ACTA CHEMICA SCANDINAVICA 12 (1958) 1—7

Anomalous Reactions of 2-Naphthylmethylmagnesium Bromide

SVEN-OLOV LAWESSON*

Department of Organic Chemistry, Chemical Institute, University of Uppsala, Sweden

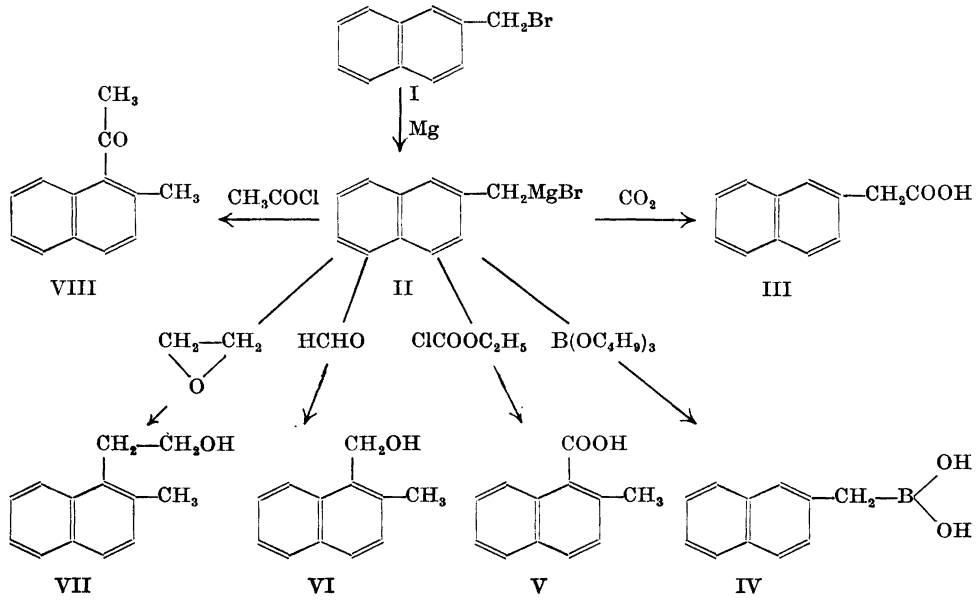
2-Naphthylmethylmagnesium bromide has been prepared with a "cyclic reactor" and its reactions with ethyl chlorocarbonate, formaldehyde, ethylene oxide and acetyl chloride have been shown to give rearrangement products. Exclusively normal products were isolated only in the reactions with carbon dioxide and tributyl borate.

Organomagnesium halides with the $-CH=CH-CH_2-MgX$ grouping often give abnormal products and since Grignard [1] himself initially conducted such a rearrangement reaction (which he did not know at that time), many investigations have been made in this field. Kharasch and Reinmuth [2] have recently summarized the situation until 1952. In connection with the preparation and study of 2-napththylmethylboronic acid as a plant growth regulator [3] it was neeessary to find out if rearrangement occurred or not and we have now further studied this and similar reactions.

The preparation of Grignard reagents from halides of the benzylic type is generally troublesome and the yields are often very low. The reason is, that under the usual conditions some metathesis will always occur between the Grignard reagent formed and the later added halide thus giving coupling products. Various strategies to avoid coupling have been tried: high dilution, excess of magnesium, etc., but the best way was introduced by Rowlands, Greenlee and Boord, who used a so called cyclic reactor [4]. By this method we have, contrary to earlier reports [3,5,6] obtained good yields of 2-naphthylmethylmagnesium bromide.

In Scheme 1, six reactions of 2-naphthylmethylmagnesium bromide are represented. 2-Naphthylmethyl bromide (I) was easily converted to the corresponding Grignard reagent (II) in the cyclic reactor (Fig. 1). In all experiments, however, small amounts of the coupling product, 1,2-di(2-naphthyl)-ethane were also isolated. The reagent II was treated with carbon dioxide, tributyl from 2-methyl-1-naphthyllithium reagent and ethylene oxide and by reduction of 2-methyl-1-naphthylacetic acid.

* Present address: Department of Organic Chemistry, University of Chicago, Chicago 37, Ill.



Scheme 1.

borate, ethyl chlorocarbonate, formaldehyde, ethylene oxide and acetyl chloride. "Normal" products were isolated only in the reactions with carbon dioxide and tributyl borate.

2-Naphthylacetic acid, prepared *via* the nitrile [7] was identical with III, obtained by carbonation of II. The hypothetical rearrangement product, 2-methyl-1-naphthylcarboxylic acid was shown by mixed meltingpoint test to be non-identical with III.

The non-identity of 2-naphthylmethylboronic acid [3] (IV) with the possible rearrangement product, 2-methyl-1-naphthylboronic acid [8] was confirmed by infrared investigation and by melting point differences.

The acid V was obtained if the reagent II was treated with ethyl chlorocarbonate and hydrolysis of the ester. The identity of V with 2-methyl-1-naphthylcarboxylic acid [9], was confirmed in this case by infrared analysis as well.

Gaseous formaldehyde gives with the reagent II exclusively 2-methyl-1-naphthylcarbinol (VI). The same compound was prepared from V by reduction with lithium aluminiumhydride or by treating 2-methyl-1-naphthylmagnesium bromide with gaseous formaldehyde [10]. For comparison the normal product was also prepared by reduction of 2-naphthylacetic acid with lithium aluminium hydride.

The abnormal product VII was formed by treating II with ethylene oxide. A review [11] of reactions between Grignard reagents and the oxirane (epoxide) ring was published some years ago. The compound VII was also prepared from 2-methyl-1-naphthyllithium reagent and ethylene oxide and by reduction of 2-methyl-1-naphtylacetic acid.

The product VIII was formed upon treating II with acetylchloride. Its hydrazone was shown by infrared analysis and by mixed melting point to be identical with the corresponding derivative of methyl-(2-methyl-1-naphthyl) ketone.

No rearrangement to the open 3-position has been observed in any of our experiments; consequently this constitutes another manifestation of the symmetrical bond fixation in the naphthalene nucleus. Furthermore our results agree with those of Gaertner [12] concerning the reactions of 2-thianaphthenylmethylmagnesium chloride with different substances. In both cases *exclusively* abnormal products were isolated (except with carbon dioxide) and these two examples show that rearrangement will occur more extensively to a position which is attacked preferentially in electrophilic substitution. There are exceptions, however, and our results might be only an indication.

EXPERIMENTAL

Apparatus and procedure

The cyclic reactor is sketched in Fig. 1. The condenser is topped by a funnel for slow addition of the halide. The magnesium turnings are amalgamated by mixing the magnesium and $HgBr_2$ in the column and then adding dry ether. The apparatus is then allowed to stand overnight, and after the ether has been swept down into the pot and renewed,

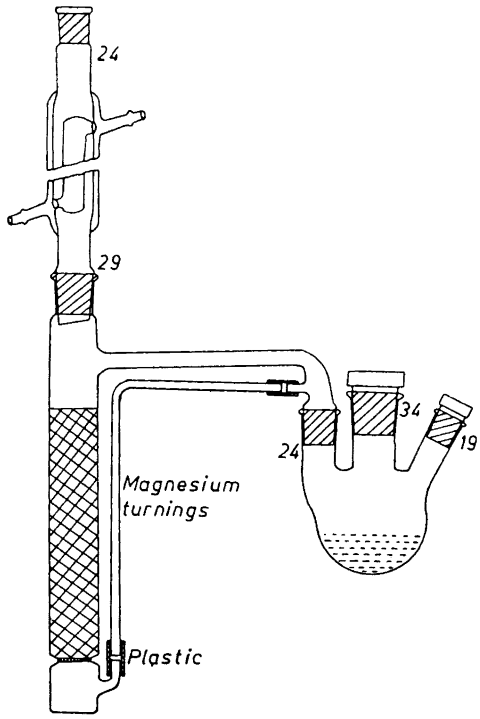


Fig. 1.

the "cycling" can start. The reactor is operated under nitrogen or at least the apparatus is swept free from oxygen before the experiment. It is furthermore important to start the column with allyl bromide or the like and then "cycle" until all the Grignard reagent is swept into the flask. Anhydrous conditions are always essential and it is also important that the addition of the halide is slow, that gentle boiling is maintained in the upper part of the Mg-column with a good ether cycling rate. High dilution must be maintained in the column (200—300 ml of ether per 0.1 mole of halide) at all times. Otherwise this method is no better than the usual pot method. Once the Grignard reagent is formed and swept into the pot it is stable against coupling.

Preparation of 2-naphthylmethylmagnesium bromide

In all experiments 0.05 mole (11 g) of I [13] was used, dissolved in 125 ml of dry ether. Hydrolysis of the Grignard reagent formed gave 2-methylnaphthalene (b.p. 108—110°C/16 mm Hg, m.p. 33—35°C) and the yield could thus be determined. The best yield was 84 % when the method of Greenlee and coworkers was used. The conventional method gave only 39 % of the theoretical, the remainder being mostly coupling products.

Carbonation of 2-naphthylmethylmagnesium bromide

The Grignard reagent II, prepared from 11 g of I, was cooled to about 0°C and then poured slowly into crushed dry ice in absolute ether. The mixture was allowed to warm to room temperature and then was hydrolyzed with water. The organic layer was separated off, the water solution extracted with ether and the combined ether layers extracted with dilute sodium hydroxide. Upon acidification of the alkaline solution, a white powder precipitated, which after recrystallisation from water-ethanol gave white needles. M.p. 140—142°C. Weight 6.9 g. Yield 74 % . With an authentitc sample [7], m.p. and mixed m.p. 139—141°. From the ether phase 0.3 g of a substance was separated, which after recrystallisation from ethanol gave white plates with m.p. 183—185°; presumably 1,2-di(2-naphthyl)-ethane [14]: m.p. 182°C.

Reaction of the Grignard reagent II with tributyl borate

The Grignard reagent, prepared from 11 g of I, was added with stirring over a two-hour period, to 15 g of tributyl borate [15] in 100 ml of dry ether at —60°C. After standing overnight it was treated with 1 M hydrochloric acid, the organic portion separated and the aqueous phase extracted with ether. The combined ether layers were extracted with 1 M sodium hydroxide. The alkaline aqueous layer was acidified with hydrochloric acid precipitating 4.5 g of the crude moist acid (Yield ≈48 %). The diethanolamine ester was prepared in the usual way [3]; m.p. 229—231°C.

Reaction of the Grignard reagent II with ethyl chlorocarbonate

The Grignard reagent, prepared from 11 g of I, was added during half an hour to a well-stirred solution of 50 ml of redistilled ethyl chlorocarbonate, cooled to —20°C in an ice-water bath. After standing with stirring overnight during which time the temperature rose to room temperature, water and 25 g of sodium hydroxide were added under gentle reflux. The alkaline solution was then acidified, liberating carbon dioxide, and then the aqueous layer was repeatedly shaken with ether. The ether was evaporated and the

residual oil was saponified by alcoholic sodium hydroxide. Upon acidifying the solution, a white powder was precipitated, which after recrystallisation from water gave fine needles. M.p. 125—127°C. Weight 6.6 g. Yield 71 %. With an authentic sample of 2-methyl-1-naphthylcarboxylic acid [9] no depression of the melting point was observed. (Found: Equiv.wt. 187.7. Calc.: Equiv.wt. 186.20.)

Reaction of the Grignard reagent II with formaldehyde

Gaseous formaldehyde [16] from 90 g of dry paraformaldehyde was carried by dry oxygen-free nitrogen into a solution of II, prepared from 11 g of I. The reaction took place at room temperature. A white precipitate was formed at once and after the solution had been cooled in an ice bath, saturated ammonium chloride was added to dissolve the magnesium compound. The solution was shaken with ether repeatedly, the organic extracts shaken free from acid and after being dried over sodium sulphate and freed from ether, the residue was distilled. The main fraction, b.p. 140—144°C/10—11 mm Hg, consisted of a heavy yellow liquid. Weight 4.4 g. Yield 51 %. The liquid was dissolved in petroleum ether and after some time faintly yellow plates were precipitated. Recrystallisation from ligroin + ether gave white plates with m.p. 114—116°C. (Found: C 84.0; H 7.24. Calc. for $C_{12}H_{12}O$(172.21): C 83.7; H 7.03.)

Reduction of 2 methyl-1-naphthylcarboxylic acid

A solution of 1.9 g of 2-methyl-1-naphthylcarboxylic acid in 50 ml of dry ether was added to an ethereal solution of lithium aluminium hydride (in excess) at such a rate that the reaction mixture boiled gently. When the reaction was over, an excess of cold water was added and then the mixture was poured into ice-cold dilute sulphuric acid. The solution was shaken repeatedly with ether, the organic layer separted, dried over sodium sulphate and evaporated. The white powder was then recrystallized from ligroin + ether, giving an almost quantitative yield of white plates. M.p. 114—116°C. Mixed m.p. with VI: 114—116°C.

Reduction of 2-naphthylacetic acid

Addition of an ethereal solution of 1.9 g of the acid to a stirred suspension of 1 g of lithium aluminium hydride in 50 ml of ether, followed by usual procedures, gave white plates of β-(2-naphthyl)-ethanol. M.p. 72—73°C. Weight 1.7 g. Yield: almost quantitative. (Found: C 83.8; H 7.00. Calc. for $C_{12}H_{12}O$ (172.21): C 83.7; H 7.03.)

Reaction of the Grignard reagent II with ethylene oxide

A solution of II, prepared from 11 g of I, was stirred in an ice-salt bath under nitrogen while excess of ethylene oxide in dry ether was added during one hour. Vigorous reaction occurred at first with each drop and a white precipitate separated. The bath was removed and stirring continued until escape of gas subsided, then ether and excess oxide were removed by distillation. Dilute hydrochloric acid was added and stirring continued until dissolution of the precipitate was complete. The ether layer was separated, the water layer shaken with ether and the organic solution combined, dried and distilled. The main fraction, boiling at 185—195°C/9 mm Hg, was a viscous colourless liquid. Weight 4.5 g. Phenylurethan, m.p. 230—232°C. (Found: C 79.1; H 6.41. Calc. for $C_{20}H_{19}O_2N$ (305.36): C 78.7; H 6.28 %.)

Preparation of β-(2-methyl-1-naphthyl)-ethanol

To 11 g of 1-bromo-2-methylnaphthalene [17], cooled to 0°C, 0.05 mole of butyllithium [18] in 50 ml of ether was added. After the spontaneous lithium-halogen exchange reaction was complete, excess of ethylene oxide in ether was added dropwise and then the usual procedure followed as above. B.p. 190–195°C/9–10 mm Hg. Weight 6.3 g. Yield 67 %. Phenylurethan m.p. 230–232°C. Mixed m.p. with the phenylurethan of VII: 230–232°C.

2-Methyl-1-chloromethylnaphthalene

This compound has been prepared before but no yields were given [19]. By repeating the experiments, low yields were obtained and mostly tarry products. A modified method is given here:

Into a 2–l flask, fitted with a reflux condenser and a teflon stirrer, were placed 65 g of 2-methylnaphthalene, 30 g of paraformaldehyde, 65 g of glacial acetic acid, 45 ml of 85 % phosphoric acid and 90 ml of concentrated hydrochloric acid. The mixture was heated at 100°C with stirring for 5 h. After the mixture had been cooled it was washed twice with cold water, then with potassium carbonate solution and finally with cold water. The organic layer was dissolved in ether, thoroughly dried over sodium sulphate and distilled. The main fraction was obtained at 165–170°C/9–10 mm Hg. Recrystallisation from ethanol gave white needles. M.p. 62–63°C. Weight 64 g. Yield 75 %.

2-Methyl-1-naphthylacetonitrile

9.5 g of 2-methyl-1-chloromethylnaphthalene and 5 g of sodium cyanide in 50 ml of aceton and 4 ml of water was refluxed for 4 h. The acetone was evaporated and water and ether were added. Excess of sodium cyanide was removed by repeated extractions with water. The ether layers were dried and the ether evaporated. The residue recrystallized from formic acid gave fine, white needles. M.p. 77–79°C. Weight 7.4 g. Yield 81 %. (Found: C 86.6; H 5.95. Calc. for $C_{13}H_{11}N$ (181.23): C 86.2; H 6.12.)

2-Methyl-1-naphthylacetic acid

a) via the nitrile. 7 g of 2-methyl-1-naphthylacetonitrile was refluxed for 12 h with excess of sodium hydroxide in a water-ethanol solution. The alcohol was distilled off and the residue extracted with ether in order to remove unsaponified nitrile. When the water solution was acidified with hydrochloric acid, the organic acid precipitated as a white powder. The acid was recrystallized from water-ethanol forming small, white needles. M.p. 176–168°C. Weight 6.5 g. Yield 84 %. (Found: Equiv.wt. 199.6; C 78.7; H 6.21. Calc. for $C_{13}H_{12}O_2$ (200.23): Equiv.wt. 200.2; C 78.0; H 6.05 %.)

b) via the Grignard reagent. 9.5 g of 2-methyl-1-chloromethylnaphthalene in 50 ml of dry ether was dropped to 1.7 g of magnesium turnings in 75 ml of ether. The reaction was initiated with a few drops of bromine. After carbonation with dry ice the reaction mixture was treated with hydrochloric acid, the ether layer was separated, the water phase extracted repeatedly with ether and the combined extracts shaken with sodium hydroxide solution. The alkaline solution was acidified with hydrochloric acid, precipitating the acid as a white powder. After recrystallisation from water-ethanol the acid was obtained as small, white needles. M.p. 176–178°C. Weight 7.1 g. Yield 71 %.

The ether phase was evaporated and the residue recrystallized, giving a white powder. M.p. 173–175°C (from ethanol). This compound seems to be 1,2-di(2-methyl-1-naphthyl)-ethane. (Found: C 93.4; H 7.15. Calc. for $C_{24}H_{22}$ (310.42): C 92.9; H 7.10.)

The same compound was formed almost exclusively when by a mistake a mechanical stirrer of *copper* was used and bromine was added as an activator. The chlorides of copper which formed apparently made the coupling product predominate and very little acid was isolated after carbonation.

Reduction of 2-methyl-1-naphthylacetic acid

The acid (2 g) was reduced with lithium aluminium hydride in the usual way. Quantitative yields. Phenyluretan, m.p. 231—233°C.

Reaction of the Grignard reagent II with acetyl chloride

The Grignard reagent (II), prepared from 11 g of I was added dropwise during one hour to a solution of 25 g of acetyl chloride in 100 ml of ether, cooled in an ice-water bath. The bath was removed and the mixture allowed to warm to room temperature, when water and ice were added to hydrolyze the excess of acetyl chloride. The water phase was shaken repeatedly with ether, the organic portions combined, washed with sodium carbonate and water, dried and distilled. The main fraction boiled at 160—170°/10 mm Hg. This was a yellow, heavy liquid, whose 2,4-dinitrophenylhydrazone melted at 236—238°C. This derivative was identical with that of an authentic sample of methyl-2(2-methyl-1-naphthyl) ketone, prepared as above from 2-methyl-1-naphthylmagnesium bromide and acetyl chloride. (Found: C 63.0; H 4.72. Calc. for $C_{19}H_{16}O_4N_4$ (364.35): C 62.6; H 4.43.)

Thanks are due to Professor A. Fredga for his keen interest in this work. A grant from the *Swedish Natural Science Research Council* is gratefully acknowledged.

The Photochemical Reaction between Nitric Oxide and *Iso*propanol, Sensitized by Benzophenone

HANS L. J. BÄCKSTRÖM and ALVAR STENERYR

Institutionen för fysikalisk kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

PETER PERLMANN*

Institutet för oorganisk och fysikalisk kemi, Stockholms Högskola, Stockholm, Sweden

The photochemical reaction between *iso*propanol and nitric oxide with benzophenone as sensitizer has been studied at 25°C using light of wavelength 366 mμ. The results indicate that, in the main reaction, one molecule of acetone, one of nitrogen, one of nitrous oxide, and two of *iso*propyl nitrite are formed for every six molecules of nitric oxide reacting. A slight side-reaction seems to be connected with the formation of a light-absorbing by-product.

The number of molecules of nitric oxide reacting per light quantum absorbed is given approximately by: $\varphi = \frac{3.5}{1+252\,c}$, where c is the concentration of NO in mole/l. The retardation of the reaction by nitric oxide must be connected with the fact that a metastable biradical state of benzophenone has to be assumed as an intermediate in the reaction. This biradical state may be identified with the triplet state responsible for the phosphorescence shown by carbonyl compounds in solid solution at low temperatures. Apparently, molecules in this state may be deactivated on collision with nitric oxide molecules before they have time to react with the alcohol. A similar deactivating effect of oxygen has been reported previously.

The mechanism of deactivation is discussed. It is concluded that nitric oxide and oxygen owe their specific deactivating power to their unpaired electrons. In a collision with the biradical, the presence of unpaired electrons in both collision partners must give rise to strong exchange forces that may lead to the formation of a bond. The complex formed, on losing its excitation energy, must be assumed to dissociate again, regenerating the original molecules in their ground states. It is pointed out that the assumed mechanism is in accord with the Wigner spin conservation rule for collisions.

A large number of photochemical reactions of carbonyl compounds are known that can best be interpreted [1, 2] by assuming that the molecule on light absorption is transformed into a biradical: $R'R''C{=}O \rightarrow R'R''\dot{C}{-}O\cdot$.

* Preliminary experiments, carried out in 1946—47. Present address: Wenner-Grens Institut, Stockholm, Sweden.

Due to the odd electron on oxygen, this biradical will react with many substances by hydrogen abstraction, the free radicals thus formed subsequently undergoing dimerization or disproportionation. Thus, a solution of benzophenone in *iso*propanol, when irradiated in the absence of oxygen, gives acetone and benzopinacol, $(C_6H_5)_2C(OH)C(OH)(C_6H_5)_2$. In the presence of oxygen, on the other hand, the reaction takes a different course, the free radicals instead reacting with oxygen, with regeneration of benzophenone and formation of acetone and hydrogen peroxide, the net result being a photosensitized oxidation of the alcohol.

As found by Berthoud [3], the rate of this photosensitized oxidation decreases with increasing oxygen pressure. This can be explained [4] by assuming that excited benzophenone molecules in the biradical state may be deactivated on collision with oxygen molecules before they have time to react with the alcohol. Since this specific deactivating power of oxygen might be connected with its paramagnetism it seemed of interest to investigate whether a similar deactivating action is exercised by another paramagnetic gas, nitric oxide.

EXPERIMENTAL

Preliminary work

In the preliminary experiments, essentially the same experimental technique was used as in the earlier work [4] on the benzophenone-sensitized reaction between alcohols and oxygen. Solutions of benzophenone in 95 % ethanol were shaken with nitric oxide at atmospheric pressure, using a glass shaking tube connected to a gas burette by means of rubber tubing. Irradiation with a mercury arc caused rapid absorption of NO, the main reaction products identified being N_2, N_2O, and acetaldehyde. Some acetic acid was also formed. The solutions soon turned slightly yellow owing to the formation of small quantities of a coloured by-product which could only be isolated as a brown tar giving a positive test for nitrogen.

The technique employed was not suitable for quantitative determinations. Owing to the formation of gaseous reaction products, one of them highly soluble in the alcohol, there was no simple relation between the measured rate of volume decrease and the rate of nitric oxide absorption. The results of experiments where the nitric oxide was diluted with nitrogen indicated, however, that the rate of reaction increased with decreasing partial pressure of NO. A corresponding effect was to be expected in runs with pure NO, as the partial pressure of NO decreased during the run owing to the accumulation of gaseous reaction products. Such an effect was, indeed, observed, but it was rather weak. Apparently it was masked by a decrease in the rate caused by the formation of the above-mentioned coloured by-product, which acted as an internal light filter. In accordance with this, successively lower rate values were obtained when the same solution was shaken repeatedly with fresh portions of pure NO. In one such experiment, where the total amount of NO absorbed by 15 ml of ethanol +2.75 mmole of benzophenone was estimated at approximately 80 mmole, 97 % of the benzophenone could be recovered as 2,4-dinitrophenylhydrazone. Thus, benzophenone was not consumed in the reaction but acted merely as a sensitizer.

As in the corresponding reaction with oxygen [4], *iso*propanol gave about the same rate as ethanol whereas with methanol the rate was definitely lower (<50 %).

When pure liquid benzophenone was shaken with NO at 60°C in the light of the mercury arc for 2 h, no perceptible reaction took place.

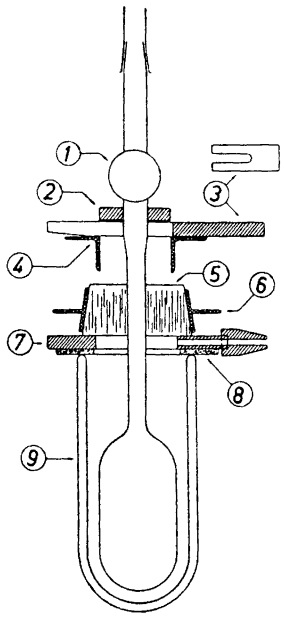

Fig. 1. Shaking tube connected to Töpler system, with arrangements for cooling with liquid oxygen under reduced pressure. (1) Stop-cock. (2) Plexiglas plate, glued on to neck of shaking tube. (3) Plexiglas wedge with groove for neck. (4) Angle-bars attached to vacuum rack. (5) Split rubber stopper with hole fitting neck, held in position by (6) metal ring. (7) Plexiglas ring with evacuation channel. (8) Rubber ring. (9) Dewar vessel with liquid oxygen. When evacuation began, the Dewar with rings 8 and 6 was forced by hand against the rubber stopper, but was soon held in position by the external pressure.

Present work

The alcohol selected for the final experiments was *iso*propanol. In principle, the experimental method employed consisted in allowing the reaction to take place in a closed shaking tube of sufficient size so that a measureable change in composition caused only a moderate decrease in the partial pressure of NO. Remaining nitric oxide as well as the quantities of N_2 and N_2O formed in the reaction were determined by isolating the different gases in the pure state by fractionation at suitable low temperatures and measuring their volumes under standard conditions.

The shaking tube, shown in Fig. 1, was made of thick-walled Pyrex tubing and carried a ground glass joint by means of which it could be attached to the vacuum system, and a stop-cock of such dimensions (bore 11 mm) as to permit the solution to be introduced into the tube by means of a pipette without danger of contamination by stop-cock grease. The wider part of the tube had a diameter of 50 mm and a length of 75 mm, the length of the neck below the stop-cock being 210 mm. The volume was 144.4 ml.

The vacuum system was of conventional type [6]. The arrangements for measuring gas volumes were:

1. A condensation trap connected to a Töpler pump and a calibrated gas burette. This "Töpler system" was connected with the main vacuum line by way of a stop-cock.
2. Another trap connected with a mercury manometer of calibrated bore. This trap-manometer system, also connected to the main line by way of a stop-cock, was used in certain cases for determining larger quantities of condensable gases. It was calibrated

against the gas burette by moving a condensable gas from one system to the other. Its volume at zero pressure was 58.4 ml.

The whole vacuum system was mounted on a rigid stand, made of angle iron. It was evacuated by a two-stage mercury diffusion pump and a fore pump. Vacuum was measured with a Pirani gauge or a McLeod gauge. All stop-cocks were lubricated with Apiezon N *. Removal of NO from the system for discarding was accomplished by adsorption on silica gel at liquid oxygen temperature in a removable trap. This arrangement was also found useful for over-night pumping-off of adsorbed gases from the system. A side-tube with a stop-cock and a ground glass joint enabled the shaking tube to be attached to the Töpler system.

The vapour pressure of nitric oxide at the temperature of liquid oxygen (90°K) is 3.3 mm. For a satisfactory separation of this gas from nitrogen it was therefore necessary to reach lower temperatures by cooling with liquid oxygen under reduced pressure. Arrangements for accomplishing this without strain on the glass parts are shown in Fig. 1. A similar arrangement was used for cooling the manometer trap. A copper gauze immersed in the liquid oxygen served to increase thermal conduction. Using pumps of sufficient capacity, temperatures of 63—65°K, as indicated by the equilibrium oxygen pressure, were reached without difficulty, corresponding to a nitric oxide pressure of about 5×10^{-4} mm.

The shaking experiments were performed at 25°C in a thermostat with a quartz window. The light source was a vertical 220 V AC mercury arc (LK 700) from Lumalampan, Stockholm, burned in series with a regulating resistance. Voltage variations were eliminated by means of a Sorensen constant voltage regulator. Relative values of the radiation intensity at 366 mμ (the only mercury line transmitted by the wall of the shaking tube and absorbed by the solution) were obtained with the aid of a thermopile and galvanometer as described earlier [4].

Materials

Nitric oxide was prepared in a special vacuum system from potassium nitrite, potassium iodide and sulfuric acid by the method of Winkler. It was freed from iodine vapour and higher oxides by passage through two large wash bottles with 50 % potassium hydroxide solution in which it was finely dispersed by means of fritted glass disks, and dried by passing through a trap at −79°C. It was then condensed at 90°K and freed from N_2O and N_2 by fractionation according to Gray [6]. The purified gas was collected in an evacuated glass bulb with stop-cock, which was later sealed to the main vacuum system.

Nitrogen was prepared by heating sodium azide in an evacuated glass system as described by Justi [7]. It was stored in the same way as NO.

Nitrous oxide. The commercial product was introduced into the vacuum system and dried by passing through a trap at −79°C. Volatile impurities were removed by pumping at 90°K.

Iso*propanol.* C.P. *iso*propanol was fractionally distilled at atmospheric pressure. Only the middle fractions were used.

Benzophenone. Merck's benzophenone, "M.P. *ca.* 48°C", previously found to be of satisfactory purity [4], was freed from traces of volatile impurities by melting in a vacuum.

Experimental procedure

In starting an experiment, 2 g of benzophenone were dissolved in 26 ml of *iso*propanol, and 25 ml of the solution introduced into the shaking tube. The tube was then attached to the Töpler system and cooled to 90°K and the air removed by pumping. With the stop-cock closed, the tube was then allowed to warm to room temperature, again cooled to 90°K, the pumping repeated, and so on, until pressure readings indicated that dissolved gases had been completely removed. Generally three such pumpings sufficed. An accurately measured quantity of NO was then condensed in the tube, whereupon the stop-cock was closed and the tube disconnected from the vacuum system.

* Much time was wasted in trying to use commercial silicone grease. No satisfactory vacuum could be maintained with this lubricant.

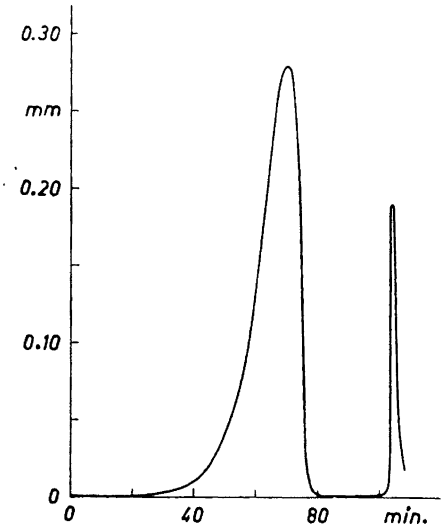

Fig. 2. Change of pressure with time during low-temperature distillation of a nitrous oxide-*iso*propanol mixture.

After an experiment, the shaking tube was again attached to the Töpler system and cooled to 64°K whereupon uncondensed gas (nitrogen) was pumped into the gas burette by means of the Töpler pump. This was repeated twice, with intermediate thawing of the solution, after which the nitrogen was recirculated through the Töpler trap, kept at −79°C, to remove alcohol vapour, and its volume again measured.

With the shaking tube at 90°K, unreacted NO was then sublimed into the manometer trap, kept at 64°K. This was repeated several times with intermediate thawing of the solution. The gas was freed from alcohol vapour by recirculation and its volume determined.

The determination of N_2O presented difficulties because of its high boiling point (−89°C) and its high solubility in the alcohol. The method finally arrived at was as follows.

With the shaking tube at about −25°C, the Dewar vessel was removed and a brass container in two parts, lined with asbestos, was placed around the neck of the tube and filled with pulverized CO_2-ice. The length of the cooled part of the tube was about 8 cm. The tube was then opened to the evacuated Töpler system (volume about 425 ml). The heating action of the surrounding air caused the solution to boil with reflux under a pressure which increased as nitrous oxide collected in the Töpler system. Approximate values of the pressure were obtained by observing the mercury levels in the two limbs of the gas burette. When after some hours no further increase in pressure was observed, the stop-cock of the shaking tube was closed, the Töpler system opened to the main line, and the gas obtained condensed in the manometer trap with liquid oxygen. The process was repeated twice, using a smaller volume (about 70 ml) to receive the gas, the shaking tube being connected only to the gas burette.

Attempts to separate the nitrous oxide from admixed alcohol vapour by recirculation through a trap at −79°C were unsuccessful. A satisfactory separation was, however, obtained in the following manner.

The bottom of the Töpler trap was covered with mercury (weight about 20 g). The gas was carefully condensed in the lowest part of this trap by cooling only the bottom with liquid oxygen. The whole trap was then brought to liquid oxygen temperature, the Dewar vessel rapidly replaced by an empty Dewar precooled to the same temperature, and the neck covered with cotton wool. The Töpler system was opened to the manometer trap, which was immersed in liquid oxygen, and the pressure read at regular intervals on the Pirani gauge.

The result of one of the model experiments, using a mixture of 216 μmole N_2O and 8 μmole *iso*propanol vapour, is shown graphically in Fig. 2. After the first pressure maximum, caused by distillation of N_2O, the pressure soon dropped to 1 or 2×10^{-3} mm. When this pressure had been maintained for 19 min, the Dewar vessel was, in this case, removed (at "100 min") in order to speed up the process. The second maximum, caused by distillation of the alcohol, appeared shortly after the mercury had melted.

The good separation obtained is ascribed to the heat capacity and thermal conductivity of the mercury lump, slowing down the heating process and causing evaporation to take place from a surface of more uniform temperature. When the method was used for the determination of N_2O, the stop-cock of the manometer trap was closed as soon as the pressure, after passing the first maximum, had reached a level of 1 or 2×10^{-3} mm. The Dewar vessel was removed, the trap allowed to reach room temperature, and the quantity of N_2O determined by reading the manometer.

The whole procedure for determining N_2O was tested by condensing measured quantities in the shaking tube. Before starting the analysis, the gas was allowed time to dissolve in the alcohol at room temperature. The following results were obtained. Throughout this paper, gas volumes are given in ml at 20°C and 760 mm.

Quantity of N_2O used, ml	5.44	9.71
» » » found, ml	5.43	9.71

After completing the analyses for the above-mentioned reaction products, any volatile constituents that might have escaped into the vacuum system and become adsorbed on the walls were again collected in the shaking tube by cooling the latter with liquid oxygen for a sufficient length of time. The solutions were then analyzed for acetone as described earlier [4], except that a photoelectric spectrophotometer, Beckman Model DU, was used. They were then stored in glass-stoppered bottles in the dark for further examination on a later occasion.

RESULTS

As shown by Table 1, nitrogen and nitrous oxide are formed in equimolar quantities irrespective of experimental conditions. Further details in connection with the experiments are given in Table 2.

Table 1. The relation between the quantities of nitrogen and nitrous oxide formed in the reaction.

N_2O » »	3.73	0.73	2.70	5.13	7.36

In Table 2, the experiments are arranged in chronological order. In the first five experiments (series I), that were of an orientating nature, the current through the lamp was kept constant at 5.00 A but no intensity measurements were made. The rate of reaction was inconveniently high. The rest of the experiments were therefore made at lower intensities, corresponding to galvanometer deflections of about 2.6 cm in experiments 6—12 (series II), and 6.0 cm in experiments 13—20 (series III). Column 3 gives the average galvanometer deflection during the run in cm.

Table 3 summarizes derived values for runs in presence of nitric oxide. Column 2 gives the average quantity of NO present in ml, columns 3 and 4 moles of nitrogen and acetone formed per mole of NO consumed, and column 5 the rate of reaction expressed as μmoles of NO consumed per minute. The

strongly deviating values within brackets may probably be ascribed to experimental errors and are left out of consideration. In Fig. 3, the remaining values in columns 3 and 4 are plotted against consumed NO in ml. The points show considerable scattering but nevertheless an unmistakable trend, especially as regards the nitrogen values. The conclusion seems justified that the main

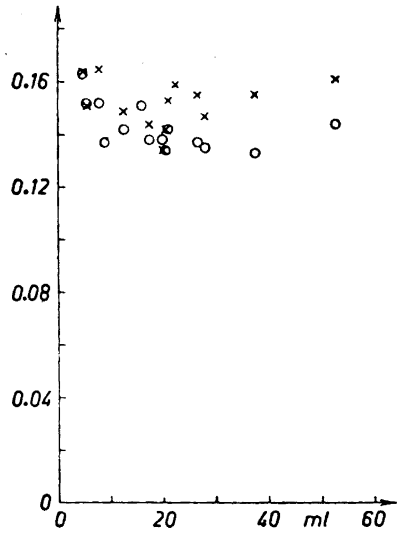

Fig. 3. Yields of nitrogen (O) and acetone (×) (mole per mole of NO) as a function of total NO absorbed (ml).

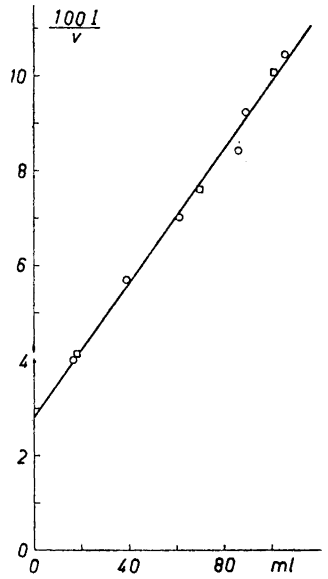

Fig. 4. Plot of $\frac{100\ I}{v}$ against initial nitric oxide in ml. I = average galvanometer deflection during run in cm, v = rate of nitric oxide absorption in μmole min^{-1}. □ Series II, O Series III. The straight line corresponds to the calculated rate equation (see text).

reaction gives rise to one molecule of acetone, one of nitrogen, and one of nitrous oxide, for every 6 molecules of nitric oxide reacting, but that the yields of nitrogen and nitrous oxide are markedly reduced as the reaction proceeds, in connection with a side-reaction. As in the preliminary work on ethanol, the solutions turned slightly yellow. In runs 6—10 the increase in light absorption at 366 mμ was followed spectrophotometrically by diluting 1-ml samples with 2 ml of *iso*propanol, and measuring the extinction in a layer-thickness of 1 mm. The values found were 0.667, 0.680, 0.680, 0.695, 0.722, as against 0.645 in a blank determination, thus increasing regularly with the amount of NO absorbed (see Table 2).

As shown by Table 3, the rate of nitric oxide absorption at constant light intensity generally decreases with increasing NO concentration, as measured by the average quantity of NO present during the run. However, runs 8, 9, and 10, show that the decrease in NO concentration taking place as a result of the reaction does not lead to a corresponding increase in reaction rate. In runs 9 and 10, the amount of NO initially present was the same as in run 8, but the percentage conversion was considerably increased by increasing the time of irradiation. The results indicate that the increase in rate normally

associated with decreasing NO concentration is here very nearly compensated by a decrease caused by the change in light absorption, an increasing fraction of the active light being absorbed by the coloured by-product formed. Under these circumstances it seems correct to relate the observed reaction rate to the quantity of NO initially present rather than to the average during the run. This has been done in Fig. 4.

In calculating the best straight line through the points by the method of least squares, runs 9 and 10 were excluded. The equation found was $\frac{100\ I}{v} = 2.73(1+0.0239[\mathrm{NO}])$.

The observed rates of acetone formation in the runs without nitric oxide, recalculated to a galvanometer deflection of 1 cm and expressed in μmole/min, were as follows:

Run No.	11	12	13	14	Average
Rate of acetone formation	5.04	5.07	5.43	5.18	5.18

Assuming a quantum efficiency of 0.5 (see page 18), the number of quanta absorbed by the solution per minute becomes $1.04 \times I \times N \times 10^{-5}$, where I represents the galvanometer deflection in cm, and N Avogadro's number. On this basis, the following formula is obtained for the quantum efficiency of nitric oxide absorption:

$$\varphi_{NO} = \frac{3.5}{1+0.0239[\mathrm{NO}]} \quad *$$

Nitrite determinations

The quantities of nitrogen and nitrous oxide formed in the reaction will account for at most 2/3 of the nitric oxide consumed. A search was therefore made for other nitrogenous reaction products. A qualitative test revealed the presence of nitrite. Attempts were accordingly made to obtain a method for determining nitrites in the reaction mixture, based on the usual spectrophotometric method for nitrite determination in water.

In the procedure of Rider and Mellon [8], nitrite is made to react with sulfanilic acid in strongly acidic solution and the resulting diazonium salt coupled with α-naphthylamine after buffering with sodium acetate in order to speed up the coupling reaction. As alkyl nitrites are very rapidly hydrolyzed in acid solution [9], this method can also be used for determining alkyl nitrites. In view of the presence of benzophenone in the reaction mixtures, we tried to work in alcoholic solutions. Experiments with pure sodium nitrite showed that the coupling process, when performed in 50 % ethanol, was completed in less than 10 min at room temperature even without buffering the solution. The addition of sodium acetate was therefore omitted. The presence of the alcohol greatly increased the stability of the resulting dyestuff solution, the extinction remaining unchanged for more than 3 h. Whether the diazotization was carried out in water or in 95 % ethanol was without influence on the final result. A diazotization time of 10 min was sufficient.

* A possible source of error in the runs without nitric oxide, which was not realized at the time, is the different behaviour of the solution when shaken with or without added gas. It would have been better to add an inert gas like nitrogen. As it is, light absorption may have been less complete than in the other runs which would lower the rate of acetone formation and cause the calculated values of φ_{NO} to come out too high.

The molar decadic extinction coefficient of the dyestuff at 520 mμ was found to be 4.30×10^4 l mole^{-1}cm^{-1}.

In studying the application of the method to alkyl nitrites, model experiments were made with redistilled amyl nitrite of 88.9 % purity, as determined by the method of van Itallie, Steenhauer and Harmsma [10]. No entirely satisfactory method was obtained. Results in the presence of benzophenone tended to be low and were not very reproducible. In the method finally adopted, the nitrite was therefore separated from the benzophenone by distillation. A sample of the reaction mixture was suitably diluted with ethanol. 1 ml of the resulting solution was rapidly introduced into a distillation apparatus of special design where it was subsequently mixed with 5 ml of 25 % ethanol and the nitrite distilled off as ethyl nitrite [11] in a current of oxygen at 70—75°C. The vapours were absorbed in 25 ml of ice-cold 95 % ethanol mixed with 1 ml of sulfanilic acid solution (0.6 g of sulfanilic acid +20 ml of concentrated hydrochloric acid + water to 100 ml). The distillation was continued for 20 min, after which the alcoholic sulfanilic acid solution was transferred to a measuring flask, mixed with 1 ml of naphthylamine reagent (0.6 g of α-naphthylamine + 1 ml of concentrated hydrochloric acid + water to 100 ml) and diluted with water to 50 ml. After standing at least 10 min, the extinction was measured at 520 mμ, using a layer-thickness of 1 cm.

In model experiments, the results obtained by this method were fairly reproducible but they were consistently about 10 % low (90.5±1 % of the theoretical value). In Table 4, the experimental values have therefore been multiplied by a factor of 1.1. They are given in moles of nitrite per mole of nitric oxide absorbed.

Table 4. Quantities of nitrite found in relation to nitric oxide consumed in the reaction (mole/mole).

Expt. No.	6	7	8	9	10	15	16	17	18	19	20
$\frac{\text{Nitrite}}{\text{NO}}$	0.116	0.088	0.097	0.262	0.239	0.131	0.293	0.234	0.306	0.168	0.273

*Iso*propyl nitrite is highly volatile (B.P. 45°C) and losses by evaporation may therefore have taken place during the long time of storing the reaction mixtures (from 2 to more than 6 months). This was definitely the case with the solution from experiment No. 15, for which determinations made 2 months previously by a preliminary method, without distillation, had given values of 0.264 and 0.266. Taken as a whole, the evidence seems to support the assumption that, in the main reaction, one third of the nitric oxide reacts to form *iso*propyl nitrite.

Solubility of nitric oxide in *iso*propanol

The solubility of nitric oxide in *iso*propanol at 25°C was determined, using an apparatus similar to the shaking tube (Fig. 1), except that it had two bulbs above each other. The lower bulb, containing the alcohol, was furnished with a magnetic stirrer. The stop-cock connecting the bulbs had a bore of 11 mm to facilitate gas diffusion. After greasing the stop-cocks, the apparatus was connected to the vacuum system, and dissolved air was removed as described earlier. Because of the large quantity of *iso*propanol used, 8 successive pumping operations were required. To avoid cracking of the glass tube surrounding the magnetic stirring rod, on solidification of the alcohol, the tube had to be made of thick glass, and with pointed ends. Starting at these points, cracks were formed in the solidified alcohol, thus relieving the strain on the tube.

After condensing a measured volume of NO in the apparatus, it was disconnected from the vacuum system, surrounded by a polythene bag and immersed in a water thermostat at 25.0°C. After 5 h, with the magnetic stirrer operated at such speed that a marked indentation was observed in the alcohol surface, the stop-cock between the bulbs was closed and the apparatus again connected to the vacuum system. The NO in the upper bulb was condensed in the manometer trap at 64°K, freed from alcohol by trap to trap distillation, and measured in the gas burette. All gas volumes were measured at three different pressures to diminish the effect of calibration errors.

The following results were obtained.

Total nitric oxide used, ml	17.46	6.425
Nitric oxide in upper bulb, ml	11.035	4.05

The volumes, as determined by weighing, were: upper bulb, 143.3 ml; both bulbs including the stop-cock but excluding the magnetic stirrer, 333.6 ml; *iso*propanol, 149.9 ml. The values calculated for the Ostwald solubility coefficient are 0.287 and 0.291, respectively. Mean value 0.289.

In the experimental formula for φ_{NO} (p. 16) the concentration of NO is given as the quantity of NO initially present in the reacting system, expressed in ml at 20°C and 760 mm of mercury. Knowing the volume of the shaking tube (144.4 ml), the volume of the solution (25 ml), and the partition coefficient, (0.289), the corresponding concentration of NO in the solution in mole/l c_{NO}, can be calculated. The formula then becomes

$$\varphi_{NO} = \frac{3.5}{1+252\ c_{NO}}$$

DISCUSSION

The following mechanism, similar to the one proposed for the corresponding reaction with oxygen [4], will account for the main features of the results obtained.

$$(C_6H_5)_2CO + h\nu \rightarrow (C_6H_5)_2CO^* \rightarrow (C_6H_5)_2\dot{C}-O\cdot \quad (1)$$

$$(C_6H_5)_2\dot{C}-O\cdot + (CH_3)_2CHOH \rightarrow (C_6H_5)_2COH + (CH_3)_2\dot{C}OH \quad (2)$$

$$2(C_6H_5)_2\dot{C}OH \rightarrow (C_6H_5)_2C(OH)C(OH)(C_6H_5)_2 \quad (3)$$

$$2(CH_3)_2\dot{C}OH \rightarrow (CH_3)_2CHOH + (CH_3)_2CO \quad (4)$$

$$(C_6H_5)_2\dot{C}-O\cdot + NO \rightarrow (C_6H_5)_2CO + NO \quad (5)$$

$$(C_6H_5)_2\dot{C}OH + (CH_3)_2\dot{C}OH + n\ NO \rightarrow \text{reaction products} \quad (6)$$

The reaction in the absence of nitric oxide is determined by steps (1)—(4), giving a quantum efficiency of 0.5 for the formation of benzopinacol and acetone *. In the presence of nitric oxide, the reaction is determined by steps (1), (2), (5), and (6). Assuming stationary state concentration for the intermediate

* Preliminary results obtained by C. Åquist in this laboratory indicate that the true value is between 0.47 and 0.57. The investigation is being continued.

radicals, and on condition that n is constant, the following expression is obtained for the quantum efficiency of nitric oxide absorption:

$$\varphi_{NO} = \frac{n}{1 + \frac{k_5 c_{NO}}{k_2 c_A}}$$

where c_A denotes the concentration of *iso*propanol.

The most important steps in the reaction mechanism will now be discussed separately.

The activation of benzophenone by light absorption

The biradical state of benzophenone appearing in the reaction scheme may be identified with the metastable triplet state responsible for the phosphorescence exhibited by carbonyl compounds in solid solution at liquid air temperatures [12]. Absorption of long-wave ultraviolet light raises the molecules to the lowest excited singlet state, from which they pass, by a process of radiationless internal conversion, to a slightly lower lying triplet level, the energy given out in the process being taken up by the surrounding solvent molecules as vibrational energy. In accordance with the selection rule prohibiting intercombinations between levels of different multiplicity, the radiative return from the triplet to the ground (singlet) level is a slow process. The rate of decay of phosphorescence under the conditions specified gives an approximate measure of the natural mean life-time of the triplet state. The value found for benzophenone [13] is 0.008 sec.

A change from a singlet to a triplet state means the unpairing of two electrons in the molecule, *i.e.* the formation of a biradical. As the structure of the triplet state of carbonyl compounds Lewis and Kasha [12] suggested a molecule in which one member of the double bond of the carbonyl group had been broken. Apparently, they were not aware of the wealth of photochemical evidence which had caused one of us [1] to postulate the existence of a biradical of this kind as an intermediate in a large group of photochemical reactions of carbonyl compounds.

In fluid solvents at ordinary temperatures the same process of internal conversion to the triplet state may be expected to take place, but the life-time of the biradicals will normally be shortened by deactivating collisions with solvent molecules to such an extent that no phosphorescence is observed under these conditions. This is the case with benzophenone. Apparently, however, the life-time is long enough for photochemical reactions to take place with suitable reaction partners.

Substances showing phosphorescence in solid solution at liquid air temperatures generally also show normal fluorescence, *i.e.* the much more short-lived radiation connected with the return from the excited singlet to the ground state. According to Kasha [14], however, fluorescence is scarcely to be observed in the case of carbonyl compounds, showing that the "forbidden" conversion to the triplet state is essentially complete. He gives the ratio of the yield of fluorescence to that of phosphorescence as $\leq 10^{-3}$. Since the natural life-time of the

excited singlet state is probably of the order of 10^{-8} sec, this means that the time required for its conversion to the triplet state under the conditions of the experiments is of the order of 10^{-11} sec.

The quantum efficiency of phosphorescence of benzophenone dissolved in EPA glass (a mixture of ether, pentane, and alcohol) at 77°K has been determined by Gilmore, Gibson and McClure [13], who found a value of 0.84 ± 10 %. There is reason to believe, however, that this is less than the natural value since it has been found [15, 16] that phosphorescent substances react photochemically with the ethanol in the solvent even at these low temperatures.

The assumption underlying step (1) in the reaction mechanism that one biradical is formed for every light quantum absorbed, thus seems to be in accord not only with the photochemical evidence [4] but also with the results of phosphorescence studies.

The reaction products

The analytical results indicate that, in the main reaction, 1 molecule of nitrogen, 1 of nitrous oxide, 1 of acetone, and 2 of *iso*propyl nitrite are formed for every 6 molecules of nitric oxide taken up by the solution. The experimental formula for φ_{NO} (p. 18), when extrapolated to zero nitric oxide concentration, gives 3.5 molecules of NO reacting for every light quantum absorbed. A value of 3.0 would make the extrapolated quantum yields for the reaction products 0.5 and 1, respectively. We accordingly assume n in step (6) to be $= 3$.

If step (6) is written for 2 light quanta absorbed and in such a way that it will account for the analytical results of the present investigation as well as for the fact, established in the preliminary experiments, that benzophenone is not consumed in the reaction, it becomes:

$$2(C_6H_5)_2\dot{C}OH + 2(CH_3)_2\dot{C}OH + (CH_3)_2CHOH + 6NO = 2(C_6H_5)_2CO + (CH_3)_2CO + 2(CH_3)_2CHONO + N_2 + N_2O$$

This equation is not balanced, 4 hydrogen atoms and 3 oxygen atoms remaining to be accounted for. The formation of one molecule of water seems likely, but the complete elucidation of the stoichiometry will require further work. We have searched the literature in vain for reactions of NO giving N_2 and N_2O in equimolar quantities. For the present we are not prepared to make any suggestions as to the probable course of the reaction. One point should be mentioned, however. The fact that nitrites are formed in the reaction might suggest that the radical formed from the alcohol in step (2) is not $(CH_3)_2\dot{C}OH$ but the alcoxy radical $(CH_3)_2CHO\cdot$, since alcoxy radicals are known to add on nitric oxide to form nitrites [17]. In several cases it has been proved definitely, however, that free radicals react with alcohols by abstracting a hydrogen atom from the α-carbon atom [18]. A case which is of particular interest in the present connection is the one reported by Symons and Townsend [16].

For the purpose of the present investigation, however, the only important question is whether the value of n in step (6) is constant or not. The results indicate that this is true for the main reaction and, as explained earlier (p. 16),

the method of correlating the observed reaction rate with the initial concentration of NO rather than with the average during the run should have largely eliminated the effect of the side reaction on the rate equation.

The formula previously found for the rate of the corresponding reaction with oxygen at 25°C under the experimental conditions used [4], as a function of the oxygen pressure, when recalculated using the known Ostwald solubility coefficient of oxygen in *iso*propanol [19], 0.2463, becomes

$$v = \frac{43.5}{1 \times 95 c_{ox}}$$

where c_{ox} is the concentration of oxygen in mole/l. The denominator in this expression is $= 1 + \frac{k_7 c_{ox}}{k_2 c_A}$, where k_7 is the rate constant for the reaction:

$$(C_6H_5)_2\dot{C}{-}O \cdot + O_2 = (C_6H_5)_2CO + O_2 \qquad (7)$$

Comparison with the expression for φ_{NO} shows that the rate constants of reactions (5) and (7) are of the same order of magnitude. This was to be expected since both reactions may be presumed to be so rapid as to be essentially diffusion-controlled [20]. This means that the rate constants in *iso*propanol at 25°C should approach a calculated limiting value [21] of about 3.5×10^9 l mole^{-1}sec^{-1}. On this basis it is found that the mean life of the biradical in pure *iso*propanol is about 10^{-7} sec and that only one collision with *iso*propanol molecules in about 10^6 leads to reaction [22].

The mechanism of deactivation by NO and O_2

The analogy between the deactivation process represented by step (5) of the proposed reaction mechanism and the phenomenon of fluorescence quenching was emphasized in an earlier paper [4]. In recent studies of the fluorescence of organic compounds in the vapour state it has been found that O_2 and NO are, without exception, equally effective as quenchers. The substances studied were, anthraquinone and a number of its derivatives [23], anthracene and two related hydrocarbons [24], and β-naphthylamine [25]. The results are interpreted in terms of a theory advanced by Karyakin, Terenin and Kalenichenko [23]. The quenching is assumed to be "paramagnetic", collisions with the paramagnetic quencher molecules enabling an otherwise forbidden transition of the singlet excited fluorescer molecule to a somewhat lower lying triplet level to take place. It is an essential feature of the theory that, for the paramagnetic mechanism to be effective, the energy difference between the excited singlet and the triplet levels should be small. In cases where this difference was of the order of 0.2 *e*V the efficiency of the quenching collisions was found to be = 1 for both O_2 and NO whereas no quenching was observed by either gas when it amounted to 0.8 *e*V.

The present case is, however, altogether different from the one discussed above. What we are dealing with is the interaction between a molecule of nitric oxide or oxygen and an excited benzophenone molecule which is not in a singlet but in a triplet state. The energy of the triplet state is 3.0 *e*V above

the ground (singlet) level[12]. Transition to the ground state by a paramagnetic mechanism appears to be a highly improbable event.

There can be little doubt, however, that the unpaired electrons of NO and O_2, that cause their paramagnetism, are also responsible for their deactivating power. In a collision with a benzophenone molecule in the biradical state, the presence of unpaired electrons in both collision partners must give rise to strong exchange forces that may lead to bond formation. The property of NO and O_2 of undergoing addition reactions with free radicals is well known. To explain the experimental results, the reaction product must be assumed only to be stable in the excited state (*cf.* Förster and Kasper [26]) and to dissociate into the original molecules in their ground states when the excitation energy is lost through collisions with neighbouring molecules *. The assumption of a quenching mechanism of this kind receives support from theoretical considerations of the ways in which electronic energy may be transformed into thermal energy [27]. It is also in accord with the Wigner spin-conservation rule for collisions [28] and thus involves no forbidden transitions. It should therefore have a high intrinsic probability.

Not every collision between the biradical and a molecule of O_2 or NO may be expected to lead to bond formation. For this to happen, the spins must be favourably oriented and presumably also other steric requirements have to be met. In addition, an energy of activation may be involved, although this can hardly be expected to be large [29]. However, the influence of these factors on the rate of the quenching reaction should be much less in solution than in the gas phase. In solution, the rate of reaction is governed primarily by the rate of diffusion of the reactants toward each other. As shown by Rabinowitch [30], the diffusion process leads to an "encounter", a set of collisions. These repeated collisions, in conjunction with molecular rotation, should markedly increase the probability of reaction. It seems significant that the rate of quenching by oxygen of the long-lived fluorescence of biacetyl in the vapour state [31] corresponds to a steric factor of about 0.1, whereas the rate in benzene solution [32] approches 50 % of the limiting value for a diffusion-controlled reaction.

In view of the above considerations, the most probable explanation of the lower deactivating efficiency of O_2 as compared to NO, which cannot be due to a difference in diffusion rate, would seem to be a difference in activation energy.

The Magnetic Properties of $[Co(NH_3)_5(NO)]Cl_2$ (black) and $[Co(NH_3)_5(NO)](NO_3)_2 \cdot \frac{1}{2}H_2O$ (red)

Studies in Magnetochemistry 21 *

R. W. ASMUSSEN, OLE BOSTRUP and J. POTTS JENSEN

The Chemical Laboratory B, Technical University of Denmark, Copenhagen, Denmark

Magnetic susceptibility measurements of 6 independent preparates of the black $[Co(NH_3)_5(NO)]Cl_2$ show that the compound does not contain unpaired electrons. Our best samples give $\chi_g = +0.17 \times 10^{-6}$ at room temperature. It has been verified that the red $[Co(NH_3)_5(NO)](NO_3)_2 \cdot \frac{1}{2}H_2O$ is diamagnetic having $\chi_g = -0.20 \times 10^{-6}$. The absorption spectrum of this compound in aqueous solution has been measured. The similarity between this spectrum and the known absorption spectra of the ordinary Co(III)-pentammineacido complexes is evident. The possible structures of the compounds are discussed. The black pentahydrate $[Co(NH_3)_5(NO)]Cl_2 \cdot 5H_2O$ does not seem to exist.

In 1903 Sand and Genssler [1,2] showed that the action of NO(g) on $[Co(NH_3)_6]^{+2}$ solutions can result in two series of salts, "red salts" and "black salts". The empirical formula of both types of compounds is $[Co(NH_3)_5(NO)]X_2$. Later the preparation and the chemical properties of these compounds were critically studied and discussed by Werner and Karrer [3] and the magnetic properties were investigated by several authors [5–9].

These puzzling complexes have received great interest and many discussions concerning the possible structures, in particular their electronic structures on basis of the above mentioned chemical and magnetic investigations, have been published [3,7,10–12,19].

On account of the attention these compounds have received and the many contradictions concerning the experimental results and their interpretations, which are stated in the literature, we found it worth while to study thoroughly a typical example from each of the two series of salts, *viz.* "the black chloride" $[Co(NH_3)_5(NO)]Cl_2$ and the "red nitrate" $[Co(NH_3)_5(NO)](NO_3)_2 \cdot \frac{1}{2}H_2O$.

* No. 20 of this series: *Acta Chem Scand.* 11 (1957) 1534.

1. The black chloride

Previously the magnetic susceptibility of this compound has been measured several times and effective magnetic moments μ_{eff} can be calculated. Thus Ray, and Bahr [6] obtained the value $\mu_{eff} = 2.78\ \mu_B$, Bose [5] found $\mu_{eff} = 2.81\ \mu_B$, Milward *et al.* [8] $\mu_{eff} = 1.63\ \mu_B$, Ghosh and Ray [7] $\mu_{eff} = 1.44\ \mu_B$, and Mellor and Craig [9] $\mu_{eff} = 1.60\ \mu_B$ (mean value).

Our examinations of the preparation-methods described in the literature [1-3,7,13] revealed that a contamination of the black chloride with the strongly paramagnetic [14] cobalt(II)hexamminechloride is very difficult to avoid. We have modified the preparation-method (compare the results in the experimental part) and have then obtained samples of $[Co(NH_3)_5(NO)]Cl_2$ which under the microscope did not reveal even traces of reddish crystals of $[Co(NH_3)_6]Cl_2$. Some data from our measurements of the magnetic gram susceptibility at 295°K, 195°K and 85°K of 6 independent preparations are given in Table 1.

Table 1. The magnetic gram susceptibility χ_g of independent samples of $[Co(NH_3)_5(NO)]Cl_2$ (black). Analyses.

Sample No.	Analysis		$\chi_g \cdot 10^6$		
	Calc. %	Found %	295°K	195°K	85°K
17	28.94 Cl 34.75 NH_3		0.171	0.316	0.526
19	28.94 Cl 34.75 NH_3	29.06 Cl 34.79 NH_3	0.262	0.417	0.730
20	28.94 Cl 34.75 NH_3	28.89 Cl 34.90 NH_3	0.198	0.373	0.485
22	28.94 Cl 34.75 NH_3	28.75 Cl 34.63 NH_3	0.367	0.634	
23	28.94 Cl 34.75 NH_3	28.83 Cl 34.91 NH_3	0.173	0.366	0.807
25	28.94 Cl 34.75 NH_3 24.06 Co	28.77 Cl 34.50 NH_3 23.95 Co	0.277	0.508	1.26

It will be seen from Table 1 that we have succeeded in obtaining the compound in a higher and better reproducible magnetic purity than hitherto reported. The reproducibility of the magnetic measurements from sample to sample is far from the usual requirements. Our experiences prove, however, that it is very difficult to eliminate the last traces of paramagnetic impurities. The temperature dependence of the susceptibility can be explained as being due to such impurities still present even in our best samples.

We conclude from Table 1 that the expressions

$$\chi_g = +0.17 \times 10^{-6} \qquad (295°K) \tag{1}$$

$$\chi_M = 245 \times 0.17 \times 10^{-6} = +41 \times 10^{-6} \qquad (295°K) \tag{2}$$

give the best statement of the present measurements of the gram and the molar susceptibility, respectively. Since a compound with one unpaired electron ($\mu = 1.73\ \mu_B$) has the molar susceptibility

$$\chi_M = 1\,260 \times 10^{-6} \tag{3}$$

at room temperature, it follows from (2) and (3) that no unpaired electrons are present. We consider this result more reasonable for a compound with an even number of electrons than the old values for the magnetic moment, which roughly correspond to — and also have been interpreted as originating from — one unpaired electron.

Concerning the chemical properties of the black chloride we shall mention the following facts: The chloride cannot be dissolved in water (even at 0°C) without decomposition to basic Co(II)-chlorides; treatment with conc. HCl or conc. NH_3 (in a N_2-atmosphere) yields $[CoCl_4]^{-2}$ and $[Co(NH_3)_6]^{+2}$-solutions, respectively, but on the other hand Nast and Rohmer [19] have shown recently that treatment of $[Co(NH_3)_5(NO)]Cl_2$ with aqueous KCN yields the yellow, diamagnetic $K_3[Co(CN)_5(NO)] \cdot 2H_2O$ which, as pointed out by Nast, very probable contains the unstable, diamagnetic [4,18] nitroxylate ion NO^- as a ligand. *I.e.*, in some reactions the black chloride behaves like a Co(II)- in other as a Co(III)-complex. The conversion from one oxidation state to another seems only to require a rather small energy.

It is, however, not only the chemical properties but also the magnetic properties and the intense black colour which may be interpreted on the basis of a structure formula represented as

$$(H_3N)_5\overset{+3}{Co}\,NO^-$$

together with the further assumption of near lying Co(II)-states. We must, however, point out that further experimental investigations on other physical properties of the compound are necessary before further advance in the discussions of the structure of the black chloride can be expected.

2. *The red nitrate (semihydrate)*

The magnetic susceptibility of this compound has been measured several times previously. The first published values of χ_g were given by Ray and Bahr[6], who found $\chi_g = -0.109 \times 10^{-6}$. Later Milward *et al.*[8] published the

Table 2. The magnetic gram susceptibilities χ_g of independent samples of $[Co(NH_3)_5(NO)](NO_3)_2 \cdot \frac{1}{2}H_2O$ (red). Analyses.

Sample No.	Analyses		$\chi_g \cdot 10^6$		
	Calc. %	Found %	295°K	195°K	85°K
1	19.19 Co 27.72 NH_3	19.11 Co 27.84 NH_3	−0.180		
2	19.19 Co 27.72 NH_3	19.21 Co 27.72 NH_3	−0.197	−0.156	−0.10
3	27.72 NH_3	27.75 NH_3	−0.159	−0.161	−0.03

value $\chi_g = -0.19 \times 10^{-6}$, and Ghosh and Ray [7] found $\chi_g = -0.201 \times 10^{-6}$. In the papers by Bose [5] and Mellor and Craig [9] it is mentioned that they have measured χ_g and found diamagnetism, but no values are given.

The results of our measurements on different preparations are given in Table 2. The agreement with the data quoted above is obvious and the slight temperature dependence of χ_g can be explained as being due to small amounts of paramagnetic impurities.

The chemical properties of the red nitrate $[Co(NH_3)_5(NO)](NO_3)_2 \cdot \frac{1}{2}H_2O$ are very different from those of the black $[Co(NH_3)_5(NO)]Cl_2$. The former salt is remarkably more stable and can, *e.g.*, be recrystallized from water with only slight decomposition. Therefore it is possible to measure a reliable absorption-spectrum and this is given in Fig. 1. The great similarity between this absorption-curve and the corresponding curves for ordinary Co(III)-pentammine complexes is evident. (Compare, *e.g.*, the spectra measured by Linhard *et al.*[15]).

It is not only these physical properties (magnetism and absorption spectrum) which indicate that the compound is a Co(III)-complex, also the chemical properties are in accordance with this assumption: The action of conc. HCl, conc. HBr or 80 % HNO_3 on the red nitrate yields chloro-, bromo-, and nitrato-pentammine salts, respectively, whereas treatment with a KCN-solution yields [16,19] $K_3[Co(CN)_6]$. We are therefore of the opinion that the red nitrate is either a pentammine Co(III) complex or a binuclear decammine Co(III)-complex.

3. The black chloride (penta-hydrate)

Frazer and Long [4] have published data (preparation and magnetic measurements) for a pentahydrate of the black chloride. We are, however, not convinced of the existence of this hydrate. We have never been able to isolate a hydrate of the black chloride. The procedure of Frazer and Long gives impure

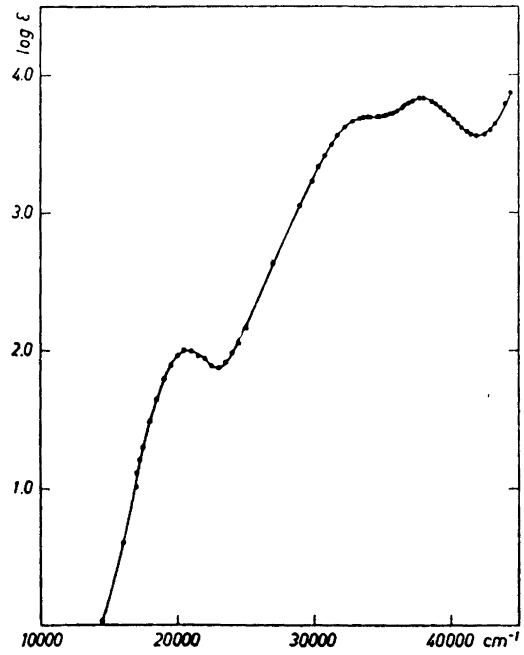

Fig. 1. Absorption spectrum of $[Co(NH_3)_5(NO)](NO_3)_2$ in aqueous solution.

samples of the anhydrous complex; furthermore we consider the analytical methods used to be unnecessarily complicated. The susceptibility was measured in rather weak fields (300 Ørsted). The value given by Frazer and Long corresponds to between 2 and 4 unpaired electrons.

EXPERIMENTAL

Preparation of the compounds

$[Co(NH_3)_5(NO)]Cl_2$. 1 000 ml of 12 % ammonia placed in the apparatus shown in Fig. 2 is cooled to 0°C by immersion of the apparatus in an ice-water bath. After the apparatus has been freed from oxygen by passing a stream of purified nitrogen through A, 50 ml of 2.50 M $CoCl_2$ is introduced at H maintaining a vigorous stream of nitrogen in order to prevent oxydation of the cobaltoammine solution formed. This solution is now treated with nitric oxide at 0°C for 5 h. Nitric oxide is then replaced by nitrogen and suction is applied at C in order to get rid of the original liquor. The crystals are purified by careful flotation with alcohol in a nitrogen atmosphere and are finally washed with alcohol and ethyl ether and dried by evacuating the apparatus. The hard, black, octahedral crystals are stored in a nitrogen atmosphere. The yield is approximately 20 % of the cobalt used.

$[Co(NH_3)_5(NO)](NO_3)_2 \cdot \frac{1}{2}H_2O$ was prepared according to Werner and Karrer [3] and recrystallized from water containing ammonia [8].

NO was prepared in an ordinary Kipp-apparatus from $NaNO_2$ (p.a. *in rotulis*) and 20 % H_2SO_4 and purified by passing through a 30 % NaOH solution and four U-tubes with solid NaOH (p.a. *in bacillis*).

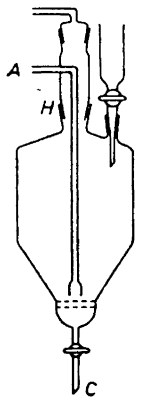

Fig. 2. Apparatus for the preparation of $[Co(NH_3)_5(NO)]Cl_2$, black.

Quantitative analysis. Co was determined as $CoSO_4$ after destruction of the complex by means of H_2SO_4. Cl was estimated as AgCl by weighing. NH_3 was determined acidimetrically (distillation of the complex with 30 % NaOH solution). The results of the analyses are given in Tables 1 and 2. In this connection it may be of interest to point out that the theoretical Co-, Cl-, and N-contents of the black chloride and those of $Co(NH_3)_6Cl_2$ do not differ very much, which will be seen from Table 3.

Table 3. Comparison of the analytical composition of $[Co(NH_3)_6]Cl_2$, $[Co(NH_3)_5(NO)]Cl_2$ and a mixture of these containing 10 % $[Co(NH_3)_6]Cl_2$.

Substance	% Co	% Cl	% NH_3	% N
$Co(NH_3)_5(NO)Cl_2$	24.06	28.94	34.75	34.31
$Co(NH_3)_6Cl_2$	25.40	30.56	44.04	36.22
Mixture of the composition: 10 % $Co(NH_3)_6Cl_2$ 90 % $Co(NH_3)_5(NO)Cl_2$	24.19	29.10	35.70	34.50

In Table 3 is furthermore given the calculated Co-, Cl-, NH_3-, and N per cents for a mixture of the composition: 10 % $[Co(NH_3)_6]Cl_2$ and 90 % $[Co(NH_3)_5(NO)]Cl_2$. The presence of as much as 10 % $[Co(NH_3)_6]Cl_2$ in a black chloride sample has, as will be seen, practically no influence upon the composition compared to that of chemical pure $[Co(NH_3)_5(NO)]Cl_2$. The magnetic gram susceptibility of this 10 % mixture is 4.6×10^{-6} and the magnetic moment is $\mu_{eff} = 1.73\ \mu_B$. The gram susceptibilities for $[Co(NH_3)_6]Cl_2$ and $[Co(NH_3)_5(NO)]Cl_2$ are 47.0×10^{-6} and 0.17×10^{-6} respectively, at 22°C. The following diamagnetic corrections were applied for Cl^-, NO^- and NH_3 [18,20], respectively: -21×10^{-6}, -18×10^{-6} and -15×10^{-6} (gram ion susceptibilities).

Magnetic measurements

The measurements were carried out as described previously [17].

Absorption spectrum

In the region below 800 mμ the measurements were carried out by means of a Cary MS recording spectrophotometer kindly placed at our disposal by professor Jannik Bjerrum. In the region 800—1 250 mμ the measurements were carried out by means of a Beckman DU spectrophotometer.

The Crystal Structure of Mo_5SiB_2

B. ARONSSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The result of an investigation of the Mo-rich corner of the Mo—Si—B system is in accordance with the phase diagram recently given by Nowotny *et al.*[1] The crystal structure of the ternary phase, Mo_5SiB_2, has been determined from single crystal data. There is definite evidence for an ordered distribution of the Si and B atoms. The Mo_5SiB_2-structure is described and discussed in comparison to similar phases, especially the ternary $Me_5Si_3(X')$-phases of the $D8_8$-type, (X′ = B, C, N, O).

After the intensive research during the last few years the binary borides and silicides of the transition metals are so well known that studies on ternary systems containing both these nonmetals have been started. It seems as if metal rich ternary (MeSiB)-phases are not uncommon and the determination of the crystal structures of these should be of a considerable crystallographic interest.

Such a ternary phase was found to exist in the Mo-Si-B system and an investigation of this system was started.* From powder photographs it was concluded that the ternary phase had a composition around Mo_5SiB_2 and that it was bodycentered tetragonal (probably isomorphous [2] with Cr_5B_3). Parthé *et al.*[3] have reported the same structure for Nb_5Si_3 and Ta_5Si_3 and call it the $T2$-structure, a notation that will be used in the following.

Before presenting the results of the refinement of the Mo_5SiB_2-structure some data are given for the Mo-Si-B system.

I. PRELIMINARY SURVEY OF THE Mo—Si—B SYSTEM

Experimental. Some alloys in the Mo—MoB—Mo_5Si_3 region were prepared from Mo powder (99.7 %), Si powder (99.9 %) and B powder of 94 % purity.** Weighed amounts

* In an early stage of this work Prof. Nowotny in Vienna kindly informed me that the same system was being studied at his institute. Therefore this investigation has been mainly devoted to the determination of the crystal structure of the ternary phase from single crystal data. Nowotny *et al.*[1] have later given a report on the Mo—Si—B system in which they stated this ternary phase to have the composition Mo_5SiB_2 and to be of the $T2$-type .

** Some boron was donated by the Borax Consolidated Ltd.

of the elements were melted twice in an arc-furnace. Powder photographs were taken in cameras of the Guinier-type, using Cu$K\alpha$-radiation. The lattice dimensions could be determined with an accuracy of ± 0.1 %.

Results. The phases observed in the powder photographs are consistent with the phase diagram of Nowotny *et al.*[1] The ternary phase was found to be in equilibrium with Mo, Mo_2B, MoB, Mo_3Si and Mo_5Si_3. The lattice parameters (l.p.) of the boundary phases differed very little ($\sim$0.1—0.2 %) from those reported for the binary compounds, indicating that the substitution of Si for B and vice versa is very limited. The smallest l.p. of Mo_5SiB_2 were observed in the Mo_2B-MoB-Mo_5SiB_2 region ($a = 5.99_8$ Å, $c = 11.02_7$ Å) and the largest in the MoB-Mo_5SiB_2-Mo_5Si_3 region ($a = 6.02_8$ Å, $c = 11.07_0$ Å). The results of the chemical analysis indicated that the atomic Si/B ratio of the ternary phase did not exceed 0.5. If the l.p.-variations depend on a variation of this ratio, the homogeneity range of Mo_5SiB_2 should be about $MoSi_{0.14}B_{0.46}$—$MoSi_{0.20}B_{0.40}$ under the applied conditions.

II. REFINEMENT OF THE CRYSTAL STRUCTURE OF Mo_5SiB_2

Experimental. A small single crystal was picked out of an alloy of the approximate composition $MoSi_{0.27}B_{0.36}$ (MoB—Mo_5SiB_2—Mo_5Si_3 region). Weissenberg photographs were taken with MoK-radiation around the a-axis. The layer lines 0—7 were recorded and the intensities of 200 reflexions were visually estimated using the multiple film technique. By plotting log I_o/I_c against $(\sin \Theta/\lambda)^2$ an empirical correction for Θ-dependent adsorption and thermal movement was obtained. Because of the adsorption, log I_o/I_c did not decrease linearly with $(\sin \Theta/\lambda)^2$. The refinement was repeated until the parameters used in the I_c-calculation differed less from the final parameters of the I_o-synthesis than the estimated standard deviation. The Fourier summations were made on the Hägg-Laurent machine [4].

As mentioned the unit cell of Mo_5SiB_2 was similar [2] to that of Cr_5B_3. Bertaut and Blum [2] found that the latter was bodycentered tetragonal ($a = 5.46$ Å, $c = 10.64$ Å) and contained four formula units. The spacegroup was D_{4h}^{18}—$I4/m\,c\,m$ with 16 Cr in 16 (l) ($x = 1/6$, $z = 0.15$) and 4 Cr in 4(c). From spatial considerations the B atoms were placed in 4(a) and 8(h) with $x = 0.375$. (The value of 0.125 given in the paper by Bertaut and Blum is probably due to a misprint.)

From the l.p. of Mo_5SiB_2 it was concluded that there were four formula units in the cell, that is 20 Mo, 4 Si and 8 B atoms. The systematic absences were consistent with the space group D_{4h}^{18}—$I\,4/m\,c\,m$. The preliminary electron density calculations confirmed this spacegroup and showed that 16 Mo atoms were situated in 16 (l) and 4 Mo atoms in 4 (c).

Starting from the parameters of Bertaut and Blum the atomic parameters of the Mo atoms were refined by carrying out successive $\varrho_o(x\,z)$ and ϱ_c $(x\,z)$ projections. (48 $h0l$ reflections were used.) The backshift corrections determined from the last synthesis were less than the standard deviations, computed with Cruickshank's formula [5].

The number of electrons found in the different maxima of the two final syntheses were counted in exactly the same way and a backshift correction

was applied to the scattering parameters obtained from the last $\varrho_o(x\,z)$ synthesis. The final atomic and scattering parameters are

	atomic par.	scattering par.
4 Mo_I in 4 (c)		42.0
16 Mo_{II} in 16 (l)	$x = 0.165_3 \pm 0.0008$	41.9
	$z = 0.138_8 \pm 0.0004$	
4 Si(?) in 4 (a)		14.0

As seen, the $\varrho(x\,z)$ projections strongly suggest that the four Si atoms of the unit cell are situated in the 4(a)-positions. In that case the 8 B atoms which are not revealed by the projection should be found in the 8 (h)-positions.

A three-dimensional F_o—F_c synthesis which was carried out in the $xy0$-section supports this hypothesis. The only significant maximum found in this section had a position corresponding to an atom in 8(h) with $x = 0.37_5$. Electron counts in the $xy0$-section gave the ratio 3.1/42 between the mentioned maximum and that of the Mo atom in origo.

It is difficult to appreciate the reliability of electron counts when atoms of widely different scattering powers are involved. The various formulæ given by Lipson and Cochran [6] suggest a standard deviation of somewhat less than 2 e per peak. The flat background of the final $\varrho(x\,z)$ and $D(xy0)$ syntheses (the background did not exceed 1/3 of the Si or B peakheight, respectively) makes this accuracy seem reasonable. Therefore, the result of the Fourier summations is taken as an evidence for an ordered distribution of the B and Si atoms in Mo_5SiB_2, the Si atoms mainly occupying the 4 (a)- and the B atoms the 8 (h)-positions.

DESCRIPTION OF THE STRUCTURE

Most of the transition metal atoms in the $T2$ phases are arranged in layers of the type shown in Fig. 1 a. Metal atom layers of this type have been called A-layers by Black [7] in his discussion of alloys of Al and transition elements. The simplest way to build up a structure of A-layers is to place successive layers exactly above each other. With this stacking of A-layers (A—A—A— . . .) there will be large cubic and smaller trigonal prismatic holes between the layers. A better packing of A-layers is obtained if every second layer is translated half the base diagonal of the unit cell. (Fulldrawn and dotted A-layers of Fig. 1 c alternate.) With this stacking (A—$A_{\frac{1}{2}\frac{1}{2}}$—$A$—$A_{\frac{1}{2}\frac{1}{2}}$— . . .) the layers fit better in each other and only one type of holes is found between the layers, namely cubic antiprismatic holes.

While the A-layer skeleton in the Al-transition metal alloys [7] consists of Al atoms, it is the transition metal atoms that form layers of this type in the structures of some borides and silicides. In Mo_5SiB_2 the sequence of A-layers (consisting of Mo atoms) is A—A—$A_{\frac{1}{2}\frac{1}{2}}$—$A_{\frac{1}{2}\frac{1}{2}}$— . . . (Two fulldrawn and two dotted layers of Fig. 1 c alternate.) Thus, there are holes of all the three mentioned types: cubic, antiprismatic and trigonal prismatic, filled by Mo, Si and B atoms respectively. The Mo atoms in the cubic holes and the B atoms are in contact and form what can be called subsidiary layers in $z = 0$ and $z = \frac{1}{2}$ (Fig. 1b). The Si atoms are situated between Mo atoms of successive subsidiary layers.

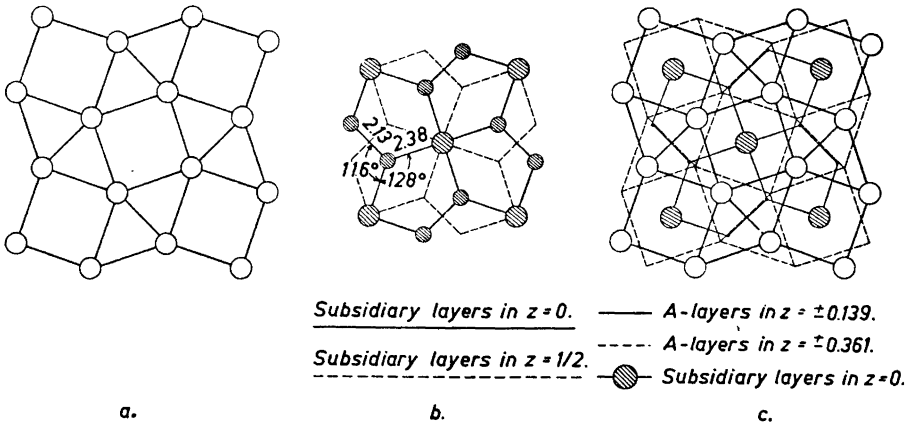

Fig. 1. a) *A*-type layer: b) Subsidiary layers of Mo and B atoms in $z = 0, \frac{1}{2}$; c) The Mo_5SiB_2-structure, projected along the *c*-axis.

As pointed out in Refs. [1,2], the atomic environments in Mo_5SiB_2 are similar to those found in related phases. The ninefold coordination around the B atoms (6 neighbours situated at the corners of a trigonal prism and 3 outside the square faces of this prism) has been found in a number of borides [8]. The ninth neighbour is a B atom at a distance of 2.13 Å. This points to a weak interaction but is another manifestation of the tendency towards B—B bonding revealed in a number of boride structures [8]. The Mo—B—Mo angle in the subsidiary layers is the same as the B—B—B angle in the boron chains of MoB (128°). The antiprismatic environment of the Si atoms (with two additional remote contacts outside the square faces of the prism) has earlier been found in the silicides of the $CuAl_2$- and W_5Si_3-types.

Table 1. Interatomic distances in Å (Estimated accuracy ±0.03 Å)

	In Mo_5SiB_2	In Mo_2B	In Mo_5Si_3*
B	— 2 Mo_I 2.38 (2)	B — 8 Mo 2.37 (8)	
	— 6 Mo_{II} 2.34 (4) 2.36 (2)	— 2 B 2.37 (2)	
	— 1 B 2.13		
Si	— 2 Mo_I 2.77 (2)		Si — 2 Si 2.45 (2)
	— 8 Mo_{II} 2.56 (8)		— 8 Mo 2.56 (8)
Mo_I	— 4 B 2.38 (4)		
	— 2 Si 2.77 (2)		
	— 8 Mo_{II} 2.72 (8)		
Mo_{II}	— 2 B 2.34, 2.36		
	— 2 Si 2.56 (2)		
	— 2 Mo_I 2.72 (2)		
	— 9 Mo_{II} 2.82, 2.85, 3.07, 3.17 (2), 3.18 (4)		

* The l.p. given in Ref.[11] have been used. Less accurate l.p. of Mo_5Si_3 have earlier been reported by this author. A redetermination has confirmed the values of Dauben, Templeton and Myers [11] within 0.05 %.

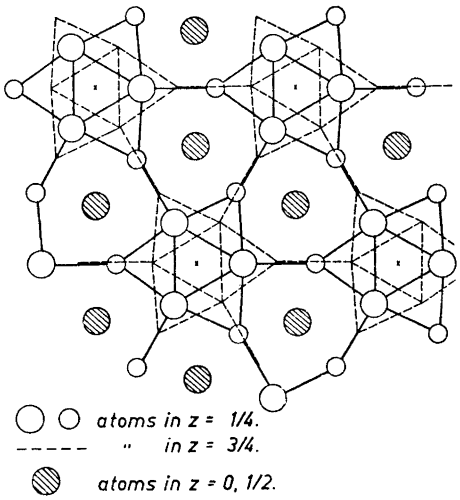

Fig. 2. The $D8_a$-structure. The position of the octahedral holes are marked with **x**.

Table 1 shows that an ordered distribution of the Si and B atoms gives Mo—B and Mo—Si distances that agree much better with those observed in Mo_2B [9] and Mo_5Si_3 [10, 11] than a disordered one. The Mo—Si distances especially would be abnormally short in a disordered structure. The fact that the atomic Si/B ratio in Mo_5SiB_2 does not exceed 0.5 probably indicates that the Si atoms can not occupy the positions giving such short distances.

DISCUSSION

As evident from the preceding paragraph the structural details of Mo_5SiB_2 are in accordance with the crystal chemical principles which have emerged from earlier studies on metal rich compounds between the transition metals and small nonmetals.

It seems as if the size factor is quite important in determining the structures in which these compounds crystallize. Hägg [12] has shown that a large number of borides, carbides, nitrides and hydrides can be classified from spatial considerations. When $r_X/r_{Me} < 0.59$ (X = nonmetal, Me = transition metal) the nonmetals are conveniently accommodated in the holes (tetrahedral, octahedral or trigonal prismatic) of simple metal lattices. When the radius ratio exceeds 0.59 these simple structures do not permit a good packing of the atoms and other structures are formed where the transition metal atoms are arranged so as to give the nonmetals larger "holes" to occupy.

The trigonal prismatic and cubic antiprismatic holes found in metal skeletons built up from *A*-type metal layers, would be suitably sized for nonmetals with r_X/r_{Me} in the range 0.65—0.85. Thus, it is not surprising that metal lattices of this type have been found among borides and silicides, *e.g.* in the

$T2$ structure. The occurrence of these structures may to a considerable extent depend on the fact that they permit a good packing of atoms with radius ratio in the above mentioned range. As pointed out by Nowotny *et al.*[1] the known $T2$ phases (Ta_5Ge_3[13], Ta_5Si_3[3], Nb_5Si_3[3], $W_5(Si, B)_3$[1], Mo_5SiB_2,[1] Cr_5B_3[2]) do indicate that the radius ratio is important for the stability of this structure. The ordered distribution of the Si and B atoms in Mo_5SiB_2 means that the B atoms occupy the smaller and the Si atoms the large holes in the Mo lattice and this also points to an influence from the size factor.

From the spatial discussion of the interstitial phases we would expect the holes in an A-type metal skeleton to be too large for carbon and nitrogen atoms (X'atoms) — especially with metal atoms from the IVa—VIa groups. Consequently we would not expect to find ternary (MeSiX') phases of the $T2$ type but rather that such phases had structures in which the Me—Si skeleton should contain octahedral holes where the X' atoms could be accommodated and thus obtain the same environment as in the wellknown stable carbides and nitrides of MeX' ($B1$ type) and Me_2X' types. (Boron and oxygen may also behave as X' elements in special cases.)

A number of ternary (MeSiX') phases have been found [14–17] for the IVa—VI a groups metals. All these phases have the composition $Me_5Si_3(X')$ and crystallize in the $D8_8$-structure [18]. They often contain quite small amounts of the X' element. It has been hinted [14, 15] that the small atoms might function interstitially but no comprehensive discussion of this possibility seems to have appeared. I think that the "stabilization" of the $D8_8$-silicides by X' atoms to some extent depends on the filling up of the octahedral holes in the $D8_8$ structure [18]. This would account for the increasing l.p. of Zr_5Si_3 (C) and Nb_5Si_3 (C) [14] with increasing carbon content and it would give some explanation to the fact that the $D8_8$-silicides have a much greater ability to dissolve X' atoms than have silicides with other structures.

It seems reasonable to assume that the interstitial solubility of X' atoms in the $D8_8$-silicides is most important for the group IV a metals and that the carbon-silicon substitution as found by Nowotny *et al.* in Mo_5Si_3 (C) will be of increasing importance with increasing group number of the metal.

The size factor has evidently a considerable influence on the occurrence of the structures mentioned in this paper and discussion from size considerations may still be of some value for the description and classification of the compounds formed by the transition metals and the small nonmetals.

Acknowledgements. I wish to thank professor Hägg for his kind interest in this work and *Statens tekniska forskningsråd* for financial support. Thanks are also due to Mr Rundqvist for many valuable discussions and Dr Lilly Gustafsson for analytical assistance.

Quantitative Micro-Determination of Proteins and Peptides

HERMAN NIELSEN

Dr. med.h.c. Herman Nielsen's Laboratory, Aabyhøj, Denmark

The spectrophotometric measurement of the colour, produced by the biuret reaction of proteins and peptides, can be replaced by measurement of the colour, produced by the copper salt of diethyldithiocarbamic acid. In this way microgram of proteins and peptides can be determined with the same accuracy as milligram by Kjeldahl. The method is easy and rapid and suitable for hospital laboratories.

The proteins and peptides in biological fluids are continuously built up and broken down, and they never maintain the same pattern. Nevertheless, their quantitative estimation is of practical importance. We have to resort to indirect analyses, and by determination of the amount of nitrogen some idea of the quantity of proteins or peptides can be obtained when other nitrogen-containing sources are removed beforehand. Native proteins can be precipitated by trichloroacetic acid or sulfosalicylic acid. Amino-acids can be removed from polypeptides by dialysis. For more than half a century the Kjeldahl method has been and still is the classical procedure for determination of proteins by multiplying the nitrogen found by an empirical factor, most often 6.25. That does not tell us anything about the structural distribution of the nitrogen atoms in the protein molecules. As the number of N in one amino-acid may be different from those of another and because of the inconstant distribution of the individual amino-acids in proteins and peptides it is impossible to calculate the number of amino-acids from the number of N-atoms, found by the Kjeldahl analysis.

Other difficulties arise when small amounts of proteins have to be examined, *e.g.* in the cerebrospinal fluid (CSF) where often less than 10 mg/100 ml has to be measured. A reliable micro-Kjeldahl analysis cannot be performed as routine in the clinical laboratories unless many precautions are taken. That is why the analytical accuracy is often replaced by some easy but very inexact method.

The extensive literature about the Kjeldahl method and its numerous modifications shows us the difficulties, and it is the scope of the present publication to find a way out of the uncertainty and try to obtain some more accurate results and propose a new method which is easy to perform and suitable for application in the clinical laboratories of the hospitals.

THE BIURET REACTION AND ITS MODIFICATION

This new method is based upon the biuret reaction in which a red-violet colour appears when a cupric salt is mixed with substances containing more than one —$CONH_2$ or —CONH—radical in their molecules. Consequently, the reaction is also given by proteins and peptides.

We are dealing here with the formation of a copper complex, established by chelation and ring closure with the metallic ion. The development of the chemistry of complex formation and the importance of ligands as donors of a lone pair of electrons for coordinative bonds is thoroughly explained in two excellent monographs by American authors [1, 2] that may be consulted for proper understanding of the structural explication to follow. Schwarzenbach [3, 4] has described the practical utilization of this knowledge for many purposes.

Fig. 1 shows a schematic structural design of the biuret reaction and the way in which peptide chains combine with cupric ions by chelation to form a multinuclear complex. The figure represents the glycyl backbone of the molecular structure of a protein, and it shows how four nitrogen atoms from the peptide bonds, —CONH—, can establish four coordinative bonds to the cupric ion. R represents the non-glycyl moiety of the individual amino-acids. All the nitrogen atoms in R are too far away from the metallic ion to produce an electrostatic field. The size of the cupric ion is small enough to be wedged between four glycyl-N, and a strong electrostatic field is established hereby stabilizing the compound.

In a strong alkaline solution uncoiling of peptide chains is effected in such a way that two peptide chains with four nitrogen atoms can be placed in coplanar position. An electronic explanation is put forward by Rây and Sen [5] and cited in the monograph by Martell and Calvin [1]. It is evident that there exists a correlation of colour and bond type, and when $3d^9$ in the lower orbit is the unpaired electron a blue colour is produced, but when $4p^5$ is occupied a red-violet colour prevails. The 4 nitrogen ligands with their 8 electrons approximate the electron configuration of Cu to that of Kr (36). They give a purely covalent coordination and 2 five-rings are established when 4 peptide bonds take part in the formation of the complex. In this way a great stability is obtained. In glycine and glycylglycine the ionic bond from Cu^{++} to the carboxyl group produces a salt-like compound with blue colour because the $4p$-orbit is not occupied.

Cox, Wardlaw and Webster [6] have pointed out that the 4 nitrogen atoms from the ligands must be coplanar with the copper ion and have proved it by X-ray analysis. The continuity of the peptide chain is not broken by the chelation and a multinuclear complex is formed. The length of the chain decides the numbers of copper ions.

From these stoichiometric considerations it appears that the ratio $4N/Cu^{++}$ or $4(—CONH—)/Cu^{++}$ can be calculated from the amount of complexed copper. The picture of a vertebral column of glycyl radicals with R representing the ribs, attached to the backbone, and the row of cupric ions, placed as a *medulla spinalis*, gives us an idea of the structural edification of the biuret compound.

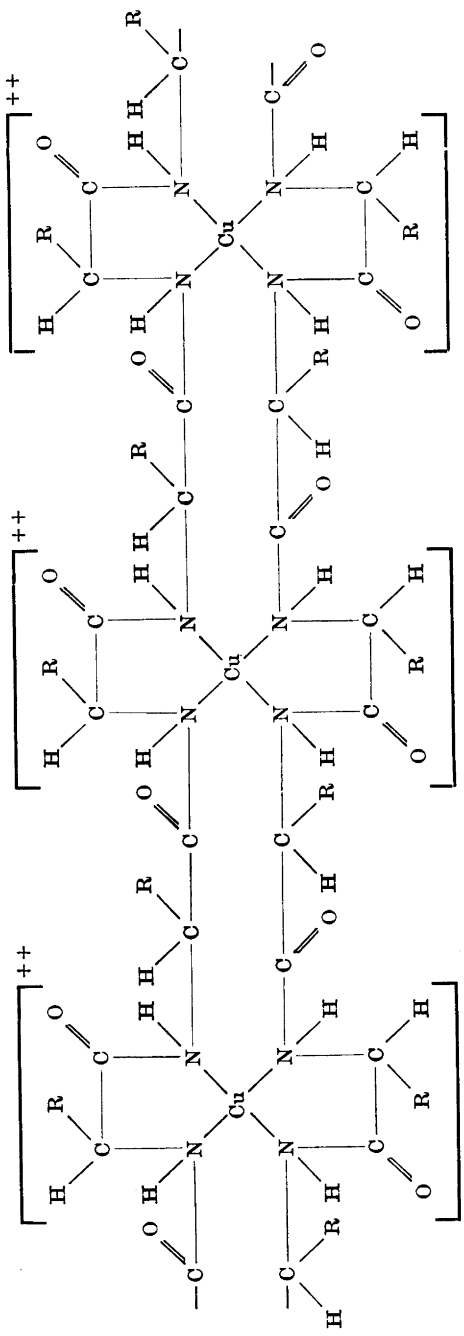

Fig. 1

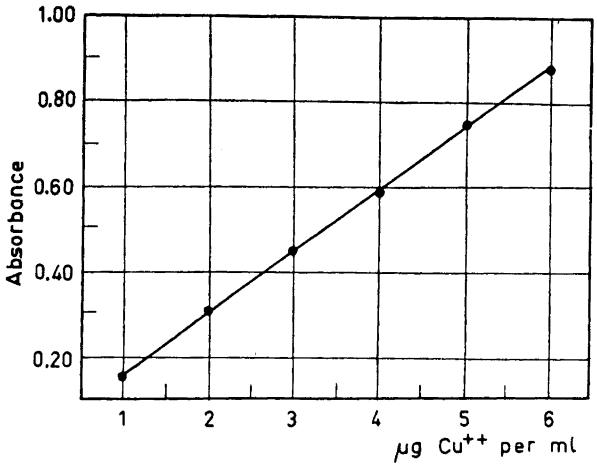

Fig. 2.

The colour of the biuret reaction compound is too faint for quantitative determination of small differences by measurement of the extinction. Moreover, there is another inconvenience which is often overlooked. A small part of the precipitated cupric hydroxide is dissolved in the strong alkaline solution of NaOH and imparts to the solution a bluish tint which moves the maximum of spectrophotometric absorbancy to lower wave-length.

PROCEDURE

Reagents. Trichloroacetic acid, 10 % aqueous sol.
Trisodiumphosphate (Na_3PO_4,$12H_2O$), 5 % aqueous sol.
Cupric sulphate ($CuSO_4$,$5H_2O$), 4 % aqueous sol.
Sodium diethyldithiocarbamate, solid. (DDTC).

Equipment. Conical centrifuge tubes
Sintered glass disc filters (3G5, Jena)
Spectrophotometer, Beckman B.

Procedure for plasma and serum. Dilute 1 ml of the sample with 49 ml of normal saline sol. Mix 1 ml of the diluted sample with at least 2 ml of the trichloroacetic reagent in a conical centrifuge tube. After centrifugation for 10 min at 3 000 r.p.m. the supernatant fluid is discarded and drained off the inside of the tube. Dissolve the precipitate in 5 ml of the phosphate reagent and add 1 drop of the copper reagent. Place the tube in a mechanical device for gentle shaking for 30 min. The excess of copper is precipitated as cupric phosphate and brought down by centrifugation for 10 min. The supernatant fluid is poured upon a sintered glass filter and by suction the complexed copper compound is collected. Mix 1 ml of the filtrate with 5 ml of the phosphate reagent and add a few crystals of DDTC. The yellow colour is fully developed in 15 min and the extinction is measured in the Beckman B against the phosphate reagent at 440 mμ.

Fig. 2 shows the absorbancy, plotted against the amount of copper, as a linear function from 1 to 6 μg of Cu++. Taking account of the dilution, here 1 500 times, and by introduction of an experimental factor of 9.80 for the ratio protein/Cu++ the percentage of protein is found directly. For instance, an extinction of 0.72 corresponds to 4.87 μg of Cu++ and 7.15 % of protein ($4.87 \times 1\,500 \times 9.80$).

Procedure for CSF. 1 ml of CSF is mixed with 1 ml of the trichloroacetic reagent in a centrifuge tube and treated as above. The filtrate from the sintered glass filter is diluted 1:1 with the phosphate reagent. Now the dilution is only 10 times, and by multiplication by the factor 9.80 the content of protein is found directly in mg/100 ml.

Since a reagent blank, carefully performed, never shows a transmission less than 98 % it can be replaced by the phosphate reagent. Cleaning of the sintered glass filters must be made by suction through the filters in the inverted position, first with 0.85 % NaCl, next with 2 N HCl and finally twice with water.

DISCUSSION

In order to separate the native proteins from peptides which also form copper complexes, we have preferred the use of trichloroacetic acid instead of sulphosalicylic acid. The latter has the inconvenience that the precipitate may adhere to the inside of the tubes. Stiff [7] has introduced cupric phosphate for reaction with the protein, but we consider cupric sulphate to be more suitable, for the reactivity of cupric ions with protein proceeds easier and more completely when the precipitation of cupric phosphate occurs at the same time. Mehl, Pacowska and Winzler [8] have found it feasible to calculate the amount of protein, bound by 1 g of copper atom in the complex. The most consistent investigations are perhaps made by Plekhan [9] who has tried to depict the structural relationship between copper and proteins. Beauchene *et al.*[10] determine the copper by flame photometry. Recently Kingsley and Getchell [11] have developed a method for quantitative estimation of small amounts of proteins in serum and in CSF by use of tetrabromophenolphthalein ethylester which in form of the blue potassium salt is absorbed to protein. They find, however, a marked difference in the binding capacity of the dye by proteins in CSF and by those of serum. With the present copper chelation method no such dissimilarity of the proteins exists.

THE ACCURACY OF THE METHOD

As already mentioned not only the native proteins but also polypeptides and oligopeptides down to tripeptides can be measured by this copper test, and the accuracy of the method can be demonstrated by the following example.

Glycylglycylglycine (GGG) was examined *. The sample was accompanied by the statement that the GGG had $2H_2O$, but had lost part of the water. 4 mg is calculated to contain 0.746 mg of N, but 0.773 mg was found. In my laboratory we determined the water content by the Karl Fischer method, according to the procedures described in detail in the monograph by Mitchell and Smith [12]. We used a micro-method where an end-point-stop device, equipped with a double triode and a magic eye as indicator, permits exact measurement. We have also examined the GGG sample by the copper chelation method and found complete accordance.

Found by	Kjeldahl	0.193	mg	of	N	per	mg	of	GGG
»	» Karl Fischer	0.194	»	»	»	»	»	»	»
»	» Cu-Chelation	0.194	»	»	»	»	»	»	»

* The author wishes to thank Professor K. Linderström-Lang and the Carlsberg Laboratories for generously providing the peptides, used in this study.

The amount of N in the water analysis is computed as follows. There is

0.222 mg of N in 1 mg of GGG, (mol.-weight 189)
0.186 » » » » 1 » » » $2H_2O$ (mol.-weight 225)

We soon found that the copper chelation method yields more accurate results than the Kjeldahl procedure when we made both kind of tests as a routine *in duplo*. Yet, by painstaking performance of the Kjeldahl analyses the deviations are in mg almost the same as are in μg those of the copper chelation method.

Structure of a Solvate of Barium Pentathionate with Acetone

OLAV FOSS and OLAV TJOMSLAND

Chemical Institute, University of Bergen, Bergen, Norway

The solvate, $BaS(S_2O_3)_2 \cdot (CH_3)_2CO \cdot H_2O$, is monoclinic with $a = 5.04$ Å, $b = 10.47$ Å, $c = 13.61$ Å, $\beta = 104°$, space group $C_{2h}^2 - P2_1/m$ and $Z = 2$. Fourier projections along the a and b axes show that the crystals are built up of layers which have the same internal structure as in the dimorphs of barium pentathionate dihydrate, but for the substitution of a water molecule by an acetone molecule.

The barium ion, the middle sulphur atom of the chain, and the water and acetone molecule lie in a crystallographic mirror plane. The values obtained for sulphur-sulphur bond lengths and angles agree within the experimental errors with those found in the dihydrates. The mean values in the three salts are: $S_1-S_2 = S_4-S_5 = 2.12 \pm 0.02$ Å, $S_2-S_3 = S_3-S_4 = 2.04 \pm 0.02$ Å, $\angle S_1-S_2-S_3 = \angle S_3-S_4-S_5 = 105 \pm 1.5°$, $\angle S_2-S_3-S_4 = 106 \pm 2°$, and the dihedral angles, $S_1S_2S_3/S_2S_3S_4 = S_2S_3S_4/S_3S_4S_5 = 108 \pm 1.5°$.

The data indicate that the outermost sulphur-sulphur bonds in the pentathionate ion are single bonds, while the middle bonds possess some double-bond character.

It was shown recently [1] that barium pentathionate, selenopentathionate and telluropentathionate when crystallized from aqueous acetone or tetrahydrofuran, occur as solvates containing one mole of water and one mole of the organic solvent per mole of salt. The crystals of the solvates are isomorphous. The solvate of barium pentathionate with acetone has now been studied by two-dimensional Fourier methods, and the pentathionate ion found to have the same configuration and dimensions as in the orthorhombic [2] and triclinic [3] dimorphs of the dihydrate.

CRYSTAL DATA

The crystals of $BaS(S_2O_3)_2 \cdot (CH_3)_2CO \cdot H_2O$ were obtained as thin, rhomb-shaped plates {001}, bounded by {110}. There is perfect cleavage along (001) and a rather pronounced tendency of twinning on the same plane. The crystals are monoclinic, with the unit cell dimensions [1]: $a = 5.04$ Å, $b = 10.47$ Å, $c = 13.61$ Å (± 0.5 %), $\beta = 104°$. There are two formula units per unit cell;

density, calc. 2.24, found 2.25 g/cm³. The only systematic absences are in the $0k0$ reflections when k is odd. Of the two monoclinic space groups compatible with these absences, the centrosymmetric one, C_{2h}^2—$P2_1/m$, was assumed to be the correct one, and this choise seems justified through the outcome of the structure analysis.

The intensities of the $0kl$ and $h0l$ reflections were estimated visually from Weissenberg photographs taken with CuK radiation. The crystals used had cross-sections of 0.09×0.06 mm and 0.11×0.07 mm, respectively, in the case of the a and b axis photographs. They were transparent and apparently unchanged after the exposures. Some difficulties were experienced in finding untwinned crystals, and in cutting the crystals because of the ready cleavage, but relatively good intensity photographs were at last obtained. A double-film, multiple-exposure technique was used; the a axis photographs, except for the strongest-exposure ones, were taken on a Nonius integrating Weissenberg camera. 158 out of 186 $0kl$ reflections and 152 out of 171 $h0l$ reflections attainable with CuK_α radiation were observed. The intensities were corrected for the Lorentz and polarization factors, but not for absorption; with $\mu = 311$ cm^{-1} for CuK_α radiation the absorption may introduce a serious error. The F_o^2 and F_o summations were made with Beevers-Lipson strips, at 6° intervals along the b and c axes and at 12° intervals along the a axis.

ANALYSIS OF THE STRUCTURE

The space group, $P2_1/m$, has fourfold general positions, and symmetry centres and mirror planes as special, twofold positions. With two formula units per unit cell, the middle sulphur atom of the pentathionate ion, the water molecule and the acetone molecule lie in mirror planes, as does also the barium ion.

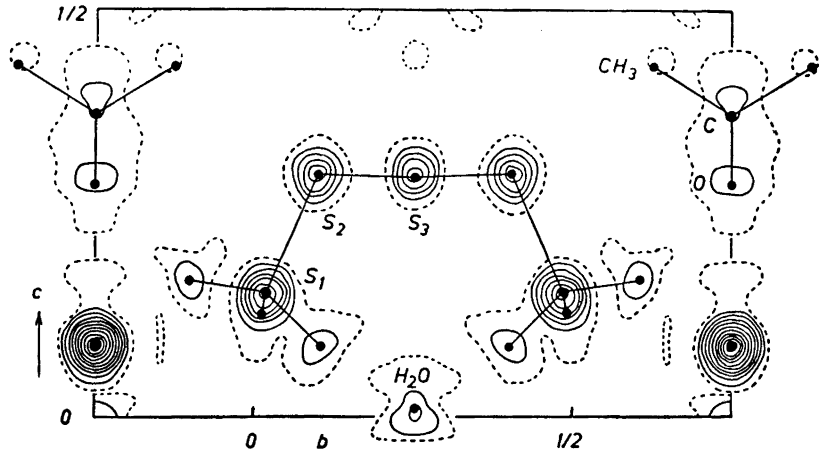

Fig. 1. Electron density projection of the acetone solvate along the a axis. The 3-electron line is dashed. Contour intervals: 10 e · Å^{-2} for the barium ion, 5 e · Å^{-2} for sulphur and oxygen atoms, and 2 e · Å^{-2} for carbon atoms.

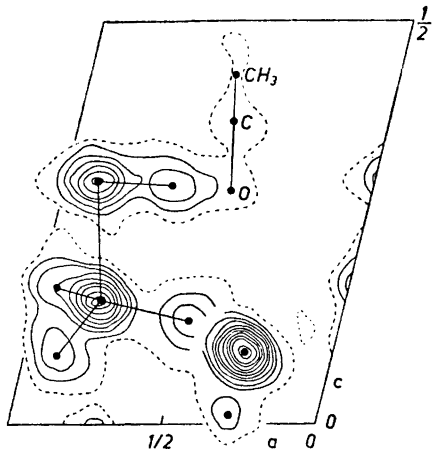

Fig. 2. Electron density projection along the *b* axis. The 5-electron line is dashed, and contours are at intervals of 8 e · Å^{-2} for the barium ion, otherwise as in Fig. 1.

The y and z coordinates of the barium ion and the three sulphur atoms of the asymmetric unit were first derived from a F_o^2 synthesis of the $0kl$ data. They differed on the average only 0.003 (maximum 0.006) from the final values. A F_o synthesis of about 60 of the largest $0kl$ terms, with signs based on the barium and sulphur contributions, gave approximate coordinates of the lighter atoms and permitted successive F_o refinements to be carried out. The *b*-axis projection was solved and refined by F_o^2 and F_o syntheses in the same way.

The $0kl$ and $h0l$ electron density maps are reproduced in Figs. 1 and 2, and the atomic coordinates are listed in Table 1. In the Table, x, y and z are in fractions of monoclinic cell edges, and x', y' and z' are orthogonal coordinates in Å referring to the same origin and to the a, b and c' axes, where c' is normal to a and b. The z coordinates from the two projections were the same for the barium ion and differed on the average 0.025 Å for the sulphur and for the oxygen atoms; the values of Table 1 are means of the two, weighted according to their apparent reliability.

The reliability index, $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$, with reflections not observed included when $|F_c|$ exceeds the observable limit, is 0.15 for the $0kl$ reflect-

ions and 0.21 for the *h0l* reflections. A list of calculated and observed structure factors is available from the authors on request. The calculated values were based on the Thomas-Fermi atomic scattering curve for xenon in the case of the barium ion, and on the Hartree curves for sulphur, oxygen and carbon. The hydrogen contributions were ignored. In the temperature factor exp $[-B(\sin^2\Theta/\lambda^2)]$ finally chosen B was 2.0 Å^2 and 4.0 Å^2, respectively, for the $0kl$ and $h0l$ reflections, except for the carbon atoms where the values, 4.0 Å^2 and 5.0 Å^2, respectively, were found to give better agreement.

DESCRIPTION OF THE STRUCTURE

The structure is built up of layers parallel to the *c* plane. The layers have the same internal structure as in the orthorhombic [2] and triclinic [3] dihydrates, but for the substitution of a water molecule by an acetone molecule. The orthogonal coordinates of Table 1, included to allow a comparison with the corresponding coordinates for the dihydrate structures [3], show close correspondence with the latter. Apart from the presence of the acetone molecule, the structures differ only in the way the layers are arranged relative to each other, as discussed earlier [1].

The pentathionate ion has mirror plane symmetry, required by the space group. The dimensions of the sulphur chain, from the coordinates of Table 1, are listed in Table 2. The standard deviations of the bond lengths and angles are probably not less than 0.04 Å and 3°, respectively. Primes are used to denote the equivalent of an atom across the mirror plane.

Table 2. Sulphur-sulphur bond lengths and angles.

S_1-S_2	= 2.11 Å	$\angle S_1-S_2-S_3$	= 106°
S_2-S_3	= 2.02	$\angle S_2-S_3-S_2'$	= 105°

$S_1S_2S_3/S_2S_3S_2'$ (dihedral angle) = 108°

The non-bonded distances within the chain are $S_1—S_3$ = 3.31 Å, $S_2—S_2'$ = 3.20 Å, $S_1—S_2'$ = 4.49 Å, $S_1—S_1'$ = 4.92 Å. The sulphur-oxygen bond lengths are $S_1—O_1$ = 1.48 Å, $S_1—O_2$ = 1.47 Å, $S_1—O_3$ = 1.47 Å, and the angles, $\angle O_1—S_1—O_2$ = 119°, $\angle O_1—S_1—O_3$ = 111°, $\angle O_2—S_1—O_3$ = 112°.

Within the experimental errors the above dimensions are the same as in the dihydrates. Also, the barium-oxygen coordination is the same, the barium ion being surrounded by nine oxygen atoms at an average distance of 2.78 Å. Six are sulphonate oxygen atoms and two are water oxygen atoms as in the dihydrates, and one is the oxygen atom of an acetone molecule. The water molecule is coordinated to two barium ions, at distances of 2.76 Å and 2.91 Å and an angle of 126°, and forms hydrogen bonds to the sulphonate oxygen atoms O_1 and O_1', at distances of 3.02 Å and an angle of 113°. This water molecule is firmly held in the lattice; it is the other water molecule of the dihydrates which in the solvate is replaced by acetone.

The carbon peaks in the electron density maps are low and diffuse, and the coordinates of these atoms are approximate only. Inclusion of the carbon

contributions with half their weight in the calculated structure factors, with the same temperature factors as for the other atoms, gave about the same R index as when they were included with full weight and the larger temperature corrections. From the coordinates of Table 1 the closest approach between methyl carbon atoms of different acetone molecules, across symmetry centres at $z = \frac{1}{2}$ and $-\frac{1}{2}$, is 3.3 Å, which is rather short. As indicated earlier [1], there appears to be a possibility that the acetone content of the solvates is non-stoechiometric, in the sense that some of the acetone positions are, statistically, occupied by water. This might leave better space for the methyl groups. On the other hand, the large c spacing, *i.e.*, layer thickness, namely 13.21 Å as compared with 10.78 Å and 10.89 Å in the dihydrates [2, 3], is caused by the acetone molecules, and complete substitution of acetone by water would lead to collapse of the structure. The layers are held together through methyl-methyl contacts, the closest methyl-sulphur approach across a layer interface being 4.1 Å, which exceeds the sum of the van der Waals radii. Sulphur-sulphur contacts across the interface, which are 3.5—3.8 Å in the dihydrates [2, 3] and there hold the layers together, do not occur in the solvate, the shortest such distance being 5.3 Å.

THE NATURE OF BONDING IN THE SULPHUR CHAIN OF THE PENTATHIONATE ION

The objective of the structure determinations of the dimorphs of barium pentathionate dihydrate and of the solvate with acetone, has been more to establish the structure of the pentathionate ion than to obtain accurate dimensional data. However, each distance and angle has in the three structures been determined independently four times, once in each half of the ion in the triclinic dihydrate and once in each of the two other structures where mirror plane symmetry is crystallographically required. Taking the standard deviation of the individual measurements as 0.04 Å for S—S bond lengths and 3° for S—S—S bond angles, the standard deviation of the arithmetical mean of the four values should be 0.02 Å for bond lengths and 1.5° for angles *. The individual and mean values are listed in Table 3, and a drawing of the pentathionate ion, with the mean bond lengths and angles indicated, is shown in Fig. 3.

Table 3. Dimensions of the sulphur chain of the pentathionate ion in barium salts.

Bond or angle	Orthorhombic dihydrate	Triclinic dihydrate	Acetone solvate	Mean value
S_1-S_2	2.14 Å	2.13, 2.11 Å	2.11 Å	2.12 Å
S_2-S_3	2.04 Å	2.04, 2.04 Å	2.02 Å	2.04 Å
$\angle S_1-S_2-S_3$	103°	106, 105°	106°	105°
$\angle S_2-S_3-S_4$	106°	107°	105°	106°
$S_1S_2S_3/S_2S_3S_4$ (dihedral angle)	110°	108, 107°	108°	108°

* The $S_2—S_3—S_4$ angle occurs only once also in the triclinic dihydrate, and the mean value of this angle should thus have a standard deviation of 2°.

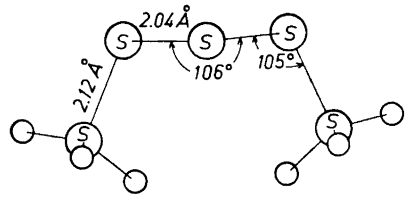

Fig. 3. The pentathionate ion as it occurs in the barium salts.

The difference, Δ, between the outermost S—S bonds, 2.12 Å, of the pentathionate ion, and the middle bonds, 2.04 Å, both with e.s.d. $\sigma = 0.02$ Å, gives $\Delta/\sqrt{2}\sigma = 2.8$ and should thus be significant. Variations in bond lengths along sulphur chains have been reported also for cesium hexasulphide [4], barium tetrasulphide monohydrate [5], barium tetrathionate dihydrate [6], and dimethanesulphonyl disulphide [7].

The middle S—S bonds in the pentathionate ion are between divalent sulphur atoms, and correspond formally to the S—S bonds of trisulphides, X—S—S—S—X. Data are available for dimethyl trisulphide [8] (S—S = 2.05±0.02 Å), *bis*(trifluoromethyl) trisulphide [9] (2.065±0.016 Å) and 2,2′-diiododiethyl trisulphide [10, 11] (2.05±0.04 Å). In disulphides, X—S—S—X, the S—S bond length is 2.05±0.02 Å in hydrogen disulphide [12], 2.04±0.03 Å in dimethyl disulphide [12], 2.053±0.019 Å in *bis*(trifluoromethyl) disulphide [9], 2.04±0.005 Å in N,N′-diglycyl-L-cystine dihydrate [13], and 2.04±0.02 Å and 2.04±0.01 Å, respectively, in the monohydrates of formamidinium disulphide diiodide [14] and dibromide [15]. The weighted mean of these nine values, if they are assumed to be equal, is 2.045 Å, as compared with 2.04 Å for the short bonds in pentathionate. In orthorhombic sulphur [16], the S—S bonds are 2.037 ±0.005 Å.

The outermost S—S bonds in pentathionate are between a divalent sulphur atom and a sulphonate sulphur atom. Bonds of this type are 2.13±0.04 Å in barium selenopentathionate dihydrate [17], 2.12±0.03 Å in ammonium telluropentathionate [18], 2.10±0.02 Å in monoclinic barium telluropentathionate dihydrate [19], and 2.12±0.03 Å in barium tetrathionate dihydrate [6]. The weighted mean is 2.115 Å, again not significantly different from the length of the corresponding bond in pentathionate.

A -S—SO_3 bond should be expected to be close to a single bond, or possibly a little shorter if some of the *pd* π-bond character of the S—S bond in the thiosulphate ion [20] is retained when two such ions combine with divalent sulphur to give pentathionate. There does not appear to be any reason for the bond to be longer than a single bond. The S—S single-bond length is somewhat uncertain; the Pauling value [21] is 2.08 Å, and Abrahams first [4] proposed 2.11 Å and later [5, 22] 2.08 Å. A S—S double-bond length of [4, 21, 22] 1.89 Å, as in the S_2 molecule in the ground state, leads, with 0.21 Å as the difference between single- and double-bond length [21, 23], to 2.10 Å, and the same value is obtained from 1.82 Å as the length of a S—C single bond [22], and the C—C single-bond radius of 0.77 Å. The data indicate that Abrahams' first proposal [4], 2.11 Å, is closer to the S—S single-bond length than is 2.08 Å. A discussion of

so small differences in bond lengths may be meaningless unless the hybridization ratio of the bond orbitals is defined, more *s* character in a σ bond leading to shorter bond lengths; however, for sulphur little information is available on this point. It appears that the 2.12 ± 0.02 Å S—S bonds of pentathionate are, at least, fairly close to single bonds.

The middle S—S bonds, of lengths 2.04 ± 0.02 Å, like the S—S bonds of the same length in di- and trisulphides and in orthorhombic sulphur, probably possess some double-bond character, arising from overlap of the $p\pi$ electron pair of one divalent sulphur atom with available 3*d* orbitals of a bond partner. Pauling's relation [23], $R = R_1 - 0.706 \log n$, leads to 22 % π-bond character, if R_1 is taken as 2.10 Å. Abrahams' curves [4,5] give about 25 %. In view of the uncertain nature of the bond order and bond length data, the figures serve only to indicate orders of magnitude.

The sulphur-sulphur bonds of the pentathionate ion readily undergo heterolysis in reactions with nucleophilic reagents [24, 25]. The principal reaction type involves a nucleophilic attack on the middle sulphur atom of the chain, and leads to the elimination of one or both of the thiosulphate groups as anions. The pentathionate thus behaves as a thiosulphate of divalent sulphur. This has been interpreted [24] as due to a certain amount of ionic character, or polarity of the σ bond, in the direction of heterolysis, on the ground that ionic character, or polarity already present, ordinarily serves to facilitate the further polarizability of the bond in the direction of polarity. The degree of ionic character can hardly be more than a few per cent; it would, however, leave a fractional positive charge on the middle sulphur atom, if the bonds from this atom were pure σ bonds.

It has been argued [26], on the basis of the K_α X-ray emission spectra from sulphur in solid potassium pentathionate, that the divalent sulphur atoms, including the middle one, have not a positive, but a negative charge. The interpretation of X-ray emission spectra in terms of charge distributions may not be quite clear-cut, and a net negative charge on the divalent sulphur atoms appears unlikely in view of the, presumably *, positive charge on the sulphur atom of the terminal sulphonate groups. However, if the middle S—S bonds of pentathionate, of lengths 2.04 Å, possess π-bond character, electroneutrality of the middle sulphur atom may not be in disagreement with ionic character, as indicated, of the σ bonds. The π-bonding, if involving for each bond to a higher degree the 3*d* orbitals of the middle sulphur atom than of the adjacent sulphur atoms, will tend to neutralize the positive charge on the middle sulphur atom due to ionic character of the σ bonds. This would not contradict the formulation, on a reactivity basis, of pentathionate as a thiosulphate of divalent sulphur, it being the direction of polarity of the σ bond, notwithstanding neutralizing charges due to π-bonding, which is indicative of the preferred direction of heterolysis of a bond, and *vice versa*.

The work has been financially supported by *Norges almenvitenskapelige forskningsråd.*

* A positive charge (though less than one) on the sulphur atom of an ionized sulphonate group, $-SO_3^-$, may be inferred from its Hammett σ values [27-30], its acidifying effect on aliphatic acids [31], and the dipole moment of sulphur-oxygen bonds [32].

The Crystal Structure of Monoclinic Barium Telluropentathionate Dihydrate

OLAV FOSS and OLAV TJOMSLAND

Chemical Institute, University of Bergen, Bergen, Norway

The monoclinic dimorph of the salt, $BaTe(S_2O_3)_2 \cdot 2H_2O$, crystallizes in a four-molecule unit cell based on the space group, C_{2h}^3-A2/m, with $a = 4.99$ Å, $b = 10.59$ Å, $c = 23.61$ Å, $\beta = 98°$. The structure has been determined by two-dimensional X-ray methods. With mirror plane symmetry crystallographically required, the telluropentathionate ion occurs in the *cis* form in this salt. The S—S—Te—S—S chain has the dimensions, S—S = 2.10 ± 0.02 Å, S—Te = 2.34 ± 0.02 Å, ∠S—S—Te = 106 ± 1°, ∠S—Te—S = 101 ± 1°. These values are within the experimental errors the same as found earlier for the *trans* form in the ammonium salt. The dihedral angle, SSTe/STeS = 103°.

The crystals have a layer structure and differ from the triclinic and orthorhombic barium pentathionate dihydrates and the acetone and tetrahydrofuran solvates only in the way of packing of the parallel layers.

Solvates of barium pentathionates with dioxane are described, containing one mole of water and half a mole of dioxane per mole of salt. The barium selenopentathionate solvate, $BaSe(S_2O_3)_2 \cdot H_2O \cdot \frac{1}{2}C_4H_8O_2$, crystallizes in the space group, C_{2h}^3-A2/m with $Z = 4$, and $a = 5.02$ Å, $b = 10.59$ Å, $c = 22.72$ Å, $\beta = 102°$, and is isostructural with monoclinic barium telluropentathionate dihydrate.

A recent study of the crystal chemistry of barium salts of telluropentathionic acid [1] led to the characterization of a trihydrate and of a triclinic and a monoclinic dihydrate. Unit cell and space group data indicated that the triclinic dihydrate is isomorphous with triclinic barium pentathionate dihydrate [2], and that the *a*-axis projection of the monoclinic dihydrate has the same symmetry as the *a*-axis projections of orthorhombic barium pentathionate [3] and selenopentathionate [4] dihydrates. A solvate of barium telluropentathionate with tetrahydrofuran furthermore exists [5], isomorphous with the solvates of barium pentathionate and selenopentathionate with tetrahydrofuran and acetone [5,6]. In the barium salts the telluropentathionate ion thus occurs in the *cis* form, with mirror-plane symmetry, like the pentathionate and selenopentathionate ions in the barium salts. This is different from the conditions

in the ammonium salt, where the telluropentathionate ion has been found to occur in enantiomorphous *trans* forms [7]. No crystal structure determination of an alkali pentathionate or selenopentathionate has been made; however, it appears likely that in alkali salts also these anions have *trans* forms, the occurrence of the *cis* form in the barium salts being due to the oxygen-coordinating powers of the barium ion, and favourable lattice conditions for the mirror-plane *cis* coordination complex.

The crystal structure of monoclinic barium telluropentathionate dihydrate has now been determined, and data obtained for a comparison of the *cis* and *trans* forms of the telluropentathionate ion. Apart from the rotational isomerism, the dimensions of the ion were found to be the same in the two forms. A further objective of the structure determination was to inquire more thoroughly into the indicated relationship [1] between the monoclinic dihydrate structure and the structures of the triclinic [1,2] and orthorhombic [3,4] dihydrates and the solvates [5,6]. As discussed earlier [1,5] and confirmed in the present work, monoclinic barium telluropentathionate dihydrate is built up of layers having the same internal structure as in the three other structure types. The layers are parallel to the *c* plane, and the structure types differ only in the way the layers are arranged relative to each other. In the triclinic dihydrates [1,2], of space group C_i^1—$P\bar{1}$ with $Z = 2$, the oblique β and α angles lead to relative displacements of successive layers in the directions of the *a* and *b* axes, while in the solvates [5,6], of space group C_{2h}^2—$P2_1/m$ with $Z = 2$, displacements occur in the *a*-axis direction only. In the orthorhombic dihydrates [3,4] of space group D_{2h}^{16}—*Pnma* with $Z = 4$, adjacent layers are related through glide planes *a* in the layer interface, and in the monoclinic dihydrate, through two-fold rotation axes in the interface.

The present structure is the fifth to be described for a telluropentathionic compound, and the first in which the S—S—Te—S—S chain has been found to have the *cis* instead of the *trans* configuration. Beside ammonium telluropentathionate [7], the earlier structures are those of tellurium dimethanethiosulphonate [8], dibenzenethiosulphonate [9] and di-*p*-toluenethiosulphonate [10].

CRYSTAL DATA

The monoclinic dimorph of barium telluropentathionate dihydrate, $BaTe(S_2O_3)_2 \cdot 2H_2O$, has the unit cell dimensions [1], $a = 4.99$ Å, $b = 10.59$ Å $c = 23.61$ Å, $\beta = 98°$. There are four formula units per unit cell; density, calc. 2.82, found 2.80 g/cm^3. The crystals occur as prisms along the *a* axis, with {001} dominant. There is a pronounced tendency of cleavage along the *c* plane.

On the basis of the systematic absences, *hkl* when $k+l$ is odd, and a comparison of the 0*kl* zone of reflections with the 0*kl* zones of orthorhombic barium pentathionate and selenopentathionate dihydrate, the space group, C_{2h}^3—$A2/m$, was originally chosen [1], and no later observations contradict this choise. The barium ion and the tellurium atom are thereby required to lie in special positions, and were found to lie in the mirror planes, as do also the water molecules.

The intensities of the 0*kl* and *h*0*l* reflections were estimated visually from Weissenberg photographs, taken with CuK_α radiation using a double-film,

multiple-exposure technique. The crystals employed had cross-sections of 0.09×0.05 mm and 0.08×0.06 mm, respectively, in the case of the *a*- and *b*-axis photographs. 156 out of 172 $0kl$ reflections and 148 out of 156 $h0l$ reflections attainable with CuK_α radiation were observed and measured. The intensities were corrected for the Lorentz and polarization factors and converted to relative structure factors in the usual way, and were ultimately brought to an approximately absolute scale by comparison with the calculated values. Although the absorption coefficient for CuK_α radiation is 531 cm^{-1}, no correction for absorption was made, mainly because of the large amount of work it would involve, but reflections likely to be most heavily influenced by absorption were omitted from the $(F_o - F_c)$ syntheses in the final stages of refinement.

Summations were made by means of Beevers-Lipson strips, at 12°, 6° and 3° intervals, respectively, along the *a*, *b* and *c* axes, except for the F_o^2 and first F_o syntheses where the summations were made at 6° intervals also along the *c* axis.

The atomic scattering curves used in the calculation of structure factors were that of Berghuis *et al.*[11] and of Viervoll and Ögrim [12], respectively, for oxygen and sulphur, and the Thomas-Fermi curve [13] for tellurium. For the barium ion a curve was constructed based on the Thomas-Fermi values [13] for xenon at small scattering angles and for electroneutral barium at intermediate and larger scattering angles.

ANALYSIS OF THE STRUCTURE

The *y* and *z* coordinates of the barium ion and tellurium atom, and also of the two sulphur atoms of the asymmetric unit, were derived from a F_o^2 synthesis of the $0kl$ data. These first coordinates gave the signs of 117 of the largest $0kl$ terms, which were used for a F_o synthesis. The resulting electron density map revealed the approximate positions of the sulphonate oxygen atoms and water molecules, and allowed F_o refinement to be carried out. Finally, a series of $(F_o - F_c)$ refinements were made.

The *b*-axis projection was solved and refined in essentially the same way. Here, however, $(F_o - F_c)$ refinement did not proceed quite satisfactorily and was therefore abandoned at a relatively early stage. One reason may be that in this projection the water molecule $(H_2O)_2$ is obscured by the tellurium atom and therefore cannot be located with any certainty; also, the overlapping makes the tellurium *x* coordinate less reliable.

The difference maps indicated individual and partly anisotropic temperature vibrations of the atoms. In temperature factor $\exp[-B(\sin^2\Theta/\lambda^2)]$ the following values of *B* were adopted in the last stages: For the $0kl$ data, 3.0 Å^2 for tellurium, 2.8 Å^2 for the sulphur and oxygen atoms except for $(H_2O)_2$ where $B = 5.0$ Å^2, and $(2.6+0.8\cos^2\varphi)$ Å^2 for the barium ion, where φ is the angle between the normal of the reflecting plane and the direction of maximum vibration of the ion. This direction is parallel to the *c* axis. For the $h0l$ data, $B = 2.8$ Å^2 for the sulphur and oxygen atoms, and $(2.6+1.0\cos^2\varphi)$ Å^2 and $(3.0+2.0\cos^2\varphi)$ Å^2, respectively, for the barium ion and tellurium atom. Here, the directions of maximum vibration make angles of 34° and 45°, respectively,

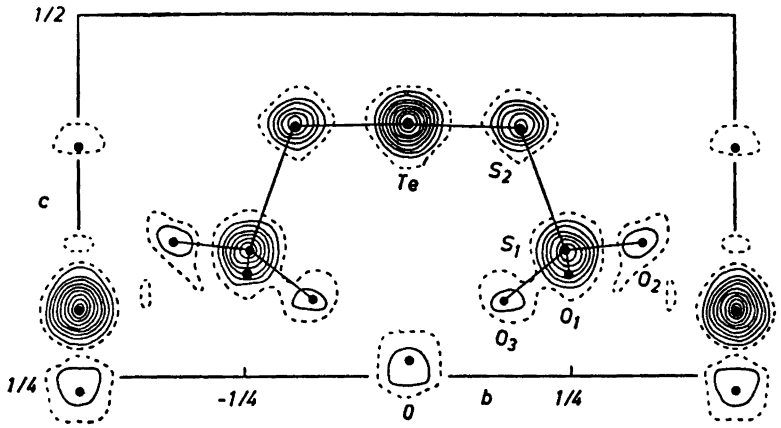

Fig. 1. Electron density projection of monoclinic barium telluropentathionate dihydrate along the *a* axis. Contour intervals: 10 e · Å^{-2} for the barium ion and tellurium atom, and 5 e · Å^{-2} for the sulphur and oxygen atoms and water molecules. The 5-electron line is dashed.

with the *c* axis in the acute angle. The temperature factors may have little physical reality in terms of thermal motions of the atoms; rather, they also represent absorption and other errors in the observed structure factors.

The final electron density maps are shown in Figs. 1 and 2, and the final atomic coordinates are listed in Table 1. The *z* coordinates are from the *a*-axis projection, since attempts to establish independent *z* coordinates from the *b*-axis projection were not made. One exception is that of O_1. It should be noted that the *b*-axis projection did not indicate changes in the *z* coordinates of the heavier atoms including sulphur.

In Table 2, observed and calculated values of structure factors are compared for all 0*kl* and *h*0*l* reflections within the range of CuK_α radiation. The strong reflections 002, 004, 006, 008, 011, 013, 015, 026 in the 0*kl* zone and 002, 004, 006, 008, 108, $\bar{1}08$, $\bar{3}04$, $\bar{3}$ 0 12 in the *h*0*l* zone have observed values markedly

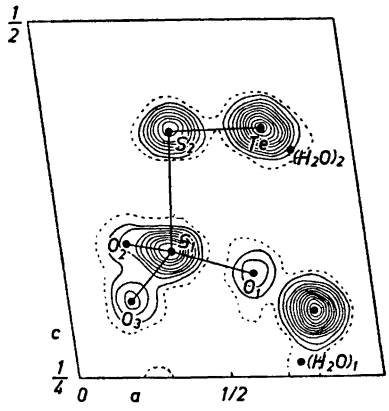

Fig. 2. Electron density projection along the *b* axis. Contours are at intervals of 8 e · Å^{-2} for the barium ion and tellurium atom, and the 8-electron line is dashed; otherwise as in Fig. 1. Each sulphur and sulphonate oxygen peak represents two exactly overlapping atoms, one on each side of the mirror plane.

lower than the calculated ones, probably due to absorption and extinction effects. These reflections were omitted from the (F_o—F_c) syntheses and from the calculation of scale factors for the respective zones, and were included in the final F_o syntheses with their calculated values. The relatively weak reflections 0 0 28, 031, 062, 0 10 2 in the 0*kl* zone and 0 0 28, 1 0 24, 206, $\bar{2}$ 0 28, 300, 304, $\bar{3}$ 0 26, 408, 4 0 16, $\bar{4}$08, 602, 606, $\bar{6}$ 0 12 in the *h*0*l* zone have small calculated values and therefore uncertain signs, and were not included in the F_o or (F_o—F_c) syntheses.

Table 1. Atomic coordinates, in fractions of monoclinic cell edges. Origin at a centre of symmetry (2/*m*).

	x	*y*	*z*		*x*	*y*	*z*
Ba	0.802	0	0.2045	S_1	0.365	0.240	0.3382
Te	0.712	0	0.4238	S_2	0.413	0.171	0.4224
$(H_2O)_1$	0.739	0	0.262	O_1	0.623	0.241	0.322
$(H_2O)_2$	0.200	0	0.091	O_2	0.240	0.360	0.343
				O_3	0.211	0.146	0.303

The reliability index, $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$, with non-observed reflections included when $|F_c|$ exceeds the observable limit, is 0.082 for the 0*kl* reflections and 0.170 for the *h*0*l* reflections, if the above-mentioned groups of strong reflections with high calculated values are omitted. With these reflections included, the R values become 0.108 and 0.190, respectively.

ASSESSMENT OF ACCURACY

The standard deviations of the coordinates of the heavier atoms were estimated from the root-mean-square gradients of the difference maps and the curvatures of the electron density peaks [14,15]. The gradients were 2.3 e · Å^{-3} in the y and z directions of the 0*kl* difference map, and 5.8 e · Å^{-3} in the x direction of the less refined *h*0*l* map. The derived standard deviations are: $\sigma(x) = 0.005$ Å, $\sigma(z) = 0.002$ Å for the barium ion; $\sigma(x) = 0.006$ Å, $\sigma(z) = 0.003$ Å for the tellurium atom; $\sigma(x) = 0.010$ Å, $\sigma(y) = 0.007$ Å, $\sigma(z) = 0.008$ Å for the sulphur atoms. The y coordinates of barium and tellurium are fixed by symmetry relations. $\sigma(x)$ for sulphur is relatively low despite the large gradient because in the *b*-axis projection exact overlapping of two and two sulphur atoms (and likewise of sulphonate oxygen atoms) occurs. $\sigma(z)$ and $\sigma(x)$ for S_1 may be larger than the given values due to overlapping with oxygen atoms in both projections. The s.d. for resolved oxygen atoms may be taken as about three times those of the sulphur atoms, except for the x coordinate of $(H_2O)_1$ and particularly $(H_2O)_2$ where the uncertainties are larger.

The above values give s.d. of 0.009 Å and 0.011—0.014 Å, respectively, for S—Te and S—S distances, and 0.3—0.4° for angles involving these atoms. Considering uncertainties in the estimates due to overlapping in some cases, and non-random errors in the observed structure factors due to absorption and other effects, s.d. of about 0.02 Å for S—S and S—Te distances and about 1° for the angles may be more realistic. Similar estimates lead to s.d. of about 0.04 Å for S—O bond lengths, 2—3° for S—S—O and O—S—O bond angles, and 0.03 Å for distances from barium to sulphonate oxygen atoms.

Table 2. Observed and calculated 0*kl* and *h*0*l* structure factors for monoclinic barium telluropentathionate dihydrate.

DESCRIPTION OF THE STRUCTURE

The telluropentathionate ion consists of a divalent tellurium atom to which are attached two thiosulphate groups, through Te—S bonds. The S—S—Te—S—S chain thus resulting has the dimensions listed in Table 3. The ion possesses mirror plane symmetry, and a prime is used to denote the equivalent of an atom across the mirror plane.

Table 3. S—S and S—Te bond lengths and angles.

S_1-S_2 = 2.10 Å	$\angle S_1-S_2-Te$ = 105.7°	S_1S_2Te/S_2TeS_2'
S_2-Te = 2.34	$\angle S_2-Te-S_2'$ = 101.2°	(dihedral angle) = 103°

Non-bonded S—S and S—Te distances.

S_1-S_1' = 5.08 Å	S_1-Te = 3.55 Å
S_1-S_2' = 4.78	S_2-S_2' = 3.62

The bond lengths and angles found in ammonium telluropentathionate [7], where the two halves of the ion are not related by symmetry, are: S—S = 2.11 Å and 2.12 Å, S—Te = 2.35 Å and 2.36 Å, ∠ S—S—Te = 105° and 104°, ∠ S—Te—S = 103°, and the non-bonded distances not dependent on rotation about the S—Te bonds: S_1—Te = 3.57 Å, S_5—Te = 3.52 Å, S_2—S_2' = 3.68 Å. The differences between these values and those of Table 3 are not significant.

Whereas the telluropentathionate ion in the ammonium salt occurs in the *trans* form, with the two terminal sulphur atoms located on different sides of the plane of the tellurium and two middle sulphur atoms, the ion in the barium salt has the *cis* form, with the terminal sulphur atoms on the same side of the plane. This is reflected in the shorter S_1—S_1' separation, 5.08 Å, in the barium salt as compared with 6.11 Å in the ammonium salt. In the latter the SSTe/STeS dihedral angles are 86° and 95°, and thus smaller than in the barium salt.

The sulphonate groups have S_1-O_1 = 1.39 Å, S_1-O_2 = 1.43 Å, S_1-O_3 = 1.45 Å, $\angle O_1-S_1-O_2$ = 117°, $\angle O_1-S_1-O_3$ = 107°, $\angle O_2-S_1-O_3$ = 117°.

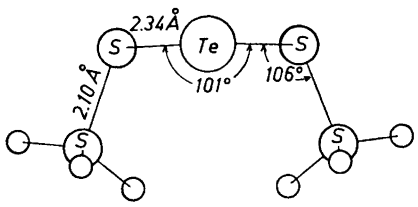

Fig. 3. The *cis* form of the telluropentathionate ion, with principal bond lengths and angles.

The small value of the second angle may be due to maximum error in the y coordinate of O_1, since this atom in the a-axis projection is overlapped by S_1.

The barium-oxygen coordination is as in the four structures of barium pentathionates determined earlier [2-4,6]. The barium ion is surrounded by nine oxygen atoms, at an average distance of 2.82 Å. The extreme values are 2.68 Å and 2.98 Å. The arrangement has been described in detail earlier [3,4] and shall not be repeated here. As in the other structures, the water molecule $(H_2O)_1$ probably forms hydrogen bonds to the sulphonate oxygen atoms O_1 and O_1'; the distances are in the present structure 3.01 Å and the $O_1—(H_2O)_1—O_1'$ angle 116°.

The structure within layers parallel to the c plane is the same as in the triclinic [2] and orthorhombic [3,4] dihydrates and, apart from the replacement of a water molecule by an organic molecule, as in the acetone and tetrahydrofuran solvates [5,6]. In the present space group, adjacent layers are related through twofold rotation axes which run parallel to the b axis in the layer interfaces at $z = 0$ and $\frac{1}{2}$. The layers are held together through non-bonded contacts between atoms of the $S_2—Te—S_2'$ groups across the interfaces. The closest approaches are: Te—Te = 4.28 Å over twofold axis at $(1,y,\frac{1}{2})$, and Te—Te = 4.42 Å, Te—S = 4.18 Å, S—S = 3.65 Å over twofold axis at $(\frac{1}{2},y,\frac{1}{2})$.

It may be noted that the origin chosen in the present work (at $2/m$ in accordance with the *International Tables* [16]) lies in a layer interface and in a mirror plane, and not in the middle of a layer and midway between mirror planes as in the earlier structure determinations [2-4,6]. To make the present b-axis projection correspond with those of the triclinic dihydrate [2] and the solvate [6] structures, another c axis should, furthermore, be chosen. The new cell, still A-centered, would have $c = 24.32$ Å, $\beta = 106°$ and be derived from the first by means of the transformation matrix, $\bar{1}00/010/201$.

SOLVATES WITH DIOXANE

In the crystals of the acetone solvate [5,6], $BaS(S_2O_3)_2 \cdot H_2O \cdot (CH_3)_2CO$, the internal layer structure differs from the dihydrate structures only in the substitution of an acetone molecule for one of the water molecules of the dihydrates. The oxygen atom of the acetone molecule is coordinated to the barium ion, like the oxygen atom of the replaced water molecule, and is located between the barium ion and the nearest layer interface, with the methyl groups directed towards the interface. A symmetrical molecule with two oxygen atoms, like dioxane, might be thought to be able to extend across the layer interfaces and replace two water molecules, one in each of two adjacent layers. Crystal symmetry and layer structure would permit such a replacement in the triclinic dihydrate structure, space group $C_i^1—P\bar{1}$ with $Z = 2$, and in the

monoclinic dihydrate structure, space group C_{2h}^3—$A2/m$ with $Z = 4$, but not in the orthorhombic dihydrate structure or in the acetone and tetrahydrofuran solvate structure. In the two permitted space groups, $P\bar{1}$ and $A2/m$, the molecular symmetries, $\bar{1}$ and $2/m$, respectively, would be required for the dioxane molecule.

Experiments have shown that barium pentathionate, selenopentathionate and telluropentathionate readily give solvates with dioxane. The seleno- and telluropentathionate solvates have been analyzed and found to have the expected composition, *i. e.*, one mole of water and half a mole of dioxane per mole of salt. The solvates are relatively stable, more so than the acetone and tetrahydrofuran solvates, and the perfect cleavage displayed by the latter crystals and those of the dihydrates is absent, in agreement with the idea that dioxane molecules extend across the layer interface and hold the layers more firmly together.

The solvate of barium selenopentathionate with dioxane, $BaSe(S_2O_3)_2 \cdot H_2O \cdot \frac{1}{2}C_4H_8O_2$, was studied crystallographically. The pale green crystals are monoclinic, and formed relatively large, short prisms extended along the a axis and bounded by {011} and {001}. The specimens examined were all persistently twinned. From oscillation and Weissenberg photographs taken with copper radiation, $\lambda(CuK_\alpha) = 1.542$ Å, the unit cell dimensions are: $a = 5.02$ Å, $b = 10.59$ Å, $c = 22.72$ Å (all ± 0.5 %), $\beta = 102°$. There are four formula units per unit cell; density, calc. 2.83, found 2.81 g/cm^3. Systematic absences, hkl when $k+l$ is odd. The $0kl$ zone of reflections has the same symmetry and intensity distribution as the $0kl$ zone of orthorhombic barium selenopentathionate dihydrate [4], of space group D_{2h}^{16}—$Pnma$, and the a-axis projections of the two salts have also very like dimensions. The unit cell dimensions and systematic absences indicate that the solvate is isostructural with monoclinic barium telluropentathionate dihydrate. These analogies leave little doubt that the space group of the dioxane solvate is the centrosymmetric one, C_{2h}^3—$A2/m$, and that replacement of two crystallographically equivalent water molecules, one in each of two adjacent layers, by one dioxane molecule occurs as indicated above.

EXPERIMENTAL

Solutions of about 1 g of barium pentathionate [2], selenopentathionate [4] and telluropentathionate [1] hydrates in 12 ml of 0.2 N perchloric acid were filtered, when necessary, then warmed to about 40 °C, and about 3 ml of 1,4-dioxane was added. On standing, the solvates crystallized, and were filtered off, washed with dioxane and then with ether, and dried for a short time in a vacuum over sulphuric acid.

The dioxane solvates are less soluble and crystallize more rapidly than the acetone and tetrahydrofuran solvates [5]. As usual, the solubilities decrease in the order, pentathionate, selenopentathionate and telluropentathionate. The crystals of the latter were very small and not suited for single-crystal X-ray work.

For analysis, the selenopentathionate was oxidized with potassium bromate and subsequently analyzed iodometrically by means of the Norris and Fay method, as described earlier [17]. The telluropentathionate was titrated directly with iodine [18].

0.2850 g substance: 22.71 ml of 0.09954 N sodium thiosulphate.
$BaSe(S_2O_3)_2 \cdot H_2O \cdot \frac{1}{2}C_4H_8O_2$ (502.7). Mol. weight found, 504.3.
0.2557 g substance: 18.31 ml of 0.1001 N iodine.
$BaTe(S_2O_3)_2 \cdot H_2O \cdot \frac{1}{2}C_4H_8O_2$ (551.3). Mol. weight found, 558.1.

The work has been aided by grants from *Norges almenvitenskapelige forskningsråd*.

Cis- and *Trans*-2,5-Dimethoxy-2,5-dihydrofuran *

JØRGEN TORMOD NIELSEN, NIELS ELMING ** and NIELS CLAUSON-KAAS

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

2,5-Dimethoxy-2,5-dihydrofuran was separated into the *cis* and the *trans* isomer by fractional distillation. Hydrogenation gave the corresponding *cis* and *trans* isomers of 2,5-dimethoxytetrahydrofuran.

The two isomers of 2,5-dimethoxy-2,5-dihydrofuran were *cis*-hydroxylated. Only one *cis*-3,4-dihydroxy-2,5-dimethoxytetrahydrofuran was isolated in each case. The corresponding diacetates were prepared. Attempts to resolve *d,l-cis*-3,4-dihydroxy-*trans*-2,5-dimethoxytetrahydrofuran into the *d*- and the *l*-form by chromatography failed. Attempts to carry out the optical resolution *via* the *l*-menthoxyacetates were also unsuccessful.

2,5-Dimethoxy-2,5-dihydrofurans, prepared by methoxylation of furans, are usually mixtures of the *cis* and the *trans* isomers [1,2]. The same applies to 2,5-dimethoxytetrahydrofurans, which are prepared from the dihydrofurans by catalytic hydrogenation. In one case, *viz.* the derivatives of 2-acetamidomethylfuran, the pair of isomers has been separated [2]. In general, however, these cyclic acetals are used as intermediates for the preparation of 1,4-dicarbonyl compounds and are therefore not separated since both isomers give the same dicarbonyl compounds on acid hydrolysis.

The parent 2,5-dimethoxy-2,5-dihydrofuran has now been separated into the pure isomers by fractional distillation. Hydrogenation gave the corresponding pure 2,5-dimethoxytetrahydrofurans. *Cis*-hydroxylation with potassium permanganate gave only one *cis*-3,4-dihydroxy-2,5-dimethoxytetrahydrofuran from each isomer. The hydroxylation reaction therefore gives no information as to the *cis-trans* relationship between the isomers. Neither did an investigation of the infrared spectra, dipole measurements of the dimethoxydihydrofurans, chromatography of the *cis*-glycols on D-lactose and on starch or the preparation of acetates and *l*-menthoxyacetates of the *cis*-glycols enable us to solve the problem of the *cis-trans* relationship. The reactions are shown in Fig. 1.

* Presented (N.E.) before the Division of Organic Chemistry at the XVIth International Congress of Pure and Applied Chemistry, Paris, France, August 1957.

** Present address: A/S PHARMACIA, Copenhagen, Denmark.

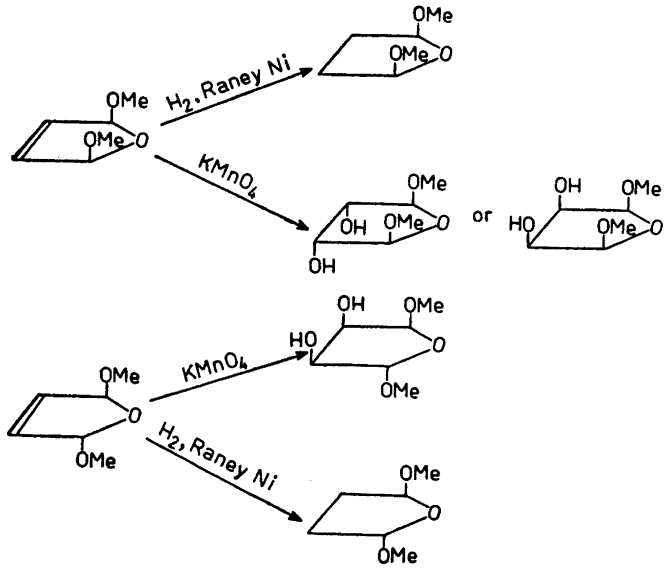

Fig. 1.

It is interesting to observe that there is a marked difference in the yields (44 and 17 %, respectively) of the two *cis*-glycols. Actually the present experiments were initiated by the desire to improve the yields of the hydroxylation reaction of dimethoxydihydrofurans, since a good general procedure for this reaction might open a simple route for the preparation of certain carbohydrates from furans.

Data of all compounds prepared during this investigation are given in Tables 1—5 of the experimental part. It will be noted that the low boiling isomer of 2,5-dimethoxy-2,5-dihydrofuran on hydrogenation gives the high boiling isomer of 2,5-dimethoxytetrahydrofuran.

EXPERIMENTAL

Microanalyses by E. Boss, K. Glens and P. Hansen

2,5-Dimethoxy-2,5-dihydrofurans (I and II). Technical 2,5-dimethoxy-2,5-dihydrofuran (175 g, n_D^{25} 1.4321), prepared by electrolysis [3], was separated into the two isomers by distillation through a 50 cm packed column [4] under 90 mm. It was inferred from the infrared spectra that the purity of the isomers was higher than 95 %. Data of the two isomers are given in Table 1.

Table 1. Data of 2,5-dimethoxy-2,5-dihydrofurans.

	C	H	OCH_3	B.p.$_{90}$ °C	n_D^{25}	Yield, % of distilland
$C_4H_4O(OCH_3)_2$ (130.1) requires	55.4	7.8	47.7			
I	55.6	7.7	47.2	96.0	1.4318	54
II	55.5	7.8	47.6	98.5	1.4331	40

The dielectric constants of dilute benzene solutions of identical concentrations of the isomers were found to be identical within the experimental error.

2,5-Dimethoxytetrahydrofurans (III and IV). This pair of isomers was prepared by catalytic hydrogenation of the pure *cis-* and *trans*-2,5-dimethoxy-2,5-dihydrofurans as described previously [5]. Their data (Table 2) were in agreement with those recorded on samples obtained by fractional distillation of technical 2,5-dimethoxytetrahydrofuran through a 50 cm packed column under 100 mm.

Table 2. Data of 2,5-dimethoxytetrahydrofurans.

	C	H	OCH_3	B.p.$_{760}$ °C	n_D^{25}	Yield %
$C_4H_6O(OCH_3)_2$ (132.2) requires	54.5	9.2	47.0			
III (prepared from I)	54.6	9.2	46.3	147	1.4148	80
IV (prepared from II)	54.7	9.2	46.7	144	1.4158	81

Cis-*3,4-dihydroxy-2,5-dimethoxytetrahydrofurans (V and VI).* I and II were *cis*-hydroxylated by a modification of the method previously described [6]. Powdered potassium permanganate (30.0 g, 0.19 mole) was added in small portions during 1.3 h with vigorous stirring to a solution of 2,5-dimethoxy-2,5-dihydrofuran (26.0 g, 0.20 mole) in water (100 ml) and acetone (100 ml). The temperature was kept at −18° to −21°. The resultant suspension was stirred for 1 h at −20° and the manganese dioxide removed by centrifugation and washed twice with water. The turbid solution was filtered and the filtrate concentrated in a vacuum to about 50 ml. Potassium carbonate (10 g) was added and the solution continuously extracted with ether overnight. The reaction products were isolated by distillation in a vacuum. Their data are given in Table 3.

Table 3. Data of *cis*-3,4-dihydroxy-2,5-dimethoxytetrahydrofurans.

	C	H	OCH_3	B.p.$_{0.1}$ °C	n_D^{25}	M.p. °C	Yield %
$C_4H_6O_3(OCH_3)_2$ (164.2) requires	43.9	7.4	37.8				
V (prepared from I)	43.9	7.4	37.9	109−110	1.4569	34-36	44
VI (prepared from II)	43.9	7.4	37.9	85−87	1.4600	67-69	17

V and VI were crystallized from ether [m.p's 34−36° and 67−69°, respectively (Hershberg apparatus, corr.)]. Another crystallization did not change the m.p's. By evaporation of the mother liquors white crystalline residues having the same m.p's were obtained.

V and VI are therefore believed to be pure isomers. This was also indicated by the infrared spectra.

VI is apparently identical with the product (b.p.$_2$ 130°, n_D^{25} 1.4600, m.p. 65−67°) obtained by Sheehan and Bloom [7] by distillation through a semi-micro fractionating column of their crude product (b.p.$_2$ 106−132°).

Since V or VI must be *d,l-cis*-3,4-dihydroxy-*trans*-2,5-dimethoxytetrahydrofuran it was attempted to resolve V and VI by chromatography on D-lactose using the technique described by Prelog and Wieland [8], but no resolution was observed. Experiments using starch as the adsorbing agent as described by Krebs, Wagner and Diewald [9] were also unsuccessful.

Diacetates of cis-*3,4-dihydroxy-2,5-dimethoxytetrahydrofurans (VII and VIII).* V (328 mg) was dissolved in a mixture of pyridine (3 ml) and acetic anhydride (3 ml) and

the mixture left standing overnight. Evaporation followed by crystallization from ether gave 346 mg of VII (white crystals).

VI (1.26 g) was acetylated as described above and the reaction product isolated by distillation. The yield was 1.47 g of VIII (colorless, viscous liquid, which did not crystallize on standing or by treatment with various solvents). Data of the two isomers are given in Table 4.

Table 4. Data of diacetates of *cis*-3,4-dihydroxy-2,5-dimethoxytetrahydrofurans.

	C	H	OCH_3	$COCH_3$	B.p.$_{0.1}$ °C	n_D^{25}	M.p. °C	Yield %
$C_4H_4O_3(OCH_3)_2(COCH_3)_2$ (248.2) requires	48.4	6.5	25.0	34.7				
VII (prepared from V)	48.5	6.7	24.7	34.5			97–98	70
VIII (prepared from VI)	48.2	6.7	24.7	34.4	90–92	1.4431		77

VII is apparently identical with the diacetate (m.p. 97–99°) reported by Zeile and Heusner [10].

l-Menthoxyacetates of cis*-3,4-dihydroxy-2,5-dimethoxytetrahydrofurans (IX, X and XI).* When treated with one mole of *l*-menthoxyacetyl chloride in pyridine V gave 33 % of a mono-*l*-menthoxyacetate (IX) and 53 % of its di-*l*-menthoxyacetate (X). Under the same conditions VI gave only its di-*l*-menthoxyacetate (XI) (yield 83 %).

Cis-3,4-dihydroxy-2,5-dimethoxytetrahydrofuran (1.35 g, 0.0082 mole) was dissolved in pyridine (10 ml) and *l*-menthoxyacetyl chloride (1.92 g, 0.0082 mole) was added dropwise with cooling at 10–15°. The mixture was left standing at room temperature overnight. Water (5 ml) was added and the mixture continuously extracted with ether for 2 h. The ether extract was washed once with a little water, dried with magnesium sulfate and distilled in a vacuum. Data of the *l*-menthoxyacetates are given in Table 5.

Table 5. Data of *l*-menthoxyacetates of *cis*-3,4-dihydroxy-2,5-dimethoxytetrahydrofurans.

	C	H	OCH_3	B.p.$_{0.05}$ °C	n_D^{25}	Yield %
$C_{16}H_{26}O_5(OCH_3)_2$ (360.4) requires	60.0	9.0	17.2			
IX (prepared from V)	59.5	9.0	17.2	175–185	1.4699	33
$C_{28}H_{46}O_7(OCH_3)_2$ (556.7) requires	64.7	9.4	11.2			
X (prepared from V)	64.3	9.4	11.8	230–235	1.4712	53
XI (prepared from VI)	64.7	9.3	11.5	222–226	1.4731	83

IX, X and XI did not crystallize on standing or by treatment with various solvents. Attempts to prepare a crystalline acetate of IX failed. Only an oil was obtained. It was therefore not possible to separate any diastereomeric forms by fractional crystallization.

Acknowledgment. We are indebted to our colleagues, Professor Børge Bak and Mr. Daniel Christensen for measuring and interpreting the infrared spectra and the dielectric constants.

ACTA CHEMICA SCANDINAVICA 12 (1958) 68—78

On the Biosynthesis of some Recently Discovered Derivatives of Glutamic Acid in Plants

PEKKA LINKO* and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

1- and 2-^{14}C-pyruvates, respectively, were fed to excised leaves of *Asplenium septentrionale* and *Phlox decussata* by different methods, and the incorporation of radioactivity into the amino compounds was followed as a function of time. No significant differences in the metabolic pattern could be found in these plants containing "new" amino acids as compared to the other plants examined. Transaminase activity is very high, alanine being most rapidly labelled. Already after a few minutes from the beginning of infiltration amino compounds contained up to 75 % of the total in 70 % ethanol soluble activity. After about 15 h glutamine was the major labelled product.

γ-Methyl-γ-hydroxyglutamic acid is shown to exist free in *Phlox decussata* by means of isotopic techniques. Hence this amino acid may be a normal metabolite in plants. The main biosynthetic route to γ-methyl-γ-hydroxyglutamic acid is most probably an aldol condensation of two pyruvate molecules, following transamination. γ-Hydroxyglutamic acid is not noticeably synthesized in the leaves of *Phlox decussata*.

The role of γ-aminobutyric acid in relation to glutamine is discussed. The most probable route from γ-AB to glutamic acid seems to be *via* glutamine.

The results indicate that glycine is not the main precursor of serine in these plants.

A great number of previously unknown amino compounds have been detected in living organisms during the last few years. Most of these compounds are found only in the 70 % ethanol soluble part, but some are thought to be protein components, too. Though it appears probable that these amino derivatives are not central metabolites in plants, it seems to be quite possible that many of them occur widely distributed in the plant kingdom.

Very little is still known about the metabolism of most of these "new" compounds. Not much could be done to solve this problem before the techniques using radioactive isotopes as tracers were available. It will be of great impor-

* Present address: Kansas State College, Department of Flour and Feed Milling Industries, Manhattan, Kansas, U.S.A.

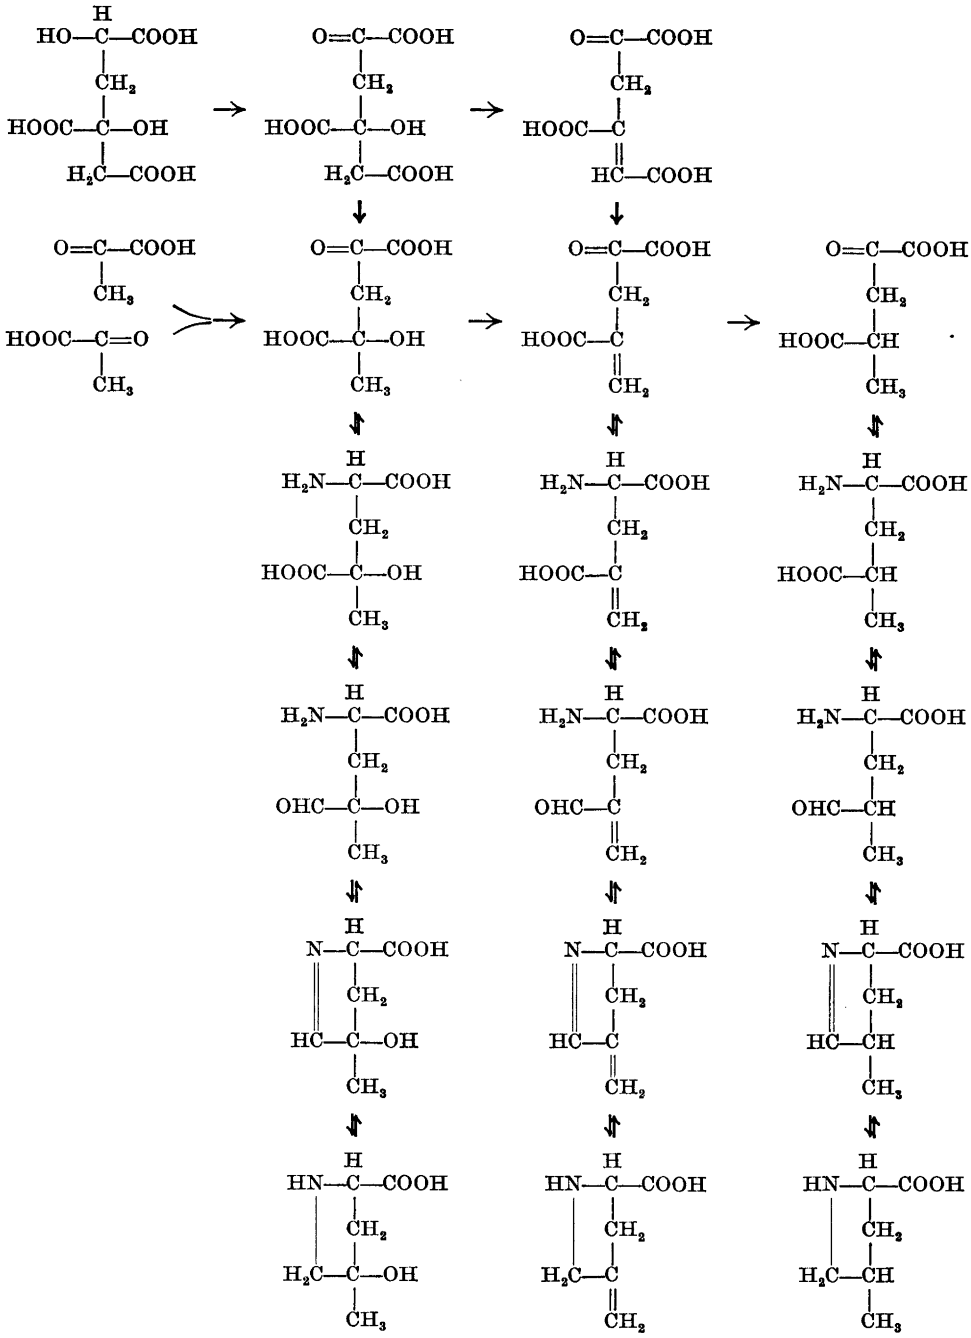

Fig. 1. Scheme of the possible biosynthetic reactions leading to γ-derivatives of glutamic acid.

tance to discover whether the metabolism of plants containing large amounts of these compounds is entirely different from that of others or if there is merely a simple enzyme block present. The latter hypothesis would explain the fact that some of these compounds, when present, are predominant among the free amino acids. In other cases they would be only very short lifetime intermediates and therefore not detectable without tracer techniques.

Already eleven monoaminodicarboxylic acids have been found to exist in plants. Four of them are derivatives of glutamic acid: γ-methyleneglutamic acid and the corresponding amide [1], γ-methylglutamic acid [2], γ-methyl-γ-hydroxyglutamic acid, γ-MHGA [2,3], and γ-hydroxyglutamic acid, γ-HGA [4]. All of these, as well as the known derivatives of γ-aminoadipic and pimelic acids [5], contain the substituents in γ-position. This has led to the assumption [6] that the primary reaction of the biosynthesis of these compounds would be an aldol condensation of either two molecules of pyruvate or one pyruvate molecule and one molecule of some other oxo compound as glyoxylic acid. Transamination would then result to the corresponding amino acid. Many of these keto acids are now known to exist free in plants [7–10].

A different possibility has been postulated by Bentley and Thiessen [11]. According to them, 2,4-dihydroxy-1,2,4-butanetricarboxylic acid, which is known to exist in dog's liver [12] and in bacteria [13], would be oxidized and dehydrated to 4-oxo-1-butene-1,2,4-tricarboxylic acid. The carboxyl group in position 1 would then be decarboxylated by means of a specific decarboxylase. Oxalocitramalic acid, which is a postulated intermediate in this scheme, is, however, not a normal metabolite [14].

A third possibility would be the biosynthesis from the corresponding proline derivatives. This hypothesis seems to be quite possible at least when γ-HGA is in question. A summary of all these reactions is shown in Fig. 1.

To test the aldol condensation hypothesis sodium 1- and 2-^{14}C-pyruvates were fed to *Asplenium septentrionale* [15] and *Phlox decussata*. In the former γ-MHGA [16] and in the latter γ-HGA [4] were known to occur.

MATERIALS AND METHODS

Plant material. *Asplenium septentrionale* was harvested in September and October. Most experiments were performed with freshly picked plants, but in some cases *Asplenium*, kept up to several months at +4°C in an open jar, was used. The results in different cases did not markedly differ from each other. *Phlox decussata* was grown in the greenhouse from a piece of root picked early in the spring under snow. Plants were used for experiments when about 10 cm high.

Radiochemicals were obtained from the Radiochemical Centre, Amersham, England.

Experiments of two different types were performed. I. 25 *Asplenium* plants (*ca.* 700 mg fresh wt.) were put in each of a series of small test tubes containing 4 ml of water. Half a cm of the plants was cut off under water, and 3 ml of the liquid was carefully pipetted away. To each of the test tubes 100 μl of sodium pyruvate solution (0.067 mg = 2.7 μC ml of water was added mixing carefully. After 2, 6 and 13 h 0.5 ml of water was added to each tube. Samples were collected after ½, 1, 2, 4, 6, 12, 24 and 48 h. The uptake of radioactivity was much higher when plants stored (and dried) at +4°C were used. II. Most of the experiments were performed by the vacuum infiltration method. About 500 —700 mg fresh wt. of plants were cut to pieces, *ca.* 1 cm long, and put into small glass jars each containing 2 ml of radioactive pyruvate solution (2—4 μC in different experiments). Samples were then subjected to a small vacuum by means of a vacuum desicca-

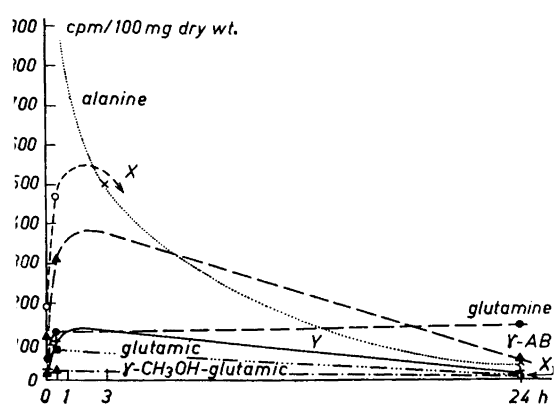

Fig. 2. Total radioactivity changes in the amino compounds of *Asplenium septentrionale* after 2-^{14}C-pyruvate infiltration.

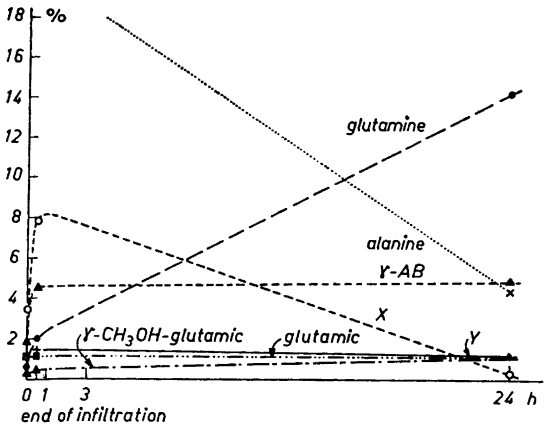

Fig. 3. Percentage of radioactivity in the individual amino compounds calculated from the total ethanol soluble activity in *Asplenium septentrionale* after 2-^{14}C-pyruvate infiltration.

tor several times after each other. The time of infiltration varied from 5 to 30 min. During this period practically all of the solution was taken up by the plants. Samples were dried lightly between filter papers and put on moist filter papers into light for different periods of time. Sometimes all of the plant material was subjected to infiltration simultaneously, and aliquots were taken after certain time intervals. All experiments with *Phlox decussata* were performed by this method.

The extraction was done with 70 % ethanol until the residue was practically colorless. Extracts were purified from salts and other materials, disturbing in paper chromatography, by passing through an Amerberlite IR-120 cation exchange resin, the extract thus being divided into the amino compound and "peptide" fractions. The amino compounds were eluted from the resin with 1 N NH_4OH. Both fractions were evaporated to a small volume *in vacuo* at 40°C. It was noticed using algae, from which good chromatograms can be made even without ion exchange treatment, that the "peptide" fraction does not continue to give a correct picture of the "anionic" compounds [17]. This is largely due to decomposition of phosphates and some other easily hydrolysable compounds including even some amino derivatives.

