed to its inhibitory action on cytochrome oxidase, but another heme enzyme, catalase, was used as a model enzyme in these studies, as it in contrast to cytochrome oxidase can be obtained in a pure state. It is of importance in this connection that catalase qualitatively behaves as cytochrome oxidase in its reaction with cyanide, as both the association and dissociation velocity constants are high [1]. It has previously been demonstrated by Chance [1] that silver ions generate free catalase from the catalase cyanide complex, due to the fact that silver ions combine with the free cyanide in equilibrium with catalase cyanide. The high toxicity of silver salts, however, apparently prevents their use as antidotes in cyanide poisoning. Incidentally we observed that organic mercury compounds had a high affinity for cyanide and could completely reactivate cyanide inhibited catalase. This suggested that these compounds may have an antidotal effect in cyanide poisoning. Of special interest were those organic mercury compounds which are used as diuretics, as they might be easily available for use as antidotes. The complete reactivation of cyanide inhibited catalase by one of these diuretics, Mersalyl (Salyrgan), is shown in Fig. 1. Experiments on rabbits [2] demonstrated, however, that Mersalyl had no antidotal effect in cyanide poisoning. Presumably the mercury compound was bound to sulfhydryl groups in the body before it could react with cyanide. (The mercurials have a very high affinity for sulfhydryl groups and their diuretic action is in fact attributed to an inhibition of sulfhydryl enzymes in the kidney.)

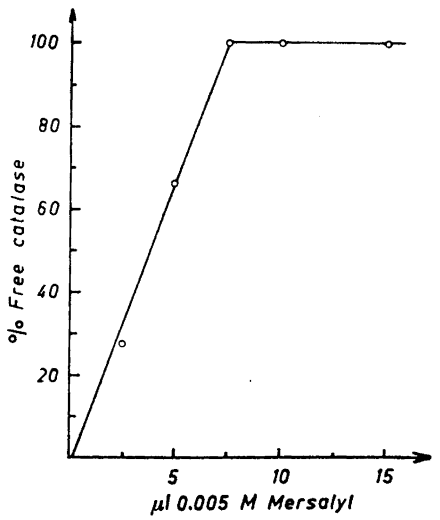

Fig. 1. Effect of Mersalyl on catalase cyanide. Horse blood catalase 0.8×10^{-6} M, cyanide 1×10^{-5} M, phosphate buffer 0.025 M of pH 7.4, final volume 3.0 ml. Indicated amounts of the mercurial added and the free catalase formed was determined spectrophotometrically from the decrease in absorbancy at 425 mµ.

Agner [3] reported that cupric salts could be used as antidotes in cyanide poisoning. This was disputed by Walther and Meyer [4] but Agner's results have been confirmed in connection with the present work [5]. However, when the effect of cupric chloride on catalase cyanide was studied, it was found that even a considerable excess of cupric

ions could not completely reactivate cyanide inhibited catalase, Fig. 2. Cupric chloride was thus inferior to Mersalyl in this respect, although it was effective as an antidote, whereas Mersalyl was not. This discrepancy could be explained when further experiments demonstrated that cuprous ions in contrast to the cupric ions very effectively liberated catalase from catalase cyanide; see Fig. 2. (The antidotal effect of cuprous chloride was not determined, as this compound is only sparingly soluble and is rapidly oxidized to cupric chloride in the presence of air). If cupric ions could be reduced to the cuprous state in the vicinity of the cyanide inhibited cytochrome oxidase, an efficient reactivation of the latter could be expected. Cupric ions are in fact reduced by ferrocytochrome c[5] and as cytochrome c is mainly present in the reduced form in cyanide poisoned cells, good possibilities exist for an intracellular reduction of the cupric ions. It is relevant that cupric ions have much less affinity for sulfhydryl groups than cuprous ions or organic mercury compounds [6,7]. (The reaction between mercaptans and cupric ions involves a reduction of the latter to the cuprous state.) This suggests that cupric ions are not so rapidly bound to sulfhydryl groups in the body as the mercurials and could then better reach the cyanide inhibited cytochrome oxidase in the central nervous system.

The crystalline horse blood catalase used in these experiments was a generous gift from Dr. R. K. Bonnichsen. The author is also grateful to Miss A.-M. Sjödén and Mr. O. Eriksson for valuable technical assistance.

On the Metabolism of 3α, 7α, 12α-Trihydroxycoprostanic Acid in the Rat *

Bile Acids and Steroids 44

R. J. BRIDGWATER

and

S. LINDSTEDT

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Tritium labelled D- and L-3α,7α,12α-trihydroxycoprostanic acids have been prepared. They have been found to be rapidly degraded to cholic acid in the rat liver, only a minor amount appearing in the bile as the taurine conjugate of the injected acid.

Bile acids with 27 carbon atoms have been found in various animals. (For a review see Haslewood [1]) 3α, 7α, 12α-25-L-trihydroxycoprostanic acid (II) has been isolated from the bile of *Alligator mississippiensis* [2] and also from the bile of *Rana nigromaculata nigromaculata* [3]. From the bile of this latter species the isomeric 3α, 7α, 12α-25-D-trihydroxy-coprostanic acid has also been isolated [3]. Both isomers have also been isolated previously from the bile of *Rana catesbiana* [4,5].

Tetrahydroxybinorsterocholanic acid (27 carbon atoms) has also been isolated from the bile of the domestic chicken [6].

Both the 25-D- and the 25-L-3α, 7α, 12α-trihydroxycoprostanic acids have been prepared by partial synthesis [7]. Haslewood has put forward the theory that the C-27 bile acids represent a primitive stage in the evolutionary chain leading up to the C-24 acids of many animals.

As the bile acids of mammals are end products of cholesterol metabolism one could expect a hydroxylated coprostanic acid to be an intermediate in the

* A preliminary report of this work was read at the Meeting of the Norwegian Biochemical Society in June, 1956 [18].

conversion of cholesterol into bile acids. This would also be in accord with the view that hydroxylations in the steroid nucleus might precede the total degradation of the side chain [8].

EXPERIMENTAL

L- and D-Trihydroxycoprostanic acids were prepared by anodic coupling of cholic acid with D- and L-methylhydrogen-α-methyl glutarate, respectively, followed by degradation of the resulting acids by the Barbier-Wieland procedure.

The sodium salts of the acids were tritiated by a platinum-catalyzed exchange with tritium water at 120° for four days [6]. The acids were then purified by chromatography with phase system F (see below) and crystallized. The L-trihydroxycoprostanic acid melted at 194—196° and had a specific activity of 2.2×10^5 c.p.m. when counted in an "infinitely thin" layer in a Tracerlab gas-flow counter. The D-form melted at 185° and had a specific activity of 5×10^5 c.p.m.

Bile fistulas were made on white rats weighing about 200 g. The bile was collected in 50 % ethanol. The conjugated bile acids were extracted with *n*-butanol after acidification to pH 1. Saponifications were carried out in sealed glass tubes in 2 N sodium hydroxide at 120° for 12 h, and the free acids extracted with ether after acidification.

The reversed-phase chromatographic technique worked out by Bergström, Sjövall and Norman [10-12] was used for separation of the bile acids. The following solvent systems were used.

System	Moving phase	Stationary phase
C (Ref.[12])	methanol / water 50/50	chloroform / "*iso*octanol" 50/50
D (Ref.[12])	water	butanol
F (Ref.[11])	methanol / water 55/45	chloroform / heptane 90/10

Each fraction from the chromatogram was titrated with 0.02 N sodium hydroxide, and an aliquot plated in an "infinitely thin" layer on an aluminium or copper planchet. These were then counted in a Tracerlab gas-flow counter. The specific activity of the isolated cholic acid was determined after combustion and conversion into tritiobutane by the methods of Glascock [13].

RESULTS

Excretion and conjugation. L-Trihydroxycoprostanic acid (1—3 mg) was neutralized with sodium hydroxide and injected intraperitoneally into a rat with a bile fistula. About 70 % of the administered activity was excreted within 24 h. The bile acids were extracted and chromatographed with phase system D. The resulting chromatogram is seen in Fig. 1. The first activity peak coincides with the titration peak caused by taurocholic acid at 10—20 ml. The second activity peak at 25—35 ml appears at the position of taurochenodeoxy acid. In this system, however, taurine-conjugated trihydroxycoprostanic acid moves as a taurine-conjugated dihydroxycholanic acid. Any free trihydroxycoprostanic acid that might occur would have remained in the stationary phase. The column was eluted and the material rerun with phase system F. No sign of free trihydroxycoprostanic acid was found. The second peak in Fig. 1 was saponified and rerun with unlabelled trihydroxycoprostanic acid with phase system F. The titration and activity peaks coincided.

Identification of cholic acid. A bile sample from a rat that had received L-trihydroxycoprostanic acid was saponified and run on a chromatogram with phase system C. An activity peak coinciding with the titration peak caused

by cholic acid was found (Fig. 2). The acid isolated from the combined fractions (60—120 ml effluent, *cf.* Fig. 2) was diluted with carrier cholic acid and the material recrystallized five times from different solvents (EtOH/aq, acetone/aq, EtOAc). Duplicate determinations of specific activity were carried out on material from the last four crystallizations. This specific activity was found to remain constant.

D-*Trihydroxycoprostanic acid.* When the D-form was given to a rat with a bile fistula and the bile acids fractionated, results identical with those described for the L-form were obtained.

DISCUSSION

As a result of earlier investigations it would appear probable that the first steps in the conversion of cholesterol into bile acids in mammals are hydroxylations in the steroid nucleus, which are then followed by the degradation of the side chain, the latter proceeding at a rapid rate. It has thus been shown that both 3α, 7α, 12α-trihydroxycoprostane, 3α,12α-dihydroxycoprostane and 3α,

(I)
(II)
(III)
(IV)
COOH
OH
HO
CH₂ · CH₂ · SO₃Na
CO · NH

7α-dihydroxycoprostane give rise to bile acids more rapidly than cholesterol itself [14–16].

It is assumed that the degradation of the side chain starts with a methyl-oxidation followed by a β-oxidation. This latter oxidation is known to be unhindered by the presence of a methyl group in the α-position (*cf.* Tryding and Westöö [17]). The present investigation clearly shows the rapid rate of the β-oxidation. It is also evident that the oxidation does not proceed beyond the cholic acid stage, the enzymatic reaction probably being blocked by the bulky steroid nucleus. It is of interest to note that the steric configuration at carbon atom 25 is of no importance, both stereoisomers being attacked to approximately the same extent.

Although no C-27 bile acids have been found in mammals they may appear as short-lived intermediates in the conversion of cholesterol(I) into bile acids.

The trihydroxycoprostanic acid (II) that was not degraded to cholic acid (III) appeared as a taurine-conjugate (IV), no trace of glycine-conjugate or free acid being found. Since both the conjugation [19,20] and the β-oxidation presumably proceed *via* a CoA-compound there is apparently a competition between the dehydrogenation and the conjugation resulting in a preponderance of the products of the former reaction.

We wish to thank Professor S. Bergström, who suggested the problem, for advice and encouragement. One of us (R.J.B.) expresses his gratitude for financial assistance from the *Clinical Research Committee of Guy's Hospital Medical School* and for facilities provided at the University of Lund. The work is part of a program supported by *Knut och Alice Wallenbergs Stiftelse* and the *Medical Faculty of Lund.*

Skilful technical assistance was given by Mr. Bengt Åkesson.

ACTA CHEMICA SCANDINAVICA 11 (1957) 414—416

On the Metabolism of Taurine Conjugated 3α, 7α, 12α-Trihydroxycoprostanic Acid in the Rat

Bile Acids and Steroids 45

SVEN LINDSTEDT and ARNE NORMAN

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The taurine conjugate of tritium labelled 3α,7α,12α-trihydroxycoprostanic acid has been prepared. In experiments on rats it was found that no splitting of the conjugate occurs in the liver but that it is split to a small extent in the intestine.

It has been shown that all bile acids naturally occurring in the rat bile are conjugated with taurine, only traces of glycine conjugates being found [1]. When the bile acids in the feces are examined by chromatography one finds only a small amount of conjugated acids [2]. When, however, the bacterial flora in the intestine has been depressed with chemoterapeutics practically all the bile acids in the feces are in the conjugated form [3]. This has led to the view that the microbial enzymes are mainly responsible for the normally occurring hydrolysis, an opinion which is further supported by the observation that certain anaerobic bacteria have a high capacity of splitting conjugated bile acids [4].

It has not, however, been definitely settled whether the digestive enzymes or enzymes in the liver are capable of splitting bile acid conjugates. Portman and Mann [5] have fed ^{35}S-labelled taurocholic acid to bile fistula rats and found 2—18 % of the radiosulfur in the urine. The hydrolysis in this case may well have been caused by bacterial enzymes attacking bile salts. Norman [6] has injected glycocholic acid-24-^{14}C intraperitoneally into bile fistula rats and into rats on which the bile fistula was made 6 h after injection. In the first case no taurocholic acid was found in the bile while in the latter about 50 % of the given amount appeared as taurocholic acid. The results indicated that no hydrolysis of the glycocholic acid occurs in the liver.

We have made similar experiments with tauro-trihydroxycoprostanic acid. The free trihydroxycoprostanic acid is known to be rapidly degraded to cholic acid in the liver [7]. If any hydrolysis of the taurine conjugates occurs in the liver one would thus expect to find activity in the cholic acid excreted in the bile.

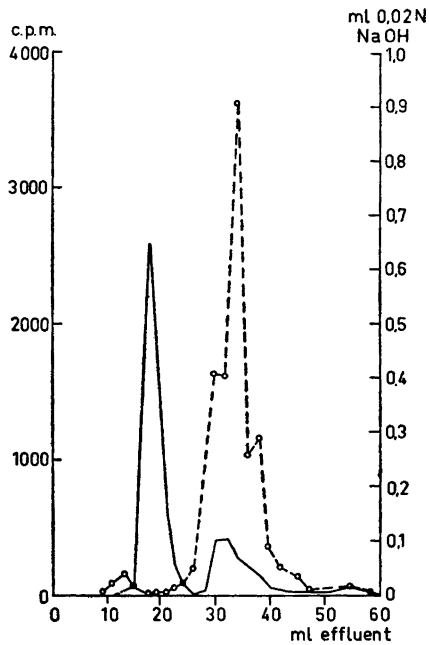

Fig. 1. Chromatography of conjugated bile acids excreted in a bile fistula rat after intraperitoneal injection of tritium labelled taurotrihydroxycoprostanic acid. Phase system D. Moving phase: water. Stationary phase: butanol. Solid line: Titration. Broken line: Radioactivity.

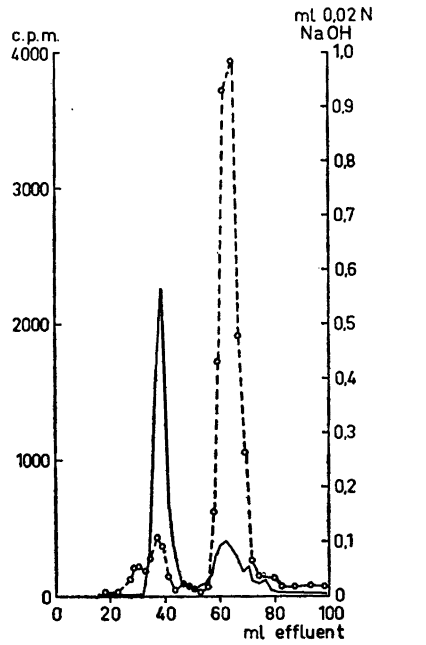

Fig. 2. Chromatography of conjugated bile acids in the bile fistula of a rat that had received an intraperitoneal injection of tritium labelled tauro-trihydroxycoprostanic acid 6 hours prior to operation. Phase system D. Solid line: Titration. Broken line: Radioactivity.

EXPERIMENTAL

Tritium-labelled 3*a*,7*a*,12*a*-25-L-trihydroxycoprostanic acid prepared by Bridgwater and Lindstedt [7] was coupled to taurine by the micromethods described by Norman [8]. The acid was purified by chromatography with phase system D (*cf.* Ref.[7]). It had a specific activity of about 250 000 c.p.m. per mg when counted in an "infinitely thin" layer in a Tracerlab gas-flow counter.

One mg of the sodium salt of the taurine-conjugated acid was administered intraperitoneally to bile fistula rats or normal rats on which a bile fistula was made 6 h after the administration. For details of the fractionation procedure see the preceding paper [7].

RESULTS AND DISCUSSION

Fig. 1 shows a chromatogram of an unhydrolyzed butanol extract of the bile excreted during a 24 h period after intraperitoneal administration of taurotrihydroxycoprostanic acid. The titration peaks at 15—25 ml and 30—40 ml are caused by taurocholic and taurochenodesoxycholic acid, respectively. No activity is present at the place of taurocholic acid, all of it being confined to a peak immediately after taurochenodesoxycholic acid at the place where tauro-

trihydroxycoprostanic acid is known to appear. For further identification the fractions containing the labelled material were hydrolyzed and rerun with phase system F (*cf.* Ref.[7]). The labelled compound now appeared at the place of free trihydroxycoprostanic acid added as carrier.

In Fig. 2 a chromatogram is shown of the bile acids excreated in a bile fistula made 6 h after injection of tauro-trihydroxycoprostanic acid. In this case about 10 % of the activity appears at the place of taurocholic acid and the rest at that of tauro-trihydroxycoprostanic acid. After hydrolysis the free bile acids were identified as cholic and trihydroxycoprostanic acid.

The results show that taurotrihydroxycoprostanic acid is excreted unchanged by the liver and indicate that the conjugating reaction in general is to no noticeable extent reversible. A slight hydrolysis of a minimum of 10 % must have occurred when the injected taurotrihydroxycoprostanic acid had taken part in the enterohepatic circulation for 6 h as this percentage of the tauro-conjugated C_{27}-acid was then recovered as the C_{24} cholic acid that was excreted as its taurine conjugate.

The Formation of Bile Acids from 7 α-Hydroxycholesterol in the Rat *

Bile Acids and Steroids 47

SVEN LINDSTEDT

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Tritium labelled 7α-hydroxycholesterol has been prepared. It has been injected intraperitoneally into bile fistula rats and cholic and chenodeoxycholic acid identified as acid metabolities. The mechanism of the degradation of cholesterol is discussed.

In the autoxidation of cholesterol the two epimeric 7-hydroxycholesterols are formed [2,3]. They have also been reported to occur in small amounts in the unsaponifiable fraction in various organ lipids [4-7]. The possibility of their formation by autoxidation during the isolation procedure has, however, not been rigorously excluded.

It has been suggested that a 7-hydroxycholesterol may appear as an intermediate in the *in vivo* degradation of cholesterol [2,8].

In this work the formation of bile acids from 7α-hydroxycholesterol is demonstrated.

EXPERIMENTAL

7α-Hydroxycholesterol was prepared essentially according to Henbest *et al.* [9,10]. 2 g of sodium formiate dissolved in 20 ml of formic acid was added to a solution of 2 g of 7α-bromocholesterylbenzoate in 20 ml of ether. After 24 h water was added and the steroid extracted with ether. The material was dissolved in 2 ml of benzene and 15 ml of methanol added. After 8 h at room temperature 1.35 g of crystals melting at 115—144° were obtained. This material was brought onto a 20 g alumina column and eluted with increasing concentration of benzene in light petroleum. The material eluted with 0—30 % of benzene in light petroleum was crystallized from benzene/methanol and yielded 0.91 g of 7α-formoxycholesterolbenzoate m. p. 150—152°. Saponification with alcoholic potassium hydroxide gave 7α-hydroxycholesterol m. p. 150°.

Tritium-labelled 7α-hydroxycholesterol. Attempts to label 7α-hydroxycholesterol by platinum catalyzed exchange in tritiated water/acetic acid or tritiated water-ethanol/

* For a discussion of the steric configuration at the 7-position see Ref.[1]. A preliminary report of this work was read at the meeting of the Norwegian Biochemical Society, June 1956 [20].

sodium hydroxide were not successful and led to extensive destruction. The labelled 7α-hydroxycholesterol was therefore synthesized by the above procedure from tritium-labelled cholesterol prepared according to Bloch [11]. To ensure the absence of radioactive contaminants it was chromatographed according to Danielsson [12] on hydrophobic kieselguhr with 50 % (v/v) aqueous *iso*propanol as moving phase and 20 % (v/v) chloroform in heptane as stationary phase. The tritium labelled 7α-hydroxycholesterol had a specific activity of 4.3×10^5 c.p.m. when counted in an "infinitely thin" layer in a gas-flow counter.

Chromatographic separations of the bile acids were performed according to Sjövall and Norman [13,14]. The following two systems were used:

Phase system	moving phase	stationary phase
C(Ref.[14])	methanol/water 50/50	*iso*octanol/chloroform 1/1
F(Ref.[13])	methanol/water 55/10	chloroform/heptane 9/1

Each fraction was titrated with 0.02 N sodium hydroxide and an aliquot plated on a copper planchet for counting in a gas-flow counter. Accurate determinations of specific activity were performed by the gas-phase counting technique of Glascock [15].

RESULTS

2—3 mg of tritium-labelled 7α-hydroxycholesterol was dissolved in 0.2 ml of ethanol and brought into a colloidal suspension by the addition of 2 ml of 0.9 % sodium chloride containing 2 mg of sodium oleate. It was injected intraperitoneally into white rats with a bile fistula, and the bile collected.

After hydrolysis in 2 N sodium hydroxide in a sealed glass tube at 120° for 8 h the bile acids were extracted and isolated by chromatography with phase system C.

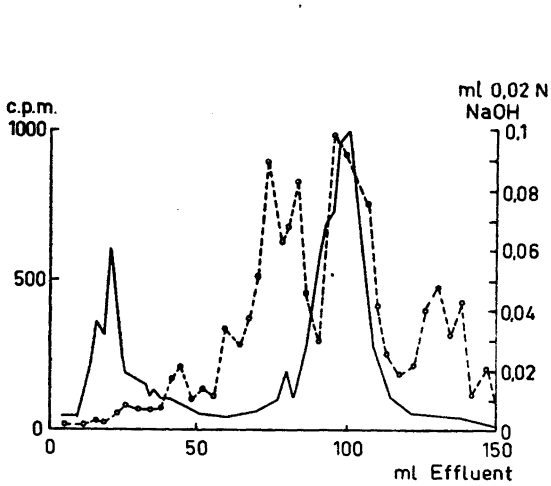

Fig. 1. Chromatogram of hydrolyzed bile after intraperitoneal injection of tritium-labelled 7α-hydroxycholesterol. Phase system C. Broken line: isotope determination. Solid line: titration values.

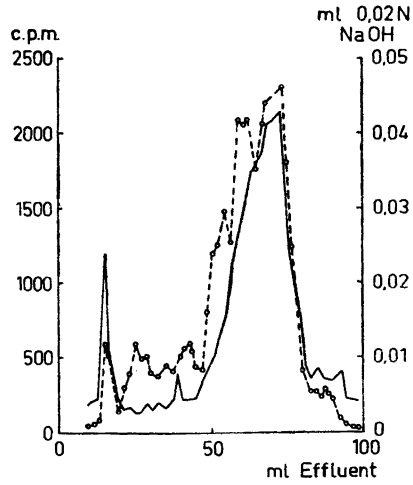

Fig. 2. Chromatogram of dihydroxy-acids after intraperitoneal administration of tritium-labelled 7α-hydroxycholesterol. Phase system F. Broken line: isotope determination. Solid line: titration values.

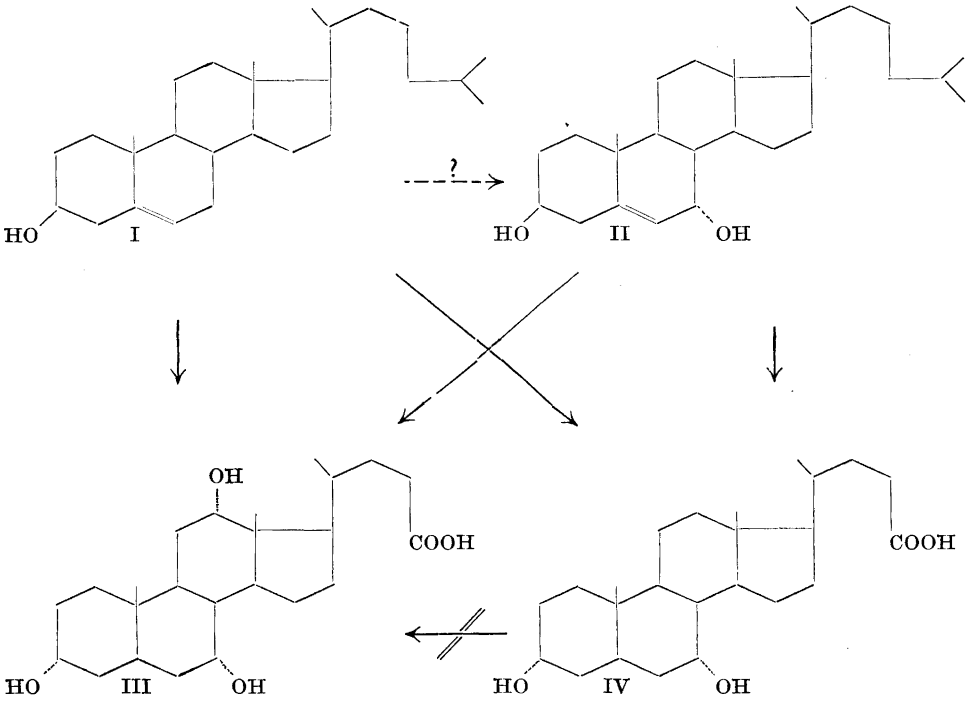

Fig. 3.

Fig. 1 shows a chromatogram where the titration peak of cholic acid appears at 80—120 ml. At the same position a peak of radioactivity is seen. This material was collected, rerun with the same chromatographic system, diluted with carrier cholic acid and recrystallized from different solvents. From each crystallization material was taken for determination of the specific activity by the gas-phase counting method [15]. It remained constant throughout five recrystallizations (EtOH, EtOAc, acetone/water) and the identity of the material with cholic acid seems established.

The material remaining in the column was eluted and rechromatographed on system F suitable for the separation of dihydroxycholanic acids. The chromatogram which is seen in Fig. 2 shows a titration peak at 50—80 ml caused by chenodeoxycholic acid in the bile. The identity of the labelled compound eluted at this position with chenodeoxycholic acid was established by recrystallization with carrier and determination of specific activity as for cholic acid.

In Fig. 1 labelled material is eluted before and after the cholic acid peak. When labelled chenodeoxycholic acid is administered to rats labelled metabolites appear at these locations [16,21] and in this experiment they probably also represent metabolites of the chenodeoxycholic acid.

DISCUSSION

In the rat cholesterol (I) gives rise to cholic acid (III) and chenodeoxycholic acid (IV) [16,17]. Work by Bergström and Sjövall [16] has, however, established that cholic acid is not formed by a 12α-hydroxylation of chenodeoxycholic acid. This type of reaction has been shown to take place when 3α,7α-dihydroxycoprostane is administered leading to the formation of cholic acid as well as of chenodeoxycholic acid [18]. This has brought further support to the view that in the formation of bile acids from cholesterol hydroxylations in the steroid nucleus precede the total degradation of the side chain [19].

Although the *in vivo* formation of 7α-hydroxycholesterol (II) from cholesterol has never been demonstrated, the results suggest the possibility that one of the primary steps in the degradation of cholesterol in the rat is a 7-hydroxylation.

A summary of some of the reactions studied in the rat is given in Fig. 3.

On the Formation of Deoxycholic Acid from Cholic Acid in the Rabbit

Bile Acids and Steroids 48

SVEN LINDSTEDT and JAN SJÖVALL

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The excretion of glycocholic acid and glycodeoxycholic acids in rabbits with a bile fistula has been studied. 30—40 h after operation glycodeoxycholic acid has almost disappeared. In rabbits with a bile fistula administered cholic acid-24-^{14}C is excreted unchanged in the fistula. In "whole" animals labelled cholic acid gives rise to labelled deoxycholic acid probably through the action of intestinal micro-organisms.

The main bile acids in rabbit bile are glycocholic and glycodeoxycholic acids [1-4]. When rabbit fistula bile collected immediately after surgery was fractionated by chromatography the amount of glycodeoxycholic acid was about ten times that of glycocholic acid [4]. On the other hand Okamura and Okamura were not able to isolate deoxycholic acid from a large amount of fistula bile [1].

In normal human bile, collected by duodenal tubage, cholic and deoxycholic acids are regularly present together with chenodeoxycholic acid [5]. The acids occur conjugated with glycin or taurin. When human bile from post-operative choledochal drainage was examined by paper chromatography no deoxycholic acid could be detected [6], nor could it be found in the duodenal contents of newborn babies [7].

The absence of deoxycholic acid from bile that has not been subjected to the action of intestinal microorganisms suggested the possibility that this acid is not primarily formed in the liver but arises from the attack of the microorganisms on some other bile acid, *e. g.* cholic acid. It has been found, that when ^{14}C-labelled cholic acid is administered to normal human subjects, and the bile acids fractionated a few days later, significant label is found in the dihydroxycholanic acid fraction [8].

In the present work the relationship between cholic and deoxycholic acids in the rabbit has been studied.

EXPERIMENTAL

Cholic acid-24-^{14}C had been prepared according to Bergström, Rottenberg and Voltz [9].

Bile fistula rabbits. Animals weighing 2—3 kg were anesthetized with ether and cannulation of the common bile duct was performed with a polythene tube just above the entrance of the common duct into the duodenum. No attempt was made to remove the gall-bladder. After operation the rabbits were given a subcutaneous infusion of 0.9 % sodium chloride at a rate of 10—20 ml per hour. This was found to be necessary as the animals otherwise died. The rabbits started eating after about one day and were fed on cabbage, carrots and oats and had access to 0.9 % sodium chloride as drinking water. When the rabbits were found to eat normally the infusion was no longer necessary. They were kept in cages that somewhat restricted their movements and could be kept in seemingly good condition for at least two weeks.

Chromatographic separation of the bile acids was carried out with reversed phase column chromatography [10] and by paper chromatography, by which technique the quantitative composition could also be determined [11,12]. Glycocholic and glycodeoxycholic acids were separated with ascending chromatography of the bile using ethylene chloride/heptane 70/30 (v/v) saturated with 70 % acetic acid as moving phase. After localization the acids were eluted and the amounts calculated from the absorbancy in 65 % sulfuric acid [13]. For identification purposes sulfuric acid absorption spectra were recorded with a self-recording spectrophotometer (Perkin-Elmer Spectracord 4 000).

RESULTS

Excretion of glycocholic and glycodeoxycholic acids in bile fistulas. The concentration of glycocholic and glycodeoxycholic acids in bile was followed in three animals. The values are given in Table 1 and show a marked decrease in the quotient between glycodeoxycholic and glycocholic acids.

A more detailed analysis of the course of the excretion was performed in animal No. 3 from which bile was collected in 2-h fractions with a fraction collector for the first 42 h following the operation and the bile acid concentration was determined in each fraction. These data have been used for con-

Table 1. Concentration of glycocholic and glycodeoxycholic acids in small samples of fistula bile collected at different times after operation.

structing Fig. 1 which shows the amounts of glycocholic and glycodeoxycholic acids excreted during each 6-h interval and also the mean bile acid concentration in these periods. A gradual shift in the proportion between the excreted amounts of glycocholic and glycodeoxycholic acids is obvious. Thus during the first periods glycodeoxycholic acid constitutes more than 90 % of the total bile acids excreted, while glycocholic acid is by far dominating in the later periods. The quotient between the amount of glycodeoxycholic acid and glycocholic acids excreted in different periods reached a maximum of 35 at 6—8 h after operation — in this period highly concentrated bile probably originating from the gall-bladder was obtained — and then decreased attaining a plateau level of 0.05 from 32 h onwards. The absorption spectra in 65 % sulfuric acid of material eluted from the glycodeoxycholic acid spot and of authentic glycodeoxycholic acid were recorded. The two spectra showed a good agreement in the first periods, while in the later a discrepancy was noted. Recordings from the first and the last 2-h intervals are shown in Figs. 2 and 3. Descending paper chromatograms in a medium suitable for the separation of glycodeoxycholic and glycochenodeoxycholic acids were run and showed that most of the acid excreted in small amount at the end of the experiment was not identical with glycodeoxycholic acid.

Fig. 1 further shows that the excreted amount of bile acids as well as their concentration fell during the experimental period. In the first 18 h a total of 550 mg of glycine conjugated bile acids was excreted. Most of this amount probably represents bile salts taking part in the enterohepatic circulation at the time of the operation.

Administration of cholic acid-24-^{14}C to rabbits with a bile fistula. Bile fistulas were made on two rabbits and cholic acid-24-^{14}C injected intraperitoneally 6 h and 36 h after the operation, respectively. The bile was collected for 3 h after the injection and hydrolyzed for 8 h at 120° C in a sealed glass tube.

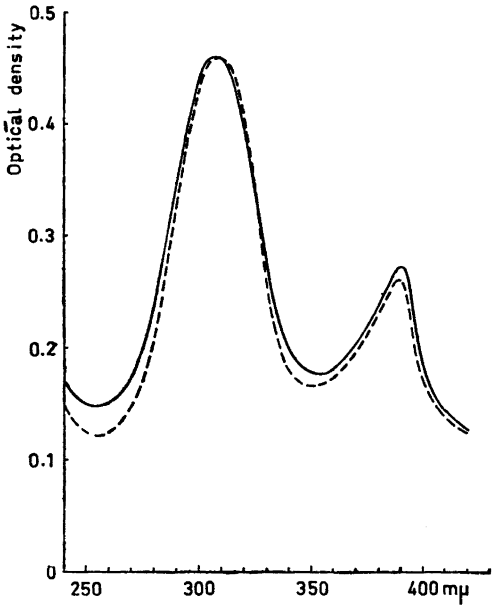

Fig. 2. Absorption spectra of glycodeoxycholic acid (——) and material from the glycodeoxycholic acid spot (0—2 hours) (- - -). Samples heated simultaneously for 10 minutes at 60° C in 65 per cent sulfuric acid.

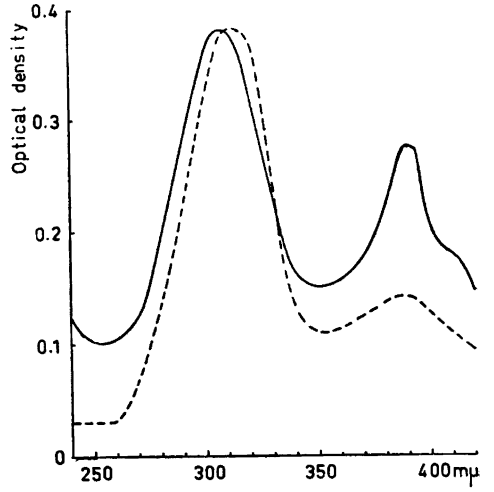

Fig. 3. Absorption spectra of glycodeoxycholic acid (——) and material from the glycodeoxycholic acid spot (40—42 hours) (- - -). Samples heated as in Fig. 2. The difference between the spectra of authentic glycodeoxycholic acid in Fig. 2 and Fig. 3 is due to minor variations in the concentration of the sulfuric acid.

A chromatogram of the free acids from the first rabbit is shown in Fig. 4. One titration peak is seen at 15—30 ml caused by cholic acid and one at 50—80 ml due to deoxycholic acid. All the activity is confined to the cholic acid peak whereas none is present in the deoxycholic acid. In the second rabbit the same result was obtained except for the almost complete absence of a titration peak at the position of deoxycholic acid.

Administration of cholic acid-24-^{14}C to "whole" animals. Two rabbits were injected intraperitoneally with labelled cholic acid. Three days later a bile fistula was made on the animals. The bile was collected, hydrolyzed and subjected to chromatography as above. The results from one of the rabbits is shown in Fig. 5. Only traces of radioactivity remain at the position of cholic acid, whereas practically all of it is found in the deoxycholic acid band. A minor amount appeared as a less hydrophilic compound. The deoxycholic acid was crystallized from acetic acid/water and gave 30 mg of crystals, m. p. 169—70 °C and a specific activity of 1 200 c.p.m. which was found to remain unchanged on further recrystallization from different solvents. The less hydrophilic compound has not been further investigated.

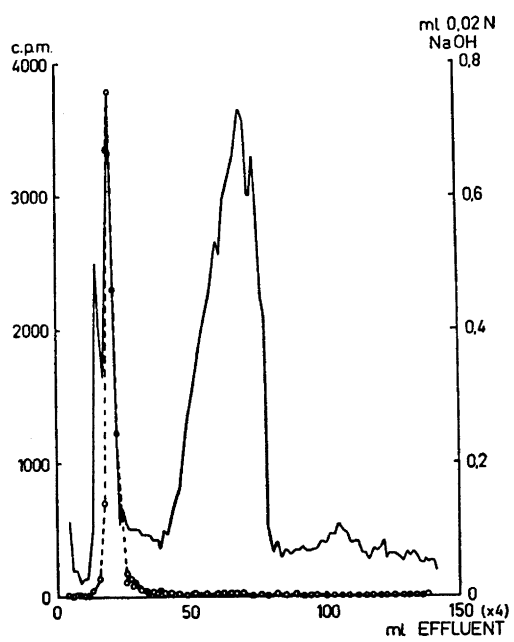

Fig. 4. Chromatography of hydrolyzed bile from a bile fistula rabbit injected intraperitoneally with cholic acid-24-^{14}C 6 hours after operation. Phase system: Moving phase: methanol/water 55/45. Stationary phase: chloroform/heptane 9/1. Solid line: titration values. Broken line: radioactivity.

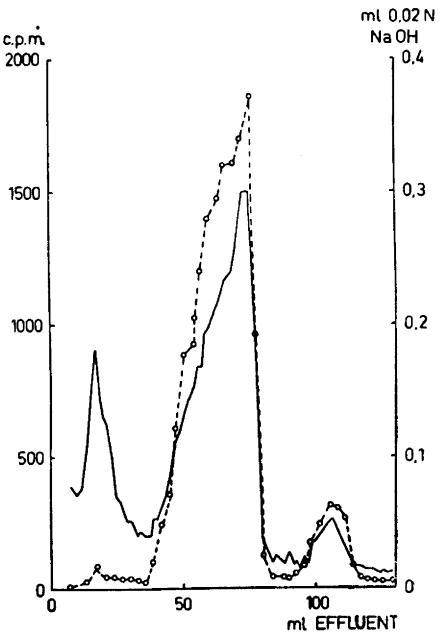

Fig. 5. Chromatography of hydrolyzed bile from a bile fistula rabbit, injected intraperitoneally with cholic acid-24-^{14}C 3 days before operation. Phase system: same as in Fig. 4. Solid line: titration values. Broken line: radioactivity.

DISCUSSION

The transformation of cholic acid into deoxycholic acid has been postulated by Japanese workers. Their conclusions, however, are mainly based on experiments in which as much as 30 g of the bile acid was fed and small amounts of the metabolites isolated from the urine (for a summary see Refs.[14,15]).

The disappearance of deoxycholic acid from bile fistula bile in 30—40 h clearly suggests that this acid is not an excretory metabolic product of the rabbit liver. The possibility remains, however, that a change in the proportion between the bile acids formed in the liver is induced by the continuous withdrawal of the bile. The very rapid disappearance of the deoxycholic acid makes this assumption less likely as do also experiments with rats where the proportion between cholic and chenodeoxycholic acid remains mainly unchanged when a bile fistula is made [16].

When labelled cholic acid is administered intraperitoneally into a rabbit with a bile fistula it is absorbed from the peritoneal cavity into the portal circulation passing through the liver into the bile fistula. If the liver was able to transform cholic acid into deoxycholic acid one would expect the label to

appear in the deoxycholic acid, even though only one passage through the liver has taken place. In the rat, *e. g.*, where certain transformations of the bile acids have been studied (*e. g.* deoxycholic acid → cholic acid; chenodeoxycholic acid → hydroxylated metabolites; *cf.* Ref.[17]) one passage through the liver suffices to give a high percentage of conversion.

When cholic acid is given to whole animals the acid will take part in the enterohepatic circulation and thus be subjected to the action of the intestinal microorganisms. It is well known that they effectively attack bile acid molecules resulting in the formation of various metabolites (*cf.* Refs.[18,19]). They may therefore be responsible for the conversion of cholic acid into deoxycholic acid or into some intermediate which is then converted to cholic acid in the liver. This is made very probable by the experiments in which labelled cholic acid was allowed to circulate for three days in the intact animal. Practically all of the recovered activity was then found in the deoxycholic acid.

The results of this work once more show the necessity of considering the influence of intestinal microorganisms in studies of cholesterol and bile acid metabolism.

Metabolism of 2-Methylstearic Acid in the Rat

N. TRYDING and G. WESTÖÖ

Department of Physiological Chemistry and Institute of Organic Chemistry, University of Lund, Lund, Sweden

The intestinal absorption and the metabolism of 2-methyl[1-^{14}C]-octadecanoic acid were found to be very similar to those of the ordinary, long, straight chain fatty acids. For the first time, however, a small amount of metabolites from 2-methylstearic acid could be isolated from the urine and identified as 2-methyladipic (1.1 %) and 2-methylsuccinic acid (0.6 %).

In extensive studies on dogs Weitzel [1] investigated the effect on metabolism of monoalkylsubstitution in the α-position of long chain fatty acids. He found that 2-ethylstearic acid was excreted in the urine to 1.2 % as 2-ethyladipic acid. Analogously he showed that 2-propylstearic acid and 2-butylstearic acid gave rise to 2-propyladipic acid (5.2 %) and 2-butyladipic acid (6.5 %), respectively. With the methods used Weitzel found that, in contrast to these higher fatty acids with comparatively large α-substituents, α-methyl-substituted acids (fed in the ester form) did not produce any short dicarboxylic acids in the urine [2,3].

Continuing the investigation on the metabolism of long, branched chain fatty acids started with 2,2-dimethylstearic acid [4] and 2,2-dimethylnonadecanoic acid [5], we have now studied 2-methyl[1-^{14}C]stearic acid. It was given *per os* to intact rats or rats with thoracic duct fistulas. The isotopic distribution in the neutral fat, phospholipids and unesterified fatty acids of the lymph has been investigated. In addition the isotope excretion has been followed in the expired carbon dioxide, the feces and the urine. The metabolites were isolated by partition chromatography and identified by repeated recrystallizations with inactive, synthetic material.

When the 2-methyl[1-^{14}C]stearic acid was fed to unanesthetized rats with lymph fistulas [6], about 60 % of the absorbed activity was recovered in the lymph lipids. This is about the same figure as those found in similar experiments with other, long chain, branched or unbranched fatty acids. The main transport form of the 2-methyl[1-^{14}C]stearic acid was as glycerides (89—96 % of the total lymph fat activity). Only small amounts of cholesterol esters were present, and just a few per cent of the acid (Table 2) was found to be in unesterified form (3.7 %) or incorporated into phospholipids (4.0 %).

The specific activities of the unesterified fatty acids were in three experiments with 2-methyl[1-^{14}C]stearic acid 75, 36 and 14 % of the specific activities of the neutral fat fatty acids (Table 2). These figures were always found to be less than 100 % for ordinary straight chain fatty acids, whereas the corresponding values for the 2,2-dimethyl[1-^{14}C]nonadecanoic acid were 200—300 %. Thus the distribution of the lymph activity between neutral fat and unesterified fatty acids was the same as for ordinary straight chain fatty acids [7] or 15,15-dimethylpalmitic acid *, and it differs from fatty acids with two methyl groups in the α-position (*i. e.*, 2,2-dimethylstearic acid [4], 2,2-dimethylnonadecanoic acid [5] and 2,2,17,17-tetramethylstearic acid [8]).

The feces were collected daily from each rat and their isotope contents determined after saponification and extraction of the acids with ether. In thirteen experiments between 3 and 31 % (mean 13 %) of the fed activity could be recovered in the feces during four days after the administration of 2-methyl[1-^{14}C]stearic acid.

Almost all the active material in the feces was identified as the 2-methylstearic acid. Consequently, throughout this investigation, the absorbed activity has been calculated as the difference between the fed activity and the activity recovered in the feces. — However, a small amount of the fecal activity (in one experiment less than 0.2 %) chromatographically appeared as 2-methylsuccinic and 2-methyladipic acid, identical with the urinary metabolites of 2-methyl stearic acid (see below). Earlier, 2,2-dimethylnonadecanoic acid has been shown to produce dicarboxylic acids in the feces as well as in the urine [5].

After feeding carboxyl-labelled 2-methylstearic acid to a rat, about 25 % of the absorbed activity was found in the expired carbon dioxide in two days. The same value was found in a parallel experiment with [1-^{14}C]stearic acid. From these data one methyl group in the α-position does not seem to hinder the oxidation of the higher fatty acids. In contrast, after administration of 2,2-dimethyl[1-^{14}C]stearic acid [4] and 2,2,17,17-tetramethyl[1-^{14}C]stearic acid [8], less than 3 % of the absorbed activity was excreted as carbon dioxide. The β-oxidation from the carboxyl end of the molecule is not possible, because the two hydrogen atoms on the α-carbon atom are substituted with methyl radicals. The different metabolism of 2-methylstearic acid and 2,2-dimethylstearic acid is also strongly reflected in the isotope recoveries in the urine.

The urine from rats fed 2-methyl[1-^{14}C]stearic acid has been found to contain 1.6—3.5 % of the absorbed activity (Table 6). (After feeding [1-^{14}C]-palmitic acid to rats less than 0.5 % of the activity can be recovered from the urine [9]). By partition chromatography and repeated recrystallizations with synthetic unlabelled compound, two of the active substances have been identified as 2-methyladipic acid (0.8—1.7 % of the absorbed activity) and 2-methylsuccinic acid (0.4—0.9 %). They were excreted partly in conjugated form. The methyl side chain of 2-methylstearic acid thus has some, although a minor effect in impeding the β-oxidation from the carboxyl end.

* To be published.

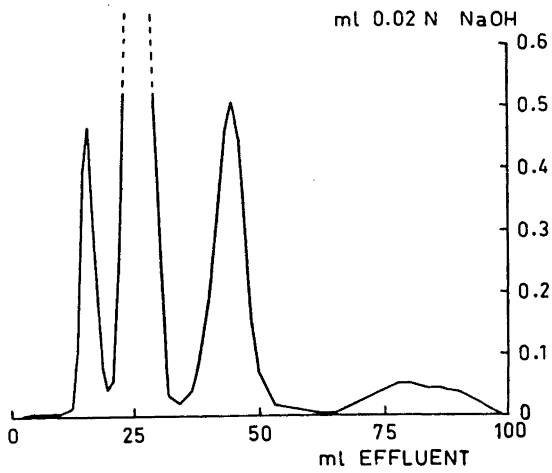

Fig. 1. Partition chromatography of part (39 mg) of an acid mixture obtained after Kolbe electrolysis of methyl hydrogen succinate and sodium 3-cyanobutyrate. Phase system C. Supporting medium: 4.5 g of hydrophobic kieselguhr.

SYNTHESES

2-Methyl[1-^{14}C]octadecanoic acid. Two different methods were used for the preparation of the labelled 2-methyloctadecanoic acids. The comparatively weakly radioactive product (0.13 μC/mg) was prepared by a Kolbe electrolysis of palmitic acid and sodium 3-[^{14}C]cyanobutyrate according to Westöö [10], the strongly active one (6.5 μC/mg) was made from inactive 2-methyloctadecanoic acid (prepared by the above method) by exchange of the carboxyl group for bromine by degradation of the silver salt (Rottenberg [11]) and reaction of the 2-bromooctadecane formed with K^{14}CN.

Silver 2-methyloctadecanoate (0.50 g) and silver acetate (0.20 g) were thoroughly mixed, pulverized and dried at 0.1 mm Hg over P_2O_5. Dry ethyl bromide (4 ml) was added and into the boiling mixture 0.13 ml of dry bromine was dropped. The boiling was continued for half an hour. Part of the ethyl bromide was distilled off, the mixture was filtered, and the filtrate was shaken with potassium iodide solution, water, sodium thiosulphate solution, and water again. It was dried over anhydrous sodium sulphate and filtered. After removal of the solvent, the residue was dissolved in light petroleum and chromatographed on 2.5 g of alumina. The front band (0.35 g) contained the 2-bromooctadecane.

Crude 2-bromooctadecane (0.11 g) was heated with K^{14}CN (0.017 mg, 0.50 mC), ethanol (2.5 ml) and water (0.7 ml) in a sealed glass tube at 95° for 24 h. The nitrile formed was hydrolyzed by heating with an excess of 10 % potassium hydroxide solution (ethanol-water, 4:1) in an autoclave at 130° for 4 h. Part of the ethanol was removed by distillation, and the rest of the solution was acidified with dilute hydrochloric acid and extracted with ether. The ether solution was washed with water, dried with sodium sulphate and evaporated to dryness. The product obtained was chromatographed according to system A (Table 1).

2-Methyladipic acid. Methyl hydrogen succinate (10.5 g) and sodium 3-cyanobutyrate (1.0 g) were electrolyzed in methanol (400 ml). The electrolysis was carried out as described earlier [5]. The slightly alkaline solution (pH 8) was evaporated to 50 ml. The products of the electrolysis were hydrolyzed in 2 N alcoholic potassium hydroxide for 2 h. The methanol was evaporated and after acidification the hydrolysate was extracted with ether. The acids obtained (4.4 g) were chromatographed three times according to system

C (Table 1). They were eluted in the following order: succinic and 2-methylsuccinic acid (in the front band), adipic, 2-methyladipic acid and 2,5-dimethyladipic acid (*cf.* Fig. 1). The 2-methyladipic acid (0.36 g) was recrystallized repeatedly from water and from benzene-light petroleum; m. p. 61° (equiv. wt. 80.1).

CHROMATOGRAPHIC SYSTEMS

The chromatographic systems used in this investigation are summarized in Table 1. System A was used for the isolation and identification of 2-methylstearic acid. Phase system B was found suitable for the separation of dicarboxylic acids with five to nine carbon atoms. The phases used in system C are more polar than those of system B, which enables also C_4-dicarboxylic acids to be chromatographed. The ordinary partition chromatography (with phase system D) was used as an alternative to the reversed phase system C.

Table 1. Chromatographic systems.

System	According to	Supporting medium	Stationary phase	Moving phase
A	Howard and Martin [12]	Hydrophobic kieselguhr (Hyflo supercel treated with dimethyldichlorosilane)	Paraffin oil (25 ml)	Acetone: water 7:3, v/v (210 ml: 90 ml)
B	Bergström and Sjövall [13] for the separation of free bile acids. Also used by Bergström, Borgström, Tryding and Westöö[4] for the separation of dicarboxylic acids	see above	*iso*-octanol (2-ethylhexanol)-chloroform 1:1,v/v (25 ml: 25 ml)	methanol: water 1:3, v/v (75 ml: 225 ml) (modified from 2:3, v/v)
C	Norman [14] for the separation of conjugated bile acids	see above	*n*-butanol (100 ml)	distilled water (300 ml)
D	Isherwood [15]	silica gel prepared according to Nijkamp [16]	0.5 N sulfuric acid (50 ml)	butanol : chloroform 1:9, v/v (30 ml: 270 ml)

The volumes of solvents given in Table 1 for each system were mixed in a separatory funnel and equilibrated at room temperature (23° C) before use. Four ml of the stationary phase were used per 4.5 g of supporting medium. Generally 9 g columns were made with solvent systems B and C, while all the chromatograms with phase system A and D were run on 4.5 g columns. The internal diameter of the chromatographic tubes used was 12 mm. The techniques of fraction collection, titration and determination of ^{14}C-activity have been described earlier [4].

METABOLIC EXPERIMENTS

A 3.6 % stock solution (I) of 2-methyl[1-^{14}C]stearic acid (specific activity 110 000 cpm/mg) in olive oil was prepared and found to have a specific activity of 3 900 cpm/mg.

Another olive oil solution (II) contained 0.045 % of the strongly active 2-methyl-[1-^{14}C]stearic acid (s. a. 5 400 000 cpm/mg). The specific activity of this solution was 2 400 cpm/mg. No differences were found in the absorption or metabolism of the two stock solutions.

Radioactivity determinations were performed with a gas flow counter (background effect 30 cpm) generally after direct plating of the samples on aluminium planchets.

The animals used in these investigations were white, adult, male rats weighing about 250 grams.

Administration of 2-methylstearic acid to rats with lymph fistula

Unanesthetized rats provided with a thoracic duct fistula [6] were fed 1 ml of the olive oil solution containing 2-methylstearic acid (stock solution I). The general procedure for the collection, extraction and separation of the lymph lipids has been reported earlier from this institute [6,7]. From Table 2 it is seen that the absorption of 2-methyl[1-^{14}C]-stearic acid varied from 69 to 96 % of the fed amount. However, the percentage of absorbed activity recovered in the lymph was relatively constant, about 60 % in three rats out of four. Almost all the lymph activity (96 % for rat No. 1, Table 2) could be recovered during the first 12 h after the administration, but the values given in the table were determined on 24-h-specimens.

Table 2. Recovery of activity in lymph fatty acids after oral administration of 2-methyl-[1-^{14}C]stearic acid to rats.

Rat No.	Per cent of administered activity absorbed	Per cent of absorbed activity recovered in lymph fatty acids	Per cent of lymph fat activity found as		
			unesterified fatty acids	neutral fat	phospholipids
1	85.3	61.2	96.5		3.5
2	69.3	62.5	5.0	88.7	6.3
3	95.7	63.2	2.4	95.6	2.0
4	91.9	45.1	3.7	92.1	4.2

Two of the experiments (Rats No. 3 and 4) complete an investigation by Borgström and Tryding on the free fatty acid content of rat thoracic duct lymph [7]. Table 3 summarizes the results of these two experiments. — Cholesterol esters could be present only in very small amounts, as only traces of the lymph fat activity could be eluted with light petroleum from a silicic acid column [17].

Table 3. Weight of different lymph fat fractions and specific activity of their fatty acids.

Rat No.	Neutral fat		Free fatty acids		s.a. of free fatty acids in % of s.a. of neutral fat fatty acids
	Weight mg	Spec. activity	Weight mg	Spec. activity	
3	690	70	48.4	25	36
4	784	50	22.6	7	14

Isotope recovery in feces after feeding 2-methyl-[1-^{14}C]stearic acid to rats

The feces from the rats were collected daily during at least four days after the oral administration of the labelled acid. After homogenization they were hydrolyzed with 5 N alcoholic potassium hydroxide. The alcohol was evaporated and the acidified mixture was extracted three times with three volumes of peroxide-free ether. In the feces from twelve animals between 3 and 31 % of the fed activity was recovered (*cf.* Tables 2 and 4).

Table 4. Isotope recovery in the urine from rats fed 2-methyl[1-^{14}C]stearic acid.

Rat No.	Per cent of administered activity absorbed	Per cent of absorbed activity recovered in the urine		
		total	chromatographically identified as	
			2-methylsuccinic acid	2-methyladipic acid
5	89.5	1.9		
6	73.3	1.6	0.5	0.9
7	94.2	2.7	0.8	1.1
8	91.1	3.1	0.8	1.5
9	84.8	3.5	0.9	1.7
10	93.2	2.3	0.4	1.0
11	80.9	2.2	0.5	0.8
12	97.0	2.3	0.6	1.1

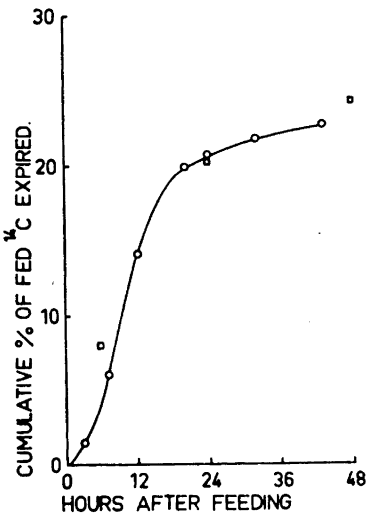

Fig. 2. Recovery of ^{14}C in expired carbon dioxide after feeding 2 methyl-[1-^{14}C]stearic acid (circles) and [1-^{14}C]stearic acid (squares) to rats.

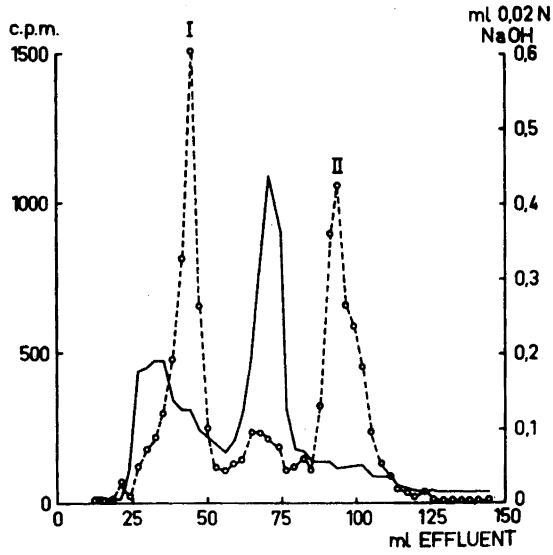

Fig. 3. Chromatography of part of an ether extract of urine from Rat No. 11. The titration peaks are caused by ordinary urine metabolites, as no carrier substances were added. Phase system B. Supporting medium: 9 g of hydrophobic kieselguhr; ——— titration curve, — — — c.p.m./fraction. Band I contains α-methylsuccinic acid and conjugated products.

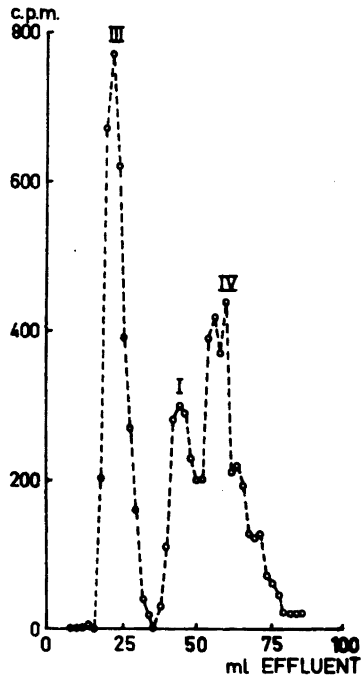

Fig. 4. Rechromatography of band I, Fig. 3. Phase system D. Supporting medium: 4.5 g of silica gel. Band I represents α-methylsuccinic acid. Band III and IV contain conjugated metabolites.

In one additional experiment the isotope contents of the feces were determined during 15 days after the administration of 1 ml of the olive oil solution (I) containing 3.6 % of 2-methyl[1-^{14}C]stearic acid. The feces from the first day after the feeding contained 8 % of the fed activity. During the second, third and fourth day 4.3, 3.4 and 1.3 % respectively appeared in the feces. In ten days the total isotope recovery was 21 %. In the next five days only 0.8 % of the fed activity was found in the feces.

The feces excreted by a rat during the first day after the administration of 2-methylstearic acid was saponified and extracted as described above. The ether extract contained 5.7 % of the fed activity. When half of this extract was chromatographed according to system A, 95 % of the activity was found unchanged in the band of 2-methylstearic acid, which appeared at 60 ml on a 4.5 g column. The other half of the ether extract was subjected to partition chromatography according to system C.

A small amount (less than 0.2 %) of the activity was found at the positions of 2-methylsuccinic and 2-methyladipic acid.

Isotope recovery in expired carbon dioxide after oral administration of carboxyl-labelled 2-methylstearic and stearic acids

A male rat weighing 250 g (Rat No. 5, Table 4) was given through a stomach tube 1 ml of the olive oil solution (I), corresponding to 0.3 ml per dm^2 of body surface (Lee [18]).

The isotope content of the expired carbon dioxide was determined with the technique described earlier [4]. The accumulation curve is shown in Fig. 2.

Another 250 g rat from the same litter was fed 1 ml of an olive oil solution of [1-^{14}C]-stearic acid with a specific acvitity of 130 000 cpm/mg *.

* Kindly placed at our disposal by Professor S. Bergström.

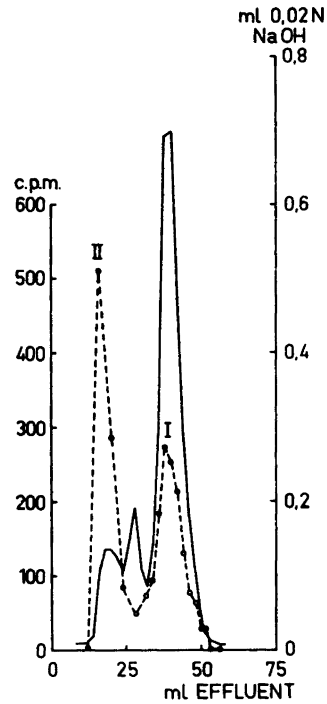

Fig. 5 *. Partition chromatography of metabolites in hydrolyzed urine together with unlabelled 2-methylsuccinic acid (5.4 mg). Phase system D. Supporting medium: 4.5 g of silica gel. ——— titration curve, — — — c.p.m./fraction.

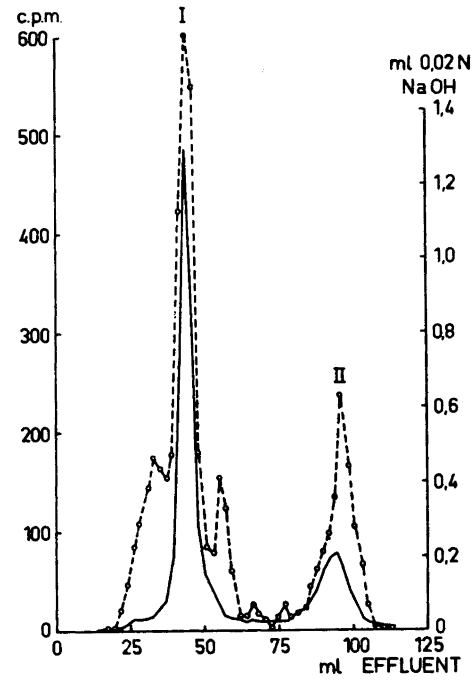

Fig. 6 *. Rechromatography of the material from the chromatogram shown in Fig. 5 and a parallel chromatogram together with synthetic 2-methyladipic acid (2.4 mg). Phase system C. Supporting medium: 9 g of hydrophobic kieselguhr; ——— titration curve, — — — c.p.m./fraction.

In four days 31.8 % of the fed activity was recovered in the feces. The CO_2 of the expired air was collected during six, twenty-four and forty-eight hours after the administration of the acid. From Fig. 2 it is seen that the $^{14}CO_2$-excretion in per cent of the absorbed activity was about the same for the two acids.

Isotope recovery in urine and identification of isotopic urinary compounds after the administration of 2-methyl[1-^{14}C]stearic acid

In order to obtain the urine completely free from fecal radioactive impurities a plastic funnel was sewn on to the cutis around the penis of the rat. The urine was collected into a flask with toluene. The activities recovered in the urine collected for 3 days after the administration of 2-methyl[1-^{14}C]stearic acid are given in Table 4. More than 75 % of the total urinary activity was excreted during the first day. The urine was acidified with hydrochloric acid and extracted three times with two volumes of peroxide-free ether. After that the urine was either extracted with butanol or continuously with ether for 24 h.

* See footnote p. 436.

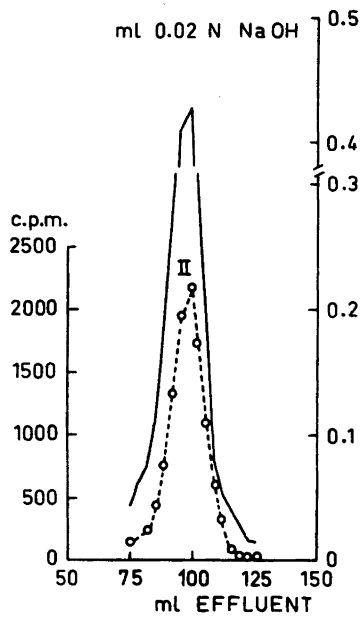

Fig. 7 *. Chromatography of an ether extract of hydrolyzed urine from Rat No. 10 together with unlabelled 2-methyladipic acid (4.0 mg). Phase system C. Supporting medium: 9 g of hydrophobic kieselguhr; ——— titration curve, — — — c.p.m./fraction.

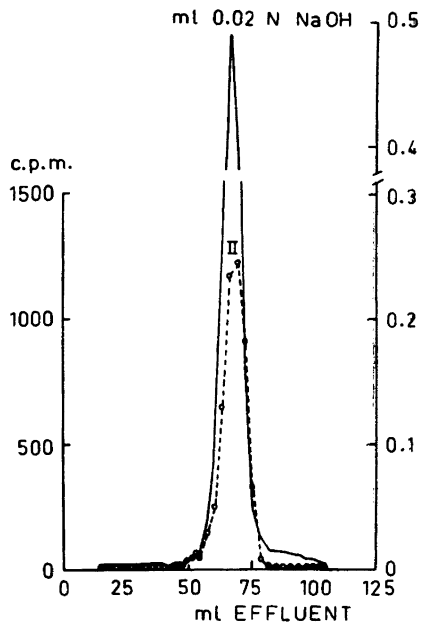

Fig. 8 *. Rechromatography of material from the active band II in a chromatogram with phase system C together with synthetic 2-methyladipic acid (2.9 mg). Phase system B. Supporting medium: 9 g of hydrophobic kieselguhr; ——— titration curve, — — — c.p.m./fraction.

The urine from Rat No. 11 was divided into two equal parts. One of these was extracted three times with two volumes of ether. The extract (17.6 mg) contained 0.8 % of the absorbed activity. Part of the ether extract was chromatographed according to system C as shown in Fig. 3. Two distinct active bands were found containing about the same amount of activity.

The other half of the urine was hydrolyzed with 2 N potassium hydroxide before acidification and analogous ether extraction.

The ether extract of the hydrolyzed urine contained 30 % more activity than the corresponding extract of unhydrolyzed urine. This finding indicates the existence of conjugated active products. The chromatogram showed two main active peaks as for the unhydrolyzed urine. However, the relation between the active bands Nos. I and II (Fig. 3) was changed. In the chromatogram of the hydrolyzed urine the second active

* The isotope and titration curves do not coincide exactly in the chromatograms of this investigation (see Figs. 5—8). The ^{14}C-labelled dicarboxylic acids seem to be somewhat less polar than the corresponding unlabelled compounds. Thus the ^{14}C-labelled acids are inclined to come out a little more slowly from the 9 g columns with the reversed phase systems B and C than does the unlabelled material (Figs. 6—8). In the ordinary partition chromatographic system (D) the 2-methyl[1-^{14}C]succinic acid tends to move more rapidly than the added unlabelled carrier (Fig. 5). These findings are in good agreement with the recent reports by Piez and Engle [19,20] on the ^{14}C-effect in amino acids, as demonstrated on the ion-exchange resin Dowex 50. An isotope effect has earlier been noticed for tritium-labelled organic acids with partition chromatography [21].

band contained 7 520 cpm (0.42 % of the absorbed amount) while 4 720 cpm (0.26 %) were found in the first band.

The first day urine from Rat No. 12 was extracted continuously with ether. The extract containing 51 000 cpm, *i. e.*, 1.9 % of the absorbed activity, was chromatographed on a 9 g column with phase system C. The two main peaks (23 000 cpm each) appeared as in Fig. 3, but in addition there was a front peak (4 000 cpm). This active material, which we have not yet identified, was found to be present also in hydrolyzed urine. After the continuous ether extraction of the first day urine, 5 600 cpm remained in the water phase. After alkaline hydrolysis, however, one half of this activity could be extracted with ether.

When the first band of the unhydrolyzed urine was rechromatographed according to system D, it was found to be heterogeneous, as it was split into three active peaks (Fig. 4). After hydrolysis, however, only two active bands remained (*cf.* Fig. 5). One of them (I) was found at the position of the titration peak of added, unlabelled 2-methylsuccinic acid (5.3 mg), the other one (II) was moving with the front.

When the material of this and a parallel chromatogram was rechromatographed with the reversed phase system C together with 2.4 mg of synthetic unlabelled 2-methyladipic acid, the titration peaks of 2-methylsuccinic acid (I) and 2-methyladipic acid (II) were found at the same positions as the two main active peaks (Fig. 6).

The ether extract of the hydrolyzed urine from Rat No. 10 was chromatographed on a 9 g column with phase system C together with 4 mg of unlabelled 2-methyladipic acid. The titration peak of this acid corresponded to the active peak II_1 (Fig. 7). Also in a chromatogram with phase system B the titration curve of synthetic 2-methyladipic acid (2.9 mg) was found at the same position as the active band II from the urine of Rat No. 7 (Fig. 8).

The ether extracts of the hydrolyzed urine from Rats No. 8 and 9 were chromatographed separately according to system B. The material from the second active bands (*cf.* Fig. 3) was rechromatographed together with 19.8 mg of inactive 2-methyladipic acid on a 9 g column of hydrophobic kieselguhr with phase system C. After addition of 132.7 mg of inactive synthetic 2-methyladipic acid, the material of the single active band was crystallized twice from water and twice from benzene-light petroleum alternately (Table 5). The specific activity was shown to remain constant. Consequently one of the metabolites of 2-methylstearic acid was 2-methyladipic acid.

Analogously the first active bands from two chromatograms with phase system C were rechromatographed according to system D before crystallization together with unlabelled 2-methylsuccinic acid (125.0 mg). The specific activity remained constant during four crystallizations from hydrochloric acid and from ether-benzene alternately

Table 5. Identification of 2-methyladipic acid in the urine of rats fed 2-methylstearic acid. Specific activity of material from the active band II of chromatogram of urinary extracts with phase system B, after rechromatography in system C recrystallized with inactive 2-methyladipic acid.

Recrystallization from	Crystal weight, mg	Counts/min/mg
water	101.2	390
benzene-light petroleum	76.0	375
water	50.3	355
benzene-light petroleum	35.4	361

Table 6. Identification of 2-methylsuccinic acid in the urine of rats fed 2-methylstearic acid. Specific activity of material from the active band I of chromatograms of urinary extracts with phase system C, after rechromatography in system D recrystallized with inactive 2-methylsuccinic acid.

Recrystallization from	Crystal weight, mg	Counts/min/mg
hydrochloric acid	98.4	154
ethyl ether-benzene	60.0	145
hydrochloric acid	41.0	150
ethyl ether-benzene	20.3	150

(Table 6). Thus 2-methylsuccinic acid was another urinary metabolite of 2-methylstearic acid. The amounts of activity which were extracted from the urine of the different rats and chromatographically identified as 2-methylsuccinic acid or 2-methyladipic acid are given in Table 4 in per cent of the absorbed activity.

We are indebted to Miss Kerstin Sjöström for valuable technical assistance. The financial support of *Statens naturvetenskapliga forskningsråd, Knut och Alice Wallenbergs Stiftelse* and the *Medical Faculty of the University of Lund* is gratefully acknowledged.

Insulin Crystals

V. The Nucleation and Growth of Insulin Crystals

JØRGEN SCHLICHTKRULL

Novo Terapeutisk Laboratorium, Copenhagen, Denmark

Beef-insulin is crystallized from a buffered solution of sodium chloride as geometrically similar rhombohedrons. During the process of crystallization running determinations of the concentration, c_s, of dissolved insulin are made. Simultaneously, samples are taken in which the crystallization is immediately arrested by diluting with a solution of zinc chloride. The concentrations of crystalline insulin, C, are determined by analyses of the stabilized samples. The total volumes and surfaces of the crystals, as well as the cumulative distributions of sizes are also determined in these samples by a special counting technique.

The total number (N), length (L), surface (S) and volume (V) of crystals are found to be mutually proportional during crystallization, except for the short initial stage.

The rate of linear crystal growth, $\dot{g}$, is found to be independent of crystal size and proportional to $(c_s-c)^2$, where c is the final concentration of dissolved insulin.

The rate of nucleation is found to be proportional to the product of g and N, L, S and V, respectively, except for the short initial stage of crystallization.

The experimental results are predicted from the simple concept that nuclei are mainly formed on the surface of the crystals. This self-reproduction of crystals was not observed when the insulin was crystallized in the twin-like distorted shape.

The outer surface of the system, exposed to glass and air, is of prime importance to the process of nucleation. Nucleation is diminished when the crystallization is carried out in a paraffin enclosure or when Tween 80 is added, and it is considerably enhanced by foam or other increase in surface.

The purpose of the present paper is to investigate the rate of nucleation and growth of insulin crystals as functions of the concentration of insulin in the crystallization mixture. In earlier papers [1,2] a crystallization method was described which yielded perfectly shaped rhombohedral zinc-insulin crystals irrespective of the species of insulin. This method is suitable for a study of the kinetics of insulin crystallization for several reasons:

1) During the process of crystallization, which is not too rapid for study, samples can be taken in which the process of crystallization can be immediately arrested with zinc ions [2].

2) The fraction of crystalline insulin in the stabilized samples can be determined accurately [2].

3) The dimensions of a crystal are completely defined by one parameter, *e. g.* the largest diagonal, l, in the crystal projection on a plane through the microscope stage [2].

4) The distributions of crystal sizes in the stabilized suspensions can be determined by a counting procedure [2].

SYMBOLS*

c_s = The concentration of dissolved insulin in per cent of the total insulin concentration which is 1.7 % or 2.42 mg/ml insulin nitrogen.

C = The concentration of crystalline insulin in per cent of the total insulin concentration.

t = The time in min from the moment buffer is added to the acid insulin solution.

t_n = A moment of nucleation.

t_* = The time when crystallization is finished.

l = The size of crystals, *i. e.* the largest diagonal in the crystal projection on a plane through one of the faces. As the crystals lie on their faces, the plane is parallel to the slide on the microscope stage. l is measured in μ.

$\mathfrak{P}(l,t)$ = The cumulative distribution of crystal sizes at the moment t, *i. e.* the number per ml of suspension of crystals which are greater than l at the moment t.

$\mathfrak{p}(l,t) = -\frac{\delta \mathfrak{P}(l,t)}{\delta l}$, *i. e.* the distribution of sizes at the moment t.

$\dot{g} = \frac{\delta l(\mathfrak{P},t)}{\delta t}$, *i. e.* the rate of linear crystal growth which is supposed to be independent of the crystal size.

$g = \int_0^t \dot{g}\,dt$ is called the growth function.

$l_{max}(t) = g(t)$ as it is supposed that nucleation occurs already at $t = 0$.

$\mathfrak{N} = N = \int_0^g \mathfrak{p}(l,t)dl$ is the number of crystals per ml of suspension.

$\mathfrak{L} = L = \int_0^g l \cdot \mathfrak{p}(l,t)dl$ is the total length of crystals per ml of suspension.

$\mathfrak{S} = S = \int_0^g l^2 \cdot \mathfrak{p}(l,t)\,dl$ is the total surface of crystals per ml of suspension, the unit of area being the area of a rhombohedron with size $l = 1\ \mu$.

* P, p, h, N, L, S and V are typed in gothics when the independent variable is t and in italics when it is g.

$\mathfrak{V} = V = \int_0^g l^3 \cdot \mathfrak{p}\,(l, t)\,\mathrm{d}l$ is the total volume of crystals per ml of suspension, the unit of volume being that of the rhombohedron with size $l = 1\ \mu$.

$\bar{l}$ = L/N, *i. e.* the average crystal size.

m_i = $l_{i+1} + l_i$, where l_i are class limits in the counting scheme.

d_i = $l_{i+1} - l_i$.

n_i' = The number of crystals in 1 small square in the counting chamber belonging to the size interval $l_i < l < l_{i+1}$.

c = The volume in ml of crystallization mixture corresponding to 1 small square in the chamber.

S_i = $f_{si} \cdot n_i'$ is the surface per ml of suspension of crystals belonging to the size range $l_i < l < l_{i+1}$, the unit of area being the area of a rhombohedron with size $l = 1\ \mu$.

$\mathfrak{h}$ = $\frac{\mathrm{d}\mathfrak{N}}{\mathrm{d}t}$ is the rate of nucleation, as it is assumed that nuclei are immediately transformed into crystals.

h_s = $\mathfrak{h}/\dot{g}$ is called the specific rate of nucleation.

r and u are positive constants in the eqn (40), $S = rV^u$.

m is the concentration of a crystallizing substance present as monomer dissolved particles.

p and q are positive powers.

a, a_1, a_2, a_3, a_4 = constants.

b_1, b_2, b_3, b_4 = constants.

c_1, c_2, c_3, c_4, c_5, c_6, c_7 = constants.

α = const. $\times\ g$.

$\beta = \frac{\sqrt{3}}{2} \cdot \alpha$.

METHODS

1. *Crystallization.* The method of crystallization has been described recently [1,2]. The volume of crystallization mixture used was 4 litres, and the concentration of insulin was 1.7 %, *i. e.* 2.42 mg insulin-nitrogen per ml. Any foam that formed was removed.

2. *Determination of the insulin in solution,* c_s. 80—90 ml of the crystallizing suspension are filtered through filter paper covered with kieselguhr. Pressure is applied in order to keep down the filtration time to within 1 min. The filtrate is acidified with 1 N HCl in order to avoid crystallization on the walls of the flask. The concentration of insulin in solution, c_s, is determined by the semi-micro Kjeldahl analysis and expressed in per cent of the total concentration of insulin in the suspensions.

3. *Determination of the crystalline fraction, C.* A 10 ml sample is stabilized with zinc, the amorphous precipitate is dissolved, and the amount of crystalline insulin determined by semi-micro Kjeldahl analysis. The procedure has been described earlier [2]. The concentration of insulin in the crystalline state, C, is expressed in per cent of the total concentration of insulin in the suspension.

4. *Determination of the total volume ($\mathfrak{V}$) and surface ($\mathfrak{S}$) of crystals, and the cumulative distribution of crystal sizes ($\mathfrak{P}$).**

The cumulative distributions of crystal sizes are $\mathfrak{P}(l, t)$. At the time t, $\mathfrak{P}$ crystals per ml are bigger than l. Hence, the distribution of crystal sizes is

$$\mathfrak{p}(l,t) = -\frac{\delta \mathfrak{P}(l,t)}{\delta l} \tag{1}$$

The total number, length, surface and volume of crystals per ml of suspension are defined by

$$\mathfrak{N}(t) = \int_0^{l_{max}} \mathfrak{p}\ (l,t)\ \mathrm{d}l \tag{2}$$

$$\mathfrak{L}(t) = \int_0^{l_{max}} l\ \mathfrak{p}\ (l,t)\ \mathrm{d}l \tag{3}$$

$$\mathfrak{S}(t) = \int_0^{l_{max}} l^2\ \mathfrak{p}\ (l,t)\ \mathrm{d}l \tag{4}$$

$$\mathfrak{V}(t) = \int_0^{l_{max}} l^3\ \mathfrak{p}\ (l,t)\ \mathrm{d}l \tag{5}$$

Thus, an insulin rhombohedron with size $l = 1\ \mu$ has unit size, unit surface and unit volume.

The $\mathfrak{N}(t)$ values are not estimated directly from countings, as it is difficult to count very small crystals. The surface areas and the volumes are calculated from the $\mathfrak{P}(l, t)$ estimates obtained by the counting technique described earlier [2]. In analogy with the previous [2] formula for V_i

$$S_i = f_{si} \cdot n_i' \tag{6}$$

where

$$f_{si} = \frac{3m_i^2 + d_i^2}{12\ c} \tag{7}$$

THEORY

1. The growth of crystals.

The time, t, is counted in min from the moment buffer is added to the insulin solution. It is assumed that crystals are formed so early that

$$\dot{\mathfrak{N}}\ (0) > 0 \tag{8}$$

where the dot symbolizes differentiation with respect to time. The number of crystals per ml of suspension increases with time as shown by the fictitious curve in Fig. 1.

* These symbols are typed in gothics when the independent variable is t and in italics when it is g.

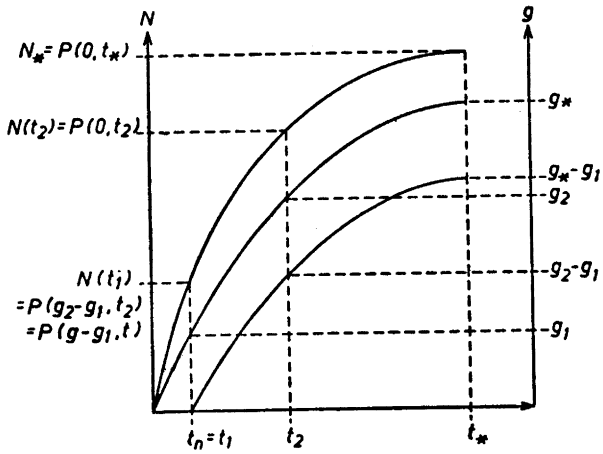

Fig. 1.

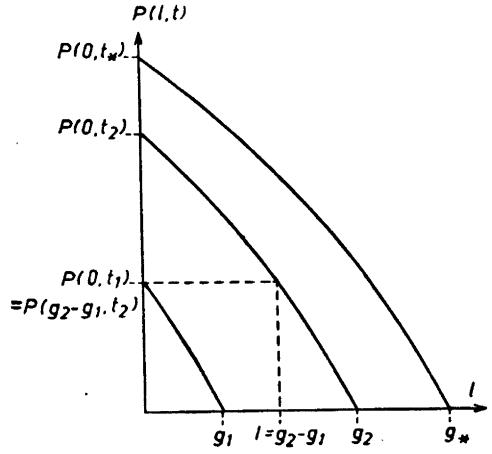

Fig. 2.

The crystallization is finished at the time t_* defined by

$$\dot{C}(t_*) = 0 \tag{9}$$

At that time the crystals are not further increasing in number, *i. e.*

$$\dot{\mathfrak{N}}(t_*) = 0 \tag{10}$$

Strictly speaking $t_* = \infty$, but in an actual experiment any t value above a certain limit may be symbolized through t_*.

The growth of a crystal proceeds as insulin is deposited on the faces which thereby move outwards in directions perpendicular to the faces. The rhombohedral shape is maintained, and the three faces meeting in an obtuse vertex move with identical rates. It is of course possible that the three opposite faces move at another rate, or even not at all. It is now assumed that the rate of movement of a face does not at any time vary between crystals having the same or different sizes. As the dimensions of a crystal are completely defined by the size, l, it follows from this assumption that at the time t all crystals grow with the same linear rate of growth, $\dot{l}(t)$. In order to distinguish between size and growth, $\dot{l}$ is denoted by the symbol $\dot{g}$. It is seen that $\dot{g}$ is a function of one parameter only, *e. g.* the time.

The maximum crystal size

$$l_{\max}\ (t) = \int_0^t \dot{g}(t)\mathrm{d}t = g(t) \tag{11}$$

is shown by the middle fictitious curve in Fig. 1. While this $g(t)$ curve indicates the size of crystals formed at $t = 0$, the curve below indicates the size of crystals formed at the arbitrary moment $t = t_n$. The moment t_n is called the moment of nucleation of these crystals. As all crystals grow with identical rates of linear growth, it follows that the size of these crystals is always $g(t)$—$g(t_n)$.

The cumulative distributions, $\mathfrak{P}(l,\ t)$, can be expressed in terms of $\mathfrak{N}(t)$ and $g(t)$. The $\mathfrak{P}$ function is considered at the arbitrary moment $t = t_2$ (Fig. 2). The total number of crystals is

$$\mathfrak{P}(0,\ t_2) = \mathfrak{N}(t_2) \tag{12}$$

At the moment t_2 no crystals are bigger than the maximum size, $g_2 = g(t_2)$, and consequently

$$\mathfrak{P}(g_2,\ t_2) = 0 \tag{13}$$

The crystals of the size l were formed at the moment t when the biggest crystals had the size g_2—l. At that moment $\mathfrak{N}(t)$ crystals were present. These are consequently the crystals which at the time t_2 are bigger than l. Hence,

$$\mathfrak{P}(l,\ t_2) = \mathfrak{N}(t) \tag{14}$$

where t is derived from

$$g(t) = g_2 - l \tag{15}$$

Inversely,

$$\mathfrak{N}(t) = \mathfrak{P}(g_2—g(t),\ t_2) \tag{16}$$

or with g as sole parameter,

$$N(g) = P(g_2—g,\ g_2) = P(g_3—g,\ g_3),\ \textit{etc.} \tag{17}$$

Thus, the number of crystals can be calculated from determinations of P and g.

As shown graphically in Fig. 2, eqn. (17) reveals the relationship between the P-functions at different g (or t) values. The horizontal distance between two $P(l)$ curves is constant, since it follows from eqn. (17) that

$$P(l,\ g_1) = P(l+g_2—g_1,\ g_2) \tag{18}$$

The same horizontal displacement of the distributions, eqn. (1), is observed by differentiation of eqn. (18) which thereby becomes

$$p(l,\ g_1) = p(l+g_2—g_1,\ g_2) \tag{19}$$

2. The nucleation

It is assumed that nuclei are immediately transformed into crystals. Hence, the rate of nucleation is

$$\mathfrak{h}(t) = \dot{\mathfrak{N}}(t) \tag{20}$$

It follows from this definition and eqn. (16) that

$$\mathfrak{h}(t) = p(g_2—g(t),\ g_2) \cdot \dot{g}(t) \tag{21}$$

Thus, the rate of nucleation at the moment t is the product of a value in the distributions of crystal sizes and the growth rate. The physical meaning of this equation can be made clear from Fig. 2 by moving one of the curves the distance $\mathrm{d}g$ to the right in the time $\mathrm{d}t$. The point of interception between curve and P-axis thereby moves $\mathrm{d}N$ upwards.

The derivative of N with respect to g

$$h_s(g) = p(g_2—g(t),\ g_2) \tag{22}$$

is obtained from eqn. (21). It is called the specific rate of nucleation and is simply a value in the distributions of crystal sizes. When the function $h_s(g)$ is known, it follows from eqn. (22) that the crystals are completely defined for every value (g_2) of the growth function. Hence, not only the size distributions but also the total volume, V, surface, S, and length, L, are defined by $h_s(g)$ and the g-value. Inversely, as will be demonstrated, inferences about $h_s(g)$ can be drawn from $V(g)$, $S(g)$ and $L(g)$.

The volume is given by eqn. (5). According to eqn. (22)

$$p(l,\ g) = h_s(x) \tag{23}$$

where

$$l = g — x \tag{24}$$

from which

$$V(g) = \int_0^g (g—x)^3 h_s(x)\mathrm{d}x \tag{25}$$

or

$$V(g) = g^3N(g) — 3g^2\int_0^g x h_s(x)\mathrm{d}x + 3g\int_0^g x^2 h_s(x)\mathrm{d}x — \int_0^g x^3 h_s(x)\mathrm{d}x \tag{26}$$

The surface, S, and the length, L, may be written in a quite analogous way, *viz.*

$$S(g) = g^2N(g) — 2g\int_0^g x h_s(x)\mathrm{d}x + \int_0^g x^2 h_s(x)\mathrm{d}x \tag{27}$$

and

$$L(g) = gN(g) - \int_0^g x h_s(x)\mathrm{d}x \tag{28}$$

By differentiation of the eqns. (26), (27) and (28) with respect to g the following is found:

$$\begin{array}{llllll} V' = 3S & S' = 2L & L' = N & N' = h_s(g) \\ V'' = 6L & S'' = 2N & L'' = N' & \\ V''' = 6N & S''' = 2N' & & \\ V'''' = 6N' & & & \end{array} \tag{29}$$

from which can be read that

$$h_s(g) = N'(g) = L''(g) = \frac{1}{2}S'''(g) = \frac{1}{6}V''''(g) \tag{30}$$

3. Volume and surface relations

From determinations of S and V in the course of crystallization, inferences can be drawn about the rates of growth and nucleation. The surface

$$S = f(V) \text{ or } \mathcal{S} = f(\mathcal{V}) \tag{31}$$

is expressed as a function of the volume. As according to eqn. (29)

$$\dot{\mathcal{V}} = 3\mathcal{S}\dot{g} \tag{32}$$

it follows that

$$\dot{g} = \dot{\mathcal{V}}/3f(\mathcal{V}) \tag{33}$$

The specific rate of nucleation is obtained from eqn. (30). The eqn. (31) is differentiated

$$S' = f'(V) \cdot V' \tag{34}$$

with respect to g. As according to eqn. (29)

$$V' = 3S \tag{35}$$

it follows that

$$S' = 3f'(V) \cdot S \tag{36}$$

and by inserting eqn. (31)

$$S' = 3f' \cdot f \tag{37}$$

When differentiation is repeated twice more, it is found that

$$h_s(g) = \frac{27}{2}\,(f^3\, f''' + 4f^2 f' f'' + f(f')^3) \tag{38}$$

and when eqn. (33) is inserted

$$h(t) = \frac{27}{6}\,\dot{\mathcal{V}}(f^2 f''' + 4ff' f'' + (f')^3) \tag{39}$$

As an example, let it be possible to express S by

$$S = r \cdot V^u \qquad g(t_1) < g < (t_2) \tag{40}$$

where r and u are positive constants. The eqn. (38) then becomes

$$h_s(g) = 81r^4u\left(u-\frac{1}{2}\right)\left(u-\frac{2}{3}\right)V^{4u-3} \qquad g(t_1) < g < g(t_2) \tag{41}$$

A few special cases of eqn. (40) will now be considered.

Case 1, $u = 2/3$. From eqn. (41) it is seen that

$$h_s(g) = 0 \qquad g(t_1) < g < g(t_2) \tag{42}$$

which means that crystallization proceeds without nucleation. The inverse inference — that equation (40) is valid with $u = 2/3$ when $h_s = 0$ — is generally false as can be understood from the eqns. (26) and (27). It is, however, true when the crystal suspension is known to be monodisperse at $t = t_1$ as may happen, *e. g.*, from a previous seeding.

Case 2, $u = 3/4$. This case is compatible with the observations made during the initial stage of the insulin crystallization. The specific rate of nucleation is calculated from eqn. (41) to be

$$h_s(g) = \frac{3^4}{2^6}\,\mathrm{r}^4 \qquad g(t_1) < g < g(t_2) \tag{43}$$

Thus, the rate of nucleation is proportional to the rate of linear growth. As the distributions of crystal sizes are identical with $h_s(g)$, all sizes of crystals formed in the time interval occur with equal frequency, *i. e.*

$$\mathrm{p}(l,\ t) = \frac{3^4}{2^6}\,\mathrm{r}^4 \qquad (t_1 < t < t_2) \tag{44}$$

when

$$l < g(t) - g(t_1)$$

Case 3, $u = 1$. This is the case actually observed except for the initial period of crystallization. The eqn. (41) shows that

$$h_s(g) = \frac{27}{2}\,r^4V \qquad g(t_1) < g < g(t_2) \tag{45}$$

which by means of eqn. (40) is changed into

$$h_s(g) = \frac{27}{2}\,r^3S \qquad g(t_1) < g < g(t_2) \tag{46}$$

From the eqns. (29) and (40) it follows further that

$$h_s(g) = 9r^2L \qquad g(t_1) < g < g(t_2) \tag{47}$$

and

$$h_s(g) = 3rN \qquad g(t_1) < g < g(t_2) \tag{48}$$

Thus, in the time interval, $t_1 < t < t_2$, the specific rate of nucleation is proportional to the number of crystals present, their total length, surface or volume. The constant mutual ratios are

$$N = 3rL = \frac{9}{2} r^2 S = \frac{9}{2} r^3 V \qquad g(t_1) < g < g(t_2) \tag{49}$$

This equation shows further that the average crystal size, L/N, is constantly

$$\bar{l} = 1/3r \qquad (t_1 < t < t_2) \tag{50}$$

The distribution of crystal sizes is obtained from eqns. (16), (22) and (48) which give

$$\mathfrak{p}(l,\ t) = 3r\mathfrak{P}(l,\ t) \qquad (t_1 < t < t_2) \tag{51}$$

when

$$l < g(t) - g(t_1)$$

From eqns. (1) and (51) it follows that

$$\mathfrak{p}(l,\ t) = f(t)\ \mathrm{e}^{-3rl} \qquad (t_1 < t < t_2 \text{ and } l < g(t)—g(t_1)) \tag{52}$$

where $f(t)$ is a function of time only.

The cumulative distribution of crystal sizes is obtained by means of eqn. (51) from which

$$\mathrm{d}\ln\mathfrak{P}(l,\ t) = —3r\mathrm{d}l \tag{53}$$

and

$$\ln\mathfrak{P}(l,\ t) = —3rl + \ln\mathfrak{N}(t) \tag{54}$$

in which

$$t_1 < t < t_2 \qquad \text{and} \qquad l < g(t) - g(t_1) \tag{55}$$

Thus in the interval (55) the logarithms of the cumulative distributions are graphically represented by the straight lines, eqn. (54). As the slopes of these lines are identical, the lines may be moved in a graph to cover each other. At $t = t_2$, eqn. (54) gives

$$\ln\mathfrak{P}(g(t_2) - g(t),\ t_2) = — 3r(g(t_2) — g(t)) + \ln\mathfrak{N}(t_2) \tag{56}$$

Using eqn. (16), the addition of the eqns. (54) and (56) shows that

$$\ln\mathfrak{P}(l,\ t) = — 3rx + \ln\mathfrak{N}(t_2) \tag{57}$$

where

$$x = l + g(t_2) — g(t) \tag{58}$$

Thus, all $\mathfrak{P}$-values observed in the time interval $t_1 < t < t_2$ will lie on the straight line, eqn. (57), provided the l-values are smaller than $g(t)—g(t_1)$.

4. The origin of nuclei

A fundamental theory of nucleation and crystal growth has been developed by Christiansen [3]. According to this theory

$$\dot{\mathfrak{N}} = \text{const. } m^p \tag{59}$$

where m is the concentration of substance present as monomer dissolved particles and p is a positive integer. This relation was demonstrated by the same author to be valid for the precipitation of barium sulphate ($p = 8$). The rate of linear growth of barium sulphate was found to be

$$\dot{g} = \text{const. } m^q \tag{60}$$

where q is positive ($q = 4$). The power q was also explained by the theory.

When the eqns. (59) and (60) are applied to the present case of insulin crystallization, the specific rate of nucleation is found to be

$$h_s(g) = \text{const. } \dot{g}^{(\frac{p}{q}-1)} \tag{61}$$

This equation is compatible with the observations in the initial stage of insulin crystallization, although as already mentioned,

$$h_s(g) = \text{const. } (V,\ S,\ L \text{ or } N) \tag{62}$$

in the main part of crystallization. Hence, the hypothesis is set up that the insulin nuclei have different origins. It is assumed that some of the insulin nuclei are formed spontaneously according to eqn. (61), and further that other insulin nuclei are formed by interaction of the solution with the faces, edges or vertices of the crystals. Thus, in the initial stage of crystallization, where crystals are few and interaction therefore insignificant, nucleation may proceed according to eqn. (61). Later the interaction becomes of overwhelming significance and thereby masks the process, eqn. (61), so much that the specific rate of nucleation follows eqn. (62).

ANALYSIS OF DATA FROM THE CRYSTALLIZATION EXPERIMENT

1. Changes with time in the concentrations of dissolved and crystalline insulin

At $t = 0$ the insulin is almost altogether (94 %) precipitated as amorphous particles. In the course of the following 50 min, 26 % of the insulin is gradually dissolved. At $t = 50$, the crystalline fraction appears in chemically measurable quantities. It increases first rapidly and later more slowly as seen in Fig. 3 and Table 1. At the same time the concentration of dissolved insulin decreases. The drop in c_s indicates that crystals grow from dissolved insulin.

2. The linear growth rate

As the crystals apparently grow from dissolved insulin being deposited on the faces, it is of prime interest to determine the functional relationship between the linear growth rate and the concentration of dissolved insulin. The $C(t)$ and $c_s(t)$ data will be used first in connection with eqn. (33). In the next paragraph it will be demonstrated that

$$G = rv \qquad (t > 60) \tag{63}$$

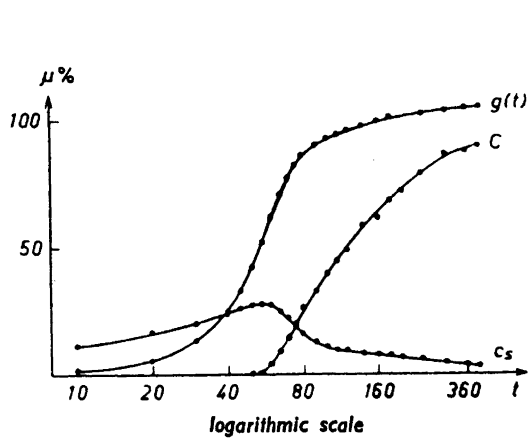

Fig. 3.