For chromatography Whatman No. 4 paper was used without prewashing. First solvent: phenol (Merck, "für Chromatographie", without distillation) saturated with water in ammonia atmosphere. Ammonia was omitted for chromatography of the "peptide" fraction. Second solvent: *n*-butanol: acetic acid: water (63:10:27). In both solvent systems HCN was used to prevent the "pink front" on ninhydrin sprayed amino acids.

Radioautograms were taken either on Ilford Ilfex X-Ray film or on Kodak's single coated Medical X-Ray tinted back film.

Radioactivity measurements of the spots on paper chromatograms were first done by extracting the spots with small amounts of water and counting the evaporated extracts on aluminium discs with Friesecke & Hoepfner, G.m.b.H., Erlangen-Bruck, scaler using Geiger tube FHZ 15/5716 (window -2.1 mg/cm^2). Later, spots were counted directly on chromatograms with a Tracerlab Autoscaler using a self made gasflow counter (DuPont mylar window). If found necessary, the results were corrected for the self absorption and coincidence.

Only semiquantitative paperchromatographical estimations were made in cases when the specific activity was determined.

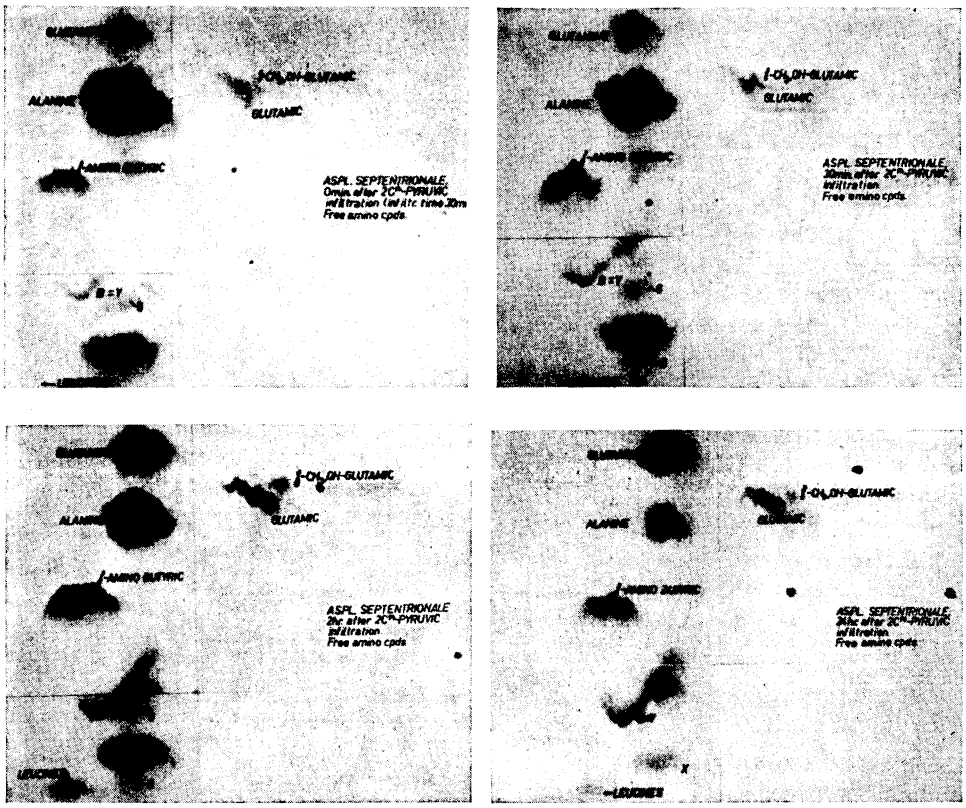

Fig. 4. Radioautograms of the amino compound fraction of *Asplenium septentrionale*. After 2-^{14}C-pyruvate infiltration.

RESULTS AND DISCUSSION

Radioactive pyruvate was readily metabolised in all experiments performed with *Asplenium septentrionale* (Figs. 2, 3 and 4). When excised shoots were allowed to take up active pyruvate solution the activity of the nutrient solution dropped to about 30 % in 2 h and to 4 % in 24 h (Table 1). A slightly higher percentage of the 70 % ethanol soluble radioactivity was incorporated into the amino compounds when pyruvate was infiltrated into the detached plants. The amino compounds contained relatively more activity after 2-^{14}C-pyruvate infiltration than when 1-^{14}C-pyruvate was used. Though pyruvate itself is found in the "peptide" fraction already after a few minutes amino compounds contained more than 50 % of the soluble activity. This amount dropped to about 10 % in 20 h when 1-^{14}C-pyruvate was given, but on 2-^{14}C-pyruvate infiltration after 24 h the amino compound fraction still contained 46 % of the activity (Table 2). The rapid labelling of this fraction was largely due to a very high transaminase activity, hence alanine being formed most

rapidly and with a rather high specific activity. When 1-^{14}C-pyruvate is used part of the active alanine may also be formed secondarily from the refixed carbon dioxide *via* 3-phosphoglyceric acid and the tricarboxylic acid cycle. The initially high activity of alanine then decreased rapidly.

Generally, 2-^{14}C-pyruvate was much more effectively utilized for the synthesis of labelled amino acids than was 1-^{14}C-pyruvate (Figs. 5 and 6). The latter is readily decarboxylated in the plant, the active CO_2 then being

reutilized to a great extent for carbohydrate synthesis etc. In this case most of the amino acids were rapidly found labelled with a low specific activity. This indicates that decarboxylation to acetyl-CoA is probably more important in the plant than is the carboxylation of pyruvate to oxalacetic acid. The relatively highest specific activity was found in the γ-MHGA. The results confirm those obtained by Miettinen [18] who showed that carboxyl labelled alanine was taken up with out breakdown by a shoot of the pea plant *(Pisum sativum)* detached from the root but was then immediately decarboxylated. On the contrary, no active CO_2 was primarily lost from 2-^{14}C-pyruvate.

An unknown amino compound X was also very rapidly labelled reaching its peak within one hour. Its activity then decreased very rapidly as did that of alanine. After 24 h almost no more activity could be found in this compound. The spot did not give a positive ninhydrin reaction, but this does not exclude the possibility that X is present in only such a low concentration that it cannot be detected by ninhydrin spray. In this case compound X would have had the highest specific activity.

It was of interest to notice that after 2-^{14}C-pyruvate infiltration no activity could be found in either aspartic acid or its amide. If aspartic acid is mainly formed by transamination from oxalacetic acid formed in turn either by the Wood-Werkman reaction or *via* the tricarboxylic acid cycle the resulting aspartate would be radioactive. Both aspartic acid and its amide were readily labelled when 1-^{14}C-pyruvate was given to the plant. Aspartic acid is known to be among the first radioactive compounds formed during photosynthetic $^{14}CO_2$ fixation by algae [17]. This agrees very well with the fact that carboxyl labelled pyruvate is rapidly decarboxylated in plants, carbon dioxide then being reutilized. Several observations have shown that the main biosynthetic route to aspartic acid in plants is not *via* transamination from oxalacetic acid [19,20]. Nelson and Krotkov [20] postulate a condensation for its formation. It now looks very probable that the two-carbon pieces possibly involved in this reaction are not directly derived from pyruvate.

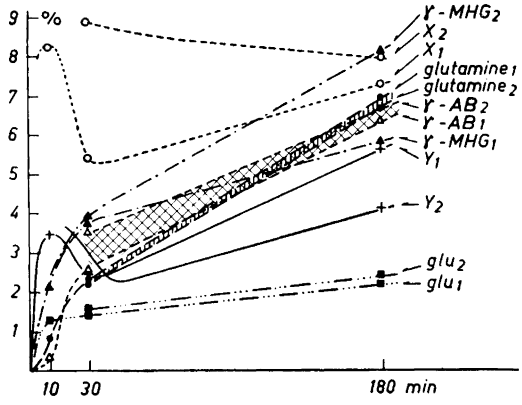

Fig. 7. The relative radioactivity changes of the individual amino compounds in *Asplenium septentrionale* after 2-^{14}C-pyruvate infiltration with (2) and without (1) inactive γ-AB addition.

In all experiments serine was labelled before glycine, which clearly indicates that it is not synthesized from the latter in *Asplenium septentrionale*. Similar results have been obtained by Tolbert and Gailey with wheat leaves [21]. In animal tissues [22,23] and in yeast [24] serine is found to be the precursor of glycine.

The radioactivity of glutamic acid rises rapidly to a certain level remaining then at a constant value. The same thing happens also with γ-aminobutyric acid (γ-AB). The specific activities of both of them are about the same. The activity of glutamine rises rapidly after a short lag period, being after about 15 h the major active compound. It is thought that the main route to γ-AB should be decarboxylation of glutamic acid [25,26]. Steward *et al.* [27,28] found only a slight activity of L-glutamic acid decarboxylase in potato tubers, which contain a high concentration of γ-AB. They suggested therefore that γ-AB was merely a precursor of glutamic acid and not its decarboxylation product. Miettinen and Virtanen [29] detected a considerable glutamic acid decarboxylase activity both in pea and alder but found no direct correlation between the concentration of γ-AB and the enzyme activity in plant tissues. According to Baptist [30] γ-AB may arise as a result of some reaction connected with protein synthesis. This is specially interesting because glutamine is thought to have some important role in protein synthesis [31,32]. Hence the role of γ-AB in relation to glutamine becomes an important question. Glutamate is known to be rapidly metabolised to glutamine and γ-ketoglutaric acid but not much to γ-AB in higher plants [33,34].

To try to trace the role of γ-AB, two experiments were performed with *Asplenium septentrionale*, in which 2-^{14}C-pyruvate only and 2-^{14}C-pyruvate with inactive γ-AB, respectively, were infiltrated to the plants (Fig. 7). The activity of the γ-AB itself was slightly increased in the latter case. This was probably due to the fact that while the rate of synthesis of active γ-AB remains the same, the γ-AB pool is diluted with the added inactive product, and hence less of the active molecules react further in a given time. This results in the enrichment of active γ-AB. The primary metabolic products from γ-AB should have slightly lowered the relative activity when inactive γ-AB is added. This

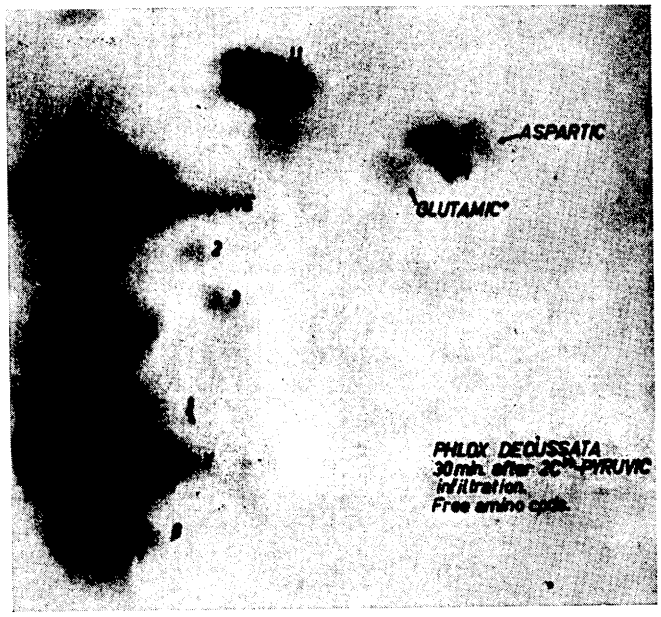

Fig. 8. Radioautogram of the amino compound fraction of *Phlox decussata*. 30 min after 2-^{14}C-pyruvate infiltration. The numbered spots are unknown. No. 1 is identified as γ-MHGA.

was found only in the case of glutamine and an unknown amino compound Y. The radioactivity of compound Y had a minimum after about 30 min, which could be explained under the assumption that two different metabolic pools of the precursor of Y exist, one of these two becoming much more slowly active. Because the radioactivity of glutamic acid was slightly increased in the latter experiment it may not be a primary carboxylation product of γ-AB. It seems much more probable that glutamic acid arises from γ-AB *via* glutamine. However, the increase of radioactivity of glutamic acid can at least be partly explained by the fact that the addition of inactive γ-AB increases the amount of nitrogen available for transamination reactions. The enzyme catalysing transamination between γ-AB and α-ketoglutaric acid is known to exist in pea [35].

γ-MHGA is rapidly labelled both with 1- and 2-^{14}C-pyruvates. In both cases the amount of radioactivity increases all the time resulting in a high specific activity as compared to other amino compounds. If the aldol condensation hypothesis is correct, pyruvic acid should be incorporated intact into the γ-derivative of glutamic acid. If this is the fact, 1-^{14}C-pyruvate would give a relatively high activity in γ-MHGA compared with the activities of glutamate and aspartate, since in this case the active carbon atom would enter directly into the molecule of γ-MHGA. Because the pyruvate molecules would undergo decarboxylation to give inactive acetyl-CoA, the only way labelled aspartic acid could be formed were the Wood-Werkman reaction of the liberated active

CO_2. From this labelled glutamic acid could then be formed. Therefore only a slight labelling of glutamic and aspartic acids would be expected. If the carbon chain of pyruvate would not enter intact into γ-MHGA, the radioactive compound could only arise from the reutilized carbon dioxide produced by decarboxylation. In such a case the Wood-Werkman reaction is probably the most important fixation mechanism, and the relative specific activities of aspartic and glutamic acids would be expected to be much higher than that of γ-MHGA. However, when 1-^{14}C-pyruvate was infiltrated to the plant γ-MHGA gained much greater specific activity than did the other amino acids. The observed difference was greater than what can be expected to arise from the possible dilution of the activities of the latter compounds during hydrolysis of inactive protein.

Active pyruvate, active pyruvate + inactive glycine, and active pyruvate + inactive glyoxylic acid, respectively, were infiltrated to the leaves of *Phlox decussata* to study whether γ-hydroxyglutamic acid would arise by a similar type of aldol condensation. In no experiments could any activity be incorporated into γ-HGA. Since the activity was rapidly incorporated into most of the other amino acids including a number of unknown amino compounds (Fig. 8) it seems very probable that γ-HGA is synthesized very slowly in the leaves, if at all. Even if this compound were to be synthesized *via* any intermediates of the tricarboxylic acid cycle in the leaves at least some radioactivity would be expected in it. However, synthesis from the protein amino acid hydroxyproline would result in an inactive product during short time experiments. It is also possible that the main site of the synthesis of γ-HGA is located elsewhere. This assumption is in good agreement with Fowden's [36] discovery that γ-methyleneglutamic acid and its amide arise during the early stages of seedling growth.

A spot with a very high specific activity was found on the place of γ-MHGA on paper chromatograms of the extracts of *Phlox decussata*. When isolated, it could indeed be shown to be identical with γ-MHGA isolated from *Asplenium*. This compound was not previously known to exist in *Phlox* and it could not even in this case be found by ninhydrin spray. The infiltration of inactive glycine did not have any significant effect on the labelling of this compound.

An interesting finding was that serine was rapidly labelled when inactive glycine was also infiltrated, but practically no formation of active serine was obtained with pyruvate infiltration alone.

All these experiments show that the most probable biosynthetic pathway of γ-MHGA in higher plants is *via* an aldol condensation from two pyruvate molecules. The final proof of this hypothesis would require a stepwise degradation of the γ-MHGA molecule and the determination of the radioactivities of each of the six carbon atoms, using pyruvate labelled in all three different positions, respectively. However, the total activity obtained in this compound was not great enough for such an experiment. The experiments with *Phlox decussata* showed in addition that γ-MHGA may be a normal metabolite in higher plants, but usually present in such a low concentration that the detection by the usual methods is not possible. This may be due to most of the newly discovered amino acids.

That no radioactivity could be incorporated into γ-HGA did not rule out the possibility of the existence of an aldol condensation with pyruvate and glyoxylate, but merely showed that this compound is not an active metabolite in the leaves of *Phlox decussata*. Generally, no significant differences in the metabolic pattern could be found in these plants containing "new" amino acids as compared to the other plants examined.

The Crystal and Molecular Structure of Ethylene Thiocyanate

RASMUS BRINGELAND and OLAV FOSS

Chemical Institute, University of Bergen, Bergen, Norway

The structure of NCS · H_2C-CH_2 · SCN has been determined from single-crystal X-ray data. The crystals belong to the space group, $D_{2h}^{15}-Pbca$, with four molecules in a unit cell of dimensions: $a = 7.39$ Å, $b = 7.81$ Å, $c = 11.48$ Å. The molecules have a centrosymmetric, *trans* form, with the cyanide groups rotated out of the SCCS plane.

The bond lengths and angles are: C—C = 1.51 ± 0.03 Å, C—S = 1.80 ± 0.01 Å, S—C = 1.63 ± 0.01 Å, C—N = 1.18 ± 0.02 Å, ∠C—C—S = 110.7 ± 0.9°, ∠C—S—C = 99.4 ± 0.7°. The results indicate that the thiocyanate group is a hybrid of the structures $\diagup S-C\equiv N$ and $\diagup \overset{+}{S}=C=\overline{N}$. A value of 172° was found for the S—C—N angle, but the deviation from linearity is probably not significant.

In the course of preliminary work on the crystal structure of sulphur dithiocyanate [1], one of the present authors became interested in the nature of bonding in the thiocyanate group and its configuration and dimensions in other covalent compounds. Ethylene thiocyanate, NCS · H_2C—CH_2 · SCN, was chosen for study because of its simple formula and since the molecules, from literature data on other symmetrically disubstituted ethanes, might be expected to lie in crystallographic centres of symmetry.

CRYSTAL DATA

Ethylene thiocyanate (1,2-dithiocyanato-ethane) was prepared from ethylene bromide by heating in ethanol solution with a slight excess of potassium thiocyanate [2]. The compound melts at 90°C and vaporizes slowly in open air at room temperature. From chloroform, it crystallized as orthorhombic plates {010}, or as bipyramids {111} with in most cases {010} more or less developed. Buff [2], in 1856, described it as crystallizing from ethanol in rhombic plates.

From Weissenberg photographs, the axial lengths are: $a = 7.39$ Å, $b = 7.81$ Å, $c = 11.48$ Å. They are based on $\lambda(CuK_\alpha) = 1.542$ Å and are

believed to be accurate to better than 0.5 %. There are four molecules per unit cell; density, calc. 1.45, found 1.42 g/cm^3. The space group, from systematic absences, is D_{2h}^{15}—*Pbca*, which has eightfold general positions, and fourfold sets of symmetry centres as special positions. It follows that the molecules are centrosymmetric in the crystals.

The intensities of the 0*kl* and *h*0*l* reflections were estimated visually from Weissenberg photographs, taken with CuK_α radiation for which the absorption coefficient of the crystals is 63.2 cm^{-1}. Crystals with small, nearly uniform diameters were used in order to minimize absorption and spot shape effects. Out of 58 possible 0*kl* reflections within the range sin $\Theta < 0.985$ (CuK_α radiation) 53 were recorded with measurable intensity, the corresponding figures for *h*0*l* being 50 out of 59. The intensities were corrected in the usual way to give sets of relative structure amplitudes; these were eventually put to an approximately absolute scale by comparison with the calculated values.

The latter were based on the atomic scattering curves of Viervoll and Ögrim [3] for sulphur and hydrogen, and of Berghuis *et al.*[4] for nitrogen and carbon.

All summations were performed by means of Beevers-Lipson strips, at 6° intervals.

DETERMINATION AND REFINEMENT OF THE STRUCTURE

There is one sulphur, one nitrogen and two carbon atoms in the asymmetric unit, apart from two hydrogen atoms, and conditions should thus be favourable for use of the heavy atom method in the initial stages.

From the *a*-axis Patterson projection, the coordinates, $y = 0.02$, $z = 0.075$ were derived for sulphur. A F_o synthesis based on 35 of the largest 0*kl* terms, with signs corresponding to the sulphur contributions alone, gave an electron density map where the general outline of the molecule could be recognized, but extensive overlapping occurred and further work on this projection was postponed until use could be made of *z* coordinates obtained from the *h*0*l* data.

The *b*-axis Patterson projection gave $x = 0.25$, $z = 0.078$ for sulphur, and these coordinates were used to derive the signs of 42 of the largest *h*0*l* terms for a subsequent F_o synthesis. Although overlapping of atoms was evident also here, the electron density map, together with considerations of probable bond lengths and the assumption of a linear thiocyanate group, allowed approximate coordinates for the nitrogen and carbon atoms to be determined. Signs were then calculated for all observed *h*0*l* structure factors, and none of these signs changed later. The electron density map thus obtained is shown in Fig. 1.

The refinement of this projection proceeded as follows. With $x = 0.25$, the sulphur atom lies in or close to the glide plane *b* at $x = \frac{1}{4}$, and overlaps with another sulphur atom belonging to a different molecule. The shape of the composite peak indicated that the sulphur atom should be slightly removed from the glide plane, and on changing *x* from 0.25 to 0.26 and then to 0.267 the reliability index *R* (using at this stage an overall, isotropic temperature correction with $B = 5.0$ Å^2) dropped from 0.135 over 0.123 to 0.115. Small adjustments in the nitrogen and carbon coordinates led to a further improve-

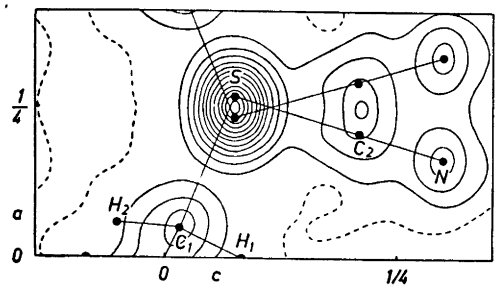

Fig. 1. Electron density projection of ethylene thiocyanate along the *b* axis. The 1-electron line is dashed, and the first full contour line is at 3 e · Å^{-2}. Intervals thereafter: 3 e · Å^{-2} for the sulphur atom and 2 e · Å^{-2} for the nitrogen and carbon atoms. The final atomic positions are marked with dots.

ment in R of about 0.01; from then on, refinement was carried out by means of (F_o—F_c) syntheses. In the first difference map, peaks appeared which were taken to indicate the positions of the two hydrogen atoms. When the hydrogen contributions were included in the calculated structure factors, with hydrogen coordinates chosen within the peaks on the basis of C—H = 1.1 Å and tetrahedral carbon, the value of R dropped by 0.02 to 0.085. Five more difference refinements were made.

Work on the *a*-axis projection was then resumed. The *z* coordinates were here, until after the fourth difference synthesis, kept equal to those found from the *h0l* data. Trial calculations on *y* coordinates relatively soon led to the determination of the correct signs of all observed *0kl* structure factors; the corresponding electron density map is shown in Fig. 2. The reliability index, using $B = 5.0$ Å^2 in the temperature factor as above, was at this stage 0.20. By trial and error, this figure was reduced to 0.13. At that stage the hydrogen contributions were included, based on the same *z* coordinates as in the *b*-projection and *y* coordinates derived by taking C—H = 1.1 Å. R then dropped to 0.115. Finally, extensive (F_o—F_c) refinement was carried out.

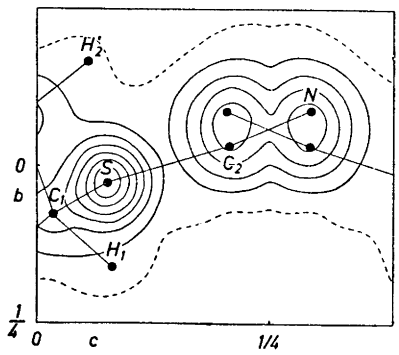

Fig. 2. Electron density projection along the *a* axis. All full contour lines are at intervals of 3 e · Å^{-2}, otherwise as in Fig. 1.

In both projections the difference maps indicated individual and partly anisotropic temperature corrections. In the temperature factor $\exp[-B(\sin^2\Theta/\lambda^2)]$ finally chosen the values of B were: For the $h0l$ data, $B = 4.6$ Å^2 and 5.5 Å^2 for the carbon atoms C_1 and C_2, respectively, 5.2 Å^2 for the nitrogen atom and $(4.3 + 0.4 \cos^2 \varphi)$ Å^2 for the sulphur atom, where φ is the angle between the normal of the reflecting plane and the direction of maximum vibration of the atom, the a axis. For the $0kl$ data, $B = 5.0$ Å^2 for C_1 and 5.7 Å^2 for C_2, and $(5.2 + 1.2 \cos^2 \varphi)$ Å^2 and $(4.5 + 1.2 \cos^2 \varphi)$ Å^2 for the nitrogen and the sulphur atom, respectively. Here, the direction of maximum vibration was for both atoms taken to be that of the b axis, although in the case of sulphur a slightly different direction was indicated in the last maps. For the hydrogen atoms, $B = 5.0$ Å^2 in both zones. The large thermal parameters are in agreement with the relatively low melting point and high sublimation pressure of the substance.

The final atomic coordinates are given in Table 1. Two independent sets of z coordinates were obtained, namely, $z(S) = 0.0770$ and 0.0765, $z(N)=0.299$ and 0.297, $z(C_1) = 0.016$ and 0.017, $z(C_2) = 0.208$ and 0.206, from the $h0l$ and $0kl$ data, respectively. The mean values are listed in the Table. The hydrogen coordinates, which of course are approximate only, are for H_1: $x = 0.056$, $y = 0.168$, $z = -0.056$, and for H_2: $x = -0.019$, $y = 0.155$, $z = 0.082$.

Table 1. Atomic coordinates, in fractions of corresponding cell edges. Origin at a centre of symmetry.

	x	y	z
S	0.268	0.027	0.0768
N	0.165	−0.088	0.298
C_1	0.051	0.080	0.016$_5$
C_2	0.205	−0.029	0.207

Observed and calculated $h0l$ and $0kl$ structure factors are listed in Table 2. The reliability index, $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$, with non-observed reflections included when $|F_c|$ exceeds the observable limit, is 0.047 for the $h0l$ data and

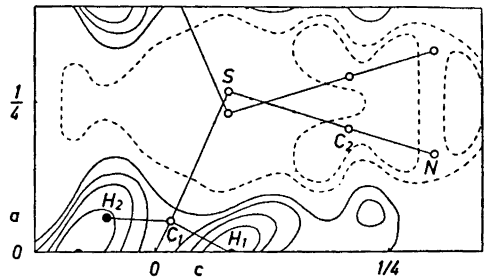

Fig. 3. Difference projection along the b axis, with hydrogen atoms *not* subtracted. Their positions are marked with dots, those of the other atoms with rings. Contour lines at −0.4, −0.2, 0.2, 0.4 ... e · Å^{-2}, with negative lines dashed.

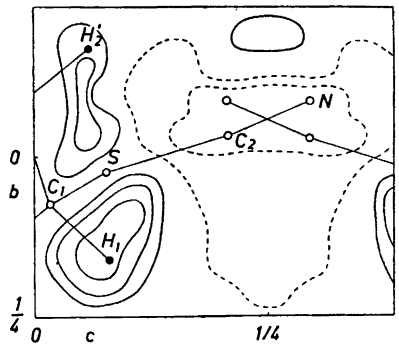

Fig. 4. Difference projection as in Fig. 3, along the *a* axis.

0.056 for the 0*kl* data. If the hydrogen contributions to F_c are omitted, the R values increase to 0.078 and 0.081, respectively. The effect is thus quite large. The difference maps of Figs. 3 and 4, calculated after ended refinement on the basis of F_c values with hydrogen contributions not included, are reproduced to show the hydrogen peaks and the assumed hydrogen positions.

The extent to which the projections could be refined was in the last stages felt to be limited by lack of accuracy of the experimental data. An estimate of random errors in the F_o, made by comparing values from different quadrants of a film, and scaled values from different films in the multiple-exposure series, led to reliability indexes of 2.5—3.0 % for the F_o for both zones.

ASSESSMENT OF ACCURACY

The standard deviation in electron density, evaluated as the root-mean-square of the figures in the difference maps, is slightly above 0.2 e · Å^{-2} for both zones, and the r.m.s. gradient of the difference maps is about 0.7 e · Å^{-3} in both axial directions of each map. The estimation of standard deviations in atomic coordinates on the basis of the gradients and the curvatures of the electron density peaks [5,6] is rendered uncertain by the rather extensive overlapping which occurs in both projections. Use of the method on the relatively well resolved nitrogen atom in the *b*-axis projection gave $\sigma(x) = 0.013$ Å, $\sigma(z) = 0.010$ Å for this atom. Assuming that the errors are the same for all three coordinates of an atom, and that they are inversely proportional to the atomic number, one gets $\sigma = 0.005$ Å for the sulphur coordinates and 0.011—0.015 Å for the nitrogen and carbon coordinates. The figures are relatively large despite the good agreement between observed and calculated structure factors, owing to the large thermal vibrations of the atoms and correspondingly low curvature of the electron density peaks. Because of the overlapping, the errors may be considerably larger than should be expected from the calculated standard deviations; however, the correspondence between the two independently determined sets of z coordinates, one from each zone, indicates that the estimates are of a reasonable order of magnitude. The difference between the z coordinates is 0.006 Å for sulphur, 0.01 Å for C_1 and 0.02 Å for C_2 and N.

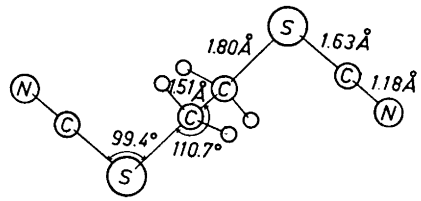

Fig. 5. The ethylene thiocyanate molecule as it appears in projection along the *b* axis.

DESCRIPTION AND DISCUSSION OF THE STRUCTURE

The dimensions of the ethylene thiocyanate molecule were calculated from the coordinates of Table 1 and are listed in Table 3. A prime is used to denote the equivalent of an atom in the other half of the molecule across the centre of symmetry.

The ethane carbon and the sulphur valency angles are normal, and the lengths of bonds involving the ethane carbon atoms correspond within the errors to single bonds, as should be expected. In the thiocyanate group the value, 172.3 ± 1.3°, obtained for the S—C—N angle indicates that the group may not be linear. Least squares straight lines through the projected atoms, with the sulphur coordinates given three times the weight of the carbon and nitrogen coordinates, pass at shortest distances of 0.011 Å, 0.064 Å and 0.031 Å, respectively, from S, C and N in the *a*-projection, and at 0.002 Å, 0.012 Å and 0.007 Å in the *b*-projection. The largest deviation occurs for C in the *a*-projection, in which this atom is subject to heavy overlapping and may well have larger coordinate errors than corresponding to the e.s.d. of about 0.015 Å. Thus, the deviation from linearity of the thiocyanate group is probably not significant.

Table 3. Bond lengths and angles.

$C_1'-C_1 = 1.51 \pm 0.03$ Å	$\angle C_1'-C_1-S = 110.7 \pm 0.9°$
$C_1-S = 1.80 \pm 0.01$	$\angle C_1-S-C_2 = 99.4 \pm 0.7°$
$S-C_2 = 1.63 \pm 0.01$	$\angle S-C_2-N = 172.3 \pm 1.3°$
$C_2-N = 1.18 \pm 0.02$	

Some non-bonded distances within the molecule.

$C_1-C_2 = 2.61$ Å	$S-N = 2.80$ Å	$S-S' = 4.36$ Å
$C_1-N = 3.59$	$S-C_1' = 2.72$	$N-N' = 8.47$

The lengths found for the S—C and C—N bonds of the thiocyanate group, namely 1.63 ± 0.01 Å and 1.18 ± 0.02 Å respectively, can be interpreted in terms of the structures:

$$\diagup S-C\equiv N \qquad \text{and} \qquad \diagup \overset{+}{S}=C=\overline{N}$$

(I) (II)

The lengths of pure single, double and triple bonds are taken to be:

S—C = 1.78 Å	C=N = 1.26 Å
S=C = 1.59	C≡N = 1.16

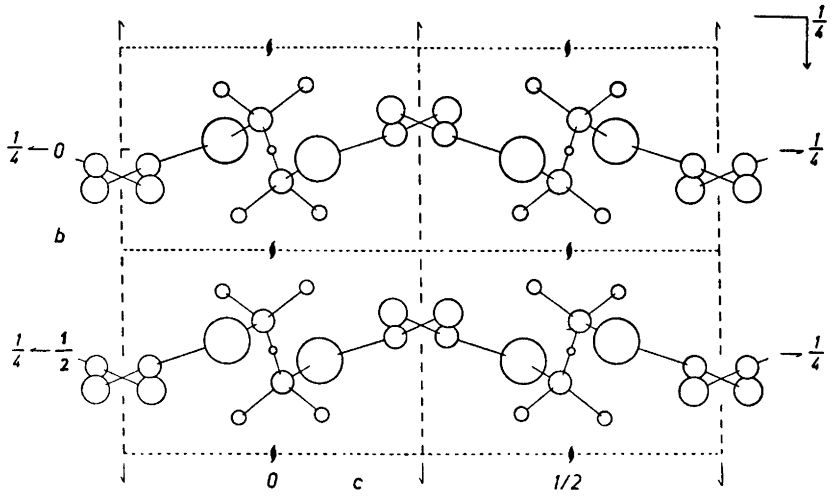

Fig. 6. The arrangement of molecules in the unit cell as seen along the *a* axis. In order of decreasing size the circles mark sulphur, nitrogen, carbon and hydrogen atoms.

In arriving at these figures, the single- and double-bond radii of carbon, 0.771 Å and 0.677 Å which are valid for sp^3 and sp^2 hybridization, respectively, of the carbon σ-bond orbitals, have been reduced by about 0.035 Å and 0.015 Å, respectively, to account for the *sp* state of hybridization of the carbon σ-bond orbitals in the thiocyanate group. The shortenings *cf.* [7,8] are based on evidence from C—H bonds with carbon in the appropriate valency states.

The found bond lengths indicate that structures I and II both contribute. The length of the thiocyanate group, *i. e.*, the S—N distance, is 2.80 Å whereas the calculated length is 2.94 Å for structure I and 2.85 Å for structure II. In view of the magnitude of the probable errors, and uncertainties in the bond order-bond length data, the results do hardly permit any conclusion beyond the one that structure II appears to be at least as important as structure I.

No structural data are available for other organic thiocyanates. Beard and Dailey [9] have made a microwave study of gaseous methyl thiocyanate, but did not determine the bond lengths. Assuming S—C = 1.61 Å and C—N=1.21 Å and a linear thiocyanate group, they arrived at 142° for the C—S—C angle, a value which appears unreasonable. Lindqvist's recent crystal structure determination of silver thiocyanate [10] led to S—C = 1.64 ± 0.03 Å and C—N = 1.19 ± 0.07 Å, and a not significant deviation from linearity of the thiocyanate group. The sulphur valency angle was here 180°, and also the nitrogen atom was covalently bonded to silver, so that the conditions are not quite comparable. The same applies to thiocyanic acid, which has the tautomeric structure H—NCS [11]. In the thiocyanate ion, from a crystal structure determination of the ammonium salt [12], the S—C and C—N bonds are 1.58 ± 0.02 Å and 1.24 ± 0.02 Å, and the ion linear. This corresponds to structure II above:

$S=C=\bar{N}$. More contribution of structure I is expected in a covalent thiocyanate, in agreement with the findings in ethylene thiocyanate.

The cyanogen halides, X—CN, are analogues of covalent thiocyanates in the respect that they contain a cyanide group linked to an atom with lone electron pairs. Particularly in the chloride, where X has nearly the same size as sulphur, conditions should be comparable, apart from the higher electronegativity of chlorine and thereby larger ionic character of the Cl—C bond relative to S—C. From microwave studies of the gases [13,14] the bond lengths in the linear cyanogen halide molecules are:

	ICN	BrCN	ClCN
X—C	1.995 Å	1.790 Å	1.630 Å
C—N	1.159	1.159	1.163

The C—N bond has in all three compounds close to triple-bond length, while the X—C bonds are about 0.1 Å shorter than single bonds. From nuclear quadropole coupling constants, estimates of the relative importance of structures corresponding to I and II were made for gaseous cyanogen iodide and bromide [15–17]. The data indicated 13 % contribution of II, X=C=N, in the iodide and 26 % in the bromide. In the chloride the percentage of II should be still higher, judging from the relative importance of $p\pi$-bonding from I, Br and Cl in aromatic compounds. Bonding conditions in the thiocyanate group thus appear to be about the same as in cyanogen chloride.

The ethylene thiocyanate molecule occurs in the *trans* configuration in the crystals, a molecular centre of symmetry being crystallographically required. This agrees with the finding from infrared measurements [18] that the compound exists in the *trans* form in the solid state, and with observations [19] that the stable form in the solid state of molecules of the types $X \cdot H_2C—CH_2 \cdot X$ and $X \cdot H_2C—CH_2 \cdot Y$ is, with few exceptions, the *trans* form. The cyanide groups are rotated out of the SCCS plane.

The arrangement of molecules in the unit cell as seen along the *a* axis is shown in Fig. 6. There are no particularly close intermolecular contacts.

Crystalline Myeloperoxidase

KJELL AGNER

Department of Clinical Chemistry, Serafimerlasarettet, Stockholm, Sweden *

A modified method for the preparation of myeloperoxidase, MPO, from pus of infected dog uteri is described. The most significant improvement is the use of a chromatographic procedure where the MPO is adsorbed on kieselguhr and later eluated from it by ammoniacal ammonium formate solution.

The myeloperoxidase has been obtained as a crystalline preparation with an iron content of 0.074 %. The enzyme behaved as would be expected for a single component in chemical and physical tests. Two atoms of porphyrin bound iron per enzyme molecule are indicated by chemical splitting of the enzyme.

The isolation of myeloperoxidase, MPO, in quantities, that will suffice for studies of the structure and properties of the enzyme, requires a starting material enriched in leucocytes or methods and equipments for separation of leucocytes from large quantities of blood.

The peroxidase preparation, described 1941 [1], was isolated from empyema fluid from tuberculous patients. This starting material has become progressively more scarce because of general medical progress. The separation of large quantities of leucocytes from blood presents certain difficulties. It has therefore been found necessary to search for another suitable starting material.

Infected dog uteri have proved appropriate. These uteri have been obtained as surgical specimens from the dog clinic at the Veterinary Institute. They have contained hemorrhagic or sometimes green coloured pus in varying amounts up to 1.5 liter. It has been possible to use the earlier published method of preparation [1] as a fractionation procedure for the purification of the MPO from this initial material. However, certain modifications have proved appropriate. The most significant of these is the adsorption of the MPO to kieselguhr and eluating the enzyme by ammoniacal ammonium formate solution.

* Present address: Department of Clinical Chemistry, S:t Görans sjukhus, Stockholm, Sweden.

PREPARATION PROCEDURE

Immediately after the operations the uteri have been taken to the laboratory and opened.

After step 3 in the preparation procedure given below the preparations usually have become purified to such an extent that it has been possible to determine the concentration of the MPO, the degree of purity, and the yield, by measurements of the absorbancy values at different wavelengths. At 430 mμ 1.0 mg of the crystalline MPO per ml has an absorbancy value of 1.2. The values for the ratios

$$\frac{\text{absorbancy}_{430\ m\mu}}{\text{absorbancy}_{280\ m\mu}} \quad \text{and} \quad \frac{\text{absorbancy}_{430\ m\mu}}{\text{absorbancy}_{390\ m\mu}}$$

has been the guidance for an approximate evaluation of the degree of purity of the preparations. The values of these ratios for the crystalline peroxidase are 0.82 and 2.0, respectively. Lower ratio values imply an admixture of impurities — proteins, heme components, etc. The figures for the amounts of MPO given for each step in the preparative procedure relate to the over-all yield from 100 ml starting material. The values are means of determinations from seven separate preparations. The variations between these values for different preparations lie within ± 35 %.

Step 1. Addition of ammoniacal ammonium sulphate solution. To every 100 ml of pus 10 ml of ammoniacal ammonium sulphate solution (800 ml of saturated ammonium sulphate solution + 100 ml ammonia) were added under stirring. At first there was a considerable gel-formation, which however, gradually disaggregated. The preparation was left at room temperature under stirring for 15—18 h.

Step 2. Precipitation with barium acetate. About 15 ml of saturated barium acetate solution were added for every 10 ml of the ammoniacal ammonium sulphate solution in the preceding step. The exact amount had to be checked for every preparation in order to avoid an excess of barium. After centrifugation the precipitate was discarded.

Step 3. Precipitation with ethyl alcohol at +5°C. The precipitate obtained at +5°C after addition of ethyl alcohol up to a concentration of 40 vol.% was discarded. The peroxidase was thereafter precipitated at about 65 vol.% ethyl alcohol. After centrifugation the precipitate was dissolved in saline.

Amount: 75 mg MPO per 100 ml of pus. Ratio: A_{430}/A_{280} = *ca.* 0.1.

Step 4. Precipitation of impurities with cadmium. Cadmium chloride solution (prepared from anhydrous powder) was added up to a concentration of about 0.02 M. The amount, which gave the optimum purification, had to be checked for every preparation. The precipitate formed was discarded after centrifugation.

Amount: 65 mg MPO per 100 ml of pus. Ratio: A_{430}/A_{280} = 0.22.

Step 5. Ammonium sulphate precipitation. The MPO was precipitated by ammonium sulphate at a concentration of 40—45 % saturation and thereafter dialysed against distilled water.

Amount: 55 mg MPO per 100 ml of pus. Ratio: A_{450}/A_{280} = 0.30.

Step 6. Adsorption on kieselguhr. Prior to its use, the commercial kieselguhr preparation was heated at 70—80°C in a large volume of 4 N hydrochloric acid solution, strained first with hot hydrochloric acid on a Büchner funnel until a negative qualitative test for iron in the wash water, and thereafter with distilled water until neutral reaction. The preparation was dried at 80°C.

For every 100 mg of MPO to be processed, 50—60 g of the dried kieselguhr powder were suspended in distilled water and packed in a chromatogram glass tube. The MPO preparation was then filtered through the column. In doing this the preparation was adsorbed on the powder in the two third upper parts of the column. The column was washed with saline and thereafter with an ammoniacal ammonium formate solution (prepared from a stock solution — equal amounts of 2 M ammonium formate and 1 M ammonium hydroxide — by adding 2 volumes of distilled water) until the eluate was free from substances absorbing at the wavelength of 280 mμ. Thereafter the MPO was eluated by the ammoniacal ammonium formate stock solution cited above.

The MPO in the eluate was precipitated with ammonium sulphate at 50 % saturation and thereafter dialysed against distilled water.

Fig. 1. MPO, recrystallized from ammoniacal ammonium sulphate solution. Dark field illumination. 300 × magnification.

Amount: 40 mg MPO per 100 ml of pus. Ratio: $A_{430}/A_{280} = 0.80$; $A_{430}/A_{390} = 1.95$.

Step 7. Crystallization from ammonium sulphate solution. Ammoniacal ammonium sulphate solution (50 volumes of saturated ammonium sulphate solution + 1 volume of ammonia) was added to the MPO solution up to a degree of saturation of about 0.40. Thereafter very small quantities of the ammonium sulphate solution were added with intervals of 2—3 h until thyxotropy was observed. After two or three days the greater part of the MPO had crystallized. The MPO-crystals separated as needles and displayed double refraction; Fig. 1.

ANALYSIS

The crystalline preparation obtained by the described procedure has been checked for homogeneity by ammonium sulphate solubility test, Fig. 2, electrophoresis at different pH-values, ultracentrifugation and diffusion. In

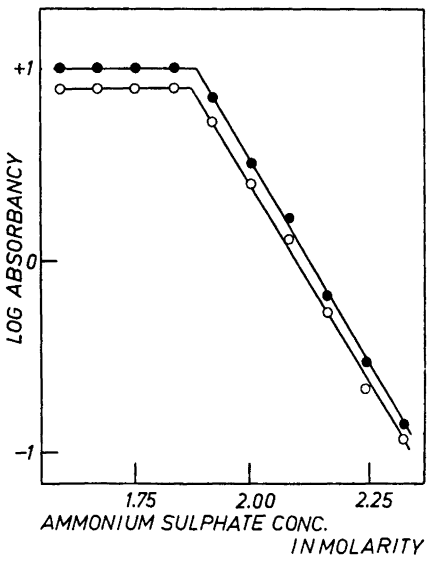

Fig. 2. Solubility of recrystallized MPO in solutions of increasing ammonium sulphate concentrations determined by spectrophotometric readings at 430 and 280 mμ. The MPO conc.: 7 mg/ml.

○—○—○ log absorbancy, 430 mμ

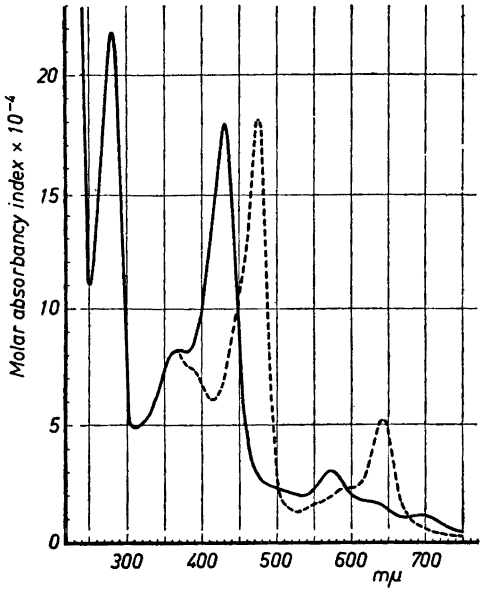

Fig. 3. Molar absorbancy index of oxidized and reduced MPO.

———— MPO oxidized
– – – – – MPO reduced

all these experiments the preparation behaved as expected for a single component. The results from the ultracentrifugation and diffusion experiments, as well as the estimation of the molecular weight, 149 000, will be described in a separate paper [2].

The molar absorbancy index values [3], A_μ, for the MPO at different wavelengths have been calculated from the absorbancy readings obtained in a Beckman spectrophotometer, model DU and are summarized in Fig. 3.

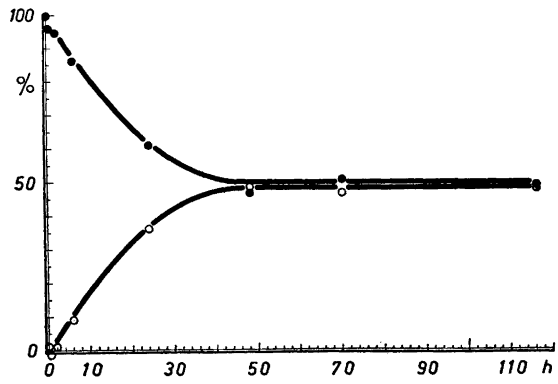

Fig. 4. Distribution of the iron after fractionation by methyl alcohol from 50 % pyridine solution after varying time.

●—●—● percentage of iron, "insoluble in methanol"

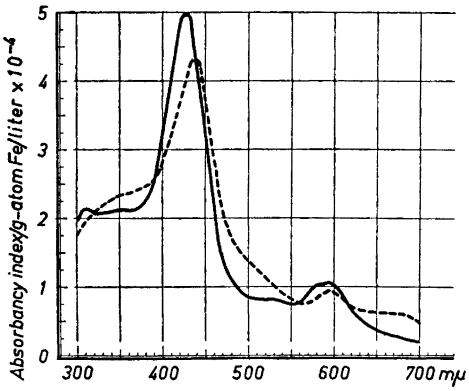

Fig. 5. Absorbancy index/g-atom Fe/liter for
the iron compound "soluble in methanol" ————
» » » "insoluble in methanol" — — — — —

The iron content of the MPO has been analysed by a modification of the method described by Lorber [4]. It was found to be 0.74 μg per mg of dry weight.

After addition of concentrated sulphuric acid and perchloric acid (0.2 ml of each) the preparation (2—8 mg) was combusted in test tubes (140 × 15 mm) at about 250°C. The heating was extinguished when the white heavy vapour had disappeared. The sample was diluted, 0.2 ml of a 20 % solution of sulphosalicylic acid was added, followed by ammonia until a yellow colour was produced. After dilution of the sample up to 5 ml the colour intensity was determined at 455 mμ in a Beckman spectrophotometer, model B, equipped with a special adapter for 50 mm long and 4 mm wide cuvettes. Absorbancy = 0.100 per μg of iron in the sample.

Procedures described for a fission of the linkages between the iron-porphyrin structures and their protein moieties by treatment with acid acetone or with some metals, e.g. silver ions, have been found to be unsuitable for breaking the bonds between the iron-porphyrin compound and the protein of the MPO. The effect of some other substances upon the MPO has been studied. It has been found that MPO splits into two parts in 50 % pyridine solution. The separation of the two fragments has been achieved by precipitation of one of them by adding 4 volumes of methyl alcohol. The second fragment is soluble in methyl alcohol. Fig. 4 demonstrates the velocity of this reaction at room temperature (about 22°C).

The reaction is a rather slow one at room temperature. The velocity increases at higher temperature. At 70°C the fission was completed within 60 min.

The absorbancy index values per g-atom of iron per liter have been determined for the two split products dissolved in 50 % pyridine solution, Fig. 5.

DISCUSSION

The crystalline MPO obtained from dog leucocytes by the procedure described above has proved to behave as would be expected for a homogeneous substance in ammonium sulphate solubility tests, ultracentrifugation, and

electrophoretic experiments at different pH-values. The molecular weight for the dog MPO calculated from the sedimentation and diffusion constants and the value for the specific volume is found to be 149 000 [2]. The iron content of the enzyme is 0.074 %. The theoretical value for the iron content, when assuming two atoms of iron per molecule of MPO, is 0.075 %. The experimental results suggest that the preparation is homogeneous and can be characterized as »pure».

The absorbtion spectrum and other properties investigated are very similar to those found for the preparations from the human starting material in 1941. The figure for the iron content given for the earlier preparation (1941) from human leucocytes was 0.1 %. However, according to the analyses, mentioned above, the iron content is found as 0.074 %. The molar absorbancy index calculated for the MPO from dog leucocytes is about 25 % higher than the values found for the preparation in 1941 *. These differences may reflect a diversity in characteristics of the MPO from the two different species. However, it cannot be excluded that the explanation for the differences might be a misinterpretation of the iron content in the previous experiments due to a shortage of material.

When acid acetone is added to hemoglobin, myoglobin, catalases, horse radish peroxidase, cytochrome a and b, the prosthetic group is released from the protein part which precipitates, while the prosthetic group remains in the dissolved state. Likewise the cysteine-porphyrin bonds in cytochrome c have been found to be broken by treatment with $AgNO_3$ and some other metal salts. If these procedures be applied to the MPO the whole molecule is precipitated without fission; therefore, the linkages between the porphyrin and the protein are more stable in this respect. By treatment with pyridine the MPO molecule is split into two parts. Each of them contain almost exactly 50 % of the original amount of iron and, thus, one atom of iron. The two components, when dissolved in 50 % pyridine solution, have absorbtion spectra, which indicate that both of the iron atoms are incorporated in porphyrin structures.

At present it is not possible to ascertain whether the two prosthetic groups are linked to the protein differently or if the findings are due to a splitting of the protein moiety into two parts.

The Molecular Weight of Myeloperoxidase

ANDERS EHRENBERG and KJELL AGNER*

Biochemical Department, Nobel Medical Institute, Stockholm, Sweden

The molecular weight of myeloperoxidase with an iron content of 0.074 % has been determined to be 149 000, which means that there are two atoms of iron per enzyme molecule. The calculations are based upon experimental results indicating a sedimentation coefficient at infinite dilution of 7.93 *S*, a diffusion coefficient of 4.81 *F* and a partial specific volume of 0.731 ml/g.

Myeloperoxidase [1] (MPO) has recently been obtained as a highly purified and crystalline preparation with an iron content of 0.074 % [2]. Therefore, it has been of interest to determine the sedimentation and diffusion coefficients of the enzyme as well as its partial specific volume and by means of these values to calculate the molecular weight.

METHODS

Sedimentation. The sedimentation studies were carried out in a Spinco analytical ultracentrifuge, model E, at a rotor speed of 59 780 rpm. The centrifuge was equipped with an automatic rotor temperature control. The inclined bar was used as schlieren diaphragm in most of the experiments; in a few cases the bar was replaced by a phase-plate [3], that facilitated the evaluation of the exposures but did not effect the results.

The sedimentation velocity was determined for enzyme concentrations from 0.8 up to 30 mg per ml. Temp. 20°C. The MPO was in these experiments as well as in the diffusion experiments stated below dissolved in phosphate buffer, 0.05 N, pH 7.0, containing also 1 % NaCl.

Diffusion. The diffusion experiments were made in a Spinco diffusion and electrophoresis instrument at a temperature of 1.17° C. Boundary sharpening was obtained by suction with a long hypodermic syringe needle cut perpendicular to its axes, and the diffusion process was followed over a period of 43 h. The optics were adjusted for studying the Rayleigh-Calvet-Philpot-interferogram at 546 mμ, and the number of fringes and the position of maxima and minima were measured out visually by means of the optical arrangements of a Hilger densitometer for spectrograms, using the slit plane as a projection screen. The cell magnification was 1.007. The diffusion coefficients were evaluated according to the "height-area" method as described by Svensson [4] and according to the moment method also described by Svensson [5] but slightly modified here.

Partial specific volume. The partial specific volume was determined for solutions of MPO, extensively dialysed against distilled water. The density was determined in a pycnometer of Sprengel-Ostwald type at 24°C.

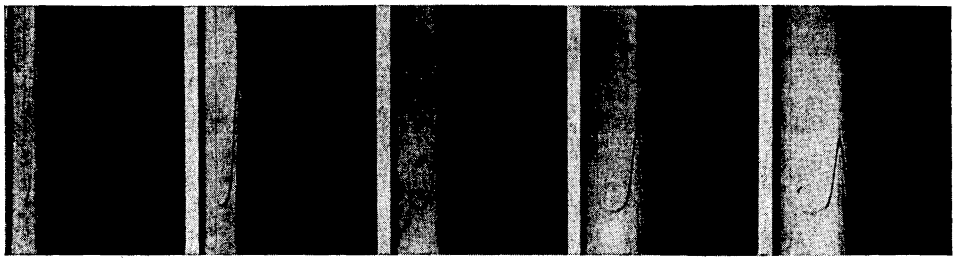

Fig. 1. Photographs taken in the ultracentrifuge during sedimentation of a myeloperoxidase solution of 10 mg/ml. First exposure taken 7 min after full speed was attained. Exposure intervals 8 min.

RESULTS

Sedimentation coefficient. The enzyme appeared to be homogeneous as far as could be judged from the photographs of the ultracentrifuge experiments, Fig. 1. The sedimentation coefficients were evaluated both from drawings made from magnified pictures and from measurements made directly on the plates in the Hilger densitometer. By means of the least square method the two sets of data were separately fitted to the equation

$$S^0_{20} = S_\infty - \beta a$$

where S_∞ is the sedimentation coefficient extrapolated to infinite dilution and a is the mean concentration of myeloperoxidase during the sedimentation in

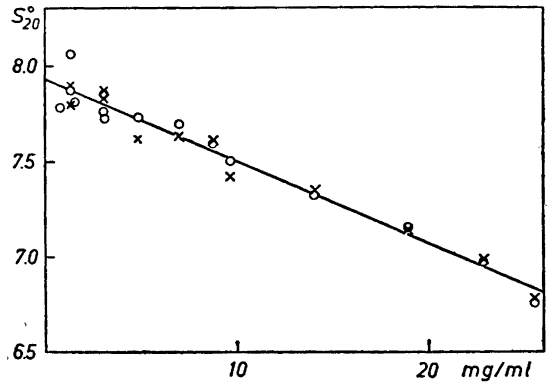

Fig. 2. Concentration dependence of the sedimentation coefficient of myeloperoxidase. Abscissa: mean protein concentration during observation in the ultracentrifuge. Ordinate: Sedimentation coefficients S^0_{20} calculated from enlarged drawings of the photographs O, and from comparator readings directly on the photographs, ×. The drawn line has been fitted to the points by the least square method.

Table 1. Diffusion data obtained by the "height area" method.

Conc.	t_0	$D_{1.17}$	D^0_{20}
mg/ml	sec	F	F
2.50	−2 170	2.467	4.813
1,30	−2 000	2.474	4.826

mg/ml. S_∞ was found to be 7.935 and 7.915 S, respectively, and β was 0.04359 and 0.04215 S ml.mg^{-1}, respectively. The following equation

$$S^0_{20} = 7.93 - 0.0429 \cdot a$$

may thus be accepted as the equation of the line that best fits the experimental data, Fig. 1.

Diffusion coefficient. Two concentrations were studied, 2.50 and 1.30 mg/ml, corresponding to the total fringe numbers of 38.50 and 20.31. When the "height-area" method was applied, the fringe interval Δn used in calculating the maximum fringe density, n'_{max}, was accordingly chosen as 10 and 5, respectively [4]. In the former experiment 6 exposures were evaluated and in the latter 8. In Fig. 3 plots have been made of $(1/n'_{max})^2$ *versus* the time and the best fitting lines, as calculated by the least square method, have been drawn. The numerical data are given in Table 1. The apparent starting time, t_0, is slightly negative because of the impossibility to produce a completely sharp boundary.

Three exposures from each experiment were also evaluated according to the moment method. The equation to be used has the following form [5]

$$D_m = \frac{\int_{n_0}^{n_c} x^2 dn}{2(t-t_0)(n_c-n_0)} = \frac{a}{t-t_0} \qquad (1)$$

where n denotes the refractive index increment measured in fringe numbers ($n_0 = 0$ and $n_c = n_{tot}$), x is the fringe coordinate measured from the center of the boundary, and t is the time of the exposure. Since the myeloperoxidase is strongly coloured, only dilute solutions could be studied, and n_{tot} was small. It thus appeared difficult to estimate the limiting parts of the integral, since x approaches infinity when n approaches zero or n_{tot} and it had to be extrapolated over relatively large intervals. This difficulty was avoided by taking the integral only over the interval that really was covered by the fringes that could be measured in the comparator. For instance, if the first minimum, $n = 0.5$, could be read, and Simpsons formula was used for the numerical integration, the lower limit, μ, of the integral equals 0.5; if instead the trapets

formula was used, $\mu = 0.25$. The same is valid for the upper limit. To compensate for the smaller interval of integration, a of eqn. (1) must be changed into the form

$$a = \frac{\int_{\mu}^{\nu} x_2 \mathrm{d}n}{2n_{tot} \int_{z_\mu}^{z_\nu} z^2 \frac{1}{\sqrt{2\pi}} \cdot e^{-\frac{1}{2}z^2} \mathrm{d}z} \qquad (2)$$

The two integrals are proportional as long as the diffusion is ideal. In the denominator integral the normalized error function $f(z) = \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}z^2}$ has been used. The corresponding limits of integration are readily found from any table of that function including its integral, since $\int_0^{z_n} f(z)dz = \frac{n_{tot} - 2n}{2n_{tot}}$. A table of the integral $\int_{-\infty}^{z} z^2 f(z)\, dz$ is easily constructed from the data of the error function table, and the denominator integral of eqn. (2) is calculated by means of the formula

$$\int_{z_\mu}^{z_\nu} z^2 f(z)dz = 1 - \int_{-\infty}^{z_\mu} z^2 f(z)dz - \int_{z_\nu}^{+\infty} z^2 f(z)dz$$

after interpolation of the values of the two later integrals in the constructed table.

Table 2. Diffusion data obtained by the moment method. t_o is taken from Table 1.

Conc.	t	$t-t_o$	$a \times 10^2$	$D_{1.17}$	D°_{20}
mg/ml	sec	sec	cm²	F	F
2.50	23 640	25 810	0.6406	2.482	4.84
	66 840	69 010	1.696	2.457	4.79
	154 200	156 370	3.845	2.459	4.80
			Mean value		4.81
1.30	20 820	22 820	0.5643	2.473	4.82
	64 020	66 020	1.644	2.490	4.86
	93 120	95 120	2.302	2.420	4.72
			Mean value		4.80

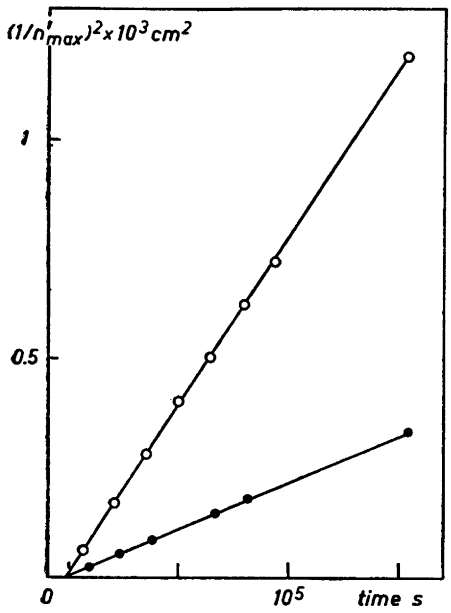

Fig. 3. Graphs from which the diffusion coefficients have been calculated according to the "height-area" method. Abscissa: time of exposure measured from end of boundary sharpening procedure. Ordinate: inverted square of maximum fringe density. Protein concentrations 2.50 mg/ml, ●, and 1.30 mg/ml, O.

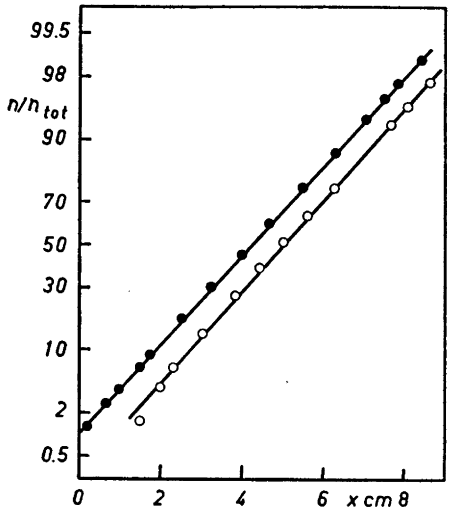

Fig. 4. Plots on a normal distribution graph showing the fit of boundary shape to that required by the ideal law of diffusion. Abscissa: measured fringe coordinates. Ordinate: relative fringe numbers. Exposures for 2.50 mg/ml at 66 840 sec, ●, and for 1.30 mg/ml at 64 020 sec, O. The drawn lines correspond to $D^{\circ}_{20} = 4.81\ F$.

The results obtained by the moment method are collected in Table 2. The zero time corrections as found by the "height-area" method have been used. For the protein concentration 2.50 mg/ml the mean value of D°_{20} is 4.81 F and for 1.30 mg/ml it is 4.80 F. It is not necessary to use the zero time corrections obtained by the "height-area" method, since according to eqn. (1) a plot of α *versus* time directly would give D_m as the slope of the line. This would, however, necessitate the evaluation of several exposures, which is rather time consuming.

The close agreement between the values obtained by the two methods might be considered as indicating that the diffusion is ideal and follows Fick's law. No dependence on protein concentration could be detected, and the mean value of all the data, $D^{\circ}_{20} = 4.81\ F$, is taken as the best value of the diffusion coefficient for the concentration range studied.

How closely the concentration distribution of the boundary fits the requirements of the law of ideal diffusion can be studied in detail in the way that has been described by Svensson [4]. A convenient and rapid method, that was

suggested to us by Lindqvist *, makes use of commercially available normal distribution graphs. On these graphs the ordinate is adjusted so that a straight line is obtained, when the integral

$$\int_{-\infty}^{z} \frac{1}{\sqrt{2\pi}} e^{-\frac{1}{2}z^2} dz$$

is plotted as a function of z. In Fig. 4 the relative fringe numbers n/n_{tot} have been plotted *versus* the fringe coordinates for two exposures, one for each concentration. The drawn lines correspond to $D^{\circ}_{20} = 4.81\ F$, and minor deviations of the points from the line is only seen in case of the lower concentration.

Partial specific volume. The apparent partial specific volume was determined in three experiments at the protein concentrations 26.17, 36.39 and 27.90 mg/ml. The following values were found: 0.732, 0.730 and 0.730. Mean value 0.731 ml/g.

DISCUSSION

Insertion of $S^{\circ}_{20} = 7.93\ S$, $D^{\circ}_{20} = 4.81\ F$ and $V = 0.731$ ml/g in the Svedberg formula yields a molecular weight of 149 000 for myeloperoxidase. The iron content of the enzyme has been determined to be 0.074 % which corresponds to an equivalent weight of 75 500 per iron atom. Each molecule of myeloperoxidase contains thus two atoms of iron — in contrast to other hitherto analyzed heme proteins which contain either one or four iron atoms per molecule.

The fricitional ratio f/f_0 is calculated to be 1.26. If the molecule is an unhydrated rotational ellipsoid the axial ratio would thus be about 5: 1.

Acknowledgements. The authors wish to thank Professor T. Storgårds and Mr. B. Lindqvist at Mjölkcentralen Laboratories, for making their Spinco diffusion and electrophoresis instrument available. Special thanks are due to Mr. B. Lindqvist for making the diffusion experiments and for helpful discussions. It is a pleasure to thank Mr. J. Grabosch, Mr. K. Ingebrigtsen and Mr. N. Ekman for valuable technical assistance. Financial support was obtained from *Stiftelsen Gustaf och Tyra Svenssons Minne* and *Knut och Alice Wallenbergs Stiftelse.*

On the Reactions and Biosynthesis of Azetidine-2-carboxylic Acid

PEKKA LINKO*

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

The hydrolysis of azetidine-2-carboxylic acid is studied.

β-Naphthoquinone sulphonate is presented as a sensitive and specific reagent for compounds containing the =CH—NH—CH= group.

Homoserine, which does not occur free in *Convallaria majalis*, is found in the acid hydrolysates of the "peptide fraction".

Uniformly labelled aspartic acid is infiltrated into the leaves of *Convallaria majalis* and the incorporation of radioactivity is followed. No activity is found in azetidine-2-carboxylic acid. Aspartic acid is readily decarboxylated to both α- and β-alanine. From the other compounds glutamic acid is primarily labelled. The activity accumulates in asparagine, glutamine and an unknown glutamic acid derivative. In the "peptide" fraction hydrolysates aspartic acid, glutamic acid and serine are labelled, whereas in the protein hydrolysates only aspartic acid is found to be labelled.

The metabolic role of azetidine-2-carboxylic acid is discussed.

Only a few years ago Miettinen *et al.*[1] for the first time isolated and identified homoserine as a free amino acid in pea *(Pisum sativum)*. According to earlier experiments [2] based only on chromatographical evidence it was known to occur in *Neurospora*. Later homoserine has been found to be widely distributed in the plant kingdom [3].

Though homoserine is rather a "newcomer" among the free amino acids in plants, some of its derivatives have been known for a long time. Kitagawa and Tomita [4] as far back as 1929 isolated canavanine, α-amino-γ-guanidinoxybutyric acid, from *Canavalia ensiformis*. Recently canavanine was also found in *Colutea arborescens* [5]. Pantonine, another homoserine derivative, was isolated from *Escherichia coli* [6]. Because there was already strong evidence for the importance of homoserine and its derivatives in the metabolism of plants, the recent discovery of azetidine-2-carboxylic acid in some *Liliaceae* plants

* Present address: Kansas State College, Department of Flour and Feed Milling Industries, Manhattan, Kansas, U.S.A.

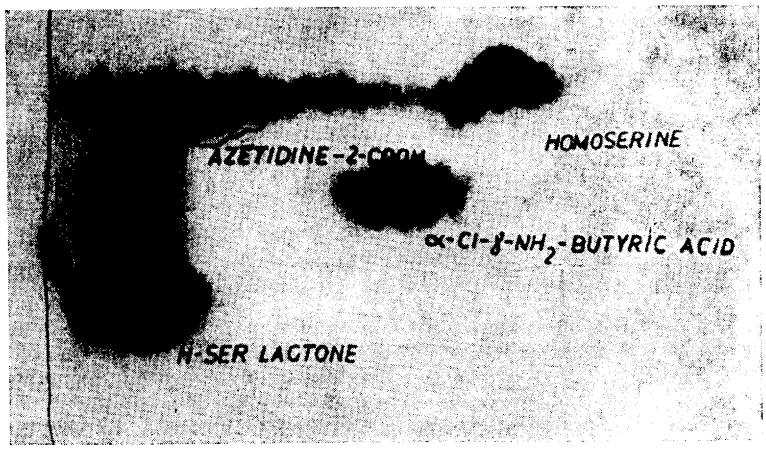

Fig. 1. The products of hydrolysis of azetidine-2-carboxylic acid by means of 6 N hydrochloric acid (sealed tube, 20 h, 100°C).

was very interesting [7–9]. This imino acid may be related to α,γ-diaminobutyric acid [10,11] or to its deamination product, aspartic-α-semialdehyde. This known intermediate in the reduction of aspartic acid to homoserine [12,13] is found to occur in yeast [14]. Hence the possibility that azetidine-2-carboxylic acid may be formed from aspartic acid in the leaves of *Convallaria majalis* was examined.

HYDROLYSIS OF AZETIDINE-2-CARBOXYLIC ACID

When azetidine-2-carboxylic acid is subjected to hydrolysis with hydrochloric acid three new spots on the chromatograms are observed in addition to that corresponding to the small amount of unchanged compound (Fig. 1) [15,7]. Two of these spots were identified as homoserine and γ-amino-α-chlorobutyric acid [9], the relative amount of the latter being [15] only about 5 %. The third compound, homoserine lactone [15], formed secondarily from homoserine, is evidently identical with spot S_3 of Fowden, which he in turn describes as α-amino-γ-chlorobutyric acid but which could not, however, be synthesized. This compound was isolated in crystalline form as the hydrochloride. It gave the typical lactone reaction with ferric chloride and hydroxylamine, could easily be hydrolysed to homoserine by barium hydroxide and was finally found identical with the synthetic product of Armstrong [16]. The optical rotation determined as a function of time (Fig. 2) was in good agreement with Armstrong's results. In contrast to the observation of Fowden that azetidine-2-carboxylic acid is stable against alkalies it was found that 4 N sodium hydroxide caused some decomposition already on standing at room temperature. Only homoserine was formed during alkaline hydrolysis. Ammonia and acids, however, did not cause decomposition at this temperature.

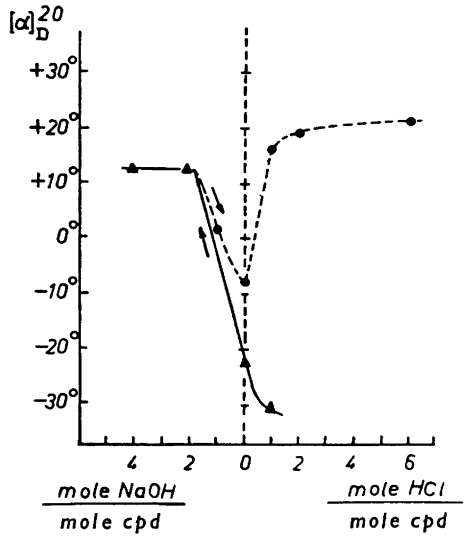

Fig. 2. The optical rotation of homoserine (---) and its lactone (———) as a function of pH.

β-NAPHTHOQUINONESULPHONATE REAGENT

Müting [17] and Giri and Nagabushanan [18] detected that α-naphthoquinonesulphonate gives, with most of the amino acids and their derivatives, colors varying from green to bluish when the paper chromatogram is dipped into the reagent. Only proline was found to give a red color reaction. Because azetidine-2-carboxylic acid also gave an intensive red color reaction, several other secondary amines were studied in respect to this reagent. Hydroxyproline, piperidine-4-carboxylic acid, sarcosine and N-phenylglycine developed a strong red color, whereas the red color caused by piperidine-2-carboxylic acid and its 5-hydroxyderivative was somewhat weaker. With peptides and N-acetylderivatives of amino acids the normal bluegreen color was obtained. The reaction is about as sensitive to secondary amines as ninhydrin and therefore seems to be a good specific reagent for the compounds containing the = CH—NH—CH= group. As the only exception so far known 1-amino-*cyclo*propane-1-carboxylic acid developed a weak red color [19].

ON THE BIOSYNTHESIS OF AZETIDINE-2-CARBOXYLIC ACID

The amount of azetidine-2-carboxylic acid in young *Convallaria majalis* plants was about 20 % or even more of the ethanol soluble nitrogen compounds. When the plants started to turn yellow in the fall, the relative amounts of most of the free amino acids increased (Fig. 3). The only noticeable exception was azetidine-2-carboxylic acid which had almost disappeared from the completely yellow plants. This is in good agreement with the results of Kemple and Macpherson [20] who noticed that the amount of all protein amino acids increased in the ethanol soluble fraction during the drying of grass. All the nitrogen

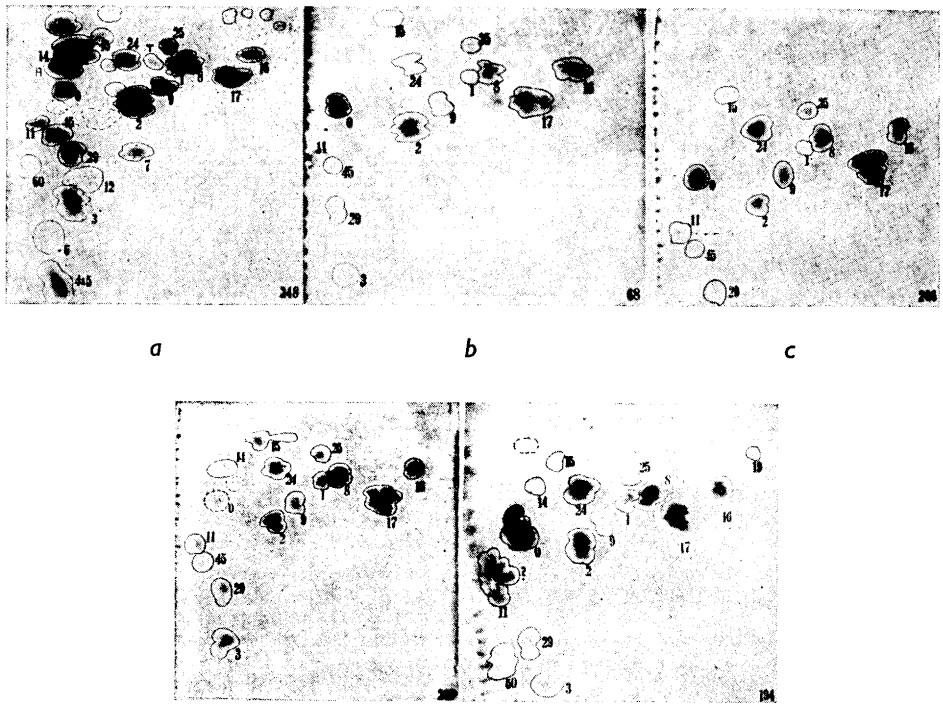

Fig. 3. Free amino acids of *Convallaria majalis*. *a*, Seeds; *b*, young leaves; *c*, partly yellow leaves; *d*, completely yellow leaves; *e*, soft part of ripe berries. 1 = gly, 2 = ala, 3 = val, 4 & 5 = leu + ileu, 6 = β-ala, 8 = ser, 9 = threo, 11 = prol, 12 = tryptophane, 14 = arg, 15 = lys, 16 = asp, 17 = glu, 24 = glu-NH_2, 25 = asp-NH_2, 29 = γ-AB, 45 = ethanolamine, 60 = piperidine-2-carboxylic acid, 0 = azetidine-2-carboxylic acid, ? = unknown compound.

liberated from proteins could be found in the free amino acids, amides, peptides and volatile bases.

During the disappearance of azetidine-2-carboxylic acid no homoserine or other "new" amino compounds were formed. However, great amounts of the imino acid were detected in the soft parts of ripe berries, while almost none was found in the seeds. It may be of interest to mention here that 1-aminocyclopropane-1-carboxylic acid also exists only in ripe fruits [19,21]. Two unknown amino compounds, which could not be detected in the other parts of the plants, were also found in the berries of *Polygonatum officinale*. One of them was isolated by fractionation on a Dowex 50 cation exchange resin column and identified as tyramine. This amine was found [22] in *Viscum album* already 1916. Later it was isolated from *Sarothamnus* [23,24] and chromatographically identified in some other plants [24,25]. The other unknown compound

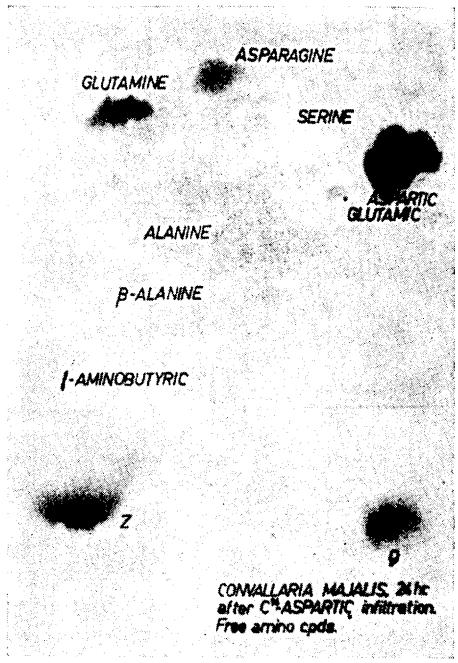

Fig. 4. Radioautogram of the amino compound fraction of *Convallaria majalis*. 24 h after uniformly labelled aspartic acid infiltration.

marked with a question mark in Fig. 3 e has not yet been identified. Both the place on the chromatogram and the graybluish color reaction with ninhydrin are characteristic to many amines.

Virtanen *et al.*[26] noticed that homoserine, which did not occur either in free state or bound in pea seeds, was rapidly formed during germination. Already after 72 h this compound was the most abundantly appearing free amino acid. After five days the relative amount of homoserine had still increased while glutamic acid and serine had decreased. The young stem and root now contained far greater amounts of homoserine than did the seed. Examination of *Convallaria* in this respect was very difficult because the seeds do not easily germinate. With a few seeds it could, however, be shown that azetidine-2-carboxylic acid behaved like homoserine during the germination of seeds.

The observation of Fowden and Steward[27] that azetidine-2-carboxylic acid was found in all parts of *Convallaria*, but in some other species only in leaves or in seeds, respectively, may be due to the changes in concentration of this compound in different parts of plants during various stages. It is interesting that in the leaves of *Fritillaria meleagris* γ-methyleneglutamic acid but no azetidine-2-carboxylic acids was found whereas in the seeds of *Fr. imperialis* the situation was quite the opposite.

The phosphorylation of the β-carboxyl group of aspartic acid is now known to be the primary reaction in threonine biosynthesis in yeast. β-Aspartyl-

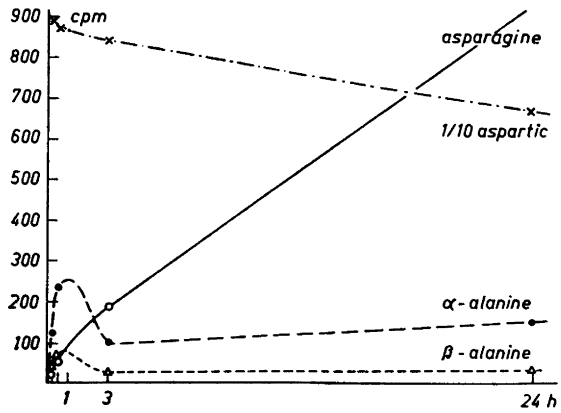

Fig. 5. Relative activities of aspartic acid and its direct biosynthetic products in *Convallaria majalis* after uniformly labelled aspartic acid infiltration.

phosphate can quantitatively be reduced to homoserine by means of a specific enzyme isolated from baker's yeast [13]. A few years later [28] it was noticed that incubation of rat liver homogenate with DL-2-^{14}C-homoserine induced labelling into α-ketobutyrate, α-hydroxybutyrate, α-aminobutyrate and propionate, but no labelling was found in threonine, methionine, alanine and α-keto-γ-hydroxybutyrate. Therefore, in this case the primary reaction would be identical with the dehydration of threonine and serine. However, α-keto-γ-hydroxybutyric acid is now known to occur in higher plants [29].

The cyclization of aspartic β-semialdehyde is the most likely reaction leading to azetidine-2-carboxylic acid. A similar type of reaction is known in the conversion of δ-aminolaevulinic acid to the porphyrin ring [30]. 4-Carb-

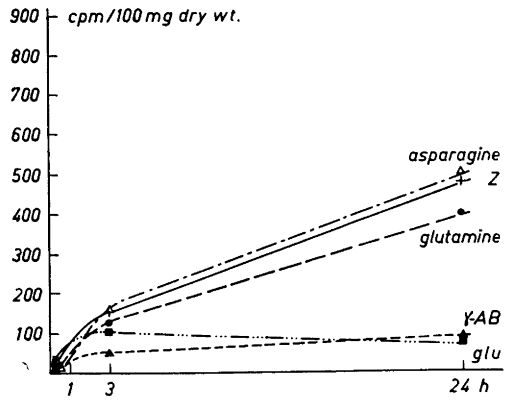

Fig. 6. Total radioactivity changes in *Convallaria majalis* after uniformly labelled aspartic acid infiltration.

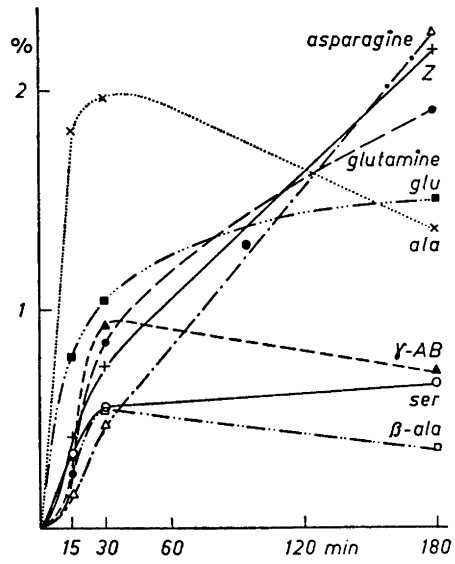

Fig. 7. The percentage of radioactivity in the individual amino compounds calculated from the total ethanol soluble activity in *Convallaria majalis* after uniformly labelled aspartic acid infiltration.

oxyl-azetidinone is also known to be formed synthetically from asparagine in phosphate buffer[31] (pH 6.7; 100°C). Uniformly labelled aspartic acid was therefore infiltrated into the leaves of young *Convallaria majalis* plants grown in the greenhouse. Similar methods were used as described earlier[32]. After half an hour there was a slight minimum in the percentage of activity of the amino compound fraction as compared to the total ethanol soluble activity. After 24 h the activity of this fraction was still 90 % of the total soluble one. No radioactivity could be found in azetidine-2-carboxylic acid (Fig. 4). Both carboxyl groups of aspartic acid were readily decarboxylated α- and β- alanine respectively, being formed (Fig. 5). The β-carboxyl was more rapidly removed. The activity of both decarboxylation products had a peak after about one hour showing that they were rapidly metabolised further. From the other compounds glutamic acid was primarily formed. After short lag periods activities in both asparagine and glutamine increased countinuously. The same was due to an unknown compound, Z, which yielded glutamic acid as the only active component on acid hydrolysis (Figs. 6 and 7).

In the acid hydrolysates of the proteins only aspartic acid was found labelled, but when the "peptide" fraction was subjected to acid hydrolysis aspartic acid, glutamic acid and serine were found to be labelled (Fig. 8). Practically all the amino acids, except azetidine-2-carboxylic acid, were found to occur in the hydrolysates. The percentage of the activity of aspartic acid had a peak after half an hour, glutamic acid being the main labelled product after 24 h. It was very interesting to find that though azetidine-2-carboxylic acid was absent in this fraction, inactive homoserine was always found in the hydrolysates. This cannot arise from azetidine-2-carboxylic acid during hydrolysis, because no α-chloro-γ-aminobutyric acid could be detected on

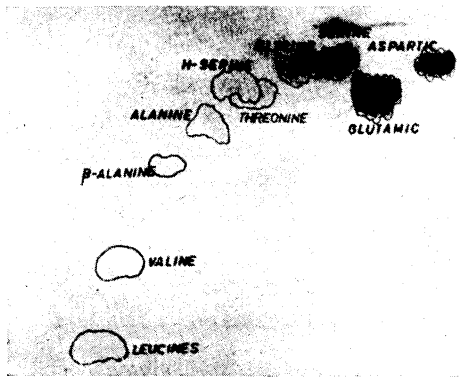

Fig. 8. A ninhydrin sprayed chromatogram of amino acids arising from the "peptide" fraction of *Convallaria majalis* in acid hydrolysis. The darkened spots were labelled after uniformly labelled aspartic acid infiltration.

the chromatograms. The experiments performed in order to show the synthesis of azetidine-2-carboxylic acid from inactive homoserine by the method of Miettinen and Virtanen [33] failed, but this could be due to the great amount of azetidine-2-carboxylic acid originally present, making comparisons very difficult. Recently, bound homoserine was found in the ethanol insoluble fraction of cowberries and cranberries [34]. Even in this case no free homoserine was found, but the berries of cowberries contained a cyclic four-carbon amino acid, 1-amino-*cyclo*propane-1-carboxylic acid [19]. It may also be mentioned here that strains of *Neurospora* requiring homoserine for growth also grow with canavanine [35].

That no radioactivity was found in azetidine-2-carboxylic acid after ^{14}C-aspartic acid infiltration may partly be due to the small amount of labelled aspartate available as compared to the relatively great amount of azetidine-2-carboxylic acid originally present in the plant thus causing great dilution of the possible active synthetic product with inactive material. However, it is most evident that the rate of synthesis of azetidine-2-carboxylic acid is much lower in the leaves than in young sprouts and that this compound may arise from the compound present in the "peptide" fraction which yields homoserine on acid hydrolysis and which in turn may be formed from aspartic acid *via* aspartic-β-semialdehyde.

I am greatly indebted to Professor Artturi I. Virtanen for his keen interest in this work and for the excellent working facilities put at my disposal. I am also indebted to Dr. Armstrong who kindly supplied samples of some synthetic homoserine derivatives.

This paper belongs to the group of investigations for which the *Rockefeller Foundation* has awarded a grant to the Foundation for Chemical Research.

Fractionation of the Lipids of Eye Lenses by Gradient Elution on Activated Silicic Acid Columns

SVEN ELOV BROLIN

Histological Department, University of Uppsala, Sweden

Dried and powdered eye lenses were extracted with chloroform and the extract was fractionated by gradient elution from activated silicic acid columns. The elution of the phospholipids was studied and several peaks with different properties were obtained. Some figures are given for the composition of the lipids from a sample of cattle eyes obtained from a Swedish abattoir.

Chloroform extracts of lens tissue contain fluorescent substances and during the present investigation attempts have been made to fractionate these. The methods previously available were not suitable for the requirements of this separation. The usefulness of silicic acid columns was demonstrated by Borgström [1] and it has been used successfully in lipid chromatography by Lea and Rhodes [2]. The theory and application of gradient elution has been described by Tiselius and coworkers (for references see Lederer and Lederer [3]).

The chemical composition of the lipids of the eye lens has been described in detail and a survey of the literature has been given by Bellows [4]. However as in other branches of lipid research the application of chromatography should provide further information on the separation and determination of the various components. The fluorescent material in the different chromatographic fractions will be described in a later paper.

MATERIAL AND METHODS

Preparation of the lipid sample. The lenses from 3 500 cattle eyes were smeared on glass plates and dried at 37°. This material was scraped off, ground in a porcelain ball mill and then extracted with chloroform in a Soxhlet for 72 h. After evaporation under reduced pressure the lipid sample was redissolved in chloroform and filtered again.

Chromatographic procedure. The columns were prepared mainly following the directions of Borgström [1]. Silicic acid (Baker) was washed with chloroform and ethanol until no further fluorescent matter was removed and then activated at 120°C for 24 h. 20 mm columns were packed with a mixture of this silicic acid powder (10 g) and filter aid (Hyflo supercel, 5 g) suspended in chloroform. A solution of the lipid extract (300 mg) in chloroform (50 ml) was poured onto each column and the column was then washed

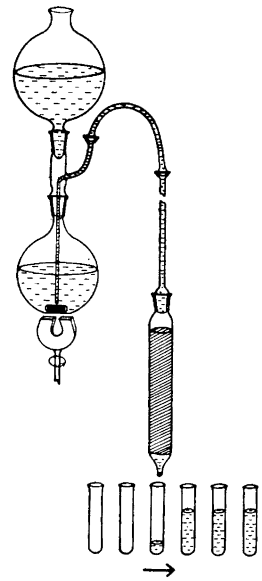

Fig. 1. The gradient elution apparatus. The solvent in the mixing chamber is mixed with a magnetic stirrer. Gradient elution is started by replacing the top vessel containing chloroform with one containing the chloroform-methanol mixture.

with pure chloroform; about 225 ml seemed to be the optimum quantity. The column was then eluted with chloroform-methanol using a gradient elution method as shown in Fig. 1. A mixture of methanol and chloroform (1:2) flowed continuously into the mixing vessel which contained about 100 ml of chloroform. Fractions were collected over 20 min intervals and the elution curves were therefore plotted against the time.

Paper chromatography. Each fraction was hydrolysed with sulphuric acid and then neutralised with baryta. The paper (Whatman No. 1) was equilibrated over the solvent in the development tank; ascending development was used; solvent composition is given in Table 3.

Spot tests on paper. Spot tests were made by dropping 0.2 ml from each fraction onto paper placed over a hot air stream. Ethanolamine and serine were made visible by spraying with 0.1 % ninhydrin in *n*-butanol and then heating at 95° for 10 min. Choline was tested for by the method of Bevan, Gregory, Malkin and Poole [5].

Quantitative determination. Phospholipids were calculated as 25 P following the method of Brante [6] which is a modification of the methods of Teorell [7] and Fiske-Subbarow [8].

Cerebrosides and gangliosides were estimated by the methods elaborated by Svennerholm [9].

Cholesterol was estimated by a routine photometric method. The sample was dissolved in chloroform (5 ml), and then acetic anhydride (2 ml) and concentrated sulphuric acid (0.2 ml) were added, the mixture was shaken mechanically in the dark for 5 min and the absorption was measured at 630 mμ.

Glycerol was determined by the method of Blix [10].

The distribution of plasmalogens in different fractions was estimated by the method described by Feulgen and Grünberg [11]. The absorption was measured directly without extraction by amyl alcohol.

The lipid fractions were weighed after evaporation of the solvent under reduced pressure.

Purification of solvents. Only analytical grade reagents were used. It was necessary to remove small amounts of fluorescent impurities because of the experimental method to be used. Distillation under water pump vacuum from a large flask immersed in a water bath at 45° gave satisfactory purification. The separation was poor unless the condenser joint was heated strongly with an electrical heating tape. No rubber connections were used.

RESULTS

General composition of the lipids. The lens powder was extracted only with chloroform but the denaturation of the proteins by drying and the long extraction period should permit sufficient release of the lipids.

It is possible to outline the composition of the lipid sample without considering the effect of the gradient elution. As stated by Borgström [1], chloroform elution will give a good separation of the phospholipids from the cholesterol esters and glycerides and the free fatty acids. Phosphorus determination on the chloroform eluate confirmed the retention of the phospolipids on the column provided the recommended volume of chloroform was not exceeded by too much. This separation is of assistance in several analytical determinations.

The amounts of glycerol and cholesterol in the lipids eluted by chloroform were determined on the material from four columns and gave mean values of 0.53 % of the original sample for glycerol and 27.5 % for cholesterol. The chloroform eluate may contain various esters but for the sake of simplicity can be regarded as containing glycerides, cholesterol and cholesterol esters. The possibility of free fatty acids being present is neglected. If the glycerides have a molecular weight as high as that of tristearin, 891, they will amount to 5.1 % of the original sample and the corresponding mean value for cholesterol and its esters will be 34.9 %. A molecular weight as low as 700 will give values of 3.6 and 36, respectively. The percentage figures are thus not influenced to any great extent by errors in the molecular weight assumed for the glycerides. A mean molecular weight lower than that of tristearin was assumed in estimating the approximate values given in Table 1.

Table 1. Constituents of the lipids.

	%
Glycerides	4.5
Cholesterol and its esters	35.5
Phospholipids	48.0
Cerebrosides	0.8
Gangliosides	(0 < 0.5)
Undefined material	11.0

Before chromatography the sample contained 48 % phospholipids. This could also be determined from the amount of phospholipid fraction obtained by chromatography. The results from 8 columns are given in Table 2 with the percentage of phospholipid worked out in three different ways. In each case they are higher than the values determined from the original sample. The 25 × P formula thus does not apply to some of the lipids remaining on the column after elution with chloroform. The gradient elution was intended to concentrate these lipids into definite fractions.

Gradient elution. The material in the fractions eluted by chloroform methanol was weighed and the phospholipids present were estimated. These values when plotted gave a reproducible pattern. There were some variations but the characteristic peaks of the curves were always recognisable. There

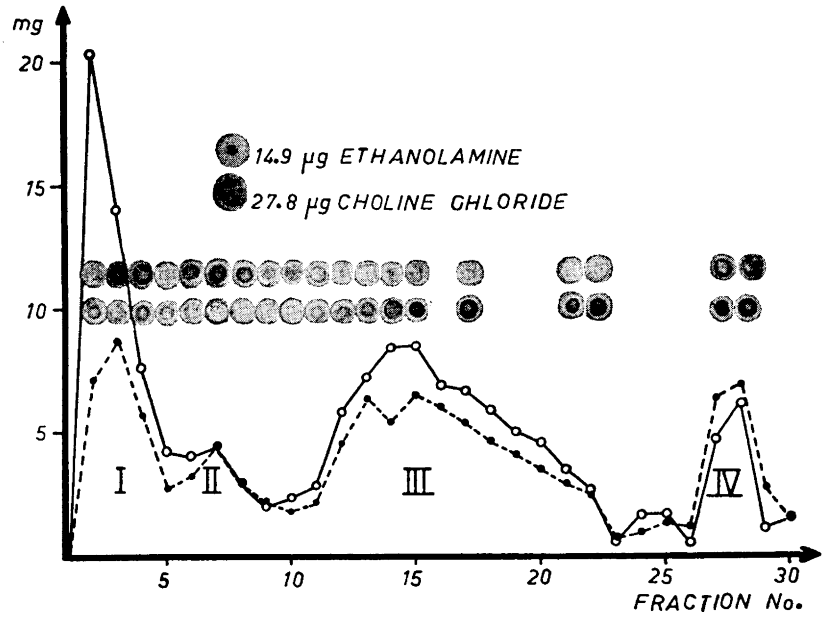

Fig. 2. Fractions obtained by elution with chloroform methanol. The unbroken line represents the lipid amount of each fraction and the dotted line the calculated weight of phospholipids. The spots show ninhydrin reactions and choline tests made on paper with material from the corresponding fractions. The four phospholipid peaks are marked I—IV.

were three phospholipid peaks designated I, II and III in Figs. 2, 3 and 4 with a further peak, IV, in the material stripped from the column with methanol. There were sometimes signs of a slightly smaller peak in front of peak I, see Figs. 3 and 4.

Spot tests for cephalins and lecithin were made on paper using the ninhydrin and choline reactions. The ninhydrin reaction was strong for peaks I and II but very weak for peak III, while the lecithin choline reaction was strong only for peak III. The cephalins should therefore be eluted in front of the lecithin (see Fig. 2). Since the cephalins can be divided into phosphatide ethanolamine and phosphatide serine peaks I and II were investigated to see whether they differed in this way. After hydrolysis the nitrogeneous constituents were separated by chromatography on paper as shown in Fig. 3. The results are shown in Table 3.

The elution curves showing also the spot tests and the paper chromatographic results indicate that the phosphatidyl ethanolamine, the phosphatidyl serine and the phosphatidyl choline are eluted in that order and correspond to the peaks I, II and III. It is also evident that the chromatogram does not give a complete separation especially for peaks I and II. The ninhydrin reaction showed only a single weak spot with an R_F value different from those of ethanolamine and serine. There can be only very little of other strongly reacting amino groups.

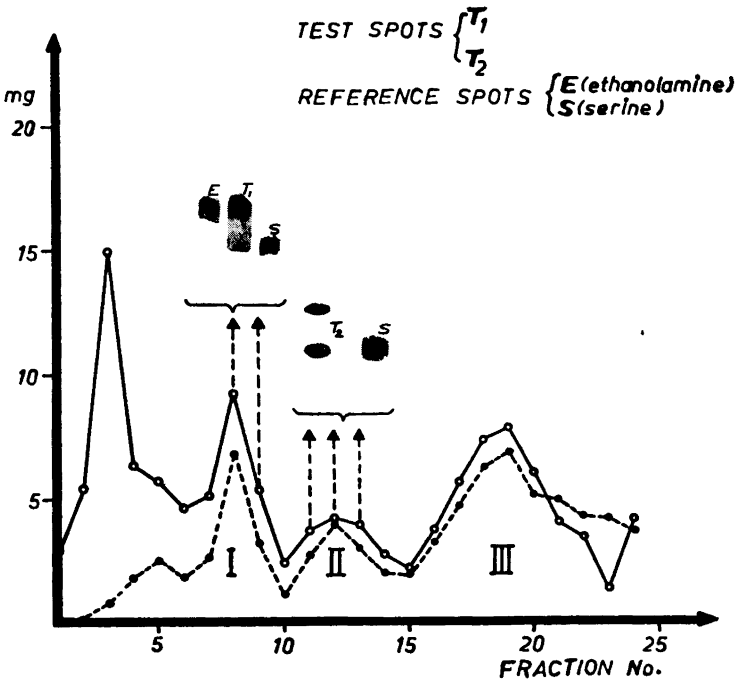

Fig. 3. Fractions obtained by gradient elution with chloroform methanol; same scale as in Fig. 2. The paper chromatograms shown were run on hydrolysed material.

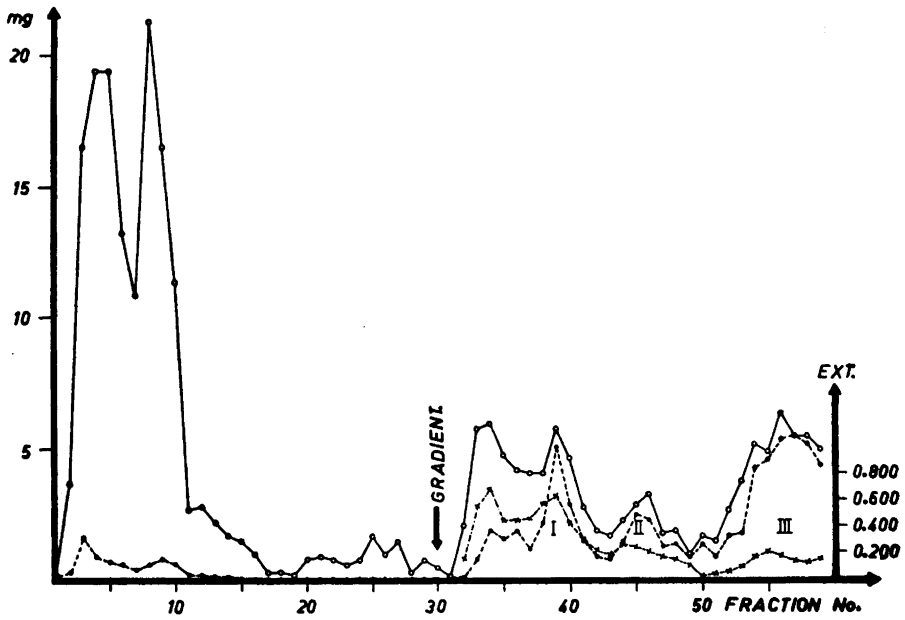

Fig. 4. Chromatogram including the fractions eluted by chloroform; scale as in Fig. 2. The distribution of Feulgen material positive is shown by the curve with crosses; scale as extinction, on the right. In this chromatogram the chloroform eluate had a higher phosphorus content than usual.

Solubility tests permit only rough conclusions to be drawn if the fractions do not contain pure compounds but seemed to accord with the elution sequence given above. The solubility in ethanol was higher for the lecithin fractions than for the first fractions while the material of peak IV was almost insoluble in ether and was preceded by fractions with low ether solubility.

The residue stripped from the column with methanol was designated peak IV and was almost solely phospholipids calculated as 25 × P. To ascertain

Table 3. Paper chromatography of hydrolysed fractions. The R_F values in brackets indicate weaker spots.

	10 h	40:10:50	0.19	0.28	0.16, 0.29, (0.60)

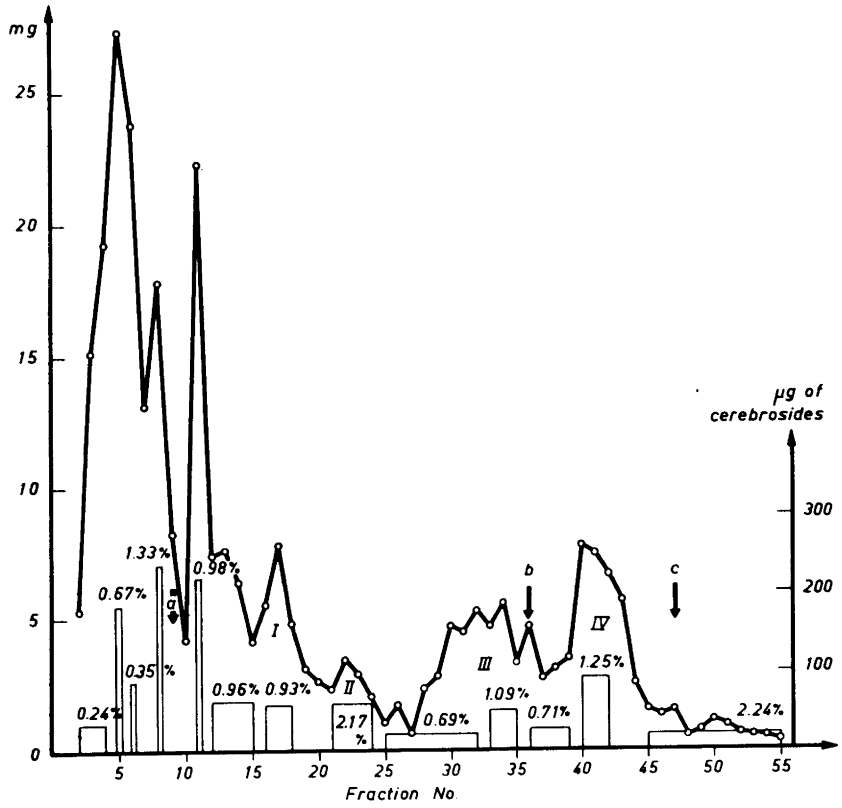

Fig. 5. Elution of the cerebrosides. The curve shows the weight eluted. The height of the columns shows the total cerebroside content of the corresponding fractions; scale on the right. The figures on the columns give the cerebroside contents of each combined fraction as a percentage of total material eluted. Phosphorus determinations were not made in this case but the position of the peaks can be deduced from the shape of the curve. The arrows indicate: a) the start of chloroform methanol elution, b) methanol in the top vessel, c) stripping with methanol. A more prolonged elution with chloroform would have given a better separation of the first fractions eluted by chloroform methanol.

whether sphingomyelin or other glycerol-free phospholipids were present the phosphatide content was calculated from the result of glycerol determinations. The mean value of four determinations was 6.3 % corresponding to 53 % glycerophosphatides using the factor 8.4. This factor should possibly be reduced to allow for the presence of compounds such as lysolecithin; small amounts of cerebrosides may also cause a slight increase. It can however be concluded that sphingomyelin or some similar compound is eluted in the peak IV region.

Lea and Rhodes [2] separated the lipids of egg yolk on silicic acid columns and found lysolecithin in the strongly adsorbed residue on the column. The possibility of this being present in the peak IV material does not invalidate the conclusions above since different phosphatidyl compounds have the same

P:glycerol ratio. The high value given by calculation with 25 × P may however obscure the presence of undefined material. Lea and Rhodes rejected the material insoluble in cold ether before chromatography and therefore would not have found sphingomyelin.

No attempts were made to follow the elution of the plasmalogens quantitatively. The Feulgen reaction was used in one case and the densities were plotted on the weight curve; see Fig. 4. High values were recorded at the beginning of the curve but further along the reaction was weaker. It might be expected that the plasmalogens and the cephalins would be eluted together. This assumption was not entirely refuted by the experimental results but was incompatible with the first part of the curve. The initial hump of peak I corresponded to a peak in the plasmalogen curve. It is therefore possible that a plasmalogen fraction was eluted just in front of the cephalins but was incompletely separated from them.

The cerebrosides amount to 0.8 % of the original lipid sample. The chromatographic fractions were grouped to give sufficient material for study, see Fig. 5. The largest amounts of cerebrosides were eluted by chloroform although some of the later fractions contained slightly higher proportions of cerebrosides. Because of the small quantities present, no attempt was made to find whether the differences in chemical composition of the cerebrosides influenced the order of elution.

The fractions eluted by chloroform methanol gave more material than that shown by phosphorus determinations on the original material. The phospholipid content in the first part of the gradient elution curve is apparently low as can be seen in Figs. 2 and 3. Cholesterol determinations were made to check the separation, but only low and insignificant values were obtained even when the preceding elution was brief.

The first fractions eluted by chloroform methanol had a low phosphorus content even after prolonged elution with pure chloroform, see Fig. 4. Taurog, Enteman, Fries and Chaikoff [12] found that magnesium oxide retains cephalins and a preliminary test showed that the undefined material eluted with the cephalins could be separated using this adsorbent.

Work on further purification of the fractions is in progress and will be published later.

This investigation was carried out with the financial assistance of the *Swedish Medical Research Council (Statens Medicinska Forskningsråd)*. The assistance of Mr. R. Kikas and Fil.kand. R. Lundquist is gratefully acknowledged. I am much indebted to Docent L. Svennerholm for the cerebroside estimations.

The Quantitative Determination of 2(3)-Benzoxazolinone from Rye Seedlings

PENTTI K. HIETALA and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

A method for the quantitative determination of the antifungal substance, benzoxazolinone (BOA), found in rye seedlings, is described. The method is based on the determination of the absorption at 275 mμ in an ethanol solution in which BOA shows a strong maximum. Before the determination of the absorption a fraction has to be prepared from the rye extract where BOA is found in its entirety, and from which disturbing substances are removed. The purification is performed in a cellulose powder column using *cyclo*hexane-ethanol-water as solvent.

After we had discovered the occurrence of benzoxazolinone as an antifungal factor in rye seedlings [1] it was important to develop a quantitative method for its determination. The method developed by us and used in this laboratory since the beginning of 1956 is reported in this paper.

PRINCIPLE

2(3)-Benzoxazolinone (BOA) is extracted from a homogenized sample with boiling water, shaken into ether, the ether is evaporated, the evaporation residue is chromatographed on a cellulose powder column using *cyclo*hexane-ethanol-water as a solvent. The fraction containing BOA is diluted with absolute ethanol to a fixed volume, and its ultraviolet absorption spectrum is measured. The 275 mμ extinction of the maximum is compared with an extinction curve determined with known amounts of BOA, by which procedure the BOA content of the sample to be investigated is obtained.

Reagents: Absolute ethanol. *Cyclo*hexane (Merck's or May & Baker's *cyclo*hexane): The ultraviolet absorption spectra of different batches of *cyclo*hexane differed noticeably. When necessary, *cyclo*hexane was purified by silica gel-aluminum oxide treatment [2]. Several batches could, however, be used as such without special purification. Ether: The ether was purified by shaking with acid ferrosulphate solution 4 to 5 times, by washing with water, and finally by distillation. Cellulose powder (Whatman, "Ashless",

W. & R. Balston & Co.). Benzoxazolinone: The product used for determination of the extinction curve was synthesized from *o*-aminophenol and urea; m. p. 141°C. Glass-wool: Merck's *pro analysi* glass-wool or ordinary glass-wool washed with acid, ethanol, and water.

Preparation of cellulose powder columns: The columns used in chromatography were prepared from cellulose powder in glass tubes, 20 cm high and 9 mm in diameter. The lower end was drawn into a short beak. The diameter of the tube should not deviate much from 9.0 mm.

Glass-wool is placed into the lower end of the tube and stopped as tight as possible with a glass rod. Cellulose powder (1.70 g) is placed on the top of the wool in 5 or 6 portions. After each addition the tube is shaken in vertical position until the powder ceases to sink, and then it is packed tight with a glass rod. The height of the finished cellulose powder column has been 5.0 ± 0.2 cm. Distilled water is absorbed through the column from below, after which distilled water is placed on top of the column and sucked through with a vacuum pump. The column should not be allowed to dry. The column is now washed once with ethanol (94 %), and twice with the solvent *cyclo*hexane-absolute ethanol-water (400:80:1). Even cellulose powder columns are obtained more quickly when using centrifugation.

PROCEDURE OF THE DETERMINATION

0.3 to 4 g of rye seedlings, homogenized in a mortar, is weighed in a Pyrex-glass centrifuge tube, 15 ml of distilled water is added, and the suspension is mixed. The tube is kept in boiling water for 20 min under occasional shaking. After that the tube is immediately centrifuged and the separated solution is filtered into a 250 ml centrifuge tube. The residue is treated four times in the same way. The combined water extract in the centrifuge tube is shaken four times with peroxide free ether. The ether solution, separated by centrifugation, if necessary, is evaporated to dryness in a glass bowl, and the residue

is transferred to a 4 ml test tube by small amounts of ether. The ether is evaporated to dryness, and the residue dissolved in *cyclo*hexane-ethanol-water solution (1.00 ml) in which it dissolved completely. 0.200 ml of the solution obtained is placed on top of the column when there is no more solvent. The solution is allowed to run into the column, 3 drops of solvent are carefully added with a pipette, and when these drops have run into the column the tube is filled to the 0 mark on a centimetre scale fastened behind the tube. A small glass tube is placed upside down on the column to prevent evaporation. When the surface of the solvent has sunk 5.6 cm, the liquid emerging from the column is collected into a 10 ml volumetric flask. BOA emerges from the column between 5.6 and 9.0 cm as could be shown in experiments with pure BOA (Fig. 1). This fraction is taken up in a volumetric flask which is then filled to the mark with absolute ethanol, and the ultraviolet absorption spectrum is measured in a Beckman spectrophotometer.

EXTINCTION CURVE

The BOA content of the solution measured is obtained from the extinction curve, or by using multiplication by a coefficient calculated from the curve. The extinction curve was obtained with the following amounts of BOA: 50, 100, 200, and 400 μg/10 ml. The same amount of solvent was placed in a 10 ml volumetric flask as when chromatographing the proper samples to be investigated. The above-mentioned amounts of BOA, dissolved in absolute ethanol, were pipetted into this solution and the flasks were filled to the mark with absolute ethanol. The blank, made by simply running the solvent through the column, showed that if the *cyclo*hexane used is pure, the effluent has no absorption, and that the measurements can as well be made using absolute ethanol in the blank.

The extinction at 275 mμ follows Lambert-Beer's law. The extinction using 1 cm quartz cells has to be multiplied by 317.0 to establish the amount of BOA contained in 10 ml solution. The logarithm of the molar extinction of the substance is 3.63. The spectrum in the region 240—300 mμ is always measured in order to find out if there is an absorption caused by foreign substances. From young rye seedlings, the BOA content of which is high, a curve nearly corresponding to that of the pure substance is generally obtained, the absorption at 245—255 mμ and 285—300 mμ being, however, somewhat higher than with pure BOA solution. Especially at 245—255 mμ this absorption has every now and then become considerably high. The BOA content has been calculated by subtracting the calculated unknown absorption from the extinction measured at the absorption maximum at 275 mμ. If the foreign absorption is high, the accuracy of the method is low.

Control of the method: 1) In order to find out if BOA in the extract from rye seedlings emerges completely from the column at the range 5.6—9.0 cm, the following experiment was performed with the rye-varieties Ensi and Kungsråg II, which in regard to winter hardiness represent extreme types among the varieties used:

Ensi, 20 seedlings, 7 days old, fresh weight 2.138 g
Kungsråg II, 21 seedlings, 7 days old, fresh weight 2.380 g

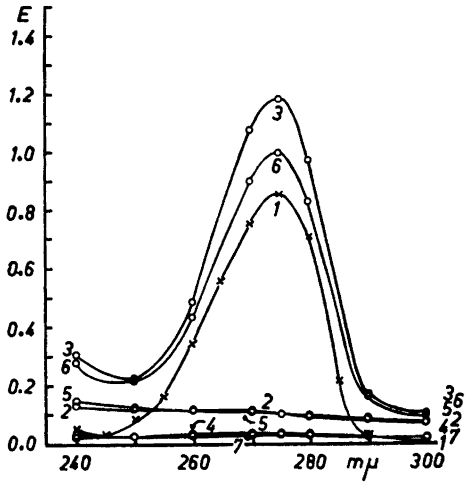

Fig. 2. BOA-Determination of Ensi and Kungsråg II rye seedlings. BOA-fraction (5.6—9.0 cm), prefraction (4.6—5.6 cm), and afterfraction (9.0—10.0 cm). E = E/g fresh weight. 1. Pure BOA. 2. Prefraction (Ensi rye). 3. BOA-fraction (Ensi rye). 4. Afterfraction (Ensi rye). 5. Prefraction (Kungsråg II rye). 6. BOA-fraction (Kungsråg II rye). 7. Afterfraction (Kungsråg II rye).

Determination and chromatography were performed in the usual way. In addition to the proper fraction containing BOA, 1 cm of solvent was taken before and after this fraction. Fig. 2 shows the spectra of pre- and afterfractions as well as the spectrum of the fraction containing BOA. The absorption maximum of BOA is completely lacking in pre- and after-fractions. It can thus be concluded that BOA has emerged entirely at the range mentioned.

Table 1. Recovery of BOA added to the rye extract.

Run	Extinction 275 mμ	μg BOA found	Recovery %
200 μl (1 μg BOA/μl)	0.628	199	99.5
100 μl BOA solution + 100 μl rye solution	0.596	189	102.5
200 μl rye solution	0.551	173	

Table 2.

1	467	2
2	442	3
3	438	5
4	455	0
5	480	5
	Mean value 456	

Table 3. Parallel determinations of BOA from different varieties of rye (field experiments).

Variety of rye	BOA μg/g fresh weight	Mean value	Deviation % from mean value
Ensi 1	334	323	3
2	312		
Onni 1	456	486	6
2	516		
Pekka 1	490	476.5	3
2	461		
Visa 1	211	211	0
2	211		
Toivo 1	458	438.5	4
2	419		

This is in accordance with the results obtained with pure BOA (*cf.* Fig. 1). Similar curves were also obtained with Pekka, Visa, and Greus rye.

2) Recovery of BOA added to the plant extract. 70 g of rye was extracted. The residue of the ether extract was dissolved into 8.00 ml solvent. The determinations were carried out as described above; details of the experiments and results in Table 1.

3) Differences between parallel determinations. The following determinations were made on August 16, from young rye seedlings (Pekka variety) cultivated in pot cultures in sand. The same solution was used in all determinations (Table 2). Some results obtained in parallel determinations on rye seedlings from field experiments are shown in Table 3.

The authors are indebted to Miss Terttu Ettala and Miss Aino Aura for determinations of BOA, and to Professor O. Pohjakallio, from the Department of Plant Pathology, University of Helsinki, for samples of rye obtained from his field experiments.

The support given by the *Rockefeller Foundation* is gratefully acknowledged.

On the Antifungal Effect of Benzoxazolinone and 6-Methoxybenzoxazolinone, Respectively, on *Fusarium nivale*

Ö. WAHLROOS and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

The decomposition of benzoxazolinone and 6-methoxybenzoxazolinone by *Fusarium nivale*, the adaptation of this fungus to benzoxazolinone, and the fungistatic or fungicidic action of benzoxazolinone on it has been investigated. The mode of inhibition of growth of *F. nivale* in media containing benzoxazolinone is discussed in relation to the results. The results suggest that benzoxazolinone has a fungistatic influence in a concentration < 0.5 mg per ml. In a concentration > 0.6 mg per ml the fungicidic influence is already prevailing and the growth of *Fusarium* is totally inhibited.

The growth curves, shown in Fig. 1, are obtained when the biological activity of benzoxazolinone (BOA), the antifungal substance found in rye seedlings, is determined in an oat-glycerol solution or on agar plates, using different BOA concentrations and *F. nivale* as test organism.

A pronounced lag period is thus observed which is the longer the higher the BOA content. Even after a long period of time no growth was observed when the BOA concentration was higher than 0.5 mg/ml.

Some experiments were performed in order to find out if the influence of BOA and 6-methoxybenzoxazolinone (MBOA) is fungistatic or fungicidic and to study the reactions underlying the lag period. In this paper these experiments and the results are described and discussed.

DECOMPOSITION OF BOA BY *F. nivale*

40 mg of BOA were added to 100 ml of Czapek's nutrient solution containing 0.63 g of glycerol per litre and sterilized for 15 min under 0.8 atm pressure. Subsequently an amount corresponding to about 7 mg dry weight of the mycelium of *F. nivale*, grown for 7 days at 20°C on oat-glycerol-agar, was added aseptically. The suspension in a 1 litre Erlenmeyer flask, closed by a cotton

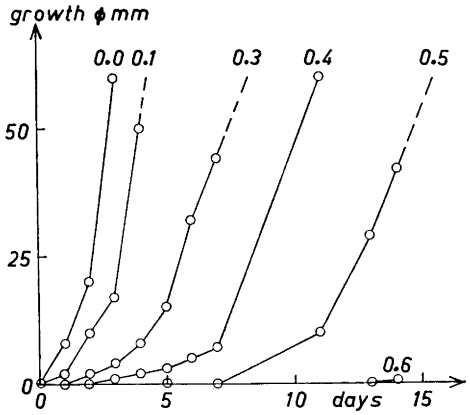

Fig. 1. Growth of the mycelium of *F. nivale* in a BOA containing oat-glycerol-medium. Curve numbers indicate the BOA content, mg/ml.

plug, was shaken in an automatical shaker at a frequency of 50 oscillations per min. A corresponding suspension without BOA was used as control. At intervals 1 ml samples were taken with a sterile pipette. The samples were diluted to 100 ml, and the absorption at 230 to 300 mμ was determined with a Beckman spectrophotometer. The BOA content was calculated from the

Broken line: The spectrum of an unshaken suspension after decomposition of BOA. Dotted line: The spectrum of *o*-aminophenol in the same suspension.

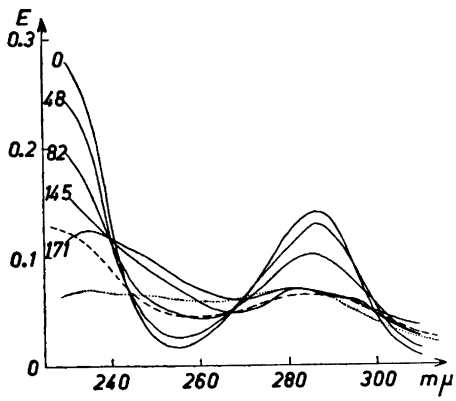

Fig. 4. Solid lines: The breakdown of MBOA effected by the mycelium of *F. nivale* in a vigorously shaken Czapek solution. Curve numbers indicate test time in hours. Broken line: 2-amino-5-methoxyphenol, partly oxidized in air. Dotted line: 2-amino-5-methoxyphenol, further oxidized in air.

absorption maximum at 270 mμ. The weight of the mycelium was determined in 5 ml samples. The results are shown in Fig. 3 and curve 1 in Fig. 2.

In another experiment, in which the BOA content was 0.67 mg per ml, and the amount of mycelium corresponded to about 70 mg dry weight per 100 ml solution, the BOA content decreased by 50 % in 45 h; after 76 h no BOA could be found in the test solution (Fig. 2, curve 2).

After 120 h a determination of BOA was made on the mycelium in 50 ml test solution; 0.041 mg of BOA was found, which is about 1/500 of the amount of BOA added at the beginning of the experiment.

It is noticeable that in all experiments it took 20 to 30 h before the decomposition of BOA started. Does this lag period depend on an adaptive formation of a BOA-decomposing enzyme? To test this possibility a new portion of BOA was added to a suspension in which the originally added BOA was decomposed. As can be seen from curve 3 A in Fig. 2 the decomposition of BOA has now started immediately.

DECOMPOSITION OF 6-METHOXYBENZOXAZOLINONE BY *F. nivale*

The experiment was performed as above. The MBOA content of the solution was 0.4 mg per ml, and the amount of mycelium corresponded to about 90 mg dry weight per 100 ml solution.

After 170 h practically all MBOA had disappeared from the solution.

CHANGES IN THE UV SPECTRUM DURING THE DECOMPOSITION OF BOA AND MBOA BY *F. nivale*

The UV spectrum of the BOA solution with the mycelium of *F. nivale* had during the experiment the same shape as the spectrum of pure BOA solution, from which fact it can be concluded that aromatic decomposition products of BOA, possibly formed during the experiment, were hardly enriched in the solution (Fig. 3). When practically all BOA had disappeared a very weak maximum at 260 mμ could be noticed. It disappeared rapidly, however.

On performing the experiment without shaking, two new maxima (at 240 and 280 mμ) were observed when BOA had disappeared (Fig. 3).

In the MBOA solution with *F. nivale* mycelium two new maxima were observed at 235 mμ and 282 mμ after 125 h as well as an inflexion point at 295 mμ which disappeared after 170 h when all MBOA was already decomposed (Fig. 4). In addition there was a maximum at 460 mμ. The change in the spectrum cannot be due to pH-variations, since the pH remained constant during the experiment. It thus seems that one or more new compounds containing a benzene ring had been formed from MBOA by *F. nivale*.

In Figs. 3 and 4 are also seen the spectra of *o*-aminophenol and 2-amino-5-methoxyphenol oxidized in the air. The latter compound also showed a maximum at 460 mμ. It is seen that the spectra do not quite correspond to the maxima observed in *F. nivale* suspensions during and after the disappearance of BOA and MBOA though there are certain similarities.

The rate of decomposition seems to depend on the amount of mycelium as well as on the original BOA concentration of the solution. MBOA seems to decompose slower than BOA. It ought to be mentioned that in an unshaken mycelium suspension BOA was no longer decomposed in a concentration of 0.5 to 0.6 mg/ml.

ADAPTATION OF *F. nivale* TO BOA

The lag period might thus be the time required by *F. nivale* to decompose BOA around the inoculate. Another possibility might be the adaptation of *F. nivale* to BOA. Therefore the following experiment was performed.

F. nivale mycelium was transferred to 20 oat-glycerol-agar plates containing 0.6 mg of BOA per ml. After 9 days growth could be seen on 12 plates. The mycelium grown on these plates was cultivated during 4 transfers on plates containing 0.6, 1.0, and 1.25 mg of BOA per ml. As early as during the second transfer *F. nivale* grew in the concentration 1 mg per ml. Even after the fourth transfer *F. nivale* did not grow in a higher concentration than this.

The observed length of the lag period at concentrations of 0.1 to 0.5 mg BOA per ml can be supposed to depend on this weak adaptation.

THE FUNGICIDIC INFLUENCE OF BOA AND MBOA ON *F. nivale*

Nine days old mycelium of *F. nivale* was transferred to sterile 0.9 % NaCl solutions containing different amounts of BOA. Each test tube contained 5 ml solution and about 5 mg dry weight of mycelium. At the contact times, shown in Table 1, samples of the mycelium were separated, washed three times with sterile 0.9 % NaCl solution and then transferred to an oat-glycerol-agar. Growth was followed during 7 days.

The results shown in Table 1 indicate that BOA has a fungicidic influence on *F. nivale* from a concentration of 0.5 mg per ml upwards. In concentrations higher than this the fungicidic influence is comparatively rapid. MBOA also exerts a fungicidic influence on *F. nivale* at least in the concentration 0.5 mg per ml (contact time 6 days).

Table 1. Growth of the mycelium of *F. nivale* after contact times of 1 to 33 days. Substrate in the growth tests oat-glycerol-agar.

mg BOA/ml	Growth Contact time, days 1	2	3	4	8	17	33
0 (control)	+	+	+	+	+	+	(+)
0.3	+	+	+	+	+	+	+
0.5	+	+	+	+	(+)	(+)	−
0.75	+	(+)	−	−	−	−	−
1.0	+	(+)	−	−	−	−	−
1.4	+	−	−	−	−	−	−

Marking of growth: + = normal growth, (+) = poor growth, − = no growth.

DISCUSSION

On the basis of the observations reported above the growth of *F. nivale* in a nutrient solution or on agar plates containing BOA or MBOA could perhaps be explained in the following way: in a concentration up to 0.4 mg per ml the influence is fungistatic, and the lag period depends on the adaptation of *F. nivale* to these substances. When growth has started, it at first proceeds slowly, and then accelerates to reach about the same rate as in a solution without BOA (Fig. 1). BOA determinations from growth flasks indicate that at this point BOA had practically disappeared from the media. In 0.5 mg per ml there is already a weak fungicidal influence, the fungistatic one still prevailing, however. When the concentration rises to 0.6 or 0.7 mg per ml, the fungicidic influence prevails, and growth is totally inhibited.

The chemical mechanism of the fungistatic and fungicidic influence of BOA and MBOA is still unknown.

As regards the way of the decomposition of BOA and MBOA by *F. nivale* it is possible that the corresponding aminophenols occur among the products, though, at least in the case of BOA, the decomposition probably goes further.

The support given by the *Rockefeller Foundation* is gratefully acknowledged.

Short Communications

On Some Unknown Metabolic Intermediates in Plants

PEKKA LINKO*

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In an earlier paper [1] from this laboratory it was reported that several unknown compounds were rapidly labelled with ^{14}C after infiltration of radioactive pyruvate into the leaves of *Phlox decussata* and *Asplenium septentrionale* (Figs. 1 and 2). When these compounds were subjected to acid hydrolysis (6 N HCl, 20 h, 105°C, sealed tube, except in case of compound No. 11, 1 N HCl, 2 h) the following results were obtained:

Spot No. 5. The only hydrolysis product detected was active alanine.

Spot No. 6. Active glutamic acid and a ninhydrin positive inactive compound, probably identical with glucosamine, were formed. It is likely that this compound may be a derivative of glutamic acid and glucosamine. It is interesting to notice that the amino group of glucosamine-6-phosphate is known to be derived from the amide-group of glutamine [2,3].

Spot No. 7. This is probably identical with compound X in *Asplenium septentrionale*. Both compounds are rapidly and heavily labelled in the beginning of the experiment, the activity decreasing soon thereafter. As the other unknown compounds in question it was first thought to be ninhydrin negative, but in one case a slight brownish-violet color developed after some hours. Therefore it is thought that

* Present address: Kansas State College, Department of Flour and Feed Milling Industries, Manhattan, Kansas, U.S.A.

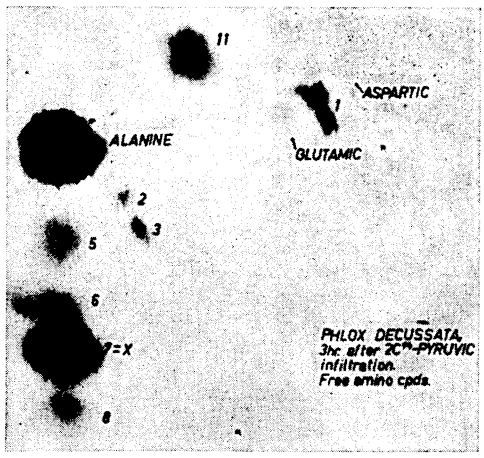

Fig. 1. Radioautogram of free amino compounds 3 h after 2—^{14}C-pyruvate infiltration into *Phlox decussata*.

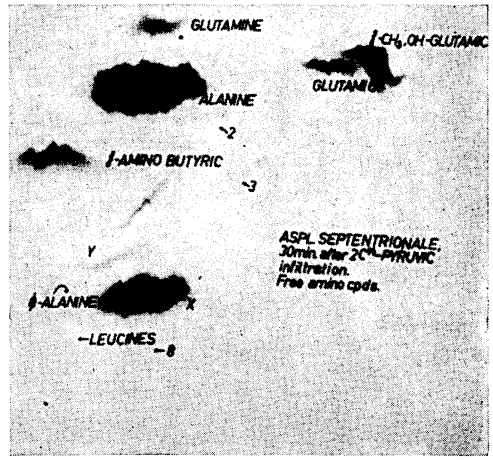

Fig. 2. Radioautogram of free amino compounds 30 min after 2—^{14}C-pyruvate infiltration into *Aspl. septentrionale*.

these compounds in general may be present only at very low concentrations, hence the specific activity being very high. On hydrolysis only one heavily active spot, again ninhydrin negative, was found. This unknown product travelled with the phenol frontier at the level of the leucines in butanol acetic acid solvent. The same result was obtained both on strong and mild hydrolysis.

Spot No. 8. Only spot found on hydrolysis was active alanine.

Spot No. 11. This compound was subjected only to mild hydrolysis and it seemed to be unaffected under these conditions. The spot was, however, most probably superimposed by an inactive spot, because great amounts of inactive γ-hydroxyglutamic acid were formed. The other possibility would be that the compound should have been only partially hydrolysed, the active carbon atom being split off. Such a case, where only one carbon atom becomes labelled after a short time, has been detected during photosynthetic $^{14}CO_2$ assimilation by blue-green algae [4]. In this case only the carbamyl group of the heavily labelled citrulline was found active.

No attempts have so far been made to identify the possible carbohydrates or other ninhydrin negative compounds which

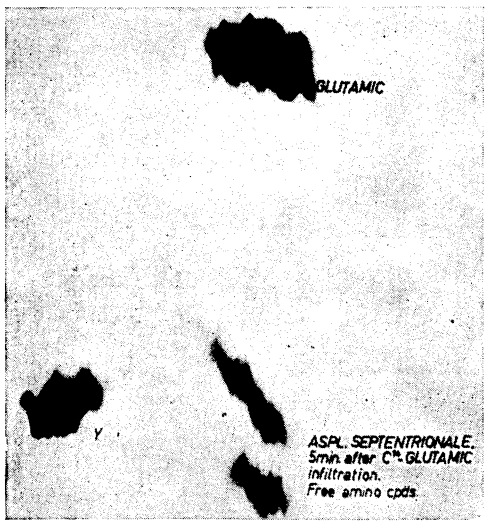

Fig. 3. Radioautogram of free amino compounds 5 min after 1—^{14}C-glutamate infiltration into *Aspl. septentrionale.*

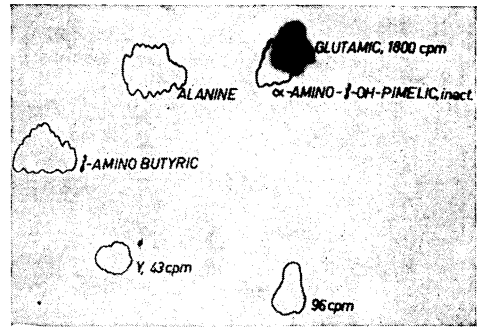

Fig. 4. Radioautogram of the products of hydrolysis of compound Y. Drawn spots are inactive ninhydrin positive compounds. Inactive glutamic acid, alanine and γ-aminobutyric acid were added on the chromatogram.

may arise during the hydrolysis of these unknown compounds.

When 1—^{14}C-glutamic acid was infiltrated into *Asplenium septentrionale* plants only three unknown compounds were found (Fig. 3). On acid hydrolysis of the major spot Y, active glutamic acid was formed in addition to inactive α-amino-γ-hydroxypimelic acid (Fig. 4) which was identified by means of paperchromatography. Even though the nature of this compound is unknown it is of great interest that α-amino-γ-hydroxypimelic acid is found bound to a compound formed as early as during a few minutes. Most of the glutamic acid is evidently readily decarboxylated thus losing its active carbon atom. If the primary reaction would be transamination to γ-ketoglutaric acid, at least some activity would be expected in other amino acids arising *via* the tricarboxylic acid cycle. It was of great interest to notice, too, that no active glutamine was found though glutamine was heavily labelled after 2—^{14}C-pyruvate and slightly labelled even after 1—^{14}C-pyruvate infiltration [1]. This is in good agreement with the assumption that glutamine may arise *via* γ-aminobutyric acid.

It has been known for a few years that the fraction of the 70 % ethanol extract of plant tissues, which passes through a cation exchange resin column, contains bound amino acids liberated on acid hydrolysis [5]. When hydrolysed after 2—^{14}C-pyruvate infiltration into *Asplenium septentrionale* mainly glutamic acid, alanine,

γ-Aminobutyric, cpm	94	163	—	—
Valine, cpm	15	—	—	—

and α-aminobutyric acid were found labelled in this fraction. Alanine was the major labelled compound after half an hour, but already after one hour the activity of glutamic acid was greater (Table 1). Whereas alanine decreased from the "peptide" fraction it increased in the proteins. However, the activity of compounds 5, 6, 7, 8 and 11 also had a peak within 10 to 30 min when 2—^{14}C-pyruvate alone was infiltrated. Glutamine was not labelled in this case. Inactive glycine, when infiltrated together with active pyruvate, caused a great inhibition of the labelling of these compounds during the first minutes after infiltration, whereafter the activity of compounds 6 and 7 as well as that of glutamic acid greatly increased, showing again the relationship of compound 6 to glutamic acid. In this case even glutamine was slightly labelled after 3 h. Glycine had only a slight inhibitory effect to the alanine containing compounds 5 and 8, while the activity of alanine itself increased due to the greater amount of nitrogen available for transamination reactions.

The Influence of Anharmonicity upon the Vibrational Probability Density and Mean Amplitudes in Diatomic Molecules

ARNE REITAN

Institutt for teoretisk kjemi, N.T.H., Trondheim, Norway

The influence of anharmonicity upon the vibrational probability density and mean amplitudes in diatomic molecules has been investigated by using two different models to describe the molecular vibrations:

a) an anharmonic oscillator with perturbation terms of first and second order in the potential function,

b) an anharmonic oscillator described by a Morse potential function.

For case a) the probability density $w(r)$, where $r = R - R_e$ is the deviation of the interatomic distance R from its equilibrium value R_e, has been calculated by two different methods. In the first place, an expression for $w(r)$ has been developed by a superposition of probability densities for the different stationary states, according to the equation

$$w(r) = \sum_v |\psi_v(r)|^2 \exp(-E_v/kT) / \sum_v \exp(-E_v/kT)$$

where E_v and ψ_v are the corresponding eigenvalues and normalized eigenfunctions for the vibrational state v, k is Boltzmann's constant, and T is the absolute temperature. The eigenvalues E_v and eigenfunctions ψ_v have been obtained by a second order perturbation calculation similar to that performed by Hutchisson [1] (the results given by this author are, however, somewhat erroneous), and the sums have been evaluated by using well known properties of the Hermite orthogonal functions.

In the second place, the probability density $w(r)$ has been calculated by making use of an analogy to the solution of the time-dependent Schrödinger equation for the system (compare Bloch [2] and Kennard [3]).

In both cases the calculations are somewhat tedious, the result is, however, quite simple:

$$w(r) = (a_0 + a_1 r + a_2 r^2 + a_3 r^3 + a_4 r^4 + a_6 r^6) w^\circ(r)$$

Table 1. The incorporation of activity into the amino acids in the hydrolysates of the "peptide" fraction after 2—^{14}C-pyruvate infiltration into *Aspl. septentrionale*.

The Influence of Anharmonicity upon the Vibrational Probability Density and Mean Amplitudes in Diatomic Molecules

ARNE REITAN

Institutt for teoretisk kjemi, N.T.H., Trondheim, Norway

The influence of anharmonicity upon the vibrational probability density and mean amplitudes in diatomic molecules has been investigated by using two different models to describe the molecular vibrations:

a) an anharmonic oscillator with perturbation terms of first and second order in the potential function,

b) an anharmonic oscillator described by a Morse potential function.

For case a) the probability density $w(r)$, where $r = R - R_e$ is the deviation of the interatomic distance R from its equilibrium value R_e, has been calculated by two different methods. In the first place, an expression for $w(r)$ has been developed by a superposition of probability densities for the different stationary states, according to the equation

$$w(r) = \sum_v |\psi_v(r)|^2 \exp(-E_v/kT) / \sum_v \exp(-E_v/kT)$$

where E_v and ψ_v are the corresponding eigenvalues and normalized eigenfunctions for the vibrational state v, k is Boltzmann's constant, and T is the absolute temperature. The eigenvalues E_v and eigenfunctions ψ_v have been obtained by a second order perturbation calculation similar to that performed by Hutchisson [1] (the results given by this author are, however, somewhat erroneous), and the sums have been evaluated by using well known properties of the Hermite orthogonal functions.

In the second place, the probability density $w(r)$ has been calculated by making use of an analogy to the solution of the time-dependent Schrödinger equation for the system (compare Bloch [2] and Kennard [3]).

In both cases the calculations are somewhat tedious, the result is, however, quite simple:

$$w(r) = (a_0 + a_1 r + a_2 r^2 + a_3 r^3 + a_4 r^4 + a_6 r^6) w^\circ(r)$$

where $w^\circ(r)$ is the probability density for the harmonic case, and the a_k's are explicitly given as functions of the temperature T, the vibrational frequency ω_e for the corresponding harmonic oscillator, and the spectroscopic anharmonicity constant x_e.

If the most probable value of R is denoted by R_m, and the values of R corresponding to a probability density equal to one half of the maximum value are denoted by $R_{h,1}$ and $R_{h,2}$, it is found that to terms of second order

$$R_{h,1} - R_m = r_h^\circ(1 + x_e^{1/2}b_1 + x_e b_2),$$
$$R_m - R_{h,2} = r_h^\circ(1 - x_e^{1/2}b_1 + x_e b_2),$$

where r_h° is the half width for the harmonic case, and the b_k's are functions of the temperature T and the vibrational frequency ω_e. The probability density curve is, as it is seen, unsymmetric, the unsymmetry appearing already in a first order treatment.

Furthermore, explicit expressions have been developed for the mean amplitudes

$$u_e = [\overline{(R-R_e)^2}]^{1/2},$$
$$u_a = [\overline{(R-\bar{R})^2}]^{1/2},$$
$$u_m = [\overline{(R-R_m)^2}]^{1/2},$$

where the reference values of the interatomic distance in the three cases are the equilibrium value R_e, the mean value $\bar{R}$, and the most probable value R_m, respectively.

In case b) of the Morse-potential approximation the calculations have been carried out in a straightforward manner, considering only the lower vibrational states. However, the numerical results obtained by the two methods seem to be in very good agreement, as indicated by the values for the hydrogen molecule listed in Table 1. The necessary spectroscopic data have been obtained from Herzberg [4]. The values obtained when assuming harmonic vibrations are also given.

N-Terminal Amino Acids of Human Pituitary Growth Hormone

F. HEIJKENSKJÖLD

Department of Clinical Chemistry, Karolinska Sjukhuset, Stockholm, Sweden

Analyses of the N-terminal amino acids of growth hormone prepared from ox pituitaries have been carried out by means of two methods. The dinitrofluorobenzene-technique (DNFB) of Sanger [1] has been applied by Li [2], who found two amino acids (phenylalanine and alanine) in equal molar proportions. These results were confirmed by the phenylthiohydantoin (PTH) method of Edman [3]. The latter method proved to be better since it was clearly demonstrable that the two amino acids were present as one mole each per mole of protein hormone [4].

This suggests a constitution formula of the ox hormone of two peptide chains linked together by SH-groups and ending in phenylalanine and alanine as N-terminal amino acids.

The following experiments were carried out to analyse the N-terminal amino acid of human pituitary growth hormone [5].

Material and methods. Growth hormone was prepared from human pituitaries by means of a method of Li and Papkoff [6]. 4 to 10 mg samples of the protein hormone were dissolved in 0.5—2.0 ml of phosphate buffer pH 9.0, ionic strength 0.1. An equal volume of 0.5 % phenylthio*iso*cyanate (Eastman Kodak) in ethanol was added and the mixture stirred for 2 h. The pH was maintained at 8.8 by the addition of small portions of 0.01 N sodium

where $w^\circ(r)$ is the probability density for the harmonic case, and the a_k's are explicitly given as functions of the temperature T, the vibrational frequency ω_e for the corresponding harmonic oscillator, and the spectroscopic anharmonicity constant x_e.

If the most probable value of R is denoted by R_m, and the values of R corresponding to a probability density equal to one half of the maximum value are denoted by $R_{h,1}$ and $R_{h,2}$, it is found that to terms of second order

$$R_{h,1} - R_m = r_h^\circ(1 + x_e^{1/2}b_1 + x_e b_2),$$

N-Terminal Amino Acids of Human Pituitary Growth Hormone

F. HEIJKENSKJÖLD

Department of Clinical Chemistry, Karolinska Sjukhuset, Stockholm, Sweden

Analyses of the N-terminal amino acids of growth hormone prepared from ox pituitaries have been carried out by means of two methods. The dinitrofluorobenzene-technique (DNFB) of Sanger [1] has been applied by Li [2], who found two amino acids (phenylalanine and alanine) in equal molar proportions. These results were confirmed by the phenylthiohydantoin (PTH) method of Edman [3]. The latter method proved to be better since it was clearly demonstrable that the two amino acids were present as one mole each per mole of protein hormone [4].

This suggests a constitution formula of the ox hormone of two peptide chains linked together by SH-groups and ending in phenylalanine and alanine as N-terminal amino acids.

The following experiments were carried out to analyse the N-terminal amino acid of human pituitary growth hormone [5].

Material and methods. Growth hormone was prepared from human pituitaries by means of a method of Li and Papkoff [6]. 4 to 10 mg samples of the protein hormone were dissolved in 0.5—2.0 ml of phosphate buffer pH 9.0, ionic strength 0.1. An equal volume of 0.5 % phenylthio*iso*cyanate (Eastman Kodak) in ethanol was added and the mixture stirred for 2 h. The pH was maintained at 8.8 by the addition of small portions of 0.01 N sodium

hydroxide. A Beckman autotitrator apparatus was used for the checking of pH and addition of alkali. When the alkali consumption had ceased three volumes of ethanol were added and the pH was lowered to 4 by addition of hydrochloric acid. After centrifugation the PTC-protein was washed three times with ethanol and lyophilized.

10 ml of N hydrochloric acid was added to the dry PTC-protein powder and the mixture was refluxed on a sandbath for 2 h. After cooling the PTH-amino acids were extracted with three 10 ml portions of ethyl acetate. The combined extracts were evaporated to dryness *in vacuo*. The dry residue was dissolved in a small volume of ethyl acetate and applied for chromatography on formamide-buffered Whatman No. 1 papers and developed with descending chromatography using xylene as a solvent [7].

Standard PTH-amino acids were always run together with the unknown. Indication of the spots was made by means of ultraviolet absorption with the aid of a fluorescence screen. For quantitative estimation of the N-terminal amino acid various amounts of the PTH-amino acid were run together with the preparations. The spots were eluated with 70 % ethanol, the volume made up to 10 ml and samples thereof read against ethanol in a Beckman spectrophotometer model DU at 269 mμ. Care was taken to make the paper pieces of exactly the same area since extracts from the formamide-buffered paper has a high blank absorption. The area of filter paper used usually had an absorption value of 0.2 (See Fig. 1).

Parts of the PTH-amino acid extracts were boiled in 2 N sodium hydroxide for 3 h in order to transform them into the original amino acid. Identification of the amino acid was made by two-dimensional paper chromatography using Whatman No. 4 paper, water-saturated phenol and collidine-lutidine according to Dent [8]. The standard PTH-amino acids used were synthetisized according to Edman [3] and the purity was checked with melting point determination and paper chromatography.

Results. Only one N-terminal amino acid was demonstrable as a PTH-preparation by the method used. The identification of this amino acid proved to be rather troublesome. Use of xylene as a solvent in the paper chromatography showed a spot with a R_F-value in the vicinity of PTH-valine or PTH-phenylalanine. Other solvents (formic acid, *n*-butanol and hexane in various proportions according to Sjöquist [9]) did not give a reliable identification though the results of chromatography

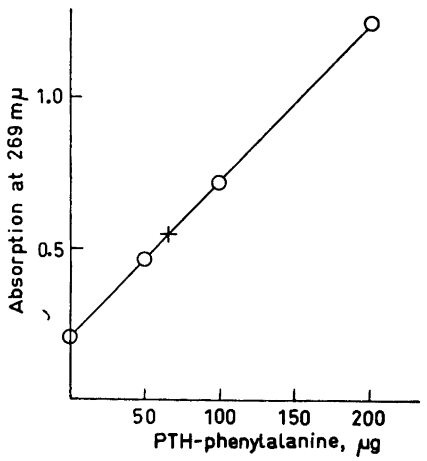

Fig. 1. Absorption at 269 mμ of a PTH-preparation from 10.0 mg of growth hormone and a standard PTH-phenylalanine preparation.

The PTH-phenylalanine from 10.0 mg of growth hormone had an absorption value of 0.550 which corresponds to 65 μg of PTH-phenylalanine (+) or 35.9 μg of phenylalanine. Thus one protein molecule contains 10 000/35.9 = 278 amino acids which means a molecular weight of about 30 600.

with xylene were confirmed. Breaking down the PTH-amino acid to the original amino acid by alkali and chromatography according to Dent [8] clearly showed the presence of phenylalanine. Quantitative determination of the PTH-phenylalanine showed that one mole of phenylalanine was present as N-terminal amino acid per mole of protein hormone.

Discussion. This study shows the presence of phenylalanine as N-terminal amino acid of human pituitary growth hormone. In contrast to the growth hormone of ox pituitaries this indicates the possibility that only one N-terminal amino acid per mole of protein is present. Thus the structure of the human growth hormone seems to differ from that of ox hormone. As already has been pointed out the ox hormone consists of two peptide chains. The human hormone, however, seems to be built up as a single peptide chain ending in phenylalanine as N-terminal amino acid. By means of the DNFB-technique phenylalanine has been demon-

strated in the human growth hormone [6]. The molecular weight calculated on basis of the quantitative analysis of N-terminal amino acid gave a value of 30 600 which is in accordance with previously reported values [10] (See Fig. 1).

On the Crystal Structure of $POCl_3 \cdot SbCl_5$

INGVAR LINDQVIST and
CARL IVAR BRÄNDÉN

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

Single crystals of $POCl_3 \cdot SbCl_5$ were prepared in capillary tubes by a method of zone melting. Rotation and Weissenberg photographs were taken around the *c*-axes with Mo-*K* and Cu-*K* radiation. The orthorhombic unit cell has the dimensions $a = 8.06 \pm 0.01$ Å, $b = 16.42 \pm 0.01$ Å and $c = 8.93 \pm 0.02$ Å. These values are in agreement with the preliminary values found earlier [1] ($a = \frac{1}{2} = 8.1$ Å, $b = 16.2$ Å and $c = 8.8$ Å). The extinctions $h0l$ for $h + l$ odd, and $hk0$ for k odd are in agreement with the centrosymmetric space-group $P\,m\,n\,b$ which has been confirmed by the structure determination. (This space group was by mistake not found in the earlier investigation [1]).

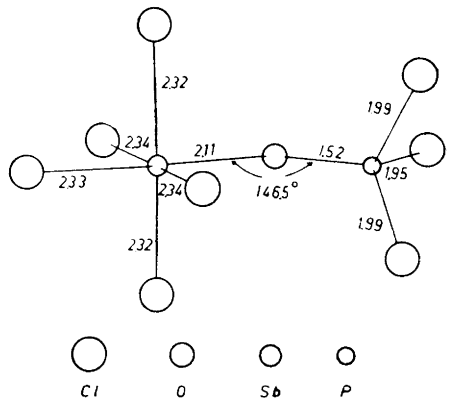

Fig. 1.

The number of molecules in the unit cell has been shown [1] to be 4.

The structure was determined from three-dimensional Patterson functions and confirmed by a three-dimensional electron density calculation. The unrefined parameters are:

4 Sb	in	$x = 0.250$	$y = 0.145$	$z = 0.079$
4 Cl	in	$x = 0.250$	$y = 0.257$	$z = 0.919$
4 Cl	in	$x = 0.250$	$y = 0.021$	$z = 0.207$
4 Cl	in	$x = 0.250$	$y = 0.226$	$z = 0.294$
8 Cl	in	$x = 0.538$	$y = 0.143$	$z = 0.070$
4 O	in	$x = 0.250$	$y = 0.073$	$z = 0.884$
4 P	in	$x = 0.250$	$y = 0.073$	$z = 0.714$
4 Cl	in	$x = 0.250$	$y = 0.464$	$z = 0.871$
8 Cl	in	$x = 0.054$	$y = 0.133$	$z = 0.633$

The shape of the $POCl_3 \cdot SbCl_5$ molecule and the interatomic distances within the molecule are given in Fig. 1. The structure is built up by the packing of such molecules. The complete structure determination will be published after refinement of the parameters.

On the Reactions in Solutions of Phosphorus Oxychloride

INGVAR LINDQVIST

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The acid-base concept suggested by Gutmann and Lindqvist [1] has already been applied in a discussion [2] of solutions in arsenic trichloride, $AsCl_3$. This short communication will deal with the differences in behaviour, compared with that in $AsCl_3$, which might be expected in phosphorus oxychloride, $POCl_3$. The main difference between these two solvents is that only $POCl_3$ contains oxygen. The reaction between bases like $(CH_3)_4NCl$ and the solvent cannot be much influenced by the presence of an oxygen atom, but it may be mentioned that $POCl_3$ has a very small tendency to react with bases, that is, to function as an acid (a detailed comparison will be made in a subsequent paper [3]). The reason for this is probably that the phosphorus atom in $POCl_3$ cannot easily increase its coordination. This is possible for As in $AsCl_3$ and Se in $SeOCl_2$, and those solvents react much better with bases.

With chlorides like $SbCl_5$, $SnCl_4$ and $TiCl_4$ which are acids in $AsCl_3$ there are certain changes in the reactions with oxychlorides. The important factor is always the increase in coordination. In $AsCl_3$ this increase can only take place in this way:

$$AsCl_3 + SbCl_5 \rightleftharpoons Cl_2AsClSbCl_5 \rightleftharpoons AsCl_2^+ + SbCl_6^- \quad (1)$$

The analogous reaction in $POCl_3$ is:

$$POCl_3 + SbCl_5 \rightleftharpoons Cl_2OPClSbCl_5 \rightleftharpoons POCl_2^+ + SbCl_6^- \quad (2)$$

The dissociations to $AsCl_2^+$ or $POCl_2^+$ and $SbCl_6^-$ have been established through potentiometric measurements [4,5].

In $POCl_3$ a competing reaction is possible, however:

$$POCl_3 + SbCl_5 \rightleftharpoons Cl_3POSbCl_5 \quad (3)$$

The further dissociation to PCl_3^{2+} and $SbOCl_5^{2-}$ is very improbable because it would require the breaking of the strong P—O bond and would lead to the formation of bivalent ions in a solvent with a very low dielectric constant.

Reaction (3) would not change the chloride ion activity but the occurrence of the reaction would decrease the apparent strength of $SbCl_5$ as an acid in $POCl_3$.

The structure of the solid compound $POCl_3 \cdot SbCl_5$ which has recently been determined [6], is built up by $Cl_3POSbCl_5$ molecules (contrary to the conclusions drawn from Raman spectroscopic work [7]). This is not in conflict with the assumption of different competitive equilibria in solution, because the equilibrium system can easily be shifted by the precipitation of the energetically most favourable solid phase.

The ionic compounds obtained by reactions (1) and (2) do not seem to have very favourable lattice energies compared with the compound found by reaction (3) and $SbCl_5$, $SnCl_4$ and $TiCl_4$ give crystalline compounds with $POCl_3$ and $SeOCl_2$ while only eutectic points are obtained with $AsCl_3$[3].

The reactions discussed so far involve only *addition* of solvent molecules, giving increased coordination. With an excess of solvent *substitution* reactions of the type:

$$Cl_3POSbCl_5 + POCl_3 \rightleftharpoons (Cl_3PO)_2SbCl_4^+ + Cl^- \quad (4)$$

cannot be quite excluded. It is true that potentiometric measurements have shown that reaction (4) does not take place [5] with $SbCl_5$ but it remains to be seen whether reactions of type (2), (3) or (4) are most important for other chlorides, *e. g.* $SnCl_4$ and $TiCl_4$.

It is obvious that investigations along the same lines as earlier drawn up for $AsCl_3$[2] are also of importance for the study of $POCl_3$ as a solvent.

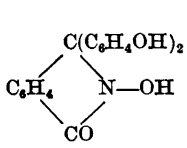
Oxidation of Phenolphthalein with Alkaline Hydrogen Peroxide

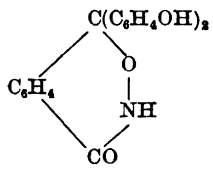
HAKON LUND

Chemical Institute, Aarhus University, Denmark

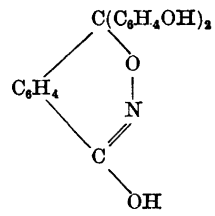
Some time ago it was pointed out [1] that the so-called phenolphthalein oxime cannot possess the structure hitherto assigned to it (I), but is a derivative of 2,3,1-benzoxazine (II).



I



IIa



IIb

It can be rearranged and hydrolyzed to *p*-aminophenol and 2-*p*-hydroxybenzoyl benzoic acid.

When in the preparation of the "oxime" an excess of hydroxylamine is present a side reaction occurs with formation of *p*-aminophenol and N-*p*-hydroxyphenyl phthalimide [1]. The final products after hydrolysis are thus 2 moles of *p*-aminophenol and one of phthalic acid.

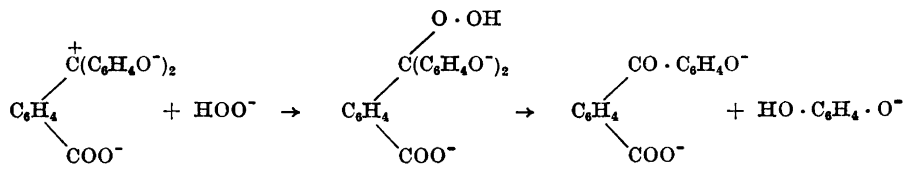
Due to the structural similarity between hydroxylamine and hydrogen peroxide it was thought worth while to examine the behaviour of the latter towards phenolphthalein in alkaline solution. It is known [2] that triphenylmethyl hydroperoxide can rearrange to benzophenone and phenol, so it was thought possible that a similar rearrangement might take place in a reaction with phenolphthalein:

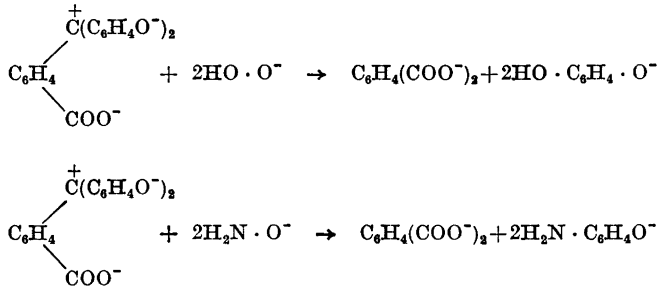
(It could hardly be expected to be possible to isolate a cyclic compound corresponding to phenolphthalein oxime.)

Preliminary experiments showed that the red colour of the alkaline solution of phenolphthalein faded rapidly after addition of hydrogen peroxide. Addition of sodium hydroxide to a suspension of phenolphthalein in 10 % hydrogen peroxide caused a rise in temperature, at first fairly slow, but suddenly extremely rapid, and most of the reaction mixture was thrown out of the flask. In order to get a controlled reaction it was necessary to keep the temperature rather low.

Only the red form of the phenolphthalein anion seems to react with hydrogen peroxide at room temperature. A solution in a large excess of 10 % sodium hydroxide brought to the fading equilibrium was left overnight at 10° after addition of an excess of hydrogen peroxide. On acidification the phenolphthalein could be recovered almost quantitatively.

When carried out under suitable conditions the reaction gave a good yield of hydroquinone; the other product was not, however, the expected hydroxybenzoyl benzoic acid, but phthalic acid, and the yield of hydroquinone could be raised to about 120 % of that calculated for the expected reaction. Obviously the reaction proceeds in a similar way as the side reaction observed with an excess of hydroxylamine:





It is noteworthy that neither hydrogen peroxide nor hydroxylamine reacts with *p*-hydroxybenzoyl benzoic acid in alkaline solution. Obviously the attack of the second molecule of hydrogen peroxide or hydroxylamine sets in at some intermediate stage, the first one having a high and the latter a lower rate of reaction as compared with the rearrangement reaction proper.

The very violent reaction observed in the preliminary experiments seems to be an oxidation of hydroquinone: addition of hydrogen peroxide to an alkaline solution of hydroquinone results in a quite similar phenomenon. How far the oxidation goes has not been ascertained, but at least some carbonic acid is formed.

Other phthaleins react similarly, although with very different velocities. Fluorescein, thymolphthalein, and α-naphtholphthalein react very slowly and the corresponding polyvalent phenols could not be isolated, but were oxidized further. At higher temperatures thymolphthalein gave, besides phthalic acid, fatty acids with the rancid odour of butyric acids.

Experimental: 1. *Phenolphthalein.* In a 3-necked flask provided with a stirrer, a thermometer, and a dropping funnel, phenolphthalein (20 g) is suspended in water (40 ml) and 30 % hydrogen peroxide (10 ml). The flask is placed in a cooling bath. Stirring is started and a 30 % sodium hydroxide solution is added dropwise at such a rate that the temperature is kept at 15 ± 2°. After about 15 ml have been added, three 5 ml portions of hydrogen peroxide are added during the addition of some 15 ml of sodium hydroxide more. It may be necessary to add one more portion of hydrogen peroxide when all solid phenolphthalein has been dissolved. After some standing the red colour of the solution turns brown (due to some oxidation of hydroquinone). The solution is acidified with conc. hydrochloric acid and cooled. A mixture of phthalic acid and hydroquinone separates and is filtered off. The filtrate is extracted twice with ether (100 ml). The ether extract combined with the mass of crystalline material is treated with aqueous potassium hydrogen carbonate. From this extract phthalic acid (9.5 g) separates on acidification. From the ether solution hydroquinone is isolated, yield 8.2 g (59 %).

2. *Fluorescein.* Fluorescein (5 g) is dissolved in 10 % sodium hydroxide (30 ml) and 30 % hydrogen peroxide (10 ml) is added. The flask is cooled under the tap and the temperature is kept at 30—35°. More portions (5 ml) of hydrogen peroxide are added when no spontaneous rise of temperature is noticed, until the orange colour of the solution changes to pure yellow. If necessary, sodium hydroxide is added to keep the solution alkaline. Addition of hydrochloric acid causes strong effervescence, indicating the oxidation of the tervalent phenol to carbon dioxide. Phthalic acid (2.1 g), yellow, but otherwise pure can be isolated.

3. *Hydroquinone and hydrogen peroxide.* Hydroquinone (1 g) is dissolved in 10 % sodium hydroxide (15 ml) and 30 % hydrogen peroxide (5 ml) is added. The temperature rises and in less than a minute the liquid boils vigorously.

The Isolation of a Green Pigment from Yeast

W. J. RUTTER* and BRITA ROLANDER

Medicinska Nobelinstitutet, Biokemiska Avdelningen, Stockholm, Sweden

In connection with attempts to find efficient means of extraction of various oxidative enzymes, yeast cells were subjected to various treatments with non-aqueous solvents. After certain preextraction conditions deep green solutions were obtained. The green pigment has been concentrated and partially purified. A colorless material present as a contaminant these purified green preparations has been crystallized.

The primary observations, together with certain of the chemical properties of the compounds are presented in this communication.

Results and discussion. Fresh bottom yeast kindly furnished by Stockholm's Hamburgerbryggeriet was washed by decantation several times with cold water and finally when the washes were almost colorless, the yeast was collected by centrifugation. The yeast cake was then extracted twice with 2 volumes ethylene glycol at −12°C. Short-time homogenization with a blendor in the cold was useful at this point. 2 volumes of acetone were added, and the very dark brown solution was filtered off at −12°. The next acetone extract was noticeably green, but was usually discarded. Extraction with ethyl ether then gave a deep green or in some cases a yellowish green solution.

If the ethylene glycol preextraction step was omitted, the procedure was much less successful. Preextraction with other agents, for example glycerol, was also less satisfactory.

All subsequent steps were carried out in the dark. The first extract was concentrated to an oil *in vacuo* at 10°C.; the oil was then dissolved in a minimum amount of acetone. A 5 ml aliquot of the green solution (equivalent to a total of 5—10 O.D. units at 650 μ) was then placed on a powdered cellulose column (3.7 × 30 cm). After washing the column with 10 volumes methanol, the green pigment remained as a narrow band at the top, while much of the yellow contaminants migrated down the column. Gradient elution with increasing concentrations of ether in acetone yielded a sharp fraction containing the green compound(s). The green material was concentrated to an oil and dissolved in acetone. Addition of methanol with cooling produced a heavy crop of colorless crystals which were removed by filtration and washed with cold methanol.

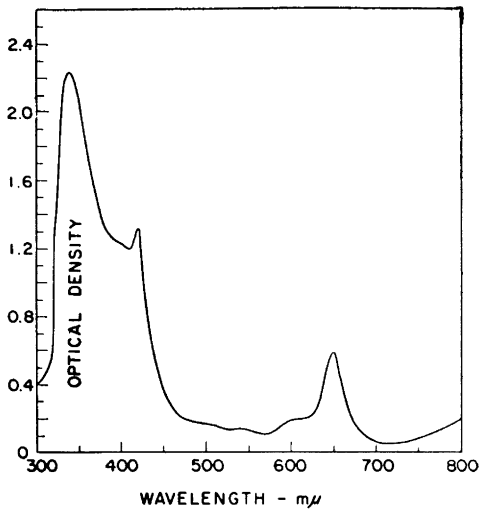

Fig. 1. Absorption spectrum of purified green pigment obtained from yeast.

The remaining deeply green solution was then concentrated and stored as an oil in the dark. The absorption spectrum of the purified green pigment is shown in Fig. 1. The spectrum is similar in form to certain hematin compounds, especially the chlorophylls [1,2]. However, no pyridine hemochromogen could be obtained under the usual conditions. Analysis of the preparation by chemical and spectroscopic means showed the presence of low concentrations of iron, and rather more magnesium. No other metals were detected. Addition of $FeCl_3$ to the green compound produced an immediate conversion to a yellow compound. The green material fluoresces intensely when irradiated with ultraviolet light, but solutions

* Postdoctoral fellow of United States Public Health Service, 1954—55; present address, Division of Biochemistry, University of Illinois, Urbana, Illinois.

are also self-quenching. The colorless crystals did not fluoresce.

The spectrum of the white crystals ($CHCl_3$) in the infra red region showed prominent absorption peak at 2 940 with a shoulder at 2 870 cm^{-1}. Less prominent peks are at 1 725, 1 605, 1 467, 1 380, 1 060, 1 035, 985 and 842 cm^{-1}. The purified green material exhibited the same prominent peak at 2 920 cm^{-1} and the shoulder at 2 860 cm^{-1}, and in addition, the absorption at 1 730 cm^{-1} was very much intensified. There was a great deal of generalized absorption from 900—1 500 cm^{-1}, with two distinct peaks at 1 465 cm^{-1} and 1 385 cm^{-1}. The spectra are not overly informative, but do suggest the possible presence of aldehyde or COOH groups in the green compound, while the white crystals could be a saturated lipid having comparatively few functional groups.

The question whether the green compound is a natural constituent with a role in the physiology of the yeast cell cannot be answered unequivocally. It can be stated that the green compound was consistently obtained from each of five different air-dried brewers yeast preparations in this laboratory. This procedure, however, did not yield a green product from bakers yeast. It is pertinent, however, that Keilin [3] reported a green fraction in initial attempts at the isolation of cytochrome c from brewers yeast in 1931. Efforts to obtain the present green compound by a suitable modification of Keilin's procedure have not proved successful.

There is some evidence which suggests that some of the efficiency of extraction of the green compound is very closely related to the state of the cells. Thus it has not been possible to obtain the green compound by extraction of fresh yeast cells, nor of cells which have been autolyzed even for short periods. It has also not been possible to obtain the green compound from freeze-dried preparations. Suitable experiments indicate that the green color is not due to an artifact of the reagents used.

The actual chemical structure of the green compound and its role in biological systems awaits clarification. It would be particularly interesting to know if present compounds have a relation to any of the physiologically important green compounds known.

Examination of the Behaviour of Liquid Mixtures in the Critical Region

HANS LUDVIG LORENTZEN and BJØRN BERGSNOV HANSEN

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

In order to investigate the shape of the co-existence curves close to the critical point, the two systems of partly miscible liquids, triethylamine-water (at the lower critical point) and succinonitrile-ethanol have been examined. The results are shown in Fig. 1, where the co-existence curves are seen to follow the "cubic rule" [1,2]

$$\Delta c = k \cdot \sqrt[3]{\Delta T} \qquad (1)$$

Δc being the composition of the individual phases measured from the critical, and ΔT the temperature distance from the critical.

It will be observed from Fig. 1 that in the case of triethylamine-water the plotted results follow the straight line as close as 1 mdeg to the critical. However, uncertainties regarding the fixation of the critical temperature involve uncertainty as regards the plots from the critical temperature to about $\Delta T = 2$ mdeg. Nevertheless, the visually obtained information about the initiation of the two phases when passing the critical temperatures

are also self-quenching. The colorless crystals did not fluoresce.

The spectrum of the white crystals ($CHCl_3$) in the infra red region showed prominent absorption peak at 2 940 with a shoulder at 2 870 cm^{-1}. Less prominent peks are at 1 725, 1 605, 1 467, 1 380, 1 060, 1 035, 985 and 842 cm^{-1}. The purified green material exhibited the same prominent peak at 2 920 cm^{-1} and the shoulder at 2 860 cm^{-1}, and in addition, the absorption at 1 730 cm^{-1} was very much intensified. Examination of the Behaviour of Liquid Mixtures in the Critical Region

HANS LUDVIG LORENTZEN and BJØRN BERGSNOV HANSEN

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

In order to investigate the shape of the co-existence curves close to the critical point, the two systems of partly miscible liquids, triethylamine-water (at the lower critical point) and succinonitrile-ethanol have been examined. The results are shown in Fig. 1, where the co-existence curves are seen to follow the "cubic rule" [1,2]

$$\Delta c = k \cdot \sqrt[3]{\Delta T} \qquad (1)$$

Δc being the composition of the individual phases measured from the critical, and ΔT the temperature distance from the critical.

It will be observed from Fig. 1 that in the case of triethylamine-water the plotted results follow the straight line as close as 1 mdeg to the critical. However, uncertainties regarding the fixation of the critical temperature involve uncertainty as regards the plots from the critical temperature to about $\Delta T = 2$ mdeg. Nevertheless, the visually obtained information about the initiation of the two phases when passing the critical temperatures

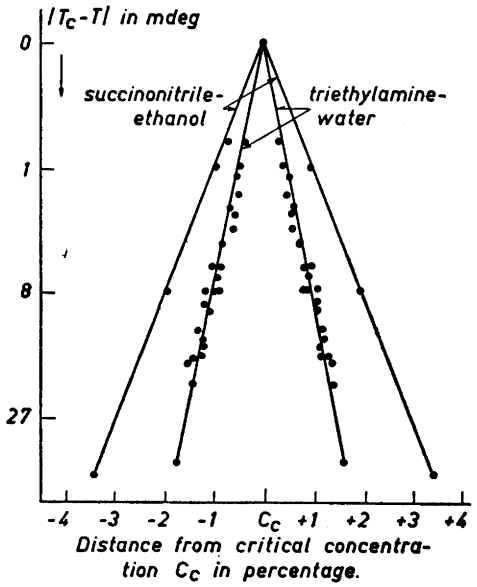

Fig. 1. Top of co-existence curves. C_c is the critical concentration. T_c is the critical temperature. Curves are obtained for the critical systems succinonitrile-ethanol and triethylamine-water. The co-existence curve for the latter is obtained through series of experiments, each series giving four to eight points on the curve.

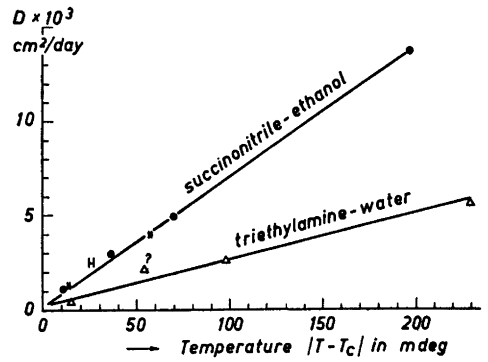

Fig. 2. Diffusion constant as a function of the temperature. For the critical system succinonitrile-ethanol the curve is obtained through two different series of experiments. The point marked ? on the critical system triethylamine-water may be due to the difficulties regarding the determination of the critical temperature — see text.

allows the assumption that the co-existence curve is regular to ΔT, this being only a fraction of a millidegree.

It should be noted that the critical temperature was not found to be constant. In the triethylamine-water system the critical temperatures seemed to have some connection with the initial concentration gradient in the sample. Impurities inside the sample may or may not be the cause of the fluctuations of the critical temperature.

The co-existence curve was determined in a large number of series, showing the critical temperature to be constant for each series. Because of the fluctuation of the critical temperature between the individual series, the critical temperature for each series had to be extrapolated from the determined concentrations of the two phases formed; in the case of the succinonitrile-ethanol system, at temperatures below the critical, and in the case of the triethylamine-water system, at temperatures above the critical.

The critical temperature, *i.e.*, the temperature at which the first sign of the development of the two phases appeared, was not observed with the requisite accuracy in most of the series. This left an element of doubt regarding the form of the co-existence curve at temperatures closer to the critical, as mentioned above.

The measurement of diffusion constants for the triethylamine-water mixture was carried out in the same way as already reported,[3] for the mixture of succinonitrile-ethanol at different temperatures from the critical. In Fig. 2 the diffusion constants found are plotted against temperature differences from the critical for both the systems examined. The two figures may permit the assumption that some correlation exists between the dD/dT of Fig. 2 and the $d\Delta c/d\sqrt[3]{\Delta T}$ of Fig. 1, the latter being the cube root of the constant of formula (1). It must, however, be remembered that the diffusion constants determined concern critical composition, whereas the two phases formed are naturally of compositions different from the critical.

The abscissa scale of Fig. 1 can be determined with greater accuracy than has been done here. However, the primary

aim of the investigations was to study the validity of the "cubic rule" [1,2] close to the critical point. The determination of the co-existence curves themselves, and the constant of formula (1) for the two mixtures was regarded as being of secondary importance.