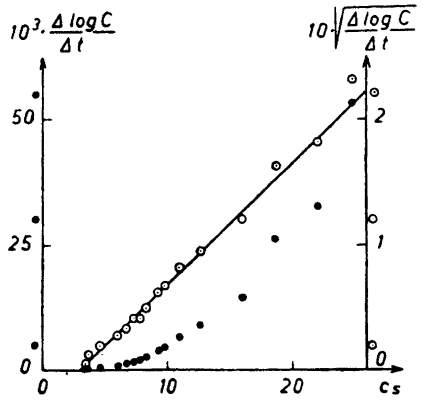

Fig. 4.

where r is a constant. Hence,

$$\dot{g} = \frac{(\dot{\ln v})}{3r} \qquad (t > 60) \tag{64}$$

and

$$\dot{g} = \frac{(\dot{\log C})}{3rM} \qquad (t > 60),\ (M = 0.4343) \tag{65}$$

Estimates of the growth rate can be obtained from

$$\dot{g}_i \approx \frac{1}{3rM} \cdot \frac{\log C_{i+1} - \log C_{i-1}}{t_{i+1} - t_{i-1}} \qquad (t > 60) \tag{66}$$

in which i is the sample number. The fractions on the right side of the equation are calculated and plotted against c_s in Fig. 4.

The configuration of the points in the graph suggests a power relation, and when the square roots of the fractions are tentatively plotted against c_s, it appears that

$$\dot{g}(t) = c_7(c_s(t) - 3)^2 \qquad (t > 60) \tag{67}$$

where c_7 is a constant. Assuming this equation to be valid for $t < 60$ also, it follows that

$$g(t) = c_7 \cdot \int_0^t (c_s - 3)^2 \, dt \tag{68}$$

The value of the integral corresponding to each sample is calculated by the approximative formula

$$\int_0^{t_x} (c_s - 3)^2 \, dt \approx \frac{1}{2} \sum_{i=1}^{i=x} (t_i - t_{i-1}) \left[(c_{s_i} - 3)^2 + (c_{s_{i-1}} - 3)^2\right] \tag{69}$$

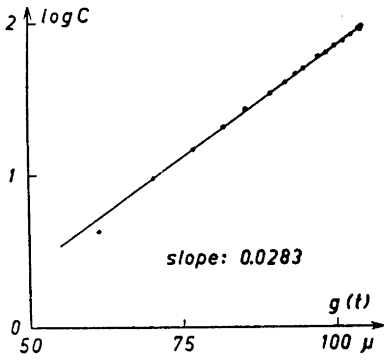

Fig. 5.

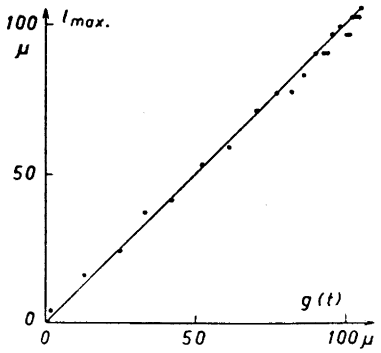

Fig. 6.

where i = 1 when $t = 0$. When crystallization was finished, the biggest crystals found were $g_* = 105\ \mu$. The value of the integral at the same time, t_*, is calculated as 3.20×10^4. Hence,

$$c_7 = \frac{105}{3.20} \times 10^{-4} = 3.28 \times 10^{-3} \tag{70}$$

which is used in eqn. (68) to calculate a $g(t)$ estimate for each sample. These estimates are now plotted against $\log C$ in Fig. 5.

The slope of the straight line is 0.0283. As from eqn. (65)

$$g(t) = \frac{\log C(t)}{3rM} + \text{const.} \quad (t > 60) \tag{71}$$

it follows that

$$r = \frac{0.0283}{3M} = 0.022 \tag{72}$$

In order to compare the $g(t)$ estimates with the size of crystals actually found, $g(t)$ is plotted (Fig. 6) against the maximum size, l_{max}, of crystals observed in all samples including those from $t < 60$. The calculated and observed maximum sizes are in agreement, also for $t < 60$.

Finally the $g(t)$ values are plotted against different quantiles in the cumulative distributions of crystal sizes (Fig. 7). The quantiles are derived from the countings by picking out of the counting tables the crystal sizes corresponding to the ϱ-value in question. The theoretical lines inserted in the figure were calculated from eqns. (68) and (88). It appears from Fig. 7 that crystals of different sizes grow with identical rates of growth and further that this rate of growth is $\dot{g}$ as calculated by means of eqn. (67). Thus, the linear growth rate is proportional to the square of $(c_s - 3)$, which may be the supersaturation but presumably is not. When the crystal suspension is left for several days, the c_s value drops below 2 %. Further, when the crystals are filtered off and resuspended in a fresh insulin-free medium of the same small molecular

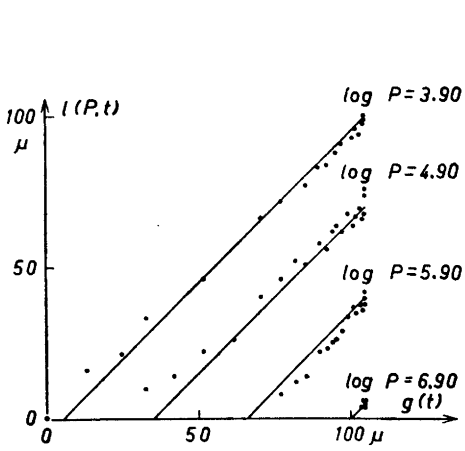

Fig. 7.

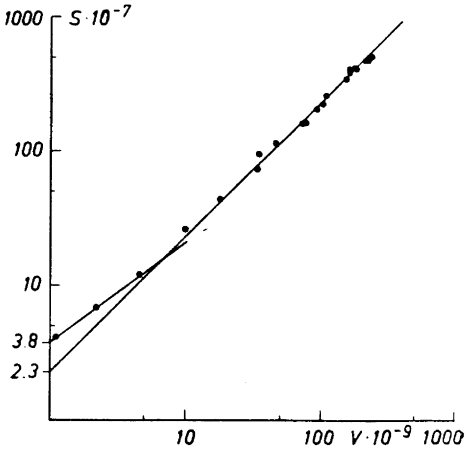

Fig. 8.

composition, c_s is found to be only 0.5 % after equilibration for two days. These supplementary findings must be considered in the chemical interpretation of eqn. (67).

3. The rate of nucleation

In the present case of crystallization the functional relationship between the total volume and surface of crystals is so simple that inferences can be drawn about the specific rate of nucleation. The V and S means from two, and sometimes more countings are plotted against each other on double logarithmic paper in Fig. 8.

The crystallization is divided into two periods, A and B, by the two straight lines with slopes 3/4 and 1. In the first initial stage

$$\text{(A)} \qquad S \approx 3.8 \times 10^{\frac{1}{4}} \times V^{\frac{3}{4}} \qquad (10^9 < V < 10^{10}) \tag{73}$$

and in the second main part of the crystallization

$$\text{(B)} \qquad S \approx 0.023 \times V^1 \qquad (10^{10} < V < V_*) \tag{74}$$

The value (0.023) of the constant in the last equation is in agreement with the former value (0.022) from the preceding paragraph.

From eqns. (73) and (43) it is calculated that

$$\text{(A)} \qquad h_s \approx \frac{3^4}{2^6} \times 3.8^4 \times 10^1 = 2 \times 10^3 \tag{75}$$

and from eqns. (74) and (48) it follows that

$$\text{(B)} \qquad h_s \approx 0.07 \times N \tag{76}$$

The eqn. (75) is a special case of eqn. (61), *viz.* the case where $p = q$. The assumption is now made, that during the whole period of crystallization nucleation proceeds according to eqn. (61) in which $p = q$. There is no incompatibility between this assumption and the eqn. (76) when it is further assumed that a second nucleation process takes place on the crystals. When N exceeds 10^5 this second process becomes dominating and especially as N increases to 10^7, the final value.

It follows from these assumptions that

$$h_s = a + b_1N + b_2L + b_3S \tag{77}$$

in which a is the constant specific rate of spontaneous nucleation, b_1N is the specific rate of nucleation from the vertices, b_2L at the edges and b_3S on the faces. As N, L, S and V become mutually proportional when about 1 % of the final crystals are formed, it is not possible to infer from the data whether or not the surface nucleation occurs on the faces or rather at the edges or vertices. However, the agreement of the data with

$$h_s = a_1 + b_1N \quad \text{(vertices)} \tag{78}$$
$$h_s = a_2 + b_2L \quad \text{(edges)} \tag{79}$$
$$h_s = a_3 + b_3S \quad \text{(faces)} \tag{80}$$
$$h_s = a_4 + b_4V \quad \text{(eqn. 45)} \tag{81}$$

will be investigated. When these four equations are differentiated by means of eqn. (29) they become ordinary differential equations

$$N'(g) = a_1 + b_1N(g) \tag{82}$$
$$N''(g) = b_2N(g) \tag{83}$$
$$N'''(g) = 2b_3N(g) \tag{84}$$
$$N''''(g) = 6b_4N(g) \tag{85}$$

having the solutions

$$N(g) = c_1\ e^{\alpha}\ (1—e^{-\alpha});\ c_1 = \frac{a_1}{b_1}\ ;\ \alpha = b_1g \tag{86}$$

$$N(g) = c_2\ \sinh\alpha;\ c_2 = \frac{a_2}{\sqrt{b_2}}\ ;\ \alpha = \sqrt{b_2}\cdot g \tag{87}$$

$$N(g) = c_3\ e^{\alpha}[1 + e^{-\frac{3}{2}\alpha}\ (\sqrt{3}\cdot\sin\beta - \cos\beta)];\ c_3 = \frac{a_3}{3c_4}\ ;\ c_4 = \sqrt[3]{2b_3}\ ; \tag{88}$$

$$\alpha = c_4g;\ \beta = \frac{\sqrt{3}}{2}\ \alpha$$

$$N(g) = c_5\ (\sinh\alpha + \sin\alpha);\ c_5 = \frac{a_4}{2c_6}\ ;\ c_6 = \sqrt[4]{6b_4}\ ;\ \alpha = c_6\ g \tag{89}$$

It follows from eqn. (48) that

$$\frac{d\ln N}{dg} = 3r \tag{90}$$

in the second period of crystallization. Hence,

$$a = 3rg = \frac{0.0283}{0.4343}\, g = 0.0652\, g \tag{91}$$

or

$$b_1 = \sqrt{b_2} = \sqrt[3]{2b_3} = \sqrt[4]{6b_4} = 0.0652 \tag{92}$$

When crystallization is finished the growth function has reached the value $g_* = 105\ \mu$ and, as will be explained later, the number of crystals is 1.02×10^7 per ml. Hence,

$$c_1 = \frac{1}{2}\, c_2 = c_3 = \frac{1}{2}\, c_5 = 1.02 \times 10^7/\text{exp.}\ (0.0652 \times 105) = 1.1 \times 10^4 \tag{93}$$

The numerical values of the constants, eqns. (92) and (93), are introduced into the eqns. (86)—(89), which are then used to calculate sets of $N(g)$ values to be compared with P-values from the observed cumulative distributions of crystal sizes.

The cumulative distribution of sizes when crystallization is finished (asterisk) can be expressed by these equations, as from eqns. (14) and (15)

$$\mathrm{P}_*(l) = N(g) \tag{94}$$

where

$$g = g_* - l \tag{95}$$

The curves in Fig. 9 represent the logarithms of $N(g)$ from eqns. (86), (87), (88), (89), (92) and (93) against l, where l is connected to g by eqn. (95). The dots represent the almost coinciding observation data gained from the three last samples. The data fit best to the curves calculated according to eqns. (87) and (88) corresponding to nucleation at edges and faces, respectively.

In order to utilize the information gathered from all the countings, their data are compiled in one graph (Fig. 10). Let the crystal sizes at $t = t_*$ be denoted by x, then it follows from eqn. (18) that

$$\mathrm{P}_*(x) = \mathrm{P}(l,\ t) \tag{96}$$

where

$$x = l + g_* - g(t) \tag{97}$$

The substitution, eqn. (97), is used in the presentation of all the $\mathrm{P}(l, t)$ values observed (Fig. 10). The scattering of the dots increases towards the lower region of the graph where the P-values are based upon counts of a few crystals only. The trend of the dots is in agreement with Fig. 9 and with the theoretical curves although too many points are below the curve in the interval $20 < x < 40$. The eqns. (87) and (88) fit best to the observations depicted in this figure also.

When the method of least squares is used (Fig. 10) on $\log \mathrm{P}_*(x)$ where $\log \mathrm{P}_*(x) > 4.4$, the slope is found to be —0.0283. A straight line with this slope was already expected in accordance with eqn. (57) and Fig. 5. The line intercepts the $\log \mathrm{P}_*(x)$ axis at 7.01. Hence, the final number of crystals is estimated as 1.02×10^7 per ml.

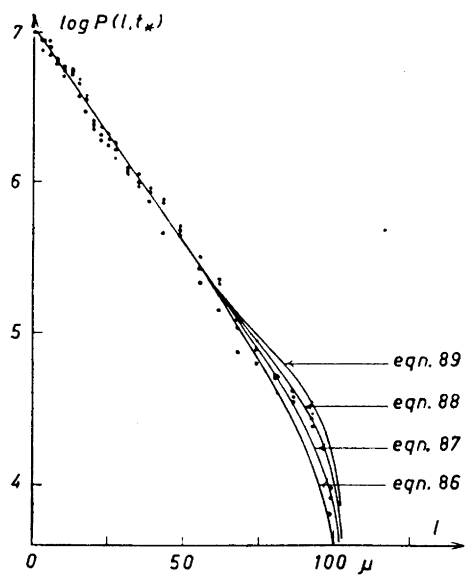

Fig. 9.

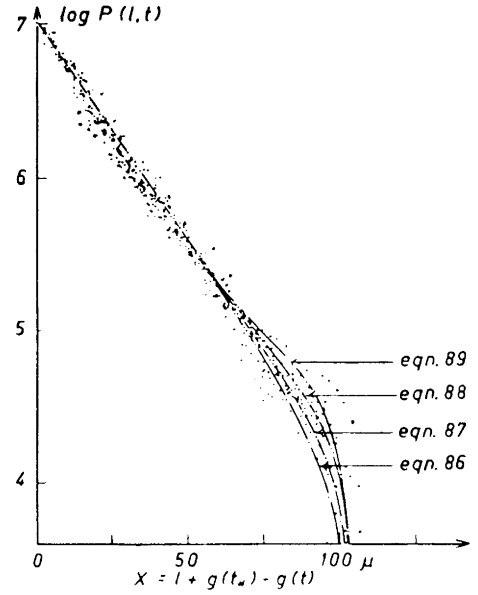

Fig. 10.

The total volumes and surfaces expected in accordance with eqns. (68), (88), (92) and (93) have been calculated and presented in Table 1 and as a curve in Fig. 11 in comparison with the observed values. The eqn. (80) is written

$$h_s = a_3 + \frac{b_3}{3} \cdot V' \tag{98}$$

which by integration becomes

$$V(g) = \frac{3}{b_3} [N(g) - a_3 g] \tag{99}$$

from which $V(g)$ can be calculated by inserting g from eqn. (68) and $N(g)$ from eqn. (88). It follows from eqn. (99) that the number of insulin crystals is proportional to the weight or volume of crystallized insulin, provided a_3 is relatively small. The surface was calculated from eqn. (80)

$$S = \frac{1}{b_3} [N'(g) - a_3] \tag{100}$$

in which

$$N'(g) = \frac{1}{3} a_3 \, (e^{a} + 2e^{-\frac{1}{2}a} \cos\beta) \tag{101}$$

is obtained by differentiating eqn. (88). There is a reasonable agreement between the calculated and observed values.

Table 1. Data relating to the crystallization experiment.

Legend to table:
(1) i, sample number.
(2) t, time in minutes from the moment of mixing.
(3) c_S, the percentage of insulin in solution.
(4) C, the percentage of insulin in the crystalline state.
(5) $g(t) = 3.28 \times 10^{-3} \int_0^t (c_S - 3.0)^2 \, dt$.
(6) $V \times 10^{-9}$, calculated from the distributions of crystal sizes observed. See eqns. (1) and (5).
(7) $V \times 10^{-9}$, predicted values from eqn. (99) in which $a_3 = 2\,094$, $b_3 = 1.385 \times 10^{-4}$ and $N(g)$ is calculated from eqn. (88) where $g = g(t)$ from column (5).
(8) $S \times 10^{-7}$, calculated from the distributions of crystal sizes observed. See eqns. (1), (4), (6) and (7).
(9) $S \times 10^{-7}$, predicted values from eqns. (100) and (101) in which $a_3 = 2\,094$, $b_3 = 1.385 \times 10^{-4}$ and $g = g(t)$ from column (5).
(10) $\dot{g} \times 10^2 = 0.328 \, (c_S - 3.0)^2$
(11) $h_S \times 10^{-3} = 10^{-3} \, N'(g)$. $N'(g)$ is calculated from eqn. (101), $g = g(t)$ from column (5).
(12) $\dot{h} \times 10^{-3} = 10^{-3} \times \dot{g} \times h_S$.

4. The microscopic appearance

The photomicrograph (Fig. 12) shows the appearance of the crystals upon completion of crystallization. The crystals are apparently not distributed in space at random. The number of crystals smaller than 4 μ (175 × magnified) was counted in the photomicrograph and estimated as 41. Out of these, 15 were free, 10 occurred in pairs, 14 were found at the edges or vertices of

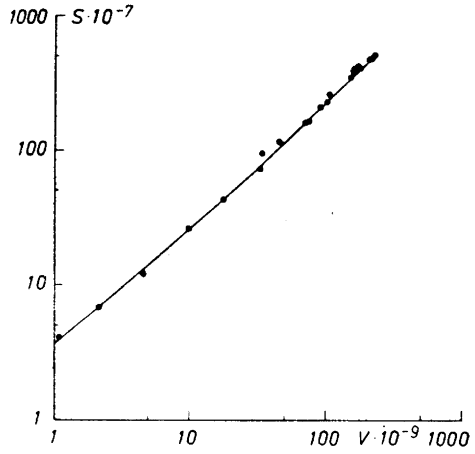

Fig. 11.

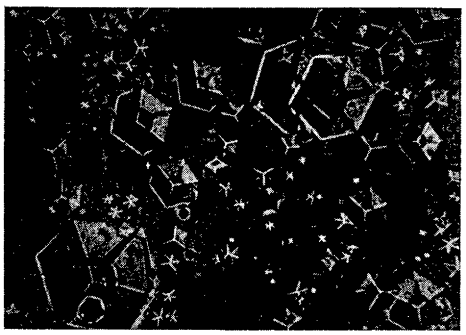

Fig. 12.

bigger crystals, and 2 on the crystal faces. It is concluded that either small new crystals wander about and become attracted and held fast by other crystals, or they originate on them.

OTHER EXPERIMENTS

1. *Crystallization of pig insulin from a clear solution.* The eqns. (78), (79), (80) and (81) which were formed on the hypotheses set up to explain the $\varrho(l, t)$ function contain some remarkable consequences. The specific rate of nucleation, being a function of g, is seen to be independent of $\dot{g}$ and of the concentration of dissolved insulin. However, in a single experiment $\dot{g}$ is certainly a function of g and it is therefore possible to express h_s and $\mathfrak{h}$ by means of $\dot{g}$. It turns out that $h_s(\dot{g})$ and $\mathfrak{h}(\dot{g})$ are complicated functions which seem to have no underlying pattern from the point of view of chemical interpretation. Thus, up to the present it has not been possible to find any explanation except for the simple hypothesis of nucleation by crystal self-reproduction. In order to test experimentally whether h_s is chemically independent of $\dot{g}$, crystallizations were made in which the concentration of dissolved insulin, and hence $\dot{g}$, varies with g in a different pattern, *i. e.* by crystallizing from a clear solution.

The composition was: 1 % pig insulin, 0.04 % Zn^{++}, 0.05 M sodium citrate, 15 % (v/v) acetone, pH = 6.2. Volume 1 l. The crystallizations were carried out in ordinary glass beakers equipped with a mechanical glass stirrer. The acetone prevented any foam formation. In one of the two experiments the glass was covered with a paraffin layer and the surface was covered with paraffin oil. The resulting cumulative distributions of crystal sizes are shown in Fig. 13.

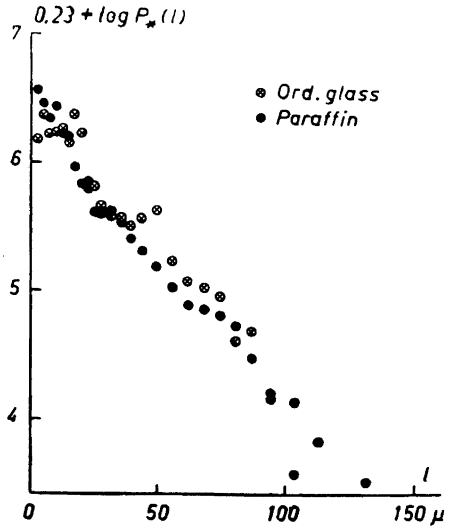

Fig. 13.

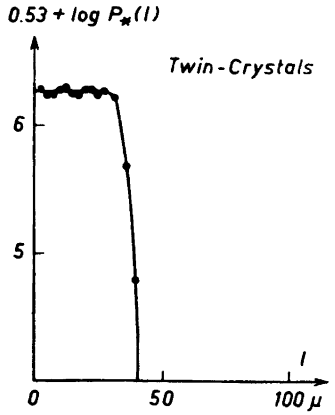

Fig. 14.

To all log ρ_* values are added log $\frac{1.7}{1} = 0.23$ so as to render direct comparison with previous figures possible. It is seen that the change of the $\dot{g}(g)$ function together with the elimination of the amorphous phase did not abolish the straight line relationship expected in accordance with the hypothesis of crystal reproduction.

2. *Crystallization of beef insulin from a clear solution.* An experiment was made using the same composition as in the case of pig insulin crystallization except for the insulin concentration which was 0.5 % and pH which was 6.7. The crystals were as expected more or less distorted apparently by twin formation [1]. The resulting cumulative distribution of crystal sizes is shown in Fig. 14. The shape of the curve is inconsistent with the eqns. (86)—(89) derived from the hypothesis of crystal reproduction. Furthermore the distribution of sizes shows a maximum at about 35 μ corresponding to a rather monodisperse suspension. It means that h_s drops sharply when the concentration of dissolved insulin decreases. Assuming that the nucleation occurs spontaneously within the solution and further that eqn. (61) can be employed in the present case, it follows that $p > q$ as in the case of barium sulphate. Thus, the mechanism of nucleation in the citrate-acetone buffer appears to depend on the species of insulin. In the sodium chloride medium, however, there is no such dependence as illustrated by the 4-litre experiment for which beef insulin was used.

It is concluded that the observed pattern of nucleation is in accordance with the fundamental concepts of spontaneous nucleation, eqn. (61), when the crystals are of the usual distorted twin-like type. The data of crystallization of plain single rhombohedrons are also in agreement with the fundamental con-

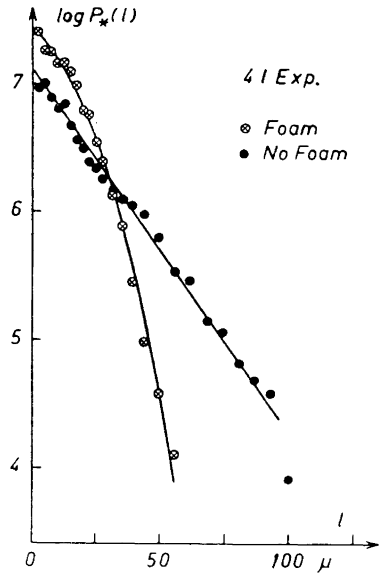

Fig. 15.

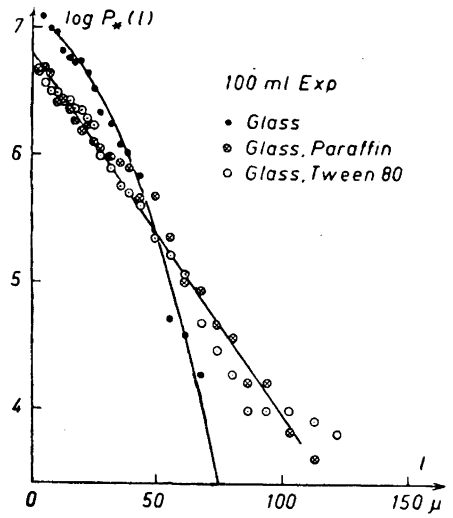

Fig. 16.

cepts when it is accepted that a second population of nuclei originates on the existing crystals. In this latter case it was estimated that $p = q$ in eqn. (61), but the masking effect of the apparent self-reproduction makes this estimate somewhat uncertain.

3. *The outer surface.* The investigation of the nucleation process is complicated by an apparent nucleation process taking place in the outer surface of the suspension.

When insulin crystallizes slowly from a calm solution, it is observed that crystals are primarily formed in the glass surface, in the surface exposed to air and on foreign bodies (*e. g.* a hair fiber) if such are suspended in the solution. In the 4-litre experiment some foam is formed on the surface. If the foam is not quantitatively removed, the crystallization yields a larger number of crystals, the maximum size becomes smaller and the graphical picture of $\log \varrho_*(l)$ becomes curved as shown in Fig. 15.

In another experiment the surface was increased (without perceptible foam) by reducing the volume of the crystallizing suspension to 100 ml. The resulting cumulative distribution of sizes (Fig. 16) resembles that of the 4-litre experiment with foam. Thus, it seems that nucleation may occur in the surface to such an extent as to cause a significant change in the distribution of sizes.

Inversely, it has been demonstrated by experiment, that the apparent excess nucleation from the surface can be reduced or eliminated. The 4-litre experiment was repeated on a 100 ml scale in 3 experiments carried out in identical apparatus. The one experiment served as the control for the case with relatively large surface. Number two beaker was covered with paraffin

and the surface of the suspension was covered with paraffin oil. The third suspension contained 0.05 % of the surface active agent Tween 80. It is seen from Fig. 16 that the paraffin cover as well as the Tween 80 causes a bigger maximum size of crystals, a smaller crystal number, and the reappearance of the straight line relationship characteristic of the 4-litre experiment when foam is absent.

DISCUSSION

Nucleation may occur within the solution, in the interfaces between solution and glass or air and on the surface of the crystals. The great changes in nucleation produced by foam or other increases in the surface, by the paraffin coating, and by Tween 80 indicate that the rate of nucleation increases towards the surface. The hypothesis of surface nucleation on the crystals provides a simple explanation of the size distributions observed. It has not been possible to determine whether this nucleation is located on the faces or rather at the edges or vertices. It is interesting that this type of nucleation is apparently wholly or partially absent when the insulin crystallizes in the twin-like distorted shape. One can imagine that the crystal reproduction may be the repeated development and disengagement of twins.

The Kinetics of the Acid-Catalysed Solvolysis of Ethylal in Water-Ethanol Mixtures

PENTTI SALOMAA

Department of Chemistry, University of Turku, Turku, Finland

The kinetics of the reversible, acid-catalysed hydrolysis of ethylal have been investigated in water-ethanol mixtures. By the stationary state principle, it has been shown that the results are in accord with a unimolecular solvolysis mechanism. The velocity of the overall solvolysis of ethylal can be measured by a refined kinetic method which makes use of determining the relative rates of the fast, product-forming hydrolysis and alcoholysis reactions of the unstable ethoxymethyl cation which is formed in the rate-determining, unimolecular reaction stage. The solvolysis rate constants are found to be closely related to the Hammett acidity function of the reaction solution, in accord with the unimolecular mechanism suggested.

The dependence of the solvolysis rate on the acidity function and on the dielectric properties of the medium have been discussed. By electrostatic theories on solvent influence on relative base strengths, an equation has been derived for the effect of medium on the velocity of a unimolecular, acid-catalysed reaction.

In several recent publications [1–4] evidence has been furnished to support the assumption that the hydrolysis of acetals takes place by a unimolecular mechanism, which in the rate-determining stage of reaction involves a formation of a positively charged carbonium ion from the conjugate acid of the acetal. In two cases, in the hydrolysis reactions of methylal [3] and trioxan [4] in concentrated aqueous acids, Hammett's acidity function was applied as a criterion of molecularity of the rate-determining reaction step.

In connection with the earlier study on the mechanisms of solvolytic reactions of ethoxymethyl acetate [5], the author also determined the rate constants for the reversible hydrolysis of ethylal

$$EtOCH_2OEt + H_2O \underset{k_a}{\overset{k_h}{\rightleftharpoons}} HCHO + 2\ EtOH\ (H^+ \text{ as catalyst}) \qquad (I)$$

in a number of water-ethanol mixtures. As the main applications hitherto made of the Hammett acidity function are to hydrolysis reactions in concentrated acids, it seemed of interest to study whether the general theory could also

be applied to the solvolysis of ethylal by dilute acid solutions, if the solvent is varied. In the present work, the earlier data on the reaction of ethylal have been extended by complementary experimental measurements, which were necessary for the kinetic applications.

RESULTS AND THEORY

Table 1 contains the values of the first-order rate constants k_h, determined for the hydrolysis of ethylal in water and in various water-ethanol mixtures at 25°C at 0.1 N hydrogen chloride concentration. The table also includes the values of the Hammett acidity function H_0 for the reaction solutions employed. These have been obtained by interpolation from the data given by Braude and Stern [6]. It is seen from the table that the values of k_h decrease continuously with increasing alcohol content of the solvent, whereas the values of H_0 pass through a maximum, *i. e.* the proton-availability of the solutions reaches a minimum, in solutions containing 50—70 moles per cent of ethanol. According to the theory (*cf.* Ref.[7]), the velocity of a mechanistically unimolecular, acid-catalysed solvolysis reaction should depend primarily on the acidity function of the reaction solution. As shown below, the requirements of the theory are satisfactorily fulfilled here, in spite of the continuously decreasing values of k_h with increasing alcohol content, depending on the fact that the values of k_h do not directly measure the velocity of a solvolysis reaction, which is assumed to be unimolecular.

Table 1. The solvolysis of ethylal in ethanol-water mixtures at 25° C at 0.1 N hydrogen chloride concentration. k_h = the first-order rate constant (in sec.$^{-1}$) for the formation of formaldehyde from ethylal. r = the molar ratio of formaldehyde and ethylal formed by the solvolysis of ethoxymethyl chloride. k_1 = the first-order rate constant (in sec.$^{-1}$) calculated for the overall solvolysis reaction of ethylal.

Mols. % EtOH	H_0	$10^6 \cdot k_h$	r	$10^6 \cdot k_1$
0	+ 1.01	16.4	∞	16.4
7.5	+ 1.20	10.3	89.0	10.4
18.2	+ 1.69	4.21	32.9	4.34
26.6	+ 1.91	2.64	20.6	2.77
34.9	+ 2.07	1.32	1.430	2.24
43.8	+ 2.19	0.861	1.008	1.72
51.2	+ 2.23	0.700	0.766	1.61
60.9	+ 2.24	0.590	0.534	1.69
69.3	+ 2.23	0.550	0.394	1.95
78.1	+ 2.16	0.539	0.280	2.46

For the sake of simplicity, let us neglect the reverse reaction, the acetalisation of formaldehyde, because this reaction does not affect the values of k_h (quite similar considerations apply to the case, in which the reverse reaction is taken into account). The unimolecular mechanism of acetal hydrolysis [2], as particularised to the hydrolysis of ethylal, is the following:

$$EtOCH_2OEt + H^+ \underset{\text{fast}}{\rightleftharpoons} EtOCH_2\overset{H}{\overset{|}{O}}{}^+Et \xrightarrow[\text{slow}]{} Et\overset{+}{O}{=}CH_2 + HOEt \quad (II)$$

$$Et\overset{+}{O}{=}CH_2 + H_2O \xrightarrow[\text{fast}]{} EtOH + H^+ + HCHO \quad (III)$$

The intermediate, unstable cation which is formed in the slow, rate-determining stage has a mesomeric structure, which is a hybridised form of the carbonium ion and oxonium ion structures. Supposing that the rate measurements are made at a fixed acid concentration, and denoting by $1/K$ the ratio of the concentration of ethylal to its conjugate acid at this acid concentration, and by k the rate constant of the unimolecular rate-determining reaction stage, respectively, it is found that the product $kK = k_1$ represents the experimental first-order rate constant of the reaction taking place at the acid concentration in question. Supposing that the reaction occurs in water, the value of k_1 is identical with the value of k_h, because only minute quantities of ethanol, formed by the hydrolysis, are present, and therefore practically all of the mesomeric cations, once having been formed, react with water molecules to give formaldehyde. Such a situation does not prevail in solvents of a moderate ethanol content. In these solvents, reaction (IV) which is the reversal of the rate-determining reaction stage competes significantly with reaction (III) for the unstable, intermediate cation:

$$Et\overset{+}{O}{=}CH_2 + EtOH \xrightarrow[\text{fast}]{} EtOCH_2\overset{H}{\overset{|}{O}}{}^+Et \quad (IV)$$

The relative contribution of this competing reaction increases with the alcohol content of the solvent, and thus the values of k_h which measure the rate of formaldehyde formation no longer represent the rate constants of the overall solvolysis reaction, k_1, which depend partly on the velocity of the rate-determining stage, partly on the pre-equilibrium of the proton uptake. In solutions containing ethanol, the other of the two rapid, product-forming reactions remains obscure, because it leads back to the initial reactant, ethylal. However, in this particular case, the relative contributions of the product-forming reactions are adapted to permit of measurements, and the values of k_1 can be determined, as shown below.

In view that both the substituting agents, water and alcohol, are the main constituents of the reaction solutions, the reactions of ethoxymethyl cation with water and alcohol molecules can be considered as first-order reactions, irrespective of their actual molecularities. Let k_{H_2O} and k_{EtOH} denote the first-order rate constants for these reactions, respectively. By the stationary state principle, it is found that

$$\frac{d[Et\overset{+}{O}{=}CH_2]}{dt} = k_1[EtOCH_2OEt] - (k_{H_2O} + k_{EtOH})\,[Et\overset{+}{O}{=}CH_2] = 0 \quad (1)$$

From eqn. (1) it follows that the rate of formaldehyde formation is given by

$$\frac{d[HCHO]}{dt} = k_{H_2O}[Et\overset{+}{O}{=}CH_2] = \frac{rk_1}{1+r}\,[EtOCH_2OEt] \quad (2)$$

in which the relative rates of the hydrolysis and alcoholysis reactions of the intermediate cation have been denoted by r:

$$r = k_{H_2O} / k_{EtOH} \tag{3}$$

On the other hand, the rate of formation of formaldehyde is given by

$$\frac{d[HCHO]}{dt} = k_h[EtOCH_2OEt] \tag{4}$$

in which k_h is the experimental rate constant for the hydrolysis reaction (I). A comparison of eqns. (2) and (4) shows that

$$k_1 = \frac{1 + r}{r} k_h \tag{5}$$

Eqn. (5), derived above, is consistent with the typical kinetic form of a unimolecular nucleophilic substitution [8].

From eqn. (5) it follows that, once we know the ratio of the rates of the rapid, product-forming reactions of the intermediate cation, the values of k_1 for the overall solvolysis reaction can be readily calculated from the values of k_h. In the present case, the values of r can be easily determined from the solvolysis products of ethoxymethyl chloride, $EtOCH_2Cl$, in the same media [5,9,10]. As the product-forming reactions involved in the unimolecular solvolysis of this compound are identical with those of the unimolecular mechanism suggested for the solvolysis of ethylal, the relative amounts of formaldehyde and ethylal formed by the solvolysis of ethoxymethyl chloride directly measure the values of r which can be also applied to the solvolysis of ethylal under the same conditions. Table 1 includes the values thus determined for r which have been taken partly from the data given in connection with the solvolysis of ethoxymethyl acetate [5], partly from the results of complementary measurements. Table 1 also gives the values calculated for k_1 by eqn. (5). It is seen from the table that the rate constants of the overall solvolysis reaction are closely related to the acidity function of the reaction solution, and pass through a minimum at approximately the same alcohol contents of the solvent, at which the proton-donating power of the acid solutions is least pronounced. This is in excellent agreement with the unimolecular mechanism suggested.

As the present method allowed the determination of the rate constants k_1 in alcohol-water mixtures of relatively widely varying values of the acidity function, thus differing from measurements on the solvolysis of alkoxymethyl esters [5,9], the dependence of log k_1 on the acidity function may be discussed in more detail. The theory in its original form suggests that a plot of log k_1 against $-H_0$ should give a straight line with a slope of unity (for references, see Ref.[7]). This relation has been found to be satisfactorily obeyed by several unimolecular hydrolysis reactions in concentrated aqueous acids. Table 2 which gives the values of log $k_1 + H_0$ for the solvolysis of ethylal in water-ethanol mixtures shows that the values increase with the alcohol content of the solvent. When the values of log k_1 are plotted against $-H_0$, it is found that the slope is somewhat less than unity, and decreases slightly, when passing to solutions of higher ethanol content. As shown below, these deviations

Table 2. The dependence of log k_1 on the acidity function and on the dielectric constant of the medium in the solvolysis of ethylal in water-ethanol mixtures at 25° C at 0.1 N hydrogen chloride concentration.

Mols. % EtOH	D	log $k_1 + H_0$	log $k_1 + H_0 - \frac{14.8}{D}$
0	78.5	− 3.78	− 3.97
7.5	68.6	− 3.78	− 4.00
18.2	57.3	− 3.67	− 3.93
26.6	50.0	− 3.65	− 3.95
34.9	44.5	− 3.58	− 3.91
43.8	39.8	− 3.57	− 3.94
51.2	36.5	− 3.56	− 3.97
60.9	32.8	− 3.53	− 3.98
69.3	30.5	− 3.48	− 3.97
78.1	28.0	− 3.45	− 3.98

from the slope of unity can be interpreted in terms of changes in the relation between the solvolysis rate and the acidity function, which may be expected to occur, when passing from water to solvents of lower dielectric constants.

Supposing the reaction mechanism to be unimolecular, the dependence of log k_1 on the acidity function is given by the equation:

$$\log k_1 = constant - H_0 + \log \frac{f_S f_{IH^+}}{f_{X^+} f_I} \qquad (6)$$

which is derived from the definition of H_0 by the Brönsted rate equation. In this equation, f's are the respective activity coefficients of the substrate S, the critical complex X^+, and the uncharged indicator base I and its conjugate acid IH^+, which have been used for the colorimetric determination of the values of H_0. As the critical complex contains only a proton, in addition to the substrate molecule, its activity coefficient is similarly affected by changes in medium as that of the conjugate acid of the substrate. Therefore, a slope of unity in the plot of log k_1 against $-H_0$ implies merely that the activity coefficient ratios of different bases to their conjugate acids are influenced by medium in a similar way, *i. e.* the relative base strengths of the different bases remain unchanged. However, such a relation is not to be expected to be valid when passing from water to solvents of lower dielectric constants.

Minnick and Kilpatrick [11] measured the relative acid strengths of a number of organic acids in water, methanol, ethanol and in water-dioxan mixtures, by determining the equilibrium constants for reactions:

$$H_1A + A_2^- \rightleftharpoons A_1^- + HA_2 \qquad (V)$$

Here, HA_1 and HA_2 are the acids, and A_1^- and A_2^- their anions, respectively. It was found that the values of the logarithms of the equilibrium constants were in all cases satisfactorily represented by functions of the form: $a+b/D$; a and b are constants for a given pair of acids, and D denotes the dielectric constant of the medium. This form of relation between the equilibrium constant and the dielectric constant is that expected by electrostatics (*cf.* Ref.[12]).

In this particular case, the success of the electrostatic theory, which has been found to fail for many other applications to solvent effects, is presumably due to the circumstance that the influence of solvent effects other than electrostatic becomes effectively masked, when changes of relative acid strengths are measured. As the electrostatic relation holds for reactions of type (V), it can be assumed that a similar relationship is valid for equilibria

$$B_1 + B_2H^+ \rightleftharpoons B_1H^+ + B_2 \qquad \text{(VI)}$$

which measure the relative strengths of a pair of uncharged bases, B_1 and B_2. It may be written

$$\log \frac{[B_1H^+][B_2]}{[B_1][B_2H^+]} = a + \frac{b}{D} \qquad (7)$$

in which a and b are constants. Taking into account that

$$\frac{[B_1H^+][B_2]}{[B_1][B_2H^+]} = \frac{f_{B_1}f_{B_2H^+}}{f_{B_1H^+}f_{B_2}} K_0 \qquad (8)$$

in which K_0 is the thermodynamic equilibrium constant, and f's are the activity coefficients, eqn. (7) implies that

$$\log \frac{f_{B_1}f_{B_2H^+}}{f_{B_1H^+}f_{B_2}} = a' + \frac{b}{D} \qquad (9)$$

in which a' is a constant, which is obtained by subtracting $\log K_0$ from a. Let B_2 denote the indicator base, which is used for the determination of the values of H_0, and let B_1 mean the basic substrate, which is undergoing an acid-catalysed, unimolecular solvolysis reaction the critical complex of which resembles closely the conjugate acid of the substrate. From eqns. (6) and (9), it then follows that

$$\log k_1 = constant - H_0 + \frac{b}{D} \qquad (10)$$

which equation represents the dependence of the velocity of the unimolecular reaction on the acidity function and on the dielectric constant of the reaction solution.

Table 2 contains the values of the dielectric constants for the water-ethanol mixtures employed. These values have been interpolated from the data of Åkerlöf [13]. A plot of $\log k_1 + H_0$ against $1/D$ for the solvolysis of ethylal in ethanol-water mixtures is found to give, within the limits of experimental accuracy, a straight line with a slope of 14.8. From the last column of Table 2, it is seen that the deviations from eqn. (10) are not larger than those, which may be ascribed to the sum of experimental errors involved in the determination of the values of $\log k_1$ and H_0.

The electrostatic theory suggests that the value of b, 14.8, found for ethylal solvolysis should be roughly of a similar order of magnitude as the values obtained by Minnick and Kilpatrick [11], when comparing the relative acid strengths of organic acids. Actually, the corresponding slopes measured for

different acid pairs varied between 5.5 and 21.0, when their signs were not taken into account. Moreover, the positive sign of b which indicates that the activity coefficient ratio of eqn. (6) decreases with increasing dielectric constant of the medium is not unexpected here. As the changes of activity coefficients of charged species with the dielectric constant are generally more significant than those of uncharged species, the decrease of the value of the activity coefficient ratio of eqn. (6) with increasing dielectric constant may be ascribed as being primarily due to a decrease in the value of f_{IH^+} / f_{X^+}. Here, IH^+ is the conjugate acid of *p*-nitroaniline or *m*-nitroaniline, which were used by Braude and Stern [6] for the determination of the values of H_0. These protonated bases have probably a more intensive charge distribution than that in the critical complex of the solvolysis of ethylal. According to eqn. (II), the rate-determining stage of the ethylal solvolysis involves a relatively large dispersal of charge. On the attainment of the transition state, the positive charge is being partly removed from the oxygen atom to a nascent mesomeric system, in which the charge is shared between a carbon atom and another oxygen atom. In addition, that carbon-oxygen bond which is broken in the rate-determining reaction step, is lengthened. In view of the less intensive electrical field around the critical complex of the ethylal solvolysis, in comparison to the fields of the conjugate acids of the nitroanilines, the activity coefficient of the critical complex is less reduced by increases in the dielectric constant of medium, as a result of which the value of f_{IH^+} / f_{X^+} decreases, when passing over to solvents of higher water content.

Activation in the Solvolytic Substitution Reactions of Unstable Alkoxymethyl Cations

PENTTI SALOMAA

Department of Chemistry, University of Turku, Turku, Finland

Measurements have been made of the reaction product composition in the unimolecular solvolysis of methoxymethyl chloride and ethoxymethyl chloride in water-ethanol mixtures at temperatures varying between 0°C and 75°C. In all cases, it was found that the relative amount of formal formed by the solvolysis, as compared with that of formaldehyde, increases with temperature. By the plots of log ([formal] / [formaldehyde]) against $1/T$, it was shown that the cation-ethanol reactions have activation energies of about 2 kilocalories per mole higher than the simultaneously occurring cation-water reactions.

The kinetic features of the fast, product-forming stages of unimolecular nucleophilic substitution reactions have been extensively discussed by Ingold, Hughes and co-workers [1–3]. In one particular case, for the reaction of di-*p*-tolylmethyl chloride in aqueous acetone containing added azide ions [3], these authors showed that the relative rate of formation of di-*p*-tolylmethyl azide, in comparison to that of di-*p*-tolylmethyl alcohol, increases with temperature by an amount which indicates that the cation-azide ion reaction has an activation energy of about 4 kilocalories per mole higher than the cation-solvent reaction, and therefore, at least the former process must be activated. On the other hand, there was no experimental evidence as to whether or not the fast cation-solvent reactions of unimolecular substitutions are activated. The theory on unimolecular solvolytic substitutions, developed by Ingold and Hughes, did not include, but did not require, an activation in these reactions.

An illustration of competing unimolecular, purely solvolytic substitution reactions, for which the relative contributions of the simultaneously occurring reactions can be easily measured at different temperatures, is furnished by the solvolysis of alkoxymethyl chlorides in water-ethanol mixtures. According to the earlier study [4], these reactions take place by the S_N1 mechanism:

$$ROCH_2Cl \xrightarrow[\text{slow}]{} R\overset{+}{O}{=}CH_2 + Cl^- \qquad (I)$$

$$R\overset{+}{O}{=}CH_2 + H_2O \xrightarrow[\text{fast}]{} HCHO + ROH + H^+; \qquad (II)$$

$$R\overset{+}{O}{=}CH_2 + EtOH \xrightarrow[\text{fast}]{} ROCH_2OEt + H^+$$

The present paper gives the results of a study, in which the solvolysis products of methoxymethyl chloride and ethoxymethyl chloride were determined at various temperatures.

The procedure used to investigate the product-forming reactions (II) was to determine the composition of the solvolysis product, this composition giving a direct measure of the relative rates of reactions (II). This method necessarily involved a performance of measurements in water-ethanol mixtures of such a composition, that the molar percentages of formaldehyde and formal formed by the solvolysis were of a similar order of magnitude, because only in such solvents the relative contributions of reactions (II) could be determined accurately enough. Although in the water-ethanol mixtures employed even the rate-determining reactions (I) were much too rapid to permit of kinetic measurements, still the compositions of the final products could be analysed. The results are collected in Tables 1 and 2. The molar percentage of formaldehyde

		70	25.0		

formed was found to be substantially unaffected by the initial concentration of alkoxymethyl chloride.

The tables show that the composition of the final product of solvolysis is dependent on temperature. In all cases the molar percentages of formaldehyde formed decrease with temperature. This indicates that the relative contribution of the latter reaction (II) increases with temperature, *i. e.* the latter reaction involves a higher energy of activation. Therefore, at least the cation-ethanol reaction must be activated. On the other hand, in view of the fact that both the reactions (II) are apparently of a similar type, there is no reason to assume that the cation-water reaction would not be activated.

Although the actual molecularities of reactions (II) cannot be determined by the available methods, these reactions can be considered as being of the first order, in view of the large excesses of water and ethanol molecules present in the reaction solvents. Supposing the Arrhenius equation to be valid for both the reactions, and denoting their respective Arrhenius parameters by A_{H_2O}, E_{H_2O}, A_{EtOH} and E_{EtOH}, and denoting by α the molar ratio of formal to formaldehyde present in the final product, it is seen that

$$\log \alpha = \log (A_{EtOH} / A_{H_2O}) - \Delta E / 2.303 RT \quad (1)$$

in which

$$\Delta E = E_{EtOH} - E_{H_2O} \quad (2)$$

According to eqn. (1), a plot of the values of log α against $1/T$ should give a straight line. Such plots are made in Figs. 1 and 2. Although there is some scattering of the values, the deviations from eqn. (1) do not exceed the experimental errors in magnitude. The slopes of the lines are seen to be of nearly the same magnitude, *viz.* —400, independently on the halide and solvent mixture used. The average value of the slopes indicates that the activation energy of the cation-ethanol reaction exceeds that of the cation-water reaction by about 1 800 calories per mole.

The theory on unimolecular solvolytic substitution, developed by Ingold and Hughes [1-3], suggests that the fast, product-forming reaction stage is an internal collapse of the solvation shell of the intermediate cation. If the theory is applied to the present case, it can be assumed that the inner solvation shell of the alkoxymethyl ion in water-ethanol mixtures consists of a number of water and ethanol molecules. When one of these molecules attains a certain, critical distance from the point of reaction, a destruction of the solvation shell occurs, and the reaction follows. One of the factors involved in the activation energies of reactions (II) may be merely due to the spatial conditions prevailing in the solvation shell. The water or ethanol molecule, which converts the solvated cation to the final product, must be able to overcome a certain amount of steric strain exerted by the neighbouring molecules present in the solvation shell, before the critical separation, which is necessary for the reaction to occur, can be attained. This may be one of the factors which give rise to a higher activation energy for the cation-ethanol reaction, in comparison to that of the cation-water reaction. As the size of ethanol molecules is larger than that of water molecules, the approach of an ethanol molecule to the critical distance of reaction is accompanied by a higher degree of destruction of the solvation shell.

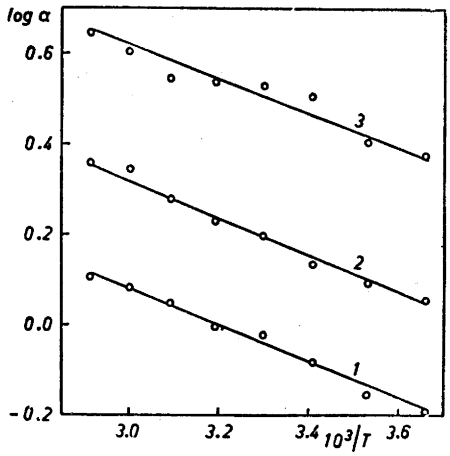

Fig. 1. Plot of log a against $1/T$ for the solvolysis of methoxymethyl chloride.

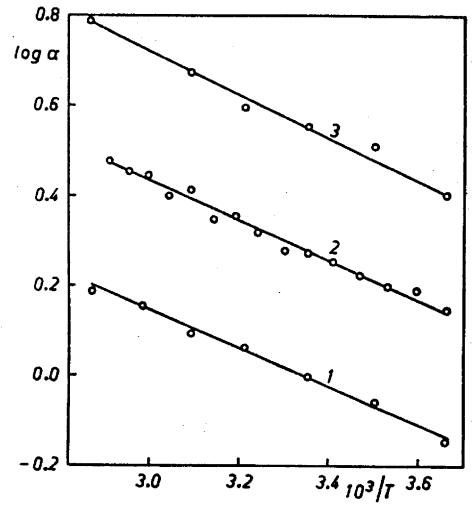

Fig. 2. Plot of log a against $1/T$ for the solvolysis of ethoxymethyl chloride.

1. 43.8 mole% EtOH. 2. 60.9 mole% EtOH. 3. 78.1 mole% EtOH.

Although reactions (II) have a certain amount of activation energy, their enormous rapidity is, however, understood by the activation entropies involved in such processes. The destructions of the solvation shells are accompanied by great decreases in order, *i. e.* the activation entropies must have large positive values, and hence the frequency factors are probably very large.

EXPERIMENTAL

The methods of preparing the materials, and those used for analysing the reaction product compositions were essentially those described earlier [4]. Owing to the great rapidity of the reactions, the product analysis could be performed almost immediately after mixing the reaction components. At relatively high temperatures, *viz.* at 50°C and above this temperature, the method of sealed bulbs was used, in order to eliminate volatility errors. In these experiments, a small, thin-walled glass ampoule containing the alkoxymethyl chloride was sealed together with small pieces of stone into a larger glass bulb which contained the reaction solvent. After the bulb, when immersed in a thermostat, had attained the thermostat temperature, the reaction components were brought together by vigorous shaking by which the small ampoule was broken. As it was verified that the subsequent reactions, the hydrolysis of formal and its reversal, were at relatively high temperatures rapid enough to effect an error in analysis, if the bulbs were kept a prolonged period of time at these temperatures, the bulbs were immersed in an ice-water mixture immediately after mixing the reaction components. After cooling, the bulbs were broken and the reaction product was analysed. By this method reproducible values were obtained even at the highest temperatures used.

Table 3 shows an example of experiments, in which the effect of initial alkoxymethyl chloride concentration on the composition of the final product was investigated. It is seen that the molar percentage of formaldehyde increases with decreasing alkoxymethyl chloride concentration. However, the increase is not material. In order to eliminate the

error due to differences in initial concentrations, all of the determinations, the results of which are included in Tables 1 and 2, were performed using approximately the same initial concentrations of the alkoxymethyl chlorides, *viz.* about 0.1 M.

Preparation of Infinitely Thin Plutonium Sources by Adsorption

M. A. EL GUEBELY and T. SIKKELAND

Chemistry Department, Joint Establishment for Nuclear Energy Research, Kjeller, Norway

Infinitely thin sources have been prepared by adsorption of ^{239}Pu from hydrochloric acid solutions onto glass, aluminium and platinum surfaces. The validity of the method was studied by autoradiography. Results show that glass and aluminium are the best surfaces for such sources. The same method has been applied for the preparation of sources of ^{233}U on glass. Segregation of Pu and U has been observed on glass as well as on metallic surfaces.

Different methods exist for the preparation of α sources as described elsewhere [1]. King has studied the adsorption of Pu(IV) at trace concentration on the internal surface of a glass pipet [2]. He found that adsorption increases as the hydrogen-ion concentration is decreased. The purpose of the present work was to examine the possibility of using adsorption of Pu on glass and different metal surfaces as a method for the preparation of infinitely thin sources of α emitters as well as to determine the best conditions in which such preparation is to be carried out.

Haissinsky *et al.*[3] have developed an autoradiographic method for the study of metallic surfaces by examining the distribution of ranges of α-particles of Po deposited spontaneously or electrolytically on these surfaces. They found that in all cases there is an apparent shortening of a certain number of ranges in the gelatine. This was explained by the penetration of a certain number of Po-atoms inside the metallic surface. This apparent shortening would be a disadvantage for the preparation of sources of α-emitters and may lead to wrong interpretations of the α-spectrum [3].

In the present work we have applied the same method for the study of the adsorbed activity.

EXPERIMENTAL

The plutonium used in our experiments was separated from irradiated uranium by ion exchange technique [4]. Pu(IV) was prepared by dissolving a Pu-residue in 9 M hydrochloric acid containing 1 drop conc. nitric acid per ml [5].

^{233}U was prepared by extraction from neutron irradiated ^{232}Th. The reagents used were of analytical grade and the water was bidistilled. The adsorption of the activity was performed by simple rotation of the glass or metal slide in the solution. The glass slides, before adsorption, were washed in *aqua regia*, sodium carbonate and finally in water. Two types of glass were used: ordinary soda-objectiveglass (0.15 mm thick) and pyrex-glass.

The aluminium plates were either rolled or electropolished and 0.1 mm thick. Before use they were washed with acetone and water.

The platinum (0.2 mm thick) was electropolished and before adsorption the slide was washed with boiling conc. nitric acid and finally in water. The different slides were, after adsorption, washed twice in water and dried by rotating in air.

The surface of the slide was then, for a certain time, brought into good contact with an α-nuclear plate, Ilford E. 1, 50 μ thick. The aluminium plates had to be kept in a desiccator with P_2O_5 during exposure to depress the chemical attack on aluminium by the photographic emulsion. The plates were developed by a conventional photographic technique [6]. Rubbing of the plates was avoided in order not to reduce the lengths of the α tracks.

The lengths of the α-tracks were measured with a microscope (type Laborlux III, Ernst Leitz). The magnification was 570: and 400 horizontal tracks for each plate were investigated (those which had an angle of less than 10° with the plane of the emulsion) [3]. In all cases corrections for the background of the slides used were applied.

RESULTS

In Table 1 are given the conditions under which the experiments were performed. The experiment with the pyrex glass gave results similar to those obtained with soda-objective glass, and is not therefore indicated here.

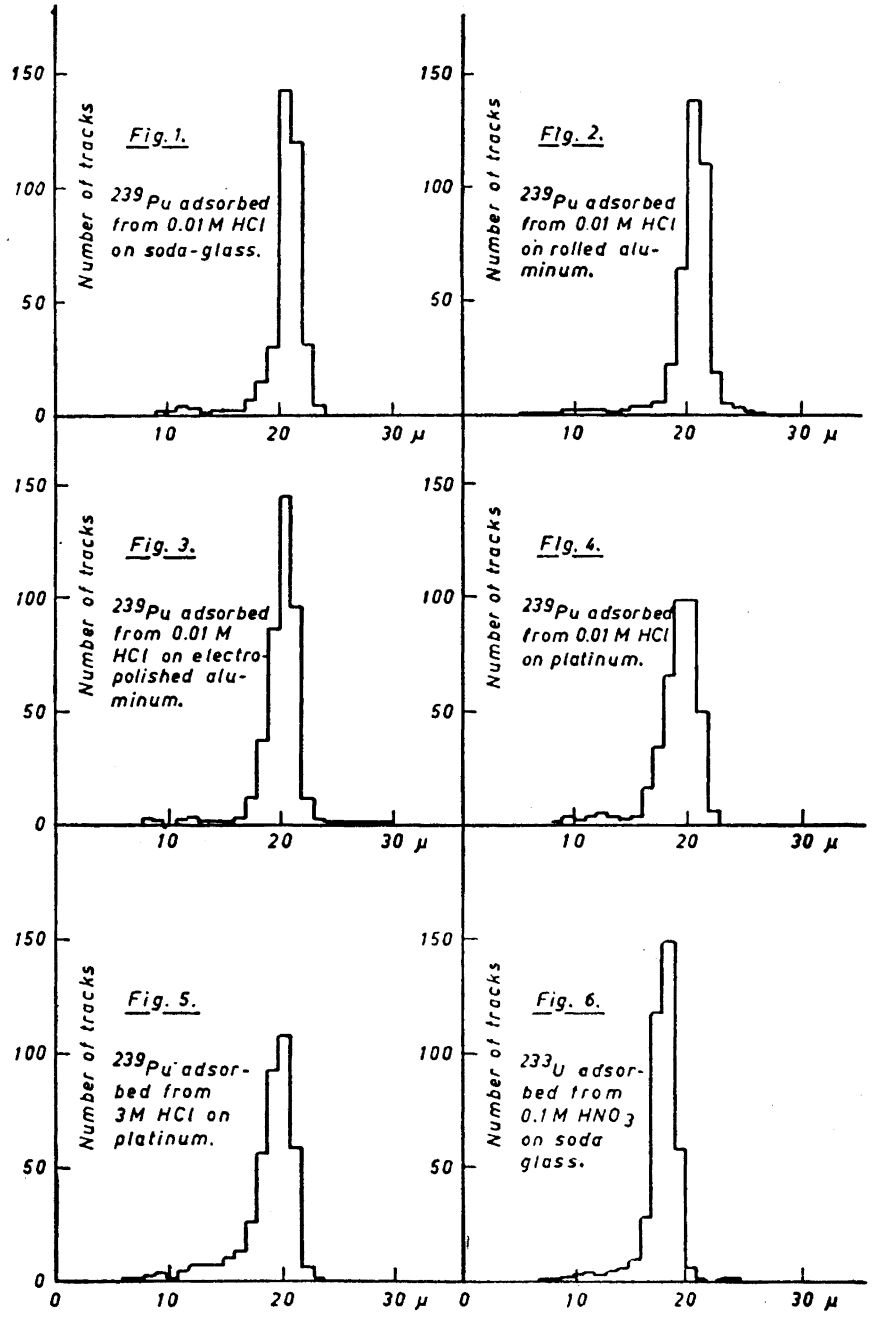

Table 1. Experimental conditions.

No.	Type of Slide	Acidity	Conc. in μg/ml	Ox. state added	Adsorption time in h.	Exposure time in h.
1.	Na-glass	0.01 M HCl	0.10	Pu(IV)	22	19
2.	Al-rolled	0.01 M HCl	0.10	Pu(IV)	4	42
3.	Electro-polished Al	0.01 M HCl	0.05	Pu(IV)	4	43
4.	Electro-polished Pt	3 M HCl	1.6	Pu(III) Pu(IV)	22	48
5.	»	0.01 M HCl	0.10	Pu(IV)	22	42
6.	Na-glass	0.1 M HNO_3	4.0	U(VI)	20	46

In Figs. 1—5 are plotted the histograms for ^{239}Pu of the number of α-tracks against their length, corresponding respectively to the experimental conditions indicated 1—5 in Table 1. Experiments were repeated several times, specially on glass (acidities from 0.01 to 3 M) and results were highly reproducible.

In Fig. 6 is given the histogram of the α-tracks of ^{233}U adsorbed onto glass (conditions 6 in Table 1).

Other experiments on Pu have shown that the shape of the histograms is independent of the lapse of time between the end of adsorption and the beginning of exposure, at least for 12 days. Again changing of acidity from 3 M hydrochloric acid (ionic species of Pu) to 0.01 M hydrochloric acid (colloidal Pu) similarly had no influence on the form of the range distribution curve.

Figs. 1—6. Histograms of number of tracks *vs.* length.

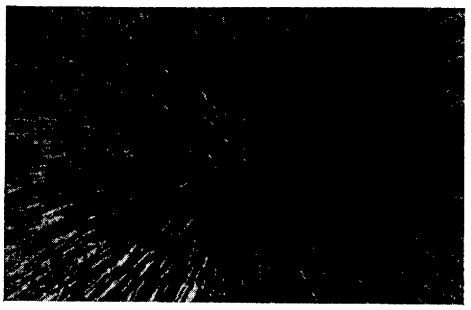

Fig. 7. Segregate on aluminium.

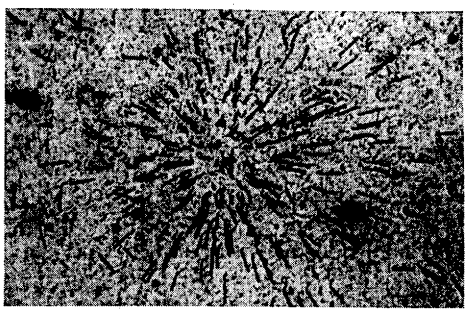

Fig. 8. Segregate on glass.

Fig. 9. Random distribution of tracks.

In all the plates examined segregates of ^{239}Pu or ^{233}U were observed on certain points. In Figs. 7 and 8 are given photographs of segregates of ^{239}Pu on aluminium and on glass, respectively, and in Fig. 9 a photograph from a region with random distribution of α-tracks.

DISCUSSION

The experiments show that the most probable range of the α-particles of ^{239}Pu (α: 5.10, 5.15, 5.17 MeV) in the Ilford E. 1 plate is 21 ± 1 μ which is in good agreement with the α-energy-range curve [7]. For that of ^{233}U (α: 4.80 MeV) we found 18.5 ± 1 μ.

Apparent shortening has been observed in the case of platinum (14 tracks per 100 have ranges shorter than 18 μ). This phenomenon is far less pronounced on aluminium and glass (only 3 tracks per 100 have ranges shorter than 18 μ).

Apparent shortening may be due to:

a) the penetration of plutonium atoms into the surface, phenomenon comparable to that found previously for polonium [3].
b) possible backscattering of the α-particles from the sample plate.

The backscattering of ^{239}Pu α-particles from platinum has been studied by Cunningham *et al*[8]. They found that identical quantities of essentially weight-

less samples of ^{239}Pu show a 3 % lower counting rate when mounted on quartz in a 50 % geometry counter than similar samples mounted on platinum and concluded that this difference is possibly due to small angle scattering in the latter case. This backscattering would be more manifest for the horizontal or nearly horizontal tracks on which we concentrated our studies. Backscattering would lead to a loss of a part of the energy of the scattered particles and hence to shorter ranges in the gelatin. In fact our experiments show that the histograms for electropolished and rolled aluminium are similar, in spite of the relatively rougher surface of the latter. This could be understood if we assume that backscattering plays an appreciable role for apparent shortening. Due to the low atomic number of aluminium, backscattering from it should be far less pronounced than from platinum. Therefore the absence practically of apparent shortening on glass and aluminium may be explained by the highly plane surface of glass objective slides and negligible backscattering from both materials. The presence of a certain number of shorter ranges for ^{233}U on glass is probably due to a trace of thorium impurity.

The study of the adsorbed phase represented certain peculiarities. In all conditions using ^{239}Pu or ^{233}U on glass or metallic surfaces, and irrespective of the acidity, part of the adsorbed atoms was distributed at random while the rest was in the form of segregates. The measurements of the length of the tracks originating from the segregates were often very difficult, due to the high activity in these regions. No conclusions regarding shortening may then be drawn from these cases. The numbers of Pu atoms accumulated in the segregate may be calculated from the number of tracks emanating from it. Assuming 2 π-geometry the number of ^{239}Pu atoms, N, corresponding to n tracks in the emulsion after d days exposure is:

$$N = \frac{24\,300 \cdot 2\ n \cdot 365}{0.69 \cdot d} = (2.57\ n/d) \times 10^7 \text{ atoms} \qquad (1)$$

Using this formula we have found segregates with 10^8 up to $\gg 10^{10}$ atoms. The number of atoms in the biggest segregates, as for example that of Fig. 7, was impossible to calculate due to the high density of tracks in their regions.

The maximum activity in 2 α-geometry of the adsorbed ^{239}Pu was 135 c/m/cm^2 which corresponds to 5×10^{12} atoms/cm^2. Assuming a homogeneous surface and taking the value of 1 Å for the radius of the Pu atom, the maximum covering of the surface in our experiments did not exceed 0.2 % of a "monoatomic" layer. Under such conditions the distribution of the energy of adsorption on the surface should play an important role in the distribution of the adsorbed atoms. The segregation phenomenon may be attributed to the presence of particularly privileged microscopic regions of the surface possessing a high energy of adsorption. Further study of this phenomenon is necessary to elucidate clearly its nature.

CONCLUSION

The experiments show that the adsorption method can be used for the preparation of extremely thin sources of plutonium. Glass and aluminium offer particularly good conditions. A relatively high pH would be preferable owing

to the higher adsorbability, probably due to the formation of radiocolloids. The adsorption method presents the advantages of simplicity and the possibility of having sources without self-absorption. The limit of the method is that a relatively high specific activity of the α-emitter is to be accounted for, but the method could be applied with good results even for ^{233}U ($T_{1/2} = 1.6 \times 10^5$y).

Acknowledgement. We are indebted to Dr. E. Sæland, Director of Isotopes, who kindly provided us with ^{233}U and to Dr. Younis for valuable help in connection with the autoradiographic technique.

One of us, M. El Guebely, wishes to express his deepest thanks to Dr. G. Randers, Director of JENER and to Dr. T. J. Barendregt, Director of Chemistry, JENER, for the hospitality and the possibility they provided him to work in the institute.

The Diamagnetic Susceptibility and the High-Frequency Term in Co(III)- and Rh(III)-Complexes

C. J. BALLHAUSEN and R. W. ASMUSSEN

Chemistry Departments A and B, Technical University of Denmark, Copenhagen, Denmark

A number of diamagnetic Co(III)- and Rh(III)-complexes are discussed on the basis of Van Vleck's formula for the magnetic susceptibility. It seems possible to correlate the measured magnetic susceptibility with the tendency for forming "covalent" complexes by means of a calculation of the high-frequency term in this formula. As to be expected it is found that the "degree of covalency" for different ligands follows the spectrochemical series closely. The theory gives an interpretation of the variation of the magnetic susceptibilities in the series of complex ions $Co(NO_2)_n\ (NH_6)_{6-n}$.

In this note the measured magnetic susceptibilities of various diamagnetic Co(III)- and Rh(III)-complexes will briefly be considered for the purpose of studying the bonding in these compounds. Diamagnetism of a complex has in the past generally been taken as an indication of "covalency" if spin magnetism could be attributed to the gaseous central ion [1]. This criterium, however, can no longer be considered to be valid, as it has been shown [2] that an "ionic" model of the same complex certainly also could lead to diamagnetism. The actual bonding in the compounds is therefore likely to be one in between these two extremes.

We will try to show that it seems possible to indicate the "degree of covalency" for a number of diamagnetic hexacoordinated Co(III)- and Rh(III)-compounds. Further, the qualitative explanation of the variation in the measured susceptibilities in the series of Co(III)-nitroammines suggested by Asmussen [3] is in accordance with the present theory. The experimental results have all been taken from the long series of measurements on Co(III)- and Rh(III)-complexes earlier carried out by one of us [3,4].

THEORY

Van Vleck [5] has shown that for a diamagnetic substance the following formula holds for the measured molar susceptibility χ_M:

$$\chi_M = \frac{2}{3} N \left(\frac{e}{2mc}\right)^2 \sum_n \frac{|(n^*|\vec{L}|o)|^2}{E_n - E_0} - \frac{Ne^2}{6mc^2} \sum_q \overline{r_q^2}$$

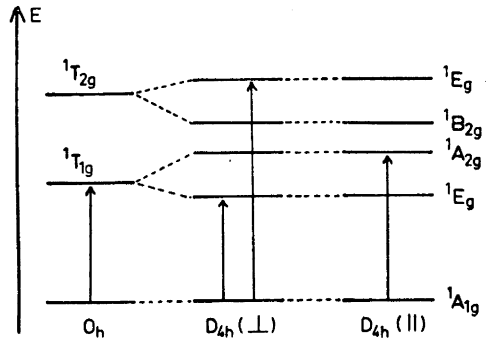

Fig. 1. The various levels and allowed magnetic dipole transitions for diamagnetic Co(III) and Rh(III) complexes.

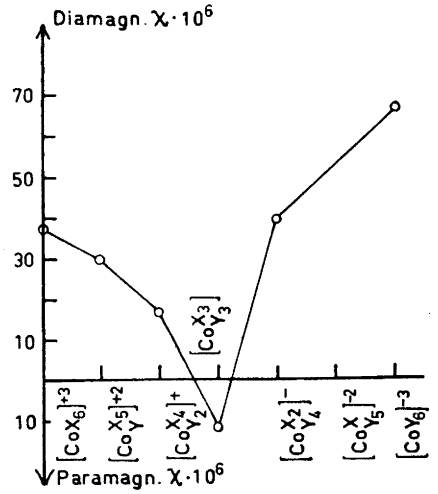

Fig. 2. The variation of the "paramagnetic increment" by substitution. The compounds are CoX_nY_{6-n} with $X = NH_3$ and $Y = NO_2^-$. The figure is taken from Ref.[3]

Here N is Avogadro's number, E_n and E_0 the energy of the upper and the lower state, e and m the electronic charge and mass, c the velocity of light and $\overline{r_q^2}$ the mean square radius for electron number q. $M^2 = |(n^*|\vec{L}|o)|^2$ is the square of the operator representing the angular momenta (unit $\hbar$) as taken between the ground and the upper state. The first term in the equation gives rise to a temperature independent paramagnetism if L is able to couple ψ_n with ψ_0; the second term is a purely diamagnetic term.

Let us assume that the crystal field approximation is valid when dealing with complexes of the transition metals. By means of the wave-functions thus obtained it is easy to calculate the high-frequency term in Van Vleck's equation. Furthermore we would expect the results to be a good approximation at least for cubic and pseudocubic complexes. However, it is perhaps instructive to see what information can be obtained by means of symmetry arguments before we give the results of such a calculation.

In complexes of symmetry O_h the angular momenta $\vec{L}$ transforms under T_{1g}. As the groundstate of a diamagnetic Co(III)- and Rh(III)-complex always transforms under A_{1g} in any symmetry, it follows that, in O_h, $\vec{L}$ can only couple the ground state to an upper state of symmetry T_{1g}. Crystal field considerations [6-7] show that such a state is found as the first excited level in diamagnetic d^6 systems, the next excited level being a T_{2g} state. Both are derived by exciting *one* electron from the groundstate, and as we are operating with determinental one-electron wavefunctions, these are thus the only excited states we need to consider in the strong field approximation.

Table 1. Variation of the diamagnetic term with various ligands. All the measured magnetic susceptibilities are from Refs.[3,4] except that of the Zn(II) complex, which was measured for this investigation by J. Potts Jensen. Details to be published later.

If the system under consideration has tetragonal symmetry D_{4h}, the magnetic moment transforms under E_g (perpendicular to the four-fold axis) and under A_{2g} (parallel to the four-fold axis). On going from O_h to D_{4h} symmetry the degeneracy of the excited states is partially removed: $T_{2g} \rightarrow B_{2g} + E_g$ and $T_{1g} \rightarrow A_{2g} + E_g$. Therefore the magnetic moment can couple the groundstate to three of the four states; A_{2g} ($\parallel$) and the two E_g ($\perp$) (*cf.* Fig. 1). Because of the different selection rules we would predict the magnetic susceptibility in diamagnetic Co(III) and Rh(III) complexes having tetragonal symmetry to be rather anisotropic.

The actual calculation gives[9] that in O_h symmetry $M^2 = 24\ \hbar^2$ for the $^1A_{1g}$ to $^1T_{1g}$ transition. With no account taken of the interaction between the two E_g states, and with the wavefunctions given by Ballhausen and Moffitt [10] we obtain for D_{4h}: $M^2 = 16\ \hbar^2$ for the transition $^1A_{1g}$ to $^1E_g(T_{1g})$, $M^2 = 8\ \hbar^2$ for $^1A_{1g}$ to $^1A_{2g}(T_{1g})$ and $M^2 = 0\ \hbar^2$ for $^1A_{1g}$ to $^1E_g(T_{2g})$. The energy differences are taken from the absorption spectra [11,12] and hence we can calculate the high-frequency term in the formula. It is interesting to notice that in D_{4h} symmetry the value of the "parallel" high-frequency term is exactly one third of the value for the high-frequency term in O_h symmetry; the denominater in the expression is namely equal for these two transitions [10].

We are interested in the diamagnetic term which can be obtained if the calculated high-frequency term is subtracted from the measured molar susceptibility of the *gaseous* metal-ion. The results are given in Table 1. The measured molar susceptibilities are all taken from Refs. [3,4] and corrected according to the prescriptions given there.

CONCLUSIONS AND DISCUSSION

It is seen from the table that the pure diamagnetic term is highly dependent upon the nature of the various ligands, having a maximum with oxalate and a minimum with cyanide as ligands. This sequence follows the spectrochemical series very closely. According to the crystal field theory we would

expect the diamagnetic term to be nearly independent of the nature of the different ligands. As this is not the case we must conclude that the complexes under consideration have at least partially "covalent" bonds. This result must then of course be taken into consideration in a recalculation of the high-frequency term. However, this is estimated to produce only a small correction of the previous calculated numbers, which is unable to change these to any considerable extent.

A reasonable explanation of the table seems thus to be that more and more electrons are donated from the ligands to the metal ion when going from oxalate towards cyanide. Ultimately a closed shell of e_g-electrons may be obtained, having the effect of lowering the diamagnetic term of the gaseous ion. This explanation is confirmed by the value of the diamagnetic term for Zn(II) complexes. Zn complexes have a filled d-shell with virtually no high-frequency term, and these compounds are seen to have a very small diamagnetic term.

Given a hexacoordinated diamagnetic Co(III)- or Rh(III)-complex with two different kinds of ligands, X and Y, placed in this sequence in the spectrochemical series. Then it seems qualitatively possible to explain the found variation [3] of the "paramagnetic increment" with substitution (*cf.* Fig. 2). As the symmetry is lowered from CoX_6 to CoX_4Y_2 and further to CoX_3Y_3 the high-frequency term in Van Vleck's formula must increase, firstly because all the higher levels can be coupled *via L* to the groundstate in the resulting low symmetry and secondly because of the depression in energy of some of the levels. By again increasing the symmetry to CoX_2Y_4 and further to CoY_6 the high-frequency term decreases again. This behaviour is just found for the measured values of the molar susceptibilities of the Co(III) nitro-ammines (Fig. 2). Both NH_3 and NO_2^- have the same value for their diamagnetic corrections so by a comparison of the different compounds this correction does not disturb. Finally we have a higher value of the molar diamagnetic susceptibility in $Co(NO_2)_6^{-3}$ than in $Co(NH_3)_6^{+3}$ because $E_n - E_0$ is greater in the former than in the latter case.

Thus there seems to be a close correspondence between the measured diamagnetism and the amount of electrons donated to the transition metal central ion. The closer the magnetism of the compounds is to that of the corresponding Zn(II) complexes, the more "covalent" they seem to be.

In this note we have followed the usual convention in assuming the diamagnetic susceptibilities of the ligands to remain unaltered by complex formation. This is probably not a very good assumption as the final analysis depends upon differences between numbers of nearly the same order of magnitude. Nevertheless, we feel that the tendency, being also what one would expect from chemical considerations, is too pronounced to be purely accidental.

Insulin Crystals

VI. The Anisotropic Growth of Insulin Crystals

JØRGEN SCHLICHTKRULL

Novo Terapeutisk Laboratorium, Copenhagen, Denmark

Rhombohedral pig insulin crystals are formed in a medium containing Indian ink. Growth of the isolated black crystals is continued in a non-coloured medium. It is observed that insulin is not deposited on three of the faces meeting in one of the obtuse vertices, whereas the three opposite faces move outwards with equal rates of growth. The rate is proportional to $(c_s - c)^2$ where c_s is the actual and c the final insulin concentration of the medium. This anisotropy of growth indicates asymmetry of the atomic configuration within the unit-cell.

The purpose of the present investigation is to examine the linear rates of deposition of insulin on the faces during crystallization. Perfect rhombohedral single crystals are obtained when pure pig insulin is crystallized from a citrate buffer and when beef insulin is crystallized from a buffered solution of sodium chloride [1]. The crystals are geometrically similar, as the faces of a growing crystal remain equal in size. Hence, the dimensions of a crystal may be defined by one parameter only, *e. g.* by the largest diagonal, l, in the crystal projection on a plane through one of the faces [2]. Previous experiments demonstrate that during crystallization in a 7 % saline

$$\frac{dl}{dt} = \text{const.}\ (c_s - c)^2 \qquad (1)$$

where c_s is the actual and c the final concentration of dissolved insulin [3]. The linear rate of growth, dl/dt, was found to be independent of the crystal size.

THEORY

The three faces meeting in one of the obtuse vertices are called A, B and C, and the opposite faces A_0, B_0 and C_0 where A is parallel to A_0, etc. The growth of a crystal proceeds as insulin is deposited on the faces which thereby move outwards in directions perpendicular to the faces. The rates of movement

caused by deposition are h_A, h_{A_0}, etc. Let the distances between parallel faces be a, b and c, respectively. Then the rates of increase of these distances are

$$\frac{da}{dt} = h_a = h_A + h_{A_0} \tag{2a}$$

$$\frac{db}{dt} = h_b = h_B + h_{B_0} \tag{2b}$$

$$\frac{dc}{dt} = h_c = h_C + h_{C_0} \tag{2c}$$

As during growth

$$a = b = c \tag{3}$$

it follows that

$$h_a = h_b = h_c = h = \text{const.} \frac{dl}{dt} \tag{4}$$

where h symbolizes the common rate of increase of the distances between parallel faces. The trigonal symmetry implicates that the atomic structure of the three faces is identical. Hence, it is assumed that

$$h_A = h_B = h_C = H \tag{5}$$

and

$$h_{A_0} = h_{B_0} = h_{C_0} = H_0 \tag{6}$$

It follows from eqns. (2), (4), (5) and (6) that

$$h = H + H_0. \tag{7}$$

EXPERIMENTAL

It has been observed that when small (5 μ) seed crystals are allowed to grow into bigger (30μ) crystals the seed particles remain in one of the obtuse vertices of the growing crystal [4]. If the rate of deposition of insulin is the same on all six faces then the seeds are expected to be enclosed in the center of the crystal. The observation reveals that insulin is not deposited on the three faces meeting in one of the obtuse vertices. This peculiarity of growth has now been substantiated by staining crystals during the first period of their growth. Indian ink is suitable for the purpose as it does not diffuse within the crystal body.

Pork insulin was recrystallized from a medium containing 0.5 % insulin, 0.08 % $ZnCl_2$, 0.05 M sodium citrate, 15 % (v/v) acetone and 1 % (v/v) Indian ink (Pelikan No. 541), pH = 6.3. The clear solution was stirred slowly mechanically. During crystal growth particles of Indian ink became enclosed in the crystal bodies and stained them. The crystals were filtered off and one part allowed to continue growing in a medium of the original composition but without Indian ink. The other part was grown in a crystallization medium containing 1.7 % insulin, 0.014 % Zn^{++} (total Zn), 0.1 M sodium acetate, 7 % NaCl, pH = 5.5. In both cases the weight of stained crystals was 10 % of the weight of insulin present.

Finally, the two crystal suspensions were fixed in gelatine in order to prevent sedimentation of all the crystals on their faces during the microscopical inspection. This revealed that the original black part of the crystal is lying in one of the obtuse vertices of the large crystal and not in the center (Fig. 1).

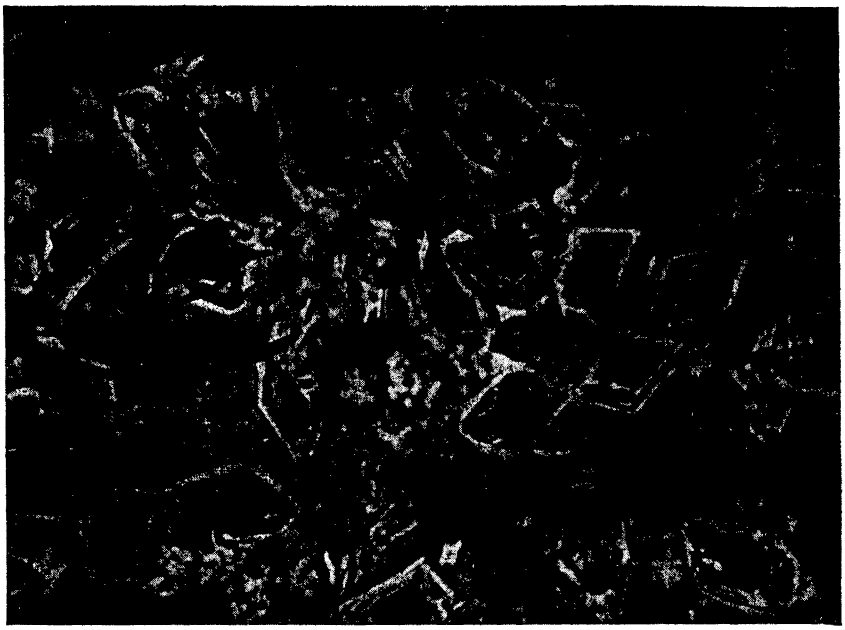

Fig. 1. Stained crystals after growth in saline medium (300 ×).

CONCLUSION

These experiments demonstrate that insulin is only deposited on the three faces meeting in one of the obtuse vertices of the crystal. The linear rate of deposition does not vary between these faces. Thus, in eqn. (7) either H or H_0 is zero. It is concluded that the atomic structure of the three moving faces is different to that of the immobile faces. The structural difference also pertains to the unit-cells as they are all identically orientated within the crystal. In other words, when the unit-cell is turned upside down so as to invert the trigonal axis, it is impossible to obtain the original atomic configuration by rotating about this axis.

Acetic, Propionic and Butyric Esters of 2-Dimethylaminoethanol, 2-Dimethylaminoethanthiol and 2-Dimethylamino-1-methylethanol

L.-E. TAMMELIN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The nine esters corresponding to 2-dimethylamino-ethanol, 2-dimethylamino-ethanthiol, 2-dimethyl-1-methyl-ethanol and acetic, propionic and butyric acid have been prepared and described as ammonium bromides and free amines. The corresponding acid-base pairs have been used for the determination of pK_a.

Esters of dimethylaminoethanol and related compounds are of interest as precursors of the choline esters in preparative work. In synthesis of the choline esters the corresponding tertiary amines are not necessarily prepared in pure form [1]. Some interest has been shown, however, in comparative studies of the tertiary and quaternary compounds in relation to cholinesterase [2,3]. Moreover, the action on the central nervous system of compounds related to the cholinesters but of the tertiary type has received attention. Some modifications of an earlier method for the preparation of choline esters [1] are therefore presented which enable the tertiary amino esters to be prepared.

It has been shown by Wilson [2,5] that the ammonium ester is more easily hydrolyzed by cholinesterases than is the amino ester in the case of dimethylaminoethyl acetate. In a system with a given pH and ionic strength, *e. g.* body fluids, the pK_a governs the quotient (amine) / (ammonium). In view of the probable pharmacodynamic disparity of the amino and ammonium forms, due, *e. g.*, to their different affinities for cholinesterase, the degree of protolysis is obviously of interest. It was therefore decided to determine the pK_a of the esters synthesized.

METHODS

The mode of synthesis followed is esterification of the ethanol or thiol by means of acid anhydride, preliminary purification by distillation and precipita-

2-Dimethylamino-1-methyl-ethanol	152°	165°	185°

tion of the amino ester by hydrogen bromide, recrystallisation or liberation of the free amine and redistillation.

Esterification. One mole of the ethanol or thiol (the thiols were prepared *ad modum* Hansen [4]) derivative is heated on a water bath with 1 mole of acid anhydride overnight. The reaction mixture is distilled. All fractions are collected, up to and including the one at the temperature given in Table 1.

Dimethylammonium ester bromides. The crude distillate from the esterification is diluted six times with anhydrous ether. Hydrogen bromide is bubbled through the solu-

tion until all amine has precipitated. The crude precipitate is recrystallized from dioxan. Thus, a pure preparation is obtained in a yield of about 65 % calculated from the alcohol or thiol. For analytical data see Table 2.

Dimethylamino esters. Sodium hydroxide in water solution is used for liberation of the free amine. Rapid ether extraction, drying of the ether solution with sodium sulfate and distillation under reduced pressure give pure preparations of the amino esters. The yield is about 70 %, calculated from the crude ammonium ester bromide.

Physical data. Densities, refractive indices, boiling points and molar refractions are shown in Table 2. The densities were determined by means of a pycnometer and the refractive index in an Abbe refractometer. Melting points were determined on a "Kofler Heizbank". Molar refractions were calculated from group and atomic refractions given by Vogel [5].

Determinations of pK_a

Due to hydrolysis of the esters, time-consuming methods such as titrations had to be avoided in the pK_a determinations. Determinations of pH in solutions of known ionic strength and concentrations of acid and base were considered to be the best method, especially as both amines and corresponding ammonium bromides had been prepared.

For every compound three solutions were prepared, each about 10^{-3} M with regard to the acid and 0.5×10^{-3} M, 10^{-3} M and 2×10^{-3} M with regard to the base. The solutions were prepared by weighing the compounds and dissolution in deionized water of a known volume. The pH determinations were performed immediately after the dissolution.

The pH meter was a PHM3 Radiometer, Copenhagen, and the electrodes (glass/calomel) were checked against a standard buffer solution of potassium hydrogen phthalate (pH 4.01). Temperature was kept at 25° C.

For calculation of pK_a, the following formula was used:

$$pK_a = pH + \log \frac{(\text{ammonium ion})}{(\text{amine})} + \log f+$$

log $f+$ is defined after Debye-Hückel, and was found to be -0.013.

RESULTS

The ammonium ester bromides are all colorless, water-soluble crystalline compounds. In the case of dimethylaminoethyl thioacetate as ammonium bromide, a faint red discoloration has frequently been observed, the origin of which is unknown. The bromides are more or less hygroscopic, but since this

Table 3.

Alcohol	pK_a		
	Acetic ester	Propionic ester	Butyric ester
Dimethylaminoethanol	8.35 ± 0.01	8.29 ± 0.01	8.31 ± 0.02
Dimethylaminoethanthiol	8.27 ± 0.02	8.28 ± 0.03	8.32 ± 0.03
Dimethylamino-methyl-ethanol	8.32 ± 0.02	8.26 ± 0.01	8.27 ± 0.01

form is fairly easy to handle, it is recommended as the normal one for laboratory work with these compounds. The amino esters are colorless, hygroscopic, water-soluble oils with very characteristic odors. Dimethylaminoethanthiol butyrate, for instance, develops odors combining the impressions of amines, thiols and butyric acid in a most disagreeable way. A hood is recommended while handling these compounds, not only because of the odors but also in view of their toxic effects.

Water solutions of the amino esters show gradual changes in pH due to hydrolysis. Ether solutions react rapidly with methyl iodide and give choline esters in a yield close to 100 %[1,4].

A list of the compounds synthesized, with analytical and physical data, is given in Table 2.

The results of the pK_a determinations are summarized in Table 3. Accuracy is indicated by means of maximum deviations in each group of three determinations.

My sincere thanks are due to Professor G. Ljunggren, Director of this Institute, for his kind interest in this work.

Electroorganic Preparations II. Oxidation of Carbinols

HENNING LUND

Leo Pharmaceutical Products, Copenhagen, Denmark

An anodic voltammetric investigation of about thirty carbinols with a vibrating platinum electrode in acetonitrile containing sodium perchlorate is carried out. The electrode reaction corresponding to the first wave of anisyl alcohol is shown by controlled potential electrolysis to be an oxidation of anisyl alcohol to anisaldehyde.

Organic electrolytic oxidations have not been investigated as much as reductions, and no controlled potential electrolysis of irreversibly oxidizable compounds seems to have been reported, although it is still more important to control the potential in anodic than in cathodic processes in order to get a well defined product.

In this investigation the purpose was to find, from a current-potential curve of a micro electrode, conditions under which carbinols could be oxidized to carbonyl compounds. As the potential of a given electrode reaction found by means of an indicator micro electrode depends upon the electrode material and the medium the first aim was to find a suitable electrode material and reaction medium.

Electrode material. The ideal micro electrode must be unattackable in the potential range used and should be independent of its 'history'. It should be easy to make with a well defined shape and area and should possess a certain mechanical strength, because it is necessary to vibrate or rotate the electrode during the measurements [1].

As cathode the dropping mercury electrode comes very near the requirements, but as mercury is oxidized at a rather low potential its use as an anode is very restricted. It was, therefore, necessary to use a solid micro electrode and the greatest advantage of the mercury electrode — the continual renewal of the surface — is thus lost.

As material for micro electrodes have been described platinum [1,2], gold [2], silver [3], copper [3] and amalgams of these, carbon [2,4], and lead dioxide [2]. Of these lead dioxide, carbon and platinum have been tried in the present investigation.

The lead dioxide electrode was made according to Lord and Rogers [2] and their results that this electrode could only be used within a narrow potential range was confirmed.

The graphite electrodes were made according to Lord and Rogers [2] and Gaylor *et al.*[4] Lord and Rogers coat the graphite electrode with Apiezon W carefully avoiding the Apiezon getting into the pores of the graphite, whereas Gaylor *et al.* impregnate the electrode with wax in such a way that the pores are filled with wax. One advantage of the carbon electrode is that a new surface can easily be produced by breaking off the tip of the electrode. Probably due to insufficient technique in preparing the electrodes the

carbon anodes gave in our hands too high residual currents and this together with the lack of mechanical strength caused us to abandon the carbon electrode as indicator electrode.

Preliminary investigations showed that platinized platinum did not possess advantages in preference to bright platinum so all further experiments were made with a bright platinum micro electrode. It had the required features, except that the surface could not easily be renewed, but as the main purpose was not analytical but to find the potential at which the electrode reaction took place this shortcoming was not deemed serious. In some cases it could even be an advantage as the electrode showed deformed curves in the cases, where the reaction products were ill-defined and tar-like.

Solvent. The solvent must not be oxidized in the potential range used, should have a high dielectric constant to diminish the resistance of the cell, be able to dissolve organic molecules as well as inorganic salts, and to take up and give off protons readily. It should be easily purified and not too expensive. The following solvents were tried: water, *t*-butanol, acetone, nitromethane, ethyleneglycol dimethylether, and acetonitrile.

Water evolves oxygen at the anode at too low potentials and this is also the case in mixtures with dioxan. *t*-Butanol has a rather low dielectric constant and its ability to dissolve inorganic salts is very limited. Nitromethane has a high dielectric constant, but a poor dissolving power for inorganic salts.

Acetone has some advantages, but as it is rather difficult to remove water and methanol to the required extent and as the current-potential curves were somewhat deformed in acetone this solvent was abandoned. Ethyleneglycol dimethylether was not found suitable as it was difficult to remove the monomethyl ether to a satisfactory degree.

Acetonitrile which was chosen as the solvent has a high dielectric constant, a good dissolving power for organic compounds and for some inorganic salts and is usable within a wide potential range. Its most serious shortcoming is its poor protolytic properties which make a buffering of the system difficult. The low protolytic capacity is not felt as much in the voltammetric investigations, where the number of reacting molecules is rather low, as in the preparative oxidations, where it is necessary to add a proton acceptor.

Supporting electrolyte. An indifferent supporting electrolyte is required to conduct the current in the solvent. Iodide, bromide, and chloride ions are oxidized at rather low potentials, nitrate a little higher, but only perchlorates were found satisfactory. Silver perchlorate and sodium perchlorate, for instance, are very soluble in acetonitrile giving solutions with a low resistance, and anhydrous sodium perchlorate in anhydrous acetonitrile is not attacked anodically until a potential at about 2.2 V *vs* the silver ion/silver electrode.

Reference electrode. The silver/silver chloride electrode in acetonitrile has been investigated by Ulich and Spiegel [5,6] who found it reproducible within 0.1 mV. The silver ion/silver electrode was found by Pleskow [7] to be reproducible within 0.1 mV. Although both electrodes were found satisfactory the latter was preferred, because it was necessary to keep the former in a separate compartment, as the chloride ions were oxidized at a too low potential. The silver ions were only in special cases undesirable in the anode compartment.

RESULTS

In Table 1 are given the half-wave potentials of a number of aromatic alcohols and one aldehyde. For the compounds giving deformed waves is given the 'half-peak' potential. All the potentials are measured against the 0.1 N silver ion/silver electrode and the half-wave potentials are corrected for iR drop in the solution. The potentials are measured in solutions containing the oxidizable compound in concentrations 10^{-4}—10^{-3} M with a voltage scanning rate of about 200 mV/min.

In the first column is given the compound, in the second one the half-wave potential and in the third one the shape of the current-voltage curve. 'Normal' means that the curve is S-shaped without peak, whereas 'deformed' indicates the appearance of a peak on the curve. Curves taken successively in

the same solution of a compound giving deformed curves are not identical, unless the electrode is cleaned in between. The fourth column gives the half-wave potential of a second wave and the fifth one the shape of this wave.

DISCUSSION

In comparing the half-wave potentials of different compounds it must be remembered that empirical rules of any significance can only be expected when the reaction mechanisms are the same and when factors as energy of activation vary only slightly. As the half-wave potentials of the carbinols are closely related to those of the parent compounds a discussion of the half-wave potentials will be postponed to a later communication.

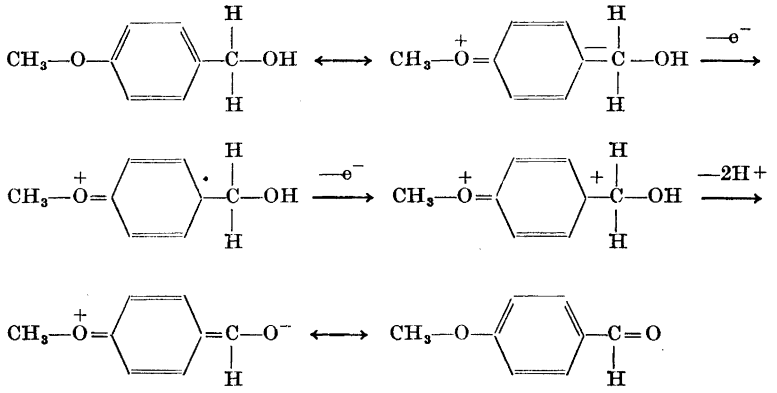
It is seen from Table 1 that the investigated compounds can be divided into three groups, the first one containing alcohols giving a normal voltammetric curve, the second group carbinols giving deformed waves and the third one not participating in any electrode reaction in the experimentally accessible potential range.

Primary alcohols of the first group show two waves unless the first wave occurs at a potential so positive that a possible second wave would be expected to occur outside the accessible potential range. It seems natural to assume that the electrode reaction corresponding to the first wave is a two electron oxidation of the carbinol to a carbonyl compound, and that the electrode reaction corresponding to the second wave is a two electron oxidation of the aldehyde to the oxidation state of a carboxyl compound.

This assumption is confirmed by the following facts. Hydroquinone and *p*-methoxybenzyl alcohol give nearly the same wave height in the same molar concentration. The molecular weight and thus the diffusion coefficient are nearly the same for both compounds, and as hydroquinone is oxidized in a two electron electrode reaction it is very likely that the same is true for anisyl alcohol. That the wave height of anisyl alcohol is diffusion-controlled is qualitatively shown by the fact that the wave height increases when the amplitude of the vibration increases. Furthermore, anisaldehyde gives a wave with very nearly the same half-wave potential as the second wave of anisyl alcohol.

Although these facts are suggestive a proof of the course of the electrode reaction can only be obtained from a preparative oxidation at a suitable potential and, as will be mentioned later, the preparative oxidation showed that the electrode reaction corresponding to the first wave was indeed an oxidation of the carbinol to a carbonyl compound.