The investigation of the triethylamine-water system was complicated by the fact that, at temperatures above, but closer to the critical, the two phases formed did not show the homogeneous composition which is to be expected. Furthermore, at temperatures below the critical, fog was occasionally seen to form inside the prism. After about an hour the fog would disappear, and the section of the concentration curve previously veiled by fog was then seen to have attained an arched form different from the arched concentration curves obtained by diffusion.

The author wishes to thank Professor O. Hassel of the University of Oslo for the interest he has shown in this work.

Reaction Kinetic Determination of the Hydroxyl-Alkoxide Equilibrium in Anion Exchangers

EERO SJÖSTRÖM and LALLI NYKÄNEN

Lääketehdas Orion Oy, Pharmaceutical Manufacturers, Helsinki, Finland

As a sequel to a previous work on the reaction mechanism between estradiol benzoate and an anion exchange resin [1], a kinetic method was developed which is reported here. This method makes it possible to follow the rate of hydrolysis (or alcoholysis) at very low ester concentrations. The method has been used for the investigation of the hydrolysis of methyl benzoate in water and in water-methanol mixtures of low methanol content. The experiments were carried out at 25 ± 0.02°C, by a batch-wise technique with constant stirring. At suitable time intervals samples were taken from the reaction mixture by means of a constant pressure apparatus. The amount of unreacted ester was estimated spectrophotometrically in the ultraviolet region.

According to Samelson and Hammet [2], the alkaline hydrolysis by anion exchangers in ethanol-water mixtures is a second order reaction. The present results show that when the hydroxyl ion concentration (the resin) is high compared with the ester, the rate constant can be calculated from the first order equation.

On adding methanol to the resin-water mixture the hydroxyl ions are in part converted into alkoxide ions owing to the reaction:

$$MeOH + HO^- \rightleftharpoons MeO^- + H_2O$$

and the hydroxyl ion concentration in the resin phase is decreased. If this reaction is the dominant factor in reducing the hydrolysis rate, it should be possible in theory to calculate the state of this equilibrium from the observed kinetic data. In fact, it was found that at low methanol

aim of the investigations was to study the validity of the "cubic rule" [1,2] close to the critical point. The determination of the co-existence curves themselves, and the constant of formula (1) for the two mixtures was regarded as being of secondary importance.

The investigation of the triethylamine-water system was complicated by the fact that, at temperatures above, but closer to the critical, the two phases formed did not show the homogeneous composition which is to be expected. Furthermore, at temperatures below the critical, fog was occasionally seen to form inside the prism. After about an hour the fog would disappear, and the section of the concentration curve previously veiled by fog was then seen to have attained an arched form different from the arched concentration curves obtained by diffusion.

Reaction Kinetic Determination of the Hydroxyl-Alkoxide Equilibrium in Anion Exchangers

EERO SJÖSTRÖM and LALLI NYKÄNEN

Lääketehdas Orion Oy, Pharmaceutical Manufacturers, Helsinki, Finland

As a sequel to a previous work on the reaction mechanism between estradiol benzoate and an anion exchange resin [1], a kinetic method was developed which is reported here. This method makes it possible to follow the rate of hydrolysis (or alcoholysis) at very low ester concentrations. The method has been used for the investigation of the hydrolysis of methyl benzoate in water and in water-methanol mixtures of low methanol content. The experiments were carried out at 25 ± 0.02°C, by a batch-wise technique with constant stirring. At suitable time intervals samples were taken from the reaction mixture by means of a constant pressure apparatus. The amount of unreacted ester was estimated spectrophotometrically in the ultraviolet region.

According to Samelson and Hammet [2], the alkaline hydrolysis by anion exchangers in ethanol-water mixtures is a second order reaction. The present results show that when the hydroxyl ion concentration (the resin) is high compared with the ester, the rate constant can be calculated from the first order equation.

On adding methanol to the resin-water mixture the hydroxyl ions are in part converted into alkoxide ions owing to the reaction:

$$MeOH + HO^- \rightleftharpoons MeO^- + H_2O$$

and the hydroxyl ion concentration in the resin phase is decreased. If this reaction is the dominant factor in reducing the hydrolysis rate, it should be possible in theory to calculate the state of this equilibrium from the observed kinetic data. In fact, it was found that at low methanol

concentrations, up to about 10% (w/w), the equilibrium constant

$$K = \frac{[MeO^-][H_2O]}{[MeOH][HO^-]}$$

can be calculated from the following equation:

$$\frac{[MeOH]}{[H_2O]} \cdot K + 1 = \frac{k}{k_{obs}}$$

where k is the true rate constant, *i.e.*, the same as in aqueous solution, k_{obs} the observed rate constant, and [MeOH] and [H_2O] the molar concentrations of methanol and of water, respectively, in the resin phase. The linear relationship between the values of [MeOH]/[H_2O] and $1/k_{obs}$ was verified by the data obtained from Fig. 1, and the resulting value for K was found to be 11.1. This equilibrium in anion exchangers has thus been determined for the first time.

A detailed description of the procedure as well as of the mathematical treatment will be published in the near future. Investigations on the hydrolysis of ethyl benzoate in water-ethanol mixtures are still in progress. Furthermore, the study of the saponification of several phenolic esters by this method has been started.

Action of Group Blocking Agents and Enzymes on Intrinsic Factor Preparations

RALPH GRÄSBECK*

Biochemical Department, Nobel Medical Institute, Stockholm, Sweden, and Fourth Medical University Clinic, Maria Hospital, Helsingfors, Finland

The binding of vitamin B_{12} appears to be of importance for the physiological action of intrinsic factor [1,2]. It therefore seemed of interest to study the mode of binding of B_{12} to the B_{12}-binding principle contained in intrinsic factor preparations. This was performed by subjecting hog intrinsic factor concentrates and pepsin-inactivated [1] human gastric juice to group blocking agents. During the course of attempts to break down the B_{12}-binding principle with proteolytic enzymes some data were obtained bearing upon the mode of binding of B_{12}, and these results are included in the following together with some data on the physiological activities of the chemically modified preparations.

Vitamin B_{12}-binding was assayed by adding radioactive ^{60}Co labeled B_{12}, whereupon the free and bound vitamin was separated with dialysis [1] or ultrafiltration [3].

The action of the group blocking agents is apparent from Table 1. A clearcut effect is observed with fluorodinitrobenzene, iodine, and monochromatic (280 mμ) ultraviolet light, whereas treatment with *p*-chloromercuribenzoate, acetic anhydride, and nitrous acid lacked effect. The absence of effect of the three last mentioned compounds makes the involvement of SH- and NH_2-groups less likely, whereas the involvement of phenol or imidazole groups seems more probable. An active tyrosinase preparation (Worthington) lacked effect, however. This does not eliminate the possibility of a phenolic group being involved, because tyrosinase has been found to lack effect on tyrosine groups of several proteins [4]. The mode of binding of B_{12} to intrinsic factor preparations seems to be much the same as in the cobalamin protein of sow's milk [3].

When both gastric juice and hog stomach preparations were subjected to thorough digestion with crystalline pepsin, trypsin, and highly purified chymotrypsin and mucinase [5] preparations, addition of B_{12} prior to digestion was found to have a marked protective action against chymotrypsin. A slight similar effect was observed in the case of pepsin, whereas B_{12} did not influence the effect of trypsin and mucinase. The latter were found not to have any effect on B_{12}-binding.

The protective action of B_{12} against chymotrypsin seemed to be limited to very few components of the intrinsic factor preparations. This was shown by digesting two identical samples, one in presence of B_{12}, and the other one in its absence. After digestion, vitamin B_{12} was added to the second sample and both samples

Action of Group Blocking Agents and Enzymes on Intrinsic Factor Preparations

RALPH GRÄSBECK*

Biochemical Department, Nobel Medical Institute, Stockholm, Sweden, and Fourth Medical University Clinic, Maria Hospital, Helsingfors, Finland

The binding of vitamin B_{12} appears to be of importance for the physiological action of intrinsic factor [1,2]. It therefore seemed of interest to study the mode of binding of B_{12} to the B_{12}-binding principle contained in intrinsic factor preparations. This was performed by subjecting hog intrinsic factor concentrates and pepsin-inactivated [1] human gastric juice to group blocking agents. During the course of attempts to break down the B_{12}-binding principle with proteolytic enzymes some data were obtained bearing upon the mode of binding of B_{12}, and these results are included in the following together with some data on the physiological activities of the chemically modified preparations.

Vitamin B_{12}-binding was assayed by adding radioactive ^{60}Co labeled B_{12}, whereupon the free and bound vitamin was separated with dialysis [1] or ultrafiltration [3].

The action of the group blocking agents is apparent from Table 1. A clearcut effect is observed with fluorodinitrobenzene, iodine, and monochromatic (280 mμ) ultraviolet light, whereas treatment with *p*-chloromercuribenzoate, acetic anhydride, and nitrous acid lacked effect. The absence of effect of the three last mentioned compounds makes the involvement of SH- and NH_2-groups less likely, whereas the involvement of phenol or imidazole groups seems more probable. An active tyrosinase preparation (Worthington) lacked effect, however. This does not eliminate the possibility of a phenolic group being involved, because tyrosinase has been found to lack effect on tyrosine groups of several proteins [4]. The mode of binding of B_{12} to intrinsic factor preparations seems to be much the same as in the cobalamin protein of sow's milk [3].

When both gastric juice and hog stomach preparations were subjected to thorough digestion with crystalline pepsin, trypsin, and highly purified chymotrypsin and mucinase [5] preparations, addition of B_{12} prior to digestion was found to have a marked protective action against chymotrypsin. A slight similar effect was observed in the case of pepsin, whereas B_{12} did not influence the effect of trypsin and mucinase. The latter were found not to have any effect on B_{12}-binding.

The protective action of B_{12} against chymotrypsin seemed to be limited to very few components of the intrinsic factor preparations. This was shown by digesting two identical samples, one in presence of B_{12}, and the other one in its absence. After digestion, vitamin B_{12} was added to the second sample and both samples

* Present address: Department of Medical Chemistry, Helsingfors University, Finland.

Table 1. Effect of group blocking agents on B_{12}-binding capacity. GJ = Gastric juice. HS = Hog stomach preparation *.

Treatment before binding assay	Effect on binding capacity
GJ or HS + 32 mg fluorodinitrobenzene/ml, pH 8.6, stirring 3 1/2 h	66 % inactivation
GJ or HS at pH 8.6, alcoholic I_2 solution added to final concentration 2.5×10^{-4} M, afterwards dialysis 21 h to remove I_2	96 % inactivation **
Same, 5×10^{-4} M I_2	beginning inactivation
HS (BFS 209) irradiated 3 h with 280 mμ UV light 4×10^{19} quanta/16 mg, O_2 supplied	25 % inactivation
HS pH 7, 1.7 mg *p*-chloromercuribenzoate/ml	None
HS in half saturated Na-acetate, 0.12 ml acetic anhydride/ml, 0°C, stirring 1 h ***	None
HS in 1 M $NaNO_2$, pH 4.6, 0°C, samples taken up to 82 h	None ****
Tyrosinase 0.2 mg/mg HS, 10^{-6} M $CuCl_2$, pH 6—7, 24 h, O_2 supplied	None

* In all experiments an Organon preparation BFS 209 was used, in many cases also other preparations. BFS 209 bound 0.27 μg B_{12}/mg and was active in the Schilling test [6] in 16.6 mg dose.
** Also complete loss of intrinsic factor activity as observed on two patients.
*** The intensity of the color produced by ninhydrin reaction dropped with 88 %.
**** 10 % inhibition was observed after 82 h. This could be due to direct diazotization of tyrosyl groups.

were dialyzed in order to remove the small molecular material. There was no observable difference in the dry weight of the two dialyzed samples. The possibility that B_{12} had a direct inhibitory action on chymotrypsin was eliminated by the failure to find any inhibition of the chymotryptic digestion of casein by similar concentrations of B_{12}.

A few samples of gastric juice were digested with chymotrypsin with and without B_{12} as described above. Afterwards both the B_{12}-binding capacity and the intrinsic factor activity were assayed, the latter using the urinary radioactivity test [6] employed in previous studies [1]. As is apparent from Fig. 1, B_{12} also protected the intrinsic factor activity. This may indicate that the B_{12}-binder is identical with intrinsic factor or a part of it. The simultaneous loss of B_{12}-binding capacity and intrinsic factor activity after iodination also points in this direction.

The explanation of the protective action of B_{12} against chymotryptic digestion is probably that the cyanocobalamin molecule covers up a chymotrypsin-sensitive bond in the molecule. In view of the above findings with group blocking agents, it is interesting to note that chymotrypsin hydrolyzes, *inter alia*, peptide bonds in which the carbonyl group is supplied by tyrosine [7].

The rate of hydrolysis of the bond which can be protected with B_{12} appears to be slow, because even in the absence of B_{12}

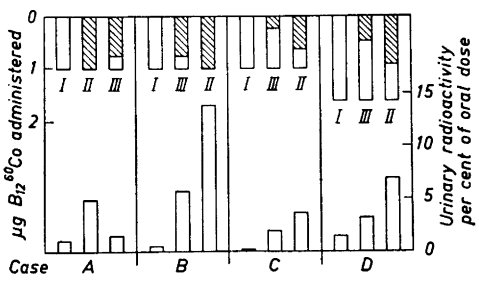

Fig. 1. Intrinsic factor assay of chymotrypsin digested gastric juice. Upper columns: Material administered. White columns: Free B_{12}. Shaded columns: Bound B_{12}. I = Basal test without intrinsic factor, II = Sample digested in presence of B_{12}, III = Sample digested in absence of B_{12}. Lower columns: Patient's response in the Schilling test [6]. *N.B.* In cases A and B sample II was not saturated with B_{12}.

some B_{12}-binding and intrinsic factor activity is retained after 20 h of digestion with high concentrations of chymotrypsin (Fig. 1).

As regards the action of chymotrypsin the present study confirms similar observations made during the preparation of commercial intrinsic factor preparations [8].

Preliminary ultracentrifugal studies [9] indicate that the B_{12}-binder — vitamin B_{12} complex remains a relatively large molecule after trypsin-chymotrypsin digestion (mol.wt. 52 000 both before and after digestion for cobalamin complex from pepsin-inactivated gastric juice). It therefore appears that the B_{12}-binder (and apparently also intrinsic factor) contains only a few bonds sensitive to the action of these enzymes.

The author is greatly indebted to Professor H. Theorell for valuable advice, to Dr. K. Yamashina for the chymotrypsin, to Dr. J. Gad Andresen for the mucinase, to Dr. H. Wijmenga for the intrinsic factor preparations, and to Dr. B. Josephson for arrangements in connection with the collection of gastric juice. Dr. J. Schuberth was kind to assist in the UV studies, and the Schilling-tests were carried out by Dr. G. Amnell. The investigation was supported by generous grants from *N. V. Barium Hydroxide as a Selective Precipitating Agent for Hemicelluloses

HANS MEIER

Wood Chemistry Department, Swedish Forest Products Research Laboratory, Stockholm, Sweden

A widely applied method of fractionating and purifying hemicelluloses is by precipitating them as their insoluble copper complexes. The separation of acidic hemicelluloses from neutral ones has been achieved by fractional precipitation using long-chain quaternary ammonium salts (*e. g.* "cetavlon") [1].

Another method has now been found which on its own, or in conjunction with known methods, may enable a more efficient fractionation to be achieved. We have observed that barium ions readily form insoluble complexes with mannans and glucomannans, probably by reaction with the vicinal *cis*-hydroxyl groups on carbon atoms 2 and 3 of the mannose units. Those complexes are precipitated from aqueous solutions on the addition of small quantities of barium hydroxide.

Ivory nut mannan A and spruce glucomannans were both precipitated comple-

Barium Hydroxide as a Selective Precipitating Agent for Hemicelluloses

HANS MEIER

Wood Chemistry Department, Swedish Forest Products Research Laboratory, Stockholm, Sweden

A widely applied method of fractionating and purifying hemicelluloses is by precipitating them as their insoluble copper complexes. The separation of acidic hemicelluloses from neutral ones has been achieved by fractional precipitation using long-chain quaternary ammonium salts (*e. g.* "cetavlon") [1].

Another method has now been found which on its own, or in conjunction with known methods, may enable a more efficient fractionation to be achieved. We have observed that barium ions readily form insoluble complexes with mannans and glucomannans, probably by reaction with the vicinal *cis*-hydroxyl groups on carbon atoms 2 and 3 of the mannose units. Those complexes are precipitated from aqueous solutions on the addition of small quantities of barium hydroxide.

Ivory nut mannan A and spruce glucomannans were both precipitated comple-

Table 1.

Sample	Galactose %	Glucose %	Mannose %	Arabinose %	Xylose %
Hemicellulose mixture from spruce	7.1	10,4	19.8	6.6	56.1
Fraction I: $Ba(OH)_2$-precipitate	12.9	17.1	51.8	3.8	14.4
Fraction II: material left in solution	1.8	3.6	1.4	9.8	83.4

tely from aqueous solutions at barium hydroxide concentrations below 0.03 M. The barium complexes of the mannans and glucomannans are easily soluble in dilute acids and even in water, but are insoluble in organic solvents and in copper ethylene diamine.

Although the use of barium hydroxide did not lead to the precipitation of a larch arabo-galactan it caused a spruce galactan to be precipitated. This may be attributed to the fact that galactose, when present either as an end-group, or as a 1,6-linked residue in a polysaccharide, contains the requisite vicinal *cis*-hydroxyl groups on carbon atoms 3 and 4. As the hemicellulose galactans are highly branched molecules they will possess a high percentage of end-groups.

A birch xylan (2.5 % glucose + galactose, 85.6 % xylose, 11.9 % uronic acids) was also precipitated from aqueous solution when the barium hydroxide concentration was made up to 0.15 M. This may be due to the formation of an insoluble barium salt by the acidic xylan.

When barium hydroxide was added to a hemicellulose mixture (extracted from spruce holocellulose with 14 % potassium hydroxide) the glucomannans were precipitated almost completely. They were, however, contaminated by other polysaccharides containing galactose, xylose and arabinose residues. The precipitation of a galactan can be attributed to the presence of vicinal *cis*-hydroxyl groups as mentioned above. If precipitation is due only to them, then it would be difficult to explain why a xylan or an arabo-xylan should be precipitated by barium hydroxide as readily as were the glucomannans. When fraction I (*cf.* Table 1) was dissolved in water and "cetavlon" was added, xylose and arabinose together with galactose and minor amounts of glucose and mannose were detected in the hydrolysate of the precipitate whereas a pure glucomannan was left in solution. The presence of a galacto-arabo-xylan may therefore be suspected. However, the xylose residues in fraction I could also be parts of a very acidic xylan. The hemicellulose fraction II (*cf.* Table 1) which had not precipitated with barium hydroxide and which accounted for nearly two thirds of the recovered material was shown to be mainly an arabo-xylan with an arabinose : xylose ratio of 1:8.5 and an uronic acid content of 19 %. Even with a high excess of barium hydroxide (more than 0.2 M) no precipitation occurred. Two explanations might be possible. Either the barium salt of this acidic arabo-xylan is soluble in barium hydroxide concentrations up to 0.2 M or the branches of arabinose residues sterically hinder salt formation of neighbouring chains.

It is evident from these preliminary experiments that the use of barium hydroxide as a precipitant will provide a complement to previous methods of fractionating polysaccharides even if the scope and limitation of the method have not yet been fully explored.

Experimental. The hemicelluloses were dissolved in water or in dilute sodium hydroxide and then saturated barium hydroxide solution was added. If a precipitate formed it was centrifuged and was purified by dissolving it in water and reprecipitating it with barium hydroxide. After centrifugation the precipitate was dissolved in 2 N acetic acid and from this solution the hemicelluloses were precipita-

ted with ethanol and were washed successively with ethanol/water, with ethanol and with ether.

The quantitative paper chromatography of the samples was carried out according to Saeman *et al.*[2] using the solvent systems ethyl acetate-acetic acid-water (3:1:3) and, for the separation of glucose and galactose, ethyl acetate-pyridine-water (2:1:2).

Preparation of Thiotaurine (Aminoethanethiosulfonic Acid)

BO SÖRBO

Research Institute of National Defence, Dept. 1, Sundbyberg, and Nobel Medical Institute, Biochemical Dept., Stockholm, Sweden

Recently [1] an enzymatic transsulfuration product from β-mercaptopyruvate and hypotaurine (2-aminoethanesulfinic acid) was identified as 2-aminoethanethiosulfonic acid, for which the shorter name thiotaurine was suggested. Thiotaurine has now been synthesized with taurine as starting material. Taurine was first transformed into phthalimidoethanesulfonyl chloride [2] and the latter then converted to hypotaurine by a novel method. The sulfonyl chloride was first reacted with phenylhydrazine to give phthalimidoethanesulfonyl phenylhydrazide which was not isolated but instead heated with an excess of phenylhydrazine and tri-*n*-butylamine in ethanol, in order to remove the phthaloyl group [3]. During this treatment it was found that the sulfonylphenylhydrazide decomposed to the corresponding sulfinic acid [4]. Hypotaurine was thus formed (yield 80 %) and precipitated with methyl ethyl ketone. Thiotaurine was then obtained from hypotaurine through treatment of the latter with ammonium polysulfide [5] and crystallized from ethanol-water (yield 40 %). Colourless crystals, m.p. about 213° (decomp.), were obtained and found to contain 22.5 % cyanide labile sulfur [6] (calc. for $NH_2C_2H_4S_2O_3H$: 22.7 %). Paper chromatography of the compound in 4 different solvent systems demonstrated only the presence of one single component. It was previously suggested that thiotaurine might be identical with an unknown sulfur containing compound from human blood, first detected by Smith and Tuller [7] by paper chromatography and reported to behave as taurine. This possibility could now be excluded, as the synthetic thiotaurine was found to be clearly resolved from taurine in the solvent system used by Smith and Tuller.

Details of this work will be published later.

Studies on the Chemistry of Lichens

XI.* Structure of Picrolichenic Acid **

CARL AXEL WACHTMEISTER

Institutionen för organisk kemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

Picrolichenic acid, $C_{25}H_{30}O_7$, a bitter compound from *Pertusaria amara* (Ach.) Nyl., has been shown to contain a carboxyl group, a lactone ring, a phenolic hydroxyl group, a methoxyl group and two *n*-amyl groups. It reacts with piperidine forming a piperidide $C_{30}H_{41}O_7N$. Mild alkaline hydrolysis followed by acidification causes decarboxylation with formation of a monocarboxylic acid (A), $C_{24}H_{32}O_6$. On decarboxylation and demethylation acid (A) affords a phenol (C), $C_{12}H_4(C_5H_{11})_2(OH)_4$, identified as 2,2′-di-*n*-amyl-4,6,4′,6′-tetrahydroxydiphenyl (XII) by dehydration to 3,7-dihydroxy-1,9-di-*n*-amyldibenzofuran (XIV), methylated and oxidised to the known 3,7-dimethoxydibenzofuran-1,9-dicarboxylic acid. These results are in harmony with a structure (XXIII) for picrolichenic acid which is further supported by infra-red and ultra-violet absorption spectra.

The crustose lichen *Pertusaria amara* (Ach.) Nyl. is widely spread in Europe, occurring on the bark of broadleaf trees such as oak and beech. It has an intense, bitter taste similar to that of quinine. This attracted early chemical investigation, and a paper by Alms on "Picrolichenin" from *Variolaria amara* Ach., a synonym of *P. amara*, appeared in 1832 in the first volume of *Annalen der Pharmacie* [1]. According to Alms, picrolichenin showed promising results in the treatment of malaria.

Zopf [2,3] obtained the bitter principle which he called "Pikrolicheninsäure", in a state of reasonable purity (m.p. 178°, decomp.) and suggested the empirical composition $C_{17}H_{20}O_5$.

For the present investigation some hundred grams of *P. amara* were collected from beech trees in Blekinge, Southern Sweden. The powdery lichen was extracted with large volumes of cold ether and a concentrated solution was left in the refrigerator to crystallise. The crude acid, isolated in 5—7 % yield from the dry lichen, was purified by treatment with aluminium oxide and

* Part X. *Acta Chem. Scand.* **10** (1956) 1404.
** Preliminary communication: *Chem. & Ind.* London **1954** 1042.

crystallisation from benzene or aqueous acetic acid. When pure, the acid forms colourless prisms, m.p. about 180° with decomposition. It is optically inactive and contains carbon, hydrogen and oxygen only. The analytical values for picrolichenic acid and a number of its derivatives and degradation products indicate the empirical composition $C_{25}H_{30}O_7$, including a carboxyl group, a methoxyl group and two C-methyl groups.

Picrolichenic acid is readily soluble in most common solvents except benzene and light petroleum. It dissolves slowly with the evolution of gas in aqueous sodium bicarbonate to give a colourless solution from which it can be recovered unchanged on acidification [3]. The solution in alkali turns brownish red when exposed to the air [1].

The acid gives an intense violet colour with ferric chloride in ethanol [2] but no coloration with 2,6-dichloroquinone-monochloroimide (Gibbs' reagent[4]), *bis*-diazotised benzidine [5] or bleaching powder [6]. However, after short treatment with cold aqueous alkali it gave a dark red colour with the benzidine reagent and a red colour with bleaching powder. This resembles the behaviour of certain easily hydrolysed depsides and depsidones. Phenolic groups were also liberated very rapidly when paper chromatographic spots of the acid were exposed to ammonia vapour.

On heating to the melting point the acid decomposed with the evolution of a gas containing carbon dioxide. A crystalline decomposition product, m. p. 153—155°, was isolated but this has not yet been subjected to thorough studies.

Short treatment of picrolichenic acid with diazomethane in the cold furnished methyl picrolichenate, m. p. 102—103,5° which was soluble in cold 0.05 N sodium hydroxide solution and gave a brownish ferric chloride reaction. Prolonged methylation with diazomethane yielded neutral methyl O-methylpicrolichenate $C_{23}H_{25}O_3(OCH_3)_2COOCH_3$, m. p. 80—82°.

Picrolichenic acid reacted in the cold with piperidine yielding a piperidide which gave a violet ferric test and was obtained in two interconvertible forms, m. p. 169—172° and 187—190° (decomp.) respectively. The piperidide titrated as a monobasic acid and gave analytical values which agreed with the composition $C_{30}H_{41}O_7N$ and thus contained all the atoms of the reacting components. On methylation with diazomethane a dimethyl derivative was formed which as shown by its low solubility in alkali and by its colour reactions contained a phenolic hydroxyl group.

Because of the sensitivity of picrolichenic acid to alkali and amines, tests for carbonyl functions were carried out with the piperidide instead of the acid itself. No positive results were obtained with carbonyl reagents under ordinary conditions.

On oxidation with permanganate picrolichenic acid afforded about 1.5 moles of volatile acids. The main component was *n*-caproic acid as indicated by paper chromatography and confirmed by the identity of the purified *p*-bromophenacyl ester with an authentic sample of *n*-caproic acid *p*-bromophenacyl ester. Paper chromatography also revealed the presence of small amounts of lower fatty acids but no spots corresponding to acids with more than six carbon atoms were observed.

These results indicate the presence in picrolichenic acid of a free carboxyl group, a lactone group, a phenolic hydroxyl group *ortho* to a carboxyl function,

a methoxyl group and two *n*-pentyl chains. Assuming the presence of two six-membered carbocyclic rings, all the carbon atoms and six of the seven oxygen atoms are accounted for.

The presence of *n*-pentyl chains in picrolichenic acid points to a relationship with the orcinol-homologue, olivetol, a fairly widespread unit in lichen acids. The empirical composition, $C_{25}H_{30}O_7$, agrees with that of a dehydrogenation product of a monomethylated depside $C_{25}H_{32}O_7$ derived from two molecules of olivetol carboxylic acid. A depside of this type, perlatolinic acid (II, R = *n*-C_5H_{11}) has been isolated from a *Parmelia*-species by Asahina and Fuzikawa [7] and picrolichenic acid might be a related depsidone such as (IV). This possibility could be ruled out by the following observations.

Picrolichenic acid after treatment with cold N sodium hydroxide solution and then acidification gave a gum which rapidly expanded to a spongy mass due to the evolution of carbon dioxide. The purified crystalline product (A) gave a violet ferric test and was found to be a monocarboxylic acid containing a methoxyl group, $C_{22}H_{28}O_3(OCH_3)COOH$ (= $C_{25}H_{30}O_7 + H_2O—CO_2$).

The acid (A) melted at about 145° with decomposition, losing one mole of carbon dioxide and forming an oily phenol (B) which was characterised by paper chromatography. It was very sensitive towards oxygen in alkaline solution and rapidly developed a brown-red colour.

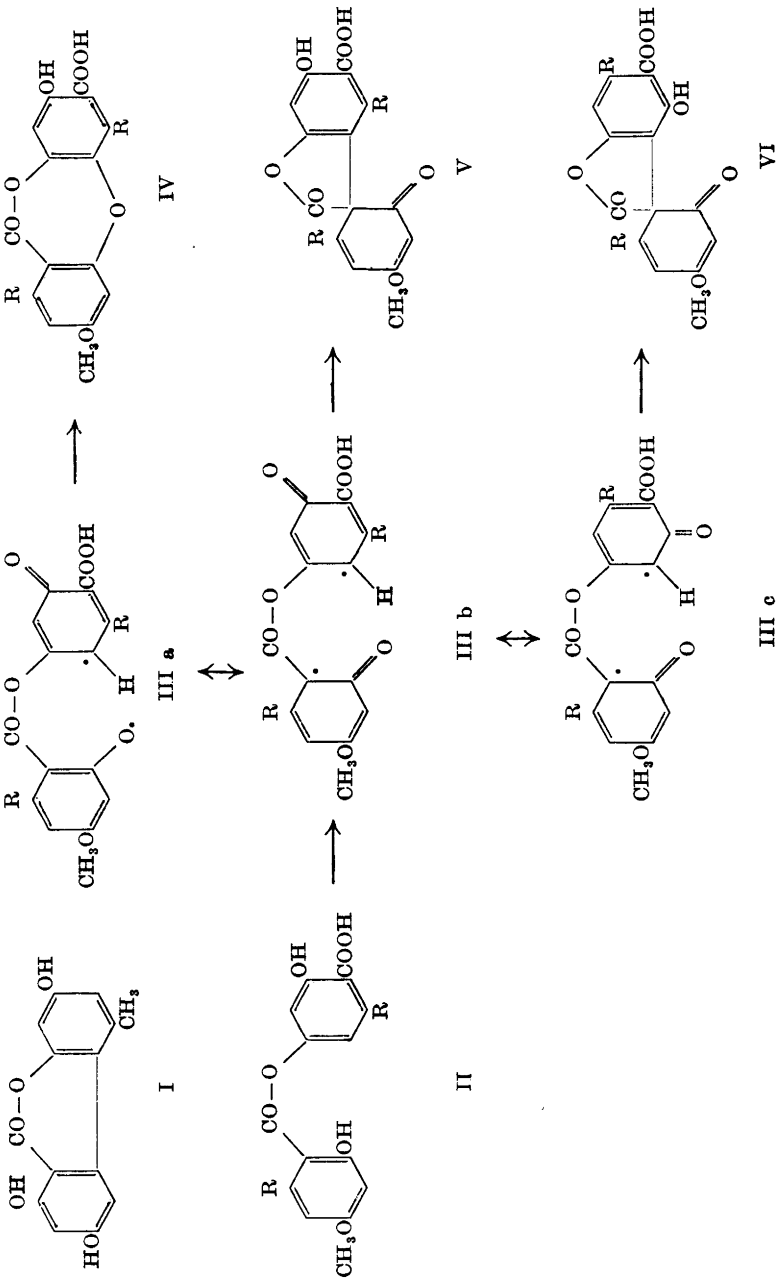
On simultaneous decarboxylation and demethylation with hydrobromic acid, the acid (A) furnished a phenol m. p. 180—181°, identical with a phenol (C), $C_{22}H_{30}O_4$, obtained directly from picrolichenic acid under similar conditions. Like phenol (B) it gave no colour with ferric chloride.

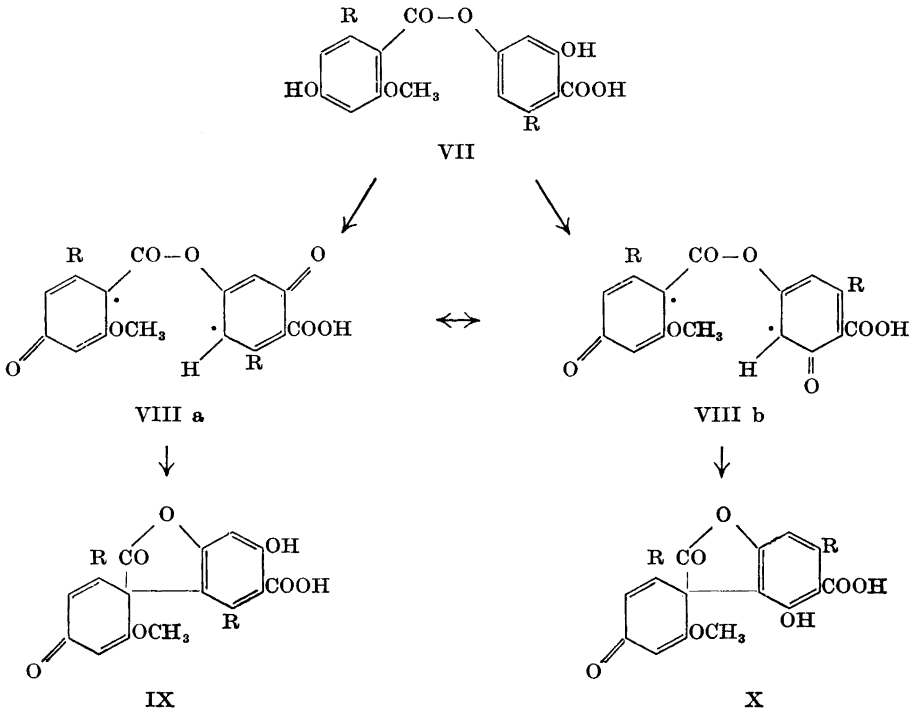
On methylation the phenols (B) and (C) afforded the same tetramethyl ether $C_{12}H_4(C_5H_{11})_2(OCH_3)_4$, m. p. 34.5—35.5°, which on bromination furnished di-, tri- and tetrabromoderivatives. The composition of the tetramethyl ether and its bromination products clearly shows that the phenol (C) and its monomethyl ether (B) are diphenyl derivatives. The U.V. spectrum of the tetramethyl ether was very similar to that of 2,2′-dimethyl-4,6,4′,6′-tetramethoxydiphenyl, the tetramethyl ether of a symmetrical diorcinol.

The acid (A) which gives a violet ferric test is obviously a carboxy derivative of phenol (B) with the carboxyl group in the *ortho*-position to a free hydroxyl group. The very facile decarboxylation of the acid indicates that there is also a free hydroxyl group in the *para*-position to the carboxyl group.

The above results indicate that picrolichenic acid contains two six-membered rings joined by a carbon-carbon bond as well as by an ester linkage. This brings to mind compounds of the ellagic acid and alternariol [8] (I) type. Such compounds, however, in contrast to picrolichenic acid do not lose carbon dioxide on acidification after alkaline hydrolysis. Moreover, structures of this type cannot be derived from orcinol derivatives.

It has been suggested [9,10] that depsidones are formed in Nature by dehydrogenation of depsides such as (II) with a mesomeric diradical (IIIa ⟷ IIIb ⟷ IIIc) as an intermediate. Coupling oxygen-carbon (IIIa → IV) would yield a depsidone. Coupling carbon-carbon (IIIb → V; IIIc → VI), however, would yield products of a structural type so far not encountered in lichens, γ-lactones containing a 2,4-*cyclo*hexadien-1-one structure (V, VI).

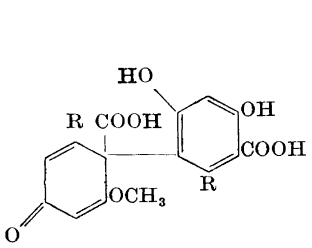




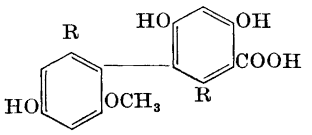
A depside precursor (VII) in which the phenolic hydroxyl group *ortho* to the ester group is methylated (or protected in some other way) would yield a diradical (VIIIa, VIIIb) which could stabilise by carbon-carbon coupling with the formation of γ-lactones (IX, X) containing a 2,5-*cyclo*hexadien-1-one structure [11].

The properties expected for γ-lactones of these types are compatible with the known chemical behaviour of picrolichenic acid. Alkaline hydrolysis of for example a lactone (IX) would yield a dicarboxylic acid (IX a) which, being a vinylogue of a β-keto-acid, should be easily decarboxylated and aromatised to a monocarboxylic acid (IX b) with a diphenyl structure. On the other hand, the dienone structure would be expected to be retained if the lactone ring opens on aminolysis to form an amide. This is exactly what was observed when picrolichenic acid was treated with piperidine. On this basis (V), (VI), (IX) and (X) (R = n-C_5H_{11}) would appear to be plausible structures for picrolichenic acid and a structure like (XI) for the piperidide.

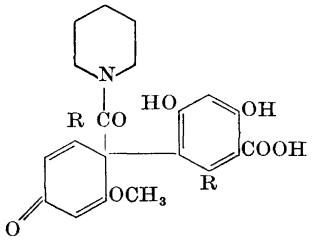
Two alternative structures would then be possible for the phenolic degradation product, (C): 2,2′-di-n-amyl-4,6,4′,6′-tetrahydroxydiphenyl (XII) and 2,4′-di-n-amyl-4,6,2′,6′-tetrahydroxydiphenyl (XIII). Tetrahydroxydiphenyls of this type undergo acid catalysed cyclisation to dibenzofuran derivatives. (XII) and (XIII) would yield homologues of 3,7- and 1,7-dihydroxydibenzofuran respectively and it would be possible to distinguish between these iso-



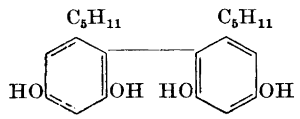
IX a



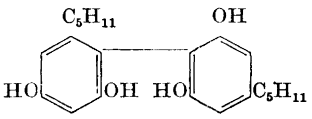
IX b



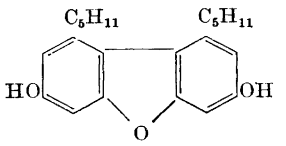
XI



XII



XIII



XIV

mers by their behaviour with Gibbs' reagent [4]. The 1,7-dihydroxy-derivative, containing a methine group in the *para*-position to a hydroxyl group, should give a blue colour with this reagent while the 3,7-derivative should give only a greyish colour [12].

When treated with zinc chloride for a few minutes at 240—250°, phenol (C) gave a phenol (D), $C_{12}H_4O(C_5H_{11})_2(OH)_2$, m. p. 124—125°, which on methylation gave a dimethyl ether. Phenol (D) gave a greyish colour with Gibbs' reagent and the solution in alkali exhibited an intense bluish fluorescence in ultra-violet light. The U.V. spectrum of the dimethyl ether was very similar to that of 3,7-dimethoxy-1,9-dimethyldibenzofuran which was synthesised essentially by a method described by Shibata [13]. This indicates strongly that phenol (D) is 3,7-dihydroxy-1,9-di-*n*-amyldibenzofuran (XIV).

The structure (XIV) of phenol (D) was definitely settled by oxidation of its dimethyl ether with permanganate. The crude oxidation product was, paper chromatographically, identical with 3,7-dimethoxydibenzofuran-1,9-dicarboxylic acid [13] and on methylation afforded a dimethyl ester $C_{18}H_{16}O_7$, m. p. 191—193.5°, identical with 3,7-dimethoxy-1,9-dicarbomethoxydibenzofuran [13].

Accordingly phenol (C) is 2,2′-di-*n*-amyl-4,6,4′,6′-tetrahydroxydiphenyl (XII), a structure which is also supported by the U.V. spectrum of its tetramethyl ether. Lower homologues show very similar properties and give oily tetramethyl ethers [13].

It follows that two structures, (XV) and (XVI), are possible for phenol (B), the monomethyl ether of (C). Two alternative structures, (XVII) and (XVIII), remain for the monocarboxylic acid (A) in view of its violet ferric reaction and easy decarboxylation. These alternatives are also biogenetically plausible, being related to orsellinic acid.

It may thus be concluded that the structures (V) and (IX) (R = n-C_5H_{11}) for picrolichenic acid are in accordance with observed facts while the alternatives (VI) and (X) are ruled out.

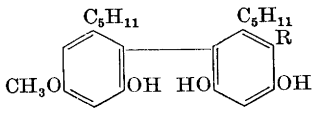
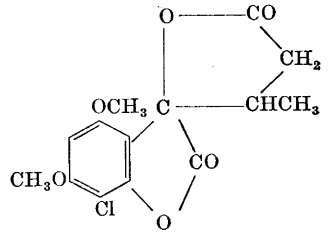
XVII : R=COOH



XVI : R=H
XVIII : R=COOH



XIX

Additional evidence in favour of a dienone-γ-lactone structure is provided by the infra-red spectra of picrolichenic acid and its derivatives (Figs. 1—4).

Picrolichenic acid (Fig. 1), methyl picrolichenate (Fig. 2) and methyl O-methylpicrolichenate (Fig. 3) all show strong absorption at 1 820—1 825 cm^{-1} but the piperidide (Fig. 4) shows no absorption in this region. Aliphatic β,γ-unsaturated γ-lactones are known [14] to absorb at about 1 800 cm^{-1} but picrolichenic acid should be compared with β,γ-unsaturated γ-lactones in which the double bond forms part of an aromatic ring. Two recent examples are 4,6-diacetoxy-7-acetyl-3,5-dimethylcoumaran-2-one (1 822, 1 780 and 1 698 cm^{-1} in the carbonyl region; $CHCl_3$-solution) [15] and the spirane γ-lactone (XIX) (1 815 and 1 795 cm^{-1}) [16]. The 1 820 cm^{-1} band of picrolichenic acid and its methyl derivatives is therefore strong support for the presence of a γ-lactone carbonyl group.

The two remaining carbonyl functions of picrolichenic acid give rise to a single band at 1 665—1 670 cm^{-1}. Methyl O-methylpicrolichenate (Fig. 3), however, shows two strong bands at 1 725—1 730 cm^{-1} and 1 665—1 670 cm^{-1} which may be ascribed to the carboxymethyl group and the dienone carbonyl group, respectively [14]. As is shown by examples from steroid chemistry [17], cross conjugated as well as linear conjugated dienones absorb strongly in a narrow region at 1 660—1 670 cm^{-1}.

Methyl picrolichenate, containing a hydroxyl group in the *ortho*-position to a carboxymethyl group, would be expected to show an ester band in the frequency range characteristic for chelated aromatic esters (1 670—1 690 cm^{-1}) [14]. Hence, the strong band at 1 665—1 670 cm^{-1} shown by the methyl ester (Fig. 2) may be due to an ester band overlapping a dienone carbonyl band. The unexpected medium intensity band at 1 725 cm^{-1} shown by this compound may indicate that chelation is weak. It should perhaps be mentioned that substituents such as methyl or bromine in the *ortho*-position to the carboxyl group of salicylic acid have recently been regarded as the cause of a decrease in the strength of chelation between the hydroxyl and the carboxyl group [18].

The infra-red spectrum of the piperidide of picrolichenic acid (Fig. 4) shows a broad absorption in the 1 650—1 725 cm^{-1} region with a maximum at 1 690—1 700 cm^{-1}, indicating overlapping of the carbonyl bands.

Picrolichenic acid and its piperidide show broad absorption in the 2 500—2 800 cm^{-1} region, indicating strongly hydrogen bonded hydroxyl groups [14]. These compounds as well as methyl picrolichenate also show a broad hydroxyl band at about 3 450 cm^{-1}. Methyl O-methylpicrolichenate has no hydroxyl absorption.

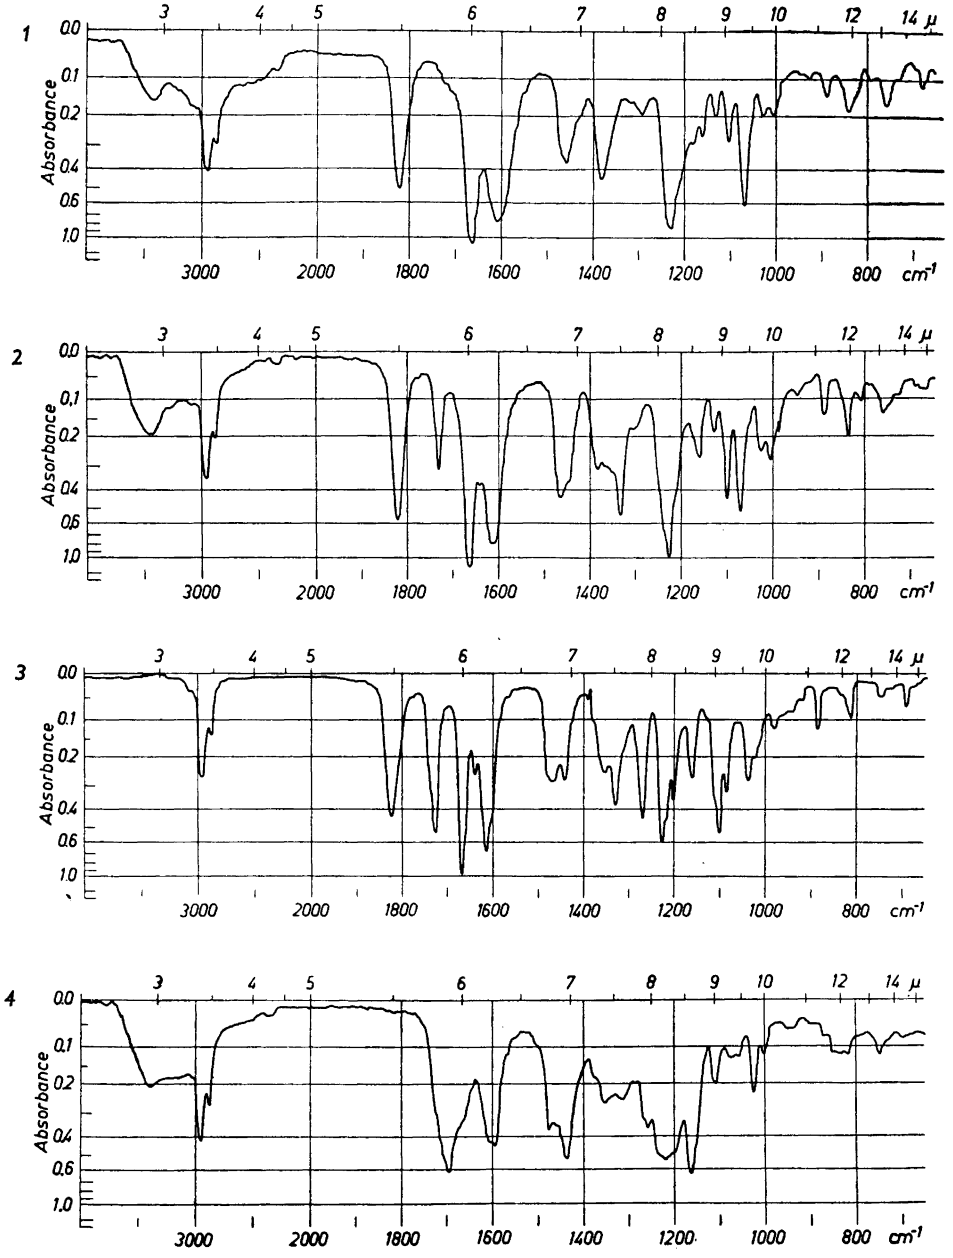


Fig. 1—4. Infra-red absorption spectra (in potassium bromide) of picrolichenic acid (XXIII) (Fig. 1), methyl picrolichenate (XXIV) (Fig. 2), methyl O-methylpicrolichenate (XXV) (Fig. 3) and picrolichenic acid piperidide (XI, R = n-C_5H_{11}) (Fig. 4).

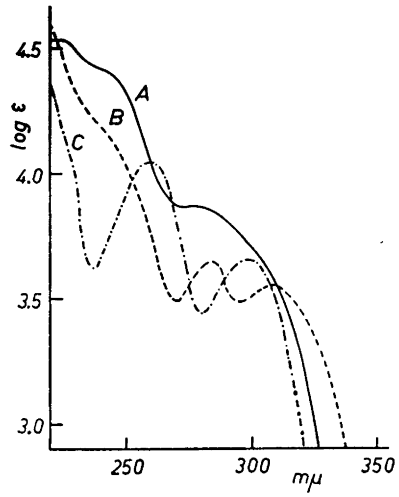

Fig. 5. Ultra-violet absorption spectra (in ethanol) of picrolichenic acid (XXIII) (A ————), picrolichenic acid piperidide (XI, R = *n*-C_5H_{11}) (B - - -) and orsellinic acid (C —.—.—.—).

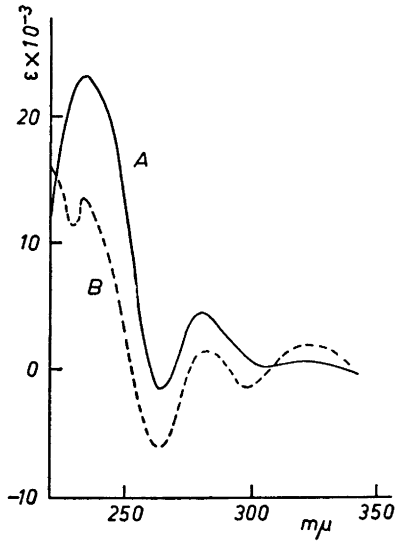

Fig. 6. Difference curves; A: Picrolichenic acid — orsellinic acid; B: Picrolichenic acid piperidide — orsellinic acid

While the main skeleton of picrolichenic acid as in (V) or (IX) (R = *n*-C_5H_{11}) appears well established, the choice between the two alternatives remains. From a biological point of view the structure (IX) derived from (VII) appears far more likely than (V). The widespread occurrence of depsidones in lichens indicates that the dehydrogenation of depsides such as (II) usually proceeds with oxygen-carbon coupling. In the case of depsides methylated as in (VII), however, oxygen-carbon coupling cannot occur and only carbon-carbon coupling is possible. A few depsides of this type are known, one example being umbilicaric acid[19], a tridepside derived from orsellinic acid.

The stability of the piperidide of picrolichenic acid may also be taken as an indication of the correctness of the structure (IX) for the acid. A piperidide derived from (V) would be expected to undergo ready *cyclo*-acetalisation and aromatisation to a dibenzofuran.

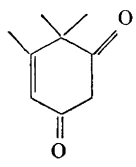
However, a final choice between the alternatives (V) and (IX) requires a knowledge of the exact position of the methoxyl group in phenol (B), the monomethyl ether of (XII). A strong indication in favour of structure (XV) for this phenol — and hence structure (IX) for picrolichenic acid — is its great sensitivity to oxygen in alkaline solution. Similar easy oxidation is characteristic of for example 2,4,2′,4′-tetrahydroxydiphenyl but not of 2,4,2′,6′-tetrahydroxydiphenyl which possesses only one hydroxyl group in a 4-position.

Since no direct conjugation exists between the two moieties of picrolichenic acid, information about the structure of the *cyclo*hexadienone part could be

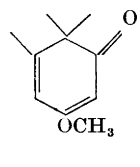
obtained by subtracting the U.V. spectrum of the aromatic part from the spectrum of the acid itself. The difference curves obtained by subtracting the U.V. curve for orsellinic acid (Fig. 5:C) — used as a model for the aromatic part of the molecule — from the curves for picrolichenic acid (Fig. 5:A) and picrolichenic acid piperidide (Fig. 5:B) are shown in Fig. 6. The two curves, of course, give only a rough idea of the spectral type of the methoxy *cyclo*hexadienone chromophore of picrolichenic acid.

2,4- and 2,5-*cyclo*hexadien-1-ones differ considerably in spectral properties, the former absorbing at a longer wavelength in the U.V. region. Wessely and Sinwel [20] report unspecific absorption in the short U.V. region for 4-methyl-4-hydroxy-2,5-*cyclo*hexadien-1-one, 2,4,6-trimethyl-4-hydroxy-2,5-*cyclo*hexadien-1-one and their acetates whereas 6-methyl-6-acetoxy-2,4-*cyclo*hexadien-1-one and related compounds which are linear conjugated showed well-defined maxima in the 290—310 mμ region (log ε 3.6—3.7).

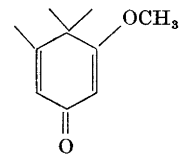
Jeger, Rüegg and Ruzicka [21] studied a system with a more direct bearing upon the present problem. A pyrolysis product of α-amyrin containing the partial structure (XX) afforded two isomeric monomethyl ethers, one of which showed a very broad maximum at 330 mμ (log ε about 3.8) and was alloted the linear conjugated formula (XXI). The isomer which showed maxima at 250 and 278 mμ (log ε 4.2 and 3.7, respectively) was given the cross-conjugated partial structure (XXII).



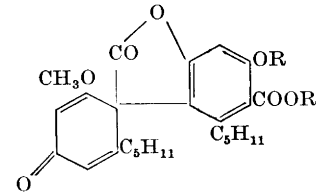
XX



XXI



XXII

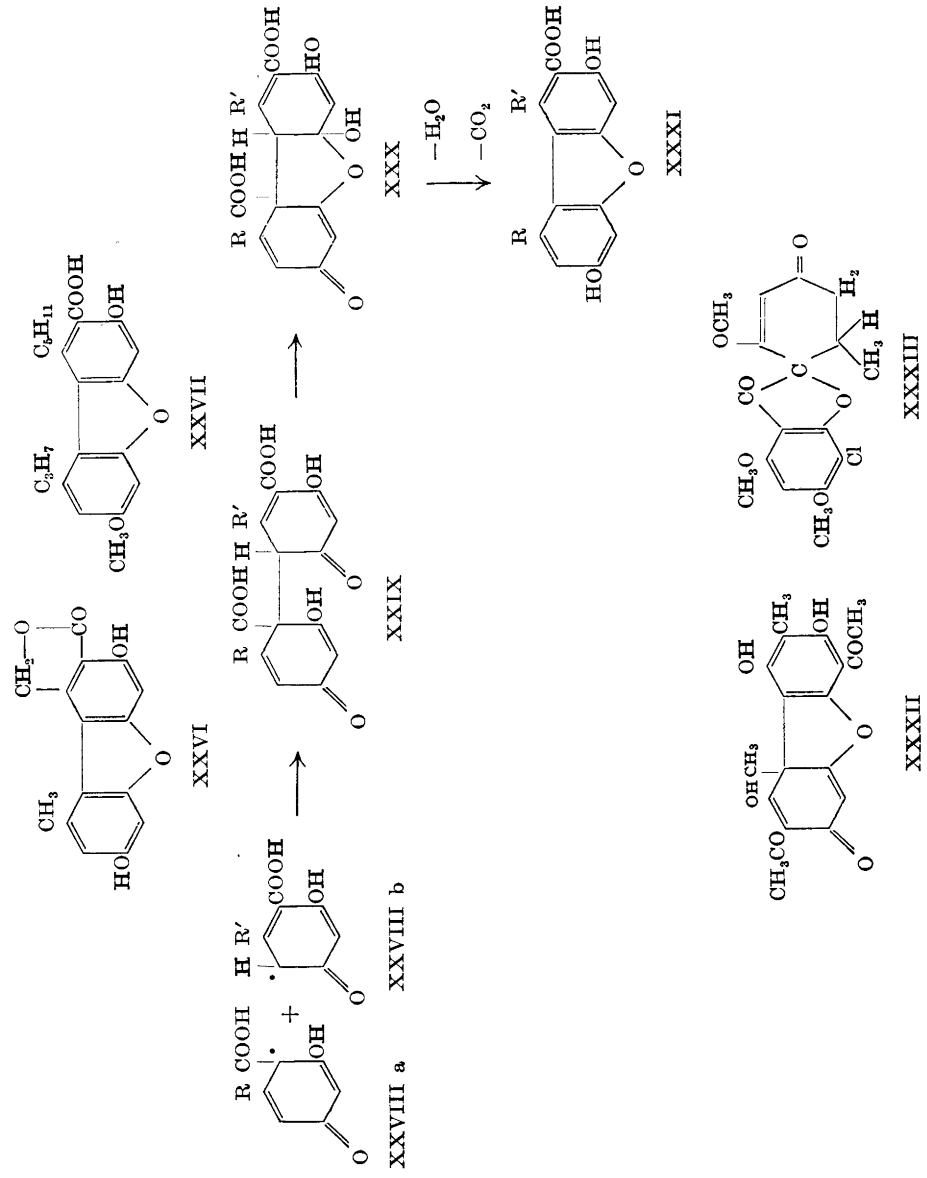


XXIII : R=R'=H
XXIV : R=H, R'=CH_3
XXV : R=R'=CH_3

One of the two difference curves mentioned above (Fig. 6) shows a distinct maximum at about 325 mμ, but this maximum is less intense (log ε 3.25) and much narrower than the broad maximum of the compound containing the structure (XXI). Both curves, however, show maxima near 235 mμ (log ε 4.4; 4.1) and 280 mμ (log ε 3.8; 3.15) corresponding roughly to the two maxima of the cross-conjugated compound (XXII) which again supports the structure (IX) for picrolichenic acid.

The chemical and physical evidence so far discussed appears to be in harmony with a structure (XXIII) (IX, R = *n*-C_5H_{11}) for picrolichenic acid. The structure of the piperidide $C_{30}H_{41}O_7N$ would then be (XI) (R = *n*-C_5H_{11}) and that of the monocarboxylic acid (A), (XVII).

There is, however, one observation which could be taken as evidence against structure (XXIII); the lack of optical activity in the compound. Several explanations could be offered to explain this inactivity, but a successful resolution of picrolichenic acid would constitute a valuable confirmation of the



structure. Work is in progress in this direction, and attempts are also being made to obtain a more direct proof of the position of the methoxyl group in phenol (B) and to elucidate the structure of the thermal decomposition product of picrolichenic acid.

The lichen acids strepsilin [22] (XXVI) and didymic acid [13] (XXVII) are dibenzofurans which unlike most depsides and depsidones contain only one carboxyl group. It appears reasonable to suggest that their biosynthesis has proceeded essentially along the same lines as picrolichenic acid (XXVIII a, b → XXXI) but that, owing to the presence of a free hydroxyl group in the *ortho*-position to the carbon-carbon linkage between the two nuclei of the radical coupling product (XXIX), a *cyclo*acetalisation to (XXX) has taken place followed by elimination of water and carbon dioxide with formation of (XXXI).

Essentially the same scheme has recently been proposed by Barton and Cohen [9]. However, the above scheme differs in details which are also of importance for an understanding of the structure of related dibenzofurans such as porphyrilic acid [12]. A full discussion of these questions will be presented elsewhere.

The unique structure (XXIII) of picrolichenic acid combines features of the depsidones and of usnic acid (XXXII) [23-25] and it may also be compared with the fungal metabolite griseofulvin [26] (XXXIII) which contains a similar spirane structure. These compounds like the dibenzofurans contain a heterocyclic ring system and it is obvious that the theory of oxidative coupling of phenols provides a common basis for a rational interpretation of their possible biosynthesis from simple phenolic progenitors.

EXPERIMENTAL

Unless otherwise stated the melting points were determined on the Kofler-Block. Whatman No. 1 paper was used for paper chromatography. The U.V. spectra were measured with a Beckman spectrophotometer, model DU. The infra-red spectra were recorded with a Perkin-Elmer double beam spectrophotometer, model 21, using the potassium bromide technique.

Isolation of picrolichenic acid (XXIII). The powdery lichen material (250 g) was extracted with cold ether (2 500 ml) in several portions and the combined extracts were concentrated to 30 ml. On standing in the refrigerator, the solution deposited a crystallisate which was collected and washed with cold ether (yield, 11.0 g). The mother liquor on evaporation in air and treatment with benzene/light petroleum (2:1) gave a second crop (6 g), contaminated by resinous material. The resulting mother liquor was not further investigated.

The first fraction (11.0 g) was dissolved in hot benzene (50 ml) and the insoluble residue was filtered off. The solution deposited a yellowish crystallisate of crude picrolichenic acid (7.4 g); a second crop (2.3 g) was obtained from the mother liquor. The fraction 6.0 g gave crude picrolichenic acid (3.0 g) on treatment with ice-cold ether and crystallisation from benzene.

The acid was purified by passing a benzene solution through a small column of alumina to adsorb some of the coloured impurities. The analytical samples crystallised (I) from benzene as prisms, m. p. 184—187° (decomp.) or (II) from aqueous acetic acid as prisms, m. p. 187—190° (decomp.) (m.p:s uncorrected, measured in a capillary tube; rate of temperature increase, 4°/min). The samples were dried *in vacuo* at 120°.

The acid, dissolved in aqueous acetone, titrated sharply with bromothymol blue as indicator. (Found: I. C 68.3; 68.6; H 6.74; 6.70; OCH_3 6.91; $C-CH_3$ 4.0; 4.0; equiv. wt. 443. II. C 67.9; H 7.15. $C_{25}H_{30}O_7$ requires C 67.9; H 6.83; OCH_3 7.01; $(C-CH_3)_2$ 6.8; equiv. wt. (as a monobasic acid) 442.5.)

The acid in ethanol ($c = 5$) or chloroform ($c = 5$) showed $[\alpha]_D^{20} \pm 0$ as measured in a 1 dm tube.

U.V. spectrum (in ethanol): Fig. 5 A; I.R. spectrum, Fig. 1.

Picrolichenic acid (0.01 % in ethanol) gave a violet colour with ferric chloride. The acid gave no colour with bleaching powder in aqueous methanol but gave a red colour when treated with bleaching powder and aqueous alkali. It gave no colour with *bis*-diazotised benzidine when tested on neutral filter paper but an intense red colour with this reagent after pretreatment with 0.1 N sodium hydroxide solution for a few minutes. As shown by spot tests on filter paper, phenolic groups were also liberated by exposure of the acid for a few seconds to ammonia vapour. Picrolichenic acid gave no colour with Gibbs' reagent when tested in a borate buffer (pH 9.0).

Thermal decomposition of picrolichenic acid. The acid (200 mg) in a test tube was heated for a few minutes in a salt bath to 210°; a gas containing carbon dioxide was evolved. The residue when distilled in high vacuum gave a yellowish, viscous oil which crystallised as prisms, m. p. 153—155° from 90 % acetic acid. The compound gave a yellowish-brown colour with *bis*-diazotised benzidine but no colour with ferric chloride.

Methyl picrolichenate (XXIV). An excess of ethereal diazomethane was added to an ice-cold solution of picrolichenic acid in ether, followed after one minute by a drop of acetic acid. Evaporation afforded the ester as an oil, which crystallised from methanol as needles, m. p. 102—103.5°. (Found: C 68.1; H 7.16; OCH_3 13.8. $C_{26}H_{32}O_7$ requires C 68.4; H 7.06; $(OCH_3)_2$ 13.6.) $[\alpha]_D^{20} \pm 0$ (ethanol, $c = 1$). I.R. spectrum, Fig. 2.

The ester was soluble in cold 0.05 N sodium hydroxide solution and gave a brownish ferric test.

Methyl O-methylpicrolichenate (XXV). Picrolichenic acid (150 mg) was treated overnight with an excess of ethereal diazomethane containing methanol. The methyl derivative (90 mg) crystallised from a solution of the oily reaction product in light petroleum (b.p. 40—60°; 70 ml) and was finally obtained from hexane as needles, m. p. 80—82°. (Found: C 68.4; H 7.21; OCH_3 20.0. $C_{27}H_{34}O_7$ requires C 68.9; H 7.28; $(OCH_3)_3$ 19.8.) I.R. spectrum, Fig. 3.

The compound was insoluble in 0.1 N sodium hydroxide solution in the cold and gave no colour with phenol reagents.

Piperidide of picrolichenic acid (XI, R = n-C_5H_{11}). The acid (720 mg) in dry piperidine (10 ml) was set aside at room temperature in an atmosphere of nitrogen. After a few days, the solution was poured with stirring into 2 N hydrochloric acid (500 ml) containing ice. The crude piperidide (800 mg) separated as a brownish precipitate which crystallised from benzene as prisms m.p. 168—172° (I); a second form (II) was obtained as prisms, m. p. 187—190° (decomp.) from 80 % acetic acid. A benzene solution of the higher melting form gave the lower melting form on seeding with it.

The piperidide in aqueous acetone titrated sharply as a monobasic acid (bromothymol blue). (Found: (I) N 2.58; OCH_3 6.29; equiv. wt 527. (II) C 68.8; H 8.09; N 2.76. $C_{30}H_{41}O_7N$ requires C 68.3; H 7.80; N 2.66; OCH_3 5.88; equiv. wt. 527.6.) $[\alpha]_D^{20} \pm 0$ (c 5.0, ethanol or chloroform.) U.V. spectrum (in ethanol), Fig. 5 B; I.R. spectrum, Fig. 4.

Colour reactions: Ferric chloride-ethanol, violet; *bis*-diazotised benzidine, yellowish brown; bleaching powder, no colour.

Prolonged methylation of the piperidide with ethereal diazomethane in the presence of methanol gave a dimethyl derivative which crystallised from methanol as prisms, m.p. 163—165°. (Found: N 2.62; OCH_3 17.0. $C_{32}H_{45}O_7N$ requires N 2.52; $(OCH_3)_3$ 16.8.) The compound gave no colour with ferric chloride but gave a yellowish-brown colour with *bis*-diazotised benzidine when tested on buffered paper (Na_3PO_4). It was slightly soluble in 1 N sodium hydroxide solution.

Permanganate oxidation of picrolichenic acid. A 1 % aqueous solution of potassium permanganate (200 ml) was added dropwise with stirring to a solution of picrolichenic acid (192 mg, 0.435 mmole) in 0.05 N sodium hydroxide solution (50 ml). After 2 h at 20°, the temperature was kept at 45° for 30 min to complete the oxidation. Excess permanganate was destroyed, the solution was acidified with sulphuric acid and the manganese sludge was dissolved by passing sulphur dioxide through the solution. The solution was extracted with ether (600 ml) and the ether phase was shaken with 1 N sodium hydroxide solution (50 ml). The alkaline solution was acidified with sulphuric acid, saturated with

sodium sulphate and steam distilled. The distillate (250 ml) contained 0.64 mmole of volatile acids, as estimated by titration.

A sample of the distillate was extracted with ether and the ether phase was analysed by chromatography using paper impregnated with dimethyl sulphoxide and a mobile phase of ether-light petroleum (b.p. 65—75°) 1:1 [27]. A reference sample containing the normal saturated acids with 2, 3, 4, 5, 6 and 8 carbon atoms was run on the same chromatogram. The spots were detected by spraying the paper with a mixed indicator solution as recommended by Duncan and Porteous [28]. The main component of the ether extract appeared as a spot with the same R_F-value as *n*-caproic acid. Faint spots of the lower fatty acids were also observed but no spots corresponding to acids with more than six carbon atoms.

The main part of the distillate, neutralised with standard alkali, was evaporated to dryness and the *p*-bromophenacylester prepared in the usual way. The crude ester (102 mg, m. p. 55—63°) on crystallisation from aqueous methanol yielded blades (50 mg), m. p. 68.5—69.5, undepressed on admixture with an authentic sample of *p*-bromophenacyl caproate, m. p. 71—72°.

Alkaline hydrolysis of picrolichenic acid. The acid (2.7 g) in 1 N sodium hydroxide solution (50 ml) was left for 40 min at 20° in a nitrogen atmosphere. The reddish solution poured into 1 N hydrochloric acid (100 ml) gave the hydrolysis product as a voluminous precipitate which changed to a gum and rapidly expanded to a spongy mass due to the evolution of gas. The product was taken up in ether and the ether solution was washed, dried and evaporated *in vacuo*. The oily residue (2.1 g) was dissolved in benzene (30 ml) and the solution was filtered through a small column of alkali-free alumina. The monocarboxylic acid (A) (XVII) separated from the filtrate as needles (1.2 g) and was recrystallised from benzene. To avoid decarboxylation which was noticeable even below the melting point of the acid the analytical sample, m. p. 145—148° (decomp.) was dried *in vacuo* at 100° for only a short time. (Found: C 68.9; H 7.55; OCH_3 7.52; equiv. wt. 419. $C_{24}H_{32}O_6$ requires C 69.2; H 7.75; OCH_3 7.45; equiv. wt. 416.5.) U.V. absorption (in ethanol): λ_{max} 264 mμ (log ε 4.06); 306 mμ (3.67). λ_{min} 254 mμ (4.01); 294 mμ (3.61).

Colour reactions: Ferric chloride, violet; *bis*-diazotised benzidine, red; bleaching powder, red-violet, changing to brown-red.

Decarboxylation of acid (A). A small sample of the acid in a test tube was heated in an oil bath for a few minutes to 150—160°; carbon dioxide was evolved. (Loss of weight, 10.5 %. Calculated for decarboxylation of a monocarboxylic acid $C_{24}H_{32}O_6$, 10.6 %). The decarboxylation product (B) (XV), obtained as a colourless oil by distillation *in vacuo*, did not crystallise. It gave a negative ferric test but otherwise gave colour reactions similar to those given by the acid (A). Paper chromatography, using the solvent system benzene-water, gave a single, somewhat elongated spot, $R_F = 0.4—0.5$. Phenol (B) in alkaline solution was rapidly oxidised in the air with the formation of a brown-red colour.

Methylation of phenol (B). The phenol (150 mg) in dry acetone (50 ml) was boiled under reflux for 8 h with potassium carbonate (5 g) and dimethyl sulphate (2.5 g). The oily reaction product, isolated in the usual way, was distilled under reduced pressure and crystallised on seeding with the tetramethyl ether of the phenol (C), described below. The crude methyl ether (m. p. 30—34°) on bromination in glacial acetic acid for 30 min afforded a dibromide which crystallised from acetic acid as prisms, m. p. 119—120°, undepressed on admixture with the dibromide of the tetramethyl ether of the phenol (C), described below. (Found: Br 29.1. $C_{26}H_{36}O_4Br_2$ requires Br 27.9.)

Demethylation and decarboxylation of acid (A). The acid (2 g) was boiled under reflux for 2 h with hydrobromic acid (20 ml, $d = 1.5$) and glacial acetic acid (25 ml) in an atmosphere of nitrogen. The reaction mixture when poured into water (300 ml) gave a voluminous, brownish precipitate which was collected, washed and dried (1.7 g). The crude phenol was dissolved in hot benzene (300 ml) and filtered through a small column of alkali-free alumina. The filtrate afforded a crystallisate (0.9 g), m. p. 175—178°. A second crop (0.5 g) was obtained from the mother liquor. Crystallisation from glacial acetic acid furnished the phenol as needles, m. p. 180—181°, undepressed on admixture with the phenol (C), obtained directly from picrolichenic acid as described below.

Degradation of picrolichenic acid with hydrobromic acid. Picrolichenic acid (5 g) was refluxed for 2.5 h with hydrobromic acid (20 ml, $d = 1.5$) and glacial acetic acid (25 ml)

in an atmosphere of nitrogen. The dark-brown reaction mixture was poured into water (500 ml) yielding a precipitate which was collected, washed and dried (4.0 g). Crystallisation from glacial acetic acid (30 ml) afforded the phenol (C) (XII) as greyish needles (1.1 g), m. p. 176–179°. The analytical sample, colourless needles from the same solvent, had m. p. 180–181°. (Found: C 73.0; H 8.61. $C_{32}H_{30}O_4$ requires C 73.7; H 8.44.)

Colour reactions: Ferric chloride, no colour; *bis*-diazotised benzidine, wine-red; bleaching powder, violet-red, changing to brown-red. Like phenol (B), the phenol (C) in alkaline solution was rapidly oxidised by air.

Paper chromatography, using the solvent system benzene-water, showed an elongated spot, $R_F = 0-0.2$ or higher, depending upon the amount of substance applied.

Methylation of phenol (C). The phenol (2.3 g) in dry acetone was boiled under reflux for 10 h with an excess of dimethyl sulphate and potassium carbonate. The tetramethyl ether was obtained as an oil which crystallised from methanol on cooling with liquid ammonia (yield, 1.9 g). After recrystallisation from methanol at −30° and distillation *in vacuo* it crystallised spontaneously, m. p. 34.5–35.5°. (Found: C 75.0; H 9.22; OCH_3 29.8; 30.2. $C_{36}H_{38}O_4$ requires C 75.3; H 9.24; $(OCH_3)_4$ 29.9.) U.V. absorption (in ethanol): λ_{max} 282 mμ (log ε 3.73); λ_{min} 261 mμ (3.34). λ = 220 mμ, log ε 4.35.

The tetramethyl ether was brominated in glacial acetic acid at room temperature. The first two moles of bromine were consumed rapidly and the excess of bromine was destroyed after 30 min by pouring the solution into water containing sulphur dioxide; the crude dibromide separated as an oil that crystallised rapidly. It was obtained from glacial acetic acid as prisms, m. p. 119.5–120.5°. (Found: Br 27.9. $C_{36}H_{36}O_4Br_2$ requires Br 27.9.)

A tribromide was obtained as the main product when the reaction time was extended to 24 h. Prisms, m. p. 106–107° from glacial acetic acid. (Found: C 47.9; H 5.63; Br 38.0; OCH_3 19.5. $C_{36}H_{35}O_4Br_3$ requires C 47.9; H 5.42; Br 36.8; $(OCH_3)_4$ 19.1.)

Prolonged bromination for 7 days gave a tetrabromide, which crystallised from glacial acetic acid as prisms, m. p. 97–98°. (Found: Br 44.0. $C_{36}H_{34}O_4Br_4$ requires Br 43.8.)

Dehydration of phenol (C). Zinc chloride (12 g) mixed with the phenol (C) (600 mg) in a test tube was heated in a salt bath to 240–250° and stirred continuously with a glass rod. The melt solidified after 4–5 min and was then cooled and extracted with water. The undissolved residue was collected, dried and dissolved in benzene (25 ml). Paper chromatography (solvent system, benzene-water) showed the main component as a spot, $R_F = 0.6-0.7$, characterised by a brownish-yellow colour with *bis*-diazotised benzidine and a greyish colour with Gibbs' reagent. A spot due to unreacted phenol (C) was also observed. The benzene solution was filtered through a small column of alkali-free alumina and the column was washed with further benzene. The absence of phenol (C) in the eluates was established by paper chromatography. Evaporation of the combined benzene solutions yielded the crude phenol (D) (XIV) (550 mg), m. p. 114–118°. It was recrystallised from benzene-light petroleum (40–60°) and showed m. p. 124–125° after sublimation *in vacuo*. (Found: C 77.3; H 8.16. $C_{32}H_{28}O_3$ requires C 77.6; H 8.29.)

The phenol (D) gave a green colour with bleaching powder but no colour with ferric chloride. An alkaline solution of the phenol showed an intense bluish fluorescence in ultra-violet light.

Methylation of phenol (D). The crude phenol (190 mg) was treated for two days with an excess of ethereal diazomethane containing methanol. Acetic acid was then added and the solution was shaken with 0.5 N sodium hydroxide solution, washed with water, dried and evaporated yielding an oil (200 mg) which crystallised on treatment with methanol. It was purified by chromatography on alumina. The material eluted by benzene was recrystallised from ethanol and from aqueous acetic acid to give the dimethylether of phenol (D) as needles, m. p. 72–73°. (Found: C 77.8; H 8.54; OCH_3 16.6. $C_{34}H_{32}O_3$ requires C 78.2; H 8.76; $(OCH_3)_2$ 16.8.) U.V. absorption (in ethanol): λ_{max} 229.5 mμ (log ε 4.37); 240.5 mμ (4.31); 255 mμ (4.07); 262 mμ (4.12); 300 mμ (shoulder, 4.24); 307 mμ (4.30). λ_{min} 238.5 mμ (4.30); 251 mμ (4.02); 257 mμ (4.06); 271 mμ (3.28).

Permanganate oxidation of the dimethyl ether of phenol (D). A solution of crude dimethyl ether (240 mg, m. p. 63–70°) in pyridine (75 ml, purified by treatment with selenium dioxide) [29] was boiled with stirring under reflux and a hot, 20 % aqueous solution of potassium permanganate was added in 5 ml portions until a total of 16 g had been added in 10 h. The solution was boiled for another 2 h, the manganese sludge was filtered

off and washed with pyridine and the combined filtrates were evaporated to dryness under reduced pressure. The residue was taken up in water and insoluble products removed from the alkaline solution by extraction with ether. For chromatography, a sample of the aqueous phase was acidified and extracted with ether. The presence in the ether phase of a number of acids was established using *n*-butanol-water and paper impregnated with trisodium phosphate [12,30]. The spots were visible in ultra-violet light. To effect complete oxidation, the main part of the aqueous phase was heated on a water bath and a 10 % permanganate solution (20 ml) was added dropwise with stirring over a 6 h period. The excess permanganate was destroyed and the manganese sludge was filtered off and washed with 0.1 N sodium hydroxide solution. The crude oxidation product (25 mg) separated from the concentrated filtrate on acidification with hydrochloric acid. The main component was chromatographically identical with 3,7-dimethoxydibenzofuran-1,9-dicarboxylic acid [13] synthesised as described below. The R_F-values on phosphate impregnated papers [12,30] were 0.05 (Na_3PO_4); 0.10 (Na_2HPO_4); 0.80 (NaH_2PO_4) (solvent system, *n*-butanol-water). The spots showed a very intense blue fluorescence in ultra-violet light.

The crude acid on methylation with diazomethane afforded a dimethyl ester, sparingly soluble in ethanol and crystallising from this solvent as needles (16 mg), m. p. 187—194°. The analytical sample, sublimed *in vacuo* and crystallised from ethanol, melted at 191—193.5° after slight sintering above 187°. The melting point was undepressed on admixture of 3,7-dimethoxy-1,9-dicarbomethoxydibenzofuran [13], m. p. 192—194°, described below. (Found: C 62.9; H 4.61. $C_{18}H_{16}O_7$ requires C 62.8; H 4.68.)

2-Iodo-3,5-dimethoxytoluene [31]. Iodine (84 g, 0.33 mole) and yellow mercuric oxide (66 g, 0.30 mole) was added in portions with stirring to orcinol dimethyl ether (45.8 g, 0.30 mole) and care was taken to keep the temperature below 50°. The solidified reaction mixture was extracted with ether (700 ml) and the ether solution was filtered and evaporated to dryness. The residue was dissolved in benzene (400 ml) and the solution was repeatedly extracted with a saturated aqueous solution of potassium iodide. The benzene solution was evaporated to dryness and the residue was distilled under reduced pressure to give 2-iodo-3,5-dimethoxytoluene (66 g, b.p. 155—170°/8 mm). It crystallised from ethanol as prisms, m. p. 84—85°. (Found: I 46.3. $C_9H_{11}O_2I$ requires I 45.6.)

The non-volatile residue from the distillation was crystallised from acetone to give (probably) 2,6-di-iodo-3,5-dimethoxytoluene as prisms, m. p. 203—204°. (Found: I 61.9. $C_9H_{10}O_2I_2$ requires I 62.8.)

The structure of the mono-iodide of orcinol dimethyl ether, not discussed in the available referate of the Japanese paper [31], follows clearly from its non-identity with 4-iodo-3,5-dimethoxytoluene [32], m. p. 96—97°.

2,2′-Dimethyl-4,6,4′,6′-tetramethoxydiphenyl [13]. 2-Iodo-3,5-dimethoxytoluene (20 g) was mixed with copper bronze (60 g) and heated in a salt bath to 200—210° for 15 min and then to 220—230° for a further 20 min. The reaction mixture was extracted with chloroform, the extract was evaporated to dryness and the residue was crystallised from ethanol (yield, 7.7 g). Distillation *in vacuo* and crystallisation from ethanol gave 2,2-dimethyl-4,6,4′,6′-tetramethoxydiphenyl as prisms, m. p. 106—107°. (Shibata [13] reports m.p. 103—104°.) U.V. absorption (in ethanol): λ_{max} 282 mμ (log ε 3.75); λ_{min} 261 mμ (3.36). λ = 220 mμ, log ε = 4.38.

Shibata [13] reports λ_{max} 282 mμ (3.7); 274 mμ (3.6); λ_{min} 262 mμ (3.4).

3,7-Dimethoxy-1,9-dimethyldibenzofuran [13]. 2,2′-Dimethyl-4,6,4′,6′-tetramethoxydiphenyl (2.5 g) was boiled under reflux for 24 h with hydrobromic acid (40 ml, d = 1.50) in an atmosphere of carbon dioxide. The material obtained from the solution on cooling was collected (1.8 g) and methylated with dimethyl sulphate and alkali to give 3,7-dimethoxy-1,9-dimethyldibenzofuran, which was distilled *in vacuo* and crystallised from ethanol as blades, m. p. 159—160°. (Shibata [13] reports m.p. 157°.) U.V. absorption (in ethanol): λ_{max} 226 mμ (4.46); 239 mμ (shoulder, 4.36); 257 mμ (shoulder, 4.10); 263 mμ (4.15) 299 mμ (4.26); 309 mμ (4.33). λ_{min} 250 mμ (4.00); 272 mμ (3.61); 302 mμ (4.25).

3,7-Dimethoxy-1,9-dicarbomethoxydibenzofuran [13]. 3,7-Dimethoxy-1,9-dimethyldibenzofuran (440 mg) in pyridine (25 ml) was boiled under reflux and a solution of potassium permanganate (5 g) in water (100 ml) was added dropwise with stirring over a period of 10 h after which the heating was continued for another 4 h. The solution was acidified

with sulphuric acid, the manganese sludge was dissolved and the crude oxidation product was collected (340 mg). It was dissolved in 5 % sodium carbonate solution and the solution was filtered and acidified with hydrochloric acid. The crude acid separated as a yellowish precipitate which was collected (220 mg). A sample was recrystallised from dioxan, yielding 3,7-dimethoxydibenzofuran-1,9-dicarboxylic acid as yellowish needles, m. p. about 300 (decomp.), characterised by paper chromatography as described above. (Shibata [13] reports m. p. 321—322° (decomp.)). The main part of the crude acid was methylated with diazomethane to give 3,7-dimethoxy-1,9-dicarbomethoxydibenzofuran, crystallised from ethanol as needles, m. p. 192—194° (Shibata [13] gives m. p. 188.5—189.5°). (Found: C 62.9; H 4.50; OCH_3 35.0. $C_{18}H_{16}O_7$ requires C 62.8; H 4.68; $(OCH_3)_4$ 36.0.)

Air oxidation of hydroxydiphenyls. 2,4,2′,6′-Tetramethoxydiphenyl [33] (20 mg) was boiled for 1.5 h with hydrobromic acid (d = 1.50; 0.5 ml) and glacial acetic acid (0.5 ml). The solution was evaporated to dryness *in vacuo*. The residue was shown by paper chromatography to contain only traces of 1,7-dihydroxydibenzofuran [33]. 2,4,2′,4′-Tetramethoxydiphenyl [34] was demethylated in the same way. Spots of 1 % solutions in acetone of the crude tetrahydroxydiphenyls and of the phenol (B) were applied to filter paper moistened with 1 N sodium hydroxide solution. The spots of phenol (B) and of 2,4,2′,4′-tetrahydroxydiphenyl turned brown-red within a few minutes but the spot for 2,4,2′,6′-tetrahydroxydiphenyl darkened only after about 30 min.

The author is indebted to Dr. J. F. Grove, Herts, England, for valuable information on the infra-red spectra of lactones.

Grants from *Hierta-Rezius fond för vetenskaplig forskning* and from *Sigrid Arrhenius fond* are gratefully acknowledged.

On the Complex Chemistry of the Tervalent Rare Earth Ions

I. The Acetate Systems of Lanthanum, Cerium, Neodymium, and Gadolinium

ARTUR SONESSON

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The complexity constants of the acetate complexes of La^{3+}, Ce^{3+}, Nd^{3+}, and Gd^{3+} have been determined. The values of the complexity constants $\beta_n = \frac{[MA_n]}{[M]\cdot[A]^n}$ that are given in Table 8 have been found in perchlorate medium of ionic strength 2 M at 20°C. The fourth constant must be considered only as a quantity formally computed from the potentiometric measurements, as an ion exchange investigation (Fronæus [1,17]) has shown that the cerium acetate system most probably does not contain anionic complexes to a detectable amount at acetate concentrations <500 mM.

The value of β_1 increases from La^{3+} to Nd^{3+}, which is expected on account of the decreasing ionic radius. The gadolinium acetate system, however, has a smaller β_1 than the neodymium system.

The fifteen elements with the atomic numbers 57 to 71 are called rare earths or lanthanons *. As all the terpositive rare earth ions have the same electron configuration $5s^2\ 5p^6$ of the outermost shell, they show great similarity with regard to their chemical properties. The decrease of the ionic radius from lanthanum to lutetium (*cf.* Herlinger [2]) leads, however, gradually to a slight change in the chemical properties. Thus, we can expect that the terpositive ions will form complexes of the same structure and of about the same strength, but that the strength of the complexes will increase from lanthanum to lutetium. Such a change has also been found by Schwarzenbach [3,4], Spedding [3,5], Vickery [6] and their coworkers. They have investigated the complex formation with some very strong complexing agents, such as ethylenediamine tetra-acetic acid and some of its derivatives, which all give chelates. These

* Spectroscopists usually do not count lanthanum among the rare earths as it has no electrons in the 4f subshell. Chemically, however, lanthanum belongs to the rare earths.

investigations also show that the increase in the stability of the complexes is not quite uniform. If the complexity constants are plotted as a function of the atomic number or the ionic radius of the rare earth, the curve will show a distinct break at gadolinium.

So far the variation of the complexity constants in the rare earth series has been studied only for polydentates. For an examination of the different steps of the complex formation, a monodentate ligand must be chosen that gives complexes of at least moderate strength. The acetate ion has proved a suitable ligand, especially as the acetate complexes are easy to investigate by potentiometric measurements. The only rare earth acetate system that has been investigated so far is the cerium(III) acetate system, the complexity constants of which Fronæus [1] has determined by the cation exchange method. In the present investigation a series of rare earth acetate systems will be examined by potentiometric measurements. In some cases the potentiometrically obtained results will be controlled by other investigations.

Calculation of the complexity constants in measurements of the free ligand concentration

By the potentiometric measurements the concentration of free ligand ([A]) has been determined in solutions with a known total concentration of the central ion (C_M) and of the ligand (C_A). The calculations are performed according to the method elaborated by Fronæus [7] (earlier works by Bjerrum [8] and Leden [9]). In the present paper only definitions of the symbols and a summary of the equations used are given.

If only mononuclear complexes MA_1, MA_2, ... MA_N are formed, we have the following equilibrium for the formation of the complex MA_n

$$MA_{n-1} + A \rightleftharpoons MA_n$$

The corresponding complexity constant β_n is defined

$$\beta_n = \frac{[MA_n]}{[M] \cdot [A]^n}$$

With β_n we can express C_M and C_A as functions of [A] and [M].

$$C_M = [M] \cdot X \tag{1a}$$

$$C_A = [A] + [M] \cdot X' \cdot [A] \tag{1b}$$

where $X = X([A])$ is defined by the equation

$$X = 1 + \sum_{n=1}^{N} \beta_n \cdot [A]^n$$

and

$$X' = \frac{d\ X([A])}{d\ [A]}$$

The ligand number $\bar{n}$ is defined according to Bjerrum [8]

$$\bar{n} = \frac{C_A - [A]}{C_M} \tag{2}$$

By plotting $\bar{n}$ as a function of log [A] we get the complex formation curve. Combination of the eqns. (1) and (2) and elimination of [M] will give

$$\frac{\bar{n}}{[A]} = \frac{X'}{X} \tag{3}$$

and after integration

$$\ln X([A]_j) = \int_0^{[A]_j} \frac{\bar{n}}{[A]} \cdot d[A] \tag{4}$$

Thus, this integration gives us corresponding values of X and [A].

The complexity constants $\beta_1, \beta_2, \ldots$ can now be calculated by successive extrapolation to [A] = 0 of the functions $X_1, X_2, \ldots$

$$\begin{aligned} X_1 &= \frac{X-1}{[A]} = \beta_1 + \beta_2 \cdot [A] + \beta_3 \cdot [A]^2 + \ldots . \\ X_2 &= \frac{X_1 - \beta_1}{[A]} = \beta_2 + \beta_3 \cdot [A] + \ldots . \end{aligned} \tag{5}$$

and so on for the following constants.

The composition of the complex system at a known [A] can be computed from the following equations.

$$\begin{aligned} \alpha_0 &= \frac{[M]}{C_M} = \frac{1}{1 + \beta_1 \cdot [A] + \beta_2 \cdot [A]^2 + \ldots .} \\ \alpha_n &= \frac{[MA_n]}{C_M} = \frac{\beta_n \cdot [A]^n}{1 + \beta_1 \cdot [A] + \beta_2 \cdot [A]^2 + \ldots .} \end{aligned} \tag{6}$$

When the complexity constants are known we can check our calculations by computing the ligand number $\bar{n}_c$ at some values of [A].

$$\bar{n}_c = \sum_{n=1}^{N} \frac{n\beta_n [A]^n}{1 + \beta_n [A]^n} \tag{7}$$

If polynuclear complexes are formed, we cannot directly use the $\bar{n}$/[A]-function for the computation of the constants of the mononuclear complexes. We assume here that the solution contains only mono- and dinuclear complexes. β'_n denotes the constant for the n:th dinuclear complex

$$\beta'_n = \frac{[M_2A_n]}{[M]^2 \cdot [A]^n}$$

We mean by Y the following function (Fronæus [7 p. 14])

$$Y([A]) = \sum_{n=1}^{L} \beta'_n \cdot [A]^n$$

Then we get for the total concentration of central ion and ligand

$$C_M = [M] \cdot X + 2[M]^2 \cdot Y$$

and

$$C_A = [A] + [M] \cdot X' \cdot [A] + [M]^2 \cdot Y' \cdot [A]$$

The expression corresponding to eqn. (3) will now be

$$\frac{\bar{n}}{[A]} = \frac{X' + [M] \cdot Y'}{X + 2[M] \cdot Y} \tag{8}$$

Thus, for a system with both mono- and dinuclear complexes $\bar{n}/[A]$ is a function of both [A] and [M]. When $C_M \rightarrow 0$, we get

$$\lim_{C_M \rightarrow 0} \frac{\bar{n}}{[A]} = \frac{X'}{X} \tag{9a}$$

Consequently, it is possible to compute the constants of the mononuclear complexes in the ordinary way by the aid of (9a).

If $C_A \rightarrow 0$, eqn. (8) will give (as $[M] \rightarrow C_M$, when $C_A \rightarrow 0$)

$$\lim_{C_A \rightarrow 0} \frac{\bar{n}}{[A]} = \beta_1 + C_M \cdot \beta_1' \tag{9b}$$

Thus, the $\bar{n}/[A]$-values at low [A] must increase with C_M if the complex system contains both mono- and dinuclear complexes.

Calculation of [A] and $\bar{n}$ from experimental data

If C'_{HA} and C'_A signify the stoichiometric concentrations of acetic acid and sodium acetate, respectively, and $[H^+]'$ the hydrogen ion concentration in a buffer solution free from rare earth ions, the following equation is valid

$$K_c = \frac{[H^+]' (C'_A + [H^+]')}{C'_{HA} - [H^+]'} \tag{10}$$

For a solution with the concentration C_M of rare earth ions and with the same stoichiometric concentration of acetate buffer as above, we denote by $[H^+]$ the concentration of hydrogen ions, by [A] the concentration of free acetate ions and by [HA] the concentration of unprotolysed acetic acid. If the rare earth perchlorate contains some free acid, its concentration $C_H = \nu \cdot C_M$ must be accounted for. Then we get

$$[HA] = C'_{HA} + C_H - [H^+]$$

and

$$K_c = \frac{[H^+] \cdot [A]}{C'_{HA} + C_H - [H^+]} \tag{11}$$

[A], which is the concentration sought, can be derived from eqns. (10) and (11). If $C'_{HA}/C'_A = \delta$ we get

$$[A] = \frac{[H^+]'}{[H^+]} \cdot \frac{(C'_A + [H^+]') (\delta C'_A + C_H - [H^+])}{\delta C'_A - [H^+]'} \tag{12}$$

This expression can (Ahrland [10]) be simplified to

$$[A] = \frac{[H^+]'}{[H^+]} \left[C'_A + \frac{C_H - [H^+] + (1 + \delta) \cdot [H^+]'}{\delta} \right] \tag{13}$$

Eqn. (13) can be used for the computation of [A] except at the very lowest [A]-values.

As the total acetate concentration in the complex solution is $C_A = C'_A + [H^+] - C_H$, we get for the ligand number

$$\bar{n} = \frac{C'_A + [H^+] - C_H - [A]}{C_M}$$

The hydrogen ion concentration has been determined by a quinhydrone electrode. If E denotes the emf of the element in (15) and E' the emf of the same element when $C_M = 0$, we have at 20°C

$$E' - E = E_A = 58.16 \log \frac{[H^+]}{[H^+]'} \qquad (14)$$

CHEMICALS USED

Rare earth perchlorates. The perchlorates were prepared from *perchloric acid* (Baker's analyzed) and lanthanum chloride *puriss.*, cerium(III) chloride *puriss.*, neodymium oxide (quality "Specpure" from Johnson, Matthey and Co, London) and gadolinium nitrate (from A. D. Mackay, New York), respectively. The nitrate and the chlorides were evaporated several times with perchloric acid until no nitrate or chloride ions could be detected. The oxide was dissolved by heating with the acid. The greatest part of the excess of perchloric acid was removed by evaporation and the residue was determined by a potentiometric pH-titration.

The stock solutions were examined in a Beckman DU Spectrophotometer. No foreign elements with absorption in the wavelength range 2 000—9 000 Å could be detected. Cerium(IV) ions could not be found in the cerium(III) perchlorate.

The concentrations of lanthanum, neodymium and gadolinium were determined according to Berl-Lunge [11] by precipitating the rare earth as oxalate, igniting the precipitate and weighing the residue as oxide. The concentrations of lanthanum and neodymium were controlled by precipitation with 8-hydroxychinoline according to Pirtea [12]. The agreement between the values obtained by the oxalate and the hydroxychinoline method was very good. The cerium content was determined volumetrically according to Weiss and Sieger [13].

Sodium perchlorate with less than 0.01 % Cl^- and ClO_3^- was prepared from the quality *purum* by two recrystallizations according to Fronæus [7, p. 31].

Calculated amounts of *acetic acid (p. a.)* and *sodium acetate* (Baker's analyzed) were used for preparation of the buffer solutions. The concentrations of acid and acetate were controlled.

Quinhydrone was prepared according to Biilman and Lund [14].

EXPERIMENTAL

By potentiometric measurements the emf of elements of the following composition was determined.

Au	Quinhydrone 10.2 mM $HClO_4$ $NaClO_4$ to I = 2.0 M	2.0 M $NaClO_4$	Quinhydrone C_M mM $Me(ClO_4)_3$ $C_H = \nu \cdot C_M$ mM $HClO_4$ C'_A mM NaAc $C'_{HA} = \delta \cdot C'_A$ mM HAc $NaClO_4$ to I = 2.0 M	Au	(15)

Here Me^{3+}, Ac^- and I denote, respectively, rare earth ions, acetate ions and the ionic strength of the solution. The concentration of perchloric acid in the left half-cell was not quite the same in all series, but the exact value did not differ very much from 10.2 mM.

The solution in the right half-cell was prepared by adding a known volume of a buffer solution S_2 to a known volume of a solution S_1 with rare earth perchlorate.

	Solution S_1	Solution S_2	
$Me(ClO_4)_3$	C_M^0	0	mM
$HClO_4$	$C_H^0 = \nu \cdot C_M^0$	0	mM
NaAc	0	$C_A^0 = 1\,000$	mM
HAc	0	$C_{HA}^0 = \delta \cdot C_A^0$	mM
$NaClO_4$	$2\,000 - 6\ C_M^0 - C_H^0$	1 000	mM

The mixing of the solutions to be measured was brought about by a stream of nitrogen, free from oxygen but containing water vapour of the pressure prevailing over a 2 M solution of sodium perchlorate. During the experiments the solutions were kept in a thermostat at a constant temperature of 20°C. Every titration series was repeated at least once. For the potentiometric measurements a Leeds-Northrup »Students Potentiometer» was used. The emfs were stable and could be reproduced within 0.2 mV with very few exceptions. The uncertainty of the E_A-values is estimated to $\pm$ 0.2 mV.

MEASUREMENTS

As a check of the applicability of the quinhydrone electrode for pH-measurements in solutions with rare earth ions, a quinhydrone element with C_H = 90 mM ($HClO_4$) and C_M = 0 mM (I = 2.0 M) was mixed with different volumes of a neodymium perchlorate solution with very nearly the same content of acid as above (I = 2.0 M). A slight deviation, increasing with C_M, was found between the calculated and the measured emfs. At C_M = 15 mM the deviation was 0.3 mV and at C_M = 100 mM as high as 1.0 mV. The direction of the deviation was such that the hydrogen ion concentration of the neodymium solution became too high. This may indicate a slight complex formation between neodymium and hydroquinone. However, a positive conclusion cannot be drawn, because at least a part of the deviation may depend on a salt error of the quinhydrone electrode and on variations of f_{H^+} and the liquid junction potentials, caused by the medium changes.

In order to obtain another check of the E_A-values obtained by the quinhydrone electrode, two titration series were repeated using a hydrogen gas electrode. If hydroquinone complexes are formed, the hydrogen gas electrode should give lower E_A-values (E_A^H) than the quinhydrone electrode (E_A^Q). The difference $E_A^Q - E_A^H$ ought to be particularly significant at high C_M and low C_A. Tables 3 D and 5 E show that generally E_A^Q is greater than E_A^H, even at such high acetate concentrations that the hydroquinone complexes must have disappeared. This confirms that the formation of hydroquinone complexes is not the only reason for the disagreement between the two sets of E_A-values.

The plausible conclusion seems to be that if rare earth-hydroquinone complexes exist, they are so weak that they cannot cause serious errors in the complexity constants computed form E_A^Q.

In order to check the tendency of the unprotolyzed acetic acid to form complexes with the rare earth ions, the solutions I and II in the table below were examined extinctiometrically.

	Solution I	Solution II	
$Nd(ClO_4)_3$	50	50	mM
$HClO_4$	100	100	mM
$NaClO_4$	1 600	1 600	mM
HAc	0	2 500	mM

The two solutions gave extinction curves that were practically identical in the wave length range 3 000—9 000 Å. Therefore, complexes with the unprotolyzed acetic acid can be excluded.

The hydrated rare earth ions (at least up to gadolinium) have only a very slight tendency to give off protons at pH <5 as shown by Moeller [15] and Fronæus [16]. This conclusion must be drawn also from the investigations related to in the present paper. The concentration of acetic acid of the buffer solutions used in the titration series has been varied widely, but the $\bar{n}/[A]$-functions of the acetate systems show no tendency to depend on the pH of the complex solutions.

On account of the complex formation the ionic strength of the solutions we measure decreases considerably at higher C_M. This causes a certain error in E_A and then also in $\bar{n}/[A]$. We can eliminate this error by determining $\bar{n}/[A]$-functions for different C_M and extrapolating them to $C_M = 0$. This method, however, is rather time-consuming as it requires several series of measurement, and, moreover, it cannot be used if we want to determine complexity constants for dinuclear complexes. In the present investigation the decrease of ionic strength has been compensated by addition of a calculated amount of sodium perchlorate. The change of emf, ΔE_A, obtained in this way, has then been plotted in a diagram against ΔI, the decrease in ionic strength. The increase in volume caused by the added perchlorate requires only a slight correction of ΔE_A. Measurements of this kind have been carried out with some rare earth acetate systems at different C_M. They have given practically the same connection between ΔE_A and ΔI.

$$\Delta E_A = 5.0 \cdot \Delta I \tag{16}$$

(ΔE_A in mV and ΔI in M). ΔI has been computed according to formula (17) from $\bar{n}$, calculated with the aid of uncorrected E_A-values.

$$\Delta I = 0.5\ C_M \cdot \bar{n}\ (7 - \bar{n}) \tag{17}$$

This formula is derived with the assumption that the solution contains only the complex $MA_{\bar{n}}^{3-\bar{n}}$ ($\bar{n}$ is the ligand number). However, assuming that four complexes are formed, the correct expression for ΔI is

$$\Delta I = C_M(3\alpha_1 + 5\alpha_2 + 6\alpha_3 + 6\alpha_4) \tag{18}$$

α is the distribution of the central ions between the particular complexes (eqn. 6). In order to be able to use eqn. (18), we must know at least approximate values of the complexity constants. However, calculations have shown

Table 1. Determination of E' as a function of C'_A for the different acetate buffers used.

↓ Buffer	C'_A mM →	9.90	29.1	74.1	130.4	230.7	333	444	546	$K_c \times 10^{+5}$ at $C'_A \approx$ 100 mM
$\delta = 0.5$	E' mV →	180.2	180.1	180.0	180.0	179.9	179.9	179.9	179.9	1.64
$\delta = 2.0$	E' mV →	145.1	145.0	144.9	144.8	144.6	144.6	144.6	144.7	1.65
$\delta = 5.0$	E' mV →	121.8	121.6	121.3	121.1	120.9	120.8	120.9	121.0	1.68

that the eqns. (17) and (16) give ΔE_A-values, which at most are only 0.2 mV higher than ΔE_A computed with ΔI from eqn. (18). As there are probably other errors in E_A on account of the medium changes, which we have no possibility of making corrections for, eqn. (17) gives a value of ΔI that is accurate enough.

The emf E' in eqn. (14) has been determined at different C'_A by measuring the emf of the element (15) with $C_M = 0$. The E'-values for the buffers used are shown in Table 1. The measurements show that the emf varies slightly when the perchlorate is gradually exchanged for acetate buffer. Additions of the most acid buffer have an especially great influence. The reason for the change of emf may be that the medium changes cause variations of the liquid junction potentials and of the activity coefficients of the hydrogen ions and the quinhydrone components. Under the presumption that E' is changed in the same way when rare earth ions are present in the solution, the variation of E' does not affect the results, as only the E_A-values are used for the computations (except for determination of the correction terms of eqn. (12)).

1. The lanthanum acetate system

The experimentally obtained values of E_A and the values of [A] and $\bar{n}$/[A] calculated from $E_A - \Delta E_A$ are collected in Tables 2A-D. The second term in the E_A-columns is the correction term ΔE_A in eqn. (16), which must be subtracted from the first term, the experimentally determined E_A-value to compensate for the reduction of the ionic strength.

Fig. 1 shows that the agreement between the $\bar{n}$/[A]-values from series with different C_M is so good that polynuclear complexes can be formed only to a very slight extent.

For the lanthanum acetate system, as for the following complex systems in this paper, the $\bar{n}$/[A]-values are independent of the ratio C'_{HA}/C'_A of the buffer solutions.

By graphical integration of the fulldrawn curve in Fig. 1, the function X in Table 4A has been computed and after that the functions $X_1 \ldots X_4$ and the complexity constants. As the lanthanum acetate system, like the other

systems of this paper, shows no tendency to stop its complex formation at $\bar{n} = 3$ (*cf.* Fig. 2), four constants have been computed.

In Table 9 the experimentally determined ligand number $\bar{n}_{exp}$, the computed ligand number $\bar{n}_c$ and the distribution of the central ion between the particular complexes are given for some values of [A].

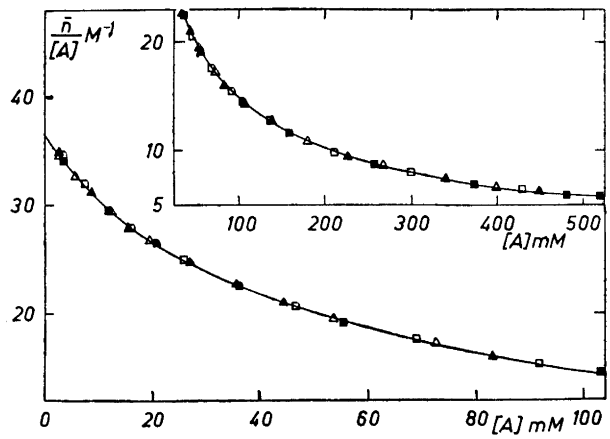

Fig. 1. $\bar{n}/[A]$ as a function of [A] for the lanthanum acetate system. The signs refer to the corresponding series in Table 2.

2. The cerium(III) acetate system

Experiments and calculations for the cerium acetate system were performed in the same way as for the preceding system. The results are to be found in Tables 3A—D and 4B. The complex formation curve is shown in Fig. 2.

Also for this system the coincidence between the $\bar{n}/[A]$-curves of the different series is so good that polynuclear complexes can be formed only to a very slight extent.

In order to check the applicability of the quinhydrone electrode, the quinhydrone series in 3D was repeated with a hydrogen gas electrode, which gave the E_A^H-values in the same table. The maximum discrepancy between uncorrected E_A^Q and E_A^H is 0.5 mV. A possible cause of this difference has been discussed on page 170.

3. The neodymium acetate system

The results obtained for this system are collected in Tables 5A-E and 7A. For this system, too, we can exclude formation of polynuclear complexes.

The series 5E was performed with both quinhydrone electrode and hydrogen gas electrode. The maximum difference $E_A^Q - E_A^H$ is + 0.8 mV.

4. The gadolinium acetate system

Measurements and calculations for this system were performed in the same way as in the foregoing systems. The results are shown in Tables 6A—D and 7B and in Fig. 3.

For this system the values of $\bar{n}$/[A] at low [A] show a slight tendency to increase with C_M. This may indicate a slight formation of polynuclear complexes. However, the value of β'_1 computed according to eqn. (9b) will be as low as 30 ± 20, and therefore the existence of dinuclear complexes must be considered as rather uncertain. The $\bar{n}$/[A]-function used for the computation of the complexity constants has been drawn in accordance to the lower $\bar{n}$/[A]-values at low [A].

DISCUSSION OF THE RESULTS

The complexity constants of the systems investigated are collected in Table 8. Table 9 gives for all four systems a comparison between determined and calculated ligand numbers ($\bar{n}_{exp}$ resp. $\bar{n}_c$) and information about the calculated distribution of the central ion between the particular complexes at some [A]-values (eqns. 6 and 7).

The limits of error given in Table 8 refer to the maximum random errors. For the four acetate systems so far examined, the potentiometric measurements have given a fourth complexity constant, the random error of which may be

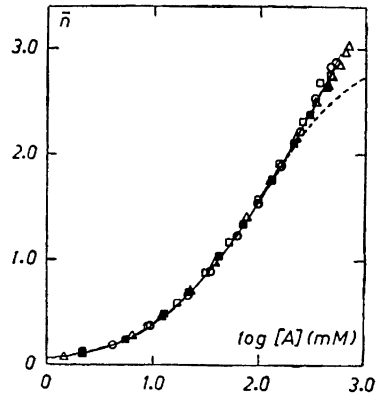

Fig. 2. The complex formation curve of the cerium acetate system. The fulldrawn curve is computed by use of β_1—β_4 and the broken curve by use of β_1—β_3 only.

estimated to about 40 %. Thus, it seems to be possible to give at least the order of magnitude of the fourth constant.

As to the systematic errors, they apparently do not affect the determination of the lower constants, as the three first complexity constants of the cerium(III) acetate system found by Fronæus [1] in a cation exchange investigation are in good agreement with the constants obtained by the author. The two sets of constants are given in Table 10. The constants published by Fron-

æus as obtained potentiometrically by the present author are those calculated without correction for the decrease of the ionic strength, and therefore they differ somewhat from the figures given below.

The fourth constant, however, seems to be rather dubious, as Fronæus found that anionic complexes are not formed to a detectable amount at acetate ion concentrations < 500 mM. This result is, moreover, supported by anion exchange measurements, Fronæus [17]. It is possible that the small

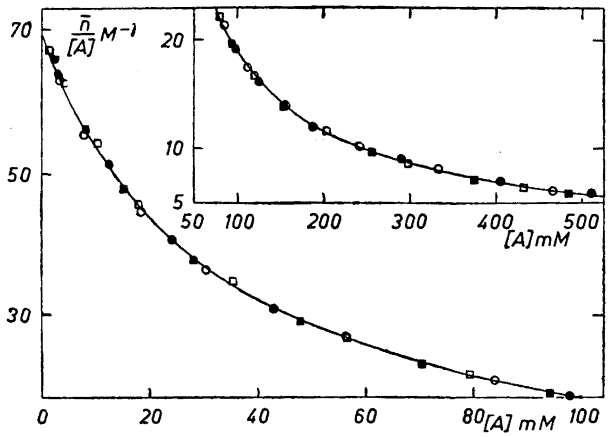

Fig. 3. The connection between $\bar{n}$/[A] and [A] for the gadolinium acetate system, according to the titration series in Table 6.

E_A-values at high ligand concentrations contain so great systematic errors that the fourth complexity constant is only imaginary. If so the complex formation curve for the cerium acetate system is represented by the broken curve in Fig. 2.

In order to exclude the dubious fourth complex, the composition of the complexity systems has been given in Table 9 only at low ligand concentrations.

Table 10. The complexity constants of the cerium(III) acetate system determined by

	the potentiometric method	the cation exchange method
β_1	48 ± 1 M^{-1}	48 ± 2 M^{-1}
β_2	490 ± 50 M^{-2}	450 ± 80 M^{-2}
β_3	1 350 ± 250 M^{-3}	1 700 ± 500 M^{-3}
β_4	1 600 ± 600 M^{-4}	—

At [A] = 100 mM β_4 would give 100 . α_4 = 1.0 and 1.6 for the lanthanum and the gadolinium systems, respectively.

Table 8 shows that the stability of the first complex increases from lanthanum to neodymium, as is to be expected from the decreasing ionic radius, whereas gadolinium gives a considerably weaker first complex than neodymium. The gadolinium complexes number two and three, however, are stronger than the corresponding neodymium complexes.

A more detailed discussion must be postponed until other acetate systems have been examined.

Professor Sven Bodforss, who has been my teacher in chemistry, suggested this investigation to me. I am very indebted to him for the valuable aid he has given me in different respects and for the interest he has always shown in my work.

Moreover, I wish to thank Dr. Sture Fronæus and Dr. Sten Ahrland for many fruitful discussions and valuable suggestions.

On Ion Exchange Equilibria

V. An Approximate Method for Calculating the Partial Molar Volumes of the Species in Ion Exchangers *

ERIK HÖGFELDT**

Brookhaven National Laboratory, Upton, L.I., N.Y., U.S.A.

By formally regarding an ion exchange system as a binary mixture of the two resin forms, partial molar volumes can be determined using the intercept method of Roozeboom. This method has been applied to the potassium-tetramethylammonium exchange on resins with DVB content 2, 10 and 26 %, reported by Gregor, Gutoff and Bregman. It is surprising to find that, to a first approximation all three systems have an ideal volume of mixing over the large range of variation, 1.3 to 18, in total molality of the resin.

Boyd *et al.* [1,2] have recently calculated equilibrium quotients for ion exchange equilibria using rigorous thermodynamics. In these calculations there is need for evaluation of a term $p(Z_B\overline{V}_A - Z_A\overline{V}_B)$ where p is the swelling pressure. $\overline{V}_A$ and $\overline{V}_B$ are the partial molar volumes of the two ionic resin forms, and Z_A, Z_B are their respective charges. Methods for calculating the swelling pressure have been described [3,4]. A method for obtaining the partial molar volume *difference* using cross differentiation relationships has recently been given by Myers and Boyd[1].

It is the aim of this paper to show how the partial molar volumes themselves can be obtained, by using the approximation that the partial molar volume of water is a constant.

The volume, V, of a resin (in this case a cation exchanger exchanging monovalent ions) is made up of three components:

$$\overline{V} = N_{AR}\overline{V}_{AR} + N_{BR}\overline{V}_{BR} + N_{WR}\overline{V}_{WR} \qquad (1)$$

* Research performed under the auspices of the U.S. Atomic Energy Commission.

** On leave of absence from the Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm, Sweden.

where N_{AR}, N_{BR} and N_{WR} are the number of moles of the three components A^+R^-, B^+R^- and water and $\overline{V}_{AR}$, $\overline{V}_{BR}$, $\overline{V}_{WR}$ their partial molar volumes. By dividing all terms with the capacity of the resin (S_o) (1) is transformed to:

$$V_e = \frac{V}{S_o} = X_{AR}\overline{V}_{AR} + X_{BR}\overline{V}_{BR} + X_{WR}\overline{V}_{WR} \quad (2)$$

where V_e = the equivalental volume

X_{AR}, X_{BR} are the mole fractions of the resin forms A^+R^- and B^+R^-

X_{WR} = the number of moles of water per equivalent of resin; no water is assumed to belong to the ions as water of hydration.

Now, Gregor *et al.*[5] as well as Boyd *et al.*[1,2] have shown that the partial molar volume of water is constant for each ionic form provided the water content of the resin is not too small. According to Boyd *et al.* $\overline{V}_{WR}$ remains constant down to $X_{WR} = 4$. Water contents as low as $X_{WR} = 4$ are never encountered when one deals with moderately cross-linked ion exchange resins in equilibrium with a water phase. Even a 26% DVB resin [6] contains more than 6 moles of water per equivalent of resin, so that on the basis of these results the constancy of $\overline{V}_{WR}$ is a good approximation even for this rather extreme case. Thus in view of the fact that the partial molar volume of water is practically the same for several different ions [5], it is reasonable to assume that the partial molar volume of water is constant. Using this assumption eqn. (2) can be rearranged to give:

$$V_e - X_{WR}\overline{V}_{WR} = \Delta V = X_{AR}\overline{V}_{AR} + X_{BR}\overline{V}_{BR} \quad (3)$$

ΔV can now be calculated using a known value for V_{WR}. According to eqn. (3) we can formally regard the resin as a binary mixture of A^+R^- and B^+R^-. By plotting ΔV against the mole fractions of the resin species, the partial molar volumes can be obtained from the intercepts of the tangent to the curve with the axes $X_{AR} = 1$ and $X_{BR} = 1$ [7,8].

In order to illustrate the method, we apply it to the data for the potassium-tetramethylammonium exchange on resins with DVB contents 2, 10 and 26 %, reported by Gregor, Gutoff and Bregman [6]. For V_{WR} we adopt the value 17.20, the mean of the two values, 17.15 for tetramethylammonium resin and 17.25 for potassium resin, reported by Gregor, Sundheim, Held and Waxman [5]. The resins used by the latter were not the same as those used by Gregor, Gutoff and Bregman. However, the resins were of the same type, being polystyrene sulfonic acid resins, and the assumption that the partial molar volume of water is the same for both sets of resins is a reasonable one. It is also assumed that the partial molar volume of water is independent of swelling pressure, which is a good approximation, since the difference between the partial molar volumes of water at 100 and 1 000 atmospheres is only 4 % [4].

In Figs. 1—3 V_e and ΔV are plotted against X_{KR} for the three different crosslinkings. It is interesting to note that straight lines are obtained in the ΔV-plots. This behavior implies, that to a first approximation all three systems behave ideally over a range between ~1.3 and ~18 in total molality of the resins.

The values obtained of the partial molar volumes obtained from the ΔV *vs* X plots are given in Table 1.

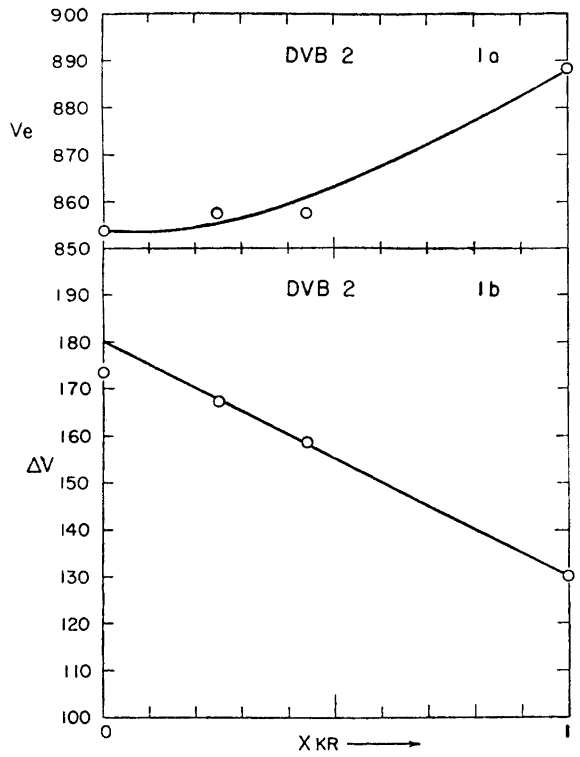

Fig. 1 a. The equivalental volume, V_e, plotted against the mole fraction of potassium, X_{KR}, in the DVB 2 resin.
Fig. 1 b. The function ΔV plotted against mole fraction of potassium, X_{KR}, in the DVB 2 resin.

Table 1. Partial molar volumes of potassium and tetramethylammonium forms in different resins; ml/equiv. of resin.

Method of evaluation	DVB 2		DVB 10		DV
	$\overline{V}_{KR}$	$\overline{V}_{(CH_3)_4NR}$	$\overline{V}_{KR}$	$\overline{V}_{(CH_3)_4NR}$	$\overline{V}_{KR}$
Extrapolation	130	180	114	154	140
Direct measurement	151	—	—	—	—

These values should be compared with directly determined volumes of pure moisture-free resinates. The measured value in Table 1 is that of Gregor *et al.*[6] who report only the dry volume for potassium saturated DVB 2.

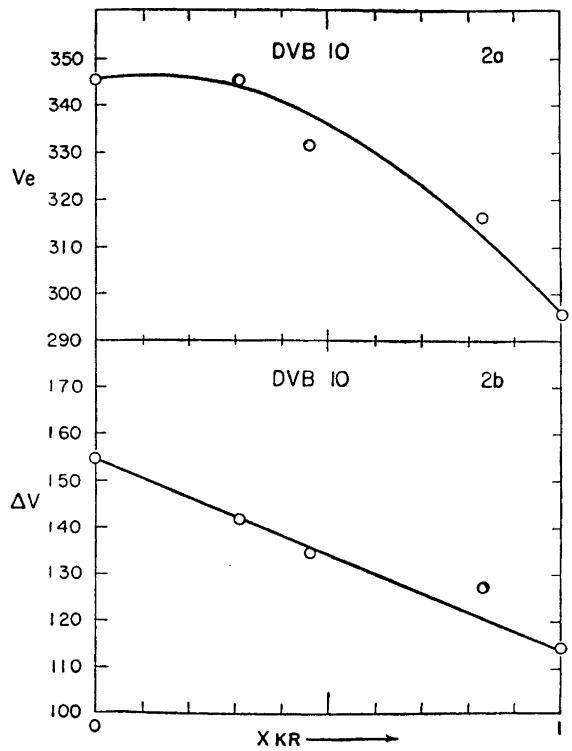

Fig. 2 a. The equivalental volume, V_e, plotted against the mole fraction of potassium, X_{KR}, in the DVB 10 resin.
Fig. 2 b. The function ΔV plotted against mole fraction of potassium, X_{KR}, in the DVB 10 resin.

As is seen from Table 1 the extrapolated volume is smaller than the directly measured volume, an effect previously noted by Gregor *et al.*[5,6] and Boyd and Soldano [4]. The latter authors ascribed it to a contraction in the total volume when the resin is allowed to swell in water. It is also seen from Table 1 that little correlation seems to exist between individual $\overline{V}$-values and degree of crosslinking or water content. However, the difference between the two partial molar volumes decreases with increasing DVB content. In Fig. 4 the partial molar volume difference is plotted against DVB content and average molality ($\overline{m}$) of resin. $\overline{m}$ is equal to the average value of the molalities for the two pure resinates. As is seen from Fig. 4 no straight line is obtained when the difference is plotted against DVB content, but a fairly good straight line is obtained when plotted against the average molality of the resin. The extrapolated value down to $\overline{m} = 0$ is 52 ml/equiv. which has no correlation with the atomic volume difference 76.1 ml/mole, given in Table VII in Ref.[6] No values for the partial molal volume difference at infinite dilution for potassium and

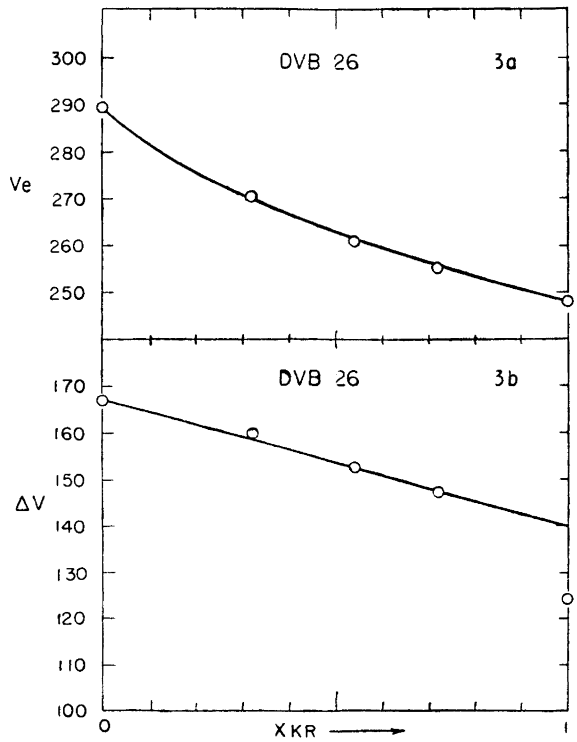

Fig. 3 a. The equivalental volume, V_e, plotted against the mole fraction of potassium, X_{KR} in the DVB 26 resin.
Fig. 3 b. The function ΔV plotted against the mole fraction of potassium, X_{KR}, in the DVB 26 resin.

tetramethylammonium salts with a common anion have been found, so no such comparison can be made. The ideal volume behavior of the potassium-tetramethylammonium system shows that the interaction between water and resin is independent of ionic composition.

If we make another choice of components such as $A^+R^-(H_2O)_m$ and $B^+R^-(H_2O)_n$ and water in order to split up the water content in water of hydration belonging to the ions and "free" water, again straight lines are obtained in the ΔV *vs* X_{KR} plots as this only means that we add the constant quantity $(n + m)\overline{V}_{WR}$ to the original ΔV.

More measurements are needed to show how far the concept of ideal volume of mixing is valid for other systems and at what molalities deviations start to occur.

Acknowledgments. The author is indebted to Dr. William Rubinson for valuable discussions and for correcting the English text.

Phenol Dehydrogenations

VIII.* Synthesis of Magnolol

J. RUNEBERG

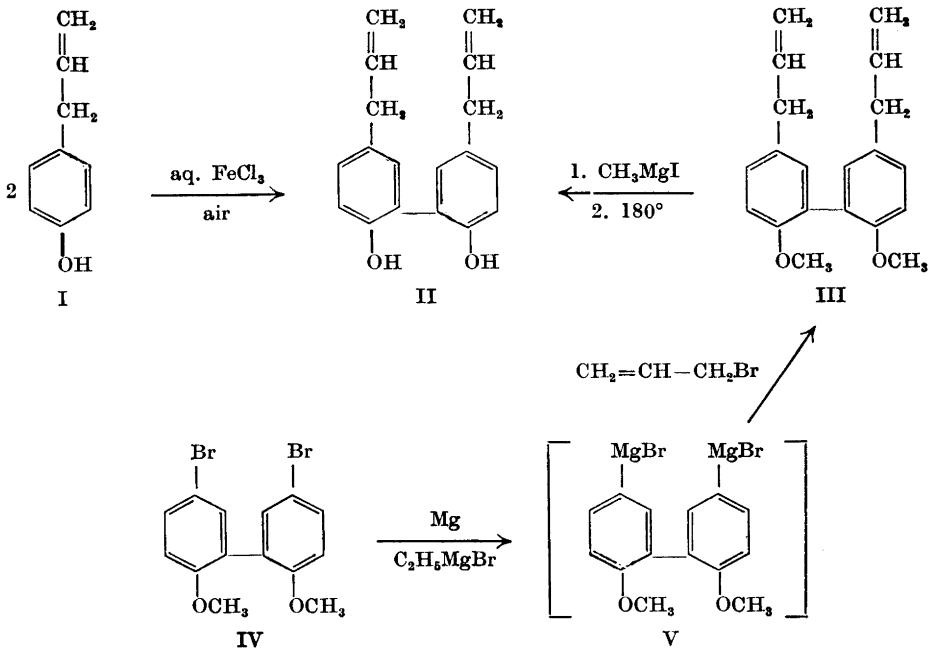
Institutionen för organisk kemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

2,2′-Dimethoxy-5,5′-dibromo-diphenyl (IV) reacted with magnesium in the presence of ethylmagnesium bromide to give the corresponding Grignard compound. This, on treatment with allyl bromide, furnished 2,2-dimethoxy-5,5′-diallyl-diphenyl (III) which on demethylation with methylmagnesium iodide afforded magnolol (II). Application of the Tschugajew reaction to 2,2′-dimethoxy-5,5′-bis-(ω-hydroxy-*n*-propyl)-diphenyl also furnished magnolol but in this case the product was difficult to obtain in a pure state. Thermal rearrangement of 2,2′-diallyloxy-diphenyl yielded 2,2′-dihydroxy-3,3′-diallyl-diphenyl as the sole identifiable product.

Magnolol, dehydrodichavicol, (II) is a constituent of the bark of some *Maynolia* species [1], and it is interesting to note that chavicol methylether occurs in other species of the same genus [2]. Magnolol was recently [3] prepared by dehydrogenation of chavicol (I) with ferric chloride and has now been synthesised by ordinary methods.

2,2′-Dihydroxy-diphenyl was easily brominated to 2,2′-dihydroxy-5,5′-dibromo-diphenyl [4]. This was methylated and the dimethylether (IV) converted into 2,2′-dimethoxy-5,5′-diallyl-diphenyl (magnolol dimethylether) (III) in good yield, using ethylmagnesium bromide as a catalyst according to a method by Short and Wang [5]. It was found necessary, however, to carry out the allylation in tetrahydro-furan solution; in diethylether no reaction took place. 2,2′-Dimethoxy-5,5′-dicarbomethoxy-diphenyl, prepared from magnolol dimethylether [1] was found to be identical with a sample prepared from 2,2′-dimethoxy-5,5′-bis-(ω-carbomethoxy-ethyl)-diphenyl (*cf.* experimental part). Demethylation of magnolol dimethylether with methylmagnesium iodide [6] furnished crude magnolol which was purified *via* its bis-phenylurethan. When the pure urethan was heated in a vacuum it dissociated into phenyl*iso*cyanate and magnolol.

* Part VII: *Acta Chem. Scand.* **11** (1957) 1060.



Following an observation that β-(4-methoxy-phenyl)-propanol on dehydration by the Tschugajew method furnished chavicol methylether, although in poor yield, an attempt was made to synthesise magnolol in a similar way. β-(4-Hydroxy-phenyl)-propanoic acid was iodinated in ammonia to β-(4-hydroxy-3-iodo-phenyl)-propanoic acid which was converted into its methyl-ether-methylester. This was then coupled by the Ullman procedure to give 2,2′-dimethoxy-5,5′-bis-(ω-carbomethoxy-ethyl)-diphenyl, which was reduced with lithium aluminum hydride to the corresponding diol. This product was converted into its bis-methylxanthate, which on heating furnished oily, crude 2,2′-dimethoxy-5,5′-diallyl-diphenyl. On demethylation with methylmagnesium iodide this material yielded a phenol which, however, failed to crystallise. The paper chromatographic behaviour of the product indicated that it consisted essentially of magnolol.

Finally, the di-allylether of 2,2′-dihydroxy-diphenyl was subjected to thermal rearrangement. The resulting phenolic product, on paper chromatographic examination, appeared to be rather inhomogeneous but it obviously contained no magnolol. Methylation of the crude rearrangement product followed by oxidation with permanganate furnished a fair yield of 2,2′-dimethoxy-3,3′-dicarboxy-diphenyl. The rearrangement obviously proceeds essentially in the normal way to give the bis-*ortho* allylated product.

EXPERIMENTAL

Melting points are uncorrected

2,2′-Dihydroxy-5,5′-dibromo-diphenyl: A solution of bromine (120 g) in chloroform (700 ml) was added dropwise with stirring at room temperature to a solution of 2,2′-dihydroxy-diphenyl (70 g) in chloroform (700 ml). After concentration to about 200 ml and cooling, a first crop of crystals (112 g) was obtained. A second crop (8 g) was recovered from the mother liquors. Yield 120 g (93 %). After one recrystallisation from ethanol-water the product melted at 186—189° (lit.[7] m. p. 188—189°).

2,2′-Dimethoxy-5,5′-dibromo-diphenyl: Dimethyl-sulphate (25 g) was added in portions with stirring to a solution of 2,2′-dihydroxy-5,5′-dibromo-diphenyl (23 g) in 10 % sodium hydroxide (100 ml). A white crystalline product precipitated. Yield 22.1 g (89 %). The product was recrystallised from 95 % ethanol, m. p. 127—129° (lit.[4] m. p. 129—130°).

2,2′-Dimethoxy-5,5′-diallyl-diphenyl (Magnolol dimethylether): Ethyl bromide (29.2 g) was added in portions to magnesium turnings (13.1 g) in tetrahydrofuran (250 ml) dried over sodium. The formation of the Grignard compound was initiated by adding a crystal of iodine and heating gently. When all the ethyl bromide (and half of the magnesium present) had reacted, the mixture was chilled in ice and a solution of 2,2′-dimethoxy-5,5′-dibromo-diphenyl (50 g) in dry tetrahydrofuran (250 ml) was added drop by drop with stirring. The reaction mixture was then stirred at room temperature for another 24 h. Allyl bromide (97 g) was now added with stirring. The reaction mixture was refluxed for 3 h, chilled, and then 2 N hydrochloric acid (300 ml) was added in portions. The tetrahydrofuran phase was separated and the water phase extracted with ether. The nonaqueous phases were combined, washed with water, dried and evaporated yielding a yellow oil (37 g). This was distilled in a nitrogen atmosphere, the main fraction (27.8 g) boiling at 165°/0.7 mm. Yield 70 % (lit.[1] b.p. 186°/5 mm).

2,2′-Dimethoxy-5,5′-dicarbomethoxy-diphenyl from magnolol dimethylether: On oxidation with potassium permanganate, magnolol dimethylether furnished 2,2′-dimethoxy-5,5′-dicarboxy-diphenyl, m. p. above 310°. Treatment with diazomethane afforded the dimethylester, m. p. 174—175° (lit.[4] m. p. 173—174°). Mixed with 2,2′-dimethoxy-5,5′-dicarbomethoxy-diphenyl obtained from 2,2′-dimethoxy-5,5′-bis-(ω-carbomethoxy-ethyl)-diphenyl (*cf.* below) the product melted at 173—175°.

2,2-Dihydroxy-5,5′-diallyl-diphenyl (Magnolol): A solution of magnolol dimethylether (10 g) in absolute ether (50 ml) was added with stirring to a solution of methylmagnesium iodide made from magnesium turnings (1.6 g) and methyl iodide (9.7 g) in absolute ether (100 ml). The ether was then removed by distillation and the temperature of the reaction flask slowly raised to 180° and kept at this level for 1 h. During the heating, gas was evolved. Small portions of water were then cautiously added to the glassy residue, followed by 2 N hydrochloric acid (75 ml). The mixture was then extracted with ether and the ether solution shaken with 2 N sodium hydroxide. Starting material (3.4 g) was recovered from the ether phase. The alkaline solution was acidified and extracted with ether. The ether extract was washed with water, dried and evaporated yielding a red-brown syrup (5.0 g). This was dissolved in benzene (50 ml) and filtered through a thin layer of aluminum oxide. The solution was evaporated and the remaining syrup distilled in a nitrogen atmosphere, yielding a main fraction (2.2 g) which boiled at 178—180°/1.0 mm. This material did not readily crystallise when scratched but crystallised immediately on seeding with magnolol obtained by dehydrogenation of chavicol[3]. Allowing for recovered starting material the yield was 37 %.

Purification of magnolol: Magnolol was purified *via* its bisphenylurethan (m. p. 143—144°) as described in a previous paper[3]. On thermal decomposition the phenylurethan afforded magnolol which was resublimed twice, m. p. 100.5—101.5° (lit.[1] m. p. 103°).

β-(3-Iodo-4-hydroxy-phenyl)-propanoic acid: Potassium iodide (400 g) and iodine (127 g) were dissolved in water and diluted to 1 000 ml. This solution (230 ml) was added drop by drop with stirring to a solution of β-(4-hydroxy-phenyl)-propanoic acid (20 g) in conc. ammonia (2 400 ml). The ammonia was evaporated in a vacuum and the volume of the solution reduced to about 400 ml. This solution was acidified stepwise with 10 N hydrochloric acid. The strongly discoloured material (2 g) precipitated first was discarded. The main fraction (26.9 g) consisted of reddish crystals. Extraction of the mother

liquor with ether gave additional material (4 g). The combined products were digested with hot benzene (150 ml) and the solution was filtered. On cooling, crystals (25.2 g), m. p. 103—108°, were obtained and concentration of the mother liquor yielded a second crop (2.7 g). Yield 79 %. For analysis a sample was extracted four times with hot ligroin and the residue was recrystallised from the same solvent, m. p. 112—113° (with sintering at 104°). (Found: I 43.30; equiv. wt. 291 (titration). Calc. for $C_9H_9O_3I$: I 43.45; equiv. wt. 292).

Methyl-β-(3-iodo-4-methoxy-phenyl)-propanoate: β-(3-Iodo-4-hydroxy-phenyl)-propanoic acid (21 g) was treated overnight with an excess of diazomethane in ether. Excess reagent was then destroyed with acetic acid, the solution was evaporated and the residue recrystallised from methanol, m. p. 42—43°. (Found: I 39.29. Calc. for $C_{11}H_{13}O_3I$: I 39.64.)

2,2'-Dimethoxy-5,5'-bis-(ω-carbomethoxy-ethyl)-diphenyl: Methyl-β-(3-iodo-4-methoxy-phenyl)-propanoate (20 g) was heated with copper bronze (60 g). At 225° a sudden reaction took place and the temperature rose to 285°. After cooling, the mixture was exhaustively extracted with acetone. The acetone was evaporated and the remaining syrup distilled in a vacuum. The main fraction, boiling at 234°/1.0 mm, crystallised on standing. Yield: 7.0 g (58 %). Recrystallised from 95 % ethanol, the product melted at 66—67°. (Found: C 68.10; H 6.99. Calc. for $C_{22}H_{26}O_6$: C 68.37; H 6.78.)

Reduction, dehydration and demethylation: Reduction of 2,2'-dimethoxy-5,5'-bis-(ω-carbomethoxy-ethyl)-diphenyl with lithium aluminum hydride afforded a viscous oil boiling at 252°/3.7 mm. A sample was converted into the bis-methylxanthate by the Tschugajew procedure (*cf.* Ref.[8]). On pyrolysis at 250°, an oil (b. p. 165—175°/1 mm) was obtained which on treatment with methyl magnesium iodide (*cf.* magnolol above) furnished an alkali soluble syrup [2.4 g from 10 g 2,2'-dimethoxy-5,5'-bis-(ω-carbomethoxy-ethyl)-diphenyl]. Samples of this product were chromatographed in the same way as the rearrangement product of 2,2'-diallyloxy-diphenyl (*cf.* below) and a spot was obtained with the same R_F-value (0.76) and colour reaction with diazotised benzidine as a blank of 2,2'-dihydroxy-5,5'-diallyl-diphenyl (magnolol). The product obviously contained magnolol but refused to crystallise.

2,2'-Dimethoxy-5,5'-dicarbomethoxy-diphenyl: On alkaline hydrolysis, 2,2'-dimethoxy-5,5'-bis(ω-carbomethoxy-ethyl)-diphenyl afforded the corresponding dicarboxylic acid, m. p. 221—222° which on oxidation with permanganate gave 2,2'-dimethoxy-5,5'-dicarboxy-diphenyl, m. p. above 310°. Dimethylester, m. p. 174—175° (lit.[1] 172°).

2,2'-Diallyloxy-diphenyl: 2,2'-Dihydroxy-diphenyl (13 g) in dry xylene (200 ml) was added to metallic potassium (5.5 g) suspended in the same solvent (100 ml) with vigorous stirring under reflux. A pale yellow salt was formed. The mixture was refluxed for 2 h and then potassium carbonate (5 g) was added. Allyl bromide (34 g) was added drop by drop and the reaction mixture was refluxed for a further 2 h. The filtered solution was extracted with 2 N sodium hydroxide, washed with water and evaporated. The residual oil was distilled in a vacuum, the main fraction (11.8 g) boiling at 142°/0.8 mm. Yield 64 %. (Found: C 80.46; H 6.91. Calc. for $C_{18}H_{18}O_2$: C 81.17; H 6.81).

Rearrangement of 2,2'-diallyloxy-diphenyl: 2,2'-Diallyloxydiphenyl (4 g) was heated at 250° for 10 min. The alkali soluble reaction product (3.8 g) was analysed by paper chromatography. A Whatman No. 1 filter paper was immersed in a solution of dimethylsulphoxide (10 %) in benzene and dried at room temperature for 15 min. A mixture of benzene (10 parts), ligroin (10 parts) and dimethylsulphoxide (0.5 parts) was used as the mobile phase. The chromatogram was run against a blank of magnolol prepared from 2,2'-dimethoxy-5,5'-diallyl-diphenyl (*cf.* above) and developed with diazotised benzidine [9]. The crude product gave the following spots: I (R_F 0.90, yellowish-brown, main spot), II (R_F 0.64, red-brown), III (R_F 0.43, red-brown), IV (R_F 0.15, red-brown). No trace of magnolol (R_F 0.76, yellowish-brown) was obtained.

On methylation with dimethyl sulphate and alkali the product yielded a neutral oil b. p. 155—156°/1.0 mm. This crude material was oxidised with potassium permanganate yielding an acid, m. p. 207—208° in agreement with the reported [4] melting point for 2,2'-dimethoxy-3,3'-dicarboxy-diphenyl (208—209°). (2,2'-Dimethoxy-5,5'-dicarboxy-diphenyl melts [1] above 300°.)

A series of model filaments showing successively increasing molecular weights were prepared by hydrolytic polymerization of ε-caprolactam (in some cases with hexamethylenediammoniumdiadipate as a co-reactant) according to an easily reproducible schedule. The molten polymer was extruded as monofilament, quenched in cold water, washed, cold drawn and subjected to a hot stretching at 190°C. A change in tenacity and viscosity number was observed at prolonged heating in an inert atmosphere. Favourable conditions for reaching a high mechanical strength were found already at a *medium* molecular weight of the treated specimen (viscosity number 1.0—1.2 in formic acid). A further increase of molecular weight did not improve the tensile properties, probably due to unfavourable flow conditions in the spinnerette at high melt viscosities, or an increased degree of entanglement at high degrees of polymerization. This limitation can be avoided by extruding the primary polymer at a stage of medium molecular weight and subjecting the hot stretched filament to a continued polymerization in solid phase. The said operation causes a significant increase of the tensile strength if carried out in an inert atmosphere at a high permanent stress. The time of reaction should not exceed two hours at 190°C.

As repeatedly emphasized by Carothers [1], orientability and fibreforming properties in high polymeric systems are distintive features of the linear molecules, intimately connected with their average absolute size. This means, among other things, that the average chain length should exceed a certain minimum (approximately 800 Å in the case of linear polyamides and polyesters). As a consequence, in polymer homologous series, the degree of polymerization has a marked influence on solubility and mechanical properties. Thus in 66 nylon [2] the tensile strength is known to increase in relation to the molecular weight, the increments being large in the region representing low and medium molecular weights but fairly low at higher ones. This saturation phenomenon is found in most linear macromolecular systems, for instance in fibres of polyethylene, polyvinyl chloride, polyacrylonitrile, polyamides, polyesters and cellulose acetate, but its physical significance is difficult to elucidate.

Table 1. Tenacity and viscosity number of cold drawn filaments, obtained from a polymerizing system of caprolactam, water and coreactant. (The hydrolytic reaction step is not included in the schedule but found in the experimental part below.)

Sample index	Time of reaction, min.	Viscosity number (in formic acid) * of polymer **				Tenacity, g/denier (aver. denier ~500)

III: 5 % coreactant
IV: 7.5 % coreactant

The present paper deals with the tensile properties of homologous polymer series of ε-caprolactam and some copolymers with hexamethylenediammoniumdiadipate. Model filaments of the different polymers have been obtained by melt extrusion into cold water, followed by a "cold" stretching at room temperature. The latter operation is generally considered to develop a high mechanical strength in the direction of the fibre axis due to an increased orientation with subsequent formation of crystalline regions between adjacent molecules. It seems apparent, however, that a saturation effect enters at medium molecular weights, as shown in Table 1. As the possibility *a priori* must be precluded that the strength of oriented molecules rises to a maximum and then falls off, it appears reasonable to seek for an explanation of the actual discrepancy in some imperfections of the fibre, inherently connected with the molecular weight.

In the case of polyamides and polyesters it has generally been stated [3] that molecular weight and melt viscosity are unambigously dependent according to the formula:

$$\ln \eta = A + B M_w^{\frac{1}{2}} + E/RT$$

where η indicates the melt viscosity in arbitrary units, A and B constants, M_w the weight average molecular weight, E the activation energy of flow, R the gas constant and T the temperature in Kelvin units. The expression emphasizes that the viscosity of the molten polymer rapidly increases at increasing degrees of polymerization. Its numerical value may well be above 10^6 cps

Table 2. A comparison, showing the ultimate strength and elongation at break for two types of fibres after rapid hot stretching at 190°C. (Fibres I:7—IV:7 are labeled as *medium* viscosity polymers, I:11—IV:11 as *high* viscosity polymers, in accordance with the preceding table.)

Fibre	Denier after stretching	Breaking load, kg (Scott tester)	Tenacity, g/denier	Ultimate elongation, %
I:7	420	2.75	6.6	11.8
II:7	442	3.02	6.8	12.7
III:7	469	3.21	6.8	12.0
IV:7	386	2.43	6.3	13.1
I:11	483	2.60	5.4	12.1
II:11	445	2.58	5.8	11.6
III:11	415	2.27	5.5	12.9
IV:11	501	2.81	5.6	13.7

at equilibrium in a polymerizing system. Such a dope shows a rheology similar to glass. On extrusion through a cylindrical orifice, especially at a low shear stress, all essential features of the liquid polymer will remain in the subcooled state, obtained by quenching in cold water. The behavior of this specimen at subsequent cold stretching will largely depend upon the internal friction. This magnitude has the same characteristics as viscosity and can also be estimated according to the cited formula. It leaves no doubt that a low temperature and a high degree of polymerization can cooperate in such a manner, that rupture occurs before cold flow ("necking") sets in.

Such a filament can be subjected to stretching at elevated temperature, even in the vicinity of its melting point ("hot stretching"), but experience shows that such an operation alone is insufficient to develop a high mechanical strength. Due to an increased molecular mobility above the second order transition temperature a hot stretching enhances the effect of cold drawing, as seen from Table 2, but is inefficious to impart a high degree of orientation upon the chain molecules directly from the isotropic state.

Another influence of molecular weight arises from the change in shape of the weight distribution function of the polymer at increasing extent of reaction. In the case of most probable distribution the weight fraction w_n showing a degree of polymerization n at an extent of reaction p is given by [4]

$$w_n = n \cdot p^{n-1} \cdot (1-p)^2$$

This function shows a distinct maximum already at $p = 0.9$, corresponding to an average degree of polymerization $n = 1/(1-p) = 10$, but is very broad at $p = 0.98$ ($n = 50$). The internal friction between single chain molecules can hardly be independent of this change of distribution, as it predicts the presence of an increasing number of *very* long molecules at high extents of reaction. This would increase the probability of chain rupture at cold drawing. In fact such a degradation has frequently been observed to judge from a slight but significant change of viscosity number.

Table 3. Tenacity and viscosity number of polyamide fibres on prolonged heating in an inert atmosphere at 190°C under stress (2 g/denier). Polymer I: homopolymer of caprolactam, polymer IV: copolymer (cf. Table 1).

Time of heating, min.	Type of fibre

	I : 7		I : 11		IV : 7		IV : 11	
	Tenacity g/denier	Visc. number	Tenacity g/denier	Visc. number	Tenacity g/denier	Visc. number	Tenacity g/denier	Visc. number
0	5.6	1.18	4.6	1.32	5.3	1.31	4.6	1.47
15	5.9	1.22	5.4	1.34	6.4	1.33	5.8	1.47
30	6.4	1.22	6.5	1.36	7.4	1.34	7.1	1.49
45	7.1	1.25	6.7	1.36	7.8	1.36	7.6	1.49
60	7.1	1.24	6.8	1.36	8.3	1.38	7.9	1.50
75	8.2	1.26	6.8	1.36	8.6	1.38	7.9	1.50
90	8.3	1.31	6.9	1.37	8.8	1.41	7.8	1.49
120	8.1	1.30	6.8	1.34	8.9	1.42	7.8	1.51
150	8.3	1.32	—	—	8.7	1.40	7.7	1.48
180	8.1	1.26	6.6	1.34	8.3	1.34	7.4	1.49
240	8.1	1.26	6.3	1.34	8.1	1.34	7.3	1.48

Chain rupture at cold stretching might also occur by a high degree of molecular entanglement (irreversible looping). Recent calculations [5] on simplified models indicate that in polymerhomologous series this phenomenon increases in relation to the degree of polymerization. It is obviously also connected with the internal friction. Its influence on physical properties is wellknown from the theory of rubber elasticity and needs no discussion here. The absence of a network structure in the actual polymers does not principally prevent a qualitative comparison. At rapid plastic deformation (400—450 % elongation) of a polyamide fibre the internal friction acts in a similar manner as crosslinks in a network. In other words the time available for a long molecule to extricate itself from entanglements with adjacent ones is too short, resulting in chain rupture.

To sum up, the observed maximum of tenacity at medium molecular weights, observed in Table 1, appears to be a superposed effect due to gradually increasing imperfections of the fibre. Most of these can be avoided by selective choice of molecular weight and stretching temperature(s).

When the second stretching was carried out at 190° C on unstabilized polymer, an increase of viscosity number was observed on prolonged heating (Table 3), indicating that a continued polymerization in solid phase takes place. This statement is also valid for copolymers. Under carefully controlled conditions it gives a considerable increase of tenacity (Table 3) provided it is carried out at high stress (2 g/denier) in an inert atmosphere. This reactivity of polyamides below their melting point is known from previous investigations [6] and considered to be a consequence of the accumulation of end groups in the amorphous phase, where chain mobility is high. A number of important appli-

cations of this effect seem to have been overlooked, before all its usefulness of eliminating imperfections in the weakest, most disordered regions of the polymer structure.

EXPERIMENTAL

Model filaments were prepared by hydrolytic condensation polymerization of ε-caprolactam and water. In some cases 66 nylon salt was added as a coreactant to increase the plasticity of the polymer on stretching (reducing the melting point and the second order transition temperature). The reaction was carried out in the absence of a chain stopper.

Apparatus: An autoclave of stainless steel, volume approximately 1 000 ml, fitted with a surrounding jacket (a cylinder of aluminium) serving as heat transfer medium from an electrically heated plate. Samples of the molten polymer were extruded during the reaction through a horisontally directed needle valve and a cylindrical orifice. As a mantle for heat control in the valve served an aluminium block, electrically heated by a copper-bolt, placed in a bore. This arrangement for extrusion proved to work very satisfactory by applying different pressures (carbon dioxide or water vapour) in the autoclave. At the beginning, *e. g.* when the melt is mobile and non-filogenic, great care must be exercised to avoid sprinkling of the hot liquid.

Chemicals: Caprolactam, recrystallized from ethyl acetate and dried in a slow current of carbon dioxide at room temperature. Added to the autoclave as a saturated (80 % by wt.) aqueous solution.

Nylon salt. The commercial grade was purified by dissolving in distilled water to give a 40 % (by wt.) aqueous solution, filtered and precipitated in a large excess of methanol, analytical grade. The alcohol was removed in a current of dry carbon dioxide at room temperature.

Schedule of reaction: The autoclave was charged with 750 ml aqueous solution of monomer(s). A first, hydrolytic reaction step was carried out at 260°C during 120 min. After release of pressure to 4 atm, polymerization was continued for another 2 h, when samples were drawn every 15 min from the heated bottom valve.

Purification: Rapid cooling of the model filaments in a water bath between extrusion nozzle and bobbin, followed by washing in water for 15 min and cold stretching to at draw ratio of 4.5. After a further extraction with water at room temperature the fibre was subjected to hot stretching at 190°C. Part of the cold drawn fibres were used also for measurements of primary tensile strength.

Studies on the Hydrolysis of Metal Ions

21. The Hydrolysis of the Tin(II) Ion, Sn^{2+}

R. STUART TOBIAS

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The hydrolysis of Sn(II) has been studied in a constant ionic medium (3 M ClO_4^-) at 25°C by two series of electrometric titrations. In one series, $[H^+] = h$ was measured with a glass electrode, and in the other $[Sn^{2+}] = b$ was measured with a tin amalgam electrode.

A mathematical analysis has been made of the two families of curves $Z(\log h)_B$ and $\eta(\log h)_B$, where Z is the average number of ligands (hydroxyl groups) bound per tin(II), B is the total Sn concentration, and $\eta = \log B/b$. The main product of the hydrolysis reaction is $Sn_3(OH)_4^{2+}$, and the equilibrium constant of the reaction $3\,Sn^{2+} + 4\,H_2O \rightleftharpoons Sn_3(OH)_4^{2+} + 4\,H^+$ was found to be $\log K_{43} = -6.77 \pm 0.03$. Deviations at low values of Z, η, and B indicate the presence of $Sn_2(OH)_2^{2+}$ and $SnOH^+$. The following equilibrium constants were found: $2\,Sn^{2+} + 2\,H_2O \rightleftharpoons Sn_2(OH)_2^{2+} + 2\,H^+$, $\log K_{22} = -4.4_5 \pm 0.15$; $Sn^{2+} + H_2O \rightleftharpoons SnOH^+ + H^+$, $\log K_{11} = -3.9_2 \pm 0.15$.

The first attempt to determine the products of the hydrolysis of tin(II) solutions and the equilibrium constants for their formation was made by Prytz [1] in 1928. Solutions of tin(II) salts were prepared in various ionic media and titrated at 25° C with NaOH. A hydrogen electrode was used to follow the change in the hydrogen ion concentration; an attempt was also made to follow the change in $[Sn^{2+}]$ using a tin electrode. The data could not be explained by a simple reaction giving $SnOH^+$, but equilibrium constants were calculated on the basis of the following reaction

$$2\,Sn^{2+} + 2\,H_2O \rightleftharpoons Sn_2(OH)_2^{2+} + 2\,H^+ \quad \text{or}$$
$$2\,Sn^{2+} + H_2O \rightleftharpoons Sn_2O^{2+} + 2\,H^+$$

since such measurements cannot determine the number of solvent molecules involved. The following values of the equilibrium constant ($= K_{22}$ below) were given. $SnCl_2$ in 0.5 M KCl, 8×10^{-5}, in water, 2×10^{-3}; $SnBr_2$ in 0.5 M KBr, 5.8×10^{-4}, in water, 8.3×10^{-3}; $Sn(ClO_4)_2$ in water and 0.5 M $NaClO_4$, 1.8×10^{-3}.

Randall and Murakami [2] studied the hydrolysis of Sn^{2+} in chloride solution. The equilibrium constant for the reaction $Sn^{2+} + 2\,H_2O + Cl^- \rightleftharpoons$

$Sn(OH)ClH_2O(s) + H^+$ was obtained from solubility measurements. The constant was given as $\log K = 2.75$.

In 1939, Gorman [3] titrated tin(II) perchlorate solutions with NaOH and measured the hydrogen ion concentration with a hydrogen electrode at 25° C. The data were interpreted in terms of the reaction

$$Sn^{2+} + H_2O \rightleftharpoons SnOH^+ + H^+$$

The data were extrapolated to zero ionic strength to obtain the equilibrium constant, and a value $\log K_{11} = -1.70$ was given for 25°C.

Garrett and Heiks [4] measured the solubility of SnO in HCl solutions and interpreted the results in terms of the mononuclear species Sn^{2+}, $SnOH^+$, and $Sn(OH)_2(aq)$. From their data, we may obtain the following constants: $\log K_{11} = -2.1$, $\log K_{21} = -7.06$.

More recently, Vanderzee and Rhodes [5,6] have estimated equilibrium constants for the reaction giving $SnOH^+$ at 0°, 25°, 35°, and 45°C, assuming this to be the only hydrolysis reaction occurring in solutions with high concentrations of halide ions. The values for $\log K_{11}$ range from −1.8 at 0° to −1.6 at 40°C.

Since the hydrolysis of many metal ions has been found to yield polynuclear complexes, it is essential to study the equilibria at a number of different total tin concentrations. The aim of this work was, therefore, to investigate the hydrolysis of tin(II) by the methods developed in this laboratory [7–10] in order to elucidate the mechanism of the hydrolysis and to calculate the various equilibrium constants.

Symbols and formulas

The symbols adopted are mainly those used in the previous papers in this series.

b	concentration of free Sn^{2+}
B	total concentration of Sn(II)
$\boldsymbol{B}$	normalized value of B (27)
E_A	-emf, $E°_A$-constant, E_{jA}-liquid junction potential, all for cell A (3)
E_B	-emf, $E°_B$-constant, E_{jB}-liquid junction potential, all for cell B (4)
F_q	function of experimental data defined by (22)
$g(u) =$	$\Sigma_n k_n u^n$
h	concentration of free H^+
j_A, j_B	constants in $E_j = jh$
k_n	equilibrium constant for $(n+1)Sn^{2+} + nt\,H_2O \rightleftharpoons Sn[(OH)_tSn]_n^{(2n+2-tn)+} + nt\,H^+$
k, k_0	constants in $k_n = k^N$, hypothesis II; $k_n = k_0k^n$, hypothesis IIIa; $k_n = k_0nk^n$, hypothesis IIIb; $k_n = k_0k^n\,(n!)^{-1}$, hypothesis IIIc (AB II 28a, b, c) [8]
K_{pq}	equilibrium constant for the reaction $qSn^{2+} + pH_2O \rightleftharpoons Sn_q(OH)_p^{(2q-p)+} + pH^+$
n	number of links per complex
$\bar{n}$	average number of links per complex (11)

N	number of $Sn(OH)_t$ links in a unique complex
P_1, P_2	normalizing constants (28), (29)
p	number of OH^- in $Sn_q(OH)_p$
q	number of Sn^{2+} in $Sn_q(OH)_p$
R	ratio K_{43}/K_{22}^2
t	number of hydroxyl groups per link
u	$= h^{-t}b$
x	$= \log B - t \log h$
$x_{½}$	value of x at $y = ½$
X	normalized $x = x + \log 2 - x_{½}$ (AB II 10) [8]
y	$= Z/t$
Z	average number of (OH) bound per Sn(II)
α	normalized h (29)
β	normalized b (28)
γ_+, γ_{2+}	activity factors of H^+ and Sn^{2+}
δ	residual integral in (17)
η	$= \log B/b$
ξ	normalized x

All species may be combined with the medium ions, Na^+ and ClO_4^-, or with the solvent. The mole l^{-1}, M, is the standard unit of concentration used in all equilibrium constants. In some cases, the convenient mM unit is used in the text and headings.

METHOD

The hydrolysis of tin(II) was studied by two series of potentiometric titrations at 25°C. These will be referred to, in the following discussion, as the Z and η titrations. The free concentrations of H^+ and Sn^{2+} will be denoted by

$$[H^+] = h \qquad [Sn^{2+}] = b$$

B is the total concentration of tin in the solution, and H is the analytical excess of hydrogen ion, assuming no hydrolysis, *i. e.* all tin(II) in the form Sn^{2+}. H is therefore negative in the latter parts of the titrations. The quantities B and H are known from the analytical data.

In each Z and η titration, B was maintained constant while H was varied and h measured. The average number of OH^- bound per Sn(II), Z, could then be calculated.

$$Z = (h - H) / B \tag{1}$$

The data are most conveniently plotted in the form $Z(\log h)_B$.

In the η titrations, the free tin concentration, $[Sn^{2+}] = b$, was also measured. One can then calculate

$$\eta = \log B/b \tag{2}$$

These data are presented in the form η $(\log h)_B$.

The acidity of the solutions was increased by adding $H^+ClO_4^-$ and decreased by adding $Na^+HCO_3^-$. The use of $Na^+HCO_3^-$ as a base has been recommended

by Hedström [11] to avoid the formation of a precipitate which would be only slowly redissolved to give true equilibrium.

In both types of cells used, the reference electrode was

$$SE| = Ag|AgCl|10\ mM\ Ag^+, 2\,990\ mM\ Na^+, 3\,000\ mM\ ClO_4^-|3\,000\ mM\ Na\ ClO_4.$$

The hydrogen ion concentration was determined with the cell

$$-\ \text{glass electrode}\ |\ \text{solution S}\ |\ SE+ \qquad (A)$$

Solution S had the initial composition

$$(Sn(II),\ B\ M;\ H^+,\ H\ M;\ Na^+,\ (3 - 2B - H)\ M;\ ClO_4^-,\ 3\ M)$$

The measured emf is related to h by the following equation

$$E_A = E_A^\circ - 59.16\ \log\ h - E_{jA} - 59.16\ \log\gamma_+ \qquad (3)$$

The equilibrium tin(II) concentration was measured using the following cell.

$$-Sn,\ Hg\ (sat'd)\ |\ Solution\ S\ |\ SE+ \qquad (B)$$

The equilibrium tin (II) concentration, b, is related to the emf of cell (B) by the equation

$$E_B = E_B^\circ - \frac{59.16}{2}\log\ b - \frac{59.16}{2}\log\frac{\gamma_{2+}}{a_{Sn}} - E_{jB} \qquad (4)$$

In the two cells (A) and (B), E_A° and E_B° are constants characteristic of each cell. $NaClO_4$ was added to make all solutions 3 M in ClO_4^- with no other anions present. The activity coefficients, γ_+ and γ_{2+}, are defined so that $\lim_{c\to 0} a/c = 1$ in the solvent 3 M $NaClO_4$. Since the concentrations of tin(II) and hydrogen ions were quite low compared to the 3 000 mM ClO_4^- (Sn(II)-maximum 40 mM; H^+-maximum 70 mM), it can be assumed to a close approximation that activity factors remain constant and can be included in the E° for the cell [12] so that true stoichiometric equilibrium constants are obtained. The tin activity in the amalgam is maintained constant by the use of the mercury-rich phase of the 2-phase amalgam. At these low concentrations E_{jA} and E_{jB} are linear functions of the hydrogen ion concentration. If these junction potentials are written in the form $j_A h$ and $j_B h$, j_A has a value of -0.017 ± 0.001 mV/mM as reported earlier [12]. The value of j_B varied somewhat between titrations with different B, and the value was determined for each titration by measurements in a region where no hydrolysis occurred. j_B varied from -0.022 to -0.028 mV/mM. It seems probable that the liquid junction potentials are the same and that the difference between E_{jA} and E_{jB} is caused by the inclusion of a small correction term for minute deviations of the amalgam electrode from the Nernst equation. At any rate, the magnitude of the effect is so small that it has no significant influence on the amalgam electrode data.

When E_A° and j_A are known and E_A is measured, h may be obtained using equation (3). Similarly, b is obtained from E_B°, j_B, and measured values of E_B applying eqn. (4).

EXPERIMENTAL DETAILS

One especially difficult problem encountered during the study of the hydrolysis of tin(II) solutions is that the tin(II) ion is very easily oxidized in solution to the 4-valent state. It is almost impossible to store and handle tin(II) solutions for any length of time without having small amounts of tin(IV) formed by reaction with atmospheric oxygen, a reaction that is greatly accelerated by light. Since the reduction of tin(IV) to tin(II) by metallic tin is a very slow process, it is quite difficult to reduce tin(IV) to the +2 state quantitatively. Halide ions are also particularly undesirable when the hydrolysis of tin(II) is to be investigated, since strong complexes are formed between these ions and Sn^{2+}. The following experimental procedure was developed to circumvent these experimental difficulties.

Tin(II) perchlorate solutions were prepared by a modification of the method first described by Noyes and Toabe[13]. Standard copper(II) perchlorate solutions were prepared by dissolution of Merck (p.a.) CuO in warm dilute perchloric acid. No traces of Cl^- could be found in the solutions which were then filtered and diluted.

The copper(II) content of the solutions was determined by electrodeposition of Cu using HNO_3 as a depolarizing agent and adding a small excess of urea just before the completion of the electrolysis to destroy any accumulated nitrous acid. The accuracy was better than ± 0.1 %.

The total ClO_4^- content of the stock solution was determined by passing a definite volume through the cation exchange resin Duolite C 3 and titrating the eluate with standard NaOH. The analytical excess of H^+ in the stock solution was calculated from $[H^+] = [ClO_4^-] - 2[Cu^{2+}]$.

Standard solutions for the titrations were prepared by dilution of the stock solution with standard $NaClO_4$ and $HClO_4$.

The tin(II) solutions were prepared just before each titration to the concentration $2B$ in a modification of the apparatus described by Lingane and Pecsok [14] for the production of solutions of strong reducing agents. Hopkins and Williams' "Analar" metallic tin was used to displace copper(II) from the solutions. It was found that the hydrogen overvoltage on a pure tin surface was sufficient to prevent any reduction of H^+ so long as the solutions were free of any dissolved oxygen. Dissolved oxygen was flushed from the solutions by bubbling N_2 through them for about one hour. The tin was cleaned with dilute HCl before use, washed with water and ethanol, and dried under vacuum. Iodometric determinations of the tin(II) content of the most concentrated solution prepared (80 mM) agreed within $\pm$ 0.3 % of the value calculated on the basis of the copper displaced.

Tin amalgams were prepared in the two-limbed vessel described by Biedermann [15] by warming freshly cleaned Merck (p.a.) tin and triple distilled mercury in an atmosphere of CO_2. The two phase amalgam formed was thermostated at 25° $\pm$ 0.1 °C for about 20 h before use. Since the liquid phase of the tin amalgam contains 1.263 mole % tin at 25°C[16], amalgams with a constant tin activity could be easily prepared. The two phases were separated by passing the amalgam through a capillary tube just before the amalgam was introduced into the titration vessel.

Perchloric acid solutions were prepared by dilution of Kebo (p.a.) $HClO_4$ and standardized against $KHCO_3$ dried under CO_2 and also against standard NaOH solutions. The *sodium hydroxide solutions* were in turn standardized against potassium acid phthalate. The determinations agreed to $\pm$ 0.1 %.

Sodium hydrogen carbonate solutions were prepared from Merck (p.a.) $NaHCO_3$ containing less than 0.01 % Cl^-.

Sodium perchlorate solutions were prepared by neutralizing a solution of $HClO_4$ (p.a.) with Merck (p.a.) $NaHCO_3$. The solutions were filtered to remove silicates and analyzed by evaporation and drying to a constant weight. The analysis was checked by passing portions of the solution through the hydrogen form of an ion exchanger and titrating the perchloric acid with NaOH. Good agreement was found between the two methods. No chloride, chlorate, or iron could be detected in the final product.

Silver perchlorate solutions were prepared by evaporating Merck (p.a.) $AgNO_3$ with a large excess of $HClO_4$ until no nitrate could be detected in the product. The remaining $HClO_4$ was neutralized with Ag_2O, the solution filtered, and the silver determined gravimetrically as AgCl.

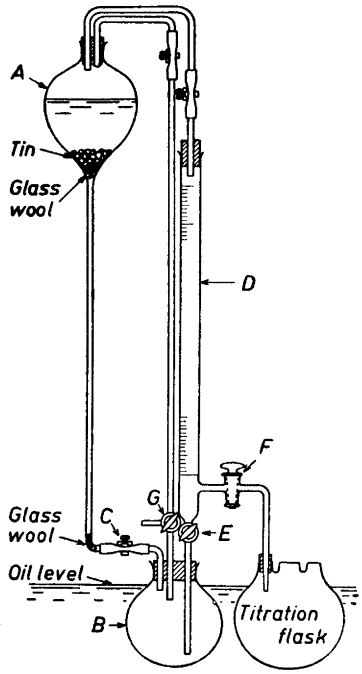

Fig. 1. Arrangement for the preparation of tin(II) solutions.

Nitrogen gas was purified by washing with 10 % H_2SO_4, 10 % NaOH, distilled water, and finally 3 M $NaClO_4$. Both the nitrogen and carbon dioxide gases were freed of oxygen by passage over hot activated copper.

Apparatus

A titration cell of the "Wilhelm" type as described by Forsling, Hietanen, and Sillén [7] was used. All measurements were made in a paraffin oil thermostat at 25° ± 0.1°C which was located in a room thermostated at approximately 25°C.

The silver reference electrode was prepared as described by Brown [17] and was coated with AgCl by electrolysis for half of an hour with a current of 0.3 mA.

The glass electrode was a Radiometer, Copenhagen, type G-102 AK. The potential of the cell

$$-\text{Glass electrode} \mid H^+ \mid \text{quinhydrone} \mid Pt+$$

was constant to ±0.1 mV indicating that eqn. (3) is valid. The emf values of the glass electrode cell (A) were read to 0.1 mV using a Radiometer PHM3 valve potentiometer. The emf values of the amalgam cell (B) were read to 0.01 mV with a Leeds and Northrup K-2 potentiometer.

The solution in the titration vessel was agitated with nitrogen gas while CO_2 was introduced over the surface of the liquid to prevent the entry of any atmospheric oxygen.

Titration procedure

Almost all of the titrations were carried out in the following manner. The preparation train illustrated in Fig. 1 was flushed with carbon dioxide for about 2 h. Approximately 100 ml of standard Cu(II) solution was introduced into the reservoir A containing the metallic tin. A strong flow of CO_2 was maintained during the addition to prevent the

entry of oxygen into the system. The flask was gently agitated for 10 – 15 min after which samples of the solution were withdrawn at C and tested for Cu^{2+}. When the solution gave no test for copper using $Fe(CN)_6^{4-}$ in dilute HCl, it was transferred to the reservoir B. The burette D could be filled by pressing the solution up with CO_2 admitted through the 3-way stopcock G. The tin solution was thus completely protected from the atmosphere during the preparation. Stopcock F was used to meter the solution during the titration.

25.00 ml of 3 M $NaClO_4$ solution was pipetted into the titration flask. About 100 g of tin amalgam was introduced into the cell from the two limbed vessel. A strong stream of CO_2 was passed over the surface of the $NaClO_4$ solution, while N_2 was bubbled into the solution. A platinum needle was used to make electrical contact with the amalgam. 25.00 ml of the tin solution T_1 (concentration 2 B) was then added. This mixture, solution S, was titrated with equal volumes v_1 of $NaHCO_3$ solution (T_2) and solution T_1. In this way, the total concentration of tin was maintained constant at B. The values of the cell constants E_A° and E_B° were obtained as illustrated in Table 1 by titration at hydrogen ion concentrations where hydrolysis was negligible.

The one exception to the above procedure was for the titration with B = 2.5 mM. In this case T_1 had a concentration of 4 B. Therefore, 75.00 ml of $NaClO_4$ (3 M) was added together with 25.00 ml of T_1. Titration was with equal volumes v_1 of T_1 and T_2 plus $2v_1$ ml of 3 M $NaClO_4$.

At the end of the titrations with 5 and 2.5 mM Sn(II), the emf values of both cells were noted. CO_2 was passed into the solution for one hour and N_2 bubbled through the solution again for 2 min. No change in either the glass or amalgam electrode potentials was observed, so that it can be assumed that there was no significant formation of complexes between tin(II) and carbonate ion even at the lowest value of $h \simeq 1.0$ mM.

Steady values of both potentials were attained rapidly, usually within 15 min, and remained constant for 10 h. At $\eta > 0.3$ the amalgam surface apparently became contaminated, since variations of 0.1 mV could be obtained by agitation of the amalgam. The glass electrode potentials were reproducible within ±0.2 mV and the amalgam potentials within ±0.05 mV.

A back titration was performed at the lowest value of B, and the points for both $Z(\log h)$ and η ($\log h$) fell on the same curve, indicating that true equilibria had been obtained even in this region.

At tin(II) concentrations of less than 2.5 mM, the amalgam electrode potentials became very sensitive to agitation of the amalgam pool even at low values of η, and hence no measurements were made for $B < 2.5$ mM.

Table 1. Standardization of electrodes for B = 20 mM.

B = 20.00 mM, H = 60.00 mM, $[ClO_4]$ = 3 M 50.00 ml
B = 40.00 mM, H = 120.00 mM, $[ClO_4]$ = 3 M v_1 ml
$[NaHCO_3]$ = 272.5 mM, $[ClO_4]$ = 3 M v_1 ml
E_A° = 316.1 ± 0.05 mV
E_B° = 777.26 ± 0.01 mV

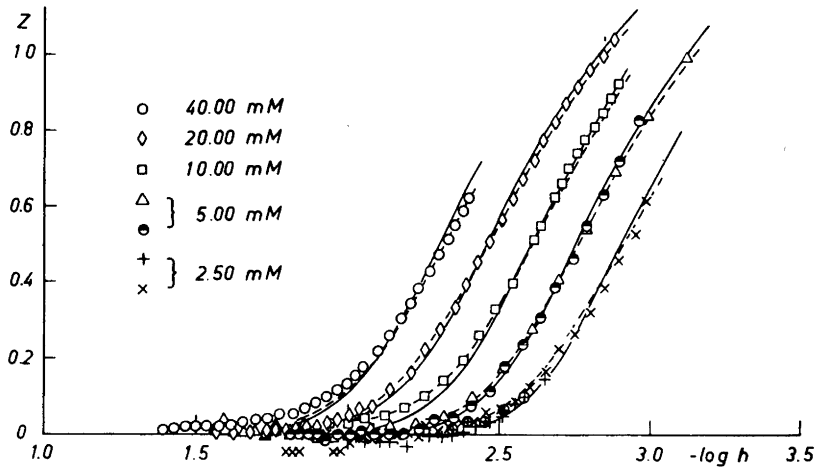

Fig. 2. Data from glass electrode measurements. Average number, Z, of OH bound per Sn as a function of log h (molar scale), B as a parameter. Full curves calculated for $K_{11} = K_{22} = 0$, log $K_{43} = -6.69$. Broken curves calculated for log $K_{11} = -3.92$, log $K_{22} = -4.45$, log $K_{43} = -6.77$. Points ◓ adjusted upward by 0.02 units.