No preparative oxidations have been performed at potentials more positive than the half-wave potential of the second wave and no conclusive evidence of the course of the reaction can be given here. From the height of the wave it is known that it is a two electron oxidation, but as no oxygen is present in the deaerated solution except in the perchlorate ions the formation of a carboxyl group is dubious.



Addition of anhydrous perchloric acid in acetonitrile (from 100 % H_2SO_4 and $Ba(ClO_4)_2$) does not affect the half-wave potential of anisyl alcohol, whereas addition of pyridine lowers the half-wave potential from 0.05 to 0.1 V. The second wave of anisyl alcohol (and that of anisaldehyde) disappears on addition of pyridine.

Carbinols giving waves with half-wave potentials below + 1.65 V are not affected by the presence of silver ions, whereas carbinols having half-wave potentials at higher potentials or not producing any wave in the accessible potential range in the presence of silver ions produce a wave about + 1.69 V. The nature of this wave is not known.

The carbinols giving deformed waves with peaks are not oxidized to the carbonyl compounds, but yield unidentified products which cover the electrode with a visible, black layer. The electrode is thereby insulated from the solution and as the current is inversely proportional to the resistance of the cell it drops, giving the current-voltage curve its characteristic peak. At low concentrations the curves are more normal because the electrode is not covered com-

pletely with the reaction product during the voltammetric measurement. More often than not the electrode could be cleaned by wiping off the black layer, but in some cases it was necessary to burn it off.

As will be shown in later communications on electrolytic oxidation of hydrocarbons, heterocyclic compounds, phenols, and amines, it is likely that the primary step in the electrode reaction is a loss of an electron from the aromatic system. The radical formed is stabilized by the removal of a second electron and two protons after the following outline which gives a possible route for the oxidation of anisyl alcohol. Not all the resonance possibilities of the radicals are given.

It is essential for the formation of an aldehyde that the radical is stable long enough for the removal of two protons from the carbinol carbon atom and that seems to require that the electron deficiency is localized during a considerable time at the carbon atom next to the carbinol carbon atom.

This is illustrated strikingly in the cases of α- and β-naphthyl carbinol, p- and m-methoxybenzyl alcohol and fluorenol. Whereas α-naphthyl carbinol produces two normal waves β-naphthyl carbinol gives only one slightly deformed wave. The methoxybenzyl alcohols give the same picture. The p-isomer gives two normal waves, the o-isomer one normal and one with a smaller wave height than corresponding to a two-electron oxidation and the m-isomer produces only one normal wave. Fluorenol gives a very pronounced peak.

The difference between α- and β-naphthyl carbinol is, according to the explanation given above, due to the wellknown fact that there are more resonance possibilities where the electron deficiency is in the α-position than in the β-position, but as the difference in resonance possibilities between the α- and the β-position is not great, the tendency of the β-naphthyl carbinol to produce a deformed wave is not pronounced. In fluorenol, however, where the probability of an electron deficiency at the carbon atoms neighbouring the 9-position is very low, the chances of getting the carbinol oxidized to a carbonyl compound are few. The oxidation takes place in some other part of the molecule (probably in the 2 and 7 positions) and it seems likely that the polymerization product thus formed would be ill-defined and tar-like, thus explaining the great tendency of fluorenol to produce deformed curves.

PREPARATIVE OXIDATIONS

The controlled potential anodic electrolysis was undertaken in order to prove the course of the electrode reaction corresponding to the first wave in the voltammetric diagram. As representative for the first group was chosen anisyl alcohol, for the second group giving deformed voltammetric curves fluorenol and as a compound between the first and the second group β-naphthyl carbinol.

When anisyl alcohol was oxidized in a medium of 0.5 M sodium perchlorate in acetonitrile at an anode potential about + 1.35 V only about 5 % of the theoretical amount of electricity was consumed and no carbonyl compounds could be detected in the reaction medium. When the same medium, however, contained a proton acceptor as pyridine in a concentration sufficiently high to combine with all the protons formed in the electrode reaction the consumption of electricity was nearly theoretical and anisaldehyde could be isolated in a yield of 72 % as its 2,4-dinitrophenyl hydrazone. As proton acceptor pyridines or quinolines could be used, but not aliphatic or aromatic amines, as they themselves gave off electrons at a potential lower than the half-wave potential of anisyl alcohol.

Oxidation of fluorenol in acetonitrile yielded both in the absence and presence of pyridine a black, insoluble tar which covered the electrode in a very short time. No fluorenone could be detected in the tar or in the solution.

Neither did β-naphthyl carbinol yield its aldehyde on electrolytic oxidation at +1.40 V, but the covering of the electrode was slower than in the case of fluorenol.

EXPERIMENTAL

Apparatus. For the voltammetric investigation a Sargent-Heyrovsky photographic recording polarograph Model XII was used. The electrode potential was controlled by a Lingane-Jones potentiostat [8]. The coulometer used was an electromechanical current integrator [9].

The construction of the platinum micro electrode is shown in Fig. 1. The electrode tip is a platinum wire 4.0 mm long with a diameter of 0.5 mm. The vibrator was manufactured by Fisher Scientific Company, Switzerland. The advantages of this electrode are its simplicity in construction and absence of rotating parts, which makes the exclusion of oxygen easy. It has the disadvantage that the amplitude of the vibration is difficult to measure exactly, and for analytical purposes the rotating electrode is more appropriate.

The electrolysis cell was similar to that used in Part I [10]. The reference electrode was a silver wire in a 0.1 M silver perchlorate and 0.5 M sodium perchlorate solution in acetonitrile separated from the test solution by a fritted glass diaphragm.

Materials. The *acetonitrile* (Eastman, white label) was purified according to Walden and Birr [11]. The acetonitrile purified in this manner shows less infra-red absorption than Eastman's 'Spectro grade' acetonitrile. The pure acetonitrile is only slightly hygroscopic and can be stored for a month in a flask equipped with an effective drying tube.

The *acetone* was purified according to Livingstone [12].

Sodium perchlorate (Riedel-de-Haën, p.a.) was dried without further purification at 145°—150° for 24 h and finally in vacuum over P_2O_5 at 150°. As the dry product is very hygroscopic it was stored over P_2O_5.

Silver perchlorate. To a stirred solution of 24.5 g dry sodium perchlorate in 100 ml acetonitrile is added drop by drop a solution of 34 g silver nitrate in 100 ml acetonitrile. The precipitate of sodium nitrate is filtered off, the solution evaporated to 50 ml and

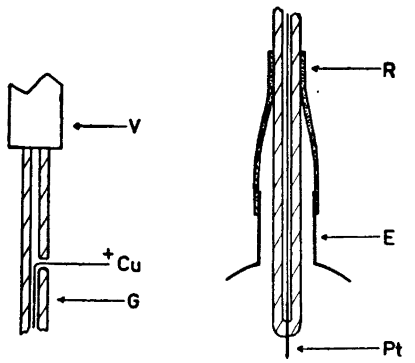


Fig. 1. Vibrating platinum electrode. V is a vibrator, Cu a copper wire soldered to the platinum wire Pt. G is a glass capillary tube, R a rubber tube, and E the electrode chamber.

traces of sodium nitrate are removed by centrifuging. On addition of dry ether the silver perchlorate is brought to crystallization. The crystals are washed with a mixture of ether and acetonitrile, 1:1, and dried in vacuum. The composition of the crystals correspond to $AgClO_4$, 3 CH_3CN (found: Ag 31.5, Calc. for $C_6H_9N_3AgClO_4$: Ag 32.6). On heating, the crystals dissolve in their acetonitrile. If this acetonitrile is evaporated at elevated temperature a solid cake of silver perchlorate remains, which is known [13] to be explosive. The crystals containing acetonitrile were, therefore, used and the solutions were made up according to the silver analysis.

The following carbinols were prepared *from the corresponding acids or acid derivatives* by reduction with $LiAlH_4$: IV, m.p. 61° (59.5°—60° [14]); V, m.p. 81° (80.5° [15]); X, m.p. 72° (72°—73° [16]). *From the carbonyl compounds* by reduction with $LiAlH_4$: XIX, m.p. 154° (155°—56° [17]); XXIII, m.p. 85° (84°—86° [18]); XXV, m.p. 68° (68° [20]). From the carbonyl compounds by reduction with aluminium isopropoxide: VI, m.p. 71.5° (71°—72.5° [20]); VII, b.p. 128°—30°/10 mm (242° [21]); VIII, m.p. 69.5° (70° [21]); IX, m.p. 76° (76°—76.5° [20]); XVIII, m.p. 71° (71° [22]); methyl *p*-iodophenyl carbinol, m.p. 52°—52.5°, has not been described before. It was recrystallized from heptane. (Found: C 38.71; H 3.79; I 51.00. Calc. for C_8H_9OI: C 38.76; H 3.66; I 51.13); XX, m.p. 161° (161°—62° [23]).

From a carbonyl compound and a Grignard compound: XVI, b.p. 84°—88°/1 mm (87°—89°/2 mm [24]); XV, b.p. 105°—10°/10 mm (95°/1 mm [25]); XXI, m.p. 66° (65°—66° [26]).

XI, m.p. 59° was made according to Ref.[27]; XXIX, m.p. 136° according to Ref.[28]; XXX, m.p. 102° according to Ref.[29].

Electrolytical oxidation of anisyl alcohol. 35 ml 0.5 N sodium perchlorate in acetonitrile were deaerated with purified nitrogen [30] and oxidizable impurities were removed by electrolysis at an anode potential of +1.50 V. When the current had reached a stationary value (residual current) 59.3 mg (0.43 mMole) of anisyl alcohol and 106.5 mg (1.35 mMole) of pyridine were added and the carbinol was oxidized at an anode potential of +1.35 V *vs.* the 0.1 N silver ion/silver electrode. The platinum anode had an area of 10 cm^2; the initial current was 60 mA and decreased in the course of 5 h to about 1 mA. The amount of electricity used was, after correction for residual current, 81 coulombs (theoretically 82 coulombs for 100 % oxidation).

4 ml of the anode chamber solution was evaporated and the residue extracted with carbon tetrachloride. An infra-red spectrum of this solution was identical with that of actual anisaldehyde in carbon tetrachloride. The rest of the anode solution was evaporated through a small column and the residue dissolved in ethyl alcohol. The carbonyl compound was precipitated as its 2,4-dinitrophenyl hydrazone. After recrystallization from xylene were obtained 89 mg (m.p. 249°—51° (253°—54° [31]). The 89 mg (plus those from the test) correspond to a yield of 72 % of anisaldehyde, but the actual yield may have been somewhat higher.

This investigation was carried out at the Chemistry Department of Harvard University, Cambridge 38, Mass. 1954—1955. The author wishes to express his thanks to Dr. L. F. Fieser and Dr. J. J. Lingane for their kind interest and for many facilities which have been put at his disposal.

Studies on Carbamates

XII. The Carbamates of the Butylamines

MOGENS BALLUND JENSEN

The Royal Danish School of Pharmacy, Copenhagen, Denmark

The velocity constants for the reaction "amine + CO_2 → carbamic acid" and the equilibrium constants for the equilibrium "carbamate$^-$ + + $H_2O \rightleftharpoons HCO_3^-$ + amine" have been determined for *n*-, *sec.*-, *iso*-, *tert.*-, di-*n*- and di-*iso*-butylamine. Di-*sec.*-butylamine and carbon dioxide form no carbamate in aqueous solution. Di-*tert.*-butylamine could not be prepared.

1. The velocity constant for the reaction "amine + CO_2 = carbamic acid" and the equilibrium constant for the reaction "carbamate$^-$ + H_2O = HCO_3^- + amine" have been determined for the following amines:

1) $CH_3 \cdot CH_2 \cdot CH_2 \cdot CH_2 \cdot NH_2$	*n*-butylamine
2) $CH_3 \cdot CH_2 \cdot CHCH_3 \cdot NH_2$	*sec.*-butylamine
3) $(CH_3)_2CH \cdot CH_2 \cdot NH_2$	*iso*-butylamine
4) $(CH_3)_3C \cdot NH_2$	*tert.*-butylamine
5) $(CH_3 \cdot CH_2 \cdot CH_2 \cdot CH_2)_2NH$	di-*n*-butylamine
6) $(CH_3 \cdot CH_2 \cdot CHCH_3)_2NH$	di-*sec.*-butylamine
7) $((CH_3)_2CH \cdot CH_2)_2NH$	di-*iso*-butylamine

but not for

8) $((CH_3)_3C)_2NH$	di-*tert.*-butylamine

the synthesis of which failed although several attempts were made.

The experimental and theoretical conditions are analogous to those of the carbamates previously investigated. Detailed information concerning the method of analysis, theory, significance of constants *etc.* is to be found in previous papers [1].

2. The butylamines were purified by distillation through wire gauze columns. The fractions employed for the experiments had the following boiling points: No. 1 (commercial product): 77.4° C (764 mm Hg); No. 2 (prepared by the author): 63.4—63.8° C (768 mm Hg); No. 3 (Eastman Organic Chemicals): 67.6° C (755 mm Hg); No. 4 (Light and Co. Ltd.): 43.8—44.1° C

(749 mm Hg); No. 5 (commercial product): 159.8—160.3° C (765 mm Hg); No. 6 (Light and Co. Ltd.): 136.0—136.8° C (760 mm Hg) and No. 7 (FLUKA AG.): 140.5—140.6° C (765 mm Hg).

Sec.-butylamine was prepared from methyl ethyl ketoxime by reduction with metallic sodium. The oxime was prepared from hydroxylamine hydrochloride and methyl ethyl ketone [2].

3. An attempt to prepare the carbamate of amine No. 6, *i. e.* di-*sec.*-butylamine, was unsuccessful whereas the carbamates of the other six amines were prepared not only in solution but also as solids in the following manner:

A small portion, *viz.* about 2 ml of butylamine was distributed on the inner surface of a 300 ml Erlenmeyer-flask and carbon dioxide was lead into the flask whereby a white compound was formed; a little more amine was added followed by further carbon dioxide *etc.*

The content of amine in the compounds was determined by acidimetric titration. The content of carbon dioxide was determined by acidimetric titration of the barium carbonate formed when the carbamate was dissolved in a solution of sodium hydroxide and barium chloride and then heated.

The analysis gave the following results. In the case of the four primary amines, *i. e.* Nos. 1, 2, 3 and 4, a content of 76.7 %, 75.0 %, 76.6 % and 76.7 % amine, respectively, was found; the content of carbon dioxide was found to be 23.8 %, 22.0 %, 22.9 % and 23.0 %, respectively. These results correspond to the formula $C_4H_9NHCOOH_3NC_4H_9$ (theoretical values: 76.9 % amine and 23.1 % carbon dioxide).

In the case of di-*n*-butylamine, *i. e.* No. 5, a content of 85.4 % of amine and 14.0 % of carbon dioxide was found. This corresponds to a formula analogous to the above, *viz.* $(C_4H_9)_2NCOOH_2N(C_4H_9)_2$ (theoretical values: 85.4 % amine and 14.6 % carbon dioxide).

In the case of di-*iso*-butylamine, *i. e.* No. 7, a content of 81.2 % amine and 18.5 % carbon dioxide was found. This would be in accordance with the formula $(C_4H_9)_2NCOOH_2N(C_4H_9)_2$, $(C_4H_9)_2NCOOH$ (theoretical values: 81.5 % amine and 18.5 % carbon dioxide).

The solutions of the aminium carbonate, $(AmH)_2CO_3$, were prepared by mixing equivalent amounts of solutions of aminium chloride and sodium carbonate.

4. All the experiments were carried out at 18° C, and the velocity constants were calculated by means of Briggs' logarithms, the unit of time being the minute. As in previous investigations, the activity coefficient f for a monovalent ion was calculated from Bjerrum's expression $-\log f = 0.3 \sqrt{c_{ion}}$. The data presented in the later tables are corrected for blank values, *viz.* 1—5 units of the percentage.

5. Hall and Sprinkle [3] have found the dissociation constants for *n*-butylaminiumion and di-*n*-butylaminiumion at 18° C to be $10^{-10.76}$ and $10^{-11.46}$, respectively. Bredig's [4] corrected values for the dissociation constants for *sec.*-butylamine, *iso*-butylamine, *tert.*-butylamine and di-*iso*-butylamine at 25° C are $10^{-3.44}$, $10^{-3.58}$, $10^{-3.55}$, and $10^{-3.41}$, respectively. As the heat effect of the reactions is very slight, these values may also be used for 18° C. The value of K_{H_2O} was fixed at $10^{-14.22}$.

* Found by analysis: 29 and 43 %, respectively. The listed values are corrected to zero time.

On the reaction 'amine + carbon dioxide → carbamic acid'

500 ml of an aqueous solution containing both amine and sodium hydroxide were placed in a 2 litre flask. Approximately 250 ml of carbon dioxide were substituted for an equal amount of atmospheric air in the gas phase above this solution, and the flask was shaken vigorously for about 2 min to obtain absorption of the carbon dioxide.

The experimental results for the addition of carbon dioxide to the amines together with the calculated velocity constants are listed in Table 1. Since the carbamate of *tert.*-butylamine is very rapidly decomposed it was found necessary to delay the conversion to carbonate by the addition of dimethylamine immediately after the shaking with carbon dioxide. If the solution is made 0.5—1 M with regard to dimethylamine, about 98 % of the carbon dioxide dissociated from the carbamate of *tert.*-butylamine is converted into the carbamate of dimethylamine, which decomposes very slowly into carbonate [5]. Nevertheless, some decomposition takes place during the 1—2 min which elapse between the shaking with carbon dioxide and the addition of dimethyl-

[a] The solution was 0.1 M with regard to $NaHCO_3$ corresponding to $c_{HCO_3^-} = 0.10$.
[b] Calculated from the data on the decomposition of the carbamate, see Table 3.
[c] The solution was 0.012 M with regard to $NaHCO_3$ corresponding to $c_{HCO_3^-} = 0.012$.

amine; the listed values are corrected to zero time on the basis of the velocity constants determined in section IV.

It is seen from Table 1 that no carbamate was found in the case of di-*sec.*-butylamine, nor was it found in another experiment where a solution containing only the amine (0.04 M), but no sodium hydroxide, was shaken with carbon dioxide. In connection with this it should be mentioned that di-*iso*-propylamine does not react with carbon dioxide in aqueous solution either [6].

The low value of $k_{CO_2 \cdot Am}$ for *tert.*-butylamine compared to that of other primary alifatic amines should also be noted.

No experiments as already mentioned, were carried out with di-*tert.*-butylamine, but since neither di-*iso*-propylamine nor di-*sec.*-butylamine form carbamates in aqueous solution a similar passivity towards carbon dioxide is to be expected in the case of di-*tert.*-butylamine.

The equilibrium 'carbamate ⇌ carbonate'

In some cases experiments have been carried out from the carbamate side and from the carbonate side, in other cases from the carbonate side only.

Table 2 shows the composition of the equilibrium solutions and the equilibrium constant, K_{Eq}, for the reaction 'carbamate$^-$+H_2O=HCO_3^-+amine'.

It is seen from Table 2 that measurable amounts of carbamate are formed in the experiments with *n*-butylamine, *sec.*-butylamine, *iso*-butylamine, and di-*iso*-butylamine while only small amounts are formed in the case of *tert.*-butylamine. No detectible amounts of carbamate were found in the experiment with di-*sec.*-butylamine.

In the experiments with di-*n*-butylamine it was not possible to obtain more than a few per cent of carbamate, the amine being slightly soluble in water, *i. e.* the solution was only about 0.02 M with regard to amine.

In the case of *tert.*-butylamine and di-*n*-butylamine the value of K_{Eq} was not calculated from the experiments on equilibrium but this value was obtained in another way, *viz.* indirectly from the data on the velocity of the decomposition of the carbamates in strong alkaline solution, see next section.

The velocity of the conversion 'carbamate → carbonate'

The decomposition, in alkaline medium, of the carbamates of the amines previously investigated may be explained by assuming that the decomposition is a two-stage reaction, *viz.*

$$\text{carbamate} = \text{amine} + \text{carbon dioxide}$$
$$\text{carbon dioxide} = \text{carbonate}$$

and the velocity constants may be calculated from the expression

$$k_{\text{amate}} = \frac{k_{CO_2 \cdot Am} \cdot K_{Eq} \cdot K_{H_2O} \cdot \frac{1}{K_{CO_2}}}{c_{OH^-} + \frac{k_{CO_2 \cdot Am}}{k_{CO_2 \cdot OH}} \cdot c_{Am}}$$

On the assumption that there is the same two-stage reaction for the decomposition of the carbamates of the butylamines it is possible to calculate, in advance, the velocity constants in the case of *n*-butylamine, *sec.*-butylamine, *iso*-butylamine and di-*iso*-butylamine. The experiments on the decomposition of the carbamates in alkaline medium together with the calculated values of k_{amate} are listed in Table 3. Considering the nature of the experimental conditions the agreement may be described as rather satisfactory.

In the case of *tert.*-butylamine and di-*n*-butylamine the value of K_{Eq} was then calculated from the experimental value of k_{amate} by means of the above expression. The values of K_{Eq} determined in this way correspond to a theoretical content of less than 1 % and 2.6 % carbamate, respectively, in the experiments on equilibrium with *tert.*-butylamine and di-*n*-butylamine (Table 2).

As seen from Table 3 the carbamate of *tert.*-butylamine is rapidly decomposed. The experiments were carried out in such a way that 100 ml of the solution under investigation were quickly adjusted to 0.5—1 M with regard to dimetylamine and the time was noted; on addition of dimethylamine the conversion of carbamate to carbonate was brought to a standstill.

The author wishes to express his sincere thanks to Professor, dr.phil. Carl Faurholt, Head of the Department of Inorganic Chemistry, for his very kind interest in this work.

Isolation of 2-L-Amino-3-hydroxy-1-propane Sulphonic Acid from *Polysiphonia fastigiata*

BÖRJE WICKBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The low-molecular weight internal salts and carbohydrates from the red alga *Polysiphonia fastigiata* have been investigated. A new internal salt, shown to be 2-L-amino-3-hydroxy-1-propane sulphonic acid, and in addition mytilitol, laminitol, mannitol and a glycosidic compound were isolated.

It has recently been shown that taurine and certain N-substituted taurine derivatives [1,2] seem to be common constituents of the red algae. The red alga *Polysiphonia fastigiata*, *Florideae*, order *Ceramiales*, from which dimethyl-β-propiothetin chloride [3] and 2-D-glyceric acid α-D-mannopyranoside [4,5] have previously been isolated, has now been found to contain an internal salt, 2-L-amino-3-hydroxy-1-propane sulphonic acid (I), together with scyllitol, mytilitol, laminitol, mannitol and a new glycoside which is non-reducing and has the chromatographic properties of a disaccharide.

I

While scyllitol occurred only in very small quantities the amount of mytilitol found makes it most probable that this compound originates from the alga itself. The red algae *Gelidium cartilagineum* [1] and *Gigartina leptorhynchos* [2] gave mytilitol in very small quantities only and since it has been isolated from the blue mussel *Mytilus edulis* it was supposed that it might come from contaminating invertebrates in the samples extracted.

The isolation of laminitol and mannitol support earlier findings [6] that these substances are common in the red as well as in the brown algae.

The mannitol mother liquors, which contained mannitol and compounds with lower R_F-values, were hydrolysed yielding a mixture containing only traces of reducing sugar. The hydrolysate was acetylated and the acetates subjected to paper chromatography in a methyl sulphoxide-petroleum ether system [7]. The presence of mannitol, laminitol and mytilitol was indicated but only traces of sorbitol and no dulcitol.

The new internal salt can formally be derived from D-cysteic acid by reduction of the carboxyl group and therefore the name D-cysteinolic acid is suggested for the compound. It seemed to travel a little slower than taurine both on a carbon column and on paper chromatograms run in ethyl acetate-acetic acid-water (3:1:1). The compound could be detected on paper chromatograms by spraying with ninhydrin reagent but rather strong heating was required to produce the colour. When the silver nitrate-sodium ethoxide reagent was used the substance first appeared as a lighter spot which darkened only after several hours.

After purification by adsorption on Amberlite resin IR 400 in the OH-state and subsequent elution with dilute acetic acid and recrystallisation, the compound had m. p. 279—282° (decomp.), $[\alpha]_D^{23} + 7°$ (water) and gave an analysis which agreed fairly well with the composition $C_3H_9NO_4S$. A sample was oxidised with sodium periodate in aqueous solution. The mixture was buffered with sodium bicarbonate; potassium iodide and sodium arsenite solutions were added, and the excess arsenite titrated with iodine solution. No sharp endpoint could be detected, indicating that some reaction between iodine and the oxidised compound was occurring. Instead the periodate consumed was determined by the addition of potassium iodide and hydrochloric acid to the oxidation mixture and titration with sodium thiosulphate. A periodate consumption of 1 mole was indicated. One mole of formaldehyde determined as the dimedon complex was liberated.

These facts are in accordance with the formulation of the internal salt as 2,3-(amino-hydroxy-)-1-propane sulphonic acid, which upon periodate oxidation should give formylmethane sulphonic acid; this would be expected to undergo further oxidation. By analogy with the naturally occurring L-cysteine and L-cysteic acid the structure 2-D-amino-3-hydroxy-1-propane sulphonic acid seemed to be the most probable for the compound, and L-cysteinolic acid was therefore synthesised from L-cysteine. The latter was benzylated, the S-benzyl cysteine esterified with ethanol and the ethyl ester reduced to S-benzyl cysteinol. After removal of the benzyl group the cysteinol was oxidised with bromine in acid aqueous solution. From the reaction product a compound was isolated in 24 % yield based upon S-benzyl-L-cysteine, which was the only crystalline intermediate. It had the same melting point (279—281°) and chromatographic behaviour as the internal salt from the alga, but the opposite optical rotation, $[\alpha]_D^{23} -6°$ (water); the mixed melting point of the two compounds showed a strong depression. As the X-ray diffraction patterns of the natural and synthetic materials were identical it follows that the internal salt from the alga is D-cysteinolic acid and thus configurationally related to the rare D-amino acids. It is also of interest that neither taurine nor its derivatives have been found in amounts sufficient to permit their isolation.

EXPERIMENTAL *

The alga (360 g) was extracted continuously with ether for 3 days and then with methanol for 14 days. The methanol extract was concentrated *in vacuo*, the residual syrup stirred with water and the aqueous solution after filtration passed through Amberlite IR 120 and IR 4B and then concentrated to dryness yielding a syrup (9.9 g). After standing for two months the syrup was dissolved in ethanol-water (50 %) depositing crystals which were removed (Fraction 1). The filtrate was passed through a layer of decolorising carbon, concentrated to dryness, the residue dissolved in water (150 ml) and this solution added to the top of a carbon-Celite column (1:1, 35 × 4.5 cm). The column was first eluted with water (2 000 ml) and then with dilute ethanol the concentration of which was linearly increased (0—30 %, 4 000 ml). Fractions were collected automatically and investigated by paper chromatography using as solvent ethyl acetate-acetic acid-water (3:1:1). As it turned out that the sample had not been completely deionised before being put on the column, the appropriate fractions were combined and filtered through Amberlite IR 120 and IR 4B.

Fraction No. 1 contained a mixture of cyclitols.

Fraction No. 2 contained D-cysteinolic acid in addition to traces of compounds with the R_F-values of glycerol, volemitol and scyllitol.

Fraction No. 3 contained D-cysteinolic acid and mytilitol.

Fraction No. 4 contained laminitol and traces of D-cysteinolic acid.

Fraction No. 5 contained small amounts of mannitol and traces of laminitol.

Fraction No. 6 contained mannitol.

Fraction No. 7 contained mannitol and traces of compounds with lower R_F-values.

The next fractions contained small amounts of several compounds with the chromatographic characteristics of non-reducing disaccharides. Hydrolysis yielded mixtures which on paper chromatograms gave spots for galactose, glucose and glycerol. The following fractions were more closely examined:

Fraction No. 8 gave one principal spot with the R_F-value of α,α-trehalose. A hydrolysed sample gave one strong spot for glucose and two faint spots for galactose and glycerol in a butanol-pyridine-water (3:1:1.5) solvent.

Fraction No. 9 contained several components one of which, with a low R_F-value, predominated. After hydrolysis, a sample run in the butanol solvent gave spots with the R_F-values of galactose and glycerol.

As only traces of reducing sugars could be present, the above fractions were further purified by treatment with Amberlite IR 400 in the OH-state to remove internal salts. These were recovered by elution of the ion exchanger with 5 % acetic acid.

Carbohydrates. After combining the appropriate fractions, purification by chromatography on carbon and recrystallisation gave the following carbohydrate compounds:

Scyllitol (9 mg) from fractions 1 and 2, m. p. 300° (decomp.), acetate m. p. 275—280°;

Mytilitol (150 mg) from fractions 1, 3 and 4, m. p. 266—269°, acetate m. p. 186—188°, undepressed on admixture with mytilitol hexaacetate;

Laminitol (213 mg) from fraction 1 and 4, m. p. 270—274°, acetate m. p. 155—157°, alone or admixed with authentic laminitol;

Mannitol (108 mg) from fractions 5, 6 and 7, m. p. 160—162° alone or admixed with an authentic sample of D-mannitol;

Unknown compound (60 mg) from fraction 8. It was chromatographically similar to α,α-trehalose and gave a strong glucose spot after hydrolysis. After standing for several months the syrup has started to crystallise.

Unknown compound (200 mg) from fraction No 9, m. p. 196—198°, $[\alpha]_D^{23}$ +88° (water, $c = 1.8$). After a sample had been hydrolysed in 0.2 N HCl at 108° for 14 h a strong spot, indistinguishable from that of galactose, and a rather faint spot with the R_F-value of glycerol were obtained on chromatograms run in butanol-pyridine-water (3:1:1.5). This substance will be further investigated.

The mannitol mother liquors from fractions Nos. 6 and 7 could also contain other hexitols as well as mannitol and on paper chromatograms they gave additional spots with

* All melting points are corrected.

lower R_F-values. They were hydrolysed in 0.2 N HCl at 100° over night. Paper chromatograms of the hydrolysate showed 2 strong spots with the R_F-values of a hexitol and a C-methyl cyclitol, while only traces of reducing sugars were detectable. A sample of the mixture was acetylated, and the acetates subjected to paper chromatography on Whatman No. 1 filter paper impregnated with methyl sulphoxide, using petroleum ether (b. p. 65—75°) or petroleum ether-*iso*propyl ether (1:2) as the mobile phase. The chromatograms were afterwards soaked with dilute silver nitrate solution (saturated solution-water 1:100), dried and sprayed with 1 N NaOH in ethanol. Mannitol and laminitol were indicated together with traces of sorbitol but no dulcitol.

Internal salts

From fractions Nos. 2, 3 and 4 only, an internal salt was obtained in appreciable amounts (325 mg), m. p. 270—275°. After adsorption on Amberlite IR 400 in the OH-state, elution with 5 % acetic acid and recrystallisation from dilute ethanol it had m. p. 279—282° (decomp.) and $[\alpha]_D^{23}$ + 7° (water, c = 2.0). (Found: C 23.6; H 5.88; N 8.27; S 18.0. Calc. for $C_3H_9NO_4S$: C 23.2; H 5.85; N 9.03; S 20.7.)

Of the combined mother liquors from fractions Nos. 2, 3 and 4, a sample (*ca.* 10 % of the total amount) was oxidised with excess periodate to decompose any D-cysteinolic acid. After de-ionising and evaporating, less than 1 mg of material was obtained. On paper chromatograms several ninhydrin-positive components were detected, none of which, however, could be taurine or N-methyltaurine.

The periodate consumption of the internal salt from fractions Nos. 2, 3 and 4 could not be determined as described previously [2] since the products of oxidation interfered with the titration of excess arsenite with iodine in a sodium bicarbonate buffer. Instead the sample (*ca.* 1 mg) in water (0.5 ml) was oxidised with 0.03 M sodium periodate (1 ml). At intervals potassium iodide solution (20 % in water, 0.5 ml) and 2 N hydrochloric acid (2 ml) were added and the liberated iodine titrated with 0.05 N sodium thiosulphate. After about 20 min the periodate consumed was 1.0 mole and this value rose to about 1.2 in 3 h.

The formation of formaldehyde upon periodate oxidation was 0.9 mole as determined by the method of Reeves [8]. Dimedone compound m.p. 191—193,5° alone or admixed with an authentic sample.

Synthesis of L-cysteinolic acid

S-Benzyl-L-cysteine was prepared following the directions of Hegedüs [9]. In a three-necked 500 ml flask equipped with a stirrer, dry L-cysteine hydrochloride (13 g) was added in portions to liquid ammonia (200 ml) and then sodium was added until a stable blue colour was produced. After the excess of sodium had been removed by the addition of small amounts of ammonium chloride, freshly distilled benzyl chloride (10.5 ml) was added. The ammonia was allowed to evaporate and the flask was evacuated and heated to 50° for 30 min. The residue was extracted with water, the solution filtered and the filtrate after extraction with ether brought to pH 5—6 with hydrochloric acid. After standing in a refrigerator overnight, the S-benzyl-L-cysteine was filtered off and washed with water. Yield 14.9 g (85 % of theory), m. p. 203—206° (decomp.).

S-Benzyl-L-cysteine ethyl ester. S-Benzyl-L-cysteine (14.9 g) was refluxed for 3 h in dry ethanol (300 ml) containing sulphuric acid (10 ml). After cooling on ice and neutralisation with a cooled solution of potassium carbonate (15 g) in water (20 ml) the mixture was filtered with Celite and the filtrate concentrated to dryness. The residue was covered with ether and 2 N sodium hydroxide solution (100 ml) added with cooling and shaking. The ether extract was dried over potassium carbonate and after filtration evaporated to dryness yielding an oil (9.6 g).

From the aqueous alkaline solution benzyl cysteine (4.2 g) was recovered by neutralisation with hydrochloric acid.

S-Benzyl-L-cysteinol was prepared by a method analogous to that used by Karrer and Aman [10] for the synthesis of S-propyl-L-cysteinol. A solution of S-benzyl-L-cysteine ethyl ester (9.6 g) in dry ether (80 ml) was slowly added to a solution of lithium aluminium

hydride (3 g) in dry ether (150 ml) contained in a three-necked flask with a stirrer and a condenser. After the mixture had been stirred for an additional 30 min, excess hydride was decomposed by the addition of ethyl acetate (20 ml) in ether (20 ml) and a mixture of water (6 ml), ethanol (10 ml) and ether (20 ml). After standing overnight the ether solution was filtered by suction from the precipitate, dried over potassium carbonate and concentrated to dryness. Crude S-benzyl-L-cysteinol was obtained as an oil (8.1 g).

L-Cysteinol. The debenzylation of S-benzyl-L-cysteinol was carried out by the method of du Vigneaud. Sodium was added to a solution of crude S-benzyl-L-cysteinol (8.1 g) in liquid ammonia (*ca.* 200 ml) until a stable blue colour appeared. The mixture was allowed to stand for 30 min and then neutralised by the addition of ammonium sulphate (7 g). After most of the ammonia had evaporated the flask was evacuated and kept at 50° for 15 min. The residue was extracted with dry ethanol (150 ml), the solution was filtered and the filtrate concentrated. The residual syrup was dissolved in water (100 ml) and the solution after extraction with ether concentrated under reduced pressure yielding a syrup (5.5 g). This amount exceeds the theoretical yield by 1.1 g, probably due to insufficient drying. Paper chromatograms of the product run in ethyl acetate-acetic acid-water (3:1:1) gave only one strong and a few very faint spot when sprayed with ninhydrin reagent.

L-Cysteinolic acid. While the oxidation of cystine to cysteic acid with bromine in hydrochloric acid solution [11] proceeds smoothly (80–90 % yield), the oxidation of L-cysteinol under the same conditions gave an inferior result. Preliminary experiments which were followed by paper chromatography indicated that the oxidation took several different routes, yielding mainly two compounds behaving as internal salts, one of which proved to be the enantiomorph of the internal salt from the alga. The other component did not crystallise readily and seemed to be unstable upon prolonged storage. It was not further investigated.

Probably hydrolytic reactions took place also, since if the solution after saturation with bromine at 35° was heated to boiling for a short time and cooled, more bromine was then rapidly absorbed.

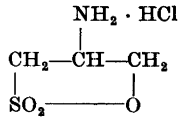
To a solution of crude L-cysteinol (2.7 g) in 1 N hydrochloric acid (50 ml) bromine was added, with stirring, at such a rate that it was immediately consumed and the temperature did not rise above 35°. After 8.8 g of bromine had been added the uptake of bromine was very slow and the mixture was left over night at room temperature. More bromine

Table 1. Spacing values.

Internal salt from the alga (D-cysteinolic acid)		Synthetic L-cysteinolic acid	
d (Å)	I/I_1	d (Å)	I/I_1
9.35	100	9.27	100
5.07	5	5.06	10
4.69	70	4.69	85
4.22	10	4.23	15
4.13	50	4.13	70
3.91	35	3.90	50
3.65	25	3.65	35
3.35	15	3.35	15
3.26	10	3.26	10
3.16	70	3.16	30
3.13	15	3.13	25
2.73	35	2.73	35
2.51	5	2.51	10
2.31	10	2.31	10
2.25	5	2.25	10
1.95	5	1.95	10
1.88	5	1.88	10

(0.25 g) was then quickly consumed. After the reaction mixture had been heated to boiling for a few minutes and cooled to room temperature, bromine (0.5 g) was added until no more was absorbed.

After concentration *in vacuo*, dilution with water and de-ionisation with Amberlite IR 120 and IR 4B the reaction mixture was taken to dryness yielding an amorphous mixture (2.7 g). This was separated on a carbon-Celite column (1:1; 35 × 4.5 cm) using water as eluant. A fraction was obtained which on paper chromatograms gave a spot indistinguishable from that of the internal salt from the alga. Concentration and crystallisation from dilute ethanol gave a product with m. p. 265—275° (decomp.). The yield was 1.16 g or 24 % calculated from the S-benzyl-L-cysteine utilised. Further recrystallisation yielded a pure product m. p. 279—281° (decomp.), $[\alpha]_D^{23}$ −6° (water, c = 2.0). Mixed m. p. with the internal salt from the alga (m. p. 279—282°) 245—260°.



X-Ray diffraction. The X-ray diffraction patterns for the cysteinolic acid from the alga and for synthetic L-cysteinolic acid (Table 1) were determined on a "Norelco X-ray Diffraction Apparatus with High Angle Goniometer" (Philips Co).

(Cu K_α) = 1.5418 Å. The samples for examination were finely ground, suspended in ethanol and spread in a thin layer on glass plates and the ethanol allowed to evaporate.

The discrepancies between the relative intensities (I/I_1) obtained from the two samples may be due to slightly different orientation of the crystals.

Acknowledgement. The author is indebted to *Statens Naturvetenskapliga Forskningsråd* for financial support, to *Norsk Institutt for Tang- og Tare-forskning, Trondheim*, for a generous gift of the alga, to Tekn.lic. S. T. Lundin, Stockholm, for the X-ray diffraction investigations and to Ing. L. Mikiver and Ing. Gurli Hammarberg for their skilful assistance.

Added in proof: Recently the synthesis and oxidation of cysteinol has been described by J. C. Crawhall, D. F. Elliott and K. C. Hooper (*J. Chem. Soc.* **1956** 4066). These authors have found that oxidation of cysteinol hydrochloride with bromine water yields cysteic acid and occasionally the sultone II. No cysteinolic acid was produced.

II.

With a view to these findings, L-cysteic and L-cysteinolic acid were compared. A sample of L-cysteic acid decomposed at ca 275° on rapid heating, whereas L-cysteinolic acid melted at 279—281° before any considerable decomposition took place. The mixed samples rapidly decomposed at 260—270°. On a paper chromatogram run in a butanol-pyridine-water mixture (2:3:1.5) mixture the R_F values were 0.17 and 0.35 for L-cysteic and L-cysteinolic acid respectively.

Fractionation of the Phosphorus-Containing Proteins of Rat Liver Cell Supernatant

JOHN GLOMSET

Institute of Medical Chemistry, University of Uppsala, Sweden

Rat liver supernatant proteins have been fractionated by ammonium sulfate precipitation, zone electrophoresis and ion exchange chromatography with special reference to phosphoserine and phosphothreonine-containing proteins. Several phosphorus-containing fractions have been obtained which together account for most of the protein-bound phosphoserine and phosphothreonine present.

In earlier publications from this laboratory [1,2] direct evidence was presented concerning the nature of a type of phosphoprotein present in liver. Methods were described by which crystalline phosphoserine and phosphothreonine could be isolated from partial hydrolysates of cell protein. And it was observed that these two phosphorylated amino acids could be prepared from each of the cell fractions obtained by the differential centrifugation method of Hogeboom and Schneider [3]. Moreover, experiments were described which indicated that protein-bound phosphorus might possibly play an active role in the metabolism of the cell. Recently, this possibility has been considerably strengthened by the work of Sutherland [4,5] and of Ågren and Engström [6,7] The former found that liver phosphorylase, a phosphoprotein, is inactivated by dephosphorylation and becomes active again after rephosphorylation. The latter authors presented evidence to show that an exchange of the phosphorus of a muscle phosphorylase and yeast hexokinase preparation occurred during the reactions catalyzed by these enzymes.

In the present paper a separation of the soluble phosphorus-containing proteins of rat liver has been attempted in order to provide a basis for subsequent studies of their structure and function. Both conventional precipitation methods and the more recent methods of ion exchange chromatography and zone electrophoresis have been employed. Several phosphorus-containing peaks have been obtained by zone electrophoresis and phospho-protein fractions corresponding to two of these and containing a considerable part of the protein-bound phosphoserine of the cell sap have been isolated. A preliminary report of some of this work has been published [8]. Some preliminary metabolic experiments have also been performed.

EXPERIMENTAL

Three month old male Wistar rats from the departmental colony were employed as experimental animals. They averaged about 300 g in weight and had not been fasted previously. Generally, they were injected intraperitoneally with 1—2 mC carrier-free radioactive phosphate 1—2 h previous to each experiment. The rats were killed by cervical dislocation and their livers quickly perfused *via* the hepatic portal vein, first with ice-cold isotonic NaCl and then with ice-cold 0.25 M sucrose solution, both solutions having been made up with glass-distilled water and adjusted to a pH of 7.4 with KOH. The perfusion was performed *in situ* using a long plastic tube connected to a syringe. After the plastic cannula had been inserted into the vein and securely tied in place, a few ml of saline were forced into the liver and then the abdominal and thoracic *vena cava* were cut to allow the free flow of blood from the liver. During perfusion the liver was cooled with ice-cold sucrose. The perfused livers were minced with a scissors and homogenized in 9 vol. of 0.25 M sucrose for 2 min in a homogenizer of the Potter & Elvehjem type consisting of a smooth-walled glass tube fitted with a teflon pestle (manufactured by Arthur H. Thomas Co., Philadelphia). The liver supernatant was then prepared essentially according to Hogeboom [9]; the microsomes, however, were spun down at 30 000 R.P.M. for one hour in rotor No. 40 of the Spinco model L preparative centrifuge. All centrifugations and manipulations were carried out at 0°—2°C. Furthermore, all solutions were made up with glass-distilled water using analytical grade reagents and were adjusted to pH 7.4 with KOH unless otherwise noted. All glass-ware and instruments were rinsed with glass-distilled water before use.

Precipitation with ammonium sulfate. Fractions were obtained by adding to the supernatant a saturated aqueous solution of ammonium sulfate, the pH of which had been adjusted so that it was 7.0 after ten-fold dilution. Fraction "AS 50" was obtained by adding 1 vol. of saturated ammonium sulfate. The resulting precipitate was then washed three times with 50 % saturated ammonium sulfate. The first washing having been combined with the original supernatant, fraction "AS 85" was obtained by adding additional saturated ammonium sulfate solution to 85 % saturation. This fraction was also washed three times. The two precipitates were then dissolved in 0.06 M tris(hydroxymethyl)aminomethane buffer, pH 7.8 (unless otherwise noted) and then dialyzed for 2 h before application to the zone electrophoresis columns. In all the ammonium sulfate fractionation experiments, the sucrose used in preparing the cell sap contained 0.01 M versene.

Zone electrophoresis was performed according to Porath [10] on 150 × 3 cm columns. Generally "tris" buffers were employed at a pH of 7—8 and a concentration of 0.03—0.1 M. The electrophoresis required from 36—48 h and was always performed in the cold.

Ion exchange chromatography. Triethylaminoethyl cellulose columns and sulfomethyl cellulose columns prepared according to Porath [11] and ECTEOLA columns prepared at room temperature according to Peterson and Sober [12] (however, using cellulose linters instead of solka floc) were employed for the protein fractionation experiments. The columns were of varying dimensions, but the exchanger was always supported by cellulose discs at the lower end of the column. The chromatography was always carried out in the cold.

The chromatographic and electrophoretic fractionations were followed spectrophotometrically at 260 and 280 mμ. Cold precautions were taken at all possible points. ^{32}P determinations were made on aliquots of the fractions and counted on an automatic scaler. For a more specific determination of the phosphoserine and phosphothreonine-containing proteins, the two amino acids were isolated from partial hydrolysates of the protein fractions as described previously [1,2]. For a crude estimation of the relative amounts of radioactive phosphoserine and phosphothreonine present in the fractions the total activity of the two phosphorus-containing amino acids was determined. For concentration of the protein fractions the ultrafiltration apparatus described by Aronsson [13] was employed. Phosphorus determinations were performed as described previously [2]. The following abbreviations have been used: "tris" = tris(hydroxymethyl)-aminomethane; RNA = ribonucleic acid; PCA = perchloric acid; TEAE = triethylaminoethyl cellulose; ATP = adenosine triphosphate.

RESULTS

The first step of the fractionation procedure was initially planned to comprise a precipitation method in order to concentrate the supernatant (initial volume 140 ml), remove organic phosphorus compounds of low molecular weight and obtain a preliminary fractionation of the proteins.

In preliminary experiments [8] ethanolic fractionation by the method of Cohn *et al.*[14] was attempted. Fractions containing relatively increased amounts of phosphoserine and phosphothreonine proteins could be obtained, but it was difficult to obtain satisfactory reproducibility from experiment to experiment (on the basis of radioactive phosphoserine determinations and the relative number and amount of peaks present when the fractions were subjected to zone electrophoresis) although adequate reproducibility could be obtained with aliquots of the same supernatant preparation. Moreover, similar difficulties were encountered in fractionating solubilized proteins from mitochondria (unpublished results). It was also noted that even when the method was slightly modified so that the first precipitation was performed at a lower ethanol concentration (10 % by volume) some apparent denaturation of a nucleoprotein, phosphoprotein fraction was obtained under such mild conditions as pH 5.8, 10 % ethanol, —3°C, 45 min. Thus, in every experiment a residue remained after the first precipitation step which could not be redissolved although several different solvent systems were tried.

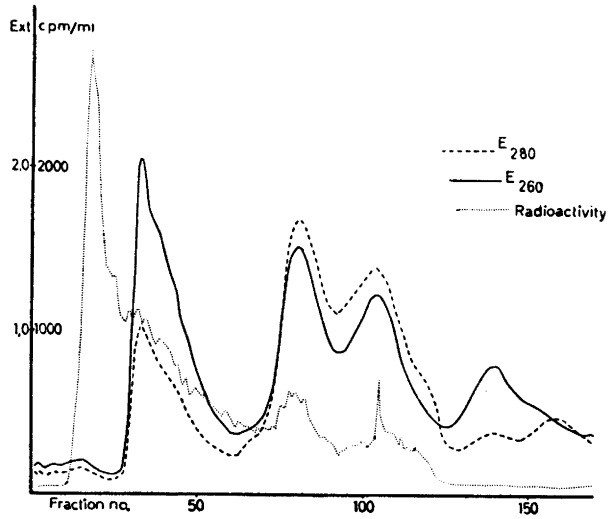

Fig. 1. Electropherogram of liver cell supernatant, fraction "AS 50". 2 rats injected with 1 mC ^{32}P 1 h previous to liver perfusion. Supernatant prepared with 0.25 M sucrose — 0.01 M versene, pH 7.4. 1 vol. saturated ammonium sulfate added: precipitate washed thrice, dialyzed 2 h; insoluble material removed by centrifugation. Clear solution displaced into the zone electrophoresis column with 50 ml buffer (0.06 M tris, pH 7.8). Electrophoresis for 45 h at 40 mA (1 300 V). Fractions of approximately 5 ml collected. Each measured at 260 mμ and 280 mμ; 1 ml aliquots taken for ^{32}P determination.

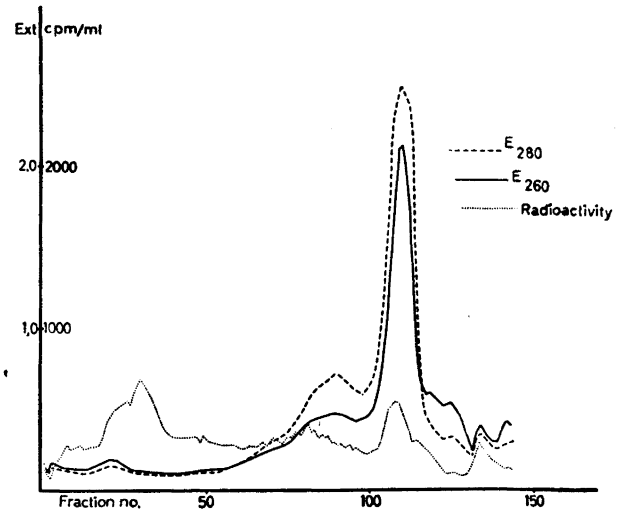

Fig. 2. Electropherogram of liver cell supernatant, fraction "AS 85". Same experiment as shown in Fig. 1. Precipitate obtained with 85 % saturated ammonium sulfate. Treated in same manner as fraction "AS 50".

Ammonium sulfate precipitation. In view of the difficulties encountered in the ethanolic fractionation experiments, a cruder separation into only 2 fractions was attempted, using ammonium sulfate precipitation. Subsequently, the precipitates were further fractionated using a more selective method (zone electrophoresis). In preliminary experiments it was found that approximately 80 % of the phosphoserine protein fraction of the supernatant fraction (and a nearly proportionate amount of the total RNA as estimated by measuring the total quantity of 260 mμ adsorbing material released by warm PCA extraction) could be precipitated by adding 1 vol. saturated ammonium sulfate solution to the cell sap, the resulting precipitate corresponding to 30—40 % of the total cell sap protein by weight. Further, it was found that little or no enzymatic dephosphorylation could be demonstrated after the phosphoserine protein-containing fractions had been allowed to stand in the cold for a period of 48 h (the maximum time usually employed for the zone electrophoresis).

The results of a typical experiment where ammonium sulfate fractionation was followed by a further separation of the fractions by zone electrophoresis are shown in Figs. 1 and 2.

As is apparent, both the ammonium sulfate precipitation and the electrophoresis yield a rather sharp separation of the cell sap proteins. Moreover, this two step separation is reproducible, although it must be mentioned that the ammonium sulfate fractionation at this pH causes the irreversible precipitation of a small amount of protein when the ammonium sulfate concentration approaches 35 % saturation so that this protein does not appear on the zone electrophoresis diagram.

Another point to be mentioned is that some of the protein migrating toward the cathode has not been included in the electrophoresis diagram, it having moved into the unstabilized buffer region.

The fractions which have been of the greatest interest in the present investigation are those which contain radioactive phosphorus. As may be seen there are a number of radioactive peaks. The first radioactive peak of the "AS 50" fraction remained soluble after cold PCA had been added to a final concentration of 0.6 N and was found to consist mainly of inorganic phosphate. The second peak was found to contain RNA. Radioactive phosphoserine and phosphothreonine were isolated in relatively large amounts from the third and fourth radioactive peaks and also from the main peak of fraction "AS 85". The identity of the remaining peaks is under investigation. The adsorption properties of the most slowly moving fractions suggest the presence of relatively large amounts of bound nucleotide. Most of the 260 mμ-adsorbing material of these fractions could be released from the protein by treatment with cold 0.6 N perchloric acid.

Ion exchange chromatography. In a series of experiments acidic and basic cellulose derivatives were substituted for the precipitation with ammonium sulfate as the first step in the procedure. It was found that when the supernatant was passed through the acidic exchanger, sulfomethyl cellulose, at pH 6.0 almost no phosphoprotein was adsorbed and most of the additional cell sap protein also passed through the column. Moreover, when the cation exchanger was used in an attempt to fractionate an already purified phosphoprotein fraction some denaturation apparently occurred.

The basic exchangers used were triethylaminoethyl cellulose and ECTEOLA cellulose. The former is rather similar in its properties to the DEAE cellulose described by Sober and Peterson (see Porath [10]) and affords a similar separation of serum proteins (unpublished experiments). Columns 10 cm in length and 3 cm in diameter were usually employed. The fresh cell sap (usually of a pH of 6.8—7.0) was allowed to pass through the column in the cold room, the column having previously been equilibrated with 0.005 N or 0.01 N tris buffer, pH 7.4. The column was then washed with 0.01 N buffer and subsequent fractions were displaced from the column by successively higher concentrations of Cl^- ion obtained by increasing the concentrations of the buffer solution or by adding NaCl. Fig. 3 shows the type of separation obtained.

Fraction I (not included in the curve) consists of those cell sap components which have not been adsorbed by the ion exchanger under these experimental conditions and comprises about 30 % of the total cell sap protein by weight. This fraction contains only a very small amount of the total radioactive phosphoserine protein and 4 % or less ot the total material yielding 260 mμ adsorbing substances when extracted with warm PCA. In most preparative experiments fractions II—V were combined. The combined fraction then amounted to about 30 % of the total cell sap protein, roughly 20 % of the radioactive phosphoserine protein and about 12 % of the total "RNA". Also, for cruder, initial separations VI—IX were combined corresponding to about 20 % of the total protein but more than 60 % of the total radioactive phosphoserine protein and RNA. Reducing the pH of the displacing buffer (to pH 6 or 5) did not cause the displacement of any additional protein from the column.

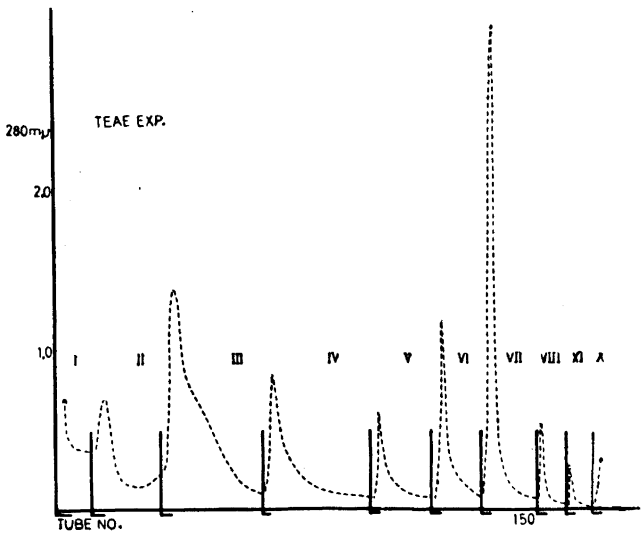

Fig. 3. Fresh supernatant prepared with 0.25 M sucrose from 2 rats, chromatographed on a 3 × 10 cm TEAE column, previously equilibrated with 0.005 M "tris", pH 7.4, subsequently washed with 0.005 M "tris", pH 7.4 to obtain fraction 1. Stepwise elution at same pH with 0.01 M "tris", 0.05 M "tris" + 0.05 M NaCl, 0.05 M "tris" + 0.1 M NaCl, 0.05 M "tris" + 0.2 M NaCl, 0.05 M "tris" + 0.5 M NaCl, 0.1 M "tris" + 0.9 M NaCl, 0.1 M "tris" + 1.5 M NaCl to obtain fractions II—IX, respectively. Remaining adsorbed material eluted with 2 % NaOH. Approximately 15 ml fractions taken, measured at 280 mμ.

However, an additional fraction (not shown in the curve) which corresponded to about 10 % of the total protein was displaced from the column by 2 % NaOH. This apparently corresponds to protein, denatured during the chromatographic procedure (however, see discussion) and in several experiments was found to contain between 20 and 30 % of the total radioactive phosphoserine protein as well as a considerable amount of RNA. Experiments in which the initial pH of the ion exchange column was lower (6.2) (that of the cell sap had also been reduced) yielded no reduction in the amount of "denatured" phosphoprotein. Nor did increasing the initial chloride concentrations of the cell sap and column have a favorable effect.

When TEAE fractions II—V were combined, ultrafiltered, dialyzed and subjected to zone electrophoresis the electropherogram shown in Fig. 4 was obtained. The main peak appears to correspond to the last radioactive peak in Fig. 1. Moreover, when in another experiment, material corresponding to the latter peak was chromatographed on a TEAE column it was found to be eluted with Cl-concentrations corresponding to fractions II—V. TEAE fractions VI—IX yielded the electropherogram shown in Fig. 5. The main peak resembles the third radioactive peak in Fig. 1. The identity of the two peaks was confirmed by chromatography of peak 3, Fig. 1, on a TEAE column. It should be noted that the most slowly moving peaks in Fig. 1 are contained

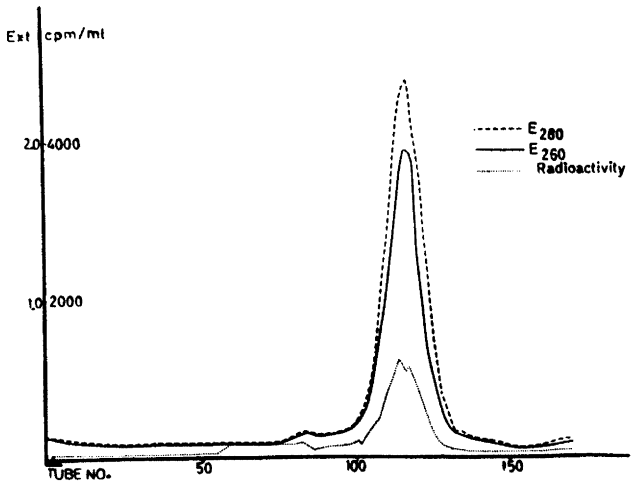

Fig. 4. Same experiment as in Fig. 3. Electropherogram of TEAE fraction corresponding to fractions III—V, Fig. 3. After ultrafiltration and dialysis, electrophoresis and elution as in Fig. 5.

in TEAE fractions VI—IX which otherwise contains only the faster moving electrophoretic components. As may be seen in both Figs. 1 and 5 the slower moving components appear to contain bound nucleotide material, which

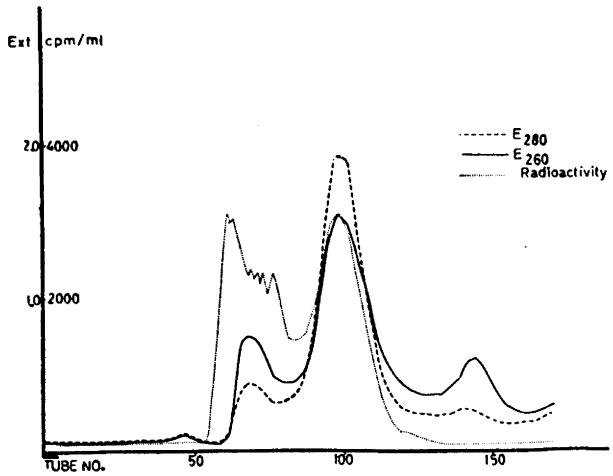

Fig. 5. Electropherogram of TEAE fraction corresponding to fractions VI—VIII, Fig. 3. 4 rats injected with 1.5 mC ^{32}P each, 2 h previous to perfusion. Supernatant prepared with 0.25 M sucrose, pH 7.4, chromatographed on 3 × 10 cm TEAE column. Fraction corresponding to fractions VI—VIII, Fig. 3, ultrafiltered and applied to electrophoresis column. Electrophoresis in 0.1 M "tris", pH 7.8 for 46 h, 45 mA (900 V). Fractions collected and measured as in Fig. 1.

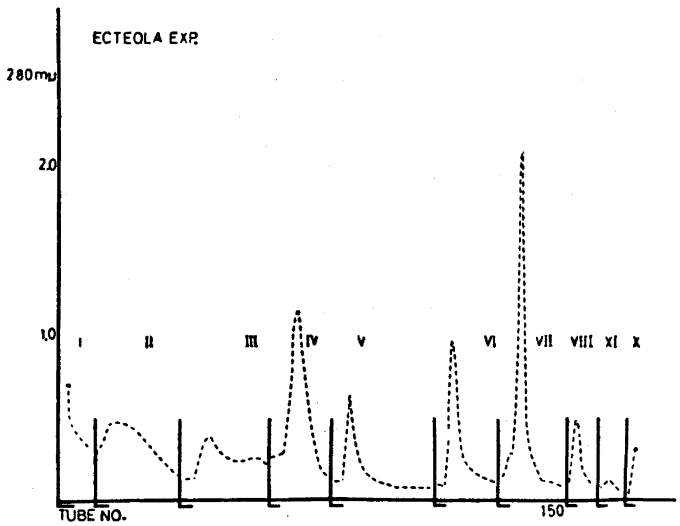

Fig. 6. Fresh supernatant prepared with 0.25 M sucrose from 2 rats, chromatographed on a 3 × 10 cm ECTEOLA column under conditions identical to those in the TEAE experiment shown in Fig. 3.

although released for the most part by cold perchloric acid, does not appear to contain phosphorus which has exchanged with other nucleotide compounds of the cell.

ECTEOLA columns were also found to be useful for the fractionation of the acidic cell sap proteins. While a large part of the total cell sap protein passes through the column with 0.005 N tris, pH 7.4, the phosphoserine and phosphothreonine proteins are retained and may be displaced to yield a fractionation pattern which is quite similar to that of the TEAE columns. Moreover, electropherograms of the ECTEOLA fractions were similar to those obtained with the corresponding TEAE fractions. As is the case with the TEAE columns some of the phosphoprotein is retained by the column in such a way that it can only be displaced by weak NaOH. An elution curve is reproduced in Fig. 6 for purposes of comparison.

Incubation experiments. Some preliminary incubation experiments have been carried out with the whole rat liver supernatant fraction. When a mixture of ^{32}P-containing nucleotides fortified with highly radioactive $AT^{32}P$ was added to fresh non-radioactive supernatant from two rat liver homogenates incorporation of ^{32}P into not only the phosphoserine but also the phosphothreonine of the protein could be demonstrated. Moreover, incorporation of the isotope could also be demonstrated in an experiment in which 1 mC inorganic ^{32}P was added to fresh rat liver supernatant and the mixture shaken at 20—21° C for 15 min. While under these conditions no exchange of RNA phosphorus occurred, the phosphoserine and phosphothreonine isolated from hydrolysates of the protein both contained ^{32}P.

DISCUSSION

Determination of phosphoproteins. Although phosphorus conceivably may be bound to protein in a number of ways, the experiments described in the present paper have mainly concerned those proteins of rat liver cell sap which contain phosphoserine and phosphothreonine. As yet these are the only two phosphorylated amino acids which have been isolated from liver protein. These amino acid derivatives may be qualitatively determined as described previously [1,2], but, unfortunately, there is still no satisfactory method for their quantitative determination in protein linkage. The methods which have hitherto been employed for the determination of protein phosphorus have been based on the old observation by Plimmer [15] that the phosphorus of casein is relatively alkali labile. Thus, Schmidt and Thannhauser [16] and Johnson and Albert [17] among others have subjected organ protein to partial alkaline hydrolysis and designated the liberated inorganic phosphorus as "phosphoprotein phosphorus". The reliability of this type of method for the determination of phosphoserine and phosphothreonine proteins has been questioned earlier [1]. Moreover, since then Crosby *et al.*[18] have reported that the alkaline hydrolysis method used by them to obtain RNA nucleotides from rat liver does not hydrolyze all of the phosphoserine present, and this has been confirmed by the author, under more vigorous alkaline hydrolysis conditions (unpublished experiments). Thus, the alkaline hydrolysis method would definitely seem inadequate when applied to liver phosphoprotein determination.

In the experiments described in this paper the protein separations have been followed by (1) measuring the radioactivity of the protein fractions eluted from the columns and (2) measuring the total ^{32}P-activity of the phosphoserine and phosphothreonine fractions isolated from partial hydrolysates of the fractionated proteins using Dowex 50. The determinations have thus necessarily been only approximate and have not included phosphoproteins in which there is a negligible uptake of radioactive phosphate under the conditions of these experiments. Yet they have been of value here since the phosphoproteins which have been of greatest interest have been those in which the phosphorus itself is metabolically active, with extent and rapidity of uptake of radioactive phosphate being taken as a provisional measure of metabolic activity.

Fractionation methods. It seems likely that the difficulty in obtaining reproducible precipitation of the cell sap phosphoproteins using the method of Cohn may be the result of the very factor, *viz.* co-precipitation, which has made the method so selective when used for the fractionation of serum proteins in the hands of Cohn and collaborators. Thus, small differences in the protein and inorganic cation concentrations of the cell sap caused by irregular perfusion or an altered adsorption of soluble proteins onto the intracellular particles as result of changes in the pH of the cell sap during the preparation could conceivably result in significant changes in the fractionation pattern. This would be especially true for the more highly charged proteins which would normally show a strong tendency to form co-precipitates. To reduce these effects in the subsequent ammonium sulfate fractionation experiments the following steps were taken. 0.01 M versene was included in the homogenization medium (and perfusion media). The precipitation was carried out at

pH 7.0 and only a few fractions were taken to facilitate the subsequent zone electrophoresis.

In the experiments with the strongly basic ion exchangers it was found that a considerable amount of phosphoprotein + nucleoprotein material ostensibly became strongly bound to the column (the fractions eluted with NaOH). Experiments designed to prevent this effect were not successful. It seems possible that denaturation of the proteins has occurred here. To further investigate this possibility experiments with more weakly basic ion exchange columns would be of value. Another possibility is that all or a major part of the strongly "adsorbed" material is in fact submicroscopic particulate matter [19] which has not been sedimented in the centrifugal fields employed here. It is perhaps significant that roughly proportional amounts of phosphoprotein + nucleoprotein material is "denatured" or rendered insoluble by (1) treatment with low concentrations of ethanol, (2) passage through ion exchange columns, (3) precipitation with low concentrations of $MgCl_2$ (unpublished experiments).

The ion exchange experiments described here have been of a preparative nature, and no attempt has been made to obtain a finer separation of the less strongly bound, non phosphothreonine or phosphoserine-containing proteins. Some experiments have been carried out where the purified phosphoamino acid-containing fractions were rechromatographed on TEAE columns with gradient elution but so far neither these nor re-electrophoresis experiments have yielded a subfractionation of the main phosphorus-containing peaks shown in Figs. 4 and 5. However, additional attempts to purify the phosphoprotein fractions are in progress as well as incubation experiments with the purified fractions. These experiments will be reported in a later paper.

Acknowledgments. This investigation was supported by grants from the *Medical Faculty of the University of Uppsala.* The author wishes to thank Prof. Gunnar Ågren for the privilege of working in his laboratory. He is also indebted to Dr. Jerker Porath for generous gifts of TEAE-cellulose and for many valuable discussions. Thanks are also due to Mrs Margot Persson for faithful technical assistance.

Ornithine Carbamyl Transferase from Rat Liver

PETER REICHARD

Biochemical Department, Karolinska Institutet, Stockholm, Sweden

An enzyme (ornithine carbamyl transferase) has been purified from rat liver which catalyzes the formation of citrulline according to: L-ornithine + carbamyl phosphate ⇌ L-citrulline + phosphate. The enzyme moved as a single compound during paper electrophoresis between pH 5.0 and 8.5 with an isoelectric point around 8.1. A minor impurity amounting to *ca.* 5—8 % was found during ultracentrifugation.

The reaction greatly favoured citrulline synthesis, the equilibrium constant being *ca.* 10^6. Out of 26 amino acids tested only L-ornithine was able to accept the carbamyl group of carbamyl phosphate. Inhibition by SH-reagents was observed and partial protection from inhibition could be obtained with each of the substrates, tentatively indicating binding of both substrates to SH groups of the enzyme. Isotope exchange experiments indicated that the transfer reaction was of the single displacement type.

The citrulline phosphorylase of Krebs *et al.*[8] has been found to be identical with ornithine carbamyl transferase.

By coupling ornithine carbamyl transferase with aspartate carbamyl transferase [5] synthesis of carbamyl aspartate was obtained from citrulline + aspartate in the presence of phosphate.

The work of Grisolia and Cohen [1] has demonstrated that citrulline is formed enzymically in mammalian liver through a transfer of the carbamyl group of an active carbamyl compound to ornithine. Jones *et al.*[2] recently synthesized carbamyl phosphate and demonstrated its identity with the active carbamyl compound.

Our interest in carbamyl transfer reactions originated from investigations of the enzymic formation of carbamyl aspartate, an intermediate in pyrimidine biosynthesis. We found that this substance was formed from aspartate, CO_2 and NH_3 in the presence of ATP and acetylglutamate and that carbamyl phosphate (CAP*) was an intermediate in the reaction [3-5]. An enzyme (aspartate carbamyl transferase) which catalyzed the transfer of the carbamyl

* The following abbreviations are used in this paper: CA = carbamyl, CAP = carbamyl phosphate, P_i = inorganic phosphate, ATP = adenosine triphosphate, PCA = perchloric acid, tris = tris(hydroxymethyl)amino methane, CMBA = *p*-chloromercuribenzoic acid, EDTA = ethylenediamine tetraacetic acid.

group was purified a hundredfold from *E. coli* [5] and a study of the mechanism of its action was made. The limited supply of the starting material and the relative instability of the purified enzyme made further purification difficult.

The present investigation was started with a twofold purpose. First it was intended to study a carbamyl transfer reaction with an essentially pure enzyme. Second it was of interest to investigate whether the citrulline forming enzyme by a reversal of its action could form carbamyl phosphate which then together with aspartate would give rise to carbamyl aspartate. Such a reaction would represent a second mechanism for the utilization of the carbamyl group of citrulline for pyrimidine synthesis [6], the first being the transfer of the carbamyl group of citrulline to a phosphate group of ATP with the formation of CAP [7]. In this connection it was also of interest to determine whether citrulline phosphorylase as described by Krebs *et al.*[8] was identical with the citrulline forming enzyme.

After purification of the enzyme from rat liver the following stoichiometric reaction could be demonstrated:

$$\text{Carbamyl phosphate} + \text{L-ornithine} \rightleftharpoons \text{L-citrulline} + \text{phosphate} \quad (1)$$

The name ornithine carbamyl transferase is proposed for this enzyme.

MATERIALS AND METHODS

L-*Citrulline-carbamyl-*^{14}C was synthesized according to Smith [9]. In spite of repeated crystallizations the compound contained a small amount (*ca.* 1 %) of ornithine. For the determination of the equilibrium constant this amino acid was removed by paper electrophoresis (1 h, 12.5 V/cm) in 0.1 M acetic acid. Using acid washed Whatman filter paper (No. 3) 300 μmoles of citrulline could be run on one sheet. A small strip was sprayed with ninhydrin to locate the amino acids. The main amount of citrulline was then eluted with water from the paper. After evaporation to dryness it was redissolved in a small amount of water and used directly. On paper chromatography (phenol:water, 9:1) no ornithine could be detected.

^{14}*CA-aspartate* was synthesized according to Nyc and Mitchell [10], *CAP* according to Jones *et al.*[2] DL-*Ornithine*, L-*ornithine* and DL-*ornithine-2-*^{14}C were commercial samples (Schwarz laboratories, Inc. and California Foundation for Biochemical Research).

Protein determinations were made by the method of Bücher [11]. When checked by nitrogen analysis of PCA precipitates at different points during the preparation good relative agreement was obtained. During zone electrophoresis and chromatography protein was measured by light absorption at 280 mμ.

Determination of enzyme activity. Forward reaction. The enzyme was incubated for 15 min at 37° with 30 μmoles of CAP, 100 μmoles of DL-ornithine and 100 μmoles of tris buffer, pH 7.3—7.4, in a final volume of 1.0 ml. The tubes were then immediately immersed in an ice bath and the amount of inorganic phosphate present was determined directly on 0.02 ml aliquots by the Lowry-Lopez [12] method. Readings were made after 5 min. A blank without enzyme was treated in the same manner.

Under those conditions the difference between the amount of inorganic phosphate formed in the sample containing enzyme and the blank was proportional to the amount of enzyme added (Fig. 1) up to a value of *ca.* 6—8 μmoles.

One unit of enzyme activity was defined as a difference of 1 μmole of P_i formed under the above conditions. The specific activity of the enzyme was defined as units/mg protein.

Sometimes the amount of citrulline formed was determined rather than P_i. In this case the enzyme reaction was stopped by the addition of 0.1 ml of 4.4 M PCA and citrulline [13] determined directly on aliquots. This method was more time consuming but was used whenever high accuracy was desired or when substances were present which inter-

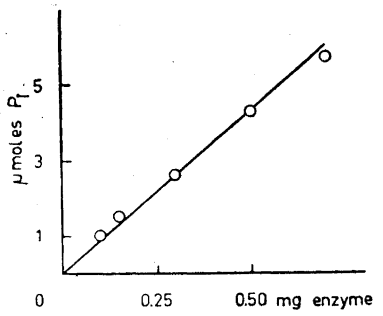

Fig. 1. Enzymic formation of P_i from CAP. Standard conditions as described in text.

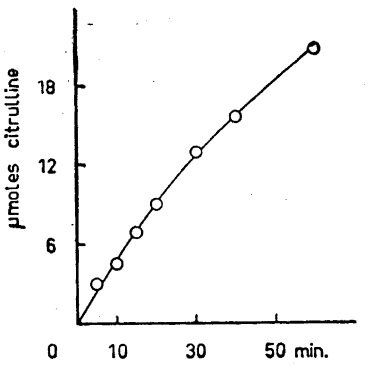

Fig. 2. Time curve of transferase action. Standard conditions with citrulline determination.

fered with phosphate analysis. Identical results were obtained with both methods. A *time curve* of the enzyme reaction is demonstrated in Fig. 2 (citrulline determinations).

Back reaction: It could be demonstrated that the arsenolysis of citrulline [8] is carried out by ornithine carbamyl transferase. The rate of the back reaction was measured by the formation of $^{14}CO_2$ from citrulline-carbamyl-^{14}C in the presence of arsenate. In principle the method was the same as the one used earlier for the determination of CAP formation from citrulline [7]. The enzyme was incubated with 6 µmoles of citrulline-^{14}C (130 000 ct/min/µmole) and 100 µmoles of arsenate buffer, pH 6.7, for 15 min at 37° in a stoppered Warburg vessel, containing 4 N NaOH in the center well and 9 N H_2SO_4 in the side arm. The vessel was cooled on ice, 100 µmoles of $NaHCO_3$ were added and the acid tipped into the main compartment. After shaking for 30 min at 37° the alkali from the center well was precipitated with barium hydroxide, the formed $BaCO_3$ was washed with hot water, filtered on to a paper disk of standard size, and counted as an infinitely thick sample in an end window Geiger-Müller counter. The number of µmoles $^{14}CO_2$ formed could then be calculated from an experimentally determined conversion factor.

One unit of enzyme activity for the back reaction was defined as the amount of enzyme which under the above conditions formed 0.1 µmoles of CO_2.

The same general technique was used during the determination of the equilibrium constant, with the exception that phosphate buffer was used instead of arsenate. In this case the purified (paper electrophoresis) citrulline was used.

Ion exchange chromatographies. The chromatographic separation of CAP from P_i was performed as described earlier [5]. CA-aspartate was separated from citrulline by gradient elution chromatography on Dowex-2-formate (diam. 0.9 cm, length 11 cm) with a 250 ml mixing flask receiving 4 N formic acid. Citrulline was eluted with water, while CA-aspartate appeared after 7—8 column volumes.

RESULTS AND DISCUSSION

Purification of the enzyme

The work of Grisolia and Cohen [1] has demonstrated the localization of the enzyme in the particulate fraction of rat liver. In conformity with these authors the starting material for our enzyme preparation was an acetone powder of "rat liver residue". Essentially no activity was found in the supernatant fraction.

Preliminary experiments were carried out with rat, rabbit and beef liver. By far the highest activity was observed in crude extracts of rat liver and it was also found that fractionation with ammonium sulfate gave better results in this case. Further work was therefore carried out with rat liver.

Preparation of the acetone powder. All work was performed in a cold room at +2°. The livers (500—600 g) from 80 rats were homogenized in a Waring blendor (low speed) in 3 liters of 1.15 % KCl. The solution was poured through a double layer of cheese cloth and then centrifuged in a Sharples centrifuge (rotor size 200 ml) at 25 000 r.p.m. The flow through the rotor was adjusted to a rate of 50—60 ml/min.

The sediment was removed from the rotor and suspended in a minimum amount of 0.05 M phosphate buffer, pH 7.4. Liver residues from six centrifugations may be conveniently pooled at this point.

The suspension was mixed in a Waring blendor with a five to ten fold excess of acetone (—15°). After filtration the residue was once more treated with cold acetone, filtered again and dried in a desiccator.

The livers from 100 rats corresponded roughly to 40—50 g powder.

Extraction of the acetone powder was carried out with 0.05 M tris buffer, pH 7.4, containing 0.001 M EDTA *. It was found that the enzyme was not appreciably inactivated by heating at 52° for 1 h (*cf.* Ref.[1]). The extraction was therefore directly carried out at this temperature.

The acetone powder (205 g) was ground in a mortar with 2 050 ml of buffer. The suspension was immersed in a water bath of 55° and stirred continuously. When the temperature inside had reached 52° the outside temperature was lowered to the same value and heating was continued for one hour. The solution was then cooled in ice water. From this point all operations were performed at 0—4°.

The suspension was centrifuged in the No. 21 head of a Spinco centrifuge (15 min at 12 000 r.p.m.). The residue was washed with 600 ml of buffer. By addition of more buffer the protein concentration was adjusted to 1 %. Volume 3 150 ml.

Solid *ammonium sulfate* (880 g) was added slowly and under stirring. The solution was allowed to stand overnight and the clear supernatant was decanted. The cloudy bottom layer was centrifuged and the precipitate was discarded. To the combined supernatants (3 500 ml) was added 585 g of solid ammonium sulfate and precipitation allowed to take place overnight. The precipitate was centrifuged in the Spinco centrifuge (12 000 r.p.m. at 15 min), and dissolved in 0.05 M tris buffer, pH 7.4, final volume 210 ml. The clear solution was dialyzed against a total of 9 liters of 0.01 M tris buffer for 16 h.

Alcohol precipitation. The volume of the dialyzed solution was adjusted to 1 120 ml with 0.01 M buffer, giving a final protein concentration of 1 %, and 28 ml of 2 M KCl was added.

The solution was placed in a cooling bath and 50 % ethanol (360 ml) was added slowly under constant stirring. During the operation the temperature of the bath was lowered to —3°. After standing for 1 h the formed precipitate was centrifuged and discarded.

* All solutions throughout the whole preparation contained 0.001 M EDTA.

To the clear supernatant more 50 % ethanol (560 ml) was added slowly while the temperature of the cooling bath was lowered to —5°. After standing for 1 h the precipitate was centrifuged (P_2). A third precipitate (P_3) was obtained after addition of 250 ml of 50 % ethanol and standing for 3 h at —10°. To the supernatant after centrifugation was added 100 ml of 50 % ethanol and the solution was allowed to stand at —10° overnight, yielding a fourth precipitate (P_4). The clear supernatant after centrifugation always contained very little activity. Each precipitate (P_2, P_3 and P_4) was dissolved separately in *ca.* 150 ml of 0.01 M tris buffer, and all solutions were assayed for protein and enzyme activity. The bulk of activity was located in P_2 and P_3*.

Second ammonium sulfate fractionation. P_2 and P_3 were combined (290 ml) and 5 ml of M tris buffer, pH 8.5, was added. A saturated solution of ammonium sulfate (pH 8.0, 320 ml) was added dropwise under constant stirring. After 30 min the solution was centrifuged and the precipitate discarded. Solid ammonium sulfate (54 g) was added to the supernatant and precipitation allowed to take place overnight.

After centrifugation the resulting precipitate was dissolved in 0.01 M tris buffer, pH 7.4, and dialyzed against a total of 6 liters of the same buffer for 24 h.

DEAE adsorption. Attempts to chromatograph the enzyme on DEAE cellulose columns [14] were unsuccessful. It was difficult to obtain complete adsorption of the enzyme, a large amount of activity disappeared during the procedure and the results were not very reproducible. By batchwise treatment with DEAE cellulose in the presence of phosphate buffer it was possible, however, to remove acidic impurities from the enzyme and to obtain further purification.

Five g of the cellulose powder prepared according to Peterson and Sober [14] was washed first with 500 ml of M phosphate buffer, pH 7.4 in a chromatographic column, and then with three 20 ml portions of 0.01 M phosphate buffer, pH 7.4. The cellulose was then suspended in an equal volume of 0.01 M phosphate buffer (90 mg of dry cellulose per ml).

One ml of 0.1 M phosphate buffer, pH 7.2, and 28 ml of the cellulose suspension were added to the dialyzed solution (70 ml) from the second ammonium sulfate precipitation step. After 10 min the cellulose was filtered off by suction and washed twice with 10 ml of 0.01 M phosphate buffer.

Saturated ammonium sulfate (102 ml), pH 8.0, was added to the filtrate (102 ml) and the resulting precipitate was discarded after centrifugation. Solid ammonium sulfate (21 g) was added to the supernatant and precipitation allowed to take place overnight.

The precipitate was centrifuged and dissolved in the smallest possible amount of 0.05 M tris buffer, pH 7.4. It was dialyzed for 18 h against a total of 4 liters 0.03 M tris buffer, pH 8.5.

Zone electrophoresis. After the previous step the solution was deep red. Paper electrophoresis demonstrated that at pH 8.5 the enzyme could be

* In some preparations P_4 was also used for the further purification. In one preparation practically all activity was contained in P_2.

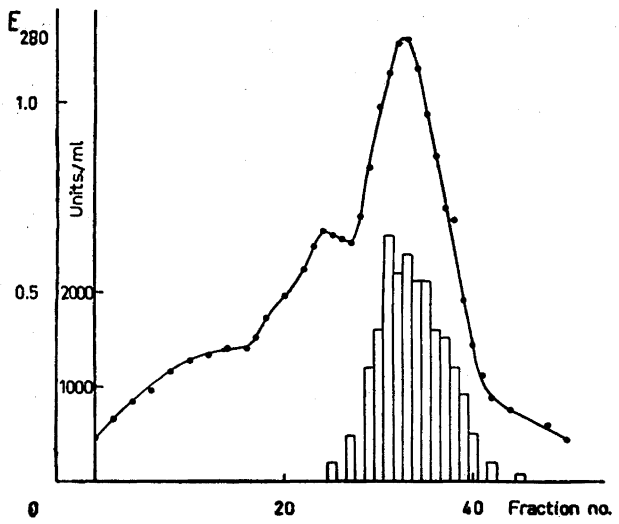

Fig. 3. Zone electrophoresis of ornithine carbamyl transferase. Continuous curve = E_{280}; stepped curve = enzyme activity.

separated from the coloured components. At this pH the enzyme moved very slowly towards the anode, while the coloured components moved faster in the same direction. Separation on the preparative scale was therefore carried out by electrophoresis on a cellulose column according to Porath [15].

The size of the cellulose column was 7.1 $cm^2 \times 52$ cm. Tris buffer (pH 8.5, 0.03 M) was used for the electrophoresis. The enzyme (240 mg of protein, volume = 5 ml) was applied to the top of the column. It was displaced 10 cm downward on the column by buffer. A current of 30 mA at a voltage of 5.5 V/cm was applied for 20 h. Ice water was circulated through the cooling jacket of the column during the electrophoresis.

The proteins were eluted from the column with buffer. Fifteen minute fractions (5—7 ml) were collected and analyzed for protein (light absorption at 280 mμ) and enzyme activity (Fig. 3). The enzyme started to appear after 160 ml. The first 39 ml containing enzyme were discarded, since the specific activity was lower than in the following fractions. Between 200 and 250 ml the specific activity of the protein was constant. These fractions were pooled and the volume of the solution concentrated by ultra filtration. During this process the filtration sac was suspended in 0.01 M tris buffer, pH 7.4, to avoid precipitation of salts on the outside of the membrane *.

A summary of the purification procedure is given in Table 1. The specific activities of an extract of whole liver acetone powder and of a 0° extract of

* The total recovery of enzyme and protein after zone electrophoresis was always low and never exceeded 60 %, probably because of adsorption of proteins to the ethanolyzed cellulose.

I am much indebted to Dr. J. Porath and Mr. J. Glomset for advice in connection with the zone electrophoresis prior to publication of Dr. Porath's paper [15].

Table 1. Purification of ornithine carbamyl transferase from rat liver.

acetone powder from liver residue are also included in the table for comparison.

Properties of the enzyme. The concentrated enzyme solution (1—3 % protein) had a slightly yellowish colour. It was kept at 0° and lost little activity over a period of 4 months. After freezing in buffer solution some precipitation and denaturation sometimes occurred.

Because of the scarcity of the material no free electrophoresis was carried out. On paper electrophoresis between pH 5.0 and 8.5 the protein migrated as a single component. The isoelectric point was around 8.1. On ultra centrifugation * (protein concentration 0.4 % in 1 % NaCl and 0.01 M tris buffer, pH 7.4) two peaks were observed. The main component had a sedimentation constant ($s_{w,20}$) of 5.5 *S*, while a minor component amounting to *ca.* 5—8 % of the main peak had a sedimentation constant of *ca.* 8 *S*.

Properties of the transferase reaction

The *stoichiometry* of reaction (1) is demonstrated in Table 2. The slightly larger formation of P_i than citrulline is fully explained by the non-enzymic decomposition of CAP during the incubation.

Isolation of L-*citrulline.* In a large scale experiment 1 600 μmoles of L-ornithine, 2 000 μmoles of CAP and 5 000 units of transferase were incubated for 15 min at 37°. The solution was then put in a boiling water bath for 1 min

Table 2. Stoichiometry of transferase reaction.

	L-Ornithine	CAP	Citrulline	Phosphate
		μmoles		
Initial	40.0	40.7	0	2.1
Final	21.2	20.5	18.6	22.9
Δ	18.8	20.2	18.6	20.8

Incubation for 5 min at 37° with 60 units of transferase, vol. 1 ml.
Ornithine was determined by ion exchange chromatography. CAP was determined by phosphate analysis [12] (phosphate after 5 min at 100° minus P_i).

* I am indebted to civ.ing. A. Ehrenberg for performing the ultra centrifugation.

and thereafter poured through a Dowex-2-formate column (diam. 0.9, length 15 cm). The column was washed with 20 ml of water and the washing evaporated to a small volume *in vacuo*. $CuCl_2$ (800 μmoles) was added and the solution allowed to crystallize in the refrigerator overnight.

The crystals were filtered by suction and washed carefully with cold water. They were then suspended in 20 ml of boiling water and decomposed with H_2S for 2 h. The CuS was removed by filtration and the solution evaporated to dryness *in vacuo*. The residue was crystallized twice from 95 % alcohol. The product (145 mg) melted with decomposition at 232—235° (uncorr.). A mixed melting point with authentic citrulline gave the same value. It showed $[\alpha]_D^{25} = +24°$ in 6 N HCl as compared to a value of 26° for authentic L-citrulline.

Dependence on substrate concentration. The Lineweaver-Burk plots in Fig. 4 demonstrate the dependence of the reaction rate on the concentrations of CAP and ornithine, respectively. No inhibition was observed at substrate concentrations up to 0.05 M. When DL-ornithine was used but the substrate concentration was calculated only from the amount of L-ornithine present (triangles in Fig. 2) identical results were obtained as with pure L-ornithine. This demonstrates that (a) only the L-isomer was participating in the reaction, (b) D-citrulline did not influence the reaction rate when present in equimolar concentration with the L-isomer.

From the two curves Michaelis constants of 1.4×10^{-3} and 4.1×10^{-4} can be calculated for L-ornithine and CAP, respectively.

The *pH optimum* (7.3) of the reaction is demonstrated by Fig. 5.

Specificity of the reaction. The following amino acids (60 μmoles of L-isomer, 120 μmoles of DL-isomer) were incubated with 12 μmoles of CAP, 200 μmoles of tris buffer, pH 7.4, and 90 units of transferase: L-α-alanine, β-alanine, DL-α-aminoadipic acid, L-arginine, L-asparagine, L-aspartic acid, L-citrulline, L-cysteic acid, L-glutamic acid, L-glutamine, glycine, L-histidine, DL-homoserine, L-hydroxylysine, L-*iso*leucine, L-leucine, L-lysine, L-methionine, L-norleucine, L-phenylalanine, L-serine, L-threonine, L-tryptophane, L-tyrosine and L-valine.

None of these substances had the ability to bring about the enzymic dephosphorylation of CAP *.

Inhibition of transferase activity. The effect of several different enzyme inhibitors is demonstrated in Table 3. The inhibition by phosphate and arsenate is explained by the fact that phosphate is one of the products of the reaction. Inhibition was also observed with the SH-inhibitors iodosobenzoate and *p*-chloromercuribenzoate and could be partially reversed by glutathione. Of interest was also the observation that both substrates had the capacity to protect the enzyme to some degree from inhibition. Thus the inhibition was higher if CMBA (10^{-7} M) was added to the buffered enzyme solution before either of the two substrates than if one substrate was added before the inhibitor.

* J. M. Lowenstein and P. P. Cohen (*J. Biol. Chem.* **220** (1956) 227) have found that a low speed supernatant solution of rat liver was able to form a small amount of homocitrulline from lysine + CAP. Our experimental conditions would not allow a demonstration of enzyme activity with lysine which amounts to less than 0.5 % of the activity with ornithine.

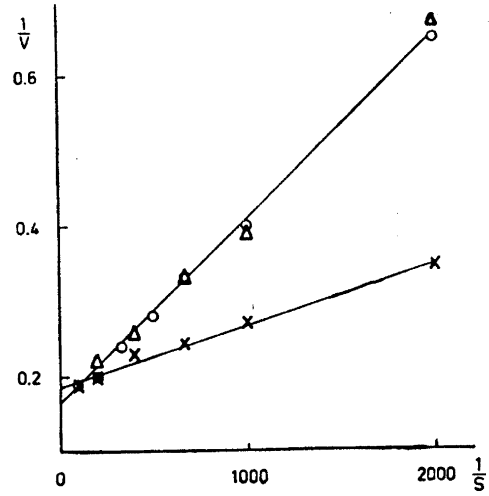

Fig. 4. Dependence of transferase action on CAP (×), L-ornithine (○) and DL-ornithine (△). In the last case the substrate concentration was calculated from the amount L-ornithine in the DL-isomer. Standard conditions except for substance under investigation. Citrulline determination.

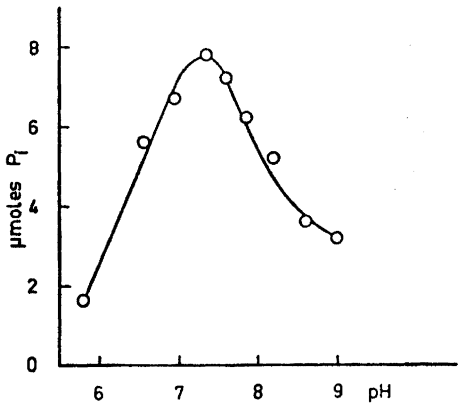

Fig. 5. pH curve of transferase action. Standard conditions but with tris and imidazol buffers at pH values indicated. Phosphate determination.

This demonstration is similar to results obtained earlier with aspartate carbamyl transferase. In this case the presence of both substrates was necessary for protection from CMBA.

A tentative interpretation for both transferases is that SH-groups are involved during the enzyme reaction and that both substrates are bound to these groups during the reaction.

Reversibility and equilibrium of transferase reaction. The equilibrium of the reaction greatly favoured citrulline synthesis but reversibility could be readily demonstrated and the equilibrium position measured from the back reaction with the aid of isotopic compounds.

The qualitative formation of radioactive CAP from $^{32}P_i$ and L-citrulline in the presence of transferase could be demonstrated by paper chromatography and ion exchange chromatography [5].

The quantitative measurement of the amount of CAP formed under different experimental conditions was carried out by using citrulline-carbamyl-^{14}C as substrate. Radioactive CAP was formed only in the presence of both enzyme and phosphate. CAP was decomposed with acid and the radioactive CO_2 formed was measured as described in the experimental part for the back reaction. Time curves of CAP formation with different amounts of substrates and large amounts of enzyme are demonstrated in Fig. 6.

All curves show at first a very rapid formation of CAP followed by a much slower linear increase. The curves are interpreted in the following way: The

Table 3. Inhibition of transferase reaction.

Incubation under standard conditions with 5 units of transferase. In the last three experiments the indicated substrates were added to the enzyme before the inhibitor. In all other experiments the inhibitor was first added to the buffered enzyme solution (0°) and CAP + ornithine was added afterwards in a small volume.

rapid phase represents the attainment of the equilibrium. The formed CAP undergoes, however, a slow non-enzymic decomposition and disappears from the reaction. This in turn pulls the reaction towards more formation of CAP which results in the second slow phase of the curve. By extrapolation to zero time a correction can be obtained for this non-enzymic decomposition.

The equilibrium constant

$$K_{eq} = \frac{[\text{citrulline}]\ [\text{phosphate}]}{[\text{ornithine}]\ [\text{CAP}]}$$

was calculated from the three experiments of Fig. 6 and values of 89 000, 103 000 and 114 000 were obtained, giving an average value of 10.2×10^4. The reasonable conformity between the three values is good support for the correctness of the applied method.

Identity of citrulline phosphorylase and ornithine carbamyl transferase. Krebs *et al.*[8] described an enzyme from mammalian liver which formed CO_2, NH_3 and ornithine from citrulline in the presence of phosphate or arsenate. These authors could not demonstrate the formation of a phosphorylated intermediate. It seemed nevertheless rather probable that their enzyme was identical with ornithine carbamyl transferase and that their inability to demonstrate the formation of carbamyl phosphate was dependent on the equilibrium position of the reaction and on the fact that carbamyl phosphate at that time had not been described in the literature.

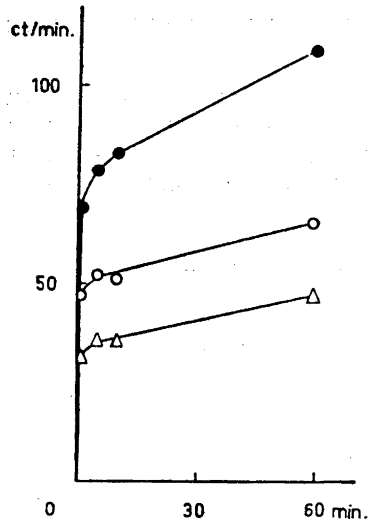

Fig. 6. Formation of ^{14}CAP from citrulline-carbamyl-^{14}C (see text). Experimental conditions (for one point): 40 units of transferase, vol. 1 ml, temperature 37° in all experiments. *Upper curve:* 94 μmoles of phosphate (pH 7.4), 28 μmoles of citrulline. *Middle curve:* 47 μmoles of phosphate, 28 μmoles of citrulline. *Lower curve:* 47 μmoles of phosphate, 14 μmoles of citrulline.

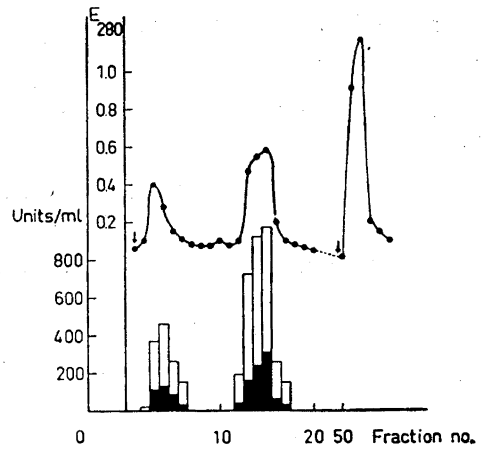

Fig. 7. Identity of citrulline phosphorylase with ornithine carbamyl transferase. 20 mg of transferase (specific activity = 1 500) was adsorbed to a column (0.61 cm² × 14 cm) of DEAE cellulose which had been washed with 0.02 M phosphate buffer, pH 7.4. Elution (4 ml fractions / h) was started with 0.01 M phosphate, pH 7.2, at the first arrow, changed to M KH_2PO_4 at the second arrow. Each fraction was analyzed for protein (E_{280}, continuous curve) transferase activity (upper stepped curve) and arsenolysis of citrulline (shaded stepped curve).

The arsenolysis of citrulline could be readily demonstrated with the pure transferase preparation. It was also found that the ratio between the rate of arsenolysis of citrulline and the rate of citrulline formation from ornithine and CAP was the same in a crude liver extract and with the enzyme after final purification. Further proof was obtained when the enzyme was chromatographed on a column of DEAE cellulose after the second ammonium sulfate precipitation step. In each chromatographic fraction the amount of protein, citrulline formation from ornithine, and arsenolysis of citrulline was determined (Fig. 7). It is evident that the rates of the two enzyme reactions follow each other closely in all fractions.

It should be mentioned that the two peaks with enzyme activity in Fig. 7 do not represent two transferases. The first peak merely represents a break through of non adsorbed protein. The total amount of protein and of enzyme in this peak depended on the load of the column.

Coupling of ornithine carbamyl transferase with carbamyl transferase

In previous investigations we were interested in the formation of carbamyl aspartate from citrulline [7]. We found that CAP could be formed from citrulline and ATP in the presence of acetyl glutamate (reaction 2 below). CA-aspartate could then be formed from CAP + aspartate through the action of aspartate carbamyl transferase (3):

$$\text{Citrulline} + \text{ATP} \xrightarrow[\text{glutamate}]{\text{acetyl}} \text{CAP} + \text{ornithine} + (\text{ADP}) \qquad (2)$$

$$\text{CAP} + \text{aspartate} \longrightarrow \text{CA-aspartate} + \text{phosphate} \qquad (3)$$

The equilibrium of reaction (3) is very favourable for CA-aspartate formation [5]. This together with the formation of CAP by the reversal of the citrulline forming reaction as demonstrated above made it very likely that an alternative formation of CA-aspartate from citrulline might take place through the participation of the two carbamyl transferases:

$$\begin{aligned} \text{Citrulline} + P_i &\longrightarrow \text{CAP} + \text{ornithine} \qquad (4) \\ \text{CAP} + \text{aspartate} &\longrightarrow \text{CA-aspartate} + P_i \qquad (3) \end{aligned}$$

To test this possibility the following experiment was carried out: Two μmoles of citrulline-carbamyl-^{14}C (130 000 ct/min/μmole) + 100 μmoles of L-aspartate + 500 μmoles of phosphate, pH 7.4, were incubated with 800 units of ornithine carbamyl transferase and 250 units of aspartate carbamyl transferase for 15 min at 37°. The reaction was stopped by the addition of 0.2 ml of 4.4 M PCA and, after neutralization with KOH, CA-aspartate (0.52 μmoles calc. from total ^{14}C) was obtained by ion exchange chromatography *.

In a corresponding experiment with ^{14}CA-aspartate + ornithine + phosphate only trace amounts of radioactivity in the citrulline fractions could be demonstrated **.

It is thus clear that two enzymic ways exist for the transfer of the carbamyl group of citrulline to aspartate. Both involve the intermediate formation of CAP and the formation of CA-aspartate from CAP + aspartate. The relative importance of the two pathways is dependent on the availability of ATP and phosphate in the cell. Both reactions are strongly inhibited by

* The fractions containing CA-aspartate were pooled and evaporated to dryness *in vacuo*. The residue was dissolved in 2 ml of hot water and 100 μmoles of carrier non-labeled CA-aspartate was added. CA-aspartate was recrystallized and its specific activity determined. From this value and the specific activity in the citrulline-carbamyl-^{14}C the amount of CA-aspartate formed during the enzyme experiment could be calculated by the isotope dilution method (*cf.* Ref[3]). A value of 0.46 μmoles was obtained.

** It has not been possible to determine the equilibrium constant for aspartate carbamyl transferase, since only very small amounts of $^{14}CO_2$ were formed from ^{14}CA-aspartate + phosphate. The absence of inhibition by phosphate or arsenate [5] and the fact that practically no citrulline could be obtained from ^{14}CA-aspartate in the presence of phosphate by the combined action of the two carbamyl transferases indicate that the equilibrium position is still more favourable for the synthesis of the carbamylamino acid than in the case of ornithine carbamyl transferase.

Table 4. Isotope exchange experiments with $^{32}P_i$.

	Reisolated P_i		Reisolated CAP	
	μmoles	ct/min/μmole	μmoles	ct/min/μmole
Complete	61.0	0.62×10^6	9.8	3.61×10^3
No ornithine	44.7	0.90×10^6	21.3	1.94×10^3
No enzyme	45.8	0.89×10^6	20.7	1.89×10^3
No enzyme and ornithine	44.7	0.98×10^6	20.5	1.78×10^3

Complete experiment: 40 μmoles of CAP and $^{32}P_i$ (1.02×10^6 ct/μmole), 100 μmoles of DL-ornithine and 15 units of enzyme. Incubation 15 min at 37°, vol. 1 ml.

ornithine and are of minor significance as compared to the *de novo* formation of the carbamyl group of CAP from CO_2, NH_3 and ATP in the presence of acetyl glutamate [1].

We have also tested the ability of the purified ornithine carbamyl transferase to form CAP from citrulline + ATP in the presence of acetylglutamate and absence of phosphate [7] (reaction (2) above). No such activity could be demonstrated.

The mechanism of the reaction

Enzymic citrulline formation might be imagined to involve the intermediate formation of a carbamyl enzyme:

$$\text{CAP} + \text{Enzyme} \rightleftharpoons \text{CA-Enzyme} + P_i \quad (5)$$

$$\text{CA-Enzyme} + \text{L-Ornithine} \rightleftharpoons \text{L-Citrulline} + \text{Enzyme} \quad (6)$$

This possibility was tested by isotope exchange experiments. The reversible reaction (5) was excluded by the absence of enzymic exchange of isotope between $^{32}P_i$ and CAP (Table 4). In the presence of ornithine, however, such an exchange did take place. This again demonstrates the reversibility of the over all reaction (1).

When ornithine-^{14}C was incubated together with nonlabeled citrulline and enzyme no enzymic isotope exchange took place in the absence of phosphate

Table 5. Isotope exchange experiment with ornithine-^{14}C.

	^{14}C (ct/min) in	
	Citrulline	Ornithine
Phosphate buffer	6 000	42 000
Tris buffer	0	40 500

Experimental conditions: 2 μmoles of DL-ornithine-2-^{14}C (6.1×10^5 ct/μmole), 1 μmole of L-citrulline, 100 μmoles of phosphate buffer or 5 μmoles of tris buffer, pH 7.4, 80 units of enzyme. Vol. 0.14 ml, incubation 15 min at 37°.

Inactivation with 0.02 ml 4.4 M PCA. After centrifugation aliquots were directly subjected to paper electrophoresis (2 h, 5 V/cm) in 0.1 M ammonium acetate buffer, pH 5.0 (see experimental part). The areas corresponding to citrulline and orn thine were eluted with 10 ml of water and counted.

(Table 5) while one eighth of the isotope was transferred from ornithine to citrulline in the presence of phosphate.

As in the case of aspartate carbamyl transferase the isotope exchange experiments speak against the formation of a carbamylated enzyme. The mechanism for both carbamyl transferases seems to involve instead a single displacement [16] reaction during which both CAP and ornithine are attached to the enzyme. The carbon-oxygen bond of CAP is then broken simultaneously with the formation of the new carbon-nitrogen bond.

The participation of SH groups during the reaction is indicated from inhibition experiments for both carbamyl transferases. The partial protection from inhibition by both CAP and ornithine tentatively indicates that these substances are bound to SH groups of the enzyme during the displacement reaction.

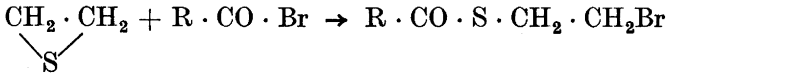
The Preparation of Thiocholine Esters



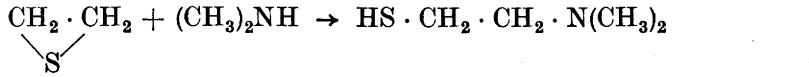
BERTIL HANSEN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

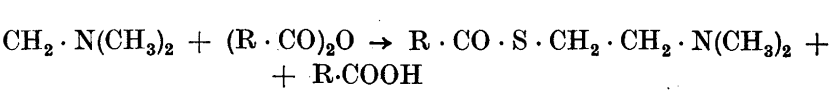
Ethylene sulphide has been prepared. From this the thiocholine esters of acetic, propionic, *n*-butyric, *n*-valeric, and benzoic acids have been synthesized in two ways. According to the first method, ethylene sulphide was treated with acyl bromides, and the 1-bromoethanethiol-(2) esters formed were transformed to thiocholine esters by trimethylamine. By the second method, dimethylamine and ethylene sulphide gave 1-dimethylaminoethanethiol-(2), which was esterified with acid anhydrides and then quaternized with methyl iodide. The methods are discussed, and the second one recommended for use.

Esters of thiocholine have, during the last years, attracted much interest within biochemistry because of their relationship to choline esters [1], and in histochemistry as a means for localizing choline esterases in tissues [2]. It thus seemed reasonable to study the preparation of thiocholine esters.

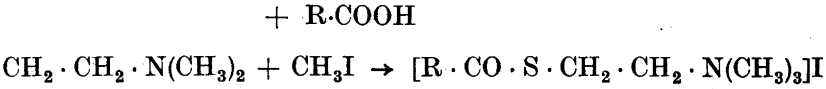
Several methods for the synthesis of acetyl thiocholine have been described in the literature [3–5]. Of these methods, the one according to Ivin [5] (Method A) seemed to be the most convenient and thus was used with some modifications.



$$\mathrm{CH_2 \cdot CH_2} + \mathrm{R \cdot CO \cdot Br} \rightarrow \mathrm{R \cdot CO \cdot S \cdot CH_2 \cdot CH_2Br}$$



$$\mathrm{R \cdot CO \cdot S \cdot CH_2 \cdot CH_2Br} + \mathrm{(CH_3)_3N} \rightarrow \mathrm{[R \cdot CO \cdot S \cdot CH_2 \cdot CH_2 \cdot N(CH_3)_3]Br}$$



Moreover, a new method (Method B) using acylation of 1-dimethylaminoethanethiol-(2) with acid anhydride and subsequent quaternization with methyl iodide was tested.

$$\mathrm{CH_2 \cdot CH_2} + \mathrm{(CH_3)_2NH} \rightarrow \mathrm{HS \cdot CH_2 \cdot CH_2 \cdot N(CH_3)_2}$$

$$\mathrm{HS \cdot CH_2 \cdot CH_2 \cdot N(CH_3)_2} + \mathrm{(R \cdot CO)_2O} \rightarrow \mathrm{R \cdot CO \cdot S \cdot CH_2 \cdot CH_2 \cdot N(CH_3)_2} + \mathrm{R \cdot COOH}$$

$$\mathrm{R \cdot CO \cdot S \cdot CH_2 \cdot CH_2 \cdot N(CH_3)_2} + \mathrm{CH_3I} \rightarrow \mathrm{[R \cdot CO \cdot S \cdot CH_2 \cdot CH_2 \cdot N(CH_3)_3]I}$$

The reaction between alkene sulphide and amines other than dimethylamine has been discussed in two earlier papers [6,7]. The last two steps are analogous to those used by Tammelin [8] for the preparation of choline esters.

The ethylene sulphide required for the two methods was synthesized by modifying a method used by Bordwell and Andersen [9] for the preparation of propylene sulphide.

EXPERIMENTAL

Ethylene sulphide. To a mixture of 80 g (1.05 mole) of thiourea, 250 ml of water and 30 ml (0.55 mole) of concentrated sulphuric acid, a solution of 49 ml (1.00 mole) of ethylene oxide in 125 ml of xylene was added. The mixture was continuously stirred and the temperature was kept below +10°. A solution of 106 g (1.00 mole) of anhydrous sodium carbonate in 500 ml of water was added during 3 h without external cooling. After a further half-hour's stirring, the organic phase was separated, dried with calcium chloride and filtered. Distillation through a 25 cm glass spiral column gave 29 g (0.48 mole) of ethylene sulphide at 55—56°. Yield 48 %.

The experiments had to be performed in a well ventilated fume-hood because of the odours evolved.

Method A

Esters of 1-bromoethanethiol-(2). 59 ml (1.00 mole) of ethylene sulphide was dissolved in 300 ml of dry carbontetrachloride, and 1.00 mole of acid bromide was added. The temperature of the reaction mixture increased to about 40°. The small precipitate formed was removed. The carbontetrachloride was distilled off at ordinary pressure. The residue gave a colourless product when distilled at reduced pressure. The results are given in Table 1.

Table 1. Esters of 1-bromoethanethiol-(2).

Acid	Formula	Mol.wt.	B. p./mm Hg	Yield in g from 1 mole of ethylene sulphide
Acetic	C_4H_7BrOS	183.1	66—8°/6	123
Propionic	C_5H_9BrOS	197.1	78—80°/6	138
n-Butyric	$C_6H_{11}BrOS$	211.1	96—7°/8	114
n-Valeric	$C_7H_{13}BrOS$	225.1	75.5°/0.9	157
Benzoic	C_9H_9BrOS	245.1	113—8°/0.4—0.5	220

Esters of thiocholine bromide. 90 ml (1.20 mole) of anhydrous trimethylamine were added to a mixture of 1.00 mole of ester of 1-bromoethanethiol-(2) and 1 l of dry acetone, cooled to —10°. White crystals were as a rule formed within a quarter of an hour. After a week at room temperature, 1 l of dry ether was added to precipitate the ester of thiocholine bromide still in solution. The precipitate was filtered off and recrystallized for analyses as follows: the acetic, propionic and benzoic derivatives from ligroin/absolute ethanol (1:1), the butyric derivative from dry acetone and the valeric derivative from dry acetone/ligroin (2:1). After drying in a vacuum desiccator the melting-points and analyses, given in Table 2, were obtained.

Method B

1-Dimethylaminoethanethiol-(2). 59 ml (1 mole) of ethylene sulphide, dissolved in 100 ml of dry ether, were cooled to —10° and 88 ml (1.33 mole) of anhydrous dimethylamine were added. The mixture was allowed to stand at room temperature for 4 days.

Table 2. Esters of thiocholine bromide.

Acid	Formula	Mol. wt.	M.p. *	C		H		Br		Yield in %
				calc.	found	calc.	found	calc.	found	
Acetic	$C_7H_{16}BrNOS$	242.2	227°	34.7	35.0	6.7	6.7	33.0	32.9	65
Propionic	$C_8H_{18}BrNOS$	256.2	196°	37.5	37.6	7.1	7.0	31.2	31.2	96
n-Butyric	$C_9H_{20}BrNOS$	270.2	150°	40.0	40.2	7.5	7.4	29.6	29.6	94
n-Valeric	$C_{10}H_{22}BrNOS$	284.3	114°	42.3	42.3	7.8	7.8	28.1	28.4	94

* Determined with a "Kofler Heizbank".

The small precipitate formed was removed. The dimethylamine and the ether were distilled off at ordinary pressure. The residue was fractionated through a 25 cm glass spiral column under reduced pressure. The fraction collected at 58—59°/63 mm contained 73 g (0.70 mole) 1-dimethylaminoethanethiol-(2). In the distillation flask a few ml of a high boiling liquid remained. $n_D^{25} = 1.4630$; $d^{25} = 0.8943$ g/cm³. (Found: C 46.0; H 10.6. Calc. for $C_4H_{11}NS$ (105.2): C 45.7; H 10.5).

Esterification of 1-dimethylaminoethanethiol-(2). 117 ml (1.00 mole) of 1-dimethylaminoethanethiol-(2) and 1.05 mole of acid anhydride were mixed. The temperature at once rose to 70—100°, except in the reaction with benzoic anhydride when it rose to only about 40°. The mixture was distilled under reduced pressure until the temperature exceeded the values given in Table 3. Almost no residue remained in the distillation flask. The distillates were colourless and evil-smelling. The viscosity of the benzoic derivative was very high.

Table 3. Esters of 1-dimethylaminoethanethiol-(2).

Acid	Acetic	Propionic	*n*-Butyric	*n*-Valeric	Benzoic

Esters of thiocholine iodide. The distillate from the esterification of 1.00 mole of 1-dimethylaminoethanethiol-(2) was dissolved in 750 ml of dry ether and 100 ml (1.60 mole) of methyl iodide were added. A white precipitate was formed at once. After three days at room temperature it was filtered off and dried in a vacuum desiccator. Recrystallization did not change the melting-points or analyses given in Table 4.

DISCUSSION

In method A no analyses have been made of the esters of 1-bromoethanethiol-(2), because of their partial decomposition during the distillation. If they were allowed to stand for a few weeks, a red-violet colour appeared, probably caused by the oxygen in the air. The addition of trimethylamine to the bromo esters was found to proceed much faster in acetone than in ether.

The 1-dimethylaminoethanethiol-(2) prepared in method B can also be obtained from 1-dimethylamino-2-chloroethane hydrochloride [4,10,11], but in that case a great part of the thiol is oxidized to the corresponding disulphide. The reactions between acid anhydrides and the thiol start at room temperature and are very exothermic because of the heat of neutralization evolved during the formation of the ammonium salt instead of the free acid and aminoester. This shows that it is impossible to separate the esters of the 1-dimethylaminoethanethiol-(2) from the acids by directly applied distillation. However, the acid impurities do not seem to have a bad effect on the subsequent quaternization. The tertiary esters can be prepared from their hydrobromides [12].

Of the two methods used for the preparation of thiocholine esters, method B is to be preferred. It gives iodides which are less hygroscopic than the bromides obtained according to method A and the products formed give correct analyses without recrystallization. The only disadvantage is that method B is restricted to mono esters.

My thanks are due to the Head of this Institute, Professor G. Ljunggren, for his kind interest in this work.

The Effect of Salicylic Acid, Benzoic Acid and some of their Derivatives on Oxidative Phosphorylation

INGMAR BOSUND

The Wenner-Gren Institute for Experimental Biology, University of Stockholm, and Swedish Institute for Food Preservation Research, Gothenburg, Sweden

Salicylic acid (10^{-2} M) and benzoic acid (10^{-1} M) cause an uncoupling of oxidative phosphorylation from respiration in isolated rat liver mitochondria. Similar results are obtained with 5-nitro-salicylic acid and with methyl benzoate.

The growth inhibiting effect of salicylic and benzoic acids on microorganisms has been the subject of many studies with the purpose of elucidating the mode of action of these compounds. In recent years investigations have been published which call attention to the possibility that the growth inhibiting effect might originate, at least to some extent, in an inhibition of the formation or utilization of high energy compounds [1-5]. In order to obtain further evidence, the effect of salicylic and benzoic acids and some of their derivatives on the oxidative phosphorylation in isolated rat liver mitochondria was studied in this work.

EXPERIMENTAL

Preparation of mitochondria. The preparation of mitochondria was carried out according to the method of Schneider and Hogeboom [6]. The rats were killed by decapitation and the livers put in 0.25 M ice-cold sucrose as fast as possible. In this solution the liver was cut into small pieces and rinsed several times with sucrose solution. The homogenization was carried out in a Potter-Elvehjem homogenizer. The homogenate was diluted to *ca.* 100 ml with 0.25 M sucrose and centrifuged at 1 600 *g* for 10 minutes. The supernatant was decanted and recentrifuged at 4 100 g for 20 min. The mitochondria were washed twice with *ca.* 100 ml sucrose each time.

Materials. Yeast hexokinase was used as a stock solution which had been prepared according to Berger *et al.*[7] with minor modifications [8]. ATP, as the crystalline disodium trihydrate, had been furnished by the Sigma Chemical Company, St. Louis, Mo., U.S.A., and $H_3{}^{32}PO_4$ by the Radiochemical Centre, Amersham, England. All solutions were prepared in glass-distilled deionized water.

Incubation procedure. Mitochondria from one liver were suspended in 13.3 ml 0.25 M sucrose containing 116 mg $K_2H^{32}PO_4$, 144 mg glucose and 12 mg ATP. The pH was adjusted to 7.5 by means of glass electrode. To this suspension 1.3 ml 0.1 M $MgCl_2$ was added and the suspension was diluted to 20 ml with 0.25 M sucrose. In all experiments 1.5 ml of this suspension was added to each vessel.

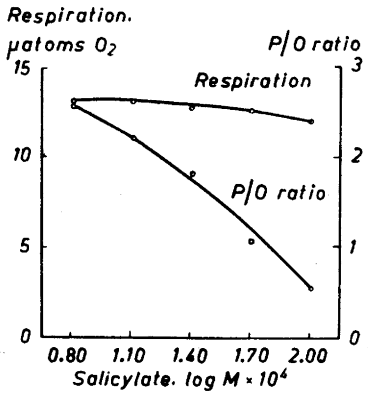

Fig. 1. The effect of increasing concentrations of salicylate on oxidative phosphorylation. Each vessel contained besides the suspension described in the experimental part 30 μmoles potassium α-ketoglutarate as substrate and potassium salicylate in the concentrations indicated in the figure. Experimental conditions: gas phase, air; temp., 30°C; time of incubation, 20 min.

Analytical procedures. Oxygen consumption was measured by the conventional Warburg technique. The described suspension and neutralized solutions of the different inhibitors were added to the main compartments of the Warburg vessels, substrates and hexokinase (0.1 ml of the stock solution) to the sidearms. The centre wells contained 0.2 ml 2 M KOH, absorbed on a roll of filter paper. The final volume of solution in the vessels was adjusted to 2 ml with 1.15 % KCl. Manometer readings were made at 5 min invervals, starting 5 min after the addition of substrate and hexokinase from the sidearms. Oxygen consumption for the period 0—5 min was calculated by extrapolation. At the end of the experiments, enzymatic activity was terminated by the addition of 0.2 ml 5 M H_2SO_4. Phosphate uptake was determined as the ratio of organic phosphate formed to inorganic phosphate added by the isotope distribution method described by Lindberg and Ernster [9].

RESULTS

The effect of increasing concentrations of salicylate on oxidative phosphorylation and oxygen consumption with α-ketoglutarate as substrate is illustrated by Fig. 1.

The figure shows that salicylate at a concentration of about 1×10^{-2} M almost completely inhibits phosphorylation, while the inhibition of oxygen consumption is negligible. Similar results are obtained if α-ketoglutarate is replaced by pyruvate + malate, succinate, or glutamate.

Table 1. The effect of salicylate on oxidative phosphorylation.

Additions	Without hexokinase	With hexokinase	
	Oxygen μatoms	Oxygen μatoms	P/O ratio
None	4.6	11.2	2.5
DPN + cytochrome c	5.3	11.7	2.3
Salicylate	9.4	8.5	0.6
Salicylate + DPN + cytochrome c	10.3	9.6	0.5

The final concentrations of the substances added to the suspension of the mitochondria were as follows: DPN, 6.8×10^{-4} M; cytochrome c, 10^{-5} M; potassium salicylate, 10^{-2} M, Each vessel contained 30 μmoles potassium α-ketoglutarate as substrate. Experimental conditions as in Fig. 1.

Table 1 exemplifies an experiment which shows that salicylate, at the concentration mentioned above, is able to induce an almost maximum level of respiration in the absence of hexokinase. This is a further indication that salicylate uncouples phosphorylation from respiration, since, in this case, respiration proceeds in the absence of a terminal phosphate acceptor.

Experiments with benzoate showed that this substance had a similar effect, which, however, became noticeable only at still higher concentrations than those which were necessary in the case of salicylate. The results of a typical experiment with benzoate are shown in Table 2. The relatively high concentrations of benzoate caused a partial inhibition of respiration along with the effect on phosphorylation. It was possible to bring up the respiration to the original level by the addition of DPN and cytochrome c, without, however, a simultaneous recovery of the phosphorylation. This indicates that the inhibition of respiration is a secondary effect, due to a release of DPN and cytochrome c from the mitochondria.

Similar pictures are obtained if glutamate is replaced by other substrates such as succinate and α-ketoglutarate.

Table 2. The effect of benzoate on oxidative phosphorylation.

Additions	Without hexokinase	With hexokinase	
	Oxygen μatoms	Oxygen μatoms	P/O ratio
None	3.5	12.3	2.1
DPN + cytochrome c	6.7	12.2	2.0
Benzoate	8.2	10.7	1.0
Benzoate + DPN + cytochrome c	8.7	12.1	0.9

Experimental conditions as in Fig. 1. Each vessel contained 30 μmoles potassium glutamate. DPN and cytochrome c were added at the same concentrations as in Table 1. The benzoate concentration was 8×10^{-2} M.

In order to further elucidate the mode of action of salicylate and benzoate on oxidative phosphorylation, the effect of some related substances was investigated. Of these compounds 5-nitro-salicylic acid (which differs from 2,4-dinitrophenol only by the replacement of one of the nitro groups by a

Table 3. The effect of 5-nitro-salicylic acid on oxidative phosphorylation.

Substrate	Without 5-nitro-salicylic acid		With 10^{-3} M 5-nitro-salicylic acid		With 10^{-2} M 5-nitro-salicylic acid	
	Oxygen μatoms	P/O ratio	Oxygen μatoms	P/O ratio	Oxygen μatoms	P/O ratio
Glutamate	13.4	2.3	12.8	1.8	11.1	0.14
Succinate	13.8	1.5	13.9	1.2	4.8	0.15

Each vessel contained 30 μmoles substrate. Experimental conditions as in Fig. 1.

carboxyl group) and methyl benzoate inhibited phosphorylation to about the same extent as did salicylic acid, while 4-hydroxy-salicylic, 5-hydroxy-salicylic and 4-amino-salicylic acids (PAS) were without effect. Table 3 shows the results of an experiment with 5-nitro-salicylic acid.

DISCUSSION

It is evident from the results described in this paper that salicylic and benzoic acids produce an effect on oxidative phosphorylation, which is reminiscent of that obtained with 2,4-dinitrophenol. The concentrations required to obtain a marked effect are of the same magnitude as those required for a complete suppression of bacterial growth at the pH in question (7.5). As is well known, however, the growth inhibiting effect of salicylic and benzoic acids increases as the pH is lowered. This is probably due to the fact that the undissociated molecules of these acids are more lipophilic than the respective anions and, thus, more easily taken up by the bacteria. Such a correlation is well conceivable to prevail even in the present case, where an increasing lipid solubility might facilitate the penetration of these inhibitors into the mitochondrial structure. This point is, however, hard to test in experiments with isolated mitochondria, which lack the mechanism by which bacterial cells can make themselves independent at least to some extent of the pH of the environment. A lowering of the pH in such experiments may thus render oxidative phosphorylation impossible.

This work is part of an investigation supported by *Statens Naturvetenskapliga Forskningsråd* and *Statens Tekniska Forskningsråd*.

I wish to express my sincere gratitude to Professor Olov Lindberg for allowing me to perform these experiments at his Institute and to Dr. Lars Ernster for indispensable advice and valuable discussions throughout the work. I also wish to thank Professor Gösta Ehrensvärd for providing me with samples of some of the inhibitors and for stimulating discussions.

Crystallographic Studies of Calcium and Strontium Hydroxyapatites

CURT LAGERGREN and DIEGO CARLSTRÖM

Department of Medical Physics, Karolinska Institutet, Stockholm, Sweden

From X-ray crystallographic investigations on apatites in the system $Ca_{10}(PO_4)_6(OH)_2-Sr_{10}(PO_4)_6(OH)_2$ it was found that no solid solutions could be formed in the region $Ca_3Sr_7(PO_4)_6(OH)_2$ to $Ca_7Sr_3(PO_4)_6(OH)_2$. The mixed apatite $Ca_5Sr_5(PO_4)(OH)_2$, however, was shown to have a very well ordered lattice. In the light of these experimental findings, it is concluded that strontium ions in the inorganic crystalline phase of bone are probably bound rather firmly to the surface of the extremely small apatite crystallites.

The localization and metabolic control of many trace elements by the skeleton has been known for a number of years. Recently, the number of cationic radioactive emitters found to be preferentially incorporated in bone has increased and of these, strontium, because it has many atomic characteristics and chemical properties similar to calcium and is probably metabolized and incorporated in the same fashion, has received particular attention [4,5,15].

This study was undertaken in order to determine the manner in which strontium is incorporated into the inorganic crystal phase of bone. Although the exact molecular structure of the inorganic bone crystals has not been definitely agreed on by workers in the field, there is general agreement that it differs but little from calcium hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$). In the apatite structure several isomorphic substitutions are known to occur and in some cases a continuous series of solid solutions have been demonstrated to exist. For example the mixed apatites in the system $Ca_{10}(PO_4)_6(OH)_2$—$Ca_{10}(PO_4)_6F_2$—$Ca_{10}(PO_4)_6Cl_2$ have been thoroughly investigated by means of X-ray diffraction [16,17] and the calcium-lead-hydroxyapatites have also been shown to form solid solutions [10]. However, relatively little is known about the strontium apatites. Pure strontium hydroxyapatite ($Sr_{10}(PO_4)_6(OH)_2$) has been synthesized in several ways [8,12] and natural mineral fluorapatite containing less amounts of strontium has been described [9], but investigations have not been carried out on the mixed calcium-strontium apatites.

There are three possible ways by which the Sr ion could be incorporated into the inorganic crystalline structure of bone. Because of the extremely

small size (approx. 220 Å × 50 Å) of the Ca apatite crystallites in bone [3,6], there is consequently a large surface area available to which the Sr ion could be bound. This mode of incorporation has been shown to exist for many other ions. Sr could also be incorporated as part of the apatite lattice as an isomorphic substitution for calcium, or a combination of both isomorphic substitution and surface binding could occur.

Because Sr^{++} has a larger ionic radius than Ca^{++} (1.13 *versus* 0.99 Å) isomorphic substitution of Sr^{++} for Ca^{++} will result in an enlargement of the unit cell dimensions. This difference in the lengths of the axes of the unit cell can be detected by X-ray diffraction and it should therefore be possible to correlate the degree of expansion of the lattice with the amount of isomorphic substitution of Sr^{++} for Ca^{++} that occurs.

EXPERIMENTAL

Material. Pure calcium and strontium hydroxyapatites, (in the following abbreviated to CaHA and SrHA) were synthesized in aqueous solutions at a pH of about 9 by adding a dilute solution of Na_2HPO_4 to solutions of Ca and Sr nitrate. The precipitates formed were thoroughly washed with water and samples were heated at 900°C for 2 h after which crystallographic homogeneity was determined by X-ray diffraction. No diffraction lines other than those of pure apatite could be detected. In addition, as a control, a commercial strontium phosphate was similarly heated and this sample showed almost pure SrHA containing only small amounts of $Sr_3(PO_4)_2$. Since it was not found possible to synthesize the desired mixed apatites in aqueous solutions, these mixed apatites were made in the solid state. Several different methods were tried but the most satisfactory results were obtained by heating mixtures of the respective apatites to high temperatures. After the non-constituent water of the pure CaHA and SrHA were accurately determined a series of mixtures with known mole fractions of Ca and Sr were prepared and these mixtures were heated for 4 h at 1 300° ± 15°C. It was found that at lower temperatures and/or shorter durations the reactions did not proceed to completion and that the original apatites could occasionally be detected by X-ray diffraction.

Methods. A Philips diffractometer unit with nickel-filtered copper radiation was used. In order to get the highest possible precision and to avoid errors depending on the varying absorption in the specimens, a standard substance (silicon) with an accurately known lattice constant (a = 5.4306 Å) was mixed with all samples. As it was evident that several of the solid solutions gave badly defined diffraction lines only the strongest reflections could be used for measurements. However, as the (00 * 4) — reflection was superimposed on the (40 * 2—04 * 2)-reflection when the specimens contained large amounts of strontium the c-axis could not be determined with sufficient accuracy in all cases and it was therefore decided to determine only the a-axis by measuring the (14 * 0—41 * 0)-line. For the pure CaHA and SrHA which gave well defined diffraction patterns it was possible to determine both axes with high precision by measuring reflections in the region 60°—70° Θ.

RESULTS

The lattice constants for pure CaHA and SrHA were found to have the following values:

$Ca_{10}(PO_4)_6(OH)_2$	$a = 9.42_3$ Å	$c = 6.88_4$ Å	$c/a = 0.7306$
$Sr_{10}(PO_4)_6(OH)_2$	$a = 9.76_1$ Å	$c = 7.27_7$ Å	$c/a = 0.7455$

The axes dimensions of CaHA are in very good agreement with earlier published precision measurements [1,3,11,13] whereas those for SrHA showed a much larger deviation from the only other measurements in the literature

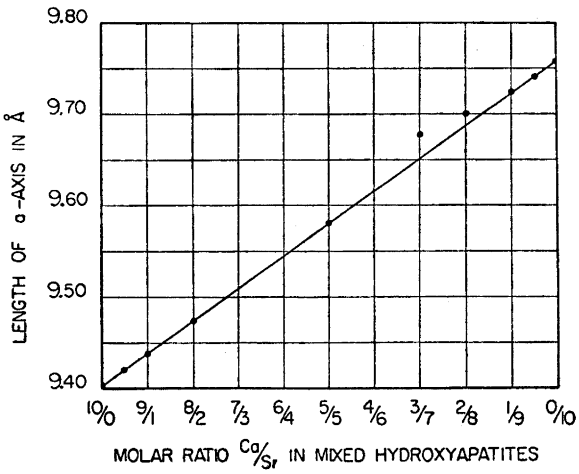

Fig. 1. Graph showing the relationship between the length of the *a*-axis and the degree of substitution in mixed Ca-Sr-hydroxyapatites.

($a = 9.74$; $c = 7.20$ kX) [8]. The change in the c/a ratio causes the general appearance of the diffraction pattern of SrHA to differ considerably from that of CaHA.

The diffraction patterns of the mixed Ca-Sr-HA were of a varying character. The diffraction lines showed a noticeable broadening when one Sr^{++} was introduced in the CaHA-unit cell, and with two Sr^{++} ions in the lattice the reflections were almost impossible to measure. The solid solutions, Ca_7Sr_3HA and Ca_6Sr_4HA, gave no recognizable patterns at all. On the other hand the compound Ca_5Sr_5HA appeared to have an almost perfect lattice and the diffraction lines were as well defined as in the pure Ca or SrHA. The next member in the series, Ca_4Sr_6HA, again gave an extremely bad diffraction pattern without identifiable reflections. With increasing amounts of Sr in the lattice the diffraction patterns became better and better and that of Ca_1Sr_9HA was almost as good as that of pure SrHA. The lengths of the *a*-axis for the mixed apatites in the Ca-SrHA-system have been plotted in Fig. 1. In order to compare the pure members (CaHA, SrHA) with the mixed ones in this series under comparable conditions, pure CaHA, and SrHA were also heated to 1 300° C. This resulted in a decrease of the *a*-axis of 0.02 Å. In order to find at what temperature ranges this effect occurred, 6 different samples of CaHA were heated for 4 h at temperatures between 900° and 1 300°C. The result is shown in Fig. 2.

DISCUSSION AND CONCLUSIONS

From Fig. 1 it is evident that the alteration in the *a*-axis dimension is directly proportional to the degree of substitution as long as the amount of substitution is low. The well crystallized apatite, Ca_5Sr_5HA, also shows an

a-axis dimension midway between the pure CaHA and pure SrHA. However, the *a*-axis dimension of the strontium apatites deviates more and more from the straight line as their content of calcium increases and the *a*-axis of Ca_3Sr_7HA corresponds in reality to the one expected for Ca_2Sr_8HA. Since, as already has been pointed out, the diffraction patterns of these compounds were very poorly defined, it was impossible to measure the position of the reflections with accuracy, or to judge whether these solid solutions were pure, or if they were instead made up of several badly crystallized products. Thus, it seems most possible that the apatite which is indicated in the diagram in the position of Ca_3Sr_7HA was not formed during the heating but rather it was mainly composed of the solid solution Ca_2Sr_8HA. With the exception of the intermediate apatite Ca_5Sr_5HA, it is evident that only about two Sr ions or two Ca ions can be forced into the respective CaHA and SrHA lattices without a total collapse of the structure. But even at this moderate degree of substitution the lattice is badly distorted and evidently no solid solutions can be formed in the range Ca_3Sr_7HA to Ca_7Sr_3HA. This conclusion was very surprising in the light of the statement [10] that a continuous series of solid solutions could be formed in the system $Ca_{10}(PO_4)_6(OH)_2$—$Pb_{10}(PO_4)_6(OH)_2$, as it seemed by all means that Sr^{++} should be easier to introduce into the lattice than the larger Pb^{++}. However, on careful examination of the paper by Müller [10] on the calcium-lead apatites, it appears that he did not synthesize or investigate the solid solutions between Ca_7Pb_3HA and Ca_2Pb_8HA with exception of the intermediate apatite Ca_5Pb_5HA. From this work it is also evident that in spite of heat treatment Ca_7Pb_3HA was so badly crystallized that only the strongest reflections in the X-ray diffraction pattern could be measured. For these reasons it seems most likely that the conclusions reached above regarding the Ca—Sr apatites also apply to the Ca—Pb apatites, and that both Sr^{++} and Pb^{++} deviate too much in size from Ca^{++} to be able to form continuous series of solid solutions. It is interesting to note that the intermediate Ca_5Sr_5HA and Ca_5Pb_5HA both exist, and apparently these mixed, apatites are not solid solutions but have a more or less ordered structure possibly forming a superlattice.

The contraction of the *a*-axis of CaHA at temperatures above 1 000°C (see Fig. 2) has not been described before. It has long been known that a total loss of the constitutional water of CaHA is inconsistent with the apatite structure and that a pure oxyapatite ($Ca_{10}(PO_4)_6O_2$) does not exist, but it has been shown [2] that a partial loss of the water can occur without the destruction of the apatite lattice. As no special efforts were made to measure the loss of water or to work in an absolutely water-free atomsphere (CaHA can be synthesized from perfectly dry components in the presence of water vapour even at 1 000°C [7,14],) no definite explanation can be given to the shrinkage of the *a*-axis, but it seems most reasonable that this phenomenon is due to a partial loss of the constitutional water.

From the work by Müller on Ca-Pb apatites [10] it is clear that the precipitates of mixed apatites which he prepared were very badly crystallized. The same almost noncrystalline state was found in the precipitates of Ca-Sr-apatites. In several cases in which the precipitates were heated in order to increase their crystallinity, additional lines were obtained in the diffraction

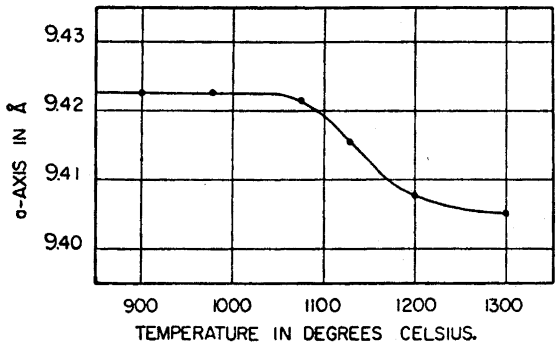

Fig. 2. Plot of the change in the *a*-axis dimension of calcium hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$) *versus* temperature.

patterns, resulting from the presence of triphosphate compounds. For that reason we abandoned the latter method of preparing the mixed apatites. However, as the heating of an apatite precipitate above 500—600°C not only causes a growth of the crystallites but also implies a total reorganization of the lattice, with the introduction into the lattice of ions previously adsorbed to the surface of the crystallites, or even creation of compounds other than those originally present, it is impossible to judge if the badly crystallized original precipitate consisted of one or several phases with or without adsorbed or surface bound ions. Thus, no direct conclusions can be drawn regarding the nature of the precipitates formed in solutions containing both Ca and Sr ions, but it is clear that even small amounts of strontium in a solution containing calcium and phosphate ions considerably inhibits the orderly crystallization of an apatite. This is a further indication that strontium ions do not easily replace Ca^{++} in the CaHA lattice.

It thus appears that because of its size the Sr ion is not well suited for any great amount of isomorphic ion exchange with calcium for positions in the lattice, particularly in the formation of the apatite lattice from dilute solutions comparable to those occurring in the body fluids. We are thus inclined to conclude that Sr^{++} introduced in the body will be bound mainly to the surface of the extremely small apatite crystallites of bone, the surface area of which has been shown to have very great binding properties for ions of various kinds [3]. The similarity in the metabolism of Ca^{++} and Sr^{++}, demonstrated in experiments with radioactive isotopes, suggests that Sr ions on the surface of the bone crystallites may be as tightly bound as Ca ions in surface positions.

The Ethylenediaminetetraacetate Complexes of Vanadium(V)

ANDERS RINGBOM, SOINI SIITONEN and BENGT SKRIFVARS

Institutet för analytisk och oorganisk kemi, Åbo Akademi, Åbo, Finland

Pentavalent vanadium forms with ethylenediaminetetraacetic acid (H_4Y) a complex compound VO_2Y^{3-} with a stability constant log $K = 18.05$. At pH values below about 3.5 the complex VO_2HY^{2-} is formed; the acidic dissociation constant of this compound is $pk = 3.60$. In alkaline solutions vanadates are formed.

The complexes of divalent, trivalent and tetravalent vanadium with ethylenediaminetetraacetic acid (EDTA) have been investigated by Schwarzenbach [1], but about the complexes of pentavalent vanadium little is known. Polarographic investigations of Pecsok and Juvet [2] and of Micka and Tockstein [3] point to the formation of some complexes. However, there seems to be no information in the literature about the composition and the stability of these compounds. In the following the results of some investigations made in order to clear up these questions will be reported.

It seems likely that in a weak acid solution a compound VO_2Y^{3-} is formed. This assumption is made on the basis of the fact that when a solution of ammonium metavanadate is titrated with the disodium salt of EDTA the acidity remains constant (pH $\sim$ 6.5) until the equivalence point is reached, which points to the reaction

$$VO_3^- + H_2Y^{2-} = VO_2Y^{3-} + H_2O$$

A compound of this formula is also in accordance with the results recently obtained by Rossotti and Rossotti [4] in an investigation on the hydrolysis products of pentavalent vanadium.

When the solution is made more acid — at pH values below 3 — another complex is formed. Equilibrium measurements showed that this reaction involves the addition of one hydrogen ion. In other words, Y^{4-} is replaced by HY^{3-} according to

$$VO_2Y^{3-} + H^+ = VO_2HY^{2-}$$

A change of the shade of the greenish yellow colour is connected with this reaction.

It is possible to determine photometrically the stability constants of the complexes on the basis of the colours of the various compounds. The stability ranges of these complexes will be clear from Fig. 1 giving the absorbance index of vanadium as a function of pH.

Tables 1 and 2 illustrate the way of calculating the equilibrium constants.

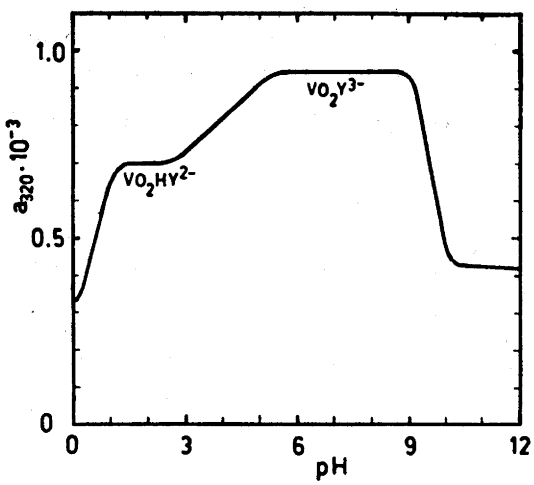

Fig. 1. Absorbance index of vanadium at an excess of EDTA as a function of pH. $C_V = 10^{-3}$, $C_{EDTA} = 5 \times 10^{-3}$.

The absorbances are designed by A. β_{HY} is the fraction of EDTA not bound to vanadium that appears as HY^{-3} ions. Usually β_{HY} is calculated from the equation

$$\beta_{HY} = \frac{[H^+]\beta_Y}{k_4}$$

β_Y can be determined graphically [5] or from the equation

$$\beta_Y = \frac{[H^+]^4}{k_1k_2k_3k_4} + \frac{[H^+]^3}{k_2k_3k_4} + \frac{[H^+]^2}{k_3k_4} + \frac{[H^+]}{k^4} + 1$$

The following values of the dissociation constants of EDTA were used: $pk_1 = 2.0$; $pk_2 = 2.76$; $pk_3 = 6.16$; $pk_4 = 10.26$. α is the fraction of vanadium present in the less coloured form (VO_2^+ in Table 1, VO_2HY^{2-} in Table 2).

Perchloric acid was used for the regulation of the acidity. The ionic strength was kept at approximately 0.1 by the addition of sodium perchlorate. The temperature was *ca.* 20°.

By combining the constants obtained above it is possible to calculate in addition the following constant

$$K_{VO_2Y} = \frac{[VO_2Y^{3-}]}{[VO_2^+]\,[Y^{4-}]} = \frac{K_{VO_2HY}\,k_{VO_2HY}}{k_4} = 10^{18.05}$$

The vanadium(V)-EDTA complex is thus almost as strong as the corresponding copper complex.

Fig. 1 points to the formation of vanadates in alkaline solution. It is likely that the compound stable at the pH range 10—12 is a pyrovanadate [6] and that in a still more alkaline solution orthovanadate VO_4^{3-} is formed.

This investigation has been supported by grants from *Statens Naturvetenskapliga Kommission*, Finland.

3-Hydroxyphthalic Acid, a Metabolite in *Penicillium islandicum* Sopp

STEN GATENBECK

Department of Physiological Chemistry, Wenner-Gren Institute, University of Stockholm, Sweden

In an investigation of *Penicillium islandicum* Sopp 3-hydroxyphthalic acid was isolated from the culture medium. The structure was proved by paper chromatography and degradation to *m*-hydroxybenzoic acid.

It has been shown previously [1-3] that the mycelium of *Penicillium islandicum* Sopp, when grown on a synthetic medium containing glucose as the sole source of carbon, contains large amounts of red pigments consisting of a mixture of islandicin, iridoskyrin, skyrin, rubroskyrin and erythroskyrine. Of these pigments islandicin is 1,4,5-trihydroxy-2-methylanthraquinone, iridoskyrin a dimeric derivative of islandicin and skyrin a dimeric derivative of *Frangula* emodin (4,5,7-trihydroxy-2-methylanthraquinone). The structures of rubroskyrin and erythroskyrine are unknown.

During the studies of the biological formation of islandicin, the culture medium of *P. islandicum* Sopp has been examined for aromatic substances. The examination has been made by paper chromatographical methods with a technique elaborated at this laboratory by Ehrensvärd and his group [4].

The ether extract of the acidified culture medium contains very small amounts of aromatic compounds detectable with the reagents used. 3 or 4 different aromatic substances could be detected. One of them has been identified as 3-hydroxyphthalic acid which has not previously been obtained from any natural source.

3-Hydroxyphthalic acid was identified after isolation by fractionation on a silica gel column. The crude fraction was extracted in a countercurrent distribution apparatus. The amount of natural 3-hydroxyphthalic acid was estimated to be 1—2 mg per litre culture medium by comparing the fluoroscence in UV light of a solution of the natural product with a standard solution of synthetic 3-hydroxyphthalic acid [5] in ether. Owing to the difficulty in getting the acid in a pure, crystalline form the identification was made by comparing its color reactions and R_F values in 6 different solvents with those of pure,

synthetic 3-hydroxyphthalic acid. Furthermore, the natural product was decarboxylated to *m*-hydroxybenzoic acid which was identified in the same way by comparison with synthetic *m*-hydroxybenzoic acid.

3-Hydroxyphthalic acid has a very close structural relationship to 3,5-dihydroxyphthalic acid which occurs in *Penicillium brevi-compactum* [6]. According to Oxford and Raistrick [7,8] dihydroxyphthalic acid appears to be an oxidation product of the different propyl derivatives of β-resorcylic acid which accompany 3,5-dihydroxyphthalic acid in *P. brevi-compactum*. The biological formation of 3-hydroxyphthalic acid in *P. islandicum* does not seem to follow the same route because the corresponding methyl- and propyl derivatives of salicylic acid cannot be detected in the culture medium. Nor can the 3-hydroxyphthalic acid in the culture medium be looked upon as a degradation product of islandicin or any other pigment because the acid is formed at an early stage during growth at a time when there is hardly any pigment production. The question whether 3-hydroxyphthalic acid is a metabolite in a reaction series leading to the formation of islandicin or represents a by-product in this chain will be a subject for further investigations.

EXPERIMENTAL

Culture conditions. Culture medium: Czapek-Dox solution: Glucose, 50.0 g; $NaNO_3$, 2.0 g; KH_2PO_4, 1.0 g; KCl, 0.5 g; $MgSO_4 \cdot 7H_2O$, 0.5 g; $FeSO_4 \cdot 7H_2O$, 0.01 g; distilled water 1 l.

Ten 1-litre flat-bottomed culture flasks plugged with cotton wool each containing 500 ml of Czapek-Dox solution were sterilized. Small inoculates of *P. islandicum*, strain N.R.R.L. 1036, were placed in the flasks. The cultures were incubated in the dark at 24°C and were harvested after 20 days' incubation.

Isolation of 3-hydroxyphthalic acid. The orange-yellow culture medium was separated by filtration from the mold mycelium which was washed with distilled water. The acid medium, pH 4, was neutralized with 33 % aqueous NaOH and evaporated at reduced pressure on a water bath to about 500 ml. The concentrated solution was acidified with conc. HCl and extracted 6 times with a total amount of 2 l of ether. The ether solution was dried over anhydrous Na_2SO_4 and then evaporated to about 100 ml. The evaporation was continued in an air stream under a heating lamp to almost dryness. The last trace of solvent was removed in a vacuum-desiccator over silica gel. The residue was dissolved in 4—5 ml of acetone and the solution added to a silica gel column (45 × 2.5 cm). The 3-hydroxyphthalic acid was eluted with a mixture of acetone:chloroform (1:3). The column was illuminated with UV light and the band with the light blue fluorescence of 3-hydroxyphthalic acid was collected. This fraction, intensively red colored, was evaporated to dryness. The residue was fractionated in an ordinary manual Craig distribution apparatus consisting of 50 transfer tubes, each tube holding 20 ml. An aqueous solution of 3 % formic acid was used as stationary phase and the mobile phase consisted of methyl *iso*butyl ketone equilibrated with the stationary phase. The residue was dissolved in 10 ml of the mobile phase and placed in the first transfer tube together with 10 ml of the stationary phase. The colored substances run in the front and after 40 transfers the 3-hydroxyphthalic acid could be localized to the tubes 25—34 by illumination with UV light. The solutions in these tubes were collected and the methyl *iso*-butyl ketone was removed by distillation at reduced pressure. The remaining aqueous solution was extracted several times with ether. The collected ether phases were evaporated in an air stream under a heating lamp. The residue that had a faint yellow color was dissolved in about 1.5 ml of boiling water. The solution was treated with a little active carbon and filtered hot, leaving a colorless filtrate.

Identification of 3-hydroxyphthalic acid. The filtrate was cooled in a refrigerator overnight. A very small precipitate was formed. The mixture was shaken with an equal volume of ether. Paper chromatograms were run from the ether solution on Whatman

filter paper No. 1 in 6 different solvents at 22°C. The composition of the solvents has been elaborated at this laboratory and they have been extensively used for identification of organic substances in the *Penicillium* series. The solvents are [4]:

A. methyl *iso*butyl ketone/4 % aqueous formic acid
B. chloroform/methanol, 2 % aqueous formic acid
C. benzene, methyl ethyl ketone/2 % aqueous formic acid
D. benzene/2 % aqueous formic acid
E. water, methyl ethyl ketone, diethylamine
F. methyl ethyl ketone, acetone, aqueous formic acid

On each paper chromatogram were placed: I, natural product; II, pure, synthetic 3-hydroxyphthalic acid; III, a mixture of I and II. The chromatograms were analyzed with a) UV light, b) *p*-nitrobenzenediazoniumfluoborate in 50 % aqueous ethanol + ammonia, c) aqueous ferric chloride. I, II and III had the same R_F values and gave spots indistinguishable from each other with all the reagents used; a) gave a light blue fluorescence, b) an orange color, c) a violet color.

The following R_F values were obtained:

Solvent	A	B	C	D	E	F
R_F value	0.60	0.08	0.05	0.00	0.00	0.83

The water-ether solution of natural 3-hydroxyphthalic acid was heated on a water bath until the ether had evaporated. An equal volume of conc. H_2SO_4 was added to the remaining aqueous solution and the mixture was refluxed for 2 h at 125°C. A corresponding amount of synthetic 3-hydroxyphthalic acid was treated in the same way. The solutions were cooled to room temperature and extracted with ether. The ether solutions were tested paper-chromatographically in the same solvents as above. On each chromatogram were placed: 1. H_2SO_4-treated natural product, 2. H_2SO_4-treated synthetic 3-hydroxyphthalic acid. 3. synthetic *m*-hydroxybenzoic acid. The chromatograms were analyzed with d) *p*-nitrobenzenediazoniumfluoborate in 50 % aqueous ethanol + ammonia, e) 2,6-dibromoquinonechlorimide in dioxan + ammonia. 1, 2 and 3 gave identical spots with the same R_F values and the same color reactions, *i. e.* with d) a reddish brown color, e) a blue color.

Solvent	A	B	C	D	E	F
R_F value	0.86	0.45	0.35	0.01	0.09	0.91

No 3-hydroxyphthalic acid could be detected.

Acknowledgment. The author is indebted to Professor G. Ehrensvärd for his stimulating interest in this work.

Quantitative Analysis of Aryloxysilanes

BENGT SMITH

Institutionen för Organisk Kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

Two new methods for the quantitative analysis of aryloxysilanes have been developed. The first one involved bromide-bromate titration in glacial acetic acid, the second titration with potassium methoxide in anhydrous ethylenediamine using *o*-nitroaniline as an indicator. The scope and limitations of the methods have been discussed. The first method was also applicable to phenyl orthoesters of carboxylic acids.

The investigation of silanes, especially of those containing aryloxy, alkoxy, alkyl and aryl groups in different combinations bonded to a silicon atom has for a long time been hampered by the lack of convenient rapid methods for their quantitative analysis. To ascertain their purity it has been necessary generally to determine the silicon, carbon and hydrogen content which is, as a rule, a time consuming procedure. The present investigation was undertaken in an attempt to improve this situation.

BROMIDE-BROMATE TITRATION

Recently it was shown by the present author [1] that many phenols can be titrated directly in glacial acetic acid using bromide-bromate solution. In view of the ease with which aryloxy groups bonded to silicon are split off by hydrolysis it seemed justified also to investigate whether the method was applicable to aryloxysilanes. This proved to be the case for such aryloxysilanes in which the corresponding free phenol was directly titratable (see Ref.[1]). Thus phenoxy-, *o*-cresoxy-, *m*-cresoxy-, *p*-cresoxy- and 2,6-xylenoxysilanes could be accurately analyzed. Judging from the amount of bromine consumed, the bromine atoms entered the vacant *ortho* and *para* positions *. The bromide-, bromate method was applicable to all aryloxysilanes investigated, with the above-mentioned aryloxy groups, except those where tertiary butoxy groups

* No investigation has been made of the mechanism of the reaction or of the products formed. Thus it is unknown whether hydrolysis takes place prior to the reaction with bromine or if the aryloxysilane is brominated as such.

also were linked to the silicon atom. A decreased reactivity of tertiary alkoxysilanes in various reactions has been observed previously [2,3]. In the present case the inactivation is most likely due to shielding of the silicon atom and the *ortho* positions of the aryloxy group (see also p. 560). Although the "direct" titration method failed, the *tert.*-alkoxyaryloxysilanes could be analyzed by hydrolyzing the silanes in a mixture of glacial acetic acid and conc. hydrochloric acid and then titrating the mixture with bromide-bromate solution. The accuracy is, however, somewhat less than that of the "direct" titration method.

As might be expected the "direct" titration method failed for those aryloxysilanes where the corresponding phenol had to be analyzed by the excess method (see Ref.[1]). Thus, the bromine consumption of thymoxytriethoxysilane and the corresponding carvacryloxysilane was too low. Application of the "excess" bromination method under the conditions used for the determination of the free phenols (*cf.* Ref.[1]) resulted in a too high bromine consumption. Under the prevailing conditions bromine obviously reacts with the ethoxy groups or the ethyl alcohol formed by hydrolysis.

The direct titration method was also suitable for the quantitative determination of phenyl orthoesters of carboxylic acids as demonstrated by the analysis of phenyl diethyl orthoformate and the corresponding orthoacetate.

PROCEDURE

About 1.5 mequiv.* of the aryloxysilane were dissolved in the prescribed amount of glacial acetic acid (see Table 1 and below) and 5 ml of conc. hydrochloric acid added. Sixteen ml of a 0.1 N potassium bromide-bromate solution were then dropped into the solution as fast as the bromine was consumed. After addition of 5 ml of a 10 % solution of potassium iodide the liberated iodine was titrated with 0.1 N thiosulfate using starch as an indicator.

Ir the case of aryloxysilanes with tertiary butoxy groups the solution was heated on a boiling water bath for half an hour after the addition of the conc. hydrochloric acid and then treated as above.

All of the phenoxysilanes as well as the phenyl orthoesters were titrated in 5 ml of glacial acetic acid, the rest of the aryloxysilanes in 20 ml of the same solvent. For accurate results it is recommended not to deviate too much from these volumes.

TITRATION WITH POTASSIUM METHOXIDE IN ETHYLENEDIAMINE

Day *et al.*[4,5] have investigated the reaction between esters of carboxylic acids and ammonia or amines. Among the most reactive participants in this reaction were phenolic esters and ethylenediamine. This circumstance was utilized by Glenn and Peake [6] for the quantitative determination of phenolic esters of carboxylic acids. These compounds undergo aminolysis in excess ethylenediamine at room temperature to form phenols and amides of ethylenediamine. The resulting phenols were titrated using potassium methoxide in benzene-methanol.

The postulated mechanism of the reaction involves a nucleophilic attack by the amine on the carbonyl carbon atom of the ester followed by the libera-

* It is assumed that each vacant *ortho* or *para* position consumes 2 equiv. of bromine.

tion of the phenol. This mechanism is also supported by the finding in this work that no reaction takes place between the phenyl orthoesters in Table 1 and ethylenediamine. On the other hand, nucleophilic attack by amines would be possible in the aryloxysilanes. These compounds have been shown to undergo exchange reactions, which are assumed to proceed through a nucleophilic mechanism with intermediate addition compounds [7].

The necessary qualifications for a ready reaction between ethylenediamine and an aryloxysilane thus seemed to be met, and this suggested the possibility of a quantitative determination of the aryloxysilanes. The result of the application of the Glenn and Peake method to the aryloxysilanes, however, was not that expected. The consumption of potassium methoxide was invariably too high (see Table 1). Thus, while the tetraaryloxysilanes should consume 4 equiv. of potassium methoxide per mole, values between 4.85 and 4.96 equiv. per mole were obtained. The aryloxytrialkoxysilanes should consume 1 equiv. of potassium methoxide according to theory, but the experimental values were 1.81 to 1.87. For the diaryloxydialkoxysilanes the corresponding values were 2.80 to 2.88 instead of 2 and the only triaryloxyalkoxysilane tested, triphenoxymethoxysilane, consumed 3.80 equiv. instead of 3. A small number of alkylphenoxysilanes were also titrated. It was found, that the excess consumption of potassium methoxide decreased as alkyl groups were substituted for phenoxy groups on the silicon atom.

From the above it is evident that the excess consumption of potassium methoxide is related to the structure of the organosilicon compound but independent of the number of aryloxy groups linked to the silicon atom. The reason of the high values is evidently to be sought in the organosilicon compounds present in the solution after the aminolysis of the aryloxysilanes. By analogy to the reaction between phenolic esters of carboxylic acids and ethylenediamine it can be assumed that phenols and aminosilanes are formed in the aminolysis of aryloxysilanes. An aminolysis of alkoxy groups, if such are present, might also take place. Thus in the case of the tetraaryloxysilanes the end products should contain silanes in which the silicon atom is linked to four nitrogen atoms. In the case of the alkoxyaryloxysilanes the same type of compounds might be formed as well as structures in which the silicon atom is linked to both oxygen and nitrogen. The carbon-silicon bonds in the alkylaryloxysilanes can be assumed to be unchanged after the aminolysis which thus results in structures with carbon and nitrogen atoms linked to the silicon atom. Finally, during the titration the methyl alcohol which is present in the reaction medium might react with the aminosilanes resulting in an exchange of methoxy groups for amino groups. Obviously, it is impossible to predict with any certainty the exact structure of the compounds formed.

We will now consider the question as to why these compounds consume potassium methoxide. The ability of certain organosilicon compounds to add reagents with electron-donor atoms with the formation of penta- and hexacovalent compounds is well known *. While it has been possible to isolate addition compounds between halogenosilanes and amines or amides [9-12], no similar adducts between organosilicon compounds and oxygen bases have

* For a detailed discussion of these types of compounds see Stone and Seyferth [8].

been recorded so far (see, however, Ref.[13]). However, they have been assumed to occur as intermediates in several reactions. In the base-catalyzed rearrangement of organopolysiloxanes, bases, such as potassium methoxide, were found to be effective [14]. It was postulated that the first step in the base-catalyzed reaction is the coordination of the oxygen atom in the base to a silicon atom in the siloxane. The alcoholysis of alkoxysilanes in the presence of sodium alkoxides has been assumed to proceed *via* pentacovalent silicon intermediates formed from the alkoxysilane and alkoxide ion [15]. In a study of the hydrolysis of triphenylsilyl fluoride Swain *et al.*[16] obtained kinetic evidence of the formation of intermediate adducts between this compound and water. Other similar examples exist [17,18].

The obvious conclusion to be drawn from this discussion is that the "excess" potassium methoxide is used up by addition to the silicon atom. We may consider the organosilicon compounds in question as Lewis acids which are neutralized by the base present. This assumption is in accordance with the decrease in excess base consumption in the series $(CH_3)_nSi(OC_6H_5)_{4-n}$ when n increases from 0 to 3. Replacement of a phenoxy group by a methyl group should cause a decrease in *L*-acidity from inductive as well as steric reasons *.

Not only aryloxysilanes can be titrated with potassium methoxide in ethylenediamine. This method was also found applicable to alkoxysilanes. Thus tetraethoxysilane in two runs used up 0.98 and 1.00 equiv. of potassium methoxide per mole and methyltriethoxysilane 0.72 and 0.73 equiv. per mole. Trimethylethoxysilane consumed less than 0.01 equiv. per mole and tetraethylsilane did not react at all with potassium methoxide **. Here only *L*-acidity is present while in the case of the aryloxysilanes the sum of the *H*-acidity and *L*-acidity is obtained. It is unsettled whether the alkoxysilanes remain unchanged or an aminolysis of the alkoxy groups takes place. A sharp decrease in acidity as ethoxy groups are replaced by methyl groups is clearly shown. It was not the purpose of this paper to investigate the reaction between alkoxysilanes and potassium methoxide in ethylenediamine. The few results presented here are, however, promising from a practical as well as a theoretical point of view. This reaction might find valuable application for identification and quantitative analysis of organosilicon compounds and also for studying the relationship between the structure of the latter and their ability to react with electron donating compounds.

The results of the analysis of 19 aryloxysilanes are summarized in Table 1. It is seen that compounds for which the bromination method failed, as thymoxytriethoxy- and carvacryloxytriethoxysilane, can be titrated readily (Nos. 17 and 18). On the other hand the method failed for aryloxysilanes with a tertiary butoxy group linked to the silicon atom (Nos. 8 and 10). For these compounds the modified bromination procedure was applicable. The two methods thus complement each other. The variation of the excess base consumption (due to the *L*-acidity of the organosilicon compounds) makes the

* As pointed out previously it is not the *L*-acidity of the phenoxysilane that is measured but of a reaction product the exact structure of which is unknown.

** This is in accordance with the fact that the coordination number of silicon rises above four only when it is bonded to highly electronegative elements [8].

potassium methoxide method less accurate than the bromination method. However, the reproducibility for one and the same compound is generally very good under identical conditions *. It is possible that a separate measurement of the *H*-acidity and *L*-acidity can be attained potentiometrically, thus increasing the accuracy of the method.

PROCEDURE, REAGENTS AND SOLUTIONS

The aryloxysilanes were prepared in this laboratory. The synthesis of some of them was previously described [7].

Potassium methoxide, 0.1 N. The procedure of Fritz and Keen [19] was used in the preparation of the potassium methoxide solution. About 4 g of potassium were dissolved in 20 ml of absolute methanol and 50 ml of benzene in a loosely stoppered flask. Methanol was added until the solution became homogeneous, then benzene until the solution became cloudy, then it was cleared again with methanol and so on until 1 liter of clear solution was obtained. It was standardized using phenol or one of the cresols.

Indicator. *o*-Nitroaniline, 1.5 g, was dissolved in 100 ml of benzene.

Titration procedure. About 0.5 mequiv.** of the sample was weighed into a small glass tube. To 25 ml of anhydrous ethylenediamine in a 100 ml Erlenmeyer flask were added 2 drops of indicator solution. The flask was stoppered with a cork with a hole fitting the tip of a 10 ml burette. Potassium methoxide solution was added until the yellow colour changed to orange-red. Then the tube with the sample was added and the titration continued to the reappearance of the orange-red colour. During the titration the solution was rapidly stirred using a magnetic stirrer. To obtain reproducible results it was necessary to use a colour standard. A recommended procedure is to add the theore-

* The quality of the ethylenediamine seems to be of some significance for the results.

** On the basis of the aryloxy groups present.

tical amount of titrant to a phenol sample and use this solution as a colour standard. However, the colour fades rather rapidly. It is better to prepare a second standard of the same colour intensity as the first using methyl orange and the appropriate amounts of acid and alkaline water solutions. This standard is stable for months.

The Structure of the High Temperature Modification of Lithium Sulfate *

T. FORLAND and J. KROGH-MOE

The Pennsylvania State University, Department of Ceramic Technology, College of Mineral Industries, University Park, Pennsylvania, U.S.A.

The high temperature modification of lithium sulfate has been found to be cubic with a unit cell length of 7.07 Å. The sulfate groups are arranged in a face centered lattice, and the cations can probably exchange between tetrahedral and octahedral positions.

The monoclinic, room-temperature modification of anhydrous lithium sulfate has been studied by Albright [1]. At 575 °C a transition takes place. Wyrouboff observed that the birefringence disappeared at the transition point and concluded that the high temperature modification was cubic [2]. A cubic symmetry is indicated by the present X-ray investigation.

Table 1 gives observed lines and their relative intensities for lithium sulfate determined from a powder pattern taken at 610 °C with filtered Cu$K\alpha$ radiation. It was noted that the relative X-ray intensities from a sample of the low temperature modification were different before and after being heated above the transition point. Preferred orientation is therefore taking place, and the intensities given in Table 1 cannot be regarded as reliable. Hence no effort was made to use these intensity values for a structure determination.

The observed lines can be indexed by means of a face centered cubic lattice with an edge length:

$$a = 7.07 \text{ Å}$$

A density of 2.07 corresponds to 4 formula units in the unit cell. The monoclinic modification has a density of 2.22 at room temperature.

From conventional space group considerations a structure of the high temperature lithium sulfate modification can be derived. This structure will

* Office of Naval Research Technical Report No. 72 under Contract N6 onr 269 Task Order 8, NR 032—264, The Pennsylvania State University, University Park, Pennsylvania. Mineral Industries Contribution No. 56—17. Reproduction in whole or in part is permitted for any purpose of the United States Government.

Table 1. Scattering angles and intensities observed for lithium sulfate at 610° C with CuK_α radiation.

2θ	$\frac{4 \sin^2\theta}{\lambda}$	Int.
21.8	0.0600	24
25.2	0.0803	7
35.9	0.1600	7
42.4	0.2202	7
44.4	0.2404	2
58.4	0.4000	1

be shown to be not quite satisfactory, however, since it does not account for rotation or oscillations of the sulfate groups. By assuming that equivalent atoms take equivalent fixed crystallographic positions, all but two space groups can be ruled out. Only the space groups $F23$ and $F\bar{4}3m$ will simultaneously take 4 sulfur, 8 lithium, and 16 oxygen atoms in one unit cell. With either of these space groups the following coordinates can be assigned to the atoms:

S 0, 0, 0.
O $u, u, u;\ u, \bar{u}, \bar{u};\ u, u, \bar{u};\ \bar{u}, \bar{u}, u.$
Li two of the following three coordinates:
1/4, 1/4, 1/4; 3/4, 3/4, 3/4; 1/2, 1/2, 1/2.

If it is assumed that the tetrahedral sulfate group has the usual sulfur-oxygen distance of about 1.50 Å, the parameter u will have the value 0.12. Of the possible lithium positions, those given by the coordinates 1/4, 1/4, 1/4 and 3/4, 3/4, 3/4 correspond to a tetrahedral coordination with respect to sulfate groups, though the former gives the cation a 4 coordination and the latter a 12 coordination with respect to oxygen. In the following, however, both these positions shall be referred to as tetrahedral. The position 1/2, 1/2, 1/2 is 6 coordinated by sulfate groups, and will hence be referred to as octahedral though the coordination number with respect to oxygen is 12.

Except for the positions and numbers of the cations this structure of lithium sulfate appears identical with the structures derived for the high temperature modifications of sodium and potassium perchlorates [3,4] and borofluorides [5]. The sodium and potassium ions in these structures will occupy the spacious octahedral 1/2, 1/2, 1/2 positions. This position provides a lithium ion with a too large space. In accordance with this, no analogous cubic high temperature modification has been found for lithium perchlorate and borofluoride.

The structures discussed above lead to some improbable interatomic distances. In lithium sulfate the closest approach of two oxygens belonging to different sulfate groups will be 2.56 Å. Lithium ions in the 1/4, 1/4, 1/4 positions would be surrounded by oxygen at a lithium-oxygen distance of 1.56 Å. Thus the 1/4, 1/4, 1/4 lattice sites provide the lithium ions with a too small space. On the other hand, both the 1/2, 1/2, 1/2 and the 3/4, 3/4, 3/4 lattice sites provide the lithium ions with a too large space. A rotation of the sulfate

groups through 45° around one axis, however, will increase the previously too short oxygen-oxygen distance of 2.56 Å. The closest distance between oxygens in neighboring sulfate groups will now be 3.18 Å. Now all the lithium ions can occupy tetrahedral positions, four coordinated by oxygen and with a reasonable lithium-oxygen distance of 2.06 Å. Since strong rotational oscillations must be expected for the sulfate groups, the lithium ions most probably can exchange between tetrahedral and octahedral lattice positions. With this high degree of disorder, the given space group can at most be approximately correct. It is even conceivable that the compound has a pseudocubic structure, but any weak reflections which could indicate this would only be noticeable in single crystal exposures.

X-Ray intensities observed for the perchlorates and the borofluorides do not in all cases agree with a reasonable size of the anion group. Finbak and Hassel obtained a better fit of the intensity data by assuming a rotation of the anion group [5,6]. As in the lithium sulfate, anion groups of acceptable sizes will approach each other too closely when the atoms are in positions prescribed by the adopted space group. Hence a steric hindrance to free rotation is provided. Coupled rotation or strong rotational oscillations must occur, however. In agreement with this, a fairly strong continuous background scattering is observed in lithium sulfate. The scattering has a maximum at $2\Theta = 36°$ for the Cu$K\alpha$ radiation employed. This background did not change appreciably in intensity on passing the transition point indicating strong rotational oscillation of the sulfate groups already below the transition point.

Short Communications

Small-angle Scattering of X-Rays in Aqueous Sodium Desoxycholate Solutions Containing Decanol-1

PER EKWALL and KRISTER FONTELL

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

Aqueous bile salt solutions are able to dissolve both hydrocarbons and polar lipophilic compounds. Appreciable amounts of long-chain alcohols, decanol-1 for instance, are solubilized by these solutions. For example, a 0.20 M sodium cholate solution dissolves about 28 ml of decanol per litre of solution at 40°C. A 0.20 m sodium desoxycholate solution dissolves about 55 ml of decanol per 1 000 g solution at 25°C, a 0.35 m solution about 105 ml and a 0.53 m solution about 200 ml[1]. The solubilization process involves two stages, as shown by the fact that when small amounts of decanol are added to cholate solutions, the ability of the latter to solubilize *p*-xylene is not appreciably altered, whereas the solubility of the hydrocarbon rapidly decreases when the molar ratio of decanol to cholate exceeds a certain value [2]. The same has been found to apply also in the case of desoxycholate solutions. This variation of the solubility of *p*-xylene with increasing additions of decanol to a 0.35 m sodium desoxycholate solution is shown in Fig. 1 a; the solubility of *p*-xylene remains almost unaltered as the decanol content increases to 50 ml per 1 000 g of solution, but then falls off rapidly as more decanol is added.

The mentioned variation in the solubility of *p*-xylene is accompanied by changes in the small-angle X-ray scattering by the solutions [3]. The X-ray scattering has been investigated with the same apparatus and technique we have used in our earlier investigations [4]. Fig. 2 shows photometer recordings of the X-ray films obtained with 0.35 m sodium desoxycholate solutions containing different amounts of decanol. As long as the decanol content is below about 40 ml per 1 000 g of solution, the small-angle X-ray pattern remains largely unaltered. As larger amounts of decanol are dissolved the pattern becomes

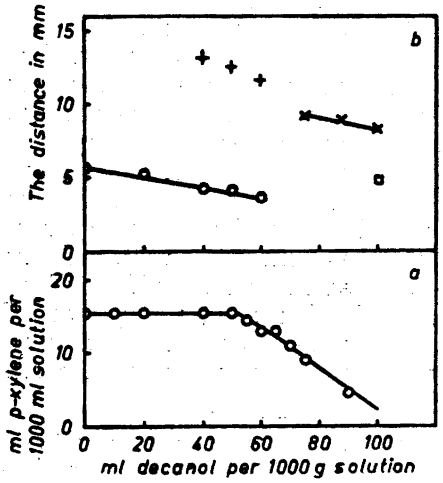

Fig. 1. a) The maximum solubility of *p*-xylene in 0.35 molal sodium desoxycholate solutions containing different amounts of decanol-1. b) The distance of the intensity maxima from the incident beam in the small-angle X-ray patterns of 0.35 m sodium desoxycholate solutions containing different amounts of decanol-1. The inner maximum. Points marked O and □. The outer maximum. Points marked × and +. The intensity maxima + are very vague and blurred.

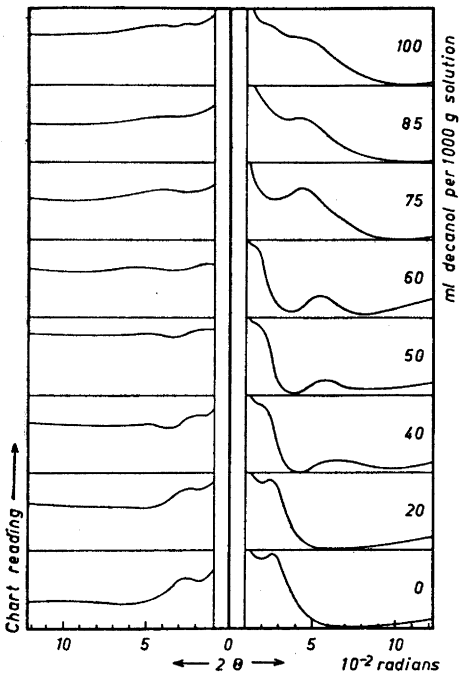

Fig. 2. Photometer recordings of the small-angle scattering by 0.35 M sodium desoxycholate solutions containing different amounts of decanol-1. a) Left side. Recordings obtained with the same photometer sensitivity for all films and with the photometer set to zero for unexposed areas of the films. b) Right side. Recordings obtained when the full-scale reading was set equal to the difference in maximum blackening and background for each film separately.

less and less distinct until it finally fades into the background. At the same time a new very diffuse ring which is located farther from the incident beam gradually becomes evident. When the decanol content is increased further to a high value close to saturation a second inner ring appears at a distance from the incident beam which almost coincides with that of the ring for the original desoxycholate solution or at a somewhat smaller distance. The curves in Fig. 1b show the shift of the intensity maxima with increasing decanol content. — We have found the same phenomenon to occur also with 0.53 m and 0.20 m sodium desoxycholate solutions containing decanol.

Exposures made with an ordinary X-ray powder camera have indicated the occurrence of a similar phenomenon to that described above. At low decanol contents the same pattern is obtained as for pure sodium desoxycholate solutions with Bragg spacings at 2.7—3.3 Å and 6.0—6.2 Å. At higher decanol contents, about 100 ml of alcohol per 1 000 g of a 0.53 m sodium desoxycholate solution, a new ring with a Bragg spacing of 4.5—5.0 Å appears. This spacing corresponds to that of pure decanol; in these quite clear solutions there is no separated decanol and practically all the dissolved decanol is in the solubilized state.

The observation that the original small-angle X-ray pattern for desoxycholate solutions disappears gradually and is replaced by another pattern indicates that decanol effects a radical rearrangement of the micelle structure. It is obvious that desoxycholate micelles are able to incorporate only a limited amount of decanol before their structure undergoes a change. When this critical molar ratio of decanol to desoxycholate is exceeded, the original micelles break down and a new type of mixed micelle composed of bile salt and decanol is formed. These new micelles are not able to solubilize *p*-xylene. It seems probable that the long paraffin chains of the alcohol molecules (alcohol is present in these solutions in molar ratios of decanol to desoxycholate from 1:1 to 2:1) primarily determine the structure of the new micelle. The appearance of a new short spacing at 4.5—5.0 Å possibly indicates the occurrence of parallel-oriented paraffin chains, obviously an arrangement resembling that in micelles of association colloids of the paraffin-chain type.

Study of the Relation between Brightness Reversion and Carbonyl Content in Cellulose Pulp

INGVAR JULLANDER and KURT BRUNE

Research Laboratory, Mo och Domsjö AB, Örnsköldsvik, Sweden

Giertz [1] in a study of the brightness reversion of pulp upon heating, found for sulfite pulps a reasonably good correlation between the brightness reversion during heating and carbonyl content (copper number) as well as carboxyl content.

The discovery and subsequent commercial manufacture of the strong reducing agent sodium borohydride has given the cellulose chemist means to reduce the carbonyl groups in carbohydrates to alcohol groups. Treatment of pulp with sodium borohydride results in improved hot alkali stability and sometimes slightly increased viscosity [2,3]. Recently Giertz and McPherson [4] in connection with a study of the coloring matter formed when pulp is heated, also reported an experiment where partial borohydride reduction of an overbleached sulfite pulp resulted in reduced brightness reversion.

The aim of the present work was to investigate further the connection between carbonyl content (measured as copper number) and brightness reversion. Even a complete reduction of pulp can be made under mild experimental conditions. It is therefore unlikely that any other undesirable changes take place in the pulp.

Air-dried pulp was defibrated with a mechanical stirrer in water into which sodium borohydride had been dissolved in amounts corresponding to 0.1—10 % calculated on the pulp. Pulp concentration 2 %. The mixture was kept at 50°C for 3 h. The slightly alkaline solution was then sucked off on a Büchner funnel, the cellulose pulp washed several times with water, then acidified with acetic acid and finally washed again with water to a pH of around 6.5. Drying in air at room temperature.

Copper number was determined according to Braidy [5]. Pulp sheets were formed and brightness measurements performed in an Elrepho instrument. The brightness reversion was calculated by means of the Kubelka and Munk theory as recommended by Tongren [6], Mc Intyre [7] and Giertz [1] and by the last author expressed as "post-color" value (pc-value). The pc-value can be regarded as a relative measure of the amount of coloring substance formed during the heat treatment.

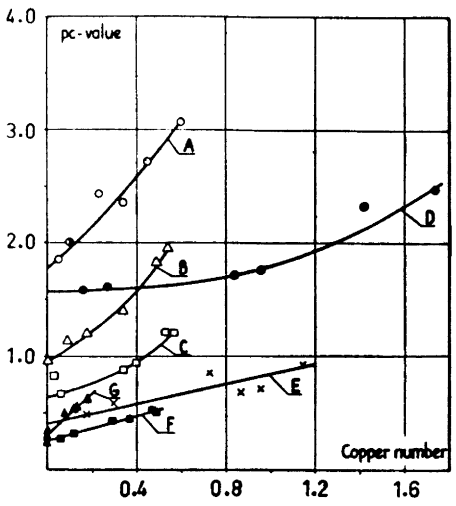

Fig. 1. Brightness reversion (pc-value) as a function of copper number for different types of pulp.

A, B and C — bleached sulfate paper pulps from pine.
D — bleached sulfite paper pulp from spruce.
E — bleached sulfite pulp from spruce, dissolving grade.
F — bleached, cold-alkaline treated sulfite pulp from spruce.
G — bleached cotton linters.

On each curve in Fig. 1 the point with the highest copper number corresponds to pulp treated only with water in blank experiments. The carbonyl content was then reduced by increasing amounts of sodium borohydride down to such low values as to allow an extrapolation to copper number zero.

It can be seen that the carbonyl groups on an average are responsible for approximately half the brightness reversion. In the cases studied so far, the slope of the curves seems to be higher for sulfate pulps and linters than for sulfite pulps, but the experimental material is too scanty to

allow a conclusion that this applies to all types of sulfite and sulfate pulps. Highly refined sulfite pulp is at least as good as linters as far as brightness stability is concerned, in spite of the higher copper number.

Aliphatic Ditellurides

GÖRAN BERGSON

Chemical Institute, University of Uppsala, Sweden

Only two aliphatic ditellurides are described in literature; ditellurium-diacetic acid ($HOOCCH_2TeTeCH_2COOH$) and ditellurium-α-dipropionic acid [1,2]. These substances have been prepared by reduction of the trichlorotellurium compounds obtained by the interaction of tellurium tetrachloride with the corresponding acid anhydrides. This method seems to be suited only for the introduction of the tellurium function in the α-position relative the carboxylic group.

The author has started an investigation of synthetic methods for aliphatic ditellurides in general. This paper gives a preliminary report of the reaction between aliphatic halogen compounds and the Te_2^{2-} ion. The first electronic excitation band for di-*n*-butylditelluride and ditellurium-diacetic acid has been determined and compared with that for disulfides and diselenides extensively studied by Schotte [3,4] and Bergson [5,6]. An infra-red investigation of the ditellurides is being prepared. A polarographic investigation of ditellurium-diacetic acid has been started by Nygård [7].

A sodium ditelluride solution was prepared by dissolving finely powdered tellurium in an alkaline solution of sodium formaldehyde sulphoxylate (Rongalite C). When excess Rongalite C is used for the preparation of sodium telluride solution the tellurium is readily dissolved [8], but in the preparation of sodium ditelluride the molar ratio between tellurium and Rongalite C must be 2:1, and it is then necessary to reflux and to stir the mixture for several hours. The sodium ditelluride solution (which certainly contains also some telluride and polytelluride) reacts readily with *n*-butyl bromide. An attempt to prepare ditellurium-diacetic acid in this way from chloroacetic acid failed, because this acid oxidized the ditelluride ion to elementary tellurium, and from the reaction mixture acetic acid was isolated. Sodium telluride reacts in the same way with chloroacetic acid. Here we have a difference between tellurium, selenium and sulfur, because disulfide-, sulfide-, diselenide- and selenide ions react in the normal way with α-haloacids. These facts should be compared with the oxidative action of *vic*-dihalides on selenoles [9,10] contrary to their behavior towards thiols, and with the oxidation of sodium disulfide by bromomalonic ester [11].

Di-*n*-butylditelluride has an absorption band with maximum at 3 990 Å as can be seen from Fig. 1. The author has shown that the lowest electronic excitation energy for disulfides and diselenides can be expressed by an empirical formula with the parameters α and β:

$$E = \alpha\sqrt{k} + \beta$$

with $\alpha_S = \alpha_{Se}$, where k is the number of hydrogen atoms joined to the α-carbon atom [6]. The author hopes to be able to test the validity of this relation for ditellurides. An increase in excitation energy is found when the molecule contains a carboxylic group close to the S—S or Se—Se group. For diselenium-diacetic acid ($HOOCCH_2SeSeCH_2COOH$) the band is overlapped by a high intensity band (λ_{max} = 2 290 Å) and is only detectable [5] as an inflexion at 2 930 Å. The same behavior has been found for ditellurium-diacetic acid (inflexion at 3 600 Å). The 2 290 Å band of the selenium compound has its correspondence in a band with λ_{max} = 2 730 Å.

allow a conclusion that this applies to all types of sulfite and sulfate pulps. Highly refined sulfite pulp is at least as good as linters as far as brightness stability is concerned, in spite of the higher copper number.

The same behavior has been found for ditellurium-diacetic acid (inflexion at 3 600 Å). The 2 290 Å band of the selenium compound has its correspondence in a band with λ_{max} = 2 730 Å.

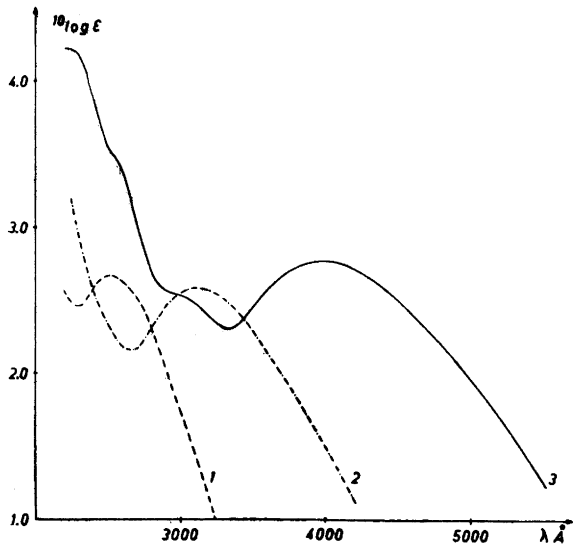

Fig. 1. Ultraviolet absorption of:
1. Di-*n*-propyldisulfide [13].
2. Di-*n*-butyldiselenide [5].
3. Di-*n*-butylditelluride, in (*cyclo*hexane).

Experimental: Di-n-butylditelluride. In a 500 ml three necked flask 9.24 g Rongalite C and 9.0 g sodium hydroxide are dissolved in 200 ml water. The flask is flushed out with nitrogen, and 15.32 g finely powdered tellurium is added. The mixture is vigorously stirred under reflux for 5 h. After that time 16.4 g *n*-butyl bromide is added dropwise, the mixture is allowed to cool, and the stirring continued for 30 min. The content of the flask is extracted with 2 × 150 ml ether, the extract dried with $CaCl_2$, and the ether distilled off in a nitrogen atmosphere. The residue is distilled in vacuum (nitrogen) and the fraction boiling between 112—115°/1.5 mm Hg is collected. The ditelluride is a dark red oil with a pungent smell. Yield 23 %. (58.70 mg subst. gives 40.91 mg Te. Found: Te 69.7. Calc. Te 69.1). The analysis was carried out according to Drew and Porter [12].

Ditellurium-diacetic acid was prepared according to Morgan and Drew [1]. The spectra were determined with a Beckman model DU (2 200—4 000 Å) and a Beckman model B (4 000—5 500 Å) photoelectric spectrophotometer.

Anion Exchanging Polymers from Sodium Cellulose Xanthate and Polyethylenimine

SVEN SONNERSKOG

A-B Svenskt Konstsilke, Borås, Sweden

Alkaline solutions of sodium cellulose xanthate react with polyethylenimine at room temperature. If an excess (weight by weight) of the latter polymer is present, solidification gradually takes place, accompanied by a strong syneresis. The final, transparent gel shows all distinctive features of rubber elasticity in a qualitative sense. Another striking change is established at a subsequent purification of the gel in water. The specimen keeps its geometric shape and degree of swelling virtually unchanged. Furthermore, this purified gel is insoluble in cuprammonium solution.

The time required for complete gelation is highly dependent on the composition and physical state of the viscose. At a given salt index a technical grade of viscose reacts faster than a corresponding one, from which anions such as trithiocarbonate have been removed by ion exchange. Such a solution shows a slightly greenish yellow colour even after complete gelation, which would imply that a reformation of trithiocarbonate ions is suppressed. Appreciable amounts of sulphide ions are formed, however, as can be seen by successive tests with standard reagents. It is apparent that a reaction takes place between cellulose xanthate ions and polyethylenimine, carbon disulphide acting as an interlinking agent. As is known, there is always a small amount of free carbon disulphide present in every viscose [1] at equilibrium. In the actual case the *added* polymer acts as an acceptor of CS_2, thus also causing a gradual dexanthation of the cellulose, but this circumstance alone does not explain the observed insolubility in cuprammonium.

The rates of gelation of technical viscoses are shown in Fig. 1. At a high salt index the gel point is reached within two hours, to judge from the viscosity increments in a Cochius tube. At a low salt index gelation is very slow. The change of viscosity during the same time is insignificant, but gelation is complete within 20—24 h. The same statement is valid for all viscoses, purified by anion exchange before the addition of coreactant. Their flow diagrams are not included here due to this circumstance.

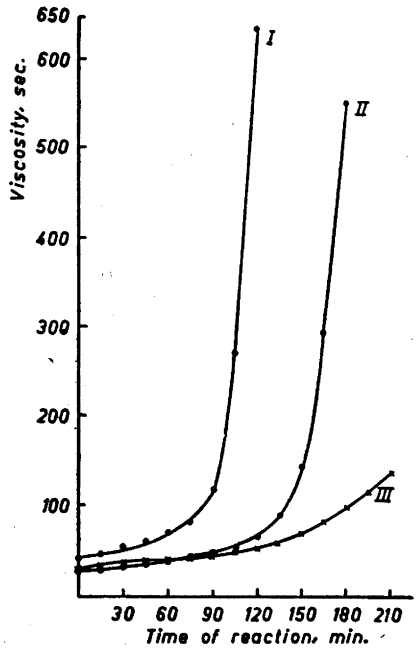

Fig. 1. Diagram, showing the viscosity increments in a Cochius tube at the gelation of technical viscoses, containing an excess (w/w) of polyethylenimine). Weight ratio polyethylenimine / cellulose = 3. Content of polymers in solution = 16 %. Type of Cochius tube: length = 195 mm, diam. = 18 mm, length of air bubble = 20 mm (approx). Temperature of solution 19.0° C.

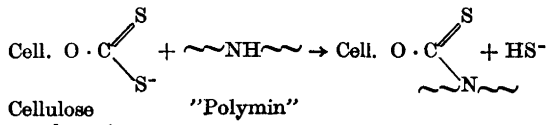
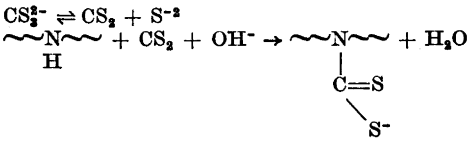
Curve I: Low degree of ripeness, high salt index. (Index = 21).
Curve II: Medium degree of ripeness, salt index = 10.
Curve III. High degree of ripeness, low salt index. (Index = 2).

Purification of the final crude reaction mixture is simple in principle but tedious in practice. The following description is valid for the specimen obtained in accordance with curve II in Fig. 1. The jelly was cut into chips, soaked in running distilled water for several days, until tests for sulphide ions were negative. This operation was repeated after swelling in dilute sodium hydroxide solution (strength 4 % b.w., temperature 70°C, time of



swelling 60 min.). For complete regeneration the wet chips were immersed in cold 1 N hydrochloric acid for 24 h, followed by washing in distilled water, soaking in sodium hydroxide solution and a final washing with hot distilled water until the excess of inorganic base has been removed.

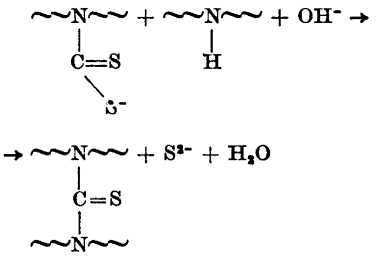
The highly swollen, transparent chips show an average water content of 92 %. Drying at 70—80°C reduces the volume at least a tenfold. The dry polymer is a brittle, light yellow or amber, transparent resin, which cracks into flakes on rewetting. Polymer, prepared from viscose of medium degree of ripeness, showed a nitrogen content of 13.6 % (Kjeldahl) and a sulphur content of 2.1 % (Grote-Krekeler).



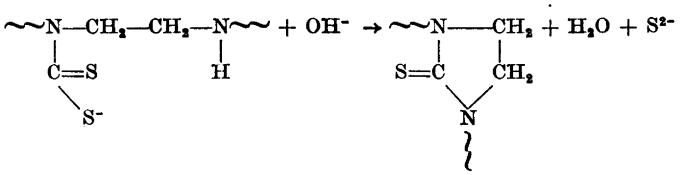
The wet polymer (primary gel or reswollen resin) acts as an anion exchanger. Chloride ions are adsorbed at the regeneration step in hydrochloric acid. This is easily seen at the addition of dilute nitric acid to a washed sample; chloride ions immediately reappear in the aqueous phase, as indicated by silver nitrate. Ion exchange in sodium hydroxide solution operates in an analogous manner and was used for determination of exchange capacity. A direct titration of chloride ions liberated by 1 N sodium hydroxide showed a value of 4.15 mequiv./g dry polymer. An alternative test, carried out by passing the aqueous phase through a hydrogen saturated cation exchanger, followed by alkalimetric titration, showed a capacity of 4.40 mequiv./g dry polymer.

It is apparent that a considerable amount of polyethylenimine has been linked to the cellulose molecules. As the interaction between the two components ends in non-solubility in cuprammonium, the formation of infinite networks by a chemical reaction between the two polymer species seems most probable. The polyelectrolyte (cellulose xanthate), as well as polyethylenimine possesses abundant degree of functionality for a cross-linking reaction. Available information from analogous cases [2] indicates a reaction scheme as follows:

1. Formation of N-substituted thiourethans:



2. Formation of a derivative from dithiocarbamic acid. This may occur at random along chain molecules:



possibly accompanied by a minor formation of thiourea groupings, low enough to prevent insolubilization. (Alkaline solutions of polyethylenimine do not change their solubility characteristics when saturated with carbon disulphide at room temperature):

Interlinking:

Intralinking:

At the purification of the crude reaction mixture components according to (2) are removed. All essential features of the reaction seem to be satisfactorily explained by the two cases in combination, *e. g.*

a. The formation of sulphide ions during the reaction.

b. The decreased rate of gelation when trithiocarbonate ions are removed by ion exchanger.

c. The regular formation of trithiocarbonate ions in viscose is suppressed by polyethylenimine.

d. The presence of sulphur and nitrogen in the purified polymer.

The analytical data permit an estimation of an average structural unit of the infinite network. This building unit may be preferably expressed by telling the numbers of anhydroglucose units and ethylenimine units statistically shared to a single interlinking unit:

$$\frac{b \text{ units of ethylenimine} \mid \text{interlinking unit } (> C{=}S)}{a \text{ anhydroglucose units}}$$

Weight of building unit $= 162a-1+44+43b-1 = 162a+43b+42 = M_w$

Two equations are obtained from analytical data:

$14b/M_w = 13.6/100$, $32/M_w = 2.1/100$

with approximative solution (whole numbers) $a = 5$, $b = 15$, $M_w = 1\,500$.

$\%\,N_{calc} = 14.0$, $\%\,S_{calc} = 2.1$

The calculated building unit M_w contains 14 centres where anion exchange is possible. The maximum exchange capacity would thus be $14\,000/1\,500 = 9.3$ mequiv./g dry polymer, which should be compared with 4.4 mequiv./g, found in the actual case. Such a relation seems in no way unreasonable.

on the ratio of the E-values at 693 mμ and 620 mμ of the antimony trichloride reaction, and a good agreement was found. The formula for the calculation of vitamin A_2 in our method has been derived from the absorption data reported for all-*trans* vitamin A_1 by Cama, Collins and Morton [5] and for vitamin A_2 by Cama and Morton [3].

In the spectrophotometric methods used at present for the determination of vitamin A, the exact absorption data of the pure substance are indispensible for the correct calculation of the results. This also applies to the proposed [4] joint ultra-violet-spectrophotometric determination of vitamin A_1 and A_2. From the investigation of Abdullah *et al.*[6] and recently Barnholdt and Hjarde [7], the expected existence of isomeric forms of vitamin A_2 has been demonstrated. During our extensive study of vitamin A components in fish liver and liver oils, we have found reason to conclude that the vitamins A are stored *in vivo* as the all-*trans* isomers. During our routine investigations of fish livers, samples of perch liver were found to be devoid of vitamin A_1 and *cis* isomers (maleic anhydride reaction). This made it of interest to examine more carefully and in detail the U.V.-absorption curve. The measurements were carried out with a Beckman Spectrophotometer Model DU. The results are reported in Table 1, and compared with the values of Cama and Morton [3] in Fig. 1. As may be noted, the absorption maximum in ethanol of vitamin A_2-alcohol was found at 351 mμ, with a second peak at 286 mμ, in agreement with the previous findings. The ratio $E_{286} / E_{351} = 0.320$ is lower, however, than the value 0.393 reported by Cama and Morton [3], indicating a higher degree of purity. It may further be noted that a small but distinct peak was observed at 277 mμ ($E_{277} / E_{351} = 0.417$). Actually, this peak was indicated already when the observations of Cama and Morton [3] were plotted graphically.