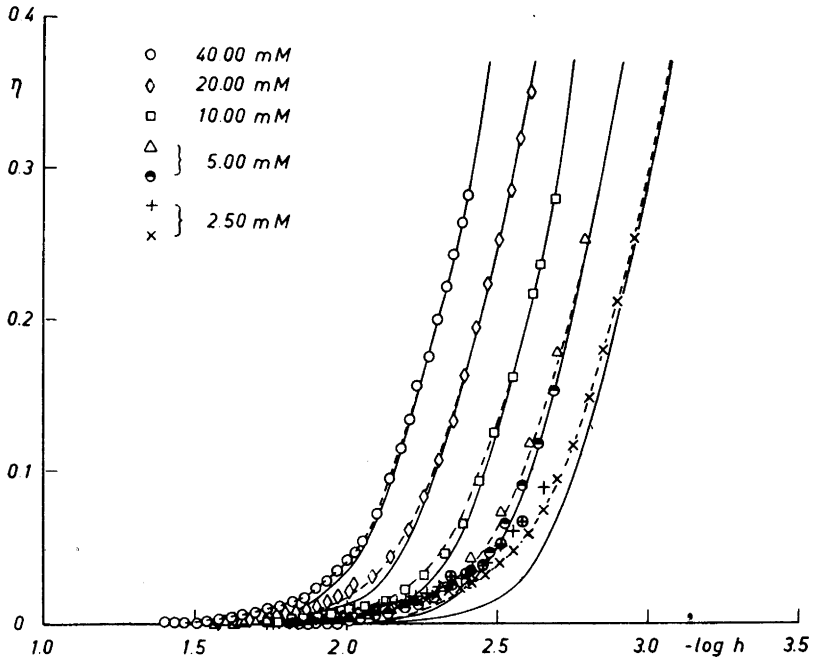

Fig. 3. Data from amalgam electrode measurements, $\eta = \log B/b$ as a function of log h (molar scale), B as a parameter. Curves calculated for the same sets of constants as in Fig. 2.

THE MAIN PRODUCTS OF HYDROLYSIS

Fig. 2 gives the data $Z(\log h)_B$ as calculated from the emf values of the cell (A), using eqns. (1) and (3). Fig. 3 gives the data η $(\log h)_B$ calculated using eqns. (2) and (4) together with the emf values of cells (A) and (B). Table 2 gives the values of log h, Z, and η for each titration.

It is seen from Figs. 2 and 3 that Z and η are functions of both B and h, which indicates that at least one polynuclear species is formed during the hydrolysis of tin(II) solutions. If only mononuclear complexes were formed, Z and η would be functions of the single variable h.

In order to evaluate the data, several different approaches will be tried in the following discussion.

"Core + links" approach

The systematic treatment developed by Sillén [8,18] will be closely followed in this discussion. It has frequently been observed that the products formed by the hydrolysis of metal ions can be described by a general "core + links"

* Back titrations

formula, *i. e.* $Me[(OH)_tMe]_n$ where t is a constant and n may be a constant or have several integral values [15,19–22]. If all of the complexes can be described by the "core + links" hypothesis, the curves $Z(\log h)_B$ and $\eta\,(\log h)_B$ must form a family of parallel curves with a constant spacing along the log h axis. The value of t, the number of hydroxyl groups per "link", may be obtained from (5).

$$\left(\frac{\partial \log B}{\partial \log h}\right)_Z = \left(\frac{\partial \log B}{\partial \log h}\right)_\eta = t \qquad (5)$$

It is seen that the data for the hydrolysis of tin(II), given in Figs. 2 and 3, form approximately parallel curves. The spacing between the curves gives the difference quotients

$$\left(\frac{\Delta \log B}{\Delta \log h}\right)_Z = \left(\frac{\Delta \log B}{\Delta \log h}\right)_\eta = 2.0 \qquad (5a)$$

It follows from eqn. (5) that the value of t may be obtained directly from the slope of the curves $\log B\ (\log h)_Z$ and $\log B\ (\log h)_\eta$ given in Figs. 4 and 5. Neglecting the slight deviations at low B, the data form straight lines with slopes of 2.0.

The value of t obtained may be tested by plotting Z and η *versus* $\log B - t \log h$. Since the limitation to "core + links" species requires Z and η

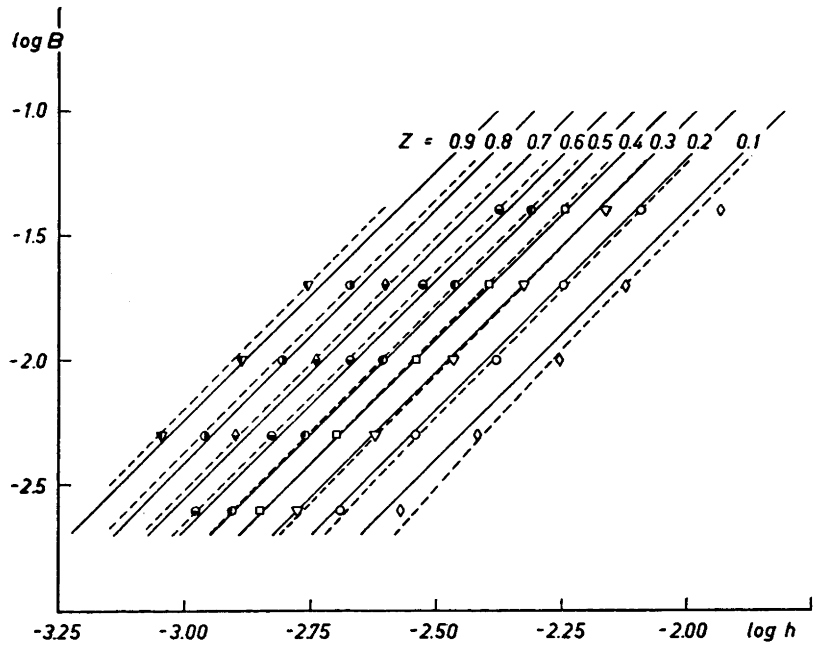

Fig. 4. log B as a function of log h, Z as a parameter. Full curves calculated for $K_{11} = K_{22} = 0$, log $K_{43} = -6.69$. Broken curves calculated for log $K_{11} = -3.92$, log $K_{22} = -4.45$, log $K_{43} = -6.77$.

to be functions of the single variable $u = (bh^{-t})$ and $Bh^{-t} = f(u)$, Z and η are functions of the variable (Bh^{-t}). The data are most conveniently plotted as

$$y = Z/2 \textit{ versus } x = \log (Bh^{-t})$$
$$\eta \textit{ versus } x = \log (Bh^{-t})$$

These data are given in Figs. 6 and 7.

Since all of the experimental points seem to describe the same curve within the range 40 mM $\geqslant B \geqslant$ 5 mM, the "core + links" hypothesis may be considered a good explanation of the data. A significant discrepancy occurs for $B = 2.5$ mM in the plot $\eta(x)$. Deviations in this direction are to be expected if mononuclear species are formed in addition to the "core + links" complexes. Although this deviation appears to be beyond the experimental error, a discussion of the effect will be postponed until the data have been evaluated in the region where the $y(x)$ and also the $\eta(x)$ curves coincide for $t = 2$.

Direct analysis of the curves $y(x)$ and $\eta(x)$

As outlined by Sillén in AB II[8], it is possible to calculate the equilibrium constants for the "core + links" complexes directly from the experimental data $y(x)$ and $\eta(x)$.

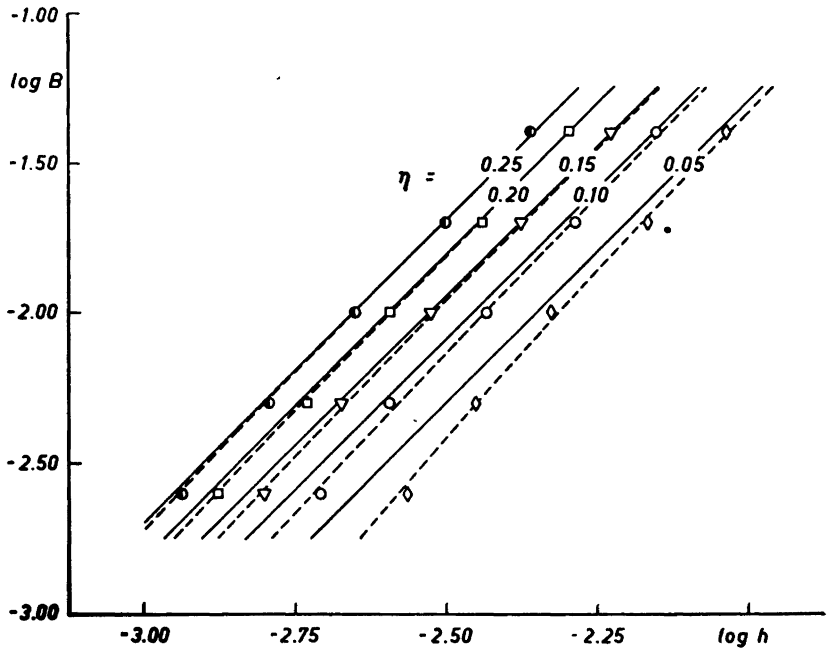

Fig. 5. log B as a function of log h, η as a parameter. Curves calculated for the same sets of constants as in Fig. 4.

If k_n is defined as the equilibrium constant for the reaction

$$(n + 1)\ Sn^{2+} + 2n\ H_2O \rightleftharpoons Sn[(OH)_2Sn]_n^{2+} + 2n\ H^+,$$

then

$$B = b + \sum (n+1)\ [Sn[(OH)_2Sn]_n^{2+}] = b + \sum (n+1)k_n h^{-2n} b^{n+1} \qquad (6)$$

Substituting $u = (h^{-2}b)$ into (6)

$$B = b\ (1 + \sum (n+1)k_n u^n) \qquad (7)$$

if $g = \sum k_n u^n$, $\frac{dg}{du} = g'$, substitution into (7) gives

$$B = b\ \frac{d}{du}\ (u + ug) = b(1 + g + ug') \qquad (8)$$

From (8) it is seen that

$$(1 + g) = u^{-1} \int_0^u Bb^{-1}\ du = u^{-1} \int_0^u 10\eta\ du \qquad (9)$$

It follows directly from the definitions of u, x, and η that

$$\log u = x - \eta. \qquad (10)$$

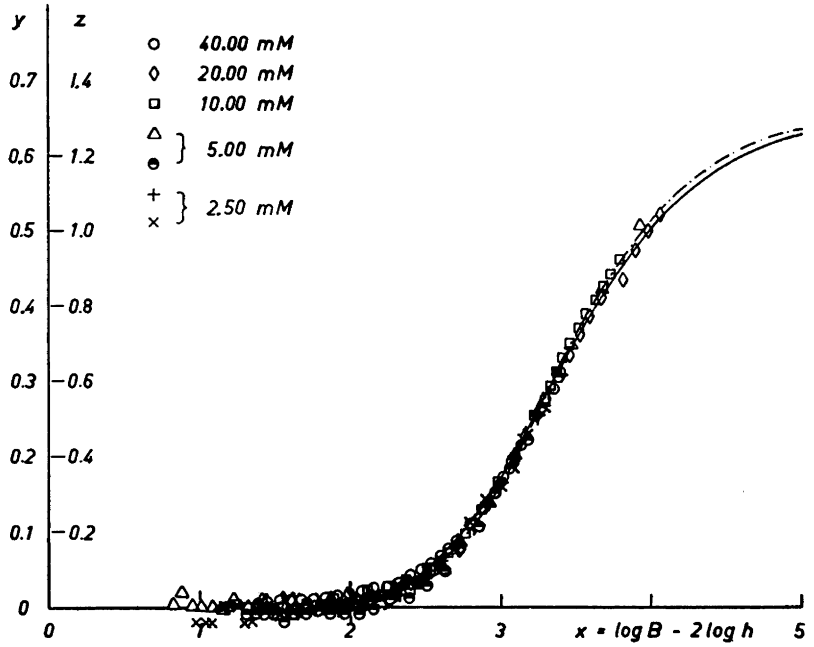

Fig. 6. Z or $y = Z/2$ as a function of $x = \log B - 2 \log h$. All experimental points are shown using the same symbols as in Fig. 2. Full curve calculated for $K_{11} = 0$, $\log K_{23} = -4.43$, $\log K_{43} = -6.74$. Broken curve calculated for $\log K_{43} = -6.69$.

Therefore $g(u)$ may be obtained from the amalgam electrode data $\eta(x)$, using (9) and (10).

One may also calculate the average number of links in the complexes (average degree of polymerization) defined by

$$\bar{n} = \frac{\sum nc_n}{\sum c_n} = \frac{ug'}{g} \tag{11}$$

Substituting from (8)

$$\bar{n} = \frac{Bb^{-1} - g - 1}{g} \tag{12}$$

η can also be obtained as a function of u from the glass electrode data $y(x)$ using the eqn. (15) given by Sillén in AB II [8]. In the present case $y = Z/t = Z/2$.

$$\eta = y \log e + \int_{-\infty}^{x} y dx \qquad \text{together with} \tag{13}$$

$$\log u = x - \eta \tag{10}$$

Although $g(u)$ may then be obtained from (9) as with the amalgam electrode data, it is simpler to apply a relation obtained from eqns. (5a) and (8a) in AB II[8].

$$\log (1 + g) = \eta + \log (1 - y) \tag{14}$$

Equation (14) may be easily derived in the following way. The total number of bound OH groups per liter of solution is given by the following equation (comparing with equations (6) to (8)).

$$BZ = \sum 2n[\mathrm{Sn}[(\mathrm{OH})_2\mathrm{Sn}]_n^{2+}] = 2b\sum nk_nu^n = 2bug' \tag{15}$$

Inserting $Z = 2y$, $Bb^{-1} = (1 + g + ug')$ (8), and $Bb^{-1} = 10^{\eta}$ '(definition) and eliminating Bb^{-1} and ug' gives $(1 + g) = 10^{\eta}(1 - y)$. Upon taking logarithms we obtain (14).

Substituting (14) into (12) we obtain

$$\bar{n} = \frac{y}{1 - y - bB^{-1}} \tag{16}$$

Using (13), (10), and (14), one may obtain $\eta(x)$ and $g(u)$ from the glass electrode data $y(x)$.

In order to calculate $g(u)$ form the amalgam electrode data, a smooth curve was drawn through the data $\eta(x)$ using the lowest values of η where slight deviations occurred at low values of η. η was then read off for a number of values of x. Using eqn. (10), a new curve was constructed for B/b as a function of u. The integration in eqn. (9) was made graphically. The data for g, u, and $\bar{n}$ calculated from eqn. (12) are given in Table 4. Since from eqn. (11) $\bar{n} = u\ g'/g = \mathrm{d}\log g/\mathrm{d}\log u$, $\bar{n}$ may also be obtained from a plot of log g *versus* log u. This is given in Fig. 8. In order to evaluate the polynuclear complexity constants, the function $gu^{-1} = k_1 + k_2u + \ldots$ was plotted *versus* u in Fig. 9.

In a similar fashion, a smooth curve was drawn through the glass electrode data $y(x)$. Again when deviations occurred at low values of y, the lowest values were chosen for each x. The values of B/b, log g, and log u were calculated using

eqns. (10) and (14), performing the integration in (13) graphically. These data together with the values of $\bar{n}$ calculated with eqn. (16) are given in Table 3. The data are plotted as log g *versus* log u together with the amalgam electrode data in Fig. 8. The function gu^{-1} is also plotted *versus* u in Fig. 9 together with the amalgam data.

In performing the integration in eqn. (13), it was assumed that the residual integral

$$\delta = \int_{-\infty}^{x=1.7} y\ dx = 0 \qquad (17)$$

It is seen from the data in Tables 3 and 4 and the slope of the curve in Fig. 8 that $\bar{n}$ rises from approximately 1.7 to 2.0, indicating that the trimer $Sn[(OH)_2\ Sn]_2^{2+}$ predominates at high values of y and η. It is seen from the $y(x)$ data that $\bar{n}$ approaches 2.0 as a limit, *i. e.* $d\bar{n}\,/\,du = 0$ at high values of u. This indicates that no complexes higher than the trimer are present in significant amounts.

The data were also used to calculate the number of hydroxyl groups bound per complexed metal atom. This quantity $BZ(B-b)^{-1}$ had an average value 1.30 ± 0.03 for $2.6 \leqslant x \leqslant 3.5$ indicating the complex is primarily $Sn_3(OH)_4^{2+}$.

The values of the equilibrium constants for the dimer and trimer "core + links" complexes may be obtained from the slope and intercept of the curve in Fig. 9. The following values were obtained

$$\log K_{22} = -4.4_3 \pm 0.15$$
$$\log K_{43} = -6.74 \pm 0.04$$

The solid lines in Figs. 6 and 7 were calculated with these constants.

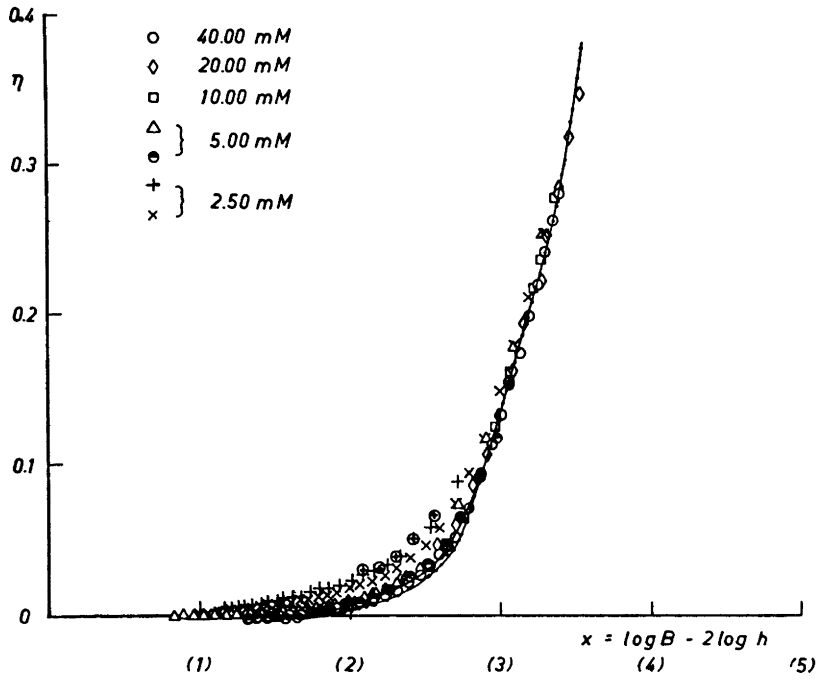

Fig. 7. η as a function of $x = \log B - 2 \log h$. All experimental points are shown using the same symbols as in Fig. 3. Curves calculated for the same sets of constants as in Fig. 6.

Comparison with simple reaction mechanisms

The experimental curves $y(x)$ and $\eta(x)$ were compared with the families of curves $y(X)$ and $\eta(\xi)$ calculated for the simple reaction mechanisms outlined in AB II[8] and part 8[19] of this series.

No agreement was found between the experimental curves and those calculated on the basis of hypothesis I. This hypothesis assumes that no soluble complexes occur and only a precipitate is formed.

Good agreement was obtained between the experimental and theoretical curves calculated for hypothesis II with $N = 2$. This hypothesis assumes the formation of a single soluble complex where n has the single value N. This again indicates that the trimer $Sn[(OH)_2Sn]_2^{2+}$ is the main complex formed by the hydrolysis of solutions of tin(II). The equilibrium constant for the reaction may be obtained in the following way. The constant k is defined by

$$k_n = k^N, \tag{18}$$

when n has the single value N and where k_n is the equilibrium constant for the reaction

$$(n + 1)\ Sn^{2+} + nt\ H_2O \rightleftharpoons Sn[(OH)_tSn]_n^{2+} + nt\ H^+$$

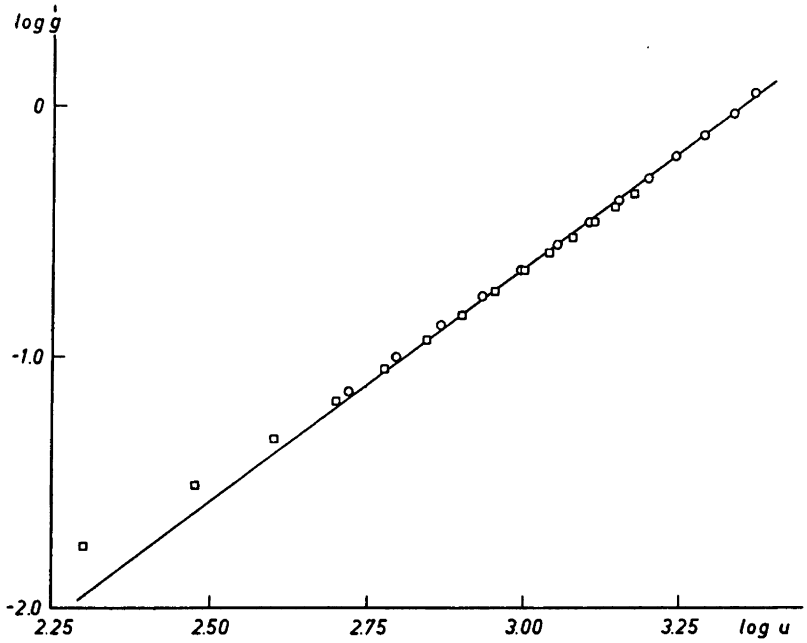

Fig. 8. Direct analysis of the curves $y(x)$ (Fig. 6) O, and $\eta(x)$ (Fig. 7) □: log g as a function of log u, together with the best straight line of slope 1.92.

By moving the calculated curves $y(X)$ and $\eta(\xi)$ across the experimental points, the differences $(X-x)$ and $(\xi-x)$ can be read off at the position of best fit. The value of k is then obtained directly from one of the relations

$$(X-x) = \log 2 - x_{½} = -\log 2 + \log k \text{ [(24), (25) AB II}^{8}\text{]} \quad (19)$$

where $x_{½}$ = value of x at $y = 1/2$, or from

$$(\xi-x) = \log k + \tfrac{1}{2} \log 3 \text{ [(59) AB II}^{8}\text{]} \quad (20)$$

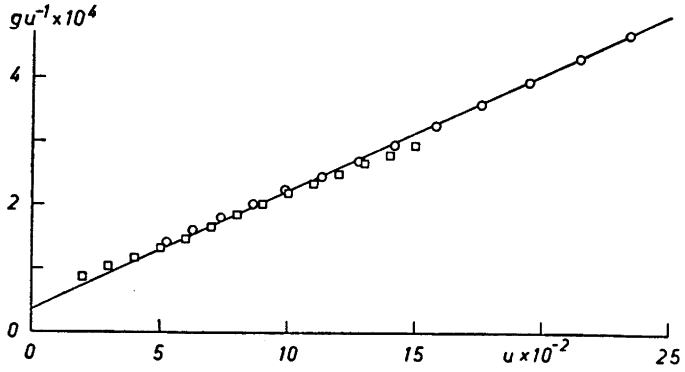

Fig. 9. gu^{-1} as a function of u. $y(x)$ data O, $\eta(x)$ data □. Straight line drawn for log $K_{43} = -6.74$, log $K_{32} = -4.43$.

The best overall fit between the curves $y(X)$ and $y(x)$ gave log $k = -3.36$. If the deviations at low values of y were ignored and the curves matched so the best fit was obtained at high values of y where effects due to complexes lower than the trimer would be small, log $k = -3.37$. The value of the equilibrium constant for the reaction

$$3\ Sn^{2+} + 4\ H_2O = Sn_3(OH)_4^{2+} + 4H^+$$

is related to k by

$$K_{43} = k^N = k^2 \tag{18a}$$

The best overall fit is obtained with log $K_{43} = -6.72$ or for the best fit at high values of y, log $K_{43} = -6.74$.

The curves $\eta(x)$ and $\eta(\xi)$ were compared in the same way. The best overall fit was obtained with log $k = -3.34$, which corresponds to log $K_{43} = -6.68$. From the best fit at high values of η, log $k = -3.37$ which again corresponds to log $K_{43} = -6.74$.

The curves $y(X)$ and $\eta(\xi)$ were also calculated for the repeated mechanisms (AB II[8]), III-a, -b, -c for different values of k_0. A satisfactory agreement could not be obtained between these curves and the experimental data $y(x)$ and $\eta(x)$ using any of these hypotheses. In particular, large deviations occurred for $y > 0.3$, as the theoretical curves all rose too sharply. This is caused by the consideration of polymers higher than the trimer in all of these hypotheses.

Comparison with these simple mechanisms has verified the information obtained from the direct analysis of the experimental data, *i. e.* there seems to be no evidence for the formation of complexes higher than the trimer $Sn_3(OH)_4^{2+}$ during the hydrolysis.

If one views both sets of data $y(x)$ and $\eta(x)$ simultaneously, the best overall fit is with log $K_{43} = -6.69 \pm 0.04$; however, significant deviations occur at both high and low values of y and η. The full lines in Figs. 2, 3, 6, and 7 are calculated for log $K_{43} = -6.69$. The best fit to both sets of data at high values of y and η is obtained with log $K_{43} = -6.74 \pm 0.04$, a value which is identical with that obtained by direct analysis of the data.

Secondary reactions

Although it appears that the main parts of the curves $y(x)$ and $\eta(x)$ are compatible with the formation of a single complex $Sn_3(OH)_4^{2+}$, there are definite deviations at low values of Z,η, and B indicating the presence of small amounts of other complexes.

In an attempt to establish the formulas of the secondary products, an approach similar to that used by Kakihana and Sillén [22] will be used.

It is first assumed that only one other complex besides $Sn_3(OH)_4^{2+}$ is formed. The equilibrium constants for the two species will be written as K_{pq} and K_{43}. Charges will be omitted in the following equations.

$$\begin{aligned} B &= [Sn^{2+}] + q[Sn_q(OH)_p] + 3\ [Sn_3(OH)_4] \\ &= b + qb^q h^{-p} K_{pq} + 3\ b^3 h^{-4} K_{43} \\ BZ &= pb^q h^{-p} K_{pq} + 4\ b^3 h^{-4} K_{43} \\ BZ\ b^{-3} h^4 &- 4K_{43} = pb^{(q-3)} h^{(4-p)} K_{pq} \end{aligned} \tag{21}$$

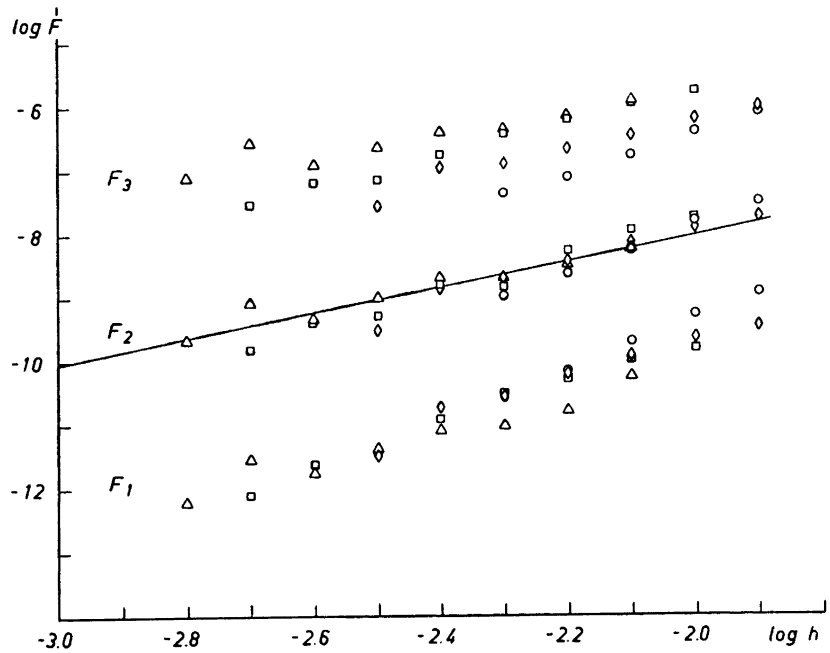

Fig. 10. log F_1, log F_2, and log F_3 (eqn. 22) *versus* log h. Straight line (log F_2) calculated using log $K_{22} = -4.30$. The experimental points are given for 40 mM$>B>$5 mM.

Let
$$(BZ\ b^{-3}h^4 - 4K_{43})b^{(3-q)} = F_q \quad (22)$$
$$\log F_q = \log pK_{pq} + (4\text{-}p) \log h \quad (23)$$

The function F_q was calculated for $q = 1$, 2, and 3, assuming $K_{43} = -6.74$, using the data from the glass and amalgam electrodes for 5 mM $\leq B \leq$ 40 mM, and plotted *versus* log h. If the deviations from the single complex curve can be attributed primarily to one other complex, one should obtain a straight line with slope $(4\text{-}p)$ and intercept log pK_{pq} when the correct value of q has been chosen.

The data are shown in Fig. 10. For $q = 2$ the data form a good approximation to a straight line with a slope of 2. The data for $q = 1$ and 3 both exhibit a greater spread. In agreement with the result of the direct analysis, the hydrolysis data can be well explained for the range 5 mM$\leq B \leq$40 mM by the formation of two polynuclear complexes $Sn_2(OH)_2^{2+}$ and $Sn_3(OH)_4^{2+}$. A value of log $K_{22} = -4.3 \pm 0.2$ is obtained from the position of the best straight line in Fig. 10.

It is still necessary to explain the deviations at the lowest value of B, 2.5 mM. The only reasonable explanation of these deviations is, besides experimental errors, the presence of mononuclear complexes. The method of Hedström [24] was used to obtain values for the mononuclear constants. Using data for both b and h, we may calculate

$$\frac{B\text{-}b}{b} = (K_{11}h^{-1} + K_{21}h^{-2} + K_{31}h^{-3} + \ldots) + 2b\ (K_{12}h^{-1} + K_{22}h^{-2} + K_{32}h^{-3} + \ldots) + 3b^2\ (K_{13}h^{-1} + K_{23}h^{-2} + \ldots) + \ldots \quad (24)$$

Plots were made of (a) $[(B—b)/b]h$ and (b) $[(B—b)/b]h^2$ *versus* b. Because the main complex is a trimer, the functions vary essentially as the square of b. This renders the extrapolation to $b = 0$, required to determine the mononuclear constant, quite inaccurate. If a single complex $SnOH^+$ is formed, the intercept of plot (a) should be K_{11}, while if $Sn(OH)_2$ (aq) is formed the intercept of (b) should be K_{21}. The data appear to be best satisfied by the formation of a mononuclear complex $SnOH^+$ with $K_{11} = 1.2 \times 10^{-4}$. The determination of K_{11} is quite inaccurate, since the extrapolation is governed almost entirely by the set of points for $B = 2.5$ where the experimental errors are greatest.

If the proper mononuclear constant has been chosen, a plot of $\left[\left(\frac{B—b}{b}\right)h—K_{11}\right]h/b$ *versus* b should give a straight line with intercept $2K_{22}$ and $3K_{43}\,h^{-2}$ as slope. Values of $K_{11} = 1.1$, 1.2, and 1.3×10^{-4} were tried, and the best family of straight lines was obtained with $K_{11} = 1.2 \times 10^{-4}$ and gave a value of $\log K_{22} = -4.5 \pm 0.15$. The value of K_{43} obtained in this way is quite inaccurate, $\log K_{43} = -6.7 \pm 0.2$.

Calculation of equilibrium constants with normalized projection maps

Since the effects due to mononuclear and dinuclear complexes are slight, it is best to refine the values of the constants using the method of projection maps.

In the present work, the quantities b, h, B, H are known. The presence of the two polynuclear species may be considered established by the previous discussion; however, there is still some question as to the composition of the mononuclear complex(es).

For this reason projection maps were constructed for the two extreme cases (a) one mononuclear complex $SnOH^+$ (b) one mononuclear complex $Sn(OH)_2$.

In the first case (a)

$$B = b + K_{11}bh^{-1} + 2K_{22}b^2h^{-2} + 3K_{43}b^3h^{-4} \quad (25)$$

$$\eta = \log\ (1 + K_{11}h^{-1} + 2K_{22}bh^{-2} + 3K_{43}b^2h^{-4}) \quad (26)$$

$$BZ = K_{11}bh^{-1} + 2K_{22}b^2h^{-2} + 4K_{43}b^3h^{-4} \quad (27)$$

It is convenient to prepare two different projection maps of the variables

$$\log B = f(\log h)_Z$$
$$\log B = f(\log h)_\eta$$

and to compare these with the calculated, normalized projection maps $\log \boldsymbol{B}\ (\log \alpha)_Z$ and $\log \boldsymbol{B}\ (\log \alpha)_\eta$. The normalized variables β and α are defined by the following equations.

$$\beta = b \cdot 10^{P_2} \qquad \boldsymbol{B} = B \cdot 10^{P_2} \quad (28)$$

$$\alpha = h^{-1}\ 10^{P_1} \quad (29)$$

where P_1 and P_2 are constants.

The two constants P_1 and P_2 may be obtained by the displacement of the curve log $\boldsymbol{B}$ (log a)$_Z$ with respect to log B (log h)$_Z$ and also by the displacement of log $\boldsymbol{B}$ (log a)$_\eta$ with respect to log B (log h)$_\eta$, since

$$P_1 = \log a - \log h$$
$$P_2 = \log \boldsymbol{B} - \log B$$

In order to obtain simple equations for calculation, the constants P_1 and P_2 are chosen so that all equilibrium constants will be eliminated from the equations. This necessitates the assumption of some relation between two of the constants. Since the data at high Z and η are well satisfied by the two constants for $Sn_2(OH)_2^{2+}$ and $Sn_3(OH)_4^{2+}$ (*cf.* Figs. 6, 7), a relation will be chosen between K_{22} and K_{43} which satisfies the values obtained by direct analysis.

$$R = K_{43}K_{22}^{-2} = 10^{2.13}$$

By the proper choice of the constants P_1 and P_2, we may make the following equations, analogous to (25)—(27), valid.

$$\boldsymbol{B} = B \cdot 10^{P_2} = (\beta + \beta\alpha + 2\beta^2\alpha^2 + 3R\beta^3\alpha^4) \quad (30)$$
$$\eta = \log (1 + \alpha + 2\beta\alpha^2 + 3R\beta^2\alpha^4) \quad (31)$$
$$\boldsymbol{B}Z = (\beta\alpha + 2\beta^2\alpha^2 + 4R\beta^3\alpha^4) \quad (32)$$

Inserting (28) and (29) into (30)—(32) and comparing with (25)—(27), gives the necessary condition that

$$\begin{aligned} \log K_{11} &= P_1 \\ \log K_{22} &= 2P_1 + P_2 \\ \log K_{43} &= 2 \log K_{22} + 2.13 \end{aligned} \quad (33)$$

The diagram log $\boldsymbol{B}$ (log a)$_\eta$ was constructed by solution of (31) for β using various values of η and a. The values of β were then substituted into (30). The diagrams log $\boldsymbol{B}$ (log a)$_Z$ were constructed by solution of eqn. (34) for β (eqn. (34) is obtained by eliminating $\boldsymbol{B}$ from (30) and (32))

$$(3Z—4)a^4R\beta^2 + 2a^2(Z—1)\beta + Z(1 + a) — a = 0 \quad (34)$$

This was done for several values of a for each Z giving β. As before, substitution of β into (30) gives $\boldsymbol{B}$.

The construction of the maps for $Sn(OH)_2$ was done in the same manner as for $SnOH^+$. The predominance of an uncharged species cannot be considered unlikely, since the predominating mononuclear complex formed by the hydrolysis of Be^{2+} is apparently [22] $Be(OH)_2$. Also in the hydrolysis of Hg(II)[25], the predominating product is $Hg(OH)_2$ (aq). In this case the equations are

$$B = b + K_{21}bh^{-2} + 2K_{22}b^2h^{-2} + 3K_{43}b^3h^{-4} \quad (35)$$
$$\eta = \log (1 + K_{21}h^{-2} + 2K_{22}bh^{-2} + 3K_{43}b^2h^{-4}) \quad (36)$$
$$BZ = 2K_{21}bh^{-2} + 2K_{22}b^2h^{-2} + 4K_{43}b^3h^{-4} \quad (37)$$

Using the same normalized variables,

$$\boldsymbol{B} = B \cdot 10^{P_2} = \beta + \beta\alpha^2 + 2\beta^2\alpha^2 + 3R\beta^3\alpha^4 \quad (38)$$
$$\eta = \log (1 + \alpha^2 + 2\beta\alpha^2 + 3R\beta^2\alpha^4) \quad (39)$$
$$BZ = 2\beta\alpha^2 + 2\beta^2\alpha^2 + 4R\beta^3\alpha^4 \quad (40)$$

and

$$\log K_{12} = 2 P_1 \qquad \log K_{22} = 2 P_1 + P_2 \qquad (41)$$
$$\log K_{43} = 2 \log K_{22} + 2.13$$

In the position of best fit for the two sets of maps calculated for $SnOH^+$,

$$P_1 = \log \alpha + \log h = -3.925 \qquad (42)$$
$$P_2 = \log B - \log B = 3.40 \pm 0.02.$$

Thus from eqns. (33)

$$\log K_{43} = -6.77 \pm 0.03$$
$$\log K_{22} = -4.4_5 \pm 0.15$$
$$\log K_{11} = -3.9_2 \pm 0.15$$

Comparing the experimental data $\log B\ (\log h)_\eta$ with the curves $\log B\ (\log \alpha)_\eta$ calculated assuming the mononuclear complex $Sn(OH)_2$ a good fit could be obtained for $P_1 = -3.23$ and $P_2 = 2.01$. The agreement between the curves $\log B\ (\log \alpha)_Z$ and the experimental data $\log B\ (\log h)_Z$ was, however, extremely bad for these values of P_1 and P_2, the deviations being far greater than the experimental error. In this case, the advantages of having the complete set of data (B b H h) are apparent, since it allows the rejection of faulty hypotheses which appear to satisfy one of the individual sets (B b h) or (B H h).

Since the projection maps allow the simultaneous determination of the polynuclear and mononuclear constants, the above values will be taken as final.

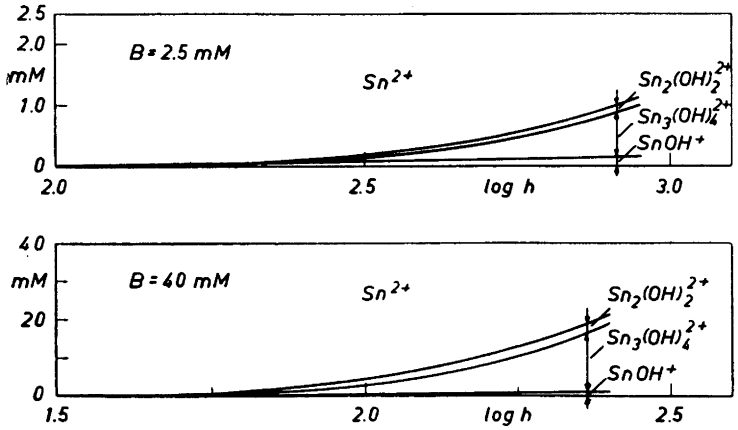

Fig. 11. Distribution of complexes for total tin(II) concentrations B = 2.5, 40 mM as a function of log h, calculated using the constants determined in this work. If a vertical line is drawn for a given value of h, the segment of the line falling in a given area, *e. g.* $Sn_2(OH)_2^{2+}$, represents the concentration of Sn(II) present as this complex in the solution at equilibrium.

The broken lines in Figs. 2 and 3 are calculated with this final set of constants. The projection maps for the final set of constants are given by the broken lines in Figs. 4 and 5.

Fig. 11 shows the distribution of the total tin(II) over the various species as a function of log h and for the total concentrations B = 2.5 mM, 40 mM.

DISCUSSION

Potentiometric measurements giving the set of data (B H b h) for 40 mM $\geq B \geq$ 2.5 mM have shown that the hydrolysis of tin(II) solutions gives the trimer $Sn_3(OH)_4^{2+}$ as the predominating product. In addition, as would be expected, small amounts of the lower complexes $Sn_2(OH)_2^{2+}$ and $SnOH^+$ also are formed. Precipitation occurs shortly above Z = 1.0, and no evidence has been found for the existence of higher polymers than the trimer.

As evidence that the trimer is the primary product, one may cite the good agreement of the values of the equilibrium constant for the reaction

$$3\ Sn^{2+} + 4\ H_2O \rightleftharpoons Sn_3(OH)_4^{2+} + 4\ H^+$$

calculated by different methods.

Direct analysis of $y(x)$ and $\eta(x)$ curves	-6.74 ± 0.04
Curve fitting of data $y(x)$, $y > 0.2$ and $\eta(x)$, $B \geq 5.0$ mM	-6.74 ± 0.04
Projection maps log B (log $h)_Z$ and log B (log $h)_\eta$	-6.77 ± 0.03

The equilibrium constant for the reaction

$$Sn^{2+} + H_2O \rightleftharpoons SnOH^+ + H^+$$

was determined primarily from the data η(log h) for the single value of B=2.5 mM. Unfortunately, K_{11} could not be obtained from data at concentrations lower than 2.5 mM as Z, h, and η could not be measured with sufficient accuracy.

Since the data can be explained by the following equilibria

$$Sn^{2+} + H_2O \rightleftharpoons SnOH^+ + H^+, \quad \log K_{11} = -3.92 \pm 0.15$$
$$2Sn^{2+} + 2H_2O \rightleftharpoons Sn_2(OH)_2^{2+} + 2H^+, \quad \log K_{22} = -4.45 \pm 0.15$$
$$3Sn^{2+} + 4H_2O \rightleftharpoons Sn_3(OH)_4^{2+} + 4H^+, \quad \log K_{43} = -6.77 \pm 0.03$$

it would perhaps be suitable at this time to critically examine the earlier work on the hydrolysis of tin(II) solutions.

As was mentioned earlier, the preparation and handling of solutions of tin(II) presents a rather serious problem, because of the ease with which these solutions become contaminated by small amounts of the much stronger aquo-acid Sn(IV). Milda Prytz, working in N. Bjerrum's laboratory, has the reputation of having been a very careful worker. In her work on tin(II), great care was taken to avoid the oxidation of tin(II), and it is therefore of interest to recalculate these data assuming $Sn_3(OH)_4^{2+}$ to be the hydrolysis product. Because of the nature of the experiments, the values obtained can be considered only roughly approximate. The data, recalculated to give K_{43}, may be summarized as follows.

Mol. conc. $NaClO_4$	B mM	Z	$-\log h$	$\log K_{43}$
0	54.5	0.26	1.85	−5.9
0	43.6	0.29	1.89	−5.7
0	5.45	0.44	2.62	−6.4
0	4.36	0.47	2.68	−6.4
0.5	54.5	0.23	1.91	−6.2

It is seen that the value of K_{43} for the two lowest concentrations of tin(II) and the measurement in 0.5 M $NaClO_4$ agree fairly well with the value calculated above. In this work, the small number of data and their limited accuracy made it impossible to choose the correct reaction.

Gorman [3], also working with perchlorate solutions, obtained a value of $\log K_{11} = -1.70$, corrected to infinite dilution. These data indicate that tin(II) is a much stronger aquo-acid than the work of Prytz does, and if recalculated to give K_{43}, give a constant which is too large by a factor of about 10^2. In this work, the wrong hydrolysis reaction was chosen for the calculations, and a large part of the effect measured was probably caused by tin(IV).

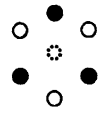
The experiments of Garrett and Heiks [4] were also performed quite carefully to prevent oxidation of tin(II); however, the value of the constant for the reaction

$$SnO(s) + 2H^+ \rightleftharpoons Sn^{2+} + H_2O, \quad K_s = [Sn^{2+}]\,[H^+]^{-2}$$

given in this work is actually the sum of a series of constants $K_s + 2K_s^2K_{22} + 3\,K_s^3K_{43}$, since solubility measurements cannot distinguish between species with the same charge. The hydrolysis constant K_{11} for the monomeric species cannot be obtained with any accuracy when the concentration of the species is very much lower than that of ions with higher charges, as occurs in this case.

In the work of Vanderzee and Rhodes [5], the value of K_{11} was estimated from a term correcting the deviations in the tin(II) halide complexity constants at different hydrogen ion concentrations. Since the effect was quite small, it would be greatly influenced by traces of tin(IV), and the values cannot be considered reliable.

The relatively large value of the constant K_{43} determined in this work and the fact that the data give no indication that species with more than three atoms are formed in any significant concentration makes it unlikely that the complex $Sn_3(OH)_4^{2+}$ has an open chain structure. A ring structure would be more plausible, *e. g.*



● tin atoms
◌ oxygen atoms below plane of paper
O oxygen atoms above plane of paper

The complex may also contain fewer water molecules such as $Sn_3O(OH)_2^{2+}$, for the equilibrium measurements give no information about the number of solvent molecules bound in the complex. Since equilibrium measurements can give no proof of a structure and there are no crystallographic data available for basic salts of tin(II), no definite conclusions can be drawn.

It may be noted here that a large number of the hydrolysis products of cations may be written in the form $Me[(OH)_2Me]_n$, *i. e.* the "core + links" form with $t = 2$. Among others, Fe(III)[11,19] Cu(II)[26], VO^{2+}[27], Sc^{3+}[28,29], In(III)[15], UO_2^{2+}[21], and Sn(II) appear to exhibit this behavior. When the cation is divalent as in the case of tin(II), the link is uncharged, and the ratio of hydroxide groups to metal ions is the same as in the precipitate.

The author is greatly indebted to Professor Lars Gunnar Sillén for having suggested the problem and for valuable discussions during the course of the work. I would also like to thank Drs. George Biedermann and Åke Olin for help on practical aspects of this research. This work has been made possible by a Post Doctoral Fellowship granted to the author by the *United States National Science Foundation*. It forms part of a program supported by the *Swedish Natural Science Research Council*.

Charakterisierung des Substitutionstyps der Tetracen-Derivative durch ihre Infrarot-Spektren

ARNLJOT NÆRLAND

Forsvarets Forskningsinstitutt, Kjeller pr. Lillestrøm, Norwegen

Bei den einfachen Aromaten von Typ des Benzols bestehen Beziehungen zwischen Frequenz der γ-Schwingung ("out of plane wagging") und Zahl und Stellung der Substituenten, die die Ermittlung des Substitutionstyps von Benzolderivaten erlauben. Es wird in dieser Arbeit bestätigt, dass bei den Derivaten des Tetracens mit vier linear anellierten Benzolringen die gleichen Beziehungen gültig sind.

In den Infrarot-Spektren verschiedener substituierter Benzole treten im Bereich zwischen 11 und 15 μ sehr intensive Banden auf, die für den Substitutionstyp charakteristisch sind. Die intensivsten Banden dieses Gebietes sind Normalschwingungen zuzuordnen, bei welchen die am Benzolring stehenden Wasserstoffatome oder die Kohlenstoffatome senkrecht zur Ringebene schwingen [1]. Bei diesen Deformationsschwingungen von Wasserstoffatomen schwingen alle oder fast alle in Phase [2]. Deformationsschwingungen dieser Art nennt man im deutschen Schriftum »γ-Schwingungen».

Wenn in einem Molekül mehrere Benzolringe von verschiedenen Substitutionstypen durch eine Bindung verknüpft sind, treten im IR-Spektrum die charakteristischen γ-Schwingungsbanden unabhängig von einander auf [3]. Unübersichtlicher liegen die Verhältnisse bei Molekülen, in denen Benzolringe von verschiedenem Substitutionstyp anelliert sind. So treten nach eigenen Untersuchungen die γ-Schwingungen der Naphthalinderivate, wahrscheinlich wegen Zusammenkuppelung der zwei gleichen Benzolringe, nicht in demselben Bereich auf wie bei Benzol. Bei den höheren linear und angular anellierten kondensierten Aromaten scheinen dieselben Gesetzmässigkeiten wie beim Benzol zu gelten. Systematische Untersuchungen, welche dieses bestätigen, sind bei Anthracenen [4], 1,2-Benzanthracenen,[5] und 1,2-*Cyclo*pentenophenanthren durchgeführt worden.[6]

Es wird in dieser Arbeit eine ähnliche Untersuchung für Tetracen-Derivate unternommen. Untersucht wurden Tetracen selbst, acht mono- und di-substituierte und neun tetrasubstituierte Verbindungen. Die Verbindungen wurden im festen Zustand (gepresst in Kaliumbromid) gemessen und, wenn löslich,

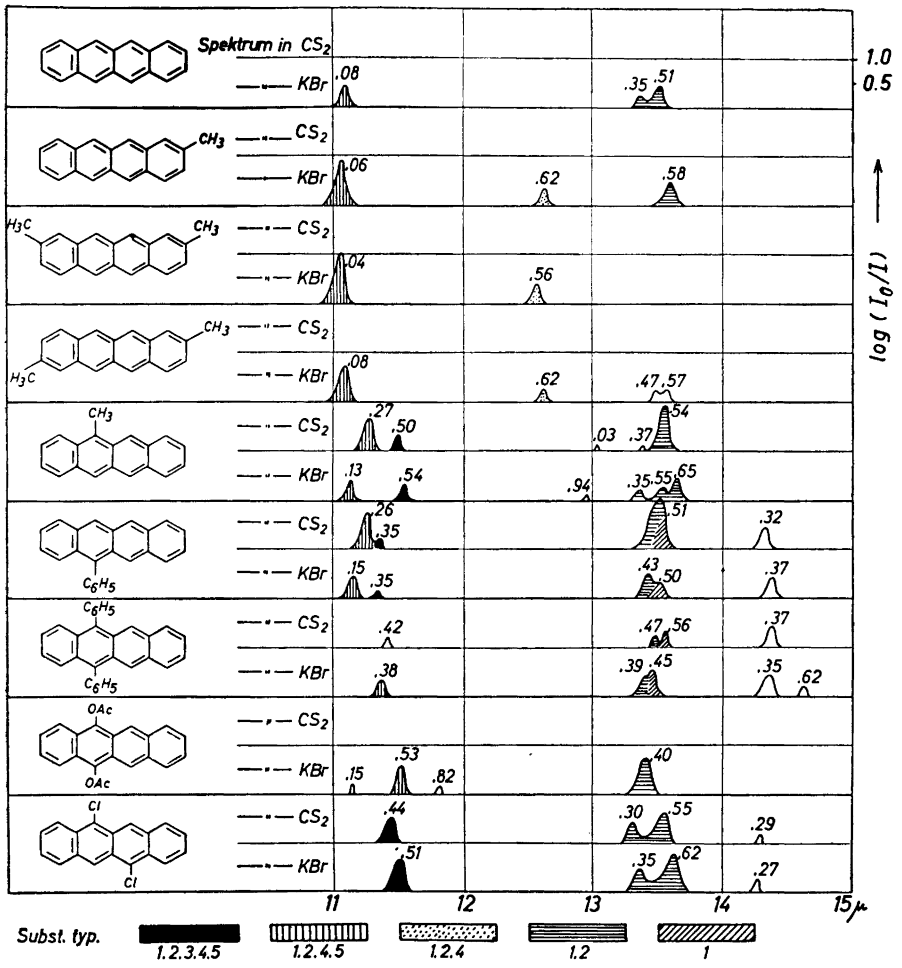

Abb. 1. γ-Schwingungsbanden für Tetracen, sowie mono- und disubstituierte Derivate.

auch in CS_2-Lösung. Die Spektren wurden mit dem Perkin Elmer Modell 21 Infrarot Spectrophotometer aufgenommen. Die γ-Schwingungsbanden für Tetracen, sowie mono- und disubstituierte Tetracene sind in Abb. 1 und für die tetrasubstituierten Tetracene in Abb. 2 angegeben.

Beim Tetracen selbst und Derivaten mit einem Substituenten in den entständigen Ringen liegt die Bande für den 1,2,4,5-Substitutionstyp bei 11,1 μ (Abb. 1, senkrecht schraffiert). Wird der mittelständige Ring substituiert, verschiebt sich die Bande nach rot bis 11,4 μ für Diphenyltetracen und 11,5 μ für Tetracenhydrochinon.

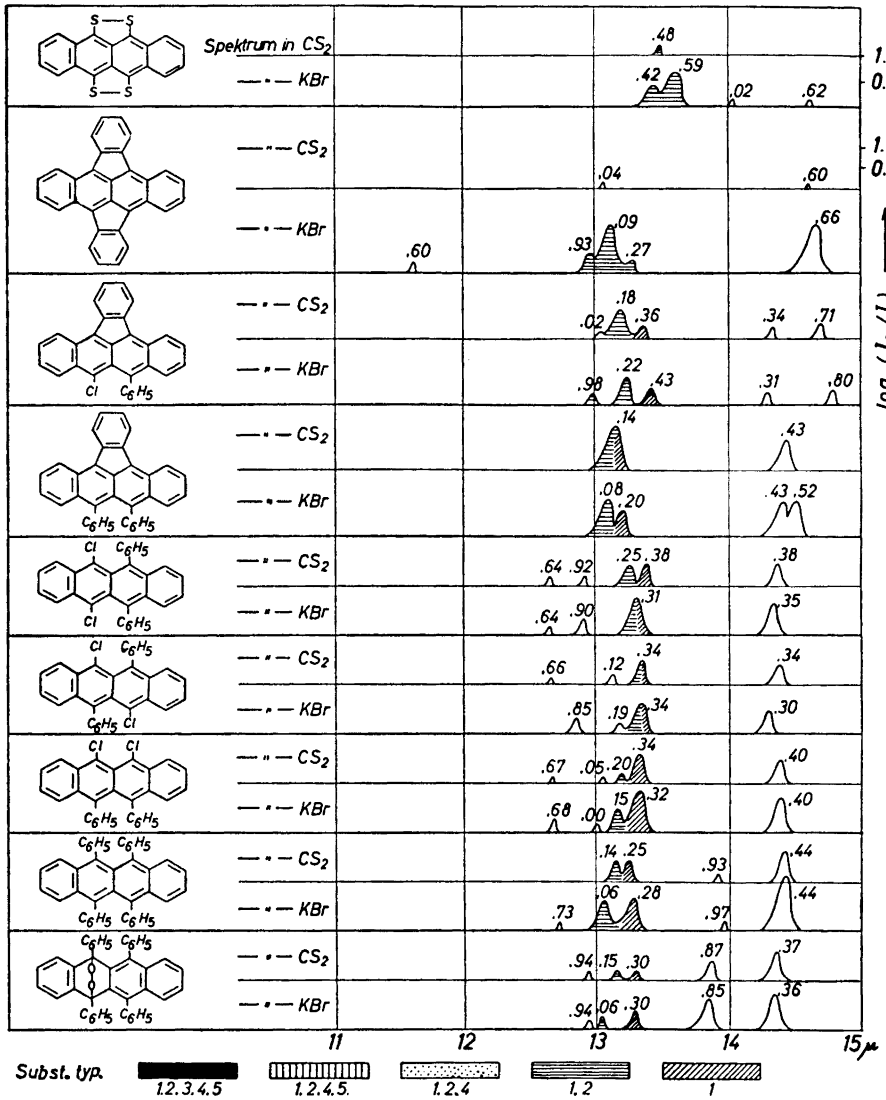

Abb. 2. γ-Schwingungsbanden für tetrasubstituierte Tetracen-Derivate.

Die Bande für die *ortho*-Disubstitution (1,2-Substitutionstyp) liegt in der Gegend zwischen 13,4 und 13,6 μ (Abb. 1, horizontal schraffiert). Sind die beiden mittelständigen Ringe substituiert, verschiebt sich, mit Ausnahme von Tetracentetrasulfid, die Bande nach blau (Abb. 2). So liegt bei Diphenylentetracen eine starke Bande bei 13,1 μ, die von dem *ortho*-Substitutionstyp herrührt. Bei den Verbindungen, in welchen die eine Phenylengruppe durch

Tabelle 1. Lage der γ-Schwingungen bei den Derivaten des Tetracens.

Substitutionstyp		Zahl der Verbind.	*Bereich der γ-Schwingung*	
			Wellenlänge μ	Wellenzahl cm^{-1}
1,2,3,4,5	Lsg.	3	11,35–11,50	881–870
	fest	3	11,35–11,54	881–866
1,2,4,5	Lsg.	3	11,26–11,42	888–876
	fest	8	11,06–11,53	904–867
1,2,4	Lsg.		–	–
	fest	3	12,56–12,62	796–792
1,2	Lsg.	13	13,10–13,55	763–738
	fest	16	13,06–13,65	766–733

Chlor und Phenyl oder durch zwei Phenylgruppen ersetzt sind, kommt, ausser der Bande bei 13,1 μ, längerwellig eine andere Bande vor, die von dem Benzol-monosubstitutionstyp herrührt. Dazu kommt bei allen Phenylsubstituenten eine γ-CC Bande bei 14,4 μ. Bei den drei Dichlor-diphenyl-tetracenen, Rubren und Rubren-photooxyd ist die Wahl zwischen der Bande für die *ortho*-Disubstitution und die Monosubstitution schwieriger zu machen. Beim Vergleich mit Phenylentetracen wird die kurzwelligere Bande dem *ortho*-Disubstitutionstyp zugeordnet.

Die Bande des Pentasubstituierten 5,11-Dichlortetracens liegt bei 11,5 μ (in Abb. 1, schwarz ausgezogen). Bei dem Methyltetracen und dem Phenyltetracen kommt dazu kurzwelliger eine Bande, die von dem 1,2,4,5-Tetrasubstitutionstyp herrühren muss.

Bei den Verbindungen von 1,2,4-Trisubstitutionstyp liegt die Bande ziemlich konstant bei 12,6 μ (in Abb. 1, punktiert).

Wenn man die Spektren in festen Zustand und in CS_2-Lösung vergleicht, sieht man, dass die Banden in festem Zustand im allgemeinen stärker aufgespaltet sind.

Die Bereiche der γ-Schwingungen in Lösung und im festen Zustand sind in Tabelle 1 zusammengestellt. Die Bereiche der γ-Schwingungen der Tetracen-Derivate stimmen mit denen der anderen kondensierten Aromaten gut überein [4].

Die Spektren von Tetracen-5,12-chinon und Tetracen-5,11-chinon wurden ebenfalls aufgenommen. Die bei den Kohlenwasserstoffen gefundene Zuordnung der γ-Schwingungsbanden konnten aber für diese Verbindungen nicht bestätigt werden.

Zum Dank verpflichtet bin ich den Herren Prof. Cook, Glasgow, Dr. E. A. Coulson, Teddington, Prof. Charles Dufraisse, Paris, und Prof. Louis F. Fieser, Cambridge (Mass.) für die Überlassung von Proben. Die übrigen untersuchten Verbindungen wurden im

hiesigen Laboratorium dargestellt. Die Substanzen wurden, sofern sie nicht analysenrein vorlagen, vor Aufnahme des Spektrums durch Chromatographie an Aluminiumoxyd oder durch Umkristallisation gereinigt.

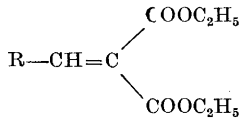
The Addition of Grignard Reagents to Alkylidenemalonic Esters

GUST.-AD. HOLMBERG

Institutet for organisk kemi, Åbo Akademi, Åbo, Finland

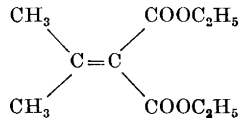
Some aliphatic and aromatic Grignard reagents were allowed to react with ethylidenemalonic and *iso*butylidenemalonic esters. In all cases the corresponding *sec.*-alkylmalonic esters were isolated. The main reaction thus seems to be 1,4-addition to the conjugated system.

For a planned investigation it was necessary to know the way in which ethylidenemalonic ester (I a) and *iso*butylidenemalonic ester (I b) react with Grignard reagents. The literature does not give any information regarding these reactions. However, 1,4-addition has previously been observed in reactions between different Grignard compounds and *iso*propylidenemalonic ester (II).[1,2]



R = (a) CH_3
(b) $CH(CH_3)_2$

I



II

As the second methyl group at the β-carbon atom in this ester can hardly alter the course of the reaction with Grignard reagents it was expected that 1,4-addition would also occur with ethylidenemalonic and *iso*butylidenemalonic esters.

This prediction was confirmed when the esters were allowed to react with some aliphatic and aromatic Grignard reagents. The reaction products, *sec.*-alkylmalonic esters, were characterized by conversion into the corresponding barbituric acids. If the latter were not previously known compounds, the malonic esters were also saponified and the corresponding malonic acids iso-

lated. These were then decarboxylated to the corresponding monocarboxylic acids. Both the malonic acids and the monocarboxylic acids were converted into their *p*-nitrobenzyl esters for identification.

The results are collected in Tables 1 and 2.

EXPERIMENTAL

The reactions between the Grignard reagents and the alkylidenemalonic esters were performed in a 250-ml flask fitted with a reflux condenser, a dropping funnel, and a stirrer with precision ground glass bearing. The upper ends of the condenser and the dropping

funnel were fitted with calcium chloride tubes. A Grignard reagent was prepared from 0.15 mole of an alkyl or aryl halide, 0.15 mole (3.60 g) of magnesium turnings, and 70 ml of dry ether. After the flask containing the reagent had been cooled in cold water, 0.10 mole of alkylidenemalonic ester was gradually added. After the addition, the stirring was continued for 20 min. The solution was then poured into a mixture consisting of 70 ml of conc. hydrochloric acid, 200 ml of water and about 100 g of ice. After shaking, the organic phase was washed with water and with a dilute potassium carbonate solution. The acid water solution was extracted once with ether, and the ether layer was also washed with water and potassium carbonate before it was combined with the main portion. After drying with anhydrous sodium sulphate, the ether was evaporated and the residue distilled under reduced pressure. The yields and the boiling points are collected in Table 1.

The corresponding barbituric acids were prepared in the following way. A sodium ethoxide solution was prepared from sodium (0.55 g) and absolute ethanol (30 ml). Urea (1.44 g) and malonic ester (0.02 mole) were added. The mixture was boiled for six hours on a boiling water bath. If a precipitate had formed during this time, it was filtered, washed with a small quantity of absolute ethanol, and dissolved in water. The barbituric

acid was then precipitated by adding hydrochloric acid. If a precipitate had not formed in the barbituric acid condensation, the alcohol was distilled off under reduced pressure, the residue treated with water and ether, and the barbituric acid in the water phase precipitated by adding hydrochloric acid. The filtered acids were recrystallized from ethanol or aqueous ethanol. The melting points are collected in Table 2 and analytical data for the new barbituric acids in Table 3.

The new malonic esters were converted into the corresponding acids in the following way. The ester (5 g) was boiled for 5 h with a solution of potassium hydroxide (5 g) in water (5 ml) and ethanol (50 ml). In some cases a precipitate of the corresponding potassium salt formed during this time or when the mixture was allowed to cool. The salt was filtered and dissolved in water. The corresponding malonic acid which precipitated on adding hydrochloric acid was filtered. A smaller amount of the same compound could be extracted from the filtrate with ether. A less pure sample was also obtained when the alcoholic filtrate was evaporated, the residue treated with water and ether, and the aqueous phase acidified with hydrochloric acid.

If a precipitate of potassium salt had not formed during the saponification, the alcohol was distilled off and the residue treated with water and ether. The malonic acid was then isolated from the aqueous phase as above.

When 1,2-dimethylpropylmalonic ester (prepared from methylmagnesium bromide and *iso*butylidenemalonic ester) was saponified, no precipitate was formed on adding hydrochloric acid to the aqueous solution. The solution was then extracted three times with ether. After drying and evaporation of the ether, the malonic acid was crystallized by treatment with ligroin and recrystallized from a mixture of benzene and ligroin.

The malonic acids were decarboxylated by heating in a oil bath at 180° until evolution of carbon dioxide ceased. On treatment with ligroin the monocarboxylic acids crystallized. The latter were purified by recrystallization from the same solvent. The yields based on the decrease in weight during the decarboxylation were 97—99 %.

The melting points of the acids are collected in Table 2 and the analytical data for the new compounds in Table 4.

The *p*-nitrobenzyl esters were prepared according to Reid [3].

Mean Amplitudes of Vibration for the C—H Stretching

S. J. CYVIN

Institutt for Teoretisk Kjemi, Norges Tekniske Høgskole, Trondheim, Norway

Approximate formulae for mean square amplitudes of vibration for the C—H stretching are evaluated. Characteristic numerical values are tabulated.

Calculations of mean amplitudes of vibration from spectroscopic data have proved to be of great interest in molecular structure studies [1]. In the present work the C—H bond distances are studied, and explicit formulae for the mean square amplitudes are given.

When small harmonic vibrations are assumed, the formula to be used is [2]

$$u^2 = \langle r^2 \rangle_{\mathrm{Av}} = \sum_i (hC_i^2/4\pi)\lambda_i^{-\frac{1}{2}} \qquad (1)$$

where $\langle\rangle_{\mathrm{Av}}$ denotes the time average, $\lambda_i = 4\pi^2\nu_i^2$, ν_i being a fundamental frequency, h is Planck's constant, and C_i are the coefficients in

$$r = \sum_i C_i Q_i \qquad (2)$$

where Q_i is a normal coordinate, and r denotes the deviations from the equilibrium C—H distance. The dependence on temperature could be omitted in this case, because the C—H stretching frequencies are comparatively high. The coefficients in eqn. (2) can be computed by means of a normal coordinate analysis. Wilson's GF matrix method [3,4] is very useful for this purpose.

As pointed out by Wilson [4], it is a good approximation to separate the extreme high C—H stretching frequencies in a molecule from the remaining fundamentals. This is very useful in the problem of mean amplitudes of vibration, as explicit formulae for u can be evaluated by applying the method. As a first example, the allene molecule shall be considered, and the formula is going to be worked out in details in the next section.

THE ALLENE MOLECULE

The allene molecule model is of symmetry V_d. If the four C—H distances are taken as a reducible representation of the group, the symmetric structure

$$\Gamma = A_1 + B_2 + E \tag{3}$$

is obtained. Following Wilson's method [3,4], the three symmetry coordinates

$$\begin{aligned} s^{(A_1)} &= (1/2)\ (r_1 + r_2 + r_3 + r_4) \\ s^{(B_2)} &= (1/2)\ (r_1 + r_2 - r_3 - r_4) \\ s^{(E)} &= 2^{-\frac{1}{2}}(r_1 - r_2) \end{aligned} \tag{4}$$

Table 1. Characteristic expressions by calculating mean amplitudes for C—H stretching in certain molecules.

		A_2''	$K_2 = (k + 2k') - (k'' + 2k''')$	$\mu_H + \mu_C\,(1 + 2\cos 2\alpha)$	2 954 [5]
		E'	$K_3 = (k - k') + (k'' - k''')$	$\mu_H + 2\mu_C\sin^2\alpha$	2 994.3 [5]
		E''	$K_4 = (k - k') - (k'' - k''')$	$\mu_H + 2\mu_C\sin^2\alpha$	2 963 [5]
Ethane (staggered)	D_{3d}	A_{1g}	$K_1 = (k + 2k') + (k'' + 2k''')$	$\mu_H + \mu_C\,(1 + 2\cos 2\alpha)$	2 899.2 [5]
		A_{2u}	$K_2 = (k + 2k') - (k'' + 2k''')$	$\mu_H + \mu_C\,(1 + 2\cos 2\alpha)$	2 954 [5]
		E_g	$K_3 = (k - k') + (k'' - k''')$	$\mu_H + 2\mu_C\sin^2\alpha$	2 963 [5]
		E_u	$K_4 = (k - k') - (k'' - k''')$	$\mu_H + 2\mu_C\sin^2\alpha$	2 994.3 [5]
Methane	T_d	A_1	$k + 3k'$	μ_H	2 914.2 [5]
		F_1	$k - k'$	$\mu_H + (4/3)\mu_C$	3 020.3 [5]

are formed. r_1 and r_2 are the deviations from equilibrium C—H distances at the atom C_1, r_3 and r_4 at the atom C_3. The corresponding elements on the principal diagonal of the symmetrized F and G matrix are shown in Table 1. k is the principal force constant for C—H stretching, k' is the interaction force constant between the C—H stretchings at the same carbon atom, and k'' at different carbon atoms. μ_H and μ_C are the inverse masses of H and C atoms, and the equilibriun H—C—H angle is denoted by 2α. From the transformation (4) we obtain

$$r_1 = (1/2)s^{(A_1)} + (1/2)s^{(B_2)} + 2^{-\frac{1}{2}}s^{(E)} \tag{5}$$

Wilson's approximation of separating the extreme high C—H stretching frequencies is equivalent to assuming the symmetry coordinates in eqn. (5) to be proportional with the normal coordinates,

$$\begin{aligned} s^{(A_1)} &= (\mu_H + 2\,\mu_C \cos^2\alpha)^{\frac{1}{2}}\, Q^{(A_1)} \\ s^{(B_2)} &= (\mu_H + 2\,\mu_C \cos^2\alpha)^{\frac{1}{2}}\, Q^{(B_2)} \\ s^{(E)} &= (\mu_H + 2\,\mu_C \sin^2\alpha)^{\frac{1}{2}}\, Q^{(E)} \end{aligned} \tag{6}$$

Then the coefficients C of eqn. (2) can easily be computed, their squares being

$$\begin{aligned} A_1\text{:}\ C^2 &= (1/4)\ (\mu_H + 2\,\mu_C \cos^2\alpha) \\ B_2\text{:}\ C^2 &= (1/4)\ (\mu_H + 2\,\mu_C \cos^2\alpha) \\ E\text{:}\ C^2 &= (1/2)\ (\mu_H + 2\,\mu_C \sin^2\alpha) \end{aligned} \tag{7}$$

Hence eqn. (1) gives the explicit formula for the mean square amplitude of C—H as

$$u^2 = (h/16\pi)\,(K_1^{-\frac{1}{2}} + K_2^{-\frac{1}{2}})\,(\mu_H + \mu_C \cos^2\alpha)^{\frac{1}{2}} + (h/8\pi)\,K_3^{-\frac{1}{2}}\,(\mu_H + 2\mu_C \sin^2\alpha)^{\frac{1}{2}} \tag{8}$$

where the force constants from Table 1 have been introduced according to

$$\begin{aligned} A_1\text{:}\ \lambda_1 &= K_1(\mu_H + 2\mu_C \cos^2\alpha) \\ B_2\text{:}\ \lambda_2 &= K_2(\mu_H + 2\mu_C \cos^2\alpha) \\ E\text{:}\ \lambda_3 &= K_3(\mu_H + 2\mu_C \sin^2\alpha) \end{aligned} \tag{9}$$

The formula (8) is based on following approximations: 1) Small harmonic vibrations are assumed, 2) the temperature dependence is omitted, 3) the high C—H stretching frequencies are separated from the remaining fundamentals. This will be referred to as the first approximation.

FURTHER APPLICATIONS

The method has been applied to several representative molecules containing the C—H bond and are listed in Table 1. The principal diagonal elements of the symmetrized F and G matrices are included in the table, as well as the experimental fundamentals. Troughout the table, the principal force constant for C—H stretching is denoted by k and the interaction constants for pairs of adjacent C—H bonds by k'. The remaining force constants are

Methane	0.07781	0.07781	0.07780	0.07781

GENERAL FORMULAE

As a second approximation for u^2, the interactions between bonds attached to different C atoms may be omitted. By doing this, general formulae are obtained for the four types of C—H distances, depending on the number of H atoms attached directly to the C atom. The formulae are listed in Table 3.

The third approximation for u^2 is obtained by putting the interaction constant k' equal to zero in the second approximation formula. Simultaneously, the numerical values 120° and 109°28' have been inserted for the H—C—H angle in the methylene and methyl groups, respectively.

In the third approximation, only the principal C—H stretching force constant, k, is included. By making the corresponding approximation in the G matrix, the proper element on the principal diagonal to be used is $\mu_H + \mu_C$. Hence a general formula for all types of C—H distances is obtained, which is listed in Table 3 as the fourth approximation. This last formula is naturally identical with the second and third approximation for C—H of the ≡CH type.

NUMERICAL CALCULATIONS

All the approximate formulae have been applied for numerical calculations of u values for the molecules here considered. The calculations were based on individual force constants, as obtained from the experimental fundamentals (see Table 1). The results are summarized in Table 4.

Table 5. Characteristic values of mean amplitudes for C—H stretching.

k (10^5dyn cm^{-1})	4.4	4.6	4.8	5.0	5.2
u (Å)	0.0800	0.0791	0.0783	0.0775	0.0767
k (10^5dyn cm^{-1})	5.4	5.6	5.8	6.0	6.2
u (Å)	0.0760	0.0753	0.0746	0.0740	0.0734

CONCLUSION

It may be concluded that the introduced approximations are very good. It is seen from Table 4 that they do not affect the results appreciably. Hence if the C—H stretching force constant is assumed to have a characteristic value in several different molecules, it is possible to give a characteristic value for the root mean square C—H amplitude as well. In Table 5 the proper u values are enumerated in the actual region of force constant values.

Investigation on the Oxidation Mechanism of Titanium

P. KOFSTAD, K. HAUFFE* and H. KJÖLLESDAL

Central Institute for Industrial Research, Blindern, Oslo, Norway

Oxidation of titanium has been studied in the temperature region 300—1 000°C. Four different rate laws have been found in the indicated temperature intervals: logarithmic (< 300°C), cubic (300—600°C), parabolic (600—850°C), and parabolic + linear (> 850°C) rate laws. The indicated temperature regions are only approximate as the rate laws observed are also dependent upon the duration of the oxidation and the amount of oxygen present in the metal before the start of the oxidation. Thus the initial rate laws observed at any temperature eventually changes into the rate law corresponding to the higher temperature interval. For example at 300°C the oxidation follows a logarithmic rate law for the initial 300 min whereupon it gradually changes into a cubic rate law.

The following oxidation mechanisms are proposed: The logarithmic rate law is interpreted as an oxide film formation perhaps governed by a Mott-type mechanism, the cubic rate law is associated with a diffusion of oxygen into the titanium metal, the parabolic rate law is interpreted in terms of the usual Wagner high-temperature mechanism and with the assumption that a diffusion of oxygen ions through the TiO_2 scale is the rate determining step (< 1 000°C), and the linear rate law results from cracks in the oxide scale due to stresses in the oxide and a phase boundary reaction being the rate-determining reaction.

The reaction of oxygen with titanium at different temperatures has been studied by numerous investigators [1–23]. A comparison of the different reports and publications, however, shows large disagreements and discrepancies which include both rate laws and rates of oxidation.

The published data indicate that the processes involved in the reaction are rather complex, and no simple interpretation can be given to the diverse phenomena observed at different temperatures and oxygen pressures. This state of affairs is partly due to the high oxygen solubility in titanium and the possibility of formation of different oxides (TiO, Ti_2O_3, Ti_3O_5, and TiO_2) in the oxide scale. A probable reason for the disagreements between different

---

* Present address: Farbwerke Hoechst, Frankfurt am Main, Germany.

published data is the presence of gaseous impurities (O_2, H_2, N_2) and C in titanium and different pretreatments of titanium used by different investigators. It is well known that titanium dissolves large amounts of oxygen without forming an oxide scale at high temperatures (> 800°C) and low pressures ($p_{O_2} < 10^{-3}$ mm Hg), and dissolved oxygen introduced during pretreatment such as annealing between rolling runs, etc., may change the characteristics of the oxidation reactions.

The mechanism of oxidation of titanium was investigated by studying the rate laws of oxidation and rate of oxidation as a function of temperature and oxygen pressure. As the knowledge of the structure and degree of order of the oxide scale is of primary importance in consideration of oxidation mechanisms, the oxide scale was studied by means of X-ray diffraction, electron microscopy, and metallographic techniques. Furthermore, because of the high solubility of oxygen in titanium and as the kinetics of oxygen penetration into the metal may be of importance for the rate laws observed, the oxygen penetration into titanium during the oxidation was studied by metallographic and microhardness techniques.

EXPERIMENTAL METHODS

Both high-purity van Arkel titanium and commercial Kroll titanium were used in the studies. Spectrographic analysis gave the following results:

	Impurities present		
Type of Ti	0.1 %	0.01 %	traces, 0.001 %
Van Arkel Ti		Fe, Mn, Al, Sn, Mg, Cr	Cu
Kroll Ti	Mg, Fe	Si	Ca, Cu, Fe, Sn, Mn

No analysis was made of gaseous impurities (O_2, N_2, H_2) and C. However, hardness measurements on the titanium gave fair indication as to the impurity level. The hardness, HV_{10}, was measured to 90—100 for the van Arkel titanium and 120—130 for the Kroll titanium annealed in high vacuum at 800°C for 30 min. These results indicate that only small amounts of impurities were present in the titanium.

The titanium was melted in a laboratory type argon arc furnace. The melting was performed with an auxiliary wolfram electrode. A watercooled copper crucible permitted melting of 5 different samples each weighing about 20 g. All samples were remelted.

After melting, the buttons were coldrolled to the desired thickness in a small rolling mill. For specimens of small thickness, it was necessary to anneal in high vacuum at 800°C between rolling runs. The metal sheets were cut in specimens about 3 × 1 cm². The thickness of the specimens varied between 0.05 and 0.003 cm, depending upon the testing temperature. The specimens were furthermore degreased in chloroform and acetone, polished with emerycloth and alumina and finally rinsed in distilled water.

The reaction of oxygen with titanium was measured both by a gravimetric and a volumetric method. The gravimetric method was employed at high temperatures (700—1 000°C), and the experimental setup consisted essentially of a quartz helix hung vertically in a tube. The test specimen was suspended in a platinum wire, and the weight gain was followed by measuring with a cathetometer the vertical displacement of a pointer on the spring. By this method the weight gain was measured with an accuracy of $\pm 5 \times 10^{-5}$ g.

The measuring unit was incorporated in a vacuum system which was made of Pyrex with the exception of the reaction tube, which was made of transparent silica. The system was connected *via* a liquid air trap to a set of oil diffusion and rotary oil pumps.

Before the start of each run, the system was evacuated. After allowing time for temperature stabilization in the furnace surrounding the reaction tube, the run was started by closing the highvacuum line and admitting oxygen to the system. During oxidation at low pressures ($<$ 1 mm Hg) oxygen was continuously pumped through the system and the pressure was regulated with a fine control needle valve.

In the temperature region 300—700°C the weight gain of titanium reacting with oxygen ranged from a few μg per cm^2 at 300°C to a few hundred μg per cm^2 at 700°C after about 5 h of oxidation. The gravimetric apparatus was not sensitive enough for this purpose, and the oxidation rate was therefore studied by measuring the volume of oxygen absorbed by the titanium specimen.

Essentially the apparatus consisted of a reaction chamber (with as small a volume as possible) connected to a large reference volume with a long uniformly graduated capillary. The absorption of oxygen was followed by observing the movement of a small, mobile drop of diethylphthalate indicator from the reference volume to the reaction chamber. In order to increase the mobility and thereby the sensitivity of the indicator drop, the capillary was treated with a water-repellent silicone compound.

With the exception of the reaction tube, which consisted of transparent silica, the apparatus was made entirely of Pyrex. The whole system was connected to an oil diffusion and a rotary oil pump.

The temperature in the furnace was regulated by a transductor regulator in combination with a platinum resistance thermometer within $\pm$ 0.1°C. The rest of the apparatus was enclosed in a chamber, its temperature being kept at 25 $\pm$ 0.1°C.

In order to have a constant temperature gradient from the furnace to the rest of the system, the part of the reaction chamber which was outside the furnace, was equipped with a water jacket, through which water was pumped from a constant temperature bath kept at 25 $\pm$ 0.1°C. A transparent silica rod was placed within the reaction chamber to reduce the volume, and the test specimens were suspended with a short platinum wire connected from a hook at the top of the reaction tube.

Before the start of the run the reaction chamber was evacuated, the furnace was lowered in position and the temperature adjusted to within $\pm$0.1°C. The run began when the highvacuum line was closed off, and the oxygen was admitted to the reaction chamber. Before measuring the movement of the indicator, the pressures in the reaction chamber and the reference volume were equalized *via* a short-cut line for 10 sec. Thus for each run there was an unrecorded period of about 20 sec. Comparison with the gravimetric method at 700—800°C gave excellent agreement.

The X-ray diffraction investigations of the oxide scales were carried out by means of a General Electric XRD-3 recording X-ray diffractometer.

The preparation of metallographic specimens of the oxidized titanium specimens proved rather difficult as the brittle oxide layer became heavily crushed and displaced during grinding and polishing. A number of methods were tried, and the mounting procedure which was finally adopted, was the following: After silver-coating by evaporation of silver *in vacuo* the specimens were heavily electroplated with copper and finally mounted in Wood's metal.

Although this procedure at last was found to be the most satisfactory for this very special type of specimens, it did in no way give the perfect results. Due to the brittle nature of the oxide scale and the outer part of the metal, a trench was usually left between the oxide and the metal.

Only transverse sections of the oxidized specimens were examined. After grinding, polishing with a finegrained diamond paste and final polishing with levigated alumina, the oxide layer was examined. The metal core was best examined after etching for approximately 30 sec. A mixture of 1 part conc. HNO_3 + 1 part $(HF)_n$ in 2 parts of glycerol was found superior to etchants without HNO_3.

The microindentation hardness testing was performed with a Reichert microhardness tester (No. 1109) used in connection with a Reichert universal camera microscope (model MeF). The indenter was a Vickers pyramid.

Variations in microhardness at a single load over transverse sections of the specimens were recorded. A comparatively low load — 17 g — was chosen in order to allow a reason-

able number of indentations to be made. All microhardness indentations were made on specimens which had finally been electropolished and etched. The orientation of the various grains had a clearly visible effect on the shape of the indentation, and sometimes also on the calculated microhardness. Thus passing from one grain into another with a different orientation sometimes resulted in a jump in the hardness curve. Mostly, this effect was not pronounced. It is felt that the reported curves represent a fair average of the microhardness at the various depths below the specimen surface.

The shape of the base of the indentations mostly was not exactly square due to orientation differences of the grains. Near the edges the indentations were mostly very elongated in a direction perpendicular to the metal sheet surface. This is a concequence of the unavoidable rounding of the edges both during the mechanical- and the electropolishing. Normally the surface of the indentation is calculated by using the square of the mean length of the two diagonals of the base of the indentation. In the case of very elongated indentations this leads to an unreasonable large surface. Thus, instead of the square of the mean length, the product of the lengths of the diagonals has been used for d^2 in th formula

$$H_m = 1\,854.4\,\frac{p}{d^2}\ \mathrm{kg/mm^2}$$

when calculating the reported microhardness values.

The hardness values close to the edges are very approximate only for said reason; in addition the brittle metal near the edges often crumbled even under the low load used.

A number of oxidized titanium specimens were studied by electron microscopy (RCA EMU 2D). All specimens were preshadowed and studied by a single stage carbon replica technique. This technique included 1) shadowing of the surface of the test specimen by vacuum evaporation of platinum under a certain angle, 2) direct vacuum evaporation of carbon on the preshadowed surface, 3) pressing the carbon side of the sample against molten polystyrene, 4) dissolving the specimen (TiO_2 layer and Ti) in a mixture of H_2SO_4 and $(HF)_n$ at about 60°C, and after 5) dissolving the polystyrene, the specimens were ready for examination in the electron microscope.

EXPERIMENTAL RESULTS

During the course of the investigations a striking feature of the oxidation of titanium compared to other metals was the difficulty in obtaining satisfactory reproducibility and regularity in the results.

In the opinion of the authors this irregularity may be traced back to different pretreatment of the samples (rolling, high-vacuum preannealing etc.). Unless the pretreatment is performed under very controlled conditions, varying amounts of impurities may be introduced causing irregular oxidation behaviour. It seems of particular importance to achieve a high vacuum ($< 10^{-5}$ mm Hg) during annealing between rolling runs and before the start of the oxidation. As will be seen from the present results, titanium oxidizes equally fast at 10^{-3} mm Hg as at 1 atm. oxygen pressure. Thus, annealing at 10^{-3} mm Hg will cause a partial oxygen saturation of the outer layer of the titanium even without formation of an oxide scale, and this again brings about a different oxidation behaviour. On the basis of microhardness tests on transverse sections of the specimens it was found necessary to anneal the samples (0.30 mm thick) for 24 h at 850°C and $p_{O_2} < 10^{-4}$ mm Hg in order to obtain specimens homogeneous with respect to dissolved oxygen.

In a discussion of the experimental results it is convenient to distinguish between high temperature oxidation (600—1 000°C) and low temperature oxidation (300—600°C).

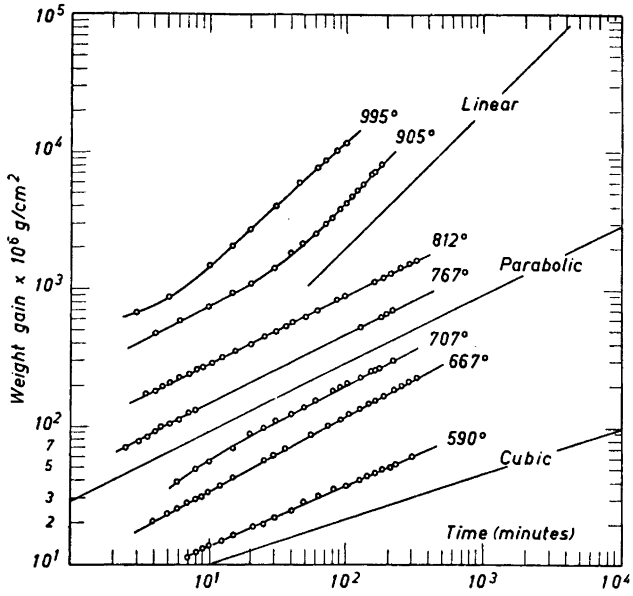

Fig. 1. Oxidation of melted and annealed (30 min at 800°C and $p_{O_2} < 10^{-4}$ mm Hg) van Arkel titanium (600—1 000°C).

High temperature studies. A large number of experiments were carried out on van Arkel titanium, Kroll titanium, and RC-55 titanium. Generally, the length of oxidation lasted for 5 h, while in a few cases the oxidation reaction was followed for 1 week.

Considering the studies as a whole, a striking feature was the irregular oxidation behaviour in the temperature region 900—1 000°C. This irregularity was often associated with sudden increases in the oxidation rates, *e.g.* changes from (approximately) parabolic to (approximately) linear rate laws.

Another feature is the dependence of the oxidation on the type and purity of titanium. The experiments show that the Rem-Cru titanium type RC-55 (containing max. 0.2 % C) was oxidized faster than the relatively pure Kroll titanium (HV_{10} = 120—130) and the van Arkel titanium (HV_{10} = 90—100).

Melted van Arkel titanium. The van Arkel titanium was annealed for 30 min at 800°C at a pressure of 10^{-4} mm Hg. In addition, all specimens were annealed for 10 min in high vacuum at the oxidation temperature, as it took about 10 min to obtain a satisfactory temperature constancy in the furnace before the start of the oxidation run.

The results on melted van Arkel titanium between 600 and 1 000°C are shown in Fig. 1. The oxidation follows a parabolic rate law between approximately 600 and 850°C, while at higher temperatures there seems to be a gradual change from this to an approximately linear one with time. It is interesting to note that the shift from a parabolic rate law region to a generally linear rate law region occurs near to the temperature where titanium changes from

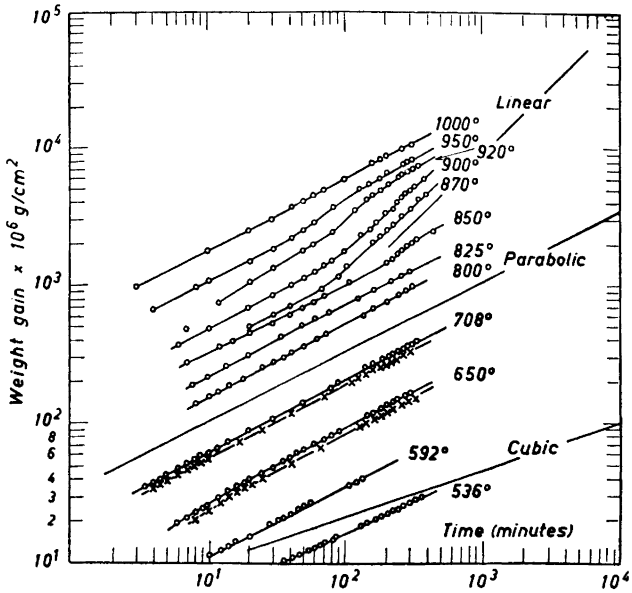

Fig. 2. Oxidation of Kroll titanium 536 and 592°C oxidized in dry air.

the α- to the β-modification. This effect is not unreasonable considering the importance of oxygen solubility in titanium metal during the oxidation reaction, and considering the higher rate of diffusion of oxygen in β- than in α-titanium.

The colour of the oxide scale after 5 h of oxidation in 1 atm. O_2 were as follows: At 1 000°C — light yellow, at 900°C — white, at 800°C — light grey, at 700°C — dark grey, and at 600°C — metallic grey.

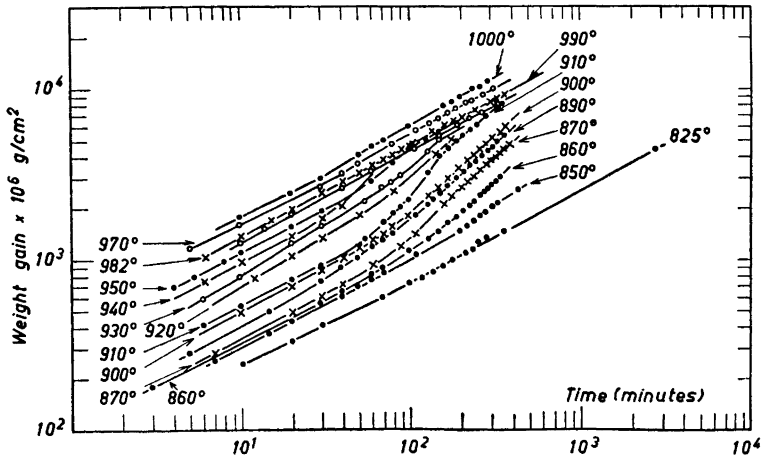

Fig. 3. A detailed study of oxidation of Kroll titanium (800—1 000°C).

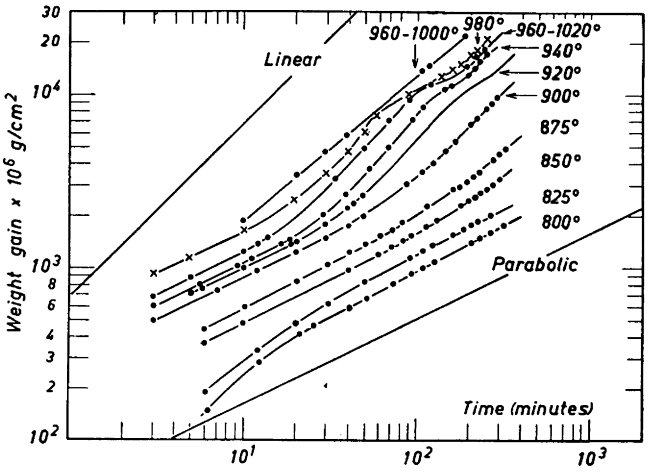

Fig. 4. Oxidation of RC-55 titanium (800—1 020°C).

Kroll titanium. The results on the oxidation of Kroll titanium (cold-rolled and annealed for 10 min in high vacuum of $< 10^{-4}$ mm Hg before the oxidation run) show the same characteristics as for melted van Arkel titanium. As seen in Figs. 2 and 3 the oxidation follows a parabolic rate law between 600 and 800°C, while there are changes from initial parabolic rate laws in the temperature region 850—950°C. It is interesting to note that while van Arkel titanium oxidizes according to an approximately linear rate law at 1 000°C, the oxidation of Kroll titanium again follows an approximately parabolic rate law at this temperature.

The colour of the oxide scales were grey blue, sometimes mottled blue grey white at temperatures above 850°C; at lower temperatures the appearance of the oxide was as for van Arkel titanium.

RC-55. For the sake of comparison it was also of interest to study the oxidation behaviour of a type of commercial titanium. It was also felt that a plate of such titanium would be rather homogeneous both as far as the impurity concentrations and structure of titanium were concerned.

The studies were carried out on RC-55 (max. 0.2 % C) samples (annealed for 10 min at $p_{O_2} = 10^{-4}$ mm Hg at the oxidation temperature) in the temperature region 800—1 000°C. The results are shown in Fig. 4. Compared to the unannealed Kroll titanium the oxidation rates are higher by 50—100 %. Furthermore, one may say that at all temperatures the oxidation initially follows a parabolic rate law which changes into an approximately linear rate law. There seems to be no definite increase in the oxidation rate between 950 and 1 000°C.

The oxidation of RC-55 gave grey oxide scales at 800°C; above 850°C the colour was yellow and mottled brown-yellow.

The effect of the partial pressure of oxygen on the rate of oxidation. Considering studies of oxidation of metals and alloys in general, the effect of the partial

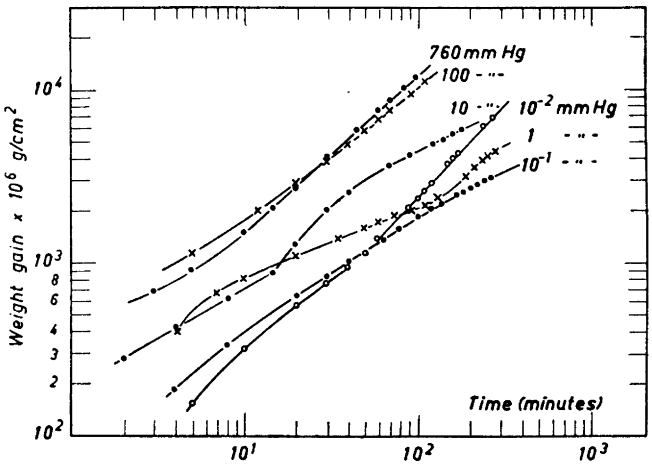

Fig. 5. The effect of oxygen pressure on the oxidation of van Arkel titanium at 1 000°C.

pressure of oxygen on the oxidation rate is of importance in elucidating the mechanism of oxidation. In the case of oxidation of titanium with formation of a compact TiO_2-scale one should on the basis of the general theory of oxidation not expect any effect of the oxygen pressure on the oxidation rate. This should, however, not hold in case of approximately linear rate laws as found for titanium above 900°C. Furthermore, it was of interest to study this effect as the competition between the oxide layer formation and oxygen solution effect probably plays an important role in the oxidation reaction. It is well known that when titanium with TiO_2 films is treated in high vacuum at high

temperatures (> 700—800°C), the oxide film dissolves in the titanium, forming a solution of oxygen in titanium. There should consequently exist a temperature dependent critical pressure below which no oxide layer is formed during the initial period of the reaction.

The effect of oxygen pressure was studied at 1 000, 900, 800, and 700°C by oxidizing annealed (30 min at 800°C at $p_{O_2} < 10^{-4}$ mm Hg) van Arkel titanium at oxygen pressures of 760, 100, 10, 1, 10^{-1}, 10^{-2}, and 10^{-3} mm Hg. The results shown in Figs. 5, 6, and 7 were somewhat unexpected, but brought forth new interesting data with regard to the basic processes of the reaction.

Generally one may say that the oxidation is oxygen pressure dependent under conditions of approximately linear rate laws, *e.g.* at 900 and 1 000°C, while the oxidation is oxygen pressure independent under conditions of parabolic rate laws, *e.g.* at 700 and 800°C. At 900 and 1 000°C it is seen that the oxidation behaviour is rather irregular at oxygen pressures below 100 mm Hg. The most interesting conclusions, however, which can be drawn from the curves, is that the oxidation rate does not decrease regularly with decreasing oxygen pressure; rather there exists a certain oxygen pressure ($\sim 10^{-1}$ mm Hg) below which the oxidation rate again increases. The reason for the dependence of the oxidation rate on the oxygen pressure at temperatures above 900°C is probably due to the competition between oxide layer formation and oxygen solution effects.

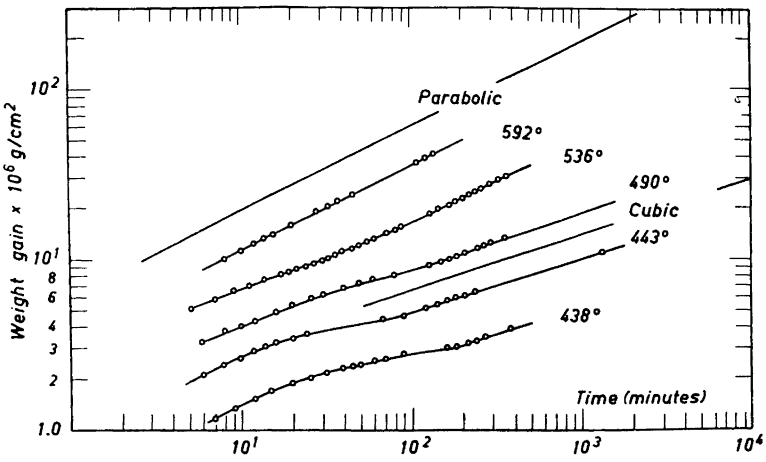

Fig. 8. Oxidation of Kroll titanium in dry air (400—600°C).

It was also interesting to note the effect of oxygen pressure on the appearance and colour of the oxide scale. At 1 000°C the colour changed from light-yellow to white in going from 760 to 0.1 mm Hg. At 10^{-2} and 10^{-3} the colour of the oxide was metallic bluegrey and grey, respectively. At 900°C the colour remained white down to 0.1 mm Hg; below this pressure the colour changed to bluegrey and grey. At 800°C the colour remained light grey in going from 760 to 0.1 mm Hg; at 10^{-2} and 10^{-3} mm Hg the colour was grey white and mottled blue grey, respectively. At 700°C the colour of the surface was dark grey in the pressure range 760 — 1 mm Hg, but the appearance became increasingly metallic with decreasing pressure. At and below 10^{-1} mm Hg the surface was mottled white dark grey.

Low temperature oxidation studies. Low temperature oxidation experiments were made in the temperature region 300—600°C. The characteristic feature of the oxidation reaction in this temperature region is that the oxidation follows non-parabolic rate laws; a logarithmic rate law was found up to about 300°C, while a cubic rate law was obeyed in the temperature region 300—600°C. There are no definite transition temperatures, but rather transition intervals where both rate laws may be found, depending upon the length of oxidation.

The studies were carried out on both cold-rolled, unannealed Kroll titanium and high vacuum annealed (30 min at 800°C) van Arkel titanium. The results are shown in Figs. 8 and 9. The general characteristics of the oxidation reaction are the same for both types of titanium. The logarithmic rate law was found below about 300°C for the length of oxidation of about 5 h, and the cubic rate law was found between 300 and 600°C, while the reaction obeyed a parabolic rate law above approximately 600°C. Furthermore, the duration of the logarithmic rate law period decreased with increasing temperature. Correspondingly the duration of the cubic rate law decreased with

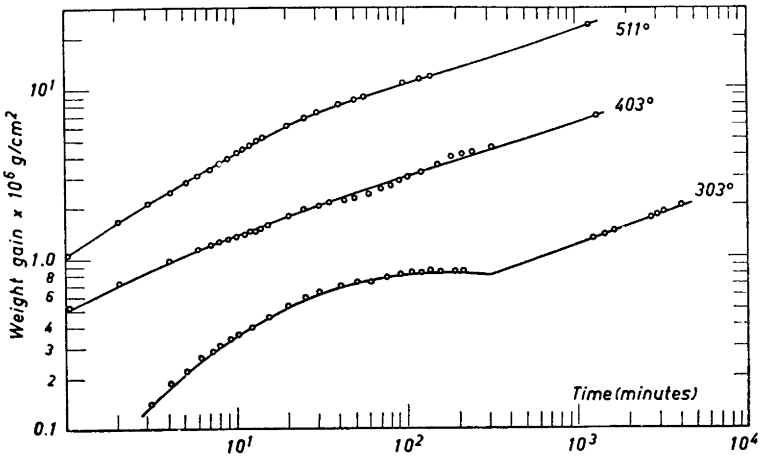

Fig. 9. Oxidation of annealed (30 min at 800°C and $p_{O_2} < 10^{-4}$ mm Hg) van Arkel titanium in dry air (300—500°C.)

increasing temperature at around 500—600°C, until the cubic rate law could no longer be observed and the reaction followed a parabolic rate law at still higher temperatures.

Kofstad and Hauffe [23] have previously proposed that the cubic rate law as found in oxidation of titanium is associated with oxygen solution effects in the titanium metal. With this as a working hypothesis a series of experiments were initiated to investigate the effect of increasing oxygen content on the rate of reaction and the rate law at definite temperatures. According to this hypothesis the duration of the cubic rate law should decrease with increasing oxygen content, and it should eventually disappear for heavy oxygen-saturated titanium. The preliminary studies along these lines substantiated these conclusions.

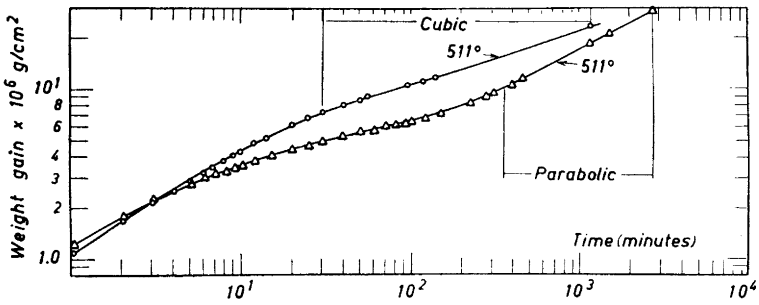

Fig. 10. Oxidation of van Arkel titanium (O) and titanium containing 4 at.% oxygen (△) at 511°C.

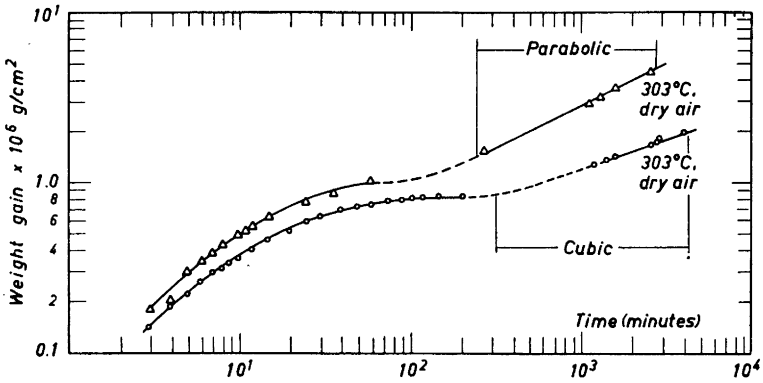

Fig. 11. The effect of oxidation-high vacuum cycles on the oxidation of van Arkel titanium (○) at 303°C. Prior to the oxidation run at 303°C, the oxygen-enriched specimen (△) was oxidized for 4 000 min at 403°C with subsequent annealing for 10 min in high vacuum at 800°C.

In Fig. 10 is shown the difference in oxidation behaviour at 511°C between van Arkel titanium containing 4 at.% oxygen and van Arkel titanium which was made by oxidizing the titanium and treating the specimens in high vacuum ($p_{O_2} = 10^{-5}$ mm Hg) for 24 h. As seen, the van Arkel titanium follows a cubic rate law after about 30 min of oxidation, while the 4 at.% O-Ti alloy oxidizes somewhat slower and follows a parabolic rate law after about 300 min.

Similar experiments at 403 and 303°C gave corresponding results. In these experiments high vacuum annealed van Arkel titanium specimens were oxidized for several days at 403°C, *e.g.* in the cubic rate law region. During these treatments thin films of TiO_2 were formed, but by treating the specimens in high vacuum at 800°C for 10 min the oxide films dissolved in the titanium. The oxidation-high vacuum annealing cycles were continued up to 5 times, and the oxidation was thus measured on titanium samples with increasing oxygen content. It is clear that such short annealing periods in no way distributed the oxygen uniformly through the sample. On the other hand, the outer layer of the titanium metal became more and more saturated after each oxidation-high vacuum cycle. The oxidation experiments consequently gave qualitative results as to the effect of oxygen concentration on the oxidation reaction. Qualitatively the effect of these oxidation-high vacuum annealing cycles in the cubic rate law region was to reduce the duration of the cubic law period. Furthermore, the cubic rate law would also completely disappear for samples which had previously been oxidized for the necessary length of time. Thus the cubic rate law could not be observed for specimens which had previously been oxidized for 2 600 min at 400°C with subsequent annealing for 10 min in high vacuum at 800°C.

Similarly, at 300°C the oxidation of van Arkel titanium followed the logarithmic rate law for the first 300 min, whereupon it changed into a cubic rate law. Oxidizing previously oxidation-high vacuum annealed specimens,

the cubic rate law disappeared. After an initial logarithmic period the oxidation followed a parabolic rate law as shown in Fig. 11. The surface of the specimens showed blue or yellow interference colours when oxidized in the cubic and logarithmic rate law regions.

Structural investigations. A number of X-ray diffraction diagrams taken of specimens oxidized in pure oxygen indicated only rutile in the oxide scale.*

* Only in one case was the presence of TiO and Ti_2O_3 established with certainty. During a run oxidizing van Arkel titanium at 900°C and low pressures, the oxygen was accidentally saturated with water vapor. The subsequent X-ray diagram showed that the oxide scale, which was black, consisted solely of TiO and Ti_2O_3. This means that any TiO and Ti_2O_3 formed were only present in amounts smaller than a few percent.

Fig. 19. Van Arkel titanium oxidized for 5 h at 700°C. 375 ×.

Fig. 20. Van Arkel titanium oxidized for 5 h at 800°C. 375 ×.

Specimens of Kroll titanium oxidized at 900 and 1 000°C for different length of time were also investigated by electron microscopy techniques. The specimens were cold-rolled and oxidized without high vacuum annealing. This procedure resulted in a preferred orientation in the titanium metal structure, and this again had its effect on the oxide scale. The results are shown in Figs. 12—18.

After 2 min of oxidation the crystals were at both temperatures small and spherical, but in some spots there was a tendency to a preferred orientation. Especially for the specimens oxidized at 900°C the crystals began to take on a lengthened form with normally developed crystal faces. After 10 min of oxidation the 900°C specimens differed from those at 1 000°C in that the rutile crystals were parallel and stretched lengthways, and they showed a decidedly preferred orientation over large parts of the surface. At 1 000°C the crystals were much larger and there was a much smaller tendency to preferred orientation. After one hour of oxidation the specimens at 900°C did not differ appreciable from those oxidized for 10 min, while the specimens oxidized at 1 000°C showed that the tendency to preferred orientation became less pronounced and there was evidence of surface diffusion and crystal growth.

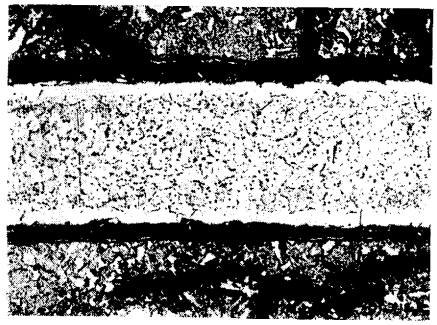

Fig. 21. RC-55 titanium oxidized for 5 h at 825°C. 75 ×.

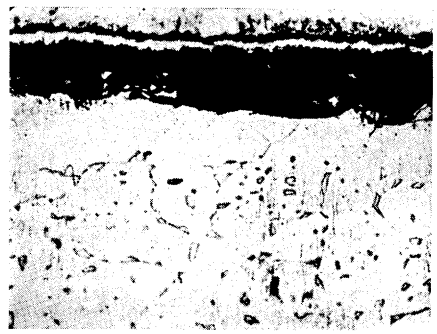

Fig. 22. Fig. 21. at a higher magnification. 325 ×.

Specimens oxidized longer than one hour at 1 000°C showed large crystal growth steps and less preferred orientation. At 900°C the crystals remained relatively small. Even for an oxidation period of 27 h did crystals show a high degree of preferred orientation. At both temperatures the formation of elbow twins was a common phenomenon.

By removing the oxide scale with tape, the back side of the oxide layer was investigated. These investigations showed small, spherically formed crystals without crystal faces for both temperatures and for different lengths of oxidation.

Metallographic examination of a large number of specimens has given the following visual picture of the oxide scale and the metal beneath for oxidation of titanium above 700°C.

The first oxide layer which can be observed, appears to be dense and even, and to be in very close contact with the underlaying metal. Growing in thickness, there can be observed a formation of thin layers parallel to the surface. The density seems to decrease as there appears a large number of elongated holes in the oxide layer which hardly can be a result of polishing alone, although polishing may increase their size and give an exaggerated impression of the amount of total porosity.

When the oxide has reached a rather large thickness, it is comparatively easy to polish and to retain, while at some earlier stage it breaks and is partly removed during polishing.

The oxide layer seems to consist of one phase only; a slightly different tone sometimes observed near the interface oxide/metal is believed only to be an optical effect due to internal reflection. Examination under polarized light (crossed Nicols) shows no sign of the presence of more than one phase.

Already shortly after the first traces of an oxide layer can be observed microscopically, a sort of boundary can be seen to move slowly inwards into the metal core in cold-rolled, unannealed specimens. The area between this boundary and the oxide layer is characterized by a larger grain size, and the grains are more or less columnar with their largest extension perpendicular to the surface. This area is very brittle, and when it reaches a certain thickness, fragments start to break out during polishing. This is shortly before the oxide layer has become thick enough to stand up against the strain of polishing, which means that at any stage of oxidation, there will be hard particles breaking out making the polishing very difficult. Further the holes or grooves formed collect debris and liquids which stain the specimen during drying.

The metal core inside this moving boundary has a much smaller grain-size, and the grains show a more random orientation. It is suggested that this moving boundary represents the delineation between an outer area with a very high oxygen content and an inner core containing only the original or a very low amount of oxygen. Further the boundary is believed at any time to be situated in that part of the metal where the micro-hardness testing shows the very steep change in hardness.

There naturally is a distinct difference in microstructure between the specimens which were oxidized in cold-rolled condition and the specimens which were annealed before oxidation. The last-named shows very much larger grains, very often extending right through the whole cross-section of the specimen. Grain growth during oxidation of such specimens therefore becomes unimportant, and a formation of columnar crystals can hardly be observed.

As most of the photographs show several details, their description has been postponed. In Figs. 19 and 20 are shown the oxide scales formed after oxidation of van Arkel titanium in 1 atm. O_2 for 5 h at 700 and 800°C, respectively. The dark spots near the oxide/metal interface in Fig. 21 are due to holes from the breaking out of hard and brittle particles during polishing.

Fig. 21 (RC-55 titanium oxidized for 300 min at 825°C) shows on both sides of the specimen a comparatively well conserved oxide layer under the plating. Beneath the oxide scale follows a groove where most of the brittle metal has been removed during the polishing. The inner part of this brittle layer stille remains in place, and the boundary between this layer and the rest of the core has revealed a different structure after etching. Fig. 22 shows a detail at higher magnification.

Micro-hardness measurements were made on transverse sections of a series of specimens oxidized for various lengths of time (10 min, 5 h, and 24 h) and at different temperatures. Some of the specimens were oxidized in the cold-rolled condition, others after annealing for 20 min at 1 000°C.

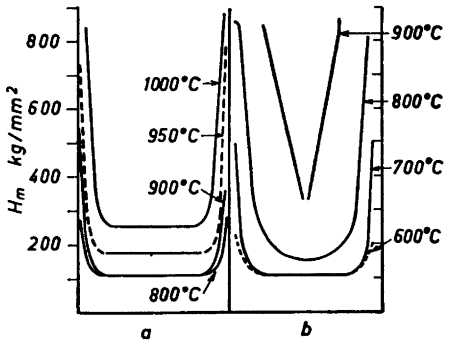

Fig. 23a. The effect of temperature on the oxygen penetration into Kroll titanium after oxidation for 10 min.
Fig.b. The effect of temperature on the oxygen penetration into van Arkel titanium after 5 h of oxidation.

In Fig. 23 a and b are shown the effect of temperature on the oxygen penetration into the titanium metal after oxidation for 10 min and 5 h, respectively. The data shown in Fig. 23 a were obtained by oxidizing Kroll titanium in the cold-rolled condition for 10 min, while Fig. 23 b gives the result of oxidation of van Arkel titanium. All the plates had a thickness of 0.03 cm before the start of oxidation. The results show clearly that oxygen penetration into titanium metal plays an important role in the oxidation reaction.

As seen, the oxygen is concentrated near the metal/oxide interface after oxidation at temperatures below 700°C, while the oxygen penetrates to the core of the specimens by oxidizing at 800°C and above. Especially may be noted the large oxygen penetration above 900°C when the titanium exists in its β-modification. This result is in agreement with the fact that the rate of diffusion of oxygen is much larger in the β- than in the α-phase, even though the solubility of oxygen is higher in the β-modification.

In Fig. 24 is shown the effect of length of oxidation on the oxygen penetration into the van Arkel titanium at 800°C. At this temperature titanium exists in its α-modification with a relatively low rate of oxygen diffusion compared to that of β-titanium, and consequently the inner part is only slowly saturated with oxygen. Most of the oxygen is concentrated at or near the metal/oxide interface, the slope of the oxygen penetration curve is decreasing sharply when going from the metal/oxide interface into the metal.

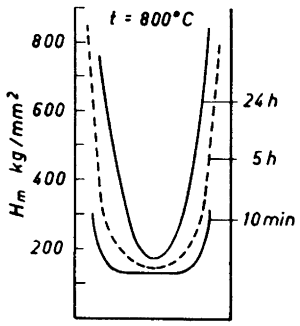

Fig. 24. The effect of length of oxidation on the oxygen penetration into van Arkel titanium after oxidation at 800°C.

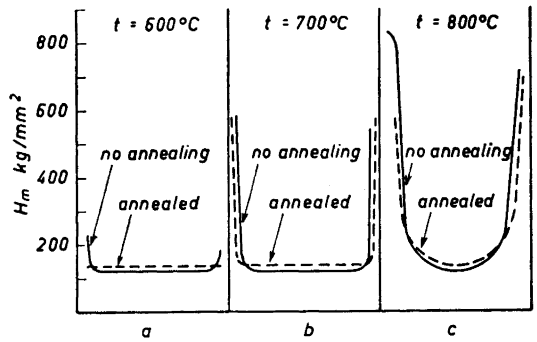

Fig. 25. a, b, c. The effect of annealing (20 mins at 1 000°C and $p_{O_2} < 10^{-4}$ mm Hg) before the oxidation run on the oxygen penetration into van Arkel titanium after 5 h of oxidation at 600, 700, and 800°C, respectively.

Figs. 25 a, b, and c show the effect of the oxygen penetration curves for van Arkel titanium after 5 h oxidation at 600, 700, and 800°C, respectively. All the specimens did have a thin outer zone enriched with oxygen, which was introduced in the metal during annealing between rolling runs. Half of the specimens were oxidized as such, and the other half annealed for 20 min at 1 000°C at $p_{O_2} = 10^{-4}$ mm Hg before the start of the oxidation. The results clearly show the effect of this annealing. Qualitatively one may say that during the annealing the oxygen in the outer zone has diffused into the specimen, and has become distributed throughout the specimen. The hardness throughout the sample is thereby increased as shown by the raising of the oxygen penetration curves in the annealed specimens compared to the unannealed. Correspondingly, the steep parts of the oxygen penetration curves are displaced further into the metal in the case of the unannealed specimens.

It is very reasonable that the effect of annealing has a decisive effect on the oxidation characteristics as the kinetics of the oxygen penetration into the metal very possibly plays an important role in the oxidation reaction. When titanium is oxidized in the cubic rate law region (300—600°C), there is some evidence that the kinetics of oxygen diffusion into the metal is responsible for the cubic rate law. Furthermore, the concentration of oxygen in the outer layer also determines the duration of the cubic rate law period.

DISCUSSION

All the above described results clearly indicate that the mechanism of oxidation of titanium is very complex, and no simple interpretation can be given to the diverse phenomena observed at different temperatures and oxygen pressures. The main reason for this state of affairs is partly due to the high oxygen solubility and the resulting interplay and competition between oxide film formation and oxygen dissolution effects.

Oxidation mechanism

a. Oxide scale. From a thermodynamic reasoning and comparing with iron, one might in the case of oxidation of titanium expect to find a sequence of oxides in the oxide scale with TiO near the metal/oxide phase boundary, Ti_2O_3 in an intermediate region, and TiO_2 at the outer part of the oxide scale. Assuming a compact oxide scale, the amounts of each oxide would on the basis of the Wagner theory of oxidation be dependent upon the rate of formation of the independent oxides, *e.g.* upon their respective defect structures and the rate of ion diffusion through each phase.

Actually, when oxidizing titanium in oxygen, both the X-ray diffraction and metallographic studies show that the oxide scale only consists of one phase, which is rutile. Considering the accuracy of these methods, one may conclude that any TiO and Ti_2O_3 formed are present only in amounts smaller than a few percent.

TiO_2 is a n-type semiconductor and has an oxygen deficient structure [25]. It is generally accepted that this oxygen deficiency results in oxygen ion vacancies rather than interstitial titanium ions in the rutile lattice [26].

b. Diffusion. The oxygen ion vacancies may facilitate a higher rate of diffusion for oxygen than for titanium in TiO_2, and consequently the inward diffusion of oxygen from the outer layer of the oxide might be expected to determine the rate of oxidation of titanium.

Almost all investigators studying the oxidation of titanium below 1 000°C have on the basis of various evidence (marker studies, scratches, and surface markings on the metal specimens) suggested that this mechanism is correct [5,12,21]. Recent marker studies by Kinna and Knorr at 1 000 and 1 200°C indicate that in addition to oxygen ion diffusion, diffusion of titanium ions also plays an important role during the oxidation [22].

There has in this investigation not been made any direct attempts as to establish whether oxygen or titanium ions migrate through the oxide scale. The metallographic and electron microscopy studies do indicate, however, that an overwhelming oxygen diffusion takes place during oxidation below at least 900°C. As the oxide layers grow in thickness, there can in the oxide layer be observed a formation of thin layers parallel to the surface, which indicate that the growth of the oxide layer takes place at the metal/oxide interface. The electron microscope pictures of titanium oxidized for different lengths of time (up to 27 h) at 900°C show a high degree of preferred orientation, which do not change appreciably with the duration of the oxidation. This shows that the crystal growth and corresponding surface diffusion of titanium ions is small at this temperature. Hence titanium ions seem to be relatively immobile at this temperature. This could mean that migration of titanium ions through the oxide scale can hardly be responsible for the oxidation of titanium. At 1 000°C the surface of the oxide scale showed a much smaller tendency to preferred orientation than at 900°C; specimens oxidized longer than one hour at 1 000°C showed large crystal growth steps and few signs of preferred orientation. Thus, at this temperature the surface diffusion of titanium ions seems more pronounced. It is of course to expect that surface diffusion is much faster than volume diffusion, but the observation is at least

in qualitative agreement with the results of Kinna and Knorr, who find that both titanium and oxygen ions migrate through the oxide scale during oxidation at 1 000°C and above.

The relative importance of oxygen ion and titanium ion diffusion through the oxide scale during oxidation of titanium may be described by the following qualitative considerations: Even though the defect structure of rutile favours a predominant oxygen ion diffusion, the titanium ions are of course not frozen in their lattice positions. The question of titanium ion diffusion is also a matter of thermal energy of the ions and potential energy barriers between neighbouring lattice positions. One could perhaps conclude that the activation energy for oxygen ion diffusion is much smaller than the activation energy for titanium ion diffusion in TiO_2. But this situation only implies that the oxygen ion diffusion is the most probable diffusion process in TiO_2 at lower temperatures, but titanium ion diffusion becomes increasingly important with increasing temperature.

For considerations of the oxidation mechanism of the titanium oxidation below 1 000°C, it will be assumed that the oxygen-ion diffusion determines the oxidation reaction.

c. Rate laws. The reported studies on the oxidation rates and the rate laws of oxidation at different temperatures are all in general agreement with data previously reported by other investigators and as reviewed by Kofstad and Hauffe [23]. The rate laws found in this investigation may be represented as follows: The oxidation follows a logarithmic rate equation up to approximately 300°C, a cubic rate law is found in the temperature region 300—600°C, a parabolic rate equation is obeyed between 600 and 850, while no clearcut rate law is found above 850°C. The rate laws observed at high temperatures ($>$ 850°C) may often be described as an initial parabolic rate law followed by a linear rate law, while in other cases the rate law may be interpreted as a mixture of linear and parabolic rate laws.

It should be pointed out that there are no definite temperatures at which the oxidation changes rate law; rather there are temperature intervals where different rate laws may be observed depending upon the duration of the oxidation. At 300°C for example, the logarithmic rate law is conformed with for approximately 300 min whereupon the rate changes into a cubic rate law. With increasing temperature, the duration of the logarithmic rate law period becomes increasingly shorter. Similarly at approximately 550°C the oxidation will for a relatively short period obey the cubic rate law, when after longer periods the oxidation will follow a parabolic rate law. In the parabolic rate law region between 600 and 850°C the oxidation will eventually increase abruptly at very long oxidation periods and change into approximately a linear rate law. The time during which the parabolic rate equation is obeyed, becomes shorter with increasing temperatures until at 900°C the oxidation follows approximately a linear rate law after 10 min of oxidation.

The interpretation of the mechanism of oxidation of titanium is complicated by the high solubility of oxygen in titanium. It is thus not only necessary to consider the formation of an oxide layer and the rate of diffusion of ions through this layer, but also the dissolution of oxygen in titanium, *e.g.* the rate of diffusion of oxygen through oxygen-enriched titanium.

There is no unequivocal interpretation of the logarithmic rate law. It is, however, well known that the oxidation of many metals follows a logarithmic rate equation. This type of relationship is often interpreted in terms of electric field effects across very thin oxide films (up to 50 Å) [27]. After the oxygen is adsorbed on the oxide surface, they combine with electrons and from chemisorbed oxygen ions because of the relatively high electron affinity of oxygen. The chemisorption gives rise to an electric field across the oxide film. According to Hauffe [24] the transfer of electrons across the oxide film is the rate-determining step in the reaction during the logarithmic rate law period.

Another derivation of the logarithmic rate law at low temperatures for oxide films thicker than 50 Å, is due to Evans [28], who makes use of the assumption that the effective area undergoing oxidation is not constant. This situation may be due to disarrayed oxide films, for instance at the junction of grains or the intersection of slip planes. If oxygen at such points can reach the metal, oxidation is likely to penetrate inwards along such paths of disarray, producing localized oxidation and thereby not an uniform film thickening. This situation may also arise in cases where there is a zone mixed with, or consisting of metal and interpenetrating metal and oxide as observed by Vernon, Calman, Clews, and Nurse oxidizing iron below 200°C [29].

Other interpretations of the logarithmic rate law have been proposed by Rideal and Jones [30], Uhlig [31], and Landsberg [32].

At the present time it is difficult to decide as to the correct mechanism in the logarithmic region in the case of titanium oxidation. According to the reported data the logarithmic rate law is obeyed until the weight gain/cm^2 equals about 1×10^{-6} g, which corresponds to a film thickness of approximately 60 Å. On the other hand, the data of Gulbransen and Andrew [23] may be interpreted as obeying a logarithmic rate law up to a weight gain of at least 6×10^{-6} g/cm^2 corresponding to a film thickness of at least 360 Å. Further investigations of this problems are therefore necessary. In this respect it would also be of importance to study the effect of oxygen pressure on the rate of oxidation.

It is reasonable to assume that the logarithmic rate law is associated with an oxide film formation, as it is very unlikely that a diffusion of oxygen into the metal would yield such a rate law. The rate of dissolution and diffusion of oxygen in titanium is consequently very small compared to the rate of film formation during the logarithmic rate law period.

With regard to the cubic rate law in general a few attempts have been made to work out a theoretical treatment. Mott [37] predicted the cubic rate from theoretical studies in connection with the logarithmic equation. A derivation of this rate law has also been made by Hauffe, Engell, and Ilschner in order to interpret the oxidation of nickel at 400°C[33]. The derivations of both Mott and Hauffe presupposes a p-type oxide film, and as TiO_2 is an n-type conductor, these approaches are not applicable in the case of oxidation of titanium.

In view of the fact that the cubic rate law is followed up to about 600°C, where the oxidation is appreciable, it seems that it cannot be interpreted in terms of electric field effects across the oxide layer. These approaches assume a relatively thin oxide film with a maximum thickness of a few hundred Ångströms, a condition which is not well satisfied in the case of titanium

oxidating at 500—600°C. On this basis Kofstad and Hauffe [23] suggested that the cubic rate law was due to another mechanism.

In view of the high solubility of oxygen in titanium it was reasonable to suggest an interpretation of the cubic rate law in terms of diffusion of oxygen through the outer layer of the oxygen-enriched titanium. Using this as a working hypothesis several studies were made, which substantiated this assumption.

In this connection it is interesting to note that the oxidation of zirconium also follows a cubic rate law between 350 and 950°C [34]. As in the case of titanium, it is here also evident that electric field effects cannot explain this high temperature oxidation mechanism. Zirconium and titanium are very much alike in having a very high oxygen solubility, and it is possible that this effect is responsible for the cubic rate law. Furthermore, there is evidence that the rate of diffusion of oxygen in titanium is dependent upon the oxygen concentration in titanium [35].

If the cubic rate law is interpreted in terms of oxygen dissolution in the outer layer of the titanium, one could expect an effect of the oxygen concentration in the titanium on the duration of the cubic rate law period. The length of this period should decrease with increasing oxygen content, and it should eventually disappear for heavily oxygen-saturated titanium.

As seen in Figs. 10 and 11, our preliminary studies along these lines substantiated these assumptions. At 511°C (Fig. 14) the cubic rate law period was shorter for the titanium containing 4 at. % O_2 than for pure titanium. Furthermore, the oxidation changed into a parabolic rate law after about 300 min of oxidation in the case of the oxygen-enriched specimen.

Similar experiments at 403 and 303°C showed corresponding effects. At these temperatures the oxidation was performed on specimens which were highly enriched with oxygen in the outer layer of the titanium by oxidizing the specimens and thereupon treating them in high vacuum at 800°C for 10 min in order to dissolve the oxide film. The intention was to shorten the duration of the cubic rate law period, until the cubic rate law disappeared completely for heavily oxygensaturated specimens. Similarly, at 303°C the oxidation of van Arkel titanium obeyed the logarithmic rate law for the first 300 min and is followed by a cubic rate law, but by oxidizing previously oxidation-high vacuum annealed specimens the cubic rate law disappeared. After an initial logarithmic rate law period the oxidation now followed a parabolic rate law.

On the basis of these studies the following qualitative picture may be given of the oxidation process in the cubic rate law region: The very first part of the reaction involves a chemisorption of oxygen on the titanium, followed by an oxide film formation, the oxide consisting of TiO_2. At the same time the diffusion of oxygen into the titanium metal also takes place: we thus have a competition between oxide film formation and oxygen dissolution in the metal. At low temperatures ($\sim$ 300°C) the diffusion of oxygen into the titanium is so small that the oxide film formation is the predominant feature of the reaction. The oxidation accordingly follows a logarithmic rate law which prevails as long as the rate of oxide film formation is very much faster than the rate of oxygen dissolution. The distinctive stamp of

the logarithmic rate law is of course the rapidly decreasing rate of oxidation with increasing time, and at a certain time (which becomes increasingly longer with decreasing temperatures) the rate of dissolution of oxygen will eventually become the predominant feature of the oxidation reaction. At this time interval, the oxidation changes from a logarithmic to a cubic rate law, as observed when titanium is oxidized at 303°C (Fig. 11).

This same situation does of course exist at higher temperatures. At increasing temperatures, however, the rate of oxygen dissolution plays an increasingly predominant role as compared to the oxide film formation obeying the logarithmic rate law. The logarithmic law period consequently becomes shorter with increasing temperatures. In addition, the oxidation neither follows a logarithmic nor a cubic rate law during the first stages of the oxidation in the temperature region 400—500°C. The observed oxidation may be interpreted as a mixture of a logarithmic and a cubic rate law, as both the rate of oxide film formation and oxygen dissolution is of the same order in this time interval. The rate of oxide film formation rapidly decreases, whereupon the diffusion of oxygen becomes the determining mechanism.

If the proposed interpretation of the data is correct, it would imply that the oxide film has an approximately stationary thickness when the oxidation follows the cubic rate law. The oxygen which dissolves in titanium is taken from the TiO_2 scale; however, a decrease in the thickness of the oxide film would immediately be counteracted by an increase in the electric field across the oxide (assuming the mechanism proposed by Mott). This immediately causes a growth of the oxide film until it reaches the stationary thickness. One way of testing this hypothesis would be to measure the growth of the oxide film in the cubic rate law region.

This may be done by continuously following the oxide film formation by means of X-ray or electron diffraction studies. Of importance in elucidating the mechanism in the logarithmic and cubic rate law regions would also be to study the oxidation as a function of the oxygen pressure.

In the results given in Fig. 11 it is shown that the cubic rate law eventually disappears when the outer region of the titanium becomes heavily enriched with oxygen, and the oxidation eventually follows a parabolic rate law even at 300°C. The following interpretation is proposed to explain this phenomenon: The parabolic rate law, as observed for oxygen enriched specimens even at 300°C, is assumed to represent a growth of the oxide film. However, in order that TiO_2 be formed, the chemical potential of oxygen in the TiO_2 phase, $\mu_{(TiO_2)}$, must be equal to the chemical potential of oxygen dissolved in titanium at the metal/oxide phase boundary, $\mu_{(Ti)}$:

$$\mu_{(TiO_2)} = \mu_{(Ti)}.$$

During the cubic rate law region oxygen dissolves in the titanium, and oxygen consequently continuously migrates away from the region of the titanium in the immediate neighbourhood of the metal/oxide phase boundary. Thus during the cubic rate law period the chemical potential of oxygen in titanium, $\mu_{(Ti)}$, does not reach the value necessary for a further growth of the TiO_2 oxide film. Only when the region of the titanium metal at the metal/oxide interface becomes saturated with oxygen, does the condition exist for a

further growth of the oxide film. When this saturation value is reached, the oxidation does not follow the cubic rate law any longer, rather we get a growth of the oxide scale. The rate determining reaction now becomes the diffusion of oxygen ions through the oxide scale with a corresponding parabolic rate law of oxidation. During the parabolic rate law period the diffusion of oxygen into the titanium metal does of course go on at the same rate, and as the oxygen ion diffusion through the oxide film is the slower process, the oxygen penetrates deeper into the titanium metal core with increasing time, as found by the micro-hardness studies at 800°C (Fig. 24).

The discussion and interpretations presented are of course only qualitative. The interpretations are only given in order to explain the kinetics of the oxidation reaction.

Another interpretation of the parabolic rate law in terms of electric field effects in the oxide film as proposed by Engell and Hauffe [36] for oxidation of zinc at 300°C, may also be considered. It is felt, however, that the interpretations presented may serve as a useful working hypothesis for further studies on the elucidation and understanding of the oxidation mechanism in this temperature region.

Several studies can be proposed for testing the hypothesis. Again it would be of invaluable help to study the growth of the oxide film during oxidation with X-ray or electron diffraction techniques. Furthermore, the oxygen pressure dependence of the oxidation would also provide clues as to the oxidation mechanism. According to this hypothesis all the rate laws (logarithmic, cubic and parabolic) should also be observed during oxidation at one temperature such as 300°C, provided that the oxidation is followed for the necessary length of time. This has not been done at this temperature, as the oxidation as shown in Fig. 11 was only followed for about 3 days. In order to obtain the parabolic rate law at this temperature a length of oxidation of several weeks, perhaps months, will be needed when oxidizing an oxygen free titanium specimen.

The same interpretation of the parabolic rate law for oxygen-enriched specimens at temperatures below 500°C, is proposed to be valid for the parabolic rate law region between 600 and 850°C. When oxidizing oxygen-free specimens at these temperatures, the region of titanium metal at the metal/oxide interface becomes saturated so fast with oxygen, that the cubic rate law is not observed. The parabolic rate law is consequently obeyed after a few minutes of oxidation. The diffusion of oxygen through the oxide is the slower and therefore the rate determining step in the reaction. Simultaneously oxygen diffuses into the titanium metal, and it penetrates deeper into the titanium metal core with increasing length of oxidation as shown by the micro-hardness studies of the oxygen penetration during oxidation at 800°C (Fig. 24).

For long periods of oxidation in this temperature region, the oxidation rate increases abruptly, and the rate law changes into an approximately linear rate law. As pointed out by several investigators [5,12,13] this is a result of the cracking of the oxide scale with subsequent formation of a porous oxide scale. The Pilling-Bedworth ratio is in the case of titanium equal to 1.76, and this

results in stresses in the oxide scale producing cracks and fissures, which causes the linear rate law.

At temperatures of 900°C and above, the oxide scale apparently reaches the critical thickness after a few minutes of oxidation, and the oxidation therefore follows an approximately linear rate law in this temperature region. In addition the effect of the allotropic transformation of titanium at 883°C may have some effect on the oxidation rate in the linear rate law region. Oxygen diffuses faster in β- than in α-titanium, and when there is no protective oxide layer, this increased rate of diffusion in the β-titanium may partially account for the fast oxidation in the linear rate law region. It should be kept in mind, however, that even when oxidizing in the β-region, the outer oxygen-enriched layer of the titanium metal will consist of α-titanium, as dissolved oxygen raises the transition temperature of the α-β transition.

The data on Kroll titanium indicates that the oxidation follows an approximately parabolic rate law at 1 000°C, while the oxidation of van Arkel titanium follows a linear rate law at the same temperature. The reason for this difference is not clear, but one explanation may be that the impurities in the Kroll titanium has a beneficial effect on the mechanical properties of the oxide scale. The reappearance of the parabolic rate law when Kroll titanium is oxidized at 1 000°C, may be interpreted in terms of a sintering effect of the oxide. As pointed out by Jenkins [12,19], rutile has a Tammann temperature of about 1 000°C, and one might consequently expect a relatively high rate of sintering at these temperatures. The difference between Kroll and van Arkel titanium, therefore, may be traced back to the larger amounts of impurities present in Kroll titanium. Impurities of magnesium and iron (present in Kroll titanium) would tend to increase the defect structure of TiO_2, thereby suggesting a higher sintering effect in the case of Kroll titanium. This would decrease the porosity of the oxide scales; furthermore, the growth stresses would be more easily relieved, thereby preventing the formation of cracks in the scale. An investigation of the density of the oxide scale formed would be of help in elucidating this problem.

The electron microscope pictures of the surface of Kroll titanium oxidized at 1 000°C also supports the assumption of a sintering effect at this temperature. The pictures show little preferred orientation of the oxide surface even after 10 min of oxidation, thus indicating that the surface diffusion of ions is relatively fast.

d. Effect of oxygen pressure. The studies of the effect of oxygen pressure on the oxidation rate of van Arkel titanium also brought forth new interesting data with regard to the oxidation mechanism, although further studies are necessary for definite interpretations of the results.

The effect of oxygen pressure was studied at 700, 800, 900, and 1 000°C. Generally one may say that the oxidation is oxygen pressure dependent at 900 and 1 000°, *e.g.* under conditions of approximately linear rate laws, while the oxidation is oxygen pressure independent within the limits of error under conditions of parabolic rate laws at 700 and 800°C. On the basis of the general theory of oxidation, one should in the case of oxidation of titanium with formation of a compact TiO_2-scale, expect no dependence of oxygen pressure on the oxidation rate [21]. This should, however, not be the case under conditions

of linear rate laws as found for van Arkel titanium at 900 and 1 000°C, and in which case the rate determining step probably is a phase boundary reaction at the metal/oxide interface. The present results are therefore generally as would be expected.

As the oxidation of titanium is complicated by oxygen dissolution in titanium, one might at low pressures expect to observe an effect due to the competition between the oxide layer formation and oxygen dissolution. This is particularly so, as it is well known that when titanium with TiO_2 films is treated in high vacuum at high temperatures, (> 700—800°C), the oxide film dissolves in the titanium, forming a solution of oxygen in titanium. There should consequently exist a temperature dependent critical pressure below which no oxide layer is formed during the initial period of the reaction. An oxide layer formation would only occur when the outer layer of the titanium becomes saturated with oxygen thereby raising the chemical potential of oxygen to the value permitting formation of TiO_2.

The oxygen pressure dependence at 900 and 1 000°C may be interpreted in terms of these suggestions. At these temperatures it is seen that the oxidation behaviour is rather irregular below 100 mm Hg. The interesting part is that the oxidation rate does not decrease with decreasing pressure below an oxygen pressure of 10^{-1} mm Hg. Rather the oxidation rate again increases when the oxygen pressure is decreased to 10^{-2} and 10^{-3} mm Hg.

Judging from the results at 1 000°C it is evident that the oxide scale has an increasingly protective effect at 10, 1 and 0.1 mm Hg as compared to 1 atm. and 100 mm Hg. The reason for this is not clear, but it is suggested that the lower oxygen pressures increase the oxygen ion vacancies in the TiO_2. This in turn permits a higher rate of diffusion of ions with a corresponding sintering effect. At pressures below 0.1 mm Hg the competition between oxide film formation and dissolution of oxygen in titanium plays a more dominant role. The tendency to oxide film formation decreases, and at a certain pressure no oxide will be formed. The titanium metal under these conditions is exposed to oxygen atmosphere, and the oxygen migrates directly into the metal. There will be growth of an oxide scale only when the outer layer of the titanium metal is saturated with oxygen.

e. Colour of oxide scales. In this connection it is also interesting to note the change in colour of the oxide scale formed when oxidizing at different pressures. It is well known that rutile may change its colour with changing oxygen content and with small additions of foreign oxides [36–38]. The oxygen deficient structure may with Schottky symboles be expressed as

$$\text{Nil} \rightleftharpoons O_{\square}^{\cdot\cdot} + 2\Theta + \tfrac{1}{2}\, O_2^{(g)}$$

where Nil designates a structure without defects, the squares are ion vacancies, the dots are positive excess charges, and Θ are free electrons. TiO_2 is an n-conductor and with decreasing oxygen content, electrons may be captured according to one or both of the following equations:

$$O_{\square}^{\cdot\cdot} + \Theta \rightleftharpoons O_{\square}^{\cdot} \quad \text{(blue F-center)}$$
$$Ti^{+4} + \Theta \rightleftharpoons Ti^{+3} \quad (Ti^{+3}\text{-ions are blue}).$$

Thus, rutile generally shows an increasingly blue colour with decreasing oxygen content. However, the significance of the observed colour change as a function of oxygen pressure is not clear at the present.

Acknowledgement. This work forms part of a research project sponsored by Air Research and Development Command, Department of the U.S. Air Force.

The authors wish to express their thanks to J. Markali, N. Norman, and E. Bull Simonsen for electron microscopy, X-ray diffraction and metallographic investigations, respectively. Our thanks are also due to S. Leirnes who carried out the oxidation — high vacuum annealing experiments.

The Chemistry of the Natural Order Cupressales

XX.* Heartwood Constituents of the Genus *Widdringtonia*

H. ERDTMAN and B. R. THOMAS

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The heartwoods of the five recent South African *Widdringtonia* species have been subjected to a comparative chemical investigation. A series of new sesquiterpenoid compounds have been isolated including the hydrocarbon widdrene, the alcohol widdrol, two sesquiterpene alcohols containing two oxygen atoms and a series of acids one of which, widdrenic acid, has also been obtained as an oxidation product of widdrene. Cedrol was usually present in these conifers and eudesmol was isolated from two species.

Superficially the family *Cupressaceae* appears to be a fairly recent, homogeneous group of conifers. However, in contrast to other families it is spread all over the world and there is evidence in favour of the view that the northern and southern genera have long been geographically separated. The family is therefore certainly old — though probably not one of the very oldest — and a comparison of the northern and southern genera is consequently a matter of considerable interest.

Some taxonomists regard the southern genera including *Actinostrobus*, *Callitris*, *Diselma*, *Neocallitropsis (Callitropsis)*, *Widdringtonia*, *Fitzroya*, *Pilgerodendron* and *Libocedrus sensu stricto* as forming a sub-family *Callitroideae*. Of these genera *Callitris* was the subject of the classical studies of Baker and Smith [1] and the monotypic *Neocallitropsis* was investigated by Simonsen [2]. *Diselma* [3], *Pilgerodendron* [4] and *Austrocedrus* [5] (part of *Libocedrus sensu lato*) which are also monotypic have recently been investigated in this laboratory.

Guaiol and (—)-dihydrogeranic acid (callitrol) were found to be characteristic for *Callitris*. Recent unpublished work (Erdtman and Jamieson) showed the presence of eudesmol in *Callitris Roei* (Endl.) F. Muell. and it is quite possible that small amounts of eudesmol occur in other *Callitris* species also. No tropolones were found in any of the *Callitris* species investigated here.

* Part XIX. *Acta Chem. Scand.* **11** (1957) 902.

Pilgerodendron contained sesquiterpenes of the cadinene type but no characteristic constituent was isolated from the heartwood samples of *Diselma Archeri* available. *Austrocedrus* remains the only known tropolone-producing conifer from the southern hemisphere.

The northern monotypic genus *Tetraclinis* (North Africa, southern Spain) has been included in the southern *Callitroideae* but this does not appear entirely justifiable, either geographically, botanically or chemically. The heartwood chemistry indicates on the contrary some affinities with the northern genera.

Of the southern genera, apart from two included in *Libocedrus sensu lato*, only *Callitris* and the African *Widdringtonia* contain more than one or two species and the latter were therefore selected for a comparative study. No chemical relationship to *Tetraclinis* was discovered.

Widdringtonia is a South African genus with five recent species, *W. cupressoides* (L) Endl., *W. dracomontana* Stapf., *W. juniperoides* (L) Endl., *W. Schwarzii* (Marloth) Mast. and *W. Whytei* Rendle. The heartwoods of these species are fragrant and resistant to insects and Docent E. Rennerfelt (private communication) has found that the heartwoods of *W. Whytei* and *W. juniperoides*, the only economically important species, are very resistant to wood decaying fungi *(Coniophora, Lentinus, Poria)*.

We have been able to investigate all five species. The ether soluble part of the acetone extract of the heartwood was an oil possessing a pleasant "cedar wood" odour. There was insufficient of the oil of *W. cupressoides* for a detailed examination but it appeared to resemble that from *W. dracomontana*. Eudesmol was isolated from both of these closely related species. The oils from the latter and from the remaining species were similar although eudesmol was not isolated from the other three. This does not necessarily mean that eudesmol is absent from these other species. The oils appeared to consist mainly of sesquiterpenes with some higher boiling substances. There were only traces of monoterpenes or compounds of similar boiling point range present.

The compounds isolated and a very approximate estimate of the amounts present in the various species are listed in Table 1. The figures are subject to the uncertainties of the estimation and to the wide variations possible in biological material.

The oils were separated into neutral and acid fractions and the former were fractionally distilled. The hydrocarbon fraction consisted of at least two sesquiterpenes of which the lower boiling, $C_{15}H_{24}$, $[\alpha]_D - 107°$, was the principal constituent. This compound, called widdrene*, appears not to have been isolated before but has since been encountered in *Platycladus (Biota) orientalis* [5] and in *Chamaecyparis thyoides* (Enzell, unpublished). Titration with perphthalic acid and the I.R. and U.V. spectra indicated the presence of a trisubstituted double bond. Like cedrene, widdrene must therefore be tricyclic.

Oxidation of widdrene with selenium dioxide gave an aldehyde widdrenal, $C_{15}H_{22}O$, m.p. 75—76°, which is a suitable derivative for the characterisation of widdrene. The compound possessed a strong cedar wood odour espe-

* *Added in proof:* According to Y. Hirose and T. Nakatsuka [*J. Jap. Wood Res. Soc.* **4** (1958) 26], the 'thujopsene' of J. Kawamura [*Bull. Imp. For. Exp. Stn. Japan No.* **30** (1930) 59] from *Thujopsis dolabrata* is essentially identical with widdrene.

Table 1. Constituents of *Widdringtonia* heartwoods.

Species:	*Whytei*	*juniperoides*	*Schwarzii*	*cupressoides*	*dracomontana*
(As a percentage of the air dried wood)					
Total oil (ether soluble acetone extract)	12	15	7.5	0.5	4
Neutral	8	11	5	0.25	3
Alkali soluble	4	4	2.5	0.25	1
(As a percentage of the total oil)					
Neutral	65	65	65	50	80
Low boiling (terpenes etc)	2	0	0		0
Widdrene ($C_{15}H_{24}$)	10	30	30		25
WiddreneII	2	5	3		present
Widdrol ($C_{15}H_{26}O$)	10	10	5	0	3

cially when in a slightly impure or an autoxidised state. The U.V. spectrum shows that it is an $\alpha\beta$-unsaturated aldehyde. Further oxidation with either silver oxide or with alkaline hydrogen peroxide gave the corresponding $\alpha\beta$-unsaturated carboxylic acid, widdrenic acid, $C_{15}H_{22}O_2$, m.p. 169°.

Ozonolysis of widdrene gave a keto acid $C_{15}H_{24}O_3$, m.p. 166—168°, which on oxidation with hypobromite furnished a dicarboxylic acid, widdrene dicarboxylic acid, which readily formed an anhydride. This acid was also obtained from widdrenal by oxidation with alkaline hydrogen peroxide. It was recovered unchanged when treated with hydrogen chloride in chloroform and this, together with the result of the ozonolysis, makes the possibility of the presence of a *cyclo*propane ring or an unreactive double bond unlikely.

These reactions indicate that widdrene like cedrene contains the system C—C=C(CH_3)—C in one of the rings. As in the case of cedrene, dehydrogenation experiments failed to give any characteristic products.

The second slightly higher boiling hydrocarbon provisionally called widdrene II was present only in small amount. It was dextrorotatory and appears to be an isomer of widdrene but it is uncertain whether it is entirely pure.

Further fractional distillation of the neutral oils gave a crude crystalline mixture of sesquiterpene alcohols which were most readily separated by chromatography on alumina. *Widdringtonia Whytei*, *W. juniperoides* and *W. Schwarzii* contained cedrol which is widespread in the Cupressales and a new sesquiterpene alcohol, widdrol. Eudesmol was obtained from *W. dracomontana* together with cedrol and widdrol, while eudesmol only was isolated from the small amount of wood of *W. cupressoides*. No eudesmol was obtained from the first three species although its presence cannot be excluded.

Widdrol melts at 98° and has the composition $C_{15}H_{26}O$, $[\alpha]_D$ + 105°. It could be crystallised only with difficulty but after careful chromatography it could be purified by sublimation along a temperature gradient. The I.R. and U.V. spectra and a perphthalic acid titration indicated the presence of a double bond. It was attacked by ozone and was readily dehydrated by acidic reagents to a mixture of hydrocarbons. Widdrol was acetylated with difficulty and is therefore probably a tertiary bicyclic alcohol. Selenium dehydrogenation gave an oil from which a small amount of 1,7-dimethyl-4-*iso*propylnaphthalene was isolated as the picrate. Since only a small yield of this unusual hydrocarbon was obtained, widdrol may perhaps not contain a preformed naphthalene ring and could be a spirane of the type considered by Ruzicka to constitute intermediates in the biosynthesis of cedrene.

The alkali soluble fraction of the oils contained little or no tropolones or phenols except for *W. cupressoides* which contained some material showing a phenolic type of U.V. spectrum but was insufficient for further investigation. The other four species gave resinous or crystalline acid fractions that all appeared to contain similar mixtures of acids. Four of the acids could be isolated in a crystalline form by crystallisation or by distillation of their methyl esters. One of the acids was identical with widdrenic acid (see above). Acid II, m.p. 190°, like widdrenic acid was $\alpha\beta$-unsaturated. The purity and composition of the acids III and IV are not yet absolutely certain since analyses gave variable results. Judging from the U.V. spectra, acid III appears to be aromatic. On reduction of the ester with $LiAlH_4$ a product was obtained which gave a typical benzenoid spectrum (λ_{max} 263 mμ, ε 900) and the preparations so far available yielded terephthalic acid on oxidation with dilute nitric acid. It was not affected by ozone under normal conditions. Acid IV had a different U.V. spectrum and was readily oxidised by ozone.

This exploratory study indicates that the genus *Widdringtonia* constitutes a rather homogeneous but distinctly separated group of general Cupressales character sharing with some northern genera, widdrene, cedrol and widdrol (the latter has recently been found in *Chamaecyparis thyoides*) and with some southern genera, eudesmol. The isolation of large amounts of sesquiterpene acids from these woods serves to emphasise the necessity of employing the extractive technique in investigations for the purpose of taxonomic comparison.

The co-occurrence of cedrol and eudesmol in at least *W. dracomontana* is interesting in view of the biogenetic schemes suggested by Ruzicka according to which their biosynthesis proceeds along different routes.

EXPERIMENTAL

Rotations were measured in chloroform; U.V. spectra in 95 % ethanol except where otherwise specified. The benzene-alcohol-water azeotrope was usually employed to dry solutions during evaporation. All m.p.s were taken on a hot stage.

Isolation of the oils. The ground, air-dried heartwood of each species was extracted with acetone for two days and the extract concentrated to a small volume. The material was then poured into a large volume of ether. The ether insoluble material which in the case of *W. Whytei* was obtained in large amount was discarded. The ether solution was shaken with water to remove acetone and then with 10 % sodium hydroxide solution to remove the acid fraction which was recovered by extraction with ether after acidification with dilute hydrochloric acid. Removal of the ether gave viscous oils. The neutral fractions from *W. dracomontana* deposited a considerable amount of a white material which was insoluble in light petroleum. The oil was therefore diluted with light petroleum, allowed to stand and further amounts of the material which separated were filtered off. This material was combined with that obtained by chromatography (see below).

All the neutral oils were treated in largely the same way and the separations of the constituents will therefore not be described separately except where they are divergent.

Neutral fractions. These oils after quick preliminary distillation under reduced pressure (about 10 mm) were fractionally distilled through a spinning band column. The hydrocarbons that distilled first (b.p. 115—130°/10 mm) were carefully fractionated and gave, after a small forerun, two fractions only. The material that followed (b.p. 140—150°/10 mm) contained the sesquiterpene alcohols and was distilled as a single fraction until the distillate ceased to crystallise when cold. The next fraction remained a viscous oil on standing; it was readily eluted from alumina by light petroleum and appeared to be the principal component of the higher boiling material. This and the remaining resinous material of still higher boiling point has not yet been investigated.

There was insufficient oil available from *W. cupressoides* for distillation.

Widdrene. The first hydrocarbon fraction was an oil of constant boiling point, b.p. 118—120°/10 mm, $[\alpha]_D$ −107°, n_D^{22} 1.5042. (Found: C 87.91; H 11.80. $C_{15}H_{24}$ requires C 88.16; H 11.84). The U.V. absorption spectrum showed only non-conjugated double bond absorption in the 210 mμ region. Titration with perphthalic acid in ethanol solution was almost complete after 36 h with the consumption of 0.9 mole of perphthalic acid. No attempt was made to isolate widdrene from *W. cupressoides* but widdrene with the same physical constants was isolated from the other four species. Widdrene possesses an odour very similar to that of cedrene, perhaps slightly stronger. The odour increased on standing, probably due to autoxidation.

Widdrenal. Widdrene (1 g) and selenium dioxide (600 mg) were heated in alcohol (20 ml, 95 %) under reflux for 4 h. The reaction solution was cooled, filtered, evaporated to dryness and the product sublimed under reduced pressure on to a cold finger and recrystallised from light petroleum to give *widdrenal*, m. p. 75—76°, $[\alpha]_D$ −27° (*c*, 1.8), λ_{max} 252 mμ, ε 6 000. (Found: C 82.12; H 10.3. $C_{15}H_{22}O$ requires C 82.52; H 10.15).

Widdrenic acid. Widdrenal (100 mg) was added to an aqueous suspension of silver oxide and the mixture heated for one hour on the steam bath. The suspension was acidified and extracted with ether. The ether solution was taken to dryness and the product recrystallised from ethanol and sublimed to give *widdrenic acid* (30 mg), m. p. 169°, $[\alpha]_D$ −86° (*c*, 1.8), λ_{max} 245 mμ, ε 5 000 (*n*-heptane). (Found: C 76.77; H 9.19. $C_{15}H_{22}O_2$ requires C 76.88; H 9.47).

Ozonolysis of widdrene. Ozone was passed through a solution of widdrene (10 g) in a mixture of methanol and ethyl acetate (1:1, 100 ml) at −75° until the solution turned blue. The solution was shaken with zinc dust activated with acetic acid, filtered, washed with water and then evaporated to dryness. The product was crystallised from methanol (5 g) and sublimed *in vacuo* to give a *keto-acid*, m. p. 166—168°, $[\alpha]_D$ −129° (*c*, 2.1). (Found: C 70.91; H 9.59. $C_{15}H_{24}O_3$ requires C 71.40; H 9.59). The keto-acid (200 mg) was treated with excess sodium hypobromite solution for 3 h. The solution was extracted with ether and then sulphur dioxide was bubbled through until the colour was discharged. It was then acidified and extracted with ether and this ether extract was washed with water and taken to dryness to give a resin which was crystallised from methanol to give *widdrene dicarboxylic acid* (130 mg), m. p. 215°, $[\alpha]_D$ −57° (*c*, 2.1). (Found: C 66.06; H 8.72. $C_{14}H_{22}O_4$ requires C 66.10; H 8.73).

The *dimethyl ester* was prepared by methylation with diazomethane and was purified by sublimation under reduced pressure, m. p. 71—73°, $[\alpha]_D$ −59° (*c*, 2.0). (Found: C 68.38; H 9.11. $C_{16}H_{26}O_4$ requires C 68.13; H 9.25).

The acid (100 mg) was refluxed in acetic anhydride (5 ml) for one hour and the reaction mixture was then evaporated to dryness. The resultant resin was sublimed on to a cold finger and crystallised from light petroleum-chloroform to give *widdrene dicarboxylic acid anhydride*, m. p. 113°, $[\alpha]_D$ +39° (*c*, 2.9). (Found: C 70.86; H 8.42. $C_{14}H_{20}O_3$ requires C 71.15; H 8.53).

Widdrene dicarboxylic acid was also obtained by treating widdrenal (300 mg) in methanolic potassium hydroxide solution (20 ml, 5 %) with hydrogen peroxide (2 ml, 30 %) for 3 h at room temperature. The reaction mixture was diluted with water, extracted with ether, acidified and extracted again with ether. This last ether extract was washed with water, evaporated to dryness and the resultant resin crystallised from ethyl acetate, m. p. and mixed m. p. 213—214°.

Widdrene II. The hydrocarbon fraction boiling slightly higher than widdrene was redistilled to give a constant boiling *fraction*, b. p. 128°/10 mm, $[\alpha]_D$ +50° (*c*, 3.0), n_D^{22} 1.5160. (Found: C 87.75; H 11.47. $C_{15}H_{24}$ requires C 88.16; H 11.84). (See forthcoming publication by Enzell and Erdtman on the purification and structure of the main component of this material.)

The sesquiterpene alcohol fractions. After the hydrocarbons had been distilled off, further distillation of the oil gave a large fraction, b. p. 140—150°/10 mm which crystallised on cooling. This material was dissolved in light petroleum and adsorbed on alumina. It was then eluted with benzene. The first fractions gave cedrol which was crystallised from aqueous methanol and then sublimed, m. p. and mixed m. p. 87—89°, $[\alpha]_D$ +10° (*c*, 2.0). Further elution with benzene-ether (1:1) gave a crystalline material which was sublimed, crystallised from cold light petroleum and resublimed along a temperature gradient to give *widdrol*, m. p. 98°, $[\alpha]_D$ +105° (*c*, 2.3), $\varepsilon_{210\,m\mu}$ 1 500. (Found: C 80.98; H 11.71. $C_{15}H_{26}O$ requires C 81.03; H 11.78). It gave a coloration with tetranitromethane.

The alcohol fraction from *W. dracomontana* was treated slightly differently. After removal of the sesquiterpenes the whole of the remaining material was chromatographed on alumina. The cedrol was eluted with benzene and then further elution with benzene-ether (9:1) gave crude crystalline eudesmol which was rechromatographed, recrystallised twice from light petroleum and sublimed, m. p. and mixed m. p. 83—84°, $[\alpha]_D$ +45° (*c*, 1.9). The infrared spectrum of this material was identical with that of an authentic sample of the natural mixture of isomers.

Elution with benzene-ether (1:1) gave widdrol and final elution with benzene-methanol (9:1) gave a product which was crystallised from chloroform-light petroleum to give a white powder which was combined with the material already isolated directly from the crude neutral oil by crystallisation from light petroleum (see above). This was recrystallised several times from chloroform-light petroleum to give a *diol*, m. p. 137—138°, $[\alpha]_D$ −24°. (Found: C 74.81; H 11.54; M (Rast) 239. $C_{15}H_{28}O_2$ requires C 74.93; H 11.75; M 240). An active hydrogen determination gave 0.81 %; two active hydrogens require 0.83 %.

The neutral fraction from *W. cupressoides* was too small for distillation (2.0 g from 700 g of wood) and was therefore chromatographed directly. The benzene-ether (9:10) eluate crystallised partially and on crystallisation from light petroleum and sublimation gave eudesmol, m. p. and mixed m. p. 80—82°, $[\alpha]_D$ +45°.

A sample of the neutral oil from *W. juniperoides* was chromatographed directly after first removing the widdrenes by distillation. In addition to widdrol and cedrol this chromatogram, on elution with ether-methanol (9:1) and recrystallisation of the material in this fraction from light petroleum gave an *alcohol*, m. p. 154°, $[\alpha]_D$ −9°. (Found: C 75.40; H 10.80. $C_{15}H_{26}O_2$ requires C 75.58; H 11.00). An active hydrogen determination gave 0.47 %; one active hydrogen requires 0.42 %. The compound was unattacked by ozone.

Dehydrogenation of widdrol. Widdrol (1 g) and selenium (1 g) were heated at 300° for 24 h in an atmosphere of carbon dioxide. The product was distilled to give an oil (400 mg) with an ultraviolet spectrum corresponding to somewhat less than 50 % of a naphthalenoid hydrocarbon. The picrate of the hydrocarbon was recrystallised five times from methanol to give a small amount of a picrate, m. p. 91—93°, mixed m. p. with the picrate of 1,7-dimethyl-4-*iso*propylnaphthalene, undepressed.

The acid fractions. The sodium hydroxide soluble fractions of the oils were dissolved in a small volume of ether and allowed to stand at 0° for some time. The material that crystallised was separated by crystallisation from a mixture of ether and light petroleum and then from methanol to give *acid I*, m. p. 169—170°, $[\alpha]_D$ −86° (*c*, 1.9), mixed m. p. with widdrenic acid prepared from widdrene (see above) undepressed. The material slightly less soluble in ether gave on recrystallisation from ether-light petroleum and from ethyl acetate, the *acid II*, m. p. 190—191°, $[\alpha]_D$ −76° (*c*, 1.9), $\varepsilon_{220\ m\mu}$ 5 000 (*n*-heptane). (Found: C 76.49; H 9.61; equiv.wt. (titration) 234. $C_{15}H_{22}O_2$ requires C 76.88; H 9.47; equiv.wt. 224).

An attempt was made to separate the two acids by distillation of the methyl esters, prepared by esterification with diazomethane, through a spinning band column. The boiling point curve (85 % b.p. 157—162°/10 mm) showed no obvious separation; the middle fractions contained a mixture that on crystallisation from light petroleum gave *widdrenic acid methyl ester*, m. p. 109—110°, $[\alpha]_D$ −99° (*c*, 2.0). (Found: C 77.69; H 9.85. $C_{16}H_{24}O_2$ requires C 77.39; H 9.73). Saponification of this compound by heating in 10 % methanolic potassium hydroxide solution for 3 h under reflux gave widdrenic acid, m. p. 169—170°. Attempted isomerisation of this ester or of the acid II ester by either acid or alkaline treatment failed.

The end fractions from the distillation through the spinning band column were chromatographed on alumina. Light petroleum eluted an ester which on saponification and recrystallisation from light petroleum gave a crystalline acid material, *acid III*, m. p. 160—161°, $[\alpha]_D$ +63° (*c*, 2.4), λ_{max} 240 mμ, ε 12 000. Benzene-light petroleum eluted an ester which was saponified by refluxing in 10 % aqueous methanolic potassium hydroxide solution for 2 h. Recrystallisation from light petroleum gave an *acid IV*, m. p. 138—140°, λ_{max} 302 mμ, ε 6 000. The acid III, m. p. 160—161°, could also be obtained from a mixture of the two by ozonolysis. These two acid products gave varying analytical results on repeated analysis but were apparently C_{15} compounds with two oxygen atoms.

The acid III (100 mg) was heated with nitric acid (15 ml, 10 %) for 24 h at 170°. The crystalline material that separated from the reaction mixture on cooling was filtered off (20 mg) and methylated with diazomethane. The ester was recrystallised from methanol to give terephthalic acid dimethyl ester, m. p. and mixed m. p. 143—144°.

Acid III (10 mg) was esterified with diazomethane and the reaction mixture was taken to dryness, dissolved in dry ether and refluxed with $LiAlH_4$ for 2 h. The solution was cooled, ethyl acetate was added, then water and acid. This mixture was extracted with ether and taken to dryness. The product showed a U.V. maximum at 263 mμ, ε 900.

Our thanks are due to Mr. J. Beard, the Natal Tanning Extract Company Ltd, Pietermaritzburg, Natal, the Chief Forest Products Officer, Forest Products Institute, Pretoria, and the District Forest Officers, Cathedral Peak, Natal, Stormsrivier and Kingwilliamstown, Cape, for their kind assistance in collecting the wood samples, to Professor F. Šorm, Prague, for a sample of the picrate of 1,7-dimethyl-4-*iso*propylnaphthalene, to Professor Pl. A. Plattner, Basel, for a sample of α-cedrene, and to *Statens Naturvetenskapliga Forskningsråd* for financial support.

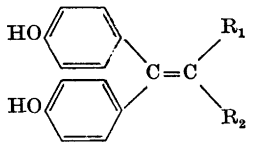
1,1-Di-*p*-hydroxyphenyl-2,2-diethyl-ethylene, a New Isomer of Stilbestrol

JEAN FRANÇOIS MIQUEL

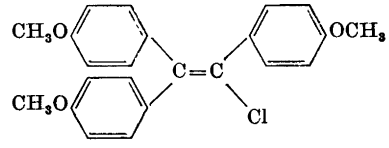
The Pharmacological Institute, University of Uppsala, Sweden

Interchanging one of the ethyl groups of diethylstilbestrol with one of the *para*-hydroxyphenyl groups gives a substance, 1,1-di-*p*-hydroxyphenyl-2,2-diethyl-ethylene, which is 50—100 times less estrogenic than diethyl-stilbestrol and is able to interfere with the vaginal estrus reaction if given intravaginally to spayed rats receiving estrogen systemically. The synthesis is made through the *p*-hydroxy-2-ethyl-butyrophenone or directly through the dimethyl ether obtained by an abnormal Friedel-Crafts reaction. The demethylation of the phenolic methoxyl groups must be effected with potassium hydroxide in triethyleneglycol. The demethylated compound decomposes on warming or in acidic media. The U.V. absorption of the new compound has been determined in different solvents.

In connection with work concerning the antagonism between natural or synthetic estrogens and related substances [1], the 2-alkylderivatives of 1,1-di-*p*-hydroxyphenyl-ethylene (I) became of interest. These substances are related to the substituted polyarylethylenes and particularly to TACE (trianisyl-chloroethylene) (II)



I



II

No alkyl-derivatives of I are described in the literature except 1,1-di-*p*-hydroxyphenyl-propylene which was prepared by Wessely [2]. He found the diacetate to give 66 % estrus response in 100 μg per rat. Later Lacassagne *et al.*[3] showed that the free compound has a very weak estrogenic activity, giving 66 % response at 15 mg/rat.

We have prepared several of the 2-alkyl and 2,2-dialkyl derivatives but the present report is concerned only with compound III: 1,1-di-*p*-hydroxy-

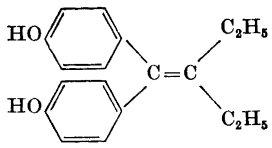
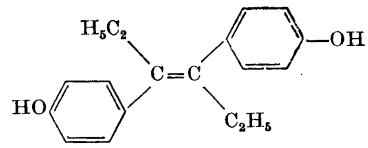
phenyl-2,2-diethyl-ethylene (*aa*DE for brevity). This compound is an isomer of diethyl-stilbestrol (IV) the difference being the transposition of an ethyl group and an aromatic group. Hence *aa*DE represents an interesting connection between diethyl-stilbestrol and the triphenyl-ethylene series.



III



IV

In a similar way Campbell [4] has studied the same transposition in the hexestrol series, where it causes a 50 000 fold drop in activity. In the case of the present compound the transposition has much less effect, the activity of *aa*DE is only 50 to 100 times less than that of diethyl-stilbestrol. Tested according to the technique of Bárány *et al.*[1], it interferes with the vaginal estrus reaction. Under the same conditions diethyl-stilbestrol is inactive. Further biological data will be reported elsewhere.

*aa*DE is prepared by a Grignard reaction of *p*-bromo-anisole with the *p*-methoxy-2-ethyl-butyrophenone (V). The carbinol (VI) so obtained dehydrates spontaneously during the distillation to give 1,1-di-*p*-methoxyphenyl-2,2-diethyl-ethylene (VII) which is then demethylated (Chart I).

The new ketone (V) is prepared with good yields:
a) (74 % from the acid) by methylation of the *p*-hydroxy-2-ethyl-butyrophenone (VIII) obtained by the action of BF_3 on a mixture of diethyl-acetic acid and phenol;
b) (70 % from the acid) by a Friedel-Crafts reaction between diethyl-acetyl chloride and anisole in carbon disulfide.

The hydroxyketone (VIII) is a colourless and microcrystalline substance, the methoxy compound is a pleasantly smelling pale yellow oil which can be demethoxylated easily by pyridine hydrochloride.

Following earlier work on the U.V. absorption of hydroxyarylketones [5] we have now studied the absorption of compounds V and VIII in different solvents. Both show the characteristic band of the *para*-acetophenones. After solution in equal volumes of ethanol and 0.1 N NaOH, the bathochromic effect for the paramethoxy group is weak even for the stronger band, the maximum being 265 mμ in *cyclo*hexane, 273 mμ in ethanol and 277 mμ in the alkaline solution. For the parahydroxyketone the shift is from 280 mμ in ethanol to 328 mμ in alkaline solution and the intensity increase from log $\varepsilon = 4.17$ to log $\varepsilon = 4.41$. The first band shows in this case a shift from 221 mμ to 238 mμ (Fig. 1).

The dimethoxy derivative (VII) can be directly obtained in competition with the methoxyketone (VI) by an interesting modification of the Friedel-Crafts reaction, using more drastic conditions of temperature and the anisole in large excess. This reaction described for the first time by Gattermann [6], who obtained 1,1-di-*p*-methoxyphenyl-propene in addition to *p*-methoxy-propiophenone, has lately been studied by Mentzer and Xuong [7] and extended

to the preparation of the triphenyl-ethylene derivatives by Xuong and Buu-Hoï [8]. We have previously determined the proportions of such 1,1-diaryl-ethylenes in the simultaneous preparation of *ortho*- and *para*-hydroxy-aryl-ketones[9]. Now yields of the ethylene derivative are varying from 12 to 20 % and at the same time 44—55 % of the ketones, calculated from the acid chloride used.

By chromic oxidation of the ethylene derivative (VII) *p,p'*-dimethoxy-benzophenone is formed in good yield. Demethylation of VII cannot be done by hydrobromic acid or other acidic agents which have little activity and produce polymerisation of the hydroxy compound formed. The best demethylation results are obtained with potassium or sodium hydroxide in boiling triethylene glycol.

The compound *αα*DE is a colourless microcrystalline substance. The melting point is 163° (instantaneous m.p.). It is soluble in ethanol, acetone,

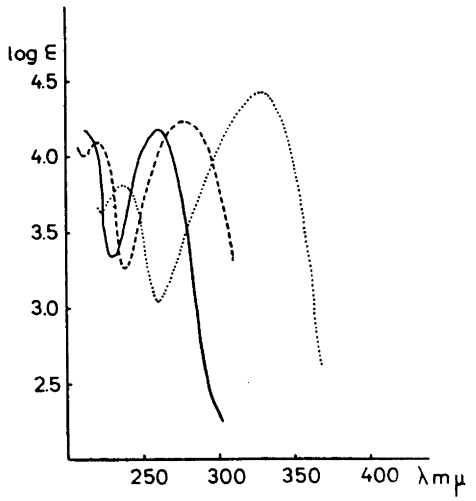

Fig. 1. —— *p*-hydroxy-2-ethyl-butyrophenone (VIII) in *cyclo*hexane. ------ compound VIII in ethanol 50 %, HCl 0.1 N 50 %. ····· compound VIII in ethanol 50 %, NaOH 0.1 N 50 %.

less soluble in benzene. It can be recrystallized from ligroin (100—125°), *cyclo*hexane, or a mixture: methanol 70 %, water 30 %. It is stable under alkaline and neutral conditions but very quickly formes coloured resins in acidic media. It gives a dipropionate, m.p. 89° and a dibenzoate, m.p. 184°. By reduction with nickel-aluminium alloy it forms compound IX which has previously been prepared by Campbell [4] by the action of diethyl-acetaldehyde on phenol.