The results presented make a revised value of the absorption maximum of a purified (crystalline) all-*trans* vitamin A_2 of importance for further studies of this vitamin.

*iso*Thiocyanates XXV *. Methyl 4-*iso*Thiocyanatobutyrate, a New Mustard Oil Present as a Glucoside (Glucoerypestrin) in *Erysimum* Species

ANDERS KJÆR and ROLF GMELIN

Chemical Laboratory of the University of Copenhagen, Denmark

A few years ago it was noticed in this laboratory [1] that seeds of various species of the genus *Erysimum (Cruciferae)* contain a mustard oil glucoside which is different from those formerly recognized in Nature. A substantial seed sample of *Erysimum rupestre* DC., procured by cultivation of the plant on a larger scale **, has now made it possible to characterize and identify the new glucoside for which we wish to introduce the name *glucoerypestrin* ***.

According to paperchromatographic analysis, glucoerypestrin is accompanied by minor amounts of glucocheirolin in seed extracts of *E. rupestre*. The partly purified, glassy glucoside fraction yielded a crystalline product on acetylation. Fractional crystallization of this from 90 % ethanol afforded a homogeneous specimen of *glucoerypestrin tetraacetate monohydrate*, decomposing at 188–190° (uncorr.) †; $[\alpha]_D^{23}$ −18.0° (H_2O, c = 1.7). (Found ††: C 37.40; H 4.85; N 2.05; K 6.19. Calc. for $C_{20}H_{28}O_{15}NS_2K, H_2O$ (643.7): C 37.32; H 4.70; N 2.18; K 6.07). The infra-red spectrum was of the usual type [3,4] and did not provide much information as to structural details.

Deacetylation with 1.5 N methanolic ammonia, under carefully controlled conditions, furnished the alkali-labile, paperchromatographically homogeneous glucoerypestrin which, in turn, was subjected to enzymic hydrolysis with myrosinase at pH 6.7. The resulting mustard oil, isolated by ether extraction or distillation at diminished pressure, yielded a crystalline, optically inactive *thiourea* (IIa), $C_6H_{12}O_2N_2S$, m.p. 93° (uncorr.) (Found: C 40.85; H 6.83; N 15.65; S 18.60; OCH_3 17.58. Calc.: C 40.90; H 6.87; N 15.90; S 18.20; OCH_3 17.61), on treatment with methanolic ammonia, again under strictly controlled conditions. The ultra-violet spectrum of the thiourea (in EtOH) was of the usual type (λ_{max} 243 mμ (ε 12 600), λ_{min} 223 mμ (ε 1 500). A very strong band at 1 728 cm^{-1} in the infra-red spectrum (in KBr) was suggestive of the presence of an ester grouping in the thiourea. On paper chromatography in water-saturated chloroform, the new thiourea travelled at a rate corresponding to an R_{Ph}-value of 0.65 [5].

Reaction of the *iso*thiocyanate with aniline and 1-naphthylamine in methanolic solutions afforded the nicely crystalline *phenylthiourea* (IIb), $C_{12}H_{16}O_2N_2S$, m. p. 91° (uncorr.) (Found: C 57.00; H 6.39; N 11.01. Calc.: C 57.12; H 6.39; N 11.11), and *(1-naphthyl)-thiourea* (IIc), $C_{16}H_{18}O_2N_2S$, m. p. 132° (uncorr.) (Found: C 63.70; H 5.85; N 9.03. Calc.: C 63.56; H 6.00; N 9.27), respectively.

$$SCNCH_2CH_2CH_2COOCH_3$$
I

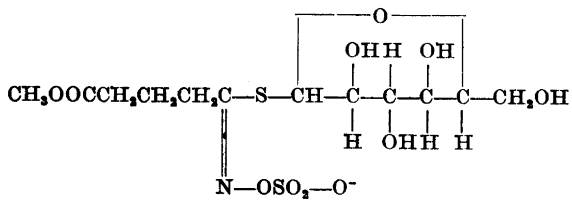
$$R—NHCSNHCH_2CH_2CH_2COOCH_3$$
IIa : R = H
IIb : R = C_6H_5
IIc : R = 1-$C_{10}H_7$

The cumulate data suggested that the new mustard oil was *methyl 4-isothiocynatobutyrate* (I), an assumption fully verified through the following synthesis.

* Part XXIV of this series: *Acta Chem. Scand.* **11** (1957) 184.

** We are much indebted to the *Botanical Garden of the University of Copenhagen* for the cultivation of this and other biennial *Erysimum* species.

*** This name has been preferred to the more consistent designation "glucoerysimin" in order to avoid confusion with the cardiac glycoside erisimin of similar provenance (*cf.* Ref.[2]).



† It has been observed in this laboratory that the decomposition temperature of most acetylated *iso*thiocyanate glucosides is very dependent on the rate of heating. The present value was determined in capillary tubes by inserting the sample at 140° and raising the temperature at a rate of 8° per min.

Polymorphism may also in some cases contribute to the widely varying values observed (M. G. Ettlinger, private communication).

†† A Karl Fischer titration gave: 2.85 % H_2O. Calc. for the monohydrate: 2.80 %.

Treatment of 4-aminobutyric acid with hydrogen chloride in anhydrous methanol gave a quantitative yield of *methyl 4-aminobutyrate hydrochloride* * as hygroscopic needles, m. p. 96—99° (uncorr.) (Found: C 38.70; H 7.69; Cl 22.71. Calc. for $C_5H_{12}O_2NCl$ (153.6): C 39.09; H 7.88; Cl 23.08). Equimolecular amounts of thiocarbonyl chloride in chloroform, and the hydrochloride, dissolved in water containing excess sodium carbonate, reacted to give the mustard oil (I) as an almost colourless oil, b. p. 70° at 0.2 mm, n_D^{25} 1.5066. (Found: C 45.40; H 5.82; N 8.77; S 20.22. Calc. for $C_6H_9O_2NS$ (159.2): C 45.26; H 5.70; N 8.80; S 20.14). Upon reaction with ammonia, aniline and 1-naphthylamine, respectively, the synthetic mustard oil yielded thioureas (IIa, b, c) identical with those obtained from the natural *iso*thiocyanate, as apparent from mixed melting point determinations and coinciding infra-red spectra.

The presence in glucoerypestrin of glucose and sulphate has been unequivocally established by paper chromatography subsequent to enzymic hydrolysis. In accord with the notable discovery of Ettlinger and Lundeen [7], leading to a revised general structure for the mustard oil glucosides, glucoerypestrin splits off hydroxylamine on hydrolysis with strong acids. Hence, the formula (III) is considered likely to be a correct expression for the glucoerypestrin anion **.

III

Of several *Erysimum* species investigated thus far in this laboratory, seeds of *E. ochroleucum* DC. and *E. pumilum* DC. exhibited the same glucoside pattern as *E. rupestre* DC. In a recent survey of paperchromatographic analyses of a considerable number of plants, Schultz and Wagner [8] list the R_B-values 0.65 and 0.68 in *n*-butanol : acetic acid : water (4:1:3) and *n*-butanol : pyridine : water (6:4:3), respectively, for a glucoside present in *E. pumilum* DC. and *E. rupestre* DC. *f. aurantiacum*. There can be little doubt that this glucoside is glucoerypestrin.

A detailed account of the present work, together with some biogenetic considerations, will form the subject of a forthcoming publication.

Microanalyses were performed in this laboratory by Mr. P. Hansen. The work is part of investigations supported by *Statens Almindelige Videnskabsfond (The Danish State Research Foundation)* and *Carlsbergfondet (The Carlsberg Foundation)*. A special grant from *Kai Hansens Fond* is gratefully acknowledged.

Silicon Determination in Low-Boiling Organosilicon Compounds by Acid Digestion

BENGT SMITH

Institutionen för Organisk Kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

Several methods have been proposed for the quantitative determination of silicon in organosilicon compounds *. The best analytical method from the standpoint of accuracy is considered to be the acid digestion method [1]. The compound is oxidized generally by fuming sulphuric acid alone or mixed with fuming nitric acid and the residual silicon dioxide weighed. It is usual to carry out the oxidation either in a Kjeldahl flask with the mouth closed by a glass balloon or in a crucible [2]. The former technique is applicable to compounds with boiling points even below 100° C (*cf.* Ref.[2] pp. 54 and 143). The latter method is best suited to high-boiling compounds or resinous polymers, because of the losses of material which can easily take place during the initial oxidation period. This limitation to the crucible method is regrettable since from the standpoint of speed and simplicity it is superior to the Kjeldahl method. The present paper is a description of an adaption of the crucible method to the analysis of low-boiling organosilicon compounds.

The new method might be called "the double crucible method" since two transparent quarts crucibles, volumes 10 and 50 ml, respectively, are used (Fig. 1). The empty crucibles are heated over a Meker burner for 15 min and then weighed. The inner crucible is filled with a mixture of 2 ml of 60 % fuming sulphuric acid and 2 ml of fuming nitric acid (d = 1.50) and cooled in iced water. The substance (calculated to give about 0.05 g of silicon dioxide) is weighed in a sealed glass ampoule. The tip of the ampoule is broken and the ampoule immediately placed in the acide-filled crucible as shown by Fig. 1. The substance is slowly driven out of the ampoule by heating the top with a small flame. The comparatively large depth reduces the risk of any material escaping through the layer of acid. As soon as the ampoule is empty the heating of the crucibles is begun using a low flame. The heating must be done carefully until the sample has frothed. Most types of organosilicon compounds froth violently on digestion with a mixture of sulphuric and nitric acid, and the flame must be removed until the frothing has subsided. This tendency to froth has led to the use of the outer larger crucible which catches any overflow from the small crucible. The heating is continued until the crucibles are dry and they are heated finally over a Meker burner to constant weight. Half an hour is generally enough. Residual silicon dioxide is calculated back to silicon in the original sample.

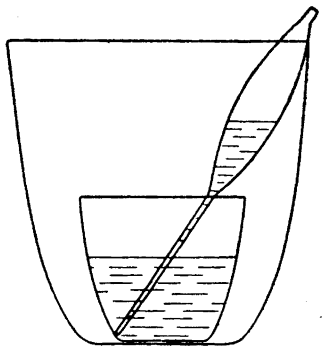

Fig. 1. Arrangement for acid digestion.

This method is also suited to the analysis of organosilicon compounds which react violently with the acid digestion mixture *e. g.* certain aminosilanes and silazanes. Table 1 contains analytical values for trimethylethoxysilane and hexamethyldisiloxane which cannot be analysed using the ordinary crucible method (*cf.* Ref. [1]).

Table 1. Analysis values, using the "double crucible method".

Compound	B. p. °C (760 mm)	% Si	
		Found	Calc.
Hexamethyldisiloxane	100	34.56 34.41	34.60
Trimethylethoxysilane	75	23.83 23.88	23.75

* A review has been given by McHard *et al.*[1]

The success of the present method depends on the following conditions which differ from those in the ordinary crucible method. The substance is weighed in an ampoule, a stronger oxidising acid mixture is used, which is cooled at the start of the reaction, a comparatively thick layer of acid hinders material from escaping, and the large outer crucible diminishes the risk of spoiling the analysis by the frothing of the mixture. As the volume of the acid mixture is kept small by the use of the inner crucible the time required for the expulsion of the acid fumes is shortened too.

A New Synthesis of Selenanthren-5,10-dioxide

GÖRAN BERGSON

Chemical Institute, University of Uppsala, Sweden

Selenanthren-5,10-dioxide (IV) is of considerable theoretical interest because it might exist in a *cis-* and a *trans*-form if there is a pyramidal configuration at the selenium atom. Neither optical nor geometrical isomerism has been demonstrated for selenoxides in spite of several attempts[1]. Recently Gould and McCullough [2] suggested that *cis-trans* isomerism was to be expected for 1,4-di-selenane-1,4-dioxide. Owing to the great difficulties in the synthesis of 1,4-diselenane its oxidation products were never prepared. Following a suggestion of professor Arne Fredga the present author started an investigation of the oxides of selenanthren (I). Since then Gould and Burlant [3] have reported very promising results of a study of 1,4-diselenane. They have prepared a 1,4-dioxide and will determine its structure by X-ray methods.

The present paper describes a new synthesis of selenanthren-5,10-dioxide. A detailed report of the studies of selenanthren oxides and thianthren oxides will be published elsewhere.

Selenanthren-5,10-dioxide was first prepared by Krafft and Kaschau [4] by the oxidation of selenanthren with nitric acid. In 1951 Cullinane [5] reported a modification of the same method, and established the melting point to be 265°. He also characterized a hydrate and a dihydrochloride of IV. The present author has prepared selenanthren-5,10-dioxide in a way represented by the reaction scheme below.

The dioxide obtained by this method is identical with the product of Cullinane, as has been shown by IR-spectra (Fig. 1) and mixed melting points. The peak at 13.05 μ is due to out-of-plane vibration of the hydrogen atoms in the benzene nucleus,

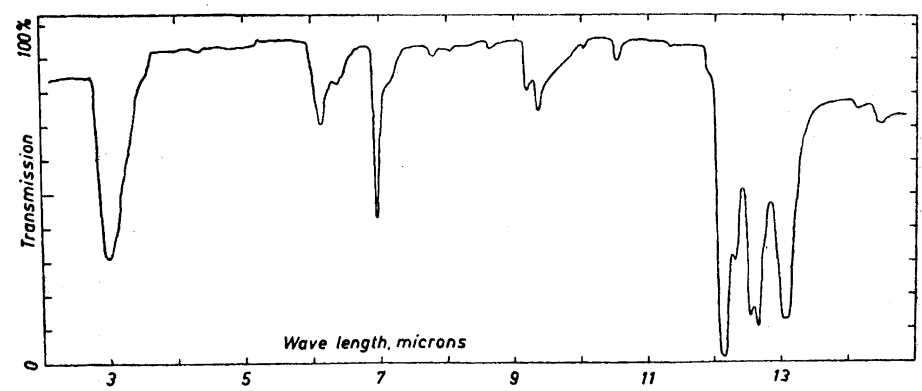

Fig. 1. Infrared absorption spectrum of selenanthren-5,10-dioxide in pressed KBr. Perkin Elmer model 21 spectrometer with NaCl prism.

The success of the present method depends on the following conditions which differ from those in the ordinary crucible method. The substance is weighed in an ampoule, a stronger oxidising acid mixture is used, which is cooled at the start of the reaction, a comparatively thick layer of acid hinders material from escaping, and the large outer crucible diminishes the risk of spoiling the analysis by the frothing of the mixture. As the volume of the acid mixture is kept small by the use of the inner crucible the time required for the expulsion of the acid fumes is shortened too.

A New Synthesis of Selenanthren-5,10-dioxide

GÖRAN BERGSON

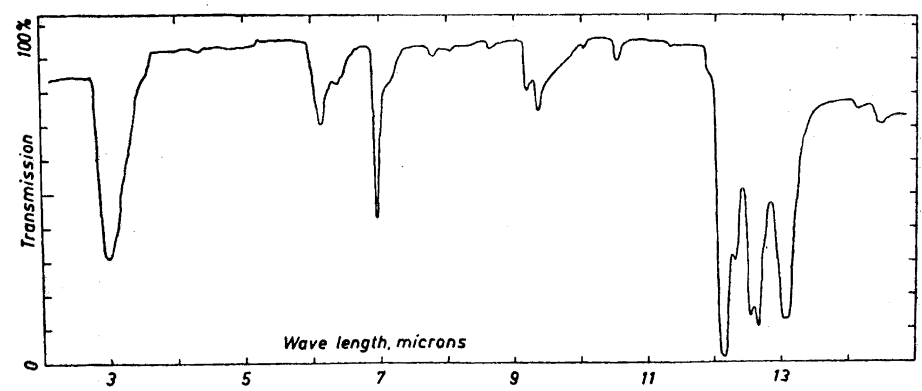
Chemical Institute, University of Uppsala, Sweden

Selenanthren-5,10-dioxide (IV) is of considerable theoretical interest because it might exist in a *cis-* and a *trans*-form if there is a pyramidal configuration at the selenium atom. Neither optical nor geometrical isomerism has been demonstrated for selenoxides in spite of several attempts[1]. Recently Gould and McCullough [2] suggested that *cis-trans* isomerism was to be expected for 1,4-di-selenane-1,4-dioxide. Owing to the great difficulties in the synthesis of 1,4-diselenane its oxidation products were never prepared. Following a suggestion of professor Arne Fredga the present author started an investigation of the oxides of selenanthren (I). Since then Gould and Burlant [3] have reported very promising results of a study of 1,4-diselenane. They have prepared a 1,4-dioxide and will determine its structure by X-ray methods.

The present paper describes a new synthesis of selenanthren-5,10-dioxide. A detailed report of the studies of selenanthren oxides and thianthren oxides will be published elsewhere.

Selenanthren-5,10-dioxide was first prepared by Krafft and Kaschau [4] by the oxidation of selenanthren with nitric acid. In 1951 Cullinane [5] reported a modification of the same method, and established the melting point to be 265°. He also characterized a hydrate and a dihydrochloride of IV. The present author has prepared selenanthren-5,10-dioxide in a way represented by the reaction scheme below.

The dioxide obtained by this method is identical with the product of Cullinane, as has been shown by IR-spectra (Fig. 1) and mixed melting points. The peak at 13.05 μ is due to out-of-plane vibration of the hydrogen atoms in the benzene nucleus,



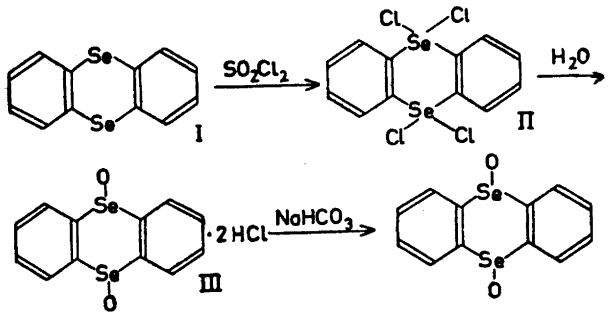


Fig. 1. Infrared absorption spectrum of selenanthren-5,10-dioxide in pressed KBr. Perkin Elmer model 21 spectrometer with NaCl prism.

and the peaks at 12.15, 12.32, 12.55 and 12.65 μ must be due to the presence of the Se-O groups. (IR-spectra of selenoxides have not been described in the literature.) A comparison of this peak system with the characteristic absorption peaks for S—O in the *trans-* and *cis*-form of thianthren-5, 10-dioxide suggests that the selenoxide is not a pure *trans-* form but rather a *cis*-form or a mixture of both or perhaps a dioxide with planar configuration [6].

Experimental: Selenanthren-5,5-10,10-tetrachloride (II). To a solution of 1.55 g of selenanthren in 100 ml of dry benzene, 5.0 g (excess) of SO_2Cl_2 in 50 ml of benzene was added. The mixture was boiled under reflux for 30 min. The tetrachloride separated as a yellow fine crystalline solid. About 70 ml of benzene was then removed by distillation, and from the cooled reaction mixture the tetrachloride was obtained by filtration. It was washed with dry benzene and then dried in vacuum, m. p. 208—209.5° (decomp.). Yield 2.10 g (89 %). (Found: Se 34.3; 34.7; Cl 31.3. Calc. for $C_{12}H_8Se_2Cl_4$: Se 34.9; Cl 31.4).

Selenanthren - 5,10 - dioxide dihydrochloride (III). 2.00 g of selenanthren tetrachloride was hydrolysed with 100 ml of boiling water. After filtration and evaporation the dihydrochloride was obtained as a white solid in quantitative yield, m. p. 228—229° (decomp.). (Found: Se 38.1; Cl 17.1. Calc. for $C_{12}H_8O_2Se_4 \cdot 2HCl$: Se 38.4; Cl 17.1).

Selenanthren-5,10-dioxide (IV). 1.25 g of selenanthren-5,10-dioxide dihydrochloride was dissolved in 100 ml of water. 0.56 g of $NaHCO_3$ was added and the solution evaporated on a water bath. The residue was extracted with 100 ml of boiling chloroform and after evaporation the crude dioxide (m. p. 256—258°) was obtained in quantitative yield. This product was washed with 50 ml of ether and 15 ml of water and then recrystallized from water. The dioxide separated on cooling as a hydrate which was dried to constant weight at 120°. In this way selenanthren-5,10-dioxide with m. p. 264—265° (decomp.) was obtained. Yield 0.68 g (66 %). (Found: Se 46.3. Calc. for $C_{12}H_8O_2Se_4$: Se 46.2). The selenium analyses have been carried out according to Fredga [7].

Thanks are due to Mr. Stig Bergwall for technical assistance with the IR-spectra. A grant from the *Swedish Natural Science Rese-Research Council* is gratefully acknowledged.

Preparation of Lithium Azide

NIELS HOFMAN-BANG

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The most common methods for the preparation of lithium azide, LiN_3, are interaction of lithium sulfate and barium azide, and, especially, neutralization of aqueous hydrazoic acid with lithium hydroxide. Considering that preparation and handling of hydrazoic acid require care, it occurred to me that sodium azide and

lithium sulfate, which is generally kept on stock in a laboratory, might interact to give lithium azide and sodium sulfate.

The four salts in question are all soluble in water. Lithium azide is soluble and sodium azide is sparingly soluble in ethanol (0.22 g NaN_3 per 100 g at 0 °C), while lithium and sodium sulfate are insoluble. Even in 75—80 % ethanol the solubilities of lithium and sodium sulfate are very small. Based on these facts the following method of preparation has been worked out:

1.30 g of sodium azide and 1.41 g of lithium sulfate, Li_2SO_4, H_2O, which is 10 % in excess, are dissolved in 7 ml of water by shaking and gentle heating. 35 ml of ordinary 96 % ethyl alcohol are now added in a thin stream, while stirring with a spatula. After 10 min (it has been ascertained that a longer time is of no effect) the mixture is filtered. The precipitate, which consists of sodium and lithium sulfate, is washed with a few ml of ethanol, and the filtrate plus the washing liquid is evaporated on a water bath to near dryness. Finally, it is dried at 80 °C in a drying oven. The theoretical yield of lithium azide is 0.98 g, while actually 1.02—1.04 g is obtained. This raw product contains no sulfate but a few per cent of sodium. It can be purified by 2 min digestion with 10 ml 96 % ethanol at about 35 °C, filtering the undissolved sodium azide, and evaporating and drying as above. The yield is usually *ca.* 0.6 g lithium azide of a purity not less than 99.5 %. It contains a slight trace of organic material due to the use of ethyl alcohol.

The purified lithium azide has been analyzed by two methods. The content of azide has been determined according to Martin [1] by oxidation with Ce(IV). Analysis of two products of lithium azide gave 99.5 % and 99.5 %. The same two products were analyzed by conversion to lithium sulfate and weighing [2]. The results were 100.2 % and 99.7 % lithium azide, respectively. Thus it seems that the prepared lithium azide is slightly "basic" due to loss of hydrazoic azid when evaporating.

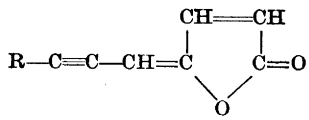
The Rearrangement of *cis*-2-en-4:6-diyn-oic Acids to $\alpha\beta$-Unsaturated γ-Lactones

PER KOCH CHRISTENSEN



Sintef, Norges Tekniske Høgskole, Trondheim, Norway

The so called "Composit-Cumulene I" originally reported by Sørensen and Stavholt [1] was given the structural formula I

$$CH_3—CH_2—CH_2—CH_3—CH_2—CH=C=C=CH—COOCH_3 \qquad I$$

based on the UV-absorption and the hydrogenation to a hexahydro derivative with an odour of strawberry like methyl caprate.

A reinvestigation of this compound isolated from scentless mayweed *(Matricaria inodora* L.) showed that the substance contained a disubstituted acetylenic bond (2 190 cm^{-1}) and the carbonyl frequency (1 793 and 1 765 cm^{-1}) indicated a five-ring lactone. Hydrogenation with $Pd/BaSO_4$ showed a consumption of 5 moles of hydrogen and the product was a saturated five-ring lactone with carbonyl frequency at 1 786 cm^{-1}. The formula accordingly had to be revised [2,3] and the substance was found to be the lactone II (R = *cis* $CH_3—CH=CH—$)

II

The formation of this type of lactone from the free 2-*cis*-acid III was first observed when III ($R=CH_3C\equiv C-C\equiv C-$) was treated with dilute sodium hydrogencarbonate [3]

$$R—C\equiv C—CH=CH—COOH \qquad III$$

On measuring the ultra-violet absorption of an alcoholic solution of *cis*:*cis* matricaria acid III ($R=CH_3CH=CH-C\equiv C-$) in a UV-recorder (Beckman DK) it was noticed that on scanning the spectrum of two solutions with different concentrations, the absorption curve was markedly different the second time. The long wave-

lithium sulfate, which is generally kept on stock in a laboratory, might interact to give lithium azide and sodium sulfate.

The four salts in question are all soluble in water. Lithium azide is soluble and sodium azide is sparingly soluble in ethanol (0.22 g NaN_3 per 100 g at 0 °C), while lithium and sodium sulfate are insoluble. The Rearrangement of *cis*-2-en-4:6-diyn-oic Acids to $\alpha\beta$-Unsaturated γ-Lactones

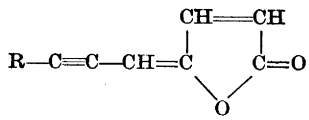
PER KOCH CHRISTENSEN



Sintef, Norges Tekniske Høgskole, Trondheim, Norway

The so called "Composit-Cumulene I" originally reported by Sørensen and Stavholt [1] was given the structural formula I

$$CH_3—CH_2—CH_2—CH_3—CH_2—CH=C=C=CH—COOCH_3 \qquad I$$

based on the UV-absorption and the hydrogenation to a hexahydro derivative with an odour of strawberry like methyl caprate.

A reinvestigation of this compound isolated from scentless mayweed *(Matricaria inodora* L.) showed that the substance contained a disubstituted acetylenic bond (2 190 cm^{-1}) and the carbonyl frequency (1 793 and 1 765 cm^{-1}) indicated a five-ring lactone. Hydrogenation with $Pd/BaSO_4$ showed a consumption of 5 moles of hydrogen and the product was a saturated five-ring lactone with carbonyl frequency at 1 786 cm^{-1}. The formula accordingly had to be revised [2,3] and the substance was found to be the lactone II (R = *cis* $CH_3—CH=CH—$)

II

The formation of this type of lactone from the free 2-*cis*-acid III was first observed when III ($R=CH_3C\equiv C-C\equiv C-$) was treated with dilute sodium hydrogencarbonate [3]

$$R—C\equiv C—CH=CH—COOH \qquad III$$

On measuring the ultra-violet absorption of an alcoholic solution of *cis*:*cis* matricaria acid III ($R=CH_3CH=CH-C\equiv C-$) in a UV-recorder (Beckman DK) it was noticed that on scanning the spectrum of two solutions with different concentrations, the absorption curve was markedly different the second time. The long wave-

length absorption had shifted to longer wave-lengths with stronger intensity while the short wave-length absorption (~ 2 570 Å) had undergone a hypsochromic shift with lower intensity. This phenomenon was further investigated, and it turned out that on dissolving *cis:cis* matricaria acid in a solvent containing water, in this case 95 % ethanol, the rearrangement free acid → lactone took place spontaneously. In absolute ethanol (~ 99.8 %) the speed of reaction was very much slower.

A solution of the free acid in dry tetrahydrofuran was stable and the UV-absorption was quite similar to a solution in hexane. Addition of distilled water to the tetrahydrofuran immediately caused rearrangement to the lactone.

Working in a mixture of tetrahydrofuran and buffers (1:1) the reaction took place with a measurable speed in the interval pH ~ 4.5 – 11. Above pH ~ 11 also other reactions occurred and the product was no longer pure. Measurement of reaction velocities by means of UV-absorption was impossible.

In the interval pH ~ 6 – 11 the rate of reaction was approximately constant. The reaction appeared to be of first order with half-times of ~3.5 min at 30 °C and ~ 11 min at 20 °C. Below pH ~ 6 the rate decreased rapidly.

The same rearrangement in water-containing solvents has been followed starting

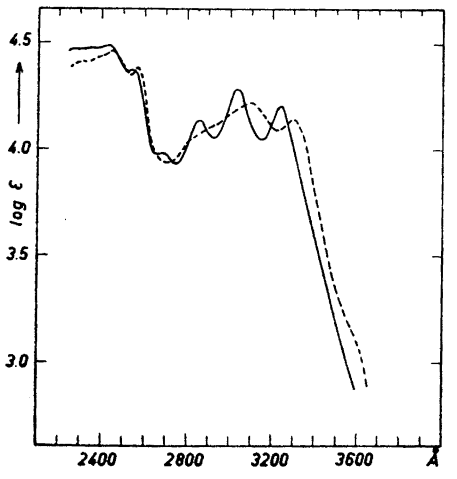


Fig. 1. 2-*trans* Matricaria acid, — — — in dry tetrahydrofuran; ——— in tetrahydrofuran-water (10:1).

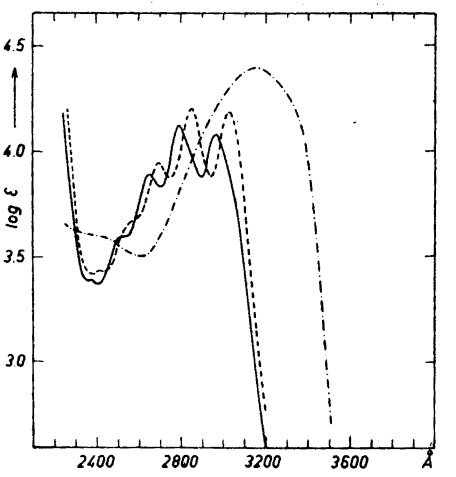

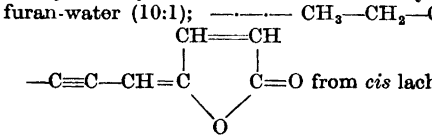

Fig. 2. trans Lachnophyllum acid, — — — in dry tetrahydrofuran; ——— in tetrahydrofuran-water (10:1); —·—·— $CH_3—CH_2—CH_2$

from *cis* lachnophyllum acid.

with *cis* lachnophyllum acid (III, R = $CH_3—CH_2—CH_2—C≡C—$). According to Ref.[3] it also takes place with *cis* dehydro matricaria acid (III, R = $CH_3—C≡C—C≡C—$) at pH = 8.4. Other substances have not yet been tried.

When the rearrangement was followed in the UV-recorder with rapid successive scannings of the spectrum, it turned out that with the *cis:cis* matricaria acid no direct transformation from the free acid spectrum to the lactone spectrum took place, but some intermediate absorption with more pronounced fine structure (Fig. 3, curve 1) was observed. The transformation from the normal free acid spectrum to this spectrum took place in less than 0.5 min.

In order to be able to make a reasonable guess as to the origin of the absorption of this compound, some 2-*trans* matricaria acid was dissolved in tetrahydrofuran with water. This acid is incapable of forming a lactone for steric reasons and gave immediately after having been dissolved (< 0.5 min) a spectrum entirely different

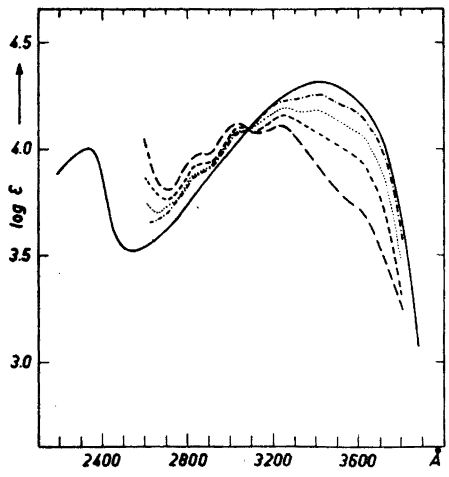

Fig. 3. Rearrangement of di *cis* matricaria acid in 95 % ethanol. *Curve 1:* – – – 0.5—3.5 min after dissolving the acid, start at long wavelengths. *Curve 2:* ——— 80 min after dissolving the acid, total lactone formation. Other curves measured at intermediate times.

from that of the acid dissolved in hexane or dry tetrahydrofuran. In these two solvents the spectrum of the 2-*trans* acid (Fig. 1) was very similar to the spectrum of both the 2-*trans* and the 2-*cis*-ester with no marked fine structure in the long wavelength area (2 800—3 400 Å). When dissolved in tetrahydrofuran with water (10:1) a marked fine-structure developed with bands at 2 850, 3 035 and 3 240 Å (Fig. 1). The 2-*trans* lachnophyllum acid gave the same overall picture with a shift from 2 690, 2 850 and 3 025 Å in dry tetrahydrofuran to 2 645, 2 790 and 2 965 Å in tetrahydrofuran-water (10:1) (Fig. 2).

The substances *trans* ($HC{\equiv}C-CH=CH-COOH$ and *trans* $(-C{\equiv}C-CH=CH-COOH)_2$ gave the same shift to shorter wavelengths, although less pronounced.

When 2-*cis*-matricaria acid is dissolved in 0.01 N ethanolic H_2SO_4, there is no formation of the fine-structure spectrum.

If samples are withdrawn at certain time intervals from a solution of the *cis*-acid in 95 % ethanol the reaction can be stopped with acid. Analysis of these samples in UV now gives as result a set of curves where the intermediate curves between pure acid and pure lactone are mixtures of the normal acid spectrum and the lactone spectrum.

At present it is not possible to give a detailed reaction mechanism, but from the spectral studies two general routes are possible:

A: Fine-structure complex ⇌ free acid → lactone

B: Free acid ⇌ fine-structure complex → lactone

The choice between the two must await more detailed studies, the most probable is apparently B. If, in B, the equilibrium acid ⇌ complex is over to the right, there would be an apparent isosbestic point [4] in the UV-curves from the reaction fine-structure complex → lactone. (Fig. 3).

Holman and Sørensen [5] reported in 1950 some spectral and oxidation studies on matricaria ester and the free acid. Their curve for the UV-absorption of the acid in ethanol can now be interpreted as being the curve for a mixture of the free acid and the lactone formed from it. The sharp maximum at ~ 2 580 Å in the pure free acid been reduced and indicates a fairly large amount of lactone formation. The maximum at 3 250 Å corresponds to the rapidly developed maximum in solvents containing water.

This work is in progress and further results will be published elsewhere.

Autoradiographic Studies on the Effect of Cathodic Prepolarization on Metallic Surfaces

M. A. EL GUEBELY*

Curie Laboratory, Paris, France

The effect of cathodic prepolarization of platinum, gold and silver electrodes has been studied. It has been found in all cases that the velocity of the spontaneous deposition of Po is greater on a prepolarized than on a non-polarized electrode. Studies of the histograms of the α-particles of Po showed a relative increase of the apparently shortened trajectories in case of the previously polarized electrodes.

The effect of prepolarization on the process of electro-deposition of radio-elements was noticed by Haissinsky [1] in a study of the cathodic deposition of ThC on a gold electrode. The curve representing the quantity deposited in function of time manifested a maximum which indicated the possibility of a change of the state of the cathodic surface during electrolysis. In fact he noticed moreover that if the electrolysis is carried out under the same conditions, using a fresh electrode in a solution exempt from the radio-element, and then the radio-element is added while continuing the electrolysis, the maximum disappears and the deposition curve has a normal form. Since then the same author and his collaborators studied different aspects of this interesting phenomenon. Danon and Haissinsky [2] have indicated that the Nernst law is not applicable to the deposit of RaE (10^{-16} M) on a gold cathode in nitric acid solution except after prepolarization of the electrode. Haissinsky and Coche [3] have found, in the case of the cathodic deposition of Po on tantalum, a modification in the form of the deposition curve as well as a displacement of the critical deposition potential towards more positive values as a result of the prepolarization of the electrodes. Ferradini [4] has observed a spontaneous deposit of Pa on platinised platinum which was prepolarized anodically. Finally our recent studies [5] on Rd-Ru have shown that prepolarization of the cathode plays a decisive role on the electro-deposition of this radio-element. In all cases studied, except for platinised platinum, there is practically no

* Present address: Egyptian Atomic Energy Commission, El-Dokky, Cairo.

deposit at ordinary temperature without prepolarization, while after prepolarization under favourable conditions practically quantitative deposits can be obtained.

The object of this study is to provide a direct evidence of the modification of the metallic surface produced by the cathodic prepolarization of metallic electrodes.

EXPERIMENTAL

In the present work we have used the autoradiographic method which has been previously utilized by Haissinsky *et al.*[6] in their studies of the metallic surfaces.

In our experiments we have studied the spontaneous deposit of Po on prepolarized and non-polarized platinum, gold and silver electrodes. All the electrodes were pure and electro-polished thin metallic foils. They were further purified chemically. Platinum electrodes were ignited in an oxidising flame and then boiled with concentrated nitric acid while gold electrodes received the nitric acid treatment only. Silver electrodes were purified by introducing them rapidly for a few times in 50 % HNO_3. The water used for washings and preparation of solutions was bidistilled and different reagents were of analytical purity.

Prepolarization was effected by electrolysing 10 ml of N H_2SO_4 using these electrodes as cathodes while separating the cathodic from the anodic compartments by an appropriate electrolytic bridge. The anode was a thin platinum wire. Concerning conditions of prepolarization, *cf.* Table 1.

Table 1. Conditions of prepolarization.

Metal	Current density (in mA/cm²)	Time, h	Temperature, °C	Approximate cathode potential, V
Pt	500	5	85	−2
Au	2.7−1.3	48	ordinary	−0.6
Ag	2−1	48	ordinary	−0.7

Each polarized electrode was washed and introduced together with a non-polarized foil into 10 ml of a normal sulphuric acid, 10^{-12} N in Po, for 20 h. The solution was stirred mechanically while the two foils were kept at equal distance from the stirrer. Each foil was washed and dried and an α-nuclear plate, Ilford C_2 50 microns then applied for an hour to the surface that was opposite to the stirrer. The plates were then developed by the appropriate photographic technique [7] and then examined under a microscope.

RESULTS

The microscopic examination of the nuclear plates consisted of establishing the topographic distribution of the trajectories of the α-rays on the metallic surface, by counting their number per field of vision of the microscope (150 fields studied for each plate) and by measuring the ranges of the α-particles in the gelatine (300 per plate). In these studies we have limited our measurements of ranges to the horizontal tracks, *i. e.* those for which practically the total length is visible for the same focussing.

Fig. 1. Prepolarized Pt foil.

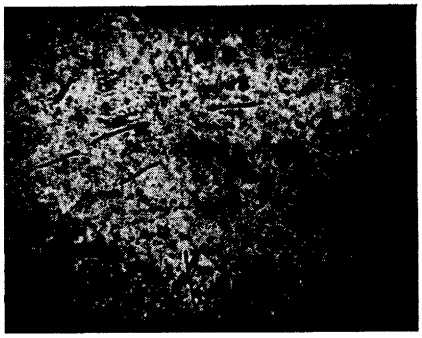

Fig. 2. Non-polarized Pt-foil.

Our results show that:

a) The tracks are distributed in all cases at random. No priviliged accumulation of the deposited Po atoms was found at certain points of the surface, as was found [6] in case of Po in HNO_3 and ^{239}Pu and ^{235}U in hydrochloric and nitric acids, respectively [8].

b) The velocity of the spontaneous deposition of Po is always greater on a prepolarized than on a non-polarized foil, the ratio between the two velocities being 2 for Pt, 1.64 for Au and 1.75 for Ag.

Figs. 1 and 2 represent, for example, two fields of vision, the first for a prepolarized Pt foil and the other for a non-polarized one.

c) The curves A and B of Figs. 3, 4 and 5 represent the distribution of the ranges of the α-particles of the spontaneously deposited Po atoms on Pt, Au and Ag foils, respectively; A for the non-polarized foils and B for the prepolarized ones.

DISCUSSION

The results obtained indicate that the most probable range of the α-particles of Po in Ilford C_2 plates is 21 ± 1 μ which is in good agreement with the value found previously [6].

The study of the histograms in Figs. 3, 4 and 5 representing the distribution of the ranges of the α-particles of Po shows that the curves are deformed in the case of the prepolarized foils. This deformation corresponds to a relative increase of the apparently shortened ranges. Apparent shortening of the ranges of the α-particles of Po spontaneously or electrolytically deposited on metallic surfaces has been attributed by Haissinsky *et al.*[6] to penetration of a certain number of Po atoms into the surface. In a recent work [8] on the adsorption of Pu on glass and metallic surfaces we admitted that back-scattering of the α-particles from the carrying surface may, together with the penetration factor,

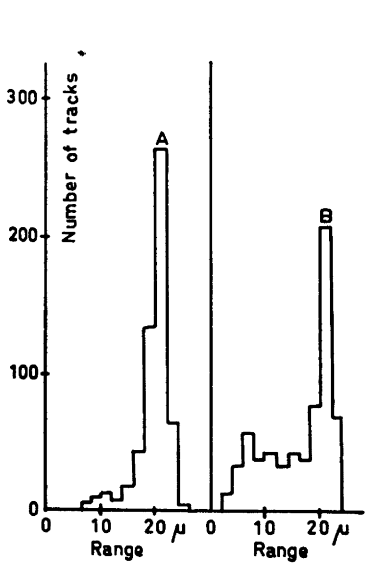

Fig. 3. Histograms of α-particles of Po on platinum foils.

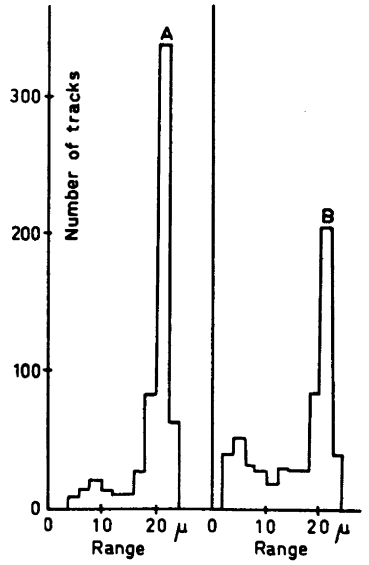

Fig. 4. Histograms of α-particles of Po on gold foils.

play a role in the phenomenon of apparent shortening. However, the observed increase in the apparent shortening in case of prepolarized electrodes cannot possibly be due to an increase in back-scattering since the only possible chemical change of the metallic surface in our experimental conditions would be the inclusion of hydrogen under one form or another. It seems therefore more plausible to suppose that cathodic prepolarization leads to a micro-deformation of the metallic surface connected with the formation of ultramicro pores or lacunae which would facilitate the penetration of a further number of the deposited atoms into the surface. Such deformation may be due to adsorption and desorption of hydrogen, or to the possible formation of a trace of a hydride which may be hydrolysable as in the case of Pt and Pd, or volatile as in the case of Pb and which would as such separate from the surface.

The increased heterogeneity of the metallic surface connected with a more favourable distribution of "active centres" would in general explain the observed effects of prepolarization on the spontaneous and electro-deposition of radio-elements. The higher velocity of spontaneous deposition of Po on prepolarized electrodes may thus be attributed to the increased number of "active centres". A similar explanation might account for the more positive critical deposition potential of Po on prepolarized tantalum. However, in certain particular cases, the chemical changes of the surface have to be taken into consideration together with the physical changes. Such is for example the case of the spontaneous deposition of Pa on anodically prepolarized platinised platinum where atomic oxygen is supposed to play a role [4]. It is again equally important, for the explanation of the induction period in the cathodic

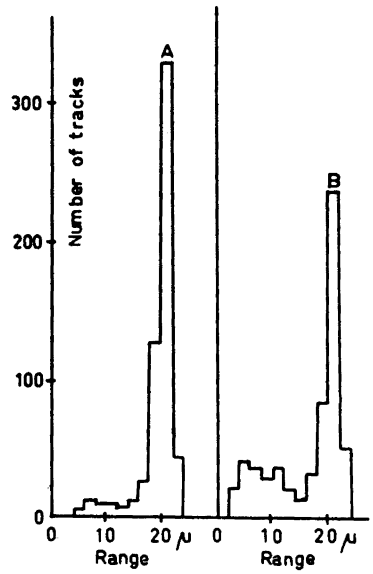

Fig. 5. Histograms of the α-particles of Po on silver foils.

deposition of Rd-Ru, to consider the possible accumulation on the cathodic surface of atomic hydrogen which would effect the reduction of the strong Ru complexes to more easily reducible forms [5].

Finally segregation of Po in HNO_3, as well as of Pu in HCl and U in HNO_3 solution, on metallic and / or glass surfaces was attributed to the possibility of existence of particularly priviliged regions having a relatively high energy of adsorption [8]. However, the absence of the segregation phenomenon in case of Po in N H_2SO_4 solution, as has been indicated in the present work, seems to suggest that, in addition to the distribution of the energy of adsorption on the metallic surface, one has to consider the role of the solvent and probably also the nature of the deposited atoms.

Acknowledgement. I should like to express my deepest thanks to Professor M. Haissinsky for his continuous advice and encouragement, and to Mademoiselle Albouiy for her help concerning the autoradiographic technique.

Studies on Bile Acid Salt Solutions

I. The Dissociation Constants of the Cholic and Desoxycholic Acids

PER EKWALL, TORSTEN ROSENDAHL and NILS LÖFMAN

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

The dissociation constants of cholic and desoxycholic acids have been evaluated from data obtained by potentiometric titration of aqueous solutions of their sodium salts with hydrochloric acid at 20 °C. The values obtained are: cholic acid, $pK_A = 4.98 \pm 0.05$, $K_A = 1.05 \times 10^{-5}$; desoxycholic acid $pK_A = 5.17 \pm 0.04$; $K_A = 6.76 \times 10^{-6}$.

Sodium cholate behaves as a normal uni-univalent electrolyte up to a concentration of 0.014—0.015 M; for sodium desoxycholate, the corresponding concentration limit is 0.0045—0.0055 M. Above these concentration limits, deviations occur which are due to micelle formation. After a transition region which for sodium cholate extends to a concentration of approximately 0.05 M and for sodium desoxycholate to about 0.01 M, a concentration range is reached in which the micelle formation is fully developed and which is characterized by a high, nearly constant ratio of the activities of the bile acid and its anion.

Many attempts have been made to determine the dissociation constants of the bile acids. Bondi [1] used conductance values to calculate the dissociation constant of glycocholic acid, Hammarsten [2] determined the constants of tauro- and glycocholic acids by potentiometric titration, whereas Henriques [3] utilized colorimetric pH-determinations to obtain the dissociation constants of several bile acids. Josephson [4] calculated the dissociation constants of a number of bile acids from potentiometrically determined pH values of aqueous solutions of the sodium salts to which different amounts of hydrogen chloride had been added. With the aid of glass electrode measurements, Kumler and Halverstadt [5] determined the dissociation constants of six bile acids in 50—67 % ethanol-water solutions and from these values they calculated the approximate values of the constants in water by assuming that the constants of all the acids in pure water are 17 times greater than in 50 % ethanol-water. They emphasized, however, that the difference is not constant for different acids and hence "an exact calculation of K_A values in one solvent cannot be made from those in another solvent" [5].

The values reported by the above-mentioned authors are collected in Table 1. The values are seen to deviate considerably from each other.

Table 1. The dissociation constants of bile acids.

Acid	Bondi	Hammarsten	Henriques	Josephson	Kumler and Halverstadt
Glycocholic acid	$1.32 \cdot 10^{-4}$	$4.0 \cdot 10^{-5}$	$1.66 \cdot 10^{-3}$	$3.55 \cdot 10^{-5}$	
Taurocholic »		$6.77 \cdot 10^{-2}$	$5.89 \cdot 10^{-4}$	$2.75 \cdot 10^{-2}$	
Glycodesoxycholic »			$3.47 \cdot 10^{-3}$	$10.49 \cdot 10^{-5}$	
Taurodesoxycholic »			$1.18 \cdot 10^{-3}$	$1.23 \cdot 10^{-2}$	
Cholic »				$6.46 \cdot 10^{-6}$	$1.12 \cdot 10^{-5}$
Desoxycholic »				$3.8 \cdot 10^{-7}$	$1.08 \cdot 10^{-5}$
Apocholic »					$1.09 \cdot 10^{-5}$
Lithocholic »					$1.02 \cdot 10^{-5}$
Dehydrocholic »					$1.22 \cdot 10^{-5}$
Dehydrodes-oxycholic »					$1.24 \cdot 10^{-5}$

At the time these determinations were carried out, very little was known about the colloidal properties of the bile acid salts; these properties may have affected many of the results. It occurred to us that the values of the dissociation constants should be checked. We have therefore carried out a redetermination of the dissociation constants of cholic and desoxycholic acids [11–13].

EXPERIMENTAL

Cholic acid (Hoffman-La Roche, Basel) was recrystallized several times from 96 % ethanol. The sample used in the measurements had after drying a m. p. of 197 °C.

Desoxycholic acid (Hoffman-La Roche, Basel) was recrystallized three times from glacial acetic acid, dissolved in ethanol and precipitated with ether two times, and boiled in water for 3 h. After drying the sample had a m. p. of 172–173 °C.

The sodium salts of both acids were prepared by dissolving the corresponding acids in absolute ethanol and neutralizing the warmed solutions with equivalent amounts of sodium ethylate in absolute ethanol. The salts crystallizing from the solutions on cooling were dried *in vacuo* over phosphorus pentoxide at an elevated temperature.

The determination of the dissociation constants involved potentiometric titration of aqueous solutions of the bile acid sodium salts with dilute hydrochloric acid. The pH values were determined with a valve potentiometer (Radiometer PHM3, Copenhagen) fitted with a glass electrode and a saturated calomel electrode as reference electrode. The titrations were conducted in a nitrogen atmosphere and were performed so that the method of Back and Steenberg [6] for the determination of the solubilities and solubility products of the acids could be utilized. Before the titration a slight excess of sodium hydroxide solution was added to the bile acid salt solution and the titration was continued over the equilibrium point until the bile acid began to precipitate.

RESULTS

Figs. 1 and 2 show two typical titration curves. The first parts of the curves are quite normal. The liberated acid, particularly cholic acid, has, however, a tendency to remain in solution, whereupon a supersaturated solution is produced. When precipitation finally occurs, the pH of the solution increases abruptly to the equilibrium value of the solution saturated with acid.

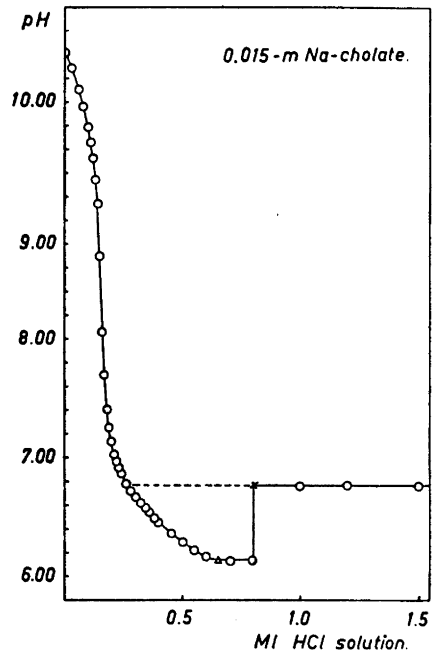

Fig. 1. Potentiometric titration of sodium cholate with HCl. 20 ml 0.0150 M sodium cholate solution + NaOH. Titrant: 0.0500 M HCl. △ The solution became turbid. × Precipitation occurred.

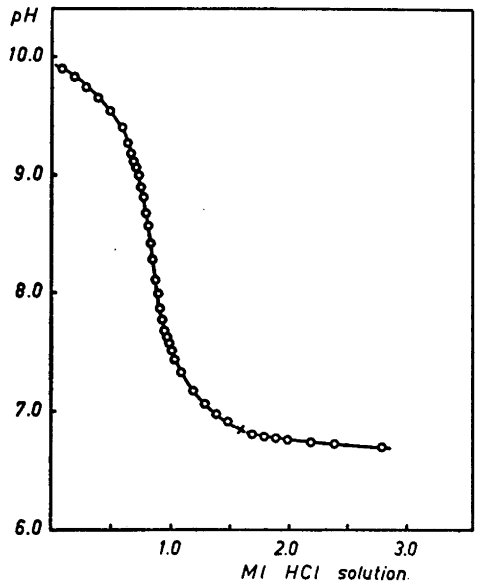

Fig. 2. Potentiometric titration of sodium desoxycholate with HCl. 40 ml 0.0050 M sodium desoxycholate solution + NaOH. Titrant: 0.0050 M HCl. × Precipitation occurred.

The calculation of the dissociation constants was based on the assumption that the ordinary dissociation equilibrium of weak acids is valid:

1. $$\frac{a_{H_3O^+} \cdot a_{A^-}}{a_{HA}} = K_A$$

Only the first parts of the titration curves which were unaffected by precipitation of acid or supersaturation were used in the calculations which were based on eqn. 2 [6].

2. $$pK_A = pH_x + \log \frac{C_s + C_{OH^-} - C_{H_3O^+}}{C_{tot} - C_s - C_{OH^-} + C_{H_3O^+}} + \frac{0.5\sqrt{\mu}}{1+\sqrt{\mu}}$$

where

$$(C_s + C_{OH^-} - C_{H_3O^+}) \cdot f_{HA} = a_{HA}$$

and

$$(C_{tot} - C_s - C_{OH^-} + C_{H_3O^+}) \cdot f_{A^-} = a_{A^-}$$

(pH_x is a recorded pH value; C_s is the corresponding concentration of hydrogen chloride added after the equivalence point and C_{OH^-} and $C_{H_3O^+}$ the corresponding hydroxyl and hydroxonium ion concentrations; C_{tot} is the original concentration of bile acid salt recalculated to the conditions at the point x; a_{HA} and a_{A^-} are the activities of the undissociated bile acid and its anion, respectively, and f_{HA} and f_{A^-} the corresponding activity coefficients; μ is the ionic strength of the solution).

In the calculation of pK_A, we have used 10—20 titration points after the equivalence point which yielded conforming values for the constant. The results of the calculations are given in Tables 2 and 3.

The titrations of dilute cholate solutions up to 0.014 M give a constant value of the dissociation constant of cholic acid: $pK_A = 4.98 \pm 0.05$ (Fig. 3). In the range from 0.015 to 0.040 M, the pK_A values increase with cholate concentration. Beginning with the 0.05 M and up to 0.20 M cholate solution, the

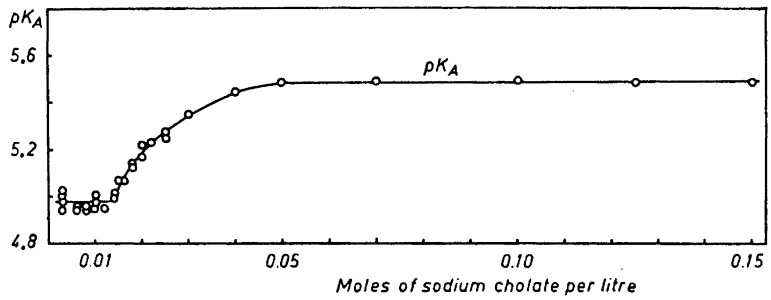

Fig. 3. The dissociation constant of cholic acid determined by potentiometric titration of sodium cholate solutions of different concentration with HCl.

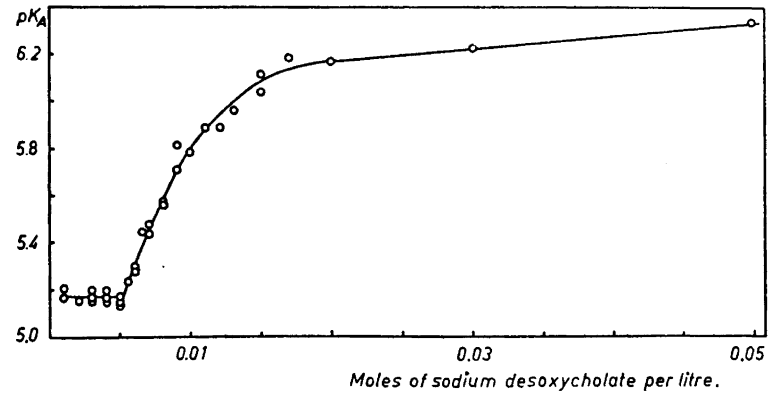

Fig. 4. The dissociation constant of desoxycholic acid determined by potentiometric titration of sodium desoxycholate solutions of different concentration with HCl.

titrations again give a constant pK_A value, $pK_A = 5.48 \pm 0.01$, which is considerably higher than the value obtained for the dilute cholate solutions.

The results for desoxycholic acid are similar (Fig. 4). At high desoxycholate dilutions, up to 0.005 M, the dissociation constant is constant, $pK_A = 5.17 \pm 0.04$. The value of the constant then increases rapidly in the concentration range from 0.006 to 0.010 M, but more slowly above the latter concentration. The highest value of pK_A obtained was 6.35. Values relating to concentrations higher than 0.05 M are uncertain.

DISCUSSION

Many earlier studies have shown that sodium cholate and desoxycholate behave as normal uni-univalent electrolytes only in relatively dilute solutions [7-13]. The deviations from the normal behaviour that occur at higher concentrations are due to micelle formation. One of us has previously established that the power to solubilize hydrocarbons is first observed when the concentration of the solution exceeds 0.015 M in the case of cholate and 0.005 M in the case of the desoxycholate [9-13]. This indicates that micelle formation sets in approximately at these concentrations. The micelle formation influences many of the other properties of the solutions.

The method we have used to calculate values of dissociation constants assumes that micelle formation does not take place and gives correct values only if this condition is fulfilled. Consequently only those values are reliable that apply to dilute solutions whose concentrations are below the limits given above. Accordingly, the following values are presented for the dissociation constants of the two bile acids:

Cholic acid: $pK_A = 4.98 \pm 0.05$; $K_A = 1.05 \times 10^{-5}$ (20 °C)
Desoxycholic acid: $pK_A = 5.17 \pm 0.04$; $K_A = 6.76 \times 10^{-6}$ (20 °C)

These dissociation constants are definitely higher than those reported by Josephson [4]. The value for cholic acid agrees very well with that calculated by Kumler and Halverstadt [5], but our value for desoxycholic acid is lower than their value.

Kumler and Halverstadt [5] remarked that the dissociation constants of the unconjugated bile acids should be of the same order as the constants of the higher aliphatic carboxylic acids, *i. e.* $1.0—1.4 \times 10^{-5}$, since the bile acids can be considered derivatives of valeric acid with a sterol group in the γ position. They presumed that the introduction of an unsubstituted sterol nucleus should lead to a decrease in the acid strength; hydroxyl and ketonic groups substituted on the sterol nucleus should strengthen the acid properties, but owing to the distance separating them from the carboxyl group, their effect can only be very slight. Kumler and Halverstadt thus came to the conclusion that the dissociation constants of cholic and desoxycholic acids should be almost equal, since the only structural difference between them is the presence of a hydroxyl group in position 7 in cholic acid which is separated from the carboxyl group by seven carbon atoms and that both acids should be approximately equal in strength to caproic acid ($K_A = 1.32 \times 10^{-5}$). Their own measurements of the dissociation constants in ethanol-water solutions and also the calculated values for water solutions seemed to verify these assumptions. Josephson's value for

the dissociation constant of cholic acid was, however, seventeen times as great as the value obtained for desoxycholic acid, and both acids, especially the latter, seemed to be much weaker than caproic acid. Our results verify the assumption of Kumler and Halverstadt that the dissociation constants of both acids are of the same magnitude as but slightly lower than that of caproic acid. The presence of one hydroxyl group more in cholic acid than in desoxycholic acid molecule seems, however, to influence the acid strength in water more than Kumler and Halverstadt presumed.

The reason for the very low value of desoxycholic acid obtained by Josephson is evident from our study. When the calculation of the value of the dissociation constant is based on pH measurements in 0.01—0.015 M solutions and the presence of micelles in these solutions is not taken into account, the values obtained are approximately $16—8 \times 10^{-7}$. Josephson's calculations were based on measurements of solutions whose concentrations were 0.01 M. Furthermore, many of the measurements were carried out on solutions supersaturated with bile acid.

From the data we have presented, also the concentrations at which the properties of the solutions begin to deviate from those typical of solutions of uni-univalent electrolytes become clearly evident. These deviations are indicated by the increased values of the dissociation constant when the concentration exceeds 0.013—0.015 M for sodium cholate and 0.0045—0.0055 M for sodium desoxycholate. At these concentrations, micelle formation by bile acid anions evidently begins, which is in accordance with the results of other measurements carried out in this laboratory [9-13].

If it is assumed that the equilibrium is correctly represented by eqn. 1 in all concentration ranges and that the values of K_A are those given above, it is obviously possible to determine from the experimental data the ratio of the activities of the bile acid and its anion at different concentrations and at different stages of the titrations. We shall only draw attention to the variation of this activity ratio with the concentration of the bile acid salt. The pH values at the equivalence points have been employed to determine this relationship. It is seen from Fig. 5 that the activity ratio remains constant in cholate solutions above 0.05 M and nearly constant in desoxycholate solutions above 0.010 M. This provides an explanation for the observation that the apparent dissociation constants calculated from the experimental data for the more concentrated bile acid salt solutions remain practically constant at values higher than the correct value. In solutions above 0.015 M in cholate and above 0.005 M in desoxycholate the bile acid anions associate to micelles in increasing proportion [9, 11-13], as a result of which the activities of the free anions are lowered. On the other hand, solubility measurements conducted in this laboratory have shown that a part of the bile acid molecules are solubilized by the micelles [11, 14] and as a consequence the activity of the bile acid molecules is lower than would otherwise be the case. Micelle formation and solubilization thus tend to maintain the ratio of the activities of bile acid molecules and bile acid anions nearly constant at higher concentrations.

Our study shows that sodium cholate behaves as a normal uni-univalent electrolyte only up to a concentration of about 0.014 M and that micelle formation obviously is fully developed when the concentration exceeds 0.05 M. In

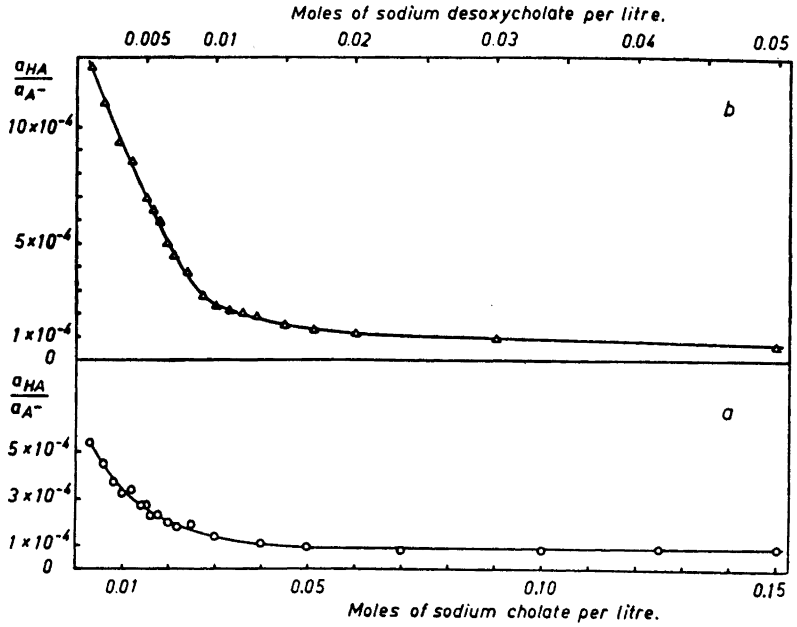

Fig. 5. The ratio of the activities of bile acid and its anions in sodium cholate and desoxycholate solutions.
a) Sodium cholate solutions.
b) Sodium desoxycholate solutions.

the concentration range between these two limits, evidently only a part of the cholate anions have undergone micelle formation. — Sodium desoxycholate behaves normally up to a concentration of about 0.0045 M and micelle formation is obviously fully developed in solutions above 0.01 M; between these two limits there is a transition region.

Mercury(II) Halide Mixed Complexes in Solution

II. Complexity Constants of the Binary Complexes

Y. MARCUS*

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Complexity constants for mercury(II) halide complexes were determined by solvent (benzene) distribution for 0.50 M $NaClO_4$ ionic medium and 25°. The constants found are:

Reaction	Constant	Chloride	Bromide	Iodide
$Hg^{2+} + HgX_2 \rightleftharpoons 2HgX^+$	log K	0.26 ± 0.03	0.94 ± 0.06	1.91 ± 0.07
$HgX^+ + X^- \rightleftharpoons HgX_2$	log k_2	6.3 ± 0.2	8.3 ± 0.3	
$HgX_2 + X^- \rightleftharpoons HgX_3^-$	log k_3	0.95 ± 0.03	2.27 ± 0.02	3.67 ± 0.02
$HgX_2 + 2X^- \rightleftharpoons HgX_4^{2-}$	log k_3k_4	2.00 ± 0.05	4.02 ± 0.02	6.04 ± 0.02

These values agree with published potentiometric values, except for bromide, but the solvent distribution value of log K agrees with a redetermined potentiometric value of log $K = 0.94 \pm 0.03$. The constants found here will be taken to apply in the solvent distribution work on the mixed complexes.

In order to study the relative stability of the mixed mercury(II) halide complexes, the complexity constants of the binary complexes were measured, using the same ionic medium and temperature, and the same method (solvent distribution), as later on for the ternary systems. The binary constants have previously [2] been determined by potentiometric methods for these same conditions, namely 25° and 0.50 M (perchlorate + halide) ionic medium. As a check on the assumption that benzene has no effect on the aqueous equilibria, some potentiometric measurements were made on comparable solutions with and without benzene.

Symbols. The symbols used here are defined in part I[1] p. 330.

EXPERIMENTAL

The experimental details of the solvent distribution experiments are described in part I[1] p. 331. The potentiometric measurements followed the procedure of Sillén and Infeldt [3].

* Permanent address: Israel Atomic Energy Commission, Hakiryah, Tel-Aviv, Israel.

The titrations consisted of adding (Hg^{2+} + Br^-) titrant to 100.0 ml (Hg^{2+} + Hg_2^{2+}) solution in the titration vessel. The 0.2 M bromide stock solution was tested for iodide, but no coloration by iodine could be detected by the nitrite-starch test, whereas adding I^- to a ratio $(I^-)/(Br^-) = 5 \times 10^{-5}$ gave an observable coloration. The titrations were performed in a thermostated bath at 25.0 ± 0.1° and N_2, free from O_2, was bubbled through the solution during the titration. The reference electrode was Ag, AgCl/10 mM Ag^+, 10 mM H^+ 480 mM Na^+ 500 mM ClO_4^-// and two Pt electrodes, compared against it, usually agreed to within 0.05 mV. Steady potentials were obtained 5 min after the addition of titrant, and the potentials usually deviated no more than 0.03 mV from values obtained 25 min later.

DETERMINATION OF K, THE EQUILIBRIUM CONSTANT FOR $Hg^{2+} + HgX_2 \rightleftharpoons 2\ HgX^+$

Derivation of equations, solvent distribution

In solutions of mercury and halide, where the stoichiometric ratio X/M is 2.00 or less, the only species occurring will be M^{++}, MX^+ and MX_2, provided the solutions are not so dilute that X^- also appears (see below, p. 603). The pertinent equilibrium reaction will then be

$$M^{++} + MX_2 \rightleftharpoons 2\ MX^+;\ K \tag{1}$$

The mass balances of mercury and halide will be

$$M = [M] + [MX] + [MX_2] + [MX_2]_{or} \text{ and} \tag{2}$$

$$X = M\bar{n} = [MX] + 2[MX_2] + 2\ [MX_2]_{or} \tag{3}$$

The equilibrium constant of (1) will give

$$[MX]^2 = K\ [M]\ [MX_2] \tag{4}$$

When such an aqueous solution is equilibrated with benzene,

$$[MX_2]_{or} = \lambda\ [MX_2] \tag{5}$$

and the distribution ratio of mercury will be

$$D = [MX_2]_{or}\ ([M] + [MX] + [MX_2])^{-1} \tag{6}$$

Eliminating all concentrations from (2), (3), (4), (5) and (6), the following expression for K is obtained:

$$K = \frac{[\bar{n}(1 + D)\ \lambda - 2D\ (1 + \lambda)]^2}{D[(1-\bar{n})\ (1 + D)\lambda + D(1 + \lambda)]} \tag{7}$$

For the special case $\bar{n} = 1.00$ this reduces to:

$$K_{\bar{n}=1.00} = [\lambda - D(2 + \lambda)]^2\ D^{-2}\ (1 + \lambda)^{-1} \tag{7a}$$

Although eqn. (7) is valid for all values of $\bar{n}$ less than 2.00, the best accuracy is obtained with $\bar{n}$ around unity.

Experimental results, solvent distribution

Table 1 gives the results for the three halides, as log D ($\bar{n}$). The M values are also given, although they do not enter the calculations. The values of log

K were obtained by solving numerically (7) — or (7a) in the case of bromide — and are averaged at the end of each section. The values of λ, obtained from part I[1], are given at the top of each section.

Potentiometry

The value of K for bromide from the solvent distribution experiments differs sufficiently from the earlier potentiometric value to warrant being checked. The method of Sillén and Infeldt [3] used in the earlier potentiometric work was followed. These authors showed that if v ml titrant (X M Br^- + M M Hg^{2+}) is added to 100.0 ml solution (M M Hg^{2+} + some Hg_2^{2+}), the potential of a Pt electrode against a suitable reference electrode at 25° will be

$$E_v = E_0 - 29.58 \log (1 + v/100) + 59.16 \log mM^{-1} \quad (8)$$

where E_0 is the potential before the addition of any titrant. The ligand number will be

$$\bar{n} = Xv\ (100 + v)^{-1}\ M^{-1} \quad (9)$$

and combined with mM^{-1} obtained from (8) this gives

$$K = (2 - 2mM^{-1} - \bar{n})^2\ (mM^{-1})^{-1}\ (mM^{-1} + \bar{n} - 1)^{-1} \quad (10)$$

Table 2 gives the values of K (numerical averages from the values at individual points) obtained for several experiments with solutions at different con-

centrations, with benzene present in some of them. (The solutions were saturated with benzene by passing the N_2 through benzene before bubbling it through the solution in the titration vessel for a sufficient time.)

From Tables 1 and 2 the new potentiometric value of K is seen to agree very well with the solvent distribution value. Also, the presence of benzene

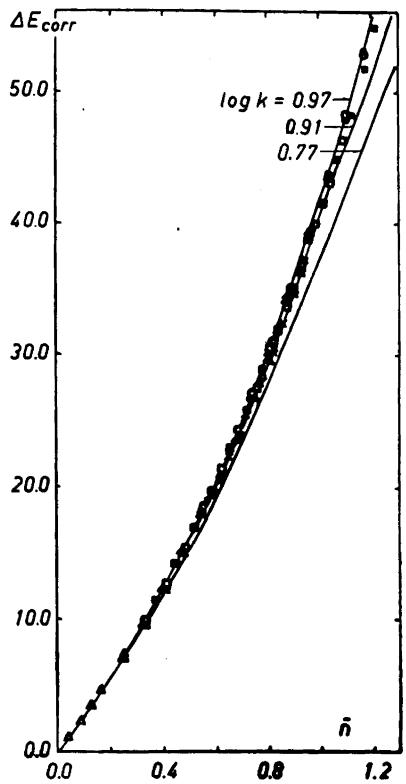

Fig. 1. The dilution corrected potential difference $E_v - E_0 + 29.58 \log (1 + v/100)$ as function of the ligand number $\bar{n}$, for the reaction $Hg^{2+} + HgBr_2 \rightleftharpoons 2\ HgBr^+$. The symbols refer to Table 2. The curves were calculated with the indicated constants.

does not seem to affect the equilibrium in the aqueous phase. The results of the experiments are also shown in Fig. 1, where the data $E_v—E_0 + 29.58 \log (1 + v/100)$ as function of $\bar{n}$ are compared with curves calculated with various constants K. The best fit is evidently with $\log K = 0.94 + 0.03$, while the former potentiometric value of Sillén and Infeldt [3] $\log K = 0.77$ does not fit the present data *.

DETERMINATION OF k_2, THE EQUILIBRIUM CONSTANT OF $HgX^+ + X^- \rightleftharpoons HgX_2$

Derivation of equations

If a solution of MX_2 is sufficiently diluted, the dissociation $MX_2 \rightleftharpoons MX^+ + X^-$ will become appreciable, and the D values will deviate from λ. The concentration should, however, not be so low that the further dissociation of $HgX^+ \rightleftharpoons Hg^{++} + X^-$ becomes noticeable. If, then, the mass balance is $M = [MX] + [MX_2] + [MX_2]_{or}$, the charge balance is $x = [MX]$ and the ratio $\bar{n} = 2.00$, eqn. (11) may be derived:

$$k_2 = D\ \lambda\ (1 + D)\ (\lambda—D)^{-2}\ M^{-1} \qquad (11)$$

The value obtained for k_2, combined with that of K found above, yield the value of k_1.

It may be mentioned in passing that the disproportionation $2\,HgX_2 \rightleftharpoons HgX^+ + HgX_3^-$, equilibrium constant k_3/k_2, was neglected in this work. Strictly speaking the distribution expression in HgX_2 solutions should be $\lambda = \lambda'(1+2\sqrt{k_3/k_2})^{-1}$, where λ' is the true distribution coefficient of the species MX_2. Inserting the values of k_3/k_2 one finds $\log \lambda \approx \log \lambda' + 0.0008$, so that the difference between λ and λ' is much smaller than the experimental error.

Experimental results

As is seen from equation (11), the constant k_2 is inversely proportional to M, and as k_2 is of the order of 10^6 for chloride, and larger still for the other halides, this means that very low M values are necessary. If, moreover, the value of $(\lambda—D)$ should be larger than 10 % λ, in order that the values do not become too uncertain, the upper limits for $\log M$ are: chloride —4.5, bromide —5.8, and iodide —7.2. The specific activity of the mercury available was, however, too low to permit a sufficient dilution of the solutions, so that no value of k_2 for iodide, and only rough estimates for chloride and bromide could be obtained. Results are shown in Table 3. The constants were calculated only from the experiments indicated, since for the others the results were too uncertain.

* It is very remarkable that such a large difference has been found between the potentiometric values of K determined in 1943 and now. Gunnar Infeldt was a very careful worker and a good analyst, and in general his values have been well confirmed, when they have later on been checked by others. One possible explanation is that there was some impurity in the bromide used by Infeldt, although it is hard to see what this could have been. Since Gunnar Infeldt has passed away in the meantime, and no samples of the old solutions are left, it is impossible to make sure.
Lars Gunnar Sillén

Table 3. The constants k_2, k_1 and β_2 for chloride and bromide.

	log M	log D	log k_1	log k_2	log β_2

	−6.06 ± 0.08	−0.17 ± 0.12			

DETERMINATION OF k_3 AND k_3k_4, THE EQUILIBRIUM CONSTANTS OF $HgX_2 + X^- \rightleftharpoons HgX_3^-$ AND $HgX_2 + 2X^- \rightleftharpoons HgX_4^{2-}$

When there is an excess of free halide, *i. e.* when $\bar{n} > 2.00$, the complexes HgX_3^- and $HgX_4^{=}$ are gradually formed, whereas species with $\bar{n} < 2$ may be completely neglected. The solvent distribution will then follow the expression:

$$D = [MX_2]_{or}\,([MX_2] + [MX_3] + [MX_4])^{-1} = \lambda\,(1 + k_3x + k_3k_4x^2)^{-1} \quad (12)$$

The constants k_3 and k_3k_4 may be found by the following methods.

Curve fitting

For applying the curve fitting method [4], the normalized variables Y and Z are introduced:

$$Y = \log \lambda - \log D = \log (1 + v + pv^2) \qquad Z = \log v \qquad (13a)$$
$$v = k_3x \text{ and } p = k_4/k_3$$

or, alternatively:

$$Y' = \log \lambda - \log D = \log (1 + p'v' + v'^2) \qquad Z' = \log v' \qquad (13b)$$
$$v' = (k_3k_4)^{1/2}\,x \text{ and } p' = (k_3/k_4)^{1/2}.$$

The data in the form log D (log x) are plotted, and compared with families of curves $Y(Z)_p$ or $Y'(Z')_{p'}$, whence the values of:

$$\log D\ (Y = 0) = \log D\ (Y' = 0) = \log \lambda$$
$$\log x\ (Z = 0) = -\log k_3$$
$$\log p = \log k_4 - \log k_3$$
$$\log x\ (Z' = 0) = -1/2 \log k_3k_4$$
$$\log p' = 1/2 \log k_3/k_4$$

are obtained. In practice, the best values of log k_3 are obtained from the Y, Z, v, p family, while those of log k_3k_4 are best obtained from the Y', Z', v', p' family.

Linear plots

An alternative method is to transform eqn. (12) so that its plot will be a straight line from which k_3 and k_3k_4 are obtained as intercept and slope:

$$(\lambda\ D^{-1} - 1)\ x^{-1} = k_3 + k_3k_4x \qquad (14a)$$

or, alternatively:

$$(\lambda\ D^{-1} - 1)\ x^{-2} = k_3x^{-1} + k_3k_4. \qquad (14b)$$

In practice it is found that k_3 is best obtained as the slope when the left term of (14b) is plotted *vs* x^{-1}, and k_3k_4 is best obtained when the left term of (14a) is plotted *vs* x.

Experimental results

Experimental data log D(log x) were obtained in the following ranges of concentrations:

$-4.1 < \log [Cl^-] < -0.7$; $-4.0 < \log [Br^-] < -1.0$; $-5.3 < \log [I^-] < -2.1$

In every case $X > 100\ M$ (except for the lowest [I], where $X > 10\ M$), so that x may be safely put equal to X. Plots of the data are shown in Figs. 2, 3 and 4 for chloride, bromide and iodide. The data for bromide are also given in Table 4.

Table 4. The distribution of $HgBr_2$ as function of excess bromide concentration.

$-\log x$	$-\log M$	$\log D$	$-\log x$	$-\log M$	$\log D$
4.01 ± 0.03	5.0	0.150 ± 0.030	2.01	4.6	−0.400 ± 0.007

2.60	4.6	−0.020 ± 0.010	1.11	4.6	−1.740 ± 0.045
2.50	4.6	−0.060 ± 0.010	1.10	4.0	−1.830 ± 0.010
2.41	4.6	−0.120 ± 0.007	1.01	4.0	−1.930 ± 0.010
2.23	4.6	−0.230 ± 0.007			

Values of log x are ±0.005 when not otherwise indicated. Values of log M are ±0.05.

The curve fitting technique outlined above was applied to the data, as also was the alternative method of linear plots, first transforming the data to the forms of eqns. (14a) and (14b). The results are shown in Table 5. Curves calculated from the average constants of Table 5 appear as solid lines in Figs. 2, 3 and 4. The less accurately obtained constants (in parenthesis) were not included in the average.

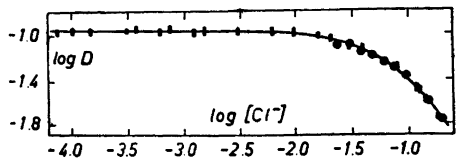

Fig. 2. Log D for $HgCl_2$-benzene-ionic medium as function of log x, excess chloride concentration. ● $M = 5.10^{-4}$ M, ■ $M = 2.10^{-5}$ M, ———— calculated with log $k_3 = 0.95$ and log $k_3k_4 = 2.00$.

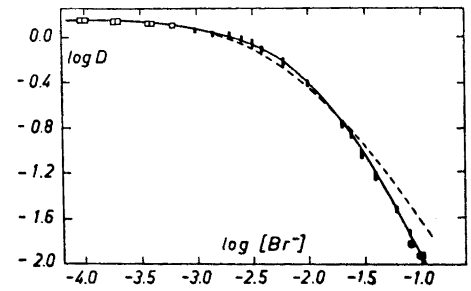

Fig. 3. Log D for $HgBr_2$-benzene-ionic medium as function of log x, excess bromide concentration. ● $M = 1.10^{-4}$ M, ■ $M = 2.5 \cdot 10^{-5}$ M, □ $M = 1.10^{-5}$ M, ———— calculated with log $k_3 = 2.27$ and log $k_3k_4 = 4.02$, - - - - - - - - calculated with log $k_3 = 2.41$ and log $k_3k_4 = 3.67$.

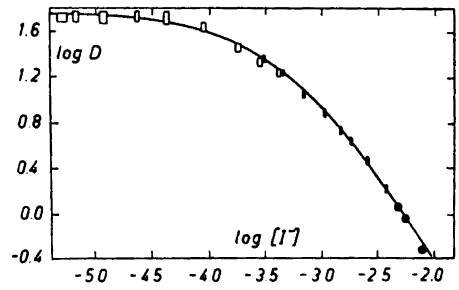

Fig. 4. Log D for HgI_2-benzene-ionic medium as function of log x, excess iodide concentration. ● $M = 8.10^{-5}$ M, ■ $M = 4.10^{-5}$ M, □ $M = 2.10^{-5}$ M, ———— calculated with log $k_3 = 3.67$ and log $k_3k_4 = 6.04$.

It may also be stated in passing that experiments with various M's showed no formation of polynuclear complexes, as all points were on the same curve (see Figs. 2, 3 and 4). This is not surprising at the low concentrations of mercury(II) employed.

PREVIOUS WORK

The constants obtained in this work are compared with those obtained in the careful and systematic potentiometric study of Sillén *et al.* (Ref.[2] summarizing their results) at the bottom of Tables 1 and 5. Agreement between the two sets of constants is quite good for the chloride and the iodide, within the stated limits of error, but much less so for the bromide. In the latter case, curves calculated with the earlier constants do not fit the present data (Figs. 1 and 3).

Table 5. The constants k_3 and k_3k_4 for the equilibria $HgX_2 + X^- \rightleftharpoons HgX_3^-$ and $HgX_2 + 2X^- \rightleftharpoons HgX_4^{2-}$ respectively.

The values of K were obtained by the solvent distribution and the potentiometric methods with about the same accuracy, and agreement for chloride and iodide is excellent, but although the solvent distribution value for bromide agrees well with the new potentiometric value, both are 0.17 ± 0.08 log units higher than the previous potentiometric value. The solvent distribution method gives much more accurate values of k_3 than the potentiometric method, and the values obtained here all lie within the (wide) limits of error given for the potentiometric constants. The values of k_3k_4 are of comparable accuracy, agreeing very well for iodide, fairly well for chloride but not at all for bromide.

One reason for the discrepancy may, perhaps, be the fact that the potentiometric value of k_3k_4 was obtained in a region of concentration (0.15—0.40 M) where the bromide is a very high fraction of the total ionic medium, so that the assumption of constant activity factors may no longer be valid. In the present study, concentrations ranged at most to 20 % exchange of bromide for perchlorate.

Moreover, it is felt that the potentiometric values of k_3 and k_3k_4 were obtained in rather a round-about way, by directly determining β_3 and β_4, while β_2 was obtained by a method depending on the experimentally difficult "maximum potential titration". The difference in β_2 which would bring k_3k_4 into agreement with the present value corresponds to a difference of about 9 mV in the potential. Of this, 3 mV is due to the different K values used.

The remaining 6 mV and the difference in K are difficult to explain; perhaps they are due to an impurity in the bromide solutions used previously (see foot-note p. 603).

The work done previously to 1946—1948, was fully discussed by Sillén *et al.* (Refs.[3] p. 61; [5] p. 52; [6] p. 482; 487; [7] p.505; [8] p. 828) and since then, few determinations of the pertinent equilibrium constants have been undertaken. The authors not mentioned in the above references usually did not use a constant ionic medium, so that their results are not comparable with the above. Tourneux's [9] values obtained from the solubility of KCl in $HgCl_2$ solutions extrapolate to log $k_3k_4 = 2.0$ at 25°, while Grinberg and Nikolskaya [10] quote a similar value. They also give log β_4 as 16.23 21.64 and 30.28 for $HgCl_4^=$ $HgBr_4^=$ and $HgI_4^=$. Peschanski [11] found for $HgCl_3^-$ log $k_3 = 0.52$ at 18° and ionic strength 0.5, while for $Hg^{2+} + HgCl_2 \rightleftharpoons 2\ HgCl^+$ she found log $K = 0.40$ at 17°, the first being lower, the second higher than the present values for 25°. The method she employed — continuous variation for UV light absorption — is, however, open to much criticism. Strocchi [12] states that species MX_3^- and $MX_4^=$ are formed, without giving formation constants, Yatsimirskii [13] gives log $k_1 = 12.36$ for HgI^+, while a year later Yatsimirskii and Shutov [14] revised this to log $k_1 = 13.15$. Finally, Golub [15] gives log $\beta_4 = 30.18$ for $HgI_4^=$ at "constant ionic strength", and Damm and Weiss [16] give for unspecified conditions log $k_1 = 6.80$, log $\beta_2 = 13.60$, log $k_3 = 0.57$ and log $k_3k_4 = 2.03$.

DISCUSSION

The constants k_3 and k_3k_4 together with the distribution coefficient are adequate for describing the behaviour of mercury halide complexes at $n \geq 2$, *i. e.* the region important to mixed-complex formation. The values of λ for the 0.5 M perchlorate ionic medium obtained here (Table 5) have already been compared with values obtained otherwise in part I[1]. To complete the picture, values of β_2 are also necessary. The values found here for k_2 give only the orders of magnitude of the constants (see p. 603):

Chloride, solvent distribution	log $\beta_1 \sim 6.6 \pm 0.2$	log $\beta_2 \sim 12.9 \pm 0.3$
potentiometry	$= 6.74 \pm 0.02$	$= 13.22 \pm 0.02$
Bromide, solvent distribution	$\sim 9.2 \pm 0.3$	$\sim 17.5 \pm 0.5$
potentiometry	$= 9.05 \pm 0.03$	$= 17.33 \pm 0.04$

Work on mixed bromide-iodide complexes, to be described in part IV, led to a value for log $\beta_2(HgI_2) - \log \beta_2(HgBr_2) = 6.94 \pm 0.03$. Accepting the potentiometric value of log $\beta_2(HgI_2) = 23.82 \pm 0.04$, this yields a value for log $\beta_2(HgBr_2) = 16.88 \pm 0.06$, in closer agreement with 16.98 ± 0.04, the value obtained from the directly determined log $\beta_4(HgBr_4^=) = 21.00 \pm 0.03$ [8] and the solvent distribution value log $k_3k_4 = 4.02 \pm 0.02$, than is 17.33, the potentiometric value of β_2. To have a consistent set of equilibrium constants, the values log β_2 13.22 ± 0.02 for $HgCl_2$ and 23.82 ± 0.04 for HgI_2 are borrowed from the potentiometric investigation, 16.88 ± 0.06 for $HgBr_2$ is obtained from part IV, and the values of K, k_3 and k_3k_4 are taken from the solvent distribution work described above. The resulting constants are tabulated in Table 6.

The author wishes to thank the *Israel Atomic Energy Commission* for a research grant abroad, Professor Lars Gunnar Sillén for the facilities provided, and particularly for his advice, comments and criticism, and Dr. Helen S. Dunsmore for improving the English presentation.

Mercury(II) Halide Mixed Complexes in Solution

III.[1] The Uncharged Mixed Complexes

Y. MARCUS*

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The equilibrium constant K of the reaction $HgA_2 + HgB_2 \rightleftharpoons 2HgAB$ was determined by studying the distribution of mercury between benzene and an aqueous solution. The distribution coefficient λ_{11} of HgAB was obtained from the extreme parts of the log distribution ratio *vs* log total B/total A curve, while K was obtained from the middle part of the curve. The values (log λ_{11}, log K) are: HgClBr (-0.42 ± 0.04, 2.0 ± 0.5), HgClI (0.28 ± 0.02, 1.75 ± 0.20), HgBrI (0.79 ± 0.04, 1.10 ± 0.20). The "stabilization constant", *i. e.* the ratio of the experimental to the statistical value ($= 4$), is larger than unity for these complexes, more so for the aqueous phase than for the organic phase.

A mixture of MA_2 and MB_2 will contain also MAB, according to the equilibrium reaction

$$MA_2 + MB_2 \rightleftharpoons 2MAB; \quad K = [MAB]^2\,[MA_2]^{-1}\,[MB_2]^{-1} \qquad (1)$$

Owing to the extraordinary stability of the uncharged mercury (II) halide complexes, all species other than MA_2, MAB and MB_2 may be neglected. The above reaction was studied by measuring the mercury distribution between benzene and an aqueous ionic medium, for the pairs A—B: Cl—Br, Cl—I and Br—I.

Symbols. The symbols used here were defined in part I [2].

Experimental. The experiments were in the main carried out as described in part I[2]. Benzene solutions of MA_2 and MB_2 were mixed and shaken at 25° with an equal volume of the aqueous ionic medium, 0.490 M $NaClO_4$ + 0.010 M $HClO_4$, in this way ensuring that $\bar{n}_{A,B} = 2.00$ for all the solutions. The mercury concentration was about 10^{-4} to 10^{-5} M, so that no dissociation $MX_2 \rightleftharpoons MX^+ + X^-$ had to be feared (see part II[1]). R, the ratio of the reactants A/B, was obtained from the volume ratio of the benzene solutions of MA_2 and MB_2, the relative concentration of which was determined by the ratio of their radioactivities. By choosing suitable volume and activity ratios it was possible to cover and measure accurately a range of 4 to 5 powers of ten in R.

* Permanent address: Israel Atomic Energy Commission, Hakiryah, Tel-Aviv, Israel.

DERIVATION OF EQUATIONS

Let a benzene solution of MA_2 be mixed with one of MB_2 and the mixture be shaken with an equal volume of the ionic medium. The general equations governing the distribution will be (in addition to (1) above):

$$MA_{2\,or} + MB_{2\,or} \rightleftharpoons 2MAB_{or}; \quad K_{or} = K\lambda_{11}^2\,\lambda_{20}^{-1}\,\lambda_{02}^{-1} \tag{1a}$$

$$[MA_2]_{or} = \lambda_{20}[MA_2]; \quad [MB_2]_{or} = \lambda_{02}\,[MB_2]; \quad [MAB]_{or} = \lambda_{11}\,[MAB] \tag{2}$$

The ratio R will be given by

$$R = \frac{2[MB_2]\,(1 + \lambda_{02}) + [MAB]\,(1 + \lambda_{11})}{2[MA_2]\,(1 + \lambda_{20}) + [MAB]\,(1 + \lambda_{11})} \tag{3}$$

and the distribution ratio D by

$$D = \frac{\lambda_{20}\,[MA_2] + \lambda_{11}\,[MAB] + \lambda_{02}\,[MB_2]}{[MA_2] + [MAB] + [MB_2]} \tag{4}$$

Determination of λ_{11}. Consider now the gradual addition of MB_2 to a large excess of MA_2. As a first approximation this will result in the gradual formation of MAB by reactions (1) and (1a), while the concentration $[MB_2]$ will remain negligible, provided that R remains small. If $[MA_2]$ and [MAB] are eliminated from (3) and (4) — and $[MB_2]$ neglected — the following expression is obtained

$$D = \frac{\lambda_{20}\,(1 + \lambda_{11})\,(1-R) + 2\lambda_{11}\,R\,(1 + \lambda_{20})}{(1 + \lambda_{11})\,(1-R) + 2\,R\,(1 + \lambda_{20})} \tag{5}$$

From this the linear expression for λ_{11}

$$2(1 + \lambda_{20})\,RD + (D-\lambda_{20})\,(1-R) = (2(1 + \lambda_{20})R - (D-\lambda_{20})\,(1-R))\lambda_{11} \tag{6}$$

is obtained, where λ_{11} is the slope when the left term is plotted *vs* the term in brackets on the right.

The ratio R must not be decreased too much, if λ_{11} is to be obtained accurately from (6), as otherwise there will be too large a spread in the points. On the other hand, as R is increased towards unity, the assumption $[MB_2] \approx 0$ is no longer valid if $K \neq \infty$, so that a plot of (6) will be curved, and λ_{11} will be the limiting slope at $R = 0$. Actually, as will be seen below, K is large and the plot of (6) is linear, within experimental errors, up to about $R = 0.40$.

The same arguments can be applied to the opposite case, *i. e.* when MA_2 is added to a large excess of MB_2, and R is very large. Then:

$$D = \frac{\lambda_{02}\,(1 + \lambda_{11})\,(R-1) + 2\lambda_{11}\,(1+\lambda_{02})}{(1+\lambda_{11})\,(R-1) + 2\,(1 + \lambda_{02})}\ \text{,and} \tag{7}$$

$$2(1 + \lambda_{02})\,D + (\lambda_{02}-D)\,(R-1) = (2(1 + \lambda_{02}) + (\lambda_{02}-D)\,(R-1))\lambda_{11}, \tag{8}$$

so that λ_{11} may be obtained also from plotting eqn. (8).

The distribution coefficient of MAB, λ_{11}, is thus obtained independently from the two ranges where R is small and where it is large.

Determination of K. It remains now to consider the intermediate region where $R \sim 1$ and it is no longer permissible to neglect any of the species MA_2, MAB and MB_2. If, then, the concentrations of these species are eliminated from (1), (3) and (4), and the equations solved for K, the following is obtained:

$$K = 4[(\lambda_{02}-D)(1+\lambda_{20})R-(D-\lambda_{02})(1+\lambda_{02})]^2[2(1+\lambda_{02})(D-\lambda_{11})+(1+\lambda_{11})(R-1)(D-\lambda_{02}]^{-1}[2(1+\lambda_{20})(D-\lambda_{11})R-(D-\lambda_{20})(1+\lambda_{11})(R-1)]^{-1} \quad (9)$$

which simplifies in the case of $R = 1.00$ to

$$K = \frac{((\lambda_{02}-D)(1+\lambda_{20})-(D-\lambda_{20})(1+\lambda_{02}))^2}{(1+\lambda_{20})(1+\lambda_{02})(D-\lambda_{11})^2} \quad (9a)$$

In this way K is obtained from the distribution at $R \sim 1$ combined with the value of λ_{11} obtained above. To test its validity, it is inserted into the general equations (3) and (4). Introducing the parameter $y = [MB_2]^{\frac{1}{2}}[MA_2]^{-\frac{1}{2}}$, the expressions:

$$R = \frac{2y^2(1+\lambda_{02}) + K^{\frac{1}{2}}y(1+\lambda_{11})}{2(1+\lambda_{20}) + K^{\frac{1}{2}}y(1+\lambda_{11})} \quad (10)$$

and

$$D = \frac{\lambda_{20} + \lambda_{11}K^{\frac{1}{2}}y + \lambda_{02}y^2}{1 + K^{\frac{1}{2}}y + y^2} \quad (11)$$

are obtained, and a plot of log D *vs* log R, calculated with y as auxiliary variable, may then be compared with experimental values.

Table 1. Distribution data for the Hg—Br—I neutral complexes.

0.20	−5.1	0.795 ± 0.015	2.70	−5.0	1.740 ± 0.015

All values of log R are ±0.01, all values of log M are ±0.1. Symbols in Fig. 3 are: log M −4.1 to −4.3 ●, log M −4.5 to −4.6 ■, and log M −4.8 to −5.1 ▲.

EXPERIMENTAL RESULTS

The distribution values obtained for the pair of ligands Br—I are given in Table 1, while for all three pairs Cl—Br, Cl—I and Br—I the data are given as log D (log R) curves in Figs. 1, 2 and 3.

In order to obtain λ_{11}, plots were made (Fig. 4) of eqns. (6) — squares — and (8) — circles — for the ranges of low R and high R, for the above three pairs of ligands, using the values of λ_{20} and λ_{02} found previously (part I[2]): log $\lambda(HgCl_2) = -0.963$, log $\lambda(HgBr_2) = 0.152$, log $\lambda(HgI_2) = 1.77$, in conjunc tion with the present data.

Fig. 4 shows that the plots are linear in the regions used, $R < 0.40$ and $R > 2.5$, and shows also very good agreement of the slopes in these regions with each other, so that the value of λ_{11} obtained expresses the data well.

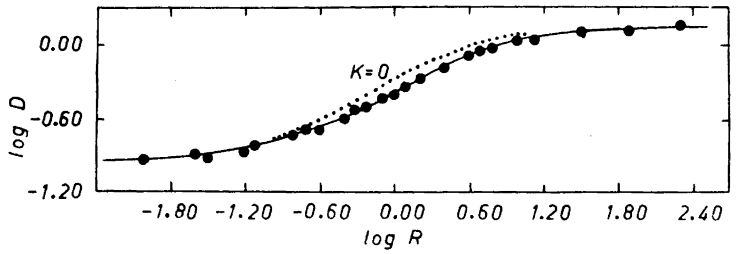

Fig. 1. The distribution ratio D of mercury between benzene and aqueous solutions in system Hg-Cl-Br, as function of the ratio R of $HgBr_{2\ tot}$ / $HgCl_{2\ tot}$ ● experimental points, ——— calculated with log $\lambda_{11} = -0.42$ and log $K = 2.0$, ... calculated with $K = 0$.

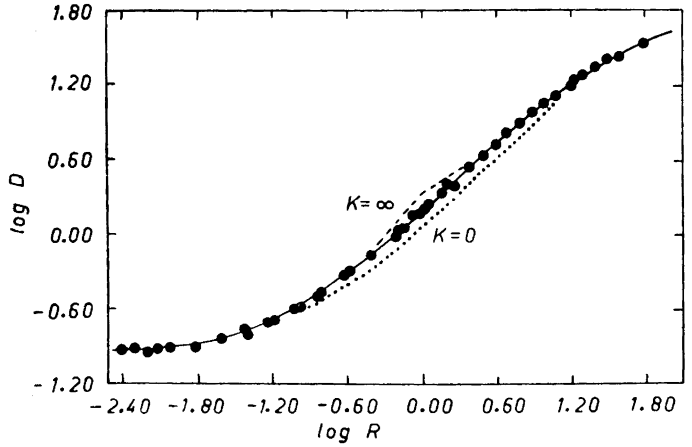

Fig. 2. The distribution ratio D of mercury between benzene and aqueous solutions in system Hg-Cl-I, as function of the ratio R of $HgI_{2\ tot}$ / $HgCl_{2\ tot}$ ● experimental points, ——— calculated with log $\lambda_{11} = 0.28$ and log $K = 1.75$, ... calculated with $K = 0$, — — — — calculated with $K = \infty$.

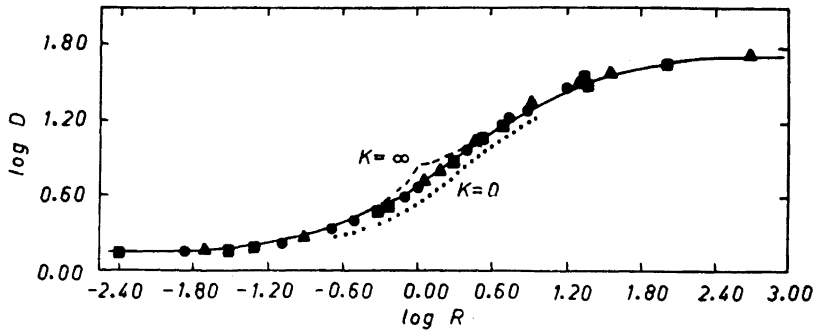

Fig. 3. The distribution ratio D of mercury between benzene and aqueous solutions in system Hg-Br-I, as function of ratio R of $HgI_{2\ tot}$ / $HgBr_{2\ tot}$. ●, ■, and ▲ experimental points explained in Table 1, ——— calculated with $\log \lambda_{11} = 0.79$ and $\log K = 1.10$, ... calculated with $K = 0$, — — — calculated with $K = \infty$.

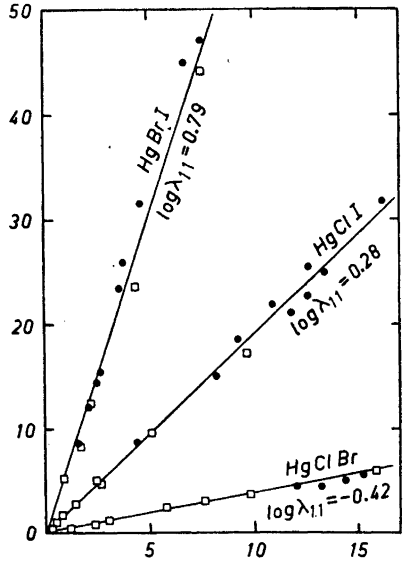

Fig. 4. Plots of eqns. (6) and (8) (□ and ●, respectively), where both sides of the equations were multiplied by the same arbitrary constant to bring them down to the same scale. The best straight lines drawn have slopes equal to the λ_{11} values given in the text.

Ordinate: □ $\text{const}_1(2(1+\lambda_{20})\ R\ D+(D-\lambda_{20})\ (1-R))$
● $\text{const}_2(2(1+\lambda_{02})D+(\lambda_{02}-D)(R-1))$

Abscissa: □ $\text{const}_1(2(1+\lambda_{20})R-(D-\lambda_{20})(1-R))$
● $\text{const}_2(2(1+\lambda_{02})+(\lambda_{02}-D)(R-1))$

The values of λ_{11} obtained are:

$\log \lambda(\mathrm{HgClBr}) = -0.42 \pm 0.04$ $\log \lambda(\mathrm{HgClI}) = 0.28 \pm 0.02$
$\log \lambda(\mathrm{HgBrI}) = 0.79 \pm 0.04$

For the range $-0.4 < \log R < 0.4$, the experimental values of R and D, together with the binary and ternary distribution coefficients listed above, were inserted into eqn. (9) to calculate K. The values obtained (numerical averages) are:

$\log K(\mathrm{HgClBr}) = 2.0 \pm 0.5$ $\log K(\mathrm{HgClI}) = 1.75 \pm 0.20$
$\log K(\mathrm{HgBrI}) = 1.10 \pm 0.20$

The values of λ_{11} and K were inserted into eqns. (5), (7) and (11) and the calculated distribution plotted in Figs. 1, 2 and 3 (dashed curves for (5) and (7) in the range $-0.4 < \log R < 0.4$, otherwise solid curves), agreeing well with the data.

Had no mixed complexes been formed, *i. e.* $K = 0$, the dotted curves in Figs. 1, 2 and 3 would have been obtained. These, however, do not agree with the experimental data, so that the formation of the ternary complexes in solution might be considered proved.

DISCUSSION

The equilibrium in the aqueous phase. The significance of the constants obtained above may be seen in Fig. 5. In it is plotted the mole percentage of the three species MA_2, MAB and MB_2 as function of $\log R$. The continuous curves were calculated with the experimental value $K = 56$ for Hg—Cl—I, but they express also approximately the cases of Hg—Cl—Br and Hg—Br—I, since the K values possess wide limits of error, and since the curves are not too sensitive to the exact value of K, provided it is "large". It is seen that MAB is an important species in the range of about $-1.2 < \log R < 1.2$. Moreover, it is seen that $[MB_2]$ is negligibly small up to $\log R = -0.4$ and that $[MA_2]$ is so above $\log R = 0.4$ as assumed in the calculations.

If K were equal to infinity, MAB would be completely stable at $R = 1$, and $[MA_2]$ and $[MB_2]$ would remain negligible respectively right up to and above $R = 1$. This is shown by the long-dashed curves in Fig. 5.

Had the mixed complex formation proceeded statistically, there would have been at equilibrium 25 mole % MA_2, 25 mole % MB_2 and 50 mole % MAB when $R = 1$. The equilibrium constant would then have been $(0.50)^2 (0.25)^{-1} (0.25)^{-1} = 4$. Fig. 5 shows this case by a pair of short-dashed curves. The area enclosed between them is smaller than that corresponding to the observed K, or in other words, the mixed complexes are more stable than statistically expected. The difference $\log K - \log K_{\mathrm{stat.}} = \log K - 0.60$ may be called the stabilization constant, $\log K_{\mathrm{stab.}}$:

$\log K_{\mathrm{stab.}}(\mathrm{HgClBr}) = 1.4 \pm 0.5$ $\log K_{\mathrm{stab.}}(\mathrm{HgClI}) = 1.15 \pm 0.20$
$\log K_{\mathrm{stab.}}(\mathrm{HgBrI}) = 0.5 \pm 0.2$

More will be said about this in part V of this series.

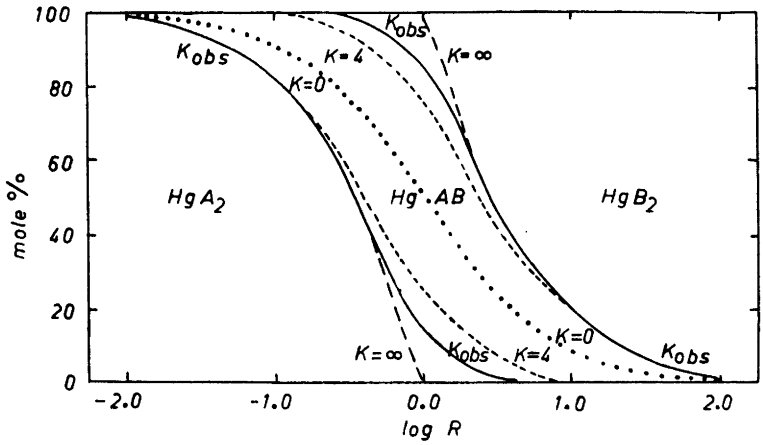

Fig. 5. The mole percentage of the species MA_2, MAB and MB_2 as function of the ratio R of $MB_{2\ tot}$ / $MA_{2\ tot}$. ——— calculated with observed value of K (for HgClI), — — — calculated with $K = \infty$, - - - - - - calculated with $K_{stat.} = 4$, ... calculated with $K = 0$.

Finally, had there been no mixed-complex formation, $K = 0$, then, of course, the area of MAB would have vanished, and the single dotted curve in Fig. 5 would have described the system MA_2—MB_2.

The equilibrium in the organic phase. Equilibrium and stabilization constants may also be calculated for the organic phase according to eqn. (1a):

HgClBr	$\log K_{or} = 2.0 \pm 0.5$	$\log K_{or\ stab.} = 1.4 \pm 0.5$
HgClI	$= 1.51 \pm 0.20$	$= 0.91 \pm 0.20$
HgBrI	$= 0.76 \pm 0.20$	$= 0.16 \pm 0.20$

The statistical value for the distribution coefficient of the ternary complexes is the geometrical mean of the coefficients of the binary complexes, and is compared below with the observed values:

HgClBr	$\log \lambda_{11}$ observed $= -0.42 \pm 0.04$	$\log \lambda_{11}$ statis. $= -0.40 \pm 0.02$
HgClI	$= 0.28 \pm 0.02$	$= 0.40 \pm 0.02$
HgBrI	$= 0.79 \pm 0.04$	$= 0.96 \pm 0.02$

It is seen that the distribution coefficient is significantly smaller, at least for HgClI and HgBrI, than the statistically calculated value. This means that the ternary complex is more favoured in the aqueous than in the benzene phase, as may also be seen by comparing the respective stabilization constants in the two phases.

Previous work. Previous reports of mercury(II) mixed halides are quite numerous. Although Pelt and Boes [3] could not find an indication for HgClBr formation from solubility measurements on mixtures of $HgCl_2$ and $HgBr_2$,

Losana [5] and later Scholter and Bijvoet [4] found a solid, so called B-phase, made up of linear HgClBr molecules. However, with solids, mixed compound formation might be confused with mixed crystal (solid solution) formation. Mixed $Hg(Cl_2, Br_2)$ crystals have thus been found formed from melts [6] or solutions [7]. Oppenheim [8] claimed almost 90 years ago that HgBrI precipitates (and may be sublimed unchanged) if an alkyl iodide is added to an acetone solution of $HgBr_2$. Köhler [9] ten years later gave a method to prepare what he stated to be HgClI. Vournazos [10] concluded that a mixed bromide-iodide compound of mercury, which he claimed contains the ion $Hg_2Br_4I^-$, is formed when water insoluble iodides dissolve in acetone solutions of $HgBr_2$.

All the above is evidence (though sometimes disputed) for the formation of solid ternary complexes, but there is also evidence for their formation in solution. Delwaulle and Francois, in a number of papers [11], reported that ethanolic, methanolic and aqueous solutions of mixtures of mercury(II) halides show Raman lines which could not be ascribed to either of the binary components, but must be due to a ternary compound. Moreover, they state [11d] that the intensity of the Raman lines is proportional to the concentration, so that in principle it should have been possible to calculate the equilibrium constants. Unfortunately, the authors generally neither calculated the constants, nor reported their primary data, so that their results are only qualitative.

The one exception to this is the constant $K = 2{,}0 \pm 0{,}2$ reported for the reaction $HgCl_2 + HgBr_2 = 2\ HgClBr$ in methanol [11c]. This constant is smaller than the statistical value, but the reliability of the constant seems to be less than its reported precision indicates, because of larger possible errors in the quantities entering its calculation.

Even in the vapour phase the ternary compounds seem to be rather stable. Although Hintz and Jellinek [12] found that the vapour phase above a $HgCl_2$—$HgBr_2$ mixture is an ideal mixture, Wehrli and Milazzo [13] found stable HgClBr and HgBrI vapours that dissociate only under UV radiation. Müller [14] measured the spectra of MAB vapours already at temperatures as low as 50° C. He prepared HgBrI according to Oppenheim's procedure [8] and HgClI and HgClBr according to Köhler's [9]. The special "mixed" bands he observed in the spectra were most intense for HgClI. He explained this effect by pointing out that HgClI has the most unsymmetrical weight distribution among the three ternary compounds.

Although the authors cited above indicate qualitatively the formation of mixed halide compounds HgAB, no values of the equilibrium constants for aqueous solutions seem to have been hitherto reported.

The author wishes to thank the *Israel Atomic Energy Commission* for a research grant abroad, Professor Lars Gunnar Sillén for the facilities provided, and particularly for his advice, comments and criticism, and Dr. Helen S. Dunsmore for improving the English presentation.

The Anion Exchange of Metal Complexes

The Silver — Thiosulphate System

Y. MARCUS

Israel Atomic Energy Commission Research Establishment and Royal Institute of Technology, Department for Inorganic Chemistry, Stockholm 70, Sweden

The silver thiosulphate system has been studied by an anion exchange method. Batch equilibrations and column elutions gave silver distribution data between Dowex-1-thiosulphate resin and solutions of $Na_2S_2O_3$ in the concentration range 0.01—4 M. The thiosulphate concentrations in the resin in excess over its capacity were measured, and the activity of thiosulphate ion in the resin calculated. This together with the distribution data yielded the "ideal" distribution curve, whence it appears that if the resin species is $RAgS_2O_3$, then $Ag(S_2O_3)_3^{5-}$ will predominate in the solution. For the reaction $Ag(S_2O_3)_2^{3-} + S_2O_3^{2-} \rightleftharpoons Ag(S_2O_3)_3^{5-}$ the concentration quotient at 1—2 M ionic strength is $k' = 2.5 \pm 0.5$, while for $Ag(S_2O_3)_3^{5-} + 1/2\ R_2S_2O_3 \rightleftharpoons RAgS_2O_3 + 5/2\ S_2O_3^{2-}$ the constant is $K'' = 5$.

The complex systems previously studied in this laboratory were of the type in which a neutral complex could form. The anion exchange method developed for studying complex systems may, however, also be applied to systems in which neutral complexes are unable to form. This has already been demonstrated by the calcium citrate system [1], for which, however, the data are rather scant. It was thought, therefore, that it would be of interest to work out a similar system in detail.

The silver thiosulphate system was chosen, as it has already been studied by a number of authors [2-4], and complexity constants are available for comparison. The system has been shown to be mononuclear, so that in the sequence of species: Ag^+, $Ag(S_2O_3)^-$, $Ag(S_2O_3)_2^{3-}$ ... no neutral species appears.

Apart from the general interest in the silver-thiosulphate system (for photography), there is also a specific interest in its anion-exchange behaviour, in connection with the separation of silver from other metals or its recovery from spent photographic solutions. Lure and Perenyslova [5] have applied the resin *m*-phenylenediamine sulphate to silver-thiosulphate solutions. The silver was absorbed (as $Ag(S_2O_3)_2^{3-}$ according to the authors), but was rapidly reduced to Ag_2S, the resin functioning as catalyst.

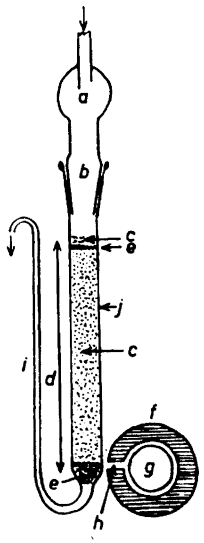

Fig. 1. The column for elution experiments. a: dropping rate counter; b: standard taper 14/35 ground joint; c: Dowex-1-X10 thiosulphate resin; d: distance between top and bottom of column $d = 8.0 \pm 0.2$ cm; e: glass wool plugs; f: lead shield; g: G.-M. cylindrical counter; h: 3 mm diameter hole in shield; i: 1 mm diameter capillary tube; j: 4.8 mm inner diameter glass column.

In order to apply the anion exchange distribution data quantitatively to complexity calculations, it is necessary, as has been pointed out before, to know the activity of the ligand in the resin. This could not be found in the literature, and had to be determined in addition to the silver distribution.

EXPERIMENTAL

Materials. A known weight of > 99.9 % pure silver wire, irradiated by A. E. R. E. Harwell, England, to produce ^{110}Ag (half life = 9 months), was dissolved in moderately concentrated nitric acid. The solution was then neutralized with ammonia and diluted with water to 1.00×10^{-4} M in silver and about 0.01 M in nitrate.

Sodium thiosulphate pentahydrate was dissolved in water to saturation (about 4 M), and from this stock solution others were prepared by dilution. No mould growth was observed in the concentrated solution during more than a month.

Dowex-1 resin, 10 % cross-linked and 100—200 mesh, was converted from the chloride to the thiosulphate state by passing a tenfold excess of 2 M sodium thiosulphate through a column of the resin. Finally, after destruction of the thiosulphate in the effluent by adding 1 M sulphuric acid, heating to coagulate the sulphur and centrifuging it off, no more chloride could be detected. The resin was then thoroughly washed with water, and a portion shaken with 1 M ammonium nitrate showed no remaining chloride.

Pyrex glass was ground to a powder of 100—200 mesh, washed with dilute nitric acid and water and dried.

All other reagents were of analytical grade.

Procedure. The column for the elution studies consisted of a narrow glass tube (Fig. 1), of inner diameter 0.48 cm (cross section $A = 0.180 \pm 0.003$ cm^2). It contained a weight $w = 0.725 \pm 0.002$ g of air dried resin to a height $d = 8.0 \pm 0.2$ cm above a glass wool plug. A G.-M. counter surrounded by a thick lead shield was mounted with a window in the shield opposite the bottom of the resin column. On top of the resin was another, narrow, glass wool plug, on top of which was placed a small portion of resin (50.0 ± 1.0 mg), previously saturated with radioactive silver (absorbed from 0.05 M sodium thiosulphate). Thiosulphate solutions were passed through the column to elute the silver.

The active zone passed the distance d cm from the top of the column to the counter at the bottom at a known volume of eluant, V ml, obtained from the maximum in a plot of counting rate *vs.* volume. Similar arrangements are described by Forsling [6] and Kraus and Moore [7].

Batch experiments were made by shaking resin with solution for 16—20 h, which was shown to be two to three times in excess of that needed for equilibration. The dipping G.-M. tube used for radioassay counted only the gamma rays owing to its rather thick walls.

For measuring the excess thiosulphate in the resin, portions of resin or glass were shaken for 2 h with aliquots of thiosulphate solutions. The solid was then quantitatively filtered off, and thiosulphate was determined in the filtrate by titration with iodine solutions standardized against pure solid arsenic(III) oxide. The powder on the filter was washed thoroughly with water, then shaken for 2 h with a hundred times excess, on an equivalent basis, of 5 % sodium chloride. The selectivity coefficient value of Wheaton and Bauman [21] for the sulphate-chloride exchange was taken as indicative of that of the thiosulphate-chloride exchange. On this basis it was calculated that at equilibrium with the 5 % sodium chloride (0.85 M), no more than 0.2 % of the thiosulphate will remain on the resin. The sodium chloride solution was filtered away and the powder was again washed. In the combined filtrate and washing, thiosulphate was determined. In this way both the solution and the resin thiosulphate concentration were known for equilibrium.

All experiments were repeated and agreed within ± 1.5 %. They were made at room temperature, about 25—30 °C.

RESULTS

No significant influence of silver concentration on the anion exchange distribution in the silver concentration range 2×10^{-6} to 2×10^{-4} M with a thiosulphate concentration of 0.64 M could be found. The value of the distribution obtained from eight measurements was $D = 180 \pm 15$. The formation of polynuclear complexes in the solutions is thus very unlikely.

Batch equilibrations, using 4×10^{-3} to 1.28 M thiosulphate solutions, with equilibrium concentration of silver less than 5×10^{-6} M and loading less than 1 % of the capacity, gave the distribution values D in Table 1.

Elution experiments using 0.10 to 4.24 M thiosulphate solutions gave the distribution values appearing in Table 2. They were calculated in the following way, based on the method of Kraus and Moore [7].

Table 1. Anion exchange distribution of silver as function of thiosulphate concentration; batch method.

Thiosulphate concentration M	$-\log a_{Na_2S_2O_3}$	log D (ml/g)	Thiosulphate concentration M	$-\log a_{Na_2S_2O_3}$	log D (ml/g)

An elution constant E is defined by eqn. (1)

$$E = d \cdot A \cdot V^{-1} \tag{1}$$

where d, A and V are the quantities defined above. E is related to the volume distribution coefficient D_v by eqn. (2)

$$E = (D_v + i)^{-1} \tag{2}$$

where i is the fractional interstitial volume, having the value 0.45 (this, however, need not be known accurately for large enough distributions). The mass distribution coefficient D is related to D_v by the specific volume of the resin $d \cdot A \cdot w^{-1}$ where w is the weight of the resin in g in the d cm long column:

$$D = d \cdot A \cdot w^{-1} \cdot D_v = w^{-1} \cdot V - (i \cdot d \cdot A \cdot w^{-1}) \tag{3}$$

Inserting the particular values for the column amployed, D is obtained in terms of V directly as

$$D = 1.38\ V - 0.9 \text{ ml/g} \tag{4}$$

Table 2. Anion exchange distribution of silver as function of thiosulphate concentration; column method.

Thiosulphate concentration M	$-\log a_{Na_2S_2O_3}$	log D (ml/g)	Thiosulphate concentration M	$-\log a_{Na_2S_2O_3}$	log D (ml/g)
0.10	1.37	3.45 ± 0.05	0.96	0.62	1.81 ± 0.05
0.20	1.14	2.99 ± 0.07	1.49	0.47	1.43 ± 0.06
0.30	1.00	2.79 ± 0.05	2.00	0.36	0.94 ± 0.20

0.72	0.72	2.08 ± 0.05	4.24	−0.05	0.16 ± 0.10
0.96	0.62	1.88 ± 0.05			

Values of the activity coefficients of thiosulphate solutions were taken from Stokes [8] and converted from the molal to the molar scale.

A log D(log $a_{Na_2S_2O_3}$) plot is shown in Fig. 2 for values of both Tables 1 and 2.

The thiosulphate capacity of the resin was determined to be 1.255 ± 0.003 mmole/g. The chloride displaced from the resin amounted to 2.55 mequiv/g, which means that the thiosulphate occupies 2.55/1.255 = 2.0 sites on the resin, as would be expected from its charge.

The water content of air-dried resin was determined in a "drying pistol" at 78° C, and was found to be 29.5 ± 0.3 % W/W.

The concentration of thiosulphate in a resin in equilibrium with a thiosulphate solution is made up of three parts: the fixed capacity, the invading electrolyte, and the surface-sorbed material, *i. e.* the part contained in a mechanically-held film on the surface, of the same concentration as the bulk of the solution, and assumed to be equal to the amount sorbed on a similar glass powder surface. Table 3 gives the thiosulphate concentrations in these three categories as functions of solution concentration in the range 0.01 to 2 M.

In cases where the excess electrolyte is small, and at low thiosulphate concentrations, the combined amounts "excess electrolyte" + "glass" were obtained directly from the difference between initial and final thiosulphate concentration in the solution. At high thiosulphate concentrations, when this becomes inexact, the thiosulphate displaced from the resin by 5 % sodium chloride, *i. e.* the "total resin" concentration was the directly measured quantity.

Table 3. Thiosulphate concentration on resin and glass as function of solution concentration.

Solution M	Total resin mmole/g	Glass mmole/g	Net resin mmole/g	Excess electrolyte mmole/g
0.010	1.265	0.005	1.260 ± 0.005	0.005 ± 0.005

1.00	1.67 ± 0.01	0.047	1.62 ± 0.01	0.37 ± 0.01
2.02	2.48 ± 0.01	0.098	2.38 ± 0.01	1.13 ± 0.01

CALCULATIONS

The resin thiosulphate activity was calculated by the method used by Kraus and Moore [9] and by Gottlieb and Gregor [10]. At equilibrium the activities of sodium thiosulphate are equal in both phases:

$$(Na)^2(S_2O_3) = 4[S_2O_3]^3 f_{\pm}^3 = (Na)_r^2(S_2O_3)_r = [Na]_r^2[S_2O_3]_r f_{\pm r}^3 \qquad (5)$$

where parentheses denote activities, square brackets — concentrations, suffix r — resin phase, no suffix — solution phase and $f_{\pm}$ the average activity coefficients.

In order to compare the two phases, resin concentrations were converted to mole/liter by the factor 3.40 kg/l, obtained from the water content of the air-dried resin. This factor was assumed to be independent of the thiosulphate concentrations because no expansion or contraction of the resin could be observed when the concentration of the eluant was changed in the column experiments.

The term $[Na]_r$ is equal to twice the "excess electrolyte" in Table 3, as this is the only sodium ion source in the resin. The term $[S_2O_3]_r$ is equal to "net resin" in Table 3. Rearranging eqn. (5), the ligand activity in the resin is obtained

$$\log (S_2O_3)_r = \log [S_2O_3]_r f_{\pm r} = 2/3 \log \text{"net resin"} + \log [S_2O_3] + \quad (6)$$
$$+ \log f_{\pm} - 2/3 \log \text{"excess electrolyte"} - \log 3.40$$

Eqn. (6) introduces the activity of a single ion — $S_2O_3^{2-}$ — which necessitates an extrathermodynamic assumption. As the resin phase is a concentrated aqueous solution, at least 2.5 equiv. per 295 g water, *i. e.* 8.5 N, it is felt that this is a region where the Debye-Hückel term of the activity coefficient plays a minor role compared with the hydration term. Thus $f^r_{S_2O_3^{2-}}$ was assumed equal to $f_{\pm r}$. As regards the aqueous solutions, although their concentration range was mainly much lower than that of the resin, the same assumption was made, as the alternate extreme assumption: $\log f_{S_2O_3^{2-}} = 4 \log f_{Na^+}$ led to a curve concave upwards, *i. e.* representing a decreasing formation function $\bar{n}$ with increasing concentration, and this is untenable.

Values of the ligand activity calculated from eqn. (6) are given in Table 4.

Table 4. Resin ligand activity as function of solution activity.

$[Na_2S_2O_3]$ M	0.010	0.020	0.050	0.100	0.300	0.706	1.00	2.02
$-\log (S_2O_3)$	2.14	1.97	1.60	1.35	1.00	0.72	0.62	0.36
$-\log (S_2O_3)_r$	1.2	1.1	1.02	0.94	0.81	0.75	0.73	0.67

An arbitrary standard state will be defined as that corresponding to unit solution activity, and from extrapolation of the values of Table 4 — which, incidentally gives a linear plot — the value $\log (S_2O_3)^0_r = -0.56$ was obtained from eqn. (7)

$$\log (S_2O_3)_r = \log (S_2O_3)^0_r + F(\log (S_2O_3)) \quad (7)$$

The main reaction of absorption of silver by the resin may be formulated as

$$Ag(S_2O_3)_p^{1-2p} + (p - 1/2)R_2S_2O_3 \rightleftharpoons R_{2p-1}Ag(S_2O_3)_p + (p - 1/2)S_2O_3^{2-} \quad (8)$$

where p might be 1,2,... and R is one equivalent of resin cation. The range of variation of the resin ligand activity is not very large, so it may be assumed that only one value of p must be considered, and the total concentration of silver on the resin is $[Ag(S_2O_3)_p]_r$.

The equilibrium constant of reaction (8) will have the resin ligand activity to the $(p - 1/2)$ power. It has been shown before [1] that this means that the ideal distribution D_0 is obtained from the measured D from the relationship

$$\log D_0 = \log D - (p - 1/2) \cdot F(\log (S_2O_3)) \quad (9)$$

As in the thiosulphate range employed the function F has negative values ($\log (S_2O_3)^0_r$ greater than any value of $\log (S_2O_3)_r$), the actual "invasion" correction will give a curve $\log D_0$ ($\log (S_2O_3)_r$), above the $\log D$ curve, and with a steeper slope.

The values $p = 1$, 2 and 3 were tried and found to yield $\log D_0$ curves with limiting slopes of —2.5, —2.9 and —3.3, respectively. However, only the value of $p = 1$, giving a slope of —2.5, is consistent with the presence of $Ag(S_2O_3)^{3-}_2$ and $Ag(S_2O_3)^{5-}_3$ in the solutions under consideration, to which the evidence points [2-4,17,18,20]. That this is so may be seen from the expression for D_0 which may easily be derived (see also Ref.[1]).

$$D_0 = k_\alpha \beta_p (S_2O_3)^{0p-1/2}_r (S_2O_3)^{1/2} / (\beta_2 (S_2O_3)^2 + \beta_3 (S_2O_3)^3) =$$
$$= K \ (S_2O_3)^{-3/2} (1 + k_3 (S_2O_3))^{-1} \quad (10)$$

where $K = k_\alpha \beta_p \beta_2^{-1} (S_2O_3)^{0p-1/2}_r$, and k_α is the equilibrium constant of (8).

Combining eqns. (9) and (10), $\log D$ is obtained in terms of $\log (S_2O_3)$

$$\log D = (p - 1/2) \cdot F(\log (S_2O_3)) + \log K - 3/2 \log (S_2O_3) - \quad (11)$$
$$- \log (1 + k_3 (S_2O_3)$$

Using $p = 1$ and the values $\log K = 2.1 \pm 0.1$ and $\log k_3 = 1.7 \pm 0.2$, the calculated solid curve in Fig. 2 is obtained, and is considered as giving the best fit with the experimental data. However, owing to the relatively large random errors in the data, especially in the low concentration range, the curvature of the plot in this range, indicating the presence of $Ag(S_2O_3)^{3-}_2$ in the most dilute solutions, may not be real. The data could also be fitted by a curve $\log D = 1/2$ F($\log (S_2O_3)$) + $\log K$ — 5/2 $\log (S_2O_3)$ (and even by a straight line of slope —5/2, which neglects the invasion correction), but these curves would mean that no $Ag(S_2O_3)^{3-}_2$ is present in this concentration range. The fit of these latter two curves is poorer than the fit obtained when unity is not neglected in comparison with $k_3(S_2O_3)$ in this range (eqn. (11)). The value found for k_3 may be considered as the lower limit of the equilibrium constant.

DISCUSSION

The value of the complexity constant found, k_3, is not immediately comparable with reported values, as the latter are all concentration constants, while the former is valid for zero ionic strength. However, by replotting the D_0 distribution curve against the thiosulphate concentration, instead of against its activity, a concentration quotient $k'_3 = 2.5 \pm 0.5$ is obtained, which is consistent with the experimental data. The main effect of the transition of $Ag(S_2O_3)^{3-}_2$ to $Ag(S_2O_3)^{5-}_3$ occurs in the range 0.3 to 0.7 M thiosulphate, therefore this value of k'_3 should be valid around ionic strengths of one to two.

Bodländer's values [2] may be regarded only as approximate, but they are of the correct order of magnitude: $\beta_2 = 10^{13}$ and $\beta_3 = 3.5 \times 10^{13}$, *i. e.* $k_3' = 3.5$. Concentration quotients valid at 2 M ionic strength were obtained by Ölander and Adelson [3], using a potentiometric method, at 25° C. They obtained $\beta_2 = 6.0 \times 10^{12}$ and $\beta_3 = 1.15 \times 10^{13}$, *i. e.* $k_3' = 1.9$. Chateau and Pouradier [4] assume that the activity coefficient of $Ag(S_2O_3)_2^{3-}$ is equal to that of $S_2O_3^{2-}$ (obtaining $\beta_2 = 2.8 \times 10^{13}$), but that the coefficient of $Ag(S_2O_3)_3^{5-}$ is different, obtaining β_3 values in the range 1.5×10^{14} to 5.0×10^{14}, or, extrapolated to zero thiosulphate concentration, 1.4×10^{14}, *i. e.* $k_3 = 4.8$. They worked at 20° C, also employing a potentiometric method. No other determinations of k_3 are reported.

Determination of other constants in the silver-thiosulphate system were also made. Pawelka [11] found $\beta_2 = 2.4 \times 10^{13}$, while Ferrell and coworkers [12] obtained only an approximate estimate of 4×10^{14} for this constant. Carriere [13] found by a conductivity method $\beta_1 = 7.4 \times 10^8$, and Chateau and Pouradier [14], working at 70° C with a potentiometric method found it to be 2.75×10^7.

The assumption of the presence of both $Ag(S_2O_3)_2^{3-}$ and $Ag(S_2O_3)_3^{5-}$ in thiosulphate solutions of moderate concentrations is supported by much additional, though qualitative, evidence. Conductivity measurements of Ryabchikov and Silnichenko [15] and of Saxena and Jain [16] indicate the presence of $Ag(S_2O_3)^-$ and $Ag(S_2O_3)_2^{3-}$ in dilute solutions. Potentiometric determinations of Ashihara and Matsuda [17], Schmitz-Dumont and Schmitz [18], Brehmer [19] and Spacu and Murgulescu [20] indicate the presence of $Ag(S_2O_3)_2^{3-}$ and $Ag(S_2O_3)_3^{5-}$ in more concentrated solutions. It appears that, except when the silver concentration is high (when $Ag(S_2O_3)^-$ and possibly even polynuclear complexes form), $Ag(S_2O_3)_2^{3-}$ and $Ag(S_2O_3)_3^{5-}$ are the complex silver species present in thiosulphate solutions.

Using the constant K in eqn. (10), it is possible to state the main reaction with the resin not in terms of eqn. (8), which considers the exchange of the first anionic complex $Ag(S_2O_3)^-$, but in terms of the complexes actually present in the solutions. At low concentrations:

$$Ag(S_2O_3)_2^{3-} + 1/2\ R_2S_2O_3 = RAgS_2O_3 + 3/2\ S_2O_3^{2-} \qquad (12)$$

$$\log K' = \log K - 3/2\ \log (S_2O_3)_r^0 = 2.38 \pm 0.10$$

and at high concentrations:

$$Ag(S_2O_3)_3^{5-} + 1/2\ R_2S_2O_3 = RAgS_2O_3 + 5/2\ S_2O_3^{2-} \qquad (13)$$

$$\log K'' = \log K' - \log k_3 = 0.7 \pm 0.2$$

Whichever of these reactions is used, it is important to realize that silver is absorbed quite strongly from dilute solutions but only weakly from concentrated ones, there being a span of five powers of ten in the distribution coefficients. Anion exchange separation from metals not absorbed from dilute thiosulphate solutions is thus possible, with subsequent elution of the silver with a concentrated thiosulphate solution.

Acknowledgement. Thanks are due to Dr. I Dostrovsky, Scientific Director, Israel Atomic Energy Commission Research Establishment, under whose direction the experimental part of this work was carried out, for his help and encouragement, and to Mr. A. Citron for his assistance in the elution experiments. Thanks are also due to Prof.

L. G. Sillén, the Royal Institute of Technology, Stockholm, in whose laboratory the manuscript was prepared, for its critical discussion. The help of Dr. H. S. Dunsmore and of Miss Myra Ockrant in improving the English presentation is also acknowledged.

Sulfite and Complex-bound Cyanide as Sulfur Acceptors for Rhodanese

BO SÖRBO

Research Institute of National Defence, Dept. 1, Sundbyberg 4, and Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

The catalytic effect of rhodanese on the reaction between thiosulfonates and sulfite has been demonstrated. Rhodanese, combined with thiosulfate, can in part reactivate cyanide inhibited cytochrome oxidase. A similar effect on the cyanide compounds of catalase and methemoglobin was also demonstrated. Vitamin B_{12} (cyanocobalamin) was not converted to the corresponding thiocyanate compound by the action of rhodanese and thiosulfate. A possible function of cobalamins in thiocyanate metabolism is suggested.

Previous studies of the substrate specificity of rhodanese [1,2] have demonstrated that thiosulfonates could replace thiosulfate as sulfur donor in the enzyme catalyzed reaction. Up to this time cyanide was the only known sulfur acceptor in the system. The present paper reports that sulfite can replace cyanide as acceptor; the reaction products being in this case thiosulfate and the corresponding sulfinate. The effect of rhodanese and thiosulfate on certain cyanide complexes of biological importance have also been investigated.

EXPERIMENTAL

Materials. Rhodanese was a twice crystallized preparation from beef liver [3]. The thiosulfonates were prepared as previously described [2]. Catalase was a recrystallized preparation from beef liver and methemoglobin was prepared by oxidizing a rabbit blood hemolysate with ferricyanide, followed by dialysis in order to remove excess ferricyanide. Cytochrome oxidase was a 10 % rabbit brain homogenate in 0.01 M phosphate buffer of pH 7.4. Ferrocytochrome c was a commercial beef heart preparation, reduced with hydrogen in the presence of platinum asbestos.

Methods. The formation of thiosulfate from a mixture of a thiosulfonate and sulfite was followed with the iodometric titration method given by Foss [4]. A correction for "induced oxidation" was obtained by titrating standard amounts of thiosulfate in the presence of the thiosulfonate and sulfite. The disappearance of the cyanide complexes of catalase and methemoglobin was followed spectrophotometrically at 425 and 630 mμ, respectively. Cytochrome oxidase activity was assayed spectrophotometrically by following the oxidation of ferrocytochrome c at 550 mμ[5]. A test for the formation of thiocyanate from vitamin B_{12} was developed on the base of the copper-pyridine-reaction [6]. For this

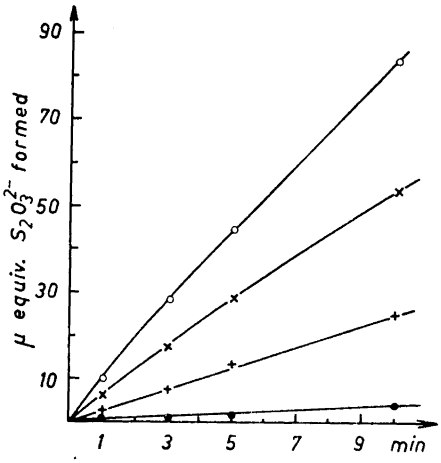

Fig. 1. Reaction between thiosulfonates and sulfite.
●●● Ethanethiosulfonate, spontaneous reaction.
○○○ In the presence of 6.8 μg rhodanese.
+ + + Toluenethiosulfonate, spontaneous reaction.
× × × In the presence of 13.5 μg rhodanese.
Test conditions: Final volume 5 ml, pH 7.4, phosphate concentration 0.1 M, thiosulfonate and sulfite 0.05 M, bovine serum albumin 0.005 %, temp. 20 °C. Reaction stopped at indicated time by the addition of 0.5 ml formaldehyde followed by 10 ml 10 % KI and 2.5 ml 10 % acetic acid. Titrated with 0.01 N iodine with starch as indicator.

test, 0.5 ml of reaction mixture, containing 0.005 M vitamin B_{12} and 0.01 M thiosulfate in 0.1 M phosphate buffer pH 7.4 was incubated with rhodanese and the enzyme, then destroyed by heating the sample in boiling water for 2 min. The sample was cooled and 0.05 ml 0.1 M KCN was added, in order to liberate thiocyanate from any thiocyanatecobalamin formed, followed by 4.5 ml water, 1 ml pyridine and 1 ml 10 % $CuSO_4$, $5H_2O$. Any copper-pyridinethiocyanate complex formed was then extracted with 2 + 1 + 1 ml bromobenzene and the optical density of the latter determined at 410 mμ. Vitamin B_{12} is not extracted by bromobenzene, but appropriate blank determinations had to be carried out, as both cyanide and thiosulfate interfered with the determinations. Recovery experiments demonstrated that a conversion of 5 % of the cyanide of vitamin B_{12} could be safely detected by this method.

RESULTS

The rhodanese catalyzed reactions between two thiosulfonates and sulfite and the corresponding spontaneous reactions are shown in Fig. 1. In agreement with Foss [4] it was found that the spontaneous reaction between toluenethiosulfonate and sulfite was more rapid than the corresponding reaction with ethanethiosulfonate. The rhodanese catalyzed reaction was on the contrary more rapid with ethanethiosulfonate. A similar behaviour of the thiosulfonates was previously [2] noticed in their reactions with cyanide. A comparison between the two sets of data demonstrates that sulfite is inferior to cyanide as sulfur acceptor in the rhodanese reaction. With ethanethiosulfonate as

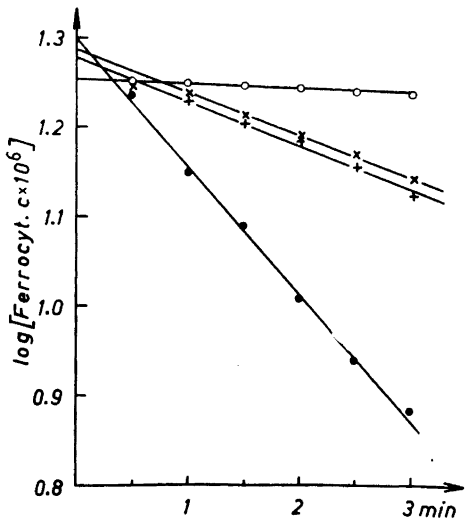

Fig. 2. Reactivation of cyanide inhibited cytochrome oxidase by rhodanese.

○○○ Cytochrome oxidase + 0.001 M cyanide ($k = 0.18 \times 10^{-3}$sec^{-1}).
× × × Cytochrome oxidase + 0.001 M cyanide + 0.05 M thiosulfate + 36 μg rhodanese/ml added in the indicated order. Tested immediately after the rhodanese addition ($k = 1.8 \times 10^{3-}$ sec^{1-}).
+ + + The same tested 15 min. later ($k = 1.8 \times 10^{-3}$sec^{-1}).

The oxidase activity assayed by adding 0.04 ml of the reaction mixtures to 4.0 ml of ferrocytochrome c (appr. 2×10^{-5} M) and following the reaction at 550 mμ. Figures in brackets indicate the first order reaction constant.

donor and sulfite as acceptor, 1 μg of rhodanese gave 6.4 μ-equiv. of thiosulfate in 5 min, whereas with cyanide as acceptor 10 μ-equiv. of thiocyanate were formed. With *p*-toluenethiosulfonate as donor and sulfite as acceptor 1 μg of rhodanese formed in 5 min 1.1 μ-equiv. of thiosulfate and the corresponding value with cyanide was 3.8 μ-equiv. of thiocyanate. (These values have been corrected for the effect of the spontaneous reaction.)

In connection with a study of the antidote effect of rhodanese in cyanide poisoning it became of interest to study the activity of rhodanese to transform complex-bound cyanide into thiocyanate. As the toxic properties of cyanide is attributed to its strong inhibitory action on cytochrome oxidase, the established antidote effect of rhodanese combined with thiosulfate [7] suggests, that this combination can reactivate cyanide inhibited cytochrome oxidase. Albaum *et al.*[8] have previously demonstrated that another cyanide antidote, methemoglobin, in part reactivates cytochrome oxidase. When rhodanese + thiosulfate was added to cyanide inhibited cytochrome oxidase (Fig. 2), a rapid reactivation was in fact obtained, but it was incomplete. As thiosulfate, thiocyanate and sulfite at the actual concentrations did not affect the oxidase, it must be concluded also that the conversion of cyanide to thiocyanate was

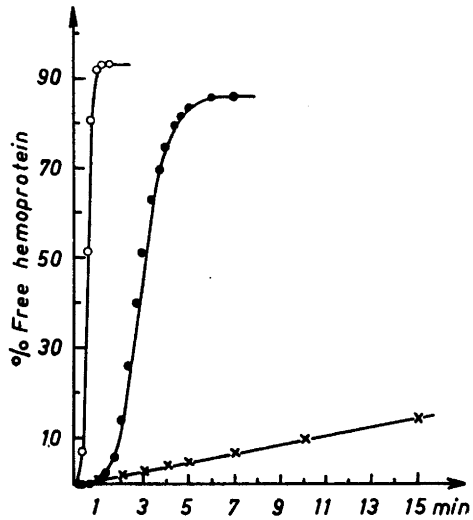

Fig. 3. Action of rhodanese on cyanide compounds of catalase and methemoglobin.

●●● 2.8×10^{-6} M catalase + 3.10^{-4} M cyanide + 0.05 M thiosulfate in 0.025 M phosphate buffer pH 7.4. At zero time rhodanese (8.6 μg/ml) added.

○○○ As the preceding with 39 μg rhodanese/ml.

××× 1.3×10^{-4} M methemoglobin + 3×10^{-4} M cyanide in 0.025 M phosphate buffer pH 7.4. After 5 minutes incubation thiosulfate (to 0.05 M concentration) and rhodanese (36 μg/ml) were added.

The lag period observed in the two curves with catalase corresponds to the time necessary for converting the excess of cyanide into thiocyanate.

incomplete, although rather high concentrations of rhodanese and thiosulfate were used. Thiosulfate alone had no reactivating effect on the inhibited cytochrome oxidase, as the rhodanese activity of brain homogenates is low. The behaviour of the cyanide complexes of two other heme proteins was then investigated. Catalase cyanide was rapidly reactivated by the action of rhodanese and thiosulfate, whereas methemoglobin cyanide reacted much more slowly (Fig. 3). These results are explained, if rhodanese does not react with the heme-bound cyanide but only with the free cyanide (hydrocyanic acid), which is in equilibrium with the heme-cyanide complex. The dissociation velocity constant for catalase cyanide is about 3 000-fold greater than that for methemoglobin cyanide [9,10], which explains the much more rapid reaction with the catalase compound. The reaction with catalase cyanide like that with cytochrome oxidase cyanide was incomplete even in the presence of high concentrations of rhodanese. However, 93 % of the catalase cyanide was converted to free catalase as compared with 33 % of cytochrome oxidase cyanide under similar conditions *. When the rhodanese concentration was reduced

* The maximum conversion, obtainable with methemoglobin cyanide, could not be determined, as the reaction was so slow, that about 24 h were required for equilibrium, and free methemoglobin was not completely stable under these conditions.

5-fold, the maximum conversion of catalase cyanide was reduced to 86 %, indicating that the concentration of rhodanese also influences the extent of conversion. From the known values for the dissociation constants of catalase cyanide [9] (K: 4×10^{-6}) and cytochrome oxidase cyanide [5] (K: 7×10^{-7}) it was possible to calculate the concentration of free cyanide (hydrocyanic acid), which would give the final value of inhibited heme-enzyme. This calculation gives 1.2×10^{-6} M cyanide in the cytochrome oxidase experiment and 3×10^{-7} M cyanide in the corresponding catalase experiment. This discrepancy, observed in repeated experiments, is yet unexplained.

Vitamin B_{12} (cyanocobalamin) is a cyanide complex of biological importance. Furthermore, it was of interest to test cyanocobalamin as a substrate for rhodanese. When cyanocobalamin (0.004 M) and thiosulfate (0.01 M) were incubated for 30 min at pH 7.4 and 20 °C in the presence of high concentrations of rhodanese (39 μg/ml) no conversion of cyanocobalamin to thiocyanatocobalamin was detected. In the light of the previous results this was not unexpected, as the cyanide is very tightly bound to the cobalt in vitamin B_{12} and thus no free cyanide is accessible to rhodanese.

DISCUSSION

The formation of thiosulfate from a thiosulfonate and sulfite by the action of rhodanese may occur in the body as both thiosulfonates [11] and sulfite can be formed by enzymatic mechanisms. The precursors to thiosulfonates are, however, a sulfinic acid and β-mercaptopyruvic acid, and as the latter gives thiosulfate directly with sulfite in an enzymatic reaction [11], this latter reaction is probably of greater importance.

As cyanide, vitamin B_{12} and thiocyanate are in a dynamic equilibrium *in vivo* (demonstrated by isotope experiments [13]) the failure of vitamin B_{12} to react with rhodanese is of certain interest. It is possible that the cyanide of vitamin B_{12} is first released from the cobalt atom by specific mechanisms before being converted to thiocyanate by the rhodanese system. It is also possible that this conversion occurs through other enzyme systems. In this connection an interesting metabolic function of vitamin B_{12} may be considered. Vitamin B_{12} is in part present in liver not only as cyanocobalamin but also as hydroxycobalamin (vitamin B_{12}a) [13]. The latter has a very high affinity for cyanide and it is possible that the presence of hydroxycobalamin may change the overall equilibrium of certain enzyme systems, so that thiocyanate may be converted to cyanide (bound in vitamin B_{12}) and a sulfur compound, even though the equilibrium constant of these enzyme systems are in favour of the formation of thiocyanate from cyanide. Thiocyanate could thus be converted to thiosulfate by rhodanese, or more interesting, thiocyanate and pyruvic acid may yield mercaptopyruvic acid by the action of an enzyme, which catalyses the formation of thiocyanate from mercaptopyruvic acid and cyanide [14]. A subsequent transamination of mercaptopyruvic acid would then give cysteine and the net result would be a synthesis of cysteine with thiocyanate as the sulfur source. Wokes and Picard [15] have also recently proposed a mechanism, although different from that outlined above, by which the sulfur of thiocyanate could be converted into the sulfur containing amino acids by the action of

vitamin B_{12}. It must be added that no experimental evidence for the formation of cysteine from thiocyanate has as yet been obtained, but experiments designed to test this hypothesis, using sulfur labeled thiocyanate, are now planned in this laboratory.

The author is very grateful to Miss A. M. Sjödén for her valuable technical assistance.

Constituents of Pollen

II.* Long-chain Hydrocarbons and Alcohols

MARTIN NILSSON, RAGNAR RYHAGE and ERIK von SYDOW

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm; Kemiska Institutionen, Karolinska Institutet, Stockholm; Kemiska Institutionen, Uppsala Universitet, Uppsala, Sweden

Some waxy, crystalline fractions isolated from pollen have been investigated by mass spectrometry. This method has proved to be most convenient for the investigation of these mixtures of long-chain natural products.

Pollen from *Pinus montana* contains *n*-tetracosanol-1, *n*-hexacosanol-1 and *n*-octacosanol-1, while pollens from *Zea mays* and *Alnus glutinosa* have been found to contain paraffins; maize *n*-pentacosane and *n*-heptacosane, alder mainly *n*-heptacosane and *n*-nonacosane.

For the investigation of pollen constituents carried out at the Royal Institute of Technology, Stockholm, some representative plants have been chosen; the gymnosperm *Pinus montana*, Mill. and the angiosperms *Zea mays*, L. and *Alnus glutinosa*, Gaertn., representing mono- and dicotyledons respectively [1].

The present paper deals with the ether-extractable material from these pollens. The amount of ether-extract was approximately the same in pine and alder pollen (around 9 %), but rather small (2 %) in maize pollen. This difference is, however, not so significant as the amount of ether-extract in the maize pollen apparently varies widely from year to year [1]. The extracts were divided into acid and neutral fractions; the neutral fractions were semisolid and crystalline material deposited when the hot solutions in acetone (ethanol) were left to cool. These crystalline products had a waxy consistency and appeared to consist of long-chain aliphatic compounds.

X-Ray powder photographs of the different long-chain mixtures were taken in a Guinier camera using Cu-$K\alpha$ radiation. They were all very similar and one of them is shown in Fig. 1. The appearance and distribution of the strong diffraction lines indicate that the mixtures consist of long straight-chain hydrocarbons with no substituents or only smaller ones (*e. g.* paraffins and alcohols). The chains are packed in the common *ortho*-rhombic structure [2-4] with the chain-plane of each molecule approximately perpendicular to that of the next.

* Part I. *Acta Chem. Scand.* **10** (1956) 413.

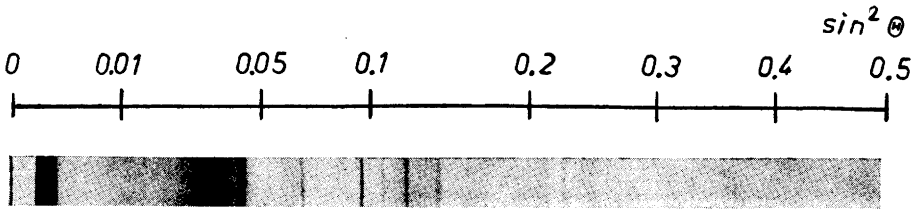

Fig. 1. Guinier X-ray powder photograph of the crude long-chain mixture from *Alnus glutinosa* pollen. Cu-*Kα*-radiation. Exposure 4 h.

To show the nature of the long-chain mixtures they were investigated using the mass spectrometer described by Ryhage [5], which has been used in structural research on long-chain compounds and mixtures [6,7].

Mountain pine gave a large amount (1 %) of a material, m. p. 70—74°, which when treated with urea in methanol formed a complex [8]. Purification by recrystallisation and by complex formation did not raise the melting point appreciably (72—74°). The elementary analysis was consistent with the composition $C_{24}H_{50}O$ and hence the product was presumed to be a mixture of straight chain alcohols in the C_{24}—C_{26}-region.

Similar fractions have frequently been isolated from plants. On careful fractionation and X-ray investigation they have generally proved to be mixtures of closely related alcohols, sometimes contaminated with hydrocarbons [9,10]. The mass spectrometric investigation, discussed in detail in a later section, showed that the product from *P. montana* contained *n*-tetracosanol-1, *n*-hexacosanol-1 and *n*-octacosanol-1. The mass spectrum of the crude product was easily interpreted and the investigation of the purified material merely served to confirmed the result.

The crude materials from maize and alder pollen were therefore investigated directly although their melting point intervals were very broad. The mass spectra showed them to consist largely of paraffins and also revealed the presence of other compounds so they were purified by filtration through alumina and the preliminary results confirmed by an additional mass spectrometric analysis. The maize pollen contained *n*-pentacosane and *n*-heptacosane and the alder pollen *n*-heptacosane, *n*-nonacosane and smaller amounts of *n*-tricosane and *n*-pentacosane.

DISCUSSION

The investigation has revealed a marked difference between the gymnosperm pollen, which contains large quantities of longchain alcohols and the angiosperm pollens, which contain smaller amounts of paraffins.

Paraffins have been found in angiosperm pollen earlier; "tricosane" in hazel pollen [11], "heptacosane" in pollen from sugar beet [12] and as a mixture in maize pollen [10,13]. A fraction closely related to "ceryl alcohol" has been found in pollen from a pine [12] and in an investigation of *Pinus silvestris* pollen a waxy substance, m. p. 80°, has been obtained [14], which can now be supposed to be a wax alcohol mixture.

If the ether-extracted pollens were extracted with alcohol a further quantity of lipid material was obtained, which was obviously retained by the pollen membrane during the ether extraction (*c. f.* Ref.[15]). It may be presumed that the waxes dealt with in this paper are located on or near the surface of the pollen grains in the same way as plant waxes in general are located in the outer layer of the tissues [16]. The function of the pollen waxes is apparently the same as that of plant waxes in general — a barrier against loss of water — as shown by the striking parallel between the waxy conifer-needles [17] and the heavily wax-impregnated pine pollen.

The gymnosperms are wind-pollinated whereas the angiosperms are generally pollinated by insects and this might have some connection with the differences between the long-chain compounds in the gymnosperm and the angiosperm pollen.

EXPERIMENTAL

Extraction, isolation and purification

The melting points were determined on a Kofler block. The pollen samples were collected in 1954 by *A. B. Cemille*, Vegeholm, Sweden, and contained at least 99 % of the right pollen [1].

Air-dried pollen (500 g) was exhaustively extracted with ether in a Soxhlet apparatus (*ca.* 2 weeks); the extraction temperature was *ca.* 25°. The ether was evaporated, the residue dissolved in chloroform and extracted with 2 M potassium hydroxide. After appropriate back extractions an acid fraction and a neutral fraction were obtained. The neutral fractions were dissolved in a minimum amount of hot acetone (for maize ethanol) and the crystalline precipitate obtained after cooling collected.

Pinus montana gave 8.0 % ether-extract giving 3.6 % neutral material, from which 1.0 % crystalline material, m. p. 70—74°, was obtained. The corresponding figures for *Zea mays* were 2.0, 1.1, 0.2 %, m. p. 48—58° and for *Alnus glutinosa* 10.0, 8.5, 0.6 % and m. p. 57—64°, all percentages being calculated on an air-dried pollen basis.

The crude product from *P. montana* was recrystallised from acetone and dissolved in a hot solution of urea in methanol (160 g/l). On cooling long needles separated. The urea complex was collected and decomposed with chloroform and dilute hydrochloric acid, the chloroform layer was separated, evaporated and the product recrystallised from acetone, m. p. 72—74°. (Found: C 81.4; H 13.8. Calc. for $C_{24}H_{50}O$: C 81.4; H 14.1.)

For purification of the maize and alder products, samples (*ca.* 1 g) were dissolved in methyl *cyclo*hexane (50 ml), passed through a column of alumina (10 × 1.5 cm, 20 g) and the column was washed with the same solvent (150 ml). On evaporation colourless waxes were obtained; from maize 65 % of input with a melting point range of 45—60°, from alder 55 %, m. p. 55—70°. Elution with benzene (200 ml) gave 10 and 15 %, m. p. 45—55° and 60—75°, respectively, of pale yellow waxy material. Further elution with ethyl acetate and methanol gave discoloured, heterogeneous material. The methyl *cyclo*hexane fractions are referred to in the next section as purified products, the benzene fractions were investigated with the mass spectrometer but the spectra were too complicated for interpretation presently. The other fractions were not further investigated.

Mass spectrometric study

The mass spectrometer used is that described by Ryhage [5]. For typographic reasons only the high mass regions of the mass spectra are shown in the figures. The mass spectrum of the crude product from *Pinus montana* is shown in Fig. 2. This is a spectrum typical of long-chain compounds. In the C_{28}-, C_{26}- and C_{24}-alkyl groups of peaks there are two comparatively strong peaks corresponding to $C_nH_{2n}^+$ and $C_nH_{2n-2}^+$, which is typical of a long-chain alcohol with n carbon atoms [6]. Such an alcohol gives, however, also

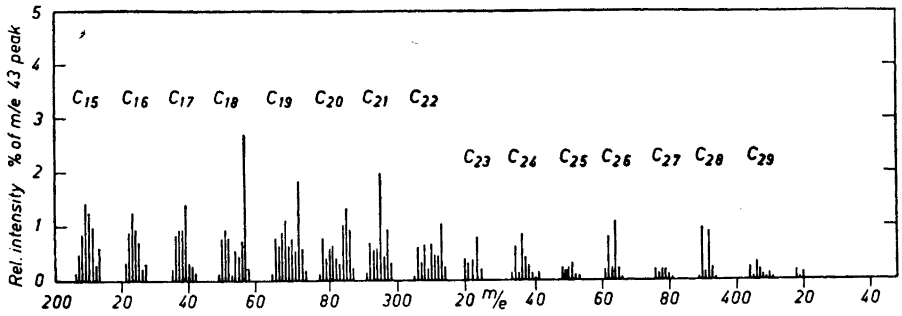

Fig. 2. Mass spectrum of the crude long-chain mixture from *Pinus montana.*

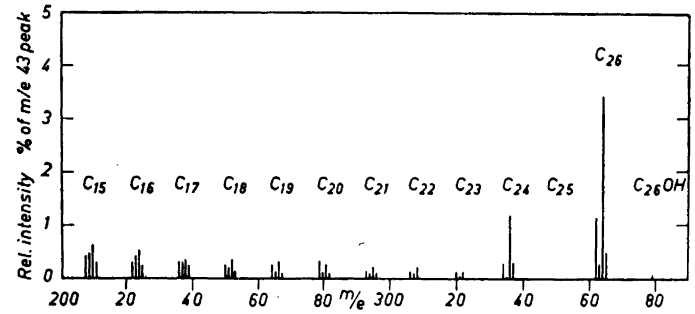

Fig. 3. Mass spectrum of pure *n*-hexacosanol-1.

peaks at *m/e* corresponding to $C_{n-2}H_{2n-4}^+$ and $C_{n-2}H_{2n-6}^+$ but these are much lower. For comparison the spectrum of pure *n*-hexacosanol is shown in Fig. 3. In the case of *P. montana* there are peaks at *m/e* = 392 ($C_{28}H_{56}^+$) and *m/e* = 390 ($C_{28}H_{54}^+$) indicating the presence of *n*-octacosanol-1. There are also peaks at *m/e* = 364 ($C_{26}H_{52}^+$) and 362 ($C_{26}H_{50}^+$) which to a small part are due to fragmentation of *n*-octacosanol-1 and to a larger extent to fragments from *n*-hexacosanol-1. The same thing is valid for the peaks in the C_{24}-group, which indicate smaller amounts of *n*-tetracosanol-1, as the peaks in the C_{22}-group are lower. There are no obvious signs of any other long-chain compounds. The purified mixture from *P. montana* was also analysed and found to contain more *n*-octacosanol-1 and less *n*-tetracosanol-1 than the crude product, which is of course consistent with the larger solubility of the shorter alcohols.

The mass spectra of the products from *Zea mays* and *Alnus glutinosa* are also typical of long chain compounds, but in this case of *n*-hydrocarbons. The mass spectrum of the purified product from *Zea mays* is shown in Fig. 4 and that of the crude product from *Alnus glutinosa* in Fig. 5. Mass spectra of heavy normal and branched chain hydrocarbons have been extensively studied by O'Neal and Wier [18]. A normal chain hydrocarbon spectrum always contains a strong parent peak corresponding to the unfragmented molecule and a series of peaks corresponding to $C_nH_{2n+1}^+$ with *n* up to the number of carbon atoms in the molecule.

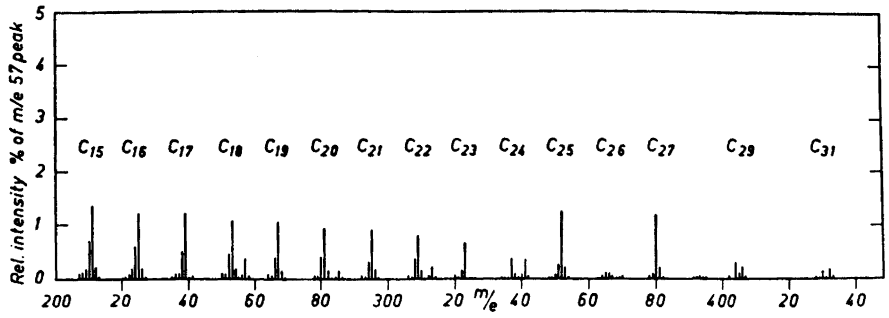

Fig. 4. Mass spectrum of the purified product from *Zea mays*.

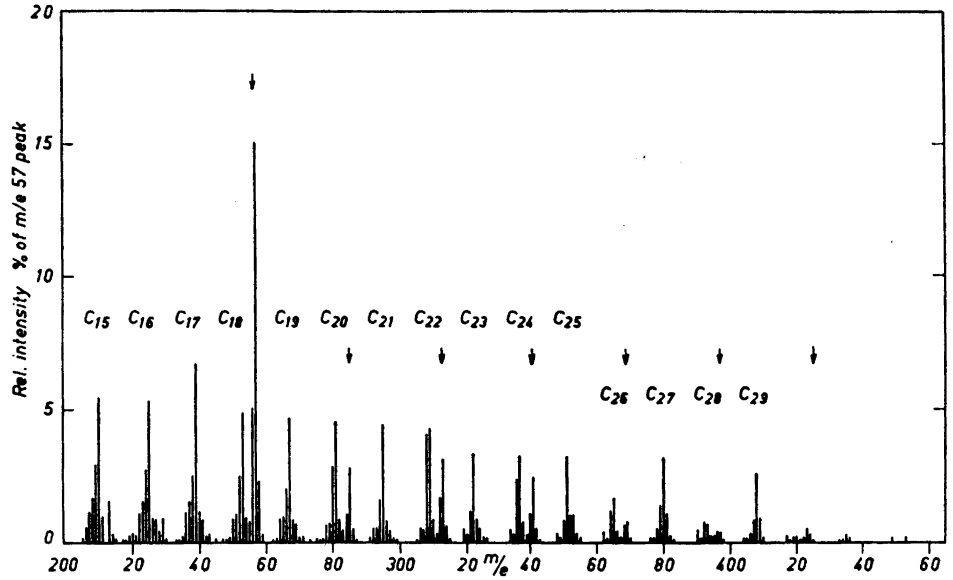

Fig. 5. Mass spectrum of the crude product from *Alnus glutinosa*.

It can be seen that the spectra of the mixtures from *Zea mays* and *Alnus glutinosa* (Fig. 4 and 5) are characteristic for hydrocarbons. The first one contains only *n*-pentacosane and *n*-heptacosane while the last one contains *n*-heptacosane, *n*-nonacosane and traces of *n*-tricosane and *n*-pentacosane. There are peaks in both spectra, which cannot be referred to fragments of these hydrocarbons, but which indicate the presence of other compounds. Thus the spectrum of the crude product from *A. glutinosa*, which had a faint yellow colour, had strong peaks at $m/e = 257 + n \times 28 = 285, 313, 341$ .... (marked with arrows in Fig. 5). This might indicate some sort of conjugated system attached to a fragment with a molecular weight approximately equal to 257. The same series of peaks was also recognised in the spectrum of *P. montana* although the intensities were lower.

The weak peaks in the C_{29}-and C_{31}-regions of the maize spectrum cannot be due to saturated hydrocarbons or alcohols but possibly to unsaturated hydrocarbons. In lack of reference substances no conclusions should be drawn however. In the crude products from maize and alder there are also smaller amounts of other compounds, probably containing oxygen. The investigation of the purified mixture from alder gave no further information.

Acknowledgements. We are indebted to *A. B. Kabi* for generous gifts of pollen, to Prof. E. Stenhagen for a sample of pure *n*-hexacosanol-1, which he had obtained from Prof. A. C. Chibnall, and one of us (M. N.) to *Statens Tekniska Forskningsråd* for a fellowship.

Infrared Absorption Spectra of *ortho*- and *para*-Linked Polyphenyls

JOHANNES DALE

Forsvarets Forskningsinstitutt, Kjeller, Norway

The absorption spectra of biphenyl, *o*- and *p*-terphenyl, *o,o'*-, *o,p'*- and *p,p'*-quaterphenyl have been recorded from 2 to 25 μ both in solution and in the solid state. Oriented crystallization takes place when melts of the linear compounds solidify between salt plates. Some of the bands observed in the spectra obtained by the KBr technique are lacking in the oriented crystal spectra; they must be due to vibrations polarized parallel to the long molecular axis. Most of the vibrations seem to occur independently within each ring of the chain, and assignments can be made on the basis of the assignments for methylbenzenes given by Pitzer and Scott [12]. For the linear compounds the intensity variation of the bands classified as due to in-plane skeletal deformation modes suggests that these vibrations are coupled together, the selection rules being determined by the symmetry of the whole molecule, and that the molecules are planar in the crystalline state, but non-planar in solution.

The synthesis of *o,p'*-quaterphenyl is described.

In connection with a study of the ultraviolet spectra of through-conjugated polyphenyls in the solid state and in solution (*cf.* the following paper [1]), it was of great interest to know whether any change of conformation would occur in going from one state to the other, since such changes would be expected to affect the degree of interaction between the π-electron systems of the linked benzene nuclei. In particular it was of importance to ascertain whether the *p*-polyphenyl molecules are planar in solution as they are known to be in the crystal [2–5], or non-planar, as has been established for biphenyl in the gaseous state [6]. For one of the non-linear compounds, *o,o'*-quaterphenyl, one might even anticipate, as a result of the tendency towards coplanarity, the existence of *cis*- and *trans*-like conformations, for which the electronic absorption spectra would be expected to differ.

Biphenyl and all the possible *o*- and *p*-linked terphenyls and quaterphenyls were studied. Of these, *o,p'*-quaterphenyl has not been described before, and a method for its synthesis is given in the experimental part.

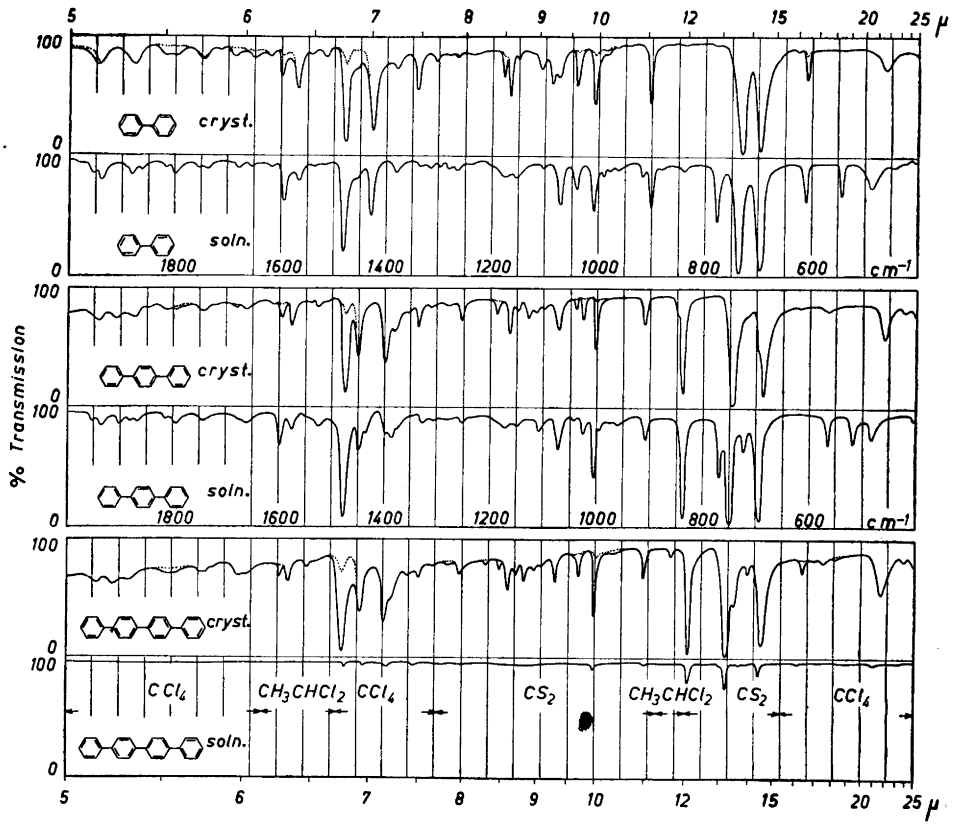

Fig. 1. Infrared spectra of linear polyphenyls in solution (1 % or saturated, 1 mm cell thickness) and in the solid, crystalline state. The dotted curves represent spectra of melts solidified between salt plates (0.01 mm layer thickness) in regions where these differ from the spectra of pressed KBr disks (full line). The solvents used in the various regions have been indicated in the lower part of the figure.

Infrared spectra of some of these compounds have been reported earlier [7–11], but these spectra are partly of poor quality, especially for solids prepared as mineral oil mulls [10]; they are mostly not available for both solid state and solution; and they cover only the NaCl-region, or part of it [7]. Since the skeletal deformation vibrations would be expected to be most sensitive to changes of molecular shape, it was considered especially important for the present purpose to include the long-wave region from 15 to 25 μ (KBr-prism).

The infrared spectra are given in Figs. 1 and 2. Below 5 μ they are very similar, the absorption due to the various CH-stretching modes appearing as an unresolved band at 3 040—3 060 cm^{-1} for all members. This region has not therefore been reproduced in the figures and will not be further discussed. The solid state spectra were taken both of solidified melts and of pressed KBr-

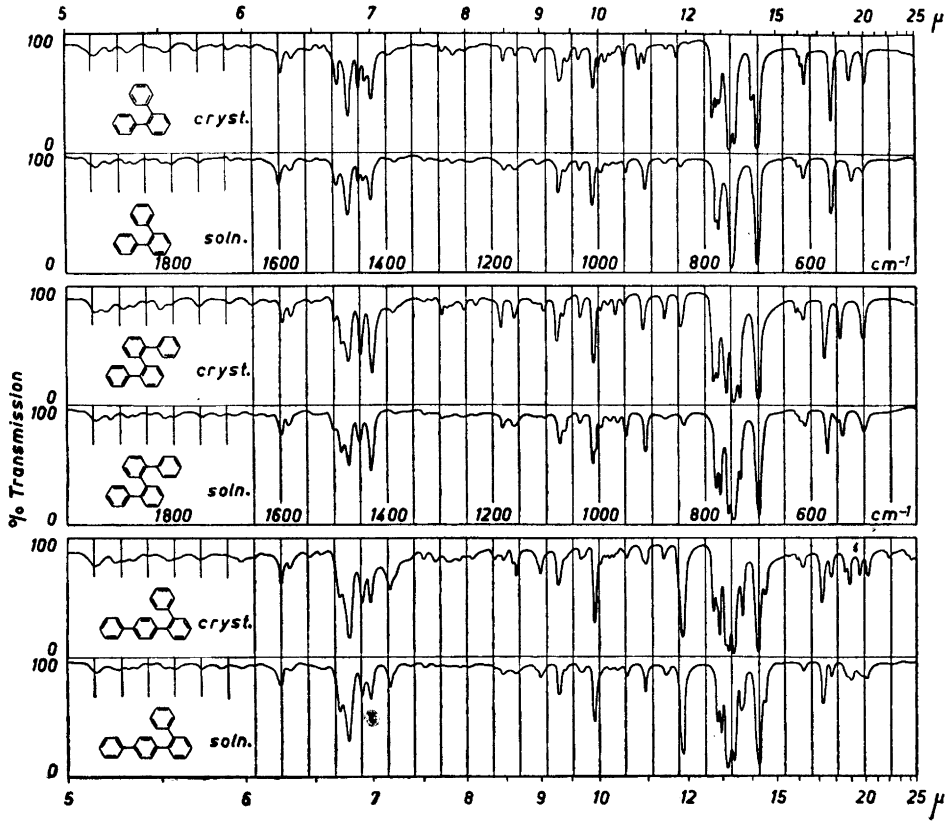

Fig. 2. Infrared spectra of non-linear polyphenyls in solution (1 %, 1 mm cell thickness) and in the solid, crystalline state. Pressed KBr disks and solidified melts give indistinguishable spectra. The solvents used in the various regions have been indicated in Fig. 1.

disks. While these were identical for the non-linear compounds, it was observed that for the linear compounds some of the bands present in the KBr-disk spectra were missing or of very low intensity in the spectra of the solidified melts. Evidently, oriented crystallization between the salt plates must be responsible for this effect *, since just these compounds tend to crystallize in very thin leaflets. It was also observed that if the linear polyphenyls are sublimed on to a salt plate, the same bands are absent in the spectra. It is easy to understand that in this case the leaflets that are oriented parallel to the salt plate must make by far the largest contribution to the absorbing area. Now it is known from X-ray diffraction that these molecules have their long axis perpendicular to the main plane of the crystal leaflets [2-5]. The bands that are

* From a spectrum of biphenyl, published by Richards and Thompson [6], it may be seen that they have also had a strongly oriented sample, apparently without being aware of it.

absent in the oriented samples must therefore be due to those vibrations which are polarized parallel to the long axis, and we have thus a means of sorting out vibrations of this symmetry type.

It was further found that when the solution spectra were compared with the solid state spectra, there are practically no differences in the non-linear compounds (Fig. 2), whereas for the linear compounds (Fig. 1) some bands present in the solution spectra disappear completely in the spectra of the solid, crystalline state *. For this latter case one is thus at once forced to conclude that the molecules, which are planar in the solid state, become non-planar in solution, since by such a change the symmetry of the molecule will be altered (loss of symmetry center) and the selection rules will change. However, this concerns only a few bands below 800 cm^{-1}; the remaining bands seem to behave as if they belonged to separate rings with the same substitution, as has already been noted by Cannon and Sutherland [10].

BANDS CHARACTERISTIC OF MONO-SUBSTITUTED BENZENES.

A complete assignment of the main bands below 1 600 cm^{-1} in the biphenyl spectrum, and most of the bands in the other spectra, could be made on the basis of the assignment given by Pitzer and Scott for methylbenzenes [12], because of the fortunate circumstance that most of the vibrations seem to occur independently within each nucleus. Since there are no disturbing bands due to methyl groups, and the vibrations of symmetry class A_1 can be identified with certainty, as shown above, it is believed that the present assignments for biphenyl (Table 1) are quite reliable, and may be of value in the revision of Pitzer and Scott's data which Plyler considers necessary [13]. To be specific, vibrations 6a and 6b (using Wilson's numbering scheme [14]) had to be interchanged, although good arguments have been advanced for their classification in monosubstituted benzenes based on the mass sensitivity of the lower frequency band and constancy of the higher one [13]. Furthermore, vibrations 19b, 3 and 5 had to be shifted to much higher frequencies; for vibration 5 the new position is in good agreement with calculations by Cole and Thompson [15].

By comparing the classification according to main vibrational type in Table 1 with the spectrum of biphenyl in Fig. 1 it is seen that the bands due to CC-stretching modes (ν CC in Table 1) are rather similar in solution and in the solid state, except that for the pair just below 1 600 cm^{-1}, 8a is more intense than 8b in solution, while 8b is the stronger band in the solid. Their assignment is strongly supported by the appearance of intense Raman lines [16] at 1 600 and 1 584 cm^{-1}. The bands attributed to CH-in-plane-deformation modes (δ CH) are characterized by being sharp in the solid, but broad and diffuse, even weak, in solution. This broadening may perhaps be due to interaction between the hydrogen atoms and the solvent, or to oscillations of the rings about some interplanar equilibrium angle. The bands which represent CH-

* The spectrum of biphenyl as mineral oil mull, given by Burton and Richards [9], reveals that it is actually a mixture of solid and solution; the substance must have been partly dissolved by the oil.

Symmetry type" refers to the symmetry of the separate ring; not of the whole molecule. An asterisk denot the vibration is strictly infrared inactive, but occurs in violation of the selection rules.

and CC-out-of-plane-deformation modes (γ CH and γ CC) * are very similar in both states, except that the 16b vibration is displaced to higher frequency in solution.

The remaining three bands due to the CC-in-plane-deformation modes (δ CC), illustrated for benzene in Fig. 3, are the most important ones, since two of these bands, 12 ** and 6b, are just those which do not appear in the solid; the third one, 6a, disappears on lengthening the chain (*p*-terphenyl) and reappears on further lengthening (*p,p'*-quaterphenyl). It would seem reason-

* It should be emphasized at this point that of the two bands 10b and 4, which are very strong and characteristic in monosubstituted benzenes, 10b is chiefly a γ CH-vibration, while 4 is chiefly a γ CC-vibration. They are both commonly and confusingly referred to in the literature as γ CH-vibrations [11,17].

** This vibration has been assigned by Frühling [16] to a strong Raman line at 1 028 cm^{-1}, close to its frequency in benzene, but this line is rather due to the 18a vibration which in the infrared gives rise to a band at 1 042 cm^{-1}.

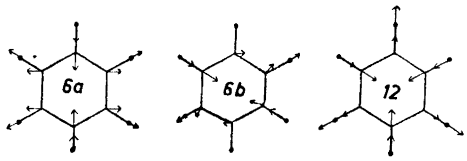

Fig. 3. The three normal modes of in-plane-deformation vibration of benzene according to Pitzer and Scott [12].

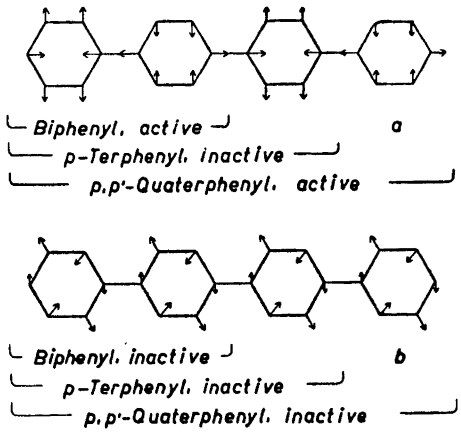

Fig. 4. "Whole-molecular" vibrations obtained by coupling in-plane-deformation modes of the rings in the manner suggested by the intensity variations of the corresponding bands; a) vibration 6a; b) vibration 6b.

able to expect that skeletal deformation vibrations in the plane should be coupled most strongly through the whole molecule, more so than skeletal deformation vibrations perpendicular to the molecular plane. But although the selection rules seem to be determined by the symmetry of the whole molecule, the frequencies are apparently not much affected; thus, Raman lines are observed in solid biphenyl at the same frequencies as for the infrared bands 12 and 6b in solution [16].

Let us now consider the 6a vibration. If it is coupled together as shown in Fig. 4a (the other possible manner would lead to stretching of the bond connecting the rings), it is easy to see that this will explain why the vibration should be allowed in the infrared for biphenyl, *p,p'*-quaterphenyl, etc., but forbidden for *p*-terphenyl, *p*-quinquiphenyl, etc., and why it is unaffected by rotation of the rings relative to each other about the connecting bonds or "pivot bonds" upon dissolution.

The 6b vibration can be coupled together in the manner shown in Fig. 4b. This coupled vibration would give rise to no absorption in planar molecules irrespective of the length, in agreement with the spectral evidence (Fig. 1). In non-planar molecules of any length it will become allowed, and the intensity

will depend on the interplanar angle. The forbidden 6b vibration of the *p*-disubstituted ring (Table 2) which "transmits" the coupled vibration through the longer chains, is apparently so mixed with the 6b vibration of the monosubstituted rings that two bands appear, subject to the same "molecular" selection rules (*cf.* the terphenyl spectrum). Their classification is obviously only tentative.

The 12 vibration is more difficult to interpret. If it is coupled together in a manner analogous to the coupling of 6a above, one should expect absorption both for planar and non-planar molecules irrespective of the number of nuclei in the chain. Instead, a band appears only in the solution spectra. There are other ways in which this vibration may be coupled to fit the observations, but since additional assumptions are needed, further discussion does not seem justified.

However, the important fact is that the three vibrations which do not obey the selection rules of separated rings, all belong to the skeletal in-plane-deformation modes. The only obvious conclusion from the behaviour of these bands is that the linear polyphenyl molecules are planar in the solid crystalline state, and non-planar in solution. Nothing definite can be said about the magnitude of the interplanar angle, but since Frühling [16] has concluded from polarization measurements of the Raman lines of liquid biphenyl, that the molecules have a center of symmetry, the interplanar angle may be quite small.

It remains to be mentioned that a band corresponding to the 7a vibration, which in toluene represents stretching of the CC-bond between the methyl group and the ring [12], is not found in the biphenyl spectrum, since it would here correspond to the pivot-bond stretching, which, even with less symmetric substitution than in biphenyl, would be expected to be inactive in the infrared, but give a very strong, polarized Raman line. In fact, the strongest line observed in the Raman spectrum of biphenyl [16, 18] as well as the terphenyls [18, 19], is at around 1 280 cm^{-1} and has been attributed to this stretching mode [18]. The absence of this band in the infrared spectrum strongly confirms this assignment. A very weak band at 1 275 cm^{-1} in the infrared spectrum of *p,p'*-quaterphenyl might be due to stretching of the two unsymmetrically substituted pivot bonds, since it is polarized parallel to the long axis of the molecule.

A strong band is present at 1 089 cm^{-1} in solid biphenyl but absent in solution and in all the other compounds. Its origin is uncertain. On the other hand, a few of the weak bands can be interpreted. Thus, the inactive 10a vibration can be detected at 840 cm^{-1} in biphenyl. It may be significant that it belongs to the γ CH-vibrations which are generally the strongest bands of aromatics. The weak band at 1 377 cm^{-1} is probably the first overtone of vibration 4 at 696 cm^{-1}.

Of the normal vibrations still not accounted for, there are five CH-stretching modes: 2, 7b, 13, 20a, and 20b; and one CC-stretching mode: 14. Then there is one CH-out-of-plane deformation mode, 17a, which is only Raman active, and one CC-out-of-plane deformation, 16a, active in the Raman [16] at 402 cm^{-1}. Vibrations 18b and 11, which are CH-in-plane and out-of-plane deformations respectively in benzene, would in biphenyl correspond to bending vibrations of the rings against each other and should occur below 400 cm^{-1}.

In the spectra of the remaining polyphenyls it is possible to trace most of the bands due to vibrations in monosubstituted rings through the whole series (Table 1). The very constant frequency of many of them is noteworthy. In *o*-terphenyl a few bands split in the solid, possibly because of non-equivalence of the two mono-substituted rings caused by packing effects in the crystal lattice. In *o,p'*-quaterphenyl doubling of some bands persists even in solution, since the two rings are unequally substituted.

BANDS CHARACTERISTIC OF DISUBSTITUTED BENZENE RINGS

The bands that are left over must then be due to vibrations within *para*- and *ortho*-disubstituted benzene rings, respectively. The most characteristic of these bands have been tentatively classified on the basis of Pitzer and Scott's work [12], and are given in Tables 2 and 3. Of course, other bands due to the disubstituted rings may be hidden by bands already assigned to monosubstituted rings. In particular, the bands are so numerous below 800 cm^{-1} for the more complex molecules, that their classification is rather uncertain.

For *p*-disubstituted rings (Table 2) the most characteristic bands are the CC-stretching 19b at 1 400 cm^{-1} and the CH-out-of-plane-deformation 17b at 830—840 cm^{-1}. It should be noted that a few vibrations give infrared bands in violation of the selection rules.

Table 2. Tentative assignments of some characteristic absorption bands of *para*-disubstituted benzene rings in polyphenyl chains (see Footnote to Table 1).

Main vibrational type	Numbering acc. to Wilson	Symmetry type	*p*-Terphenyl		*p,p'*-Quaterphenyl		*o,p'*-Quaterphenyl	
			cryst.	soln.	cryst.	soln.	cryst.	soln.
ν CC	19b	B_{2u}	1 401	~1 400	1 399	~1 395	1 392	1 393
δ CH	3	B_{3g}*	1 256	~1 254	1 256			
	18a	B_{1u}	1 027	1 026				
γ CH	17b	B_{3u}	838	840	826	825	839	832
δ CC	12	B_{1u}		723			728	728
	6b	B_{3g}*	~ 565	565	570		558	558

For *o*-disubstituted rings (Table 3) the bands are more numerous, but less characteristic. In *o,o'*-quaterphenyl there is a doubling of the CC-stretching 19b, but since the two rings are identical, the reason may be strong coupling between them for this stretching mode. It will be noticed that the γ CH-vibration 10a has been correlated with a band at 750 cm^{-1}. This is in agreement with calculations by Cole and Thompson [15], although Pitzer and Scott did not assign the strong band at 740 cm^{-1} of *o*-xylene to this mode [12]. Two other γ CH-vibrations, 5 and 17a, give rise to bands in violation of the selection rules.

Table 3. Tentative assignments of some characteristic absorption bands of *ortho*-disubstituted benzene rings in polyphenyl chains (see Footnote to Table 1).

	6a	A_1	558	558	570	567	576	575

They are weak in *o*-terphenyl, but stronger in *o,o'*-quaterphenyl where the selection rules are not strictly valid because the two substituents on each ring are unequal.

The great similarity between the solid state and the solution spectra of the non-linear polyphenyls even below 800 cm^{-1} would indicate that there are no great conformational differences between these two states. However, a small increase in interplanar angles upon dissolution would not lead to a change in symmetry and selection rules as it does in the linear series, and such widening of interplanar angles might well take place. Whether a mixture of *cis*- and *trans*-like conformations of *o,o'*-quaterphenyl exists in solution, or the *trans*-like conformation is alone present in both solution and solid, cannot be decided with certainty, but the spectra are so similar that the latter alternative appears most likely.

EXPERIMENTAL

The *spectra* were recorded in a Perkin-Elmer double-beam instrument, Model 21, using a NaCl prism from 2 to 15 μ and a KBr-prism from 15 to 25 μ. 1 % solutions in a 1 mm cell were used, except for *p*-terphenyl and *p,p'*-quaterphenyl which were measured as saturated solutions. In addition to CCl_4 and CS_2 it was found necessary with this cell thickness to use ethylidene chloride to get reliable readings in a few wavelength regions (Fig. 1).

Biphenyl and p-*terphenyl* (1,4-diphenylbenzene) were commercial samples purified by sublimation.

p,p'-*Quaterphenyl* (4,4'-diphenylbiphenyl) was prepared according to Bowden [20], recrystallized from benzene, and sublimed *in vacuo*.

o-*Terphenyl* (1,2-diphenylbenzene) and o,o'-*quaterphenyl* (2,2'-diphenylbiphenyl) were prepared as described by Bachmann and Clarke [21]. *o*-Terphenyl was recrystallized from methanol; *o,o'*-quaterphenyl first from ethanol, and then several times from acetone.

o,p'-*Quaterphenyl* (2,4'-diphenylbiphenyl) was prepared in the following manner: A mixture of *o*-iodobiphenyl (4 g), *p*-iodobiphenyl (4 g), and 10 g of finely ground copper powder (commercially available as "copper bronze" pigment) was heated to 260° C for 30 min, then cooled and extracted with benzene. The extract was purified by running it

through an alumina column. Some of the *p,p'*-quaterphenyl that is formed in the reaction had entered the extract, but separated out on evaporation. Formed biphenyl could be removed either by distillation or by chromatography from petrol ether on alumina, but it was not possible to separate *o,p'*-quaterphenyl from formed *o,o'*-quaterphenyl by either method, nor by fractional crystallization. However, when the mixture was very slowly crystallized from ethanol, the *o,o'*-compound formed large bipyramids, while the *o,p'*-compound crystallized as long, thin needles. By decanting off the stirred mixture, only the fine needles followed the liquid. The needles were allowed to settle, and the mother liquor decanted back. By repeating this procedure about 20 times, a quantitative separation could be effected. Yield: 0.9 g *o,p'*-quaterphenyl or 20 % of the theoretically possible total yield of quaterphenyls. Since the yield of *o,o'*-quaterphenyl is 1.1 g or 25 %, it is probable that the yield of *o,p'*-quaterphenyl may be increased by using more *p*-iodobiphenyl than *o*-iodobiphenyl.

The needles were recrystallized several times from acetone, giving large beautiful monoclinic crystals melting at 117.5—118 °C (as compared with 118.5 °C for the *o,o'*-compound). C and H content, as well as molecular weight, were in good agreement with calculated values.

Ultraviolet Absorption Spectra of *ortho*- and *para*-Linked Polyphenyls

JOHANNES DALE

Forsvarets Forskningsinstitutt, Kjeller, Norway

The electronic absorption spectra of biphenyl, *o*- and *p*-terphenyl, *o,o'*-, *o,p'*- and *p,p'*-quaterphenyl have been measured in solution down to 195 mμ. By adapting the pressed disk technique, good solid state spectra could be obtained with KCl down to 210 mμ. They are very similar to the solution spectra; the bands are broad and without structure. In oriented samples of the linear polyphenyls the "conjugation band" in the region 250—300 mμ is so reduced that a weak hidden transition at 275 mμ is revealed; this band does not move with chain length and shows vibrational structure. The strongest band in all spectra is found at about 205 mμ.

The observed bands have been tentatively interpreted, and factors of importance for the development of vibrational structure briefly discussed.

Interplanar angles in the solid state have been considered in relation to intermolecular forces which seem to favour mutually perpendicular orientation of ring planes in adjacent molecules.

An earlier study of the electronic absorption spectra of polyenes [1] led to the conclusion that all minor bands had to be interpreted as overtone transitions of the total chromophore and could hardly be due to independent partial chromophores, as had been suggested in some cases. It could also be shown that the minor bands correspond in wave length location with the main band of shorter chromophores of lengths equal to integral fractions of the chromophore considered, and that stereochemical factors determine the distribution of extinction value among the bands.

The principle was found to be valid even in more complicated systems. However, in the series of "through-conjugated" polyphenyls, which consist of chains of *ortho*- or *para*-linked benzene nuclei, the experimental material was rather meagre, since only the spectrum of biphenyl [2] was known below 210 mμ. For the terphenyls the spectra were complete above 210 mμ [3–5], but for *o,o'*- and *p,p'*-quaterphenyl only incomplete spectra have been reported [6,7]. For all these compounds, as well as for *o,p'*-quaterphenyl, the preparation of which

has been described in the preceding paper [8], the spectra have now been extended down to 195 mμ in solution and have been given as full curves in Fig. 1.

Since biphenyl and the *p*-polyphenyl molecules have been shown to be planar in the solid, crystalline state [9-12], and infrared spectroscopic evidence has been given in the preceding paper indicating that they are non-planar in solution [8], it was of interest to record also the spectra of the solids, as it would be expected that the degree of interaction between the π-electron systems of

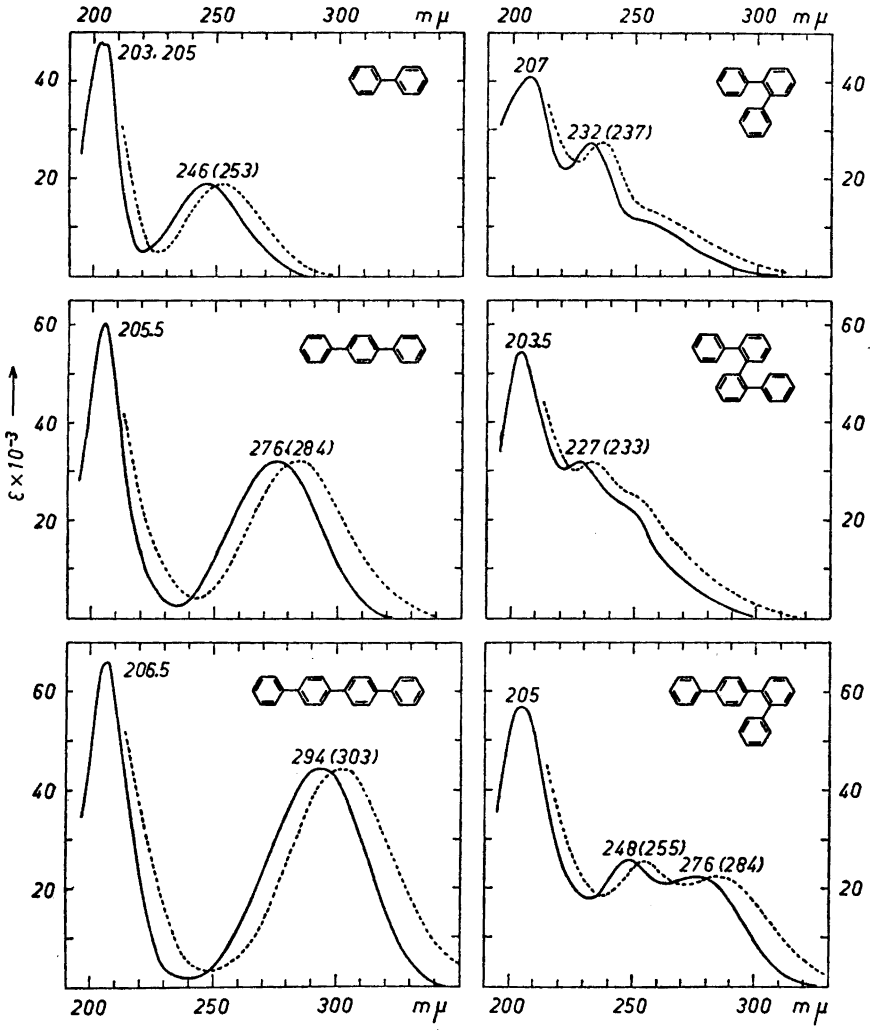

Fig. 1. Ultraviolet spectra of polyphenyls in hexane solution (full lines) and as pressed KCl-disks (dashed lines). The extinction scale of the latter curves is arbitrary.

the rings might be different and manifest itself as a spectral change. By adapting the well known KBr pressed disk technique developed for infrared spectroscopy [13], but using KCl instead of KBr, good qualitative spectra could be obtained down to 210 mμ, and have been given as dashed curves in Fig. 1. Unfortunately, reliable absolute extinction values could not be obtained, and the extinction of the main band has been arbitrarily set equal to its extinction in solution.

The most surprising feature of Fig. 1 is that there are no significant differences between solution and solid state spectra; just a normal, or slightly larger than normal, red-shift which increases with wave length in the same way as the red-shift observed with compounds like naphthalene and anthracene (see Experimental part), which obviously cannot assume other conformations in solution than in the crystal lattice.

VIBRATIONAL STRUCTURE

Another interesting result is that there is no indication of vibrational structure in the solid state spectra of the linear polyphenyls. It has been suggested by Merkel and Wiegand [14] that the lack of structure in the solution spectrum of biphenyl etc. is due to the non-planarity of the molecules, which would imply that vibrational structure should appear in the solid state if the molecules are then planar. The presence of vibrational structure is, however, a very doubtful criterion of coplanarity, as it is well recognized that when voluminous substituents occupy all four *ortho*-positions of biphenyl, the pronounced structure of the low intensity band of the unconjugated benzenoid chromophore is rather an indication that the rings are not coplanar [3,15], although each isolated chromophore is of course strictly planar. Since the broad, structureless appearance of the conjugation bands of the linear polyphenyls persists in the planar molecules of the crystal, whereas condensed aromatics show sharp structure both in solution and in the crystal, the explanation proposed by Kortüm and Dreesen [16] receives considerable support; these authors have emphasized that the appearance of vibrational structure is more a question of rigidity than of coplanarity of the molecules. In biphenyl the lack of structure was assumed to be connected with the possibility of low-frequency torsional oscillations of the rings against each other. This possibility is still present when the interplanar equilibrium angle is zero, since the double bond character of the "pivot bond" is rather small ($\sim$10 %), and this bond is therefore not very stiff even when the rings are coplanar. In polyenes the "single" bonds are much stiffer; hence, structure develops.