EXPERIMENTAL

p-Hydroxy-2-ethyl-butyrophenone (VIII)

a) 12.6 g of diethyl-acetic acid and 12 g of phenol were slowly saturated during 2 h with BF_3. The temperature was then slowly elevated to 60—80° and kept there during one hour. The reaction product was poured into water, the ketone distilled easily under pressure 175°/1 mm. The ketone was dissolved at 25° in *cyclo*hexane and then recrystallized in the icebox as shiny soft colourless needles, m. p. 70°, yield 15.75 g (82 %).

b) 5 g of the methoxy derivative was refluxed with 5 g of pyridine hydrochloride for 20 min, then poured into water and extracted with ether. The organic layer was washed with water, dried, the ether distilled off and the ketone distilled. B. p. 175°/1 mm, yield 3.2 g (68 %). (Found: C 75.03; H 8.44. Calc. for $C_{12}H_{16}O_2$ (192.25): C 74.97; H 8.39).

Semicarbazone, colourless needles, m. p. 191° (from diluted ethanol). (Found: N 16.70. Calc. for $C_{13}H_{21}O_2N_3$ (251.32): N 16.72).

p-Methoxy-2-ethyl-butyrophenone (V)

13.5 g (0.1 mole) of diethyl-acetyl chloride [10] was mixed with 12 g anisole (0.1 mole + 10 %) in 80 ml of carbon disulfide, the mixture was cooled to 0° and 15 g of aluminium chloride added, the temperature being kept under 5°. After 24 h the mixture was refluxed one hour and poured into dilute cold hydrochloric acid. The organic layer taken up with ether was washed with 10 % aqueous sodium hydroxide, with water, then dried (Na_2SO_4) and the solvent removed by distillation. The distillation at 16 mm and 150—178° gave a yield of 16 g (78 %). A rectification at 16 mm and 172° afforded nearly colourless oil. n_D^{24} 1.5280 (Found: C 75.55; H 8.72. Calc. for $C_{13}H_{18}O_2$ (206.27) C 75.69; H 8.80).

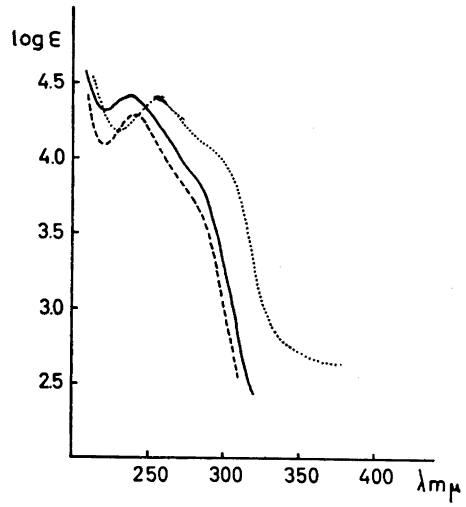

Fig. 2. ——— *aa*DE (III) in ethanol. ------ dimethylether *aa*DE (VII) in ethanol. ..... *aa*DE (III) in ethanol 50 %, NaOH 0.1 N 50 %.

Synthesis of a mixture of ketone (V) and ethylene (VIII)

13.5 (0.1 mole) of diethyl-acetyl chloride, 50 g anisole and 13 g aluminium chloride were mixed with good stirring keeping the temperature between 20 and 30°. After 24 h the mixture was refluxed during one hour and left at room temperature for 72 h. After normal decomposition and treatment, the red oil was distilled. The ketone distilled first under water pump pressure between 170° and 175°. When the temperature rose to 180° the oil pump was used and the ethylene (VIII) distilled at 195—200° under 1 mm Hg. After two recrystallizations from ethanol the ethylene melted at 90—91°.

The proportion of ketone and ethylene seems to depend on the time of contact between the reactants: with a time of 48 h the yield was an average of 61 % ketone and 8 % ethylene, with a time of 96 h the yield came to 42 % ketone and 8 % ethylene. (Found for the ethylene: C 80.93; H 8.12. Calc. for $C_{20}H_{24}O_2$ (296.39) C 81.04; H 8.16).

1,1-Di-*p*-methoxy-phenyl-2,2-diethyl-ethylene by Grignard reaction

11 g of *p*-bromo-anisole were slowly added to 3 g of magnesium-turnings in 80 ml anhydrous ether. After the end of the reaction the mixture was refluxed half an hour, then ice-cooled and 10 g of the ketone (VI), dissolved in 30 ml dried ether, slowly added. After the classical treatment and distillation the orange yellow oil crystallized spontaneously and gave after two recrystallizations in ethanol 10.7 g (72.4 %) of colourless microcrystalline substance. Melting point 90—91°. A mixture of crystals with those obtained by the abnormal Friedel-Crafts reaction gave the same melting point. (Found: C 80.96; H 8.24. Calc. for $C_{20}H_{24}O_2$ (296.39) C 81.04; H 8.16). Péteri[11] who obtained this substance as by-product in a synthesis of diethylstilbestrol gives a melting point of 86-88°.

Oxidation of 1,1-di-*p*-methoxy-phenyl-2,2-diethyl-ethylene

The preceding ethylene (2.5 g) treated with chromic acid (2 g) in acetic acid gave an exothermic reaction: the green solution was then poured into water. The solid precipitate was filtered and recrystallized from ethanol, m. p. 143—144°. The literature [12] gives the same melting point for *p,p'*-dimethoxy-benzophenone. (Found: C 74.28; H 5.76. Calc. for $C_{15}H_{14}O_3$ (242.26) C 74.36; H 5.83).

1,1-Di-*p*-hydroxyphenyl-2,2-diethyl-ethylene (*aa*DE) (III)

5 g of the ethylenic derivative (VIII) was refluxed with 5 g of potassium hydroxide in triethylene glycol with good stirring during 3 h. The mixture was then poured into 60 ml cold water, extracted with ether then acidified to pH 3 under ether. The ether layer was carefully washed with water until pH 6.6, dried with Na_2SO_4 and the ether distilled off. The oily precipitate crystallized on standing; after several recrystallizations from methanol (70 %) and water (30 %) long, colourless, soft needles were obtained, m. p. 163° (instantaneous m. p.), yield 3.2 g (76 %). (Found: C 80.37; H 7.61. Calc. for $C_{18}H_{20}O_2$ (268.34): C 80.56; H 7.51).

The dipropionate was obtained easily by refluxing the crude product with propionic anhydride in pyridine. After 30 min the mixture was poured into water, warmed to decompose the excess of anhydride and slightly acidified with hydrochloric acid, the dipropionate extracted with ether, the ether layer washed with a carbonate solution, with water, and dried (Na_2SO_4). The dipropionate recrystallized from ethanol as a colourless microcrystalline substance, m. p. 89—90°. (Found: C 75.74; H 7.42. Calc. for $C_{24}H_{28}O_4$ (380.46): C 75.76; H 7.42).

The dibenzoate was obtained by action of benzoyl chloride on an alkaline solution of *aa*DE. It recrystallized from ethanol and melted at 183—185°. (Found: C 80.60; H 5.84. Calc. for $C_{32}H_{28}O_4$ (476.54): C 80.64; H 5.92).

1,1-*p*-Hydroxy-phenyl-2,2-diethyl-ethane (IX)

1 g of *aa*DE was dissolved in 30 ml of 10 % NaOH and warmed to 90°. 2.5 g of nickel aluminium alloy was added in small portions with stirring, the mixture was then refluxed during one hour, filtered, the residue washed with hot water and the filtrate poured into hydrochloric acid. The precipitate was extracted with ether which was washed with water, dried and distilled off. The crystals mixed with oil were recrystallized from benzene, m. p. 168°. Campbell [4] who has prepared this compound by condensation of the diethylacetaldehyde with phenol, gives the same melting point.

This work was supported by grants to prof. E. Bárány from the *Swedish Cancer Society.*

On the Crystal Structure of the Rubidium Salt of Hydroxymalonic Dialdehyde

GEORG LUNDGREN and BENGT AURIVILLIUS

Institute of Inorganic and Physical Chemistry, University, Stockholm; Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The crystal structure determination of the rubidium salt of hydroxymalonic dialdehyde (= rubidium "reductonate", $Rb(C_3H_3O_3)H_2O$) is reported. The lattice is monoclinic with $a = 8.3 \pm 0.1$ Å, $b = 18.3 \pm 0.2$ Å, $c = 4.0 \pm 0.1$ Å, $\beta = 93° \pm 1°$. The space group is $P2_1/a$ (No. 14 in the International Tables [1]). The x and y parameters for the atoms have been determined. The z parameters were not calculated since the main features of the structure appeared in its xy projection.

When trying to solve the crystal structure of hydroxymalonic dialdehyde ("reductone") we found that it is probably non-centrosymmetric (space group No. 33 $Pn2_1a$ [1])[2]. The problem of determining the structure should then be very much facilitated if we could get some information concerning its C—O skeleton by investigating some related compounds. The work was thus begun by studying the structures of bromomalonic dialdehyde and rubidium "reductonate" (the rubidium salt of hydroxymalonic dialdehyde). A report concerning the crystal structure of the first compound will be given in *Acta Chem. Scand.*[3] and the second one is dealt with here.

A crystalline preparation of rubidium "reductonate" was kindly supplied by Professor Hans von Euler and Mr H. Hasselquist. It had been prepared by mixing water solutions of rubidium carbonate and hydroxymalonic dialdehyde. By very slow addition of acetone, crystals of rubidium "reductonate" then separated as leaf-like, rather long, yellowish, deliquescent plates. By evidence from the X-ray data, the formula of the compound was later on found to be $Rb(C_3H_3O_3)H_2O$.

By rotation and Weissenberg photographs the symmetry of the crystals was found to be monoclinic with the following cell dimensions:

$$\begin{aligned} a &= 8.3 \pm 0.1 \text{ Å} \\ b &= 18.3 \pm 0.2 \text{ Å} \\ c &= 4.0 \pm 0.1 \text{ Å} \\ \beta &= 93° \pm 1° \\ V &= 607 \text{ Å}^3 \end{aligned}$$

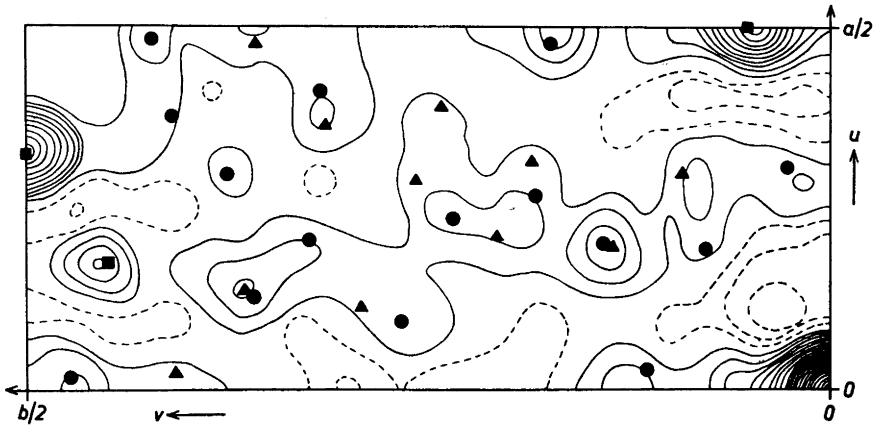

Fig. 1. The Patterson projection $P(uvp)$ for $Rb(C_3H_3O_3)H_2O$. In the figure the final vectors Rb—Rb (■), Rb—O (●), and Rb—C (▲) have been indicated. Dashed lines indicate negative values.

The following reflections were found to be systematically absent:

$$h0l \text{ with } h = \text{odd}$$
$$0k0 \text{ with } k = \text{odd}.$$

This is characteristic of the space group $P2_1/a$, which is another orientation of $P2_1/c$ (No. 14 in the International Tables of X-ray Crystallography [1]).

Because of the deliquescency of the crystals, their density could not be determined. However, by comparing the cell volume (607 Å^3) with that of hydroxymalonic dialdehyde (380 Å^3), we see that there should be 4 or 6 formula units in the unit cell.

POSITIONS OF THE RUBIDIUM ATOMS

The positions of the rubidium atoms were determined from the Patterson projection $P(uvp)$ (Fig. 1) using the estimated intensities corrected for polarization and Lorentz effects. It shows two large maxima: one at $u = 0.324$, $v = \frac{1}{2}$ and one at $u = \frac{1}{2}$, $v = 0.050$, which should certainly correspond to Rb—Rb vectors. They could be explained only if four rubidium atoms are situated in the point position 4(*e*): $\pm(xyz)$; $\pm(\frac{1}{2} + x, \frac{1}{2} - y, z)$ with $x_{Rb} = 0.088$ and $y_{Rb} = 0.225$.

If there are six formula units per unit cell, we should have two additional rubidium atoms in one of the positions 2(*a*)—2(*d*). This would demand a Rb—Rb peak at $u = \frac{1}{2}$, $v = \frac{1}{2}$ in $P(uvp)$. Since there is a negative region at that point, we could safely say that the unit cell contains only four rubidium atoms and consequently only four organic anions.

Since the *c* axis is very short and only a limited number of reflections could be registered in $0kl$, we did not determine the *z* parameters of the atoms. However, this was not necessary since our intention of getting a rough picture of the C—O skeleton could be fulfilled even if the *z* parameters were not known.

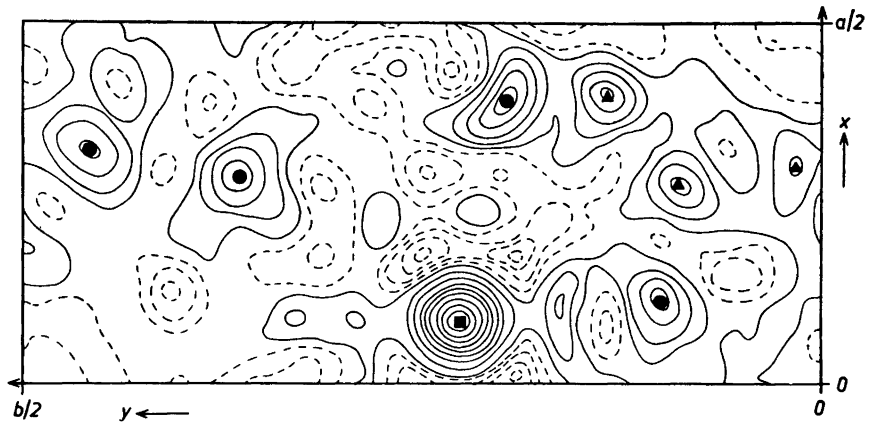

Fig. 2. The final electron density projection $\varrho(xyp)$ of $Rb(C_3H_3O_3)H_2O$. The positions of the Rb (■), C (▲) and O (●) atoms have been indicated. In the rubidium peak only every third contour has been marked. Dashed lines indicate negative values.

POSITIONS OF THE LIGHT ATOMS

To determine the positions of the light atoms the electron density projection $\varrho(xyp)$ was calculated. The signs of the F values were at first determined from the known rubidium contributions to the intensities. Later on, when the x and y parameters of the light atoms were approximately known, $\varrho(xyp)$ was corrected by considering the scattering of the light atoms also. However, only a few changes in the signs of the structure factors were necessary.

As is seen in Fig. 2, $\varrho(xyp)$ shows some low maxima which could be ascribed to oxygen and carbon atoms. Their parameters are:

4 A_1 in	4(e):	$\pm(xyz)$;	$\pm(\frac{1}{2}+x,\frac{1}{2}-y,z)$	with	$x = 0.11_6$, $y = 0.10_1$
4 A_2 »		»	»	»	$x = 0.39_1$, $y = 0.19_8$
4 A_3 »		»	»	»	$x = 0.32_1$, $y = 0.45_8$
4 A_4 »		»	»	»	$x = 0.28_7$, $y = 0.36_5$
4 A_5 »		»	»	»	$x = 0.27_5$, $y = 0.09_0$
4 A_6 »		»	»	»	$x = 0.39_8$, $y = 0.13_4$
4 A_7 »		»	»	»	$x = 0.29_9$, $y = 0.01_7$

In addition there are some very weak maxima close to the large rubidium maximum. They are, however, certainly false peaks caused by diffraction effects from the heavy rubidium atom [4].

Space arguments were used to decide the nature of the atoms A_1 to A_7. It was assumed that oxygen atoms are situated at least 2.60 Å apart. The projection of an O—O distance on the xy plane is thus at least 1.67 Å since the two oxygen atoms could be at most $c/2 = 2.0$ Å apart in the z direction. Now, the xy projections of the shortest distances A_1—A_5, A_2—A_6, A_3—A_7, A_5—A_6, and A_5—A_7 are 1.2_8 Å, 1.1_8 Å, 1.4_7 Å, 1.3_0 Å, and 1.3_5 Å, *i.e.* they

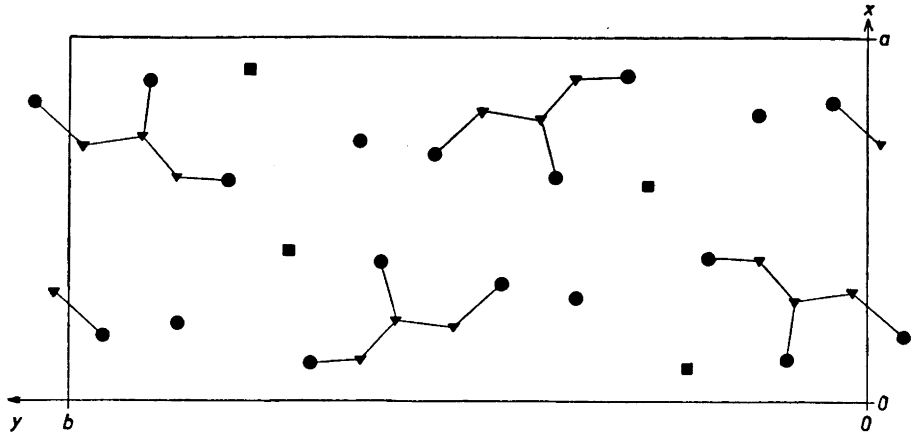

Fig. 3. Schematic picture of the atomic arrangement in the crystals of $Rb(C_3H_3O_3)H_2O$. The positions of the rubidium atoms have been marked with ■, the positions of the carbon atoms with ▲, and the positions of the oxygen atoms with ●.

are all shorter than 1.67 Å. Consequently there must be at least one carbon atom in each of these pairs. In addition to the chemical fact that the carbon atoms must form a chain, this leads to the conclusion that A_1, A_2, and A_3 are oxygen atoms and A_5, A_6, and A_7 carbon atoms. We have thus identified the atoms in the organic anion.

As for the remaining peak, A_4, it must correspond to a molecule of water of crystallization. The presence of such a molecule is also reflected in the relatively large difference in cell volume between the potassium and rubidium salts [2].

STRUCTURE PROPOSED FOR $Rb(C_3H_3O_3)H_2O$

The following x and y parameters are thus proposed for $Rb(C_3H_3O_3)H_2O$: Space group: $P2_1/a$. 4 formula units per unit cell.

4	Rb	in	4(*e*)	with	x	=	0.088	and y = 0.225
4	C_1	»	»	»	x	=	0.27_5	» y = 0.09_0
4	C_2	»	»	»	x	=	0.39_8	» y = 0.13_4
4	C_3	»	»	»	x	=	0.29_9	» y = 0.01_7
4	O_1	»	»	»	x	=	0.11_6	» y = 0.10_1
4	O_2	»	»	»	x	=	0.39_1	» y = 0.19_8
4	O_3	»	»	»	x	=	0.32_1	» y = 0.45_8
4	O_4	(H_2O)		»	x	=	0.28_7	» y = 0.36_5

4(*e*): $\pm(xyz)$; $\pm(\frac{1}{2}+x,\frac{1}{2}-y,z)$

With these parameters the intensities of the *hk*0 reflections were calculated. They were then corrected by an exponential factor of $10^{-0.34\sin^2\Theta}$ obtained with the ordinary procedure for the calculation of temperature factors. As

is seen in Table 1, the agreement between observed and calculated data is satisfactory. The R value according to Booth [5] is 0.17 (absent reflections not included).

DISCUSSION OF THE STRUCTURE

Fig. 3 shows a schematic picture of the xy projection of the structure with the projected interatomic distances indicated. As is seen, the organic anion shows the same configuration as in bromomalonic dialdehyde [2], *i.e.* the oxygen atoms are situated on the same side of the C—C chain.

The coordination Rb—O is rather difficult to determine since the z parameters are not known. However, if we assume that the distances between rubidium and oxygen atoms in contact are about 3.0 Å, we see that the differences in the rubidium and oxygen z parameters should be in the vicinity of $c/2 = 2.0$ Å for Rb (0.088, 0.225)—O_1(0.11_6, 0.10_1), Rb(0.088, 0.225) —O_2 (0.39_1, 0.19_8), and Rb(0.088, 0.225)—O_2(-0.10_9, 0.30_2). Every other z difference gives some Rb—O distances less than 2.8 Å (= the sum of the ionic radii). The rubidium atom is thus in contact with at least 6 oxygen atoms forming a trigonal prism.

The xy projections of the distances between the water molecule O_4 and two rubidium atoms are 3 Å. Thus, if they all three have the same z parameter, the water molecule would be in contact with two rubidium atoms, which seems to be very plausible. We would then have a coordination Rb—8 O in the crystals.

The authors are much indebted to Professor Hans von Euler for his kind, continuous interest in this work. They also wish to thank Professor Lars Gunnar Sillén for valuable discussions.

Synthesis and Reactions of Cinnamyl Phenyl Sulfide

CAMILLA JUSLÉN and TERJE ENKVIST

Chemical Institute of the University of Helsingfors, Finland

Cinnamyl phenyl sulfide was synthesized as part of a study on model compounds for thiolignin. The sulfide was found to be formed from a mixture of cinnamyl alcohol and thiophenol by elimination of water even at room temperature during irradiation with sunlight or ultraviolet light, or alternatively on moderate heating in the presence of aluminium sulfate or sulfuric acid dissolved in glacial acetic acid. The addition of thiophenol to the ethylenic bond also occurred as a side reaction. The ethylenic bond in cinnamyl phenyl sulfide reacted very slowly with, for instance, soda alkaline permanganate solution, bromine, hydrogen peroxide or perbenzoic acid, the two last-named reagents giving mainly cinnamyl phenyl sulfoxide and sulfone. This led to some doubt as to the actual structure of the sulfide. It can however readily be synthesized from cinnamyl bromide and potassium thiophenolate, and its infrared spectrum points to the presence of an ethylenic double bond. Oxidative degradation of the cinnamyl phenyl sulfide with perbenzoic acid or with permanganate solution gave, among other products, sulfuric, benzoic and benzene sulfonic acids. Degradation by hydrogenation with Raney nickel gave benzene and phenyl propane. Thus in fact the cinnamyl phenyl sulfide has a structure corresponding to its name, but its ethylenic bond is peculiarly slow to react.

SYNTHESES

The present work is a continuation of the studies on thiolignin formation with the aid of model compounds by the one of us (E)[1] and later also by Zentner [2] and Lindgren and Mikawa [3]. As it seems probable that thiolignin contains substantial amounts of monosulfidic sulfur [4], it was of special interest to study the formation and properties of lignin model compounds containing such sulfur.

The present paper is an account of the synthesis and reactions of cinnamyl phenyl sulfide. In a later report, corresponding investigations on several other thiolignin models will be described.

Perhaps the most striking observation made during these syntheses was the ease with which sulfides could be formed by splitting off water from cinnamyl or vanillyl alcohol and thiophenol (formula I). The reaction occurred even at room temperature on irradiation with ultraviolet light or sunlight,

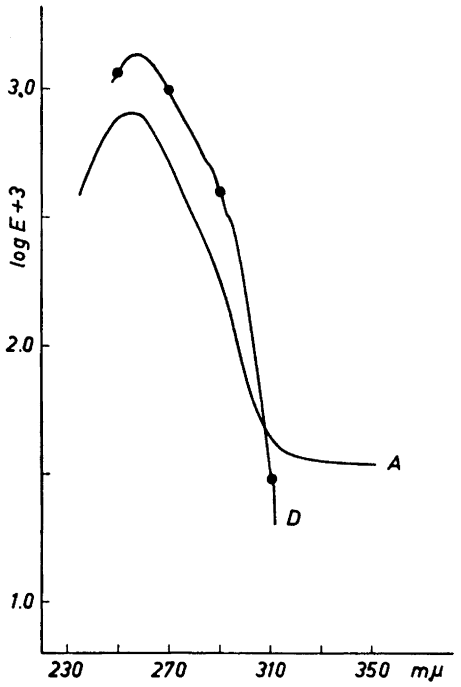

Fig. 1. UV spectrum of cinnamyl phenyl sulfide. D = in dioxan solution. A = in 0.5 N alcoholic sodium hydroxide.

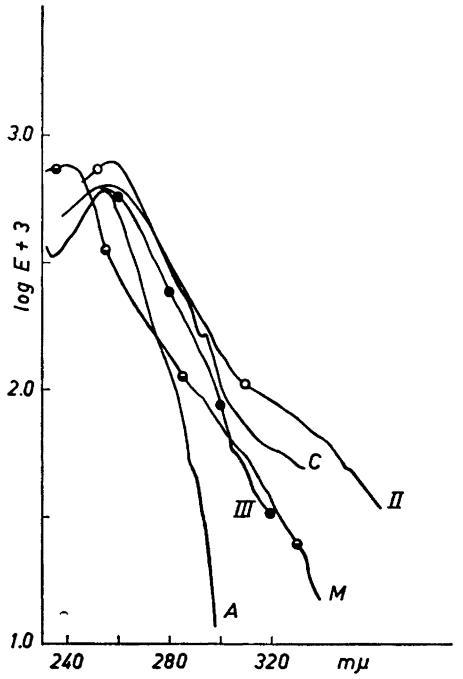

Fig. 2. UV spectra of cinnamyl disulfide (C), of allyl phenyl sulfide (A), of 2-methyl thiocoumarane (M) and of fractions II and III obtained on heating cinnamyl phenyl sulfide.

or alternatively on very moderate heating in the presence of aluminium sulfate or hydrogen ions. Table 1 gives a survey of the syntheses carried out.

The table shows *inter alia* that addition of thiophenol to the ethylenic bond also occurred during the photosynthesis. Attempts to add thiophenol to the ethylenic bond in cinnamyl phenyl sulfide in acetone solution with piperidine as catalyst failed.

I $C_6H_5{\cdot}CH{:}CH{\cdot}CH_2OH + HS{\cdot}C_6H_5 = C_6H_5{\cdot}CH{:}CH{\cdot}CH_2{\cdot}S{\cdot}C_6H_5 + H_2O$
Cinnamyl phenyl sulfide(IV)

THE PROPERTIES OF CINNAMYL PHENYL SULFIDE

Structure. Cinnamyl phenyl sulfoxide has been described in the literature by Barnard[5], who also synthesized cinnamyl phenyl sulfide (private communication), but without publishing anything about it. In June 1956, when the main part of our experimental work was already completed, Briscoe, Challenger and Duckworth [6] published a synthesis of cinnamyl phenyl sulfide and an attempt to determine its structure by reaction with Chloramine T.

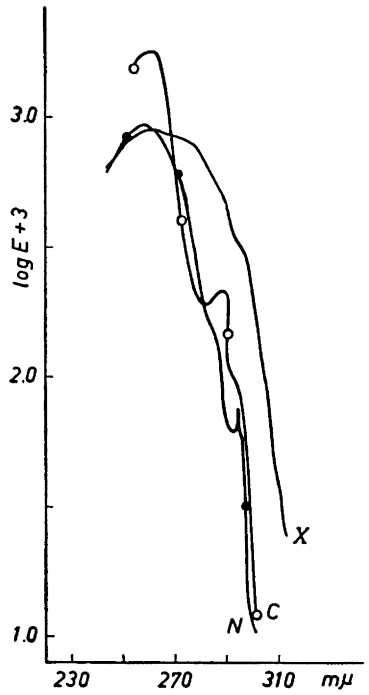

Fig. 3. UV spectra in dioxan of cinnamyl phenyl sulfoxide (X) and sulfone (N) and of cinnamyl alcohol (C).

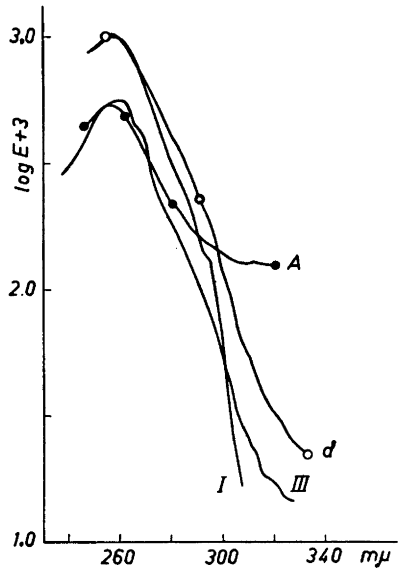

Fig. 4. UV spectra of by-products at syntheses of cinnamyl phenyl sulfide. A = addition product of cinnamyl alcohol and thiophenol (photosyntesis, 1 a). Solvent 0.5 N alcoholic sodium hydroxide. I and III, respectively, first and third chromat.-fraction from synthesis 1 c in dioxan. d = second chromat.fraction from synthesis 1 d in dioxan.

Our work concerning cinnamyl phenyl sulfide started with a photosynthesis of this substance at room temperature from cinnamyl alcohol and thiophenol carried out by Mr Eino Lonkila and one of us (E), in which about 9 mole % of crystalline sulfide was isolated by vacuum sublimation mainly in the fraction 190—230° at 15 mm. Even at this stage it was observed that cinnamyl phenyl sulfide does not react in the usual Baeyer test for unsaturated substances with soda-alkaline permanganate solution at room temperature. This observation led to further investigations concerning the double bond in cinnamyl phenyl sulfide and also raised the question of whether the sulfide possesses the simple structure IV or whether a Claisen rearrangement has occurred during its formation leading ultimately to a thiocoumarane or thiochromane structure (*cf* Ref.[7,8]).

Ultraviolet and infrared spectra. The ultraviolet absorption spectrum of cinnamyl phenyl sulfide (Fig. 1) shows a single maximum at about 255 mμ,

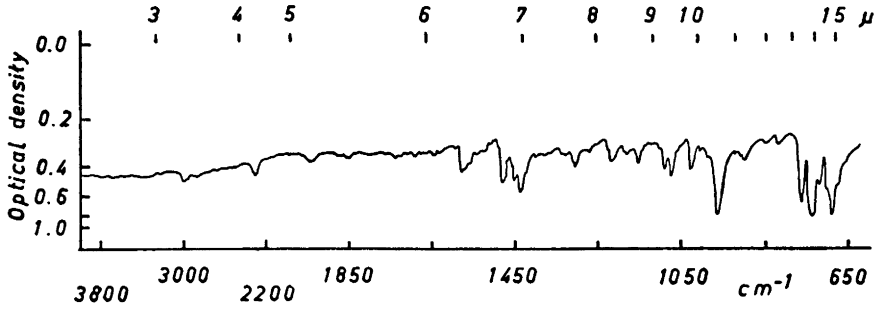

Fig. 5. Infrared spectrum of cinnamyl phenyl sulfide, without solvent.

very much like that of allyl phenyl sulfide and of cinnamyl disulfide, but distinctly different from that of 2-methyl thiocoumarane (Fig. 2). The cinnamyl phenyl sulfoxide and sulfone as well as cinnamyl alcohol have an absorption maximum at a somewhat longer wave length (Fig. 3).

The infrared spectrum of cinnamyl phenyl sulfide (Fig. 5) has an absorption band at 960 cm^{-1}, probably caused by the wagging swings of the :CH·-group. Substances containing a CH_2:C-group show absorption[9] at about 890 cm^{-1}. This band is lacking for cinnamyl phenyl sulfide, showing that rearrangement to vinyl groups during the formation of cinnamyl phenyl sulfide is improbable. Moreover, the absorption band of the hydroxyl groups [9] at 3 380 cm^{-1} is lacking, in contrast to the IR-spectrum of the addition product of cinnamyl alcohol and thiophenol (Fig. 6), where the hydroxyl group could also be demonstrated by acetylation, and which thus very probably contains the substances V or VI or both of them.

V. $C_6H_5CH{\cdot}(SC_6H_5){\cdot}CH_2CH_2OH$ VI. $C_6H_5{\cdot}CH_2{\cdot}CH(SC_6H_5)CH_2OH$

γ-thiophenoxy-γ-phenylpropanol β-thiophenoxy-γ-phenylpropanol

The ethylenic bond in olefines causes absorption at about 1 660 cm^{-1} also, and cinnamic acid absorbs characteristically at 1 590 cm^{-1} and still more strongly [10] at 1 625 cm^{-1}. This latter absorption also occurs in the spectrum

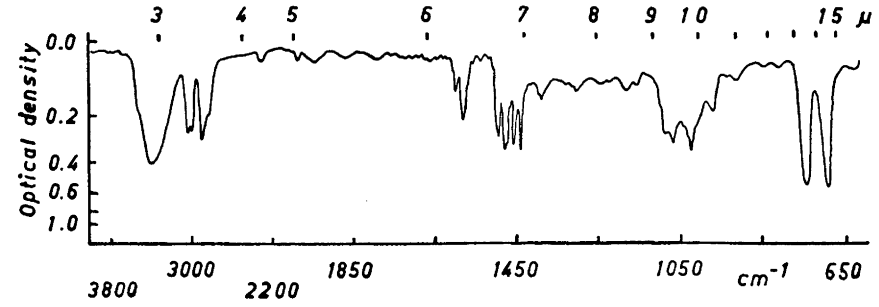

Fig. 6. Infrared spectrum of the addition product of cinnamyl alcohol and thiophenol.

of cinnamyl alcohol and is probably due to the ethylenic bond. In this area of the spectrum of cinnamyl phenyl sulfide, there is an absorption band only at 1 575 cm^{-1}. Probably in this substance, as well as in *trans*-stilbene and indene [11], the absorption band caused in the area in question by the ethylenic bond coincides with the absorption of the double bonds in the benzene nucleus.

OXIDATION REACTIONS

With hydrogen peroxide. Samples of cinnamyl sulfide were oxidized with hydrogen peroxide to the sulfoxide and the sulfone. No glycol derivative, but only the sulfone, could be found among the oxidation products, even after oxidation with 4 moles of 30 % H_2O_2 in acetone solution in UV light for 2 weeks.

The sulfoxide was obtained in 94 mole % yield by using equimolar amounts of hydrogen peroxide and cinnamyl phenyl sulfide at room temperature. The sulfoxide appears in two modifications, one with m.p. 78°, primarily obtained at chromatographic separation on an aluminium oxide column, and another melting at 91.5—92°, formed for instance on recrystallization of the other form from hot petrolether-chloroform solution. The m.p. of Barnards cinnamyl phenyl sulfoxide is recorded as 68°C, but he has privately reported that this figure is a misprint and should be 78°C, and that he likewise has found two modifications of the sulfoxide. A mixed m.p. of our sulfoxide of m.p. 78° and a corresponding sample kindly supplied by Dr Barnard showed that the substances were identical.

With reagents for the ethylenic bond. The sulfide as well as the sulfoxide and the sulfone only very slowly decolorized soda-alkaline permanganate solution at room temperature, after hours of standing, whereas, for instance, cinnamyl alcohol and freshly distilled allyl phenyl sulfide, prepared according to Claisen [12], immediately decolorized the reagent. It was found, however, that cinnamyl phenyl sulfide showed some of the reactions of the ethylenic bond. Thus, when it or the corresponding sulfone are dissolved in pure pyridine, they decolorize potassium permanganate solution.

With tetranitromethane, golden yellow colors were given by cinnamyl phenyl sulfide, the corresponding sulfoxide and sulfone, as well as cinnamyl alcohol, whereas allyl phenyl sulfide gave a red color.

Organic sulfides in general add bromine, and the method of Siggia [13] for determination of sulfidic sulfur makes use of this fact. Cinnamyl phenyl sulfide gave the following bromine numbers: McIlhiney's method [14] (addition only, 3.7 % of the total bromine consumption was found to be due to substitution) 92, Kauffmann's [15] method 89, Siggia's method 117. The theoretical value for cinnamyl phenyl sulfide is 141, supposing that the sulfide sulfur and the ethylenic double bond each of them add two bromine atoms. The actual bromine consumption is thus considerably lower than the theoretical value.

Oxidation with perbenzoic acid.[16] Fig. 7 shows the uptake of oxygen in g.atoms from perbenzoic acid per mole of cinnamyl phenyl sulfide at +3°. It can be seen that 2 atoms of oxygen are added to one molecule of the sulfide within one day, after which the uptake is very slow, in all only 2.72 atoms being consumed after 42 days. According to Stoll and Seebeck [17], in unsatura-

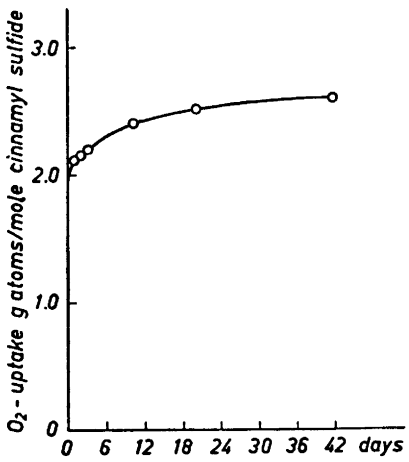

Fig. 7. Oxidation of cinnamyl phenyl sulfide with perbenzoic acid.

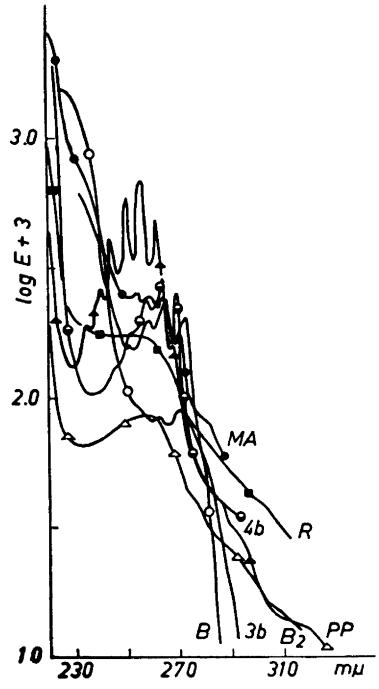

Fig. 8. UV spectra of degradation products of cinnamyl phenyl sulfide. 3 b = crude benzene sulfonic acid from synthesis 3 b. B = benzoic acid from 4 a. MA = mixture of acids (M.A.) from synthesis 4 b. 4 b = purified benzene sulfonic acid from synthesis 4 b. Bz = benzene from synthesis 5. PP = phenyl propane from synthesis 5. R = residue from synthesis 5.

ted sulfides containing an allyl group the sulfur is oxidized faster than the ethylenic bond by perbenzoic acid.

From the neutral fraction of the reaction products, only cinnamyl phenyl sulfone could be isolated. Thus, the fast uptake of the first two oxygen atoms is obviously due to addition to the sulfur, and the later slow uptake of oxygen to the ethylenic bond.

Oxidative degradation. A sample of cinnamyl phenyl sulfone was oxidized with perbenzoic acid, this time at room temperature. Among the acidic oxidation products benzene sulfonic acid could be detected through mixed m.p. of the S-benzyl thiuronium salt.

Cinnamyl phenyl sulfide was oxidized in benzene suspension with soda-alkaline potassium permanganate in aqueous solution for 59 h at room temperature. The reaction products contained cinnamyl phenyl sulfoxide and sulfone, benzoic acid in a yield of 53 mole %, and further benzene sulfonic acid (mixed m.p. of S-benzyl thiuronium derivative) and sulfuric acid.

Table 1. Syntheses of cinnamyl phenyl sulfide.

Reagents	Method [1]	Reaction time	Reaction product	Yield, mole %
Cinnamyl alcohol (II) + thiophenol (III)	Photosynthesis (1 a)	14 days	Cinnamyl phenyl sulfide (IV) + V or VI	9 13
II + III	Press.heating with Al-sulfate (1 b) [2]	16 h	IV	25
II + III	Boiling in acet. acid + H_2SO_4 (1 c)	16 h	IV	85
Cinnamyl bromide + C_6H_5SK	Boiling in acetone (1 d)	8 h	IV	83
»	Boiling in benzene (1 e)	4 h	IV	72

[1] The numbers in parentheses mean paragraphs in the experiment. part.
[2] In a sealed glass tube.

DEGRADATION BY HYDROGENATING TREATMENT WITH RANEY NICKEL

It is well known that treatment with Raney nickel [18] allows the sulfur in thioethers to be replaced by hydrogen. Cinnamyl phenyl sulfide was boiled with a great excess of Raney nickel in alcoholic suspension. Benzene (demonstrated with UV spectrum and from nitration and mixed m.p. determination *m*-dinitrobenzene so formed) and phenylpropane were formed (identified as 2-mono- and 2,4-diacetamino phenylpropane, obtained according to scheme VII).

VII. $C_3H_7{\cdot}C_6H_5 \xrightarrow{HNO_3} C_3H_7{\cdot}C_6H_4{\cdot}NO_2 + C_3H_7{\cdot}C_6H_3(NO_2)_2 \xrightarrow{Sn + HCl}$

$C_3H_7{\cdot}C_6H_4{\cdot}NH_2 + C_3H_7{\cdot}C_6H_3(NH_2)_2 \xrightarrow{\text{acetylation}} C_3H_7{\cdot}C_6H_4{\cdot}NH{\cdot}COCH_3 + C_3H_7{\cdot}C_6H_3(NH{\cdot}COCH_3)_2$

Thus, the hydrogenation with Raney nickel has followed the simple scheme VIII.

VIII. $C_6H_5CH = CH{\cdot}CH_2{\cdot}S{\cdot}C_6H_5 + 6H \rightarrow C_6H_5CH_2CH_2CH_3 + H_2S + C_6H_6$

All these facts thus prove that the cinnamyl phenyl sulfide in fact has the structure IV but that the ethylenic bond reacts very slowly with the usual oxidizing reagents. The same low reactivity seems also to characterize the corresponding sulfoxide and sulfone.

Attempt at obtaining a Claisen rearrangement of cinnamyl phenyl sulfide. As no Claisen rearrangement to *o*-cinnamyl thiophenol or further to a thiocoumarane or thiochromane could be observed during the syntheses of cinnamyl phenyl sulfide, this substance was heated in an atmosphere of nitrogen in order to promote rearrangement or destructive splitting. The sulfide decomposed somewhat below 260°C. From the reaction products

57 % of unchanged starting material could be isolated and further a small amount of thiophenol, which after autoxidation gave phenyl disulfide, proven by mixed m.p. with an authentic sample. Among the neutral products two liquid chromatographic fractions (II and III) showed sulfur contents only a little lower than the starting material and UV spectra not dissimilar to that of 2-methyl thiocoumarane (Fig. 2). The high recovery of starting material indicates, however, that the cinnamyl phenyl sulfide is not easily rearranged or split up.

EXPERIMENTAL PART

1. Syntheses of cinnamyl phenyl sulfide

a) *Photosynthesis.* 1.250 g (0.009 moles) cinnamyl alcohol and 1.000 g (0.009 moles) of thiophenol were allowed to stand 2 weeks in a quartz tube sealed with a rubber stopper 15 cm from a mercury (quartz) lamp. The reaction product was dissolved in ether, washed with 2 N sodium hydroxide and water, dried, and isolated by evaporation of the solvent. The dryings in the present work were generally carried out with sodium sulfate. The residue was recrystallized several times from 99 % ethanol (preparation P) m. p. 78°, undepressed on admixture with a preparation of cinnamyl phenyl sulfide kindly supplied by Dr. Barnard. (Found: C 79.54; H 6.27; S. 14.06 [1]; mol. wt. (Cryosc. Beckmann) 221. Calc. for $C_{15}H_{14}S$: C 79.60; H 6.23; S 14.17, mol.wt. 226). UV-spectrum Fig. 1, IR-spectrum Fig. 5. Yield of crude product with m. p. 74—75° 0.191 g (9 mole %).

By-products: The mother liquor from the crystallization of the cinnamyl phenyl sulfide was evaporated. The residue was washed with cold methanol in order to remove cinnamyl alcohol, and dried in vacuum. The yield was 0.310 g of yellow oil. It was dissolved in 20 ml carbon tetrachloride-petrolether 1:1 and chromatographed in a column containing 20 g of aluminium oxide (Brockmann). By elution with a total of 15 ml of carbon tetrachloride a small first fraction was obtained, which was dark violet in UV light and showed a m.p. 59—60°, undepressed on admixture of *diphenyl disulfide.*

By further elution with ether and alcohol containing carbon tetrachloride a liquid second fraction was obtained, which was lemon yellow in UV light. Yield 0.299 g. It was chromatographed anew with the same solvents. The Baeyer test was positive and the oil gave a red color in tetranitromethane. UV-spectrum Fig. 4. IR spectrum Fig. 6. (Found: C 73.11; H 6.60; S 13.23; mol. wt. (Beckm. cryosc.) 241. Calc. for $C_{15}H_{16}SO$: C 73.73; H 6.59; S 13.12; mol. wt. 244.)

Acetylation: 0.318 g of substance from another, quite similar experiment was heated 4 h on a water bath with 0.76 ml of acetic anhydride and 0.63 ml of pyridine, using a calcium chloride tube to exclude moisture. The reaction product was poured into 10 ml H_2O, was extracted with ether, washed with sodium hydrogen carbonate solution, dried, and, after evaporation, further dried in vacuum over phosphorus pentoxide. (Found: S 11.31; CH_3CO (according to Ref.[20]) 14.61. Calc. for. $C_{17}H_{18}SO_2$: S 11.20; CH_3CO 15.03.) The product is obviously V or VI.

b) *With aluminium sulfate.* 5.954 g (0.044 mole) of cinnamyl alcohol, 4.706 g (0.043 mole) of thiophenol and 0.359 g anhydrous aluminium sulfate were heated in a sealed glass tube 16 h at 127°. Here, as well as in the following syntheses c—e, the neutral reaction product was isolated in the same way as the cinnamyl phenyl sulfide at the photosynthesis. Yield 2.418 g of m.p. 75—76°. Repeated re-crystallization raised the m.p. to 78°, undepressed on admixture of cinnamyl phenyl sulfide from the photosynthesis.

c) *In acetic and sulfuric acid:* 15.342 g (0.114 mole) of cinnamyl alcohol and 12.669 g (0.115 mole) of thiophenol were refluxed 16 h in 100 ml acetic acid containing 10 ml 2 N H_2SO_4. The cinnamyl phenyl sulfide was isolated in the same way as at the photosynthesis. Yield 21.811 g with m.p. 74—76°, undepressed on admixture of sulfide from the photosynthesis. From the mother liquors liquid fractions were obtained by chromatography on aluminium oxide in about the same way as in the photosynthesis, giving the following data: yield 0.115 g, S 3.69, mol. wt. (Childs [21]) 361; 0.098 g, S 5.97; 0.044 g, S 9.65, mol.wt. (Childs) 344; UV spectra Fig. 4.

[1] All sulfur determinations were made titrimetrically according to Grote-Krekeler [19].

d) *From cinnamyl bromide in acetone:* 2.200 g (0.020 mole) thiophenol, 3.940 g (0.020 mole) of cinnamyl bromide, 2.800 g anhydrous potassium carbonate and 6 g acetone were refluxed 6 h. Yield 3.739 g cinnamyl phenyl sulfide of m.p. 74—75°, undepressed on admixture of sulfide from synthesis 1 a. The substance from the mother liquors (0.317 g of yellow oil) was chromatographed on aluminium oxide in carbon tetrachloride-toluene 1:1 and eluted with toluene containing amounts of ethyl ether rising successively from 10 to 50 %. The first fraction was small and showed a m.p. of 61°, undepressed on admixture of diphenyl disulfide. The second fraction was a yellow oil; yield 0.229 g, S 13.22. UV spectrum, Fig. 4, d.

e) *From cinnamyl bromide in benzene.* 7.615 g of cinnamyl bromide (0.0386 mole) and 4.275 g (0.0388 mole) of thiophenol were refluxed 4 h in 16 g benzene containing 5.41 g of anhydrous potassium carbonate. Yield of cinnamyl phenyl sulfide 6.329 g of m.p. 74—76°, after further recrystallization from ethanol 78°, undepressed on admixture of sulfide from 1 a.

2. Investigation of cinnamyl phenyl sulfide. Oxidation with hydrogen peroxide

a) *To sulfoxide.* 0.226 g (0.001 mole) cinnamyl phenyl sulfide were dissolved in 20 ml glacial acetic acid and 0.001 mole 30 % hydrogen peroxide were added with stirring. After the mixture had stood 5 days at room temperature, water was added. The precipitated yellow oil was dissolved in chloroform, washed with sodium hydrogen carbonate solution and dried. After evaporation in vacuum the residue crystallized on cooling to 0°. Yield of crude product 0.227 g (94 mole %); m. p. 90—91° after recrystallization three times from hot petrolether containing 5 % chloroform. (Found: S 13.18. Calc. for $C_{15}H_{14}SO$: S 13.23). UV spectrum, Fig. 3, X. 70 mg of the crude sulfoxide were not purified by recrystallization, but were chromatographed on aluminium oxide (Brockmann) with carbon tetrachloride as solvent and eluting first with carbon tetrachloride containing 5—20 % of ether and then with ether containing 10—20 % of ethanol. The main fraction melted at 76—78°. When a sample of this sulfoxide was recrystallized from hot petrolether containing 5 % chloroform it was transformed into a substance of m. p. 91.5—92°.

b) *To sulfone.* This oxidation was made in the same way as a), but using the double amount (0.002 mole) of 30 % hydrogen peroxide. The reaction product was isolated by the same method as the sulfoxide. Yield 0.236 g (92 mole %); m.p. 111—112° after recrystallization from ligroin; UV spectrum, Fig. 3, N. (Found: C 69.89; H 5.47; S 12.32. Calc. for $C_{15}H_{14}SO_2$: C 69.74; H 5.46; S 12.41.)

c) *Oxidation in UV light.* 0.226 g (0.001 mole) cinnamyl phenyl sulfide was dissolved in 10 ml acetone containing 0.004 mole of 30 % hydrogen peroxide, and was irradiated 10 days in a quartz test tube at 10 cm distance from a mercury lamp. The reaction product was isolated as the sulfone under 2b. M. p. 110—111°, undepressed on admixture of cinnamyl phenyl sulfone from synthesis 2b.

3. Oxidations with perbenzoic acid

a) *Oxidation of cinnamyl phenyl sulfide.* 0.452 g cinnamyl phenyl sulfide were weighed in an Erlenmeyer flask equipped with a ground glass stopper; 50 ml of 0.1249 M solution of perbenzoic acid in chloroform were added and allowed to stand at +3°, in a refrigerator together with a blank perbenzoic acid solution without sulfide. 5 ml samples of the oxidation mixture and the blank solution were titrated with sodium thiosulfate after addition of a potassium iodide solution acidified with acetic acid (Fig. 7). After 41.6 days the neutral reaction products were isolated from the benzoic acid-$CHCl_3$ solution after washing with sodium hydrogen carbonate solution and once with water, drying, evaporating and drying again in vacuum over phosphorus pentoxide. Yield 41 mg of an oil which was dissolved in 20 ml carbon tetrachloride and chromatographed in a column containing aluminium oxide (Brockmann). Only one band could be seen in ultraviolet light. Yield 34 mg, m. p. 109—111°, undepressed on admixture of cinnamyl phenyl sulfone from 2 b.

b) *Oxidation of cinnamyl phenyl sulfone.* 0.190 g cinnamyl phenyl sulfone were oxidized with 0.1429 M perbenzoic acid in $CHCl_3$ at room temperature during 42.6 days.

Thereafter the solution was washed with 5 ml cold water. The water layer was allowed to evaporate at 30° in a glass bowl. The residue, a clear, thickish liquid, was washed with 4 ml ether, and dried 5 h in vacuum over phosphorus pentoxide. Yield 119 mg; UV-spectrum, Fig. 8, 3b. The substance was neutralized with 0.2 N sodium hydroxide and a S-benzyl-thiuronium salt prepared in the usual way [22], m. p. after recrystallization three times from 50 % ethanol 143—145°, undepressed on admixture with S-benzyl thiuronium salt of benzenesulfonic acid of m. p. 147°.

4. Oxidation with permanganate

a) 1.706 g (0.007 mole) of cinnamyl phenyl sulfide were suspended in 60 ml 2 N sodium carbonate solution. 70 ml benzene and thereafter a solution of 4.762 g potassium permanganate in 200 ml water were added with stirring during 59 h. The manganese dioxide precipitate was filtered off and washed first with 2 N soda solution, then with hot water and at last with benzene. The mixed liquids were allowed to separate into a benzene and an alkaline water layer. The benzene layer was dried and evaporated in vacuum, the residue (neutral products) weighing 0.636 g. It was chromatographed on aluminium oxide (Brockmann) as described under 1 a. Three fractions were obtained in yields of 0.101, 0.326 and 0.099 g, m. p. 74—76°, 90—92°, 109—111°, undepressed on admixture of cinnamyl phenyl sulfide, sulfoxide and sulfone, respectively.

The soda alkaline layer was acidified (indicator Congo red) with 2 N sulfuric acid and extracted with ether. Drying and evaporation in vacuum gave a crystalline residue, which was purified by sublimation in vacuum; yield 0.495 g, m. p. 121°, undepressed on admixture of benzoic acid; UV-spectrum, Fig. 8 B.

b) 1.6108 g cinnamyl phenyl sulfide was oxidized with 4.495 g potassium permanganate as under 4 a. The soda-alkaline layer was passed through a cation exchanger Amberlite IR-120, the volume of the liquor so passed being 645 ml and the pH about 1. 150 ml of the solution was evaporated at about 30°, and dried over phosphorus pentoxide. Yield 235 mg; UV-spectrum, Fig. 8 MA. The mixture of acids (MA) thus obtained was chromatographed 16 h at 18° on Whatman paper No. 1 with 50 μg in each spot and *n*-butanol saturated with ammonium carbonate buffer [23] as mobile phase. The spots were developed with 0.1 N silver nitrate solution, or with phenol and 0.5 N sodium hydroxide according to Löffler [24]. Two spots were obtained corresponding to the R_F-values 0 and 0.30, respectively. Since the solution gave a barium salt insoluble in acidic solution, and the substance in the first spot did not give any characteristic UV-spectrum, and a blank chromatography of dilute sulfuric acid also gave $R_F = 0$, the first spot obviously corresponds to sulfuric acid. Parallel tests with benzoic and benzene sulfonic acid showed that both gave $R_F = 0.30$. Therefore an undeveloped spot with $R_F = 0.30$ from a new chromatogram was extracted twice with 5 ml ice-water, a treatment which dissolves benzene sulfonic acid, but leaves the benzoic acid practically undissolved. The UV-spectrum of the cold water eluate (Fig. 8, 4b) is identical with that of autenthic benzene sulfonic acid purified by paper chromatography. A fresh portion of the mixture of acids (MA) described was extracted with ether to remove benzoic acid. The residue (171 mg from 150 ml of acid solution) was converted to an S-benzyl thiuronium salt, m.p. after recrystallization three times from 50 % ethanol 143—145° undepressed on admixture of the corresponding derivative of authentic benzene sulfonic acid.

5. Degradation by hydrogenation

3.722 g cinnamyl phenyl sulfide dissolved in 400 ml aldehyde-free ethanol were refluxed 7 h with about 30 g Raney nickel. The nickel sulfide formed was filtered off and washed with alcohol and ether. Water was added to the filtrate, which was extracted five times with ether. The ether solution was dried with calcium chloride and distilled at 760 mm by means of a Skärblom-Linder column [25]. After the ether had distilled off, the following fractions were obtained: b.p. 79—80°, 0.765 g, UV-spectrum Fig. 8, Bz; b. p. 159—160°, 1.181 g, UV-spectrum Fig. 8, PP, n_D 1.4918 (18.4°C), and residue 0.061 g, UV-spectrum Fig. 8, R. The fraction of b. p. 79—80° was nitrated according to Ref.[26].

The reaction product after recrystallization from 50 % ethanol had m. p. 90°, undepressed on admixture of *m*-dinitrobenzene. The fraction of b. p. 159—160° was redistilled, 0.5 g of the distillate was nitrated and the nitration product reduced to a mixture of amines. This mixture was separated into monoamine and diamine, of which only the former gives an ether soluble salt with tin chloride in presence of hydrochloric acid. Both amines were acetylated, all according to [27]. The acetylated diamine was purified by chromatography on silica gel with chloroform and sublimation in vacuum, m. p. 207—208°. (Found: C 66.63; H 7.72; N 11.88. Calc. for $C_{13}H_{18}N_2O_2$: C 66.64; H 7.74; N 11.96). The acetylated monoamine was purified in a corresponding way, m. p. 97°. The corresponding authentic derivatives were prepared from phenyl propane obtained from benzyl magnesium chloride and diethyl sulfate according to Ref.[28]. No depression on the m. p. occurred on admixture of the two pairs of preparations.

A grant from *Statens naturvetenskapliga kommission* (Helsingfors) to one of us (Enkvist) is gratefully acknowledged.

Infrared Spectral Properties of Hydrogen Bonding Systems Containing Anions

HENNING LUND

Leo Pharmaceutical Products, Copenhagen, Denmark

It is found that hydrogen bonding of the type R—X—H...Y takes place in cases, where Y is an anion, and the spectral properties of a number of such systems are reported. The existence of this kind of hydrogen bonding systems explains the presence of a band about 3 300 cm^{-1} in the spectra of quaternary ammonium halides in a solution of chloroform stabilized with ethanol, but not found in pure chloroform solution.

Several investigations on infrared spectra of hydrogen bonding systems have been made and it is wellknown that hydrogen bonding affects the band about 3 μ attributed to the X-H stretching mode in three ways: The band shows a frequency shift $\Delta\nu$, it has an increased half intensity band width $\Delta\nu_{1/2}$ and the integrated absorption of the band is increased. Investigations of hydrogen bonding systems of the type R—X—H···Y have been made for systems in which X is oxygen, nitrogen or sulfur and Y is oxygen, nitrogen, sulfur or halogen.

No reports, however, seem to have been made on the spectral properties of hydrogen bonding systems in which Y is an anion. Kuhn [1] has shown that addition of dry hydrogen chloride to a solution of a diol in carbon tetrachloride solution weakens the band due to the internally bonding, whereas the free OH band remains unchanged. In the spectrum given (Ref.[1], p. 2497) there is a band about 3 300 cm^{-1} which in view of the results of the present investigation can be attributed to a hydrogen bonding system of the same kind as described here. The investigation of such systems might be of some value in the current discussion on "increased ionic character" [2] or "charge transfer" [3] as a model for explaining the high intensities of the hydrogen bonding stretching mode, and the spectral properties of a number of such systems are reported here.

RESULTS

Unfortunately only an instrument equipped with a sodium chloride prism was available for the investigation and more accurate values would have been obtainable if a lithium fluoride prism could have been used. The frequencies

are believed to have an uncertainty of about 20 cm^{-1} although the reproducibility is somewhat better, and the half intensity band widths are probably correct within 10—15 cm^{-1}. As a measure for the intensities of the bands were chosen the apparent integrated intensity $B = 2.303 \int \varepsilon_\nu \, d\nu$, which by assuming a Lorentzian shape of the band was approximated [4] to $B = (2.303/c \cdot l) \cdot \pi/2 \cdot \Delta\nu_{1/2} \cdot \log_{10} (T_0/T)$, where c is the concentration in mole/liter, l the cell length in cm, $\Delta\nu_{1/2}$ the apparent half intensity band width in wave number units and $\log_{10} T_0/T$ the apparent optical density. The validity of the approximation is open to discussion, but as the experimental conditions due to the poor dispersion of the rock salt prism in the 3 μ region were not the best obtainable a tedious graphical integration of the bands seemed not warranted. The integrated intensities of the bands were reproducible within 5 % and give a satisfactory internal measure for the band intensities.

In Table 1 are compiled the spectral properties of some O—H and N—H compounds (0.10 M) in carbon tetrachloride solution containing 10 mg/ml tetrabutylammonium bromide. In the first column are given the compounds, in the second one the apparent optical density of the band due to the hydrogen bonding system involving the bromide ion and in the third one the frequency in wave number units of the band. The apparent half intensity band width $\Delta\nu_{1/2}$ in wave number units and the apparent integrated absorption B in units of liters · $moles^{-1}$ · cm^{-2} are listed in column four and five, respectively, and in the last one are compiled the frequency shift $\Delta\nu$ between the band due to the monomer X—H stretching mode and the band due to the hydrogen bonded anion-complex.

The effect of varying the Y compound in a series of R—X—H···Y complexes containing the same proton donor was investigated and the spectral

properties of a few of such systems are listed in Table 2. The apparent molar volumes Φ of the anions [5] are included in the table. The spectra of the salts were obtained in chloroform solution containing 0.10 M *p*-cresol and the salt in a concentration corresponding to 10 mg/ml tetrabutylammonium bromide (0.031 M). The cations were in all cases tetrabutylammonium except for the chloride where benzyltributylammonium chloride was used. The spectra were measured in chloroform instead of carbon tetrachloride, as only a few of the salts were sufficiently soluble in carbon tetrachloride.

DISCUSSION

It appears from Table 1 that for the alcohols investigated there is a general trend towards greater $\Delta\nu_{1/2}$, $\Delta\nu$ and B as the acidity of the proton donor increases. The same tendency is found for the phenols as long as the hydroxyl group is not seriously sterically hindered. No simple correlation between $\Delta\nu_{1/2}$, $\Delta\nu$ or B and the acidity constant was, however, found. This is understandable as it may rather be the strength of the proton donor as a Lewis acid than as a Brønsted acid that would enter into such a correlation. It is especially for the sterically hindered phenols that the difference in acid strength as a Lewis acid and a Brønsted acid is noticeable, as the steric hindrance does not affect the proton donor as a Brønsted acid to any appreciable degree, whereas it seriously affects its ability to act as an electron acceptor. $\Delta\nu_{1/2}$ and $\Delta\nu$ increase from phenol through 2,4-dibromophenol to 2,4,6-tribromophenol, whereas the integrated intensity B remains nearly constant from phenol to 2,4-dibromophenol, but decreases significantly when going to the sterically more hindered 2,4,6-tribromophenol.

The lack of the relevant data on the strength of the proton donors as Lewis acids under the experimental conditions makes it difficult to substantiate the expected correlation, but it is a question whether the spectral properties of such systems are not the best accessible measure of the strength of the proton donors as Lewis acids.

In the amine series the most basic amine has the lowest integrated intensity and the least basic amine the highest in accordance with what was found for the alcohols and phenols. Whether the three bands found in the spectrum of diphenylamine are due to well defined polymeric complexes as found for methanol at low temperatures [6] is not known.

From Table 2 it can be seen that complexes containing the same proton donor but different anions have very different spectral properties. No explana-

tion of this difference in behaviour of the anions has been found, although it may be pointed out that for the inorganic ions there apparently is a connection between the apparent molar volumes Φ of the anions and the integrated intensities in such a way that B increases when the apparent molar volume Φ decreases.

The integrated intensities of the band due to the hydrogen bonded anion-complex are somewhat smaller in chloroform than in carbon tetrachloride solution, which might be explained by the greater tendency of chloroform to form molecular interactions similar to hydrogen bonding interactions with electron donors [7]. The competition between chloroform and *p*-cresol about the anions will lower the concentration of the *p*-cresol-anion complex thus diminishing the integrated intensity of the band relatively to its intensity in carbon tetrachloride.

Tsubomura [8] found a smooth curve by plotting $\Delta\nu$ against B for different acceptors and phenol as proton donor. The data from Table 2 do not fit such a correlation, but measurements obtained with better instruments are needed to give unambiguous results. Huggins and Pimentel [9] obtained a linear connection between $\Delta\nu$ and $\Delta\nu_{1/2}$ for a wide variety of hydrogen bonding systems. The spectra of the hydroxyl compounds fit such a relation as long as all sterically hindered compounds are disregarded.

Evidence of complexes of the type R—X—H···Y, where Y is an anion, have previously been found by Bartlett and Dauben [10] in the influence of phenols on the acid strength of hydrogen chloride in dioxane. The addition of a phenol to a solution of hydrogen chloride in dioxane enhanced the acid strength of the hydrogen chloride and this was explained by the assumption of the formation of a complex of the type R—O—H···Cl—H with an acid strength higher than that of hydrogen chloride in dioxane. It was generally found that the acidity of the complex was the higher the stronger the phenol was as an acid in water, but in certain cases as 2,4,6-trichlorophenol where steric hindrance may interfere the enhancement of the acidity obtained on addition of a certain amount of the phenol was not as great as would be expected from the acidity constant of the phenol in water. Alcohols did also increase the acidity of hydrogen chloride in dioxane, but to a lesser degree than did the phenols.

This is in agreement with the results of Swain [11] who measured the rate of the reaction between triphenylmethyl chloride and methanol in a benzene solution containing excess of pyridine. The reaction was found to be first order in triphenylmethyl chloride and second order in methanol. The addition of phenol, which alone reacts relatively slowly with triphenylmethyl chloride, caused one phenol molecule to replace one methanol in the third-order rate equation together with a sevenfold increase in the rate constant. *p*-Nitrophenol caused a greater than twentyfold increase in the rate. This was taken as evidence for the better ability of the phenols compared with methanol to solvate the leaving halogen by hydrogen bonding. It has further been found that it was impossible to dissolve 10 mg/ml tetrabutylammonium iodide in carbon tetrachloride, but the same concentration was readily obtainable when carbon tetrachloride containing 0.10 M *p*-cresol was used as the solvent.

By comparing the integrated intensities B and $\Delta\nu_{1/2}$ from this investigation with the data of Tsubomura [8] and Huggins and Pimentel [9] it appears that the strength of the hydrogen bonding from a hydroxyl compound to a bromide ion is between the strength of the hydrogen bonding from the hydroxyl compound to diethyl ether and to triethyl amine.

The existence of hydrogen bonding systems involving anions explains the presence of a band in the 3 μ region in the spectra of quaternary ammonium halides in a solution of chloroform stabilized with 1 % ethanol, as the ethanol forms hydrogen bonding to the halide ion. In a solution of quaternary ammonium halides in pure chloroform or chloroform stabilized with hexane no band appears in the infrared spectrum about 3 300 cm^{-1}.

EXPERIMENTAL

The spectra were recorded with a Beckman IR-2 single-beam infrared spectrophotometer equipped with a sodium chloride prism. The slit width used throughout the work was 0.095 mm and the cell length 0.40 mm. The spectra were obtained by first recording the spectrum of a solution of the proton donor in carbon tetrachloride and then the spectrum of the same solution containing the salt.

The carbon tetrachloride was Merck's analytical grade. The solution of *p*-cresol in chloroform was made from Riedel de Haën's analytical grade chloroform, which was washed five times with water, dried over calcium chloride and fractionated.

The tetrabutylammonium bromide was prepared by refluxing tributylamine with 10 % excess butylbromide in about 7 times the volume acetonitrile for two days. The solution then remained clear on cooling and the solvent was evaporated *in vacuo*. The residue was crystallized from chloroform-ether, and the resulting crystals, which contained chloroform, were recrystallized from tetrahydrofuran-ether, methanol-ether or benzene-ether. The bromide prepared in this way is transparent to ultraviolet light [12].

The tetrabutylammonium iodide was precipitated from an aqueous solution of the bromide with potassium iodide. The nitrate was prepared by metatesis in acetonitrile between silver nitrate and tetrabutylammonium bromide. The picrate was precipitated from an aqueous solution of the bromide.

The benzyltributylammonium chloride was prepared analogously to the tetrabutylammonium bromide in acetonitrile solution. It melts at 164—65°, solidifies and melts again at 170°. (Found: C 72.98; H 10.88; N 4.39; Cl 11.29. Calc. for $C_{19}H_{34}NCl$: C 73.17; H 10.98; N 4.49; Cl 11.36).

The O—H and N—H compounds were either commercially available or prepared according to wellknown procedures. They were purified by conventional means before use.

Determination of Rate Constants of Hydrolysis by a Distribution Technique and its Application to *iso*Propoxy-methyl-phosphoryl Chloride

LENNART LARSSON

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

An improved formula [1] for the determination of the distribution constant of a compound reacting with one of the phases according to a first order reaction is given. Based on this formula a method for the study of rapid hydrolyses is described. The application of the method is illustrated by the determination of the rate of the hydrolysis of *iso*propoxy-methyl-phosphoryl chloride, and its relationship to that of the corresponding fluorine derivative (Sarin) is discussed.

In an earlier paper [1] the author has deduced the following formula for the calculation of the distribution constant of a compound which reacts with one of the phases according to a first order or a pseudo-first order reaction:

$$\ln [A]_{aq} = - \frac{k \cdot t}{\frac{v_{org}}{v_{aq}} k_d + 1} + C \qquad (1)$$

where $[A]_{aq}$ = concentration of unhydrolysed compound in the aqueous phase;
C = integration constant;
k = reaction rate constant of A in water;
k_d = distribution constant of A between organic and aqueous phase;
t = time;
v = phase volume.

By plotting log $[A]_{aq}$ against t a straight line is obtained the slope of which, α, is

$$|\alpha| = \frac{0.4343\ k}{\frac{v_{org}}{v_{aq}} k_d + 1} \qquad (2)$$

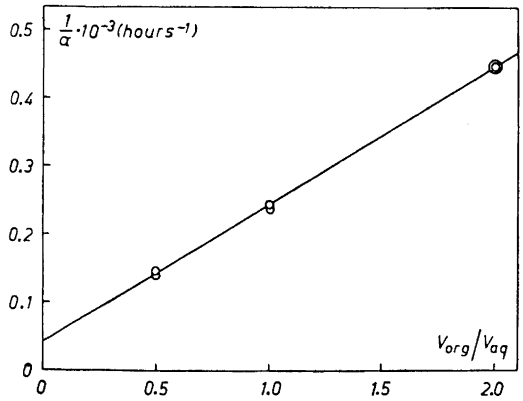

Fig. 1. The reciprocal of the rate of the hydrolysis of 2-methoxy-ethyl nicotinate at various ratios of xylene and water.

The application of the formula was illustrated by the determination of the distribution constant of the ester 2-methoxy-ethyl nicotinate between xylene and water. The rate constant of the hydrolysis was determined in a separate experiment. However, both the rate constant and the distribution constant can be determined simultaneously from a series of experiments where the ratios of the phase volumes are varied. If eqn. (2) is rearranged to

$$\frac{1}{|\alpha|} = \frac{k_d}{0.4343\ k} \cdot \frac{v_{org}}{v_{aq}} + \frac{1}{0.4343\ k} \qquad (3)$$

it appears that a straight line is obtained when $1/|\alpha|$ is plotted against v_{org}/v_{aq}. The rate constant, k, is thus obtained from the intercept of the ordinate and the distribution constant, k_d, from the slope of the line. This is illustrated in Fig. 1 by the example given in the previous paper [1]. As shown in Table 1, k and k_d determined in this way agree well with earlier results.

Table 1. The rate constant of the hydrolysis of 2-methoxy-ethyl nicotinate and its distribution constant between xylene and water.

	According to	
	eqn. (3)	previous paper [1]
k hours^{-1}	5.36×10^{-2}	5.07×10^{-2}
k_d	4.67	4.28

The problem can also be considered as a consecutive reaction *i.e.*:

$$A_{org} \underset{k_{aq}}{\overset{k_{org}}{\rightleftharpoons}} A_{aq} \xrightarrow{k_1} P$$

where P is a hydrolysis product. If this system is treated according to the improved steady-state approximation given by McDaniel and Smoot [2], and $k_{aq}/k_{org} = k_d$, then

$$\ln [A]_{aq} = - \frac{k_1 \cdot t}{\frac{v_{org}}{v_{aq}} \left(k_d + \frac{k_1}{k_{org}} \right) + 1} + C \qquad (4)$$

If $k_{org} >> k_1$ which is the case in slow reactions, eqn. (4) is reduced to eqn. (1). In rapid reactions none of the constants can be neglected and we get, analogously to eqn. (3)

$$\frac{1}{|\alpha|} = \frac{1}{0.4343} \left(\frac{k_d}{k_1} + \frac{1}{k_{org}} \right) \cdot \frac{v_{org}}{v_{aq}} + \frac{1}{0.4343\ k_1} \qquad (5)$$

Obviously from this equation, k_1 can be determined, by plotting $1/|\alpha|$ against v_{org}/v_{aq}; k_d, however, cannot be determined, because it is not possible to estimate k_{org}.

The distribution technique is particularly suitable for studies of rapid hydrolysis. The diminished rate due to the inert phase added permits measurements of reactions which in aqueous solutions run too fast for accurate determinations. The technique was therefore used in the determination of the rate constant of the hydrolysis of *iso*propoxy-methyl-phoshoryl chloride. The study of this hydrolysis forms part of an investigation of the influence of the substituents on the rate of hydrolysis of Sarin analogues [3]. *Iso*propoxy-methyl-phosphoryl chloride is assumed to hydrolyse according to a first-order reaction when the pH is maintained constant, and eqn. (5) is thus valid.

EXPERIMENTAL

Materials: *Iso*propoxy-methyl-phosphoryl chloride was synthesized by reacting methyl-phosphoryl dichloride [4] with *iso*propanol, and was freshly distilled before use. B.p. 51°C/4 mm Hg; n_D^{25} 1.4275; d_4^{25} 1.140.

Chloroform: E. Merck; anal. reagent.

Procedure: The rate of the hydrolysis of *iso*propoxy-methyl-phosphoryl chloride during the distribution between chloroform and a 0.100 M solution of potassium chloride was studied at pH 7.00 and 25.0°C. The pH was maintained constant by means of an automatic recording titrator [5] which was standardized before each run against a 0.05 M solution of potassium hydrogen *o*-phthalate (pH 4.01). A constant temperature, circulating water bath maintained the jacketed reaction vessel at ± 0.1°C or better.

A 0.80 mM stock solution of the compound in dry chloroform was prepared. Experiments were performed with four different ratios of the volumes of chloroform solution to aqueous solution as shown in Table 2. The total volume of each sample was 40 ml.

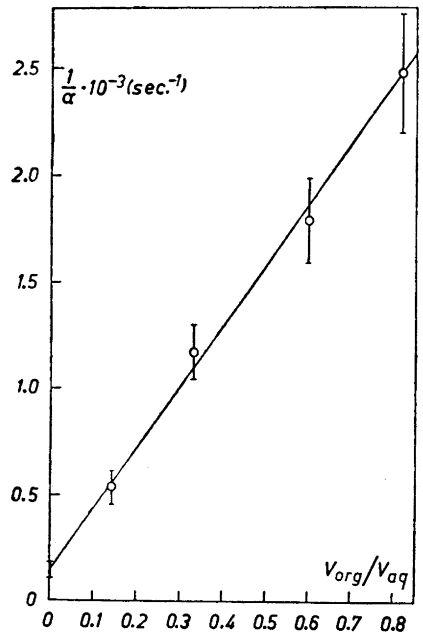

Fig. 2. The reciprocal of the rate of the hydrolysis of *iso*propoxy-methyl-phosphoryl chloride at various ratios of chloroform and water.

Table 2. Ratio of the volumes of chloroform solution to aqueous solution.

v_{org} / v_{aq}	5 : 35	10 : 30	15 : 25	18 : 22

The aqueous solution was in advance adjusted to the desired pH. The addition of pure chloroform to the aqueous solution has no influence upon pH. Each set of experiment was repeated five times. Some difficulties arose in getting a suitable speed of the magnetic stirrer. Too rapid stirring caused great fluctuations of pH during the run owing to chloroform splashing over the electrodes and shielding them. On the other hand slow stirring did not permit equilibrium to be attained. With a few exceptions the variations of pH during the runs were ± 0.1 or less. The products formed in the hydrolysis, hydrochloric acid and *iso*propoxy-methyl-hydroxy-phosphine oxide, are assumed to be completely soluble in the aqueous phase at the actual pH. The curves obtained were treated according to Guggenheim [6]. Straight lines were obtained the slopes of which were calculated. The straight lines indicate that no appreciable association did occur in the chloroform phase [1].

RESULTS AND DISCUSSION

When $1/|\alpha|$ is plotted against v_{org}/v_{aq} for the hydrolysis of *iso*propoxy-methyl-phosphoryl chloride in various ratios of chloroform and water at pH 7.00 a straight line is obtained as shown in Fig. 2. The equation of the line was calculated by the method of least squares with weighted values (9:5:2:1). The intercept of the ordinate of the line was found to be (0.151 ±

0.041) $\times 10^3$ which corresponds to a rate constant of the hydrolysis of $(1.5 \pm 0.4) \times 10^{-2}$ sec.$^{-1}$.

If it is assumed that the rate of the hydrolysis of *iso*propoxy-methyl-phosphoryl chloride is proportional only to the hydroxyl ion concentration as is valid for Sarin [3], the bimolecular rate constant, k_2, would be 1.2×10^5 1 mole^{-1} sec.$^{-1}$, *i.e.* 5×10^3 times greater than that of the fluorine derivative (Sarin). Because of the greater electronegativity of fluorine which makes the phosphours atom more electron deficient and positive, the formation of the P-OH bond is facilitated more in the fluorine than in the chlorine compound. By using Pauling's values of electronegativity of P, Cl and F a rough calculation according to Hannay and Smyth [7] shows that the P—F and P—Cl bonds are 43 and 17 % ionic, respectively. If the difference in the ionic character of the bonds is the rate determining factor, one would expect that the fluorine compound would hydrolyse more rapidly than the chlorine compound. The considerably greater hydrolytic stability of the fluorine derivative may, however, be ascribed principally to the higher bond energy of the P—F bond, 120 kcal/mole, in comparison with that of the P—Cl bond, 80 kcal/mole [8].

The author is indebted to Professor G. Ljunggren, Director of this Institute, for the kind interest he has shown in this work. The author wishes also to express his thanks to Fil.lic. K.-E. Almin, Swedish Forest Products Research Laboratory, for valuable discussions.

An Investigation of the Me_5Si_3-MeSi Region of the Mn-Fe-Si and some Related Systems

BERTIL ARONSSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

From X-ray diffraction data it has been concluded that there is a Me_5Si_3-MeSi two phase region in the Mn—Fe—Si systems at 950°C. The lattice parameters of the MeSi and Me_5Si_3 phases as functions of composition have been determined as well as tie lines in the two phase region. Some observations on the corresponding part of the Cr—Mn—Si, Cr—Fe—Si and Cr—Co—Si systems have been made.

It has been found that the metal with the higher atomic number is enriched in the cubic MeSi phase which is the Si richest phase present in the investigated region of the systems mentioned. The relation of the lattice parameter variations of the Me_5Si_3 phases to the morphotropy of these phases is discussed.

The physical and chemical properties of the borides, carbides and nitrides of the first transition series metals show that the stability of these compounds decreases with increasing atomic number of the metal [1,2,21,22]. In accordance with this decrease in transition metal-non metal "affinity" it has been observed that in Me_1-Me_2-X systems (Me = transition metal from the first transition series, X = nonmetal) the metal with the lower atomic number is concentrated in the X richest phase present [3–6]. This was found to be so in the Me_2B-MeB two phase region of Me_1-Me_2-B systems, in which Hägg and Kiessling [6] determined the distribution of various metal pairs between the two phases mentioned. They found that the larger the difference in atomic number of the metals the more pronounced was the enrichment of the lower atomic number metal in the MeB phase.

In order to see if similar trends were displayed by Me_1-Me_2-Si systems, the Me_5Si_3-MeSi section of some ternary silicide systems has been studied. From older work it is known that Mn_5Si_3 [7] and Fe_5Si_3 [8] as well as MnSi [9] and FeSi [10] are isomorphous. Preliminary experiments indicated that there was a Me_5Si_3-MeSi two phase region in the Mn-Fe-Si systems. The main interest has been devoted to this system as the distribution of the Mn and Fe atoms could be determined in the same way as in the ternary boride systems [6].

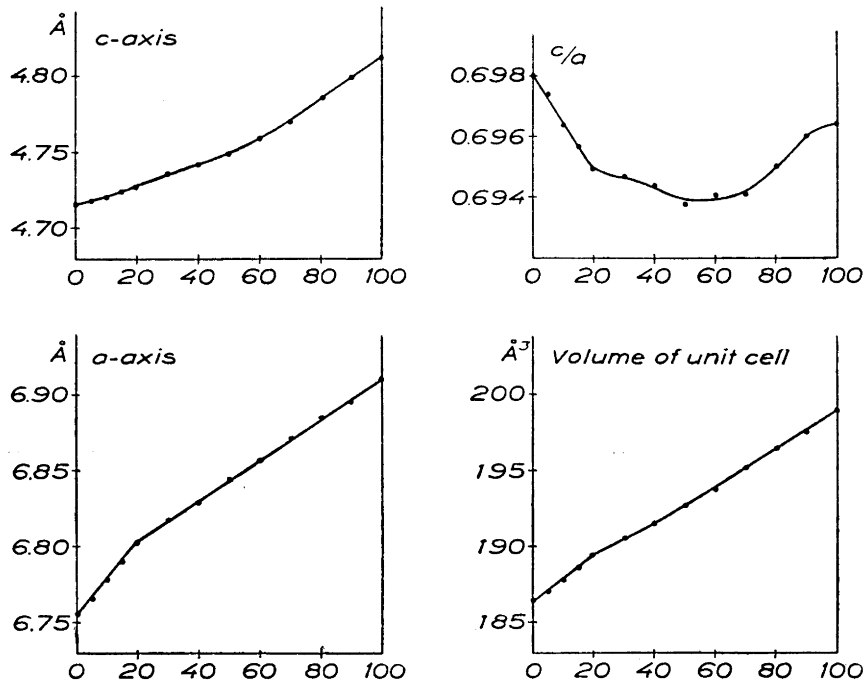

Fig. 1. Unit cell dimension of the Me_5Si_3 phase as function of the atomic ratio Mn/(Mn + Fe) × 100.

In connexion with these investigations information has been collected about the variation of the lattice parameters (l.p.) of the Me_5Si_3 phases with composition. Some relation between these l.p. variations and the morphotropy among the Me_5Si_3 phases has been found and is discussed in the last part of this paper.

EXPERIMENTAL

Weighed amounts of the elements in powder form (claimed purity $\geq$ 99.8 % except for Co which contained 0.45 % Ni) were melted twice in an arc furnace and subsequently annealed in evacuated silica tubes for 8 days at 950°C. As it was found that the compositions obtained from chemical analysis deviated very little from the nominal composition only six alloys were analysed. The analyses added up to 99.2 $\pm$ 0.5 %.

24 alloys were made in the Mn—Fe—Si system, 13 on the Me_5Si_3 line (4 analysed), 4 on the MeSi line (2 analysed) and 7 with compositions $MeSi_{0.75}$ or $MeSi_{0.80}$. Four of the Me_5Si_3 alloys contained traces of a (FeMnSi) and one of (Mn, Fe)Si. For these alloys the Mn/Fe ratio in the Me_5Si_3 phase may be slightly different from that in the alloy. However, this difference was estimated to be too small to affect the l.p. of Me_5Si_3 significantly. In each of the Cr—Me′—Si systems (Me′ = Mn, Fe, Co) four alloys were made with compositions $Cr_{0.2}$ $Me'_{0.8}$ $Si_{0.63}$, $Cr_{0.4}$ $Me'_{0.6}$ $Si_{0.63}$, $Cr_{0.6}$ $Me'_{0.4}$ $Si_{0.63}$ and $Cr_{0.8}$ $Me'_{0.2}$ $Si_{0.63}$.

Powder photographs were taken in a Guinier type focussing camera, using Cr$K\alpha$-radiation. All powder samples were mixed with some CaF_2 before the exposure and the l.p. which are thought to be reliable to about $\pm$ 0.03 % are given assuming the cube edge of CaF_2 to be 5.4630 Å [11] at 21°C.

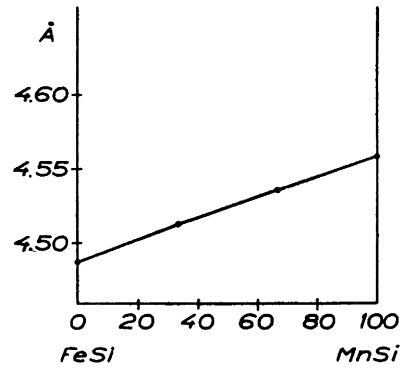

Fig. 2. Cube-edge of the MeSi phase as function of the atomic ratio Mn/(Mn + + Fe) × 100.

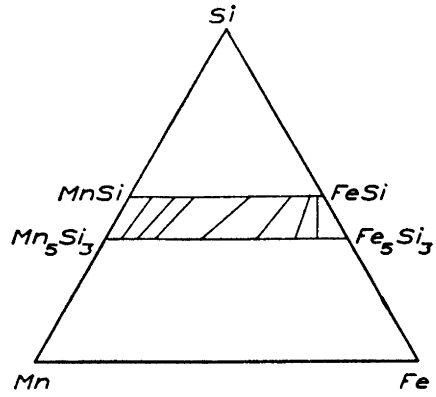

Fig. 3. Some tie lines in the Me_5Si_3-MeSi region of the Mn—Fe—Si system at 950°C.

RESULTS

The Mn-Fe-Si system. All the Me_5Si_3 alloys showed sharp and unsplit powder lines corresponding to the $D8_8$-structure [8]. The variations of the unit cell constants with composition are given in Fig. 1. It was concluded that, at 950°C, the Me_5Si_3 line in the Mn-Fe-Si system is a single phase line (or very nearly so). Similarly it was found that the MeSi line is a single phase line (Fig. 2). For the alloys in the two phase region the l.p. (lattice parameters) of the two phases were determined. From the curves in Fig. 1 and 2 the composition of the two phases in equilibrium with each other was obtained and tie-lines in the Me_5Si_3-MeSi two phase region could be drawn (Fig. 3).

The distribution ratios have been defined and determined as in the paper by Hägg and Kiessling [6]. Let x'_{Mn} be the atomic fraction Mn/(Mn + Fe) and x'_{Fe} the atomic fraction Fe/(Mn + Fe) in the Me_5Si_3-phase. x''_{Mn} and x''_{Fe} are the corresponding fractions in the MeSi phase. In order to be ≤ 1 the distribution ratios are defined as $\alpha_{Mn} = x''_{Mn}/x'_{Mn}$ and $\alpha_{Fe} = x'_{Fe}/x''_{Fe}$. The variations of the distribution ratios as function of $(x'_{Mn} + x''_{Mn})/2$ are given in Fig. 4.

As seen from Fig. 3 and 4, iron is enriched in the MeSi phase. At small Fe concentrations about twice as much iron will be found in this phase as in the Me_5Si_3 phase.

The Cr-Me'-Si systems (Me' = Mn, Fe, Co). Besides the cubic MeSi phase the (Cr, Mn)$Si_{0.63}$ and (Cr, Fe) $Si_{0.63}$ alloys were found to contain Cr_5Si_3 with dissolved Mn or Fe (T 1 (W_5Si_3)-type structure) [12–14] and (or) Mn_5Si_3 (Fe_5Si_3) with dissolved Cr ($D8_8$-type structure [7]). In these systems there are probably a T 1-MeSi two phase region, a T 1-$D8_8$-MeSi three phase region and a $D8_8$-MeSi two phase region. The composition of the MeSi phase could be estimated from its l.p. which was assumed to vary according to Vegard's law from

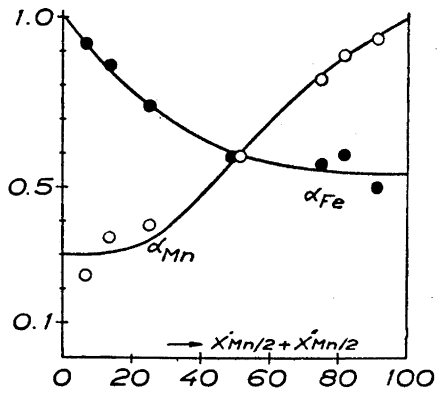

Fig. 4. The distribution ratios α_{Fe} and α_{Mn} as function of $(x'_{Mn} + x''_{Mn})/2$ (See text).

CrSi to MnSi and from CrSi to FeSi. It was found that Mn and Fe, respectively, were enriched in this phase and this enrichment was more marked for Fe.

In all the (Cr, Co)$Si_{0.63}$ alloys the MeSi phase had a cube edge of 4.449 ± 0.004 Å which corresponds closely to that of pure CoSi (4.447 Å) [9]. Therefore, in the Cr-Co-Si system practically pure CoSi is in equilibrium with some Si poorer phase (or phases).

Thus, it has been found that in the investigated part of the Cr-Me'-Si systems the metal with the higher atomic number is concentrated in the MeSi phase.

The l.p. vs composition curves. The unit cell constants of the $D8_8$ phase vary quite irregularly from Mn_5Si_3 to Fe_5Si_3. Especially remarkable is the variation of c/a which goes through a minimum at about $(Fe_{0.5}Mn_{0.5})_5Si_3$. No careful determinations of l.p. variations of the Me_5Si_3 phases in the other systems were made but it was observed that when Cr was dissolved in Mn_5Si_3 or Fe_5Si_3 there was a decrease in c/a for the $D8_8$ phase while the solution of Mn or Fe in Cr_5Si_3, on the contrary, increased the c/a ratio for the latter phase.

DISCUSSION

This study of the Me_5Si_3-MeSi region of some Me_1-Me_2-Si systems (Me = Cr, Mn, Fe, Co) has revealed regular trends in the distribution of the metals: The larger the difference in their atomic number the more pronounced is the enrichment of the *higher* atomic number metal in the MeSi phase. This behaviour is opposite to that found in ternary boride and carbide systems of the same metals: In these systems the *lower* atomic number metal is always concentrated in the nonmetal richest phase. Results of investigations of this type certainly depend on the parts of the ternary systems which are actually studied and no farreaching conclusions can be drawn from the above observations. It seems, however, as if the silicides of Cr, Mn, Fe, Co do not show the same decrease in stability with increasing atomic number of the metal as do the borides, carbides and nitrides.

The l.p. variations of the T 1 and $D8_8$ phases may be worth a few comments. Of the Me_5Si_3 silicides of the first series transition elements Ti_5Si_3 [15], Mn_5Si_3 [7] and Fe_5Si_3 [8] have the $D8_8$ structure while V_5Si_3 [16] and Cr_5Si_3 [13] have the T 1 (W_5Si_3) structure. In the presence of small amounts of carbon, V_5Si_3 (C) [17] and Cr_5Si_3(C) [18] also crystallize in the $D8_8$ structure. The Me_5Si_3 phases belong to a group of phases the structures of which are characterized by straight rows of atoms. In the T 1 and $D8_8$ phases these rows run parallel to the c-axis and the smaller c/a-value these phases have, the shorter are the interatomic distances in the rows ($= c/2$) compared with the average interatomic distances in the structure. Looking at the c/a values of the $D8_8$ phases (V_5Si_3 and Cr_5Si_3 contain some C) we see that the smallest values are found for V and Cr

		Ti	V	Cr	Mn	Fe
$D8_8$	c/a	0.691	0.679	0.676	0.696	0.698
	$c/2$	2.59 Å	2.42 Å	2.36 Å	2.41 Å	2.36 Å
T 1	$c/2$		2.38 Å	2.30 Å		

This gives sense to the fact that c/a for Mn_5Si_3 and Fe_5Si_3 decreases (to about 0.684 and 0.693, respectively) when Cr is dissolved in these phases. It is also compatible with the general observation that rows with the closest contacts between the row atoms are formed by the Va and VIa groups metals (*e.g.* in phases of the β-W and σ-type).

As seen from the table the distances between row atoms ($= c/2$) in the V_5Si_3 and Cr_5Si_3 T 1 phases are still shorter than in the $D8_8$ phases of these metals, which indicates that the atomic arrangement in the T 1 structure is such that the row atoms are closer to each other than they would be in a $D8_8$ structure of the same elements. The Va and VIa group metals being those which form rows with the shortest contact, it is not surprising that the T 1 structure is chosen by V_5Si_3 and Cr_5Si_3 while Ti_5Si_3, Mn_5Si_3 and Fe_5Si_3 crystallize in the $D8_8$ structure.

In a number of investigations it has been shown that several $D8_8$ phases only exist as ternary phases [*e.g.* V_5Si_3 (C) [17] and Cr_5Si_3 (C) [18]] containing small amounts of a third component (B, C, N or O) [19,20]. It is possible that Ti_5Si_3, Mn_5Si_3 and Fe_5Si_3 are in reality ternary phases, too, owing their existence to the presence of small non metals such as C, N or O, but this has not yet been proved.

Acknowledgement. The author wants to thank Professor Hägg who has kindly read the manuscript. I am also indebted to Mr. S. Rundqvist for many stimulating discussions and Dr. Lilly Gustafsson for analytical assistance.

A grant from the *Swedish State Council for Technical Research* is gratefully acknowledged.

On the Reaction between Substituted Malonic Esters and Methylene Bromide. I

LENNART EBERSON

Department of Organic Chemistry, Chemical Institute, University of Lund, Sweden

Diethyl methyl-, ethyl-, *n*-propyl-, *iso*propyl-, *n*-butyl-, *iso*butyl-, *n*-amyl-, benzyl-, and acetaminomalonates in the form of their sodium compounds react with methylene bromide in ethanolic solution to form 1,3-disubstituted 1,1,3-tricarbethoxypropanes with the elimination of *one* carbethoxy group as diethyl carbonate, whereas diethyl phenyl- and carbethoxymalonate give 1,3-disubstituted 1,3-dicarbethoxypropanes with the elimination of *two* carbethoxy groups. Diethyl *neo*pentylmalonate yields *α-neo*pentylacrylate, and diethyl *tert.*-butylmalonate and ethyl phenylacetate give no reaction. A reaction scheme is proposed. The preparation of the corresponding glutaric acids from the esters above is described.

The present investigation deals with the reaction between substituted malonic esters and methylene bromide and its use for the preparation of $\alpha\alpha'$-disubstituted glutaric acids. The author has previously found [1] that when the sodium compound of diethyl trimethylsilylmethylmalonate (I, R = $(CH_3)_3SiCH_2$) was allowed to react with methylene bromide in ethanolic solution a triethyl ester was obtained according to formula (1):

$$2\ \underset{\text{I}}{R.CH(COOEt)_2} + CH_2Br_2 + 2\ OEt^- \longrightarrow \underset{\text{II}}{\begin{matrix} R.C(COOEt)_2 \\ | \\ CH_2 \\ | \\ R.CHCOOEt \end{matrix}} + EtOH + (EtO)_2CO + 2\ Br^- \qquad (1)$$

i.e., one carbethoxy group was eliminated. Attempts to prepare the tetraethyl ester by carrying out the synthesis in an inert solvent (toluene or xylene) at a higher temperature resulted in the formation of diethyl bromomethyl-tri-

methylsilylmethylmalonate (III, R = $(CH_3)_3SiCH_2$) which did not react further with a second molecule of I:

$$R.C(Na)(COOEt)_2 + CH_2Br_2 \xrightarrow[140°]{\text{xylene}} R.C(CH_2Br)(COOEt)_2 + NaBr \quad (2)$$

III

An examination of the literature on similar reactions yielded incomplete and with the above result incompatible information, and therefore a more detailed study of the reaction was undertaken. Guthzeit and Dressel [2,3] stated that diethyl malonate and methylene iodide gave 1,1,3,3,-tetracarbethoxypropane in about 80 % yield, diethyl ethylmalonate and methylene iodide a mixture boiling over a large interval [3], and diethyl benzylmalonate and methylene iodide 1,3-dibenzyl-1,1,3,3-tetracarbethoxypropane [3]. Diethyl methylmalonate and methylene iodide gave 1,3-dimethyl-1,1,3,3-tetracarbethoxypropane according to Bischoff [4] and von Auwers [5]. Diethyl acetaminomalonate did not react with methylene iodide [6]. Souther [7] found that diethyl phenylmalonate and methylene iodide reacted according to formula (3):

$$2\ R'.CH(COOEt)_2 + CH_2I_2 + 2\ OEt^- \longrightarrow$$

$$\begin{array}{l} R'.CHCOOEt \\ \quad | \\ \quad CH_2 \\ \quad | \\ R'.CHCOOEt \end{array} + 2\ (EtO)_2CO + 2\ I^- \quad (3)$$

IV ($R' = C_6H_5$ or COOEt)

i.e., two carbethoxy groups were eliminated. However, of the above statements only the first- and last-mentioned were wholly established while the others were not demonstrated satisfactorily.

The following substituted malonic esters were investigated with respect to their reaction with methylene bromide in ethanolic solution: diethyl methyl-, ethyl-, *n*-propyl-, *iso*propyl-, *n*-butyl-, *iso*butyl-, *tert.*-butyl-, *n*-amyl-, *neo*pentyl-, phenyl-, benzyl-, carbethoxy-, and acetaminomalonate. Ethyl phenylacetate was also investigated.

Diethyl methyl-, ethyl-, *n*-propyl-, *iso*propyl-, *n*-butyl-, *iso*butyl-, *n*-amyl-, benzyl-, and acetaminomalonate all reacted according to formula (1) to yield the triesters II. To establish that the inconsistency with the statements from the literature was not due to the nature of the halogenide, methylene iodide was also used in the reaction with diethyl methyl-, ethyl-, and benzylmalonate. However the same result was obtained. Diethyl *tert.*-butylmalonate and ethyl phenylacetate did not give any reaction at all, whereas diethyl *neo*pentylmalonate reacted according to formula (4):

$$(CH_3)_3CCH_2CH(COOEt)_2 + CH_2Br_2 + 2\ OEt^- \longrightarrow$$

$$\begin{array}{l} (CH_3)_3CCH_2C{=}CH_2 \\ \qquad\quad | \\ \qquad\quad COOEt \end{array} + EtOH + (EtO)_2CO + 2\ Br^- \quad (4)$$

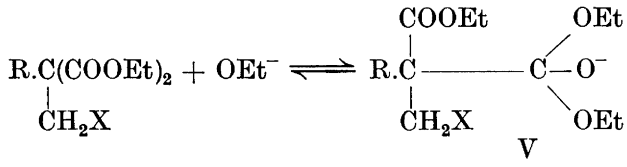
The ethyl *α-neo*pentylacrylate was identified by conversion to the corresponding acid, which was known from the work of Hadley *et al.*[8] Diethyl phenylmalonate and tricarbethoxymethane reacted according to formula (3).

A few bromomethyl-alkylmalonates (III, R = CH_3, C_2H_5, *n*-C_5H_{11}, and *neo*-C_5H_{11}) were prepared in toluene solution with excess of methylene bromide. These compounds were thermally stable up to 300°C. III, R = CH_3, reacted with the sodium compound of diethyl methylmalonate to give II, R = CH_3.

The triethyl esters with R = methyl, ethyl, and *iso*propyl were hydrolyzed and decarboxylated directly by boiling with 70—80 % sulphuric acid, while that with R = acetamino was converted into *αα'*-diaminoglutaric acid according to the method of Hellman, Lingens, and Folz[6]. The other compounds were hydrolyzed by boiling with 10 % ethanolic potassium hydroxide (the acid hydrolysis was not used on account of the insolubility of the acids formed in this medium) and the tricarboxylic acids could then easily be decarboxylated by heating to 160—170°. The glutaric acids could be separated into high- and low-melting forms by fractionated crystallization from suitable solvents.

DISCUSSION

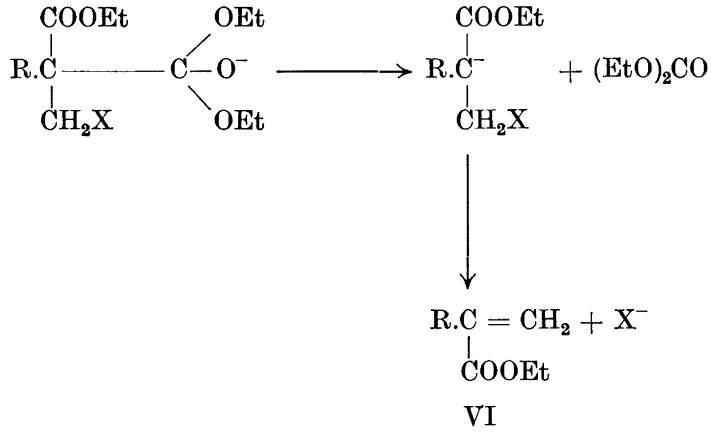
The first step in the reaction between a methylene halogenide and a substituted malonic ester in ethanol must be the formation of a bromomethylmalonic ester (III) according to formula (2). The next step is the reaction of an ethoxide ion with III to form the intermediate anion V which then decomposes into an *α*-substituted acrylic ester (VI) with the



(5)

V

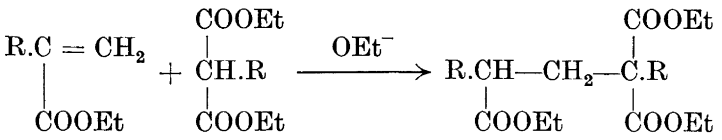
elimination of one molecule of diethyl carbonate and one halide ion:



(6)

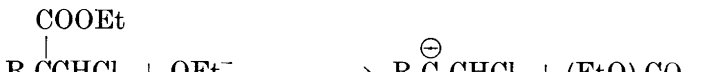
VI

The last stage consists of a Michael addition of VI to a second molecule of the malonic ester (7):

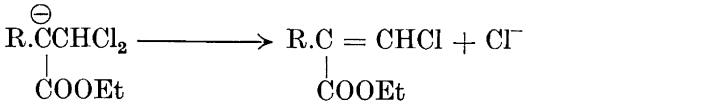


(7)

There is much evidence which favours the above reaction sequence. The formation of the bromomethylmalonic ester III is usually difficult to accomplish in ethanolic solution even with a large excess of methylene halogenide as it immediately reacts further with ethoxide ion. However, when R is a bulky group as trimethylsilylmethyl, the bromo compound can be isolated in good yield [1]. This is not possible with malonic esters containing small R groups (*e.g.* methyl or ethyl). A compound of the type III possesses a *neo*pentyl structure and thus is very unlikely to react according to an S_N2-mechanism with an $R.\bar{C}(COOEt)_2$-ion. Instead the bromomethyl group, being an electronegative substituent, promotes the elimination of a carbethoxy group by ethoxide ion. This cleavage reaction has been found to be enhanced by other electronegative groups such as the phenyl [9–11], nitro [12], vinyl [13], 2,4-dinitrophenyl [14], 2- or 3-indenyl [15], and dichloromethyl group [16]. The behaviour of dichloromethyl-alkylmalonic esters towards ethoxide ion has been studied by Bowman and Rexford [16] and they proposed the following reaction mechanism for the reaction:



(8)



(9)

Reactions (8) and (9) are analogous to (5) and (6).

The elimination of two carbethoxy groups when R is phenyl or carbethoxy, *i.e.*, an electronegative substituent, is readily explained by the reactions (10), (11), and (12):

(10)

(11)

$$\begin{array}{l} \mathrm{R'.C(=CH_2).COOEt} \\ \mathrm{R'.CH_2COOEt} \end{array} \xrightarrow{\mathrm{OEt^-}} \begin{array}{l} \mathrm{R'.CHCOOEt} \\ \mathrm{CH_2} \\ \mathrm{R'.CHCOOEt} \end{array} \qquad (12)$$

$(\mathrm{R'} = \mathrm{C_6H_5}$ or COOEt)

The alternative route whereby a malonic ester of this type first reacts according to formula (11) and then according to (13)

$$2\ \mathrm{R'CH_2COOEt} + \mathrm{CH_2X_2} + 2\ \mathrm{OEt^-} \longrightarrow \begin{array}{l} \mathrm{R'.CHCOOEt} \\ \mathrm{CH_2} \\ \mathrm{R'.CHCOOEt} \end{array} + 2\ \mathrm{X^-} + 2\ \mathrm{EtOH} \qquad (13)$$

$(\mathrm{R'} = \mathrm{C_6H_5}$ or COOEt)

can be ruled out in the case of R′ = phenyl, as ethyl phenylacetate fails to react with methylene bromide. This is not so in the case of R′ = carbethoxy, however, where both reaction paths are possible.

The isolation of the intermediate α-substituted acrylic ester has been accomplished for R = *neo*pentyl. It is possible that this reaction may be used as a good preparation method for such compounds after certain modifications, but no experiments in this direction have yet been undertaken.

The last step (7) has been demonstrated for R = methyl by von Auwers and Köbner [17], Hoch and Karrer [18], and Ruhl [19].

As a general preparation method for αα′-disubstituted glutaric acids the reaction has several advantages over the existing ones. The starting materials are easily available and the reaction products are easy to isolate and purify. The most serious limitation is the failure of malonic esters containing bulky R groups (such as *tert.*-butyl and *neo*pentyl) to react. The unreactivity of diethyl *tert.*-butylmalonate may in part be due to the considerably reduced acidity of this compound in ethanolic solution as compared with *n*-alkylmalonic esters.

EXPERIMENTAL

All reagents used were carefully dried and fractionated in a glass-helix packed column of about ten theoretical plates. In the malonic ester syntheses precautions were taken to exclude moisture from the reaction vessels. Determinations of the melting points were made with a Kofler micro hot stage. The analyses were carried out at the Department of Analytical Chemistry, Chemical Institute, Lund.

1,3-Dimethyl-1,1,3-tricarbethoxypropane (II, R = CH_3). To a solution of 4.6 g (0.2 mole) of sodium in 80 ml of absolute ethanol 34.8 g (0.2 mole) of diethyl methylmalonate was added, followed by 17.4 g (0.1 mole) of methylene bromide. The reaction mixture was boiled for 20 h after which time it was almost neutral. It was neutralized with a few drops of glacial acetic acid, the ethanol was distilled off through a short column, and water added to dissolve the sodium bromide. The organic layer was taken up in

ether, the ether solution washed with water, and finally dried with anhydrous magnesium sulphate. After distilling off the ether the residue was distilled *in vacuo*. This method yielded 7.5 g (64 %) of diethyl carbonate, b. p. 65—70°/60 mm, and 24.0 g (83 %) of 1,3-dimethyl-1,1,3-tricarbethoxypropane, b. p. 153—154°/11 mm, n_D^{20} 1.4343, d_4^{20} 1.0471, r_D 0.2489. Möller [20] reported b. p. 156—158°/15 mm for the same compound prepared from diethyl methylmalonate and ethyl α-bromo*iso*butyrate, and Ruhl [19] reported b.p. 142—145°/5 mm for a sample prepared from diethyl methylmalonate and ethyl methacrylate.

The reaction was also carried out with methylene iodide instead of the bromide. Diethyl carbonate was obtained in 61 % yield and the triester in 87 % yield.

α,α'-Dimethylglutaric acid. The 1,3-dimethyl-1,1,3-tricarbethoxypropane was hydrolyzed by boiling with 70 % sulphuric acid until the oily layer had disappeared which required about 5 h. The solution was cooled in ice and the solid was filtered and washed with a small amount of ice water. After drying in a vacuum desiccator the yield of the crude acid mixture was 92 %. The separation into diastereoisomers was made according to Möller [20]. A high-melting form was obtained, m. p. 140—141°, in 30 % yield, and a low-melting, m. p. 125—127°, in 37 % yield. Möller reported 139—140° and 127°, respectively [20].

Diethyl bromomethyl-methylmalonate. To a mixture of 23.0 g of 20 % sodium-toluene dispersion and 100 ml of dry toluene there was added 0.2 mole of diethyl methylmalonate at such a rate that the reaction mixture boiled gently. 0.4 mole of methylene bromide was added in one portion and the mixture was boiled with stirring for 3 h. After cooling water was added, the toluene solution separated, washed with water, and dried with anhydrous magnesium sulphate. Distillation yielded 38.0 g of diethyl bromomethyl-methylmalonate (71 %), b. p. 98—100°/3 mm, n_D^{20} 1.4503, d_4^{20} 1.3085. (Found: C 40.7; H 5.8; Br 29.7; r_D 0.2055. Calc. for $C_9H_{15}O_4Br$: C 40.5; H 5.7; Br 29.9; r_D 0.2051.)

Reaction between diethyl bromomethylmethylmalonate and diethyl methylmalonate. 0.2 mole of sodium was dissolved in 70 ml of absolute ethanol, 0.2 mole of diethyl methylmalonate added and finally 0.2 mole of diethyl bromomethyl-methylmalonate dropped into the warm solution during a period of 30 min. The reaction mixture was boiled for 20 h and then worked up in the usual way. A 61 % yield of diethyl carbonate and an 85 % yield of II, R = CH_3, were obtained.

1,3-Diethyl-1,1,3-tricarbethoxypropane (II, R = C_2H_5). This compound was prepared as the methyl derivative from 0.2 mole of sodium in 80 ml of absolute ethanol, 0.2 mole of diethyl ethylmalonate, and 0.1 mole of methylene bromide. The reaction yielded 7.2 g (61 %) of diethyl carbonate and 20.8 g (66 %) of 1,3-diethyl-1,1,3-tricarbethoxypropane, b.p. 144—145°/4 mm, n_D^{20} 1.4395, d_4^{20} 1.0321. (Found: C 60.4; H 9.1; r_D 0.2551. Calc. for $C_{16}H_{28}O_6$: C 60.7; H 8.9; r_D 0.2566.)

When methylene iodide was used in the above reaction, a 46 % yield of diethyl carbonate and a 56 % yield of triester were obtained.

α,α'-Diethylglutaric acid. 1,3-Diethyl-1,1,3-tricarbethoxypropane was hydrolyzed by boiling over night with 75 % sulphuric acid. The yield of crude acid mixture was 90 %, and it was separated into diastereoisomers according to the method of Berner and Landmark [21]. The high-melting acid was obtained in 32 % yield, m. p. 118—121°, and the low-melting one in 25 % yield, m. p. 92—94°. Berner and Landmark reported 119—120° and 93.5—94.5°.

Diethyl bromomethyl-ethylmalonate. This synthesis was carried out in exactly the same way as for diethyl bromomethyl-methylmalonate from 23.0 g of 20 % sodium-toluene dispersion in 100 ml of dry toluene, 0.2 mole of diethyl ethylmalonate and 0.4 mole of methylene bromide. 27.0 g (48 %) of the bromo compound was obtained, b.p. 105—107°/3 mm, n_D^{20} 1.4521, d_4^{20} 1.2753. (Found: C 43.0; H 6.1; Br 28.6; r_D 0.2117. Calc. for $C_{10}H_{17}O_4Br$: C 42.7; H 6.1; Br 28.4; r_D 0.2114.)

Kötz and Zörnig [22] have prepared the corresponding chloromethyl and iodomethyl derivatives.

*1,3-Di-*n*-propyl-1,1,3-tricarbethoxypropane (II, R = n-C_3H_7).* From 0.2 mole of sodium dissolved in 80 ml of absolute ethanol, 0.2 mole of diethyl *n*-propylmalonate, and 0.1 mole of methylene bromide were obtained 6.0 g (51 %) of diethyl carbonate and 23.4 g (68 %) of the triester, b.p. 152—153°/2 mm, n_D^{20} 1.4415, d_4^{20} 1.0091. (Found: C 62.7; H 9.2; r_D 0.2619. Calc. for $C_{18}H_{32}O_6$: C 62.8; H 9.4; r_D 0.2611.)

α,α'-Di-n-*propylglutaric acid.* The triester was hydrolyzed by boiling over night with 10 % ethanolic potassium hydroxide. The ethanol was distilled off and the triacid precipitated in almost quantitative yield upon acidification with concentrated hydrochloric acid. A small amount was recrystallized from ethyl acetate-petroleum ether, m. p. 165—170° (decomp.) (Found: C 55.1; H 7.8. Calc. for $C_{12}H_{20}O_6$: C 55.4; H 7.8.)

The crude triacid was decarboxylated by heating to about 170° until the gas evolution ceased. The resulting product was separated into two forms by fractionated crystallization from a mixture of ethyl acetate and petroleum ether (1:4) giving a 33 % yield of the high-melting form, m. p. 110—112°, and a 19 % yield of the low-melting form, m. p. 81—82°. (Found for the high-melting form: C 61.1; H 9.3; equiv.wt. 107.8. Found for the low-melting form: C 61.0; H 9.3; equiv.wt. 108.6. Calc. for $C_{11}H_{20}O_4$: C 61.1; H 9.3; equiv.wt. 108.1.)

*1,3-Di*iso*propyl-1,1,3-tricarbethoxypropane (II, R = i-C_3H_7).* This compound was prepared as before from 0.2 mole of sodium in 20 ml of absolute ethanol and 100 ml of dry toluene (the toluene was added in order to raise the boiling point), 0.2 mole of diethyl *iso*propylmalonate, and 0.1 mole of methylene bromide. 13.5 g (39 %) of 1,3-di*iso*propyl-1,1,3-tricarbethoxypropane was obtained, b.p. 153—155°/4 mm, n_D^{20} 1.4462, d_4^{20} 1.0219. (Found: C 62.6; H 9.5; r_D 0.2627. Calc. for $C_{18}H_{32}O_6$: C 62.8; H 9.4; r_D 0.2611.) No attempt to isolate the diethyl carbonate formed was made as its boiling point differs too little from that of toluene.

*α,α'-Di*iso*propylglutaric acid.* The triester was hydrolyzed by boiling with 80 % sulphuric acid for 6 h. The yield of crude acid mixture was 94 %. The mixture was dissolved in benzene, treated with decolorizing carbon and allowed to cool. Crystals rich in the high-melting modification separated and were filtered off. From the mother liquor crystals rich in the low-melting form could be isolated. The final purification was performed by two crystallizations from hot water, the melting points of the pure acids being 140—141° and 118—119°, respectively. The yields were 40 and 23 %, respectively. (Found for the high-melting form: C 60.7; H 9.3; equiv.wt. 108.3. Found for the low-melting form: C 60.8; H 9.3; equiv.wt. 107.8. Calc. for $C_{11}H_{20}O_4$: C 61.1; H 9.3; equiv.wt. 108.1.)

1,3-Di-n-*butyl-1,1,3-tricarbethoxypropane (II, R = n-C_4H_9).* From 0.2 mole of sodium dissolved in 80 ml of absolute ethanol, 0.2 mole of diethyl *n*-butylmalonate, and 0.1 mole of methylene bromide were obtained 6.2 g (53 %) of diethyl carbonate and 27.5 g (74 %) of the triester, b.p. 180—182°/7 mm, n_D^{20} 1.4433, d_4^{20} 0.9936. (Found: C 64.3; H 9.6; r_D 0.2670. Calc. for $C_{20}H_{36}O_6$: C 64.5; H 9.7; r_D 0.2679.)

α,α'-Di-n-*butylglutaric acid.* The triester was hydrolyzed by boiling over night with 10 % ethanolic potassium hydroxide. The ethanol was distilled off and the triacid precipitated in quantitative yield upon acidification with concentrated hydrochloric acid. A small amount was recrystallized from ethyl acetate-petroleum ether, m. p. 155—160° (decomp.). (Found: C 58.3; H 8.5. Calc. for $C_{14}H_{24}O_6$: C 58.3; H 8.4.)

The crude triacid was decarboxylated by heating to about 170° until the gas evolution ceased. The product solidified upon standing and the solid was dissolved in petroleum ether. After cooling in an ice-bath the crystals were filtered. They consisted of almost pure high-melting form. Two further fractions of crystals rich in the high-melting form were collected. They were combined and recrystallized once from petroleum ether, giving a 41 % yield of the pure high-melting form, m. p. 92—93°. The mother liquor from the first filtration was evaporated and the residue left in a vacuum desiccator over night, whereby it solidified slowly. It could be recrystallized from petroleum ether if the solution was cooled to −50° and the crystals rapidly filtered, m. p. 53—56°, yield 21 %. Kögl and Erxleben [23] have prepared the *α,α'*-di-*n*-butylglutaric acids by the reaction between disodium 1,1,3,3-tetracarbethoxypropane and *n*-butyl iodide followed by hydrolysis of the tetraester and decarboxylation. They found the m.p.'s 95—96° and 53—56°, respectively.

*1,3-Di*iso*butyl-1,1,3-tricarbethoxypropane (II, R = i-C_4H_9).* From 0.2 mole of sodium dissolved in 80 ml of absolute ethanol, 0.2 mole of diethyl *iso*butylmalonate, and 0.1 mole of methylene bromide were obtained 4.2 g (34 %) of diethyl carbonate and 19.0 g (51 %) of the triester, b.p. 152—4°/1.5 mm, n_D^{20} 1.4428, d_4^{20} 0.9929. (Found: C 64.3; H 10.0; r_D 0.2669. Calc. for $C_{20}H_{36}O_6$: C 64.5; H 9.7; r_D 0.2679.)

*α,α'-Di*iso*butylglutaric acid.* The triester was hydrolyzed by boiling over night with 10 % ethanolic potassium hydroxide. The ethanol was distilled off and the triacid preci-

pitated with concentrated hydrochloric acid in quantitative yield. A small amount was recrystallized from ethyl acetate-petroleum ether, m. p. 165—170° (decomp.). (Found: C 58.3; H 8.4. Calc. for $C_{14}H_{24}O_6$: C 58.3; H 8.4.)

The crude triacid was decarboxylated by heating to about 170° until the gas evolution ceased. The product solidified upon cooling and could be separated into two forms by fractionated crystallization from petroleum ether as in the case of the *n*-butyl derivative. A 28 % yield of the high-melting form, m. p. 85—87°, and a 23 % yield of the low-melting one, m. p. 80—82° were obtained. The high-melting isomer was found to be monotropic and transformed to a stable crystalline modification at about 90°, which then melted at 101—102°. When the liquid was allowed to solidify above 90° the stable form crystallized, whereas solidification at temperatures below this point gave the unstable form with the m. p. 85—87°. (Found for the high-melting form: C 63.8; H 9.9; equiv.wt. 121.6. Found for the low-melting form: C 63.9; H 10.1; equiv.wt. 121.4. Calc. for $C_{13}H_{24}O_4$: C 63.9; H 9.9; equiv.wt. 122.1.)

*1,3-Di-*n*-amyl-1,1,3-tricarbethoxypropane (II, R = n-C_5H_{11}).* From 0.2 mole of sodium dissolved in 80 ml of absolute ethanol, 0.2 mole of diethyl *n*-amylmalonate, and 0.1 mole of methylene bromide were obtained 6.7 g (57 %) of diethyl carbonate and 31.0 g (77 %) of the triester, b.p. 168—171°/2 mm, n_D^{20} 1.4443, d_4^{20} 0.9797. (Found: C 65.7; H 10.0; r_D 0.2713. Calc. for $C_{22}H_{40}O_6$: C 65.9; H 10.1; r_D 0.2724.)

*α,α'-Di-*n*-amylglutaric acid.* The triester was boiled over night with 10 % ethanolic potassium hydroxide. The ethanol was distilled off, and the triacid precipitated in quantitative yield with hydrochloric acid. A small amount was recrystallized from ethyl acetate-petroleum ether, m. p. 140—142°. (Found: C 60.5; H 8.9. Calc. for $C_{16}H_{28}O_6$: C 60.7; H 8.9.)

The crude acid was decarboxylated by heating to 170° until the gas evolution ceased, and the acid mixture was dissolved in petroleum ether, filtered, and allowed to cool. The crystals were filtered, and the mother liquor was evaporated to half its volume. A further fraction of crystals was obtained which was combined with the first one and recrystallized from petroleum ether, m. p. 113—5°. After evaporation of the mother liquor from the second filtration an oil was obtained, which turned to a semisolid mass upon standing. Attempts to isolate the other form from this were not successful, owing to its very poor crystallizing properties and great solubility in the common solvents. The yield of the isomer with m.p. 113—115° was 43 %. (Found for the isomer with m. p. 113—115°: C 66.1; H 10.3; equiv.wt. 136.7. Calc. for $C_{15}H_{28}O_4$: C 66.1; H 10.4; equiv.wt. 136.2.)

*Diethyl bromomethyl-*n*-amylmalonate.* This compound was prepared as above from 23.0 g of 20 % sodium dispersion in 100 ml of dry toluene, 0.2 mole of diethyl *n*-amyl malonate, and 0.4 mole of methylene bromide. 34.0 g (53 %) of the bromo compound was obtained, b. p. 132—133°/3 mm, n_D^{20} 1.4534, d_4^{20} 1.1831. (Found: C 49.0; H 7.5; Br 24.2; r_D 0.2286. Calc. for $C_{13}H_{23}O_4Br$: C 48.3; H 7.2; Br 24.7; r_D 0.2270.)

*Ethyl α-*neo*pentylacrylate.* When 0.2 mole of sodium dissolved in 80 ml of absolute ethanol, 0.2 mole of diethyl *neo*pentylmalonate * and 0.1 mole of methylene bromide was boiled for 24 h and the reaction mixture worked up in the usual manner the only isolable product except recovered starting material was 12.0 g (71 %) of ethyl *α-neo*pentylacrylate, b.p. 68—70°/11 mm, n_D^{20} 1.4273, d_4^{20} 0.8806. (Found: C 69.8; H 10.7; r_D 0.2917. Calc. for $C_{10}H_{18}O_2$: C 70.5; H 10.7; r_D 0.2915.) The ester was hydrolyzed by boiling with 10 % ethanolic potassium hydroxide. The ethanol was evaporated and the acid precipitated by hydrochloric acid. It soon solidified and was filtered and finally recrystallized from dilute acetic acid, m. p. 43—44°. The *p*-bromophenacyl ester had m. p. 53—55°. Hadley *et al.*[8] reported for the acid m. p. 39° and for its *p*-bromophenacyl ester 56°.

An attempt to carry out the reaction at 160° in a steel bomb gave the same result.

*Diethyl bromomethyl-*neo*pentylmalonate.* This compound was prepared as above from 23.0 g of 20 % sodium-toluene dispersion in 100 ml of dry toluene, 0.2 mole of diethyl *neo*pentylmalonate, and 0.4 mole of methylene bromide. 24.0 g (37 %) of the bromo compound was obtained, b.p. 147—150°/13 mm, n_D^{20} 1.4588, d_4^{20} 1.2035. (Found: C 48.5; H 7.1; Br 24.4; r_D 0.2271. Calc. for $C_{13}H_{23}O_4Br$: C 48.3; H 7.2; Br 24.7; r_D 0.2270.)

---

* The author is indebted to docent A. Brändström, *AB Pharmacia*, Uppsala, for this material.

Diethyl α,α'-diphenylglutarate (IV, R' = C_6H_5). This compound was prepared as above from 0.2 mole of sodium dissolved in 80 ml of absolute ethanol, 0.2 mole of diethyl phenylmalonate, and 0.1 mole of methylene bromide. 19.0 g (80 %) of diethyl carbonate and 21.5 g (63 %) of very viscous diethyl αα'-diphenylglutarate, b. p. 183–184°/1 mm, n_D^{20} 1.5274, was obtained. Souther [7] reported b.p. 216–217°/7 mm.

α,α'-Diphenylglutaric acid. The diethyl ester was hydrolyzed by boiling with 10 % ethanolic potassium hydroxide for one hour, and the acid mixture obtained was separated into diastereoisomers by fractionated crystallization from benzene. The melting points and yields of the pure acids were 187–188° (40 %) and 159–160° (22 %), respectively. Souther [7] reported the melting points 185–186.5° and 164.5–165.5°.

1,3-Dibenzyl-1,1,3-tricarbethoxypropane (II, R = $C_6H_5CH_2$). From 0.2 mole of sodium in 80 ml of ethanol, 0.2 mole of diethyl benzylmalonate, and 0.1 mole of methylene bromide were obtained 5.8 g (49 %) of diethyl carbonate and 34.0 g (77 %) of the very viscous triester, b.p. 224–227°/2 mm, n_D^{20} 1.5176. (Found: C 70.7; H 7.4. Calc. for $C_{36}H_{32}O_6$: C 70.9; H 7.3.)

The reaction was also carried out with methylene iodide whereby a 72 % yield of the triester was obtained.

α,α'-Dibenzylglutaric acid. The triester was hydrolyzed by boiling over night with 10 % ethanolic potassium hydroxide. The ethanol was distilled off and the acid precipitated by hydrochloric acid in quantitative yield. A small amount was recrystallized from ethyl acetate-petroleum ether, m. p. 155–160° (decomp.). (Found: C 67.4; H 5.7. Calc. for $C_{20}H_{20}O_6$: C 67.3; H 5.7.)

The crude acid was decarboxylated by heating to 170° until the gas evolution ceased, and the acid mixture was dissolved in benzene, filtered, and allowed to cool. The crystals were filtered off and from the mother liquor one further fraction with about the same melting point was obtained. The combined fractions were recrystallized two times from 80 % acetic acid, m. p. 149–150°. The mother liquor from the second filtration was evaporated. The residue was a crystal mass with m. p. 120–140°. In spite of many recrystallizations from various solvents and solvent pairs no sharply melting isomer could be obtained from this. (Found for the isomer with m. p. 149–150°: C 72.8; H 6.5; equiv.wt. 155.3. Found for the crystals with m. p. 120–140°: C 72.9; H 6.5; equiv.wt. 156.0. Calc. for $C_{19}H_{20}O_4$: C 73.1; H 6.5; equiv.wt. 156.2.)

Reaction between tricarbethoxymethane and methylene bromide. From 0.2 mole of sodium dissolved in 80 ml of absolute ethanol, 0.2 mole of tricarbethoxymethane, and 0.1 mole of methylene bromide 12.2 g (52 %) of diethyl carbonate and 18.3 g (55 %) of 1,1,3,3-tetracarbethoxypropane, b.p. 189–191°/11 mm were obtained.

α,α'-Diaminoglutaric acid. 0.2 mole of sodium was dissolved in 150 ml of absolute ethanol, 0.2 mole of diethyl acetaminomalonate was added followed by 0.1 mole of methylene bromide. The reaction mixture was boiled for 36 h, filtered and the ethanol distilled off on the water-bath through a short column. Then the pressure was lowered to about 60 mm Hg and a small amount, 2.1 g (18 %), of diethyl carbonate was collected. The residue, which was contaminated with unreacted starting material and sodium bromide, was hydrolyzed directly according to the method of Hellman *et al.* The yield of pure α,α'-diaminoglutaric acid was 3.6 g (23 %). It darkens and decomposes at 270–280°.

The author wishes to express his sincere gratitude to Professor Erik Larsson for his kind interest in this work. A grant from the *Kungliga Fysiografiska Sällskapet* is gratefully acknowledged.

Kinetics of the Hydrolytic Cleavage of Organic Protolytes

BERTIL HANSEN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

A method for the investigation of the hydrolytic cleavage of organic protolytes is described. It is based on automatic titrations at constant pH. The mathematical treatment is given. By using a "curve fitting" method the reaction rate constants of the basic and acidic forms of the protolyte and its dissociation constant can be calculated. The method is tested with the hydrobromide of 2-dimethylaminoethyl-thiolopropionate.

The most common method for measuring the alkaline hydrolysis of a compound is to dissolve the compound in excess alkali and then after different long times titrate the alkali not used up in the reaction. In another well-known method the reaction takes place in a buffer solution with the pH remaining almost constant. The reaction can be followed in various ways, *e.g.* by taking optical measurements of the concentration of one of the reaction products as a function of time.

When the compound to be hydrolyzed is a protolyte as, for instance, an ester of an amino acid or a mono ester of a di-basic acid, the composition of the reaction mixture becomes rather complicated. Because of protolysis the compound may exist simultaneously in both acidic and basic forms which react with different rates. For the determination of the corresponding rate constants it is important to know the dissociation constant of the compound. But if the reactions not are so slow that they can be neglected in the buffer zone of the compound, it will be difficult or even impossible to measure the dissociation constant by common methods. This means that we may have three constants which must be regarded as unknowns in all calculations. If the first of the two experimental methods mentioned above is used, the mathematical treatment will be very laborious. When choosing the buffer method the theoretical treatment becomes rather simple, if it is valid to assume that the ions of the solution do not affect the reactions. Unfortunately this is seldom true.[1,2]

This paper describes how the hydrolysis of a protolyte can be investigated according to a method which does not seem to have been used before. It is based on an automatic titration of the reaction mixture so that the pH is

maintained constant.[3] During the reaction the consumption of titrant is recorded, and the curve so obtained is used for the calculation of the reaction velocity. The reaction is carried out at several pH-values, and the resulting rate constants are plotted in a diagram. By comparing this (Fig. 1) with a family of standard curves (Fig. 2) it is possible to find the velocity constants of the hydrolysis of the two forms of the protolyte as well as its dissociation constant. The method is very similar to the buffer method but has the advantage of no complicated effects due to the ions of the solution.

THEORY

A mathematical expression of the alkaline hydrolysis of a protolyte is deduced on the following assumptions.

1) The hydrogen ion activity is constant during the whole reaction.

2) All experiments are carried out at the same temperature.

3) For each of the acidic and basic forms of the compound the reactions with molecules and ions other than the hydroxyl ion can be neglected. That means that there are only two reactions running in parallel, and both are of the second order.

4) The ionic strength is the same in all experiments, and during the reaction it changes only slightly. For that reason the activity factors according to the Debye-Hückel theory can be regarded as constants.

The deduction here is carried out for an ester containing an amino group in its alcohol part, because an ester of this kind was used in the experiments described later in the paper. The result can, however, easily be applied to other classes of compounds.

Symbols

E and EH^+	= ester to be hydrolyzed
HA and A^-	= acid formed in the reaction
B and BH^+	= alcohol formed in the reaction
[E]	= concentration of E
[EHE]	= total concentration of ester
h	= activity of the hydrogen ions
oh	= activity of the hydroxyl ions
k_1 and k_2	= second order reaction constants for the hydrolysis of E and EH^+ resp.
K_E', K_A' and K_B'	= mixed acid dissociation constants of E, HA and B resp. at the actual temperature and ionic strength.
K_w	= thermodynamic ionic product of water.
t	= time
f	= activity factor
C	= integration constant
x and y	= coordinates of the family of standard curves
u and v	= coordinates of the experimental curve
p	= parameter
hydr (as index)	= due to hydrolysis
prot (as index)	= due to protolysis

The protolytic equilibria of the solution are

$$E + H^+ \rightleftharpoons EH^+ \quad (1) \qquad A^- + H^+ \rightleftharpoons HA \quad (2)$$
$$B + H^+ \rightleftharpoons BH^+ \quad (3) \qquad H^+ + OH^- \rightleftharpoons H_2O \quad (4)$$

They are determined by the equations

$$\frac{[E]\cdot h}{[EH^+]} = K'_E \quad (5) \qquad \frac{[A^-]\cdot h}{[HA]} = K'_A \quad (6)$$
$$\frac{[B]\cdot h}{[BH^+]} = K'_B \quad (7) \qquad h \cdot oh = K_w \quad (8)$$

The reactions between the hydroxyl ions and E and EH^+ may be written

$$E + OH^- \xrightarrow{k_1} A^- + B \quad (9)$$
$$EH^+ + OH^- \xrightarrow{k_2} A^- + BH^+ \quad (10)$$

These reactions must be followed by immediate changes in the equilibria (1)—(4).

When differentiating the expression for the total concentration of the ester

$$[EHE] = [E] + [EH^+] \quad (11)$$

we get

$$d[EHE] = d[E] + d[EH^+] \quad (12)$$

The changes of [E] and $[EH^+]$ are due partly to the reactions (9) and (10) and partly to the changes in the equilibrium (1). We may then write

$$d[E] = d[E]_{hydr} + d[E]_{prot} \quad (13)$$
$$d[EH^+] = d[EH^+]_{hydr} + d[EH^+]_{prot} \quad (14)$$

The protolytic change (1) gives

$$d[E]_{prot} = -d[EH^+]_{prot} \quad (15)$$

If we now add up (12)—(15) we see that

$$d[EHE] = d[E]_{hydr} + d[EH^+]_{hydr} \quad (16)$$

The hydrolysis reactions (9) and (10) give us the following differential equations

$$-d[E]_{hydr} = k_1 \cdot [E] \cdot [OH^-] \cdot dt \quad (17)$$
$$-d[EH^+]_{hydr} = k_2 \cdot [EH^+] \cdot [OH^-] \cdot dt \quad (18)$$

According to assumption 1 (p. 325)

$$h = \text{constant} \quad (19)$$

and eqn. (5) written

$$[E] \cdot \frac{h}{K'_E} = [EH^+] \quad (20)$$

then shows that [E] is directly proportional to $[EH^+]$ independently of (9) and (10).

Using (20) when combining (16)—(18) we get

$$-\mathrm{d[EHE]} = (k_1 + k_2 \cdot \frac{h}{K'_E}) \cdot [\mathrm{E}] \cdot [\mathrm{OH^-}] \cdot \mathrm{d}t \tag{21}$$

According to (11) and (20)

$$[\mathrm{E}] = \frac{[\mathrm{EHE}]}{1 + \frac{h}{K'_E}} \tag{22}$$

and consequently

$$-\mathrm{d[EHE]} = \frac{k_1 + k_2 \cdot \frac{h}{K'_E}}{1 + \frac{h}{K'_E}} [\mathrm{EHE}] \cdot [\mathrm{OH^-}] \cdot \mathrm{d}t = k_3 \cdot [\mathrm{EHE}] \cdot [\mathrm{OH^-}] \cdot \mathrm{d}t \tag{23}$$

where

$$k_3 = \frac{k_1 + k_2 \cdot \frac{h}{K'_E}}{1 + \frac{h}{K'_E}} \tag{24}$$

Because of assumption 4 (p. 325) and the eqns. (8) and (19) we have

$$[\mathrm{OH^-}] = \frac{oh}{f_{\mathrm{OH^-}}} = \text{constant} \tag{25}$$

The only variables of (23) are consequently [EHE] and t. The integration of (23) gives

$$\ln[\mathrm{EHE}] = -k_3 \cdot [\mathrm{OH^-}] \cdot t + C \tag{26}$$

We see that the hydrolysis can be treated as a reaction of the first order, and the rate constant $k_3 \cdot [\mathrm{OH^-}]$ contains the three unknowns k_1, k_2 and K'_E.

If k_3 is determined at three different h-values and the obtained sets of values, (h_a,k_{3a}), (h_b,k_{3b}) and (h_c,k_{3c}), are inserted into (24), we get an equation system which has solutions with respect to k_1, k_2 and K'_E. However, the expressions obtained have no practical interest because they consist mainly of a large number of differences, which, as a rule, are small and so give rise to large errors in the calculated constants, *e.g.*

$$k_1 = \frac{h_a h_b k_{3c}(k_{3a}-k_{3b}) + h_b h_c k_{3a}(k_{3b}-k_{3c}) + h_c h_a k_{3b}(k_{3c}-k_{3a})}{h_a h_b\ (k_{3a}-k_{3b}) + h_b h_c\ (k_{3b}-k_{3c}) + h_c h_a\ (k_{3c}-k_{3a})}$$

In his paper on graphical methods Sillén [4] emphasizes the usefulness of "curve fitting methods" for determination of, *e.g.*, equilibrium constants, when the direct calculations give unsatisfactory accuracy. Such a method has for that reason been developed for the determination of k_1, k_2 and K'_E from the sets of values $(h,\ k_3 \cdot [\mathrm{OH^-}])$ obtained from the experiments.

Let us start by looking for a suitable family of standard curves with which an experimental curve can be compared. We shall find that a useful family is obtained from the equation

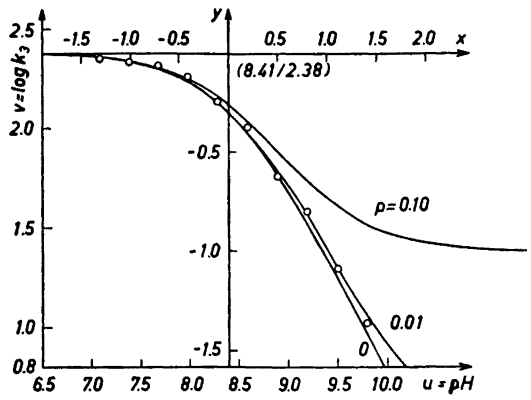

Fig. 1. The experimental values plotted in the family of curves for $u_0 = 8.41$, $v_0 = 2.38$.

$$y = \log \frac{p + 10^{-x}}{1 + 10^{-x}} \tag{28}$$

by plotting the function in an (x,y)-diagram for certain values of p (Fig. 2). After substituting

$$\begin{cases} u = \text{pH} = -\log\ h \\ v = \log\ k_3 \end{cases} \tag{29}$$

into (24) we get

$$v = \log\ k_2 + \log \frac{\frac{k_1}{k_2} + \frac{10^{-u}}{K'_E}}{1 + \frac{10^{-u}}{K'_E}} \tag{30}$$

The family of (u,v)-curves that can be obtained by giving different values to k_1/k_2 in (30) is the same as the family from (28) except that the origins do not coincide.

Let us now use the experimental values of h and k_3 for plotting an (u,v)-diagram (Fig. 1). When comparing the family (28) and the experimental curve (Fig. 1), we see that, for parallel abscissae, the best fit gives a value $p = p_0$. As the shapes of the curves are dependent only on p_0 and k_1/k_2, respectively, these values must be equal

$$p_0 = \frac{k_1}{k_2} \tag{31}$$

The curves are brought to cover each other, and the coordinates (u_0,v_0) of the origin of the (x,y)-system are read off.
As $x = 0$ must correspond to

$$\frac{10^{-u_0}}{K'_E} = 1 \tag{32}$$

in (30), and $y = 0$ to

$$v_0 = \log\ k_2 \tag{33}$$

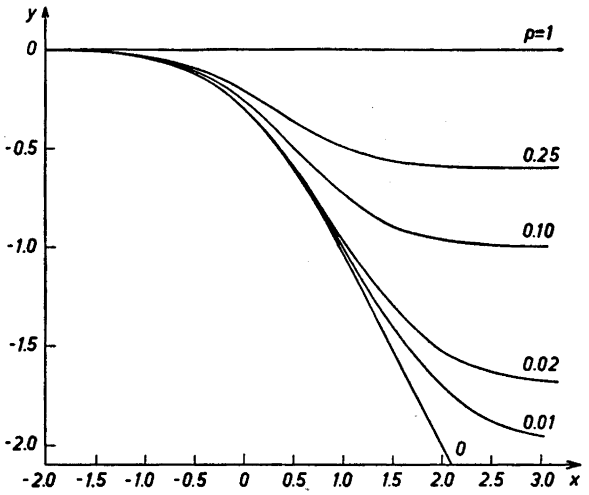

Fig. 2. Some standard curves of the family.

we have obtained three equations (31)—(33) from which k_1, k_2 and K'_E can be calculated.

It is worth mentioning that the family of standard curves can be restricted to values of p in the interval $0 \leqq p \leqq 1$. For $p > 1$ we make the following rearrangement of (28)

$$\begin{cases} x = -x' \\ y = y' - \log\ p' \\ p = 1/p' \end{cases} \tag{34}$$

which gives

$$y' = \log \frac{p' + 10^{-x'}}{1 + 10^{-x'}} \tag{35}$$

We see that (28) and (35) are the same equation, and as $p' = 1/p'$ the family of curves made up for $0 \leqq p \leqq 1$ also can be used for $p > 1$.

This division of the family into two classes requires that, before comparing the curves, we have to find out to which of the classes the experimental curve belongs.

1. If v decreases with increasing u it means that $0 \leqq p \leqq 1$ and we can compare the curves directly and read off the values p_0, u_0 and v_0.

2. If v increases with increasing u we have the case $p > 1$ and must first make the rearrangement of (29)

$$\begin{cases} u = -u' \\ v = v' \end{cases} \tag{36}$$

i.e. we reverse the paper on which the experimental curve is drawn. It is then possible to compare the curves and read off the values p'_0, u'_0 and v'_0. Remembering that (u'_0, v'_0) does not correspond to $x = 0$, $y = 0$ but to $x' = 0$, $y' = 0$, we can calculate k_1, k_2 and K'_E from eqns. (31)—(34) and (36).

EXPERIMENTAL

The hydrolysis experiments have been carried out with the hydrobromide of 2-dimethylaminoethyl-thiolopropionate[5,6] by using the automatic recording titrator described by Larsson and Hansen.[3] The reactions took place in a nitrogen atmosphere at 25° ± 0.1°. From the recorded consumptions of 0.05 M sodium hydroxide the first order rate constants $k_3 \cdot [OH^-]$ were calculated according to Guggenheim.[7]

Assumption 4 (p. 325) was considered fulfilled by performing the reaction in 0.1 M potassium chloride and starting with 0.6 mM concentration of the ester.

The glass electrode used was of the type Radiometer G 202 B and the reference electrode a saturated calomel electrode, Radiometer K 300. The electrodes were standardized against 0.05 M potassium hydrogen *o*-phthalate, pH 4.01. The pH-fluctuations during a single experiment were within ± 0.01 pH-units.

RESULTS

Though many of the experiments were carried out in the pH-range where both the 2-dimethylaminoethyl-thiolopropionate and the reaction product containing the amino group have a good buffering effect the curves plotted for the calculations of $k_3 \cdot [OH^-]$ (eqn. (26)) were straight lines. This shows that the reaction really is first order at constant pH.

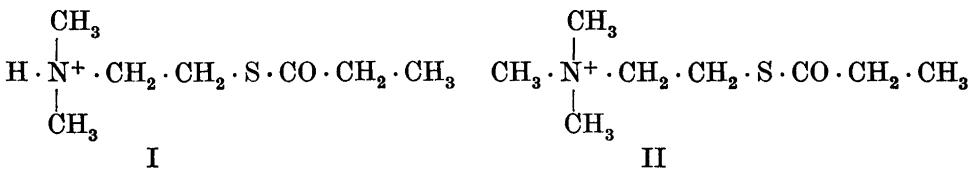
As a rule two or more experiments were carried out at each pH. The deviations from the mean values of $k_3 \cdot [OH^-]$ were always less than 5 %, which if they would be due only to the readings of the of the pH-scale corresponds to the acceptable error of 0.02 pH-units or 1 mV.

In Fig. 1 the result was plotted according to (29) with pH on the abscissa and log k_3 on the ordinate. $[OH^-]$, which is required for the calculations of k_3 from $k_3 \cdot [OH^-]$, was obtained from pH assuming [8] $K_w = 10^{-14.00}$ and $f_{OH^-} = 0.76$ (eqn. (25)). As the plotted curve had a negative slope it was immediately comparable with the family of curves (Fig. 2). The comparison showed (Fig. 1) that we had the best fit for a small value of p. The exact p_0-value could not be determined because for practical reasons it was impossible to perform any experiments at pH > 10 and so the curve could not be extended far enough to the right. However, the values $u_0 = 8.41 \pm 0.01$ and $v_0 = 2.38 \pm 0.01$ could be read off. The errors given were estimated from the largest movements of the curves that could be done without getting an unacceptable fit. To the errors must also be added the systematic error 0.02 which was the accuracy of the pH-meter. The calculations of K_E' and k_2 (eqns. (31)—(33)) gave $K_E' = (3.9 \pm 0.3) \times 10^{-9}$ mole/l and $k_2 = (2.4 \pm 0.2) \times 10^2$ l/mole · sec. Regarding k_1 we can only say that $k_1 << k_2$ because it was impossible to find a p_0-value.

Estimating [8] $f_{EH^+} = 0.76$ we can calculate the thermodynamic dissociation constant of the ester $pK_E = 8.29 \pm 0.03$. From pH-measurements of mixtures of aqueous solutions of 2-dimethylaminoethyl-thiolopropionate and its hydrobromide Tammelin [5] found $pK_E = 8.28 \pm 0.03$ which agrees with the value above.

It is very interesting to compare the velocity constant of the alkaline hydrolysis of the acidic form of 2-dimethylaminoethyl-thiolopropionate (I)

and that of the corresponding quaternary compound, propionyl-thiocholine (II), which has been investigated by Heilbronn [9].



I II

Though both I and II have a positively charged ammonium group the second order rate constant of I is 240 times greater than that of II. The experimental material is, however, insufficient to be used for an explanation of the difference.

To Professor G. Ljunggren, the head of this Institute, I wish to express my gratitude for his interest in this work.

Radiation Induced Tritium Labeling of *p*-Aminosalicylic Acid (PAS)

JAN RYDBERG and ÅKE HANNGREN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden; Medical Clinic, Serafimer Hospital, and Pharm. Dept., Royal Veterinary College, Stockholm, Sweden

Wilzbach's [1] method of mixing tritium gas with organic substances for labeling them with tritium was used to introduce tritium into *p*-aminosalicylic acid (H—PAS) and its sodium salt (Na—PAS) and the specific activity was studied as a function of time and agitation. Higher activities were obtained with Na—PAS and with agitation than with H—PAS or without agitation. The results are summarized in Fig. 3. Specific activities of the order of 30 mC/g could be obtained in a day.

In the last few years a number of methods have been described for the direct labeling of organic substances by exposing them to radioactive isotopes of high kinetic energy *e.g.* [2-11]. This makes it possible to label substances which previously have been found difficult or impossible to label by other methods as, *e.g.*, chemical synthesis, biosynthesis or isotopic exchange. To this group of substances belongs a great number of complicated organic molecules of biochemical importance. Since the labeling by this direct method is non-specific (a great number of other labeled organic compounds are also formed), the methods for isolating the desired product in pure form are of fundamental importance, and generally constitute the most difficult part of the process. However, very elaborate and selective purification methods are now available as *e.g.* various chromatographic methods.

An important addition to the methods of direct labeling was recently reported by Wilzbach [1] who found that if organic compounds are exposed to tritium gas, some of the hydrogen in the compounds is exchanged for tritium.

This exchange is induced by the β-radiation from the tritium. Some of these reactions may be written

$$T_2 \sim\sim\rightarrow T + T \qquad 1\,a$$
$$RH \sim\sim\rightarrow R + H \qquad 1\,b$$
$$R + T_2 \rightarrow RT + T \qquad 1\,c$$
$$R + T \rightarrow RT \qquad 1\,d$$
$$RH + T \rightarrow RT + H \qquad 1\,e,$$

where RH is the organic compound being irradiated.

The first two reactions indicate how radicals are produced by the β-radiation field. The following reactions show how these radicals may react to form the labeled compound RT; of these reactions, (1d) is least probable. The last reaction can also be regarded as a formation of RT through isotopic exchange. Ions (*e.g.* T^+, T^-, R^-) may be formed in a similar manner, and these ions may also react with each other or with the radicals to form RT. The radiation field is fairly intense and amounts, for 1 Curie of T_2-gas, to about 10^6 rad/min in the volume of the pure gas; the radiation absorbed by solid or liquid samples depends somewhat on the experimental conditions, but may well amount to 10^5 rad/min.

This kind of labeling may not necessarily be induced by the radiation from tritium: It seems quite possible to use radiation from other sources, such as from the decay of other isotopes * or from high-voltage accelerators.

For autoradiographic studies of the pharmacological properties of the tuberculostatic agent *p*-aminosalicylic acid (PAS) [12], tritium labeled PAS was needed. In a previous paper [10], the labeling of PAS with recoil tritons has been reported; however, only low specific activities (~1.5 mC/g) were obtained. In order to obtain higher specific activities, the method of using tritium gas for the labeling of PAS has been investigated. The results are reported in this paper.

EXPERIMENTAL

Apparatus. The apparatus used is shown in Fig. 1. It consists in principle of two vessels, one for the tritium stock (F) and one for the sample to be exposed (A), and a gas-pumping mechanism. The apparatus, which is very compact, is made entirely of glass. It is operated in the following manner:

After the whole system has been evacuated, stop-cock J is connected only to vessel E, and K is closed. The tritium ampoule, F, is then broken by the magnet, and the T_2 gas is allowed to distribute itself through stop-cock D into vessel E. Stop-cock D is then switched over so that A and E are connected through stop-cock B. Air is then let into vessel L *via* stop-cock K, and the mercury level in E is allowed to reach just below stop-cock D, which is then closed. In this manner about 55 % of the T_2 originally present in F is introduced into the reaction vessel A.

If it is desired to remove the reaction vessel from the apparatus, stop-cock B is closed, and the T_2 gas in the volume between B and E is pumped out and transported back to F by repeatedly lowering the mercury level in E when C and E are connected, and raising the level when E and F are connected. This pumping action is effected by turning stop-cock K so that air is either let in or removed from vessel L. Part A—B can then be removed after D has been closed.

When parts A and B are removed from the rest of the apparatus, part C becomes filled with air. This air has to be removed before the tritium gas in volume A—B can be recovered so that the tritium gas will not be diluted with air. This air is therefore removed by the vacuum pump through D—E—J—K; since some T_2 is always left in the hole in stop-cock D, it will be lost during the evacuation process. The amount of this loss is 2—3 % of the total amount T_2 in vessel F. Thus, in about 20 experiments, 50 % of the T_2 has been lost in this way. Corrections (factor f_p) for this successive decrease of the T_2-amount are made in the experiments recorded later.

Labeling experiments. The amount of PAS used in the labeling experiments was varied between 30 and 100 mg. The tritium gas was purchased from AERE, Harwell, and contained 98.8 wt % of T_2, the rest being H_2. The amount of tritium gas in the reaction vessel was at maximum about 2.6 curies at a pressure of about 240 mm Hg, and at minimum about 1.6 curies. All experiments were carried out at room temperature (20 ± 2°C).

* This has recently been shown by Turton, C. N. *Intern. J. of Appl. Radiation and Isotopes* **2** (1957) 182, who used the radiation from ^{85}Kr to improve labeling with ^{14}C in organic compounds.

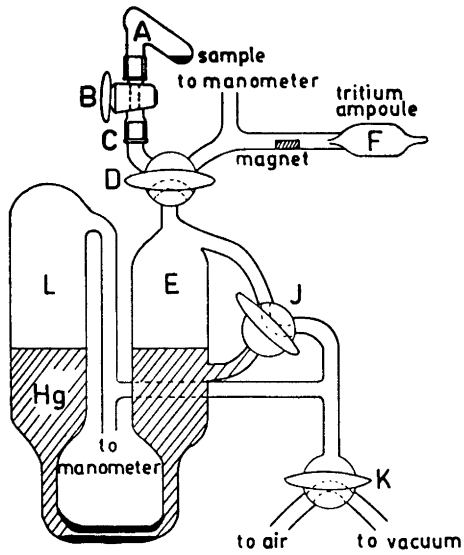

Fig. 1. Apparatus used for the exposure of organic samples to tritium gas.

Chemical procedures. *p*-Aminosalicylic acid (H—PAS, which looks somewhat similar to fineground corn meal) and sodium *p*-aminosalicylate (Na—PAS, which consists of mm-sized crystal needles) of highest commercial purity were used; the products were kindly supplied by AB Ferrosan, Malmö. In order to purify the H—PAS, which has a somewhat greyish color, the same purification procedure was used as described below for the tritiated product. All other chemicals were of analytical grade.

As the primary purification method liquid-liquid extraction was chosen. This method is very suitable for large amounts of samples and the fundamental laws governing the extraction processes are well known, *cf. e.g.* Ref.[13]

The tritiated PAS-sample was dissolved in a mixture of equal volumes of amyl alcohol and 0.1 M $NaHCO_3$ in water (about 10 ml for each 100 mg PAS). Under these circumstances about 95 % of the PAS goes into the aqueous phase. This aqueous phase was then washed 5 times with equal volumes of amyl alcohol. The aqueous phase was then cooled with ice and acidified with HCl to pH ~3; after about one hour PAS—HCl has precipitated and can be filtered off.

This PAS—HCl is put into 1 mM HCl, and the resulting aqueous solution is extracted with an equal volume of amyl alcohol. About 97 % of the PAS now moves over to the organic phase, from which it can be recovered by careful evaporation.

The chemical yields of a great number of such runs have been 50—70 %. The tritium yield, *i. e.* the ratio between non-labile tritium found in the purified PAS product and the total tritium content found in evaporated samples of the crude product dissolved in amyl alcohol, was found to be around 20 %.

The purity of the product was checked by paper chromatography, as described in a previous paper [10], in which the principle of the purification method is more extensively treated.

Tritium measurements. All radioactivity measurements were made on solid samples in a 2 π internal gas-flow proportional counter (Nuclear Measurements Corp., Indianapolis). Corrections for resolving time could be neglected at counting rates $\lesssim$5 000 counts per sec.

The samples were prepared by dissolving a weighed amount of purified, tritiated PAS in a known volume of ethyl alcohol, and carefully evaporating 0.1 ml on flat plates heated to 55°C, *cf.* Ref.[14]

Table 1. Results of tritiating experiments and calculations of specific activity ($f_b = 1.14$ except otherwise stated; f_s is taken from Fig. 2).

RESULTS AND CALCULATIONS

The labeling runs. Most of the labeling experiments have been »static», *i.e.* the solid sample has been kept with the tritium gas in the reaction vessel for a certain time without any agitation. However, it was believed that agitation would increase the specific activity of the product, so a number of runs were made in which the reaction vessel (parts A and B in Fig. 1) was removed from the apparatus and vigorously shaken in a rocking machine. It was found that with H-PAS the sample stuck to the walls of the vessel, so that in effect the sample did not move at all (called »baking» in Table 1). The introduction of broken glass pieces into the reaction vessel and careful drying of the H-PAS

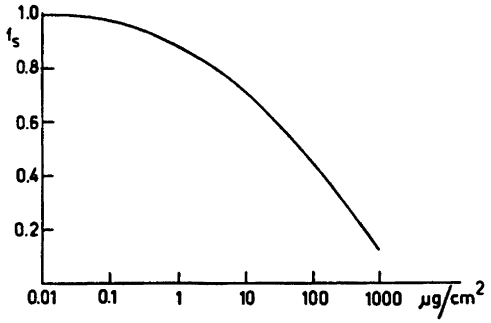

Fig. 2. Correction factor, f_s, for the self-absorption of the tritium beta-radiation in solid PAS samples [14].

did not much increase the agitation of the sample. The results of these runs (see Table 1) also indicated that there was not any great difference between these "agitation" runs and the "static" runs.

This "baking" of the H-PAS samples is believed to be due to electrostatic phenomena. Since H-PAS is amphoteric, while Na-PAS is not, it was hoped that better results would be obtained with the latter. The subsequent experiments showed that no baking at all was obtained with Na-PAS. The only experiments with "true" agitation have therefore been carried out on Na-PAS.

It was thought that the static experiments with H-PAS could be extrapolated to "agitation" by means of the results on agitation of Na-PAS, *i.e.* that labeling would be equally efficient in H-PAS and Na-PAS under identical conditions. In order to check this, static runs with Na-PAS were also made; these are recorded in the fourth part of Table 1.

The results of the various runs are given in Table 1, where also the specific activity has been calculated.

Calculation of specific activity. In order to calculate the true specific activity, S, of non-labile tritium in the PAS product, the following equation [14] was used

$$S = \frac{0.90 \times 10^{-12} \cdot I}{m \cdot f_s \cdot f_p \cdot f_b} \text{ curies/g PAS}$$

where I is the measured activity in counts/min (cpm) in a sample of weight m grams on a plate with a back-scattering factor, f_b, (for the β-radiation from tritium, f_b is 1.14 for aluminium, 1.24 for stainless steel and 1.50 for platinum [14]). The correction factor, f_s, for the self-absorption and self-scattering in the samples is taken from Fig. 2. In order to make all experiments comparable, corrections for the decrease in the amount of tritium gas used in the successive experiments are made through the gas correction factor, f_p, which arbitrarily has been put equal to 1.00 when the reaction vessel contains 2.6 curies of T_2. The factor 0.9×10^{-12} is obtained from $1/2.2 \times 10^{12} \cdot f_g \cdot f_e$, where 1 curie $= 2.2.10^{12}$ dpm, $f_g = 0.50$ is the geometry factor, and $f_e = 1.0$ is the counter efficiency for tritium betas.

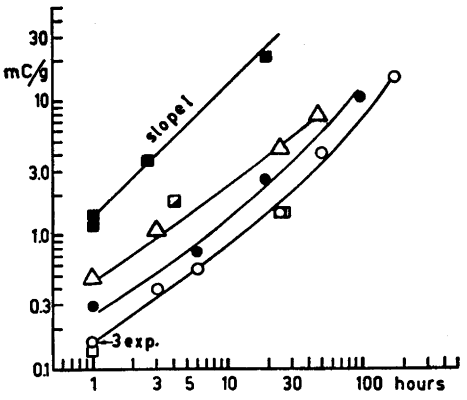

Fig. 3. Specific activity of tritium in non-labile positions in PAS (S mC/g) as a function of time of exposure to tritium gas (t hours). The symbols refer to: ○ 100 mg H—PAS and no agitation, △ 30 mg H—PAS and no agitation, ● 100 mg Na—PAS and no agitation, □ and ◪ 100 mg H—PAS and agitation, ■ 100 mg Na—PAS and agitation.

Reproducibility. The reproducibility of S seems to be surprisingly good. Thus, for static runs with 100 mg samples of H-PAS, $S = 0.15 \pm 0.01$ mC/g has been obtained in three different runs with several months intermission and using two different sources of tritium gas. The poorest reproducibility so far obtained is recorded for 104 mg H-PAS during 24 h, where the deviation between two measurements amounts to about 6 %. However, it is seen from Fig. 3 that some points deviate much more from the average curve drawn through the points of a set of experiments, indicating that the reproducibility sometimes is much worse.

DISCUSSION

The results of the various experiments are shown in Fig. 3, where the specific activity, S mC/g, is plotted as a function of time of exposure to tritium gas (t hours). The general tendency of S to increase with t is obvious, and also expected as long as radiation damage is negligible. When radiation damage becomes important one would expect the curves to level off and then to decrease with a further increase in exposure time t. However, the curves of the "static" experiments marked ○, △ and ● in Fig. 3 tend rather to bend upwards at high irradiation times, which seems quite surprising.

It is thought that mainly the surface layer of the H-PAS sample is labeled. This is supported by the fact that the specific activity of the 30 mg H-PAS samples (marked △), which expose about the same surface area to the tritium gas as the 100 mg samples, are almost exactly 3 times as high as that of the 100 mg H-PAS samples (marked ○).

H-PAS is a fine powder, while Na-PAS is macro-crystalline, thus making samples of the latter more porous. It is therefore believed that the tritium gas diffuses more rapidly into the Na-PAS sample than into the H-PAS sample, causing labeling not only in the surface layer. This assumption may explain why higher specific activities are obtained with Na-PAS (marked ●) then with H-PAS (marked ○) in the "static" runs.

Table 2. Comparison of specific tritium activities obtained in non-labile positions of substances similar to PAS using different labeling methods.

Substance	Met hod	Specific activity	Reference

» »	tritium exposure	14 »	Wilzbach [1]
» »	accelerated tritons	< 10 »	Wolfgang, Pratt, Rowland [8]
Salicylic acid	recoil tritons	0.1 »	Kaplan [15]
p-Amino salicylic acid	recoil tritons	1.5 »	Hanngren, Rydberg [10]
Na-*p*-aminosalicylate	tritium exposure	~100 * »	this work

* Extrapolated from the upper straight line of Fig. 3 on the assumption that no macro-decomposition of PAS occurs.

The agitation of Na-PAS causes increased labeling owing to the continuous exposure of new surfaces towards the radiation and the tritium gas; the repeated breaking of the Na-PAS crystal needles because of the agitation further increases this effect. As would be expected when the diffusion effect is eliminated through agitation, the specific activity (experiments marked ■) rises almost linearily with exposure time (slope 1 in the log-log scale of Fig. 3).

These experiments show the importance of a very intimate contact between the tritium gas and the sample. Since radiation damage does not seem to interfere for radiation times $\lesssim$ 1 week, very high specific activities should be obtainable; the extrapolated straight line for Na-PAS (marked ■ in Fig. 3) gives, e.g., ~100 mC/g PAS after ~3 days agitation.*

In Table 2, a comparison is made of different methods of labeling organic compounds similar to PAS. The experiments refer to a reaction time of about 3 days, except in the case of accelerated tritons (0.5 h). These experiments are somewhat difficult to compare, even if the recoil tritons in all cases have been produced in a neutron flux of about 10^{12} n/cm^2/sec. If the simplicity of the technique of the tritium exposure method is considered, its superiority over the other methods is obvious, especially when the sample is vigorously agitated in the tritium gas.

As pointed out in the introduction, radiation other than the β-particles from tritium should be useful in producing reactive radicals. If more radicals can be produced, with negligible radiation damage in a shorter time, still higher specific activities may be obtainable.

Acknowledgements. The authors are indebted to the head of FOA 1, Prof. G. Ljunggren, for permission to carry out this work at his institute. They are also grateful to Mrs. B. Olausson and Mr. E. Johansson for experimental assistance.

* *Added in proof:* Later experiments have confirmed this.

Alkaline Hydrolysis of Glycosidic Linkages

III. An Investigation of some Methyl α- and β-Glycopyranosides

ELISABETH DRYSELIUS, BENGT LINDBERG and OLOF THEANDER

Träkemiska avdelningen, Svenska Träforskningsinstitutet, and Institutionen för Träkemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

The alkaline hydrolysis of the α- and β-glycopyranosides of glucose, galactose, mannose, xylose and arabinose has been investigated. The glycosides with the aglyconic group and the hydroxyl at $C_{(2)}$ in the *trans* position reacted much faster than the corresponding *cis* anomers, indicating that the former reacts *via* the 1,2-anhydrosugars. Within each group of glycosides, the reactivity increases with the conformational instability of the most stable chair form of the glycoside.

An investigation of the alkaline hydrolysis of cellobiitol and lactitol was described in Part II of this series and it was demonstrated that cleavage of the glycosidic linkage in these substances followed at least two different mechanisms. One of these was assumed to proceed *via* the 1,2-anhydrosugar to the 1,6-anhydrosugar, which was isolated from the reaction products in both cases. The other mechanism, resulting in the formation of 1,4-anhydrosorbitol, was assumed to involve a nucleophilic attack upon the $C_{(4)}$ carbon atom of the sorbitol unit, thus leading to a fission on the other side of the glycosidic oxygen atom.

The present paper describes an investigation of the methyl α- and β-glycopyranosides of D-glucose, D-galactose, D-mannose, D-xylose and L-arabinose. The glycosides were treated with 10 % aqueous sodium hydroxide at 170° for varying times, the solutions were then deionised and the yields of neutral material were determined. The neutral products consisted essentially of unchanged starting material with traces only of other components such as 1,6-anhydroglucopyranose, 1,6-anhydrogalactopyranose and unknown substances. The rate constants for the alkaline hydrolysis were calculated for a first order reaction, assuming that the concentration of alkali, which was present in considerable excess, was constant during the reaction. The values determined in this way are not very accurate, especially for the short reaction times when only a small amount of the material had reacted. Nevertheless they should give an idea of the relative reactivities of the glycosides investigated. The yields and rate constants are summarised in Table 1. It is evident from Table 1 that in all pairs of glycosides, the anomer with methoxyl and

Table 1. Alkaline hydrolysis of methyl glycopyranosides in 10 % sodium hydroxide at 170°.

* Rate constants expressed in Briggs logarithms and in hours.

$C_{(2)}$ hydroxyl group *trans*, react considerably faster than the *cis* anomer. The same is true for the alkaline degradation of the phenyl glycosides (summarised in Ref.[2]) and is explained by the ready formation of the corresponding 1,2-anhydrosugar. The latter is highly reactive and, in the hexose series, when the configuration is favourable, gives the 1,6-anhydrosugar in good yield. As previously demonstrated [1], these 1,6-anhydrosugars are more sensitive to alkaline hydrolysis than the alkyl glycosides and consequently only small amounts accumulate. The presence of 1,6-anhydroglucose and 1,6-anhydrogalactose after alkaline treatment of the methyl β-glucoside and β-galactoside was demonstrated by paper chromatography and further supports the assumption that the reaction *via* the 1,2-anhydride is of major importance for the alkaline hydrolysis of the "*trans*"glycosides.

The relative rates of acid (Ref.[3], p. 209) and alkaline hydrolysis for the "*cis*" and "*trans*" glycosides are given in Tables 2 and 3. For the acid hydrolysis, the relative rates of hydrolysis are explicable by the principles of conformational analysis, as shown by Edward [4] and Huber [5]. A similar analysis of the alkaline hydrolysis, which obviously proceeds by at least two different mechanisms, is not intended. However, some generalisations seem to be

Table 2. Relative rates for acid and alkaline hydrolysis of the *cis* methyl glycopyranosides.

Methyl glycopyranoside	Acid hydrolysis, k_{rel} *	Alkaline hydrolysis, k_{rel} *
α-D-glucoside	1.0	1.0
α-D-galactoside	5.2	3.9
β-D-mannoside	5.7	4.4
α-D-xyloside	4.5	4.8
β-L-arabinoside	9.0	4.0

* $k_{rel} = 1$ for methyl α-D-glucopyranoside.

Table 3. Relative rates for acid and alkaline hydrolysis of the *trans* methyl glycopyranosides.

Methyl glycopyranoside	Acid hydrolysis, k_{rel} *	Alkaline hydrolysis, k_{rel} *
β-D-glucoside	1.9	10
β-D-galactoside	9.3	23
α-D-mannoside	2.4	11
β-D-xyloside	9.0	23
α-L-arabinoside	13.1	40

* $k_{rel} = 1$ for methyl α-D-glucopyranoside.

valid. Firstly, as stated above, the reaction is considerably facilitated by a *trans* arrangement of the aglyconic group and the hydroxyl at $C_{(2)}$, and it is most probable that the hydrolysis of these glycosides involves the intermediate formation of an 1,2-anhydride. Secondly, there is a qualitative agreement between the rates of acid and alkaline hydrolysis within each group. The value for the alkaline hydrolysis of the β-L-arabinoside is somewhat low, but, with that exception, the agreement is remarkably good. This shows that the acid and alkaline hydrolysis are influenced in a similar way by steric factors in the glycosides, and that they both increase with the conformational instability of the most stable chair form of the glycoside (*cf.* Ref.[3], p. 209).

EXPERIMENTAL

The glycosides were prepared by conventional methods and purified until m. p. and specific rotation were in agreement with the accepted values and no impurities could be detected by paper chromatography.

The glycoside (1.000 g) was dissolved in 10 % sodium hydroxide (7 ml, 2.62 N). The solution, in a stainless steel autoclave, was heated at 170° in an oil thermostat for different times. When cold the solution was deionised by filtering through a column, containing a mixed bed of the ion exchange resins Amberlite IR 120 and Dowex 2, in their hydrogen and hydroxyl states, respectively. The column was carefully washed, the solution was concentrated to dryness under reduced pressure in a rotary evaporator and the residue was dried to constant weight over phosphorus pentoxide in a vacuum. The product was usually crystalline. It was investigated by paper chromatography in three different solvent systems. In most cases, only unchanged starting material was detected, but the products from the β-glucoside and β-galactoside also contained small amounts of material, which was chromatographically indistinguishable from the corresponding 1,6-anhydrosugars and traces of unknown components.

Methyl β-mannopyranoside was investigated in the form of its crystalline tetraacetate, in this case using a larger excess of 10 % sodium hydroxide to compensate for the acetic acid liberated.

When a glycoside was dissolved in the alkali and recovered without heating by the procedure above, the recovery was between 99 and 100 %.

On the Purification of Prorennin with a Note on the Recrystallisation of Rennin

BENT FOLTMANN

Chr. Hansen's Laboratory Ltd., Copenhagen, Denmark

Prorennin was extracted from dried calf-stomachs, using a solution of 2 % $NaHCO_3$. After clarification with $Al_2(SO_4)_3$, neutralisation with Na_2HPO_4 and reprecipitation with NaCl, a purified preparation was obtained. N-Determinations and paperelectrophoresis indicated that at least 50 % of the protein was prorennin. Paperelectrophoresis was carried out with crystalline rennin for purposes of comparison, and it was found that the isoelectric point of prorennin is about 0.3 pH unit higher than that of rennin. Crystallisation and recrystallisation of rennin are described.

Few investigations have been published concerning prorennin, the inactive precursor of the milk-clotting enzyme rennin. Only one attempt has been made to purify the pro-enzyme (Kleiner and Tauber[1]). As the preparation by Kleiner and Tauber actually appears to be rather impure, experiments have been carried out to produce a high-grade prorennin preparation.

METHODS AND RESULTS

Determination of the milk-clotting activity of samples from the preparation was carried out as a relative test, using fresh skim-milk and a sample of liquid rennet as basis for comparison. The activity is expressed in rennin units (RU) according to Berridge [2]. The eluates from the paperelectrophoresis experiments called for a very sensitive test. This determination was carried out with 5 ml skim-milk and 5 ml acetate buffer pH 4.9 (Ege and Menck-Thygesen [3]). In this determination, the activity is expressed directly as the inverse of the time of coagulation. The activity is illustrated in relation to each separate experiment.

Activation. The activation of prorennin was carried out at pH 2 for 15 min for samples of the preparation (*cf.* Ege and Lundsteen [4]). The eluates from the paperelectrophoresis only had a very slight buffer capacity, and as the determination of the milk-clotting activity of these samples was carried out in a milk/acetate mixture, it was most convenient to activate the eluates in acetate buffer pH 4.6 during 20 h before testing (Holwerda [5]).

110 ml dialysed ** during 7 h against 2 × 2 l distilled water	145	9	1 000	1.77	560	33

* During the clarification operation pH fluctuated between 6.1 and 6.9.

** The dialysis was carried out in a rotating bag (Visking Cellulose) at 2°C during 2 h against 2 l of distilled water, and 5 h against a further 2 l of distilled water. (The dialysis was not prolonged in order to prevent activation during the experiment. The final product was not, therefore, free of salt. The N-contents of the freeze-dried preparation was 84 mg N/g.)

Prorennin. After preliminary experiments, the following procedure was adopted: 7 dried calf-stomachs, (taken from a charge proved to have a high prorennin/rennin value), were finely cut, and extracted with 3 000 ml of 2 % $NaHCO_3$ at room temperature whilst stirring continuously. After 2 h, the tissue was separated by means of centrifugation, and the muddy raw extract was purified as described in Table 1. After freeze-drying 135 ml of the purified dialyzate, 2.7 g of powder were obtained. The preformed activity of this powder was 3.6 RU/mg N, the activity after activation 500 RU/mg N.