On the other hand, the great increase in vibrational structure of the main absorption band through the series *p*-polyphenyls → polyenes → polyynes might be explained alternatively by the rapidly decreasing number of normal vibrations of the right symmetry type that according to the Franck-Condon principle can be coupled with the electronic transition. For instance, quinoid polarization of a benzene ring would already be expected to excite three E_{2g} vibrations, which all involve appreciable percentages of CC-stretching [17] but have so different frequencies (1 595, 1 178, and 606 cm^{-1} in the ground state, and somewhat lower in the excited state) that the peaks may overlap each other

and the structure become blurred. In the transition responsible for the conjugation band of biphenyl and the *p*-polyphenyls the situation will of course be very much more complicated, since the electronic transition depends on the symmetry of the chromophore, that is, the whole molecule, whereas most of the vibrations are related to the symmetry of the separated ring in which they occur [8]. A very large number of different vibrations will therefore be coexcited.

The strongest transition of a polyene should mainly arouse one or several symmetrical C=C stretching modes, with frequencies just above 1 600 cm^{-1} in the ground state, since calculations by Kynch and Penney [18] show that the length of the "single bonds" remains almost unchanged during the transition, whereas the "double bonds" increase in length, especially the central ones. But also other modes of the same symmetry, classified as mainly CH-in-plane-deformations and with frequencies in the region 1 300—1 400 cm^{-1} [19], will probably involve much CC-stretching. The spacings 1 570 cm^{-1} and 1 230 cm^{-1} observed at low temperatures [20] agree well with these expectations, and are so close that peaks spaced at the average value of about 1 400 cm^{-1} are quite distinct under ordinary conditions.

In polyynes one or several symmetrical C≡C stretching frequencies at about 2 000 cm^{-1} will be the only ones that can be excited in an electronic transition which preserves the linear shape of the molecule. This explains the enormously sharp peaks in these spectra [21].

The above statements are not contradicted by the very sharp structure of the well known and weak 260 mμ band of benzene, because this forbidden transition, $^1A_{1g} \rightarrow {}^1B_{2u}$, is of a symmetry type [22] which will arouse strongly only the breathing frequency at 923 cm^{-1} in the excited state, neglecting the single quantum of the E_{2g} vibration at 520 cm^{-1} which is necessary to deform the skeleton and make the transition possible.

However, it is most likely that for the development of structure both these factors must be considered of importance: a rigid structure; and relatively few vibrations, or several with close-lying frequencies, that can couple with the electronic transition. This is equivalent to saying that the normal vibrations should depend on the symmetry of the whole chromophore.

REVELATION OF HIDDEN TRANSITIONS

The lack of structure in the spectrum of solid biphenyl as pressed KCl-disk would seem to be in conflict with the qualitative statement by Merkel and Wiegand [14] that sharp peaks appear in the spectrum of biphenyl crystals*. However, in view of the marked orientation effects observed with the linear polyphenyls in the infrared (*cf.* preceding paper [8]), one should expect that, also in the ultraviolet, bands that are due to transitions with dipole moment along the long molecular axis, such as the strong conjugation band, would disappear in the spectra of thin layers of solidified melts or sublimed crystals, so that weak bands which are transversely polarized, and normally hidden

* The banded absorption at 300—330 mμ, observed in thin crystal plates of biphenyl [23], is so extremely weak that it must be due to some singlet-triplet transition, and is of little interest in this connection.

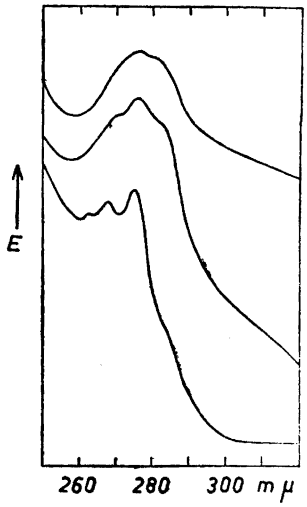

Fig. 2. Ultraviolet spectra of oriented solid samples of linear polyphenyls; bottom, biphenyl; middle, *p*-terphenyl; and top, *p,p'*-quaterphenyl. Incident radiation is parallel to the long axis of the molecules.

by the stronger band, may be detected. This could be confirmed experimentally, either by letting an extremely thin film of melted substance ($< 1\ \mu$) solidify between silica plates; by evaporation of a thin layer of solution; or by sublimation on to a silica window. The absorption curves of oriented samples of biphenyl and the linear polyphenyls are shown in Fig. 2 and reveal that there is a band showing structure with a maximum at about 275 mμ for all compounds. Although the extinction coefficients could not be determined exactly, they may be very roughly estimated to about 1 000—2 000. These values are reasonable, since appreciably lower values would not be sufficient to let this band protrude from the rudiments of the strong band, which, at least for longitudinally polarized bands in the infrared, amounts to about 5 % of the full value [8]. The extinction coefficient, which for biphenyl is 19 000, would thus be reduced to about 1 000.

The 275 mμ band can scarcely be due to the forbidden transition, discussed by Platt [2], between a localized π-orbital with a longitudinal node and a polyene-like orbital (see below). This transition has been assumed by Platt to be hidden by the conjugation band and predicted to move towards the red about half as fast upon lengthening of the system, whereas the 275 mμ band remains stationary throughout the series. Rather, it may be related to the forbidden 260 mμ transition in benzene, as already suggested by Wenzel [24] for the hidden transition in biphenyl, and for which she deduced, from a comparison with substituted biphenyls, position and intensity in good agreement with the present findings. Correcting for the "normal red-shift", the location of the peaks of biphenyl corresponds very well with the peaks of a mono-substituted benzene ring like toluene [5]. The less resolved structure and very slight red-shift in *p*-terphenyl and *p,p'*-quaterphenyl is presumably due to overlapping of similar bands arising from *p*-disubstituted rings, since the peaks in the *p*-xylene spectrum [5] are shifted to the red as compared with toluene. According to the ideas outlined above, the presence of structure in

this band can also be taken as an indication that the transitions occur within each isolated rigid ring, rather than as an indication of coplanarity of the rings.

The conjugation band can also be weakened, and shifted to shorter wave lengths, by providing large deviations from coplanarity, so that the weak hidden transition in each ring may be revealed. The well-known effect of large alkyl-substituents in the *ortho*-positions of biphenyl is an example of this [3]. Furthermore, in the vapour phase [25] the angle of twist is as large as 45°, and the hidden transition is probably identical with the structureless absorption tail that appears in the gas spectrum [26] at around 270 mμ. The lack of structure, the broadening towards the red, and the increase in intensity with temperature (170—520° C), may be explained by the increased population of vibrational levels in the ground state. Some of the vibrations destroy the hexagonal symmetry of each ring so that the electronic transition becomes allowed.

INTERPLANAR ANGLES

The displacement towards the ultraviolet and the weakening of the conjugation band must be related to the reduced electronic interaction when the interplanar angle is increased. According to calculations by Guy [27] this angle of twist may become as large as 22° before the resonance energy is appreciably reduced, and somewhere between 45 and 68° before it reaches zero. Since the spectra of solids and solutions are so similar, one should therefore expect that the interplanar angle of biphenyl in solution would not exceed much the value of 22°. The values of +34°, —27° and +24° reported for solid 1,3,5-triphenylbenzene [28] are surprisingly large, since the steric repulsion between *ortho*-hydrogen atoms should be the same as in biphenyl. Moreover, both molecules have angles of twist near 45° in the vapour phase [25, 29]. The planar structure of solid biphenyl and the *p*-polyphenyls is not immediately understandable as being necessary to obtain the most favourable packing, because the molecules are in fact rather loosely packed, having their planes not parallel, which would give the densest packing, but mutually inclined at an angle of approximately 66° [9, 11]. On the other hand, the molecules of solid 1,3,5-triphenylbenzene form an approximately layer arrangement [28], and in this case planar molecules would obviously have been able to pack more densely.

A simple explanation can be arrived at by assuming that intermolecular forces operate in such a way that aromatic hydrocarbon molecules tend to avoid being stacked with their planes parallel, and instead prefer mutually perpendicular orientation. Whether these forces are simply repulsive forces between filled π-orbitals, or some sort of bonding forces between hydrogen atoms and π-electrons, is irrelevant for the present discussion. The crystal structure of benzene [30] most strikingly demonstrates this feature; adjacent molecules have their planes mutually perpendicular and form a loosely knit structure. More elongated molecules like naphthalene and anthracene also have their planes tilted away from each other, but at somewhat smaller angles [31]. It will now be easily realized that the planar conformation of *p*-polyphenyl molecules is best suited to obtain a relatively large inclination angle between the ring planes of adjacent molecules with a minimum of empty space between the molecules.

The larger disk-like molecules, like coronene and ovalene [31], cannot be packed in this manner, because too large voids would result. Instead, they are stacked in columns, but the molecules of adjacent columns still have their planes perpendicular to each other. In 1,3,5-triphenylbenzene, packing of mutually perpendicular molecules would be very awkward and lead to an excessively loose structure. The molecules therefore have to form roughly planar layers [28], but phenyl groups of each layer can be twisted about the pivot bond to make fairly large angles with the planes of phenyl groups in the next molecular layer twisted in the opposite sense. In this way the curious crystal structure, the large and dissimilar angles of twist, and the lack of perfect cleavage parallel to the molecular layer planes can be understood. The apparent strength of the intermolecular forces in the crystal suggests that the angles of twist may even be smaller in solution than in the solid for this compound.

In *o*-terphenyl the angle between adjacent ring-planes is 45—50° in the solid [32], and increases to very roughly 90° in the vapour phase [33]. Considering the spectral similarity, the angle at *ortho*-links in solution most likely is not much larger than in the solid. However, this conclusion concerning one state, the ground state, based entirely on the ultraviolet spectrum, which involves two states, is presented with much reserve.

EMPIRICAL CLASSIFICATION OF THE BANDS

Several authors have calculated the energy levels of biphenyl and the *p*-polyphenyls [34–38], but their results will not be discussed here. The present approach will instead be limited to correlations of a more qualitative nature.

The strongest band in the spectra of all the polyphenyls investigated appears at around 205 mμ. According to Platt [2], transitions between localized π-orbitals within each mono- and *p*-disubstituted benzene ring, that is, orbitals which have a longitudinal node and thus cannot conjugate with adjacent rings to form polyene-like whole-molecular orbitals, would be expected to give rise to intense absorption in this region. This is then a band for which the term "partial" is certainly justified.

The long-wave absorption bands, except weak bands like the hidden transition in biphenyl, which will not be further considered, should originate from transitions between whole-molecular, polyenelike π-orbitals made up from ring orbitals with no longitudinal node [2], and are the bands to be considered when testing the validity of the empirical rule established for polyene spectra [1]. At *ortho*-links the molecular orbital picture will not be so simple, and, of course, there will be a great steric hindrance preventing coplanarity, so that the electronic interaction will be reduced, and a blue shift of all bands might be expected.

When trying to correlate the bands, the wave length position of the main band of the linear polyphenyls must be plotted against number of linked chain nuclei. The question then arises which value should be used for benzene. The strongest band of benzene is at 185 mμ [5], but there are reasons for using a value of about 205 mμ; on the one hand, because this medium intensity band in benzene fits best with the value obtained from extrapolation of wave length

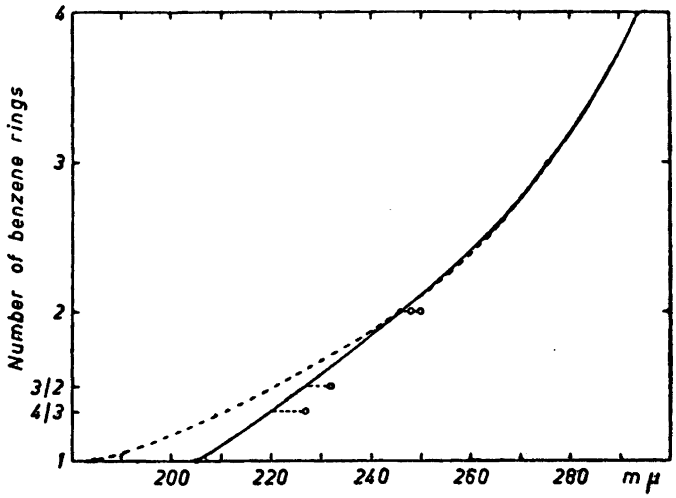

Fig. 3. Wave length position of the "conjugation band" of linear polyphenyls plotted against number of benzene rings. Dashed curve is obtained by using an alternative value for benzene. Positions of assumed overtone bands of non-linear polyphenyls have been indicated as circles; horizontal lines give the deviation from estimated values.

position and intensity of the conjugation band of *p*-polyphenyls [24]; on the other hand, because it happens to be the center of gravity of the four one-quantum transitions which are assumed to arise from strong splitting due to the high symmetry of benzene [39]. In Fig. 3 both values have been used in drawing the lines used for calculation. Experimentally observed wave lengths for assumed overtone bands have been given as circles, and are seen to come closest to the 205 mμ curve.

Considering the linear polyphenyls first, it is seen that there are here no overtones, and none would be expected either in such a strictly linear chain, except possibly a weak λ_3-band in *p,p'*-quaterphenyl. The band at 205 mμ may in part be due to the overtone transition corresponding to one benzene ring in all compounds, that is, λ_2 for biphenyl, λ_3 for terphenyl, and λ_4 for quaterphenyl; it may be of special preference, since there would be no displacement of electron density from one ring to the other during excitation [1, 40].

In *o*-terphenyl the step-out at around 260 mμ may be regarded as a λ_1-band which is reduced in intensity and shifted to shorter wave lengths because of the bent shape and steric hindrance. The λ_2-band at 232 mμ is correspondingly stronger since it is allowed in this bent molecule and takes over much of the intensity.

In *o,p'*-quaterphenyl the bands at 276 and 248 mμ are similarly interpreted as λ_1- and λ_2-bands, respectively. A λ_3-band should be of no special preference, and is not observed.

In *o,o'*-quaterphenyl it is necessary to assume that the λ_1-band is so degraded because of the many sterically hindered links and the kinked shape, that it is represented by the absorption tail in the 270—290 mμ region. In a hypo-

thetical coplanar *trans*-conformation the λ_2-band would be forbidden, but as the molecule cannot become planar, it will be weakly allowed. The observed shoulder at 250 mμ is in good agreement with this expectation. A *cis*-like conformation would require a strong λ_2-band, so it is believed that the molecule has a *trans*-conformation both in solution and in the solid phase. This conclusion is supported by the lack of significant differences between the two states both in the ultraviolet and the infrared [8] absorption spectra. The λ_3-band would be strongly allowed, and would also have to take over intensity from the hindered transitions; it fits well with the strong band at 227 mμ.

Also for the non-linear polyphenyls one would expect an overtone band to coincide with the partial band at 205 mμ.

Admittedly, the agreement between the graphically estimated and the observed wavelength maxima is only qualitative, but certainly better than might be expected considering the complexity of these branched π-electron systems. However, one should be cautious and not attach too much theoretical significance to this result, but consider it only as an empirical classification. It is noteworthy that the spectra might in this way be interpreted in a more satisfactory manner than by postulating partial chromophores consisting of 1, 2 or 3 benzene rings. Much more convincing material, illustrating the success of the "overtone" interpretation and the failure of the "partial chromophore" concept, will be presented in a later paper on the spectra of conjugated chains consisting of alternating ethylenic bonds and benzene nuclei (stilbene homologs).

EXPERIMENTAL

The preparation or origin of the compounds studied has been given in the preceding paper [8].

The *solution spectra* were recorded in a Beckman DK-1 instrument using hexane as a solvent. In the lowest wave length region 2 mm silica cells were used.

The *solid state spectra* were measured in a Beckman DU instrument. The disks were pressed under vacuum in the usual manner, but were of only half the ordinary thickness. Since KBr starts to absorb appreciably below 240 mμ, KCl was tried and found useful throughout the whole range of the instrument. Disks of 0.55 mm thickness made from 150 mg KCl (Merck, *p. a.*), which had been precipitated from water solution with hydrochloric acid to obtain small particle size [41], showed a transmission of around 75 % at 400 mμ, 65 % at 300 mμ, 55 % at 250 mμ, 40 % at 220 mμ, and 25 % at 205 mμ. Using KCl which had been melted and rapidly cooled [42], the transmission was still better, namely 80 %, 75 %, 65 %, 55 %, and 40 %, respectively, at the corresponding wave lengths (*cf.* Ford and Wilkinson [43]). However, it was easier to get the organic substance evenly dispersed in the precipitated salt, so that the loss by scattering was much smaller, and this grade was used throughout. Usually, about 1 mg of the substance was thoroughly ground in a mortar with 200 mg KCl, preferably with a small amount of a volatile solvent. 1 mg of the dry mixture was then ground with 150 mg of new KCl, and pressed into a disk. Unfortunately, the extinction values were not reproducible. The loss of the more volatile compounds like biphenyl, and even the terphenyls, during grinding and evacuation of the press, was so great that a considerable excess of substance had to be weighed in. However, the wave length position of the extinction maxima could be reproduced as long as the disks looked clear to the eye. The spectra of disks which became slightly milky because of imperfect dispersion of the substance, showed distortion of the bands with a slight shift of the maxima (Christiansen effect) like what is very often observed in the infrared with non-transparent disks and, particularly, with mineral oil mulls [43,44].

The *normal red-shift* of rigid molecules, from hexane solution to the solid state, was determined by measuring the solid state spectra of naphthalene and anthracene (wave lengths are in mμ; values in parentheses refer to hexane solutions):

Naphthalene: 292(285), 281(275), 272(267), 223(221).

Anthracene: 394(376), 373(357), 353(339), 336(324), 318(309), 256(252), 249(246).

When the differences are plotted against wave length, the red-shift is seen to increase regularly from about 2 mμ at 220 mμ to 8 mμ at 300 mμ, and to 19 mμ at 400 mμ.

An Addendum to the Henri-Michaelis Mechanism

J. A. CHRISTIANSEN

Institute of Physical Chemistry, University of Copenhagen, Denmark

It is shown that in an enzymic reaction obeying the Henri-Michaelis law the existence of an inactive form with low energy content of the enzyme-substrate complex must exist besides the active, energy-rich form.

The Henri-Michaelis mechanism [1-3] can be written in the form

$$A + X_1 \rightleftharpoons X_2 \quad (\pm 1)$$
$$X_2 \rightarrow X_1 + B \quad (2)$$

where the stoichiometric equation of the overall reaction is A = B.

As pointed out by Haldane and Briggs [4], Michaelis in his original treatment of the reaction makes the error of assuming equilibrium as regard to (±1) which is obviously untrue, if the rate of reaction is not zero.

Application of the steady-state method yields, with s for steady state rate, X_1 for $[X_1]$, x_2 for $[X_2]$ and w_i for the probability of reaction i in unit time:

$$x_1/s = 1/w_1 + w_{-1}/w_1w_2 \quad (3)$$
$$x_2/s = 1/w_2 \quad (4)$$

or as $x_1 + x_2$ = total enzyme concentration = E,

$$E/s = (1 + w_{-1}/w_2)/w_1 + 1/w_2 \quad (5)$$

According to the mechanism $w_1 = k_1(a—x)$; $w_{-1} = k_{-1}$; $w_2 = k_2$, where $a—x = [A]$ at time t.

$$E/s = 1/k_2 + (1+k_{-1}/k_2)/k_1(a—x) \quad (6)$$

which of course agrees exactly with Haldane and Briggs' result.

Replacing $1/k_2$ by A_0 and $(1+k_{-1}/k_2)/k_1$ by A_1 and $1/s$ by dt/dx we get by integration

$$Et = A_0x + A_1 \ln a/(a—x) \quad (7)$$

where $A_1/A_0 = K_m$, the Michaelis constant. (The symbol K_m is due to Henri). Obviously

$$(k_2 + k_{-1})/k_1 = K_m \quad (8)$$

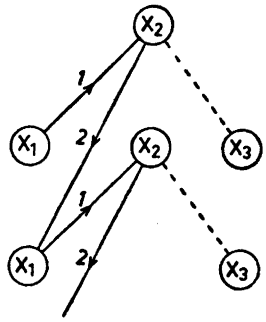

Fig. 1.

A number of enzymic reactions but by no means all yield experimentally an expression of the type (7). (It is convenient to denote the function on the right hand side of (7) by the name a chronometric integral.) Therefore a A_0 and A_1 must in these cases be of the same order of magnitude. This however is impossible if the reaction has an activation-energy. In that case the diagram of the reaction must be qualitatively as in Fig. 1.

The encircled symbols represent the "states" of the enzyme. The system proceeds along the path indicated by arrows. Vertical distances indicate qualitatively energy differences. Particularly the vertical distance between two consecutive X_1's indicates the loss of (free) energy during the reaction. Now from a well known theorem a reaction proceeding from a lower to a higher energy level has an activation energy while its reverse has none.

Further unimolecular and bimolecular rate-constants are known to be, within a few powers of ten, $10^{12} \times \exp(-Q/RT)$ sec^{-1} and $10^{11}\exp(-Q/RT)$ litre $mole^{-1}$ sec^{-1}, respectively. Therefore $1 + k_{-1}/k_2 \simeq 1$ and $k_1 a \simeq 10^9 \exp(-Q/RT)$ if $a \simeq 10^{-2}$ mole/litre. Consequently $A_1/a \simeq 10^{-9} \times \exp(Q/RT)$ sec and $A_0 \simeq 10^{-12}$ sec, that is A_0 is disappearingly small as compared to A_1/a or the reaction must be expected to be purely of the first order. If in the diagram X_2 were placed below the lower X_1 the result would be a reaction of the zeroth order.

To make $A_0 a$ and A_1 comparable it is necessary to add a reaction of the type indicated in Fig. 1 by dotted lines

$$X_2 \rightleftharpoons X_3 \qquad (\pm 3)$$

whose steady state rate is zero. (± 3) means that we assume the existence of an isomer X_3 of X_2 with a low energy-content. We now have

$$x_1 + x_2 + x_3 = E \tag{9}$$

and $x_3 = K_3 x_2$, where K_3 is large ($\simeq \exp Q_3/RT$)

$$x_1 + x_2 (1 + K_3) = E \tag{10}$$

Using (3) and (4) we thus get instead of (5)

$$E/s = (1 + w_{-1}/w_2)/w_1 + (1+K_3)/w_2 \qquad (11)$$

or

$$A_0 = (1 + K_3)/k_2;\ A_1 = (1 + k_{-1}/k_2)/k_1 \qquad (12)$$

where evidently K_3/k_2 may very well be of the same order of magnitude as $1/k_1a$.

This extension of the original picture is new but it has probably existed implicitly in the minds of the originators of the theory. It means simply that the greater part of the enzyme-substrate complex does exist in appreciable amounts in the solution but that only a minute fraction of it is active in reaction (2).

It should be added, that Huennekens [5] (p. 606) discusses a mechanism in which three forms of the enzyme-substrate complex are assumed. But these are connected in series, while in our case one of the two forms is branched off from the main closed sequence. The two assumptions (a reaction in series *versus* a branched sequence) lead to quite different kinetic expressions and only the latter one to a natural explanation of the actual occurrence of reactions of the Michaelis-type.

Gibson [6] assumes four different forms, two with high energy content and two with low but a discussion even of this rather complicated case along the lines indicated above and in former papers [3,7] by the present author again shows that K_m/a in cases where the rate depends strongly on temperature will be either very large in which case the reaction is of the first order, or very small in which case the reaction is of the zero'th order. Incidentally, the present author completely agrees with Gibson in his statement, that activation energies calculated from rate-data for reactions whose mechanism has not been unravelled have no physical significance, compare for example Ref.[8].

Thus again in contrast to the assumption that energetically different forms of the enzyme-substrate complex are inserted in series, the assumption that one (or several) of the forms is branched off from the main closed sequence leads to a natural explanation of the frequent occurrence of reactions obeying the Michaelis law.

Alkaline Hydrolysis of Glycosidic Linkages

II.* Investigation of Cellobitol, Lactitol and Maltitol

ELISABETH DRYSELIUS, BENGT LINDBERG and OLOF THEANDER

Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

The hydrolysis of cellobitol, lactitol and maltitol in alkaline, aqueous solutions at 170° has been studied as part of an investigation of the decomposition of carbohydrates during alkaline pulping. All substances were hydrolysed at roughly comparable rates. D-Glucitol, 1,4-anhydro-D-glucitol and levoglucosan were formed from cellobitol, the first two together with 1,6-anhydro-D-galactose were formed from lactitol. Another, isomeric glucitol β-glucoside was formed from cellobitol and an analogous β-galactoside from lactitol.

It was briefly reported in Part I * that some glycosides, such as methyl β-glucoside and cellobitol, although generally considered to be stable to alkali, were decomposed under the conditions of sulphate or soda cooking, *e. g.* in alkaline solution at 170°. In the present paper a more detailed investigation of some glucitol glycosides is reported.

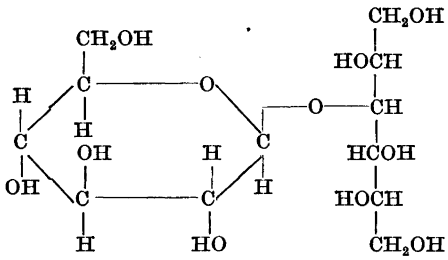
Cellobitol, lactitol and maltitol were prepared from the corresponding disaccharides by reduction with sodium borohydride [1]. Cellobitol was obtained in a crystalline state, anhydrous, m. p. 149—150°, $[\alpha]_D^{20}$ + 8°, and with one mole of water of crystallisation, m. p. 107—108°. The previously recorded m. p. is 133° [2], which might indicate that the sample investigated consisted of a mixture of the two forms above. Lactitol and maltitol were obtained as syrups.

The glycosides were dissolved in 10 % aqueous sodium hydroxide and heated in stainless steel autoclaves at 170° for various times. The alkali, together with the acids formed during the reaction, was removed by ion exchange and the yield of non-ionic material, a mixture of starting material and the products of reaction, was determined. The yields are given in Table 1. If the glucitol glycosides were completely degraded into glucitol and acidic products, the final yield should be 53 %.

* Part I, *Svensk Papperstidn.* **59** (1956) 531.

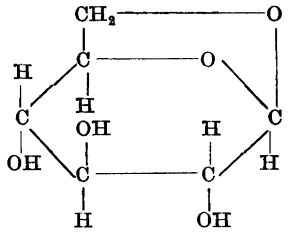
Table 1. Yield of non-ionic material, in percentage of starting material, after treatment of cellobitol, lactitol and maltitol with 10 % sodium hydroxide at 170°.

Time, h	Cellobitol, yield	Lactitol, yield	Maltitol, yield
5	73	86, 92	85, 93
24	65	61	60
48	49	53	45



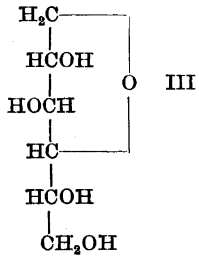
Due to mechanical losses, difficulties in drying the amorphous starting materials and products and to imperfect temperature control, the values in Table 1 are not very accurate, but they show that all the substances have been degraded to a considerable extent and at rates that are of the same order of magnitude.

A chromatographic investigation of the products from the cellobitol (I) revealed the presence of unchanged starting material, a substance with the same R_F-value as glucitol and of two substances with higher R_F-values. The product was fractionated on a cellulose column and the pure components were isolated. The substance with the highest R_F-value was identified as levoglucosan (II), the next as 1,4-anhydro-D-glucitol (arlitan) (III); both substances were identical with authentic specimens. The D-glucitol and cellobitol were also characterised. A small amount of material with an R_F-value slightly faster than that of cellobitol was also obtained.



Analogous or identical substances were obtained from lactitol, that is 1,6-anhydro-D-galactose, 1,4-anhydro-D-glucitol, D-glucitol, unknown material and unchanged starting material. The presence of glucitol and 1,4-anhydro-D-glucitol in the products obtained from the maltitol was demonstrated by paper chromatography.

The stability to alkali of the substances formed was investigated. Faint traces of 1,4-anhydro-D-glucitol and another substance with somewhat lower R_F-value, possibly 1,5-anhydro-D-glucitol (polygalitol) could be observed after treatment of D-glucitol with 10 % sodium hydroxide at 170° for 24 h. Some D-glucitol was also formed when 1,4-anhydro-D-glucitol was given an analogous treatment. Levoglucosan and 1,6-anhydro-D-galactose were more labile. The yield of non-ionic material, in this case consisting of pure starting material, decreased rapidly with the time of treatment in alkali. The percentages of unchanged levoglucosan after 1, 3 and 5 h in 10 % sodium hydroxide at 170° were 58, 35 and 25, respectively. The corresponding figures for 1,6-anhydro-D-galactose were 85, 69 and 53 % after 2, 4 and 6 h, respectively. Thus these anhydrides are considerably more labile than the glucitol glycosides and the percentage present in the reaction mixtures should consequently be quite low. As levoglucosan is the most labile of the two, it should be present in the lowest concentration, as was the case.



Levoglucosan and 1,6-anhydrogalactose are also formed by the alkaline hydrolysis of phenyl β-glucosides and β-galactosides, respectively. These reactions involve the intermediate formation of a 1,2-anhydrosugar (*cp.* Ref.[3]),

I

II

III

and it is possible that the alkaline hydrolysis of cellobitol and lactitol follows a similar route. As 1,4-anhydro-D-glucitol is formed in a higher yield in these reactions than in the analogous alkaline treatment of D-glucitol, it is evident that this is not the only mechanism by which the glycosidic linkage is cleaved. A reasonable assumption is that the 1,4-anhydro-D-glucitol is formed by a nucleophilic attack on $C_{(4)}$ of the primary hydroxyl at $C_{(1)}$ (as alkoxide) in the glucitol unit. This reaction may be preceded by the formation of an ethylene oxide ring either between $C_{(4)}$ and $C_{(5)}$ or between $C_{(3)}$ and $C_{(4)}$; of these alternatives the former appears to be the more plausible.

Fission between the glycosidic oxygen and $C_{(1)}$ in the glucose unit should therefore yield 1,6-anhydrosugar and glucitol, fission between this oxygen atom and C_4 in the glucitol unit, on the other hand, should yield glucose and 1,4-anhydro-D-glucitol. A direct attack of hydroxyl ion, either on $C_{(1)}$ in the glucose unit or on $C_{(4)}$ in the glucitol unit, should give glucose and glucitol. The glucose, of course, is rapidly decomposed into acidic products under the experimental conditions. No formation of levoglucosan from maltitol was observed, which is in agreement with the mechanism postulated; however, a small amount of this substance could easily have escaped detection.

As mentioned above, a substance moving only slightly faster on the paper chromatogram than the starting material was obtained in a low yield both from cellobitol and lactitol. The substance from cellobitol was obtained chromatographically pure and on hydrolysis yielded glucose and glucitol, identified by paper chromatography in various solvent. The specific rotation was low, $+20°$, indicating a β-glucosidic structure. The substance therefore should be a D-glucitol β-D-glucoside, isomeric with cellobitol. Analytical periodate oxidations did not give further information about its structure, as the substance

was obviously not pure. The substance from the lactitol cook was obtained chromatographically pure and on hydrolysis yielded galactose and glucitol, identified chromatographically. The formation of these substances is of considerable interest and demonstrates the possibility of transglycosidation reactions during alkaline pulping. Transglycosidations during alkaline treatment of phenyl glycosides are known [3] and have recently been further illustrated [4]; they most probably proceed *via* the 1,2-anhydrosugar. The present case seems, however, to be the first observation of a reaction of this type, starting from an alkyl glycoside.

EXPERIMENTAL.

All melting points are corrected. All evaporations were carried out under reduced pressure. Optical rotations were determined in aqueous solutions, $c \simeq 2$.

Chromatography. Whatman No. 1 and 3 MM filter papers and Whatman ashless cellulose powder, standard grade, were used.
Solvent systems: A. Methyl ethyl ketone, saturated with water.
B. Ethyl acetate-acetic acid-water, 3:1:1.
Developers: Silver nitrate-sodium hydroxide and, for the reducing sugars, anisidine hydrogen chloride.

Preparation of the glucitol glycosides. Cellobitol, lactitol and maltitol were prepared from the corresponding disaccharides by reduction with sodium borohydride following the procedure of Abdel-Aker *et al.*[1]. After deionisation, the boric acid was removed by repeated distillations with methanol. Lactitol and maltitol were obtained as syrups. Crystallisation of cellobitol from methanol yielded the anhydrous substance, m. p. 149–150° $[\alpha]_D^{20}$ +8°. By crystallisation from aqueous ethanol it was obtained with water of crystallisation, m. p. 106–108°. After drying in a vacuum at 75° over phosphorus pentoxide, the loss in weight corresponded to 1 mole water per mole cellobitol.

Alkaline treatment, procedure. A known amount of substance was dissolved in 7–10 parts of 10 % aqueous sodium hydroxide and transferred into a stainless steel autoclave. The air was replaced with nitrogen and the autoclave heated at 170° for various times. The heating was performed either in a gas-heated oil bath (shorter reaction times) or in an electrically heated oven. The cooled solution was then filtered through a column, prepared from equal parts of the ion exchange resins Amberlite IR 120 and Dowex 2, in the hydrogen and hydroxyl state, respectively. The eluate and washings were concentrated to dryness and weighed. The yields of non-ionic products which were obtained from cellobitol, lactitol, maltitol, levoglucosan and 1,6-anhydro-D-galactose after alkaline treatment for various times are given in the account above.

Products from the alkaline treatment of cellobitol. Anhydrous cellobitol (8.56 g) was dissolved in 10 % aqueous sodium hydroxide (50 ml), kept at 170° for five hours and worked up as described above. The yield of non-ionic material was 6.24 g. Unchanged starting material (5.1 g) was recovered by crystallisation from 90 % aqueous ethanol. The material from the mother liquors (1.00 g) was fractionated on a cellulose column (20 × 4.5 cm), using solvent system B as eluant. The following fractions, listed in the order in which they eluted from the column, were obtained.

a. Levoglucosan, 33 mg. Recrystallisation from ethanol yielded the pure substance, m. p. 178–180°, undepressed on admixture with authentic material.

b. 1,4-Anhydro-D-glucitol, 475 mg. The substance was further purified by recrystallisation from ethanol. M. p. 116–117°. $[\alpha]_D^{20}$ −22°. The substance was indistinguishable from an authentic sample, prepared according to Soltzberg, Goepp and Freudenberg [5].

c. D-Glucitol, 209 mg. M. p. after recrystallisation from ethanol, 96–97°. The acetate was also prepared, m. p. 101–102°, undepressed on admixture with an authentic sample.

d. Unknown + cellobitol, 76 mg.

e. Cellobitol, 277 mg.

The unknown substance in fraction *d* was further purified by chromatography on thick filter paper, using solvent system B. It had an R_F-value slightly higher than that of cellobitol. The chromatographically pure substance (25 mg) on hydrolysis yielded glucose and glucitol, as identified by paper chromatography. The amorphous product had $[\alpha]_D^{20}$ + 20° and on periodate oxidation with 0.03 N sodium metaperiodate solution rapidly consumed about 7.1 moles of periodate with the formation of 2.7 moles of formic acid. These results would not be expected from a pure hexitol glycoside and indicate that the substance was not pure.

Products from the alkaline treatment of lactitol. Lactitol (2.80 g) was treated with 10 % aqueous sodium hydroxide at 170° for 5 h and worked up as described above. The non-ionic products (2.37 g) were fractionated on a cellulose column, (27 × 4.5 cm), using solvent system A as eluant. The following fractions, listed in the order in which they were eluted from the column, were obtained.

a) 1,6-Anhydro-D-galactose, 0.18 g. The substance was purified by recrystallisation from ethanol. $[\alpha]_D^{20}$ −22°, m. p. 224−226°, undepressed on admixture with an authentic sample.

b) 1,4-Anhydro-D-glucitol (0.18 g). M. p. 116−117°, after recrystallisation from ethanol.

c) Glucitol, 0.40 g.

d) Lactitol, 1.49 g.

The lactitol contained small amounts of a substance with slightly higher R_F-value, which was isolated by chromatography on thick filter paper. It yielded galactose and glucitol on hydrolysis but was not further investigated.

Separation of Mucopolysaccharides on a Cellulose Column

SVEN GARDELL

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

A column technique is described for the separation of mucopolysaccharides by fractional elution with alcohol.

The method has been applied on amounts from 10 mg up to 4 g of material.

The separation of mucopolysaccharides from nucleus pulposus and from cornea as well as the separation of chondroitinsulfuric acid and heparin monosulfuric acid is described.

Fractional precipitation from an aqueous solution with organic solvents is the most commonly used technique for the separation of the components of a mixture of polysaccharides. Sometimes clearcut separations can be obtained by varying the pH and the ionic strength and by adding metal ions such as calcium, barium or lead. In the majority of cases, however, and especially if the polysaccharides are closely related, the separation of the different types of polysaccharides is a tedious procedure. In spite of repeated precipitations and washings it is seldom possible to achieve complete separations. Moreover, the fractional precipitation methods can only be applied on a rather large scale, a drawback, which makes such methods of very limited value in metabolic studies in which frequently minute amounts of material have to be separated in pure form.

In such cases electrophoretic methods have been used (Boström and Gardell [1], Dorfman *et al.*[2]). However, these methods can be used only in such cases where a distinct difference in electrophoretic mobility exists, *e. g.* between hyaluronic acid and chondroitinsulfuric acid.

The use of partition methods is restricted mainly because of lack of suitable pairs of liquids. In a few cases this difficulty has been overcome by the use of "carriers" such as fatty amines [3–5]. The paperchromatographic separation of heparin and chondroitinsulfuric acid has also been reported [6].

Fractionation can also be obtained by a column technique, in which the column is used mainly as a carrier for the material to be separated. These are selectively brought into solution and eluted from the column by stepwise or

gradual changes in the composition of the eluting solvent. This principle has been used by Desreux and Ghauysen [7] for the separation of nucleic acids and by Zahn and Stahl [8] and recently by Zittle and Della Monica [9] for the separation of proteins.

In this work closely related acid mucopolysaccharides have been separated on a cellulose column by means of fractional or gradient elution. Ethanol of varying concentrations together with barium acetate has been used as the eluting solvent. The method has been applied on a micro scale as well as on preparative scale.

EXPERIMENTAL

Preparation of the column. Columns of different sizes are prepared from Whatman cellulose powder *. A suitable quantity of the powder for the preparation of a 20 cm long column is mixed with water to a rather thin slurry. This mixture is poured into a suction flask care being taken that the flask is not filled to more than one fifth of its total volume. The flask is connected to a water pump and gently rotated during evacuation. In this way most of the air present in the cellulose is removed, a procedure which greatly facilitates the even packing of the column.

The slurry is then poured into a chromatographic tube and allowed to settle to constant height. About one bed volume of water is then passed through the column with air pressure of 30—40 cm Hg. After washing with water under hydrostatic pressure of about 2 m until no carbohydrate can be detected in the effluent, the column is equilibrated with 80 % ethanol containing 0.3 % barium acetate.

Preparation of the sample. The polysaccharide mixture to be separated is dissolved in a 0.3 % aqueous solution of barium acetate. A solution containing about 10 % of the polysaccharide mixture is prepared.

Addition of the sample to the column. About 0.5 ml of the polysaccharide solution per cm^2 of cross section area of the column is added on top of the latter and allowed to drain in slowly. The walls of the tube are then washed with a small amount of 0.3 % barium acetate.

Elution of the material. The elution of the material from the column can be accomplished either by the use of ethanol in stepwise decreasing concentrations or by an arrangement where it is possible to decrease the ethanol concentration continuously. In the latter procedure the effluent is collected by means of a suitable fraction collector.

In both cases the column is first washed with at least three bed volumes of 80 % ethanol containing 0.3 % barium acetate in order to ascertain complete precipitation of the material on top of the column. With this washing little or no carbohydrates appears in the effluent.

In order to find the best conditions for a stepwise elution, *i. e.* the concentration of alcohol and the volume in each step, it is advisable to make a preliminary run. In such a run a suitable difference in ethanol concentration in the elution solvents between each step would be 5 %. A volume of three to four bed volumes is sufficient.

In the case of a continuous decrease of the ethanol concentration a suitable gradient is also chosen on the basis of a preliminary run either stepwise or made with an arbitrarily chosen gradient.

The concentrations and volumes as well as the concentration gradients used in actual experiments are given below.

The flow rate through the column must not exceed 5—10 ml per h per cm^2 cross section area of the column.

Analyses of the fractions. The fractions can be treated according to the purpose of the experiment. In general a qualitative or quantitative carbohydrate reaction is performed on the fractions.

* Whatman cellulose powder standard grade obtained from W. and R. Balston Ltd, England.

In the present investigation the carbazole [10] and the cysteine [11] reactions of Dische were carried out. Column chromatography of aminosugars [12] and neutral monosaccharides [13] were also used.

RESULTS AND DISCUSSION

The fractionation of the polysaccharides from nucleus pulposus by means of stepwise elution

The polysaccharides were prepared as described earlier [14,15]. Fifty mg of the polysaccharide preparation was dissolved in about 0.5 ml of 0.3 % barium acetate solution and applied on top of a column 1 × 20 cm prepared according to the principles given above. The polysaccharides were then eluted with solutions of decreasing alcohol concentrations. All solvents contained 0.3 % barium acetate. Fifty ml of each solution was used. The composition of the elution solvents as well as the aminosugar analysis of the fractions are given in Table 1.

Table 1. Fractionation of the nucleus pulposus polysaccharides by means of stepwise elution.

Per cent EtOH in elution solvent	Glucosamine-HCl			Galactosamine-HCl		
	mg	Per cent of total hexosamine	Per cent recovery	mg	Per cent of total hexosamine	Per cent recovery
80	0.0	0	0	0.0	0	0
50	6.02	99.2	10.2	0.05	0.8	0.6
45	17.30	95.4	29.3	0.84	4.6	1.0
40	12.9	92.6	21.9	1.03	7.4	1.3
35	4.82	89.1	8.2	0.59	10.9	0.7
30	4.70	81.0	8.0	1.10	19.0	1.3
25	1.60	50.0	2.7	1.60	50.0	2.0
20	0.82	16.1	1.4	4.26	83.9	5.2
15	0.60	3.3	1.0	17.80	96.7	21.8
10	0.60	2.2	1.0	27.08	97.8	33.2

In another experiment 4 g of the same material was fractionated on a column 6.5 × 23 cm. The elution was carried out with 80, 50, 35, 25 and 20 % of ethanol containing 0.3 % of barium acetate, and finally with 0.3 % barium acetate solution. Two litres of each of the solvents was used. The fraction eluted with 35 % ethanol and that eluted with barium acetate solution were concentrated *in vacuo* to about 50 ml each, made faintly acid with acetic acid and precipitated with alcohol. The precipitates were dissolved in 50 ml of water and reprecipitated with alcohol. The analysis of these fractions are given in Table 2.

From these experiments it is evident that the mucopolysaccharides from nucleus pulposus can be fractionated into at least two components, one appear-

Table 2. Analysis of the two main fractions from the nucleus pulposus polysaccharides (air dry substance).

	Fraction I eluted with 35 % ethanol	Fraction II eluted with barium acetate solution
Weight	1.33 g	2.14 g
Ash	24.3 %	31.9 %
Nitrogen	2.60 »	2.00 »
Micro Kjeldahl		
Sulfur in ester sulfates	5.45	4.83
Glucosamine-HCl	21.1 » (59.1 of the total glucosamine)	0.3 »
Galactosamine-HCl	0.3 »	22.8 » (82.4 % of the total galactosamine)
Galactose	16.8 »	—
Fucose	2.3 »	—

ing at an ethanol concentration of about 10—15 %. Most of the glucosamine was found in the first component and correspondingly most of the galactosamine was found in the second component.

Fractionation of the polysaccharides from nucleus pulposus by means of gradient elution

The arrangement used in order to obtain the concentration gradient was described by Lindberg and Wickberg [16].

A column 1 × 20 cm was used, prepared as described above. After the application of the polysaccharide mixture (145.5 mg dissolved in about 1.5 ml of the barium acetate solution) the column was first washed with 60 ml of 80 % ethanol containing barium acetate in the concentration described above. The column was then connected to the gradient arrangement. Vessel I, closest to the column, was filled with 350 ml of 80 % ethanol containing 0.3 % barium acetate, and vessel II was filled with 0.3 % barium acetate solution alone to hydrostatic equilibrium with the solvent in vessel I. The ratio between cross section area of the vessels was vessel I / vessel II = 2.7. The effluent was collected in 5—7 ml fractions. Each fraction was analysed with Dische's carbazole method as modified by Gurin and Hood [10] and by the cysteine method of Dische and Shettles [11]. 0.5 ml aliquots were used for each test.

In Fig. 1 the results of these analyses are plotted against the fraction numbers. The cysteine reaction showed a peak for hexoses and methyl pentoses with a maximum in fraction 25 and after this peak practically no colour was found. The carbazole reaction, on the other hand, showed several peaks one of which coincides with the peak given by the cysteine reaction. In the later part of the curve a large unsymmetrical peak, probably composed of several small peaks, is visible.

It is claimed [11] that the cysteine reaction is specific for hexoses and methyl pentoses, and that no colour is given by uronic acids. The carbazole reaction on the other hand is known to give much stronger colour for uronic acids than

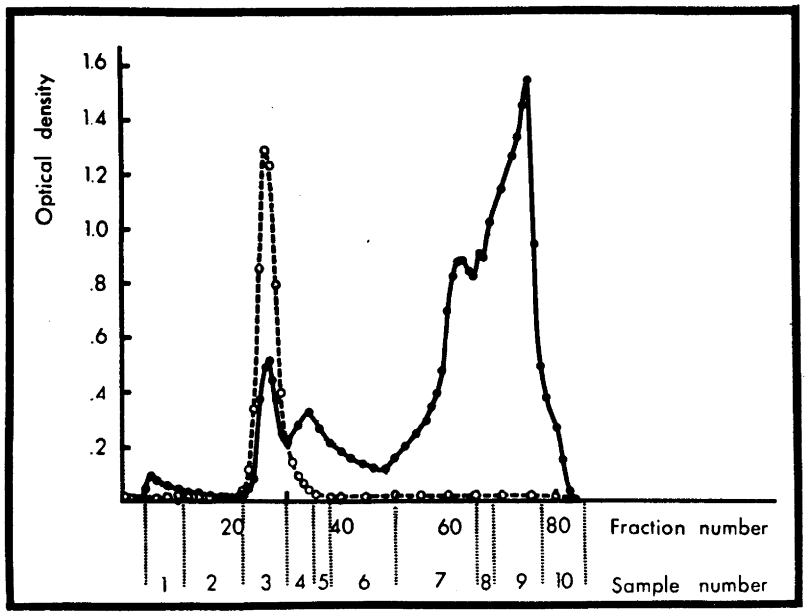

Fig. 1. Gradient elution from a cellulose column 1 × 20 cm of 145.5 mg of the polysaccharide mixture from nucleus pulposus. The fractions are analysed with the cysteine method of Dische and Shettels [11] and the carbazol method as modified by Gurin and Hood [10]. The fractions are pooled in ten samples as shown by the dotted lines.

for the hexoses. It is thus evident that in the peak given by the cysteine reaction a polysaccharide containing hexose — and methyl pentose — is present whilst the other peaks indicate uronic acid-containing substances.

The fractions were pooled as indicated in the figure and each of the ten samples thus obtained were evaporated to dryness and dissolved in 2 ml of water. 0.5 ml of this solution was hydrolyzed with an equal volume of concentrated hydrochloric acid for 8 h on a boiling water bath and the aminosugars determined as described by Gardell [12]. The result is given in Table 3.

Although two main components can be distinguished, the purity of the components obtained by gradient elution is not the same as that obtained by stepwise elution.

In the method of Zahn and Stahl [8] and in that of Zittle and Della Monica [9], the mixture to be separated was precipitated on the supporting medium suspended in the precipitating solvent. As this principle might give better conditions for the separation it was also tested in this case. Five g of Hyflo-Super Cel or cellulose powder was suspended in 50 ml of 80 % ethanol containing 0.3 % barium acetate, and 50 mg of the nucleus pulposus polysaccharides dissolved in about 5 ml of 0.3 % barium acetate solution was added. After thorough mixing the mixture was poured on a glass filter funnel and eluted with the aid of the same gradient as used above. In both cases the separation was very poor.

Table 3. Aminosugar analysis of the fractions obtained by gradient elution of the nucleus pulposus polysaccharides. The fractions are pooled as indicated in Fig. 1.

Fractional precipitation of the nucleus pulposus polysaccharides

In order to compare the efficiency of the column technique with that of the conventional fractional precipitation methods an alcohol fractionation of the nucleus pulposus polysaccharides was performed.

511 mg of the polysaccharide fraction was dissolved in 50 ml of a 3 % solution of barium acetate and fractionated at $\pm$ 0 °C with ethanol. The solution to be fractionated was constantly stirred and the alcohol was added very slowly until a turbidity appeared. The stirring was then continued for half an hour and the precipitate was then centrifuged in a Spinco centrifuge at 30 000 *g*, washed and dissolved in water and reprecipitated with several

volumes of alcohol from a faintly acid solution. The supernatant from the high speed centrifugation and the washings were combined and the fractionation continued on this solution. The result of the fractionation is given in Table 4.

Although it is possible to obtain the galactosamine containing portion in a rather pure state the glucosamine-containing one is not obtained with the same purity as with the column technique. The yield of the pure fractions is also much smaller.

Fractionation of a polysaccharide mixture from bovine cornea

As the cornea is known to contain different mucopolysaccharides [17–19] a fractionation experiment was also carried out on a polysaccharide fraction from this tissue.

The polysaccharides were prepared by proteolytic digestion of bovine corneas followed by extraction with 90 % phenol as described earlier [14,15]. A preparation was obtained which contained 2.99 % N and 18.3 and 13.2 % of glucosamine and galactosamine, respectively, calculated as the hydrochlorides. This polysaccharide was fractionated on a micro scale.

11.2 mg was dissolved in about 0.15 ml of the 0.3 % barium acetate solution and fractionated on a column 0.5 × 7 cm. The carbohydrate content of the fractions was determined by the cysteine reaction [11] and by the carbazole [10] reaction. 0.5 ml aliquots were taken for each determination. The rest of the fractions were evaporated to dryness and hydrolyzed with 0.5 ml of 6 N hydrochloric acid for the determination of their aminosugar composition. The result of the fractionation is given in Table 5.

Table 5. Analysis of the fractions obtained by stepwise elution of the polysaccharide mixture from bovine cornea. 6 ml of each solvent was used. D_{396} and D_{426} represent the optical densities given by the fractions in the cysteine reaction [11] at 396 mμ and 426 mμ, respectively. D_{530} represents the optical density given by the carbazole reaction [10] at 530 mμ.

Fractionation of chondroitinsulfuric acid and heparin monosulfuric acid

These two polysaccharides are isomers with almost the same electrophoretic mobility and can be fractionated by means of fractional precipitation of their barium salts with alcohol [20]. They can also be completely separated using the column technique described above.

10 mg of heparin monosulfuric acid prepared from ox lung and 10 mg of chondroitinsulfuric acid from costal cartilage prepared according to Boström and Månsson [21] were mixed and the mixture was fractionated on a column 1 × 20 cm. In the fraction eluted with 20 % ethanol only galactosamine was found and correspondingly only glucosamine was found in the fraction eluted with 10 per cent ethanol.

This work has been aided by grants from the *Swedish State Medical Research Council.*

The Crystal Structure of $InOHF_2$

HANS-ERIK FORSBERG

Department of Inorganic and Physical Chemistry, University, and Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm, Sweden

$InOHF_2$ has been investigated by X-ray methods. It has a monoclinic unit cell and the unit cell dimensions are

$a = (5.780 \pm 0.005)$ Å
$b = (5.157 \pm 0.005)$ Å
$c = (3.874 \pm 0.005)$ Å
$\beta = 98.74° \pm 0.02°$
$V = 114.1$ Å^3
$Z = 2$

A structure is proposed with atomic positions for the indium, oxygen and fluorine atoms in space group No. 5-*C*2. The parameters of the atoms (p. 681) were determined from Patterson projections and improved by back shift calculations.

The indium atoms are surrounded by two oxygen and four fluorine atoms so that a coordination In-6X is obtained.

The hydrogen atoms are situated either between the fluorine atoms forming F-H-F bonds or between the fluorine and oxygen atoms forming F-H-O bonds.

The structure may be described as a three dimensional framework (distorted ReO_3 structure).

The crystal structure of the isomorphous compounds InOCl and InOBr has recently been determined [1] and in connection with this investigation attempts were made to prepare indium oxide fluoride. With the method described by Enslin and Dreyer [2], no crystals large enough for single crystal X-ray investigations were obtained but, by hydrothermal hydrolysis of almost saturated indium(III) fluoride solutions of different acidities, a new compound could be prepared. Its formula proved to be $InOHF_2$ while Enslin and Dreyer gave the formula of their substance as InOF·aq. This paper presents the structure determination of $InOHF_2$.

PREPARATION OF THE CRYSTALS

Indium (III) fluoride [2,3] was obtained by dissolving indium hydroxide, prepared by treating a solution of indium(III) nitrate with aqueous ammonia, in 40 % hydrofluoric acid. The solution was then evaporated until crystals of $InF_3(H_2O)_3$ separated. After cooling, the crystals were filtered off, washed with water and dried in air.

Indium oxide fluoride was prepared as follows. A solution of 400 mg $InF_3(H_2O)_3$ dissolved in 6.5 ml HF (2 M) was poured into a Pt-crucible which was then kept at 300° C in an autoclave. After 18 h, the autoclave was cooled and the precipitate filtered off. It consisted of small transparent crystals of $InOHF_2$.

The crystals are insoluble in water but dissolve completely in hot dilute hydrochloric or nitric acid.

ANALYSIS

A sample, which had been dried in air, was decomposed by fusion with sodium and potassium carbonates. After cooling, the melt was leached with water and the residue filtered off. The amount of *fluoride* in the filtrate was determined gravimetrically as PbClF [4].

For the determination of *indium*, a sample was dissolved in nitric acid, evaporated, and then ignited and weighed as In_2O_3.

The *hydroxide* was determined as water by Hartwig-Bendig's modification of Penfield's method as described by Kolthoff and and Sandell [5].

The *density* of the crystals was determined from the loss of weight in benzene.

	Found		Calculated for $InOHF_2$
% In	67.8	67.6	67.60
% F	22.9	23.0	22.38
% OH	9.5	9.5	10.01
Density	4.8_9	4.9_1	4.94 (*cf.* below)

UNIT CELL AND SPACE GROUP

From rotation (around [100], [010] and [001]) and Weissenberg photographs (0*kl*, 1*kl*, *h*0*l*, *h*1*l*, *hk*0 and *hk*1), taken with Cu*K* radiation, it was concluded that the crystals are monoclinic with $a \approx 5.8$ Å, $b \approx 5.1$ Å, $c \approx 3.9$ Å and $\beta \approx 99°$. More accurate values of the unit cell dimensions were calculated from a powder photograph in a focusing camera of Guinier type (*cf.* Table 1). (Cu$K\alpha$ radiation, internal standard KCl with $a = 6.2930$ Å).[6]

$$\begin{aligned} a &= (5.780 \pm 0.005) \text{ Å} \\ b &= (5.157 \pm 0.005) \text{ Å} \\ c &= (3.874 \pm 0.005) \text{ Å} \\ \beta &= 98.74° \pm 0.02° \\ V &= 114.1 \text{ Å}^3 \end{aligned}$$

The mean value of the density is 4.90 so that there should be $1.98 \approx 2$ formula units $InOHF_2$ in the unit cell.

The only reflections systematically absent are

$$hkl \text{ with } h+k \text{ odd}$$

which is characteristic of the space groups No. 12-$C2/m$, No. 8-Cm and No. 5-$C2$.

Table 1. Powder photograph of $InOHF_2$. Cu$K\alpha$ radiation. Internal standard KCl. $a = 6.2930$ Å.

Reflections systematically absent according to space group No.5-$C2$ have been omitted.

The intensities were calculated from the expression $0.05 \cdot \frac{p}{\quad} F^2$ where p is the number

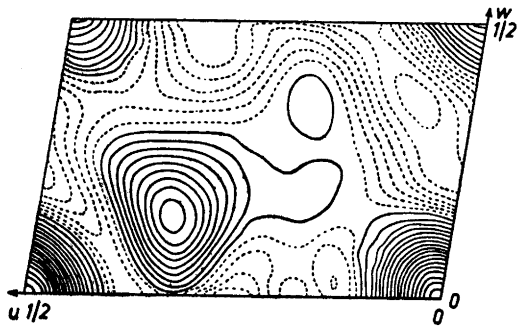

Fig. 1. The Patterson projection $P(upw)$ for $InOHF_2$. In the peaks at $P(0p0)$ and $P(\frac{1}{2}p0)$ only every second contour has been drawn. Dashed lines indicate negative values.

PATTERSON SYNTHESES

In the unit cell there are two indium, two oxygen and four fluorine atoms. To determine their positions, the Patterson projections, $P(upw)$, $P(pvw)$, and $P(uvp)$ were calculated. (Figs. 1 and 2.) Relative intensities of the reflections were estimated visually and the F^2-values were then calculated using the curves given by Lu[8]. No corrections have been applied for the absorption. In all syntheses, the value of $F^2(000)$ has been omitted. The maxima have been located by an interpolation table given by Booth [9]. In the space groups suggested by the extinctions, the possible point positions are as follows:

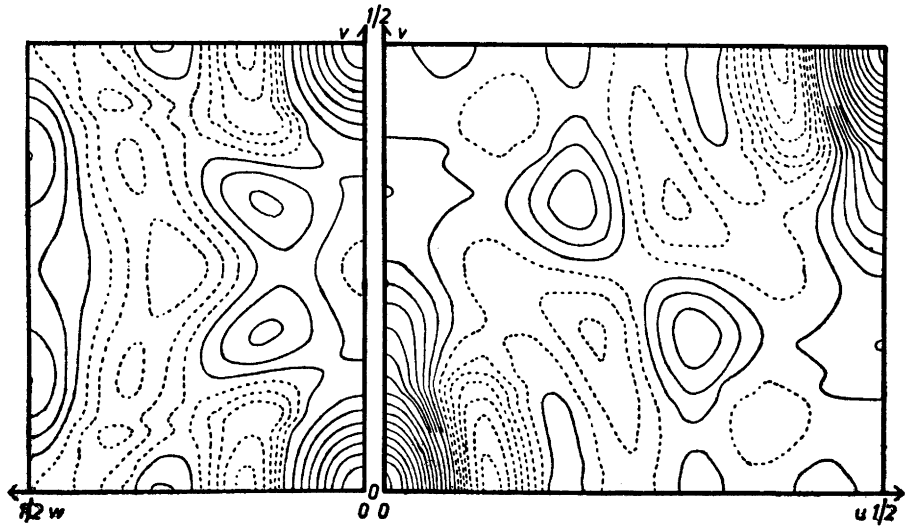

Fig. 2. The Patterson projections $P(pvw)$ and $P(uvp)$ for $InOHF_2$. In the peaks at $P(p00)$ and $P(00p)$ only every third and second contour has been drawn. Dashed lines indicate negative values.

$C2/m$	$(0,0,0;\ \frac{1}{2},\frac{1}{2},0)+$		
$2(a)$	$0,0,0;$	$4(e)$	$\frac{1}{4},\frac{1}{4},0;\ \frac{1}{4},\frac{3}{4},0$
$2(b)$	$0,\frac{1}{2},0;$	$4(f)$	$\frac{1}{4},\frac{1}{4},\frac{1}{2};\ \frac{1}{4},\frac{3}{4},\frac{1}{2}$
$2(c)$	$0,0,\frac{1}{2};$	$4(g)$	$0,y,0;\ 0,\bar{y},0$
$2(d)$	$0,\frac{1}{2},\frac{1}{2};$	$4(h)$	$0,y,\frac{1}{2};\ 0,\bar{y},\frac{1}{2}$
		$4(i)$	$x,0,z;\ \bar{x},0,\bar{z}$

Cm	$(0,0,0;\ \frac{1}{2},\frac{1}{2},0)$	$C2$	$(0,0,0;\ \frac{1}{2},\frac{1}{2},0)$
$2(a)$	$x,0,z$	$2(a)$	$0,y,0$
$4(b)$	$x,y,z;\ x,\bar{y},z;$	$2(b)$	$0,y,\frac{1}{2}$
		$4(c)$	$x,y,z;\ \bar{x},y,\bar{z}$

The indium atoms can be given arbitrarily the twofold point position $2(a)$ with $x = 0$, $y = 0$ and $z = 0$ for all three space groups. The In-In distances of $\pm(\frac{1}{2},\frac{1}{2},0)$ appear as pronounced maxima in the Patterson projections at $\frac{1}{2},p,0$, $p,\frac{1}{2},0$ and $\frac{1}{2},\frac{1}{2},p$.

In addition to the In-In peaks, the Patterson projections show other distinct maxima which should correspond to distances between indium and oxygen atoms and indium and fluorine atoms.

Since the unit cell contains two oxygen and four fluorine atoms the oxygen atoms should be situated in a twofold point position and the fluorine atoms either in two twofold or in one fourfold point position. In the Patterson projections $P(uvp)$ and $P(pvw)$ we observe a distinct maximum at $u \approx 0.325$, $v \approx 0.179$ and $w \approx 0.141$ which can only be explained as being due to atoms in the fourfold point position $4(b)$ in Cm or $4(c)$ in $C2$. Thus the fluorine atoms should be situated in one of these point positions.

The other distinct maximum in $P(pvw)$ at $v \approx 0.125$ and $w = \frac{1}{2}$ (the corresponding maximum in $P(uvp)$ is hidden by the In-In peak) must be explained as an In-O distance with the oxygen atoms in the point position $2(b)$ in $C2$. Thus we get the following parameters for the oxygen atoms (we need only consider the range $0 \leq x \leq \frac{1}{2}$, $0 \leq y \leq \frac{1}{2}$ and $0 \leq z \leq 1$).

$$2\ \mathrm{O}\ \text{in}\ C2\ 2(b)\ \text{with}\ y \approx 0.125$$

The remaining maxima in $P(uvp)$ and $P(pvw)$ on the u and w axes are small and probably caused by vectors between light atoms or by diffraction effects.

The parameters of the fluorine atoms are determined from the maximum at $u \approx 0.325$, $v \approx 0.179$, and $w \approx 0.141$ and we then notice that there are two possibilities for the sites of the atoms (we need only consider the range $0 \leq x \leq \frac{1}{2}$, $0 \leq y \leq \frac{1}{2}$ and $0 \leq z \leq 1$).

$$4\ F\ \text{in}\ C2\ 4(c)\ \text{with}\ x \approx 0.325,\ y \approx\ \ 0.179,\ z \approx 0.141\ \text{or}$$
$$x \approx 0.325,\ y \approx -0.179,\ z \approx 0.141$$

The latter alternative is excluded by the too short oxygen-fluorine distance of 1.9 Å.

FINAL PARAMETERS

The parameters given below are the mean values of those found in the Patterson projections. The only exception is the oxygen y parameter which is obtained only from the $P(pvw)$ projection (in the $P(uvp)$ projection, the In-O distance is hidden by the In-In peak). All values have been corrected by back shift calculations.

Thus the following structure is proposed for $InOHF_2$:

Space group No. 5-$C2$. Two formula units per unit cell.

	x	y	z
2 In in 2(a)	0	0	0
2 O in 2(b)	0	$0.14_9 \pm 0.01$	½
4 F in 4(c)	$0.32_8 \pm 0.01$	$0.18_0 \pm 0.01$	$0.15_4 \pm 0.01$

In Tables 2—4, the calculated structure factors are compared with the observed ones in the Weissenberg photographs $h0l$, $hk0$ and $0kl$. The reliability index

$$R = \frac{||F_{obs}| - |F_{calc}||}{|F_{obs}|}$$

is, for $h0l$, $hk0$ and $0kl$ 0.18, 0.20 and 0.15, respectively. However, for crystals like these containing both heavy and light atoms, the reliability index should not be taken as a definite proof that the structure as a whole is true but only that the arrangement proposed for the heavy atoms is essentially correct.

DESCRIPTION OF THE STRUCTURE

Figs. 3 and 4 show the structure of $InOHF_2$, projected along the b and c axes. In both projections, four adjacent unit cells are given so that the building principles of the structure will be more obvious.

If we describe our C-centered monoclinic lattice by a primitive triclinic lattice, the following unit cell dimensions are obtained: $a = b = c = (3.874 \pm$

0.005) Å and $\alpha = \beta = \gamma = 83.48° \pm 0.02°$ *. The triclinic cell can be regarded as a distorted cubic cell with approximately the same atomic arrangement as that found in ReO_3 [10]. It is thus obvious that the indium atoms have a six coordination in which the calculated distances In-O and In-F are approximately the same.

Alternatively, the structure might be formally described as being built up of layers of $(InF_2^+)_\infty$ separated by oxygen atoms (Fig. 3) or as containing chains of In-O-In separated by HF_2^- ions (*cf.* below).

The interatomic distances for the structure proposed will be (in Å):

In-In	= 3.87	F_1—F_2	= 2.9_3 and 3.87
In-O_1	= 2.08	F —F	= 3.0_8 and 3.9_2 (between layers)
In-F_1	= 2.06	O —O	= 3.87
In-F_2	= 2.11	O —F_1	= 2.8_7 and 3.7_4
F_1-F_1	= 2.4_6	O —F_2	= 2.4_9 and 2.9_3
F_2-F_2	= 3.8_0		

* The agreement of the unit cell dimensions with those of a rhombohedral unit cell must be accidental since reflexions which should be of equal intensity according to rhombohedral indices differ in intensity in the Weissenberg photographs.

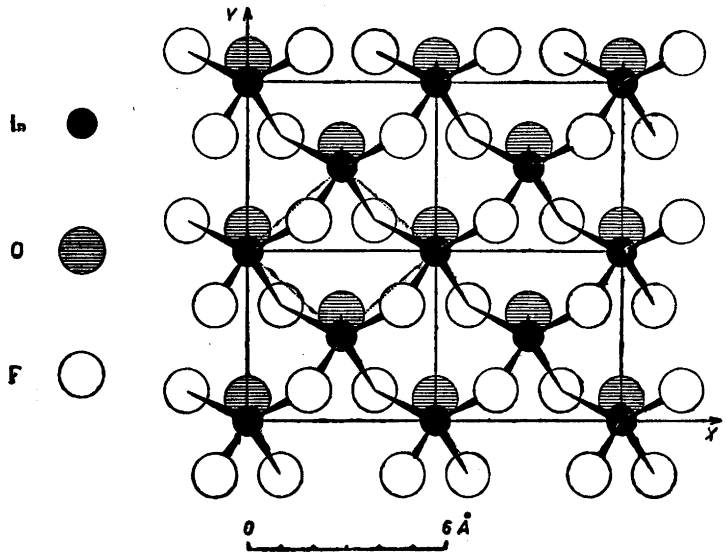

Fig. 3. The structure of $InOHF_2$, viewed along [001]. The dotted lines indicate the triclinic unit cell. (The range for the z parameter is $-0.859 \leq z \leq 0.141$.)

The error in the In-O and In-F distances is estimated to be $\pm$ 0.05 Å and in the F-F and O-F distances $\pm$ 0.1 Å. The In-O distances are about the same as those found in In_2O_3 [11] and InOCl and InOBr [1]. The shortest distance between oxygen and fluorine is somewhat shorter than that found in CeOF [12] and BiOF [13] (2.83 and 2.88 Å).

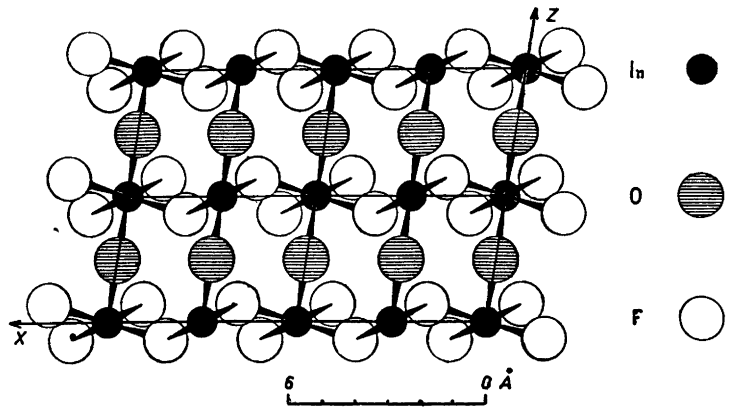

Fig. 4. The structure of $InOHF_2$, viewed along [010]. (The range for the y parameter $-0.375 \leq y \leq 0.625$.)

The long O-O distances of 3.87 Å exclude the possibility that hydrogen bonds are present between the oxygen atoms. The short distances O-F (2.49 Å) and F-F (2.46 Å) do not differ significantly. They both seem to be consistent with probable values of hydrogen bond lengths (*cf.* Pauling [14], Wells [15]). The fact that fluorine is more electronegative than oxygen might appear in favour of the existence of F-H-F bonds. On the other hand F-H-O bonds would give a more even distribution of the charge of the atoms.

Acknowledgements. The author is indebted to Professor Lars Gunnar Sillén for his helpful criticism and provision of laboratory facilities and to Professor Arne Ölander for his kind interest. The author wishes to thank Dr. Arne Magnéli and Dr. Georg Lundgren for many valuable discussions and Mr. D. G. Gillam for revising the English text.

Thanks are due to the *Consolidated Mining and Smelting Company of Canada, Ltd.* for generously supplying a large amount of indium metal of high purity.

On the Production of Vitamins by Protein-rich and Protein-poor *Rhodotorula gracilis* Yeast

NIELS NIELSEN and GOTTFRIED SCHNEIDER

Research Department, AB Kabi, Stockholm, Sweden

When *Rhodotorula gracilis* was grown in nutrient solutions containing 0.1 or 1 % asparagine or ammonium sulphate as the nitrogen source, the crude protein content of the yeast varied between 8.4 and 60.7 %, calculated on a dry yeast basis. The fat content of the yeast also varied greatly, between 71.0 and 11.6 % of the yeasts dry weight. A marked correlation was noticeable, the fat content being high if the crude protein content was low and vice versa.

The sum of the contents of crude protein and fat was relatively constant, varying between 70 and 79 % of the dry yeast when asparagine was used as the nitrogen source. When ammonium sulphate was the nitrogen source this sum varied between 60 and 67 %. This difference between asparagine and ammonium sulphate media was probably caused by the increasing acidity of the latter.

The four vitamins investigated, *viz.* riboflavin, pantothenic acid, nicotinic acid and pyridoxine were present mainly in the nutrient solution (about 50 to 80 %). On calculating the vitamin contents as μg per g dry yeast, the amounts present at the end of the fermentations were much smaller for the yeast poor in crude protein. However, expressing the amounts as μg per g crude protein, no significant difference was found between the protein-poor and protein-rich types, with the exception of pantothenic acid and possibly nicotinic acid. Nicotinic acid had a tendency to be formed in higher amounts — calculated per g of protein — in the protein-poor yeast. Pantothenic acid was not formed to any appreciable extent in the protein-poor yeast, most probably due to the fact that β-alanine was not formed.

When *Rhodotorula gracilis* was cultivated in a nutrient solution low in nitrogen but containing an excess of sugar, considerable amounts of fat were produced [1]. The fat content of the yeast was found to be very high, amounting to 60 % or more calculated on a dry weight basis. Concomittantly the crude protein content decreased and a yeast with only 12 % crude protein might be obtained. If the yeast was cultivated with an excess of nitrogen a yeast with about 50 % crude protein and 10 % fat was obtained. Thus the protein content of this yeast can be varied between wide limits only by altering the nitrogen content of the nutrient solution.

Some comparative studies on the metabolism and the chemical composition of both the protein-rich and the protein-poor *Rh. gracilis* yeast have already been carried out. Nielsen, Sandegren and Ljungdahl [2] compared the amino acid content in these two yeast types and found certain differences. The protein-poor yeast had a relatively high content of glutamic acid and alanine compared with the protein-rich yeast. β-Alanine which is a component of pantothenic acid was present in the protein-rich but not in the protein-poor yeast. Later, Nielsen and Lundin [3] made quantitative determinations of some amino acids and found that whereas the amount of *iso*leucine, leucine, lysine, phenylalanine and tryptophane was practically the same in both the protein-rich and the protein-poor yeast (expressed per g of protein), the protein-poor yeast was very low in cystine and methionine. Accordingly the sulfur-content of the protein-poor yeast was also very low. Sandegren, Ekström and Nielsen [4] found that the protein-poor yeast contained fewer sulfhydryl-groups than the protein-rich yeast. The amount of phosphatides was small in the protein-poor yeast when the results were based on the weight of the yeast but no significant differences were found between the two yeast types when the phosphatide content was expressed per g of protein [5].

These investigations demonstrated important differences in the chemical composition of protein-rich and protein-poor *Rh. gracilis*. In this paper we have investigated the formation of some vitamins, *i. e.* riboflavin, pantothenic acid, nicotinic acid and pyridoxine, in these two yeast types.

METHODS

The variations in the protein content of the yeast were induced by altering the nitrogen content of the nutrient solution. The nutrient solution used for the protein-rich yeast had the following composition: 10 g asparagine or ammoniumsulphate, 4 g KH_2PO_4 – 3 g $MgSO_4$, $7H_2O$ – 1.5 g $CaCl_2$, $6H_2O$ – 0.015 g $FeCl_3$, $6H_2O$ and 40 g glucose, made up to 1 000 ml with distilled water. The nutrient solution for the protein-poor yeast had the same composition with the exception that only 1 g of asparagine or ammoniumsulphate was used.

The yeast was cultivated in 5 litre fermentors containing 3 litres of nutrient solution. The fermentors were kept at 25° and were aerated with 0.5 litre air per 1 litre solution per min. Each fermentor was seeded with 250 ml of a culture grown for 3 days in 250 ml Erlenmeyer flasks each containing 50 ml of the nutrient solution used for the production of protein-rich yeast. This amount of yeast corresponded to about 0.4 g of dry material.

During the experiments the pH of the nutrient solution and the amount of yeast present was determined daily. After the yeast had been removed by centrifuging, the amount of nitrogen was determined in the yeast-free solution, *i. e.* the amount of nitrogen not assimilated. From these analysis the crude protein content of the yeast could be calculated. At the end of the fermentations the yeasts was collected by centrifuging and washed twice with water. The yeast was then dried at 45° and a part was used for the determination of nitrogen and fat. Another part was dried at 105° in order to express the contents of nitrogen and fat on a dry weight basis. By the fat analysis [6] the total lipid content was determined. From the nitrogen analysis the crude protein was calculated as $N \times 6.25$.

The vitamins were determined microbiologically using the methods described by Barton-Wright [7]. The yeast was separated by centrifuging and the vitamin content determined on the nutrient solution directly and on the yeast after treatment according to Ref. [7].

RESULTS

Five experiments with a nitrogen-rich and five with a nitrogen-poor nutrient solution were carried out. Four of these experiments (2 with a nitrogen-rich and 2 with a nitrogen-poor nutrient solution) were made with ammonium sulphate as the nitrogen source and in the others asparagine was used.

At the beginning of the fermentations growth was as good in the nutrient solution low in nitrogen as in that containing excess nitrogen. After about 2 days, however, the nitrogen in the nitrogen-poor medium was practically consumed and the growth in these fermentors became slower. This reduction in growth rate becames apparent first when the crude protein content of the yeast is below 20 %. The growth rate of a yeast with 20 or 60 % crude protein is almost the same which was found to be the case in all experiments independent of the nitrogen source used.

A remarkable and important difference between the fermentations with ammonium sulphate as the nitrogen source and those with asparagine, is the resulting pH of the nutrient solution. Whereas the pH remains about 5 during the fermentations with asparagine the final pH is about 2 in the fermentations with ammonium sulphate as the nitrogen source. The acidity of the latter nutrient solution is due to the well known fact that the ammonium ions are taken up and the solution becomes more acid. This acidity is no doubt the reason why the growth is somewhat slower when ammonium sulphate is the nitrogen source. Most probably it is also the reason why the fat production is slightly less and the production of nicotinic acid is higher (see below).

The values obtained for the crude protein and fat content of the yeast at the end of the fermentations are summarized in Table 1. In this table the fermentations are arranged according to the crude protein content of the yeast.

The values given in Table 1 clearly show that both the crude protein content and the fat content of the yeast can be varied greatly by altering the nitrogen content of the nutrient solution. The crude protein content varied between 8.4 and 60.7 % and the fat content between 11.6 and 71.0 %. When the crude protein content is low the fat content is high and vice versa, which shows an inter-relationship between the two.

Table 1. Crude protein and fat content of the yeast at the end of the fermentation.

Expt. No.	Crude protein, % of dry weight	Fat, % of dry weight	Crude protein + fat, % of dry weight	Nitrogen source
10	8.4	71.0	79.4	asparagine
5	10.0	64.0	74.0	asparagine
6	10.2	63.2	73.4	asparagine
1	18.4	47.1	65.5	am. sulphate
2	25.4	41.2	66.6	am. sulphate
3	43.2	17.5	60.7	am. sulphate
4	43.8	15.7	59.5	am. sulphate
9	50.8	19.4	70.2	asparagine
7	53.5	16.7	70.2	asparagine
8	60.7	11.6	72.3	asparagine

The sum of the contents of crude protein and of fat is relatively constant, varying between 70 and 79 % of dry yeast, when the yeast is grown in the nutrient solutions containing asparagine as the nitrogen source. When the yeast is grown with ammonium sulphate as the nitrogen source this value is appreciably lower, ranging between 59 and 65 % of the dry yeast. Relatively little fat is formed when ammonium sulphate is the nitrogen source. The difference between the composition of the yeast grown with asparagine and with ammonium sulphate is probably caused by the different pH values during the fermentation, the nutrient solution being more acid when ammonium sulphate is employed. It must, however, be remembered that no determinations of protein *per se* were made but that only the nitrogen content multiplied by 6.25 was taken as a measure of the protein content of the yeast. If the yeast contains a large number of non protein compounds this would be included in the figures for crude protein.

The vitamins riboflavin, pantothenic acid, nicotinic acid and pyridoxine were determined both in the cell-free nutrient solution and in the yeast both during fermentation and at the end of the fermentation. It was found that the largest quantity of the vitamins was present in the nutrient solution, the yeast only contained some 20—50 % of the total amount.

Table 2 gives the amounts of the vitamins found at the end of the fermentations. The values are calculated both per g dry yeast and per g of protein. The 10 fermentations are arranged according to the crude protein content of the yeast.

Table 2. Vitamin content of protein-rich and protein-poor yeast at the end of the fermentation.

Expt. No. Experiment	10	5	6	1	2	3	4	9	7	8
Nitrogen source	asp.	asp.	asp.	ams.	ams.	ams.	ams.	asp.	asp.	asp.
Crude protein, %	8.4	10.0	10.2	18.4	25.4	43.2	43.8	50.8	53.5	60.7
Riboflavin										
μg/g yeast	28	61	65	100	124	161	187	250	140	150
μg/g protein	333	610	637	543	488	373	427	492	262	247
Pantothenic acid										
μg/g yeast	0	4	5	0	0	35	45	150	420	420
μg/g protein	0	40	49	0	0	81	103	295	785	692
Nicotinic acid										
μg/g yeast	30	97	86	190	210	465	421	105	77	124
μg/g protein	357	970	843	1 033	827	1 076	961	207	144	204
Pyridoxine										
μg/g yeast	4	3	4	12	14	16	17	10	13	16
μg/g protein	48	30	39	65	55	37	39	20	24	26

As can be seen from Table 2, the amounts of pantothenic acid present depended on the crude protein content of the yeast. If the crude protein content was low, no or very little pantothenic acid was present. The reason for the low pantothenic acid content in the protein-poor yeast may be that one of the components of this vitamin, β-alanine, is not formed when the nutrient solution is deficient in nitrogen. Nielsen, Sandegren and Ljungdahl [2] found β-alanine to be absent in protein-poor *Rh. gracilis* yeast whereas it was present in the protein-rich yeast.

With regard to the other vitamins the differences between the amounts present in the protein-rich and protein-poor yeast were not so striking. The amounts, calculated per g of yeast are somewhat smaller for the protein-poor yeast compared with the protein-rich one; for nicotinic acid this difference is rather insignificant. If calculated on g of protein, however, the amounts present are at least as high for the protein-poor yeast as for the protein-rich. There seems to be a tendency for the protein-poor yeast to be somewhat richer in the vitamins estimated than the protein-rich one, when calculated on a protein basis, which especially holds true for nicotinic acid. With regard to pantothenic acid the amounts present were, as mentioned above, very small in the protein-poor yeast.

The nicotinic acid appeared to be produced in higher amounts when the yeast was cultivated in the ammonium sulphate medium which was probably due to the low pH of the nutrient solution.

The vitamin contents of the protein-poor yeast, when calculated per litre nutrient solution, were of course much smaller than for the protein-rich one, due to the fact that the production of yeast was much less.

The amounts of vitamins calculated as μg per g did not vary much during the fermentation in the case of the protein-rich yeast. With regard to the protein-poor type a decrease could be noticed due to the fact that the yeast was growing poorer in protein, but if the vitamin content is expressed as μg per g protein the values were relatively constant during the fermentation. Calculated per litre nutrient solution a marked increase naturally occurs during the fermentation because of the increase in the amount of yeast.

In earlier investigations [8] it was found that the addition of thiamine and pantothenic acid stimulated the growth of *Rh. gracilis*, whereas the addition of nicotinic acid, riboflavin or pyridoxine had no effect. This is in good agreement with the fact that pantothenic acid under certain conditions is not formed at all or only in small amounts.

Studies on the Hydrolysis of Metal Ions

20. The Hydrolysis of the Cd Ion, Cd^{2+}

Y. MARCUS

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden *

Potentiometric (glass electrode) titrations of Cd^{2+} with NaOH in 3 M (Na^+) ClO_4^- ionic medium at 25° C were made. At first a slight hydrolysis was observed (not much more than 1 %), according to $Cd^{2+} + H_2O \rightleftharpoons CdOH^+ + H^+$, $\log K_{a1} = -9.0 \pm 0.2$, and subsequently precipitation of $Cd(OH)_2$ was found with $pL \geq 15.6$. There was no evidence for polynuclear species.

The method of study employed was the one in general use in this laboratory. Cadmium solutions were titrated with NaOH at 25.0 ± 0.1° C, at constant Cd concentrations (= B), and in an ionic medium of 3 000 mM (Na^+) ClO_4^-. The cell used was: Ag, AgCl / 10 mM Ag^+, 2 990 mM Na^+, 3 000 mM ClO_4^-/ 3 000 mM $NaClO_4$ / B mM Cd^{2+}, H mM H^+, 3 000—2B—H mM Na^+, 3 000 mM ClO_4^- / glass electrode. In the range of pH under consideration the liquid junction potential could be neglected, and the electromotive force E in mV followed the expression

$$E = E_0 - 59.16 \log h = E_0 + 59.16\ ph \qquad (1)$$

where h is the concentration of free hydrogen ions. The solutions were swept with purified nitrogen during titrations to guard against CO_2. The titrations proved to be completely reversible and reproducible. Above ph 6 considerable time was needed for attainment of equilibrium, and at a definite higher ph precipitation could be observed.

H_0, the excess acid present in the solutions, and E_0 were calculated by successive approximations from the portion of the titration data where no hydrolysis occurred (ph below 4). The average number of hydroxyl ions bound per metal ion, Z, was calculated from

$$Z = (h - H_0 - H)\ B^{-1} \qquad (2)$$

where H was the analytical excess acid (acid added — base added / total volume), and h was obtained from the measured electromotive force by (1).

---

* Permanent address: Israel Atomic Energy Commission, Hakiryah, Tel Aviv, Israel.

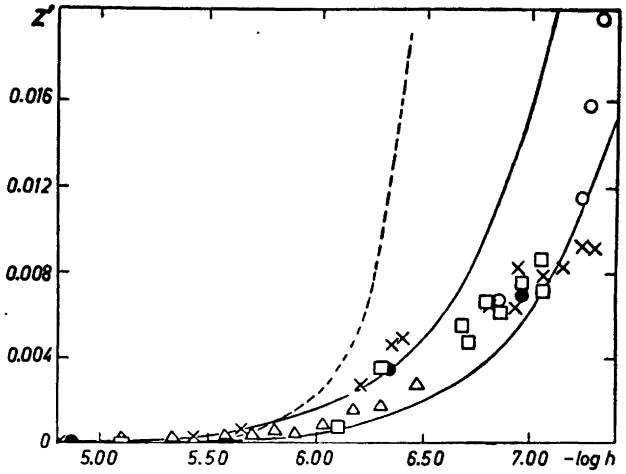

Fig. 1. The average number of hydroxyl ions bound per metal ion, Z', as function of the free hydrogen ion concentration $-\log h$. The symbols refer to the Cd concentrations B: × 10.7 mM, ○ 26.8 mM, □ 53.6 mM, ● 107.1 mM, △ 910 mM. The curves ——— were calculated with the limiting values of log K_{a1} −8.8 and −9.2, while - - - - - was calculated with the constant for reaction (4), log $K_{a2} = -14.6$. Selection of a different value for K_{a2} will only shift the curve horizontally to left or right, but it will not fit the data.

Titrations were made for five B values between 10 and 900 mM, and the data $Z(-\log h)_B$ calculated. The scattering was very considerable, because Z was usually much smaller than 0.01. Some acid impurity was found to be titrated together with the Cd, and its contribution, about 0.001 units, was subtracted from the Z values to give Z'. A plot of Z' against -log h is shown In Fig. 1.

Fig. 1 shows that B has no significant effect, as all points seem to fall on the same curve. A plot of log Z' against -log h gave a straight line log $Z' = (-8.09 \pm 0.17) - (0.86 \pm 0.03) \log h$ as was found by a least squares treatment.

The following mechanisms were considered:

$$p\ Cd^{2+} + q\ H_2O \rightleftharpoons Cd_p(OH)_q^{2p-q} + q\ H^+,\ p \neq 1 \quad (3)$$

$$Cd^{2+} + 2\ H_2O \rightleftharpoons Cd(OH)_2 + 2\ H^+ \quad (4)$$

$$Cd^{2+} + H_2O \rightleftharpoons Cd(OH)^+ + H^+ \quad (5)$$

Mechanism (3) requires the data to show an effect due to B, and is ruled out. Mechanism (4) requires a slope of +2 in a log Z against $-\log h$ plot, and does not agree with the data (see also Fig. 1). Mechanism (5) is therefore the most likely. The equilibrium constant K_{a1} is given by

$$K_{a1} = [CdOH^+]\ h\ [Cd^{2+}]^{-1} \approx Z\ h \quad (6)$$

Table 1. The ph of beginning precipitation and the solubility product of $Cd(OH)_2$.

pB	1.970	1.572	1.271	0.970	0.041
ph	7.43	7.29	6.91	6.85	6.50
pL	15.5	15.4	15.8	15.7	15.5

because $Z = [CdOH^+]\ B^{-1}$ and as Z was very small, $B \approx [Cd^{2+}]$. From (6) follows $\log Z = \log K_{a1} - \log h$, and a plot of $\log Z$ against $-\log h$ should have unit slope. The observed slope of 0.86 is fairly near to unity, and the best straight line with unit slope through the points has $\log K_{a1} = -(9.0 \pm 0.2)$.

Chaberck, Courtney and Martell [1] found with a glass electrode $pk = \log [CdOH^+]\ [H^+]\ [Cd^{2+}]^{-1} = -11.6$ at 30° and 0.1 M KCl ionic medium. These authors state, however, that "at best the value of k listed is reliable to only one significant figure". Earlier, the value $\log K_w - \log K_{a1} = -5.52$ was calculated by Jellinek [2] from distribution data of Löfman [3], while Kullgren [4] found by a kinetic method $\log K_{a1} = -9.49$ at 100°. The last two constants are of the same magnitude as the value found here. Hayek [5] found negligible solubility of CdO in $Cd(ClO_4)_2$ solutions, which shows negligible formation of polynuclear hydrolysis products.

The approximate ph of beginning precipitation enables one to calculate a lower limit of the solubility product L

$$pL \geq 2\ pK_w - 2\ ph + pB \qquad (7)$$

Assuming pK_w, the dissociation constant of water, to be 14.22, the data in Table 1 give the average $pL \geq 15.6$.

The following values of pL were previously reported in literature: Akselrud [6] 14.58, Kertman [7] 13.65, Bodländer [8] 13.65, Tananaev [9] 12.62, all at 18° C, Kovalenko [10] 15.81 at 22° C and Piater [11] 14.22 at 25° C, all for infinite dilution.

Note added in proof: Since the completion of this work Gayer and Woontner [12] have published results of their solubility measurements at 25°C: $\log K_{a1} = -9.3$ and $pL = 14.31$, besides values for species formed in alkaline solutinos.

The author wishes to thank the *Israel Atomic Energy Commission* for a research grant abroad, and Professor Lars Gunnar Sillén for his helpful discussion of the work.

Surface Balance Studies of Bile Acid Monolayers

I. Cholanic and Glycocholanic Acid Monolayers

PER EKWALL, REINO EKHOLM and ARNE NORMAN*

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

A continuously recording surface balance has been employed to study monomolecular layers of cholanic and glycocholanic acids spread on acid substrates of pH 2. Both acids form monolayers of the condensed type on compression. Already at the point 0, where the surface pressure begins to increase, the monolayer molecules are densely packed and oriented more or less vertical to the substrate surface with the alkyl chain and its terminal carboxyl group projecting into the surface. The differences between bile acid and cholesterol monolayers are discussed.

The cholanic acid monolayer is liquid at 20°C; the surface layer solidifies only after the collapse point has been passed. At temperatures below 14°C the glycocholanic acid monolayer is solid already at point 0 and remains so on further compression. Between 15° and 22°C a transition from a liquid to solid state occurs on compression; above 26°C the surface layer solidifies only after its collapse. The phase transformation in the monolayer is accompanied by a decrease in the internal energy amounting to 1 000 to 2 000 cal/mole. An increase in the sodium chloride content of the substrate has the same effect on the transformation as a moderate decrease in temperature.

There appears to be only one investigation that has dealt with the monolayer properties of bile acids. Adam, Askew and Danielli [1] studied the properties of apocholic and β-apocholic acid monolayers which they seem to have compressed to an area of about 100 Å^2 per molecule and to a surface pressure of 9 dynes / cm. They found that both acids form gaseous monolayers in which the longitudinal axes of the molecules apparently lie parallel to the surface owing to the fact that the molecules contain three hydrophilic groups that are situated fairly far apart.

In connection with investigations of micelle formation in bile acid salt solutions in progress at the Institute of Physical Chemistry of the Åbo Aka-

* Present address: Department of Physiological Chemistry, University of Lund, Lund, Sweden.

demi [2-7,15], we considered it of interest to study the monolayer properties of the bile acids [8]. We present the results of a surface balance study of the monolayer properties of cholanic and glycocholanic acids on acid substrates in this paper.

MATERIALS AND METHODS

The bile acids were synthesized by one of us (A. N.) at the Department of Physiological Chemistry of the Lund University. The methods of synthesis and the physical properties of the acids have been described in earlier publications [9].

The cholesterol which was included as a reference compound was from Hoffmann-La Roche AG, Basel; it melted at 148.5°C.

Owing to the low solubilities of the bile acids in benzene, chloroform was employed as solvent. The chloroform solutions of the bile acids contained 2×10^{18} molecules per ml. (It was found that cholanic acid and cholesterol monolayers yield slightly smaller area values (by 0.8 Å^2 per molecule) when chloroform than when benzene is the solvent. The surface pressures were not affected by the solvent. The observed difference may be due to the fact that the solubility of chloroform in water is ten times greater than that of benzene.)

The chloroform solutions of the bile acids were added to the surface of the aqueous substrate in a Langmuir trough from an Agla micrometer syringe. The surface pressure-area curves of the monolayers were recorded with an automatic, self-recording surface balance of the Wilhelmy-Dervichian type (as improved by Andersson-Groth, Ställberg-Stenhagen and Stenhagen [10]). Compression of the monolayer was begun 2 min after the substance had spread on the substrate surface. The rate of compression was 13 – 14 cm/min; the area values were found to be completely, and the pressure areas practically, independent of the rate of compression in this range. (When much lower rates of compression were employed, this was no longer the case; the area values tended to decrease and the pressure values to increase as the rate of compression was diminished. When the rate of compression was appreciable higher, from 25 – 50 cm/min, the pressure-area curves were no longer reproducible.)

The substrate was water or a 3 M sodium chloride solution; in both cases the pH was lowered to 1.9 – 2.0 with hydrochloric acid.

The viscosities of the monolayers were examined by a modified talcum powder method. If the powder did not move when a weak current of air was blown on the layer, the monolayer was judged to be solid.

EXPERIMENTAL RESULTS

Typical pressure-area curves recorded for the cholanic and glycocholanic acid monolayers are shown in Figs. 1 and 2. Curves for cholesterol monolayers recorded under identical conditions have also been drawn in the figures. The notations used to designate various characteristic points on the pressure-area curves in these figures will be employed for reference in the following.

Characteristic data for bile acid and cholesterol monolayers are given in Table 1. The thicknesses of the monolayers at the collapse point, K_{extr} or K_{max}, have been calculated by assuming that the densities of all the monolayer substances are 1.067 g/ml, *i. e.*, that of crystalline cholesterol. (In the literature we have found only the density value for norcholanic acid, $d = 1.13$).

On a salt-free substrate the bile acid monolayers must be compressed to an area of 44 Å^2 per molecule before the surface pressure begins to increase. With cholanic acid the pressure then increases steeply up to the collapse point. (The peak at the collapse point disappears when a lower rate of compression is employed.) In the pressure-area curve for glycocholanic acid a curvature

showing that a transition takes place is seen at a pressure of 6.0 dynes / cm; on both sides of the transition region, the curves have a large slope. The pressure required to effect collapse of the glycocholanic acid monolayer is almost 50 % greater than that required for the cholanic acid monolayer. The area per molecule at the collapse point is 40 Å² for cholanic acid and 39 Å² for glycocholanic acid.

The area and pressure values recorded on a 3 M sodium chloride substrate are generally slightly higher than those recorded with pure water as substrate. An exception is the area value at point 0 for glycocholanic acid which is 1.4 Å² per molecule lower. This is due to the fact that the transition range and the

lower section in the pressure-area curve of glycocholanic acid do not become evident when the sodium chloride content of the substrate is high enough; this is shown by the curves in Fig. 3 recorded with increasing salt concentration.

In order to determine the effect of temperature on the transition that occurs in the glycocholanic acid monolayer, pressure-area curves were recorded at different temperatures (Fig. 4). It was found that at temperatures below 14 °C the monolayer is solid already at point 0 and remains so on further

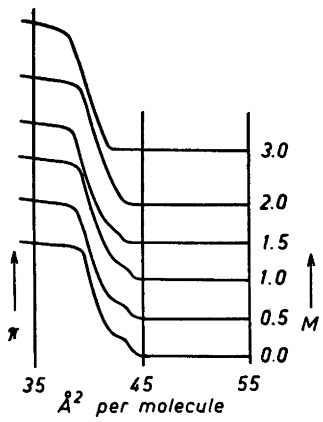

Fig. 3. Effect of substrate salt content on the glycocholanic acid monolayer. Range 0—3 M NaCl. pH 2. 20°C.

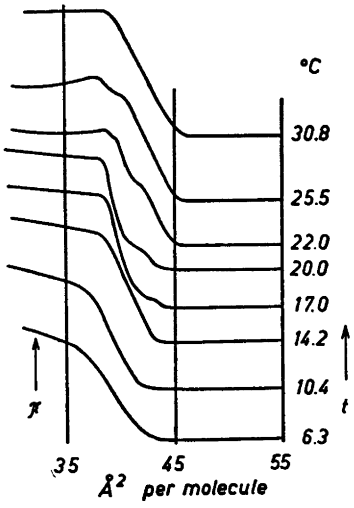

Fig. 4. Effect of temperature on the glycocholanic acid monolayer. Water of pH 2.

compression. At temperatures where the transition is observed, the monolayer is liquid up to the transition point (the point "tr"), but is solid above the latter, at least up to 22 °C. At temperatures above 26 °C, however, the surface layer becomes solid only after the monolayer has collapsed. A transition from a liquid to a solid phase thus occurs at the point tr, at least at temperatures between 15° and 22 °C.