Crystalline rennin was prepared from rennet after four precipitations with NaCl (Berridge [6], Alais [7]). The fourth precipitate was dissolved in distilled water to give a solution of 2 000 RU per ml. The NaCl enclosed in the wet precipitate produced a concentration in the final solution of approximately 1 N

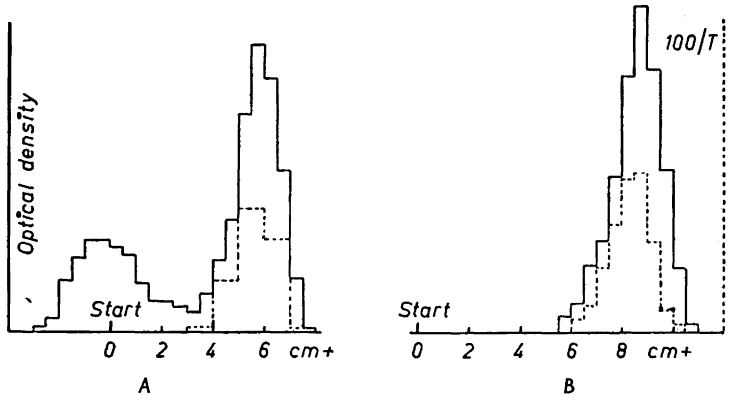

Fig. 1. Paperelectrophoresis of purified prorennin (A) and crystalline rennin (B). The samples are run 7 h in phosphate buffer, pH 6.0, ionic strength 0.1. Field strength 7 V/cm, room temperature. Full line: Colour after staining with bromophenol blue. The density is determined at 595 mμ after elution. Dotted line: The milk-clotting activity of the eluates illustrated as the inverse time of coagulation (in case of prorennin after activation).

NaCl. pH was regulated to 5.4 with 0.5 M phosphate buffer, pH 5.9, (5—10 ml were added per 100 ml solution).

From this solution, 1/2—2/3 of the active material crystallised in rectangular plates after 3—5 weeks in a refrigerator. The crystals were separated by means of centrifugation, and after gently washing with distilled water (2°C) they were dissolved in distilled water to give a solution of 3 000—5 000 RU per ml. Recrystallisation took place after addition of NaCl to a final concentration of 1 N, pH 5.4. When adding NaCl, a precipitate of amorphous rennin was noticed between 0.1—0.3 N NaCl. The precipitate dissolved when the salt concentration was further raised. The yield of the recrystallisation was 90 %. The activity of 10 preparations varied from 880 RU/mg N to 1 000 RU/mg N.

Paperelectrophoresis was carried out according to Kunkel and Tiselius [8]. Experiments were conducted with two spots (0.025 ml) in parallel. One strip was stained with bromophenol blue, and the colour was eluted with 0.1 equimolar hydrocarbonate/carbonate buffer. From the other strip, the enzyme was eluted with buffer, (phosphate buffer 0.05 M, pH 6.3 in the case of rennin, acetate buffer 0.1 M, pH 4.6 in the case of prorennin).

Fig. 1 illustrates two experiments with paperelectrophoresis at pH 6.0 (phosphate buffer, ionic strength 0.1) of purified prorennin and crystalline rennin. The experiment shows a clear difference in mobility of the two proteins. Further electrophoresis experiments at pH's ranging from 5.5 to 7.5 indicate by extrapolation that the isoelectric point of prorennin is about 0.3 pH-unit higher than that of rennin, or approximately 5.0 (Schwander, Zahler and Nitschmann [9], Hankinson [10]).

DISCUSSION

Kleiner and Tauber stated that 1 ml of a solution of 50 mg prorennin preparation in 100 ml of water, after activation, would clot 10 ml reconstituted skim-milk in 11 min at 40°C. As one RU is defined as the rennin activity which clots 10 ml of reconstituted skim-milk in 100 sec at 30°C, it may be surmised that Kleiner and Tauber's preparation, after activation, has had a rennin activity of about 0.3 RU per mg dry substance, (N-contents were not stated). Concerning the rennin activity before activation, a relative rennin activity of less than 5 % would not have been noticed, using the method described by Kleiner and Tauber.

The prorennin preparation resulting from the present work was not fully free of milk-clotting activity, but as experience has shown that purified prorennin easily activates during the process, the milk-clotting activity may be due to rennin formed during the fractionation. Meanwhile, the pre-formed rennin activity is less than 1 % of the total activity.

Assuming that the N-content of prorennin and rennin is of the same order of magnitude, the potential activity of the prorennin preparation corresponds to a prorennin content of approx. 50 %. The milk-clotting activity at the sharp main peak of the paperelectrophoresis indicates that this peak represents the prorennin. The area under this peak, compared with the total area, corresponds fairly well to the above-mentioned 50 %-content of prorennin in the preparation.

As the curve of the milk-clotting activity in the eletrophoresis of crystalline rennin conforms to that of the stained protein, the crystalline rennin should be regarded as electro-homogeneous under the conditions present.

The recrystallisation of rennin described above seems more convenient, and gives a better yield than that previously used by Berridge and Alais. After completion of this work, attention has been drawn to a paper read by Berridge before the International Circle of Research Workers in Dairying (Bern 1957). This paper mentions a recrystallisation similar to that described above.

Short Communications

A Sensitive and Stable Color Reaction for the Quantitative Determination of Vitamin K_1

KURT SCHILLING and HENRIK DAM

Department of Biochemistry and Nutrition, Polytechnic Institute, Copenhagen, Denmark

Various reactions have been proposed for the chemical determination of vitamin K_1. Some of them are based on photometric measurement of a characteristic color obtained with special reagents, others make use of the oxidation-reduction properties of the quinone structure of vitamin K.

Color reactions are preferable in cases where a great number of samples shall be tested.

Among the known color reactions the most promising seems to be that of Irreverre and Sullivan [1]. In this procedure the sample is mixed with an alcoholic solution of sodium diethyldithiocarbamate and treated with sodium ethylate. A transient blue color develops and is measured continuously. The maximum value, which is obtained after about 5 min is used for calculation. Later, the blue color changes to a weak orange yellow.

The disadvantages of this method are the instability of the color and the limited keeping quality of the reagent which makes it necessary to prepare it freshly every day.

It seems likely that the C-N-S grouping in the diethyl-dithiocarbamate is responsible for the development of the color. Therefore, a series of chemical compounds with a similar atomic arrangement have been tested, and attempts made to modify the conditions of the reaction in such a way that stable reagents can be used. A common feature of most of the reactions with these substances was the appearance of a transient violet followed by a yellow to orange color. Various attempts to stabilize the blue or violet color were not successful. The orange end-stage, however, showed in some cases such an intense light absorption that it was adopted for the measurement. Best results were obtained with 5-imino-3-thion-1,2,4-dithiazolidine (xanthane hydride, "perthiocyanic acid") under the conditions described below.

Experimental. Reagents. 1. 80 % saturated xanthane hydride in ethyl alcohol, made by shaking the alcohol with an excess of recrystallized xanthane hydride prepared according to Chattaway and Stevens [2], filtering and addition of 1/4 vol. of alcohol.

2. 1 N KOH in water.

Procedure. 3 ml of the sample dissolved in ethyl alcohol are mixed with 1 ml xanthane hydride solution and 1 ml 1 N KOH. The mixture is placed in a water bath of 50°C for 10 min, and immediately afterwards cooled under the tap. The light absorption is measured at 410 mμ against a reagent blank prepared with 3 ml alcohol instead of the sample. The vitamin content is read from a standard curve prepared in the same way using varying amounts of vitamin K_1.

Results. Standard curves obtained with various concentrations of vitamin K_1 ("Merck", U.S.A.) at three different wavelengths are presented in Fig. 1. Beer's law is followed in the range up to 100 μg/ml. As shown in the figure higher readings may be obtained at shorter wavelengths, but on account of the increasing blank correction, 410 mμ has been chosen for the measurements.

The present method has the following advantages: The reagents are stable for months. The resultant color is stable, the absorption showing a decrease of only

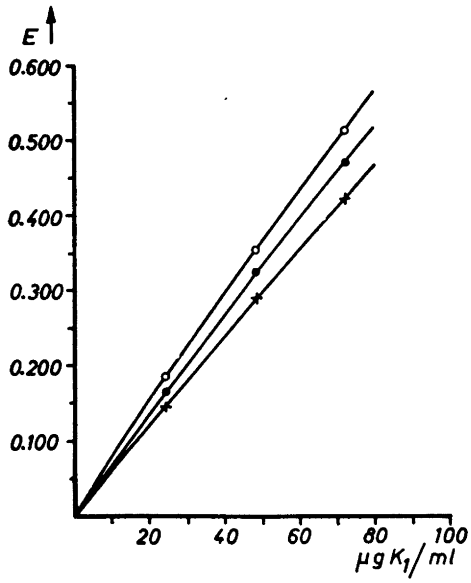

Fig. 1. Absorbancy readings with various amounts of vitamin K_1 at three different wavelengths.

○ 390 mμ. ● 400 mμ. + 410 mμ.

a few per cent after 24 h. The intensity of the light absorption measured at 410 mμ is about twice that obtained with diethyldithiocarbamate according to Irreverre and Sullivan.

When 2-methyl-1,4-naphthoquinone was used instead of vitamin K_1 a reddish color with an absorption maximum about 440 mμ was obtained. Tocopherol-quinone gave only a very slight color, a circumstance which is of importance when the method shall be adapted for the determination of vitamin K in plant material. An analytical procedure for this purpose will be described in a subsequent communication [3].

Colorimetric Estimation of Vitamin K_1 in Plant Material

KURT SCHILLING and HENRIK DAM

Department of Biochemistry and Nutrition, Polytechnic Institute, Copenhagen, Denmark

When vitamin K_1 is to be determined chemically in plant material, the main problem is the separation of the vitamin from interfering substances prior to the measurement.

For this purpose, chromatographic methods in which the vitamin is absorbed on a column have been tried but with little success because absorption of the vitamin usually leads to partial destruction. The best procedure appears to be purification through the hydroquinone form as described by Scudi and Buhs [1], followed by titration with dichlorophenolindophenol. However, this procedure must be carried out in a sealed apparatus without access of air, wherefore it is rather precarious and not very suitable for routine determination.

The difficulties adhering to the usual chromatographic procedures are overcome in the present method in which the extract containing the vitamin is passed through dicalciumphosphate, which absorbs certain accompanying substances but does not retain vitamin K_1. Thereafter the purified extract is submitted to the color reaction with xanthane hydride. The resulting stable coloring matter is soluble in an alkaline water phase, whereby it can be separated from substances with interfering color, especially carotenes.

The principle of the color reaction was described previously [2], but in the present procedure it had to be modified on account of the high lipid content of the extracts.

Experimental. Reagents. 1. Dicalcium phosphate, activated with disodium phosphate according to Moore [3], dried at 110°C and kept in a desiccator over saturated potassium thiocyanate solution as described by Bro-Rasmussen, Hjarde and Porotnikoff [4].

2. 80 % saturated xanthane hydride in ethyl alcohol made by shaking the alcohol with an excess of recrystallized xanthane hydride (5-imino-3-thion-1,2,4-dithiazolidine, "perthiocyanic acid") prepared according to Chattaway and Stevens [5], filtering and adding 1/4 vol. of alcohol.

a few per cent after 24 h. The intensity of the light absorption measured at 410 mμ is about twice that obtained with diethyldithiocarbamate according to Irreverre and Sullivan.

When 2-methyl-1,4-naphthoquinone was used instead of vitamin K_1 a reddish color with an absorption maximum about 440 mμ was obtained. Tocopherol-quinone gave only a very slight color, a circumstance which is of importance when the method shall be adapted for the determination of vitamin K in plant material. An analytical procedure for this purpose will be described in a subsequent communication [3].

Colorimetric Estimation of Vitamin K_1 in Plant Material

KURT SCHILLING and HENRIK DAM

Department of Biochemistry and Nutrition, Polytechnic Institute, Copenhagen, Denmark

When vitamin K_1 is to be determined chemically in plant material, the main problem is the separation of the vitamin from interfering substances prior to the measurement.

For this purpose, chromatographic methods in which the vitamin is absorbed on a column have been tried but with little success because absorption of the vitamin usually leads to partial destruction. The best procedure appears to be purification through the hydroquinone form as described by Scudi and Buhs [1], followed by titration with dichlorophenolindophenol. However, this procedure must be carried out in a sealed apparatus without access of air, wherefore it is rather precarious and not very suitable for routine determination.

The difficulties adhering to the usual chromatographic procedures are overcome in the present method in which the extract containing the vitamin is passed through dicalciumphosphate, which absorbs certain accompanying substances but does not retain vitamin K_1. Thereafter the purified extract is submitted to the color reaction with xanthane hydride. The resulting stable coloring matter is soluble in an alkaline water phase, whereby it can be separated from substances with interfering color, especially carotenes.

The principle of the color reaction was described previously [2], but in the present procedure it had to be modified on account of the high lipid content of the extracts.

Experimental. Reagents. 1. Dicalcium phosphate, activated with disodium phosphate according to Moore [3], dried at 110°C and kept in a desiccator over saturated potassium thiocyanate solution as described by Bro-Rasmussen, Hjarde and Porotnikoff [4].

2. 80 % saturated xanthane hydride in ethyl alcohol made by shaking the alcohol with an excess of recrystallized xanthane hydride (5-imino-3-thion-1,2,4-dithiazolidine, "perthiocyanic acid") prepared according to Chattaway and Stevens [5], filtering and adding 1/4 vol. of alcohol.

Table 1. Absorbancy readings on samples of vitamin K_1 and alfalfa extracts.

	E	$E_{average}$	E_{calc}

200 μg K_1 *	0.352	0.339	
200 μg K_1 *	0.319		
200 μg K_1 **	0.335		
10 ml extract	0.081		
10 ml extract	0.089	0.092	
20 ml extract	0.182	(10 ml)	
20 ml extract	0.216		
10 ml extract + 200 μg K_1	0.433		
10 ml extract + 200 μg K_1	0.403	0.423	0.431
20 ml extract + 200 μg K_1	0.501	0.501	0.523

* Measured directly.
** Measured after passage through dicalcium phosphate column and evaporation.

3. 4 N KOH in methanol.

Procedure. A petroleum ether extract of the material to be tested is prepared. The solution is passed through a column of dicalcium phosphate. The chlorophylls and xanthophylls remain in the upper part while the carotenes are distributed along the column. Elution is carried out with petroleum ether, until the β- and α-carotene-bands have passed out. The eluate is evaporated to dryness *in vacuo* at 20°C and redissolved in 3 ml benzene. After addition of 1.5 ml xanthane hydride solution and 0.5 ml methanolic KOH the sample is placed for 5 min in a water bath of 50°C and cooled immediately afterwards under the tap. 10 ml petroleum ether and 2 ml 50 % alcohol are added, and after thorough shaking the upper layer is siphoned off and discarded. The extraction is repeated once with 10 ml petroleum ether, and finally the light absorption of the aqueous layer is measured at 410 mμ against a reagent blank prepared in the same way with 3 ml benzene instead of the extract.

Results. The procedure was standardized with vitamin K_1 ("Merck", U.S.A.) and applied to an extract from dried alfalfa. Representative results are shown in Table 1. When a petroleum ether solution of vitamin K_1 was passed through a dicalcium phosphate column, evaporated to dryness and taken up in benzene, no loss was encountered as compared with samples where chromatography was omitted. Readings on the extract were proportional to the sample size, and when vitamin K_1 was added to extract samples of different size the absorbancy was equal to the sum of absorbancies from separate measurements on extract and vitamin samples.

Tocopherol quinone may be present in extracts from plant material, but as previously reported [2] it gives only a slight color when using the present procedure.

From the absorbancy readings the vitamin K_1 content of the alfalfa meal was calculated to be 28 μg/g, a figure which is in good agreement with previous biological determinations on this material.

Bifunctional Amines and Ammonium Compounds. VII *

Base Strengths of Some *Tert.* Amino Alkyl Ethers

JØRGEN FAKSTORP and GRETHE SPEGGERS

Research Division, Aktieselskabet Pharmacia, Copenhagen — Vanløse, Denmark

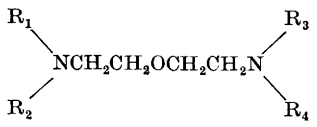
It was thought that information concerning the role of charge distribution in the structure-activity relations of a series of biologically active bis-quaternary ammonium salts of aliphatic ethers currently being studied in these laboratories could be had by determining the dissociation constants of the tertiary precursors of these ammonium compounds. The values found are recorded here.

Method. The freshly distilled tertiary amines were estimated by perchloric acid titration. A quantity sufficient to give 100 ml of a 0.0025 M solution was dissolved by addition of the equivalent amount of 0.1 N HCl. This solution was backtitrated according to Marshall [1] (*cf.* also Gero and Markham [2] and Campbell, Fatora and Campbell [3]).

The values for pK obtained with an observed pH > 9 are corrected for contribution of hydroxyl ions present thus:

$$pK = pH - \log \frac{C_B - C_{OH^-}}{C_{BH^+} + C_{OH^-}}$$

The pK values are plotted in Fig. 1 against the number of methyl substituents in the amino groups (lower tracing pK_1, upper tracing pK_2).



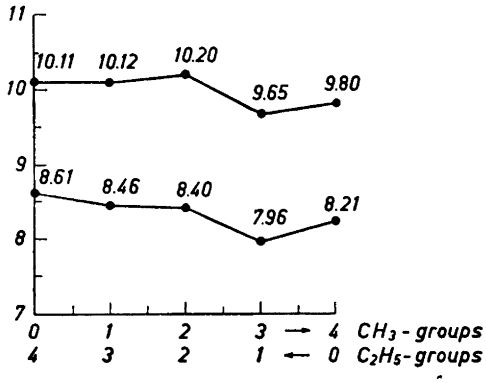


Fig. 1

The ionization constants do not differ very much within the series although both the first and second ionization constant pass through a minimum obtained with the bis-(2-diethyl-amino-2'-ethylmethyl-amino)-ethyl ether.

The interpolation of an ether oxygen between the two nitrogen atoms ought to enhance the inductive mutual hindrance of basic action between them. Thus these amino ethers should be weaker bases than the corresponding polymethylene diamines. No values are recorded for N-alkylsubstituted polymethylene-diamines, but Gero [4] has reported the pK_1 and pK_2 values for the unsubstituted pentamethylene-diamine to be 9.13 and 10.25, respectively.

Occurrence in Plaice Myogen of a Low Molecular Weight Protein of Abnormal Amino Acid Composition

J. W. JEBSEN* and G. HAMOIR**

Laboratory of General Biology, Institute Van Beneden, University of Liège, Belgium

The ultracentrifugation of the myogens of frog [1], carp [2] and plaice [3] has shown the presence in these mixtures of a fraction amounting to 40—55 % in the carp and to approximatively 25 % in the plaice sedimenting with a rate of about 1.5 Svedberg units which does not occur in rabbit myogen. A component of this fraction precipitating at neutral pH between 90 and 100 % saturation of ammonium sulphate has been crystallized from carp muscle extracts by Henrotte [4] and further investigated by Hamoir [5]. Its ultraviolet absorption appears to be exclusively due to phenylalanine the amount of which has been evaluated spectrophotometrically to about 15 %. We show here that a similar protein exists in plaice myogen too.

This mixture has been fractionated with neutral ammonium sulphate. The fraction precipitating between 90 and 100 % saturation has been examined by electrophoresis in presence of phosphate buffer of $\mu = 0.05$ and pH = 7.5. A gradient representing about 30 % of the protein content of the fraction and 2 to 3 % of the myogen separates quickly from the slower ones. The corresponding component has been isolated by preparative electrophoresis and examined by ultracentrifugation and spectrophotometry. It sediments as a single peak with a corrected rate of sedimentation of 1.4—1.5 *S*. Its ultraviolet spectrum at pH = 7.5 and 13 is reproduced in Fig. 1. At neutral pH three maxima are observed at 253, 259 and 265 mμ which correspond closely to those of phenylalanine [6,7]. If the absorption at 259 mμ is exclusively ascribed to phenylalanine and if use is made of Fromageot and Schneck's [6] data for the absorption of this amino acid, its content can be evaluated to 16 %. A small absorption of another origin is, however, apparent in both curves at 275—290 mμ. As it varies from one preparation to the other, it is probably due to an impurity containing tyrosine or cystine. The protein isolated from plaice myogen differs in net charge from the crystalline component found by Henrotte [4]. Is electrophoretic mobility at $\mu = 0.05$ and pH = 7.5 on the descending side is of -6.5×10^{-5} cm^2 volt^{-1} sec^{-1} while that of the carp protein at $p = 0.075$ (0.05 in phosphate and 0.025 in NaCl) and pH = 7.3 is of -3.20×10^{-5} cm^1 volt^{-1} sec^{-1}. The content of basic and acid amino acids thus probably varies according to the origin.

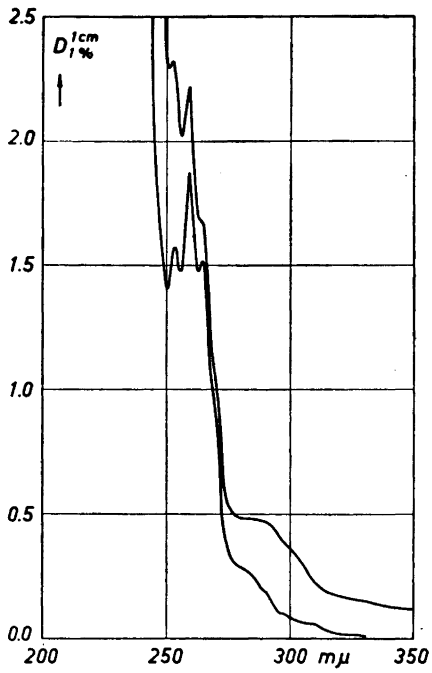

Fig. 1. Ultraviolet spectra at neutral pH (lower curve) and in presence of 0.1 N NaOH (upper curve) of a low molecular weight protein of plaice myogen.

An abnormal type of proteins characterized by a low rate of sedimentation, a very high salting-out range, a high content in phenylalanine and the absence of tyrosine and tryptophane appears therefore to occur generally in fish muscle.

On the Possibility of Periodic Transformations of Enzymes during their Action as Catalysts

J. A. CHRISTIANSEN

Københavns Universitets Fysisk-Kemiske Institut, Copenhagen, Denmark

Against the existence of periodic chemical reactions one may argue that chemical reactions have no inertia, and that for this reason periodic phenomena cannot occur during their advancement. This argument evidently is based on an analogy with mechanical systems like pendulums.

It is, however, not true that inertia is a necessary condition for periodicity in all mechanical systems. *E. g.* an Archimedean screw acting as a motor delivers water periodically and in equally great portions to the lower basin with a well defined frequency. But this frequency is evidently determined by circumstances which have nothing to do with the inertia of the system. Consequently this argument is not valid.

Another argument seems, however, at a first glance to be conclusive. To fix our ideas, let us assume that an irreversible overall reaction (B)

$$B_1 + B_2 + B_3 \rightarrow A_2 + A_3 + A_1 \quad (B)$$

is catalyzed by an enzyme according to the sequence (A)

$$\begin{aligned} B_1 + X_1 &\rightleftharpoons X_2 + A_2 \ (\pm 1) \\ B_2 + X_2 &\rightleftharpoons X_3 + A_3 \ (\pm 2) \\ B_3 + X_3 &\rightleftharpoons X_1 + A_1 \ (\pm 3) \end{aligned} \quad (A)$$

(In preparation for a future paper the A's and B's of Ref.[5] have been interchanged.) The B's and the A's are intended to symbolize the "substrates" while X_1, X_2 and X_3 mean three different forms of the enzyme or complexes of the enzyme with the substrates. The affinity of the overall reaction (B) then compels the enzyme to perform cyclic transformations in the direction 1231. The question now is whether the partition fractions of the enzyme on three forms become steady asymptotically or whether they perform periodic variations around certain mean values. By application of well known ideas one arrives at a system of three linear equations between

the three partition fractions and their first derivatives with respect to time. The solutions of this system are certainly aperiodic and by the way, the two decay constants become so large, that steady state is asymptotically arrived at in minute fractions, *e. g.* 10^{-8}, of a second.

Thus periodic variations should be excluded. However, from nerve physiology it is known with certainty that periodic synchronous phenomena actually occur in certain nerves or rather in their end-organs. As now living organisms have so far as known only chemical reactions as ultimate causes of all observable events which take place in them, we may state with a probability approaching certainty that periodic chemical changes actually occur in nature.

To solve this dilemma one might look for mechanisms of the Volterra [1] type, which allow the appearance of periodic changes. This has been done, *i. a.* by Bonhoeffer [2] and Prigogine [3,4], but such mechanisms must be so artificial that it is hardly possible to believe in their occurrence, *e. g.* in living organisms.

We are therefore turned back on mechanisms of the type described above. Now in solving the corresponding equations we have implicitly assumed, that concentrations and their derivatives with respect to time can be determined simultaneously so accurately as we please. But this may not be true. We can certainly, *e. g.* by means of a "flash" method, determine the concentrations of the forms of the enzyme accurately, at a certain time. But the determination of the derivatives requires a second observation after the lapse of a certain not too short time interval, during which the concentrations may have varied in some unknown way, the more so as the first "flash" to give an observable effect must have changed the state of the enzyme and may have caused some chemical change. Therefore the more accurately we try to determine the concentrations by making the time interval short, the less accurate becomes the determination of the rate of change and *vice versa*.

We thus arrive at the result, that the validity of our system of differential equations can neither be proved nor disproved by direct experiments that is, they are physically unrealistic.

Therefore the occurrence of rhythmic chemical changes in the partition fractions need not surprise us, neither be it surprising that it is actually possible, as shown elsewhere [5], to calculate a frequency of oscillations with time in the values of these fractions.

We have only to remember that the aperiodic and the oscillatory treatment of the kinetic problem mutually exclude each other although separately both are possible.

Distillation Head for the Distillation of Small Amounts of Liquids

ARNE B:SON GROTH

Department of Applied Organic Chemistry, Royal Institute of Technology, Stockholm, Sweden

A distillation head suitable for semi-micro distillation columns has been designed and tested. Above all the author has tried to attain the following results:

1. As small a volume of liquid as possible that will adhere to the walls of the distillation head and the condenser.
2. Absence of stopcocks and ground glass joints.
3. Adjustable and continuous outlet.
4. Fitness for use in distillations at atmospheric pressure as well as under vacuum.

One of the difficulties encountered in the distillation of small amounts of liquid in a column provided with an ordinary distillation head, is the fact that a major part of the liquid to be distilled will remain in the condenser and on the walls of the tube connecting the condenser to the receiver. Usually, this tube has an internal diameter of 1.5—2 mm. Part of this remaining liquid will be in a state of

the three partition fractions and their first derivatives with respect to time. The solutions of this system are certainly aperiodic and by the way, the two decay constants become so large, that steady state is asymptotically arrived at in minute fractions, *e. g.* 10^{-8}, of a second.

Thus periodic variations should be excluded. However, from nerve physiology it is known with certainty that periodic synchronous phenomena actually occur in certain nerves or rather in their end-organs. As now living organisms have so far as known only chemical reactions as ultimate causes of all observable events which take place in them, we may state with a probability approaching certainty that periodic chemical changes actually occur in nature.

To solve this dilemma one might look for mechanisms of the Volterra [1] type, which allow the appearance of periodic changes. This has been done, *i. a.* by Bonhoeffer [2] and Prigogine [3,4], but such mechanisms must be so artificial that it is hardly possible to believe in their occurrence, *e. g.* in living organisms.

We are therefore turned back on mechanisms of the type described above. Now in solving the corresponding equations we have implicitly assumed, that concentrations and their derivatives with respect to time can be determined simultaneously so accurately as we please. But this may not be true. We can certainly, *e. g.* by means of a "flash" method, determine the concentrations of the forms of the enzyme accurately, at a certain time. But the determination of the derivatives requires a second observation after the lapse of a certain not too short time interval, during which the concentrations may have varied in some unknown way, the more so as the first "flash" to give an observable effect must have changed the state of the enzyme and may have caused some chemical change. Therefore the more accurately we try to determine the concentrations by making the time interval short, the less accurate becomes the determination of the rate of change and *vice versa*.

We thus arrive at the result, that the validity of our system of differential equations can neither be proved nor disproved by direct experiments that is, they are physically unrealistic.

Therefore the occurrence of rhythmic chemical changes in the partition fractions need not surprise us, neither be it surprising that it is actually possible, as shown elsewhere [5], to calculate a frequency of oscillations with time in the values of these fractions.

We have only to remember that the aperiodic and the oscillatory treatment of the kinetic problem mutually exclude each other although separately both are possible.

Distillation Head for the Distillation of Small Amounts of Liquids

ARNE B:SON GROTH

Department of Applied Organic Chemistry, Royal Institute of Technology, Stockholm, Sweden

A distillation head suitable for semi-micro distillation columns has been designed and tested. Above all the author has tried to attain the following results:

1. As small a volume of liquid as possible that will adhere to the walls of the distillation head and the condenser.
2. Absence of stopcocks and ground glass joints.
3. Adjustable and continuous outlet.
4. Fitness for use in distillations at atmospheric pressure as well as under vacuum.

One of the difficulties encountered in the distillation of small amounts of liquid in a column provided with an ordinary distillation head, is the fact that a major part of the liquid to be distilled will remain in the condenser and on the walls of the tube connecting the condenser to the receiver. Usually, this tube has an internal diameter of 1.5—2 mm. Part of this remaining liquid will be in a state of

continual "remixing" with the new condensate, and in this way will contribute to a decrease of the efficiency of separation. The other fraction, which under normal conditions moves slowly through the narrow tube connecting the outlet stopcock to the receiver, will cause a variable difference between the boiling points at the condenser and the receiver ends. Moreover, a stopcock is usually stained with lubricating grease, and this will influence the purity of the distillate in the distillation of small amounts of liquids.

Sager [1], Naragon and Lewis [2], Gould, Holzman and Nieman [3] have designed distillation heads for semi-micro distillation columns.

The author has designed a distillation head in which the distillate is collected through a capillary tube (about 1/10 mm internal diameter). The inlet of this capillary lies on a somewhat lower level than that of the outlet. In order to be able to obtain a continuous and adjustable stream of distillate from the distillation head to the receiver, it is necessary to have an appropriate pressure difference between the distillation head and the receiver. The manner in which this is reached is demonstrated in the flow sheet shown in Fig. 1. According to this figure, the pressure difference between the distillation head and the receiver is adjusted by means of stopcock d, *i.e.* the reflux ratio is regulated. For this purpose, a simple and efficient stopcock may consist of a piece of ordinary vacuum hose which can be squeezed, on a few centimeters of its length, between two metal plates. This effect can be arrived at by using a clamp for rubber tubes and two elongated (rectangular) metal plates. It is recommended that the diameter of the capillary outlet does not exceed 1/10 mm, since otherwise it will not have enough inertia during the short pressure variations due to an uneven boiling.

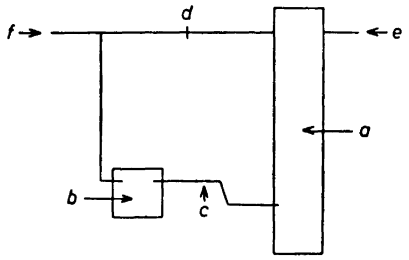

Fig. 1. Flow sheet. a) Distillation head. b) Receiver. c) Capillary tube. d) Adjustable stopcock.
Distillation at atmospheric pressure: e) Introduction of a small gas stream. f) To the surrounding atmosphere.
Distillation under vacuum: e) Introduction of gas through a very fine capillary. f) To vacuum pump.

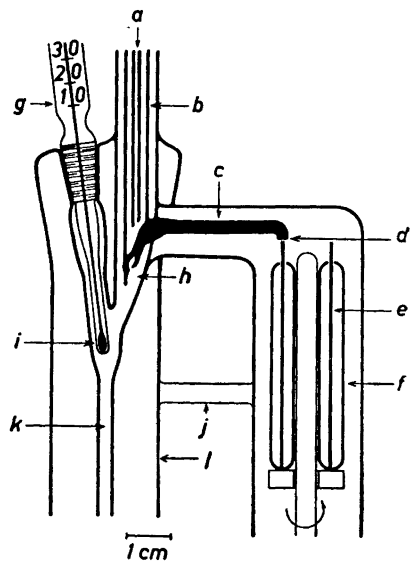

Fig. 2. Description of the distillation head. a) Cooling water. b) Condenser. c) Capillary tube. d) Outlet for distillate. e) Capillary tubes. f) Small test tubes. g) Thermometer. h) Inlet for distillate. i) Thermometer bulb or pocket for a thermocouple (better results are obtained if they are provided with an elongated tip). The distance between the thermometer and the glass walls must be between 1.5 to 2.0 mm. j) Brace. k) Column, 3 mm internal diameter (the packing of the column is not shown in the figure). l) Silvered high-vacuum jacket (the upper part is only halv-silvered).

The distillation head which has been designed by the author is described in Fig. 2. The distillate is sucked from the drop hanging from the tip of the condenser. It is gathered by means of a system similar to that shown by Gould *et al.*[3], *i.e.* through capillaries standing in small test tubes. The capillaries must then be adjusted so as to reach just under the outlet.

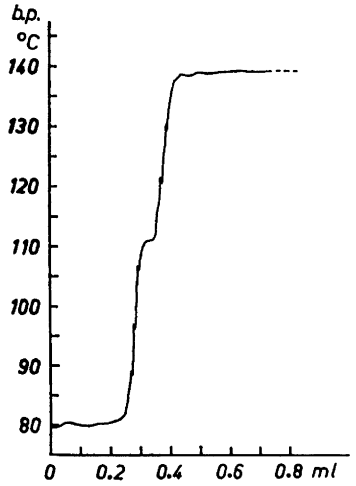

Fig. 3. Distillation curve for a mixture consisting of 0.3 ml benzene, 0.05 ml toluene and 1.0 ml xylene. The temperature was recorded by means of a thermocouple and a recorder.

This will prevent the formation of large drops.

Fig. 3 shows a distillation curve obtained with the apparatus shown in Fig. 2.

It may even be said that this kind of outlet can be applied to larger distillation apparatus. In that case, the system will be designed in such a way that the condensate will drop on the end of the capillary which will have the form of a small cup, with a "dropping tip" at the "outer" bottom.

The construction of the apparatus was executed by the glassblower's firm of Werner Glas (Stockholm).

N-Terminal Amino Acids of Human and Bovine Prothrombin

STAFFAN MAGNUSSON

Chemistry Department II, Karolinska Institutet, Stockholm 60, Sweden

Miller and van Vunakis [1], analyzing bovine prothrombin (~1 500 NIH u/mg), prepared according to Seegers [2], found no N-terminal or C-terminal amino acids, using Sanger's 1-fluoro-2,4-dinitrobenzene method and digestion with carboxypeptidase, respectively.

Recently Miller [3] analyzed bovine prothrombin which he had further purified (~2 000 NIH u/mg) by chromatography on the carboxylic cation exchanger Amberlite IRC 50. He found one mole of N-terminal alanine per mole of prothrombin, again using Sanger's method.

The present author has analyzed bovine and human prothrombin, both prepared according to Seegers [2], using the phenyl-*iso*thiocyanate method of Edman [4] for determination of N-terminal amino acids.

Experimental. Bovine prothrombin was prepared from 20 liter portions of bovine blood. The yield of prothrombin, when freeze-drying the isoelectric precipitate at pH 4.6, after first discarding the precipitate at pH 5.4, was generally 300—400 mg.

Human prothrombin was prepared by the same method from one lot of 3 200 ml pooled plasma from some fifty donors. The yield was 116 mg.

Two methods were used for routine determination of activity.

1. The prothrombin-proconvertin method of Owren and Aas [5], with the modification that barium sulfate adsorbed bovine plasma according to Brodthagen [6] was used as source of fibrinogen and factor V.

2. Activation of prothrombin by dissolving it in 25 % w/w of aqueous trisodium citrate according to Seegers [7]. Clotting activity of the thrombin generated was determined every 15 min, using as substrate bovine fibrinogen (Blombäck and Blombäck [8]) in tris(hydroxymethyl)amino methane buffer of ionic strength 0.15 and pH 7.5.

One of our bovine preparations was compared with a sample of prothrombin (No. 55/02/10) containing 26 000 U/mg tyrosine, obtained from Dr. Seegers and was found to have the same activity as the one of

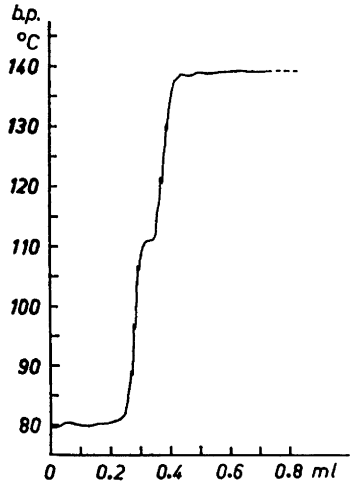

Fig. 3. Distillation curve for a mixture consisting of 0.3 ml benzene, 0.05 ml toluene and 1.0 ml xylene. The temperature was recorded by means of a thermocouple and a recorder.

This will prevent the formation of large drops.

Fig. 3 shows a distillation curve obtained with the apparatus shown in Fig. 2.

It may even be said that this kind of outlet can be applied to larger distillation apparatus. In that case, the system will be designed in such a way that the condensate will drop on the end of the capillary which will have the form of a small cup, with a "dropping tip" at the "outer" bottom.

The construction of the apparatus was executed by the glassblower's firm of Werner Glas (Stockholm).

N-Terminal Amino Acids of Human and Bovine Prothrombin

STAFFAN MAGNUSSON

Chemistry Department II, Karolinska Institutet, Stockholm 60, Sweden

Miller and van Vunakis [1], analyzing bovine prothrombin (~1 500 NIH u/mg), prepared according to Seegers [2], found no N-terminal or C-terminal amino acids, using Sanger's 1-fluoro-2,4-dinitrobenzene method and digestion with carboxypeptidase, respectively.

Recently Miller [3] analyzed bovine prothrombin which he had further purified (~2 000 NIH u/mg) by chromatography on the carboxylic cation exchanger Amberlite IRC 50. He found one mole of N-terminal alanine per mole of prothrombin, again using Sanger's method.

The present author has analyzed bovine and human prothrombin, both prepared according to Seegers [2], using the phenyl-*iso*thiocyanate method of Edman [4] for determination of N-terminal amino acids.

Experimental. Bovine prothrombin was prepared from 20 liter portions of bovine blood. The yield of prothrombin, when freeze-drying the isoelectric precipitate at pH 4.6, after first discarding the precipitate at pH 5.4, was generally 300—400 mg.

Human prothrombin was prepared by the same method from one lot of 3 200 ml pooled plasma from some fifty donors. The yield was 116 mg.

Two methods were used for routine determination of activity.

1. The prothrombin-proconvertin method of Owren and Aas [5], with the modification that barium sulfate adsorbed bovine plasma according to Brodthagen [6] was used as source of fibrinogen and factor V.

2. Activation of prothrombin by dissolving it in 25 % w/w of aqueous trisodium citrate according to Seegers [7]. Clotting activity of the thrombin generated was determined every 15 min, using as substrate bovine fibrinogen (Blombäck and Blombäck [8]) in tris(hydroxymethyl)amino methane buffer of ionic strength 0.15 and pH 7.5.

One of our bovine preparations was compared with a sample of prothrombin (No. 55/02/10) containing 26 000 U/mg tyrosine, obtained from Dr. Seegers and was found to have the same activity as the one of

Seegers, when activated in 25 % sodium citrate. All preparations used in this work had the same or slightly higher activity.

The general procedure for determining N-terminal amino acids was the following. To 0.3 μmoles of prothrombin dissolved in 1 ml of water and 2 ml of pyridine is added 0.1 ml of phenyl*iso*thiocyanate. Coupling is performed at room temperature, keeping the pH at 8.4—9.0 by occasionally adding 0.1 M NaOH. Excess phenyl*iso*thiocyanate is then removed by washing once with benzene and repeatedly with acetone. (In quantitative determinations, where amino acids are added, the acetone washing is replaced by several washings with benzene and freeze-drying.) The vacuum-dried PTC-derivative is then heated in 1 M HCl on a boiling water bath for 60 min. PTH-Amino acids are extracted with ethyl acetate and identified by paper chromatography, using solvents D and E of Edman and Sjöquist [9] and an heptane:formic acid: ethylene chloride solvent (Sjöquist [10]). Spots are visualized by ultraviolet fluorescence on a cadmium borate screen [9] and eluted over night in 95 % ethanol at room temperature. The technique described is mainly in accordance with Blombäck and Yamashina [11].

Results. In qualitative experiments on bovine prothrombin only alanine was identified as N-terminal amino acid in several different preparations. No positive evidence for the occurrence of histidine or arginine in N-terminal position could be obtained.

Assuming the yield of PTH-alanine from N-terminal alanine in prothrombin to be the same as from added free alanine, we found the following amounts (calculated on moisture-free substance and using the value 62 700 for the molecular weight [12]):

Prothrombin, No.	Moles N-term. alanine per 62 700 g prothrombin	Solvent system
33	0.80	D, E[9]
43	0.87	D, E[9]
67	0.85	Sjöquist [10]

With human prothrombin for lack of material only one determination was made. In this case also alanine was found to be the only N-terminal amino acid. Its PTH-derivative was identified by paper chromatography in solvent D and the above mentioned solvent of Sjöquist [10]. Furthermore it had an absorption spectrum in the ultraviolet which is characteristic for PTH-amino acids. Quantitatively 0.7 moles/mole were found, assuming the human and bovine prothrombins to have the same molecular weight.

Preliminary experiments to determine changes in N-terminal amino acids during activation in citrate were performed on bovine prothrombin. At maximum thrombin clotting activity the activation mixture was found to contain alanine, glycine, *iso*leucine (or leucine), phenylalanine, threonine, aspartic and glutamic acids in N-terminal position.

Isolation of ^{32}P-labeled Phosphoserine from a Preparation of Intestinal Alkaline Phosphatase Incubated with Radioactive Inorganic Phosphate

LORENTZ ENGSTRÖM and GUNNAR ÅGREN

Department of Medical Chemistry, University of Uppsala, Sweden

In a previous paper it was demonstrated that ^{32}P-labeled phosphoserine could be isolated from a yeast hexokinase preparation incubated with radioactive ATP or glucose 6-phosphate [1]. This was taken as evidence of the formation of an intermediate enzymephosphate in the hexokinase reaction. In the reaction a P—O linkage is opened [2] which means that according to our result a phosphoryl group is transferred to the enzyme. The actual site of the phosphoryl group on the enzyme has so far not been investigated. Stein and Koshland [3] have shown that a P—O linkage also is opened when alkaline phosphatase acts on glycerol phosphate, phenyl phosphate and 3′-adenosine monophosphate. The formation of an intermediate enzymephosphate in the reaction of this enzyme would be of considerable interest.

In our experiments we have used a commercial preparation *. Since the enzyme reaction is reversible it should be possible to use radioactive inorganic phosphate as a substrate. 500 mg of enzyme dissolved in 25 ml of water was incubated with 2 mC ^{32}P. After half a minute the protein was precipitated with trichloroacetic acid. The precipitate was hydrolyzed and radioactive phosphoserine could be isolated as previously described [1]. Alkaline phosphatase activity is completely inhibited by a 0.05 M solution of versene [5]. During these conditions no radioactive phosphoserine could be isolated.

The enzyme was purified by ethanol fractionation at −5°C. In the presence of 0.05 M magnesium acetate 75 % of the phosphatase activity was recovered between 37 and 50 % ethanol. The incorporation of activity in the phosphoserine phosphorus ran parallel with the increase of enzyme activity. To exclude an unspecific reaction between inorganic phosphate and protein-bound serine a number of proteins were incubated with a 2-fold increase of ^{32}P-labeled phosphate but otherwise during the same conditions as in the enzyme experiments. Crystalline serum albumin, egg albumin, pepsin, chymotrypsin, insulin and a γ-globulin preparation were used. No trace of radioactive phosphoserine could be revocered from the hydrolyzed proteins.

In a series of experiments 500 mg samples of enzyme and 2 mC ^{32}P were incubated at different pH for 5 min at room temperature. The total radioactivity of the isolated phosphoserine fractions measured in a L.K.B. Robot Scaler was the following:

pH 5	24 600 cpm (counts per min)	pH 8	13 200 cpm
pH 6	45 000 cpm	pH 9	7 900 cpm
pH 7	34 400 cpm	pH 10	2 200 cpm

At pH 5 the preparation could not be completely dissolved. If the reaction between enzyme and substrate is formulated as follows:

$$\text{Enzyme} + [H_2PO_4^-] \rightleftharpoons \text{Enzymephosphate} + [OH^-]$$

a decrease of hydroxyl ions should drive the reaction to the right. This should be accompanied by an increase of the activity of the phosphoserine isolated from the enzyme-phosphate which was actually found.

The investigation was supported by grants from the *Gustav and Tyra Svensson Memorial Foundation* and the *Swedish Medical Research Council.*

A Note on the Isolation of Solamargine from *Solanum nigrum*

PER M. BOLL

Department of Organic Chemistry, The Royal Danish School of Pharmacy, Copenhagen, Denmark

In the course of an investigation of alkaloids occurring in different species of the plant genus *Solanum* two alkaloidal glycosides were chromatographically detected in *S. nigrum*. The one with the highest R_F-value was subsequently isolated and identified as solamargine, an alkaloidal glycoside first isolated from *S. marginatum* [1].

The isolation procedure reported by Kuhn and Löw [2] was followed. The green, oily residue obtained by this procedure was dissolved in water-saturated 1-butanol and chromatographed on a column of wet-packed alumina (Alcoa). Elution with water-saturated 1-butanol gave a yield of 650 mg alkaloid mixture from 2.93 kg of fresh plant tops.

Using the same developing solvent and technique as Kuhn and Löw [2] for paper chromatography two alkaloid spots with $R_{\alpha\text{-solanine}} = 1.04$ and $R_{\alpha\text{-solanine}} = 1.72$ were obtained (travelling distance of solvent 31.2 cm. The R_F- and $R_{\alpha\text{-solanine}}$-values depend highly upon both experimental conditions and travelling distance of solvent).

When the alkaloid mixture, dissolved in water-saturated 1-butanol, was rechromatographed on a column of wet-packed alumina (Alcoa) and eluted with water-saturated 1-butanol the alkaloid residue consisted mainly of the alkaloid component with the highest R_F-value. Repeated crystallization from ethanol-water (1:1) gave a chromatographically pure compound, m.p. 304–310°C (decomp., corr.), $[\alpha]_D^{23} = -99°$ (methanol, *c* 0.531). (Literature values for solamargine [1]: m. p. 301°C (evacuated tube, decomp.), $[\alpha]_D^{20} = -105°$ (methanol)). Potentiometric titration of the glycoside with 0.02 N perchloric acid in glacial acetic acid gave an equivalent weight of 914 (calc. 868 for anhydrous solamargine).

At this stage of the investigation a review article was published by Schreiber [3]. In his paper a footnote was added in proof stating that two chromatographically detected alkaloids, γ- and δ-solanigrine, from *S. nigrum* [4] were identical with solasonine and solamargine, respectively. No analytical results were submitted.

The aglycone was isolated by acid hydrolysis of the glycoside following the procedure used by Briggs *et al.*[1] The aglycone melted at 199–200°C, $[\alpha]_D^{23} = -98°$ (methanol, *c* 0.481). No melting point depression was observed when mixed with authentic solasodine (Literature values for solasodine [1]: m.p. 197.5–198.5°C, $[\alpha]_D^{20} = -97.1$ (methanol)). The infrared spectrum of the aglycone was identical with the spectrum of solasodine.

The acidic mother liquor remaining after hydrolysis of the glycoside and precipitation of the aglycone was by means of paper chromatography shown to contain D-glucose and L-rhamnose. Aliquots were chromatographed on Whatman No. 1 paper at 23°C. Aniline hydrogen phthalate was used as detecting reagent.

The solvent mixture 1-butanol-ethanol-water (8:1:2) revealed spots with the following R_F-values: 0.44 L-rhamnose, 0.16 D-glucose.

The solvent mixture ethyl acetate-water -pyridine (2:2:1) revealed spots with the following R_F-values: 0.48 L-rhamnose, 0,27 D-glucose.

The results were controlled by parallel runs of pure monosaccharides alone and in mixtures.

The author is indebted to Professor H. Baggesgaard Rasmussen for valuable discussions and to Dr. K. Schreiber, Mühlhausen/Thür. for a specimen of solasodine. The work is part of investigations supported by *Statens almindelige Videnskabsfond (The Danish State Research Foundation)*.

The Sialic Acids of Hog Gastric Mucosa

PAULA ATTERFELT, INGEMAR BLOHMÉ, ANDERS NORRBY and LARS SVENNERHOLM

Department of Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden

The mucoids and the mucopolysaccharides of hog gastric mucosa have been subject to great interest because they contain compounds of physiological importance as, *e. g.*, the intrinsic factor and the bifidus factor. Several carbohydrate components have been isolated from the gastric mucosa, but hitherto not the sialic acids, although Werner and Blix [1] have determined their amount in gastric mucosa to 3—5 %. In previous papers [2-4] it has been shown that the composition of the sialic acids in hog material showed large variations. In the pancreas and the submaxillary gland N-glycolylsialic acid was the main component, but in the serum proteins N-glycolylsialic acid constituted only 10—15 % of the total sialic acids. Therefore, we postulated that in the epithelial mucins N-glycolylsialic acid occurred practically pure but in the glycoproteins of serum type N-acetylsialic acid was the dominating acid.

Experimental. Isolation of sialic acids. Fifty stomachs from hogs were collected immediately after slaughter and washed free from food contaminants and floating mucus. The mucosal linings of the corpus and the canalis were scraped off — yield 2.3 kg — and poured into 10 l of ethanol. The mixture was brought to boiling. The ethanol was filtered off and the residue was treated with ethanol once more. The residue was then treated with weak sulphuric acid and the sialic acids isolated as described for human liver [5]. The yield of lyophilized sialic acids was 580 mg which constituted about 80 % of the calculated value. The sialic acids were crystallized from a methanol-water solution by adding diethyl ether. Yield 534 mg (Fraction A).

As the ethanol solution also gave a positive sialic acid reaction it was concentrated *in vacuo* to about 1 l. It was shaken three times with chloroform in a separatory funnel for removing the lipids. After filtration the lipid-free solution was run through Dowex 50 (H^+) and then on a column with Dowex 1 in hydroxyl-formate (9:1, v/v) form. (Because of the large amount of salt the sialic acids were not attached to the anion exchange resin when it was in acetate or formate form.) The sialic acids were eluted from the resin with 0.3 N formic acid as earlier described [5]. Yield 110 mg. The yield of crystallized material was only 56 mg due to an accident at the crystallization (Fraction B).

Results. Elementary analysis. Fraction A: C 42.37; H 6.22; N 4.42. Calc. for N-acetylsialic acid ($C_{11}H_{19}NO_9$): C 42.72; H 6.19; N 4.53. Calc. for N-glycolylsialic acid ($C_{11}H_{19}NO_{10}$): C 40.61; H 5.89; N 4.31. *Glycolic acid* was determined with the method of Klenk and Uhlenbruck [6] with minor modifications [3]. Fraction A: 4.5 % glycolic acid, corresponding to 19 % N-glycolylsialic acid. Fraction B: 5.8 % glycolic acid, corresponding to 25 % N-glycolylsialic acid. *Optical rotation:* Fraction A: $[\alpha]_D^{20} = -30.8°$.

Paper partition chromatography: As solvent was used *n*-butanol-*n*-propanol-0.1 N hydrochloric acid (1:2:1, v/v). Two spots were indicated with the same position as N-acetylsialic acid and N-glycolylsialic acid. The *X-ray powder diagrams* were of the O-sialic acid (N-acetylsialic acid) type [7]. The *infrared spectrum* was of the same type as that of a mixture of the two sialic acids.

Discussion and summary. The sialic acids from hog gastric mucosa have been isolated and crystallized. They were obtained in a good yield and were shown to be a solid solution of 20 % N-glycolylsialic acid in 80 % N-acetylsialic acid. The ratio N-glycolylsialic acid/N-acetylsialic acid is somewhat greater than in the serum proteins but far from the ratio in the submaxillary mucin. If the hypothesis is valid that the mucoids of the mucous secretions of hog is practically pure N-glycolylsialic acid, the sialic acids in gastric mucosa are mainly derived from proteins of serum type.

The great amount of free sialic acids is remarkable as they have not been found earlier in free form in biological materials. The sialic acids were not liberated during the isolation by the boiling ethanol, as free sialic acids were indicated also at the precipitation of the mucosa with ethanol in the cold. They were probably liberated by the hydrochloric acid in the stomach but no test was made for sialidase. Work is now in progress to analyse the concentration of free sialic acids in the gastric juice from normal and achlorhydric subjects.

Recently it was described that some carbohydrates enhanced the vitamin B_{12} absorption [8]. It is possible that the free sialic acids may be of importance for this transport.

The Losses of Vitamin A during Chromatography

GEORG LAMBERTSEN and OLAF R. BRÆKKAN

Governmental Vitamin Laboratory, Norwegian Fisheries Research Institute, Bergen, Norway

When the irrelevant absorption in the spectrophotometric determination of vitamin A exceeds certain limits, the geometric correction method according to Morton and Stubbs [1] is unreliable, and purification of the vitamin A fraction by chromatography is recommended. Actually chromatography is included in the procedure described in official methods in some countries. The chromatography is most often carried out on alumina columns by some modification of the method described by Gridgeman, Gibson and Savage [2] for the estimation of vitamin A in whale liver oils. A certain activity of the alumina is needed to obtain a sufficient separation of the unsaponifiable substances, but unfortunately a higher activity also means a higher loss of vitamin A in the procedure. In our experience the most potent oils give the highest losses, even up to 10 % for some vitamin A concentrates. Such losses can be counteracted by deactivation of the alumina. Usually a standardized activity is obtained by uniform water addition. To avoid this difficulty the use of a softer adsorbent, *e.g.* calcium phosphate has been introduced [3]. It is, however, of importance to obtain standardized columns in different laboratories, and alumina is the adsorbent preferred as it can be obtained readily in uniform quality everywhere as "Aluminium Oxide Standardized for Adsorption analysis according to Brockman". As mentioned above, a softening of the alumina is necessary to make it useful. Such deactivation will, however, result in a reduced separation of the components in the unsaponifiable matter. A limit thus has to be found where conditions are optimal all factors considered. This means that a certain loss is unavoidable, and must be controlled and taken into consideration by using a standard.

We have been trying to find substances which, added to the vitamin A fraction, would reduce the losses during the chromatography. Gridgeman *et al.*[2a] found it advisable to add cholesterol to make up the weight of the unsaponifiable matter if this amounted to less than 0.35 g. We found cholesterol to be of no effect in preventing the loss of vitamin A. Neither did several other types of substances, *e.g.* fatty alcohols or glyceryl ethers, have any such effect. The unsaponifiable matter of ground nut oil, however, gave a striking reduction in the loss. In one experiment the unsaponifiable matter of 0.5 g of ground nut oil gave a recovery of 98 % of a total of 2 000 I.U. vitamin A compared to 90 % without addition. The effect was found in the fraction of the unsaponifiable matter passing the alumina column with a speed similar to vitamin A. Analysis on paraffinated paper as described by Green, Marcinkiewicz and Watt [4] showed that the effective fraction contained γ-tocopherol. Pure γ-tocopherol (Eastman-Kodak) was then tried, and the effect was obtained with as little as 200 μg added per 1 000 I.U. vitamin A put through the column. α-Tocopherol had no effect, but as other slow moving tocopherols might be effective, the unsaponifiable matter of other vegetable oils were tried. Soy bean oil with its high concentration of γ- and δ-tocopherols (1.000 μg per g compared with 200 μg per g in ground nut oil) protected effectively against losses. Alumina columns of the

The Losses of Vitamin A during Chromatography

GEORG LAMBERTSEN and OLAF R. BRÆKKAN

Governmental Vitamin Laboratory, Norwegian Fisheries Research Institute, Bergen, Norway

When the irrelevant absorption in the spectrophotometric determination of vitamin A exceeds certain limits, the geometric correction method according to Morton and Stubbs [1] is unreliable, and purification of the vitamin A fraction by chromatography is recommended. Actually chromatography is included in the procedure described in official methods in some countries. The chromatography is most often carried out on alumina columns by some modification of the method described by Gridgeman, Gibson and Savage [2] for the estimation of vitamin A in whale liver oils. A certain activity of the alumina is needed to obtain a sufficient separation of the unsaponifiable substances, but unfortunately a higher activity also means a higher loss of vitamin A in the procedure. In our experience the most potent oils give the highest losses, even up to 10 % for some vitamin A concentrates. Such losses can be counteracted by deactivation of the alumina. Usually a standardized activity is obtained by uniform water addition. To avoid this difficulty the use of a softer adsorbent, *e.g.* calcium phosphate has been introduced [3]. It is, however, of importance to obtain standardized columns in different laboratories, and alumina is the adsorbent preferred as it can be obtained readily in uniform quality everywhere as "Aluminium Oxide Standardized for Adsorption analysis according to Brockman". As mentioned above, a softening of the alumina is necessary to make it useful. Such deactivation will, however, result in a reduced separation of the components in the unsaponifiable matter. A limit thus has to be found where conditions are optimal all factors considered. This means that a certain loss is unavoidable, and must be controlled and taken into consideration by using a standard.

We have been trying to find substances which, added to the vitamin A fraction, would reduce the losses during the chromatography. Gridgeman *et al.*[2a] found it advisable to add cholesterol to make up the weight of the unsaponifiable matter if this amounted to less than 0.35 g. We found cholesterol to be of no effect in preventing the loss of vitamin A. Neither did several other types of substances, *e.g.* fatty alcohols or glyceryl ethers, have any such effect. The unsaponifiable matter of ground nut oil, however, gave a striking reduction in the loss. In one experiment the unsaponifiable matter of 0.5 g of ground nut oil gave a recovery of 98 % of a total of 2 000 I.U. vitamin A compared to 90 % without addition. The effect was found in the fraction of the unsaponifiable matter passing the alumina column with a speed similar to vitamin A. Analysis on paraffinated paper as described by Green, Marcinkiewicz and Watt [4] showed that the effective fraction contained γ-tocopherol. Pure γ-tocopherol (Eastman-Kodak) was then tried, and the effect was obtained with as little as 200 μg added per 1 000 I.U. vitamin A put through the column. α-Tocopherol had no effect, but as other slow moving tocopherols might be effective, the unsaponifiable matter of other vegetable oils were tried. Soy bean oil with its high concentration of γ- and δ-tocopherols (1.000 μg per g compared with 200 μg per g in ground nut oil) protected effectively against losses. Alumina columns of the

type used for vitamin A chromatography will not separate dimethyltocols from momomethyltocols, and the effect of the unsaponifiable matter may be a joint effect of γ- and δ-tocopherols. This is indicated by the fact that soy bean oil containing 5 times as much totally of these tocopherols than ground nut oil, is effective in one-fifth of the concentration.

The effect of these tocopherols is not one of simple displacement, as γ-tocopherol failed to elute further vitamin A from a column where vitamin A had passed through without protection. It may be a pure antioxidant effect protecting against oxidative substances in solvents and adsorbent. A more likely theory is that the tocopherols take the place of vitamin A in irreversible adsorption on the alumina. This is indicated by the recovery of anhydrovitamin A by ethanol elution of a column where vitamin A had passed with a loss.

The last 1—2 % loss of vitamin A during chromatography may arise from the diffusion of the vitamin A-band on the column. It was possible to prove the presence of vitamin A by concentration of the fractions leaving the column before and after the vitamin A-fraction. Carr-Price spot tests or fluorescence test with U.V.-light had given no positive reaction of vitamin A in these fractions.

Tocopherol-fractions useful for the purpose of protection against losses of vitamin A in chromatography can be produced easily from a proper vegetable oil, and be stored in hexane in the freezer for a couple of months. It is recommended to add a suitable aliquot of such a solution to the vitamin A fraction before chromatography of medium and high potent oils.

The Isolation of O-Phosphoethanolamine from the Rest Protein Fraction of *Escherichia coli* B

CARL-HENRIC DE VERDIER and GUNNAR ÅGREN

Institute of Medical Chemistry, University of Uppsala, Sweden

In earlier communications [1,2] it has been shown that acid hydrolysates of the Schneider rest protein fractions from mammalian organs contain O-phosphoserine and O-phosphothreonine. Phosphoserine has also been isolated from the corresponding protein fraction of yeast [3] but in other microorganisms phosphorylated hydroxyamino acids of different composition seem to dominate in the acid hydrolysates [4,5].

It has now been possible to isolate O-phosphoethanolamine in crystalline form from the acid hydrolysate of the rest protein fraction of *E. coli*. Previously published methods for isolation have been followed. The bacteria were harvested at the end of the lag phase. They had been cultivated for about 2 h on a medium containing 1 mC radioactive phosphate per liter [5] to facilitate the identification of phosphorus compounds. Fig. 1 shows the elution curve of the hydrolysed cell walls in the first step of purification through a Dowex-50 column. Of the three main peaks (I, III, V) No. I consists of inorganic phosphate, No. III is a mixture of at least three ninhydrin positive compounds which are not identical with phosphoserine or phosphothreonine. No. V is practically pure phosphoethanolamine. Peak No. II is probably a nucleotide since it gives UV-absorption at 260 mμ and no ninhydrin reaction. A hydrolysate of peak No. IV shows on a paper chromatogram mainly ethanolamine and a few other weaker ninhydrin spots. Sufficient amounts of material for the identification of peak No. V was obtained by mixing radioactive bacteria with large amounts of unlabelled cells. For large scale cultivation the microorganisms were incubated in a 1 000 liter tank on the same medium for about 20 h. The usual yield of fresh bacteria from a single cultivation was about 2.5 kg. Material from two cultivations was used in this study.

type used for vitamin A chromatography will not separate dimethyltocols from momomethyltocols, and the effect of the unsaponifiable matter may be a joint effect of γ- and δ-tocopherols. This is indicated by the fact that soy bean oil containing 5 times as much totally of these tocopherols than ground nut oil, is effective in one-fifth of the concentration.

The effect of these tocopherols is not one of simple displacement, as γ-tocopherol failed to elute further vitamin A from a column where vitamin A had passed through without protection. It may be a pure antioxidant effect protecting against oxidative substances in solvents and adsorbent. A more likely theory is that the tocopherols take the place of vitamin A in irreversible adsorption on the alumina. This is indicated by the recovery of anhydrovitamin A by ethanol elution of a column where vitamin A had passed with a loss.

The last 1—2 % loss of vitamin A during chromatography may arise from the diffusion of the vitamin A-band on the column. It was possible to prove the presence of vitamin A by concentration of the fractions leaving the column before and after the vitamin A-fraction. Carr-Price spot tests or fluorescence test with U.V.-light had given no positive reaction of vitamin A in these fractions.

Tocopherol-fractions useful for the purpose of protection against losses of vitamin A in chromatography can be produced easily from a proper vegetable oil, and be stored in hexane in the freezer for a couple of months. It is recommended to add a suitable aliquot of such a solution to the vitamin A fraction before chromatography of medium and high potent oils.

The Isolation of O-Phosphoethanolamine from the Rest Protein Fraction of *Escherichia coli* B

CARL-HENRIC DE VERDIER and GUNNAR ÅGREN

Institute of Medical Chemistry, University of Uppsala, Sweden

In earlier communications [1,2] it has been shown that acid hydrolysates of the Schneider rest protein fractions from mammalian organs contain O-phosphoserine and O-phosphothreonine. Phosphoserine has also been isolated from the corresponding protein fraction of yeast [3] but in other microorganisms phosphorylated hydroxyamino acids of different composition seem to dominate in the acid hydrolysates [4,5].

It has now been possible to isolate O-phosphoethanolamine in crystalline form from the acid hydrolysate of the rest protein fraction of *E. coli*. Previously published methods for isolation have been followed. The bacteria were harvested at the end of the lag phase. They had been cultivated for about 2 h on a medium containing 1 mC radioactive phosphate per liter [5] to facilitate the identification of phosphorus compounds. Fig. 1 shows the elution curve of the hydrolysed cell walls in the first step of purification through a Dowex-50 column. Of the three main peaks (I, III, V) No. I consists of inorganic phosphate, No. III is a mixture of at least three ninhydrin positive compounds which are not identical with phosphoserine or phosphothreonine. No. V is practically pure phosphoethanolamine. Peak No. II is probably a nucleotide since it gives UV-absorption at 260 mμ and no ninhydrin reaction. A hydrolysate of peak No. IV shows on a paper chromatogram mainly ethanolamine and a few other weaker ninhydrin spots. Sufficient amounts of material for the identification of peak No. V was obtained by mixing radioactive bacteria with large amounts of unlabelled cells. For large scale cultivation the microorganisms were incubated in a 1 000 liter tank on the same medium for about 20 h. The usual yield of fresh bacteria from a single cultivation was about 2.5 kg. Material from two cultivations was used in this study.

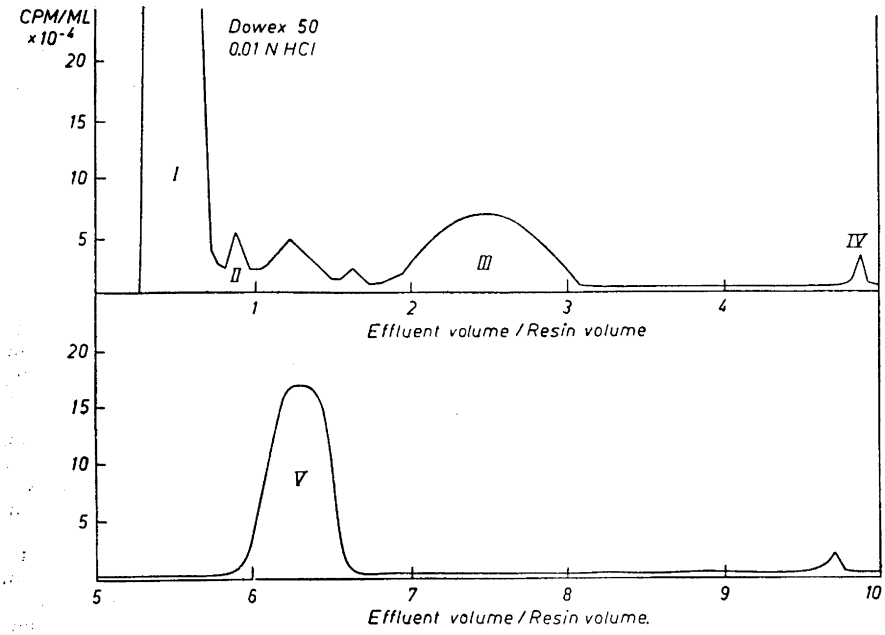

Fig. 1. Radioactivity curve from a hydrolysate of membranes from *E. coli*. incubated for 2½h in a ^{32}P-containing medium. The curve is obtained by plotting the number of impulses per min (cpm) in 1 ml aliquots of each tube.

The identity of peak No. V was verified by elementary analysis (Found: C 17.4; H 5.9; N 9.6; P 23.8. Calc. for $C_2H_8O_4NP$ (141): (C 17.0; H 5.7; N 9.9; P 22.0) and by paper chromatography and ionophoresis. The Debye-Scherrer powder photograph of material from peak No. V was identical with the pattern of a purified commercial preparation of phosphoethanolamine *. The spacings obtained are given in Table 1.

Free phosphoethanolamine has been reported to occur both in normal and neoplastic animal tissues [6]. Ethanolamine has also recently been found in an acid hydrolysate of a peptide-phospholipide-polysaccharide complex from *E. coli* [7]. Recent reports also describe the natural occurrence of phosphatides where the nitrogen moiety consists of a polypeptide [8]. To our knowledge protein-bound phosphoethanolamine has previously not been desribed. We have not found this substance in chromatographic purification of acid hydrolysates from mammalian tissues or in other microcrganisms such as baker's yeast or *L. casei*. The Schneider protein fraction of *E. coli* contained between 0.3—0.5 % of fatty acids. Calculated only as phosphatidylethanolamine the acid hydrolysate of this

amount of phospholipid would have yielded less phosphoethanolamine than actually isolated. On the other hand after extraction of lipids in the bacteria the remaining fraction of nucleic acids and protein still contained about 3 % of fatty acids. By the subsequent extraction of nucleic acids with hot 5 % trichloroacetic acid a cephalin-protein compound may have been hydrolyzed giving a part of the phosphoethanolamine bound to the protein part. At present time it is not possible to decide whether the compound is a constituent of a phosphoprotein or represents a link in a lipoprotein complex. In this connection it must be reminded about the fact that *E. coli* as a Gramnegative bacterium contains more phospholipids than a Grampositive microorganism as *L. casei* [9,10]. However, phosphoethanolamine cannot only be isolated from the rest proteins of the walls but also from water soluble fractions of proteins obtained after centrifugation at 105 000 *g* for 30 min at 0°C and precipitation with ethanol or acetone [5].

Note on the Mutual Solubility of Molybdenum Trioxide and Wolfram Trioxide

SVEN WESTMAN and ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

Previous studies on the molybdenum trioxide-wolfram trioxide system have shown that the mutual solubility of these two substances, if there is any at all, is very low [1] (experiments performed at room temperature using samples prepared at 700°C). Access to a Guinier focusing camera with strictly monochromatized $CuK\alpha_1$ radiation has made possible a quantitative estimation of the limits of solubility.

The samples studied were prepared by prolonged heating of intimate mixtures of the two trioxides (both of reagent grade) in sealed, evacuated silica tubes at 700°C. Precautions as described elsewhere [2] were taken to ensure a constant temperature during the annealing time (two periods, of about one week each with intervenient regrinding of the specimen). The samples were quenched in water from the heating temperature. Potassium chloride (Analar, British Drug Houses, $a = 6.2919$ Å at 20°C [3]) was added to the powder specimens as an internal standard [4].

For wolfram trioxide the following unit cell dimensions were obtained:

$a = 7.306 \pm 0.001$ Å, $b = 7.541 \pm 0.001$ Å,
$c = 3.845 \pm 0.001$ Å, $\beta = 90.85° \pm 0.05°$.

The axial lengths exceed by about 0.3 % those derived previously from photographs taken without an internal standard [5,6]. The axial ratios and monoclinic angles obtained from the two experiments are, however, in fair agreement.

Addition of molybdenum trioxide caused slight, continuous modifications of the wolfram trioxide powder pattern up to the approximate composition $W_{0.96}Mo_{0.04}O_3$, which evidently represents the limit of solubility under the conditions mentioned above. These changes are exclusively attributable to a decrease of the length of the a axis, which for the latter composition was found to reach the limiting value of 7.301 ± 0.001 Å, while the other unit cell dimensions were not perceptibly altered.

Note on the Mutual Solubility of Molybdenum Trioxide and Wolfram Trioxide

SVEN WESTMAN and ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

Previous studies on the molybdenum trioxide-wolfram trioxide system have shown that the mutual solubility of these two substances, if there is any at all, is very low [1] (experiments performed at room temperature using samples prepared at 700°C). Access to a Guinier focusing camera with strictly monochromatized $CuK\alpha_1$ radiation has made possible a quantitative estimation of the limits of solubility.

The samples studied were prepared by prolonged heating of intimate mixtures of the two trioxides (both of reagent grade) in sealed, evacuated silica tubes at 700°C. Precautions as described elsewhere [2] were taken to ensure a constant temperature during the annealing time (two periods, of about one week each with intervenient regrinding of the specimen). The samples were quenched in water from the heating temperature. Potassium chloride (Analar, British Drug Houses, $a = 6.2919$ Å at 20°C [3]) was added to the powder specimens as an internal standard [4].

For wolfram trioxide the following unit cell dimensions were obtained:

$a = 7.306 \pm 0.001$ Å, $b = 7.541 \pm 0.001$ Å,
$c = 3.845 \pm 0.001$ Å, $\beta = 90.85° \pm 0.05°$.

The axial lengths exceed by about 0.3 % those derived previously from photographs taken without an internal standard [5,6]. The axial ratios and monoclinic angles obtained from the two experiments are, however, in fair agreement.

Addition of molybdenum trioxide caused slight, continuous modifications of the wolfram trioxide powder pattern up to the approximate composition $W_{0.96}Mo_{0.04}O_3$, which evidently represents the limit of solubility under the conditions mentioned above. These changes are exclusively attributable to a decrease of the length of the a axis, which for the latter composition was found to reach the limiting value of 7.301 ± 0.001 Å, while the other unit cell dimensions were not perceptibly altered.

For pure molybdenum trioxide, unit cell dimensions were obtained in fair agreement with previous data [6], *viz.*

$a = 3.9628 \pm 0.0007$ Å $b = 13.855 \pm 0.003$ Å
$c = 3.6964 \pm 0.0006$ Å

The powder patterns of molybdenum trioxide samples containing minor additions of wolfram trioxide gave lattice parameters slightly different from those of pure molybdenum trioxide. Thus the a axis was found to decrease to a limiting value of 3.9590 ± 0.0006 Å at the approximate composition $Mo_{0.96}W_{0.04}O_3$ while the b and c axes reached maximum lengths of 13.862 ± 0.003 Å and 3.6989 ± 0.0007 Å, respectively, at the composition $Mo_{0.98}W_{0.02}O_3$. The results might possibly indicate a considerable deviation from linearity of the parameter changes associated with the substitution of wolfram for molybdenum atoms in the molybdenum trioxide structure. The experimental evidence, however, scarcely allows such a conclusion to be made with any degree of confidence. The limit of solubility may thus only be roughly estimated to be about 3 mole % of wolfram trioxide.

The intermediary range of composition of the system was not studied in any detail. It seems likely, however, that the phase relations in this region [1] are somewhat more complicated than assumed previously.

The low mutual solubility in this system is another instance of the marked difference in crystal-chemical behaviour often shown by molybdenum and wolfram [7]. The variations of the unit cell dimensions associated with the solubility indicate that the metal-oxygen octahedra change towards a more regular shape with inrceasing wolfram content. This is also in accordance with previous observations [2,7].

This investigation was carried out in connection with studies on metal oxides and related compounds financially supported by the *Swedish Natural Science Research Council.*

A Cytidylic Acid — Peptide Complex from *Polyporus squamosus*

ROLF BERGKVIST

Institute of Biochemistry, University of Lund, Sweden

During the past ten years a variety of ribonucleotides has been isolated and identified from various natural sources. These substances are all nucleoside-5′-mono- or polyphosphates with the exception of triphosphopyridine nucleotide which contains a nucleoside-2′-phosphate moiety and the 2′- and 3′-phosphates obtained by chemical or enzymic hydrolysis of nucleic acids. A recent report has revealed the presence of a new guanosine-3′-phosphate derivative in alcoholic extract of brewer's yeast [1]. In the course of a study of the acid-soluble nucleotides of *Polyporus squamosus* we have isolated one hitherto unknown cytosine nucleotide (CMPX). It is the purpose of this report to present the experimental data about this substance. CMPX appears to be a nucleotide-peptide complex with one phosphate group in the 2′- or 3′-position of the ribose moiety.

The isolation and quantitative analysis of the acid-soluble nucleotides of *P. squamosus* was accomplished using the method described in an earlier paper [2]. The nucleotides were isolated by extraction with cold perchloric acid and, after removal of interfering substances, the solution was applied to a Dowex 1 (formate form) column. The elution of the substances was performed with increasing concentrations of formic acid or a mixture of formic acid and sodium formate. Among the different components eluted from the column, which will be presented in detail later, we obtained the CMPX peak after adenosine-5′-phosphate by elution with 0.1 M formic acid. The quantity of the nucleotide was about 10 μmoles per 1 000 g of

For pure molybdenum trioxide, unit cell dimensions were obtained in fair agreement with previous data [6], *viz.*

A Cytidylic Acid — Peptide Complex from *Polyporus squamosus*

ROLF BERGKVIST

Institute of Biochemistry, University of Lund, Sweden

During the past ten years a variety of ribonucleotides has been isolated and identified from various natural sources. These substances are all nucleoside-5′-mono- or polyphosphates with the exception of triphosphopyridine nucleotide which contains a nucleoside-2′-phosphate moiety and the 2′- and 3′-phosphates obtained by chemical or enzymic hydrolysis of nucleic acids. A recent report has revealed the presence of a new guanosine-3′-phosphate derivative in alcoholic extract of brewer's yeast [1]. In the course of a study of the acid-soluble nucleotides of *Polyporus squamosus* we have isolated one hitherto unknown cytosine nucleotide (CMPX). It is the purpose of this report to present the experimental data about this substance. CMPX appears to be a nucleotide-peptide complex with one phosphate group in the 2′- or 3′-position of the ribose moiety.

The isolation and quantitative analysis of the acid-soluble nucleotides of *P. squamosus* was accomplished using the method described in an earlier paper [2]. The nucleotides were isolated by extraction with cold perchloric acid and, after removal of interfering substances, the solution was applied to a Dowex 1 (formate form) column. The elution of the substances was performed with increasing concentrations of formic acid or a mixture of formic acid and sodium formate. Among the different components eluted from the column, which will be presented in detail later, we obtained the CMPX peak after adenosine-5′-phosphate by elution with 0.1 M formic acid. The quantity of the nucleotide was about 10 μmoles per 1 000 g of

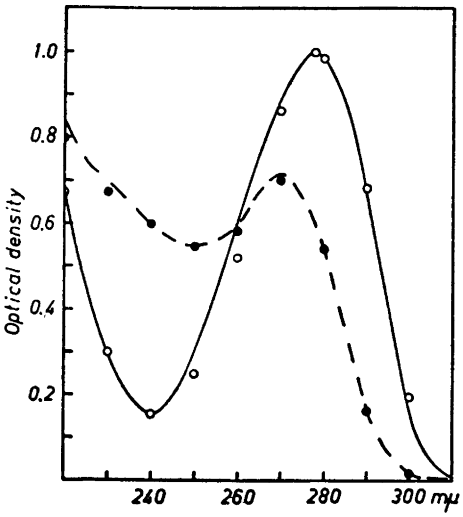

Fig. 1. Ultraviolet absorption curves for CMPX in comparison with 3′-cytidylic acid in acid and in alkali. ———— CMPX in acid and — — — in alkali. O 3′-cytidylic acid in acid and ● in alkali.

material (wet weight) corresponding to 1.3 % of the total nucleotide content in the acid extract. The substance was concentrated and freed from the eluents by adsorption on norite and elution with ammoniacal ethanol. The ultraviolet absorption spectrum of CMPX was very similar to that of cytidylic acid, either in acid or in alkali (Fig. 1). Moreover, cytosine could be identified by paper chromatography in two different solvent systems and its spectrum after hydrolysing CMPX in 70 % perchloric acid for 1 h at 100°C. Analysis showed the presence of one mole of acid-stable phosphorus per mole of base. After hydrolysis of CMPX with 0.05 N hydrochloric acid for 30 min at 100°C the two isomeric cytidine-2′- and 3′-phosphates could be identified as can be seen from Fig. 2, which also shows the chromatographic and ionophoretic behaviour of the unhydrolysed CMPX in comparison with the authentic cytosine nucleotides. The nucleotides were located by contact printing in ultraviolet light. The identities of the nucleotides were confirmed by cutting the appropriate spots out of the paper, eluting the substances, and determining their absorption spectra after the appropriate blank corrections. The hydrolysis mixture contained approximately equal amounts of the 2′- and 3′-phosphates. No consumption of periodate could be shown by CMPX or its hydrolysis products. From the experimental data it is impossible to establish the position of the phosphate group or the eventuality of a cyclic 2′:3′-phosphate.

Although the unhydrolysed nucleotide was ninhydrin-negative, the presence of a short peptide or of amino acids could be revealed by paper chromatography after hydrolysis with 6 N hydrochloric acid at 120°C for 20 h. The hydrolysate was subjected to two-dimensional chromatography using phenol saturated with water in the first direction and *n*-butanol — acetic acid — water (4:1:5) or *n*-propanol — water (7:3) in the second direction. After dipping the paper in an acetone solution of ninhydrin at least 8 ninhydrin-positive spots could be detected. Sufficient material

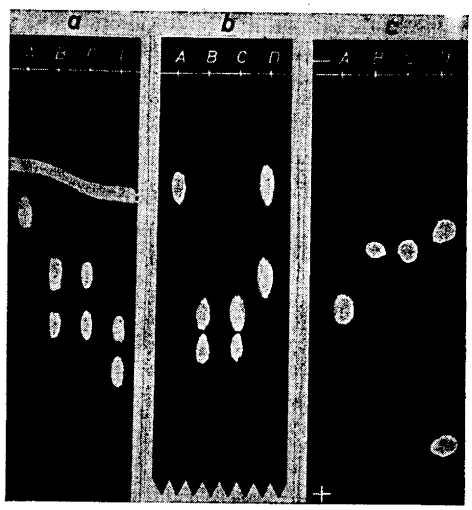

Fig. 2. Paper chromatography and ionophoresis of CMPX and its hydrolysis products in comparison with authentic cytosine nucleotides. (a) Descending chromatogram on long Whatman No. 1 paper (100 cm) in saturated ammonium sulphate solution — *iso*propanol — water (79:2:19) for 35 h. (b) Descending chromatogram in ethanol — 1 M ammonium acetate, pH 7.5 (75:30) for 85 h. (c) Ionophoresis in 0.1 M sodium acetate buffer, pH 4.15; 20 V/cm; 6 h. A) CMPX; B) hydrolysed CMPX; C) 2′- and 3′-cytidylic acid; D) cytidine-5′-mono- and diphosphate.

was not available to permit satisfactory analysis of the spots but the presence of the following amino acids were clearly indicated: leucine, valine, alanine and glycine. Spots corresponding to glutamic acid and aspartic acid were also obtained.

The behaviour of CMPX on acid hydrolysis, together with the ultraviolet absorption spectra suggests that the amino acids or peptide are attached to the ribose moiety and not directly to the pyrimidine ring. Complexes between purine nucleotides and amino acids have been detected in alkaline digests of ribonucleic acids prepared from calf pancreas, rabbit liver and yeast; and these authors proposed a phosphoamide linkage [3]. The amount of CMPX was too small for a more detailed study of the linkage between the two parts of the complex; but in view of the present data the possibility of a phosphoamide linkage is not excluded.

The peaks containing 2′- and 3′-cytidylic acid, which had been eluted with 0.02 M formic acid contained several ninhydrin reacting substances, but we have not found any of them attached to a nucleotide. A substance that shows the same elution position and the same properties as CMPX has been detected in the acid extract of the mycelium of a strain of *Penicillium urticae* [4].

On Different Methyl Derivatives of Hexathia-adamantane

KJELL OLSSON

Chemical Institute, University of Uppsala, Uppsala, Sweden

If thiol acetic acid, formic acid and dried zinc chloride are mixed and left at room temperature, a precipitate is gradually formed. This is usually difficultly soluble in all ordinary solvents and decomposes without melting at approximately 300°. By varying the proportions between the reactants, fractionating the obtained products with the aid of various solvents and recording the infra red spectra of the fractions, five different colourless crystalline compounds were isolated. Two of these were recognized as known compounds, *viz.* hexathia-adamantane (I), recently prepared from formic acid and hydrogen sulphide in strongly acidic media by Fredga and Olsson [1] and its tetramethyl derivative (V), prepared long ago by Bongartz [2] through the action of dried zinc chloride on thiol acetic acid alone. The structure (V) accepted nowadays was proposed much later by Fredga [3].

The analysis and infra red spectra of the remaining three compounds showed these to be mono-, di- and tri-methyl-hexathia-adamantane ((II), (III) and (IV), respectively). The structures (II)—(IV) agree completely with the fact that the properties of the corresponding compounds are intermediate between those of (I) and (V) and vary in a regular manner in the series. Thus the solubility increases rapidly when passing form (I) to (V), but only (IV) and (V) are appreciably soluble in ordinary solvents. The volatility increases in the same direction. All of the compounds can be sublimed *in vacuo*, though (I) requires heating for hours at 225° and 10^{-3} mm Hg. Only (V) melts without decomposition (at 224—225°)[2], whereas (I)—(IV) decompose without melting at higher temperature. Unsymmetrically substituted hexathia-adamantanes like (II)—(IV) have not been prepared before.

As is to be expected the reaction product gets richer in the highly methylated hexathia-adamantanes with increasing excess of thiol acetic acid and *vice versa.* Since certain details of the procedures for the preparation of (II) and (IV) have not been worked out as yet, only the preparation of (III) will be more closely described here. A more detailed account of this investigation, possibly extended to some more thiol acids, will soon be given elsewhere.

Experimental. 3.2 g of dried zinc chloride is added to a mixture of 6.9 g (6.4 ml) of freshly distilled thiol acetic acid (b.p. 91—96°) and 0.98 g (0.80 ml) of absolute formic acid in a hood. In the beginning, the zinc chloride slowly dissolves, hydrogen sulphide is evolved, and gentle heat is generated. A precipitate

was not available to permit satisfactory analysis of the spots but the presence of the following amino acids were clearly indicated: leucine, valine, alanine and glycine. Spots corresponding to glutamic acid and aspartic acid were also obtained.

The behaviour of CMPX on acid hydrolysis, together with the ultraviolet absorption spectra suggests that the amino acids or peptide are attached to the ribose moiety and not directly to the pyrimidine ring. Complexes between purine nucleotides and amino acids have been detected in alkaline digests of ribonucleic acids prepared from calf pancreas, rabbit liver and yeast; and these authors proposed a phosphoamide linkage [3]. The amount of CMPX was too small for a more detailed study of the linkage between the two parts of the complex; but in view of the present data the possibility of a phosphoamide linkage is not excluded.

The peaks containing 2′- and 3′-cytidylic acid, which had been eluted with 0.02 M formic acid contained several ninhydrin reacting substances, but we have not found any of them attached to a nucleotide. A substance that shows the same elution position and the same properties as CMPX has been detected in the acid extract of the mycelium of a strain of *Penicillium urticae* [4].

On Different Methyl Derivatives of Hexathia-adamantane

KJELL OLSSON

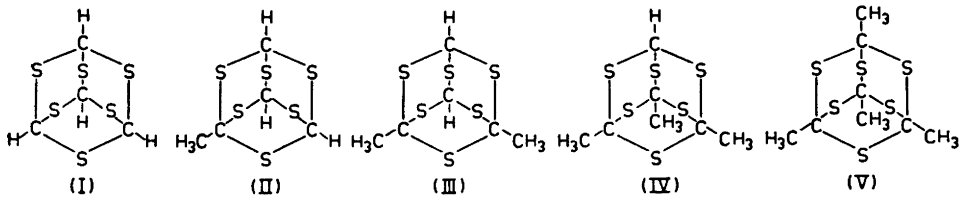
Chemical Institute, University of Uppsala, Uppsala, Sweden

If thiol acetic acid, formic acid and dried zinc chloride are mixed and left at room temperature, a precipitate is gradually formed. This is usually difficultly soluble in all ordinary solvents and decomposes without melting at approximately 300°. By varying the proportions between the reactants, fractionating the obtained products with the aid of various solvents and recording the infra red spectra of the fractions, five different colourless crystalline compounds were isolated. Two of these were recognized as known compounds, *viz.* hexathia-adamantane (I), recently prepared from formic acid and hydrogen sulphide in strongly acidic media by Fredga and Olsson [1] and its tetramethyl derivative (V), prepared long ago by Bongartz [2] through the action of dried zinc chloride on thiol acetic acid alone. The structure (V) accepted nowadays was proposed much later by Fredga [3].

The analysis and infra red spectra of the remaining three compounds showed these to be mono-, di- and tri-methyl-hexathia-adamantane ((II), (III) and (IV), respectively). The structures (II)—(IV) agree completely with the fact that the properties of the corresponding compounds are intermediate between those of (I) and (V) and vary in a regular manner in the series. Thus the solubility increases rapidly when passing form (I) to (V), but only (IV) and (V) are appreciably soluble in ordinary solvents. The volatility increases in the same direction. All of the compounds can be sublimed *in vacuo*, though (I) requires heating for hours at 225° and 10^{-3} mm Hg. Only (V) melts without decomposition (at 224—225°)[2], whereas (I)—(IV) decompose without melting at higher temperature. Unsymmetrically substituted hexathia-adamantanes like (II)—(IV) have not been prepared before.

As is to be expected the reaction product gets richer in the highly methylated hexathia-adamantanes with increasing excess of thiol acetic acid and *vice versa.* Since certain details of the procedures for the preparation of (II) and (IV) have not been worked out as yet, only the preparation of (III) will be more closely described here. A more detailed account of this investigation, possibly extended to some more thiol acids, will soon be given elsewhere.

Experimental. 3.2 g of dried zinc chloride is added to a mixture of 6.9 g (6.4 ml) of freshly distilled thiol acetic acid (b.p. 91—96°) and 0.98 g (0.80 ml) of absolute formic acid in a hood. In the beginning, the zinc chloride slowly dissolves, hydrogen sulphide is evolved, and gentle heat is generated. A precipitate



soon starts to form. The mixture is left at room temperature overnight, stirred with 20 ml of conc. hydrochloric acid to dissolve precipitated zinc compounds, and filtered with suction. The precipitate is thoroughly washed with conc. hydrochloric acid, water, methanol and two 25 ml portions of chloroform in that order. The almost colourless product is refluxed for 5 min. with 100 ml of pyridine. The boiling mixture is rapidly filtered through a fluted filter paper. The filtrate is left in the refrigerator overnight. The crystals formed are filtered off, recrystallized from pyridine (95 ml per g of dry substance; a very small amount of insoluble material is removed by rapid filtration of the hot solution) and dried *in vacuo* at 100° for 1 h. Yield about 700 mg of pure dimethyl-hexathia-adamantane (III). (Found: C 26.35; H 2.95; S 70.84. Calc. for $C_6H_8S_6$ (272.5): C 26.44; H 2.96; S 70.60.)

From the chloroform washings, about 200 mg of (IV) is obtained by evaporation to 10 ml, addition of 20 ml of ether, and recrystallization of the precipitate from 5 ml of pyridine. The optimum yield of (IV) (about 600 mg) is obtained, if the amount of formic acid is decreased to 0.35 ml.

From the undissolved residue after the pyridine extraction, about 200 mg of (II) is obtained by recrystallization from 10 ml of dimethyl sulphoxide. The optimum yield of (II) (about 1 g) is obtained, if equal volumes of formic acid and thiol acetic acid are used.

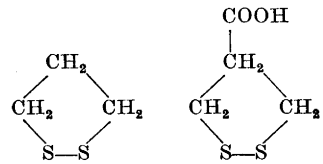
The Strain in the 1,2-Dithiolane Ring

GÖRAN BERGSON and LENNART SCHOTTE*

Chemical Institute, University of Uppsala, Sweden

The 1,2-dithiolane ring (I) has been an important unit in modern sulphur chemistry since its presence in 6-thioctic acid was discovered [1]. The hypothesis advanced by Calvin and co-workers [2] about the role of 6-thuoctic acid in the photosynthesis has caused many efforts to determine the steric strain in the 1,2-dithiolane ring. A necessary condition for Calvin's hypothesis to be true is that the strain is at least 20—25 kcal/mole. The estimates of the steric strain reported in the literature are widely scattered as can be seen from Table 1.



The exact structure of the 1,2-dithiolane ring in 1,2-dithiolane-4-carboxylic acid (II) is now known thanks to an X-ray investigation performed by Professor Olav Foss [3]. On the basis of this investigation, we have calculated the strain energy in a classical manner [4], *i.e.* with the assumptions that the strain is composed of three terms: stretching, bending and torsion. This method gives a strain of 16—30

* Both authors contribute equally.

The exact structure of the 1,2-dithiolane ring in 1,2-dithiolane-4-carboxylic acid (II) is now known thanks to an X-ray investigation performed by Professor Olav Foss [3]. On the basis of this investigation, we have calculated the strain energy in a classical manner [4], *i.e.* with the assumptions that the strain is composed of three terms: stretching, bending and torsion. This method gives a strain of 16—30

* Both authors contribute equally.

Table 1.

Strain, kcal/mole	Compound	Reference and method
27	1,2-Dithiolane 6-Thioctic acid	Calvin [2]; UV.
min. 11	1,2-Dithiolane	Calvin [2]; Conformation analysis.
6	1,2-Dithiolane	Calvin [2]; Equilibrium measurements.
4—5	1,2-Dithiolane 6-Thioctic acid	Sunner [5]; Thermochemical measurements.
min. 16	1,2-Dithiolane-4-carboxylic acid	This work; Conformation analysis.

kcal/mole, when uncertainties in structural parameters and assignments of normal valence angles are taken into account. We believe that our smallest value (16 kcal/mole) is too far form the values found in the thermochemical measurements to be explained as due to differences in the structural parameters for 1,2-dithiolane-4-carboxylic acid on the one hand and 6-thioctic acid and the unsubstituted 1,2-dithiolane ring on the other. As far as steric strain is concerned it is therefore our opinion that Calvin's hypothesis about the rôle of 6-thioctic acid in photosynthesis cannot be disregarded.

A detailed report of our calculations will soon be pulished in *Arkiv Kemi*.

Composition of Products Formed by Thermal Neutron Fission of ^{235}U

I. Compilation of Nuclear Data of the Fission Products

JAN PRAWITZ and JAN RYDBERG

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

An extensive compilation is made of the data up to July 1957 for the fission yields, decay schemes, half-lives and thermal neutron cross sections of the ^{235}U fission products.

For the calculation of the beta activity, mole fraction and isotopic composition of the fission elements (Part II[26] and III[27] of this series), an extensive compilation has been made of the fission yields, modes of transformation, half-lives and thermal neutron cross sections of the ^{235}U fission products. Similar compilations have previously been made, *e.g.* by Coryell and Sugerman [1, 2], Steinberg and Glendenin [28], and Lock [17]. These compilations are either less comprehensive or less up to date than the present paper.

In this paper most of the data have been covered up to July 1957. The decay schemes and half-lives are taken mainly from Nuclear Science Abstracts. The thermal neutron capture cross sections are taken from Hughes and Harvey [29]. In the compilation of fission yield values [1–25], mass spectrometric data have generally been preferred; all values have been standardized towards a cumulative fission yield of 6.32 ± 0.24 % for ^{140}Ba [12]. The sum of the fission yields amounts to 202 %.

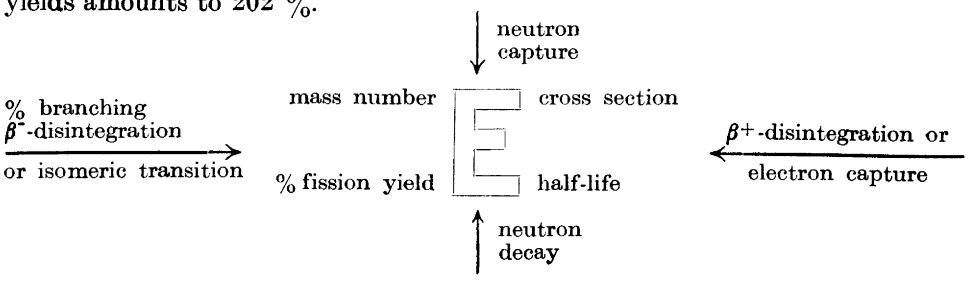

Fig. 1. Key to the presentation of the data; E stands for Element. The figure is more extensively explained in the text.

Table 1. Fission products decay scheme. Legend to the presentation is given in Fig. 1; ----→ stands for a presumptive transformation.

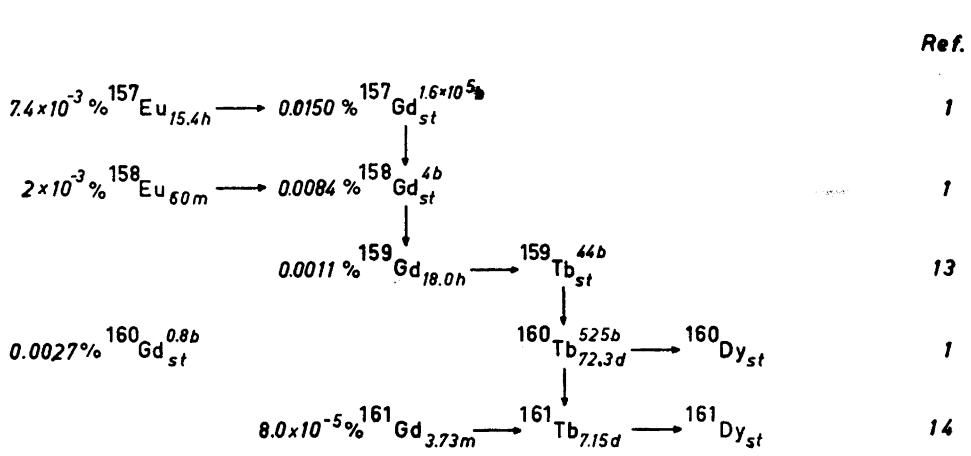

Fig. 1 shows the method of presenting the data, which are given in extenso in Table 1. The arrows indicate the formation process; percentage figures are given when branching ratios are known. The cross sections are given in barns and millibarns (indicated by *b* and *mb*) and half-lives in years (*y*), days (*d*), hours (*h*), minutes (*m*) or seconds (*s*). The percentage value given in front of the element is the cumulative fission yield value, except for underlined values, which refer to primary yields.

The authors wish to thank the head of FOA 1, Professor G. Ljunggren, for his continuous interest in and support of this work.

Composition of Products Formed by Thermal Neutron Fission of ^{235}U

II. Chemical Composition of Stable and Radioactive Fission Products

JAN PRAWITZ and JAN RYDBERG

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The chemical composition of stable and radioactive fission products has been calculated for seven different irradiation times between 1 day and 2 years, and for three different neutron fluxes, 10^{12}, 10^{13} and 10^{14} n cm^{-2} sec^{-1}. The results are given in the form of curves showing the β-activity (Figs. 1—7) and mole fraction (Figs. 9—15) of each element as a function of cooling time from 1 day up to about 15 years. The calculations are based on nuclear data published before July 1957 [1].

For the processing of used nuclear fuels, the chemical composition of the fission products has to be known. This composition depends on a number of variables, such as the composition of the fuel "elements", the neutron energy, flux, and irradiation time in the reactor, cooling time outside the reactor, etc. If data for the fission yields, decay schemes, halflives and neutron cross sections of the fission product isotopes are known (see Part I of this series [1]), the chemical composition of the fission products formed in thermal uranium reactors may be calculated as a function of neutron flux (Φ), irradiation time (T) and cooling time (t).

Diagrams and tables of the β-activity of the fission isotopes of ^{235}U have been given by Hunter and Ballou [2], and Björnerstedt *et al.*[3] for instantaneous fission ($T = 0$), and, for various irradiation and cooling times, by Lock [4], and Moteff [5], and as an Appendix to *Progress in Nuclear Chemistry* [6]. The relative elemental activity of the most important fission products is given as a function of cooling time by Coryell *et al.*[7] and Rubinson *et al.*[8] for unpublished flux and irradiation time, and by Keneshea and Saul [10] for $\Phi = 10^{12}$ n cm^{-2} sec^{-1} and T = 1—60 d. Lock [4] gives tables of the elemental composition of the fission products obtained after three irradiation and cooling times at a very high flux (10^{15} n cm^{-2} sec^{-1}). Walton [11] has made a similar, though less comprehensive, calculation.

In this paper the β-activity and mole fraction of each fission element is calculated as a function of cooling time for various irradiation times between 1 day and 2 years and for neutron fluxes between 10^{12} and 10^{14} n cm^{-2} sec^{-1}. The calculations are based on nuclear data which have appeared in the literature up to July 1957 [1].

METHODS OF CALCULATION

A fission product isotope may be formed in several different ways: 1) as a primary fission product, 2) as a decay product in one or several chains, starting with primary fission products, or 3) through neutron capture. All these modes of formation have to be considered separately for each isotope. The elemental composition of the fission products is obtained by adding the corresponding isotopic values.

In the calculations, the following symbols are used:

A_n = activity (in disintegrations/time) of isotope in n:th generation of a primary ($n = 1$) fission product;
X_n = mole fraction (in percent) of an isotope in the n:th generation;
Φ = neutron flux (in neutrons per cm^2 per second);
T = irradiation time;
t = cooling time;
y_n = fission yield (in percent) of an isotope in a decay chain;
λ_n = disintegration constant (in time^{-1}); $\lambda_n = 0$ for stable isotopes;
τ_n = half-life; $\tau_n = \ln 2/\lambda_n$; in the calculations, τ_1 is used in a decay chain for the first isotope which has a half-life of at least one hour;
σ_n = thermal neutron capture cross section (in cm^2)
Λ_n = effective disintegration constant ($= \lambda_n + \sigma_n \cdot \Phi$).

The following equations give the relationships between activity and mole fraction of an isotope and their dependence on neutron flux, irradiation and cooling times.

$$A_n(\Phi, T, t) = R_A \cdot B(\Phi, T, t) \text{ curies per gram (gFP)} \tag{1}$$

where

$$R_A = 8.07 \cdot 10^3 \cdot y_n/T \text{ curies per gram (C/gFP); } T \text{ in days} \tag{2}$$

and

$$X_n(\Phi, T, t) = R_x \cdot B(\Phi, T, t) \text{ mole percent} \tag{3}$$

where

$$R_x = \frac{y_n}{2 \cdot \lambda_n \cdot T} \text{ mole percent} \tag{4}$$

As will be discussed in the paragraph on "burn up", R_A and R_x have this form only so long as the amount of ^{235}U is constant.

In order to convert mole percent for a certain element to weight percent (g of fission element per gram mixed fission products) the relation

$$X \text{ mole percent} = 8.6 \cdot 10^{-3} \cdot X \cdot M \text{ weight percent} \tag{5}$$

should be used, wehre M is the atomic weight of the element.

From eqns. (1—4) one obtains the simple relation

$$X_n \text{ mole percent} = \frac{6.20 \times 10^{-5}}{\lambda_n} A_n \text{ C/gFP; } \lambda_n \text{ in days}^{-1} \quad (6)$$

$B\ (\Phi,\ T,\ t)$ is calculated according to Rubinson [12].

$$\mathrm{B}\ (\Phi,\ T,\ t) = \prod_{i=1}^{n} \lambda_i \sum_{i=1}^{n} [(\prod_{j=1}^{i} \Lambda_j^{-1}) \sum_{j=1}^{i} b_j\ (1 - e^{-\Lambda_j T}) \sum_{k=1}^{n} a_k \cdot e^{-\lambda_k t}] \quad (7)$$

where $b_j = 1$ when $i = 1$,
and when $i > 1$

$$b_i = \prod_{m \neq j} \frac{\Lambda_m}{\Lambda_m - \Lambda_j},\ (m = 1,\ 2,\ \ldots\ldots\ i;\ \Lambda_m \neq \Lambda_j) \quad (7\,a)$$

and $a_k = 1$ when $i = n$,
and when $i < n$,

$$a_k = \prod_{p \neq k} (\lambda_p - \lambda_k)^{-1},\ k = i,\ i + 1,\ \ldots . n;\ \lambda_p \neq \lambda_k) \quad (7\,b)$$

In no practical cases (*i.e.* for $t > 1$ day) has it been necessary to consider $n > 5$. In the rare cases when $\Lambda_m = \Lambda_j$ and $\sigma_m = \sigma_j = 0$, eqn. 7 is no more valid. The following equation can then be used for calculating A_2

$$A_2\ (T,\ t) = R_A\ ((1 + \lambda t)e^{-\lambda t} - [1 + \lambda(T + t)]e^{-\lambda(T+t)}) \quad (8)$$

The complicated eqn. (7) can in most practical cases be considerably simplified. The following equations have been found very useful:

For $n = 1$, one obtains

$$A_1\ (\Phi,\ T,\ t) = R_A \frac{\lambda_1}{\Lambda_1} (1 - e^{-\Lambda_1 T})\ e^{-\lambda_1 t} \quad (9)$$

A similar equation is obtained for $X_1\ (\Phi,\ T,\ t)$.

For all $\sigma_i = 0$, where $i = 1,\ 2,\ \ldots .\ n$, one obtains

$$A_n\ (T,\ t) = R_A \sum_{i=1}^{n} (\prod_{j \neq i} \frac{\lambda_j}{\lambda_j - \lambda_i})\ (1 - e^{-\lambda_i T})\ e^{-\lambda_i t} \quad (10)$$

A similar equation is obtained for $X_n\ (T,\ t)$.

For $\Lambda_2 = 0$ and $\Lambda_1\ T \ll 1$ one obtains

$$X_2\ (\Phi,\ T,\ t) = \frac{y_1 \lambda_1}{2\Lambda_1} \left(\frac{\Lambda_1 T}{2} - \frac{\Lambda_1^2 T^2}{6} + \frac{\Lambda_1^3 T^3}{24} - \ldots . .\right) \quad (11)$$

For all $\sigma_i = 0$ and $\lambda_n = 0$ where i and $n > 1$, one obtains

$$X_n\ (T,\ t) = \frac{y_n}{2} - \sum_{i=1}^{n-1} X_i\ (T,\ t) \quad (12)$$

If $\sigma_1 = \lambda_1 = 0$, eqn. (11) reduces to $X_1\ (T,\ t) = y_1/2$.

For the exact calculation of the mole fractions, the factor 2, used in the denominators in the above eqns. (4), (11) and (12), should rather be 2.0025, because of the formation of ^4He through triple fission (yield 0.25 %).

DISTRIBUTION OF THE β-ACTIVITY OF THE ELEMENTS

The β-activity of the fission elements is given as a function of cooling time at various irradiation times and neutron fluxes in Figs. 1—7. Only nuclear β decays are considered here; the curves therefore do not include any "β-activity" due to internal gamma-beta conversion. In addition, very long-lived activities are summarized in Table 1.

Table 1. Long-lived isotopes with activities practically independent of T and $t < 600$ years.

Isotope	Half-life years	Decay	Activity C/g fiss.prod.
^{79}Se	6.5×10^{4}	β, γ	8.7×10^{-4}
^{87}Rb	6.2×10^{10}	β	6.1×10^{-10}
^{93}Zr	9.5×10^{5}	β	9.8×10^{-5}
^{99}Tc	2.1×10^{5}	β	4.3×10^{-3}
^{107}Pd	5×10^{6}	β	6.1×10^{-7}
^{115}In	6×10^{14}	β	2.6×10^{-16}
^{129}I	1.7×10^{7}	β, γ	6.6×10^{-7}
^{135}Cs	2.1×10^{6}	β	4.1×10^{-5}
^{142}Ce	5.1×10^{15}	α	1.8×10^{-12}
^{144}Nd	2.2×10^{15}	α	3.8×10^{-13}
^{147}Sm	1.3×10^{11}	α	2.8×10^{-10}

In the figures, the solid lines refer to a neutron flux of 10^{13} n cm^{-2} sec^{-1}. If other curves are obtained at lower or higher fluxes, this is indicated by dotted lines for 10^{12} and dashed lines for 10^{14} n cm^{-2} sec^{-1}. The effect of burn up of ^{235}U at high $\Phi \cdot T$ is discussed in a separate paragraph below.

In some cases in Figs. 1—7, only one isotope contributes to the activity of an element (*e.g.* ^{99}Mo, ^{140}Ba, ^{147}Nd), but in most cases the element contains several radioactive isotopes. However, generally only one isotope predominates at a time but, close to inflexion points, two isotopes may contribute about equally. By consulting the data in Part I[1], it is often possible to reveal the isotopic composition of the β-activity of the elements in Figs. 1—7.

Only nine elements are considerably influenced by variation in the neutron flux. They are Tc, Pd, Ag, Xe, Cs, Pm, Sm, Eu and Tb. The various fluxes influence the disintegration curves in two ways: the activity either increases (Pd, Ag, Cs, (Pm), Eu, Tb) or decreases (Eu, Tc, Xe, (Pm), Sm) with increasing neutron flux. In the former case a shorter lived isotope is formed through neutron capture in a longer-lived or stable isotope of the element. In the latter case a shorter-lived isotope captures a neutron forming a longer-lived or stable isotope of the element (*cf.* Part I[1]).

In Fig. 8, the total β-activity of the combined fission elements is given as a function of T and t (1 d $\leq t \leq$ 1 400 years). The curve for $T = 0$ was taken from Björnerstedt *et al.*[3]. If the curve for $T = 0$ is compared with the statistically calculated curve of Way and Wigner [13], one finds that their curve in some parts lies about a factor of 1.5 above the curve given by Björnerstedt

et al. On the other hand, the curve for $T = 0$ in Fig. 8 agrees almost completely with the curve given by Thornton and Houghton [14], who made calculations from known values of individual fission products.

Because the methods of calculation are, in principle, the same, almost complete agreement is obtained with the curves given for various irradiation and cooling times by Koontz and Jarrett [15], and from the summation of the curves for the individual isotopes given in Ref [6].

ELEMENTAL DISTRIBUTION OF FISSION PRODUCTS

The mole fractions of the fission product elements are given in Figs. 9—15 as a function of cooling time for the same irradiation times as given in the previous figures. While the relative activities of the fission elements vary considerably with cooling time, it is immediately seen from Figs. 9—15 that the mole fractions of the elements change very little with cooling times. For some elements, there is practically no change at all; these elements are given at the right margin of the figures. The considerable variation of the curves for Nb, Sb, and Pm is due to the fact that these fission elements consist mainly of relatively short-lived isotopes.

From comparisons of Figs. 1—7 and 9—15 it is seen that many of the elements, which make up a considerable fraction of the mass of the fission products contribute relatively little to the total radioactivity. Thus, about 50 % of the weight of the fission products comes from elements Xe, Nd and Cs, while these elements only make up about 1 % of the total β-activity (*cf.* Figs. 3 and 11 for $T = 1$ month and $t = 2$ months).

ESTIMATED ERRORS

The primary data used in these calculations are impaired by certain errors. One of these errors, *i.e.* unknown modes of branching decay, must here be neglected.

The half-lives are generally fairly accurate, but for long half-lives the standard deviations are assumed to be $\lesssim$ 10 %.

The fission yields and thermal neutron cross sections have often been determined with neutrons obtained from "thermal" uranium reactors, in which also fast neutrons are present. However, since the capture cross sections are higher in the thermal than in the fast neutron energy region, and the cross sections have relatively little influence on A and X except in a few cases, the errors in the cross sections can here be neglected.

The fission yields may be subject to much larger errors because of the presence of fast neutrons. In uranium reactors about 3 % of the fissions may be caused by fast neutrons [16]. This is especially important for the mass numbers in the valley of the fission yield curve, because the fission yields there increase considerably with neutron energy. The standard deviations in the fission yields are assumed to lie between 2 and 10 %.

With the complicated equations used for calculating A and X, it is very difficult to calculate exactly the errors due to uncertainties in the primary

Figs. 1—7. Elemental composition of fission product β-activity (in curies per g fiss. prod.) as a function of cooling time for three different neutron fluxes: ····· 10^{12}, ——— 10^{13} and ------- 10^{14} n cm^{-2} sec^{-1}. T = irradiation time.

Fig. 15.

data. However, an estimation has been made, which shows that for a standard deviation of 3 % in y and 1 % in λ, the deviations in A and X correspond to $\pm$ 0.2 mm in Figs. 1—15. For a standard deviation of 10 % in y and 5 % in λ, the deviations in A and X correspond to $\sim$1 mm for $t \approx \tau$, and to $\sim$2 mm for $t \approx 8\,\tau$. The errors increase for increasing ratio t/τ. However, it can be seen that these errors are of about the same size as the vertical thickness of the lines drawn in the figures.

Another limitation of the diagrams is discussed in the next paragraph.

THE INFLUENCE OF HIGH BURN UP

The calculations resulting in Figs. 1—15 are all based on the fundamental assumption that the amount of ^{235}U is constant during the irradiation time, T, (*i.e.* that the "burn up" of ^{235}U is low). Practically all published calculations of the kind presented in this paper, are based on the same assumption, even if this is not always explicitly stated.

The weight of fission products formed is proportional to $T \cdot \Phi \cdot \sigma_{fiss} \cdot N$, where N is the number of fissile atoms. Since all calculations in this paper refer to a constant weight of fission products (1 g or 1 mole) formed at a constant flux during a constant irradiation time, it follows that N also must be constant. If this is not the case owing to high burn up, either Φ must be increased in order to produce the fixed weight of fission products in the predetermined time T, or the time T must be increased to produce the fission products at a constant flux. In all cases, the conditions of the equations used in the calculations above are violated. The errors due to a burn up of about 10 % of the ^{235}U causes an error of $\lesssim$ 3 % in the activities or mole fractions given in the figures.

A burn up of 10 % is obtained at 1.5×10^{21} n cm^{-2}, *i.e.* at $\Phi = 10^{12}$ n cm^{-2} sec^{-1} after $T \approx 5$ years, at $\Phi = 10^{13}$ after $T \approx 6$ months, and at $\Phi = 10^{14}$ after $T \approx 18$ days. However, all calculations have been continued up to $T = 2$ years for fluxes $\leq 10^{14}$ n cm^{-2} sec^{-1}, even if the practical usefulness of the diagrams for $\Phi \cdot T > 1.5 \times 10^{21}$ n cm^{-2} may be limited to reactors especially designed to keep the ^{235}U amount constant without removing the fission products.

Acknowledgements. The authors wish to thank the head of FOA 1, Prof. G. Ljunggren, for his continuous interest in and support of these studies, Prof. A. Ölander, Mr. I. Österlund and Mr. P. E. Bergner for valuable discussion, and Miss M. Granstrand for drawing the diagrams. The English of this paper has been corrected by Dr. H. S. Dunsmore. Large size copies of the Figures may be obtained on request to the authors.

Determination of the Absolute Activity of Solid Tritium Samples

JAN RYDBERG

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

It is shown that the absolute specific beta activity of tritium in solid samples of finite thickness can be accurately determined with 2π internal gas-flow counters. The effects of self-absorption and back-scattering of tritium betas are discussed.

The new simple methods for direct labeling of organic compounds with radioactive hydrogen (for references see Ref.[1]) in combination with the low price of the latter is causing a rapid increase in the use of tritium-tagged organic compunds. This calls for simple methods of measuring tritium activities. The most commonly used seems to be the counting of gaseous samples in various ionization chambers and dissolved samples in liquid scintillation counters (*cf.e.g.* Refs.[2,3]). However, these methods require special or expensive equipment, usually not available in normal radiometric laboratories. Because of the low energy of the β- radiation of ^{3}T (upper energy limit 18 keV), measurements on solid samples present some difficulties, but these can usually be overcome by using internal gas flow counters and a refined sample preparation technique. So far only four papers [4–7] seem to have dealt with this problem in some detail. In none of these papers is the absolute determination of tritium activity discussed, and the results do not seem generally applicable to all kinds of solid tritium samples. In the present paper these problems will therefore be somewhat more extensively treated.

VARIABLES IN ABSOLUTE β-COUNTING

Zumwalt [8] has summarized the different variables which have to be considered in the determination of absolute β-activity of solid samples. Here, only the case of using internal gas-flow counters will be discussed, which limits the number of variables. The correction factors are

f_e, the efficiency of the measuring device to register all β-particles entering the detector;

f_r, the combined resolving time of the detector and the electronic and mechanical components;

f_g, the geometry of the detector viewed from the radiation source;
f_b, the back-scattering of radiation from the backing material into the counter;
f_s, the self-absorption and back-scattering of the β-radiation in the sample.

If the true specific activity is S dpm/g (disintegrations per minute per gram), and the measured activity is I cpm (counts per minute) in a sample of weight m grams, the following relation holds:

$$S = I/m \cdot f_e \cdot f_r \cdot f_g \cdot f_b \cdot f_s \quad \text{dpm/g} \tag{1}$$

When a GM-counter shows a flat plateau (*i.e.* pulse frequency is independent of anode voltage) it is generally assumed that all β-particles entering the detector are registered [9]. This is certainly true if the pulse frequency is so low that no resolution loss is obtained (*i.e.* if $f_r = 1$). The same reasoning should hold when the detector, instead of a GM-tube, is a proportional tube. Experiments made by the author have given identical results for internal gas-flow GM-counters (helium-*iso*butan mixture) and proportional counters (argon-methane mixture). Thus if solid samples are measured in the sensitive volume of these detectors, the factor f_e is very close to 1, when $f_r = 1$ and the tubes are operated at the plateau.

If flat planchettes are used to support the radiation source placed in the sensitive volume of a 2 π internal gas-flow counter, the factor f_g can be put equal to 0.5.

When the radiation source is outside the sensitive volume of the detector, the geometry of the source in relation to the detector has to be calculated (*cf.e.g* Ref.[10]). A more accurate method is to use a calibrated radiation source in the actual geometry, and to determine $f_g \cdot f_e$ in one step; this value of $f_g \cdot f_e$ is only strictly valid for the specific isotope used.

The fraction of β-radiation scattered from the backing material into the detector depends on the β-spectrum, the atomic number and thickness of the backing material. When the thickness of the backing material is $> R_0/3$, where R_0 is the maximum range of the β-particles, maximum ("saturation") back-scattering is obtained. Since accurate predictions of the value of the saturation back-scattering factor, f_b, are difficult to make for low β-energies (*cf.e.g.* Ref.[11]), this factor is most easily determined experimentally.

Fairly simple equations can be given for the dependence of the self-absorption of the mass density of the sample. The derivation and use of these equations have been discussed by several authors (*e.g.*Refs.[12–14]). However, in ordinary experimental work with thick samples it is generally not possible to distinguish between self-absorption and back-scattering in the source [16]. In order to make absolute determination of β-activity in a given sample, experimentally determined values of f_s should be used.

EXPERIMENTAL

Sample preparation

Solid samples. The samples prepared for solid counting were obtained by evaporating solutions of tritiated *p*-aminosalicylic acid (PAS) [1] in 96 % ethyl alcohol. The positions of the tritium atoms in PAS are not definitely known, but they are non-labile in water

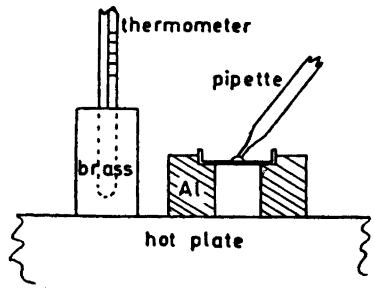

Fig. 1. Arrangement for sample preparation.

of pH 3—7. It is believed that in the alcoholic solutions no exchange of tritium takes place between the PAS and the solvent. 96 % ethyl alcohol was used because no solid residues were left after its evaporation.

Fig. 1 shows the arrangement used to prepare the samples [17]. In order to obtain reproducible samples it is important to keep the hot plate and aluminium ring at the correct temperature (in this case at 55°C), and to put the cold sample-pan on the aluminium ring just before adding the 0.1 ml of the solution through the pipette. The sample-pan should be kept perfectly horizontal and any rapid airflow around it should be avoided. Under these circumstances, there is formed a droplet, which evaporates slowly from its rim. The dry samples obtained had a diameter of 13 ± 1 mm.

The activities measured never exceeded 5 000 cps, which corresponded to a sample thickness of about 100 $\mu g/cm^2$. In order to measure on still thicker samples, inactive PAS was added to the active alcohol solution, and appropriate corrections for the dilution of the active PAS were made.

Gas samples. Gas samples were prepared by converting the tritium in solid tritiated PAS to water. This water was then reduced with magnesium to produce hydrogen for measurements in a GM-counter, according to Melander [18].

Counting arrangements

For the measurements on solid samples an internal gas-flow proportional counter (model PC-3, Nuclear Measurements Corp., Indianapolis) with 90 % A + 10 % CH_4 was used. The resolution loss was around 1 % at 5 000 cps; since higher activities never were measured, corrections for resolution loss could be neglected.

Before the introduction of a sample into the counter, the background was measured. For each sample 5—10 measurements were made to check that the counter worked properly; between each measurement, the counting tube was flushed with the counting gas. In general it was found that in such a sequence of measurements, the activity first rose slightly and then decreased. The rise is believed to be due to insufficient flushing in the beginning, and the decrease due to mechanical loss of sample from the sample-pan because of the flushing. This assumption is supported by the fact that the back-ground count rose steadily with each new sample measured. When the back-ground had reached ~1 000 cpm, the counting chamber was removed and cleaned, after which the background usually dropped to the ordinary value of ~200 cpm (unshielded). The difference between the highest and the lowest activity measured on one sample in this way never amounted to more than 7 % and in general was much less. The average between the two highest values was used.

For comparison with the results obtained on solid samples with the proportional counter, an internal gas-flow GM-counter (Model SC-16, Tracerlab Inc., Boston) using 99 % helium + 1 % *iso*butane was used in a few experiments with samples of low activity. Results completely consistent with those of the proportional counter were obtained when identical samples were used in both counters.

To check the activites obtained by the method described in this paper, a GM-counter especially made for tritium-gas samples [18] was also used (propane-hydrogen mixture at about 100 mm Hg).

Table 1. Measured activity, I, as a function of sample weight, m, for various backing materials; sample area is 1.3 ± 0.2 cm².

RESULTS

The experimental data. The results obtained are collected in Table 1. The errors given are only statistical (root mean square), owing to the number of counts measured. The error in the sample weight, which is not considered in the table, is assumed to be less than 10 %. The sample areas are not known more accurately than 1.3 ± 0.2 cm². In Fig. 2, the activity, I (cpm), is plotted against the sample weigth m (μg) on a logarithmic scale. Since the values for the various backing materials lie fairly close to each other, the scale for the three sets of data has been displaced one log unit each along the ordinate. In Fig. 3 the relative activity, I/m, is plotted against log m. The difference between the three backing materials at low sample weights is obvious here. The use of the curves in Figs. 2 and 3 shall be further discussed below.

Calculations. It has been shown (*e.g.* Refs.[12–15]) that the self-absorption of β-radiation can be well described by the equation

$$\frac{A_x}{A_0} = \frac{1 - e^{-\mu x}}{\mu x} \tag{2}$$

where A_x is the activity of a given amount of a radioactive isotope contained in a sample of thickness x mg/cm² (for $x = 0$, the activity is A_0) and μ is the absorption coefficient. If it is assumed that the sample area is constant, this relationship can be rewritten

$$I = \frac{A_0}{\mu}(1 - e^{-\mu m}) \tag{3}$$

where $I = m \cdot A_x$ is the activity from the sample area containing m mg sample (the dimension of μ in eqn. 3 is weight^{-1}). Thus if log I is plotted against log m, a curve should be obtained with the two asymptotes

$$\lim_{m \to 0} \log I = \log A_0 + \log m \tag{4a}$$

$$\lim_{m \to \infty} \log I = \log A_0 - \log \mu \tag{4b}$$

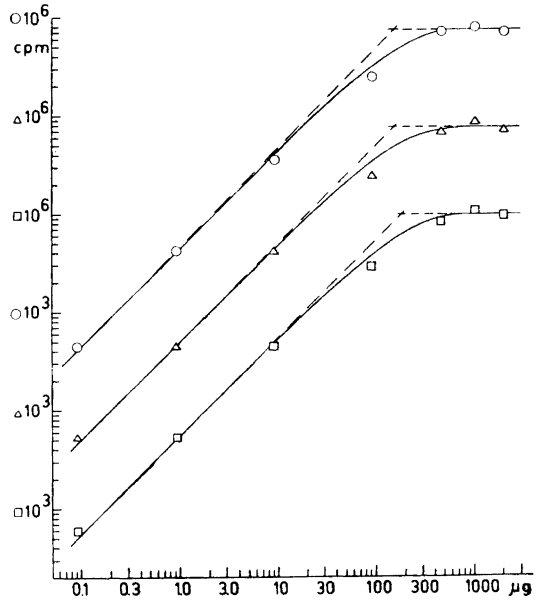

Fig. 2. Measured activity, I cpm, as a function of sample weight, m μg, at constant specific activity. The curves according to eqns. 3 and 4 are displaced one log unit along the ordinate for each backing material (○ aluminium, △ stainless steel, □ platinum backing).

The intercept between these two asymptotes occurs at $\log m = -\log \mu$. This point is easy to determine in a log I *versus* log m plot, since the asymptotes intersect each other at an angle of 135°.

Fig. 2 has been used to determine μ (in μg^{-1}) by this method as well as A_0; the asymptotes are given as dotted lines in the figure. The values obtained are given in Table 2, together with estimated errors. With these values of μ and A_0 introduced into eqn. 3, log I has been calculated as a function of log m, and the result thus obtained is given in the solid curves in Fig. 2.

Table 2. Calculations of μ (in μg^{-1}) and A_0 (in cpm) from Figs. 2 and 3.

Value	according to	Backing material		
		aluminium	stainless steel	platinum
$1/\mu$	Fig. 2	150 ± 30	145 ± 20	180 ± 20
A_0/μ	» 2	(750 ± 50) 10^3	(770 ± 70) 10^3	(1 000 ± 70) 10^3
A_0	» 2	5 000 ± 400	5 300 ± 500	5 600 ± 400
A_0	» 3	5 000 ± 200	5 900 ± 400	6 800 ± 200

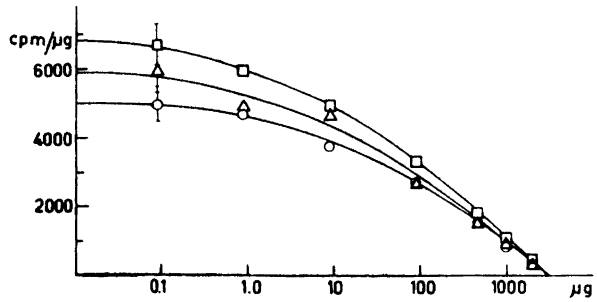

Fig. 3. Apparent specific activity, I/m (cpm/μg), as a function of sample weight, m (μg), for various backing materials (O aluminium, △ stainless steel, □ platinum).

According to eqn. 4a, A_0 can also be obtained from the plot in Fig. 3. The inaccuracy in the A_0-value obtained for $m \to 0$ is rather large; the estimated values are given in Table 2.

The difference between the A_0-values obtained with aluminium, stainless steel and platinum as backing material must be due to the back-scattering of the radiation by these materials. The back-scattering factor, f_b, has been calculated as a function of the atomic number of the backing material in Fig. 4. This has been done by first calculating the relative backscattering factor (f_b') in stainless steel and platinum towards aluminium ($f_b' = 1.00$) and the displacing the curve f_b' *versus* atomic number, Z, so that the extrapolated curve starts with $f_b = 1.00$ at $Z = 0$. In these calculations, the A_0-values obtained from Fig. 3 have been used.

DISCUSSION

The self-absorption factor. As an average of the $1/\mu$-values in Table 2 one obtains 160 ± 25 μg. Since the sample area is 1.3 ± 0.2 cm^2, this corresponds to $1/\mu = 120 \pm 25$ μg/cm^2. From the relationship [13] $d_{½} = 0.693/\mu = 0.139 R_0$, where $d_{½}$ is the half-value thickness of the beta radiation, one thus obtains $d_{½} = 0.08 \pm 0.02$ mg/cm^2 and $R_0 = 0.6 \pm 0.1$ mg/cm^2. These values should be compared with the directly measured values $d_{½} = 0.07$ mg/cm^2 (giving $R_0 = 0.5$ mg/cm^2)[19] and $R_0 = 0.23$ mg/cm^2 (giving $d_{½} = 0.032$ mg/cm^2)[20], and the calculated value $R_0 = 0.7$ mg/cm^2 (giving $d_{½} = 0.10$ mg/cm^2) from the Glendenin [21] energy-range relation. Though the agreement between these three latter values is not remarkably good, two [19,21] of them agree well with the value obtained here.

It is seen from Fig. 2 that the experimental points at intermediate sample weights (~ 100 μg) fall below the theoretical curve given by eqn. 3. The reason for this may be due partly to the fact that eqn. 2 is only strictly valid for collimated radiation, and partly to the interrelation between self-absorption and back-scattering (*cf.* Ref.[16]). As the sample thickness increases, part of the radiation is back-scattered by the sample itself rather than by the backing material and, since the sample material has a lower back-scattering power (lower average atomic number) than the backing material, less radiation will

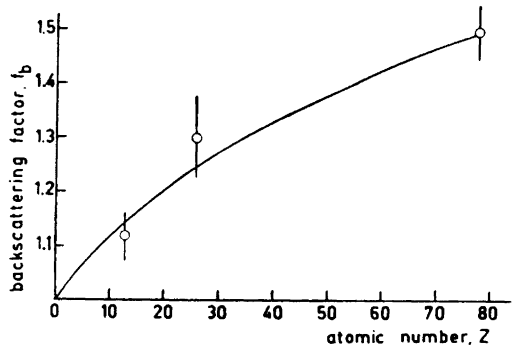

Fig. 4. Saturation back-scattering factor, f_b, as a function of the atomic number Z of the backing materials.

be scattered back into the counter. The back-scattered radiation has a much lower average energy than the unscattered beta-radiation, and is thus more easily absorbed in the sample, which lowers the fraction of back-scattered radiation reaching the sensitive volume of the counter. This is clearly indicated in Fig. 3, which shows that with increasing sample weight, the activity measured becomes more and more independent of the orginal backing material.

Thus the increasing sample weight causes the experimental points to become lower than would have been the case if only self-absorption was operating. The horizontal asymptote should, in such a case, have been situated higher than is shown in Fig. 2, and consequently a higher $1/\mu$-value would also have been obtained. On the other hand, the experimental points at low m-values in Fig. 2 do not fall exactly on the straight line, which indicates that the line of 45° slope should be somewhat displaced to the left (that this is true is seen

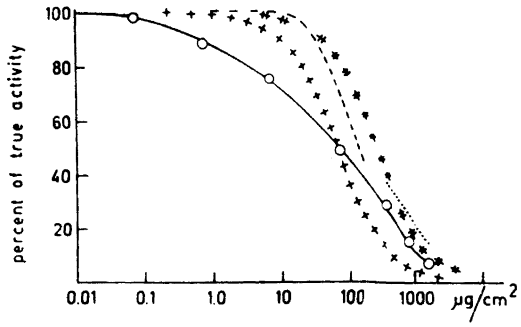

Fig. 5. Percentage of true activity measured from tritium samples of various surface thickness. The experimental results in this work is denoted by --o--o--, curves calculated according to eqn. 2 by + + + + for $R_0 = 0.2$ and by ## ## for $R_0 = 0.8$ mg/cm², while — — — — indicates results by Jackson and Lampe [7], and . . . . by Eidinoff and Knoll [4].

Table 3. Calculations of percent of true activity measured from samples of various thickness (in $\mu g/cm^2$). The A_0:values used are taken from Fig. 3, as given in Table 2.

(0.0)	(0.0)	(100) %	(100) %	(100) %	(100) %

from Fig. 3). It is difficult to estimate to what extent these two corrections affects $1/\mu$, but it is believed that the true $d_{½}$-and R_0-values are approximately equal to those obtained from Fig. 2 (*i.e.* $d_{½} = 0.08 \pm 0.02$ mg/cm², $R_0 = 0.6 \pm 0.1$ mg/cm²).

A serious consequence of this is that it points out the difficulties in using eqn. 2 for the determination of the relation between measured and true activity. As has been pointed out by Glendenin and Solomon [15], it is advisable to make self-absorption curves for each particular experimental condition if any accuracy is desired. The self-absorption factor, f_s, is therefore best obtained from curves like those in Fig. 3.

Using these data

$$f_s = \frac{100 \cdot I}{A_0 \cdot m} \% \qquad (5)$$

has been calculated as a function of m/a, (Table 3, and solid line in Fig. 5) where a is the area of the sample.

In Fig. 5, the experimental results obtained by Eidinoff and Knoll [4] (dotted curve) and Jackson and Lampe [7] (dashed curve) are also given. Considering the experimental difficulties, the agreement with the former investigation seems reasonable, but the deviation from the latter investigation is very great. The reason for this deviation may partly be that it is easier to obtain well-defined and even samples with the substances (triglycerides, fatty acids and soaps) investigated by Jackson and Lampe, than with PAS, which tends to form small aggregates of micro crystals. This may also explain why Jackson and Lampe obtained infinitely thin samples at a surface density of $\lesssim 10$ $\mu g/cm^2$, while in our case this was not obtained until $\lesssim 0.1$ $\mu g/cm^2$. However, the steeper rise of the upper part of the curve given by Jackson and Lampe compared with that of the theoretical curve lacks explanation.

The back-scattering factor. The discussion above has indicated that the A_0-values obtained at infinite sample thickness from Fig. 3 are more reliable than those obtained from Fig. 2. If a comparison is made with the results

obtained by Yaffe and Justus [11], the back-scattering factor obtained here seems far too high. However, from Seliger's [22] angle-energy relationship for scattered radiation one is bound to explain this discrepancy as being due to the use of different measuring equipment, *i.e.* in Yaffe's case, the use of low geometry and absorbing materials between the sample and the counter, which removes a considerable fraction of the soft scattered radiation.

Conclusion. Eqn. 1 has been used for the determination of the absolute specific activity, S, of a tritium sample. It has been pointed out that in a 2π internal gasflow proportional counter, the geometry can be assumed to be 50 % (*i.e.*, $f_g = 0.5$) and the efficiency 100 % ($f_e = 1$) when the counter is operated in the plateau at a reasonably low counting rate ($f_r = 1$). Methods for the determination of self-absorption (f_s) and back-scattering (f_b) have been described.

Under these conditions, S was determined for a tritiated solid PAS-sample, giving a result of 790 ± 40 dpm/mmole hydrogen. A fraction of the same sample was then analyzed for tritium as hydrogen gas internally in a GM-counter, giving 860 ± 120 dpm/mmole. Considering the uncertainties caused by all correction factors in eqn. 1, the agreement is very good, indicating the usefulness of the method described in this paper for rapid and absolute determination of tritium activities in solid samples.

On Vitamins in Sewage Sludge

VI. The Effect of Cobalt Chloride and Copper Sulphate on Vitamin B_{12} Contents of Microbially Decomposing Sewage Sludge

HALINA Y. NEUJAHR

Division of Food Chemistry, Royal Institute of Technology, Stockholm, Sweden

The effect of the addition of cobalt chloride and copper sulphate to fermenting sewage sludge was studied with respect to *E. coli* activity formed and its distribution between the different vitamin B_{12} factors.

The addition of cobalt chloride was found to stimulate the synthesis of cyanocobalamin and vitamin B_{12}-like factors in aerobically fermenting sewage sludge, whereas under anaerobic conditions its stimulating effect was less pronounced and restricted only to the initial stages of the fermentation.

The addition of copper sulphate had a detrimental effect on the formation of cyanocobalamin and of some vitamin B_{12}-like factors but not of factors Z, the formation of which in the aerobically fermenting sludge was drastically stimulated by the highest additions of copper sulphate used.

Many investigators have observed the growth promoting and vitamin B_{12} sparing effect resulting from the addition of small amounts of antibiotics, arsonic acids, and certain sulfonamides as well as of certain mineral compounds (*i.e.* cobalt, copper and iron salts) to commercial animal rations (*cf. Nutrition Revs 14* (1956) 238). It has been suggested that several of these agents may exert an influence on the intestinal synthesis of vitamin B_{12}, *i.e.* by alteration of the microbial intestinal flora (*cf. Vitamins and Hormones 14* (1956)).

Microbially decomposing sewage sludge is the site of synthesis of different vitamin B_{12} factors[1]. It has been shown in a previous investigation [2] that the addition of small amounts of several antibiotics may exert an influence upon the amounts of the different vitamin B_{12} factors synthesized during the process of microbial decomposition of sludge. A study of a similar effect resulting from the addition of cobalt chloride and copper sulphate is reported in the present paper.

EXPERIMENTAL

Fresh sludge from a settling tank of the Stockholm municipal sewage plant was disintegrated in a "Turmix" blendor, then mixed with ca. 20 % of digested sludge and diluted with water. The material thus obtained had a dry solid content of *ca.* 4 % and pH 5.0—5.5. It was fermented aerobically and anaerobically at 33°C with the addition of graded amounts of $CoCl_2 . 6H_2O$ and $CuSO_4 . 5H_2O$, respectively. The experiments were performed in conical flasks of 300 ml capacity placed in rooms with thermostatically controlled air temperature. In the anaerobic fermentations the flasks were filled with 280 ml of sludge and incubated in the thermostat. In the aerobic fermentations the flasks were placed in a shaking machine and the amount of sludge fermented was 100 ml. All additions were made before the start of the fermentations. Samples were autoclaved in the presence of KCN as described elsewhere [1]. Vitamin B_{12} activity was estimated with the aid of the cup plate, the tube and the bioautographic methods using *Escherichia coli* 113—3. Paper chromatograms were developed for 48 h at 18°C in the following two solvent systems:

Solvent system I: *sec.* butanol: H_2O:HAc (75:24:1) + 0.01 % KCN
Solvent system II: *sec.* butanol: H_2O:NH_3 (75:24:1) + 0.01 % KCN

Two standard solutions were used to identify the spots after chromatographic separation.

Standard solution 1 (S1): cyanocobalamin + factor III + factors (Z2 + Z3) [3].
Standard solution 2 (S2): factor A + factor B.

Each spot corresponded to 1 μl of the solution to be tested. The spot corresponding to that of factor A may represent a mixture of several of the following factors:

A + ψ-B_{12} + III + W + XI + X2 + X3 + X4 in solvent system I, whereas in solvent system II factors III + W can be separated from the other factors. The spot corresponding to factor A is in the following designated as "A". The spot corresponding to factor III may contain also factor W.

The following additions to the sludge were made:

% $CoCl_2 . 6H_2O$	corresp. to *ppm* Co^{++}	% $CuSO_4 . 5H_2O$	corresp. to *ppm* Cu^{++}
0.00	0	0.00	0
0.05	118	0.05	127
0.10	236	0.10	254
0.50	1 118	0.50	1 270
1.00	2 360	1.00	2 540

According to Anderson [4] digested municipal sludges may contain 315—1 980 ppm Cu^{++} (average: 643). No published data about the contents of cobalt in native or digested sludge were available. Total copper in the sludge mixtures used for the fermentation experiments was determined absorptiometrically with diethylammonium diethyldithiocarbamate in the dry ashed sludge according to the method of Abson and Lipscomb [5]. The values obtained were 22—25 μg Cu/ml sludge (determined as Cu^{++}) and showed fair constancy in several investigated batches of the sludge. These values are of a quite different order of magnitude from those reported by Anderson [4] for American digested sludge. The difference probably reflects the influence of industrial products entering sewage purification systems in Stockholm and in the American towns.

The cobalt contents in the sludge mixtures were determined absorptiometrically with 1-nitroso-2-naphthol by the method of Middleton and Stuckey [6]. The determinations were carried out on dry ashed sludge as in the case of copper. The values obtained were 0.5—0.6 μg Co/ml sludge (determined as Co^{++}). This represents an amount about ten times as large as the amount of cobalt bound in the vitamin B_{12} factors.

RESULTS

It can be seen in Fig. 1 that the highest additions of copper sulphate (0.5 — 1.0 %) caused a marked decrease in the pH of the sludge in both the aerobic and the anaerobic fermentation thus indicating that the "normal"

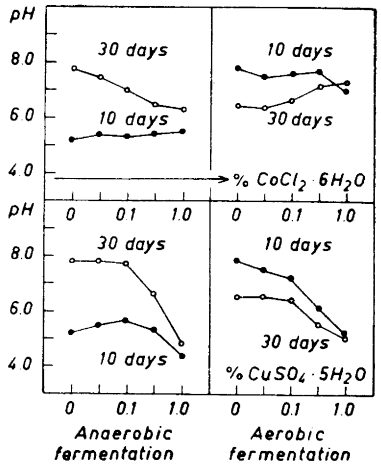

Fig. 1. Effect of addition of cobalt chloride and copper sulphate upon the pH of microbically decomposing sewage sludge.

microbial flora of the decomposing sludge had become modified by the addition. The anaerobic microbial decomposition of the sludge proceeded in two stages; the first stage lasting for at least 10 days was characterized by a lower pH (5.0 — 5.5) and the second stage by a higher pH (7 — 8).

In the aerobic process (continuous shaking) a pH value of 7 — 8 was reached already after 10 days and was followed by a drop to pH 6.5 after 20 more days of microbial decomposition.

Obviously, these differences in pH variations between the aerobic and the anaerobic processes must be taken into account when considering the differences in formation of the different vitamin B_{12} factors during these processes.

Effect of cobalt chloride

a) *Anaerobic fermentation* (Fig. 2a). The addition of 0.1 % $CoCl_2.6H_2O$ corresponding to 236 ppm of Co^{++} slightly stimulated the synthesis of cyanocobalamin and of factor B during the first 10 days of fermentation. The addition of 0.05 — 0.1 % $CoCl_2.6H_2O$, corresponding to 118—236 ppm of Co^{++}, stimulated the synthesis of factors Z in a very pronounced way. With greater amounts of cobalt chloride a detrimental effect on the synthesis of all vitamin B_{12} factors could be observed. After 20 more days of fermentation with 118 ppm Co^{++} a slightly stimulating effect on the synthesis of factors Z and of factors "A" could be noticed whereas the amount of cyanocobalamin remained unaffected by the additions of 118 and 236 ppm and rather diminished by the additions of larger amounts.

b) *Aerobic fermentation* (Fig. 2b). The effect of cobalt chloride was here much more pronounced than under anaerobic conditions. With 118 ppm of Co^{++} a drastic stimulation of the synthesis of cyanocobalamin and of factors Z could be observed after 10 days of fermentation. At the same time the amounts of factors "A" and of factor B decreased with increasing amounts

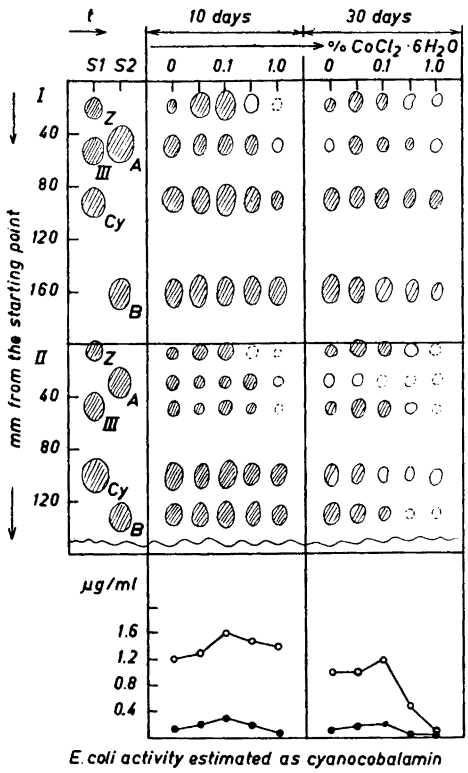

Fig. 2a. Effect of addition of cobalt chloride to fresh sewage sludge, subsequently anaerobically decomposed. Bioautogram.

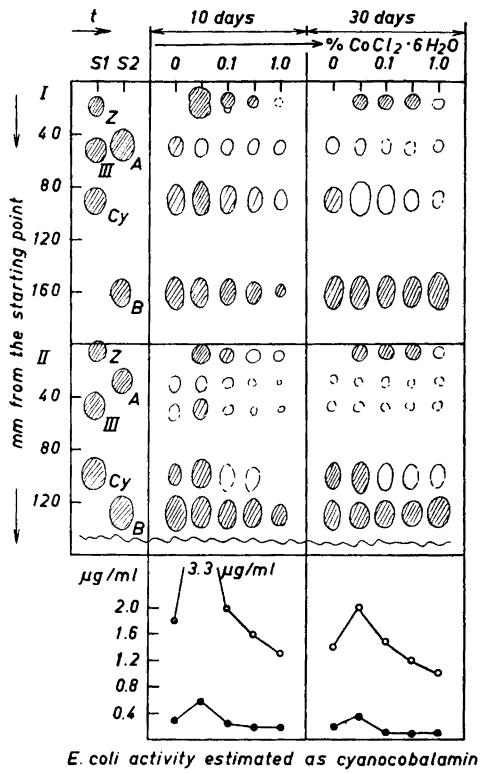

Fig. 2b. Effect of addition of cobalt chloride to fresh sewage sludge, subsequently aerobically decomposed. Bioautogram. ○——○ cup assay; ●——● tube assay.

of Co^{++}. After 20 more days of fermentation the stimulating effect on the synthesis of cyanocobalamin was still very pronounced whereas the effect on the synthesis of factors Z was less pronounced than after 10 days. The addition of 118 — 1 180 ppm of Co^{++} seemed to stimulate the synthesis of the latter factors.

The amount of factor B was greatest in the sludge with the highest addition of Co^{++} (2 360 ppm) which was accompanied by an almost total disappearance of all the other vitamin B_{12} factors.

Effect of copper sulphate

a) *Anaerobic fermentation* (Fig. 3a). The addition of 0.05 % $CuSO_4.5H_2O$ (corresponding to 127 ppm of Cu^{++}) had, after 10 days of fermentation, a slightly stimulating effect on the synthesis of all vitamin B_{12} factors. Higher additions had either no effect or a decreasing one. However, after 20 more

days, the amount of cyanocobalamin decreased in the sludge containing 0.05 % copper sulphate and still more with increasing additions of Cu^{++}, but the synthesis of factors Z and of factor B was slightly stimulated by the additions corresponding to 254 and 127 ppm Cu^{++}, respectively. With higher additions all the vitamin B_{12} factors disappeared.

b) *Aerobic fermentation* (Fig. 3b). Increasing additions of copper sulphate decreased the amount of cyanocobalamin and increased the amount of factors Z. The situation was the same after 10 days as after 20 more days of fermentation. The amount of factor III and of factor B was slightly increased after 10 days in the sludge to which 127 ppm Cu^{++} had been added.

DISCUSSION

It can be concluded from the above that the addition of cobalt chloride to fresh sewage sludge, exerts a stimulating influence on the synthesis of cyanocobalamin and of other vitamin B_{12} factors during the subsequent microbial decomposition. This influence is much more pronounced in aerobic than in anaerobic fermentation. Moreover, under anaerobic conditions the addition of Co^{++} seems to stimulate the synthesis of vitamin B_{12} factors solely during the first stage of the decomposition of the sludge (10 days, pH $\sim$ 5.5) whereas during a latter stage (20 more days, pH $\sim$ 7.5) the amount of cyanocobalamin formed remains unaffected and the synthesis of factors Z and of factors "A" is stimulated only very slightly. In the aerobic fermentation the addition of Co^{++} stimulates the synthesis of cyanocobalamin and of factors Z very markedly both after 10 and after 20 more days of fermentation, which probably may be connected with the faster decomposition rate of the aerobically fermented sludge as reflected by the changes in pH (*cf.* p. 409). In an earlier investigation [1] it has been found that the first stage (pH 5.5) of anaerobic microbial decomposition of sewage sludge is characterized by a disappearance of cyanocobalamin which is probably consumed by some microorganisms active in the sludge at this pH, whereas during the decomposition of the sludge by aerobic organisms cyanocobalamin is synthesized continuously. The present result suggests therefore the possibility that the additon of Co^{++} to sewage sludge with subsequent anaerobic decomposition may exert a stimulating influence on the formation of cyanocobalamin rather by inhibition of the organisms which consume it (or enzymes which destroy it), whereas under aerobic conditions this addition may directly stimulate the synthesis of cyanocobalamin.

The addition of copper sulphate caused a slightly increased formation of cyanocobalamin and of several vitamin B_{12}-like factors during the first stage of microbial anaerobic decomposition of sludge (pH$\sim$5.5), whereas at the later stage (pH$\sim$7.5) the amount of cyanocobalamin was decreased by the addition. In view of the well known antimicrobial properties of copper it is tempting to suggest that its stimulating effect on the synthesis of cyanocobalamin and vitamin B_{12}-like factors during the first stage of anaerobic microbial decomposition of sludge may be due to inhibition of the cyanocobalamin consuming organisms (or enzymes which destroy it) analogously to the mechanism suggested for the effect of cobalt chloride in the first stage of anaerobic fermentation.

The addition of Cu^{++} with subsequent aerobic fermentation of the sludge had a detrimental effect on the formation of cyanocobalamin and of most vitamin B_{12}-like factors but not of factors Z the amounts of which drastically increased with the highest additions of Cu^{++}.

In earlier investigations [1,3] the formation of factors with R_F-values corresponding to those of factors Z was found to accompany very often the formation of cyanocobalamin. Cu^{++} thus seems to have some selective effect on the formation of cyanocobalamin and of these factors.

The amounts of cobalt and copper added to the sludge were chosen with regard to the range of similar additions usually employed in commercial

animal rations (*cf. Nutrition Revs. 14* (1956) 238). With a view, however, to the relatively low natural contents of these elements in sludge (*cf.*p. 409) it would be of interest also to investigate the range 0—100 ppm of both additional copper and cobalt. It is thus too early to draw any conclusions about the optimal amounts of these two elements in fermenting sewage sludge for obtaining largest amounts of vitamin B_{12} factors.

Servo-controlled Wheatstone Bridge Arrangements for the Simultaneous Recording of Resistance and Capacitance

CARL-OVE ANDERSSON, FREDRIK MÖHL and EINAR STENHAGEN

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, and the Institute of Medical Biochemistry, University of Gothenburg, Sweden

The conditions for simultaneous servo-balancing of resistance and capacitance in alternating-current Wheatstone bridges of various types are discussed. A series of experiments are described which confirm the theory, and give information regarding the practical aspects of double-servo-controlled A.C. bridges.

Servo-controlled Wheatstone bridges intended for the continuous recording of resistance in electrolytic systems have been described in the literature. For references see Ref.[1] The arrangements so far described use servo control only for the resistive balance, and the capacitative balance has to be adjusted manually. It was suggested by Andersson, Mellander, and Stenhagen [1] that automatic capacitative correction might be used in the form of a standardization operation, performed in a manner similar to the automatic current standardization in D.C. millivolt recorders of, for example, the "Speedomax" type. A study of the theoretical side of the problem, however, revealed that it should be possible to balance both capacitance and resistance simultaneously by using two independent servo systems, and the results recorded in the experimental part of this communication show that servo-controlled Wheatstone bridge arrangements for the simultaneous recording of resistance and capacitance are capable of practical realization.

THEORY. CONDITIONS FOR OPERATION OF DOUBLE SERVO SYSTEM

I. Normal Wheatstone bridge (Fig. 1)

Consider the Wheatstone bridge arrangement of Fig. 1. It is assumed throughout this communication that the fixed bridge arms AD and DC are identical. The variable impedance to be recorded (for instance that of an electrolytic cell) is connected between points B and C, and considered as a

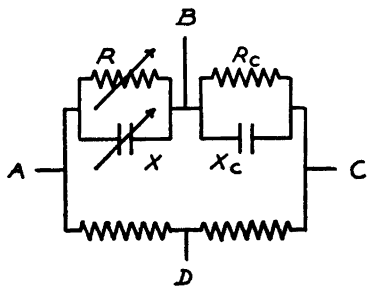

Fig. 1. Normal alternating current bridge. A and C are connected to a source of alternating current; B and D are connected to the detector. Shielding and Wagner earthing arrangements not shown.

resistance and a capacitance in parallel. A source of A.C. current is connected across points A and C. When the bridge is unbalanced, that is, when $R \neq R_C$ and/or $X \neq X_C$, an alternating potential exists across BD. The unbalance is to be automatically corrected through the variable resistance R and reactance X, each controlled by its own servo-motor. The servos are steered by the potential across points B and D, through phase-sensitive detectors. The sign of the D.C. output of a phase sensitive detector depends on the phase difference between the signal and a reference potential of the same frequency (in the present case obtained from the oscillator supplying the bridge current). If the phase difference is $< 90°$, the detector gives a D.C. component in the output current; and if the phase difference is $> 90°$, the D.C. component has the opposite sign. If the phase difference is exactly 90° (or 270°) there will be no D.C. component in the output.

We now connect two phase-sensitive detectors in parallel across BD (in practice they are connected in parallel over the output of the detector amplifier), and the D.C. outputs are fed to the R- and the X-servo, respectively. The reference potentials are termed $V_{R\ ref.}$ and $V_{X\ ref.}$

If the phase of the alternating potential V_{DB} is not exactly 90° out of phase with respect to $V_{X\ ref.}$, the X-servo receives a signal, and will adjust the reactance X until the signal output of the X-detector is zero (or is below the threshold of the servo). The R-servo will operate in a corresponding manner. If the $V_{R\ ref.}$ and $V_{X\ ref.}$ are out of phase with respect to each other,

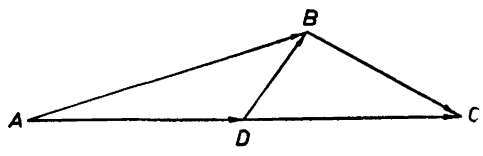

Fig. 2. Vector diagram of the potentials of the bridge shown in Fig. 1 at unbalance.

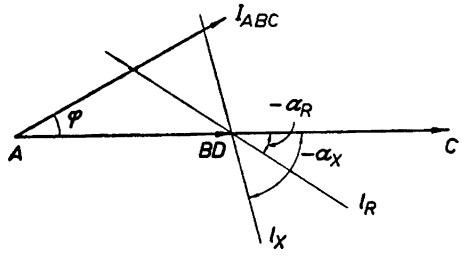

Fig. 3. Current and potential vectors of the bridge shown in Fig. 1 at balance. For the definition of I_X and I_R see text.

it is evident that V_{DB} must be zero in order that neither servo shall operate, which means that the desired balance of the bridge has been attained. The servos may be coupled to recorders that automatically record both the resistance and the reactance of the bridge-arm BC.

In order for the arrangement to function properly, two conditions must be fulfilled: (a) "Coupling" between the servos must be avoided, that is, *if one of the servos receives no signal the other servo should not be able to alter this condition;* and (b) "Parallelism" between a servo and its steering function must be avoided, that is, *if one of the servos receives a signal it must be possible for the servo in question to alter this condition.*

It should be possible to realize condition (a) approximately and condition (b) (which is the more important) exactly, by a suitable choice of phase for the reference signals. Fig. 2 shows in vector form the potentials between the four corners of the bridge at unbalance. The vector representing the potential V_{DB} can form any angle with the vector V_{AC}, but is always small compared with the latter. At balance $V_{DB} = 0$: B coincides with D as shown in Fig. 3. If $R = R_C$, and R, R_C, and X_C are kept constant, and X varies (*cf.* Fig. 1), the point B of the vector V_{DB} of Fig. 3 will move along a curve. If X is kept constant and X_C varies, point B will move along a different curve. In point D these curves have the common tangent l_X, forming an angle α_X with the vector V_{AC}. Analogous relations are valid for R, R_C, and α_R of Figs. 1 and 3. If V_{DB} is kept small we may use the approximation that the point B moves along the tangents l_X and l_R. For the purpose of our discussion we can furthermore assume that the input resistance of the detector amplifier is infinitely high, and that therefore no current flows between points B and D. Any current I_{DB} will cause changes in all potentials, and probably also in α_R and α_X. If $I_{DB} = 0$ it can be shown (see Appendix I) that $\alpha_R = -\varphi$ and $\alpha_X = -(\varphi + 90°)$, where φ is the angle between V_{AC} and I_{ABC}. It follows that if, for example, R_C changes during an experiment, and R (to keep the balance) changes in the same direction, φ and consequently also α_R and α_X will change. In the following discussion, however, we may disregard this change.

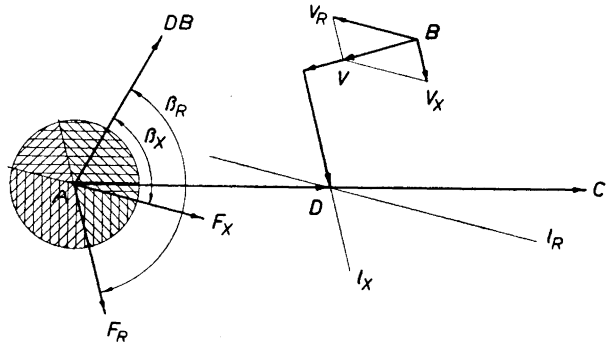

Fig. 4. Diagram illustrating the servo balancing of the bridge shown in Fig. 1.

In order to avoid coupling between the servos, the X-servo must not operate when point B is moving along l_R, and B therefore can be led back to D with the R-servo alone. The X-servo does not operate if the potential vector $V_{X\ ref.}$ is normal to l_R. Analogously, $V_{R\ ref.}$ should be normal to l_X. We then get the conditions shown in Fig. 4. The sign of the output signals from the phase detectors are determined by the angles β_R and β_X between the vector V_{DB} and the vectors F_X and F_R, respectively, which are normals to the corresponding reference potentials. When $\beta_R > 0$ (region \\\\\\) the R-servo will cause point B to move with velocity v_R towards "west-north-west" along a line approximately parallel to l_R. If $\beta_R < 0$ (region //////), v_R will point towards "east-south-east" instead. Similarly, $\beta_X > 0$ (region ≡≡≡) gives v_X pointing towards "south-south-east", approximately parallel to l_X; and $\beta_X < 0$ (region ||||||) gives v_X pointing in the opposite direction ("north-north-west"). In the circumstances illustrated in Fig. 4, both β_R and β_X are > 0 (region ▦), and v_X and v_R add vectorially to v, pointing towards "west-south-west" until point B reaches the line l_X, when the R-servo stops. Only the component v_X of v then remains ($\beta_R = \pm 180°$, but β_X still > 0), and point B moves along l_X until point D is reached. The X-servo then stops, and the bridge is balanced.

A block diagram of the suggested servo-controlled bridge arrangement with independent R- and X-servos is shown in Fig. 5. The adjustment of the phase of the reference signals with the aid of the two phase shifters may be carried out as follows. The electrolytic cell or other impedance to be recorded is connected to the bridge. The phase detectors are disconnected and the bridge balanced manually in the usual manner. The phase detectors are connected to the bridge amplifier and the balance of the bridge slightly altered by altering R only, making point B in the diagram of Fig. 3 move out from D along l_R. This will probably result in output signals from both phase detectors. However, we wish only to get an output signal form the R-detector when R is changed and therefore adjust the phase of the reference signal $V_{X\ ref.}$ of

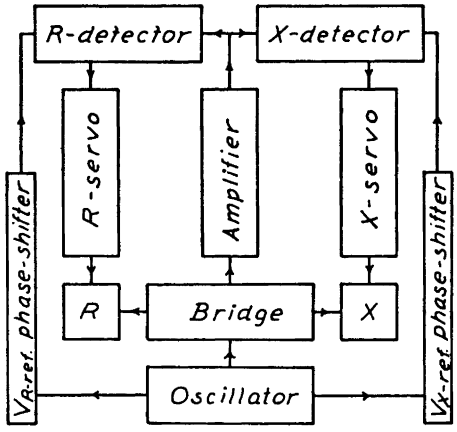

Fig. 5. Block diagram of bridge arrangement with double servo.

the X-detector until no output signal is obtained from this detector. $V_{X\ ref.}$ is then parallel to l_R. The bridge is again balanced manually, and the procedure just described repeated with reactance X and the phase shifter for $V_{R\ ref.}$ The servos are then connected. It may be necessary to shift the polarity of the servo connection if the phase of the corresponding reference signal should happen to be shifted 180°. The apparatus should now be ready for the run. For practical details see the experimental part.

A slight coupling between the servos must be tolerated for the following reasons. (a) The straight lines l_R and l_X are only approximations to the curves along which point B (Fig. 3) moves. (b) As already pointed out, the angles α_R and α_X of Fig. 3 vary with the phase-angle φ between the potential V_{AC} and the current I_{ABC}. This means that the orthogonality between the reference signals and the l-lines will not be exact. The errors can be kept small, however, provided that (a) point B is not allowed to move far away from D, that is, the servos must keep up well, and (b) the phase-angle does not undergo large absolute changes during the run. Difficulties due to phase-angle variation may be overcome by using the series bridge (see III).

II. The "potentiometer" Wheatstone bridge arrangement

The "potentiometer" bridge arrangement is extremely convenient for practical measurements of resistance, as it allows a continuous variation of the recorder range by means of a shunt across the potentiometer. In the apparatus described previously [1], the recorder range could be varied from 2 to 1 800 ohms full scale. The bridge is shown in Fig. 7. The use of a potentiometer in this manner may sometimes lead to errors in the recordings, however. Although the presence of such errors may be checked experimentally, a theoretical analysis is warranted.

As the complicated impedance of the arm BC (Fig. 7) makes theoretical calculations very difficult, the arrangement shown in Fig. 8 is used instead. The "differential" condenser (ganged X_1, X_2) is replaced by two separate condensers connected across A—B_a and C—B_c, respectively. Only X_2 should be

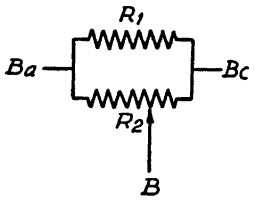

Fig. 6. Diagram showing shunted potentiometer.

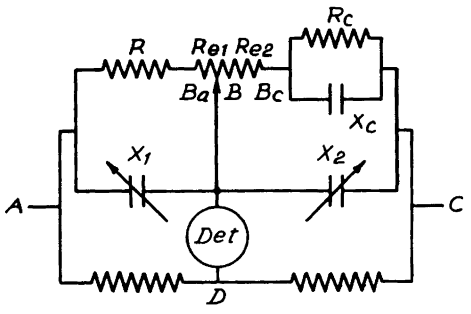

Fig. 7. Potentiometer bridge described in Ref.[1], and used in some of the experiments in Section VI.

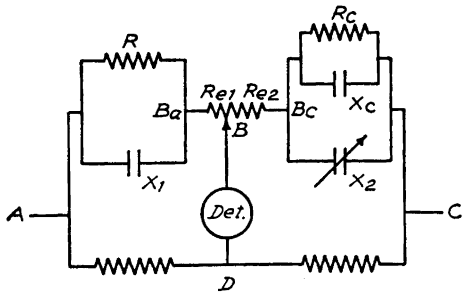

Fig. 8. Bridge arrangements recommended instead of that shown in Fig. 7.

servo-operated, as X_1, not being connected across exactly the same resistance as X_C (R is kept constant but the cell resistance R_C varies during the experiment), does not have the same action as X_C on the circuit. X_1 and X_2 should be as large as possible in order to keep φ small, because, as will be shown, a large φ causes poor linearity and poor servo action.

In order to simplify the calculations the shunted potentiometer (Fig. 6.) is replaced by the equivalent resistance R_e. The potentials B_aB and BB_c depend only on the position of B along R_1 and the total potential B_aB_c and this will be the same if the combination R_1, R_2 is replaced by the equivalent resistance

$$R_e = R_1R_2/(R_1 + R_2).$$

In the bridge arrangement of Fig. 1 it is evident that R is equivalent to R_C, and X to X_C. In the potential vector diagram given in Fig. 3 we therefore have only two "tracks" for the vector arrow point B, *viz.*, l_R and l_X. With the circuit of Fig. 8 this is no longer the case, and from the outset we have to consider four tracks, l_{RC}, l_{XC}, l_{Re}, and l_{X_1}. We need to know the answer to the following questions.

(a) Is it possible to compensate a small change in R_C with R_e only? This is of importance, particularly in the measurement of X_C. If the answer is no, it means that the condenser servo (X_2) responds both to capacitative and resistive changes of the cell, and it may be difficult to derive the capacitative changes from the recordings. This question, which is less important for the measurement of R_C, may also be formulated as follows: Do l_{RC} and l_{Re} coincide?

(b) Do l_{XC} and l_{X_1} coincide? This question is of particular importance in the measurement of R_C.

(c) What are the quantitative relations between R_C and R_e?

(d) What are the quantitative relations between X_C and X_2?

It is evident that question (b) can be answered in the affirmative, because X_C and X_2 are connected in parallel and have the same influence in the circuit. Resistance measurements are thus possible. Calculations, the details of which are given in Appendix II, show that the relation between ΔR_e and ΔR_C is

$$\Delta R_e = \frac{1}{1 - \mathrm{tg}^2\,\varphi} \cdot \tfrac{1}{2}\,\Delta R_C \qquad (14)$$

If R_e is mechanically coupled to a recorder we get a recording of ΔR_C in accordance with eqn. (14). The linearity is good, provided that φ is small and does not vary too much. If $\mathrm{tg}^2\varphi$ is less than 0.003 ($0 < \varphi < 2.75°$) ΔR_e will differ from $\frac{1}{2}\Delta R_C$ by less than 0.3 %. For phase angles smaller than the value just given, the error is thus less than the writing error of precision recorders of the "Speedomax" type. As tg φ increases with increasing frequency, the error due to the shunted potentiometer circuit will be smaller with a lowering of the frequency of the bridge current. On the other hand, the time constants of the filters necessary in the detector circuits have to be increased with a lowering of the frequency, leading to a fall in the speed of response on the part of the servos. The relation between the susceptance, $B_2 = 1/X_2$, of the condenser X_2 and R_C and X_C may be expressed by the following equations (for derivation see Appendix II).

$$\Delta B_2 = -\frac{2 \mathrm{tg}\,\varphi}{R_C^2 (1 - \mathrm{tg}^2\varphi)} \cdot \Delta R_C \tag{13}$$

$$\Delta B_2 = -\Delta \frac{1}{X_C} \tag{15}$$

If we couple a recorder mechanically to the condenser X_2, the recorder will write a curve of the sum of a susceptance curve according to eqn. (15), and a resistance curve according to eqn. (13). From Fig. 9 we obtain the value $90° - 2\varphi_2 \approx 90° - 2\varphi$ for the angle between l_{R_e} and l_X. When $\varphi = 45°$, l_{R_e} and l_X coincide. The action of the potentiometer will then be the same as that of condenser X_2, and it will be impossible to balance the bridge. It may perhaps be possible to allow values of φ as high as 30°, but it must be kept in mind that the permitted variation in φ will become less with increasing φ.

To sum up, the "potentiometer" bridge circuit is unsuitable for the recording of reactance unless tg φ is very close to zero (eqn. 13), but it may be employed for the recording of the resistive component of an impedance that does not vary over large ranges.

III. The series bridge

For the measurement of electrolytic resistance, bridges with parallel combinations of resistances and capacitances are usually employed. However, a

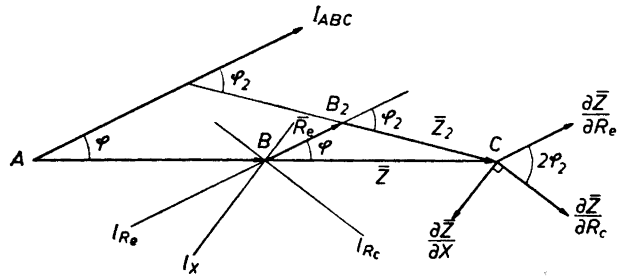

Fig. 9. Vector diagram of the bridge of Fig. 8. For explanation see text.

series bridge arrangement has two very important advantages over the parallel bridge with respect to servo control: (a) It is possible to use a shunted, servo-controlled measuring potentiometer without introducing any theoretical error; and (b) The line l_R of the potential diagram (Fig. 11) is parallel, and the line l_X normal, to I_{ABC}. If the reference potentials of the detectors are based upon the current I_{ABC}, they will retain their theoretically correct value independent of variations in φ; and if the servos follow well, there will never be any coupling between them.

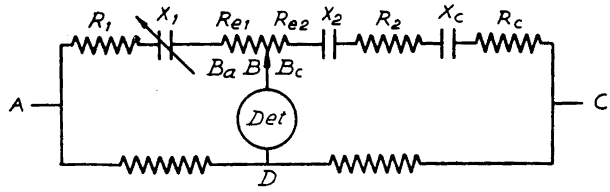

Fig. 10. Series bridge.

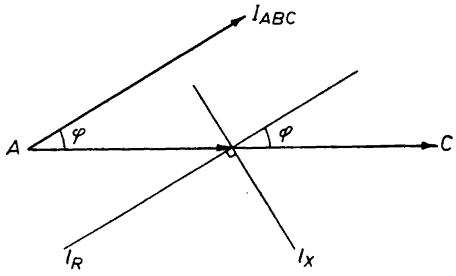

Fig. 11. Vector diagram of the series bridge.

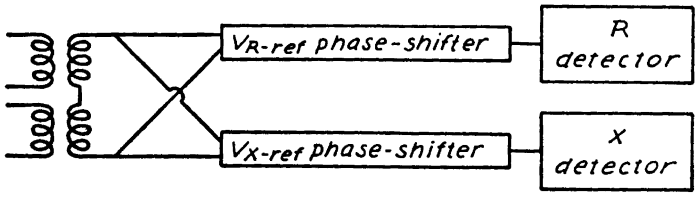

Fig. 12. Suggested detector arrangement for the series bridge.

The bridge may be connected as shown in Fig. 10. The series bridge is particularly useful when measuring impedances with large variations in φ. The reference potentials may be obtained through a suitable transformer with two identical primary windings (Fig. 12) connected in series with X_1 and X_2. An amplifier may have to be used between the transformers and the phase shifters.

In order to measure with the series bridge the parallel components of, say, an electrolytic cell, it is necessary to determine both series components and to calculate the parallel components of the cell using the following expressions

$$R_p = R_s (1 + R_s^2 B_s^2) \text{ and } X_p = \frac{R_s^2 B_s^2 + 1}{R_s B_s^2}.$$

IV. The Easton-Lamson bridge (General Radio Z-Y-bridge)

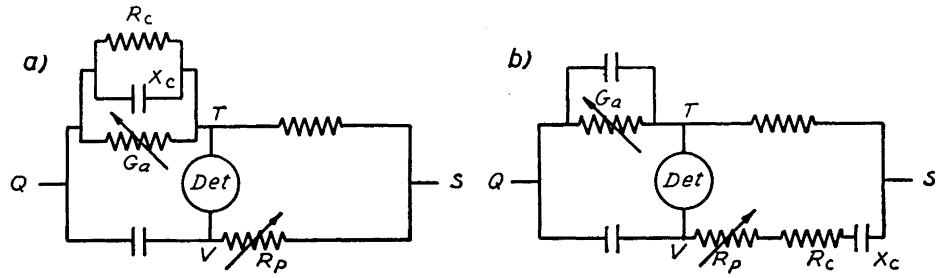

Fig. 13. a) Z—Y bridge with "cell" measured as admittance. b) Z—Y bridge with "cell" measured as impedance.

Easton and Lamson [2] have recently described the bridge arrangement shown in Fig. 13. This bridge has the distinction that it can be balanced for any type of impedance to be measured, and possesses over the normal Wheatstone bridge of Fig. 1 the advantage that both reactance and resistance are balanced with purely resistive components. It is therefore possible to use two similar resistances, one coupled to a recorder and the other to a simple servo, and simply change the connections according to whether the resistance or the reactance is to be recorded.