DISCUSSION

In contrast to apocholic acid, cholanic and glycocholanic acids form monolayers of the condensed type (Figs. 1—4). This is obviously due to the presence of only one hydrophilic group in their molecules, *i. e.*, the carboxyl group at the end of the alkyl chain.

On the basis of information reported in the literature on the configurations of the bile acids and cholesterol [11] and with the aid of molecular models constructed from Stuart atomic calottes, we have attempted to compute the smallest areas that the molecules can take up in densely packed monomolecular layers (Table 2).

Table 2. Lengths and smallest cross-sectional areas of bile acids. Calculations based on molecular models.

Compound	Length of molecule Å	Molecular area perpendicular to major axis Å²	Smallest projection area with the molecule inclined 12° from the vertical Å²
Cholanic acid	18.5	45.5	44
Glycocholanic acid	22.0	45.5	44
Cholesterol	21.8	35	35

The experimentally found areas per molecule at point 0 (A_0) are of the same magnitude as the computed areas. This shows that the bile acid molecules are densely packed already at this point. A further compression can occur only if the molecules are fitted into each other. Between the points 0 and K, the molecules are oriented almost perpendicular to the substrate surface with the alkyl chain and its terminal carboxyl group projecting into the surface. Lacking exact values for the densities of the acids, only approximate values can be calculated for the thicknesses of the monomolecular layers. They are somewhat lower than the calculated maximum lengths of the molecules, apparently because the monolayer molecules at the collapse point are inclined about 12° from the vertical and because the molecules are somewhat curved. The experimental value for cholanic acid agrees fairly well with the value for desoxycholic acid (13.5 Å) calculated from data obtained in X-ray investigations of choleic acid crystals [12].

It is interesting to compare the monolayers of the bile acids with that of cholesterol. From molecular models, Harkins, Ries and Carman [13] have estimated the smallest cross-sectional area of a cholesterol molecule (assumed

to be a parallelepiped) to be 37 Å². Our calculations gave for the minimum projection area of cholesterol the value 35 Å². The former value is in fairly good agreement with our experimentally determined area requirement at point 0, $A_0 = 37.4$ Å², and the latter with the experimental value at the collapse point, $A_{Kextr} = 35.4$ Å². The molecules in the cholesterol monolayer are thus densely packed and nearly perpendicular to the surface at the point 0. The carbon atom 3 bearing the hydrophilic hydroxyl group and the carbon atom 17 which carries the alkyl chain with its terminal carboxyl group are at opposite ends of the molecule. As a consequence the arrangement of the cholesterol and the bile acid molecules is different in compressed monolayers. The former stand with the hydrophenanthrene skeleton pointing downwards, whereas the latter stand with their alkyl chains projecting into the substrate and the ring skeleton pointing upwards. It should further be noted that the alkyl chain of the bile acids is shorter than that of cholesterol and that the rings A and B are in the *cis* positions in the bile acid molecule but in the *trans* positions in the cholesterol molecule. There is further a double bond in the 5, 6 position in cholesterol. In a study of sterol monolayers, Adam, Askew and Danielli [1] found that the introduction of a double bound in the 5, 6 position increases the area requirement by approximately 1.8 Å² and that the change in the positions of the rings A and B from *trans* to *cis* configuration increases the molecular area by approximately 2.8 Å² at a surface pressure of 20 dynes / cm. From this it may be concluded that the area requirement of the bile acid ring skeleton is larger than that of cholesterol by about 1 Å². The observed difference of 3—5 Å² between the molecular areas in bile acid and cholesterol monolayers (Table 1) is thus for the most part due to the different orientations of the molecules in the monolayers. The appreciably lower collapse pressures found for the bile acid monolayers are apparently due to the same factor. The arrangement with the alkyl chain pointing downwards and the hydrophenanthrene ring system upwards apparently results in a less dense packing and a weaker cohesion than the opposite arrangement.

Since the only difference between cholanic and glycocholanic acids is that the latter contains a conjugated glycine molecule, this must be responsible for the curvature observed in the pressure-area curve of the latter acid at temperatures between 16° and 26 °C. At the lowest temperature studied (6—7°C), the solid glycocholanic acid monolayer gives a smooth pressure-area curve (Fig. 4) and the area can be reduced to about 37 Å² per molecule before a gradual collapse occurs. The A_0 values are 45—46 Å² per molecule, and the compressibilities calculated from the slopes of the curves at the inflexion points are rather high ($-\varkappa = 5—6 \times 10^{-3}$). When, however, the temperature rises above 10°C, the compressibility diminishes gradually, the curvature at the collapse point becomes sharper, and A_{Kextr} increases to a slightly higher value. The values of the surface pressures, areas per molecule and the compressibilities at different temperatures are given in Figs. 5, 6 and 7. In the temperature range 14°—26° where the transformation is observed, the properties of the liquid phase at low pressures (Phase 1), and those of the solid phase at high pressures (Phase 2) are well defined; the compressibilities of the two phases remain constant ($-\frac{\partial A}{A \partial \pi} = -\varkappa = 3—6 \times 10^{-3}$ and 1.8×10^{-3} cm / dyne)

(Fig. 7) and the areas at the inflexion points decrease linearly with rising temperature. Above 22°C, however, the high pressure phase (Phase 2) becomes less well defined, and is no longer observed above 26°C. At temperatures above the latter the surface layer solidifies only after the collapse point has been passed.

On the basis of the two dimensional analogue of the Clausius-Clapeyron equation [14]

$$\frac{d\pi_{tr}}{dT} = \frac{\Delta H_{tr}}{T \cdot \Delta A_{tr}} \qquad (1)$$

we have calculated the changes in molar heat content, ΔH_{tr}, accompanying the monolayer transformation in the range from 17° to 24 °C. In this equation π_{tr} is the equilibrium transition pressure of the monolayer at temperature T and ΔA_{tr} is the net change in molar area. We have taken ΔA_{tr} equal to the difference between the tangents drawn to the curves at the inflexion points. The value of ΔA_{tr} decreases linearly with rising temperature between 17° and 24°C (Fig. 8).

The calculated ΔH_{tr} values vary from about —1 000 to about —2 500 cal/mole (Fig. 9). The expression $\frac{\partial \Delta H_{tr}}{\partial T}$ is negative up to 22°C, but positive above the latter temperature. Since $\left(\frac{\partial \Delta H_{tr}}{\partial T}\right)_{\pi} = C_{\pi_2} - C_{\pi_1} = \Delta C_{\pi}$ (where C_{π} is the molar heat content of the phase), the values of this expression suggest that whereas the degrees of kinetic freedom of phase 2 are restricted compared to those of phase 1 below 22 °C, the opposite is true above this temperature. Our observations show that Phase 2 is solid and has a constant low compressibility up to the latter temperature, but that the properties of this phase are

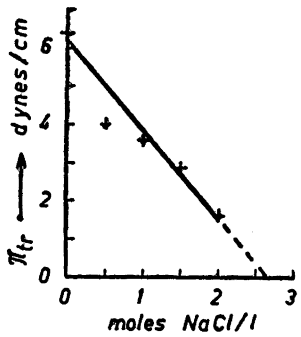

Fig. 10. Variation of the transition surface pressure with salt content of the substrate in the glycocholanic acid monolayer. 20°C.

less well defined (the compressibility increases continuously) between 22° and 24 °C. Further conclusions cannot be drawn owing to the limited experimental information available at present.

For a transformation at constant pressure, the net change in molar heat content is

$$\Delta H_{tr} = \Delta E_{tr} + \pi_{tr}\Delta A_{tr} \qquad (2)$$

where ΔE_{tr} is the net change in the molar internal energy of the monolayer system and $\pi_{tr}\Delta A_{tr}$ the work done by the system. At zero transition pressure, $\Delta H_{tr} = \Delta E_{tr}$. For the observed transition pressures, the values of ΔE_{tr} are only 10—25 cal/mole more positive than the ΔH_{tr} values; the temperature dependence of both is the same. The phase transformation is accompanied by a decrease in the internal energy, and the magnitude of ΔE_{tr} (—1 000 to —2 000 cal/mole) suggests that hydrogen bond formation takes place between the molecules in the monolayer. If this is true, it is probable that the hydrogen atom of the imino group is involved. In the range 14—22° a liquid monolayer is thus first formed which on compression is transformed into a solid layer, obviously with the formation of hydrogen bonds. This transition does not occur above 26°C, and above this temperature the glycocholanic acid monolayer is liquid up to the collapse point similarly as that of cholanic acid.

An increase in the sodium chloride content of the substrate has the same effect as a moderate decrease in temperature. The transition pressure decreases and the liquid phase 1 disappears (Fig. 10). When the salt content of the substrate becomes sufficiently high, the monolayer is directly transformed on compression into phase 2 with a low compressibility.

Surface Balance Studies of Bile Acid Monolayers

II. Monolayers of Litocholic and Glycolitocholic Acids

PER EKWALL, REINO EKHOLM and ARNE NORMAN*

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

Litocholic and glycolitocholic acid monolayers have been studied with the same experimental technique as described in Part I [2]. The pressure-area curves for both the lithocholic acids differ appreciably from the curves for the cholanic acids, evidently due to the fact that there are two hydrophilic groups in the former and only one in the latter molecules. The molecules lie flat on the substrate surface and on compression the layer is first composed of densely packed lying molecules. When this monolayer collapses, pairs of lithocholic acid molecules, probably with their hydrophilic groups opposite each other, slide up on the monolayer and form a termolecular layer of lying molecules. This triple layer collapses in turn at a somewhat higher pressure. The transformation of the monolayer to a triple layer is accompanied by an increase in internal energy amounting to about 3 000 cal/mole.

Conclusions about the probable arrangement of the bile acid ions in the micelles present in bile salt solutions are drawn from the results of the monolayer studies.

The samples of litocholic and glycolitocholic acids were synthesized as previously described by one of us (A.N.) [1]. The methods used in the investigation of the monolayers have been described in Part I of this series [2]. Chloroform was employed as solvent for the acids. The solution of litocholic acid contained 2×10^{18} molecules per ml and that of glycolitocholic acid 0.67×10^{18} molecules per ml. Moderate variations in the rate with which the monolayers were compressed was not found to have any influence on the shape of the surface pressure-area curves.

EXPERIMENTAL RESULTS

Figs. 1 and 2 show typical pressure-area curves for litocholic and glycolitocholic acid monolayers recorded on salt-free and salt-containing substrates of pH 2. In some cases also a 3 M sodium chloride solution saturated with lito-

cholic acid was used as substrate; the solubility of the acid is so low that no transfer of the acid from the bulk of the solution to the surface was detected with the surface balance during 3 h; the pressure-area curves for litocholic acid recorded on this substrate were both qualitatively and quantitatively identical with the curves recorded on 3 M sodium chloride without prior saturation of the latter with the acid.

The pressure-area curves of litocholic acid monolayers on 3 M sodium chloride were recorded at various temperatures between 10° and 40 °C. Temperature had no effect on the shape of the curve; the area values were almost unchanged, but the surface pressure decreased linearly with increasing temperature (Fig. 3).

The notations used in Fig. 1 to designate various points on the pressure-area curves will be employed in the following discussion. For comparison, the pressure-area curve for cholanic acid has also been drawn in the figures.

Observations made with talcum powder indicated that the viscosities of the surface films of lito- and glycolitocholic acids undergo marked changes at two stages during the compression; at the first stage the film becomes much more viscous and in the second stage it becomes solid.

Characteristic monolayer data for the two bile acids at 20 °C are given in Table 1.

DISCUSSION

The pressure-area curves for the two litocholic acids differ appreciably from the curves for cholanic acids. The differences are evidently due to the fact that whereas the cholanic acid molecule contains only one hydrophilic group, *viz.* a carboxyl group at the end of the alkyl chain, the litocholic acids contain an additional hydroxyl group on carbon atom 3 at the opposite end of the molecule. Molecules with two hydrophilic groups separated a longer distance from each other, exhibit a tendency to lie more or less parallel to the substrate surface and generally form monolayers of the gaseous type. The pressure-area curves in Figs. 1 and 2, however, seem to suggest that the litocholic acids form monolayers of the condensed type on compression.

We have calculated with the aid of Stuart's molecule models the dimensions of the lithocholic acid molecules and the areas the molecules take up when they lie in different positions in densely packed monolayers (Table 2). The largest values in the table give the areas taken up by the molecules when they lie flat on the surface with their longitudinal axes parallel to the surface. The ring skeleton of the molecule is rigid but the alkyl chain can be folded; consequently

Table 2. Molecular dimensions and area requirements calculated from molecular models.

	Length of molecule Å	Area requirement in monolayer					Area requirement with molecules lying on edge in termolecular layer Å² per molecule
		molecules lying flat Å² per molecule		molecules on edge Å² per molecule		molecules vertical, minimum projection area Å² per molecule	
		max.	min.	max.	min.		
Litocholic acid	18.5	107	85	79	76	44.0	28—25
Glycolitocholic acid	22.0	122	85	93	76	44.0	28—25

it is possible for the area taken up by the molecule to decrease when the monolayer is compressed without the hydrophilic groups losing contact with the substrate surface. This minimum area requirement is also given in Table 2.

A comparison of the experimental data for the litocholic acids and the calculated area requirements shows that the observed value $A_0 = 100—110$ Å² per molecule closely corresponds to that of a molecule lying flat on the surface. Accordingly, already at the point 0 the monolayer is composed of densely packed molecules lying on the surface. The pressure-area curves exhibit no sharp break point in the range 120—70 Å²; the pressure increases slowly and at the inflexion points the monolayers have a compressibility, $-\varkappa$, equal to $0.013—0.018 \times 10^{-3}$ cm/dyne.

The monolayer can be compressed to an area of 85—65 Å² per molecule before the curve bends at the break point $K_1—K_{eq}$ and becomes almost horizontal. The latter area values approximately correspond to the smallest area requirements we have calculated for densely packed molecules which still have both hydrophilic groups in contact with the substrate surface. The high compressibility of the monolayer thus appears to be due to the fact that the molecules, while remaining in the horizontal position, rearrange themselves with increasing lateral pressure so that they first take up a smaller area and are then forced to fold to some extent.

In the relatively wide range of more or less constant surface pressure which follows after the break point at $K_1—K_{eq}$, the surface film is liquid but highly viscous. In the case of litocholic acid this state of the film prevails until it has been compressed to an area of about 29 Å² per molecule, after which the pressure begins to increase. When the area is decreased to 24 Å² per molecule, the curve shows a sharp break point at K_2 which resembles a normal collapse point, and after this point has been passed the film solidifies. When trying to interpret the pressure-area curve in this range the following facts may be considered. The fact that the area values for litocholic acid did not differ when the substrate was a pure 3 M sodium chloride solution and a similar solution saturated with the acid shows that the form of the pressure-area curve between the points K_1 and K_2 is not due to the transfer of litocholic acid from the monolayer into the substrate. If, after the break point $K_1—K_{eq}$,

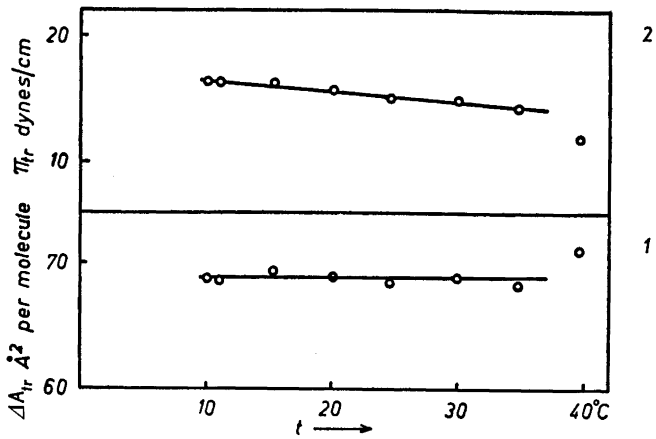

Fig. 3. 1. The change in the molecular area at the transition point, ΔA_{tr}, in the transformation of litocholic acid monolayer into a triple layer. 2. Variation of the surface pressure at the transition point.

larger and larger numbers of the monolayer molecules were forced to assume a vertical position in such a way that one of the hydrophilic groups (*e. g.* the hydroxyl group) is forced away from the substrate surface, this would finally lead to a monolayer composed of molecules in a more or less vertical position. Such a monolayer must, however, collapse after it has been compressed to an area of 44 Å² per molecule (*cf.* Part I[2]). The experimentally observed value of 24 Å² per molecule is, however, so low that it is impossible that such a monolayer of vertically oriented molecules can exist down to this point. The observed area value is on the other hand in fairly good agreement with the area requirement per molecule in a termolecular layer of molecules lying densely packed on their edges. From experiments performed using the built-up technique it is known that an arrangement of molecules such as that shown in Fig. 4 is very stable. In our case, conditions are furthermore suitable for the formation of hydrogen bonds between the hydrophilic groups when the molecules are arranged in this way. It therefore seems probable that the monomolecular layer "collapses" already at the break point K_1—K_{eq}, but when doing this pairs of litocholic acid molecules with their hydrophilic groups opposite each other slide up on the monolayer and form a termolecular layer of the type shown in Fig. 4. This transition of the monolayer into a triple layer seems to be reversible. The termolecular film collapses at K_2; here we have the real collapse point of the surface layer system. The termocular film is liquid, but

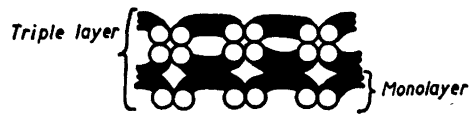

Fig. 4. Schematic arrangement of molecules in a triple layer of litocholic acid.

after the collapse at K_2, crystallization occurs, the earlier the lower the temperature.

As mentioned above, variation of the temperature between 10° and 40 °C does not effect any changes in the shape of the pressure-area curve of litocholic acid (Fig. 3). We are inclined to consider the transition from the liquid monolayer to the liquid triple layer as a transformation of the first order and have calculated the changes in molar heat content. ΔH_{tr}, in the transformation on the basis of the two-dimensional analogue of the Clausius-Clapeyron equation. The values of the equilibrium transition pressure, π_{tr}, and of the net change in monomolecular area, ΔA_{tr}, at the transformation point at different temperatures are given in Fig. 3. For the molar heat content, ΔH_{tr}, we have calculated in this way the value 1 800 cal/mole, and for the net change in the molar internal energy, ΔE_{tr}, we have found values of the order of 3 100—2 900 cal/mole.

The glycolitocholic acid monolayers behave in a similar manner as the litocholic acid monolayer. The phenomena are not, however, so distinct, primarily because the film becomes solid already before the triple layer collapses, *i. e.* when an area of 30 $Å^2$ per molecule is attained. The pressure rises but no collapse is observed to occur.

It may be mentioned that the "collapse" of the monolayers of both litocholic acids at appreciably lower surface pressures than that where the corresponding cholanic acid monolayer collapses (Figs. 1 and 2) can be ascribed to the prone arrangement of the litocholic acid molecules on the substrate surface. With this arrangement, the area of contact between the hydrocarbon parts of the molecules is only half that in a monolayer with the molecules in a vertical position. Accordingly the cohesion forces per unit area between the molecules in the monolayer must be weaker in the former case.

The results of our monolayer studies can be used to draw conclusions about the probable arrangement of bile acid ions in the micelles present in bile salt solutions. In cholanate solutions the conditions are probably such that micelles of essentially similar structure as those in the fatty acid salt solutions can be formed, *i. e.* micelles with the long anions arranged more or less parallel in double layers or in cylindrical or spheroidal aggregates in which all the hydrophilic groups face the surrounding water. In litocholate solutions a different micellar structure is more probable. In the smallest aggregates, it can be expected that the most advantageous arrangement from the energetic viewpoint is one in which 2 to 4 ions lie back to back with the hydrocarbon parts touching each other and the hydrophilic groups projecting outwards. Even larger aggregates may be assumed to be formed in a similar manner, for example, a double layer of ions with contiguous hydrocarbon parts. The size that such an aggregate can attain must however be very limited. When the aggregation proceeds further, a new arrangement must sooner or later result in which a part of the ions turn so that their hydrophilic groups approach each other, in the same way as in the termolecular films (Fig. 4). Ion-dipole interaction may play a role in keeping these anions together. A similar arrangement is possible in the micelles of the desoxycholates and cholates which have, respectively, two and three hydroxyl groups in their molecules. Our discussion thus leads to the conclusion that the association in these bile salt solutions

should result in the formation of different types of aggregates with different properties. This conclusion is to some extent confirmed by experimental findings. Our earlier investigations have revealed that the association in solutions of bile salts (desoxycholates and cholates) proceeds stepwise and that the properties of the micellar substance deviate from each other in different concentration ranges [3-4].

The Complex between Hydroxamic Acids and Ferric Ions, and the Use of the Complex for Quantitative Determination of Hydroxamic Acids, Acylderivatives and Ferric Salts

GUNNAR AKSNES

Forsvarets forskningsinstitutt, Kjeller, Norway

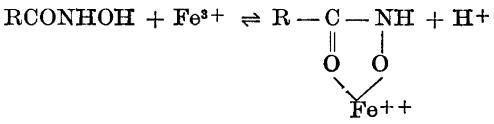
The dissociation constants of the complex between ferric ions and acet- and benzhydroxamic acids have been determined in acid solution (pH = 1.4). The ratio between hydroxamic acid and ferric ions in the complex is 1:1.

When the complex is used for quantitative determination of acylderivatives the hydroxylamine, which must always be present in excess, will influence the stability of the complex.

In weakly alkaline solution the complex between iron and hydroxamic acids is probably $Fe(RCONHO)_3$. This complex can be used for quantitative determination of ferric salts.

Hydroxamic acids and ferric ions give complex compounds which absorb light in the visible region [1,2]. For the last 10 years there has been a growing interest in this reaction, because a variety of acylderivatives can be quantitatively converted into hydroxamic acids with the aid of hydroxylamine [3–6].

Hestrin [6] observed that, when using the hydroxamic acid-ferric complex method for determination of acetylcholin, the colour of the complex will fade when the pH of the solution is allowed to get below 1.2. The quantity of ferric chloride which is necessary to give complete transformation of hydroxamic acids to the complex, is very high. Hestrin therefore concluded that the dissociating tendency of the ferric-acethydroxamic acid complex must be fairly high at the pH used (1.4).



It will be shown in this work that the complex is very stable. It is further found that the dissociating tendency of the complex observed by Hestrin is partly caused by the reduction of ferric to ferrous iron by hydroxylamine.

DETERMINATION OF THE DISSOCIATION CONSTANTS OF ACET- AND BENZHYDROXAMIC ACIDS-FERRIC COMPLEXES

In order to determine the true dissociation constants for the two complexes it was necessary to work in the absence of hydroxylamine. The hydroxamic acids (acet- and benzhydroxamic acids) were therefore synthesized separately.

The absorption curves of the two complexes at pH 1.4 are shown in Fig. 1. In Fig. 2 log ε is given as a function of the ferric ion concentration with a fixed concentration of hydroxamic acid. In Fig. 3 log ε is given as a function of the acethydroxamic acid concentration with great excess of ferric chloride (lowest ratio approx. 20). The extinction of the complex follows Beer's law over a wide range of hydroxamic acid concentrations. This enables one to determine the dissociation constants from absorption measurements.

It is commonly believed that the complex between ferric ions and hydroxamic acids in acid solution is a 1:1 complex, though this has not yet been proved:

When the hydrogen ion concentration is fixed, we therefore have:

$$K_{\text{complex}} = \frac{C_{\text{hydroxamic acid}} \times C_{\text{Fe}}^{3+}}{C_{\text{complex}}}$$

If the concentration of complex is measured in a mixture of known amounts of hydroxamic acid and ferric ions, the dissociation constant, K_{complex}, can be evaluated from the equation:

$$K_{\text{complex}} = \frac{(a-c)(b-c)}{c}$$

a = initial concentration of hydroxamic acid
b = " " " ferric ions
c = the measured complex concentration

Because the extinction of the complex follows Beer's law we have:
$C = fI$
I = log extinction (log ε)
f = proportionality factor

From this one obtains:

$$K_{\text{complex}} = \frac{(a - fI)\,(b - fI)}{fI}$$

The proportionality factor f has been evaluated by two different methods:

a) Determination of the complex extinction when a given quantity of hydroxamic acid is quantitatively transformed to the ferric-hydroxamic acid complex. This can be done by using ferric ions in great excess. Then we have:

$$C = a = fI_{\max}, \text{ hence } f = \frac{a}{I_{\max}}$$

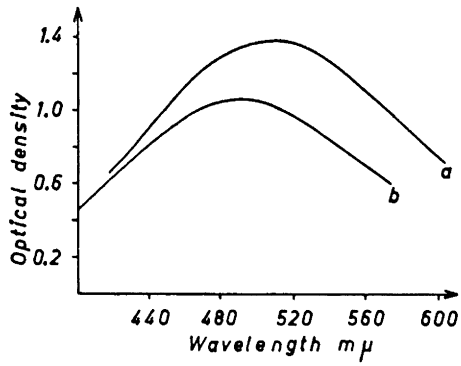


Fig. 1. (a) Absorption curves of complex between ferric ions and benzhydroxamic acid, and (b) complex between ferric ions and acethydroxamic acid. Concentration: 5 mg hydroxamic acid in 10 ml of 0.00925 M iron chloride adjusted to pH = 1.4 with hydrochloric acid.

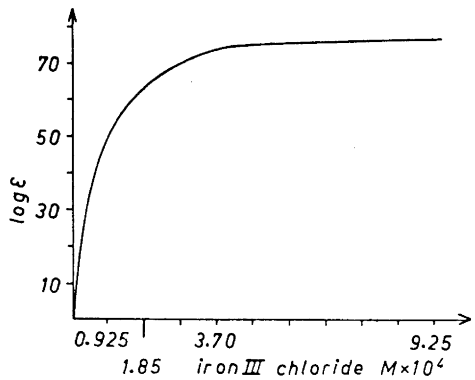

Fig. 2. Stability of ferric-acethydroxamic acid complex at constant pH (1.4). Concentration of acethydroxamic acid: 5×10^{-4} M. pH adjusted with hydrochloric acid.

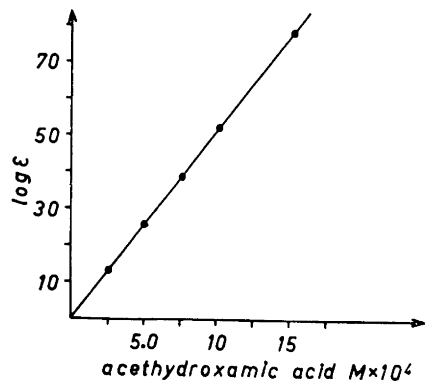

Fig. 3. log ε of ferric-acethydroxamic acid complex as function of acethydroxamic acid concentration (pH = 1.54). Concentration of ferric chloride: 0.0185 M. pH adjusted with hydrochloric acid.

b) If log ε of the complex is measured for two different sets of values for a and b, we get:

$$K_{\text{complex}} = \frac{(a_1 - fI_1)(b_1 - fI_1)}{fI_1} = \frac{(a_2 - fI_2)(b_2 - fI_2)}{fI_2}$$

f is found as the root in a second order equation.

The results are shown in Tables 1 and 2. The constancy of K_{complex} found for different values of a and b, indicates that the ratio between hydroxamic acid and ferric ions in the complex is 1:1.

THE INFLUENCE OF HYDROXYLAMINE ON THE STABILITY OF THE COMPLEX IN ACID SOLUTION

As mentioned in the introduction, hydroxylamine is always present in the solution when the complex is used for quantitative determination of acyl-derivatives.

The stability of the complex with and without a great excess of hydroxylamine, is shown in Fig. 4. The presence of hydroxylamine is seen to cause a rapid decrease in extinction during the first minutes; then the extinction drops more slowly. The reason for this rapid decrease in extinction is found in the ability of hydroxylamine to reduce ferric to ferrous ions according to the following equation:

$$2NH_2OH + 2Fe^{3+} \rightarrow 2Fe^{2+} + N_2O + 2H^+ + 2H_2O$$

The ferrous ions have been shown to give no complex formation with hydroxamic acids.

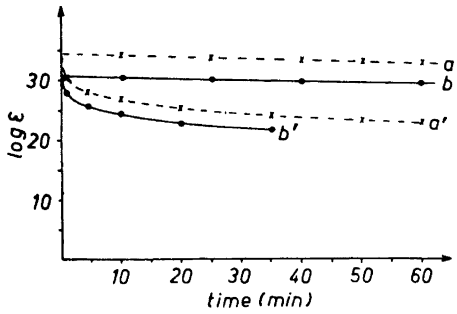

Fig. 4. Stability of ferric-hydroxamic acid complex as function of time.
a. 2.5 × 10^{-4} M benzhydroxamic acid + 1.85 × 10^{-3} M $FeCl_3$
b. 3.75 × 10^{-4} M acethydroxamic acid + 1.85 × 10^{-3} M $FeCl_3$
a'. 2.5 × 10^{-4} M benzhydroxamic acid + 1.85 × 10^{-3} M $FeCl_3$ + 0.05 M hydroxylamine
b'. 3.75 × 10^{-4} M acethydroxamic acid + 1.85 × 10^{-3} M $FeCl_3$ + 0.05 M hydroxylamine

The reaction is irreversible, but due to the formation of hydrogen ions the reaction will be greatly retarded with time in unbuffered solution (Fig. 4). The pH dependence of the reaction is shown in Fig. 5. The extinction and pH are measured 30 min after the start.

In an isolated experiment with benzhydroxamic acid and the same excess of Fe^{3+} the dissociation tendency of the complex was measured as function of pH. As seen from Fig. 5 the stability of the complex is greatly dependent on pH. The decrease in colour extinction in the presence of hydroxylamine is therefore dependent on both the reduction of the ferric concentration and the accompanying increase in hydrogen ion concentration.

Since the reduction of ferric ions by hydroxylamine will be greatly accelerated at higher pH, it is clear that when hydroxylamine is in excess, the extinction of the complex measured at fixed time intervals after mixing must show a maximum at a certain pH. On one side of the maximum (towards lower pH), the extinction of the complex will be reduced because the dissociation of the complex will increase; towards higher pH values the extinction will decrease because of rapid reduction of ferric to ferrous ions. This conclusion is clearly demonstrated in Fig. 5. The maximum is approximately pH 1.4 for both hydroxamic acids studied.

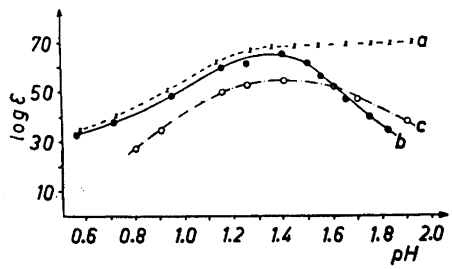

Fig. 5. pH dependence of the ferric-hydroxamic acid complex.
a. 8.41 × 10^{-3} M $FeCl_3$ + 4.57 × 10^{-4} M benzhydroxamic acid
b. 8.41 × 10^{-3} M $FeCl_3$ + 4.57 × 10^{-4} M benzhydroxamic acid + 0.182 M hydroxylamine.
c. 8.41 × 10^{-3} M $FeCl_3$ + 4.57 × 10^{-4} M acethydroxamic acid + 0.182 M hydroxylamine.
The extinction and pH were measured 30 min after start. pH was varied with hydrochloric acid.

THE VARIATION OF THE STRUCTURE OF THE FERRIC-HYDROXAMIC ACID COMPLEX WITH pH, AND THE USE OF THE COMPLEX IN ALKALINE SOLUTION FOR QUANTITATIVE DETERMINATION OF FERRIC IRON

It was of interest to study the absorption spectrum of the complex as a function of pH. Because the experiments were performed in both acid and alkaline solution, the hydroxamic acid was here used in great excess to avoid formation of ferric hydroxide.

From the absorption curves at different pH (Fig. 6) it is seen that there is a successive shift of the absorption maximum towards shorter wave length with increasing pH. At the same time the extinction of the complex increases although the iron and hydroxamic acid concentrations are kept constant. A new maximum seems to be formed at 440 mμ in neutral or weakly alkaline solution. At very high pH values this maximum disappears.

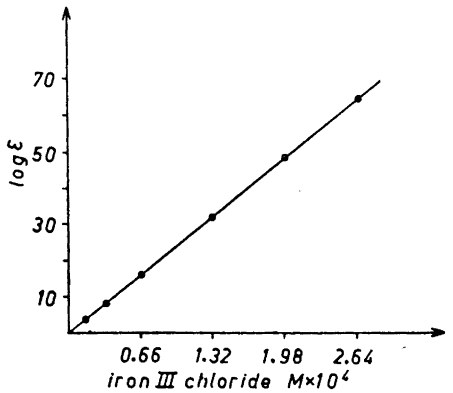

Fig. 7. Determination of ferric iron with acethydroxamic acid in alkaline solution. Concentration of acethydroxamic acid = 1.8×10^{-2} M. pH = 9.2 (*cf.* exptl. section).

The successive increase in extinction with pH suggests that the amount of hydroxamic acid in the complex increases successively with pH. This also explains the isolation of a neutral compound from alkaline alcoholic solution with an iron content corresponding to the formula $Fe(RCONHO)_3$. A possible variation of the structure of the complex with pH is the following:

$$\underset{\text{(acid)}}{Fe(RCONHO)^{++}} \rightleftharpoons \underset{\text{(weakly acid)}}{Fe(RCONHO)_2^{+}} \rightleftharpoons \underset{\text{(neutral or weakly alkaline)}}{Fe(RCONHO)_3} \rightleftharpoons \underset{\text{(strongly alkaline)}}{Fe(RCONO)_3^{---}}$$

It was of interest to examine whether the absorption maximum, which seems to be formed in weakly alkaline solution might be used for quantitative determination of ferric iron. The experiments were performed in a sodium carbonate-hydrogen carbonate buffer with great excess of hydroxamic acid. The results are shown in Fig. 7. It is seen that Beer's law is exactly valid over a wide range of ferric ion concentrations.

EXPERIMENTAL

Reagents. All reagents used were p.a. grade. The hydroxamic acids were synthesized according to descriptions in the literature [7].

Apparatus. The absorption curves were measured in a Beckman D.U. spectrophotometer. The colorimeter readings were taken with a Beckman electrophotometer. The hydrogen ion concentrations were measured with a Beckman pH meter, model H. 2.

Isolation of $Fe(C_6H_5CONHO)_3$. To a solution of 0.5 g ferric chloride and 3 g benzhydroxamic acid in 20 ml alcohol was added a 3 % solution of sodium alcoholate. A brownish precipitate was formed. It was filtered off and washed with alcohol and ether. (Found: Fe 12.20. Calc. for $Fe(C_6H_5CONHO)_3$ (464.22): Fe 12.46).

Determination of iron in alkaline solution. Reagents: Acethydroxamic acid 2 mg/ml. Buffer: 1.0 g sodium hydrogen carbonate + 0.5 g sodium carbonate in 100 ml water. Iron(III) chloride standard: 0.0001156–0.00185 M.

5 ml acethydroxamic acid solution was mixed with 1 ml iron chloride solution, and 1 ml buffer was thereafter added. The colorimeter readings were taken with a Beckman electrophotometer, filter 525 mμ.

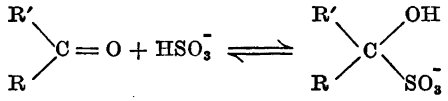
Paper Ionophoresis of Aldehydes and Ketones in the Presence of Hydrogen Sulphite



OLOF THEANDER

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, and Träkemiska Avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

A number of aldehydes and ketones of different types have been studied by paper ionophoresis in hydrogen sulphite buffers of different concentrations and pH. The method is useful for the separation and characterisation of many carbonyl compounds.

Sugars have been studied by paper ionophoresis, generally in borate buffers [1], but electrophoretic methods for the separation of other aldehydes and ketones have not yet been developed. In a recent paper, Frahn and Mills [2] describe the ionophoretic behaviour of some sugars and glycols in aqueous solutions of borate, tungstate, vanadate, molybdate, arsenite, basic lead acetate and sodium hydroxide.

In the present publication a method is described for paper ionophoresis of aldehydes and ketones after conversion to the hydroxysulphonic acids. The ionophoresis is carried out in hydrogen sulphite buffers. The formation by aldehydes and many ketones of hydroxysulphonates, which can often be obtained in a crystalline state and are easily decomposed by alkali and acids, is well known.

(I)

The present method was worked out for fractionation and characterisation of a number of carbonyl compounds obtained from the oxidation of methyl glucosides [3]. Some other carbohydrates, and some aromatic aldehydes and other carbonyl compounds have also been investigated by this method.

Hydroxysulphonic acids are strong acids and can be considered as completely dissociated in the buffers used. The rate of migration of a carbonyl compound in a sulphite buffer should therefore depend largely upon the migration velocity of the ion and on the equilibrium I, assuming of course that the equilibrium is set up sufficiently fast that the carbonyl compound and its

sulphite adduct move as one substance. By using a low concentration of hydrogen sulphite, it is obviously possible to decrease the migration velocity of substances which give an adduct with a high dissociation constant, so that they separate better from substances with low dissociation constants. The equilibrium constants and the velocity coefficients are dependent on the temperature.

In a sugar solution there is an equilibrium between the different forms, the α and β pyranosides and furanosides. The interconversion of these forms, which is, of course, influenced by pH, temperature and other factors, probably takes place through the intermediate formation of the open aldehyde or keto forms of the sugar. The equilibrium constants for the hydrogen sulphite adducts of different sugars have been determined by Sundman [4]. He found that in each of the groups: glucose and the disaccharides with glucose at the reducing end, the remaining hexoses and pentoses, the methylpentoses and the uronic acids, the equilibrium constants were fairly closely related to the mutarotation constants. The higher the mutarotation constant the lower the equilibrium constant. The fractionation of sugars on ion exchange columns in the hydrogen sulphite form has been studied by Samuelsson [5].

Since the completion of this work a paper by Frahn and Mills [6] has been published describing the ionophoresis of some sugars and oligosaccharides in hydrogen sulphite solution. Under the conditions used (0.4 M unbuffered hydrogen sulphite at room temperature) the equilibrium between the sugar and the adduct was only slowly established. Each sugar gave two spots with streaking between, one representing the uncharged sugar with no migration and the other, which became quite faint after prolonged runs, the hydroxysulphonate ion. The distances between these spots were roughly equal for isomeric sugars but decreased with the molecular weight. This makes it possible to determine the chain length of lower oligosaccharides.

The addition of hydrogen sulphite to carbonyl compounds other than carbohydrates has been studied very little. Smith and Nichols [7] studied the addition to methylbenzaldehydes. The analogous cyanhydrin reaction has been more thoroughly investigated [8–11].

As an index of migration for the ions of hydrogen sulphite carbonyl compounds the term M_v is suggested, where for any substance

$$M_v = \frac{\text{true distance of migration of the substance}}{\text{true distance of migration of vanillin}}$$

Vanillin is chosen as reference substance since it migrates reasonably rapidly. The phenolic group is not ionized under the standard conditions used. The movement due to electro-endosmotic flow is corrected for by using methyl-β-glucoside as a reference compound.

Table 1 shows the influence of pH on the separation and shows for comparison the migration rates in some buffers not containing hydrogen sulphite. Sundman [4] worked with pH 4.7 as standard, and this pH has also been chosen here as standard. The concentration of hydrogen sulphite ion has a flat maximum at about pH 5 (the dissociation constants are $K_1 = 1.66 \times 10^{-2}$ and $K_2 = 1.02 \times 10^{-7}$). A better separation can be obtained in some cases at

higher pH values (*e. g.* between 6-aldehydo- and 3-keto-methyl-β-glucopyranoside) or by using pH 4.7 and a lower concentration of hydrogen sulphite. (Table 2). It is interesting to note that a good separation is obtained between glucuronic acid and galacturonic acid, but that the reversed order of migration is obtained in the absence of hydrogen sulphite. A disadvantage of using a higher pH is the increasing ionization of phenolic groups (*e. g.* in vanillin and formylvanillin). Unbuffered hydrogen sulphite was also tried but was found, to be less satisfactory. Freshly made it had a pH of 3.8 at 0.1 M concentration but after a few runs the pH was below 3.0.

Table 2 shows migration rates for some substances in hydrogen sulphite buffers at pH 4.7 and varying concentrations. It is evident that the migration velocity increases with increasing concentration. In agreement with the argument above, the separation is improved by decreasing the concentration of hydrogen sulphite. This is also shown in Table 4 for some aromatic aldehydes and oxidized glucosides. A disadvantage of using an electrolyte of too low a concentration is the tendency to tail and the lack of reproducibility after the solvent has been used for a few runs.

The M_v values at room temperature for some aldehydes and ketones in the buffer chosen as standard, 0.1 M hydrogen sulphite buffered to pH 4.7, are presented in Table 3. These values are reproducible to within ± 0.02 units or less. The spots obtained were round and sharp. As the unsubstituted sugars gave more or less long streaking spots under standard conditions, due to the relatively slow equilibrium between sugar and adduct they were also run at 60 °C (Table 5). At this temperature they gave single, concentrated spots, but the M_v values were approximately the same as those obtained at room temperature. The M_v values are in good qualitative agreement with the equilibrium constants of sugar hydrogen sulphite adducts estimated by Sundman [4]. It is obvious that for characterising and separating sugars the method is a good complement to the borate electrophoresis method and to paper chromatography.

It will be noticed that methyl β-3-ketoglucoside has a higher affinity for hydrogen sulphite than methyl α-3-ketoglucoside. The M_v values for the oxidized glucosides in the series are comparable with the M_v values of aldehydo-pentacetylglucose and *n*-heptanal and the aldehydo-glucoside is more reactive than the keto glucosides. On the other hand the difference in affinity between keto-glucosides and ketoses is remarkable. The separation of oxidized glucosides is improved by using a lower concentration of hydrogen sulphite (Table 3) or a higher temperature [3].

It is interesting to compare periodate oxidized methyl-β-glucopyranoside with periodate oxidized methyl-β-xylopyranoside. The first gave two spots of approximately the same intensity, with streaking between, and M_v values of about 1.0 and 1.5, respectively. The other gave only one spot with an M_v value of about 1.6. Those spots might indicate one (M_v 1.0) and two (M_v 1.5; 1.6) carbonyl groups available, respectively, for the formation of hydrogen sulphite adducts *.

* *Added in proof:* These results are confirmed by recent investigations of periodate oxidized methyl glycosides (Smith, F. *et al. J. Am. Chem. Soc.* **79** (1957) 691, and Mester, L. and Móczár, E. *Chemistry & Industry* **1957** 761).

The expected contribution to the M_v value when a new carbonyl group is introduced can be seen by comparison between the M_v values of *cyclo*hexanone and *cyclo*hexane-1:3-dione. In the group of substituted benzaldehydes investigated there is in some cases no separation at all and in others a good separation, particularly with low concentration of hydrogen sulphite. Lapworth and Manske [8] have investigated the effect of different substituents on the addition of hydrogen cyanide to substituted benzaldehyde. For *ortho*-, *meta*-, and *para*-hydroxy and *para*methoxy substituted benzaldehydes the M_v values and the equilibrium constants of the corresponding cyanhydrins were parallel. An exception was found in the *ortho*- and *para*-hydroxybenzaldehydes at 20 °C. At 60 °C, however, the order of their M_v values was reversed. There was no appreciable improvement in the separation of the aromatic aldehydes when higher temperatures were used during the runs. The distance of migration of the aromatic aldehydes over the same potential gradient and time was 10—20 % greater at 60 °C than at room temperature.

Barker, Bourne and Theander [12] used a borate containing eluant for the carbon column chromatography of some sugars which were difficult to separate by ordinary carbon column chromatography, but showed different electrophoretic mobilities in borate buffers. The analogous use of sulphite in the eluant is obvious and a mixture of methyl-β-glucoside and methyl β-2-ketoglucoside has recently been separated by that method [3].

Table 1. The migration of some aldehydes and ketones in electrolytes of different pH (Whatman No. 3, room temperature, 14.8 V/cm, 3—5 h; the migration of galacturonic acid is taken as 1.00).

EXPERIMENTAL

The apparatus and technique of the paper ionophoresis are essentially the same as described by Foster [13]. The ionophoresis was usually run at room temperature on Whatman No. 3 paper, but in some cases the temperature was held at 60 °C with a thermostat circulating warm water through the condensing block, which supports the glass plates and paper. The compounds were located by the use of UV light, dinitrophenylhydrazine, silver nitrate-sodium ethoxide or anisidine hydrochloride. Methyl-β-glucoside used to indicate the endosmotic effect, was placed on the margins together with vanillin, the standard reference substance. The latter, which was also put on the middle of the starting line, was located under UV, the margin strips were cut out, methyl-β-glucoside was located with the silver reagent, and the main paper was treated with a suitable reagent. The potential gradient used varied between 12 and 18.5 V/cm; the time between 3 and 5 h. The substances to be investigated were generally applied as 1 % solutions to the dry paper. The paper was dipped and the potential gradient was applied about 5 min after the electrolyte had risen from both sides up to the starting line.

Electrolytes. The 0.1 M hydrogen sulphite solution at pH 4.7 used as standard electrolyte contained per litre, 9.5 g of dry sodium *pyro*sulphite, 8.8 g of sodium acetate trihydrate and acetic acid to a pH of 4.7 (about 2.3 ml). The buffers of pH 6 and 7 contained the same concentrations of hydrogen sulphite and were buffered with potassium dihydrogen phosphate (0.05 M) and sodium hydroxide, the electrolyte of pH 9.4 was 0.1 M sodium sulphite. The electrolytes of varying hydrogen sulphite concentration, 0.01 – 0.2 M, all contained the same amount of sodium acetate as the standard hydrogen sulphite electrolyte (0.1 M) and were adjusted to pH 4.7 with acetic acid. The non-sulphite buffers of pH 6 and 7, respectively, contained 0.05 M potassium hydrogen phosphate adjusted to correct pH with sodium hydroxide and the electrolyte of pH 4.7 contained 0.1 M sodium acetate adjusted to correct pH with acetic acid.

The periodate oxidation of the glucosides was carried out with 0.03 M sodium periodate at 4 °C for 20 h in darkness. The aldehydo and ketoglucosides were obtained by chromate

Table 5. M_v values of some sugars at 60 °C and dissociation constants (K) of the hydrogen sulphite adducts at 19 °C (Sundman [4]). (0.1 M hydrogen sulphite, pH 4.7, Whatman No. 3, 13–18.5 V/cm for 3 h).

The Synthesis of Some Organosilicon Alcohols. III

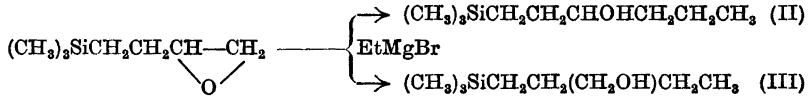
SUNE BRYNOLF

Department of Organic Chemistry, Chemical Institute of the University, Lund, Sweden

Some of the reactions of 4-trimethylsilylbutylene-1,2-oxide were studied from a synthetic point of view. Water and ammonia were added under formation of 4-trimethylsilylbutylene-1,2-glycol and 4-trimethylsilyl-1-aminobutanol-2, respectively. The oxide reacted with ethylmagnesium bromide under formation of 1-trimethylsilyl-3-methylpentanol-3 and 1-trimethylsilylhexanol-3.

In a previous paper [1] the synthesis of 4-trimethylsilylbutylene-1,2-oxide (I) from trimethylsilylmethylmagnesium bromide and epichlorohydrin *via* 4-trimethylsilyl-1-chlorobutanol-2 was reported. In this paper some of the reactions of (I) were studied from a synthetic point of view. The addition of water with perchloric acid as a catalyst yielded 4-trimethylsilylbutylene-1, 2-glycol.

$$(CH_3)_3SiCH_2CH_2CH\text{—}CH_2 + H_2O \rightarrow (CH_3)_3SiCH_2CH_2CHOHCH_2OH$$



In analogy with the investigations carried out by Andersson [2] (I) reacted with ammonia under formation of only one product, 4-trimethylsilyl-1-amino-butanol-2 (A), resulting from interaction of one mole of (I) with one mole of ammonia.

$$(CH_3)_3SiCH_2CH_2CH\text{—}CH_2 + NH_3 \rightarrow (CH_3)_3SiCH_2CH_2CHOHCH_2NH_2 \text{ (A)}$$

The constitution of (A) followed from the fact that its phthalimidoderivative, 4-trimethylsilyl-1-phthalimidobutanol-2 (B), on oxidation with chromic acid in boiling acetic acid yielded a ketone whose analyses agreed with those calculated for 4-trimethylsilyl-1-phthalimidobutanone-2. (B) was partly synthesized from (A) and phthalic anhydride and partly from (I) and phthal-imide.

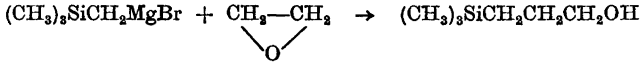
$$\left.\begin{array}{l}(CH_3)_3SiCH_2CH_2CHOHCH_2NH_2 \text{ (A)} + O(CO)_2C_6H_4 \\ (CH_3)_3SiCH_2CH_2CH\text{—}CH_2 \text{ (I)} + HN(CO)_2C_6H_4\end{array}\right\} \rightarrow (CH_3)_3SiCH_2CH_2CHOHCH_2N(CO)_2C_6H_4 \text{ (B)}$$

On interaction with ethylmagnesium bromide (I) reacted anomalously, inasmuch as it reacted both as a ketone and as an ethylene oxide. Theoretically four alcohols may be obtained; partly the oxide ring may be opened in two ways

and partly the oxide may react as if it had been rearranged to one or both of the isomeric oxo-compounds 4-trimethylsilylbutanone-2 and 4-trimethylsilylbutanal-1.

$$(CH_3)_3SiCH_2CH_2COCH_3 \xrightarrow{EtMgBr} (CH_3)_3SiCH_2CH_2COH(CH_3)CH_2CH_3 \quad (IV)$$

$$(CH_3)_3SiCH_2CH_2CH_2CHO \xrightarrow{EtMgBr} (CH_3)_3SiCH_2CH_2CH_2CHOHCH_2CH_3 \quad (V)$$



Out of the reaction mixture resulting from interaction of ethylmagnesium bromide with 4-trimethylsilylbutylene-1,2-oxide (I) two silicon-containing alcohols, (C) and (D), could be isolated. Those of their properties that were studied agreed with the corresponding properties of the alcohols (IV), 1-trimethylsilyl-3-methylpentanol-3 and (II), 1-trimethylsilylhexanol-3. (IV) was synthesized from 4-trimethylsilylbutanone-2, prepared according to Sommer and Marans [3], and ethylmagnesium bromide, and (II) from 1-trimethylsilylhexanone-3 by reduction with lithium aluminium hydride. The 1-trimethylsilylhexanone-3 was synthesized from β-trimethylsilylpropionyl chloride, prepared according to Sommer, Goldberg and Stone [4], and dipropylcadmium.

$$(CH_3)_3SiCH_2CH_2COCl + \tfrac{1}{2}(CH_3CH_2CH_2)_2Cd \rightarrow (CH_3)_3SiCH_2CH_2COCH_2CH_2CH_3$$

Besides it was shown that both (C) and (D) were non-identical with the alcohol (V), 1-trimethylsilylhexanol-4, which was obtained from 3-trimethylsilylpropylmagnesium bromide and propionaldehyde.

$$(CH_3)_3SiCH_2CH_2CH_2MgBr + OHCCH_2CH_3 \rightarrow (CH_3)_3SiCH_2CH_2CH_2CHOHCH_2CH_3 \quad (V)$$

The 3-trimethylsilylpropyl bromide was synthesized according to Sommer, Van Strien and Whitmore [5] from phosphorus tribromide and 3-trimethylsilylpropanol-1, which in its turn was prepared from trimethylsilylmethylmagnesium bromide and ethylene oxide.

It is often reported that ethylene oxides, especially the polysubstituted ones, rearrange into the isomeric ketones or aldehydes on reaction with Grignard reagents [6]. This isomerization is considered due to the presence of magnesium halide in the Grignard reagents according to the equation:

$$2RMgX \rightleftharpoons R_2Mg + MgX_2$$

In accordance with this theory no rearrangements have been observed when ethylene oxides are allowed to react with dialkylmagnesium [6]. In agreement with this the only silicon-containing alcohol (E) that could be obtained from (I) and diethylmagnesium was 1-trimethylsilylhexanol-3 (II).

In Table 1 the data of the alcohols (II), (IV), (V), (C), (D) and (E) and their 3,5-dinitrobenzoates are collected.

The diethylmagnesium was prepared from an ether solution of ethyl magnesiumbromide by precipitating magnesium bromide with dioxan and separating from the precipitate by centrifuging.

EXPERIMENTAL

4-Trimethylsilylbutylene-1,2-glycol

14 g (0.10 mole) of 4-trimethylsilylbutylene-1,2-oxide (I) were shaken for one week with 1 liter of water mixed with 2 ml of 70 % perchloric acid. The resulting aqueous solution was extracted with 300 ml of ether in an extraction apparatus. The obtained ether solution was dried with anhydrous sodium sulphate and the ether removed by distillation. Fractionation at 15 mm Hg yielded 2.0 g (0.0014 mole) of unreacted 4-trimethylsilylbutylene-1,2-oxide at 53—55° and 6.6 g (0.041 mole) of 4-trimethylsilylbutylene-1,2-glycol at 130—131°; $n_D^{20} = 1.4519$; $d_4^{20} = 0.928$. (Found: C 51.1; H 11.1; Si 17.0; M_{RD} 47.1. Calc. for $C_7H_{18}O_2Si$: C 51.8; H 11.2; Si 17.3; M_{RD} 47.3.)

4-Trimethylsilyl-1-aminobutanol-2 (A)

10 g (0.069 mole) of 4-trimethylsilylbutylene-1,2-oxide (I) dissolved in 50 ml of ethanol were dropped into a stirred ice-cooled mixture of 150 ml of conc. ammonia and 200 ml of ethanol. The reaction mixture was allowed to come slowly to room temperature. After 3 days most of the ethanol was distilled off at ordinary pressure and the resulting water solution was extracted with ether. The ether solution was dried with anhydrous sodium sulphate and fractionated. 7.5 g (0.046 mole) of 4-trimethylsilyl-1-aminobutanol-2 (A) were collected at 113—114°, 13 mm Hg; $n_D^{20} = 1.4589$; $d_4^{20} = 0.898$. After some days the aminoalcohol (A) solidified to crystals melting at 31—33°. (Found: C 52.1; H 12.0; Si 17.4; M_{RD} 49.1. Calc. for $C_7H_{19}ONSi$: C 52.1; H 11.9; Si 17.4; M_{RD} 49.2.)

The distillation residue yielded after crystallization four times from petroleum ether (b. p. 40—60°) 1.9 g of crystals melting at 89.5—92.5°, probably consisting of di-(4-trimethylsilyl-2-hydroxibutyl-1)amine, $[(CH_3)_3SiCH_2CH_2CHOHCH_2]_2NH$. (Found: C 53.9; H 11.4; Si 18.3. Calc. for $C_{14}H_{35}O_2NSi$: C 55.0; H 11.5; Si 18.4.)

4-Trimethylsilyl-1-phthalimidobutanol-2 (B) from (A)

1.5 g (0.0093 mole) of (A) and 1.4 g (0.0093 mole) of phthalic anhydride were mixed with 5 ml of water. After removing of the water by warming on a water bath, the residue was distilled at 1.5 mm Hg. The main part distilled at about 205°. The distillate yielded after crystallization once from ligroin (b. p. 80—100°) 1.6 g (0.0059 mole) of 4-trimethylsilyl-1-phthalimidobutanol-2 (B). M. p. 85.5—87°. (Found: C 61.8; H 7.2; Si 9.6. Calc. for $C_{15}H_{21}O_3NSi$: C 61.8; H 7.2; Si 9.6.)

4-Trimethylsilyl-1-phthalimidobutanol-2 (B) from 4-trimethylsilylbutylene-1,2-oxide (I) and phthalimide

10 g (0.07 mole) of 4-trimethylsilylbutylene-1,2-oxide (I) and 10 g (0.07 mole) of phthalimide were warmed for 18 h in a sealed tube at 190°. The resulting reaction product was crystallized twice from ligroin (b. p. 80—100°) and yielded 10 g (0.035 mole) of (B). M. p. 86.5—87.5°. Mixed m. p. with the product prepared from 4-trimethylsilyl-1-aminobutanol-2 (A) 86—87.5°.

4-Trimethylsilyl-1-phthalimidobutanone-2 from (B)

4.0 g (0.014 mole) of 4-trimethylsilyl-1-phthalimidobutanol-2 (B) were dissolved in 20 ml of acetic acid and warmed on a boiling water bath. A solution of 1.2 g (0.012 mole) of chromium trioxide in 5 ml of water was slowly dropped into the acetic acid solution. When all the chromic acid had been added and the solution had become brightly green, the reaction mixture was diluted with 100 ml of water. After cooling in ice the crystals were filtered off and recrystallized from ethanol. 2.8 g (0.0097 mole) of 4-trimethylsilyl-1-phthalimidobutanone-2 were obtained. M. p. 92—92.5°. (Found: C 62.3; H 6.6; Si 9.7. Calc. for $C_{15}H_{19}O_3NSi$: C 62.2; H 6.6; Si 9.7.)

2,4-Dinitrophenylhydrazone. 1.0 g (0.0035 mole) of 4-trimethylsilyl-1-phthalimidobutanone-2 was boiled for one minute with a solution of 0.7 g (0.0035 mole) of 2,4-dinitrophenylhydrazine in 15 ml of ethanol and 2 ml of conc. hydrochloric acid. After cooling the formed crystals were filtered off and crystallized twice from ethanol. 1.1 g (0.0021 mole) of the 2,4-dinitrophenylhydrazone of 4-trimethylsilyl-1-phthalimidobutanone-2 were obtained. M. p. 208.5—210°. (Found: C 53.3; H 4.9; Si 6.0. Calc. for $C_{21}H_{23}O_6N_3Si$: C 53.6; H 4.9; Si 6.0.)

Reaction of 4-trimethylsilylbutylene-1,2-oxide (I) with ethylmagnesium bromide

10 g (0.07 mole) of 4-trimethylsilylbutylene-1,2-oxide in 50 ml of abs. ether were dropped into the stirred and ice-cooled Grignard reagent prepared from 21 g (0.2 mole) of ethyl bromide, 4.9 g (0.2 mole) of magnesium and 100 ml of abs. ether. When all had been added the ice-bath was removed, and when the solution had come to room temperature it was refluxed for 20 h. The reaction mixture was hydrolyzed with water and the basic salts were dissolved in dilute hydrochloric acid. The ether layer was separated and the water layer extracted with ether. The combined ether solutions were washed with some water and refluxed for 3 h with 8 g (0.2 mole) of pulverized sodium hydroxide in order to remove the formed chloro- and bromohydrines of 4-trimethylsilylbutylene-1,2-oxide. (In a previous experiment it proved difficult to separate these from the formed silicon-containing alcohols by distillation.) The excess of sodium hydroxide and the formed sodium halides were filtered off and washed with ether. After removal of the ether by distillation at ordinary pressure, fractionation at 13 mm Hg yielded 1.8 g (0.013 mole) of 4-trimethylsilylbutylene-1,2-oxide at 48—49°, 2.8 g (0.016 mole) of 1-trimethylsilyl-3-methylpentanol-3 (C) at 81—82° and 2.6 g (0.015 mole) of 1-trimethylsilylhexanol-3 (D) at 91—92°. Data for (C): $n_D^{20} = 1.4377$; $d_4^{20} = 0.837$. (Found: C 61.5; H 12.6; Si 16.1; M_{RD} 54.6.) Data for (D): $n_D^{20} = 1.4374$; $d_4^{20} = 0.832$. (Found: C 61.8; H 12.7; Si 15.9; M_{RD} 54.9.) (Calc. for $C_9H_{22}OSi$: C 62.0; H 12.7; Si 16.1; M_{RD} 54.9.)

3,5-Dinitrobenzoate. 3,5-Dinitrobenzoate was prepared according to a method described by Cameron and coworkers [7]. 1 g of the alcohol in question was mixed with 4 ml of pyridine (dried with potassium hydroxide), whereupon 2 g of 3,5-dinitrobenzoyl chloride were added. After heating for 3 h to 100° the cooled reaction mixture was diluted with 25 ml of ether. The ether solution was washed once with 15 ml of dilute hydrochloric acid and twice with 25 ml of a 5 % sodium hydroxide solution. The ether was evaporated from the obtained ethereal solution of the 3,5-dinitrobenzoate, and the resulting crystals were washed with some dilute hydrochloric acid followed by water and crystallized two times from ethanol.

1.0 g (0.0058 mole) of (C) yielded 1.5 g (0.0039 mole) of the 3,5-dinitrobenzoate. M. p. 88—90°. (Found: C 52.0; H 6.5; Si 7.5.)

1.0 g (0.0058 mole) of (D) yielded 1.2 g (0.0031 mole) of the 3,5-dinitrobenzoate. M. p. 79—81°. (Found: C 52.0; H 6.5; Si 7.5.) (Calc. for $C_{16}H_{24}O_8N_2Si$: C 52.2; H 6.6; Si 7.6.)

Reaction of 4-trimethylsilylbutylene-1,2-oxide (I) with diethylmagnesium

200 g of dioxan in 200 ml of abs. ether were dropped into the well stirred boiling Grignard reagent prepared from 109 g (1.0 mole) of ethyl bromide, 24.3 g (1.0 mole) of magnesium and 300 ml of abs. ether. The formed precipitate was removed by centrifuging. The resulting ether solution contained 0.2 mole of diethylmagnesium. 14.4 g (0.10 mole) of 4-trimethylsilylbutylene-1,2-oxide in 50 ml of abs. ether were dropped into the stirred and ice-cooled solution of diethylmagnesium mentioned above. After all had been added the mixture was allowed to come to room temperature and was then refluxed for 20 h. After decomposition with water and dilute hydrochloric acid the ether layer was separated and the water layer carefully extracted with ether. After drying of the resulting ether solution with anhydrous sodium sulphate, the ether and dioxan were removed by distillation at ordinary pressure. Fractionation at 13 mm Hg yielded 13.7 g (0.079 mole) of 1-trimethylsilylhexanol-3 (E) at 92—93°; n_D^{20} = 1.4370; d_4^{20} 0.831. (Found: C 61.4; H 12.4; Si 16.1; M_{RD} 54.9. Calc. for $C_9H_{22}OSi$: C 62.0; H 12.7; Si 16.1; M_{RD} 54.9.)

3,5-Dinitrobenzoate. 1.0 g (0.0058 mole) of (E) yielded 1.7 g (0.0044 mole) of 3,5-dinitrobenzoate. M. p. 82.5—83°. (Found: C 51.8; H 6.5; Si 7. 5. Calc. for $C_{16}H_{24}O_8N_2Si$: C 52.2; H 6.6; Si 7.6.)

1-Trimethylsilylhexanone-3

25.6 g (0.14 mole) of cadmium chloride (dried 10 h at 110°) were added to the stirred ice-cooled Grignard solution prepared from 34 g (0.28 mole) of *n*-propyl bromide, 6.5 g (0.27 mole) of magnesium and 300 ml of abs. ether. The main part of the ether was distilled off and 300 ml of anhydrous benzene added. The rest of the ether was now distilled off, whereupon 20 g (0.12 mole) of β-trimethylsilylpropionyl chloride were quickly dropped into the stirred boiling benzene solution. The mixture was refluxed for an hour and then hydrolyzed with water followed by dilute hydrochloric acid. The organic layer was separated and the water layer extracted twice with 25 ml of benzene. After drying with anhydrous sodium sulphate the benzene was distilled off at ordinary pressure. Fractionation of the rest at 20 mm Hg yielded 14 g (0.083 mole) of 1-trimethylsilylhexanone-3 at 99—100°; n_D^{20} = 1.4303. The semicarbazone melted at 73—74°. (Sommer, Bailey, Goldberg, Buck, Bye, Evans and Whitmore [8] report n_D^{20} = 1.4294 and m. p. of the semicarbazone 72—73°.) (Found: C 62.1; H 11.7; Si 16.3. Calc. for $C_9H_{20}OSi$: C 62.7; H 11.7; Si 16.3.)

2,4-Dinitrophenylhydrazone. 1.0 g (0.0058 mole) of 1-trimethylsilylhexanone-3 was boiled for one minute with a solution of 1.1 g (0.0056 mole) of 2,4-dinitrophenyl hydrazine in 20 ml of ethanol and 2 ml of conc. hydrochloric acid. After the mixture had come to room temperature, it was cooled in ice and the obtained crystals were filtered off. Two crystallizations from ligroin (b. p. 80—100°) yielded 1.6 g (0.0045 mole) of the 2,4-dinitrophenylhydrazone of 1-trimethylsilylhexanone-3. Orange-coloured crystals melting at 96—98°. (Found: C 51.0; H 6.8; Si 7.9. Calc. for $C_{15}H_{24}O_6N_4Si$: C 51.1; H 6.9; Si 8.0.)

1-Trimethylsilylhexanol-3 (II)

8.5 g (0.049 mole) of 1-trimethylsilylhexanone-3 in 25 ml of abs. ether were dropped into the stirred mixture of 3.5 g (0.10 mole) of lithium aluminium hydride and 50 ml of abs. ether. After refluxing for two hours the reaction mixture was decomposed with water and dilute hydrochloric acid. The organic layer was separated and the water layer extracted with ether. After drying with anhydrous sodium sulphate fractionation at 13 mm Hg yielded 5.8 g (0.034 mole) of 1-trimethylsilylhexanol-3 (II) at 91—92°; $n_D^{20} = 1.4370$; $d_4^{20} = 0.830$. The alcohol gave a negative result on testing for ketone with 2,4-dinitrophenyl hydrazine according to the description above. (Found: C 61.9; H 12.6; Si 15.9; M_{RD} 54.9. Calc. for $C_9H_{22}OSi$: C 62.0; H 12.7; Si 16.1; M_{RD} 54.9.)

3,5-Dinitrobenzoate. 1.0 g (0.0058 mole) of 1-trimethylsilylhexanol-3 yielded 1.6 g (0.0042 mole) of the 3,5-dinitrobenzoate; M. p. 82—83°. (Found: C 51.9; H 6.5; Si 7.6. Calc. for $C_{16}H_{24}O_8N_2Si$: C 52.2; H 6.6; Si 7.6.)

1-Trimethylsilyl-3-methylpentanol-3 (III)

2.9 g (0.002 mole) of 4-trimethylsilylbutanone-2 in 5 ml of abs. ether were dropped into the stirred Grignard reagent prepared from 3.3 g (0.03 mole) of ethyl bromide, 0.7 g (0.03 mole) of magnesium and 10 ml of abs. ether. After having been refluxed for two hours the reaction mixture was decomposed and worked up in the usual way. Fractionation yielded 2.0 g (0.012 mole) of 1-trimethylsilyl-3-methylpentanol-3 (III); B. p. 80—81° (13 mm Hg); $n_D^{20} = 1.4380$; $d_4^{20} = 0.837$. (Found: C 61.5; H 12.6; Si 16.0; M_{RD} 54.9. Calc. for $C_9H_{22}OSi$: C 62.0; H 12.6; Si 16.1; M_{RD} 54.9.)

3,5-Dinitrobenzoate. 0.8 g (0.0046 mole) of 1-trimethylsilyl-3-methylpentanol-3 (III) yielded 1.3 g (0.0034 mole) of the 3,5-dinitrobenzoate; M. p. 89—90°. (Found: C 51.8; H 6.5; Si 7.5. Calc. for $C_{16}H_{24}O_8N_2Si$: C 52.2; H 6.6; Si 7.6.)

3-Trimethylsilylpropanol-1

88 g (2.0 moles) of ethylene oxide in 175 ml of abs. ether were dropped into the stirred and ice-cooled Grignard reagent prepared from 167 g (1.0 mole) of bromomethyltrimethylsilane, 24 g (1.0 mole) of magnesium and 300 ml of abs. ether. When all had been added the ice-cooling was removed, whereupon the reaction mixture boiled spontaneously. After the boiling had stopped the stirred mixture was refluxed for four hours and was then allowed to stand over night. The next day the reaction mixture had solidified to a gel. After decomposition with water and dilute hydrochloric acid, the ether layer was separated and the water layer extracted with ether. The combined ether solutions were washed with some water and boiled for 3 h with 40 g (1.0 mole) of finely powdered sodium hydroxide in order to remove the formed ethylene chloro- and bromohydrines. (In a previous experiment it proved difficult to separate the ethylene bromohydrine from the formed siliconcontaining alcohol by distillation.) The excess of sodium hydroxide and the formed sodium halides were filtered off and washed with ether. After removal of the ether by distillation at ordinary pressure fractionation at 27 mm Hg yielded 82 g (0.62 mole) of 3-trimethylsilylpropanol-1; B. p. 83—85°; $n_D^{20} = 1.4294$ (Sommer, Van Strien and Whitmore [5] report b. p. 83° (27 mm Hg) and $n_D^{20} = 1.4290$). (Found: Si 21.0. Calculated for $C_6H_{16}OSi$: Si 21.2.)

1-Trimethylsilylhexanol-4 (IV)

1.2 g (0.002 mole) of propionaldehyde in 5 ml of abs. ether were dropped into the stirred Grignard reagent prepared from 3.8 g (0.002 mole) of 3-trimethylsilyl-1-bromopropane, 0.5 g (0.002 mole) of magnesium and 10 ml of abs. ether. After 2 h of refluxing the reaction mixture was worked up in the usual way and yielded 1.6 g (0.0092 mole) of 1-trimethylsilylhexanol-4 (IV); B. p. 91—92° (13 mm Hg); $n_D^{20} = 1.4372$; $d_4^{20} = 0.827$. (Found: C 61.8; H 12.6; Si 16.2; M_{RD} 55.1. Calc. for $C_9H_{22}OSi$: C 62.0; H 12.6; Si 16.1; M_{RD} 54.9.)

3,5-Dinitrobenzoate. 1.0 g (0.0058 mole) of 1-trimethylsilylhexanol-4 yielded 1.0 g (0.0026 mole) of the 3,5-dinitrobenzoate; M. p. 26–27°. (Found: C 51.5; H 6.5; Si 7.5. Calc. for $C_{16}H_{24}O_6N_2Si$: C 52.2; H 6.6; Si 7.6.)

The author wishes to express his appreciation to Professor Erik Larsson for his kind interest in this work.

ACTA CHEMICA SCANDINAVICA 11 (1957) 731—740

On the Solubility Product of Precipitated Iron(III) Hydroxide

GEORGE BIEDERMANN and PAUL SCHINDLER

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden; Department of Chemistry, University of Bern, Switzerland

The solubility equilibrium of precipitated iron(III) hydroxide was investigated at 25 °C by determining the $[Fe^{3+}]$ and $[H^+]$ of solutions in contact with the solid phase. $[Fe^{3+}]$ and $[H^+]$ were measured using the cells

$$- \text{ CE} \mid \text{solution S} \mid \text{Pt} + \qquad \text{(A)}$$

$$- \text{ Glass electrode} \mid \text{solution S} \mid \text{CE} + \qquad \text{(B)}$$

CE denotes the half-cell

$$\mid NaClO_4\text{: 3 M} \mid NaCl\text{: 0.010 M, } NaClO_4\text{: 2.990 M} \mid AgCl, Ag$$

and solution S had the general composition

$$[Fe(III)] = B_3 \text{ M}, [Fe(II)] = B_2 \text{ M}, [H^+] = H \text{ M}, [Na^+] = (3.000 - 3B_3 - 2B_2 - H) \text{ M}, [ClO_4^-] = 3.000 \text{ M},$$

where H is the hydrogen ion concentration assuming no hydrolysis or precipitation. B_3 was varied from 0.001 to 0.100 M and h, the actual hydrogen ion concentration of the solutions measured with cell (B), ranged from 2×10^{-2} to 2×10^{-3} M.

The precipitation reaction attains a steady state after about 200 h shown by the fact that after this period no further systematic change in $[Fe^{3+}]$ and $[H^+]$ could be detected; see Fig. 1.

The data for precipitates older than 200 h could be explained by assuming the reaction

$$Fe^{3+} + 2\ H_2O \rightleftharpoons FeOOH\ (s) + 3\ H^+$$

with $\log K = -3.96 \pm 0.10$. Since in 3 M $NaClO_4$ $\log K_{H_2O} = \log [H^+] + \log (OH^-) = -14.22$ [15],

$$\log K_s = \log ([Fe^{3+}]\ [OH^-]^3) = -38.7 \pm 0.2.$$

On the basis of Hedström's measurements [9] and the data obtained in this work, the experimental conditions for obtaining supersaturated solutions have been discussed.

A number of investigations have been devoted to the determination of the solubility product of precipitated iron(III) hydroxide. Previous work is summarized in Table 1.

Table 1.

Author	t °C	pK_s	anion present	method
Jellinek and Gordon [1] (1924)	14	37.9	Cl^-	E(H_2), Fe(III) analytically
Britton [2] (1925)	18	37.7	Cl^-	E(O_2)
Elder [3] (1930)	?	35.4–37.5	Cl^-	E(gl, H_2)
Kriukow and Awsejevitsch [4] (1933)	18	36.5	SO_4^{2-}	E(gl, $Fe^{2,3}$ redox)
Bézier [5] (1945)	18	36.9–38.2	ClO_4^-	E(gl)
Evans and Pryor [6] (1949)	20	35.5	SO_4^{2-}	E(gl)
Aksel'rud and Fialkov [7] (1950)	18	37.5	SO_4^{2-}	E(Sb, Sb_2O_3), Fe(III) analytically

E(H_2): hydrogen electrode, E(O_2): oxygen electrode, E(gl): glass electrode, E($Fe^{2,3}$) : Fe^{2+} — Fe^{3+} redox electrode, E(Sb, Sb_2O_3): Sb, Sb_2O_3 electrode.

All of these authors, with the exception of Aksel'rud and Fialkov, employed the same approach; a potentiometric titration was made by adding NaOH to a solution containing Fe(III) until a considerable part of the iron was precipitated. The majority of the investigators [2,3,5,6] determined the pH of the solutions in contact with the solid phase; the solubility product was calculated by making the assumptions that all iron(III) in the solution is present as Fe^{3+} and that the precipitate has the composition $Fe(OH)_3$. Jellinek and Gordon [1] supplemented the pH measurements with the colorimetric or gravimetric determination of the total iron(III) content of the solution. Kriukow and Awsejewitsch [4] utilized both pH and redox potential measurements. Aksel'rud and Fialkov's pK_s value [7] is based on the determination of the pH and of the total iron concentration of $Fe_2(SO_4)_3$ solutions in contact with iron(III) hydroxide.

Gayer and Woontner have studied recently [8] the total solubility of FeOOH in $HClO_4$ and NaOH solutions at 25 °C. For solutions of pH>5 the data could be explained by assuming the equilibrium

$$FeOOH(s) + H_2O \rightleftharpoons Fe(OH)_3 \text{ (dissolved)}$$

with pK = 6.5. For more acidic solutions the interpretation of the solubility data proved to be difficult because of the simultaneous presence of a series of hydrolysis products. In the pH range 1 to 3 the predominant part of the dissolved iron was found to exist as $Fe(OH)_2^+$.

The wide discrepancies among the reported results show that the experimental conditions were not chosen adequately to provide a reliable value of the solubility product.

Though it has been recognised very early [1] that the rate of precipitation is slow at room temperature and that freshly precipitated iron(III) hydroxide is far from being in equilibrium, no evidence has been given in any work that equilibrium was established under the described experimental conditions.

Precipitation with OH^- often yields a basic salt of a composition depending on the anion present in the solution and the temperature. Thus it cannot be assumed *a priori* that FeOOH is formed, but a method must be found to ascertain the composition of the solid phase.

Since Fe^{3+} is an acid of considerable strength [9], calculations made from pH measurements without taking into account the hydrolysis constants cannot give a correct value of the solubility product.

It is desirable to study the solubility equilibrium in a broad range of hydrogen and iron concentrations in order to test the validity of the assumptions made in computing the solubility product. Using solutions of varying ionic strengths the evaluation of the emf measurements is very difficult, since no method is available to estimate accurately the activity factors in mixed electrolytes containing a number of ions of various charges at appreciable concentrations.

The present work was undertaken to determine the solubility product of precipitated iron hydroxide by emf measurements in the constant ionic medium $[ClO_4^-] = 3$ M. The method of investigation was rather similar to that worked out in this laboratory to study the hydrolysis equilibria of metal ions. Though the results are applicable only in this ionic medium, the general approach might be of some value also under other experimental conditions.

Symbols used in the text

b = concentration of Fe^{3+}.
B_2 = total concentration of iron(II).
B_3 = total concentration of iron(III).
E_{0A} = a constant, defined by eqn. 1.
E_{0B} = a constant, defined by eqn. 2.
E_j = $-16.7\ h$ mV = liquid junction potential.
h = actual hydrogen ion concentration in the test solution.
H = hydrogen ion concentration, assuming no hydrolysis or precipitation.
K = equilibrium constant defined by eqn. 3.
K_s = equilibrium constant defined by eqn. 6.
M = moles/liter.

METHOD

To study this solubility equilibrium a series of test solutions were prepared. The iron(III) concentration of the test solutions was varied between 0.001 and 0.1 M, and in each of these the hydrogen ion concentration was adjusted so that a visible precipitate was slowly formed. The $[H^+]$ and $[Fe^{3+}]$ of the test solutions were periodically examined by emf measurements, and these were extended until no further systematic concentration change could be detected.

All test solutions (S) investigated had the general composition

$[Fe(III)] : B_3$ M, $[Fe(II)] : B_2$ M, $[H^+] : H$ M, $[Na^+] : (3.000 - 3B_3 - 2B_2 - H)$ M, $[ClO_4^-] : 3.000$ M

where B_3 denotes the total concentration of Fe(III), B_2 that of Fe(II), and H is the hydrogen ion concentration assuming no hydrolysis and precipitation. The test solutions were prepared by mixing an Fe(III)—Fe(II) stock solution and a $NaHCO_3$ solution (both containing 3 M ClO_4^-) in such a ratio that a visible precipitate was formed within a few days. $NaHCO_3$ has been used as the base, since preliminary experiments have shown, in accordance with Hedström [9], that NaOH causes an irreversible precipitation. The hydrolysis of CO_2 could be neglected since the pH of the test solutions never exceeded 3. Moreover a strong stream of N_2 was led through the solutions; thus the CO_2 concentration was always very low.

The $[H^+]$ and $[Fe^{3+}]$ of the test solutions were determined by measuring the emfs of the cells

$$- \text{ CE} \mid \text{solution S} \mid \text{Pt} + \qquad \text{(A)}$$

and

$$- \text{ Glass electrode} \mid \text{solution S} \mid \text{CE} + \qquad \text{(B)}$$

CE denotes the half-cell

Ag, AgCl | 0.010 M NaCl, 2.990 M $NaClO_4$ | 3.000 M $NaClO_4$ |

The emfs of the cells (A) and (B) can be written at 25 °C

$$E_A = E_{0A} + 59.16 \log (b / [Fe^{2+}]) + E_j \qquad (1)$$

and

$$E_B = E_{0B} - 59.16 \log h - E_j \qquad (2)$$

where E_{0A} and E_{0B} are constants, b and h are the actual $[Fe^{3+}]$ and $[H^+]$ of the test solutions, and E_j denotes the liquid junction potential at the junction 3 M $NaClO_4$ | solution S. E_j was calculated with the equation $E_j = -16.7\ h$ mV determined previously [10]. The acidity constant of Fe^{2+} is so low [11] that in the pH range studied the $[Fe^{2+}]$ could be set equal to B_2. The activity factors of the reacting species were assumed to be constants; this is certainly a good approximation since the solutions were rather dilute in Fe(III), Fe(II) and H^+.

E_{0A} and E_{0B} were determined by measuring E_A and E_B with solutions of so high an acidity that the hydrolysis of Fe^{3+} could be neglected. Each time before a test solution was measured, E_{0A} and E_{0B} were checked. The constancy of these quantities for a long period was an indication that the cell equipment functioned satisfactorily.

A few series of measurements were made as potentiometric titrations with the technique usually employed in this laboratory in order to study the degree of supersaturation attained under these experimental conditions. B_3 and B_2 were kept constant in each series while the $[H^+]$ was decreased stepwise by the addition of $NaHCO_3$ until a solid phase became visible.

MATERIALS AND ANALYSIS

Iron (III) perchlorate solutions were made from $Fe(NO_3)_3 \cdot 9\ H_2O$ "Baker's Analyzed" by adding 72 % $HClO_4$ in excess and expelling the HNO_3 and a large part of the excess $HClO_4$ by heating with an infra-red lamp. In the stock solution containing about 1 M Fe(III) no NO_3^-, Cl^- and SO_4^{2-} could be detected.

Iron (III) was determined potentiometrically according to the method described by Berecki-Biedermann [12], the accuracy was ± 0.1 %. The $Na_2S_2O_3$ solution was standardized against twice recrystallized KIO_3.

Iron (II) perchlorate solution was prepared from a portion of the iron(III) perchlorate stock solution by electrolytic reduction. The iron(II) concentration was determined by potentiometric titration using $K_2Cr_2O_7$. The $K_2Cr_2O_7$ preparation was purified by recrystallisation and made water-free by melting at 400 °C. The same result was found within 0.1 % when this $K_2Cr_2O_7$ or the KIO_3 was used to standardize the thiosulfate solution.

The total iron concentration of the iron(II) perchlorate stock solution was determined by oxidizing Fe^{2+} with H_2O_2 solution. The excess peroxide was expelled by boiling, and in the cooled solution Fe(III) was titrated by the same method [12] as above.

The excess hydrogen ion concentration, H, of the Fe(III) and Fe(II) stock solutions was determined using the ion exchange resin "Duolite C3" in the hydrogen form. The hydrogen ion concentration of the eluate which is equal to the $[ClO_4^-]$ was determined with standard NaOH. H was calculated according to the equation

$$[ClO_4^-] = H + 3\ B_3 + 2\ B_2$$

$HClO_4$, NaOH, $NaHCO_3$, $NaClO_4$, and NaCl solutions were prepared and analyzed as described previously [13].

Nitrogen taken from a cylinder was freed of oxygen by passing it through hot activated copper. Acid and basic impurities were absorbed in NaOH and H_2SO_4 solutions, and finally the gas was led through water and 3 M $NaClO_4$ to obtain the right vapor pressure.

Experimental details of the emf measurements

E_A was measured with a recently certified Leeds and Northrup potentiometer of type K2, which could be read to 0.01 mV. E_B was determined with a valve potentiometer "Radiometer PHM3" Copenhagen. The sensitivity of this instrument is ± 0.2 mV.

Ag, AgCl electrodes were prepared as usual in this laboratory [13]. Redox potentials were measured with bright Pt-foils. When two electrodes were simultaneously employed they always agreed within 0.05 mV.

The glass electrodes were prepared by Dr. E. Blomgren, Uppsala. They came to equilibrium within 10—15 min and have given constant and reproducible potentials within ± 0.2 mV.

All measurements were carried out in a paraffin oil thermostat at 25.0 ± 0.1 °C.

SURVEY OF MEASUREMENTS

Procedure. Test solutions with the following B_3 values were studied: 1.000×10^{-3}, 5.00×10^{-3}, 1.000×10^{-2}, 2.50×10^{-2} and 1.000×10^{-1} M. B_2 was always chosen to be approximately equal to B_3. With lower values of B_3 than 1 mM no satisfactory results could be obtained; this may be explained by the slow rate of precipitation and the low redox- and pH-buffer capacity of such dilute solutions. In order to avoid complications due to the variation of the activity factors, the higher limit of B_3 was set at 0.1 M.

O_2 and CO_2 were expelled from the test solutions by passing a strong stream of N_2 through them for about half an hour. The vessels were then closed with well fitting rubber stoppers, which were coated with paraffin and finally they were placed in the thermostat.

Though Fe^{2+} is rather slowly oxidized by air in $HClO_4$ solutions, it was important to check to what extent oxidation might have occurred during the long periods of measurement (10—20 days). For this purpose a number of solutions were transferred immediately after preparation to glass bottles, made

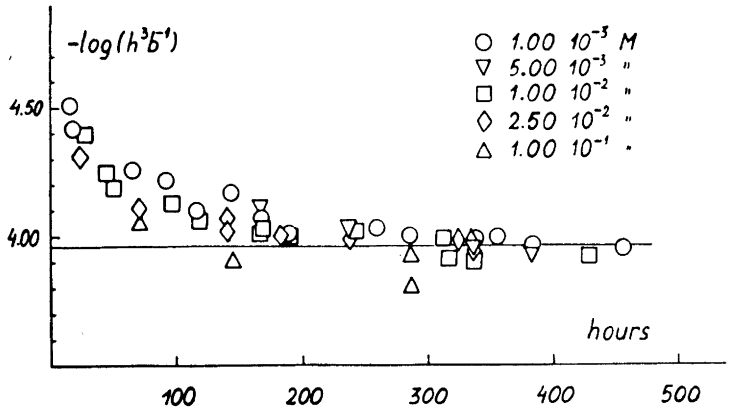

Fig. 1. Attainment of the steady state. $\log(h^3b^{-1})$ as a function of time. The horizontal line represents the solubility product $\log K = -3.96$ calculated by the plot given in Fig. 2.

free from O_2 and CO_2 by bubbling through N_2, and then the bottles were sealed and placed in the thermostat. After two weeks $\log h$ and $\log b$ were measured and found to agree within 0.01 units with the $\log h$ and $\log b$ values of solutions of the same composition, which were kept in the normal way and examined frequently. Thus no appreciable error could have been introduced by oxidation.

In the first week $\log h$ and $\log b$ varied rapidly and E_A and E_B were measured each day; later on measurements were generally made every second day.

Attainment of the steady state. The progress of the precipitation is illustrated in Fig. 1 which shows $\log(h^3b^{-1})$ as a function of the age of the test solution. The starting point of the reaction was taken when the solution was immersed in the thermostat. All test solutions were studied at least for 10 days; the majority of them were examined for a period of two weeks.

In the first 200 h the plot $\log(h^3b^{-1})^{-1}$ *versus* time is seen to give a gradually falling curve of monotonically decreasing slope; this type of time dependence indicates that the precipitation reaction is approaching to a steady state where the rate of reaction becomes negligible. This final state seems to be attained in about 200 h. As Fig. 1 shows, no further systematic variation of $\log(h^3b^{-1})$ can be detected within the limits of experimental error for test solutions older than 200 h, and all points, except one for $B_3 = 1 \times 10^{-1}$, are seen to lie in the interval —3.85 to —4.05. The uncertainty of the $\log(h^3b^{-1})$ values in the steady state may be estimated to be ± 0.05 on the basis of measurements made in solutions of the same B_3 value.

Composition of the precipitate. A chemical analysis of the precipitate could not be made, because no method was found to wash it free from the mother liquid. When the solid phase separated by centrifugation was washed with water, a colloidal solution was formed which could not be made to coagulate by centrifugation. Addition of SO_4^{2-} broke the sol very rapidly but the introduction of sulfate is of course not desirable.

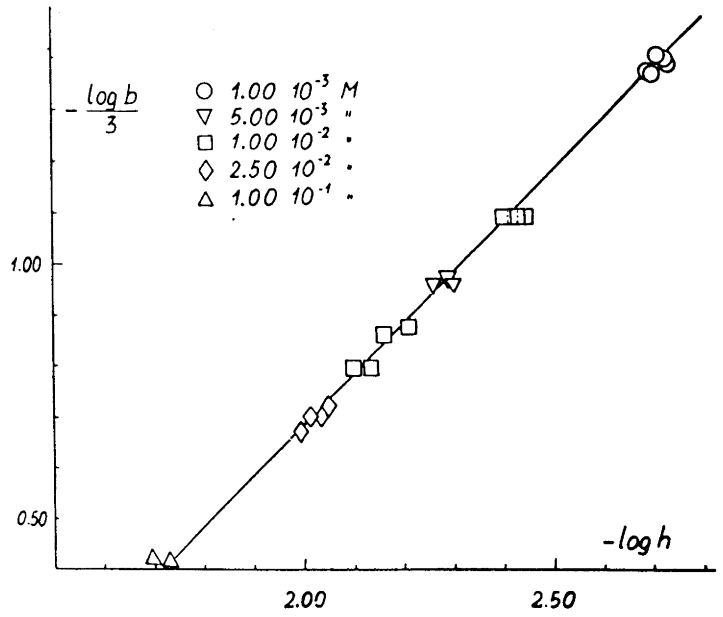

Fig. 2. Determination of log K. $\frac{\log b}{3}$ as a function of log h for test solutions older than 200 h. The line represents the equation $\frac{\log b}{3} = \log h + 1.32$.

There is, however, indirect evidence that no basic salt has been formed. Fig. 2 shows $\frac{\log b}{3}$ as a function of log h for all test solutions older than 200 h. The experimental points are seen to lie reasonably well on a straight line of unit slope. This indicates that these data may be explained by the reaction

$$Fe^{3+} + 2\ H_2O \rightleftharpoons FeOOH(s) + 3\ H^+ \quad K = h^3b^{-1} \qquad (3)$$

i. e. three hydrogen ions are set free when one Fe^{3+} is precipitated. By this type of argument it cannot be decided whether the precipitate contains OH groups ($Fe(OH)_3$), O atoms (Fe_2O_3), or both (FeOOH), because the water concentration was kept constant in all experiments. The precipitate may also contain H_2O and $NaClO_4$ but their presence cannot be ascertained because of similar reasons.

The compositions of aged precipitates formed from acidic iron(III) solutions were investigated with X-ray analyses by Weiser and Milligan [14]. They have found that, when no basic salt is formed, the solid phase always consists of FeOOH. Since there is strong evidence that no basic salt is formed from the solutions studied in this work, the precipitate has most likely the composition FeOOH. This was the reason for writing eqn. (3) in the form given.

An attempt was made to identify the fresh precipitate by X-ray diffraction using a Guinier camera with Cu$K\alpha$ radiation. All the lines in the X-ray photo-

graph could be ascribed to $NaClO_4$ except two very weak ones having 10^4 $\sin^2\Theta$ values 1 952 and 2 548. Thus by this method no definite conclusion could be made concerning the composition of the precipitate.

CALCULATION OF THE SOLUBILITY PRODUCT

Log K of eqn. (3) may be conveniently calculated by the plot $\log b^{\frac{1}{3}}$ (log h), Fig. 2. A line of unit slope was drawn through all experimental points, the intercept of which gives according to (3) $\frac{-\log K}{3}$. It was found

$$\log K = -3.96 \pm 0.10 \quad (4)$$

According to measurements made in this laboratory [15], the ionic product of water in 3 M $NaClO_4$ at 25 °C

$$\log K_{H_2O} = -14.22 \pm 0.10 \quad (5)$$

thus the solubility product expressed with OH^-, log K_s, will be

$$\log K_s = 3 \log K_{H_2O} - \log K = -38.7 \pm 0.2 \quad (6)$$

This log K_s value is considerably lower than any one reported previously; see Table 1. The discrepancy may be explained, besides other reasons, by the fact that previous work was done with quite fresh precipitates, far from being in equilibrium; see Fig. 1.

The data presented in this work give no evidence that the log K_s or the log K value calculated refers to a real equilibrium. In order to show that the steady state corresponds to a true equilibrium experiments are required which would show that the same state is attained from the reversed direction, *i. e.* by dissolving a part of the precipitate with the addition of hydrogen ions. A few experiments were made for this purpose but without success. It was found that the dissolution of the precipitate is a very slow process, and at about pH 2 no appreciable dissolution could be detected within two weeks.

Though it cannot be claimed that real equilibrium was attained in our experiments the data clearly indicate that when reaction (3) proceeds with the *formation* of the solid phase, a steady state is reached relatively rapidly which may be well described with the constant (4) or (6).

ON SUPERSATURATED SOLUTIONS

The solubility and hydrolysis equilibria of the Fe^{3+} ion are visualized in Fig. 3 where $\log(B_3/b)$ is plotted as a function of log h for the B_3 values 0.05, 0.010, 0.001 and 0.0001 M. The straight lines illustrate the solubility equilibrium (3), calculated with the constant (4) and the full-drawn curves represent the hydrolysis equilibria

$$Fe^{3+} + H_2O \rightleftharpoons FeOH^{2+} + H^+$$

$$Fe^{3+} + 2\ H_2O \rightleftharpoons Fe(OH)_2^+ + 2\ H^+$$

$$2\ Fe^{3+} + 2\ H_2O \rightleftharpoons Fe_2(OH)_2^{4+} + 2\ H^+$$

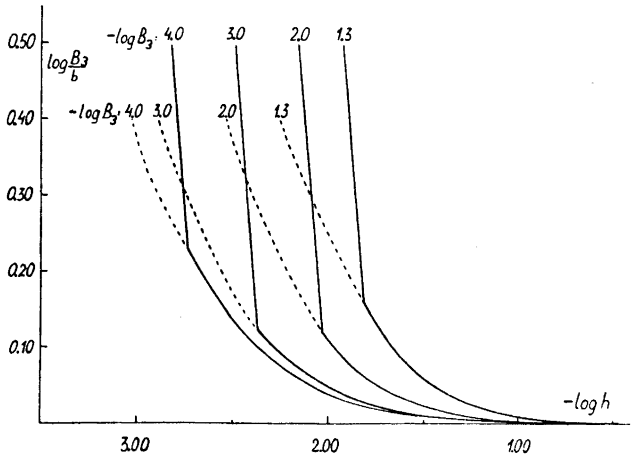

Fig. 3. The solubility and hydrolysis equilibria of the Fe^{3+} ion. $\log \frac{B_3}{b}$ as a function of $\log h$ for the $\log B_3$ values -4, -3, -2 and -1.3. The straight lines illustrate the solubility equilibrium calculated with $\log K = -3.96$; the full drawn curves represent the hydrolysis equilibria calculated with the constants given by Hedström [9]; the broken curves show Hedström's data obtained in supersaturated solutions.

calculated with the constants given by Hedström [9]. The broken curves show Hedström's experimental data obtained in supersaturated solutions with a potentiometric titration technique. He started from a practically unhydrolyzed solution and increased the pH stepwise by adding small amounts of a $NaHCO_3$ solution and a Fe^{3+} solution containing H^+ in excess. Hedström found that steady and reproducible redox and glass electrode potentials can be obtained until $\log (B_3/b)$ attains about 0.4; however above this value the potentials became unstable indicating a slow precipitation.

In order to study the conditions for obtaining supersaturated solutions a number of potentiometric titrations were made. Following carefully Hedström's technique his results could be wholly confirmed. A few series of measurements were made in a somewhat different manner. Starting from an unhydrolysed solution the pH was increased in big steps by adding each time a large amount of a $NaHCO_3$ solution and a Fe^{3+} solution containing H^+ in excess. In this case practically no supersaturation could be achieved. At the pH value where according to (4) a precipitate should be formed the potentials began to drift because of the formation of the solid phase, and no steady value was reached in one or two days.

For example when a single addition of $NaHCO_3$ solution was sufficient to cause a slight excess over the solubility product, precipitation started immediately, whereas if the same pH was attained in about ten steps no precipitation could be detected for 2—3 h.

The absence of supersaturation under these experimental conditions may be explained by the fact that, despite the vigorous agitation, a local excess of

HCO_3^- is very difficult to avoid when a relatively large amount of the base is added at once. In those regions of the solution where for a short period the pH is increased, crystal nuclei of FeOOH may be formed; when the acidity is so high that the solid phase is not stable these dissolve rapidly after the local concentration differences disappeared. In the stability region of the FeOOH (s), however, the presence of the nuclei assures that the solid phase will be formed with a high rate.

A considerable part of Hedström's measurements was made in supersaturated solutions, but this fact does not invalidate any of his conclusions concerning the hydrolysis equilibria, since under the experimental conditions chosen by him the rate of precipitation is negligible compared with that of the hydrolysis. By the study of supersaturated solutions the useful pH range could be much extended, and this has been of great help to provide a complete picture of the hydrolysis process.

This work which was carried out in the Stockholm laboratory was financially supported by *Statens Naturvetenskapliga Forskningsråd (Swedish Natural Science Research Council)* and by the *Theodor Kocher Institute*, Bern.

We are greatly indebted to Professor Walter Feitknecht and Professor Lars Gunnar Sillén for their great interest in this work and for their valuable criticism. We would like to thank to Dr. Clara Berecki-Biedermann for many valuable discussions and to Dr. Georg Johansson for his help especially in connection with the X-ray work. Mr. Frans Ericson has been of great help by making several parts of the equipment.

We are indebted to Dr. Stuart Tobias for helpful criticism of the manuscript.