Fig. 14 shows the potential diagram at unbalance. When the bridge is balanced, points T and V (corresponding to points B and D of the diagram of the normal bridge of Fig. 2) coincide, as in Fig. 15. The resistance G_a moves

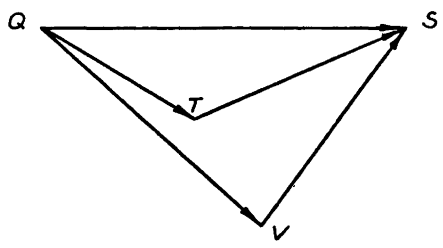

Fig. 14. Vector diagram of Z—Y bridge at unbalance.

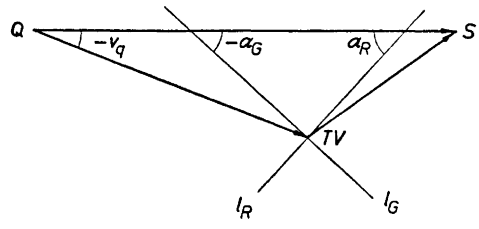

Fig. 15. Vector diagram of Z—Y bridge at balance. For explanation of I_R and I_G see text.

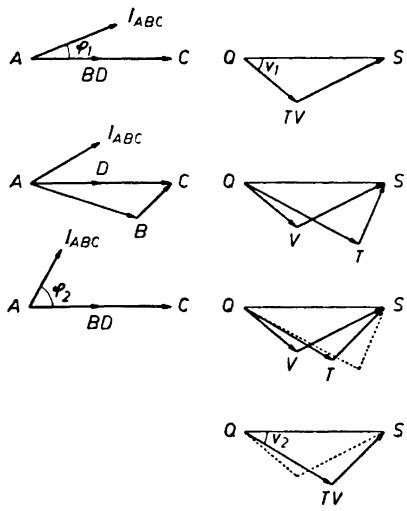

Fig. 16. Vector diagrams showing the balancing of the normal bridge left (1. Bridge balanced. 2. Unbalance introduced. 3. Balance restored with R and X.) and the Z-Y-bridge right (1. Bridge balanced. 2. Unbalance introduced. 3. T moved to balance point by means of G_a. 4. Balance restored by means of R_p.)

the point T along the line l_G, and R_p moves V along l_R. If the "cell" is measured as an "admittance", l_G and l_R correspond to l_R and l_X, respectively, in Fig. 3. The angles α_G and α_R that the lines l_G and l_R form with the impressed voltage QS are derived in appendix III. They are

$$\alpha_G = 2v_q \tag{16}$$

$$\alpha_R = 2v_q + 90° \tag{17}$$

and obviously depend only on the angle v_q between the voltages QS and QT (or QV, which is similar to QT), in the same way as α_R and α_X in Fig. 3 depend on the phase angle φ. And, unfortunately, like α, v_q cannot always be kept constant during the run.

It is clear, however, that in principle it is possible to servo-control the ZY-bridge in the same way as the normal bridge. The series of figures above (Fig. 16) shows what happens when the balance is disturbed and restored in the two cases. The impedance to be measured can be connected to the ZY-bridge in two different ways (Fig. 13). If connected as an "impedance" (Fig. 13 b) it is measured as a resistance and a reactance in series; and if it is connected as an "admittance" (Fig. 13 a) it is measured as a resistance and a reactance in parallel. In the former case the series reactance is not given by G_a directly, because the curve will give the variation of $\Delta\ 1/G_a$ and not $\Delta\ G_a$ if a linear resistance is used. (In the bridge manufactured by the General Radio Co. the measuring resistance is linear in conductance, not in resistance.) This is usually inconvenient, and it is therefore better to connect the unknown impedance according to the second alternative, and measure it as an admittance. If the connected admittance should fall outside the range of the instrument, the parameters of the bridge arms must be changed. When measuring the unknown impedance as admittance, G_a writes a curve giving the parallel resistance, and R_p a curve of the parallel susceptance.

V. Concerning the possibility of using a Wheatstone bridge with servo, without manual or servo-control of the quadrature component

Two cases are at once apparent when a single servo is sufficient, *viz.* when φ is constant and equal to zero, and when φ is constant and equal to 90°. It may be readily assumed that it should also be possible to use a single servo, when, for instance, it is desired to measure changes in resistance in cases where the capacitance remains constant (but $\neq 0$). This is in fact possible if the normal bridge arrangement of Fig. 1 is used, but is in general less satisfactory in case of the "potentiometer" circuit (Figs. 6 and 8), because, as already discussed above, a change in R_C causes both resistive and capacitative unbalance. However, if it is desired to measure only small changes in one of the parallel components, is it then necessary to keep the bridge in balance with respect to both components? A reference to Fig. 4 shows that if φ is constant, and if changes in R always make B move along straight lines parallel to l_R independent of the position of B in the plane, and if corresponding conditions are valid for l_X and X, X may remain in any position and X_C vary at will if R_C is to be measured. The R-servo and the attached recorder ought to record the same curve as when the bridge is kept in complete balance. Instead of remaining at D, the point B would move up and down along l_X, but this would have no influence on the R-servo.

Conditions are of course less perfect in practice, but the smaller the variation in Z, the nearer will be the approach to the ideal. The changes in Z to be recorded are often small compared with Z. It is, however, essential that the phase angle of the reference potential is correctly chosen.

Finally, it must be pointed out that the above reasoning implies that the detector does not lose its sensitivity when a large signal is applied, that is to say, a "logarithmic" detector amplifier cannot be used.

VI. Experimental part

The bridge and associated apparatus were the same as used previously [1], with the addition of a capacitance servo consisting of phase-sensitive detector with built in phase shifter (identical to that used for the recording of resistance) and a "Speedomax" recorder with a writing-speed of 2.5 seconds across the scale. A precision-built air-dielectric condenser * of 500 pF capacitance with linear capacitance variation, contained in a shielded box attached to the back of the recorder housing, was mechanically coupled to the recorder potentiometer shaft via an insulated bushing. A D.C. tachometer generator was attached to the recorder motor as described in the previous paper [1]. In Ref.[1] the bridge was arranged as shown in Fig. 7, but in the first series of experiments to be described below the bridge was set up as in Fig. 1, by joining points B and Bc. The servo-controlled condenser was connected between A and B. The servo was controlled by the detector signal across BD (Fig. 1) *via* the same detector amplifier ** with automatic volume control as the resistance servo, the two phase-sensitive detectors being connected in parallel across the output.

* The condenser used was of an early radio-receiver type manufactured by AB Baltic, Södertälje.

** The time constant of the A.V.C. action is about 0.2 seconds, and not 2 seconds as was erroneously given in Ref.[1]

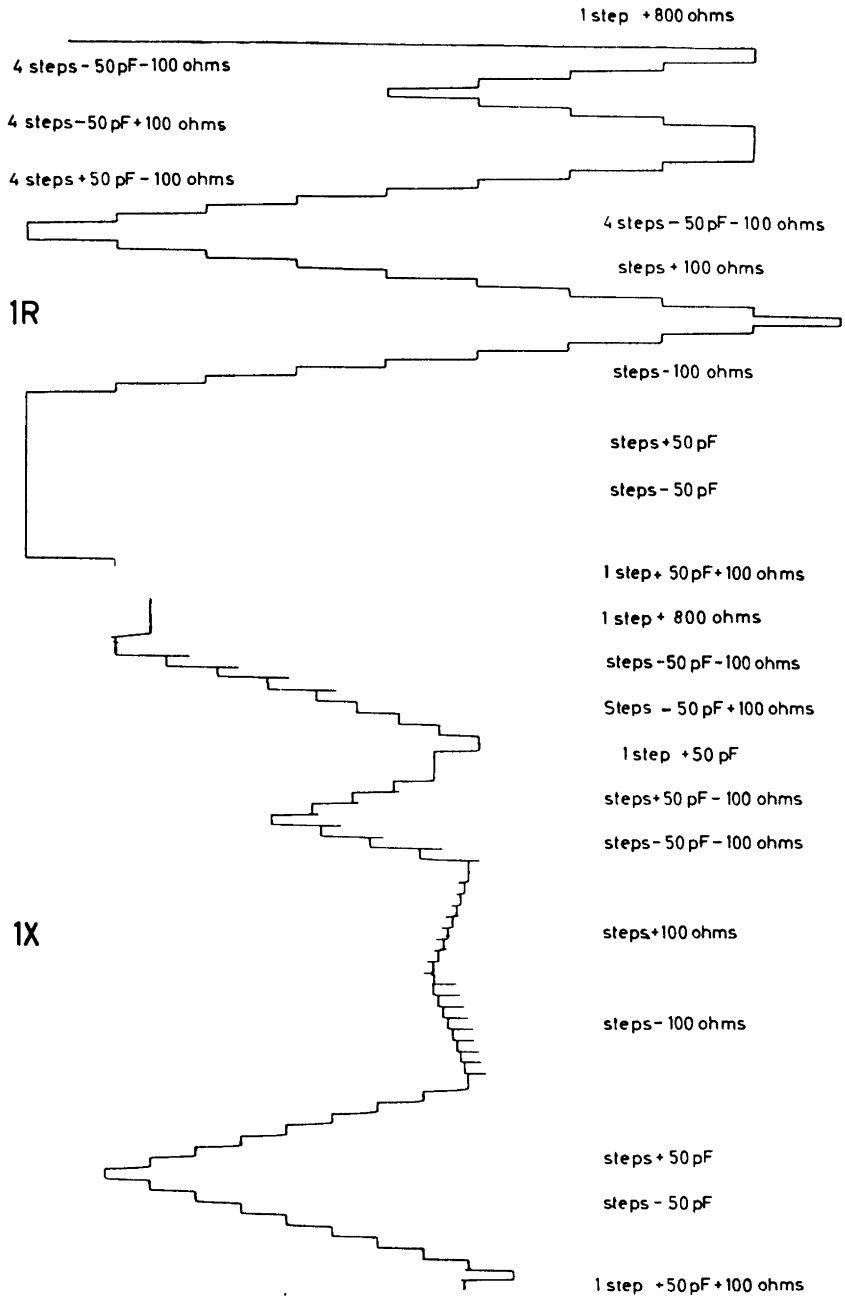

Fig. 17. Double servo-recordings using the bridge shown in Fig. 1. Sinusoidal reference potentials.

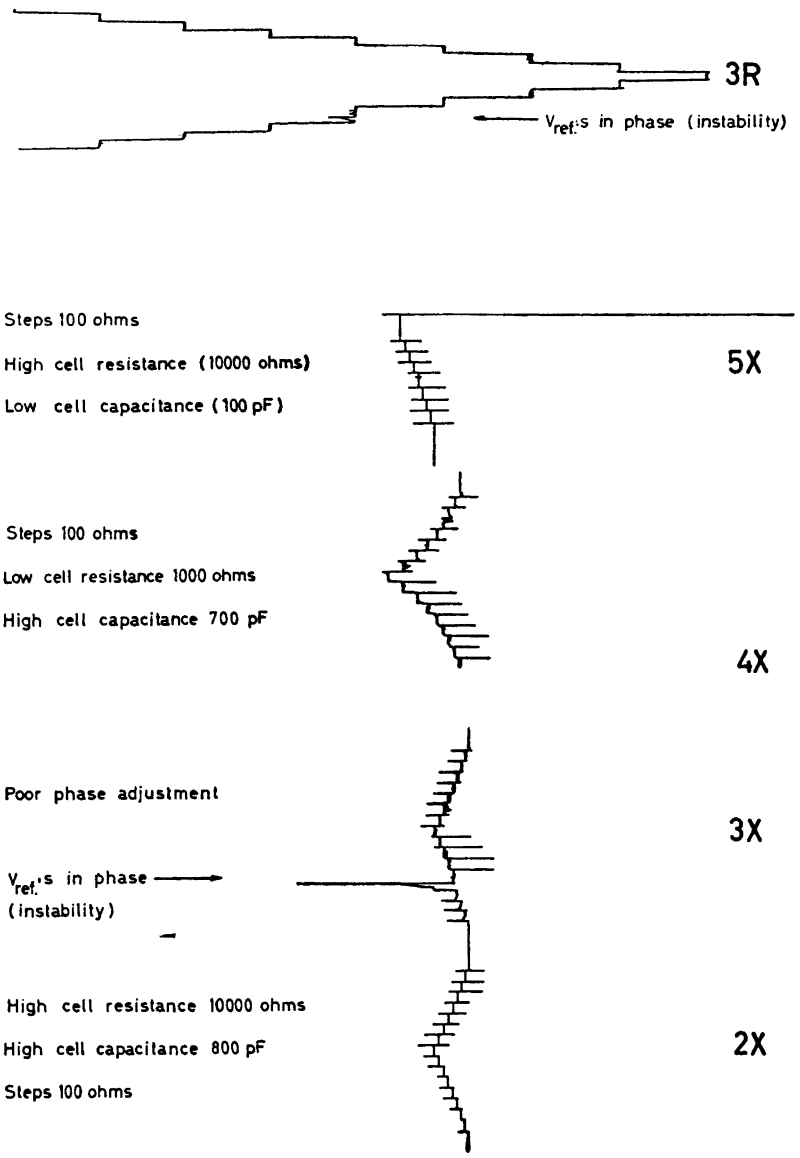

Fig. 18. Double servo-recordings using the bridge shown in Fig. 1. Square wave reference potentials.

The servo-controlled precision resistance was a wire-wound linear resistance of 1 000 ohms (*cf.* Ref.[1]), and as "cell" was used a Leeds & Northrup six-decade resistance (0 to 11 000 ohms in steps of 0.01 ohm) in parallel with a precision-variable-condenser covering the range 100 to 1 000 pF (General Radio Co., type N).

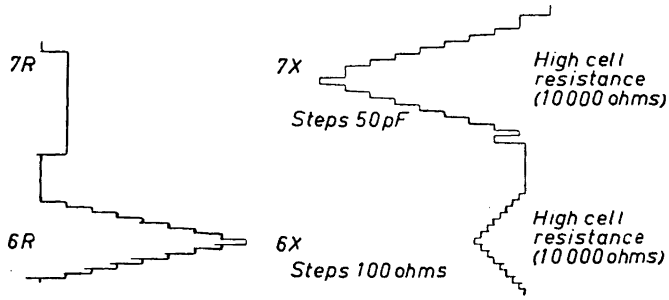

Fig. 19. Double servo-recordings using potentiometer bridge shown in Fig. 7. No shunt used. Square wave reference potentials.

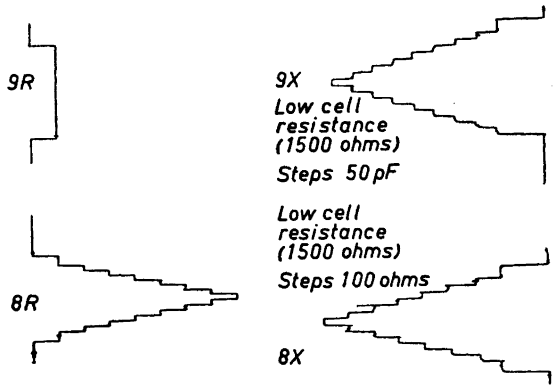

Fig. 20. Double servo-recordings using potentiometer bridge shown in Fig. 7. No shunt used. Square wave reference potentials.

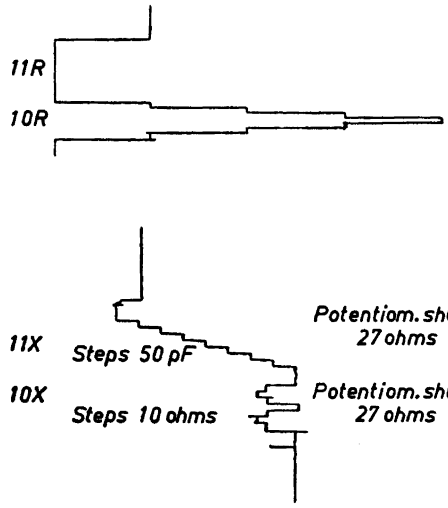

Fig. 21. Double servo-recordings using potentiometer bridge shown in Fig. 7. Recorder range 50 ohms (potentiometer shunted by 27 ohms).

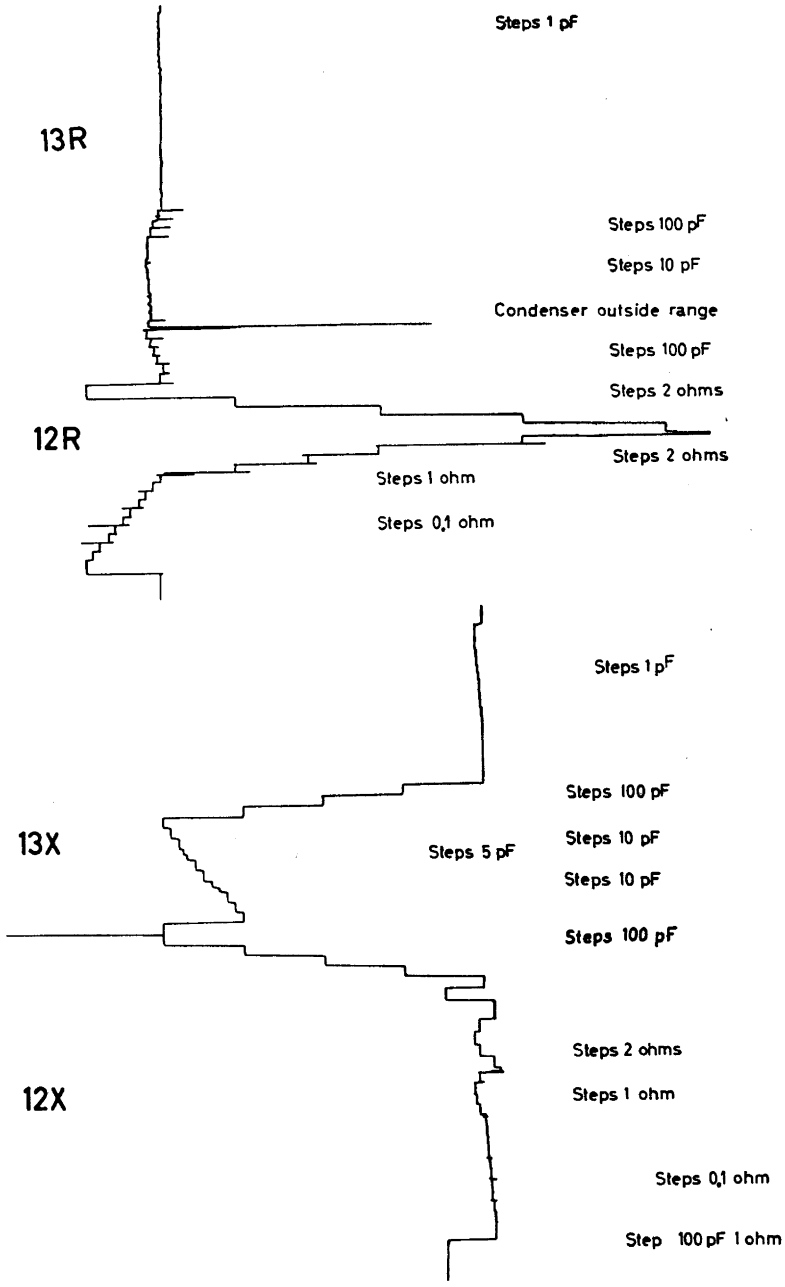

Fig. 22. Double servo-recordings using potentiometer bridge shown in Fig. 7. Recorder range 10 ohms (low resistance shunt).

The adjustment of the reference potential was found difficult, however, because operation of the phase shifter also gave a change in amplitude of the reference signal. As the two mixer-tubes in the homodyne rectifier did not have absolutely identical characteristics, this amplitude change led to an output signal from the detector even in the absence of an input signal from the bridge. Best results were obtained when the phases of the reference potentials were adjusted in such a way that small variations in resistance gave maximum signal to the resistance servo, and small variations in capacitance maximum signal to the capacitance servo. It was found later that perfect phasing could be obtained by allowing the sinusoidal reference potentials to trigger a square-wave generator (Philips type GM 2314) which delivered a square-wave reference potential of constant amplitude (pulse height) to the third grid of the L 7 mixer tubes in the synchronous rectifier. The initial adjustments could then be made as outlined in section I.

The servos were comparatively tolerant with respect to smaller degrees of incorrect phasing of the reference signals, especially at high values for "cell" resistance.

The resistance recorder was completely unaffected by changes in capacitance, but the capacitance recorder was sensitive to resistance changes, probably because the wire-wound, 1 000 ohms measuring resistance in the resistance recorder had a higher residual inductance than the "cell" resistance. The recordings $1R$, $1X$, $2X$, $3R$, $3X$, $4X$, and $5X$ shown in Figs. 17 and 18 were obtained with the bridge connected according to Fig. 1. $1X$ and $1R$ were obtained with sinusoidal reference signals, and show that the system remains stable even when the resistance and capacitance to be measured are changed in a step-wise manner, either one at a time or both simultaneously.

Compared with $2X$, $3X$ shows the influence of poor phasing. $3X$ and $3R$ show that the system becomes unstable when the reference signals are in phase. Compared with $2X$, $4X$ shows how the influence of resistance-changes on the capacitance recorder increases with decreasing total "cell" resistance. This influence did not tend to increase with decreasing total "cell" capacitance, however, as indicated by $5X$ compared with $2X$.

When the bridge was connected according to Fig. 7 with the measuring condenser connected in parallel with X_1 the influence of resistance changes on the capacitance recorder increased, as a comparison between the recordings $6X$ and $8X$ of Figs. 19 and 20, with $2X$ and $4X$, respectively, shows. With the circuit of Fig. 7, change in resistance introduces an extra reactive unbalance over and above that caused by the inductance of the measuring resistance. The resistance recorder is unaffected by capacitance changes, as shown by the recordings $7R$ and $9R$ of Figs. 19 and 20, and the R scale is completely linear from $R = 1\,000$ ohms to $R = 10\,000$ ohms ($6R$ and $8R$).

Shunting of the potentiometer caused a marked change in the influence of resistance changes on the capacitance recordings. At a measuring range of 50 ohms (shunt of 27 ohms), the capacitance recorder changed direction when the mid-point of the potentiometer was passed, as shown by the recordings $10X$ and $12X$ of Figs. 21 and 22, respectively. As shown by the recording $11R$ (Fig. 21) the resistance recorder was still insensitive to capacitance changes; but when the resistance range was decreased to 10 ohms, a certain influence became apparent ($13R$ of Fig. 22), owing to the fact that the measuring condenser across X_1 in Fig. 7 did not have exactly the same influence as X_C in the circuit. This source of error can be eliminated by using the circuit shown in Fig. 8.

CONCLUSIONS

a) It is desirable to use square-wave reference signals of constant amplitude in the homodyne rectifier, and it seems likely that the best type of detector would be a balanced push-pull detector working with square-wave input and reference signals, as discussed by Farren.[3]

b) A completely non-inductive measuring resistance in the resistance servo should be used in order to avoid errors of the capacitance recorder.

c) It is desirable to use the double servo system even in cases where only one component is being recorded, in order to preserve bridge balance. Single servo operation has been discussed in section V.

d) For direct recording of parallel components (resistance and capacitance), the bridge circuit of Fig. 1 is preferable on theoretical grounds. The potentiometer bridge of Fig. 8 may be used when φ is small or resistance only is to be recorded.

APPENDIX I

Calculation of α_R and α_X

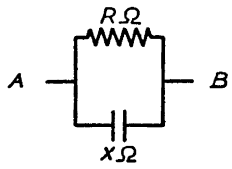

Fig. 23. Resistance and reactance in parallel.

Let us put the total impedance AB of the parallel combination of the resistance R and condenser X of Fig. 23 equal to Z. We then have $\frac{1}{\overline{Z}} = \frac{1}{R} + \frac{1}{\mathrm{j}X}$ *;

$$\overline{Z} = \frac{R\mathrm{j}X}{R + \mathrm{j}X} = \frac{R\mathrm{j}X\,(R - \mathrm{j}X)}{R^2 + X^2} = \frac{RX^2 + R^2\mathrm{j}X}{R^2 + X^2} \tag{1}$$

$$\mathrm{tg}\ \varphi = \frac{R}{X} \tag{2}$$

We want to know how $\overline{Z}$ changes when X is kept constant and R varies, and vice versa. $\overline{Z}$ forms the angle φ with the current vector, and we assume that $\frac{\partial\,\overline{Z}}{\partial\,R}$ and $\frac{\partial\,\overline{Z}}{\partial\,X}$ form the angles γ_R and γ_X, respectively, with the current vector.

$$\frac{\partial\,\overline{Z}}{\partial\,R} = \frac{(R^2 + X^2)\ (X^2 + 2\ R\mathrm{j}X) - 2R(RX^2 + R^2\mathrm{j}X)}{(R^2 + X^2)^2} =$$

$$= (X^2 - R^2 + 2R\mathrm{j}X)\ \frac{X^2}{(R^2 + X^2)^2} \tag{3}$$

$$\mathrm{tg}\ \gamma_R = \frac{2RX}{X^2 - R^2} = \frac{2\,\frac{R}{X}}{1 - \frac{R^2}{X^2}} = \frac{2\ \mathrm{tg}\ \varphi}{1 - \mathrm{tg}^2\varphi} \tag{4}$$

$$\gamma_R = 2\ \varphi \tag{5}$$

$$\frac{\partial\,\overline{Z}}{\partial\,X} = \frac{(R^2 + X^2)\ (RX + \mathrm{j}2R^2) - 2X(RX^2 + R^2\mathrm{j}X}{(R^2 + X^2)} =$$

$$= \left[2RX + \mathrm{j}(R^2 - X^2)\right] \frac{R^2}{(R^2 + X^2)^2} \tag{6}$$

* A good account of symbolic alternating current theory is given by Kemp [4].

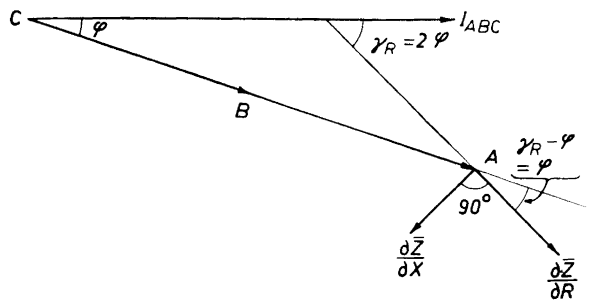

Fig. 24. Diagram showing the directions of certain partial differential quotients related to the bridge shown in Fig. 1. For explanation see text.

$$\operatorname{tg} \gamma_X = \frac{R^2 - X^2}{2\,RX} = \frac{\dfrac{R^2}{X^2} - 1}{2\,\dfrac{R}{X}} = \frac{\operatorname{tg}^2\varphi - 1}{2 \operatorname{tg} \varphi} = -\frac{1}{\operatorname{tg} \gamma_R} \tag{7}$$

$$\gamma_X = \gamma_R + 90° \tag{8}$$

If the current I_{BD} (Fig. 1) through the input circuit of the amplifier can be neglected, the current I_{AB} will be the same as the current $I_{BC} = I_{ABC}$. Fig. 24 shows this current and the impedances AB ($= \bar{Z}$) and BC at balance. If R or X are changed, the point A will move in the direction of $\partial\bar{Z}/\partial R$ or $\partial\bar{Z}/\partial X$ (respectively). If the current I_{ABC} were constant we could let the impedance vectors represent the potential vectors as well, because the latter would have the same length and direction as the impedance vectors relative to the current I_{ABC}. However, I_{ABC} does not remain constant; but the potential V_{CA} is constant provided that the oscillator has a low output resistance. If we let the impedance vectors also represent the potential vectors and change the position of point A in the diagram (*i.e.* alter $\bar{Z}$), we must therefore let the vectors stretch or shrink until the distance CA becomes the same as before, if they are to represent the potentials after the change. In Fig. 25 the point A has moved to A′ in the impedance diagram, owing to an increase of the reactance X. The vectors $\overline{CB}$, $\overline{BA}$, and $\overline{CA}$ represent the impedances and the potentials before the change. The vectors $\overline{CB}$, $\overline{BA'}$, and $\overline{CA'}$ represent the impedances after the change. In order to obtain the potential-vectors after the change, we stretch $\overline{CA'}$ to $\overline{CA'}_1$ which is equal in length to $\overline{CA}$. We then draw the line BA′ and a line parallel to BA′ through A_1'. The latter cuts CA at point B_1. The vectors $\overline{CB}_1$, $\overline{B_1A_1'}$, and $\overline{CA}_1'$ then represent the potentials, because they are related to each other in the same manner as the impedance vectors and furthermore are parallel to the latter, and CA_1' is equal to CA. We now denote the mid-points of CA′ and CA_1' by B′ and B_1'. So far the increase in X has meant that in the potential diagram the point B moves

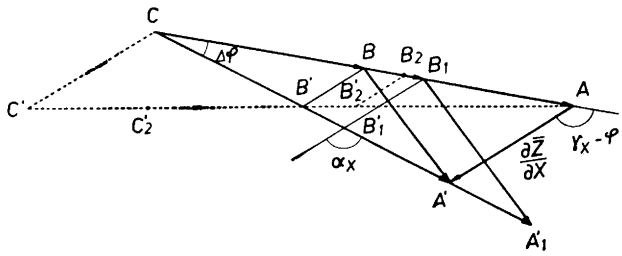

Fig. 25. Geometrical derivation of α_R and α_X of Fig. 3. For explanation see text.

to B_1 and A to A_1'. We may as well consider $\overline{CA_1'}$ to represent the initial potential across AC, however. In this case the change in $\overline{X}$ makes point B move from B_1' to B_1. The triangle $A_1'B_1C$ of Fig. 25 is then similar to the triangle ABC of Fig. 2, and, since only X has been changed, the line $B_1'B_1$ corresponds to l_X. $B_1'B_1$ is parallel to BB' because they occupy the same position in the two similarly positioned triangles A'BC and $A_1'B_1C$. The line BB' is parallel transverse of AA'C, since it cuts the sides AC and A'C at their mid-points. B'B is thus parallel to AA'. If $\Delta\ \varphi$ is small, CA_1' will be parallel to CA, and it follows that $\alpha_X = \gamma_X - \varphi = \varphi + 90°$. Similarly, it may be shown that $\alpha_R = \gamma_R - \varphi = \varphi$.

If instead of increasing X we had decreased X_C (Fig. 1), point C in the diagram of Fig. 25 would have moved to C'. B' would have remained unchanged, but instead of A_1', B_1, and B_1' we would have obtained C_2', B_2, B_2'. B_2B' is parallel to CC' and AA'. When CC' $(= \Delta\ \overline{Z}) \to 0$, $B_2B'_2 \to l_X$ and $\alpha_X \to \gamma_X - \varphi$. The line l_X thus remains the same in both cases.

APPENDIX II

The quantitative relations between the measured and the servo-operated impedance components in the case of the "potentiometer" bridge arrangement

The impedance diagram for the bridge arrangement of Fig. 8 is shown in Fig. 9. The lines l_{R_e}, l_{R_C}, and l_X have been drawn in through point B although strictly they belong to the potential diagram. It can be seen directly that for the circuit of Fig. 8 l_{R_e} is parallel to I_{ABC}, whereas l_{R_C} and l_X form the angles $2\ \varphi_2$ and $2\ \varphi_2 + 90°$ with the current I_{ABC}. In the impedance diagram of Fig. 26 we assume that R_e is small, so that $\overline{Z} = \overline{Z_2}$ and $\varphi = \varphi_2$. If R_C is now changed by $\Delta\ R_C$, the point C will move the distance $\vartheta\ R_C$ to C' towards $\partial\overline{Z}/\partial\overline{R_C}$. The bridge is now to be balanced, and for the purpose of discussion we may assume that the servos operate one at a time (in practice they work simultaneously). The R_e-servo operates first. R_{e1} decreases and R_{e2} increases simultaneously by the same amount, which means that the points A and C' in Fig. 26 move at the same rate and in the same direction, along a path parallel to I_{ABC}. It should be observed that point B retains its position, and will do so in the following because we are working with the impedance diagram

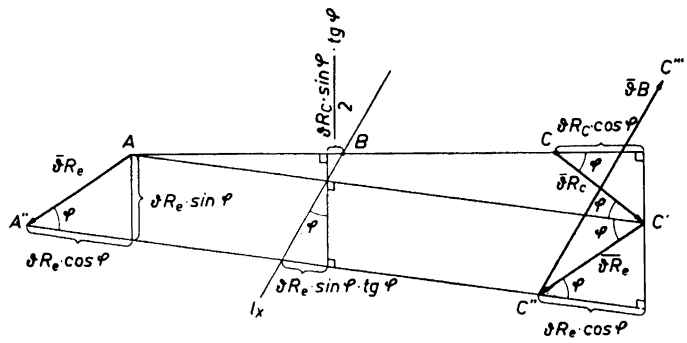

Fig. 26. Vector diagram showing the balancing of the bridge shown in Fig. 8. For explanation see text.

and not with the potential diagram. AC will thus be displaced parallel to itself. The R_e servo will stop when the line DB in the potential diagram (Fig. 2) coincides with l_X. The potential triangle will be conformate to the impedance triangle. The servo thus stops when the mid-point of AC reaches l_X in the impedance diagram. AC then occupies the position A''C''. Now the X-servo starts, and moves point B in the potential triangle (Fig. 2) along l_X to C. In the impedance diagram of Fig. 26 this corresponds to a movement of C'' towards "north-east" along a line parallel to l_X to a point C''' on line A''B prolonged. The result of these operations is, of course, that both in the potential and the impedance diagrams the triangle ABC turns into a straight line with point B at the mid-point.

As we work with condensers that have a linear capacitance variation we introduce the susceptance $B_2 = 1/X_2$ instead of X_2. We shall now investigate how R_{e2} and B_2 have to be changed in order to return the bridge to balance when R_C is changed by ΔR_C. When R_C is changed by the amount ΔR_C, $\overline{Z}$ will be changed by the amount $\partial\overline{Z}/\partial R_C \cdot \Delta R_C = \overline{\vartheta} R_C$. In order to compensate this, R_{e1} is first altered by ΔR_{e1} (and R_{e2} by $\Delta R_{e2} = -\Delta R_{e1}$), whereby $\overline{Z}$ is changed by $\overline{\vartheta} R_{e1}$. Finally, B_2 is changed by ΔB, and $\overline{Z}$ by $\overline{\vartheta} B$. ϑR_e, ϑR_C, and ϑB are indicated in Fig. 26. Bearing in mind that AC is very large compared with the differentials, and that A''C'' is going to be cut at the mid-point by l_X (so that we must add the same amount to both sides of l_X when AC is displaced from AC to A''C'') we obtain (Fig. 21) $\vartheta R_C \cos\varphi + \frac{1}{2}\vartheta R_C \sin\varphi\ tg\ \varphi + \vartheta R_e \sin\varphi\ tg\ \varphi - \vartheta R_e \cos\varphi = \vartheta R_e \cos\varphi - \frac{1}{2}\vartheta R_C \sin\varphi\ tg\ \varphi - \vartheta R_e \sin\varphi\ tg\ \varphi$;

$$\vartheta R_e = \frac{1 + tg^2\,\varphi}{1 - tg^2\,\varphi} \cdot \frac{1}{2}\,\vartheta R_C \tag{9}$$

We now turn to ϑB. The point C is evidently going to be displaced from the point C'' (at a distance of $(\vartheta R_C \sin\varphi + \vartheta R_e \sin\varphi)$ from the line AC) to a point C''' (at a distance of $\vartheta R_e \sin\varphi$ on the other side of AC). The displacement has

to take place in a direction that forms angle φ with the normal to AC. The distance ϑ B will be,

$$\vartheta \text{ B} = \frac{2\,\vartheta\, R_e \sin\varphi + \vartheta\, R_c \sin\varphi}{\cos\varphi} = (2\,\vartheta Re + \vartheta\, R_c)\text{tg}\,\varphi =$$

$$= \vartheta\, R_c \text{tg}\,\varphi\,\left(1 + \frac{1+\text{tg}^2\,\varphi}{1-\text{tg}^2\,\varphi}\right).$$

$$\vartheta \text{ B} = \frac{2\,\text{tg}\,\varphi}{1-\text{tg}^2\,\varphi}\cdot R_c \tag{10}$$

$$\overline{\vartheta\, R_c} = \frac{\overline{\partial\, Z}}{\partial\, R_c}\cdot \Delta\, R_c;\ \vartheta\, R_c = \frac{\partial\, Z}{\partial\, R_c}\cdot \Delta\, R_c$$

$\frac{\partial\, Z}{\partial\, R_c}$ is obtained from $\frac{\overline{\partial\, Z}}{\partial\, R_c}$: which has been calculated previously, eqns. 2 and 3. We obtain $\frac{\partial\, Z}{\partial\, R_c} = \frac{1}{1+\text{tg}^2\,\varphi}$, and

$$\vartheta\, R_c = \frac{1}{1+\text{tg}^2\,\varphi}\cdot \Delta\, R_c \tag{11}$$

$\frac{\partial\, Z}{\partial\, X}$ is obtained from $\frac{\overline{\partial\, Z}}{\partial\, X}$, and is equal to $\frac{\text{tg}^2\,\varphi}{1+\text{tg}^2\,\varphi}$

$$\frac{\partial\, Z}{\partial\, \text{B}} = -\frac{1}{\text{B}^2}\cdot\frac{\partial\, Z}{\partial\, X} = -\frac{R_c}{\text{tg}^2\,\varphi}\cdot\frac{\partial\, Z}{\partial\, X} = -\frac{R_c^2}{1+\text{tg}^2\,\varphi} \tag{12}$$

(Both X_c and X_2 are included in X and B).

$$\Delta\, \text{B} = \frac{\vartheta\, \text{B}}{\overline{\frac{\partial\, Z}{\partial\, \text{B}}}} = \frac{2\,\text{tg}\,\varphi}{1-\text{tg}^2\,\varphi}\cdot\frac{1}{1+\text{tg}^2\,\varphi}\cdot\frac{1+\text{tg}^2\,\varphi}{-R_c^2}\cdot\Delta\, R_c$$

$$\Delta \text{B}_2 = -\frac{2\,\text{tg}\,\varphi}{R_c^2\,(1-\text{tg}^2\,\varphi)}\cdot\Delta\, R_c \tag{13}$$

R_{e2} forms a part of the series component of the impedance Z, and we get

$$\Delta R_e = \vartheta\, R_e = \frac{1+\text{tg}^2\,\varphi}{1-\text{tg}^2\,\varphi}\cdot\frac{1}{2}\cdot\frac{1}{1+\text{tg}^2\,\varphi}\cdot\Delta\, R_c$$

$$\Delta R_e = \frac{1}{1-\text{tg}^2\,\varphi}\cdot\frac{1}{2}\cdot\Delta\, R_c \tag{14}$$

For the sake of completeness we also record how B_2 is related to X_c

$$\Delta \text{B}_2 = -\Delta\frac{1}{X_c} \tag{15}$$

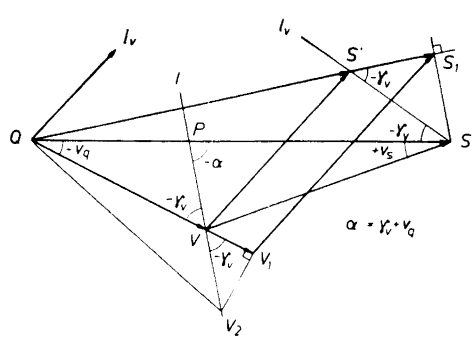

Fig. 27. Geometrical derivation of α_R and α_G of the Z—Y bridge. For explanation see text.

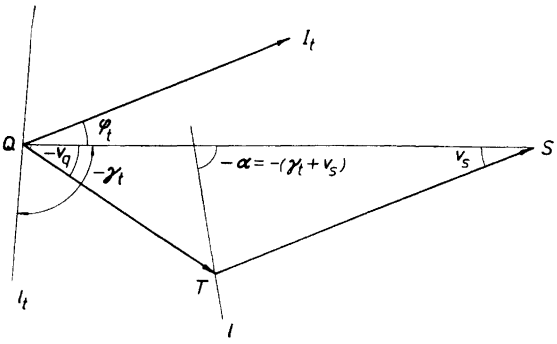

Fig. 28. Geometrical derivation of α_R and α_G of the Z—Y bridge. For explanation see text.

APPENDIX III

Calculations of α_G and α_R of the ZY-bridge

Looking at Fig. 27 we first assume that the bridge is balanced. We let the triangle QSV represent both potentials and impedances. The impedance VS is now altered, causing the point S to move along a line l_v (forming the angle γ_v with QS) to S'. The triangle QS'V represents the impedance after the unbalance has been introduced. In order to get the potential triangle we enlarge the triangle QS'V to QS_1' V_1 (sp that $QS_1' = QS$) and rotate it about Q to position QSV_2. We assume that angle $S_1'QS$ is very small, and that QS_1' is therefore parallel to QS. Triangles $S'S_1'S$ and VV_1V_2 are then conformate (proportional catheti), and the angle V_1VV_2 is equal to $-\gamma_v$. From the triangle QPV we get $\alpha = \gamma_v + v_q$, where α is the angle between line l, along which point V is displaced, and QS. When the change in the impedance VS is purely reactive, l_v will be normal to the current I_v in QVS. The impedance QV is purely reactive, and is therefore also normal to I_v. We therefore obtain $\gamma_v = v_q$ and $\alpha = 2\,v_q$. If the change in VS is purely resistive, l_v, and therefore also l, will be normal to the previous position. Similarly, for the triangle QST (Fig. 28) we get $\alpha = \gamma_t + v_s$, when Q moves along the line l_t in a direction forming angle γ_t with QS.

The impedance QT (Fig. 28) consists of a resistance and a reactance in parallel. When only the resistive component is changed we have previously shown (see Appendix I) that the line of displacement l_t of the point Q forms an angle $2\,\varphi_t$ with the current. φ_t is the angle between the impedance QT and the current vector I_t. This gives $\varphi_t - \gamma_t = 2\,(\varphi_t - v_q)$ or $\varphi_t = 2\,v_q - \gamma_t$. The impedance ST is purely resistive, and is therefore parallel to I_t. Therefore $v_s = \varphi_t = 2\,v_q - \gamma_t$, which gives $\alpha = \gamma_t + v_s = \gamma_t + 2\,v_q - \gamma_t$, or $\alpha = 2\,v_q$. If the reactive component only of the impedance QT is changed we obtain lines l_t and l normal to those in the case just dealt with.

It follows from the discussion above that a change in the reactive component of the impedance SV or in the conductance QT displaces the points V and T, respectively in the potential diagram along the same line l_G, and may therefore be used to compensate each other. Similarly, a change in the resistance of SV or the susceptance of QT will displace V or T along a line l_R normal to l_G. The angles α_G and α_R formed by the lines with the voltage QS are,

$$\alpha_G = 2v_q \tag{16}$$

$$\alpha_R = 2v_q + 90° \tag{17}$$

Acknowledgements. The theory given in this paper has been worked out by F. Möhl. We are indebted to Svenska AB Philips for the loan of square-wave generators, to Seve Radio, Mölnlycke, for the construction of apparatus, and to Professor Olof Mellander for laboratory facilities.

The Interaction of Riboflavin, FMN, and FAD with Various Metal Ions: The Riboflavin Catalyzed Photochemical Reduction of Fe^{III}, and Photooxidation of Fe^{II}

WILLIAM J. RUTTER*

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden, and Division of Biochemistry, University of Illinois, Urbana, Illinois, USA

(1) The fluorescence of riboflavin, FMN, and FAD solutions is quenched by certain divalent and trivalent metal ions. Of the ions tested, Hg^{II} and Fe^{II}, Fe^{III}, Co^{III}, and Au^{III} were particularly effective.

(2) Riboflavin, FMN, and FAD solutions catalyze a photooxidation of Fe^{II} ions and a photoreduction of Fe^{III} ions.

(3) The riboflavin catalyzed photoreduction of Fe^{III} is inhibited by oxygen, while the photooxidation of Fe^{II} is strongly dependent on oxygen. Catalase stimulates both of these processes.

(4) The mechanism of the photochemical reactions and their possible relationship to the function of riboflavin in biological systems is discussed.

In certain flavoprotein systems, the fluorescence of the free riboflavin coenzyme is lost on combination with the apoprotein [1,2]. This fact together with recent observations concerning possible interactions of metal ions in certain flavoprotein systems [3,4], prompted a study of the effect of various metal ions on the fluorescence of riboflavin, FMN, and FAD **. It was found that Fe^{III} was a remarkably effective quencher of the fluorescence of these compounds. An inquiry concerning the mechanism of the quenching phenomenon resulted in the discovery of a riboflavin-catalyzed photoreduction of Fe^{III}, as well as a riboflavin-catalyzed photooxidation of Fe^{II}. It is the purpose of this paper to report these observations, and to discuss their significance relative to the functions of riboflavin in biological systems.

MATERIALS AND METHODS

FMN and FAD were purified by ionophoresis and kindly supplied by B. Rolander. A sample of riboflavin procured from Hoffman-LaRoche was recrystallized for use in these experiments.

Crystalline catalase was procured from Worthington Biochemicals, Inc. Activity was measured by the method of Beers and Sizer [5]. One unit is defined as that amount of

* U.S. Public Health Service Fellow, Medicinska Nobelinstitutet, 1954—1955. Present address: Division of Biochemistry, University of Illinois, USA.

** Abbreviations used: FMN — flavin mononucleotide; FAD — flavin adenine dinucleotide; EDTA — ethylene diamine tetraacetate.

enzyme which decomposes 1 mg hydrogen peroxide in 1 min under standard assay conditions.

The concentration of Fe^{II} ions was quantitatively determined with the α,α'-dipyridyl reagent [6], usually from the difference spectra of appropriate experimental samples.

The intensity of fluorescence was measured with the instrument devised and constructed by Theorell and Nygaard [7]. Difference spectra were obtained with the aid of a Cary Recording double beam spectrophotometer.

Photoillumination was accomplished by means of a 250 watt lamp fixed approximately 25 cm from the incubation fluid. The entire system was enclosed in aluminum foil, and partially filled with water so the temperature of the sample remained essentially constant during the photoillumination period.

RESULTS

The fluorescence of riboflavin solutions is quenched by a variety of substances including diphenols, purines, and pyrimidines and electrolytes, particularly [8] I^- and Ag^+. Weber showed that the remarkably strong quenching effect of silver ions is apparently due to the formation of a complex with riboflavin which is non-fluorescent.

The quenching action of electrolytes on riboflavin fluorescence is not a simple function of the ionic strength, but is a function of the particular ionic species present. Theorell and Nygaard [9], for example, have found that halogen ions quench the fluorescence of FMN in the order $I^- > Br^- > Cl^- > F^-$, while $SO_4^=$, $PO_4^=$, and CH_3COO^- ions did not quench at the concentrations tested. $CaCl_2$, KCl, NaCl, and NH_4Cl were equally effective as quenching agents.

Our initial experiments were concerned with the effect of various di- and trivalent metal ions on the fluorescence of riboflavin. Table 1 presents certain of the data obtained. Most divalent ions tested were much less effective quenching agents than silver ions in this regard. Mercury, however, was more effective than Ag^+ in quenching the fluorescence of riboflavin. When $mercury^{II}$ salts were added to aqueous solutions of riboflavin, a light pink color was observed. The color change was similar, but much less pronounced than that produced by silver ions.

Of the trivalent metal ions, Al^{III} was ineffective, but Au^{III}, and especially Co^{III}, and Fe^{III} were remarkably powerful quenching agents. Both Co^{III} and Fe^{III} salts were much more effective than silver salts in quenching riboflavin fluorescence. These results were somewhat unexpected since Albert [10] has shown that divalent metals complex much more strongly with riboflavin than their trivalent counterparts. No binding of Fe^{III} by riboflavin was detected by Albert, for example. The present data nevertheless indicate an Fe^{III}-riboflavin reaction in which either a non-fluorescent complex is involved, or in which the lifetime of the excited state is decreased. A plot of the quenching of fluorescence as a function of Fe^{III} concentration is presented in Fig. 1. The solid points represent experimentally obtained values, whereas the solid curve represents the theoretical curve which would be expected if the reaction involved is simply: (Riboflavin + Fe^{III} → [Riboflavin — Fe^{III}]) and the equilibrium constant

$$K = \frac{[\text{Riboflavin}]\,[Fe^{III}]}{[\text{Riboflavin} - Fe^{III}]} = 4.6 \times 10^{-4}$$

assuming a non-fluorescent complex [Riboflavin — Fe^{III}] or one in which the lifetime of the excited state is very small compared to that of free riboflavin.

The effectiveness of Fe^{III} as a quenching agent suggested that the quenching observed with Fe^{II} ions (abnormally high for divalent compounds) might in part be due to the formation of Fe^{III} ions. It was observed that with low concentrations (<0.003 M) of Fe^{II}, unlike any of the other divalent ions tested,

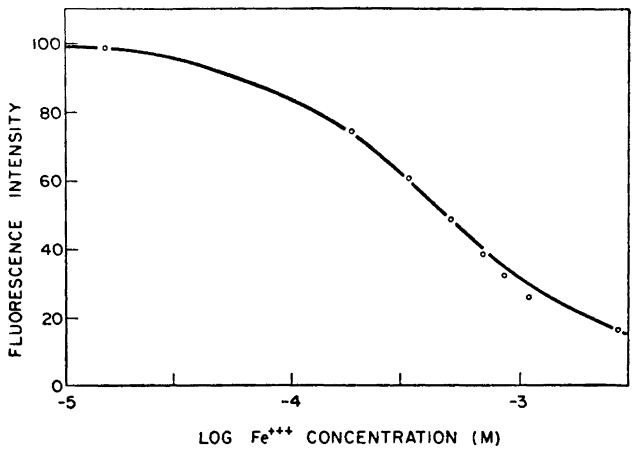

Fig. 1. Quenching of riboflavin fluorescence by Fe^{II} ions. Experimental conditions as described under Table 1.

maximum quenching was obtained only after a considerable time lag (Fig. 2). At higher concentrations of Fe^{II}, the degree of quenching did not change as a function of time; moreover the degree of quenching was approximately the same for 0.003 M and 0.1 M Fe^{II}. Preincubation in the dark did not influence this characteristic behavior. These observations suggest either that Fe^{II} itself is not a particularly effective quenching agent, but that it is converted to Fe^{III} during the course of the measurement of fluorescence, or alternatively that the

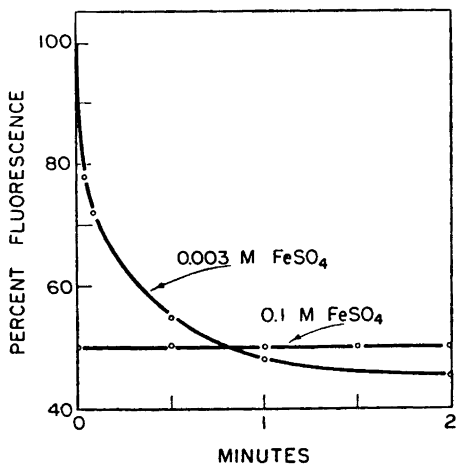

Fig. 2. Quenching of riboflavin fluorescence by Fe^{III} ions. Riboflavin present at a final concentration of 10^{-6} M, $FeCl_3$ added to the concentration indicated, pH adjusted to 5.5 with $NaHCO_3$; temperature 30°C. The per cent of fluorescence of the control riboflavin solution (no $FeCl_3$ added) is plotted as a function of Fe^{III} present.

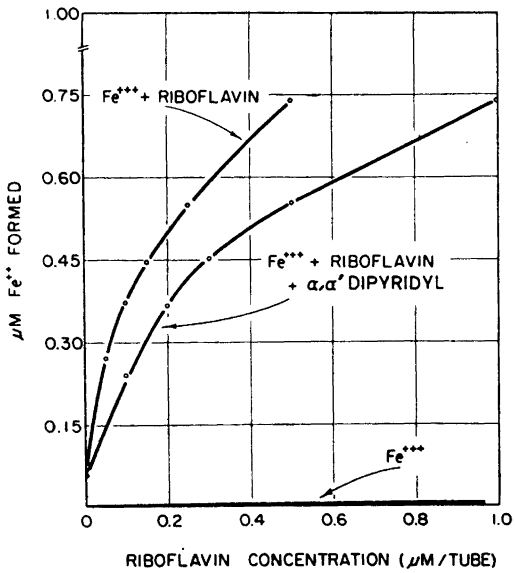

Fig. 3. Riboflavin catalysis of the photoreduction of Fe^{III}. 1 μM $FeCl_3$ was present in all experimental vessels; riboflavin at the concentration indicated; 100 mg α,α'-dipyridyl was added in 0.1 ml ethanol where indicated; pH adjusted to 5.5 in all vessels; period of irradiation, 10 min; temperature 30°C; nitrogen atmosphere. The values for Fe^{II} formation represent increments over Fe^{II} present in similar samples incubated in the dark.

final Fe^{II} riboflavin complex (having about 50 % of the original riboflavin fluorescence) is formed slowly, perhaps through several less stabile Fe^{II} riboflavin complexes.

The other trivalent metal ions which showed inhibition of fluorescence roughly equivalent to Fe^{III}, also showed anomalous quenching behavior. In the experiments with Co^{III} and Au^{III}, the quenching was strongest initially, and decreased with time to a constant level. These observations suggested that a secondary reaction was occurring: one possibility was that these compounds were being partially reduced to the divalent state. Further studies were made with Fe^{III} first, because of the role of Fe in biological systems and secondly, because of the ease of detection of Fe^{II} ions. Appropriate experiments demonstrated that there was indeed a riboflavin-catalyzed photooxidation of Fe^{II}, and a photoreduction of Fe^{III}.

Riboflavin-catalyzed photoreduction of Fe^{III}

After photoillumination of Fe^{III} solutions, an increase in the Fe^{II} concentration was detected in tubes to which riboflavin had been added. As shown in Fig. 3, the rate of formation of Fe^{II} was proportional to the riboflavin present only at comparatively low riboflavin concentrations. The inhibition of Fe^{II} formation by excess α,α'-dipyridyl may be due to complexing with Fe^{III} pre-

Table 2. Effect of oxygen and catalase on riboflavin-catalyzed photoreduction. Experimental cuvettes contained 3 μM $FeCl_3$ and 150 mμM riboflavin and 150 units catalase as indicated; total volume 3.0 ml; pH 5.5; temperature 30°C; illumination period 10 min. The values presented are increments over non-illuminated controls.

Experimental conditions	μM Fe^{II} Formed	
	O_2	N_2
1. a) Fe^{III}	0.04	0.06
b) Fe^{III} + Catalase	0.08	0.085
2. a) Fe^{III} + Riboflavin	0.205	0.500
b) Fe^{III} + Riboflavin + Catalase	0.195	0.595

sent. Fig. 4 shows that the rate of formation of Fe^{II} at a given riboflavin concentration decreases with time. This may be a result either of a conversion of riboflavin to a "less active" form, (*e. g.*, formation of lumiflavin) or perhaps a reflection of approaching the steady state condition.

The data presented in Table 2 illustrate the effect of oxygen and catalase on the photoreduction of Fe^{III} by this reaction. As might be expected, the net formation of Fe^{II} from Fe^{III} is diminished in the presence of oxygen. 10 to

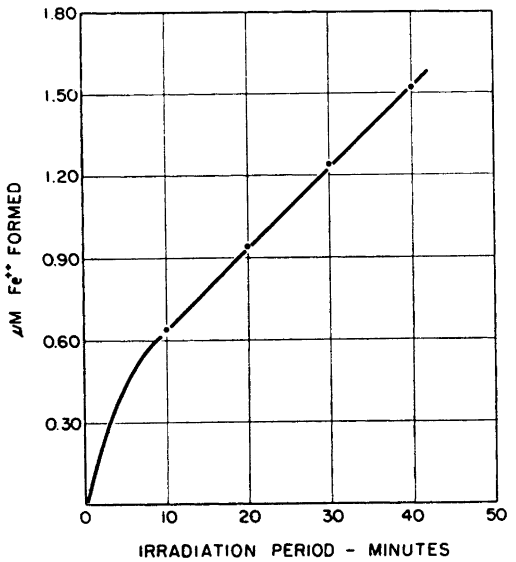

Fig. 4. Riboflavin catalysis of the photoreduction of Fe^{III} as a function of the period of photoillumination. 2 μM $FeCl_3$ and 1 μM riboflavin; 100 mg α,α'-dipyridyl, 0.1 ml 95 % ethanol present in total volume of 3.0 ml; temperature 30.0°C; nitrogen atmosphere. The values of Fe^{II} formed are increments over Fe^{II} present in similar samples incubated in the dark. (Photoillumination of Fe^{III} in the absence of riboflavin for a period of 40 min gives no change over a similar sample incubated in the dark).

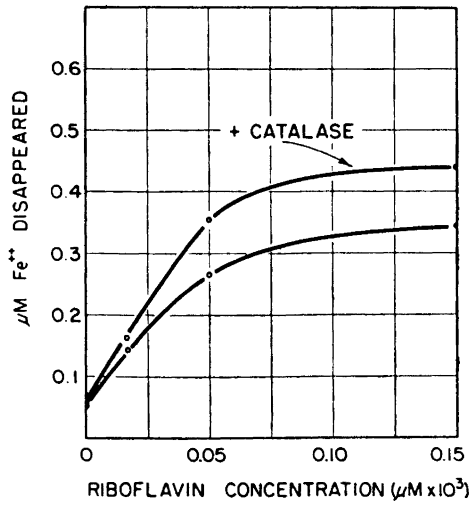

Fig. 5. Effect of catalase on riboflavin catalyzed photooxidation of Fe^{II}. 1 μM $FeSO_4$; riboflavin in the concentration indicated, and sufficient crystalline catalase to decompose 50 mg H_2O_2 per min was added to each sample where indicated; final volume 3.0 ml; pH 5.5; temperature 30°C; oxygen atmosphere; time of photoillumination, 10 min.

20 % increase in Fe^{II} formation were consistently observed in the presence of catalase.

Several attempts to obtain complete conversion of Fe^{III} to Fe^{II} by extended photoillumination periods and by large riboflavin/Fe ratios were unsuccessful. These observations prompted the question of the riboflavin catalysis of the photooxidation of Fe^{II}.

Riboflavin-catalyzed photooxidation of Fe^{II}

The effect of riboflavin on the photooxidation of Fe^{II} salts is shown in Fig. 5. The values represent the difference between illuminated and non-illuminated samples. Catalase consistently stimulated the reaction by 15 to 35 %. The effect of oxygen on the course of the photooxidation is presented in Table 3. It is noteworthy that the absence of oxygen practically eliminates Fe^{II} photooxidation. This observation together with that given in Table 2 for photoreduction of Fe^{III} establishes the conditions under which photoreduction or photooxidation can predominate.

The possibility that riboflavin catalyzed oxidation of Fe^{II} in the dark with oxygen as electron acceptor was tested. Under none of the conditions tested, could any facilitation of this reaction by riboflavin be detected. Even after incubation for 10 h in an oxygen atmosphere there was no difference in the rate of disappearance of Fe^{II} in experimental vessels with riboflavin as compared to controls containing only Fe^{II} ions. Spectral studies of riboflavin in the presence and absence of Fe^{II} ions do not indicate the presence of detectable quantities of reduced riboflavin. During photoillumination there was, of

Table 3. Effect of oxygen on riboflavin-catalyzed photo-oxidation of Fe^{II}. Each experimental cuvette contained 1 μM $FeSO_4$ and 150 mμM riboflavin when present. Total volume 30 ml, pH 5.5, temperature 30°C. The values presented are increments over non-illuminated controls.

Additions	Photoillumination period	Fe^{II} Disappearance (μM)	
		O_2	N_2
1. Fe^{II}	10	0.030	0.045
	30	0.046	0.050
2. Fe^{II} + Riboflavin	10	0.350	0.057
	20	0.437	
	30	0.467	0.067

course, conversion of riboflavin to substances not absorbing in visible region, but this conversion was not markedly influenced by Fe^{II} ions, and bubbling with oxygen did not regenerate the original riboflavin spectra.

FMN and FAD catalyzed photoreduction of Fe^{III} and photooxidation of Fe^{II}

Similar, but not so extensive studies indicate that FMN and FAD also catalyze photooxidation of Fe^{II} and photoreduction of Fe^{III} under similar conditions to those used in the riboflavin experiments.

DISCUSSION

It is known that riboflavin and FMN facilitate photooxidations and photoreductions. Recently Swallow [11] has shown that X-ray irradiation of riboflavin solutions yields a free radical stable in acidic solution, spectrally like the compound produced by chemical reducing agents [12]. Merkel and Nickerson [13] have demonstrated the photochemical reduction of riboflavin salts in aqueous systems containing riboflavin and certain other compounds, *e. g.*, Na_2EDTA, ethylene diamine, cysteine, mercapto succinic, and carboxymethyl succinic acids. Andreae [14] has shown a net formation of Mn^{III} ions upon irradiation of solutions containing Mn^{II}, pyrophosphate, one of a variety of phenols, and riboflavin. Vernon and Ihnen [15] have reported a riboflavin or FMN catalyzed photochemical oxidation of 2,6-dichlorophenol-indophenol and reduced cytochrome c.

The riboflavin catalyzed photochemical oxidation-reduction system reported here is perhaps more easily studied because it is uncomplicated in the sense that a reaction can be observed in aqueous solutions containing only riboflavin and Fe^{II} or Fe^{III}, and because the system is reversible. (This does not necessarily imply that the reduction of Fe^{III} proceeds by a reversal of the same pathway involved in the oxidation of Fe^{II}).

The data obtained are consistent with, but do not prove the postulated series of reactions.

$$R \xrightarrow{h\nu} R^* \quad (1)$$

$$R^* + 2H_2O \xrightarrow{\text{slow}} RH_2 + 2\,{}^{\bullet}OH \quad (2)$$

$$R^* + 2H^+ + 2Fe^{II} \rightarrow RH_2 + 2Fe^{III} \quad (3)$$

$$RH_2 + O_2 \xrightarrow{\text{fast}} R + H_2O_2 \quad (4)$$

$$RH_2 + 2Fe^{III} \xrightarrow{\text{fast}} R + 2Fe^{II} + 2H^+ \quad (5)$$

overall reaction for oxidation of Fe^{II}

$$2H^+ + 2Fe^{II} + O_2 \xrightarrow{h\nu} 2Fe^{III} + H_2O_2 \quad (6)$$

overall reaction for reduction of Fe^{III}

$$2H_2O + 2Fe^{III} \xrightarrow{h\nu} 2Fe^{II} + H_2O_2 + 2H^+ \quad (7)$$

(R = riboflavin; RH_2 = reduced riboflavin; $h\nu$ = photoelectric energy)

The reactions listed should be considered only as one possible formal description of the observations reported.

The interesting observations of Merkel and Nickerson mentioned earlier can perhaps be most easily interpreted in terms of a reaction like (3) above in which the metal chelate acts as an electron donor to riboflavin in the presence of light-energy.

The possible relationship of the present photochemical reactions to the function of riboflavin in biological systems is worthy of consideration. The present observations are most readily explained in terms of a direct electron transference between riboflavin and Fe, and as such, are pertinent to the proposed mechanisms of action of certain of the flavoproteins. The possibility of a role of Fe and riboflavin in photobiologic processes should also not be overlooked.

Acknowledgment. The author wishes to express appreciation to Professor Theorell for his active interest in this work and for the gracious hospitality extended by him and other members of the Biochemical Department.

The Lignin-Carbohydrate Linkage

BENGT O. LINDGREN

Wood Chemistry Department, Swedish Forest Products Research Laboratory, Stockholm, Sweden

The lignin materials which Björkman obtained by treatment of thoroughly milled spruce wood with neutral solvents, have been studied by electrophoretic methods. That fraction which he called *LCC* ('lignin-carbohydrate complex') could be separated into two subfractions having different electrophoretic mobilities. The slower subfraction was carbohydrate in nature and the other contained both carbohydrate and lignin materials. This latter fraction on electrophoresis in sodium hydroxide solution moved more slowly than did the lignin material which Björkman called *MWL* ('milled wood lignin'). The results obtained give support to Björkman's hypothesis that the lignin in the *LCC* material is chemically linked to a part of the hemicelluloses.

In spite of much work, the question of whether there is a lignin-hemicellulose linkage in wood is still not settled. The arguments for the existence of such a linkage have been summarized by Merewether [1].

A new approach to the study of this question has been made possible by the recent work of Björkman [2–5]. Wood, which had been milled vigorously under non-swelling conditions, was treated firstly with aqueous dioxane and then either with acetic acid-water or with dimethylformamide. By these means Björkman was able to isolate two lignin fractions.

The first, the *A* fraction (called by Björkman *MWL*), accounted for about 30 % of the wood lignin and contained only small amounts of polysaccharides. The second fraction, the *B* fraction (called by Björkman *LCC*), consisted of about one part of lignin to 3—4 parts of carbohydrates. As Björkman was unable to extract its lignin with those solvents which dissolved the *A* fraction, he concluded that the lignin in the *B* fraction was chemically linked to the hemicellulose components.

After milling a sample of a *B* fraction in toluene Björkman [4,5] extracted from it a material which was soluble in aqueous dioxane and consisted of about 90 % of lignin; such materials will be called *C* preparations. As it is known that chemical bonds can be broken during severe milling, Björkman attributed this chemical modification to a splitting of lignin-carbohydrate linkages. This experiment suggests that during the milling of the wood the *A* lignin may be formed in part, or in its entirety, from material similar to,

or identical to, that found in the *B* fraction. Björkman[4,5] also considered the possibility that new chemical linkages might be formed during the milling, but he concluded that this was unlikely in the present case.

It therefore appeared that the *B* fraction would be a most suitable material on which to study the potential existence of a lignin-carbohydrate linkage. An electrophoretic study of these lignin materials was therefore performed and is described below. The electrophoresis was mostly carried out on glass-fibre sheets. This procedure has been successfully used by Smith[6] to fractionate carbohydrate materials. The study was carried out on lignin and hemicellulose materials from Norway spruce (*Picea Abies* Karst.). The relative electrophoretic mobilities of various fractions are listed in Table 1.

Table 1. Relative electrophoretic mobilities of lignin and hemicellulose materials on glass-fibre electrophoretograms.

Material	Lignins				Hemicelluloses	
	A	*B*		*C*	Xylan [a]	Glucomannan[a]
		B_s	B_f			
Buffer	0.05 N sodium hydroxide					
Rel. mobilities	18–20	2–3	7–18	16–18	10	5
Buffer	Phosphate, pH 6, μ about 0.1					
Rel. mobilities	Insoluble	2–3	6–13	Insoluble	6–10	Insoluble

[a] Obtained from a chlorite holocellulose.

The position of lignin spots on the glass-fibre sheets could be located either by reason of their fluorescense when irradiated with UV-light, or by their reaction with *p*-anisidine-sulphuric acid at room temperature, or by use of the sensitive reaction with 5-nitroso-8-hydroxy-quinoline; this last reagent had been suggested previously by Feigl[7] as a spot test for phenols. The carbohydrates did not interfere with those lignin tests.

The positions of the carbohydrate spots were determined be treating the paper either with α-naphthol and sulphuric acid or with *p*-anisidine and sulphuric acid at 110°C. The lignin material *A* also gave a colour reaction with those reagents but its sensitivity was lower than with the carbohydrates. The possibility cannot be excluded that this coloration could be caused by the small amounts of carbohydrates shown to be present in the *A* preparations[3].

The electrophoretic examination showed that *B* contained two subfractions (Fig. 1) having different mobilities. The slower fraction will be called B_s and the other, B_f. The B_s fraction appeared to consist of carbohydrates uncontaminated by lignin. The B_f fraction, on the other hand, gave positive reactions for lignin. It gave also a colour reaction with the naphthol reagent but as lignin may also react with this reagent, this could not be considered as a specific test for carbohydrates. The B_f fraction, therefore, was isolated from an electrophoretogram and was treated with acid. The hydrolysate contained glucose, mannose and xylose. It was therefore apparent that in the B_f fraction there were present both carbohydrates and lignin.

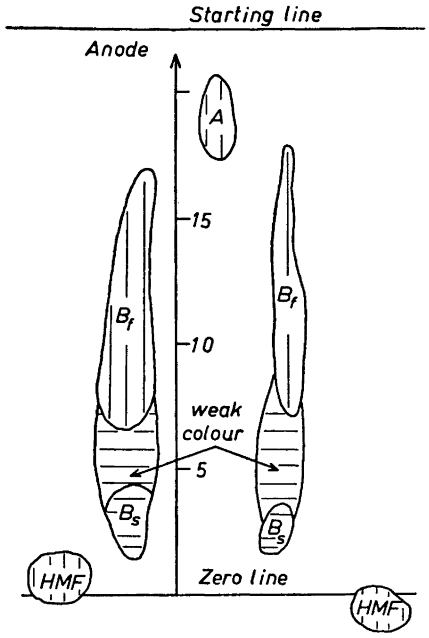

Fig. 1. Sheet electrophoretogram of *A* and *B* materials. Buffer solution, 0.05 N sodium hydroxide. Voltage, 1.8 kV. Time, 3/4 h. Developed with the *p*-anisidine spray. The area marked with vertical lines is that spot which was visible after keeping the sprayed sheet at room temperature. The area marked with horizontal lines is that spot which was visible only after heating the sprayed sheet. HMF is hydroxymethyl-furfural, which was used as reference. Ordinate = distance in cm.

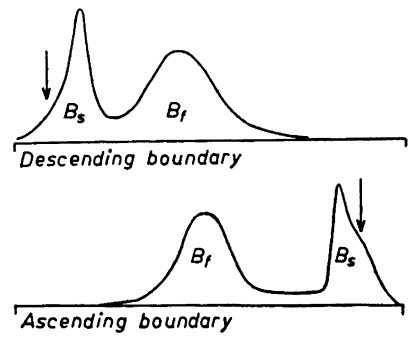

Fig. 2. Zone electrophoretic pattern for *B* material. Buffer, phosphate, pH 7.0. The arrows show the starting points.

The material in the area on the paper between the B_s and the B_f fractions gave a positive reaction for carbohydrates but the reaction was considerably weaker than was that given by the B_s fraction.

B was also fractionated by zone electrophoresis in phosphate buffer at pH 7.0. The refraction pattern (Fig. 2) showed two peaks which were evidently due to the B_s and B_f fractions. From the optical density at 280 mμ it was concluded that essentially all of the lignin was present in the B_f fraction. Assuming as a first approximation that the weights of material in the fractions are directly proportional to the areas of the peaks, the proportion between the lignin and the carbohydrate materials in B_f could be estimated as 1:1.

The fact that the B_f fraction contained both lignin and carbohydrate materials does not, of course, constitute conclusive proof of the existence of a carbohydrate-lignin linkage. It could be that the carbohydrates were free but moved at the same rate as the lignin in the B_f fraction. It was found that a xylan isolated from spruce chlorite holocellulose moved at the same rate as the B_f fraction (Table 1).

The fact that the B_f fraction moved in a neutral solution indicated that it must in some way be associated with groups which were ionised under these conditions. The mobility might be explained if the lignin component of the B_f fraction were chemically linked to a hemicellulose containing uronic acid groups. This cannot be considered as proved, however, as it may be that the ionisable groups are carboxylic groups produced during the severe milling

of the wood. It seems improbable that, during milling, such a large number of these latter groups could be formed to account for the relatively high mobility.

More satisfactory evidence of the existence of a carbohydrate-lignin linkage was obtained by a study of the *A* and *C* lignins which were not associated with carbohydrates. Those lignins moved at about the same rate on glass-fibre electrophoretograms wetted with sodium hydroxide solution (Table 1). This similarity gave further support to the suggestion that the lignin in the *A* fraction is formed during the wood milling from material of the type found in the B_f fraction.

It was also found that the electrophoretic mobility of the *A* and *C* lignin was distinctly higher than that of the B_f fraction (Fig. 1). If the material in the latter fraction is lignin chemically linked to hemicelluloses then its slower movement relative to the other lignins could easily be explained because both glucomannan and xylan move more slowly than do the *A* and *C* lignins (Table 1). It is also possible that the number of ionisable groups was higher in the *A* and *C* lignins than in the lignin in the B_f fraction. This appears to be unlikely as it was found that the proportion of phenolic groups, determined by the spectrophotometric $\Delta\varepsilon$ method [9], was about the same in the *A* lignin as in the lignin in the *B* fraction. As the relative proportion of carboxylic to phenolic groups in the lignins must be low, the former cannot contribute very much to the mobility of the fraction in alkaline solutions. It is, therefore, unlikely that the distinct difference between the lignins was due to a difference in the proportion of carboxylic groups.

In summary, four pieces of evidence may be advanced in support of the theory that a lignin-carbohydrate linkage exists in the B_f fraction *viz.*:

i) The failure to separate the B_f lignin from associated carbohydrates by electrophoresis.

ii) The mobility of the B_f fraction in neutral solution.

iii) The difference in solubility of the *A* and of the *B* fractions.

iv) The higher mobility of the *A* lignin compared to that of the B_f fraction in sodium hydroxide solution.

As mentioned earlier the first two points are not in themselves conclusive evidence proving the existence of a lignin-carbohydrate linkage. The other two points are, however, difficult to explain unless there is such a linkage between the lignin part of the B_f fraction and the hemicelluloses in that fraction.

As Björkman had found it less probable that such linkages are formed during the milling, this study supports the suggestions by Björkman, Pew, Ploetz, Richtzenhain, Traynard and others [1,10] that at least a great part of the wood lignin is linked to hemicelluloses.

EXPERIMENTAL

Lignin materials

A materials. Two samples were isolated and purified according to the normal procedure developed by Björkman [3]. Their methoxyl contents were 15.4 and 15.0 %.

B materials. Two samples were obtained from Björkman. One was isolated by extraction of the dioxane-treated, finely milled wood with acetic acid-water (1:1 v/v)[4],

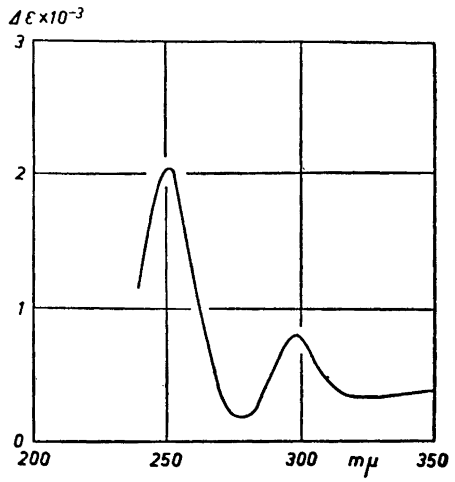

Fig. 3. $\Delta\varepsilon$ curve for *B* material. Solvents: 0.1 N sodium hydroxide and aqueous phosphate buffer, pH 7.

the other, by a corresponding extraction with dimethylformamide [4]. After purification they contained 29.5 and 27.4 % of lignin. No difference was observed in their electrophoretic mobility.

C material. One sample was obtained from Björkman [4,5]. Methoxyl content, 14.3 %.

Solutions of the materials. The lignin materials were dissolved in 0.1 N sodium hydroxide solution. By adding an equal amount of 0.1 M phosphoric acid solution a solution of *B* in a neutral buffer was obtained. By such addition to an alkaline solution of *A* and *C*, the material was precipitated.

The determination of phenolic groups in the B fractions. These determinations were carried out by the $\Delta\varepsilon$ method [9]. The two solvents used were 0.1 N aqueous sodium hydroxide and phosphate buffer (pH 7). The $\Delta\varepsilon$ curve for the *B* fraction extracted from the wood with aqueous acetic acid is shown in the Fig. 3. It shows maxima at 250 mμ, $\Delta\varepsilon$ = 2 100 and at 297 mμ, $\Delta\varepsilon$ = 780. The figures for the $\Delta\varepsilon_{max}$ of the *B* material extracted with dimetylformamide were 1 900 and 690, respectively. Published [3] values for the $\Delta\varepsilon_{max}$ of the *A* fraction are 2 100 and 800, respectively.

Sheet electrophoresis

Glass-fibre sheets. The sheets were made by C. Schleicher & Schüll, Dassel Kr. Einbeck, Germany *(Glasfaserpapier nr. 6)*.

Apparatus. The length of the strips between the electrode vessels was about 50 cm. The strips were pressed between glass plates which were cooled with water.

Procedure. Spots of the solutions (20—40 μl; conc. *ca.* 1 % for the *A* and 2 % for the *B* fractions) were put on the wet strip near the anodic side. It was found that if the solutions were spotted on to dry sheets then the materials were often irreversibly adsorbed. The strips were normally run for 3/4 h at a voltage of 1.8 kV.

The solvent movement caused by the electro-osmotic effect was in all cases stronger than the electrophoretic movement of the materials. Therefore the net effect was a movement against the cathode.

The electro-osmosis was determined by running spots of hydroxy-methyl-furfural together with the samples. This compound does not move in either alkaline or in neutral solutions and is strongly coloured by the anisidine and the naphthol reagents.

Proof of the absence of adsorption. The difference in the electrophoretic mobilities of the materials in the fractions was not due to their having been adsorbed on the glass-fibre sheets as it was shown that they followed the solvent front when they were "chromatographed" on the sheets using 0.05 N sodium hydroxide as developing solvent.

Added in proof. In later experiments when using a new lot of sheets the lignin material *A* moved considerably slower than did the front on the glass-fibre chromatograms; the

hemicelluloses (xylan, glucomannan) on the other hand followed close to the front. The *B* materials gave two spots. One moved slower than did the front and it contained both lignin and polysaccharide materials; the other followed the front and contained only polysaccharides. The lignin materials were therefore to some extent absorbed on these sheets, but if the sheets were first washed with a phosphate buffer solution (pH 6) and then with water no absorption took place.

Zone electrophoresis

Apparatus, Spinco model H. Current: 155 V, 12 mA. Time, 237 min. Buffer, phosphate, pH 7.0, $\mu = 0.1$.

From the front of the descending boundary zone 0.7 ml of the solution containing only the B_s fraction were collected. Similarly, a solution (1.5 ml) containing only the B_f fraction was obtained from the descending boundary. Both solutions gave a normal UV absorption curve for lignin. Log I_0/I were 0.78 and 18.1, respectively and the weight of lignin in those solutions was estimated as 0.01 and 0.57 mg, respectively (log ε was assumed to be 3.50 calculated on the methoxyl basis).

The ratio of the areas under the B_f peak to that under the B_s peak was about 2:1 and the B_f fraction was, therefore, calculated to contain about 2/3 of the material in the *B* fraction. As all of the lignin (1/3 of the *B* material) is present in this fraction it follows that the ratio of the weight of lignin to that of the carbohydrates is *ca.* 1:1.

Spray methods

Sensitivity. 10 µl of 0.1 N sodium hydroxide solution containing different concentrations of the lignin or of the carbohydrate materials were put on a sheet. The percentage figures reported below were the lowest concentrations at which a coloration was clearly observed after spraying.

Method for carbohydrates. Spray solution: α-naphthol (1 g) and concentrated sulphuric acid (5 ml) in *n*-butanol (100 ml). After the spraying the sheets were heated for about 2—5 min at 110°C. The carbohydrates gave blue or purple spots (sensitivity, 0.04 % for spruce xylan). The lignin gave a dark spot (sensitivity, 0.2 % for *A*).

Methods for lignin. 1) Spray solution: 5-nitroso-8-hydroxy-quinoline (1 g) in concentrated sulphuric acid (100 ml). After the spraying the sheets were kept at room temperature for some minutes. Lignin gave dark spots (sensitivity for *A*, 0.01 %). Xylan gave no coloration (the most concentrated solution tested was 1 %).

2) Spray solution: *p*-anisidine (3 g) and concentrated sulphuric acid (8 ml) in ethanol (100 ml). After the spraying the sheets were left at room temperature for 5 min. The lignin gave a yellow spot (sensitivity, 0.04 % for *A*). Xylan gave no colour (the most concentrated solution tested was 1 %). But if the sprayed sheets were heated at 110°C for 30 min the carbohydrate spots were also coloured (sensitivity 0.04 % for xylan).

Acknowledgement. The author wishes to thank Mr. B. Lindquist, Mjölkcentralen, Stockholm, for his kindness in carrying out the zone electrophoresis experiment. He is also grateful to Dr. A. Björkman for his gift of the *B* preparations used in this investigation and to Miss Marit Goliath for skilful assistence.

Studies on Glucomannans from Norwegian Spruce

II. Structural Investigations

INGEMAR CROON and BENGT LINDBERG

Institutionen för Träkemi, Kungl. Tekniska Högskolan och Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

The structures of two glucomannan fractions from *Picea abies* (Norwegian Spruce) have been investigated by methylation and periodate oxidation techniques. It is concluded that both polysaccharides (degree of polymerization, DP_n, 68 and 100, respectively) are composed essentially of α-1,4 linked sugar residues. Both polysaccharides had the same general structure. Each molecule had 3—4 branch points, which were attached to the 3-position of glucose residues. The nonreducing end groups consist principally of mannose residues.

In Part I[1] of this series the isolation of a number of glucomannan fractions from Norwegian Spruce *(Picea abies)* was reported. One fraction was isolated by hot water treatment of the holocellulose (previously swollen with dimethyl sulphoxide [2]). Most of the xylan was then removed from the holocellulose by extraction with 14 % potassium hydroxide. Subsequently, fractions of glucomannan were obtained by treatment of the residual holocellulose with potassium hydroxide-borate solutions by the method of Jones *et al.*[3] This holocellulose after dissolution in cuprammonium solution was regenerated by the addition of acetic acid. From this material another fraction was extracted by treatment with alkali borate. After purification of the fractions by way of their copper complexes they had a nearly constant proportion of glucose to mannose (1:3.5-4). The degree of polymerization of the fractions, determined osmometrically on their nitrates, increased from about 70 for the most easily extractable to 140 for the most difficultly extractable fraction. It appears to be unlikely that the very great differences in the readiness with which the various glucomannan fractions may be extracted can be due only to differences in molecular weight. Variations in the microarrangement of the molecules and in their localisation in the fibre wall could explain the differences as could also variations in their chemical structures, since a highly branched polysaccharide is more soluble than is one which is either less branched or linear.

The present paper reports studies on the structures of the glucomannans in two fractions from *Picea abies*. One was extracted with hot water and the

other with alkali-borate. The glucomannan fractions were investigated by electrophoresis on glass paper, using borate buffer and α-naphthol-sulphuric acid in butanol as spraying reagent. They proved to be electrophoretically homogeneous. No differences in mobilities between the fractions were observed. These fractions were investigated by methylation and periodate oxidation techniques. The properties of the two fractions and the results of the structural studies are given in Table 1.

The methylations were performed in each case by treating the polysaccharide once with methyl sulphate in sodium hydroxide and three times with methyl iodide and silver oxide in dimethylformamide. The latter technique, successfully used by Kuhn *et al.*[4] for the methylation of low molecular weight carbohydrates, has proved also to be very useful for the methylation of polysaccharides such as arabogalactans [5] and glucomannans. The fractionation of the products of the two hydrolyses were performed by carbon column chromatography using the gradient elution technique. In each case the only tetramethyl hexose isolated was 2,3,4,6-tetra-*O*-methyl-D-mannose, identified as its crystalline aniline derivative. On demethylation of the fraction, a trace of glucose was observed in addition to the mannose. One hydrolysate yielded two, the other three, trimethyl-hexoses. Two of those were common to both hydrolysates and were shown to be 2,3,6-tri-*O*-methyl-D-glucose and 2,3,6-tri-*O*-methyl-D-mannose. These substances are very difficult to separate by ordinary paper chromatography but were readily separated on the carbon column. The former crystallised spontaneously when the solvent was removed. The latter, which on demethylation gave mannose only, gave a crystalline aniline derivative in good yield. The fraction containing the 2,3,6-tri-*O*-methyl-D-mannose was converted into its α-acetate and chromatographed on dimethylsulphoxide treated paper using *iso*propyl ether as solvent. The fraction was found to be chromatographically homogeneous. This method was devised by Wickberg [7] and has proved most valuable for the separation of acetylated and methylated sugars. The third trimethyl-hexose (that found in only one hydrolysate) on demethylation yielded glucose. The compound was chromatographically distinguishable from both the 2,3,4- and the 2,3,6-derivatives and may have been present in the other hydrolysate but have escaped detection there due to the larger amount of material added to the carbon column; such a condition would not favour the separation of compounds travelling at nearly the same rate. A number of dimethyl-hexoses was obtained from each hydrolysate as a mixed fraction and they were separated by paper electrophoresis in borate buffer [8]. The principal component was 2,6-di-*O*-methyl-D-glucose, identified by its chromatographic and electrophoretic behaviour. Three di-*O*-methyl-D-hexoses were also observed in each hydrolysate, which were shown by demethylation studies to be mannose derivatives.

The results of the methylation studies indicate that both glucomannans contain chains of 1,4-linked glycopyranosidic glucose and mannose residues. From the value of the optical rotation those residues appear to be linked by β-glycosidic bonds. The presence of a low percentage of other linkages, for example of glucose or of mannose residues linked to the 3-positions of glucose residues, is not excluded. A part of the dimethyl hexoses isolated is certainly derived from incomplete methylation of the polysaccharide. The fairly high

Table 1. Norwegian spruce glucomannan: Properties and results of periodate oxidation and methylation studies.

	Glucomannan A	Glucomannan B
Gal:Gluc:Man:Xyl	(+):21.8:76.9:1.3	(+):19.4:79.9:0.7
DP_n	68	100

Periodate oxidation		
Consumption of periodate (moles per $C_6H_{10}O_5$)	—	0.97
Formic acid released, extrap. to zero time (moles per $C_6H_{10}O_5$)	—	0.09
Molar % methylated hexoses		
2,6-Di-*O*-methyl-D-glucose	6.4	4.4
Di-*O*-methyl-D-mannoses	2.0	0.8
2,3,6-Tri-*O*-methyl-D-mannose	66.6	72.2
2,3,6-Tri-*O*-methyl-D-glucose	17.7	18.6
? -Tri-*O*-methyl-D-glucose	1.4	—
2,3,4,6-Tetra-*O*-methyl-D-mannose	5.8	3.6
% OCH_3 in the methylated polymers	44.0	44.6

yields of 2,6-di-*O*-methyl-D-glucose and of 2,3,4,6-tetra-*O*-methyl-D-mannose, however, strongly indicate that the polysaccharides are slightly branched and that the branches are on the 3-positions of glucose residues. From the analytical figures (Table 1) the number of branches per macromolecule in the glucomannan of DP 68 is calculated as 3—4. As the corresponding calculated value for the glucomannan of DP 100 is the same it must have a relatively lower degree of branching than the other.

Those conclusions are supported by the results of the periodate oxidation studies. The consumption of about 1 mole of periodate per hexose residue accords with such a 1,4-linked structure. The glucomannan of DP 100 on oxidation released 9 moles of formic acid per 100 hexose residues. This value is somewhat higher than that to be expected from a glucomannan having only 3—4 branch-points. The reducing group, unless modified by oxidation during delignification, would yield 2 moles and the non-reducing groups 4—5 moles of formic acid. The total yield then would be 6—7 moles but if the former group were modified it would be less. The oxidised polysaccharide after reduction with borohydride was hydrolysed and the hydrolysate examined chromatographically. Glucose and a trace of mannose were detected as was expected from the methylation studies, since those glucose residues which yield 2,6-di-*O*-methyl-D-glucose should not consume periodate.

These studies do not give any other details of the glucomannan structure. Points remaining undetermined are the distribution of glucose and mannose residues and of branching points and whether the branches are of uniform length or not. The rather small differences observed between the DP_n and

DP_w values, might suggest that the polysaccharide has a main chain with rather short branches (the DP_w was calculated from viscosity measurements making the assumption that the molecules are linear). The polysaccharide is non-crystalline but yields a crystalline product on mild acid hydrolysis [1]. The obvious explanation of this is that it is hydrolysed to shorter and linear fragments which, in contradistinction to the native, branched polysaccharide, have a strong tendency to crystallise. The X-ray diagram of this degraded glucomannan is identical to that given both by ivory nut mannan A and by a hemicellulose fraction from spruce sulphite pulp. During the hydrolysis the ratio of mannose (M) to glucose (G) residues in the polymeric material dropped from 3.6:1 to 2.9:1. This is to be expected as mannosidic linkages are more susceptible to acid hydrolysis than are glucosidic linkages.

The results of this investigation are in good agreement with those reported from the studies of other wood hemicellulose glucomannans. Hamilton *et al.*[9] isolated [from *Tsuga heterophylla* (Western hemlock)] a glucomannan of specific rotation $-38°$ (in 8 % sodium hydroxide) and having M:G = 4:1. Periodate oxidation studies of this material gave results very similar to those obtained in the present investigation. Aspinall *et al.*[10] isolated [from *Picea sitchensis* (Sitka spruce)] a glucomannan having $[\alpha]_D$ $-33°$ (in 10 % sodium hydroxide) and M:G = 2.5:1. The mannose content is quite low, compared to that of other glucomannans from coniferous woods, and it is possible that the material was contaminated by a degraded cellulose of which a fraction was also, separately, isolated. A structural investigation of the glucomannan gave results fairly similar to those reported in the present paper. From aspen wood hemicellulose Jones *et al.*[11] obtained a low yield of a glucomannan fraction having M:G = 2:1. Methylation studies indicated that it had the same general structure. The presence of glucomannans in coniferous wood has also been demonstrated by other investigators [12,13] and it seems fairly certain that glucomannans are amongst the principal hemicellulose components of those woods. The presence of other mannose containing polysaccharides (galactomannans or glucogalactomannans) has also been indicated [14,15] but awaits confirmation.

EXPERIMENTAL

Paper chromatography was carried out on Whatman No. 1 and on 3 MM filter paper. Chromatographic solvents: (a) ethyl acetate-acetic acid-water (3:1:1);
(b) butan-2-one, saturated with water;
(c) *iso*propyl ether (separations on dimethylsulphoxide-impregnated paper).

Paper electrophoresis was carried out on Whatman No. 3 MM filter paper in borate buffer at pH 10.

All concentrations were performed under reduced pressure and at a bath temp. of about 40°C.

Isolation of glucomannan fractions. The procedure was described in a previous paper [1] and further work on one of the fractions (A: DP_n 68) is now described. The other fraction, on which work has been carried out, was removed from a pretreated chlorite holocellulose by 27.6 % potassium hydroxide + 4 % boric acid. The pretreatment involved treating the holocellulose successively with dimethyl sulphoxide, with hot water, with 14 % potassium hydroxide and finally with 5 % potassium hydroxide + 3 % boric acid. The fraction (B) was purified as previously described. From the results of previous studies [1] on similarly derived fractions the DP_n of this fraction was estimated to be about 100.

Methylation of the glucomannans. Material A (2.0 g) was dissolved in 22.5 % sodium hydroxide (50 ml), under nitrogen, and methyl sulphate (10 ml) was added during 1 h with vigorous stirring, the temperature being kept at 20°C by external cooling. After 6 h the solution was neutralised with 6 N sulphuric acid and the polysaccharide recovered by dialysis. Yield 2.13 g (OCH_3, 28.4 %).

The partially methylated product was dissolved in dimethyl formamide (30 ml) and methyl iodide (6 ml) was added in one portion. The solution was kept under nitrogen and silver oxide (3 g) was added during 1 h under vigorous stirring. After 20 h the insoluble material was filtered off and washed with dimethyl formamide (10 ml) and the combined filtrate and washings were poured into water (800 ml) and then concentrated. Most of the dimethyl formamide was removed by repeated co-distillation with water. 200 ml of water and potassium cyanide (2 g) was added and the methylated polysaccharide was then extracted with chloroform (3 × 150 ml). The combined chloroform phases were washed with water (3 × 50 ml) and after drying over anhydrous sodium sulphate were taken to dryness. A further quantity of methylated polysaccharide was recovered from the later aqueous washings which were dialysed against tap water and then lyophilised. The two fractions were combined and were further methylated by two treatments with methyl iodide and silver oxide in dimethyl formamide. The product (0.58 g) had OCH_3, 44.0 %.

The second glucomannan fraction (B) (4.0 g) was methylated in the same way and yielded a product (1.64 g) having OCH_3, 44.6 %.

It is essential for the success of the methylations that all the chemicals are of high purity and perfectly dry. The silver oxide should be freshly prepared. The rather low yields of methylated products are certainly due to incomplete extraction of the aqueous solutions with chloroform and the procedure can probably be considerably improved.

Hydrolysis of the methylated glucomannans. The methylated glucomannans A and B (0.58 g and 1.64 g, respectively) were dissolved in anhydrous formic acid and kept at 100° for 6 h. After concentration of the solutions, the resulting syrup was dissolved in N sulphuric acid and was kept at 100° for 6 h. The solutions were then neutralised by passing them through a column of Amberlite IR-4B and on concentration they yielded syrups (0.44 g and 1.44 g, resp.). Chromatographic examination of the hydrolysates (Solvent a) revealed the presence of di-, tri- and tetra-*O*-methyl hexoses but no glucose, mannose or mono-*O*-methyl hexoses.

Examination of the hydrolysis products from methylated glucomannan A. The hydrolysate from methylated glucomannan A (444 mg) was added to the top of a carbon-Celite column (43 × 3.5 cm) which was then irrigated with the following solvents, using the gradient elution technique.

10 — 30 % aqueous ethanol	5 000 ml
30 — 60 » » »	3 000 »

The eluate was divided into fractions (30 ml) which were examined on paper chromatograms (Solvent a and b) and on paper electrophoretograms. Those fractions which were indistinguishable were combined and taken to dryness.

Fraction 1 (26.3 mg). By paper electrophoresis four components were isolated. The principal component on demethylation yielded glucose only and was chromatographically and electrophoretically indistinguishable from authentic 2,6-di-*O*-methyl-D-glucose. The components were fractionated, in two separate experiments, on paper chromatograms and on paper electrophoretograms and quantitative determinations of the principal component were made by hypoiodite oxidations[6]. The first experiment yielded a value of 82 % but in that case the separation of the components was not as good as when paper electrophoresis was used, then a value of 76 % was obtained. The analysis of mono-*O*-methyl-D-glucoses which had been separated by paper electrophoresis has previously been used[16].

Fraction 2 (219 mg). This fraction on demethylation yielded mannose only. The aniline derivative was prepared from it in a yield of 50 %. It had m. p. 125—127°, alone or in admixture with authentic 2,3,6-tri-*O*-methyl-*N*-phenyl-D-mannosylamine. The fraction was chromatographically homogeneous. Its α-diacetate had an R_F value of 0.26 (Solvent c).

Fraction 3 (58.1 mg). The material crystallised when the solvent was evaporated. One crystallisation from ethyl acetate yielded the pure substance, m. p. 117—119°C, undepressed on admixture with authentic 2,3,6-tri-*O*-methyl-α-D-glucose. The α-diacetate had an R_F value of 0.43 (Solvent c).

Fraction 4 (4.6 mg) on demethylation yielded glucose only. The substance was chromatographically distinguishable from 2,3,4- and 2,3,6-tri-*O*-methyl-D-glucose.

Fraction 5 (20.2 mg) on demethylation yielded mannose and traces of glucose. The aniline derivative had m. p. 142—144°, not depressed on admixture with that of 2,3,4,6-tetra-*O*-methyl-D-mannose.

Examination of hydrolysis products from methylated glucomannan B. The hydrolysate of methylated glucomannan B (1.440 mg) was fractionated as above on the same column. The results are summarised in Table 1.

Periodate oxidation studies. Glucomannan B (252 mg) was kept in water overnight in the refrigerator (2—4°). Then 0.4 M sodium metaperiodate solution (25 ml) was added and the volume was adjusted to 125 ml. The solution was kept in the refrigerator and at intervals samples (5 ml) were withdrawn and analysed for periodate consumption or for formation of acids. The results are summarised in Table 2.

Table 2. Periodate oxidation of glucomannan B.

Time, h	Moles of periodate consumed per $C_6H_{10}O_5$	Acid, equivalents per $C_6H_{10}O_5$
2	0.70	0.049
26	0.89	0.074
74	0.92	0.093
102	0.95	0.096
174	0.96	0.098

The authors are indebted to Miss F. Aeschlimann for her skilful assistance.

On the Purification of Liver Alcohol Dehydrogenase

KEITH DALZIEL*

Nobel Medical Institute, Biochemical Department, Stockholm, Sweden

A modified procedure is described for the preparation of crystalline alcohol dehydrogenase from horse liver, which gives a greater yield of enzyme of apparently higher specific activity than previous methods. The recrystallised product has always contained two components on electrophoresis. The major component has been isolated by chromatography, and its properties determined.

Liver alcohol dehydrogenase has in recent years been the subject of detailed kinetic study [1-4], and its purification and characterisation is therefore a matter of some importance. Following the work of Lutwak-Mann [5], in which partial purification of the enzyme of horse liver was effected by acetone precipitation, heating to remove unwanted protein, and precipitation with ammonium sulphate, Bonnichsen and Wassén [6] crystallised the enzyme after fractionation with ethanol and ammonium sulphate. In a later method [7], which gave a more active product [2], acetone precipitation was omitted, and treatment with ethanol-chloroform mixture was introduced to remove haemoglobin [8].

A further slight modification, which apparently gave a still more active enzyme, was described by Bonnichsen and Brink [9]: the essential steps were (1) heat treatment of the aqueous liver extract, (2) fractionation with ammonium sulphate, (3) ethanol-chloroform treatment, (4) fractionation and crystallisation with ethanol.

The properties of material prepared by this method and repeatedly recrystallised to a constant activity/E_{280} ratio were described recently [10,11]. The specific extinction coefficient at 280 mμ (1 mg/ml, 1 cm) agreed with previous values [7,9], but the specific activity was again increased, by 30 % compared with that reported by Bonnichsen and Brink and by 60 % compared with that of Bonnichsen's earlier preparation [2]. Nevertheless, the protein was not completely homogeneous on electrophoresis.

A further modification of the purification procedure will be described here which has consistently given a crystalline product of this same high

* Rockefeller Fellow, 1955—57. Present address: Department of Clinical Biochemistry, Radcliffe Infirmary, Oxford, England.

activity in twice the yield of previous methods. The product has always contained a small proportion of a second active component on electrophoresis, which can be removed by chromatography. The properties of the electrophoretically homogeneous main component will be described in this and in the following paper [12].

PURIFICATION PROCEDURE

The principal differences from the previous methods [7,9] are that the ethanol-chloroform treatment is carried out first on the liver extract, and after heat treatment and ammonium sulphate fractionation, the crude product is chromatographed on carboxymethyl cellulose; the subsequent crystallisation procedure also differs slightly. The assay of the enzyme has been described previously [10].

(1) *Extraction.* Ground horse liver (5 kg) is extracted with twice the amount of water for 2 h at room temperature, or overnight in the cold, and centrifuged (2 300 r.p.m., 45 min, International Serum Centrifuge, capacity 12 l).

(2) *Removal of haemoglobin.* To the dark brown, slightly turbid extract (10 l) a mixture of ethanol (1 600 ml 95 % ethanol + 800 ml chloroform) is added very slowly with vigorous stirring. After 10 min, with occasional stirring, the denatured haemoglobin is centrifuged off (2 300 r.p.m., 30 min). The green-brown supernatant (10 l) is evaporated under reduced pressure; the minimum amount of octanol is added to reduce foaming, and the flask is immersed in a water bath at 55°. Most of the organic solvents should be removed. The dark green-brown solution (8—9 l), which may contain some precipitate of heat-denatured protein, is thoroughly dialysed at room temperature against phosphate buffer pH 7, $\mu = 0.02$ (2 × 20 l, 18 h).

(3) *Ammonium sulphate fractionation.* The enzyme is precipitated between 0.55 and 0.70 saturation at room temperature. The pH should be kept at 6.0—6.5 by the addition of ammonia. 3.5 kg ammonium sulphate per 10 l solution is added and, after 2 h the brown or green-brown precipitate is removed by centrifuging and discarded (<0.5 g enzyme). To the clear, yellow-green supernatant another 4.7 kg per 10 l is added; after 2 h, the crude enzyme is centrifuged down (2 300 r.p.m., 1 h) as a cream precipitate, and the clear yellow supernatant (<0.1 g enzyme) is discarded. (Difficulty in separating the precipitate indicates that organic solvents have not been completely removed.) The precipitate is washed into dialysis sacs with the minimum volume of phosphate buffer, $\mu = 0.1$, pH 7 (*ca.* 400 ml), and thoroughly dialysed against the same buffer (3 × 4 l) to remove ammonium sulphate, when it dissolves to give a clear yellow-brown solution.

(4) *Heat denaturation.* The dialysed solution is kept at 52° for 15 min, cooled to room temperature and centrifuged. The precipitate is washed with a small volume of buffer, and the combined supernatant and washings, containing 3—4 g enzyme, purity 5—10 %, are dialysed against phosphate buffer, pH 6.0, $\mu = 0.05$.

(5) *Chromatography.* Carboxymethylcellulose, prepared according to Peterson and Sober [13] (except that drying with ethanol is omitted), and equilibrated with phosphate buffer, pH 6.0, $\mu = 0.05$ is packed under 30 cm Hg pressure for a few hours in a column, 3 × 65 cm. The chromatography is carried out at +2°, under the same pressure, with a flow rate of about 60 ml/h. After the enzyme is put onto the column, it is washed with the same buffer until the runnings are colourless. The enzyme is completely retained, together with a yellow pigment. The runnings are first brown, then yellow, and finally colourless. The enzyme, together with the yellow pigment which may be used as an indicator, is rapidly eluted with phosphate buffer, pH 8, $\mu = 0.2$. Over 90 % of the enzyme should be recovered from the column, in a volume of 150 ml: purity 30—40 %.

(6) *Crystallisation.* (a) The enzyme solution is cooled to 0°, and cold 90 % ethanol is added gradually with continuous chilling to a final ethanol concentration of 30 % and a temperature of −12°. The mixture is left at this temperature overnight. The amorphous precipitate containing the whole of the enzyme is separated from the yellow supernatant

by centrifuging at −12°, washed once with 30 % ethanol in phosphate buffer, and well drained. (b) The remaining steps are carried out at +2°. The precipitate is washed into a dialysis sac with the minimum volume (ca 20 ml per g enzyme) of phosphate buffer, $\mu = 0.1$, pH 7, to which ammonia has been added to raise the pH to 9 and is dialysed against the same buffer until the precipitate largely dissolves to give a pale yellow solution containing some turbidity and precipitate of denatured protein. The solution is then dialysed overnight against phosphate buffer, $\mu = 0.05$, pH 7, and then against the same buffer containing 6 % ethanol for 24 h to crystallise. The crystals are separated by centrifuging, washed once with a little 6 % ethanol dialysate, and dissolved as before in phosphate-ammonia, pH 9. Denatured protein is removed by centrifuging. The very pale yellow solution contains 80 % of the enzyme removed from the column, purity [10] 95 %; the remainder is lost in the 6 % ethanol supernatant and washings. (c) On recrystallisation with 6 % ethanol in the same manner, and removal of denatured protein, the pure [10], colourless crystals are obtained in a yield of 2 g per 5 kg liver.

Electrophoresis and isolation of the main component

The recrystallised product has never been completely homogeneous on electrophoresis. The main component, which is 90 % or more of the total protein in the best preparations, has an isoelectric point of 6.8, phosphate, $\mu = 0.1$. The minor component, which moves behind the main peak at pH 6.0 (Fig. 1) and in advance of it at pH 7.4, was separated in the analytical Tiselius apparatus and found to be active. Because of the small proportion present, and the small difference between the mobilities, it has not been separated in quantity or as a distinct separate peak.

The main component can be obtained in an electrophoretically homogeneous form by chromatography on carboxymethyl cellulose. After the enzyme has been put on the column at pH 6.0, it is developed with phosphate buffer, $\mu = 0.05$, pH 6.8, until about 30 % of the enzyme has been eluted. In accordance with the electrophoretic properties and the chromatographic

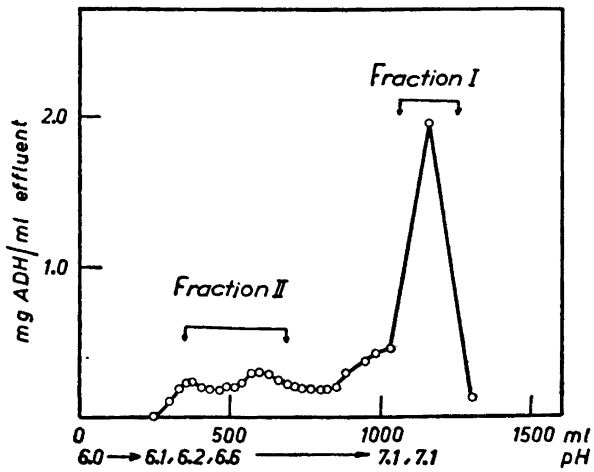

Fig. 3. Elution diagram of recrystallised enzyme on carboxymethylcellulose.

experiments described below, this fraction contains the minor constituent. The remainder of the enzyme is eluted with phosphate buffer, $\mu = 2.0$, pH 8.0, and is electrophoretically homogeneous.

Properties of the main component

The specific extinction coefficient (1 mg/ml, 1 cm) at 280 mμ was 0.42. In the spectrophotometric assay [10] the concentration of the enzyme solution is $\frac{1.13}{t_{0.2} \times v}$ mg/ml, where v is the volume in ml of the enzyme solution used and $t_{0.2}$ is the time in seconds required for the extinction at 340 mμ (1 cm layer) to increase by 0.200. The value of $\frac{1}{E_{280} \times t_{0.2} \times v}$ might be used as a "purity index". Determinations of the molecular weight, sedimentation constant and diffusion constant, and spectrophotometric titration with reduced diphosphopyridine nucleotide, are described in the following paper [12].

Further experiments on inhomogeneous preparations

In preparations in which dialysis after ethanol-chloroform treatment and evaporation was omitted, separation by centrifugation of the crude enzyme precipitated with 0.7 saturated ammonium sulphate was more difficult. The final recrystallised product was apparently pure, as judged by the purity index, but electrophoresis indicated the presence of 20—30 % of the minor component.

The electrophoretic behaviour of such a preparation is illustrated in Fig. 2 and chromatography of the same preparation in Fig. 3. The chromatography was carried out on carboxymethyl cellulose at +2°. 690 mg of recrystallised enzyme, purity index 215, in a concentration of 12 mg/ml was put on the column in phosphate buffer, $\mu = 0.05$, pH 6.0, and eluted first with phosphate buffer, $\mu = 0.05$, pH 6.6, and finally with phosphate buffer, $\mu = 0.1$, pH 7.1. The effluent was collected in 20—30 ml volumes and assayed by activity and E_{280} measurements. There was no significant variation in the purity index during the elution, but the elution diagram indicates the presence of a minor active component, estimated as 15 % of the total, although the separation from the main component is not clear cut. A similar result was obtained with another preparation.

Two fractions of the eluted enzyme, as indicated in Fig. 3, were concentrated and crystallised with alcohol, and dialysed. From fraction I, the main component, 340 mg enzyme, purity index 219, were obtained. The specific extinction at 280 mμ was 0.42, and the preparation was homogeneous on electrophoresis (Fig. 2 B). From fraction II, 40 mg, purity index 226, was obtained. The specific extinction was 0.47. Fractions I and II were mixed in the proportion 80 % I and 20 % II. The electrophoretic behaviour of the mixture (Fig. 2 C) is similar to that of the unresolved enzyme, and confirms the reality and identity of the minor active component observed in electrophoresis and chromatography.

DISCUSSION

In the purification procedures of Bonnichsen [7] and Bonnichsen and Brink [9], ethanol-chloroform treatment after ammonium sulphate fractionation does not remove all the haemoglobin, and the enzyme is crystallised from a deep red solution. By applying the ethanol-chloroform treatment directly to the liver extract, the haemoglobin is completely removed; on general grounds also there is something to be said for introducing this rather drastic treatment at as early a stage as possible. Chromatography prior to crystallisation gives a 6-fold increase fo purity, and is probably mainly responsible for the increased yield; any catalase or haemoglobin which may have escaped earlier steps is also removed here. Finally, a more rational and reproducible crystallisation procedure can be applied to the relatively pure, haemoglobin-free product.

The enzyme readily crystallises together with inactive material, and this seems to have been responsible for the low activity of the orginal crystalline product [6] compared with Bonnichsen's material. The reasons for the subsequent successive gains in activity reported by Bonnischsen and Brink [6], and by Dalziel [10] for a repeatedly recrystallised product of their procedure, are not se clear. These reports are based upon the spectrophotometric assay method of Theorell and Bonnichsen [2,10], in which the rate of reduction of the coenzyme by ethanol at pH 9.6 is measured. A similar gain in activity is indicated by fluorimetric mearurements of the maximum rate of this reaction at pH 7.15:2.5 sec^{-1} for Dalziel's preparation compared with 1.6 sec^{-1} for Bonnichsen's preparation [3], It is possible, of course, that inhibitors were present in the reagents used in the earlier work, perhaps in the less pure coenzyme

then available. There has been no further significant gain in activity by the present method of preparation. It may be mentioned, however, that the purity index of enzyme freshly eluted from carboxymethylcellulose during chromatography of the recrystallised product was usually about 10 % greater than that given above for the pure enzyme, but always decreased to the latter value after recrystallisation and dialysis.

The separation of a recrystallised enzyme into more than one active component by electrophoresis and chromatography recalls similar observations on other enzymes and proteins, especially the lactic acid dehydrogenase of heart muscle [14]. In the present case, the fact that the proportion of the minor component is increased in preparations in which alcohol, chloroform or octyl alcohol may not have been completely removed after the Tsuchihashi treatment suggests that it may be formed during the purification procedure. This question, and the properties of the minor component, require further investigation. It has been shown that the minor component has about the same specific activity as the major one, and in one determination a fraction containing a high proportion of the minor component gave a specific extinction at 280 mμ of 0.47, compared with 0.42 for the major component. This presumably accounts for the specific extinction of 0.45 previously reported [3,10] for the recrystallised enzyme.

The molecular weight of the homogeneous main component is 84 000; [12,15] the sedimentation constant is greater, and the diffusion constant smaller, than the values reported previously [2], which gave a molecular weight of 67 500 [2,11,15]. The difference in the diffusion constant is consistent with inhomogeneity of the earlier preparations. Nevertheless, the earlier finding that 2 molecules of DPNH are bound per molecule of enzyme has been reproduced with the homogeneous material [12].

Acknowledgement. The author is greatly indebted to Mr. Å. Åkeson for generous help and guidance during this work, to Mr. O. Eriksson for expert assistance, and to Professor R. Bonnichsen and Professor H. Theorell for much advice and discussion. The work was carried out during the tenure of a Rockefeller Fellowship in Medicine.

The Molecular Weight of Horse Liver Alcohol Dehydrogenase

ANDERS EHRENBERG and KEITH DALZIEL*

Biochemical Department, Nobel Medical Institute, Stockholm, Sweden

The molecular weight of highly purified horse liver alcohol dehydrogenase has been determined to be 83 300. This value is derived from a sedimentation coefficient of 5.11 S at infinite dilution, a diffusion coefficient of 5.96 F at a low protein concentration and a partial specific volume of 0.750. Titration with DPNH confirms that two molecules of coenzyme are bound per molecule of apoprotein.

Crystalline alcohol dehydrogenase (ADH) from horse liver has recently been prepared in an apparently purer and more active form than previously [1,2]. Since the kinetics and mechanism of the reaction catalyzed by this enzyme have been extensively studied, it was of interest to redetermine its molecular weight and its binding capacity for the coenzyme.

MATERIAL AND METHODS

The enzyme was prepared as described by Dalziel in the preceding article [1], including the purification by chromatography. It was precipitated by ethanol, dissolved in the proper buffer and dialyzed against the same buffer overnight immediately before the measurements. The buffer was 0.044 M phosphate of pH 7.0 with 1 % sodium chloride added for the diffusion and sedimentation experiments. The partial specific volume was determined on a sample dissolved in 0.022 M phosphate of pH 7.0. It was not possible to use a more dilute buffer because of the lability of the enzyme at lower ionic strengths. The protein concentration of this sample, determined as the difference between the dry weight of the sample and the buffer, was 9.76 mg/ml. The specific absorbancy of the protein at 280 mμ in a 1 cm layer was determined to be 0.42 for a concentration of 1 mg/ml. This value has been used for the concentration determination of the other samples.

The equipment and technique used for the sedimentation and diffusion studies and for the determination of the partial specific volume have been described elsewhere [2]. The temperature of the rotor in the Spinco ultracentrifuge was kept close to 20°C, while the diffusion experiment was made at 34°C. Both S and D were corrected to 20°C and water as solvent. The pycnometer used for the determination of the partial specific volume was equilibrated at 21.68°C. The absorbancy measurements were made in a Beckman spectrophotometer, model DU.

The DPNH used for the titration was obtained from Sigma chem. Co. The DPNH solution was assayed by measurement of the decrease of extinction at 340 mμ on complete enzymic oxidation to DPN with aldehyde and a catalytic amount of ADH, taking [3] $E_{mM} = 6.25$. The residual extinction after complete oxidation was 5 % of the initial value. The assay showed that the solid sample contained 71 % coenzymically active DPNH.

* Rockefeller fellow 1955—1957. Present address: Department of Clinical Biochemistry, The Radcliffe Infirmary, Oxford, England.

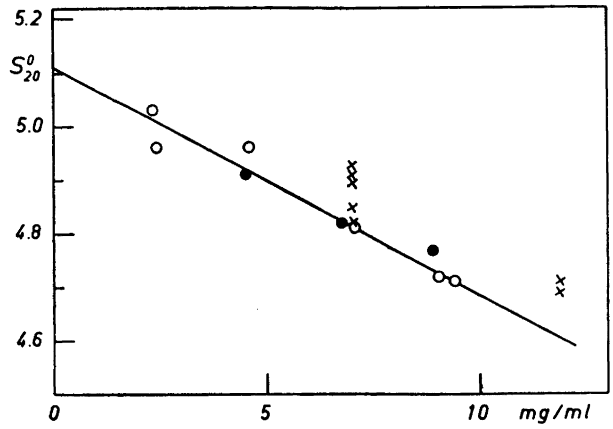

Fig. 1. Concentration dependence of the sedimentation coefficient of ADH. Abscissa: mean protein concentration during observation in the ultracentrifuge. Ordinate: Sedimentation coefficients of pure ADH, O, of a slightly less active material, ●, and the data published in an earlier investigation on salt and pH effects [4], ×.

RESULTS

Sedimentation coefficient. The sedimentation velocity was measured in six experiments at different concentrations. In Fig. 1 the corrected sedimentation coefficients, $S_{20}°$, have been plotted *versus* the mean protein concentration during the experiment. The best fitting line has been calculated by means of the least square method and is drawn in the figure. Its equation is

$$S_{20}° = 5.11 - 0.0425\ a$$

where a is the concentration of ADH in mg/ml and 5.11 is the sedimentation coefficient extrapolated to infinite dilution and measured in Svedberg units.

For comparison three values obtained on another fresh but somewhat less pure preparation (indicated by lower specific activity) have been included in Fig. 1. They do not deviate to any appreciable extent from the calculated line. Earlier data obtained in an investigation on pH and salt effects on the sedimentation [4] are also shown in the figure. This preparation was even less pure, the data are slightly higher than in the present investigation but extrapolate to about the same value at infinite dilution [4].

Diffusion coefficient: Two experiments were performed, one on "100 %" pure ADH and one on "85 %" pure ADH. The purity was judged from activity tests. In both cases the protein concentration was close to 1.54 mg/ml, and the total fringe number was found to be 24.95 and 24.78, respectively. A fringe interval, Δn, of 5 was hence chosen in the calculation of the maximal fringe density, n'_{max}.

When applying the "height-area" method the rate of increase of $\left(\frac{1}{n'_{max}}\right)^2$ with time has to be determined. The corresponding plot of data derived from six exposures on the pure ADH is given in Fig. 2. The equation of the line

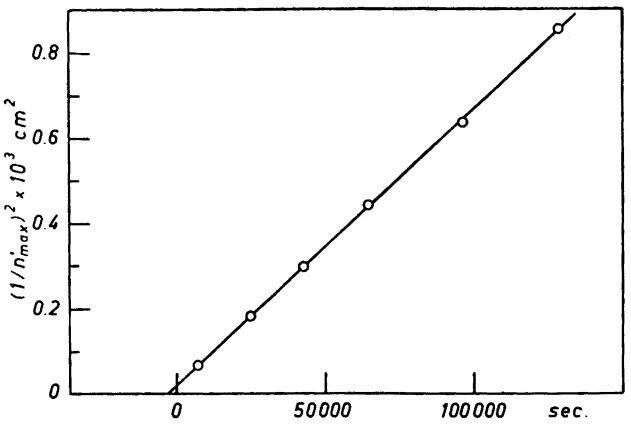

Fig. 2. Graph from which the diffusion coefficient of pure ADH has been calculated according to the "height-area" method. Abscissa: time measured from end of sharpening procedure. Ordinate: inverted square of maximal fringe density.

has been calculated by means of the least square method. The apparent starting time is at —3 100 sec. The diffusion coefficient $D_{1.31} = 3.15\ F$ which after correction becomes $D_{20^\circ} = 5.97\ F$. The fit to the laws of ideal diffusion was investigated by plotting fringe data of the last exposure, taken after 36 h, on a normal distribution graph [2], Fig. 3. The same exposure was also evaluated according to the moment method [2,5], since any small error in the zero time correction in this case can be neglected. A value of 5.93 F was found for D_{20°. $D_{20^\circ} = 5.95\ F$ is obtained as a mean value for the two methods of calculation.

The sample of 85 % active ADH gave for four exposures $D_{20^\circ} = 5.60\ F$ and $t_0 = -7\,300$ sec with the "height-area" method. The moment method applied to the last exposure, taken after 40 h, gave $D_{20^\circ} = 5.86\ F$. The same exposure has been tested on the normal distribution graph, Fig. 3. A close analysis shows that the curve is slightly S-shaped.

The partial specific volume was found to be 0.750 ($\pm$ 0.004) ml/g in a single determination.

DPNH titration. DPNH forms a compound with liver ADH in which the absorption maximum is displaced from 340 mμ to 325 mμ. This spectral shift enabled Theorell and Bonnichsen [6] to demonstrate that at pH 7 one molecule of ADH binds two molecules of DPNH. A similar spectrophotometric titration was made with the enzyme preparation used in the present investigation.

To 3 ml enzyme solution, 5.2 mg/ml in phosphate buffer of pH 7 and μ = 0.1, in a cuvette 5.1 μl portions of 16.1 mM DPNH were added on a stirrer. After each addition the absorbance was measured at 310 and 350 mμ, the wavelengths at which the specific absorptions of free and bound DPNH differ most. The titration was carried out as quickly as possible, but it was necessary to correct the absorbance differences for a slow decline of absorp-

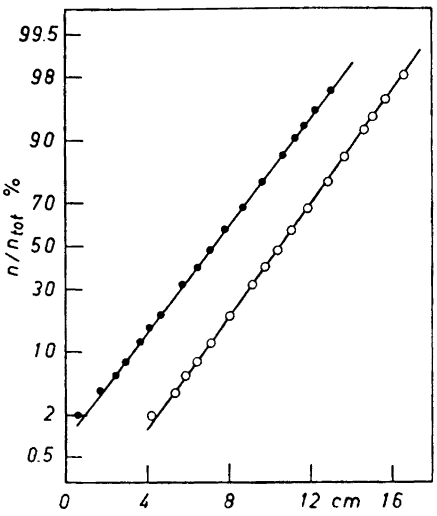

Fig. 3. Normal distribution plots for testing fit of boundary shape to that required by the ideal laws of diffusion. Abscissa: fringe coordinates. Ordinate: relative fringe numbers of exposures on "100 %" pure ADH taken after 36 h, O, and on "85 %" pure ADH taken after 40 h, ●.

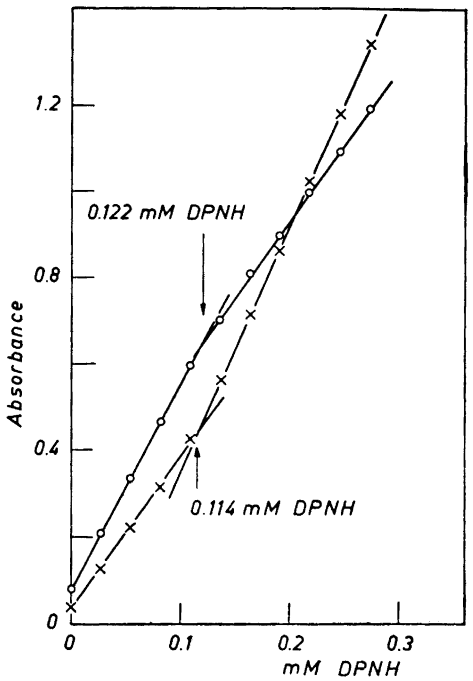

Fig. 4. Titration of ADH, 5.2 mg/ml, with DPNH. Abscissa: concentration of coenzymically active DPNH. Ordinate: Absorbance readings at 310 mμ, O, and 350 mμ, ×. The breaking points of the slopes are indicated.

tion at both wavelengths. The corrected data are plotted in Fig. 4 against the total DPNH concentration.

The equivalence point, indicated by sharp changes of slope, comes at a mean value of 0.118 mM DPNH. The titration indicates hence an equivalent weight of $5.2/118 \times 10^{-6} = 44\,000$ per binding site of the enzyme. The slopes give values of $E_{mM} = 4.8$ and 3.5 for the compound, and $E_{mM} = 3.6$ and 5.9 for free DPNH, at 310 and 350 mμ, respectively, in good agreement with previous values [6].

DISCUSSION

From the values, $S_{20}^{\circ} = 5.11\ S$, $D_{20}^{\circ} = 5.95\ F$ and $V_{sp} = 0.750$ ml/g, a molecular weight of 83 300 is calculated by means of the Svedberg formula. This is in good agreement with the value 84 400 obtained by the Archibald method [7], but deviates considerably from the value 67 500 [6,7] obtained for previous and less active preparations of ADH [8,9]. This discrepancy is due to differences mainly in the sedimentation and diffusion coefficients since the partial specific volume of the present material is 0.750 ml/g, as compared to

the previous value [6] 0.751 ml/g. The sedimentation and diffusion of the previous material was studied by Pedersen [6]. He obtained $S_{20}^{\circ} = 4.9\ S$ on a sample with a protein concentration of about 10 mg/ml when investigated in the oil driven ultracentrifuge. This becomes 4.5 S after correction for a probable error in the measured rotor temperature, as suggested by Pedersen [10]. The present material has a sedimentation coefficient of 4.7 at the same concentration. The main difference in S is thus due to the fact that our data have been extrapolated to infinite dilution. The small remaining difference indicates that the previous material contained some low molecular impurities. This conclusion is supported by the values of the high diffusion coefficient obtained by Pedersen [6], $D_{20}^{\circ} = 6.5\ F$ as calculated by the "height-area" method and $D_{20}^{\circ} = 7.3\ F$ as determined by the moment method.

The main source of error in the present determination of M is the uncertainty in the partial specific volume, which might introduce an error of about $\pm$ 2 % in M. The S and D values are more accurate than that and an error in the molecular weight 83 300 of about $\pm$ 2 000 might be estimated.

The equivalent weight of 44 000 obtained in the DPNH titration confirms [6] that two molecules of DPNH are attached to each molecule of enzyme, for which a molecular weight of 88 000 is indicated. Considering the big errors involved in the experiment this figure is much less reliable than the one given above.

The behaviour of the ADH in the sedimentation velocity experiments, the diffusion experiment and the titration experiment as well as in the molecular weight determination experiment according to Archibald [7] indicates that the present preparation [1] really has a high degree of purity. The best value of the molecular weight of horse liver ADH to be given at the present is 84 000, a mean of the figure reported here and the value obtained by Archibald's method [7].

The less active material exhibited a slightly lower diffusion coefficient, indicating some contamination of larger molecular species. It may be remarked that ADH stored in the buffer solutions for some time lost some activity and often gave higher sedimentation coefficients.

Acknowledgements. The authors wish to thank Mr. B. Lindqvist at Mjölkcentralen, Laboratories, for help in performing the diffusion experiment. Skilled technical assistance has been given by Mr. N. Ekman and Mr. O. Eriksson. Thanks are further due to the *Knut and Alice Wallenberg Foundation* for financial support.

The Catalytic Effect of Peroxidase on the Reaction between Hydrogen Peroxide and Certain Sulfur Compounds

BO SÖRBO and JAN GUSTAF LJUNGGREN

Nobel Medical Institute, Biochemical Department, Stockholm, and Research Institute of National Defence, Dept. 1, Sundbyberg, Sweden

Myeloperoxidase catalyzed the reaction between thiourea and hydrogen peroxide. Some of the reaction products were identified and the formation of an unstable intermediate was demonstrated. Myeloperoxidase also catalyzed the oxidation of thiouracil and thiocyanate, but was inactive with true thiol compounds (cysteine, thioglycolic acid, mercaptoethanol). Horse radish peroxidase was inactive with all the aforementioned sulfur compounds. The results were discussed with respect to the metabolism of the sulfur compounds and to the action of thyreostatic compounds.

In connection with research programs on the oxidation of thiol compounds in biological systems and on the biosynthesis of thyroxine, now in progress in our laboratories, the effect of peroxidase plus hydrogen peroxide on certain sulfur compounds has been investigated. Randall [1] previously reported that thiourea and thiouracil were substrates for horse radish peroxidase, but for different reasons a reinvestigation appeared to be necessary. Thus Randall followed the reaction between hydrogen peroxide and the sulfur compound by a manometric method, which was based on a conversion of remaining hydrogen peroxide to oxygen through the action of catalase. However, the inhibitory effect of the sulfur compounds on catalase [2,3] was apparently not considered. This source of error has been avoided in the present work by following the oxidation of the sulfur compounds by spectrophotometry in the ultraviolet region. The present investigation was also carried out with both animal and plant peroxidase and extended to include true thiol compounds (mercaptans).

EXPERIMENTAL

Materials. Crystalline myeloperoxidase (MPO) was a generous gift from Dr. Kjell Agner. Horse radish peroxidase (PZ-65) was a commercial preparation. Salts of formamidine disulfide [4,5] and formamidine sulfinic acid [6] were prepared according to the indicated references.

Methods. The reactions were followed in phosphate buffer of pH 7.4 at room temperature (20°C) in a Beckman DU spectrophotometer. Paper chromatography of the reaction products from thiourea was carried out on Whatman No. 1 filter paper with water saturated phenol or butanol-acetic acid-water (4:1:1) as developers. The spots were visualized with the iodine-azide reagent or with *p*-dimethylaminobenzaldehyde. Thiourea and formamidine disulfide were not separated from each other in these systems (in fact no solvent system was found, which accomplished this separation), both having the R_F values 0.54 in phenol-water and 0.42 in butanol-acetic acid-water. Formamidine sulfinic acid had R_F 0.44 in phenol-water and 0.21 in butanol-acetic acid-water. The presence of formamidine disulfide in the reaction mixtures could, however, be verified through a cyanolysis reaction. The disulfide reacted rapidly at room temperature with cyanide (0.1 M) to give thiocyanate, which could then be demonstrated in the usual manner with ferric ions. No thiocyanate is obtained from thiourea or formamidine sulfinic acid under these conditions. The formation of sulfate from thiourea and thiocyanate was demonstrated by adding barium ions to the acidified sample. The phosphate buffer in the reaction system was in this case replaced by Tris buffer (in order to avoid precipitation of barium phosphate). The time course of the enzymic reactions was the same in phosphate and Tris buffer. Cyanide was demonstrated with the pyridine-barbituric acid reaction [8] after aeration from the acidified sample into 0.1 M NaOH.

RESULTS

The oxidation of thiourea with hydrogen peroxide with and without MPO was first studied. It is known that the products of this reaction are mainly formamidine disulfide and formamidine sulfinic acid; the first being preferen-

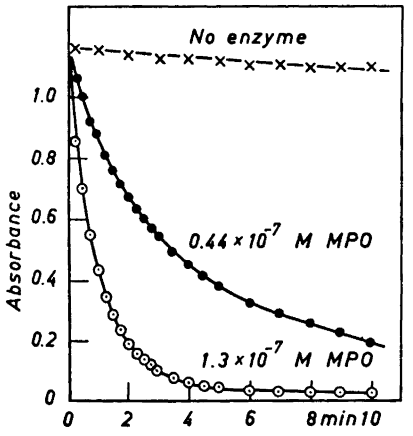

Fig. 2. Reaction of thiourea and hydrogen peroxide followed at 235 mμ. Thiourea 1×10^{-4} M, H_2O_2 2.5×10^{-4} M, phosphate 0.05 M and pH 7.4. Absorbance values corrected for the contribution of MPO.

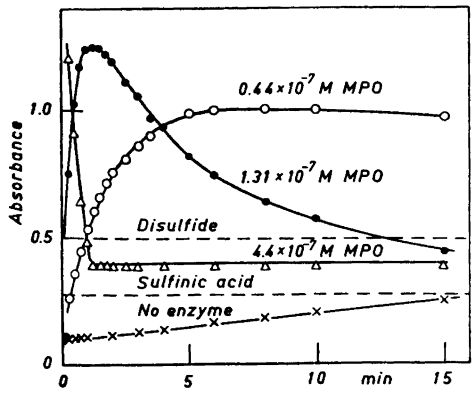

Fig. 3. Thiourea oxidation followed at 270 mμ. Thiourea 5×10^{-4} M, H_2O_2 1.25×10^{-3} M, other conditions as in Fig. 2. Absorbance values corresponding to a complete oxidation of thiourea to formamidine disulfide or sulfinic acid indicated by horisontal lines.

tially formed in acid, the latter in alkaline solution [6]. The spectra of thiourea and the anticipated reaction products * were first compared (Fig. 1) and the reaction was then followed at 235 mμ. A MPO catalyzed reaction was demonstrated (Fig. 2) and the expected decrease in absorbance observed. At 270 mμ, however, the results were different (Fig. 3). With small amounts of enzyme an initial increase in absorbance was obtained, which became more rapid at higher enzyme concentrations. The initial increase in absorbance was then followed by a secondary decrease, and when the enzyme concentration was further increased the initial phase become too rapid to be observed and only the secondary decrease could be followed. As the secondary decrease was faster at higher MPO concentrations, the results indicated that MPO catalyzed not only the formation of a primary reaction product, but also the decomposition of this product. The absorption spectrum of a reaction mixture containing the intermediate showed only a peak at 270 mμ. When the effect of hydrogen peroxide concentration was studied (Fig. 4) it was found that the secondary decrease in absorbance was obtained only with an excess of this compound. Consequently the secondary decomposition of the intermediate must be an oxidation of the latter with hydrogen peroxide. Attempts were now made to identify the reaction products. Paper chromatography (together with the cyanolysis reaction) demonstrated only the presence of formamidine disulfide and formamidine sulfinic acid, but none of these compounds could explain the high absorbance values reached in the enzyme reaction (Fig. 3), and could thus not be the unknown intermediate. Sulfate was also found in the reaction mixtures, but does not absorb light at 270 mμ. The possibility was considered that formamidine sulfonic acid [7], another oxidation product of thiourea, was the intermediate. This sulfonic acid can, however, only be obtained under anhydrous conditions and could also be excluded from being the intermediate by the following experiment. Oxidation of a sulfinic acid with hydrogen peroxide gives the

* Formamidine disulfide is stable only in acid solutions, but at pH 7.4 the spectrum of the compound was essentially unchanged for at least 1 h.

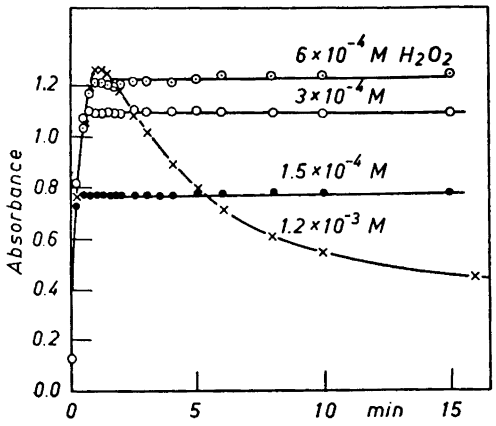

Fig. 4. Effect of hydrogen peroxide concentration on thiourea oxidation. MPO 1.3×10^{-7} M, H_2O_2 as indicated and other conditions as in Fig. 3.

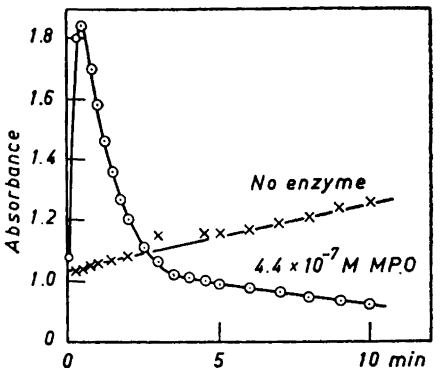

Fig. 5. Oxidation of formamidine disulfide by hydrogen peroxide. Formamidine disulfide 5×10^{-4} M, H_2O_2 2.5×10^{-3} M, phosphate 0.01 M, chloride 2×10^{-3} M and pH 7.4. Followed at 270 mμ.

corresponding sulfonic acid and if formamidine sulfonic acid was the intermediate, strong increase in absorbance should be observed at 270 mμ by treating formamidine sulfinic acid with hydrogen peroxide. This reaction should furthermore be catalyzed by MPO. However, when the experiment was performed only a slow decrease in absorbance was observed and MPO was without effect. On the other hand formamidine disulfide was oxidized by hydrogen peroxide in a MPO catalyzed reaction and an increase and decrease in absorbance, corresponding to the formation and break-down of the intermediate was observed (Fig. 5). Consequently the unknown intermediate must be an oxidation product of the disulfide on an oxidation level between a disulfide and a sulfinic acid. A disulfoxide (R-SO-SO-R) or a sulfenic acid (RSOH) would fulfil these requirements and as both are unstable compounds, which decompose to give a mixture of the corresponding disulfide and sulfinic acid [9], the results obtained by paper chromatography could be explained. As neither a disulfoxide, nor a sulfenic acid has been prepared from thiourea, it was not possible to identify the intermediate further.

Myeloperoxidase was also active with thiouracil (Fig. 6) and with thiocyanate (Fig. 7). The reaction products from thiouracil were not identified, but in the case of thiocyanate the formation of sulfate and cyanide could be demonstrated, and from Fig. 7 the formation of an unstable intermediate is also evident. The catalytic activity of horse radish peroxidase was also studied. Randall [1] had already reported that the plant enzyme catalyzed the oxidation of thiourea and thiouracil, but somewhat unexpectedly we found that the plant enzyme was completely inactive with both these compounds. (The enzyme was tried in concentrations up to 10^{-6} M or about 1 000-fold higher than those used by Randall). It might be added, that a difference in

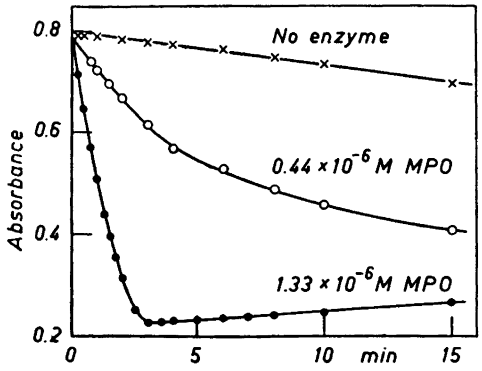

Fig. 6. Oxidation of thiouracil by hydrogen peroxide. Thiouracil 1×10^{-4} M, H_2O_2 2.5×10^{-4} M, reaction followed at 300 mμ. Other conditions as in Fig. 2.

substrate specificity has previously been observed between the animal and plant peroxidase [10,11].

Finally the action of peroxidase-hydrogen peroxide on cysteine, thioglycolic acid and mercaptoethanol was studied. The reactions were followed at pH 7.4 and 220—230 mμ, where both the thiol (0.001 M) and hydrogen peroxide (0.002 M) gave a measurable light absorption. The spontaneous reaction was rather fast in case of cysteine and slower with the other compounds, but in no case could a catalytic activity be demonstrated with peroxidase. Both the animal and plant enzyme was tried at concentrations up to 10^{-6} M. Consequently thiol compounds are not substrates for peroxidase.

DISCUSSION

The present work has demonstrated that thiourea, thiouracil and thiocyanate are substrates for animal peroxidase in contrast to true thiol compounds (cysteine, thioglycolic acid and mercaptoethanol). As thiourea, thiouracil and thiocyanate may exist in two tautomeric forms, one containing a thiol group and the other containing sulfur linked to carbon through a double bond, our results suggest that only the last tautomer (with double bonded sulfur) is the one acted upon by the enzyme. Of interest in this connection is also that thiourea, thiouracil and thiocyanate are well known thyreostatic compounds in contrast to true thiols. Peroxidase-hydrogen peroxide has been implicated with the synthesis of thyroxine [12–14], and it is possible that the antithyroid compounds exert their activity by competing with thyroxine precursors for hydrogen peroxide. It has also been suggested [15] that the thyreostatic compounds owe their activity to their reducing properties on iodine. Iodide must first be oxidized to iodine before being incorporated into the tyrosine residues, and it has been shown that the thyreostatic compounds can prevent this conversion of free iodide to organic bound iodine [16]. However, it seems in this case at first difficult to explain why thiols, such as cysteine or glutathione, which also rapidly react with iodine, do not possess antithyroid properties. But another important biochemical distinc-

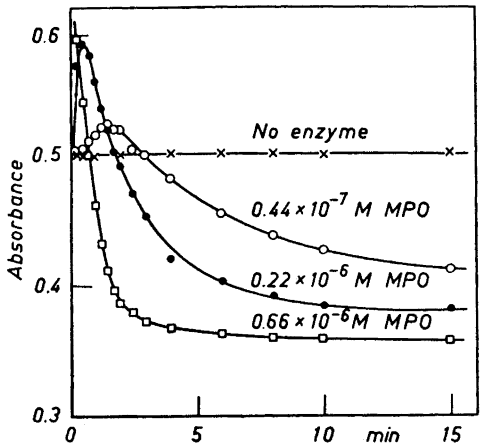

Fig. 7. Oxidation of thiocyanate by hydrogen peroxide. CNS^- 5×10^{-4} M, H_2O_2 1.25×10^{-3} M and other conditions as in Fig. 2 (235 mμ).

tion can be made between the thyreostatic active compounds and the inactive thiols, as the latter are rapidly oxidized through the cytochrome oxidase system [17] in contrast to the thyreostatic compounds. (We have verified that neither thiourea nor thiouracil reduces cytochrome c.) Thus, when thiols are introduced in the body they are probably oxidized before they can reach their presumptive site of action in the thyroid.

Work with ^{35}S-labeled thiourea has shown that the latter is in part oxidized in the body to sulfate, and that the thyroid gland is especially active in this respect [18]. Sulfate was now found to be a reaction product in the peroxidase catalyzed oxidation of thiourea, and as peroxidase is present in the thyroid gland [14] the *in vivo* oxidation of thiourea is probably catalyzed by this enzyme. Of interest in this connection is also that thiocyanate is oxidized *in vivo* to sulfate [19] and to cyanide [20]. The results now obtained strongly suggest that peroxidase is a part also of the "thiocyanate oxidase" [20] system.

When the investigation was started, it was suspected that peroxidase may be responsible for some of the biological effects of ionizing radiations. Hydrogen peroxide is formed when solutions are irradiated and an oxidation of vital thiols or disulfides to sulfinic or sulfonic acids has been suggested as a key reaction in radiation damage [21]. As some well known inhibitors for heme-enzymes, for instance cyanide [22], protect against ionizing radiation, a peroxidase catalyzed destruction of vital thiol or disulfide groups during irradiation was suggested. The results now obtained seem to exclude this possibility.

Acknowledgements. The authors are very grateful to Professor Hugo Theorell for kind advice and criticism, to Dr. Kjell Agner for generous gifts of myeloperoxidase and for valuable discussions, and are indebted to Mrs. Elsa Ekblom for technical assistance.

Solvates of Arsenic Trichloride, Phosphorus Oxychloride and Selenium Oxychloride

MARGARETA AGERMAN, LARS HENRIK ANDERSSON, INGVAR LINDQVIST and MARGARETA ZACKRISSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The liquidus curves have been studied for mixtures between each of the solutes $(CH_3)_4NCl$, $(C_2H_5)_4NCl$, $SnCl_4$, $SbCl_5$ and the solvents $AsCl_3$, $POCl_3$, $SeOCl_2$ and also for mixtures between the solvents. The following new compounds have been found: $(CH_3)_4NCl \cdot 5\ SeOCl_2$, $(CH_3)_4NCl \cdot 3\ SeOCl_2$, $(CH_3)_4NCl \cdot 2\ SeOCl_2$, $(C_2H_5)_4NCl \cdot 5\ SeOCl_2$, $(C_2H_5)_4NCl \cdot 2\ AsCl_3$, $3(C_2H_5)_4NCl \cdot 5AsCl_3$ and $POCl_3 \cdot AsCl_3$. The results are briefly discussed.

The reactions in non-aqueous ionising solvents have attracted much interest during recent years. The chemistry in arsenic trichloride, $AsCl_3$, phosphorus oxychloride, $POCl_3$, and selenium oxychloride, $SeOCl_2$, has recently been reviewed by Gutman [1,2] who mentions the fact that compounds between solute and solvent (solvates) often may be isolated. It has been pointed out by Lindqvist [3] that the knowledge of the structures of the solid solvates is necessary for any detailed discussion of solubility and solvation conditions in these solvents. We have therefore made a survey of the binary systems between some important solutes and the three solvents $AsCl_3$, $POCl_3$ and $SeOCl_2$. This study has partly confirmed earlier results, partly led to isolation of new compounds.

EXPERIMENTAL

Chemicals used. $AsCl_3$ was purified as described earlier [4] with final conductances of $0.9-1.1 \times 10^{-7}$ ohm^{-1} cm^{-1} at room temperature. $POCl_3$ was purified by distillation (boiling point +105°C). $SeOCl_2$ (B.D.H. reagents) with a conductance of 8×10^{-4} ohm^{-1} cm^{-1} at +22°C was not further purified. $SnCl_4$ and $SbCl_5$ were purified according to Dodd and Robinson [5]. $(CH_3)_4NCl$ (Eastman Kodak) was dried for 12 h at 110°C. Crude $(C_2H_5)_4NCl$ was recrystallised from acetone and dried at reduced pressure in a drying pistol at 100°C.

Analytical methods. Cl was determined by potentiometric titrations with 0.1 M $AgNO_3$. N was determined by Kjeldahl distillation. Se was analysed by reduction with sulfurous acid in hydrochloric acid solution [6]. P was determined according to a method given by Scheel [7].

Phase diagrams. The aim of the phase diagram studies has not been to obtain highly accurate data but rather to make a survey of the liquidus curves in the different binary

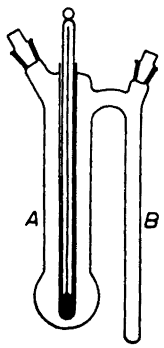

Fig 1

Fig. 1. Vessel for the phase diagram studies.

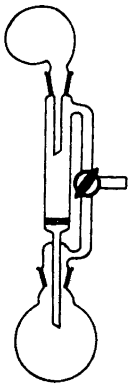

Fig 2

Fig. 2. Apparatus for the analysis.

systems, particularly for large mole fractions of solvent. A rather simple apparatus could therefore be used for these experiments (Fig. 1). With liquid solutes, the solute and solvent are poured or directly distilled into either of the two legs *A* or *B* which have been cooled to −50°C. The amount added to the *A* part has first been weighed and as the *B* tube has been calibrated, the volume of liquid transferred from *B* to *A* during the experiments can be determined (as well as the weight, because the densities are known). Solid solute is added in weighed amounts to the solvent in *A*. The error in the mole fractions obtained in this way is mainly due to adherence of liquid to the glass walls during the transfer from *B* to *A* or to vapor phase reactions, but the accuracy is good enough for our purposes. The thermometer does not dip directly into the liquid (which would have increased the difficulties of working in a closed system) but the thermal contact is improved by a small mercury drop at the bottom of the inner tube. Tests have shown that the reproducibility of the temperature reading is within ±1°. The temperature values may, however, have systematic errors of 2—3° which is of no importance in this type of study (compare also the good agreement with the results of more elaborate measurements). The results are not sensitive to small impurities if the solvates formed have congruent melting points, that is when the reactants completely crystallise as solids.

The analyses were made in an apparatus (Fig. 2) which permitted filtration and washing of the crystals formed. The crystals were then dissolved on the filter in an alkaline water solution and their mole ratios could be determined by analyses. Absolute analyses of weighed amounts of the solvates were also made in some cases but are difficult to carry out because of the extreme sensitivity of these compounds to moisture.

When our investigation was finished, we were informed by Dr. Gutmann, Vienna, of a thesis by Groeneveld, Leyden. Groeneveld has already studied three of our systems: $SnCl_4-POCl_3$, $SbCl_5-POCl_3$ and $SnCl_4-SeOCl_2$ with a more elaborate experimental technique. His phase diagrams, which have never been published, are in very good agreement with ours. The melting points he obtained for the solvates are given together with our results for comparison in the following. The good agreement proves that the very simple and rapid technique used by us was adequate for our purposes.

RESULTS

Tetramethyl ammonium chloride, $(CH_3)_4NCl$

1. $(CH_3)_4NCl \cdot AsCl_3$ and $(CH_3)_4NCl \cdot 3\ AsCl_3$ have been prepared earlier [8,9]. Part of the phase diagram has now been studied (Fig. 3 *a*) and no higher

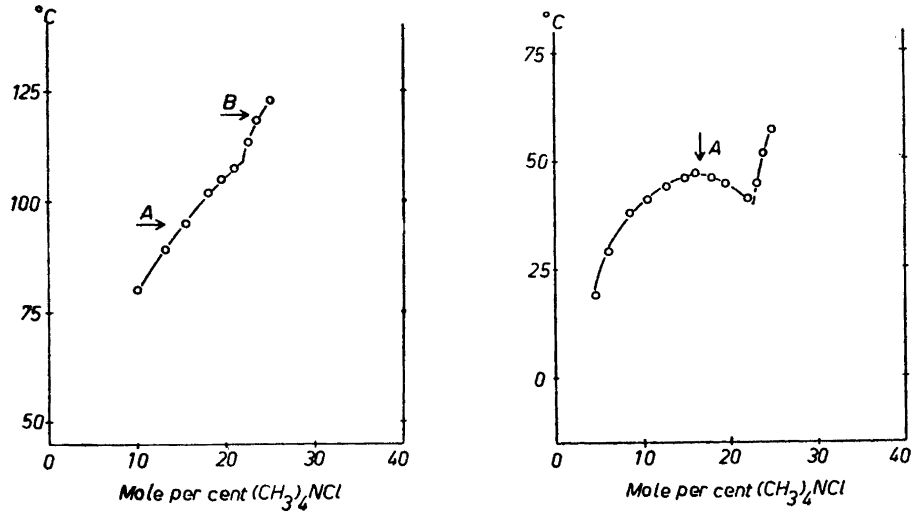

Fig. 3. a. The system $(CH_3)_4NCl-AsCl_3$. Liquidus curves for $A = (CH_3)_4NCl \cdot 3AsCl_3$, $B = (CH_3)_4NCl \cdot AsCl_3$. *b.* The system $(CH_3)_4NCl-SeOCl_2$. Liquidus curve for $A = (CH_3)_4NCl \cdot 5SeOCl_2$.

solvates have been discovered. Mole fractions of $(CH_3)_4NCl$ larger than 0.25 cannot be studied because of the boiling of the solvent.

2. The solubility of $(CH_3)_4NCl$ in $POCl_3$ is very small below + 200°C and does not permit a phase study of this type. (Gutmann [10] found 2 g/l at +20°C corresponding to a mole fraction of 0.0016.)

3. The phase diagram (Fig. 3 *b*) $(CH_3)_4NCl - SeOCl_2$ shows a maximum at the composition $(CH_3)_4NCl \cdot 5\ SeOCl_2$ where the entire liquid phase solidifies. The melting point is +45—47°C. The analysis of this compound is very difficult to carry out accurately, because the crystals lose $SeOCl_2$ when washed with, *e.g.*, ether, and small amounts of liquid adhere to the solid without being washed. The position of the maximum has, however, been studied by direct comparison of the melting points of different accurately weighed mixtures of solute and solvent.

The white residue obtained after washing with a small amount of ether had the composition $(CH_3)_4NCl \cdot 3\ SeOCl_2$. Mole ratio N : Se : Cl calculated 1 : 3 : 7, found 1.00 : 3.04 : 7.01. A thorough washing with ether gave a compound $(CH_3)_4NCl \cdot 2\ SeOCl_2$. Mole ratio N : Se : Cl calculated 1 : 2 : 5, found 1.00 : 2.01 : 5.00. In the latter case an absolute analysis proved that no ether had entered the solid compound. Calculated for N : 3.17 %, found 3.17 %.

The two compounds $(CH_3)_4NCl \cdot 2\ SeOCl_2$ and $(CH_3)_4NCl \cdot 3SeOCl_2$ could not be obtained by cooling of solutions of $(CH_3)_4NCl$ in $SeOCl_2$ because these solutions become very viscous and are always supercooled at mole fractions of $(CH_3)_4NCl$ larger than 0.25.

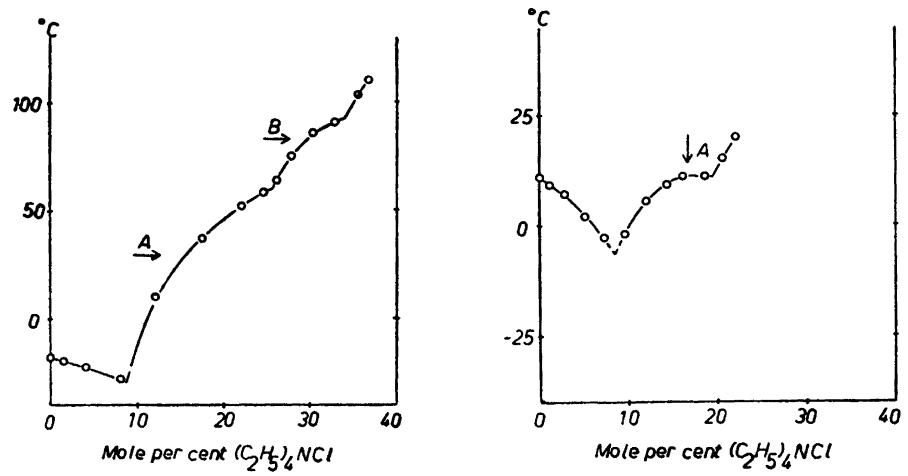

Fig. 4. a. The system $(C_2H_5)_4NCl$-$AsCl_3$. Liquidus curves for $A = (C_2H_5)_4NCl \cdot 2AsCl_3$, $B = 3(C_2H_5)_4NCl \cdot 5AsCl_3$. *b.* The system $(C_2H_5)_4NCl$-$SeOCl_2$. Liquidus curve for $A = (C_2H_5)_4NCl \cdot 5SeOCl_2$.

Tetraethyl ammonium chloride, $(C_2H_5)_4NCl$

1. The phase diagram is shown in Fig. 4 *a*. No congruently melting compounds are obtained in the concentration range studied and the compositions of the phases in equilibrium with the solution have been determined by distillation at reduced pressure at different temperatures. The same method has been used earlier [10] in the study of the compounds between $(CH_3)_4NCl$ and $AsCl_3$. We started with a dilute solution of $(C_2H_5)_4NCl$ in $AsCl_3$ and distilled at 0°C until the weight was constant. The mole ratio $AsCl_3$: $(C_2H_5)_4NCl$ was then 2.06 in agreement with a compound $(C_2H_5)_4NCl \cdot 2AsCl_3$. The temperature of the distillation was then increased to + 22°C when more $AsCl_3$ was lost until the mole ratio became 1.69 in agreement with a compound $3(C_2H_5)_4NCl \cdot 5AsCl_3$. This is no definite proof that these formulae are correct but this system has shown such interesting features that we plan a more detailed study of it.

2. The solubility of $(C_2H_5)_4NCl$ in $POCl_3$ below + 200°C is very low and does not permit a phase study of this type.

3. The phase diagram $(C_2H_5)_4NCl$—$SeOCl_2$ is shown in Fig. 4 *b*. Here the same obstacles to accurate analysis are encountered as in the case of $(CH_3)_4NCl$ but the phase diagram indicates a compound with the composition $(C_2H_5)_4NCl \cdot 5SeOCl_2$. Its melting point is +11—12°C so that the compound cannot be isolated at room temperature and no ether washings have been made.

At mole ratios larger than 0.22 it is impossible to determine the melting points with any accuracy with our methods.

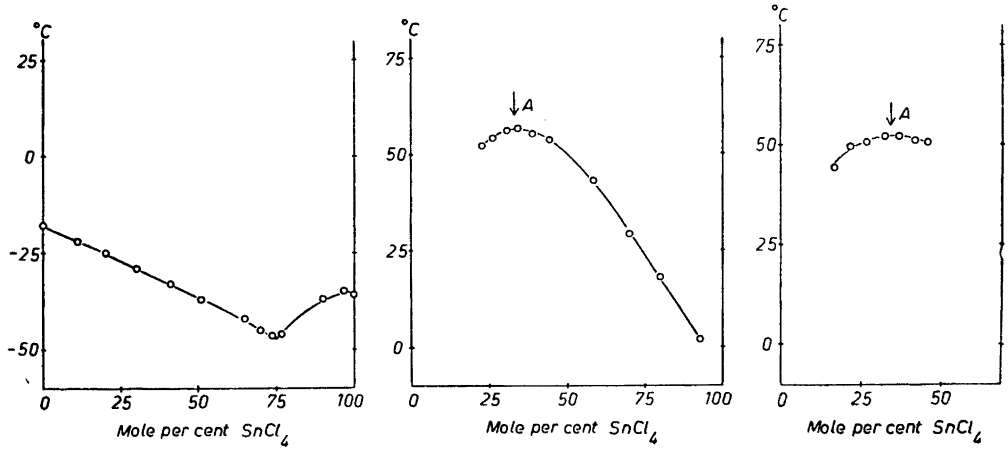

Fig. 5. a. The system $SnCl_4$—$AsCl_3$. *b.* The system $SnCl_4$—$POCl_3$. Liquidus curve for $A = SnCl_4 \cdot 2POCl_3$. *c.* The system $SnCl_4$—$SeOCl_2$. Liquidus curve for $A = SnCl_4 \cdot 2SeOCl_2$.

Tin tetrachloride, $SnCl_4$

1. The phase diagram, given in Fig. 5 *a*, does not indicate any compound formation.

2. The phase diagram $SnCl_4$—$POCl_3$ (Fig. 5 *b*) has only one, well defined maximum corresponding to the compound $SnCl_4 \cdot 2POCl_3$ with a melting point of +55—57°C (Groeneveld 56°C). Three compounds have earlier been described: 2 $SnCl_4 \cdot POCl_3$ by Oddo and Tealdi [11], $SnCl_4 \cdot POCl_3$ and $SnCl_4 \cdot 2\ POCl_3$ by Gutmann [12] who, however, did not definitely prove the existence of a definite compound $SnCl_4 \cdot 2\ POCl_3$. The existence of that solvate was proved by Payne [13] who found a melting point of $+59 \pm 0.5$°C. The compound $SnCl_4 \cdot POCl_3$ was obtained by Gutmann from $SnCl_4 \cdot 2\ POCl_3$ at low pressure. It is evident that it does not exist in the closed system which we have studied, nor does 2 $SnCl_4 \cdot POCl_3$.

3. The phase diagram (Fig. 5 *c*) shows the existence of a compound $SnCl_4 \cdot 2\ SeOCl_2$ with a melting point of +52°—54°C (Groeneveld $\sim$ 52°C). The system could not easily be studied for mole fractions of $SnCl_4$ larger than 0.50 because of the formation of two liquid phases. $SnCl_4 \cdot 2\ SeOCl_2$ has already been reported by Wise [14].

Antimony pentachloride, $SbCl_5$

1. The phase diagram $AsCl_3$—$SbCl_5$ (Fig. 6 *a*) does not show any indication of compound formation. Gutmann [8], however, obtained a small residue of the approximate composition $AsCl_3 \cdot SbCl_5$ by evaporation *in vacuo* at +30—35°C. That compound obviously must be the result of a slow irreversible reaction.

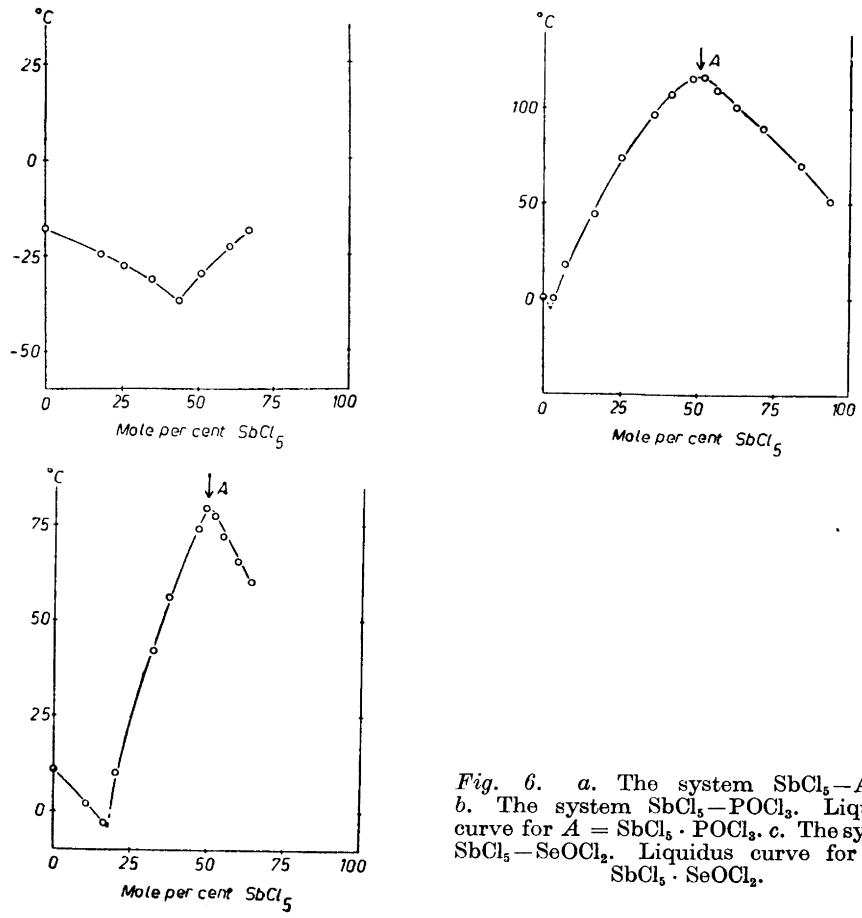

Fig. 6. a. The system $SbCl_5$—$AsCl_3$. *b.* The system $SbCl_5$—$POCl_3$. Liquidus curve for $A = SbCl_5 \cdot POCl_3$. *c.* The system $SbCl_5$—$SeOCl_2$. Liquidus curve for $A = SbCl_5 \cdot SeOCl_2$.

2. The phase diagram $SbCl_5$ — $POCl_3$ (Fig. 6 *b*) confirms the existence of the compound $SbCl_5 \cdot POCl_3$, earlier described by Weber [15] and Gutmann [12]. The melting point is +115—117°C (Groeneveld 117°C). The statement by Gutmann that the compound is not soluble in $SbCl_5$ is not in agreement with our results.

3. The phase diagram $SbCl_5$—$SeOCl_2$ (Fig. 6 *c*) shows the existence of only one compound, $SbCl_5 \cdot SeOCl_2$, with a melting point of +79—80°C. Weber [15] has already described the same solvate but Wise [14] found $SbCl_5 \cdot 2\ SeOCl_2$, the existence of which we have not been able to confirm.

Binary systems between the solvents

1. We have also studied the binary systems between the solvents. Fig. 7 *a* shows the system $POCl_3$—$AsCl_3$. The existence of a compound $AsCl_3 \cdot POCl_3$ with a melting point of —23—25°C has definitely been established.

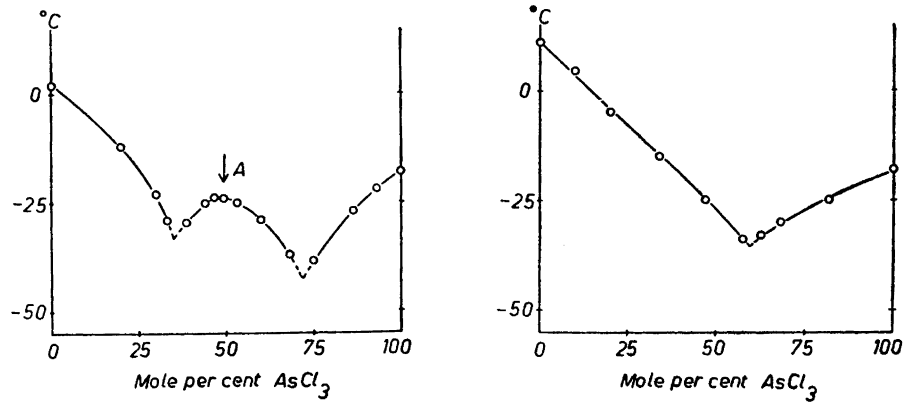

Fig. 7. a. The system $AsCl_3$—$POCl_3$. Liquidus curve for $A = AsCl_3 \cdot POCl_3$. *b.* The system $AsCl_3$—$SeOCl_2$.

2. The system $AsCl_3$—$SeOCl_2$ (Fig. 7 *b*) does not show any indications of compound formation.

3. When $SeOCl_2$ and $POCl_3$ are mixed a yellowish insoluble precipitate is formed after some hours at low mole fractions of $POCl_3$; immediately at mole fractions larger than 0.35—0.45. The composition of this precipitate corresponds to a formula $3\ SeOCl_2 \cdot 2POCl_3$ (calculated mole ratio P: Se: Cl = 2 : 3 : 12, found 2.00 : 3.04 : 11.94). When we tried to determine the melting point, part of the compound formed a red-brown vapour at about + 170°C quite like $SeCl_4$. We could not definitely ascertain whether a compound had formed or not, but we decided that a chemical reaction $3\ SeOCl_2 + 2\ POCl_3 \rightarrow 3\ SeCl_4 + P_2O_5$ had probably taken place. $SeCl_4$ and P_2O_5 are both almost insoluble in $SeOCl_2$ as well as in $POCl_3$. The reaction therefore would always lead to a product of the approximate composition $3\ SeOCl_2 \cdot 2\ POCl_3$ or $3\ SeCl_4 \cdot P_2O_5$.

The stability of solutions of $SbCl_5$ in $SeOCl_2$

The findings in the preceding section open the question of whether solutions in $AsCl_3$, $POCl_3$ and $SeOCl_2$ are stable or only metastable.

We have made one experiment to investigate this problem further. Sb_2O_5 and $SeCl_4$ were mixed in an ampoule, which was sealed (but not evacuated). After one day the mixture looked wet and the colour had become red-brown. When heated to +60°C it partly melted, as would be expected if the reaction $Sb_2O_5 + 5\ SeCl_4 \rightarrow 2\ SbCl_5 + SeOCl_2$ had taken place. This experiment strongly indicates that at least the solution of $SbCl_5$ in $SeOCl_2$ is a stable solution.

DISCUSSION

We do not want to make any far-going theoretical speculations based on this investigation but a few observations in connection with the present study may be summarised:

1. The behaviour of $POCl_3$ is quite different from $AsCl_3$ and $SeOCl_2$ in reactions with $(CH_3)_4NCl$ and $(C_2H_5)_4NCl$. These two salts have a very low solubility in $POCl_3$ (of a different order than in $AsCl_3$ and $SeOCl_2$) and give no solvates. This indicates that the solvation energy of Cl^- is smaller in $POCl_3$ than in $AsCl_3$ and $SeOCl_2$. Using the acid-base concept suggested by Gutmann and Lindqvist [16] this means that $POCl_3$ is a weaker acid than $AsCl_3$ and $SeOCl_2$.

2. $AsCl_3$ reacts with $SnCl_4$ and $SbCl_5$ quite unlike $POCl_3$ and $SeOCl_2$. The latter solvents form congruently melting solvates but $AsCl_3$ gives only eutectic mixtures (the compound $SbCl_5 \cdot AsCl_3$ can be prepared only under special conditions). In a previous paper [17] on the reactions in solutions of $POCl_3$ the reasons for the difference have been discussed.

3. $(CH_3)_4NCl$ is less soluble than $(C_2H_5)_4NCl$ in these solvents. (KCl has a still smaller solubility.) It would be interesting to study quaternary ammonium salts with larger cations to see how far the solubility increases with the cation radius.

This work has been supported by a grant from the *Swedish Natural Science Research Council* which is here gratefully acknowledged. We also wish to thank Professor G. Hägg for all facilities put at our disposal and Mr. N. Larsson for valuable help with the glass blowing.

Ultra-microsynthesis of 5-Halogeno-derivatives of Uracil

GÖSTA EHRENSVÄRD, JAN LILJEKVIST, KLAUS MOSBACH

Department of Biochemistry, University of Lund, Sweden

and PER FRITZSON

Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway

A method for preparation of 5-iodo-uracil has been worked out in ultra-micro-scale enabling the use of commercial ^{131}I at very high specific activity for the synthesis of 5-^{131}I-uracil in microgram quantities.

The demonstration that 5-bromouracil could be introduced into the deoxyribonucleic acid (DNA) of some microorganisms, especially *Escherichia coli*, replacing up to 50 % of thymine units [1,2], has now been extended to comprise 5-chloro- and 5-iodouracil [3,4]. With regard to relative rate of incorporation of the latter thymine analogues, Zamenhof *et al.*[4] have found that 5-chlorouracil may replace 21 % of thymine units, 5-iodouracil 14 %, whereas no introduction of uracil itself could be demonstrated. These observations are of considerable interest in view of the possibility of introducing 5—^{131}I-uracil into the DNA-structure in order to study the consequences of the subsequent nuclear decay ^{131}I—^{131}Xe *in situ*. This procedure might open up a new way of altering the chemical structure of DNA with the definite possibility of replacing some thymine-units by uracil, resulting from the decay of 5—^{131}I-uracil. More detailed reports with regard to the general chemical aspect of this decay reaction will be published later.

In view of the fact that 1 Curie of ^{131}I corresponds to 7.7 μg of the pure element, the synthesis of substantial amounts of 5—^{131}I-uracil with a minimum of diluting non-radioactive iodine has to be carried out in ultramicroscale. The following procedure has given up to 80 % yields of 5-iodouracil from 5 μg and less of uracil in the presence of an equivalent amount of iodine.

In principle the method is based on iodination of uracil in 0.02 M phosphate buffer at pH 7.5. Iodine is administered to the reaction mixture as a KI-solution, and liberated as iodine by the addition of an equivalent amount of chlorine in an aqueous solution. After completion of the reaction the products formed are separated by paper chromatography in a butanol-water system. In order to check the yield of 5-iodouracil and the amount and distribution of non-iodocompounds formed during the reaction, we have utilized uracil-6-^{14}C of high specific activity as the starting material, integrating the activity distributed of spots along the chromatogram. By this way, amounts down to 0.02 μg could be determined with a fair degree of accuracy. Fig. 1 gives a picture of the distribution of reaction products from a run with uracil-6-^{14}C and non-radioactive iodine as starting material, as compared with non-radioactive uracil and ^{131}I as reaction partners. With regard to the latter combination ^{131}I was

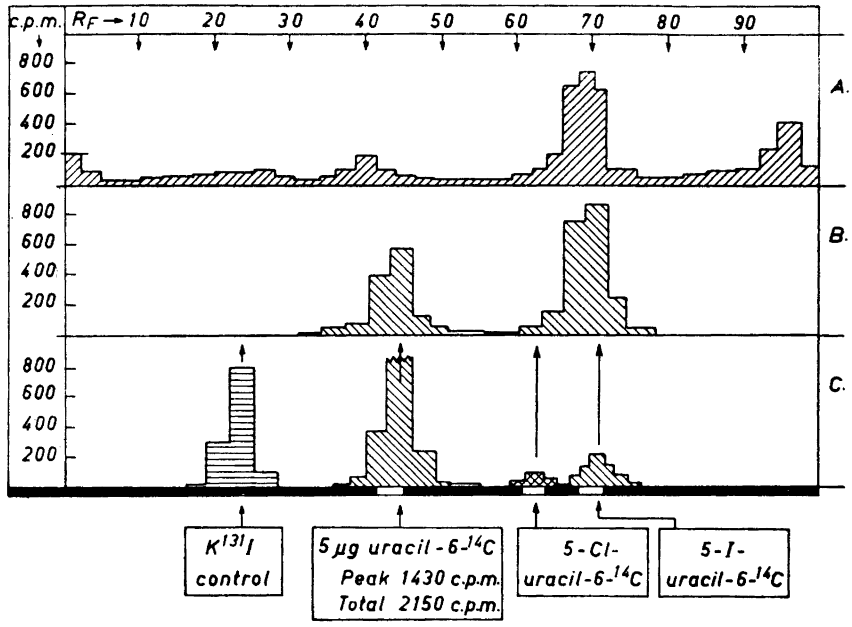

Fig. 1. Diagrammatic representation of the result of iodination of uracil in microgram quantities.

A: Iodination of non-labelled uracil with ^{131}I in tracer amounts followed by chromatographic separation of reaction products on a paper strip in butanol-water. Determination of radioactivity on sections of the paper strip gives a measure of the relative amounts of reaction products. Ordinate: counts per minute; abscissa: R_F-values.

B: Analogue experiment with uracil-6-^{14}C and non-radioactive iodine. The peak of 5-iodouracil corresponds to that of series A.

C: Controls, showing the position of K^{131}I, uracil-6-^{14}C, 5-chlorouracil-6-^{14}C and 5-iodouracil-6-^{14}C. The position of controls in substantial amounts of the three last compounds are shown as white regions in the black base-line, the determination being based on photography in UV-light.

used in tracer amounts during the working out of optimum conditions for the synthesis. The preliminary runs were carried out with uracil-6-^{14}C and non-radioactive iodine.

As seen from Fig. 1 the peak of activity corresponding to 5-I-uracil-6-^{14}C coincides with that of 5-^{131}I-uracil. Both are clearly separated from uracil, as was also verified by parallel controls of substantial amounts of uracil and 5-iodouracil (indicated by photography in UV-light at 254 mμ). With regard to the possible formation of small amounts of 5-chlorouracil a separate control with 5-chlorouracil-6-^{14}C indicates a fair separation from 5-iodouracil-6-^{14}C. In the experiments with ^{131}I we observed, in addition to the peak corresponding to 5-iodouracil, four other peaks of lower activity. Two of them have been found to correspond to KI and iodine, one remains at the starting line of the chromatogram and one follows the locus of uracil. None of the peaks, however, interferes with the locus of 5-iodouracil of $R_F = 0.68 - 0.72$.

EXPERIMENTAL

Uracil-6-^{14}C was prepared according to Fritzson [5]. It gave when chromatographed in 1 μg amounts on paper in butanol-water a total count of 600 cpm per spot. It contained 2 % 5-bromouracil.

^{131}I, as was used in these experiments, was derived from a tellurium source, together with some amounts of shortlived iodine isotopes, mainly ^{132}I. By the ordinary procedure of aeration of the tellurium solution the iodine was driven off and absorbed in a solution of 72.5 μg KI in 2.5 ml of 0.02 M phosphate buffer, pH = 7.5.

As a standard procedure, the following reagents were introduced into a 2 ml test tube, which could be attached to a small condensor by a standard glass joint. First 500 μl of a 0.02 M phosphate buffer solution, pH 7.5, containing 14.5 μg KI was added to the reaction tube, followed by 5—10 μl of a freshly made and standardized solution containing 3.5 μg of chlorine and 5 μg of uracil in 25 μl of water. The condenser was then attached to the tube and the mixture was immediately heated to gentle boiling on a micro-heating stage for 5 min. After cooling to room temperature another addition of chlorine was made, corresponding to 1.7 μg, followed by another 5 min period of heating. After cooling the reaction mixture was evaporated as a small spot on a paper strip, 23 mm wide, about 10 cm from one end. Whatman No. 1 paper was used, and the chromatogram run in a descending system of butanol saturated with water at 22°C for 18 h. Suitable controls of uracil-6-C, 5-I-uracil-6-^{14}C, ^{131}KI were made for the exact localization of the iodouracil from the reaction mixture.

After localization, by radioactivity measurement of controls, of the region containing the iodouracil formed, this region could be quantitatively eluted by 0.01 N HCl and almost quantitatively by water. Controls run in 20 μg scale show the exact UV absorbtion curve of 5-iodouracil, with an E_{max} at 283 mμ and E_{min} at 246 mμ. Table 1 gives the absorption maxima and minima for uracil and some of its halogen—derivatives (solvent: 0.01 N HCl) obtained in this laboratory.

Compound	λ_{max}	λ_{min}
Cl-uracil	273	239
Br-uracil	273	240
I-uracil	283	246
Uracil	260	228

The preparation of 5-bromouracil could be carried out as a simple variation of the procedure outlined above; the yields were about 50 %.

With regard to the preparation of 5-^{131}I-uracil using substantial amounts of ^{131}I in high concentration, adequate shielding should be used; 5 cm of lead give sufficient protection. The above method is suitable for the direct use of commercial solutions of ^{131}I in phosphate buffer for the reaction. Utilizing uracil-6-^{14}C of the highest possible activity together with substantial amounts of ^{131}I, the resulting 5-^{131}I-uracil-6-^{14}C could be used for the study of the nature of non-iodinized derivatives related to uracil, as formed in the course of the decay $^{131}I \rightarrow {}^{131}Xe$.

The State of Order in Cellulose as Revealed from X-Ray Diffractograms

JON GJÖNNES, NICOLAI NORMAN and HENRY VIERVOLL

Central Institute for Industrial Research, Oslo, Norway

A comparison has been made between the diffracted X-ray intensity from samples of cellulose and synthetized intensity curves, and it is shown that much more of the X-ray scattering from cellulose can be ascribed to crystalline reflexions than previously done. Thus the recorded intensity from samples of cellulose I (native) to a fair degree of approximation can be explained without introducing the concept of amorphous cellulose. For cellulose II(regenerated) the diffractograms can not be considered built up exclusively of crystalline reflexions, though also here the difference in cellulose qualities more seems to lie in the degree of perfection of the best ordered part of the samples than in different amounts of crystalline and amorphous material.

Several investigations have been carried out in order to determine the degree of order or crystallinity in high polymers by means of X-ray diffraction [1-3]. The methods are based upon a splitting of the coherent intensity in crystalline peaks and a continous background which is ascribed to an amorphous fraction of the sample. The coherently diffracted radiation is consequently interpreted as the sum of intensity scattered from crystalline material and from amorphous material .

The essential point in crystallinity measurements by X-ray methods has been the separation of the intensity into these two components. For substances like polyethylene where the crystalline reflexions are clearly superimposed upon a background due to the scattering from the solidified melt [2], the separation is simple and unambiguous. In the diffraction pattern for cellulose the crystalline reflexions are very broad and partly overlap. Consequently the drawing of a curve separating the two intensities is more difficult. In the procedures used by Hermans [1] and by Ellefsen, Wang Lund, Tönnesen and Öien [3] this curve touches the total intensity curve, implying that the coherent scattering from the crystalline fraction is set equal to zero at the corresponding Bragg angles.

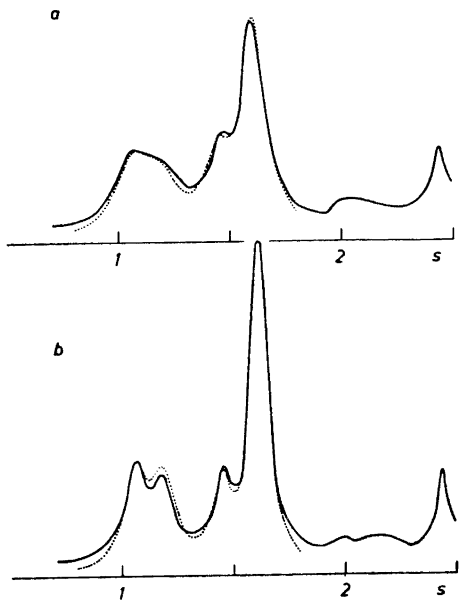

Fig. 1. Experimental (full-line) and synthetized (dotted) intensity curves for cellulose I.
a. Acetate grade wood pulp
b. Sulphuric acid treated surgical cotton

It is well known that small particle size and lattice distortion will cause a broadening of the peaks in the diffractogram, involving a general rise in background due to superposition of the tails of the lines. For cellulose the lines are very broad presumably due to both these factors. It is thus reasonable to believe that the lines may give a considerable contribution to the background in the diffractograms. In order to evaluate how far the description based on crystalline reflexions may fit the experimental data, a comparison has been made between experimental intensity curves and synthetized curves based on a limited number of crystalline reflexions.

THE EXPERIMENTAL AND SYNTHETIZED CURVES

Powder diffractograms of unoriented samples of cellulose were obtained in a Guinier vacuum camera with Cu$K\alpha$-radiation. The intensity curves were corrected for absorption and polarization and normalized to the background of incoherent and structure independent coherent scattering from a glucose unit [4]. After normalization the incoherent scattering was subtracted.

In the calculated intensity curves the crystalline peaks were supposed to have the shape of a Cauchy distribution:

$$I(s) = K \frac{\alpha}{\alpha^2 + (s - s_0)^2}$$

Here $s = 4\,\pi \sin \Theta/\lambda$, s_0 is the peak abscissa, and 2α the half width of the peak. K is a constant that depends on the structure factor of the reflexion. A characteristic feature of the Cauchy distribution is the long tails which was one reason why this function was chosen for cellulose. The Cauchy line profile has been observed for the reflexions of cold worked metals [5], and a study of the diffractograms of cellulose in fact seems to confirm that the well resolved peaks to a fair degree of approximation can be represented by Cauchy distributions.

The position of the lines were determined from the experimental intensity curves, and these curves were further used in the estimation of half widths. Since the structure factors for cellulose are not well known, the values of K also had to be evaluated from the measurements.

In the calculations only the reflexions (1 0 1), (1 0 $\bar{1}$), (0 2 1) and (0 0 2) for cellulose I and (1 0 1), (1 0 $\bar{1}$) and (0 0 2) for cellulose II were considered.

RESULTS

Four different qualities of cellulose I (native) and cellulose II (regenerated) were investigated. The full-line curves in Fig. 1, *a* and *b*, show the corrected intensity from an acetate grade wood pulp and a sulphuric acid treated surgical cotton, respectively. The dotted curves represent the calculated intensity based on the values of s_0, K and 2α in Table 1. In the same way the experimental and calculated intensity curves for the two samples of cellulose II are given by the full-line and dotted curves in Fig. 2. Curve *a* corresponds to an acetate grade wood pulp mercerized in 18 % sodium hydroxide, curve *b* to acetate grade wood pulp treated with 39 % hydrochloric acid. The values of the parameters are found in Table 2.

DISCUSSION

In its broad features the agreement between experimental and calculated intensities in Figs. 1 and 2 up to $s = 1.7$—1.8 is satisfactory. Above this value of s it is easy to obtain a good fit because of the large number of reflexions. There also exist crystalline reflexions below $s = 1.7$ which are not taken into consideration in the calculations and which would add to the theoretical

Table 1. Parameters used in the calculation of intensity curves for cellulose I.

Reflexion	s_0	K	2α	
			Wood pulp	Cotton
1 0 $\bar{1}$	1.06	25	0.20	0.12
1 0 $\bar{1}$	1.18	25	0.21	0.13
0 2 1	1.45	18	0.13	0.09
0 0 2	1.61	66	0.14	0.10

* Fig. 2 a, ** Fig. 2 b

intensity distribution and bring out a better fit between experimental and synthetized curves.

Fig. 1 shows a good correspondance between experimental and calculated intensity curves. This seems to indicate that the greater part of the investigated samples of cellulose I very likely consists of aggregates of distorted crystallites, and that only small quantities of highly disordered material are present.

For cellulose II the case is somewhat different. The background, especially in the region between the (1 0 1) and (1 0 $\bar{1}$) lines in Fig. 2, can not be explained

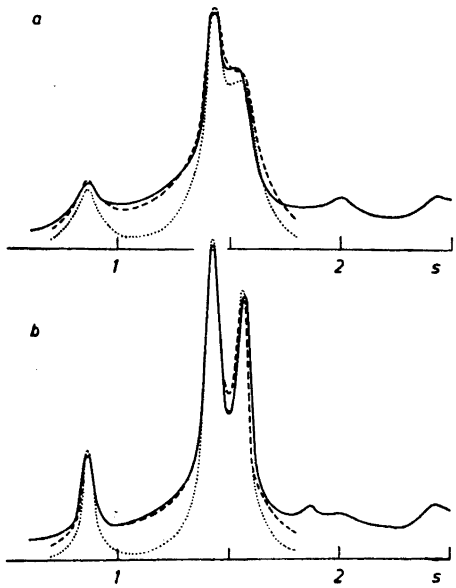

Fig. 2. Experimental (full-line) and synthetized (dotted) intensity curves for cellulose II. The broken curves correspond to synthetized intensities including an amorphous background.

b. Acetate grade wood pulp treated with 39 % hydrochloric acid.

Table 3. Computed values for the degree of amorphity by the method of Ellefsen, Wang Lund, Tönnesen and Öien [3].

Modification	Sample	Degree of amorphity %
Cellulose I	Acetate grade wood pulp	47
» I	H_2SO_4-treated surgical cotton	38
» II	Acetate grade wood pulp merc. in 18 % NaOH	57
» II	Acetate grade wood pulp treated with 39 % HCl	51

exclusively as due to the outer parts of the crystalline reflexions of the assumed shape, even if the unresolved (0 2 0) peak at $s_0 = 1.22$ is added. It is also seen that the half widths of the peaks are considerably smaller than those obtained for cellulose I. Both these facts suggest that the cellulose II samples to a higher extent than the samples of cellulose I are separable into fractions with widely different states of order. These may well include an amorphous one, corresponding to the dry ground cellulose defined as amorphous cellulose by Ellefsen *et al.*[6]

From the broken curves in Fig. 2 *a* and *b* it is seen that a better correspondance between experimental and calculated intensity curves can be obtained when an amorphous background is added to the theoretical intensity. These curves represent the superposition of scattering curves from dry ground samples of cellulose and the calculated intensities given by the dotted curves of the same figure. The ordinates were reduced to fit the estimated contents of crystalline material. The broken curves in Fig. 2 *a* and *b* both correspond to 40 % amorphous material. For the same samples the method of Ellefsen *et al.*[3] led to the values 57 % and 51 %, respectively (Table 3). It should be mentioned that the adding of an amorphous background also can improve the agreement between experimental and calculated intensity curves for cellulose I, and that a value around 5 % seems to give the best fit for both samples.

CONCLUSION

The present paper shows that it is possible to obtain good correspondance between experimental intensity curves and synthetized curves based on the sum of broad crystalline reflexions and an amorphous background. This superposition of intensities does not necessarily correspond to the true state of order in the sample. However, if a separation of the observed intensity into two components is carried out, it should be kept in mind that a considerable part of the background in the diffractogram is due to the crystalline peaks.

It should be pointed out that for samples of the same modification of cellulose, the difference in state of order seems to lie more in the degree of perfection of the best ordered fraction than in the ratio between this fraction and

the less ordered one. This is clearly illustrated in Fig. 2 where the calculations led to the same amount of amorphous material for the two samples, although the diffractograms show marked differences. These differences are expressed in the half widths used for computing the synthetized curves.

It is thus evident that any description of order or crystallinity in cellulose should take the intrinsic order of the crystallites into consideration. The half widths of the peaks here seem to be suitable parameters. Further experimental and theoretical work along this line is in progress.

This investigation is part of a research program on the structure of cellulose carried out by the Central Institute for Industrial Research and The Norwegian Pulp and Paper Research Institute. Financial support from the *Royal Norwegian Council for Industrial Research* is gratefully acknowledged.

Studies in the Determination of Silica

I. Spectrophotometric Determination of Silica as α-Silicomolybdate

LARS HENRIK ANDERSSON

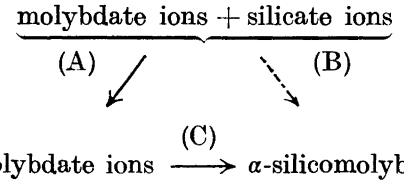
Dept. of Analytical Chemistry, Institute of Chemistry, University of Uppsala, Uppsala, Sweden

A modified silicomolybdate method is described, which is shown to be uninfluenced within wide limits by variables such as pH, molybdate and salt concentrations. The colour produced is stable for long periods of time, and extinction measurements are reproducible with good precision. The reason for these improved properties is that the stable α-silicomolybdate is used instead of the unstable β-compound.

Since the discovery in 1898 by Jolles and Neurath [1] that the reaction between silica and molybdate in water solutions to form yellow silicomolybdic acid could be used for analytical purposes, much work has been devoted to the study of this colorimetric method for silica determination. It was not until the introduction of accurate spectrophotometers, however, that more thorough investigations could be undertaken, and since about 1930 many papers dealing with the subject have been published. Despite this no definite solutions of the problems concerned have been presented, and as recently as 1952 Strickland [2] published a series of papers dealing with the preparation and properties of silicomolybdic acid. Stoll [3] and Lacroix and Labalade [4] had made more restricted experiments. The papers by Mellon [5], Mullin and Riley [6] and Arnfelt *et al.*[7] summarize and give references to the earlier literature as well as to more modern works.

Strickland's [2] most important contribution seems to be his discovery that silicomolybdic acid occurred in two forms, of which the one called β was more or less rapidly converted to the stable α-form under normal temperature and pressure. On the basis of his results he recommended the unstable β-form as suitable for analytical purposes.

Although almost all reactions involved in the formation of the silicomolybdic acids probably are very complicated, the following scheme will give a rough idea of the processes taking place in water solution:



It is not known if reaction (B) actually takes place. The molybdate as well as the silicate ions are to a certain degree polymerised, the degree of polymerisation varying with the composition of the solution. Lindqvist [8] gives the following scheme for the reactions occurring when a molybdate solution is acidified:

$$MoO_4^{2-} \rightarrow Mo_7O_{24}^{6-} \rightarrow Mo_8O_{26}^{4-} \rightarrow \text{larger complexes}$$

An attempt to study the influence of silicate polymerisation was made by Chow and Robinson [9].

In the present paper a few experiments with the earlier silicomolybdate method will be described, which show important drawbacks connected with it. After that a modified method is presented together with an investigation of the influences on that method of some important factors. Interferences from phosphorus, arsenic and germanium as well as from iron and aluminium and fluorine will be dealt with in later papers.

1. EXPERIMENTAL DETAILS

The chemicals used were of analytical grade. Distilled water for the preparation of solutions had not previously been in contact with glass, but was taken from a distillation apparatus with metal parts. All solutions were stored in polythene bottles. Ammonia solutions were prepared by dissolving tank ammonia in distilled water.

Two different preparations of silicic acid were used: one was a commercial chemical (Baker) and the other had been prepared from sodium silicate by a method similar to that used in the ordinary silica separation procedure. Both chemicals were analysed for their water contents by heating samples to constant weight in platinum crucibles, and for their silica contents by treatment with hydrofluoric and sulfuric acid, followed by heating to constant weight; the residues did not exceed 0.2 % of the amount SiO_2 taken.

The dissolution process was accomplished by fusion with Na_2CO_3 in a platinum crucible, and then digesting its contents with water in a platinum dish. In some cases the silicic acid was placed in a platinum dish together with 4 g NaOH and a few ml of water and dissolution carried out by heating on the steambath. However, solutions prepared in this last way always showed low values (by 1—2 %) compared with those prepared in the first way, which were therefore generally preferred.

Blank solutions were prepared in a manner similar to that used for the corresponding silica solutions. They were employed in the preparation of blanks and, when necessary, for diluting the standard silica solutions.

A Beckman model DU spectrophotometer, the cuvette compartment of which was maintained at a constant temperature (20.0°C unless otherwise stated), was used for all extinction measurements. The same set of three numbered cuvettes were used, the first being filled with distilled water, the second with the blank and the third with the coloured solution. A correction for their different optical properties was applied. The instrument was checked with respect to the wavelength scale (using a mercury lamp) and the extinction scale (using a K_2CrO_4 solution as described by Haupt [10]).

pH measurements were carried out with a Beckman model H 2 instrument using a glass electrode and a saturated calomel electrode. 0.05 M KH-phthalate (pH = 4.0) and 0.100 M HCl (pH = 1.1) were employed as reference solutions.

2. EXPERIMENTS WITH EARLIER METHODS

Previous methods have been tested with respect to certain variables and have turned out to be unsatisfactory in different ways. A desription of an experiment designed to furnish the extinction as a function of time at different NaCl concentrations in the solutions used will demonstrate an important property of the silicomolybdic acid system.

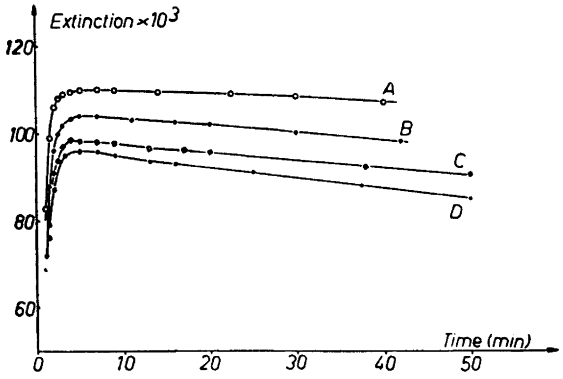


Fig. 1. Extinction-time dependence for earlier method with [NaCl] as a variable. A, [NaCl] = 0; B, [NaCl] = 0.4 M; C, [NaCl] = 0.8 M; D, [NaCl] = 1.2 M.

Of two 100 ml beakers, one was filled with 25 ml of a molybdate solution (0.04 M in Na_2MoO_4, pH = 1.5 with HCl) and the other with 25 ml of silica solution (8 mg Si/l, pH = 1.5 with HCl; appropriate amounts of NaCl added). The two solutions (20.0°C) were quickly mixed and the mixture transferred to a 1 cm cuvette. With the aid of two stopwatches, which were alternately stopped and started just at the instants the moving (the extinction was changing!) meter needle of the DU instrument indicated balance at a preset extinction value, the extinction as a function of time was obtained.

In Fig. 1 curves are given for different NaCl concentrations in the final solutions. It can be seen that the optical properties of the system are strongly influenced by NaCl additions. Actually the effect of salts containing divalent anions such as Na_2SO_4 is still more pronounced.

It follows from this and similar experiments with other salts that pH as well as molybdate concentration influences cannot be treated as independent variables and without reference to the salt content of the solutions. Factors which affect the composition of the final solution to be analysed for silica by this method must be carefully controlled.

3. A MODIFIED METHOD

If the reaction

$$\beta\text{-silicomolybdate} \rightarrow \alpha\text{-silicomolybdate}$$

is allowed to proceed completely to the right a stable yellow colour is obtained. At room temperature the reaction rate is comparatively low but is accelerated by salt additions. When the solution is heated on a steam bath the conversion is practically complete within about 3 h, the actual time being dependent on the composition of the solution in question. On this basis the following general procedure has been worked out which, with appropriate modifications, was used in the following experimental work unless otherwise stated.

The solution to be analysed is mixed with a molybdate solution in a polythene bottle and the bottle is placed on the hot steambath. After the appropriate time interval the bottle with contents is cooled to 20.0°C, transferred to a volumetric flask, made up to volume with water or a suitable solution and mixed. The extinction is measured against a blank which has been treated in an analogous way.

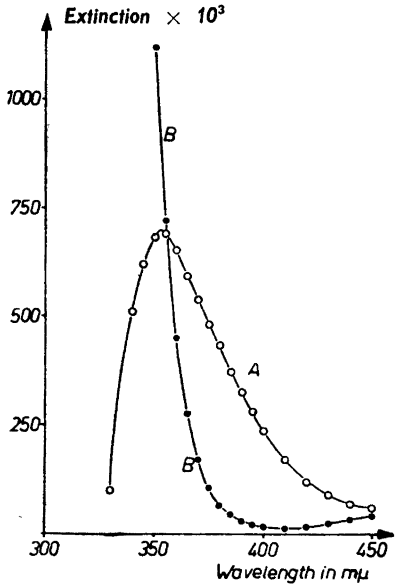

Fig. 2. Extinction as a function of wavelength. Curve A, α-silicomolybdate solution measured against the blank; B, blank measured against water.

Using this procedure the modified method was tested with respect to some important variables. Unless otherwise stated the solutions when heated on the waterbath have a volume of 20 ml, which is later diluted to the final volume, 25 ml.

3. 1. The extinction as a function of wavelength

The measurements were performed with solutions which when heated on the steambath were 0.25×10^{-3} M in Si and 0.05 M in Na_2MoO_4, with a pH of 1.5, adjusted with perchloric acid. The heating time was long enough to ensure a complete conversion to α-silicomolybdate.

In Fig. 2 is plotted the extinction-wavelength curve for α-silicomolybdate (A) and for the blank (B). The yellow complex has an extinction maximum at about 350 mμ, but at this wavelength the blank absorbs strongly. A longer wavelength should be chosen, where the blank absorbs little light compared to the solution containing silica. This is all the more necessary because the light absorption of acidified molybdate solutions depends on their pH, especially at shorter wavelengths [11]. At 400 mμ, a wavelength which has been found suitable for most purposes, the absorption due to the molybdate ion species is small and in practice independent of small pH fluctuations.

It is clear from Fig. 2 that at 400 mμ the rate of change of extinction with wavelength is numerically large. This has two consequences: it is necessary to control the wavelength setting carefully to obtain reproducible extinction values between different series of measurements, and good monochromatic light is necessary for a linear relationship between extinction and silica concentration. The corex filter supplied with the Beckman DU instrument should be used to eliminate scattered radiation.

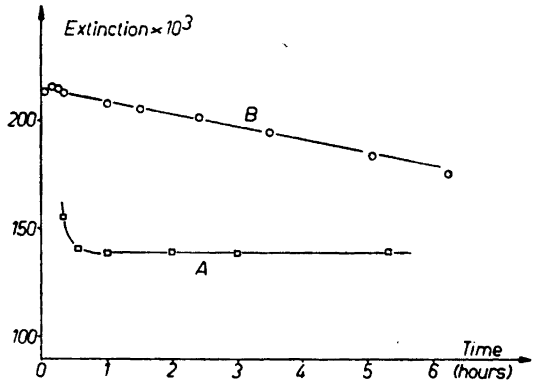

Fig. 3. Extinction-time dependence for solutions treated according to new procedure (curve A) and for solutions which have not been heated.

3.2. Extinction-time dependence

A number of solutions were prepared and put on the water-bath. They were 0.144 × 10^{-3} M in Si, 0.05 M in Na_2MoO_4 and had a pH value of 1.5, adjusted with perchloric acid. From time to time a bottle was withdrawn from the waterbath, its contents prepared according to the directions and the extinction measured. The result is shown in Fig. 3, curve A; curve B represents an identical solution which has not been heated.

The time within which a constant extinction value is obtained is subject to some variations in practice; three hours are usually enough, but solutions containing, *e.g.*, large amounts of silica seem to require a longer heating time, especially if the pH is low.

3.3. Dependence on pH and salt concentration

The solutions were the same as in 3.2, with the exception, that they contained different amounts of perchloric acid or in a few cases sulfuric acid.

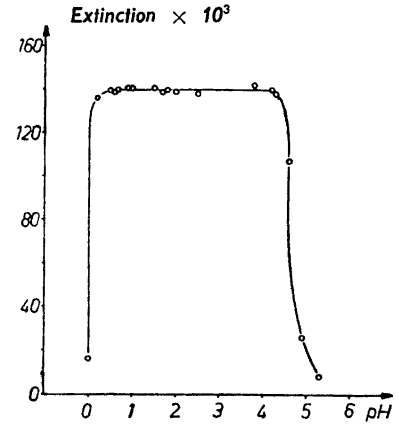

Fig. 4. Extinction as a function of pH.

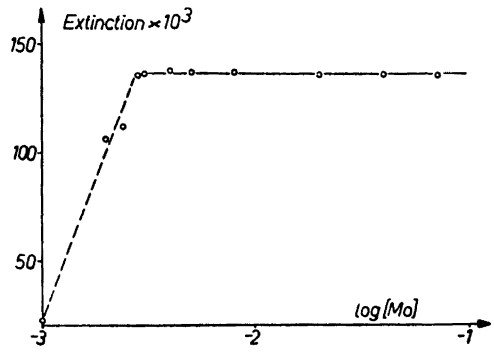

Fig. 5. Influence of the molybdate concentration.

Included in this series of measurements are also some, which have been made on solutions containing up to 0.2 moles of Na_2SO_4 per litre of final solution.

The optical density as a function of pH is plotted in Fig. 4; the horizontal line represents the mean calculated from 16 experiments. From these a maximal deviation of 1.3 % and a standard deviation of a single measurement of 0.8 % is calculated. (pH for these measurements was confined to the interval $0.5 \leqq \text{pH} \leqq 4.3$; the pH values below 1.0 are not very accurate and may well be in error with some tenths of a pH unit.)

3.4. Influence of the molybdate concentration

When treated on the steambath the solutions had the following compositions: 0.144×10^{-3} M in Si, pH in general 2.0 (in a few cases 1.5 and 3.5) adjusted with perchloric or sulfuric acid, the molybdate concentration being variable.

In Fig. 5 is given the extinction as a function of $^{10}\log[\text{Mo}]$. The minimum amount of molybdate required for a full development of the yellow colour is greater than would be calculated for a ratio [Mo] : [Si] = 12, obtained in the crystallized α-silicomolybdate both analytically [2] and from X-ray work [12].

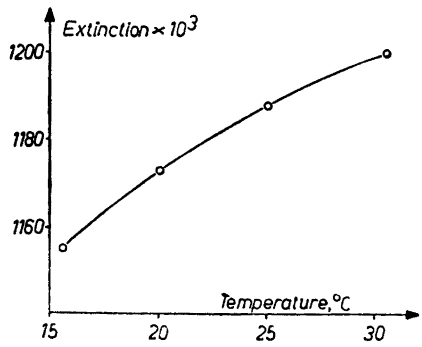

Fig. 6. Extinction as a function of temperature of the solution being measured.

Table 1. Applicability of Beers law to solutions of α-silicomolybdic acid. $k = E/c$; k = extinction coefficient, E = extinction for 1 cm cuvette length, c = molarity of Si.

Number of experiments	$c \times 10^3$	E, mean	$k \times 10^{-3}$		
			mean	max.dev. from the mean, %	Stand.dev. of a single measurement, %
5	1.200	1.461	1.218	0.6	0.4
5	0.900	1.096	1.218	0.5	0.3
5	0.600	0.733	1.222	0.5	0.2
4	0.300	0.366	1.220	0.6	0.5
2	0.120	0.146	1.22		
2	0.060	0.074	1.23		

When solutions which are about 0.2 M in Na_2MoO_4 or higher are heated on a steambath for several hours a white precipitate is often obtained, especially if the polythene bottle used has earlier contained such a precipitate. Solutions which were very concentrated in Na_2MoO_4 and have precipitated large amounts of such a solid phase, have in some cases shown extinction values slightly (about 1—2 %) lower than calculated. However, it has been found perfectly safe to use solutions which when heated are 0.05—0.1 M in Na_2MoO_4 and which may contain so much silica that the resulting extinction is about 1.5, provided no other heteropoly forming ions such as PO_4^{3-}, AsO_4^{3-}, Fe^{3+} and Al^{3+} are present. It might be added that precipitates of the above mentioned type are not easily formed in solutions containing large amounts of sulphate ions.

3.5. Influence of the temperature on the extinction

The solutions used had the following composition when heated on the waterbath: 1.25×10^{-3} M in Si, 0.05 M in Na_2MoO_4, pH = 1.5 with perchloric acid. After complete conversion to α-silicomolybdate the solutions were cooled to 20.0°C and made up to volume with water of the same temperature. Blanks were also prepared quite similarly.

In Fig. 6 the extinction is plotted as a function of the temperature of the solution being measured. No correction for volume changes has been applied. The temperature coefficient is not a constant but a function of temperature; at 20°C the extinction is seen to vary about 0.2—0.3 % per degree C. It may be that with other compositions of the solutions another extinction-temperature dependence can be obtained.

3.6. Applicability of Beers law

The measurements were carried out in the usual manner, great care being taken to ensure that the heating time on the waterbath was long enough.

The results of the measurements are summarized in Table 1. Extinctions for final silica concentrations equal to or greater than 0.3×10^{-3} M have

been measured on solutions subject to slight variations in pH (1.5 and 2.0) and in molybdate concentration (final solutions 0.04 and 0.08 M in Na_2MoO_4); in a few cases Na_2SO_4 was added so that the final solutions were 0.2 M in Na_2SO_4.

I wish to thank Dr. F. Nydahl, Head of the Department of Analytical Chemistry for his interest in this investigation and for the facilities put at my disposal.

A Peptide Material from Myosin Containing Sulfhydryl Groups

OLLE SNELLMAN

Institute of Biochemistry, University of Uppsala, Uppsala, Sweden

It has been shown that a peptide material is easily split off from myosin when firmly bound bivalent metal ions are removed. The reaction is accompanied by the appearance of a high ultra-violet absorption.

From oxidized myosin the same peptide material has been isolated as two peptides differing only in aspartic acid occurring as N-terminal group in one of them. The sequence in the peptide containing aspartic acid is Asp.CySH.Tyr.Arg.Lys.Val.Gly.Glu. Several pieces of evidence suggest that the peptide material might be part of the ATPase-active centers of the myosin.

In our investigations on myosin, we have observed, that treatments removing all calcium ions from protein cause the stability to be lost. A peptide material is gradually split off and at the same time a strong ultra-violet absorption appears. The latter has generally a maximum between 260—270 mμ but can change with treatments and also with time so that alterations can occur from one day to another. In a large number of different treatments, a release of a peptide material has been observed. This occurs, for example, after such mild treatments as an extensive washing of the rabbit myosin with 0.025 M KCl, or at mere precipitation by dilution of heart myosin. In those cases the ATPase activity will gradually be lost as the peptide material is given off.

It has also been possible [1] to divide myosin into two fractions by treatment with ammonium sulphate at 20°C. One of the fractions is stable and soluble in salt solutions only. This fraction has no phosphatase activity. When the fraction is denaturated by heat, only minute amounts of peptide material will be given off. The other fraction, which is soluble in water, is unstable and gradually gives off a strongly ultra-violet-absorbing material. It does not show any phosphatase activity. In properly designed experiments the fraction can be stabilised by calcium or magnesium hydroxide but not by potassium or sodium hydroxide [2]. This stabilisation must be achieved before the peptide

material is split off. If this is done, the fraction gives an ultra-violet spectrum in which tyrosine and tryptophan are visible, and the phosphatase activity appears again.

In denaturation by heat, certain amounts of the peptide material are given off from this fraction associated with a strong ultra-violet absorption. A peptide material can be isolated which contains the following amino acids: Asp, CySH, Tyr, Arg, Lys, Val, Gly, Glu, and has aspartic acid as its N-terminal group.

On account of certain difficulties in the preparation of the peptide material in a well defined state, other ways, to be reported here, have been tried for this isolation.

MATERIAL AND METHODS

In all experiments myosin from rabbit skeletal muscle was used and prepared according to Mommaerts and Parrish [3]. The myosin obtained was freeze-dried.

Zone electrophoresis was performed in a column according to Porath [4] with stabilizing powder according to Flodin and Kupke [5]. As buffer 0.05 M triethylamine-carbonic acid buffer at pH 7.5 or 0.05 M pyridinium acetate-acetic acid buffer at pH 3.6 was used. The eluate after the electrophoresis was taken up with a fraction collector, generally in 10 ml portions. The concentration in the samples was determined either at 270 mμ in a Beckmann D.U. spectrophotometer or with the ninhydrin reagent according to Moore and Stein [6].

One dimensional paper-chromatographic determinations were performed on the peptide material using either 70 % ethanol, or phenol buffered with citrate, or butanol:acetic acid:water (5:1:4). The last two systems were also used for the two dimensional determination of the amino acids after hydrolysis of the peptides in 5.8 N HCl at 105° for 24 h.

In the experiments with oxidized myosin an ionic exchanger (kindly supplied by Dr. P. Flodin, Pharmacia Ltd, Uppsala) was used. The resin was a special aliphatic polyamine which has a much higher purity than IR4B and did not interfere with the determinations.

TRYPSIN-DIGESTED MYOSIN

In the first experiments a trypsin digestion was directly tried on the myosin.

The myosin was dissolved in a 0.25 M triethylamine-carbonate buffer of pH 8.4 and digested with trypsin (Merck); 2 mg trypsin was used for 100 mg myosin. The digestion was performed during 2 days at 37°C. Dark bottles were used and the solution was saturated with chloroform. After the digestion the solution was evaporated *in vacuo*. The residue was dissolved in 5 ml 0.05 M triethylamine-carbonate buffer and a zone electrophoresis was made on the solution.

A diagram of such a zone electrophoresis is shown in Fig. 1, giving the ultra-violet absorption of the fractions at 270 mμ. Of the components obtained, the

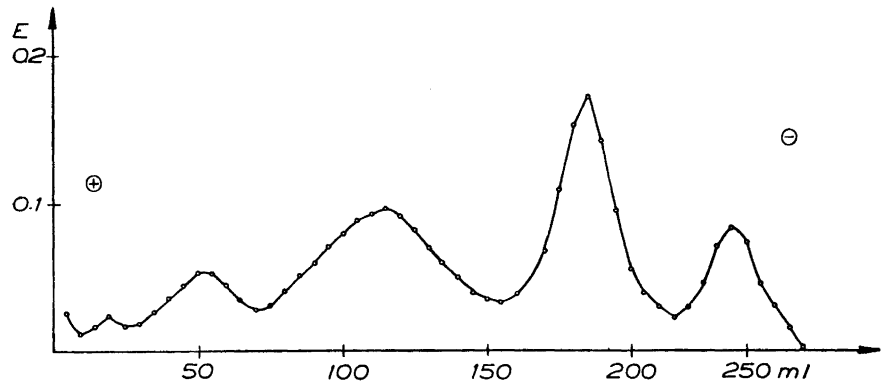

Fig. 1. Electropherogram of trypsin-digested myosin. The run was performed with 40 mA for 11 h in a 3 × 150 cm column in 0.05 M triethylamine carbonate buffer at pH 7.4. Ordinate is the optical density at 270 mμ.

two basic fractions, and sometimes also the neutral one, showed an anomalous ultra-violet absorption (see Fig. 2). The most basic component comprised about 3—4 % of the material and had an ultra-violet absorption at 270 mμ which was about 5—10 times that of any of the other components. In paper-chromatography in different solvents only one spot appeared. The amino acids occurring in this fraction were: CySH, Tyr, Arg, Lys, Val, Gly, Glu.

In the other basic fraction, several components occurred. This fraction comprised 20—25 % of the material while the neutral fraction contained about 50 % of the material.

However, the experiments did not give good reproducibility. In many cases the first component seemed to have disappeared into the second component, and also in the neutral one a strongly ultra-violet absorbing material could occur. In addition other reactions, which partly destroyed the material, appeared several times.

Another preparative method was therefore tried and gave results with a high degree of reproducibility.

PEPTIDES FROM OXIDIZED MYOSIN

The myosin was oxidized according to the method given by Harrington and Schellman [7]. The oxidized myosin was either digested with trypsin as before or treated with 11.6 N HCl at room temperature for 3 days. The solution was dried over sodium hydroxide pellets in a vacuum desiccator. In both cases the same peptide material could be isolated.

The partially broken-down myosin was dissolved in water of pH 4 and put on the ion-exchange column of the polyamine. The greatest part passed through but components containing cysteic acid were adsorbed. The adsorbed

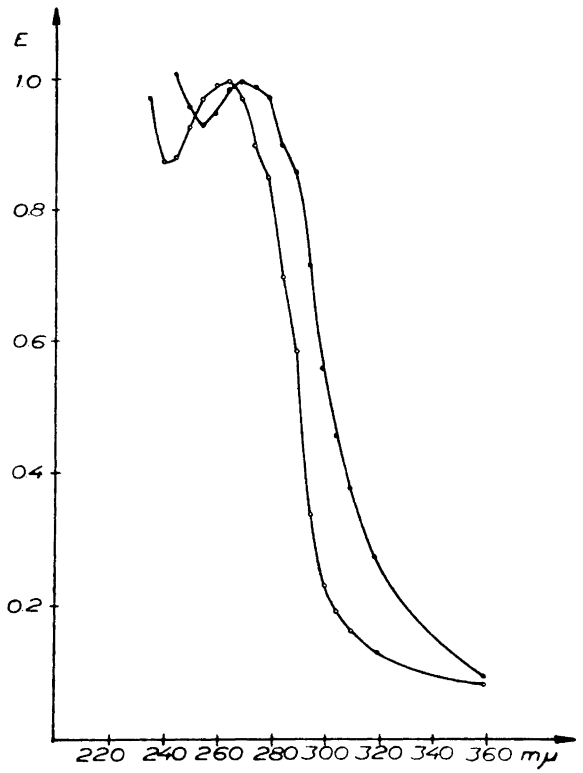

Fig. 2. Ultra-violet absorption spectrum of the most basic component. The extinction at the max. is set equal to 1.

material was eluted with water acidified with formic acid to different pH levels.

Two fractions were obtained, one at pH 2.4 and the other at pH 2.2. The two fractions were of about the same magnitude and comprise together about 8—9 % of the material.

The fraction eluted at pH 2.4 gave in zone electrophoresis one component which moved slowly to the anode. In paper-chromatography only one spot was visible.

The fraction eluted at pH 2.2 gave one component in zone electrophoresis moving a little slower than cysteic acid. In paper-chromatography only one spot was visible.

A qualitative amino acid analysis showed for the fraction at pH 2.4 the following amino acids: $CySO_3H$, Tyr, Arg, Lys, Val, Gly, Glu, and for the fraction at pH 2.2 the same amino acids and aspartic acid.

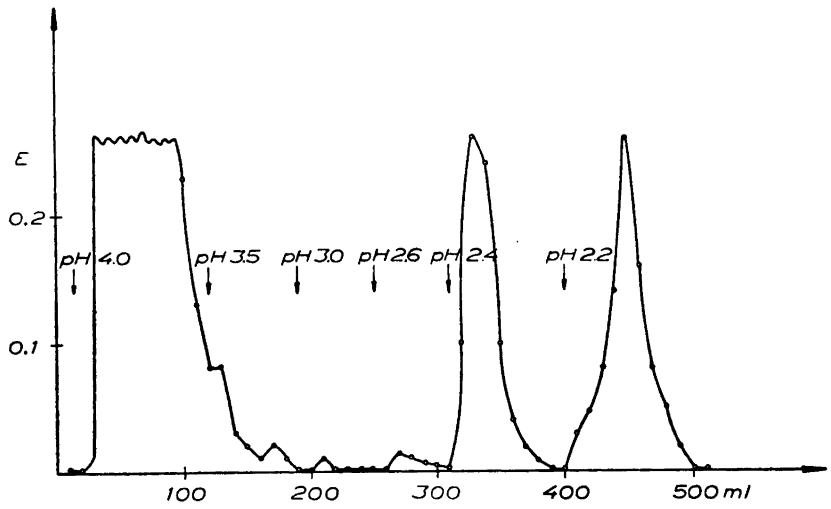

Fig. 3. Elution diagram of oxidized myosin treated with 11.6 N HCl on the polyamine column. The ordinate is the optical density as obtained with the ninhydrin reaction.

As N-terminal groups, determined according to Sanger[8], the component at pH 2.4 gave cysteic acid and the one at pH 2.2 aspartic acid. With carboxypeptidase Gly.Glu appeared in the C-terminal end in both cases.

The peptide obtained at pH 2.2 was digested with a small amount of pepsin at pH 2 for one day. The material was dried *in vacuo* and dissolved in water at pH 4 and then fractionated on the polyamine resin.

Three different main fractions were obtained. One fraction (I) that passed through; a second fraction (II) was eluted at pH 2.4, and a third one (III) in the interval pH 2.2—1.9.

The following amino acids were found in the different fractions.
Fraction I: Tyr, Arg, Lys, Val, Gly, Glu and free Asp
Fraction II: $CySO_3H$, Tyr, Arg, Lys, Val, Gly, Glu
Fraction III: Asp, $CySO_3H$, Tyr, Arg, Lys.

From these observations the sequence Asp.$CySO_3H$ (Tyr, Arg, Lys) Val. Gly.Glu can be deduced.

By zone electrophoresis of fraction III, the following peptides could be isolated

Asp.$CySO_3H$.Tyr.Arg; $CySO_3H$.Tyr.Arg; Asp.CySO/H.Tyr.Arg.Lys.

And from fraction I

Arg.Lys; Tyr.Arg.Lys.Val.Gly; Lys.Val.Gly.Glu; Gly.Glu.

The sequence then ought to be

Asp.$CySO_3H$.Tyr.Arg.Lys.Val.Gly.Glu.

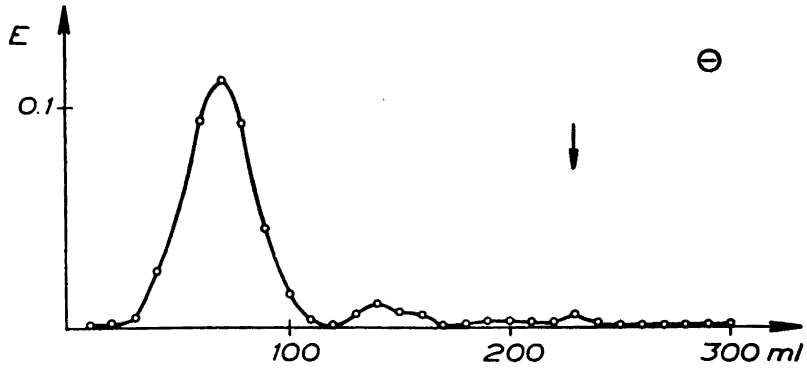

Fig. 4. Electropherogram of the component obtained at pH 2.2 from the polyamine in 0.05 M pyridinium acetate. The ordinate is the optical density as obtained with the ninhydrin reaction.

DISCUSSION

The peptide material so easily split off from myosin when firmly bound calcium is removed consists of two peptides which seem to differ only in one amino acid (aspartic acid) occurring in a N-terminal position in one of the two peptides. Several features indicate that the peptide material ought to belong to the active center of myosin which gives the ATPase activity.

The indirect evidence which support this hypothesis is:

1) Of the two fractions obtained from myosin by treatment with ammonium sulphate at 20°, only the one in which the phosphatase activity can be restored will give off substantial amounts of the peptide material on heat denaturation.

2) Obviously the peptide material is intimately connected with firmly bound calcium and the splitting off of the peptide material occurs only when the calcium is removed. Gelotte [9] has observed that the disappearance of calcium and the appearance of a strong ultra-violet absorption run parallel. The strong ultra-violet absorption is associated with the peptide. Friess [10] and Kielley and Bradley [11] conclude from their investigations on the phosphatase activity in the presence of chelating agents that a bivalent metal ion occurs in the active center. Kielley and Bradley say: "The characteristic properties of EDTA further suggest that the unidentified groups interacting with the SH group is a metal."

3) Singer and Barron [12] demonstrated the inactivation of the ATPase activity by sulfhydryl reagents. Later Kielley and Bradley [11] have studied the inactivation of the SH groups more thoroughly. From their investigation they postulate that at least two SH groups occur in the active center. We have not found any peptide with two SH groups and there does not seem to occur any other SH peptides than those two observed by us. It may therefore be that at least two such peptides occur in one active center.

According to Kielley and Bradley one of the SH groups ought to be active and the other inactive. It is very difficult to say, if there is any real difference between the two peptides obtained in regard to their state in myosin since there is not sufficient information about the mechanism for splitting off the peptides. Some slight indications exist that the difference in aspartic acid content might be real. The two peptides are obtained in the same amounts from myosin and, in an unfinished investigation about the sulfhydryl peptides in L- and H-meromyosin, mostly the peptide without aspartic acid has been found in the phosphatase-inactive L-meromyosin. The question is, however, as yet not settled.

4) Also the tyrosine group might function in the hydrolysis of ATP. Ravikowitch, Syetkina and Lyontyvea [13] have found alterations in the ultraviolet spectrum when actomyosin reacts with ATP. The absorption peak at 277 mμ in actomyosin moves and disappears into the adenine peak. This alteration was only seen in enzymatically active actomyosin, and ADP and AMP did not show this effect. The authors postulate that tyrosine and/or tryptophan takes part in the reaction. Taver and Morales [14] have also observed a similar effect.

5) Laidler and Ethier [15] have interpreted their results on the kinetics of the ATPase activity as indicating a neutralization of charge when the enzyme-substrate complex is formed and a separation of charges when the breakdown occurs. If the two basic groups of the peptide are considered to bind phosphate groups of ATP, this also fits well with the amino acid sequence of the peptide.

Thus there are several indirect pieces of evidence suggesting that the peptides belong to the ATPase-active center.

If that is so, *i. e.* the peptides are parts of the active center, they must be so situated on the myosin that at least one of the two peptides is freely exposed and can form a complex with the substrate in which most of the amino acids residues in the peptide ought to take part. For the activity the bivalent metal ion bound to the peptide is also necessary.

The fact that the treatment with ammonium sulfate can give two different and defined fractions of the myosin might indicate that the active centers, to a large extent, are located near the places where the two parts are connected. In fact, in the water soluble and calcium-hydroxide treated part aspartic acid and cysteine appears as N-terminal groups. However, further studies are necessary to confirm this tentative conclusion.

Synthesis of some Model Compounds for Thiolignin

CAMILLA JUSLÉN and TERJE ENKVIST

Chemical Institute of the University of Helsingfors, Finland

A series of model compounds for thiolignin was synthesized. Vanillyl alcohol and thiophenol were found to form vanillyl phenyl sulfide by elimination of water even at room temperature on irradiation with sunlight, or alternatively on moderate heating in the presence of aluminium sulfate or hydrogen ions. Similar reactions were carried out with other substances, including *iso*eugenol and thiophenol, and cinnamyl alcohol and *p*-thiocresol or thioglycolic acid. As a side reaction there also occurred addition of the mercaptan to the ethylenic bond. The ethylenic bond in cinnamyl cresyl sulfide reacted very slowly with soda-alkaline permanganate solution.

The present work is a continuation of our studies on cinnamyl phenyl sulfide as a model substance for thiolignin [1]. Table 1 gives a survey of the syntheses carried out.

Table 1. Syntheses of thiolignin models.

Reagents	Method [a]	time	Reaction product	Yield mole %
Cinnamyl alcohol(I) + *p*-thiocresol(II)	Pressure heating with aluminium sulfate (1)	17.5 h	Cinnamyl-*p*-cresyl-sulfide(III)+IV or V	29

XVI. $R.CHOH.C_2H_5$; α-(3-methoxy-4-hydroxy-phenyl)-propanol

R in VIII and XIV—XVI = 
Perhaps the most interesting observation made was the readiness with which vanillyl phenyl sulfide (VIII) was formed in 91 % yield by elimination of water from vanillyl alcohol and thiophenol, even at room temperature, by photosynthesis.

Attempts to add thioglycolic acid to the double bond of S-cinnamyl thioglycolic acid in acetone solution with piperidine as catalyst failed.

Of the pure crystalline substances synthesized III and VIII are, as far as we know, new ones. Of the liquid reaction products, which are possibly mixtures of isomers, IV, V, XI, XII, XIV and XV have also not been reported hitherto. X has been synthesized by Holmberg[2] but by another method than that employed by us. It can be mentioned in this connection that Freudenberg recently has prepared S-vanillyl thioglycolic acid from vanillyl alcohol and thioglycolic acid using boron fluoride as catalyst[3].

Ultraviolet and infrared spectra. The absorption spectrum in ultraviolet of cinnamyl-*p*-cresylsulfide (Fig. 1) shows a single maximum at about 255 mμ, very similar to that of cinnamyl phenyl sulfide[1], S-cinnamylthioglycolic acid (Fig. 2, H, D), allyl phenyl sulfide and cinnamyl disulfide[1], but distinctly different from that of vanillyl phenyl sulfide (Fig. 2, V), 2-methyl thiocoumarane[1] and the addition products of *iso*eugenol and thiophenol (Fig. 3). The addition product (XI or XII) of cinnamyl alcohol and thioglycolic acid shows an UV spectrum (Fig. 4) clearly differing from that of S-cinnamyl thioglycolic acid (Fig. 2). The IR spectrum (Fig. 5) lacks the absorption band of the ethylenic bond at 960 cm.$^{-1}$ The band at 1 710 cm^{-1} is very probably due to the valuence oscillations of the C:O group of the carboxyl grouping. The valence oscillations of the alcoholic hydroxyl group should occur between 2.6 and 3.0 μ. For instance, the addition product of cinnamyl alcohol and thiophenol[1]

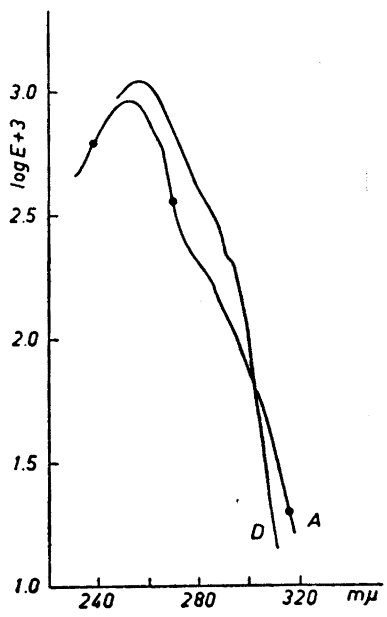

Fig. 1. UV spectrum of cinnamyl-*p*-cresyl sulfide. D = in dioxan. A = in 0.5 N alcoholic sodium hydroxide solution.

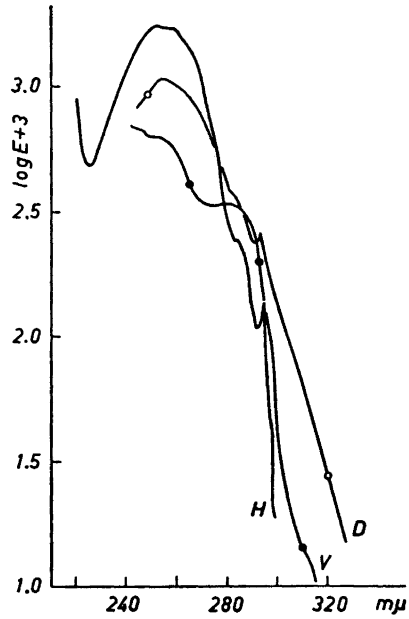

Fig. 2. UV spectrum of vanillyl phenyl sulfide and of S-cinnamyl thioglycolic acid. V = vanillyl phenyl sulfide in dioxan. H = S-cinnamyl thioglycolic acid in hexane, D = the same in dioxan.

absorbs at 2.9 μ. In Fig. 5 this bond is very broad, indicating association or hydrogen bonding [4].

Reactions of the ethylenic bonds. Cinnamyl *p*-cresyl sulfide, like cinnamyl phenyl sulfide [1], decolorized soda-alkaline permanganate solution at room temperature only very slowly, after hours of standing. In contrast, S-cinnamyl thioglycolic acid (X), as well as XI and XII, immediately decolorize the reagent. With tetranitromethane cinnamyl-*p*-cresyl sulfide gave a golden yellow color, whereas the compound XIV gave a red color.

EXPERIMENTAL

1. Cinnamyl-p-cresyl sulfide. The synthesis was almost completely analogous to the synthesis of cinnamyl phenyl sulfide [1], 0.990 g of aluminium oxide being used, however, for 0.044 mole of cinnamyl alcohol and 0.043 mole of *p*-thiocresol. The sulfide obtained was recrystallized from 99 % ethanol, yield 3.001 g, m. p. 67—68°C. (Found: C 80.20; H 7.01; S 13.14. Calc. for $C_{16}H_{16}S$: C 79.95; H 6.71; S 13.34). UV spectrum Fig. 1. From the mother liquors a main fraction was isolated by chromatography in about the same way as in the synthesis of cinnamyl phenyl sulfide [1]. (Found: S 12.09. Calc. for $C_{16}H_{18}SO$: S 12.41).

2. *Vanillyl phenyl sulfide.* a) *Photosynthesis.* Vanillyl alcohol was prepared by catalytic hydrogenation of vanillin according to Ref.[5] Yield 72 mole %.

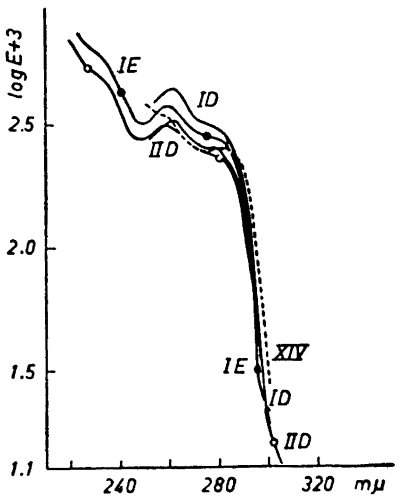

Fig. 3. UV spectrum of addition product (XIV or XV) of *iso*eugenol and thiophenol (4a). I D = first chromatographic fraction in dioxan, I E = the same in ethanol. II D = second chromatographic fraction in dioxan, II E = the same in ethanol. XIV = XIV in dioxan.

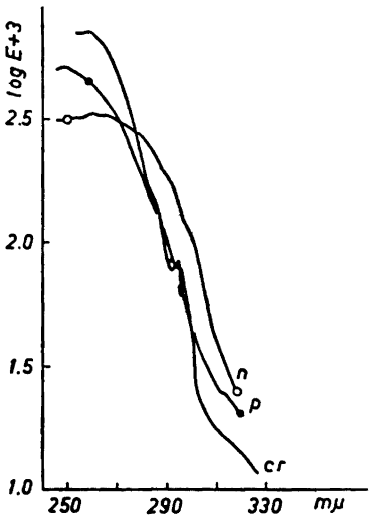

Fig. 4. UV spectra of addition products XI and XII of cinnamyl alcohol and thioglycolic acid. cr = crude, p = chromatographically purified acids. n = neutral product from 3 b.

1.54 g (0.010 mole) vanillyl alcohol and 1.100 g (0.010 mole) thiophenol were mixed in a glass test tube sealed with a rubber stopper. The tube was allowed to stand in a sunny window from December to the end of August. The reaction product was recrystallized from 99 % ethanol. Yield 2.239 g with m.p. 87—90.5°. Part of the material was chromatographed on aluminium oxide (Brockmann) previously washed with 2 N hydrochloric acid and with water, and dried 24 h at 150°, in about the same way as in the synthesis of cinnamyl phenyl sulfide [1], benzene being used instead of carbon tetrachloride, however. The sulfide thus purified melted at 91.5—92°. (Found: C 68.23; H 5.76; S 12.92; mol.weight (Beckmann, cryosc.) 239. Calc. for $C_{14}H_{14}SO_2$: C 68.26; H 5.73; S 13.02; mol.weight 246). UV spectrum Fig. 2, V.

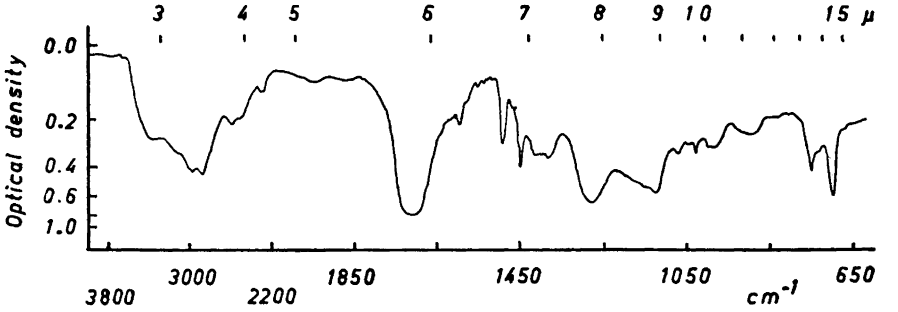

Fig. 5. IR spectrum of addition product of cinnamyl alcohol and thioglycolic acid (3 b).

120.1 mg of vanillyl phenyl sulfide were heated 5 h at 140—145° with 60.1 mg of phenyl *iso*cyanate, moisture being excluded by means of a calcium chloride tube. The phenyl carbamic acid ester formed was recrystallized three times from hot ligroin and then once more from carbon tetrachloride containing 10 % of petrol ether. Yield 86 mg; m. p. 137—138°. (Found: C 68.95; H 5.48; N 3.66; S 8.69. Calc. for $C_{21}H_{19}NSO_3$: C 69.02; H 5.24; N 3.83; S 8.77).

b) *With aluminium sulfate.* The synthesis was analogous to that used in Ref.[1], using 5.932 g of vanillyl alcohol, 4.298 g of thiophenol and 0.350 g of aluminium sulfate. The reaction product was dissolved in ether, washed three times with a sodium hydrogen carbonate solution, which dissolves the bulk of the thiophenol, and finally with water. The isolated neutral substance was recrystallized first from ligroin containing 5 % of chloroform and then from 50 % alcohol. Yield 3.406 g, m. p. 89—91°. 100 mg of the substance was chromatographed on aluminium oxide treated with hydrochloric acid, after which it showed a m. p. of 91.5—92°.

3. *S-Cinnamyl thioglycolic acid.* a) With aluminium sulfate. 3.807 g (0.0413 mole) of thioglycolic acid and 5.545 g (0.0413 mole) of cinnamyl alcohol were heated with 0.343 g anh. aluminium sulfate 17 h at 127°. The reaction product was dissolved in benzene and extracted from the benzene by repeated shaking with 2 N sodium hydroxide. The alkaline layer was acidified with 2 N sulfuric acid and extracted five times with benzene. The final benzene solution was washed with water, dried and evaporated at room temperature. The residue was dried in vacuum over phosphorus pentoxide. The yield varied in the various experiments between 45—51 mole % calculated as S-cinnamyl thioglycolic acid. By recrystallization from ligroin containing 5 % chloroform a crystalline substance with m. p. 78—79° was isolated. UV spectrum Fig. 2. (Found: C 63.46; H 5.88; S 15.35. Calc. for $C_{11}H_{12}SO_2$: C 63.43; H 5.81; S 15.40).

b) With piperidine catalyst, substances XI and XII. 2.530 g (0.0275 mole) of thioglycolic acid, 3.2210 g (0.24 mole) of cinnamyl alcohol and 0.2 ml of piperidine were dissolved in 10 ml of benzene and refluxed 36 h. The acidic reaction products were separated from the neutral ones as described under 3 a. Yield 1.593 g of yellow oil giving a positive Baeyer test, S 14.53 %, UV spectrum Fig. 4, cr. Paper chromatography was carried out on Whatman paper No. 1 with toluene-methanol-water (10:5:5), developing with 0.1 N silver nitrate solution and heating[6] 15 min at 110°, with 0.5 N permanganate solution in the dark, or with starch solution and iodine-azide solution according to Feigl[7]. Three spots corresponding to R_F 0.92, 0.88 and 0.00 were found. Of these R_F 0.92 was found by a parallel run to correspond to cinnamyl thioglycolic acid.

On chromatography on a Whatman cellulose column (32 × 2.5 cm) washed with 350 ml of the toluene-methanol-water-mixture described, 0.288 g of the substance was applied, dissolved in 4 ml chloroform, and the chromatogram was developed with the solvent mixture. The substance separated into one fraction which could be eluted with the toluene mixture, and another, which was eluted with ether-ethanol 1:1. The first fraction was a partially crystallized oil, from which S-cinnamyl thioglycolic acid with m.p. 74—76° (undepressed on admixture of acid from synthesis 3 a) could be prepared through crystallization from ligroin. The second fraction was a yellow oil, which was dried 3 days in vacuum over P_2O_5; yield 0.148 g, UV spectrum Fig. 4 p. R_F-value 0.00 with the toluene mixture. (Found: C 57.50; H 5.59; S 13.67; mol.weight (Childs) 294. Calc. for $C_{11}H_{14}SO_3$: C 58.38; H 6.24; S 14.17; mol.weight 226). IR spectrum Fig. 5. The product gave a S-benzyl thiuronium salt with m. p. 150—152°.

A sample of the neutral product was purified by chromatography on aluminium oxide in benzene solution and elution with benzene containing increasing amounts (5—50 %) of ethanol. S 9.65 %. UV spectrum Fig. 4, n.

4. *Synthesis of XIV and XV.* a) From *iso*eugenol. 4.785 g (0.0291 mole) of thiophenol were heated in a sealed glass tube 18.3 h at 127°. The yield of reaction products soluble in 2 N sodium hydroxide was 6.623 g. 4.025 g were dissolved in 15 ml of carbon tetrachloride and separated into two fractions by chromatography on 21.7 g of aluminium oxide treated with hydrochloric acid by elution with carbon tetrachloride containing 0.10 and finally 25 % ethanol. Both fractions gave a red colour with tetranitromethan. The first fraction, a light yellow oil, was obtained mainly with pure carbon tetrachloride. Yield 2.008 g, UV spectrum Fig. 3, ID and IE. (Found: C 69.56; H 6.86; S 11.52; mol.weight (Beckmann, cryosc.) 265. Calc. for $C_{16}H_{18}SO_2$: C 70.04; H 6.61; S 11.69; mol.weight 274).

Acetylation according to Ref.[1] (synthesis 1 a): reaction product a yellow oil. (Found: CH_3CO 13.23 %. Calc. for $C_{16}H_{17}SO_2 \cdot COCH_3$: CH_3CO 13.60). Phenyl carbamic ester was prepared by heating 85 mg of the fraction with a 20 mole % excess of phenyl *iso*-cyanate. The excess of reagent was removed by digestion with ligroin. The liquid reaction product was dissolved in hot ligroin containing 5 % chloroform and cooled. Only a few mg were obtained of a crystalline product, melting after recrystallization at 95—98°, the greater part remaining liquid.

The second fraction was also a light yellow oil. Yield 1.843 g, UV spectra Fig. 3, II D and II E. (Found: C 69.76; H 6.50; S 11.74; mol.weight 276. Calc. for $C_{16}H_{18}SO_2$: see above!)

The following derivatives were prepared in a manner corresponding to the first fraction: 315.3 mg were acetylated, giving a light yellow oil. (Found: CH_3CO 13.11.) Phenyl carbamic ester, m. p. 94—96°, undepressed on admixture of the corresponding derivative from the first fraction.

b) From XVI. 0.605 g (0.0033 mole) of α-(3-methoxy-4-hydroxy-phenyl)- propanol (XVI), 1.795 g thiophenol and some anhydrous aluminium sulfate were heated 17 h at 127° in a sealed glass tube. A liquid reaction product, obviously 1-thiophenoxy-1-(3-methoxy-4-hydroxy-phenyl)-propane (XIII) was isolated chromatographically as described under 4 a. Yield 0.539 g; UV spectrum Fig. 3, XIV. (Found: S 11.43. Calc. for $C_{16}H_{18}SO_2$: S 11.69.)

Some Aspects of the Nutrition of *Lactobacillus fermenti* 36 in the Tube Assay of Thiamine

Z. G. BÁNHIDI

The Wenner-Gren Institute for Experimental Biology, University of Stockholm, Sweden

Reinvestigating the nutritional requirement of *L. fermenti* 36 on different media, it was found that:

a. the alkali treated peptone is a dispensable supplement if the basal medium is completed with tryptophane, since tryptophane was shown to be an essential nutrient for *L. fermenti.*

b. by using weak inoculum, it was found that whole yeast extract and panthetine are both stimulatory for growth of *L. fermenti.*

c. charcoal treated yeast extract appeared to be inhibitory under similar conditions.

d. the inhibition with the latter and the stimulation with pantethine can be compensated by reducing the medium with cysteine and/or ascorbic acid.

e. with tryptophane and increased level of casein hydrolysate as sources for amino acids, as well as with cysteine and ascorbic acid, a semisynthetic medium can be prepared, which allows good growth and reliable uniform response toward thiamine.

f. the size of the inoculum is a crucial factor in the *L. fermenti* test and should be carefully adjusted turbidimetrically for each run.

The assay of thiamine seems to be still in its developing stage, and it is difficult to find a reliable technique when designing a program of investigation of the occurrence of thiamine and its derivatives in extracts of complex biological materials. Chemical methods can hardly be considered for such a task except for analysis of relatively pure solutions of this vitamin. While many different microbiological methods have been described for the analysis of the total vitamin B_1 content of food stuffs and other natural products, *Lactobacillus fermenti 36* was favored in most of the procedures [1-8] and this organism is still considered as a potential tool with the least failure when thiamine is analyzed [9]. Nevertheless, owing to inconsistencies in the results, several nutritional trials were performed in different laboratories in order to minimize the anomalies in the behavior of *Lactobacillus fermenti* 36 in the thiamine test [3, 7, 10, 8]. In every work referred to, the original basal medium of Sarett and Cheldelin [1] was accepted as a nutritional basis for *L. fermenti.* This medium is already supplemented with a natural extract *viz.* alkali treated

or photolysed peptone. This complex natural complement obscured the results in the usual nutritional experiments, which are rather informative if performed with pure synthetic (amino acid mixture) or semisynthetic (casein hydrolysate) media.

The present work deals with the establishment of some nutritional requirements of *L. fermenti*, the fulfillment of which renders this organism useful for the tube assay of thiamine in small amounts of tissue and organ extracts on a semisynthetic basal medium.

METHODS

Stock cultures of *Lactobacillus fermenti 36* (ATCC 9833) were kept on Bacto Micro Assay Culture Agar, stored at 6—8°C after growth for 24 h at 35°C. The stock cultures were "renewed" in every four to six weeks by transferring to a fortified litmus-skim milk medium [11]*. Several agar subcultures were prepared from a milk tube after each "renewing", and used for the preparation of inocula or for stock cultures. The fortification of the agar medium with 10 μg per liter thiamine [3,5] was found to be unnecessary in our work, probably because of the more complete composition of the Micro Assay Culture Agar compared with the original yeast extract — dextrose agar, recommended in other methods [1, 12, 13].

Inoculum was prepared by transfer from an agar subculture to Bacto Micro Inoculum Broth fortified with 10 % tomato juice filtrate[6]. After 18 h at 35°C this was found to give abundant growth compared to unsupplemented broth (see Table 1) or that with other different supplements.

The time of incubation for the inoculum was originally set at 24 h by Sarett and Cheldelin [1], but this period was decreased by others [12,5]. In this way the interference of bacteria already adapted to the breakdown products of thiamine could be avoided in the test, since the adaption was stated to occur only when cultures passed the limit of 18 h [1,5].

The cell suspension was washed twice in saline, as usual, and was used for inoculation within one hour. The density of inocula was adjusted turbidimetrically in every experiment and two or three uniformly administered drops of inoculum, respectively, were used for tubes with 7 or 10 ml of final volume. Two main type of inocula were used in our experiments, the "weak inoculum" adjusted to 90 % transmission and the "medium

Table 1. Growth of *Lactobacillus fermenti* 36 on Bacto Micro Inoculum Broth with and without addition of tomato juice filtrate. Turbidimetric readings after 18 h of incubation expressed in per cent of transmission (% T) values representing means of triplicates.

Broth / Blanks	Uncompleted	Reinforced with tomato juice	
		1 % v/v	10 % v/v
Readings against blanks as 100	33	28	13.5
Readings against inoculated uncompleted broth as 100	100	79	37.5

* Bacto Yeast Extract 5 g; Bacto Liver 1.5 g (or Parke-Davis Liver Concentrate 0.5 ml); tomato juice filtrate (canned, unseasoned) 100 ml; glucose 2 g; agar 1 g; Tween 80 1 ml; litmus 1 g dissolved in 10 ml 0.1 N sodium hydroxide and filtered; skim milk to 1 000 ml; pH should be adjusted carefully to 6.4 with 0.1 N hydrochloric acid.

strength inoculum" with 40 % T. Heavier inoculum was found to be unsatisfactory because of high blanks (*cf.* Sarett and Cheldelin [1]).

Techniques. Calibrated pyrex tubes of 18 mm diameter were used for the test with 7 or 10 ml final volume.

Media combined with standard or test solutions were autoclaved for 15 min at 1 atm. overpressure in small autoclaves, where the total time needed for heating and cooling does not exceed 45 min. While only steaming was recommended by Sarett and Cheldelin [1] in their original method, Fitzgerald and Hughes [5] found no destruction of thiamine in assay tubes when autoclaved for 10 min at 10 lb. We found serious loss of thiamine activity if the vitamin was autoclaved in pure solutions or in buffer solutions at pH 6.4—6.6. However, rather good protection could be observed if thiamine was autoclaved together with the basal media, and a comparative test with steril-filtered standards showed no special advantage in the rutine test.

Incubation was made in a water bath at 35°C for 17—18 h except when noted otherwise.

Measurement of cell growth through turbidity was achieved by readings of per cent light transmission at 6 000 Å in a Coleman Universal Spectrophotometer.

Preparations. Bacto-Peptone and Bacto-Yeast Extract were used both in the untreated form as whole extracts or in form of preparations in which the thiamine content was minimized by chemical destruction or absorption, *viz.*:

alkali treated peptone [14],
photolyzed peptone [15,12],
Norit A (charcoal) treated yeast extract [16],
sulphite treated yeast extract [17],

which were prepared according to the original prescriptions quoted.

Basal media of several different compositions were used in this work, as noted below. The composition of a semisynthetic basal medium is given in Table 2. This medium represents the recommended final medium for the thiamine test and the results of our nutritional experiments were considered for its composition. Although incorporation of further supplements was found not to improve the turbidimetric method, in case of an acidimetric semimicro assay, a completed semisynthetic basal medium was used. According to the terminology used in the description of our experiments, the medium presented herewith is a "high amino acid reduced semisynthetic medium".

In the course of the nutritional studies the following main types of media were substituted for the final basal medium, except when noted otherwise:

"Low amino acid medium" as in Table 2 with only 5 g per liter casein hydrolysate, without cysteine, ascorbic acid and pantethine.

"High amino acid medium" as above with 12 g casein hydrolysate.

"Reduced low amino acid medium" similar to the low amino acid medium but with 1 g of cysteine and 400 mg of ascorbic acid.

"Reduced high amino acid medium" as above with 12 g casein hydrolysate.

Bacto Thiamine Assay Medium was used in the present experiments in place of the Sarett and Cheldelin medium despite small differences in the composition of the two media, such as the incorporation of photolysed peptone in the former, instead of alkali treated peptone as described for the original method. Actually the Bacto medium represents the standard medium used for present analytical methods [12,5].

EXPERIMENTS AND RESULTS

Tryptophane requirement of *Lactobacillus fermenti* 36

In the original basal medium of Sarett and Cheldelin [1] tryptophane is not incorporated, despite the fact that tryptophane is usually essential for Lactobacilli [18] and is practically missing from acid hydrolyzed casein. It is to be mentioned that the same authors found tryptophane to be superfluous, similar

* Variable components.

to several other metabolites if tested in their medium which was already supplemented with alkali treated peptone. We repeated the experiment of Sarett and Cheldelin with asparagine, tryptophane, inositol and choline with the same basal medium except for omission of the alkali treated (or photolyzed) peptone supplement, and with the addition of high levels of thiamine. Whole yeast extract and norit treated yeast extract complements served for comparison. As seen on Table 3, there was no growth of *L. fermenti* with thiamine on the peptone-free basal medium lacking tryptophane. On the other hand, the addition of DL-tryptophane to the medium gave full growth which cannot be further increased with norit treated yeast extract. Repetition of the experiment with 0.1 % Tween 80 included in the medium does not alter the results. Photolyzed peptone used as supplement at similar levels gave results in agreement with those obtained with yeast extract.

Thus tryptophane must be considered as an essential nutrient for *L. fermenti*, and the addition of different thiamine-free natural extracts as supplements to the basal medium are mainly justified as sources for tryptophane. Since alkali treatment of natural extracts not only destroys thiamine, but in the mean time decreases the original tryptophane content (*cf.* Ref.[19]), the incorporation of pure tryptophane in the basal media for *L. fermenti* is preferable.

Table 3. Tryptophane as an essential nutrient for *Lactobacillus fermenti* 36. Turbidimetric readings of growth expressed in per cent transmission (% T). Blanks were adjusted 100 % T.
Basal medium according to Sarett and Cheldelin [1] with omission of the alkali-treated peptone component was used with medium size inoculum. Each value represents the mean of triplicate readings.

Media / Test solutions added	Without tryptophane	With 4 mg DL-tryptophane per 10 ml	With tryptophane plus 10 % Norit treated Yeast Extract
Thiamine 0.25 μg per 10 ml	99.5	40.5	49
Bacto-Yeast Extract 4 mg per ml	49	39	47
	as above but with 0.2 % Tween 80 in each tube

Bacto-Yeast Extract 4 mg per 10 ml	48	39	47.5

Experiments performed with faint inoculum

Inoculum size was found by several workers [3,5] to be one of the crucial points in the thiamine assay with *L. fermenti*. We found it desirable to adjust the density of the inoculum turbidimetrically in each run in order to ensure standard conditions, instead of the simple dilution of the washed inoculum 10 to 25 times. In contrast to the recommended "medium strength inoculum" (40 % T) a rather weak one was used in most of the present nutritional tests. Thus there were better possibilities for the detection of small changes in the growth of this organism due to stimulatory or inhibitory action of different supplements, which usually affect the initial growth.

Effect of yeast extract. When initial growth with thiamine standards was measured after 12 h of incubation on different supplemented media, a marked early growth stimulation was found with whole yeast extract as seen in Fig. 1. Since the stimulation was clearly correlated to different thiamine concentrations, it cannot be accounted for by the presence of excess thiamine in the yeast extract. Norit treatment removes the stimulating factor from the yeast extract. This points to the possibility that the factor in question might be one of the B-vitamin type of growth stimulants. (It will be shown in a later chapter that the stimulatory effect can probably be due to Lactobacillus Bulgaricus Factor.)

Similar early growth stimulation would be disturbing in the case of routine assay procedure if complex natural extracts must be tested. However, the effect was eliminated by using a medium strength inoculum.

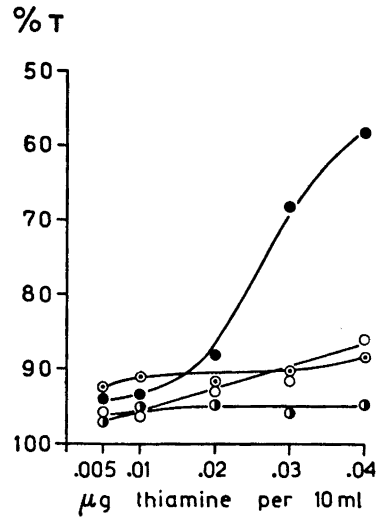

Fig. 1. Initial growth of *L. fermenti* 36 with thiamine standards using weak inoculum on different media: ○ Bacto Thiamine Assay Medium fortified with 0.1 % Tween 80; ⊙ the same with 10 % Norit treated yeast extract added; ◑ reduced low amino acid medium plus 10 % Norit treated yeast extract; ● reduced low amino acid medium with 2 mg per tube Bacto-Yeast-Extract added.

The effect of depleted yeast autolysates on the growth was considered for investigation because similar preparations were often recommended for use as supplement in assay media serving for sources of minute amounts of unidentified growth factors as well as of amino acids. Actually, thiamine-free yeast supplement was used in early work as a source of folic acid in the thiamine test [1,12], and sulphite treated yeast extract was found by Bacharach and Cuthbertson [4] to improve the visibility and diminish the "drift" when added to the Sarett and Cheldelin medium in the cup plate test. This contradicted the findings of Sarett and Cheldelin, who mention the trial with sulphite and Fuller's earth-treated yeast and liver extracts as a test for the lack of improvement in the assay of which was considered as proof for the completeness of their medium. Charcoal (Norit A) adsorption of yeast autolyzate solution originally introduced by Strong *et al.*[16] was designed as a valuable supplement in the pantothenate test with *Lactobacillus casei*, a rather exacting organism. This preparation was tested by us with success in several microbiological assay media and is believed to be preferable to sulphite or alkali treated yeast extracts because these rather harsh treatments necessarily destroy many growth factors besides thiamine, leaving behind several split products and artefacts.

Contrary to the expectations the experiment with incorporation of Norit-treated yeast extract in the basal media does not result in any improvement of the assay, but in marked inhibition of the growth of *L. fermenti* on both low and high amino acid unreduced media as seen in Fig. 2. Such inhibitory effect of a natural extract is evidently disturbing from the analytical viewpoint. Nevertheless, the inhibitory effect of the unknown substance(s) in the Norit-treated yeast extract can be compensated by using reducing agents in the media, as seen in Fig. 3.

The effect of reducing agents, especially that of cysteine [10] and of ascorbic acid [7,10], on *L. fermenti* was studied thoroughly in the last years mainly be-

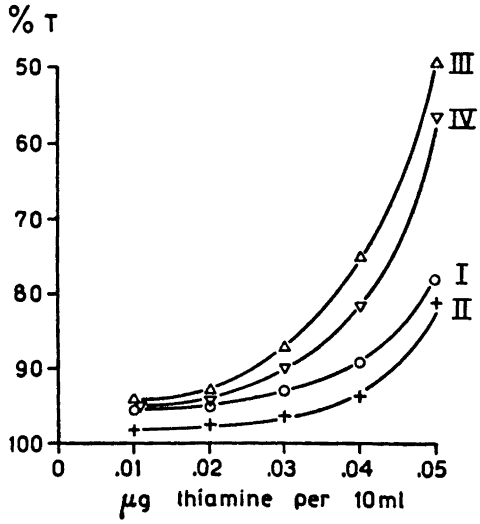

Fig. 2. Retardation of growth response of *L. fermenti* 36 toward thiamine by charcoal treated yeast extract with a weak inoculum. Curves I and II were obtained with low amino acid media, while III and IV with high amino acid media. Media in runs II and IV were supplemented with 10 % Norit A treated Bacto-Yeast-Extract. Each value show the mean of readings in duplicates after 17 h incubation.

cause of expected improvement in the response of this organism toward thiamine. Reducing agents were found to enhance the growth especially in case of light inoculum and by using fructose or maltose instead of glucose. Ascorbic acid was claimed to act not only as a reducing agent, but also as a growth factor able to replace thiamine [13]. These findings were based again on the Sarett and Cheldelin basal medium with photolyzed peptone in it.

Testing the different semisynthetic media we found some stimulations with reducing agents in case of faint inoculum (*cf.* Figs. 3 and 4) which were equali-

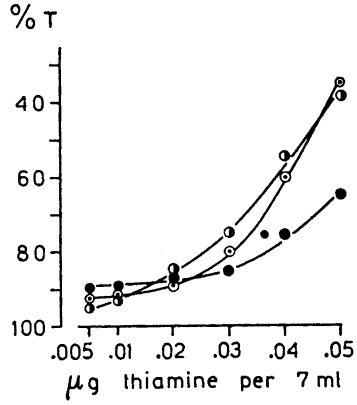

Fig. 3. Compensation of the inhibitory effect of charcoal absorbed yeast extract supplement on the growth of *L. fermenti* 36 in the thiamine tube test by reducing agents. Weak inoculum was used and readings of duplicates were made after 16 h of incubation on low amino acid media with: ⊙ no supplement; ● 10 % Norit A treated Bacto-Yeast Extract supplement; ◑ the same as the latter supplemented with additional cysteine (1 g/l) and ascorbic acid (400 mg/l).

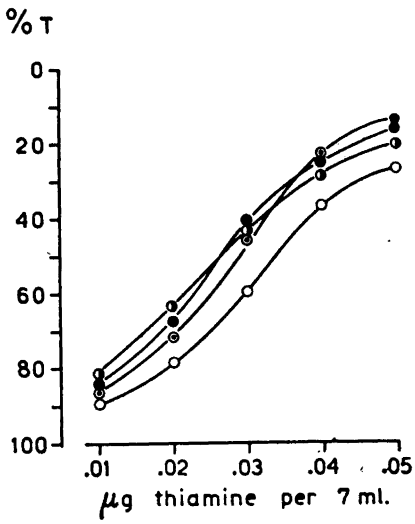

Fig. 4. Growth stimulation of *L. fermenti* 36 with pantethine. Experimental conditions similar to those for Fig. 3. Media: ○ high amino acid medium; ◑ the same with 25 μg pantethine per liter final volume; ⊙ reduced high amino acid medium; ● the latter with pantethine as above.

zed by choosing suitable medium size inoculum (*cf.* Fig. 5). It was not possible to find any significant difference between the action of cysteine or ascorbic acid supposing that cystine was present in the semisynthetic media when testing ascorbic acid. Neither could we find a concentration-dependent thiamine-replacing effect of ascorbic acid on these media.

As seen in Fig. 3 the effect of reducing agents is rather marked when overcomming the inhibitory action of charcoal treated yeast extract. The beneficial effect of reducing agents is shown also in Fig. 4, where comparison of curves ⊙ and ● gives a typical picture of growth stimulation by either cysteine or ascorbic acid or the combination, when *L. fermenti* was tested with thiamine on high amino acid medium, and the inoculum was weak.

Growth stimulation with Lactobacillus Bulgaricus Factor (LBF). As was already pointed out in connection with the interpretation of the experiment presented in Fig. 1, whole yeast extract contains some stimulatory factor(s) effective for early growth of weak inoculum. Because this type of growth stimulant might under certain conditions affect the thiamine assay, extended work seemed to be desirable at that point. Since the earlier nutritional studies with *L. fermenti* [1, 13, 10], several new growth factors and stimulatory substances — mainly B vitamins — were detected partly with the aid of exacting Lactobacilli [20]. For this reason Vitamin B_{12}, Citrovorum Factor (Folinic acid), Thioctic acid (Protogen) and Lactobacillus Bulgaricus Factor (Pantethine) were tested by us. None of these factors showed additional growth stimulation with weak inocula on the media used in our work, except pantethine which is known to be a rather typical early growth stimulant for many lactic organisms, and with wide-spread occurrence.

As seen in Fig. 4 pantethine was found to be stimulatory for *L. fermenti* in a small but significant degree on a high amino acid medium with cystine. However, this stimulation was eliminated by incorporation of reducing agents in

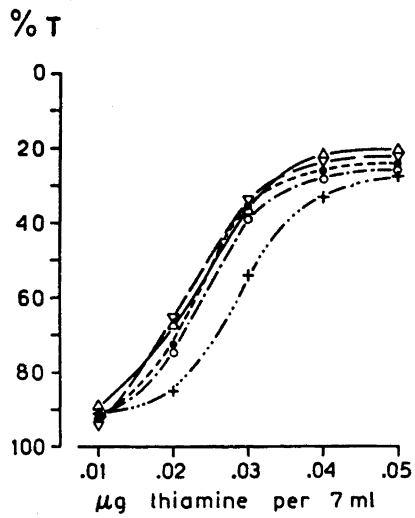

Fig. 5. Assay of thiamine standards with *L. fermenti* 36 on different media. Inoculum: 3 drops of 40 % T suspension per 10 ml media. Each value represents the mean of duplicate readings after 17 h of growth. Media 1—4, reduced high amino acid media with alkali treated peptone (20 g per l) in I (△————△); Norit A treated Bacto- Yeast Extract (10 %) in 2 (▽——▽); Pantethine (10 µg per l) in 3 (●- - -●); without supplement in 4 (○——○). For comparison in 5 (+·····+) a reduced low amino acid medium was used.

the medium. No such enhancing effect of pantethine was found to take place with more dense inocula. However, the incorporation of pantethine in a basal medium for analytical work with *L. fermenti* is still recommended.

The above results seem to be at first sight in contradiction with those of Craig and Snell [21], who found an activity coefficient of less than 0.05 with pantethine for *L. fermenti* compared with pantothenic acid as unit. Still this result cannot be compared directly with ours, since the medium used by these authors was different from that of ours (*e. g.* calcium-D-pantothenate was not incorporated in the Craig and Snell medium) and the conditions of the inocula were not specified.

Thiamine assay with medium size of inoculum

Considering the important role of the inoculum for the assay of thiamine with *L. fermenti*, a final comparison was made with inocula of 40 % transmission (2 drops per 7 ml) in different media. As seen in Fig. 5 the addition of different supplements does not influence the assay when the amount of acid-hydrolyzed vitamin-free casein is increased to a level common for vitamin assay media (12 g instead of 5 g per liter final volume). The low amount of casein hydrolysate recommended by Sarett and Cheldelin [1] was evidently calculated to be compensated by the incorporation of the peptone preparation (another source of amino acids). While the right size of the inoculum seems to be a limiting factor for reliable thiamine assay method for this organism on a semisynthetic medium, the composition of the medium is of great importance too. As a conclusion of the results presented herewith, a medium described in Table 2 is recommended for use. The addition of further supplements, though not essential, could be allowed except that the osmotic pressure of the final medium should not be too high to disturb the growth of *L. fermenti*.

Table 4. The effect of the pyrimidine and thiazole moieties of thiamine on the growth of *L. fermenti* 36 in semisynthetic media. Turbidimetric readings, 24 h of growth.

Media / Breakdown products of thiamine	Low amino acid medium with 10 % Norit A treated Bacto-Yeast Extract	High amino acid media with 0.1 % Tween 80			
		Tween 80 omitted	—	with 10 mg per liter Leucovorine	with 10 % Norit A treated Bacto-Yeast
2-Methyl-4-amino-methyl pyrimidine-hydrochloride	95	98.5	98	97	96
0.03 μg per 7 ml	*43*	98	*31.5*	94.5	98
4-Methyl-5(-oxyethyl)-thiazole	*30*	99	17.5	93.5	94.5
0.03 μg per 7 ml	94.5	99	93	92.5	94.5

The growth of *L. fermenti* with the pyrimidine and thiazole moieties of the thiamine molecule in absence of thiamine is one of the nutritional aspects which also needed to be controlled in case of introduction of a new medium. These moieties often interfere with microbiological procedures since different organisms can use one or both of these substances as precursors for the synthesis of thiamine. *L. fermenti* was reported to be unable to utilize either the pyrimidine or the thiazole parts under the first 20 to 24 h of growth, but seems to be stimulated by them during prolonged incubation [1,5]. Owing to this fact, the measurement of the growth of *L. fermenti* must take place before 18 h of incubation, which necessitates the use of turbidimetric readings instead of acidimetry. We tested both halves of thiamine on different media and found no growth after 20 h of incubation, while readings at 24 h showed occasional irregular randomly distributed growth, which points to the possibility of an adaptational mechanism (see Table 4) instead of direct utilization as is commonly believed.

Addendum: After the preparation of the present paper, the work of MaciasR[22] was considered, in which a new thiamine test method with *L. fermenti* was presented. This method is based on a medium containing 5 to 400 times higher concentrations of the different B vitamin components than the conventional levels. MaciasR's investigations were focused mainly on the carbohydrate requirements of *L. fermenti*, in variance with our present work. However, the experiments of MaciasR were conducted on the complete Sarett and Cheldelin medium, the disadvantages of which were discussed by us. Efforts to reproduce the work of MaciasR gave no satisfactory results in our laboratory.

Stability Constants of Metal Complexes with Mononucleotides

EVA WALAAS

Institute of Medical Biochemistry and Physiology, Department of Medical Biochemistry, University of Oslo, Norway

The formation constants of mononucleotide complexes with Ca(II), Mg(II) Co(II) and Mn(II) are determined. It has been shown that the formation constants of these metal complexes mainly depend upon the nature of the metal and the length of the phosphate chain in the nucleotide. With a few exceptions the stability of the complexes are characterized by the sequence Ca<Mg<Co<Mn. With increased length of the phosphate chain in the nucleotide the stability increases in the order * AMP(UMP)<ADP (UDP)<ATP(UTP). The influence of the heterocyclic base of nucleotides in metal complex formation is studied with several purines and pyrimidine riboside phosphates and with flavin nucleotides.

Enzymatic transphosphorylation reactions involving mononucleotides as the phosphate donor or acceptor depend upon metal activation. It has therefore been suggested that the metals chelate with ligand groups in the nucleotide and in the enzyme apoprotein. Information of the structure and function of such complexes may be obtained by investigations on model systems. In the present work data on the stability constants of metals with purine-, pyrimidine- and flavinnucleotides will be presented.

In recent years several investigators have determined the stability constants of adenine nucleotides with metals, particularly Mg and Ca [1-5]. The stability constants of Sr-complexes with adenosine-3′-monophosphate and cytidine-3′-monophosphate have been reported by Schubert [6], and an approximate value of the stability constant of manganese with ATP has been given by Cohn and Townsend [8]. Investigations on the weakly associated complexes of sodium and potassium with adeninenucleotides have been carried out by Melchior [7].

* Throughout the paper the following abbreviations will be used: ATP: adenosinetriphosphate, ITP: inosinetriphosphate, GTP: guanosinetriphosphate, CTP: cytidinetriphosphate, UTP: uridinetriphosphate, ADP: adenosinediphosphate, UDP: uridinediphosphate, AMP: adenosine-5′-monophosphate, UMP: uridine-5′-monophosphate, FMN: flavin mononucleotide, FAD: flavin adenine dinucleotide.

In the present work complex formation of metals with nucleotides have been studied by means of the ion exchange resin method according to Schubert [9]. The significance of three main factors for the formation constants has been considered. This involves the nature of the metal ion, and the structure of the nucleotide, particularly the length of the phosphate chain and the configuration of the heterocyclic base. Four metals most commonly required by phosphorylation reactions involving nucleotides have been investigated, which include two alkaline earth metals: Ca(II) and Mg(II), and two metals of the first transition series: Mn(II) and Co(II).

EXPERIMENTAL

Method. The ion exchange method described by Schubert [9,11] has been used for the determination of the formation constants. In the experiments solutions of nucleotides with and without addition of metals were equilibrated with an anion exchange resin. The distribution of nucleotides between the resin and the solution was determined by ultraviolet absorption measurements.

Materials

Resin. The syntetic organic anion exchanger Dowex-1, 200—400 mesh, in the chloride form was used. The resin was put through several alternate Cl^- and OH^- cycles with 5 % solutions of NaCl and NaOH. Subsequently the resin was equilibrated with 0.1 M NaCl. The supernatant solution in contact with the resin was adjusted to pH 8.0—8.2 with dilute NaOH solution. The mixture was stirred for an hour, pH of the solution tested again and readjusted until no change of pH took place after stirring. The resin was filtered, washed rapidly with distilled water and air dried. Analyses showed a moisture content of 11.6 %. All experiments were conducted with the air dried resin.

Reagents. The solutions of sodium chloride and the solutions of the chlorides of Mg, Ca, Co and Mn were prepared from Merck products, analytical grade. All nucleotides used were derived from "Sigma" Chemical Company, Saint Louis, Mo. The purity of these compounds was investigated by the chromatographic procedure of Hurlberth *et al.*[10] on Dowex-1 resin by the gradient elution technique with a formic acid system. If ultraviolet absorbing impurities were detected, pure fractions of the nucleotide to be tested were collected and lyophilized before use.

Procedure

Ten 25 ml flasks were used in each experiment. To eight of these flasks (two were used as blanks) were added a weighed amount of the prepared Dowex-1 resin and subsequently solutions of buffer, nucleotide, metal chloride and 0.1 M NaCl. The 0.01 M tris (hydroxymethyl)-aminomethane buffer used, pH 8.2, was prepared in 0.1 M NaCl. Solutions of nucleotides were prepared in 0.1 M NaCl, adjusted to pH 8.2 and added (freshly made) to the flasks. The final volume and ionic strength in the flasks were 20 ml and 0.1, respectively.

In preliminary experiments the appropriate amount of resin at the concentration of nucleotide chosen was determined (*i. e.* approximately 75 % of the nucleotide bound to the resin). The affinity of the purine-nucleotides for the resin was greater than that of the pyrimidine-nucleotides. In experiments with adenosine-, guanosine- and inosinetriphosphate, 25 mg of resin at concentrations of 0.6×10^{-4} M of nucleotide was used. In experiments with cytidine- and uridinetriphosphates 50 mg resin was used at a similar range of nucleotide concentration. With ADP and UDP 100 mg and 200 mg, respectively, were necessary to obtain 70 % binding of nucleotide to the resin. With AMP and UMP the absorption of nucleotides was somewhat lower, even when the amount of resin was in-

creased (AMP 500 mg, UMP 1 000 mg). In experiments with flavinnucleotides appropriate absorption was obtained with 200 mg (FAD) or 300 mg (FMN).

The upper limit of the nucleotide concentration to give a constant and reproducible distribution coefficient with 25 mg resin was found experimentally to be 1×10^{-4} M. No deviation in the distribution coefficient (K_d^0) was found for the concentration range employed, ($0.5-0.625 \times 10^{-4}$ M).

Solutions of divalent metals as chlorides, dissolved in 0.1 M NaCl were added to the flasks at different levels of concentration. The concentration range chosen depended upon the affinity of the metal for the nucleotide. Usually three concentrations were employed in each experiment. Because of the high affinity for the nucleosidetriphosphates, low concentrations of metals could be used in these experiments ($0.625-3.75 \times 10^{-4}$ M). With nucleosidediphosphates a range of concentration of $0.125-1.5 \times 10^{-3}$ M was used. A higher concentration was required when the affinity for the nucleotide was low. In the case of AMP, UMP, FMN and FAD $0.75-7.5 \times 10^{-3}$ M had to be used. The same formation constants were found at low and high metal concentrations. Thus, the small variations of the ionic strength in different experiments did not influence the results, since the supporting electrolyte had the much higher ionic strength of 0.1. Theoretically, the effect on K_d of increasing ionic strength in experiments with nucleosidetri- and diphosphates was negligible, when calculated according to Schubert [6]. In experiments with nucleosidemonophosphate a maximal deviation of 6 % of K_d was calculated when 7.5×10^{-3} M metal solution was used.

The general procedure in a typical experiment was as follows: Two flasks contained nucleotide without metal ion added. These flasks were used to determine the nucleotide equilibrium between the resin and the solution. Two other flasks containing nucleotide but no resin were used as blanks. In the remaining 6 flasks metal solutions at different concentrations were added together with nucleotide. The glass-stoppered flasks were placed on a mechanical shaking apparatus and shaken vigorously for 3 h, which was sufficient to obtain equilibrium. The shaking was carried out at 23°C in a constant temperature room. Thereupon the resin was spun down by slight centrifugation, and the nucleotide concentration was measured by ultraviolet absorption at 260 mμ or other appropriate wavelengths in a Beckman Spectrophotometer Model DU in an aliquot of the supernatant. In the experiments with FAD the manganese complex formation was determined by U.V. absorption measurements. The other metal complex formation constants were investigated by determining the fluorescence in a Farrand Spectrofluorometer, using excitation maximum of FAD at 360 mμ and fluorescence maximum at 520 mμ.

The method is based upon the assumption that metal nucleotide complexes exert the same U.V. absorption spectrum as the free nucleotide. This was confirmed as no shift in absorption maximum wavelength nor any change in degree of absorption was observed by addition of metal solutions to nucleotides. This is in accordance with observations made by Nanninga [4] and by Blum [12]. No effect by the metals on the fluorescence of FAD was observed either.

Calculations

The formation constant is defined by

$$K_f = \frac{(MA)}{(M)\ (A)} \tag{1}$$

where M represents the metal and A represents the complexing anion. The formation constant is regarded as an equilibrium constant for the successive reactions between the metal ion and the ligand groups giving the complex [13]. In the present work performed at pH 8.2, the phosphate chain of the nucleotides does not take up protons, and the intermediate and terminal phosphate groups are negatively charged. In a buffered solution the anions are taken up by the resin until equilibrium. The addition of Me^{2+} reduces the concentration of free nucleotide in solution and thus decreases the uptake of negatively charged nucleotide by the anion exchanger.

It is convenient to employ a simple distribution coefficient K_d, as suggested by Schubert [9] for determining the formation constants.

$$K_d = \frac{\% \text{ in exchanger}}{\% \text{ in solution}} \times \frac{\text{volum of solution}}{\text{mass of resin}} \quad (2)$$

The term K_d^0 is taken as the value of distribution coefficient in the absence of a specific complexer, such as the complexing metal cation. Therefore the value of K_f can simply be formulated:

$$K_f = \frac{(K_d^0 / K_d) - 1}{(Me^{2+})^n}$$

where (Me^{2+}) represents the molar concentration of the complexing divalent metal, K_d the measured distribution coefficient for a given concentration of the metal and n the number of ions of Me^{2+} relative to nucleotide in the complex. K_d^0 and K_d are determined by measuring the fraction of nucleotide present in the solution at equilibrium.

Eqn. (3) can be written:

$$1/K_d = 1/K_d^0 + (Me^{2+})^n \cdot K_f/K_d^0 \quad (4)$$

A plot of $1/K_d$ *versus* (Me^{2+}) for proper values of n gives a linear correlation. By extrapolating to $(Me^{2+}) = 0$, the value of $1/K_d^0$ is obtained.

By the present application of the anion exchange resin method an accuracy of $\pm$ 5 % (standard error of mean) was obtained.

RESULTS

The type of complex formation of metals with mononucleotides is illustrated in Fig. 1. By plotting $1/K_d$ (the reciprocal distribution coefficient) against metal concentration (eqn. 4) a linear correlation is obtained. This type of curve was found without exception in all experiments. Thus, in these complexes one mole of the nucleotide combines with one mole of the metal. This is in accordance with experiments performed by Martell and Schwarzenbach [3] who demonstrated monometallic complex formation with inorganic triphosphates as well as with the adenosine phosphates AMP, ADP and ATP. In the

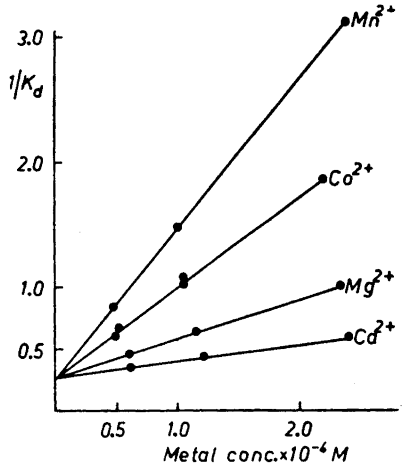

Fig. 1. Complex formation (1:1) of ATP with divalent metals. Determination by anion exchange resin method. See text for experimental conditions.

Table 1. Apparent stability constants (log K_f) of metal complexes at $\mu = 0.1$, pH: 8.2 and 23°C in 0.1 M NaCl.

Metal	ATP	ADP	GTP	ITP	UTP	UDP	CTP
Ca^{2+}	3.77	2.82	3.58	3.76	3.71		3.81
Mg^{2+}	4.04	3.15	4.02	4.04	4.02	3.17	4.01
Mn^{2+}	4.75	3.94	4.73	4.57	4.78		4.78
Co^{2+}	4.62	3.68	4.63	4.74	4.55		4.48

present work this type of metal complex formation has been demonstrated with pyrimidine and purine riboside phosphates as well as with FMN and FAD. Apparently monometallic complexes are characteristic for these group of biologically important substances.

In Table 1 the stability constants of metals with nucleoside triphosphates ATP, GTP, ITP, UTP, CTP and two of the corresponding diphosphates, ADP and UDP, are reported. The formation constants of the different metals with these compounds increase in the order Ca<Mg<Co<Mn. Thus, the lowest formation constants are obtained with Ca(II) and somewhat higher with Mg(II). This is in accordance with earlier observations on adenine nucleotides [3,5,4], and corresponds to the sequence of stability of the alkaline earth metal complexes in general as pointed out by Williams [14].

With metals of the first transition series the formation constants are considerably higher, perhaps due to the higher ability of these metals to form covalent bonds. It is of interest to note that the stability of Mn(II)-complexes with nucleoside triphosphates and nucleoside diphosphates as ligands are greater than with Co(II). Thus, the nucleotide molecule gives preference for the atomic structure of manganese with half filled 3*d*-shell. In this respect these complexes differ from the usual sequence of stability of metals with many other ligands reported by Irving and Williams [13]. This preference for manganese must be due to the molecular geometry of these nucleotides and is consistent with the high affinity of manganese for ligands of the oxygen type [15]. Thus the importance of bonding to oxygen atoms in the polyphosphate chain of the nucleotides is indicated. Table 1 shows a striking conformity of the formation constants, these being dependent upon the metal ion and the number of phosphate groups and independent of the rest of the nucleotide molecule. There is one exception to this rule, ITP forms a more stable complex with Co than with Mn, an observation which at present cannot be explained in terms of the structure of the ligand. ITP thus follows the ordinary sequence of stability: Mn<Co (Irving and Williams [13]).

Complex formation of the metals with nucleotide ligands containing one phosphate group (AMP, UMP, FMN) or with two "intermediate" phosphate groups (FAD) is of a somewhat different character (Table 2). Complexes of the 1:1 type are formed, but they are weakly associated and the order of

Table 2. Apparent stability constants (log K_f) of metal complexes at $\mu = 0.1$, pH: 8.2 and 23°C in 0.1 M NaCl.

Metal	AMP	UMP	FMN	FAD
Ca^{2+}	1.76		2.06	2.02
Mg^{2+}	1.95	2.25	2.03	2.02
Mn^{2+}	2.31		2.17	2.39
Co^{2+}	2.58		2.41	2.36

stability with different metals is not as characteristic as with the nucleoside triphosphate- and diphosphate groups. This is clearly seen from Table 3 where the relative stabilities of metal complexes with the different ligands are calculated. Particularly it should be pointed out that the great stability of manganese-complexes with nucleosidetriphosphates is not observed with nucleosidemonophosphates or with FAD which contains two phosphate groups in "intermediate" position. The stabilities of Mn(II) and Co(II) complexes with the last mentioned ligands are but slighthly higher than the stability of the Ca(II) and Mg(II) complexes, and the order of stability is not as typical as that obtained with nucleosidetri- and diphosphate compounds.

The significance of the length of the terminal phosphate chain on the formation constant is illustrated by experiments with ATP, ADP and AMP.

Table 3. Relative stability of metal nucleotide complexes (calculated ratio of K_f).

Complexing agent	Ca	Mg	Mn	Co
ATP	1	1.8	9.6	7.1
ITP	1	1.9	8.2	11.3
GTP	1	2.9	14.1	11.1
CTP	1	1.6	9.3	4.6
UTP	1	2.1	11.8	6.9
ADP	1	2.1	13.3	7.3
AMP	1	1.5	3.5	6.5
FMN	1	0.9	1.3	2.2
FAD	1	0.5	2.3	2.2

Table 4. Relative stability of metal complexes with nucleoside mono-, di- and triphosphates (calculated ratio of K_f).

Metal	AMP	ADP	ATP	UMP	UDP	UTP
Ca^{2+}	1	11.4	110			
Mg^{2+}	1	15.7	121	1	8.4	61
Mn^{2+}	1	43.2	268			
Co^{2+}	1	12.8	112			

The relative stabilities of the metal complexes with adenosinemono-, di- and triphosphates are shown in Table 4. At pH 8.2 used in the experiments these nucleotides contain, respectively, 2, 3 and 4 negatively charged oxygen atoms in the phosphate chain. In complexes with Ca(II), Mg(II) and Co(II) addition of one intermediate phosphate group in the molecule (ADP) increases the formation constant by a factor of approximately 10. Two intermediate phosphate groups (ATP) increase the stability of the complex with a factor of approximately 100. Similar results have been reported by Martell and Schwarzenbach [3] in experiments with Ca(II) and Mg(II) complexes of adenosine phosphates. This definitely, indicates the formation of chelating structures of metals with poly-phosphates in purine nucleotides. Similar observations have been made with metal complexes of condensed polyphosphates [16,3]. Experiments performed with Mg-complexes of uridine phosphates (Table 4) show that this is valid also for pyrimidine nucleotides.

The unique properties of manganese to form chelate structures with adenosine polyphosphates is indicated from Table 4. Thus, the stability constants of manganese with AMP, ADP and ATP increase by a ratio of 1:43:268. However, such a preference for manganese is not present in complexes with FAD where the two phosphate groups are in intermediate position.

DISCUSSION

In recent years considerable attention has been given to the molecular structure of metal complexes of adeninenucleotides. Thus, it has been suggested by Calvin [17] that a metal chelate structure between the metal and the phosphate residue of the ADP or ATP molecule is formed. On the other hand Szent-Györgyi [18] has proposed a structure where the 6-NH_2-group and the N_7 in the adenine as well as the phosphate residue contribute ligand groups to the metal.

In several investigations the problem has been studied by determination of stability constants of metals with adeninenucleotides. Investigations based upon titration measurements have been reported [2,3,5]. Further the problem has been studied by cation exchange method [1,6], by anion exchange method [4] and paramagnetic resonance absorption [7]. As far as the results are concerned

great discrepancies exist depending upon the method used and the experimental conditions, as discussed by Smith and Alberty [5].

The anion exchange method adopted in the present work has earlier been used by Nanninga [4]. However, the formation constants of Mg and Ca complexes with adeninenucleotides reported by him differ considerable from the results obtained in the present work. On the other hand our results completely agree with the stability of Mg and Ca adeninenucleotide complexes determined by Martell and Schwarzenbach [3] by very accurate titration measurements.

It may therefore be of some interest to point out the limitations and accuracy of the ion exchange method. Several important factors as discussed thoroughly by Schubert [11], must be taken into consideration. By the present application of the anion exchange resin method the equilibrium of nucleotide between the resin and the solution, *i. e.* K_d must be independent of the amount of nucleotides bound by the complexing metal. As mentioned in the experimental part this point was investigated by measuring K_d^0 in a system usually containing 25 mg resin at several concentrations of ATP. Above 10^{-4} M ATP, deviation in K_d^0 occurred in accordance with theoretical calculations [11]. Therefore in all experiments the nucleotide concentration was kept below the critical level. The lower formation constants reported by Nanninga can possibly be explained by the different experimental conditions with regard to the concentration of nucleotide and the amount of resin. Further it has been observed that deviation of K_d^0 occurred when more than 85 % was bound to the resin. Therefore, in each experiment, an amount of resin was chosen which permitted the determination of K_d^0 where 60—70 % of the nucleotide was absorbed. The formation constants were calculated on the assumption that the buffer ions did not form complexes with the reactants. The fact that constant values of formation constants were obtained at different metal concentrations indicated that a single complex was formed. Experimental support for this assumption was further obtained as Tris buffer at different concentrations in the range 0.05—0.005 M had no effect on the formation constant. A weak complexing action of the Na ions in the solution must be expected [8]. Finally it should be mentioned that the conformity of the extrapolated and experimental determinal K_d^0 excludes some of the disturbing factors described by Feldman *et al.*[19]

From the present work the conclusion can be drawn that two main factors determine the formation constants of metalnucleotide complexes, namely the nature of the metal and the length of the phosphate chain. The high stability of metals with di- and triphosphate ligand groups, depends upon terminal localization of the phosphate residue, such as in purine- and pyrimidine nucleotides. On the other hand the stability of metal complexes of FAD containing two intermediate phosphates groups is not increased compared with FMN or AMP.

At the pH employed no particular indication has been obtained of any significance of the heterocyclic base. This is in accordance with the findings of Martell and Schwarzenbach [3] who did not find any complex formation of metals with adenine. In the present work the stability constants of the different purine- and pyrimidinenucleosidetriphosphates were of the same order of magnitude. Further the sequences of stability were always the same, Ca<Mg<Co<Mn. The only exception is ITP characterized by the order Mn<Co.

The more stabile complexes with transition metals than with the group II A must be expected due to the more favourable acceptor factors in the former. However, the different acceptor abilities of cobalt and manganese also influence complex formation with nucleotides. The extent of increased stability characterized by the sequence AMP<ADP<ATP is much more pronounced with Mn(II) than with Co(II).

In the literature some information on the significance of metal nucleotide complexes in activation of enzymes involving phosphorylations has been given. Most commonly a requirement for Mg exists, but activation with Mn, Ca and Co has also been observed [20]. Indications that metal complexes are the actual substrates of the enzymes have been presented. Thus, with fructokinase at high ionic strength [21] and with muscle ATPase activity [22], maximal enzyme activity was obtained at a metal/ATP ratio of 1. At present scanty information is available on the structure of metal nucleotide complexes with the apoprotein part of phosphorylating enzymes [23]. This problem will be more fully discussed in a forthcoming paper. A biochemical significance of the highly stable complexes of Mn with ADP and ATP must be considered, as it is known that manganese can restore respiration and phosphorylations in Ca-inactivated mitochondrial preparations [23].

Acknowledgement. The work has been supported by grants from *Eli Lilly and Company*, and from *Det Videnskapelige forskningsfond av 1919*. A working grant has been received from the *Norwegian Council for Research and Humanities*. Thanks are due to Mrs. Reidun Midthjell for valuable technical assistance.

Synthesis of Compounds Related to Muscarufin

III.* The Ullmann Reaction with *o*-Chloro-iodobenzene

MARTIN NILSSON

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Reaction of *o*-chloro-iodobenzene with copper gave 2,2′-dichlorodiphenyl in relatively poor yield. Chlorobenzene and, surprisingly, *o*-dichlorobenzene were the major by-products but several others were also isolated.

m-Chloro- and *p*-chloro-iodobenzene gave fair yields of the symmetrical dichlorodiphenyls. No dichlorobenzenes were detected in the reaction products.

The results are discussed in relation to the mechanism of the Ullmann reaction.

Attempts to convert 2,3,5-triacetoxy-1,4-bis-(2-carbomethoxyphenyl)-benzene into 3-hydroxy-2,5-bis-(2-carboxyphenyl)-*p*-benzoquinone were not successful. This has been due mainly to the ready formation of dilactones (*cf.* Part I [1]) and to the instability to alkali of any monohydroxyquinone which might have been formed.

Some analogues without carboxyl groups were therefore prepared. The simplest, 3-hydroxy-2,5-diphenyl-*p*-benzoquinone, was obtained from 2,5-diphenyl-*p*-benzoquinone by Thiele acetylation, acid methanolysis and oxidation with nitrous acid. It dissolved readily in dilute aqueous alkali giving a violet solution, which turned brown in a few minutes. No hydroxyquinone could be recovered from this solution.

An analogue with chlorine atoms in place of the carboxyl groups was prepared with the intention of replacing them at a later stage by carboxyl groups. The Ullmann coupling of *o*-chloro-iodobenzene and 2,5-di-iodohydroquinone dimethylether gave a mixture, which was more heterogeneous than those obtained from similar couplings. On careful fractionation it gave 2,2′-dichlorodiphenyl (I), 2,5-dimethoxy-1,4-bis-(2-chlorophenyl)-benzene (II, 8 % yield based on the di-iodo compound) and a product A.

Compound II on oxidation with nitric acid gave 2,5-bis-(2-chlorophenyl)-*p*-benzoquinone. This compound, which has previously been obtained in small

* Part II. *Acta Chem. Scand.* **10** (1956) 1377.

quantities from *o*-chlorobenzenediazonium chloride and *p*-benzoquinone [2] was converted into 3-hydroxy-2,5-bis-(2-chlorophenyl)-*p*-benzoquinone by the route described above.

The product A, $C_{14}H_{12}Cl_2O_2$, m. p. 106° (yield 11 %), on treatment with nitric acid gave a quinone, $C_{12}H_6Cl_2O_2$, and was therefore presumed to be 2',4--dichloro-2,5-dimethoxydiphenyl (III).

An independent synthesis was made by a mixed Ullmann coupling of *o*-chloro-iodobenzene and 2-chloro-5-iodohydroquinone dimethylether, which gave a mixture from which 2,2'-dichlorodiphenyl, 2',4-dichloro-2,5-dimethoxydiphenyl (III) and 4,4'-dichloro-2,2',5,5'-tetramethoxydiphenyl (IV) were isolated by distillation. An unexpected by-product, 2,5-dichlorohydroquinone dimethylether (V), was also encountered in this reaction. Compound III proved to be identical with A and oxidation with nitric acid gave 5-chloro-2--(2-chlorophenyl)-*p*-benzoquinone identical with that obtained from A.

As there appeared to be a side-reaction involving a transfer of chlorine atoms in the mixed Ullmann couplings with *o*-chloro-iodobenzene it was of interest to study the reaction of *o*-chloro-iodobenzene with copper in greater detail. This reaction has previously been used for the synthesis of 2,2'-dichlorodiphenyl by Bretscher [3] (20 % yield) and by van Alphen [4]. The reaction was run under the same conditions as before, except that the reaction time was prolonged to avoid traces of unchanged starting material which might complicate the isolation procedure. No special precautions were taken to exclude air and commercial copper bronze was used without purification or activation.

Careful fractionation of the reaction product by distillation and chromatography on alumina gave: chlorobenzene (VI, 8 %), *o*-dichlorobenzene (VII, 5 %), 2,2'-dichlorodiphenyl (I, 39 %), dibenzofuran (VIII, 3 %), triphenylene (IX, 0.5 %) and two unidentified products.

Coupling of *m*-chloro-iodobenzene under the same conditions gave chlorobenzene (6 %) and 3,3'-dichlorodiphenyl (55 %) while *p*-chloro-iodobenzene gave chlorobenzene (11 %) and 4,4'-dichlorodiphenyl (63 %). No dichlorobenzene was detected in either case and the high boiling material was therefore not investigated. These results are in agreement with those of Ullmann [5] and van Alphen [6].

The copper bronze used in these experiments contained small amounts of fatty acids (*ca.* 0.4 %), partly as copper salts. According to previous experience in this laboratory it is a superior reagent for Ullmann couplings; it gives reproducible yields and usually no unchanged iodo-compounds can be recovered from reactions carried out above 220°. The isolation of dibenzofuran and small quantities of aliphatic ketones indicated, however, some uncontrolled reaction with atmospheric oxygen and with impurities in the copper. The reaction was therefore repeated under anaerobic conditions with purified copper.

The fatty acids and their copper salts were removed by ether extraction and the copper was then heated to 360° *in vacuo*. The coupling reaction was carried out under oxygen-free nitrogen using the same conditions of time and temperature as in the previous experiment. The reaction product was fractionated in a spinning band column and the distillation residue was chromatographed on alumina. Somewhat surprisingly a large amount of starting material was recovered (48 %). Chlorobenzene (VI, 8 %), *o*-dichlorobenzene

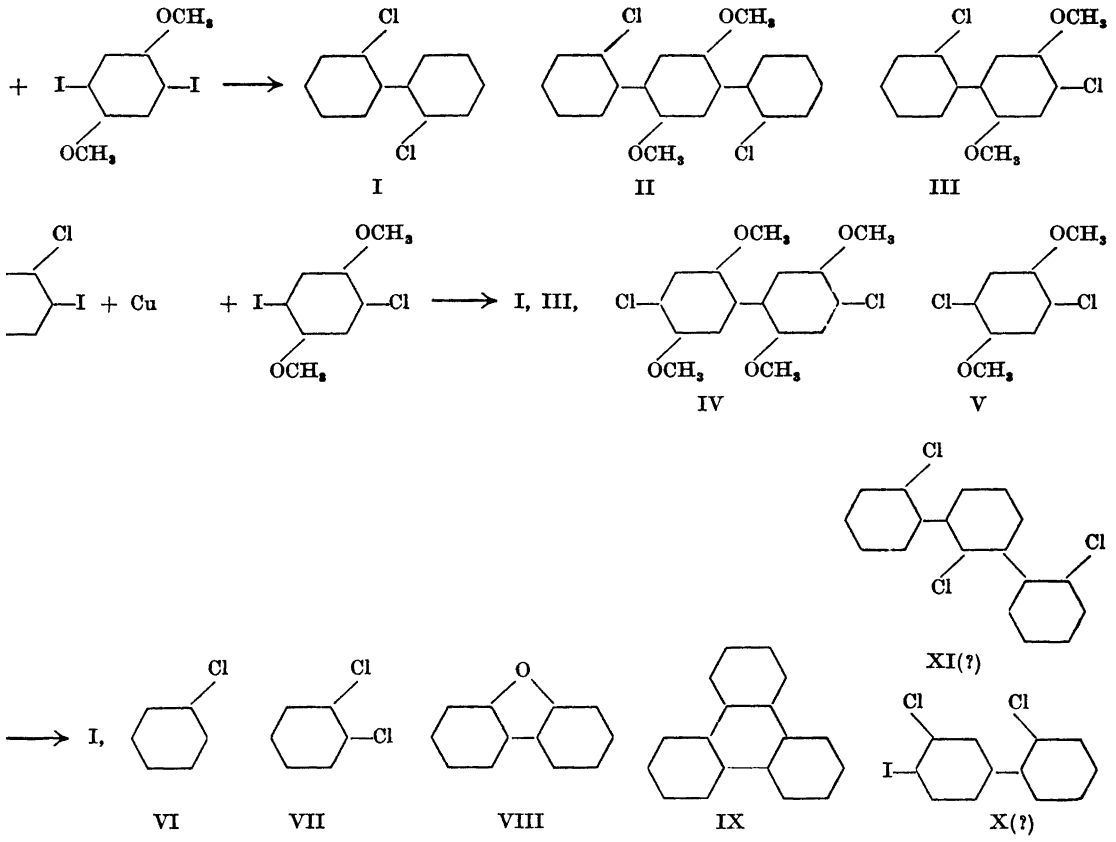

Fig. 1. Products isolated from Ullmann couplings with *o*-chloro-iodobenzene.

(VII, 3 %) and 2,2′-dichlorodiphenyl (I, 31 %) were isolated as before (yields based on starting material consumed). In addition, two new crystalline by-products were obtained. One of them, m. p. 85°, proved to be a dichloro--iododiphenyl (yield 3 %) and spectral studies indicate it to be either 2,3′--dichloro-4′-iodo- or 2,4′-dichloro-3′-iododiphenyl (X). The other one, m. p. 124°, contained carbon, hydrogen and chlorine only. UV, IR and mass spectral data showed that it was probably 2-chloro-1,3-bis-(2-chlorophenyl)-benzene (XI, yield 4 %). No triphenylene, diphenylene or dibenzofuran were detected in the mother liquors and non-crystalline fractions (UV).

The possible role of copper(I) chloride in the halogen exchange reaction was investigated briefly. 2,5-Di-iodohydroquinone dimethylether was treated with an excess of copper(I) chloride alone (250°, 15 h) and also in boiling N,N-dimethylformamide to give 2,5-dichlorohydroquinone dimethylether (*ca.* 70 % yield).

DISCUSSION

The Ullmann reaction with *o*-chloro-iodobenzene and copper gives *o*-dichlorobenzene as a by-product. Mixed Ullmann couplings with *o*-chloro-iodobenzene give other products in which aromatic iodine has been replaced by chlorine.

Somewhat similar halogen exchange reactions can be brought about by heating an iodo-arene with copper(I) chloride either alone or in a basic solvent. An analogous reaction for the conversion of bromo-arenes into the chloro-analogues has recently been patented [7]. These reactions appear to be a new example of copper-catalysed S_N reactions [8].

However, in the reaction of *o*-chloro-iodobenzene with copper no copper(I) chloride is present initially and it appears therefore as if copper(I) chloride or its equivalent is formed during the reaction and then reacts with an iodo-arene to give the halogen exchange product. This is somewhat surprising as aromatic chlorine is not attacked by copper unless it is activated, *e. g.* by a nitro or carbonyl group in the *ortho* position.

The mechanism of the Ullmann reaction is not known but has been the subject of much discussion, and free radicals, "crypto-radicals", copper organic compounds and carbanions have been proposed as intermediates. It has been suggested that the intermediate either dimerises or reacts with a second molecule of iodo-compound (*cf.* review by Fanta [9]); in the latter case the reaction may be related to the copper-catalysed substitution reactions [8].

The mobility of chlorine in the reaction with *o*-chloro-iodobenzene may be related to an intermediate or to the main reaction product, 2,2′-dichlorodiphenyl. The latter appears unlikely and it thus seems possible that chlorine can be eliminated from the intermediate from *o*-chloro-iodobenzene though not from the intermediates from *m*-chloro- and *p*-chloro-iodobenzene.

This recalls the lability of *o*-halogenophenyllithium and *o*-halogenophenylmagnesium halides, which split off metal halide giving dehydrobenzene (benzyne), which undergoes addition reactions, reacts with dienes and polymerises to diphenylene, triphenylene *etc.*[10] The isolation of small amounts of triphenylene in the present case is a slight indication of the formation of dehydrobenzene.

On this analogy the reactive intermediate in the Ullmann reaction is likely to be an arylcopper. Phenylcopper is reported to react with certain carbonyl groups and also with allyl bromide, acyl halides *etc.*[11] and it is thus possible that *o*-chlorophenylcopper can eliminate copper(I) chloride to give dehydrobenzene.

Further work is, however, necessary to establish this and to clarify the relation to the main reaction and to the dehalogenation process, which is a major side reaction in Ullmann couplings.

In the present investigations chlorobenzene was obtained as the normal dehalogenation product; some of the corresponding "dehydrogenation" products, a dichloro-iododiphenyl and a trichloroterphenyl were also isolated and together account for one third of the dehalogenation. These findings are analogous to those of Rapson and Shuttleworth [12], who obtained 2-carbethoxy- and 4-carbethoxydiphenyl from the reaction of iodobenzene with copper in the presence of ethyl benzoate.

No satisfactory explanation can as yet be given for the formation of dibenzofuran.

EXPERIMENTAL

The melting points were determined on a Kofler block. The ultraviolet spectra were measured in ethanol (99.5 %) with a Beckman DU instrument. The infrared spectra were recorded on a Perkin Elmer No. 21 instrument with a sodium chloride prism. Light petroleum refers to the fraction b.p. 40—60°. The copper used was a lithographic bronze containing *ca.* 0.2—0.5 % fatty acids, mainly stearic, palmitic and oleic acids, partly as the copper salts.

3-Hydroxy-2,5-diphenyl-p-*benzoquinone.* Perchloric acid (15 ml, *d* 1.67) was added with stirring to 2,5-diphenyl-*p*-benzoquinone [13] (20 g) suspended in acetic anhydride (300 ml). The temperature was kept below 35°. Stirring was continued for 24 h and the mixture was then poured onto crushed ice. After standing overnight the product was collected (21 g) and a portion recrystallised from ethanol (charcoal), prisms, m. p. 195—198°. Kvalnes [14] reported m. p. 191°. (Found: C 70.9; H 5.3. Calc. for $C_{24}H_{20}O_3$: C 71.3; H 5.0.)

The crude triacetate (20 g) was heated under reflux with absolute methanol (200 ml) and concentrated sulphuric acid (10 ml) for 1 h. Most of the solvent was distilled off and after cooling the hydroxyhydroquinone was collected, washed with methanol and dried. It was very sensitive to air and was therefore not purified but was suspended in acetic acid (200 ml) and oxidised with sodium nitrite (8 g) in water (40 ml) at room temperature. After a few minutes the red product was filtered off and was then recrystallised from acetic acid giving 3-hydroxy-2,5-diphenyl-*p*-benzoquinone as dark red plates, m. p. 235—238° (slight decomp.). Overall yield 50 %. (Found: C 78.2; H 4.7. Calc. for $C_{18}H_{12}O_3$: C 78.3; H 4.4.) It was further characterised as the acetate (acetic anhydride, perchloric acid, room temperature), yellow needles from acetic anhydride, m. p. 174—175°. (Found: C 75.3; H 4.6. Calc. for $C_{20}H_{14}O_4$: C 75.5; H 4.4.)

2,5-Dimethoxy-1,4-bis-(2-chlorophenyl)-benzene (II). 2,5-Di-iodohydroquinone dimethylether (40 g, 0.1 mole), 2-chloro-iodobenzene (95 g, 0.4 mole) and copper bronze (300 g) were mixed and heated in a salt bath. The reaction started at 210° and the temperature rose to 270°. After cooling, the mass was extracted exhaustively with chloroform (Soxhlet) and after removal of the solvent the extract was distilled at 0.5—1 mm. Fraction 1: b. p. below 110°, 27 g; 2: 110—130°, 2.7 g; 3: 130—160°, 5.8 g; 4: 160—230°, 15.2 g; 5: 230—290°, 8.8 g.

Fraction 1 was discarded; fraction 2 solidified and was found to be 2,2′-dichlorodiphenyl, m. p. 45—54°. Fraction 3 on trituration with *cyclo*hexane gave a product A (1.6 g) m. p. *ca.* 100° and fraction 4 on trituration with benzene-*cyclo*hexane mixtures gave a compound B (2.6 g), m. p. *ca.* 200°. Fraction 5 gave only small amounts of high melting material, which was not further investigated.

The non-crystalline parts of fractions 3—5 were combined and redistilled through a 5 cm Vigreux column and further quantities of A (1.5 g) and B (0.3 g) were obtained by trituration of the distillate.

The investigation of A is described later, B proved to be the desired terphenyl derivative II. It was recrystallised from benzene giving prisms containing *ca.* 1 mole of benzene of crystallisation. The dried product melted at 214—216°. (Found: 15 % loss of weight on drying at 100°, 1 mm. Calc. for $C_{20}H_{16}Cl_2O_2 \cdot C_6H_6$: 18 %. Found: C 66.9; H 4.6; Cl 19.5. Calc.: C 66.9; H 4.5; Cl 19.7.)

2,5-Bis-(2-chlorophenyl)-p-*benzoquinone.* Finely powdered 2,5-dimethoxy-1,4-bis-(2-chlorophenyl)-benzene (1.2 g) was suspended in nitric acid (25 ml, *d* 1.42) and the mixture was shaken for 10 min. Water (100 ml) was then added and after a few hours the precipitate was collected and recrystallised from ethyl acetate to give yellow plates or prisms, m. p. 200—202° (0.7 g). (Found: C 65.8; H 3.1; Cl 21.2. Calc. for $C_{18}H_{10}Cl_2O_2$: C 65.7; H 3.1; Cl 21.5.)

3-Hydroxy-2,5-bis-(2-chlorophenyl)-p-*benzoquinone.* The quinone (1.1 g) in acetic anhydride (20 ml) was shaken with perchloric acid (2 ml, *d* 1.67) for 15 h. The dark solution was poured onto ice and the product was collected and recrystallised from methanol (charcoal) giving *2,3,5-triacetoxy-1,4-bis-(2-chlorophenyl)-benzene*, prisms, m. p. 154—158° (0.65 g). (Found: C 61.3; H 3.7; Cl 15.1. Calc. for $C_{24}H_{18}Cl_2O_6$: C 60.9; H 3.8; Cl 15.0.)

The triacetate (0.33 g) was heated under reflux with absolute methanol (25 ml) and concentrated sulphuric acid (1 ml) for 1 h. On addition of water (50 ml) the hydroxy-

hydroquinone precipitated as a colourless solid (0.22 g). A small portion was recrystallised from methanol and sublimed giving prisms, m. p. 206—209°. (Found: C 61.6; H 3.3. Calc. for $C_{18}H_{12}Cl_2O_3$: C 62.3; H 3.5.) The main portion (0.19 g) was dissolved in acetic acid (5 ml) and oxidised with sodium nitrite (0.2 g) in water (1 ml). After 0.5 h the mixture was diluted with water (20 ml) and the orange product was collected (0.18 g). Sublimation gave 3-hydroxy-2,5-bis-(2-chlorophenyl)-*p*-benzoquinone as yellow prisms, m. p. 187—190°. (Found: C 62.2; H 2.7; Cl 20.3. Calc. for $C_{18}H_{10}Cl_2O_3$: C 62.6; H 2.9; Cl 20.5.)

Investigation of A. The crude product was recrystallised from *cyclo*hexane and from methanol giving needles, m. p. 105—106°. Qualitative tests indicated the presence of chlorine and the absence of iodine. (Found: C 59.5; H 4.3; Cl 25.2. Calc. for $C_{14}H_{12}Cl_2O_2$: C 59.4; H 4.3; Cl 25.1.) Ultraviolet absorption spectrum: λ_{max} 303 mμ, (ε 6 700), λ_{min} 270 mμ (ε 1 200), shoulder at *ca.* 255 mμ.

For oxidation, A (0.5 g) was shaken for a few minutes with nitric acid (10 ml, *d* 1.42). Water (50 ml) was then added and the product collected (0.4 g). Sublimation and recrystallisation from methanol gave needles, m. p. 111—112°, resolidifying and finally melting at 117—118°. The analytical sample was resublimed. (Found: C 56.7; H 2.2; Cl 26.1. Calc. for $C_{12}H_6Cl_2O_2$: C 56.9; H 2.4; Cl 28.0.)

Synthesis of 2',4-dichloro-2,5-dimethoxydiphenyl (III). Chlorohydroquinone dimethylether (17.2 g, 0.10 mole) in acetic acid (25 ml) was treated with iodine monochloride (19.4 g, 0.12 mole) in acetic acid (10 ml). When the initial reaction had subsided the mixture was heated overnight on the water bath. The cooled solution was treated with sulphur dioxide and some water, the colourless precipitate was collected and recrystallised from ethanol giving pure 2-chloro-5-iodohydroquinone dimethylether, m. p. 114—116°, in 56 % yield. Posternak *et al.*[15] report m. p. 114—115°.

o-Chloro-iodobenzene (12 g, 0.05 mole), 2-chloro-5-iodohydroquinone dimethylether (7.5 g, 0.025 mole) and copper bronze (48 g) were mixed and heated in a salt bath. At 210° the reaction raised the temperature to 245°. The mixture was kept at this temperature for 20 min, then cooled and extracted with chloroform (Soxhlet). Evaporation of the solvent gave an oil, which was distilled through a 5 cm Vigreux column at *ca.* 0.5 mm. Fraction 1: b. p. 75—80°, 1.1 g; 2: 90—98°, 0.9 g; 3: 98—118°, 1.4 g; 4: 140—150°, 2.6 g; 5: 180—190°, 1.9 g.

The first two fractions deposited crystalline material, which was filtered off and washed with *cyclo*hexane. The product (0.3 g) was freed from oily contaminants by sublimation and was finally purified by recrystallisation from methanol, prisms m. p. 132—133°. A second form, needles m. p. 125—127°, was occasionally observed. Mixed melting point with 2,5-dichlorohydroquinone dimethylether gave no depression. Fraction 3 solidified on standing, recrystallisation from methanol gave 2,2'-dichlorodiphenyl, m. p. 49—54°. Fraction 4 on trituration with methanol gave a product, m. p. 102—105° (1.8 g); recrystallisation from methanol and from *cyclo*hexane raised the m. p. to 105—106° alone or in admixture with A. It was further oxidised to 5-chloro-2-(2-chlorophenyl)-*p*-benzoquinone as described for A; the same dimorphism was encountered and the mixed m. p. gave no depression.

Fraction 5 solidified and was recrystallised from ethanol to give needles (0.6 g, m. p. 143—150°). Further recrystallisation from acetic acid gave plates, m. p. 154—156°, undepressed by 4,4'-dichloro-2,2',5,5'-tetramethoxydiphenyl obtained from the reaction of 2-chloro-5-iodohydroquinone dimethylether with copper. Posternak *et al.*[15] report m. p. 151°. (Found: C 56.0; H 4.7; Cl 21.0. Calc. for $C_{16}H_{16}Cl_2O_4$: C 56.0; H 4.7; Cl 20.7.)

Ullmann coupling of o-chloro-iodobenzene. *o*-Chloro-iodobenzene (95 g, 0.4 mole) and copper bronze (256 g) were intimately mixed in a flask fitted with a reflux condenser and a thermometer and placed in a salt bath (180°). The temperature was raised and at *ca.* 190° the reaction raised the temperature to 230°. When the reaction had subsided the temperature was raised further and kept at 250—260° for 2 h. The reflux condenser was replaced by a still head and some volatile material distilled off at atmospheric pressure directly from the reaction vessel. Fraction 1: b. p. 130—140°, 3.5 g; 2: 150—180°, 2.8 g. The residue was extracted with chloroform yielding on evaporation of the solvent a brown oil (*ca.* 40 g) which was distilled through a 5 cm Vigreux column at *ca.* 10 mm to give fractions 3: 45—60°, 0.15 g; 4: 60—150°, 0.91 g; 5: 140—145°, 8.95 g, and then at *ca.* 1.5 mm giving: 6: 105—125°, 13.8 g; 7: 125—140°, 2.2 g; 8: 140—175°, 1.5 g; 9: 175—185°, 2.3 g; 10: 185—210°, 1.2 g. The distillation was interrupted and the residue extracted with chloroform to give fraction 11: 3.1 g, a brown oil.

Fraction 1 from b. p. and IR data was found to be fairly pure *chlorobenzene*. Nitration gave *2,4-dinitrochlorobenzene*, m. p. 49—52°, undepressed by an authentic sample.

Fraction 2 was similarly found to be mainly o-*dichlorobenzene*. Treatment with chlorosulphonic acid gave *bis-(3,4-dichlorophenyl)-sulphone*, m. p. 175—177°, undepressed by an authentic specimen. Fraction 3 contained largely *o*-dichlorobenzene (IR), and fraction 4 appeared to be heterogeneous (IR, UV).

Fractions 5—7 largely solidified on standing and on recrystallisation afforded crude *2,2'-dichlorodiphenyl*, m. p. 55—60° (16.3 g).

Fraction 8 was triturated with ethanol to give *product C*, m. p. 156—170° (0.12 g).

The mother liquors from fractions 5—8 were combined and chromatographed on alumina (1 kg). Elution with light petroleum (1.7 l) gave an oil (4.7 g), which solidified on standing. Recrystallisation from methanol gave *2,2'-dichlorodiphenyl*, m. p. 57—60°, (3.9 g). Further elution with the same solvent (12.1) gave a semi-solid product (3.2 g) which was recrystallised from methanol to give *substance D*, m. p. 78—83° (*ca.* 2 g). Further elution with light petroleum gave crude *C* (0.5 g).

Fractions 9 and 10, which were strongly fluorescent yellow oils were combined and chromatographed on alumina (200 g). Elution with *cyclo*hexane (450 ml) gave an oil (2.9 g), which on trituration with ethanol gave *C* (0.7 g). Further elution gave fractions (0.2 g) which were triturated with ethanol to give a *product E*, m. p. 95—105° (0.04 g). Elution with *cyclo*hexane-benzene (9:1) gave a crystalline *material F*, m. p. *ca.* 190° (0.2 g).

Fraction 13 was chromatographed on alumina. The light petroleum eluate gave crude *C* (0.5 g) and *E* (0.1 g). Light petroleum-benzene (9:1) gave crude *F* (0.3 g) and a waxy product *G* (0.2 g) m. p. around 80°. Elution with benzene stripped the column giving a brownish yellow resin *H* (0.6 g).

Product C (total *ca.* 1 g) was recrystallised from ethanol and sublimed to give prisms, m. p. 179—181°. Qualitative tests indicated the presence of chlorine and absence of iodine.

C dissolved in concentrated sulphuric acid to give a blue solution. No satisfactory analysis has so far been obtained.

Product D (total *ca.* 2 g). Recrystallisation from methanol gave plates, m. p. 83—85°. The picrate was crystallised from ethanol, yellow needles, m. p. 98—101°. The UV-spectrum agreed with that of dibenzofuran and mixed m. p.s with authentic dibenzofuran and its picrate gave no depression.

Product E (total *ca.* 0.1 g) was not obtained in a state of purity. It melted around 100° and gave a picrate, m. p. *ca.* 150°.

Product F (total *ca.* 0.2 g) was recrystallised from ethanol and sublimed to give needles, m. p. 197—199°. The picrate was prepared in acetone and was recrystallised from ethanol; needles, m. p. 222—225°. The UV and IR-spectra agreed with those given for triphenylene and the mixed m. p.s with a commercial sample and the picrate prepared from it gave no depression.

Product G (total *ca.* 0.3 g). The IR spectrum of this waxy material contained bands characteristic for aliphatic ketones but no aromatic bands. This product must be a mixture of aliphatic ketones originating from the fatty acids in the copper bronze.

Product H was a brown resin with an extremely strong yellow fluorescence. The IR indicated that it was contaminated with aliphatic and ketonic material and it was not further investigated.

Ullmann coupling of m-*chloro-iodobenzene*. *m*-Chloro-iodobenzene (0.4 mole) was allowed to react with copper under the conditions described above. Direct distillation from the reaction mixture gave fraction 1: b. p. 130—135°, 3.8 g. The chloroform extract on distillation gave fraction 2: b. p. below 50°/15 mm, 0.1 g; 3: 123—130°/1.5, 21.1 g; 4: 130—140°, 8.0 g; 5: 140—160°, 3.5 g.

Fraction 1 was fairly pure *chlorobenzene* (b. p., IR) and was characterised as the 2,4-dinitro-derivative. Fraction 2 contained largely chlorobenzene. No evidence for the presence of *m*-dichlorobenzene was obtained from the IR spectrum.

The IR spectra of fractions 3 and 4 were identical but fraction 5 was contaminated by aliphatic and ketonic material. All these fractions however solidified in the refrigerator and on recrystallisation from methanol gave *3,3'-dichlorodiphenyl*, m. p. 28—29.5°, in 55 % yield. The mother liquors and the distillation residue were not investigated.

Ullmann coupling of p-*chloro-iodobenzene*. *p*-Chloro-iodobenzene (m. p. 54—57°) treated in the same way gave a distillate, b. p. 130—135°, 6.7 g, indentified as chloro-

benzene by IR and by nitration. The extract could not be conveniently distilled because of the tendency of the product to sublime. It was therefore sublimed on to a cold finger (160—170°, 2 mm) and the sublimate was recrystallised from methanol giving 4,4'-dichlorodiphenyl, m. p. 144—148°, in 63 % yield. No evidence was obtained for the presence of a dichlorobenzene and the sublimation residue was not investigated.

Coupling of o-chloro-iodobenzene under modified conditions. Copper bronze (260 g) was exhaustively extracted with ether in a Soxhlet apparatus (extract: 1.0 g of a green wax), transferred while moist to a 250 ml three-necked flask fitted with thermometer, reflux condenser and a nitrogen inlet tube, and dried by heating *in vacuo*, finally at 360°/3 mm for 2 h. After cooling the flask was filled with oxygen-free nitrogen and *o*-chloro-iodobenzene (0.4 mole), which had been freshly distilled through a 30-plate column (b. p. 136.5—137.5°/50 mm), was then added with a slow current of nitrogen passing through the apparatus, the flask was placed in a salt bath (180°) and the temperature was raised to 250° (0.5 h) and kept at this level for 2 h. There was no marked evolution of heat and in contrast to previous experiments the inner temperature was all the time somewhat below that of the bath. The reflux condenser was then replaced by a still head and some volatile material formed was distilled off in a current of nitrogen. The distillate (2.8 g, b. p. 150—210°) was shown by IR spectra to contain chlorobenzene and *o*-dichlorobenzene.

After cooling, the contents of the flask were extracted with chloroform (Soxhlet), most of the solvent was removed and the oil obtained was combined with the previous distillate and distilled through a spinning band column. The following fractions were collected: 1: b. p. 126—135°/760 mm, 1.8 g; 2: 156—175°/760, 0.9 g; 3: 100—103°/9, 46.9 g; 4: 139—149°/9, 0.5 g; 5: 149—156°/9, 8.2 g; 6: 171—181°/9, 1.0 g; 7: 189—191°/7, 2.1 g.

Fraction 1. *Chlorobenzene* as shown by b. p., IR and conversion to *2,4-dinitrochlorobenzene.*

Fraction 2. *o-Dichlorobenzene* as shown by b. p., IR and conversion to *bis-(3,4-dichlorophenyl)-sulphone.*

Fraction 3 on standing acquired a reddish colour. B. p. and IR indicated *o-chloro-iodobenzene.*

Fraction 4. UV and IR spectra indicated a mixture of *o*-chloro-iodobenzene and 2,2'-dichlorodiphenyl. No dibenzofuran or diphenylene peaks were detected in the spectra.

Fraction 5 solidified and was recrystallised from methanol to give *2,2'-dichlorodiphenyl* (7.3 g, m. p. 55—61°).

Fraction 6 was a brown oil. The UV-spectrum was of the 2,2'-dichlorodiphenyl type.

Fraction 7 on standing became reddish and partly solidified. Recrystallisation from methanol gave a *product K* (0.3 g, m. p. 67—68°).

The distillation residue on extraction with chloroform gave a reddish brown solution evaporated to give a brown oil (6.3 g), which was chromatographed on alumina (1 kg). The first and the last fractions of the light petroleum eluate (5 l) solidified giving an additional quantity of *K* (0.7 g) and a *product L* (1 g, m. p. *ca.* 120°). The intermediate fractions were colourless oils. Light petroleum-benzene (9:1, 4 l) gave colourless resins, with a blue fluorescence under a quartz lamp. The UV-spectra gave no indication of the presence of triphenylene. Benzene (2 l) stripped the column giving brownish resins with intense yellow fluorescense.

Substance K (total 1 g). Recrystallisation from methanol gave needles, m. p. 85—87° (strongly depressed by dibenzofuran). Qualitative tests indicated the presence of chlorine and iodine. (Found: C 41.3; H 1.9; Cl 20.3; I 36.2. Calc. for $C_{12}H_7Cl_2I$: C 41.3; H 2.0; Cl 20.3; I 36.4.) UV-spectrum: λ_{max} 252 mμ (ε 15 000), λ_{min} 233 mμ (ε 10 000). IR-spectrum (KBr-disc): 3 090 w, 1 640 w, 1 577 w, 1 545 m, 1 492 w, 1 460 s, 1 440 m, 1 375 s, 1 303 w, 1 275 w, 1 248 w, 1 125 w, 1 112 m, 1 080 m, 1 042 m, 1 012 s, 950 w, 890 m, 865 w, 820 m, 755 s, 730 m, 705 m, 675 m.

The C—H out-of-plane region thus indicates 1, 2 and 4 adjacent hydrogen atoms. The UV-spectrum rules out 2,2'-substitution and makes a 2-iododiphenyl improbable [16]. Substance K therefore is probably *2,4'-dichloro-3'-iodo- or 2,3'-dichloro-4'-iodo-diphenyl* (X).

Substance L (total 1 g) was recrystallised from methanol and sublimed (0.05 mm) giving needles, m. p. 122—124°. It contained chlorine but no iodine. The analysis was consistent with a dichlorodiphenyl or a trichloroterphenyl. (Found: C 64.9; H 3.4;

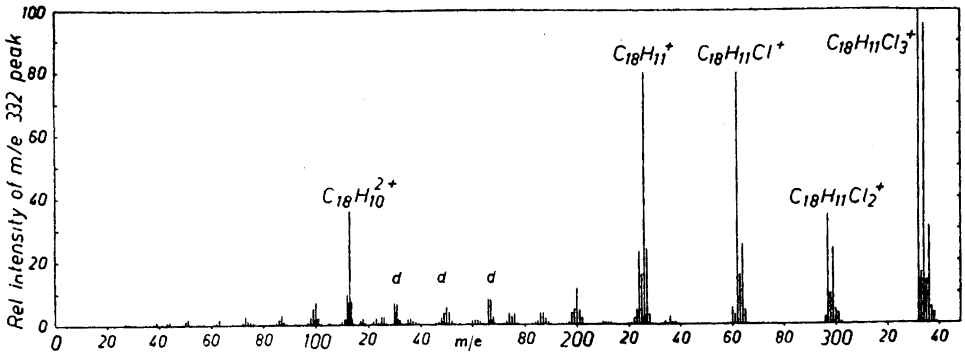

Fig. 2. Mass spectrum of compound *L* (*d* denotes doubly-charged ion).

Cl 32.0. Calc. for $C_{18}H_{11}Cl_3$: C 64.8; H 3.3; Cl 31.9.) Molecular weight determination according to Rast gave results, which were inconsistent with the low volatility of the substance.

The mass spectrum was kindly recorded by Ing. R. Ryhage, Laboratory for Mass Spectrometry, Karolinska Institutet, Stockholm, using an instrument with an all-glass heated inlet system [17]. The mass numbers were checked by recording the mass spectrum of a mixture of compound *L* and methyl *n*-eicosanate [18] obtained from Prof. E. Stenhagen. In the mass spectrum (Fig. 2) groups of peaks near m/e = 332, 297, 262 and 226 (!) indicate the successive loss of three chlorine atoms from a parent molecule $C_{18}H_{11}Cl_3$ (m/e = 332, 334, 336, 338) and compound *L* can therefore be assigned the empirical formula $C_{18}H_{11}Cl_3$.

The ultraviolet spectrum had no maxima and was very similar to that given for 2,2'--dichlorodiphenyl [19].

Infrared spectrum (KBr-disc): 3 090 m, 1 975 w, 1 950 w, 1 900 w, 1 818 w, 1 715 w, 1 635 w, 1 605 w, 1 590 w, 1 575 m, 1 493 s, 1 458 s, 1 440 s, 1 410 s, 1 260 w, 1 189 w, 1 160 w, 1 140 m, 1 080 w, 1 052 s, 1 039 s, 978 w, 956 w, 820 w, 803 s, 755 vs, 735 s, 728 m, 703 m, 690 s. The C—H out-of-plane region is thus consistent with 4 and 3 neighboring hydrogens and substance *L* is therefore probably *2-chloro-1,3-bis-(2-chlorophenyl)-benzene* (XI).

Acknowledgements. Thanks are due to Ing. R. Ryhage for the determination of the mass spectrum and to *Statens Tekniska Forskningsråd* for a fellowship.

Quantitative Estimation of Sialic Acids

III. An Anion Exchange Resin Method

L. SVENNERHOLM

Department of Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden

The increasing interest in the distribution of sialic acids in biological materials made it desirable to have a simple method for their analysis. As the colour reactions of the sialic acids are unspecific and influenced by a lot of naturally occurring substances, mainly carbohydrates, a direct analysis of sialic acid is inconvenient for many materials.

In the procedure elaborated the sialic acids are liberated with weak sulphuric acid and retained by a column with Dowex-2 in acetate form. Most of the contaminants are eluted with distilled water and then the sialic acids are displaced with an acetate buffer of pH 4.6. The concentration of sialic acid in the eluates is analysed with the resorcinol method. The optimum conditions for the liberation of the sialic acids are studied in particular.

The method has been satisfactorily applied to the analysis of sialic acids in body fluids and tissues (brain, kidney, liver, pancreas and submaxillary gland).

The concentrations of sialic acids have until now only been determined in biological fluids or isolated watersoluble compounds [1]. For these purposes some colour reactions have been applied to the unhydrolysed material and the colour developed has been determined by photometrical reading. The reactions are not specific but to a greater or lesser extent other biological compounds, mainly carbohydrates, give colours when using the reagents [2–5]. As sialic acids exist together with other carbohydrate components in biological materials, the quantitative figures for sialic acids obtained by direct colorimetry become too high. The positive error given by the other sugars has been corrected by dichromatic readings [3,4] but if the ratio total carbohydrates to sialic acids is great, it is only possible to make an approximate correction. It is also necessary to know the nature of the other sugars and their relative amount which restricts the general application of the procedure of dichromatic readings. There is also an uncertainty as to which degree the colour development of the sialic acids is influenced by substances other than carbohydrates in biological materials. Another disadvantage of direct colorimetric

analyses is that the colour development of bound sialic acids [3] is slower than that of free sialic acids. A prolonged reaction time is, however, unsuitable as the interference from the other carbohydrates then increases considerably [3,4]. It has also become an increasing need for a simple procedure at the analysis of sialic acids in tissues. In the latter case it is in general necessary to split off the sialic acids before they can be assayed with the colour reactions.

For these reasons a quantitative method was elaborated in which the sialic acids were liberated by acid hydrolysis and most of interfering substances removed on columns with an anion exchange resin.

METHODS

Preparation of the ion exchange columns

Dowex 2-X 8, 200—400 mesh, wetscreened through 150 mesh, was heated on the steam bath with three times the volume of 2 N hydrochloric acid. After the resin had settled for 30 min, the supernatant was decanted to remove the fines. After undergoing this treatment four times the resin was stirred up in water and poured into a large tube fitted with a glass filter. The resin was converted to acetate form by passing 2 N sodium acetate through the column until the effluent gave a negative test for chloride. The resin was then slurred up in 1 N acetic acid, transferred to a Büchner funnel and excessive moisture was removed by suction.

For the preparation of the columns about 3 g of the moist resin was suspended in about two volumes of distilled water and poured into a chromatographic tube (inner dimensions 0.7 × 20.0 cm), fitted with a glass filter plate (G 2) at the bottom and widened at the top (2 × 3 cm). The resin was allowed to settle to a height of 6.0 cm and excess resin then poured off. A small filter paper was placed over the resin and above it sand to a height of 0.5 cm. After washing the resin with 10 ml of 0.1 N acetic acid the column was ready for use.

Dowex 50-X 8, 100—200 mesh, was washed slowly several times on a Büchner funnel with 2 N sodium hydroxide, 2 N hydrochloric acid and distilled water in that order. A suspension of the resin in water was poured into a tube of the same dimensions as used for Dowex 2. The height of the column used was about 5 cm.

Regeneration of the columns. Having completed elution the columns were regenerated in the following order. 10 ml of each solution was used.

Dowex 2: 2 N sodium hydroxide, distilled water, 2 N sodium acetate and 0.1 N acetic acid.

Dowex 50: 2 N sodium hydroxide, distilled water, 2 N hydrochloric acid and distilled water.

Hydrolysis of the samples

Samples, containing 25—200 μg of sialic acid, were hydrolysed in small tubes having glass stoppers in 5 ml of 0.1 N sulphuric acid at 80°C and in 5 ml of 0.05 N sulphuric acid at 90°C for one hour. (When lipid extracts were investigated the lipids were dissolved in 0.5—1.0 ml of methanol by heating and the sulphuric acid was added initially in drops to give a fine emulsion.) Having been heated, the tubes were cooled to room temperature and the hydrolysates filtered into the column with Dowex 2. If the sample contained more than 0.1 mequiv. of inorganic cations, the hydrolysate was filtered into the tube with Dowex 50 which was placed immediately above the column with Dowex 2, so that the effluent from the first tube dropped into the Dowex 2 column. After filtration the hydrolysis tubes and the columns were washed twice with 5 ml of water.

Standards of 0, 100 and 200 μg N-acetylsialic acid were treated under the same conditions as the samples in each experiment.

Elution of sialic acids

The sialic acids were eluted from the Dowex 2 columns with 8 ml of 1 M acetic acid-sodium acetate buffer (pH 4.6). The effluent was collected in a 10 ml cylinder. Distilled water was added to the 10 ml mark.

Analysis of sialic acids

Resorcinol method. — Reagent. 0.2 g of resorcinol A.R. was dissolved in 10 ml distilled water. 80 ml conc. hydrochloric acid and 0.25 ml 0.1 M copper sulphate were added, and the volume was made up to 100 ml with distilled water.

Procedure: 2 ml of effluent in duplicates was pipetted into a centrifuge tube (16 × 120 mm) and 2 ml of resorcinol reagent added. The tubes were heated for 15 min in a bath of boiling water. After cooling in tap water, 5 ml of *iso*amyl alcohol was added and the tubes were vigorously shaken and chilled for 10 min in a bath of ice water. After centrifuging the amyl alcohol phase was transferred to 50 mm microcells and read in a Beckman Spectrophotometer model B at 450 and 580 mμ. In the eluates of hydrolysed tissues also ribose esters occurred. Their influence on the absorbancy values at 580 mμ was calculated from the reading at 450 mμ.

RESULTS

Stability of sialic acids in acid milieu. For the quantitative estimation of sialic acids only acid hydrolysis is applicable, as alkaline hydrolysis transforms part of the sialic acids to 2-carboxypyrrole [6,7]. The sialic acids are easily split off in acid milieu but the problem is to achieve such mild conditions that the destruction of sialic acids is negligible. The stability of the sialic acids was tested by heating N-acetylsialic acid under varying conditions and afterwards analysing the hydrolysates with the resorcinol method:

After heating N-acetylsialic acid, dissolved in distilled water, for one hour in a bath of boiling water, the absorbancy diminished by 1—2 %. When the substance was dissolved in 0.05 N and 0.1 N sulphuric acid the absorbancy diminished by 3 and 5 %, respectively. In these tests the concentration of N-acetylsialic acid was 20—40 μg/ml; if the concentration was 10-fold the destruction increased to about twice this value. Therefore, in all the following tests the low concentration of sialic acid was used. When the heating was performed at a lower temperature, 80—90°C, the destruction of N-acetylsialic acid was less. After heating for one hour with distilled water the absorbancy

Table 1. The recovery of N-acetylsialic acid (Ac. sial.) and N-glycolylsialic acid (Glyc. sial.) from Dowex 2 columns after heating with sulphuric acid under varying conditions.

Material	Sulphuric acid N	Temp. C°	Time of heating, h	No. of expts	Recovery, % M. ± S.E.M.
Ac.sial.	0.05	90	1	10	94.5 ± 0.6
Glyc.sial.	0.05	90	1	10	94.2 ± 0.6
Ac.sial.	0.05	90	2	4	89
Ac.sial.	0.10	80	1	10	95.0 ± 0.5
Glyc.sial.	0.10	80	1	10	94.3 ± 0.7
Ac.sial.	0.10	80	2	4	90
Ac.sial.	0.20	80	1	4	93

was unchanged. When heated for one hour with sulphuric acid no measurable decrease in absorbancy was found for a concentration of sulphuric acid $\leq$ 0.05 N at 90°C, $\leq$ 0.2 N at 80°C and $\leq$ 0.4 N at 70°C. The stability of N-acetylsialic acid was somewhat lower in hydrochloric acid than in sulphuric acid of the same strength. Trichloroacetic acid (10 %) and formic acid (1 N) did not destroy the sialic acid at 80 or 90°C, but the concentrations necessary for the quantitative release of bound sialic acid from, *e. g.*, serum proteins were too high for the capacity of the ion exchange resin. It was thus found that sulphuric acid was the most convenient acid for the hydrolysis. Addition of sodium chloride in a concentration of up to 10 mequiv/l did not give any measurable increased destruction of N-acetylsialic acid.

Recovery of sialic acids after the resin procedure. N-acetylsialic acid and N-glycolylsialic acid were hydrolysed with 0.05 N sulphuric acid at 90°C and with 0.1 N and 0.2 N sulphuric acid at 80°C for 1 and 2 h. The hydrolysates were then poured on the anion exchange resin columns, and after washing with water the sialic acids were eluted with 8 ml of acetate buffer as described. The recovery of the sialic acids is shown in Table 1. There was thus a difference in the recoveries of sialic acids between direct colorimetry and colorimetry after previous resin purification. Analysis of sialic acids in the effluents of the hydrolysate and the wash water were negative. Nor were any sialic acids eluted after a further addition of 10 ml of acetate buffer. This may be explained by a partial destruction of the sialic acids during the heating resulting in products still reacting with the colour reagents. However, they may be so strongly adsorbed to the resin that it is impossible to eluate them with the buffer used. At the isolation of N-acetylsialic acid with the resin technique [8], small fractions of Bial-positive substances were eluted after the main fraction. In paper partition chromatography the R_F-values for all these sialic acids were the same as those of N-acetylsialic acid. Odin and Berggård [9] found, however, when samples of sialic acids were heated with acids, that Bial-positive substances were formed which run faster than N-acetylsialic acid. Therefore it seems likely that the latter compounds will be attached so firmly to the anion resin, that they are not eluted.

It should also be pointed out that special precautions must be taken when isolating the sialic acids, which should be used as standard substances. When the sialic acids were prepared with the anion exchange method [8] and the eluates concentrated to a small volume on the water bath before lyophilization, 2–5 % of the sialic acids were changed and could no longer be attached to the resin. By eluting the sialic acid with acetate buffer, removing the sodium ions with a cation exchange resin in hydrogen form, extracting the acetic acid with diethyl ether, and lyophilizing more dilute solutions, the change of the sialic acids was negligible. For routine work it is however more simple to calculate the concentration of authentic sialic acid in a standard substance by estimating its amount. Unhydrolysed samples of the standard substances were analysed with the resin method and the yield of sialic acid determined. As the recovery of the sialic acids obtained with the described isolation procedure was 100 % after resin treatment the difference in absorbancy for the common standard substances with direct colorimetry and after resin treatment may be attributed to the change of the sialic acids during the isolation.

The destruction of the sialic acids during the liberation were also evaluated by heating biological samples for varying times. With serum and brain tissue

Table 2. Liberation of sialic acids from serum with sulphuric acid. 0.2 ml of serum was hydrolysed with 5 ml of sulphuric acid under varying conditions. The hydrolysates were treated according to the standard procedure.

Temp.	Sulphuric acid	Absorbancy			
		Heating time			
	N	1/2 h	1 h	2 h	3 h
80°C	0.05	0.906	0.904	0.894	0.875
	0.10	0.907	*0.924*	0.882	0.835
	0.20	0.888	0.890	0.850	—
90°C	0.05	0.922	*0.935*	0.881	0.817
	0.10	0.886	0.899	0.819	—

the yield of sialic acid decreased with about 5 % per hour when heated under standard conditions.

Liberation of sialic acids. Serum and brain tissue were hydrolysed with varying concentrations of sulphuric acid at 70°C, 80°C and 90°C for 1—3 h. The optimum conditions were tested by analysing the sialic acid content in the eluates from the anion exchange resin columns. The largest concentration of sialic acid was found in the materials by heating with 0.1 N sulphuric acid at 80°C for one hour or with 0.05 N acid at 90°C for one hour. In Table 2 the figures found for serum are given. At 70°C only 80—90 % of the optimum concentrations of sialic acid were achieved.

In the experiment listed the largest absorbancy was found after heating at 90°C but in most experiments maximum absorbancy was achieved after heating at 80°C. When lipid extract was hydrolysed the higher temperature often gave the largest value, while the lower temperature was optimal for tissues with a low concentration of sialic acids. It is therefore preferable to hydrolyse the samples both with 0.1 N sulphuric acid at 80°C and with 0.05 N acid at 90°C.

In recovery experiments pure N-acetylsialic acid was added to the samples before hydrolysis. The recovery of N-acetylsialic acid added to serum was 95.5 % $\pm$ 0.7. The recovery of N-acetylsialic acid added to different tissues was from 90 to 98 %. The lower the concentration of sialic acid, the lower was the recovery. It is therefore preferable to add the standard of sialic acid to each new material which is investigated if exact figures are wanted.

Anion exchange resin column. Dowex 2 X-8, 200—400 mesh, was used throughout. The resin was in the preliminary experiments used both in formate and acetate form. The capacity of the resin in retaining sialic acid was somewhat larger when it was in acetate form. Up to 5 ml of 0.4 N sulphuric acid could be added to the column without any sialic acid occurring in the effluent. If the material, however, contained more than 0.2 mequiv of inorganic cations the capacity of the resin to retain sialic acids was measurably lower. Therefore, the hydrolysed sample was first run through a Dowex-50 resin (H^+-form) when the concentration of inorganic cations was more than 0.1 mequiv.

Table 3. Elution of N-acetylsialic acid from Dowex 2 columns. 225 μg of N-acetylsialic acid was hydrolysed with 5 ml of 0.1 N sulphuric acid at 80°C for 1 h and quantitatively transferred to the resin column. Elution was performed under varying conditions. The effluent was analysed with the resorcinol method, and the total absorbancy determined.

	Acetate buffer pH 4.6			
Volume	Molarity			
(ml)	0.2	0.5	0.8	1.0
	Absorbancy			
4	—	1.25	4.60	5.45
6	—	5.50	5.85	6.10
8	0.600	6.00	6.20	6.25
10	—	—	6.20	6.15
20	—	—	6.15	6.10

Elution of sialic acid. An acetate buffer of pH 4.6 was used for the quantitative elution of sialic acid. At pH 4.6 the stability of the sialic acids is optimal, as judged from the reading of the samples in ultraviolet light [9]. The sialic acids were quantitatively eluted with 8 ml of 1 M acetate buffer (Table 3). The yield of sialic acid was neither enlarged by increasing the volume and the strength of acetate nor by changing the pH of the buffer. With a lower concentration of the acetate buffer or with a smaller volume the elution was not quite quantitative.

Sialic acid determination. Of the colorimetric methods applied for the determination of sialic acids the resorcinol method is the most sensitive one and give the lowest standard error. Therefore, it was used as the standard method. The colour development with the reagent was not influenced by an acetate concentration of up to 2 M in the samples. At the determination of sialic acid in body fluids as serum, lymph, milk, synovial fluids and transudates no other carbohydrate was eluted together with the sialic acids. However, when tissues were hydrolysed also nucleic acids were released and the phosphate esters of ribose were retained by the columns and eluted together with the sialic acids. The ribose esters were displaced somewhat slower than the sialic acids but it was impossible to eluate sialic acid quantitatively without a large part of the ribose also being eluted. A rather accurate calculation of the interference from ribose could be made by dichromatic readings, but it would be preferable to analyse the samples with another method, too. Several methods have been applied but none has been quite satisfactory. With the diphenylamine reagents [11,12] ribose had a low absorbancy, but some unknown substances in the tissues gave a false absorbancy of sialic acid. The direct Ehrlich reaction [2] was rather specific but it was insensitive with a very large standard error. A good reproducibility was also obtained with the orcinol method [3] but the absorbancy of ribose was high. The reactions mentioned will be discussed further in a forthcoming paper on the determination of sialic acid in nervous tissue [10].

Table 4. The concentration of sialic acid in different biological materials. All values are expressed as N-acetylsialic acid ($C_{11}H_{19}NO_9$).

Accuracy. The standard error of the whole procedure was calculated from duplicate determinations of 20 sera. 0.2 ml of serum was hydrolysed with 5 ml of 0.1 N sulphuric acid at 80°C for one hour. The standard deviation was $\pm$ 1.4 %. In parallel determinations the sialic acid concentration was also determined by a direct analysis of alcohol-precipitated sera and the absorbancy of the hexoses was corrected by dichromatic readings. The standard deviation with the latter procedure was considerably larger, $\pm$ 3.6 %. Normal as well as pathological sera were analysed. The agreement between the two procedures was good. The standard error was also calculated on the analyses of sialic acid in fresh brain tissue of human fetuses. The standard deviation was there $\pm$ 1.6 %.

APPLICATION OF THE METHOD

The resin separation method has been applied to hydrolysates of several biological materials. The hydrolysis was performed with 5 ml of 0.1 N sulphuric acid at 80°C and 5 ml of 0.05 N sulphuric acid at 90°C for one hour. In

general there was a good agreement between the two procedures but for some tissues with a rather low concentration of sialic acid (e.g. kidney and liver) the value found with 0.05 N sulphuric acid was 5—10 % lower. In these cases only the figures found with the stronger sulphuric acid were used for the calculations of the sialic acid content.

All the figures are calculated as N-acetylsialic acid. In the physiological state the sialic acids often contain at least one O-acetyl groups as well. Besides, instead of the N-acetyl group the sialic acids may partly be substituted by an N-glycolyl group. In fact only in human sources the N-glycolylsialic occurs in negligible amounts. In all the other species investigated (beef, horse, pig and sheep) the N-glycolylsialic acid constitutes from 10—90 % of the total amount of sialic acids [10]. The molar absorbancy index of N-glycolylsialic acid is 15—20 % greater * than that of N-acetylsialic or N,O-diacetylsialic acid in the common colorimetric methods for sialic acids [3-5]. Therefore the figures for sialic acid in many cases are too high especially in beef tissues and pig submaxillary gland where N-glycolylsialic acid constitutes at least 50 %.

All the figures are calculated from the values of the hydrolysed and resin-treated standard samples of N-acetylsialic acid. In this procedure about 5 % of the standard substance was destroyed but in some tissues (liver and kidney) the destruction of sialic acid was probably larger. However, no correction was made for this excess destruction.

Acknowledgement. The skilful assistance of Mrs. Inga Björklund and Mrs. Aino Raal is gratefully acknowledged. The investigation was supported by grants from *Statens Medicinska Forskningsråd.*

The Separation of Nucleotides by Continuous Ionophoresis

ROLF BERGKVIST

Institute of Biochemistry, University of Lund, Sweden

The separation of the adenine, guanine, cytosine and uracil 5′-ribonucleotides by continuous ionophoresis is described. The method is used for a quantitative separation and estimation of a complex nucleotide mixture.

The results obtained in a previous investigation [1] have demonstrated the value of paper ionophoresis for the separation and estimation of nucleotides. An apparatus was described which allows the ionophoretic separation of substances with very small differences in mobility. By a combination of paper chromatography and ionophoresis a complete separation of the 5′-mono-, di- and triphosphates of adenosine, guanosine, cytidine and uridine together with uridine diphosphate glucose, uridine diphosphate acetylglucosamine, diphospho- and triphosphopyridine nucleotides was obtained. The method to be described differs from the other one in that the mixture to be separated is continuously fed into the apparatus and the separated components can be continuously removed, so that it can be used for preparative purposes.

The method is based on the principle of passing a background electrolyte down a filter paper sheet by gravity. The mixture to be separated is applied at a prescribed intermediate position and passes along with the electrolyte as a narrow band. An electrical potential is applied across the filter paper curtain at right angles to the direction of flow and the various substances are deflected toward the anode or the cathode in accordance with their mobility behaviour in the electrical field.

The first successful apparatus using filter paper as a supporting medium for continuous ionophoresis was described by Grassmann and Hannig [2]. We have used a commercial model of their apparatus, which is available from the firm Bender and Hobein (Munich, Germany) under the name of "Elphor Va". This instrument has a free hanging curtain and is without cooling. A uniform field of potential is achieved by attaching the platinum wire electrodes to the vertical edges of the paper. In order to prevent diffusion of electrolysis products from the electrodes to the main body of the curtain, the electrodes are continually bathed with fresh buffer solution and are separated from the paper by a cellophan membrane. The rate of flow of the electrolyte down the paper and its composition must be kept constant. For this reason a supply of fresh

electrolyte is provided by allowing the paper to dip into a trough supplied with a device that maintains the electrolyte at a constant level. After passing through the paper the liquid is collected from 42 tongues cut in the paper along the lower edge. In this way the effluent is equally distributed over a number of fractions, each containing substances with mobilities within a certain small range. The mixture to be separated is injected by a mechanically operated syringe.

The degree of separation is determined by the electrophoretic mobility of the different components, the composition of the electrolyte, the voltage across the paper and the length of time that the substances are subjected to the field, which in turn depends on the grade of filter paper used. For a given flow rate, an increase in field intensity produces an improved resolution. When the current is too high, however, the water from the electrolyte may evaporate so rapidly that the downward flow is not sufficient to wash the paper, and in extreme cases electrolyte solids may be deposited, thus disrupting the steady state. A high flow rate enables larger amounts of material to be separated, but the separation of the different components increases the longer they remain on the paper. The final choice in the selection of experimental condition must be a compromise of the factors mentioned above.

The best separation of the nucleotides was obtained using an acetate buffer of pH 4.15, as has been shown earlier [1]. Since electrolytes of low ionic strength permit higher field intensities to be applied with relatively low current, it was found suitable to use a buffer of ionic strength 0.033. Many different types of filter paper with various degrees of porosity and thickness were tested and the best separation was obtained with Whatman No. 1 paper sheets, which were well washed with hydrochloric acid before use.

The maximum usable potential was found to be 320 volts. This voltage was applied across the platinum electrodes, and after about 6 h a steady state had been established. With this voltage a current of 17 mA was observed to flow constantly. The mechanically operated syringe was charged with the nucleotide mixture to be separated and fixed into position at a point in the upper part of the paper near the cathode and the synchronous motor was started. In order to obtain a quantitative recovery, it was necessary to collect fractions for about 20 h after all the sample had been applied to the paper.

Much useful information about the efficiency of the separation and to the location of the individual substances in the collecting tubes could be obtained from a study of the paper curtain itself. For this purpose the paper was carefully dried and then the different bands were located by making a contact print of the curtain in monochromatic ultraviolet light of 254 mμ.

The separation of mixtures of authentic adenine, guanine, cytosine and uracil nucleotides can be seen in Fig. 1, which shows the contact prints of the paper curtains from the separations. All the nucleotides tested could be separated with the exception of UDPG * and UDPAG, which were obtained as one fraction UDPX.

* Abbreviations used: A, adenosine; G, guanosine; C, cytidine; U, uridine; MP, monophosphate; DP, diphosphate; TP, triphosphate; UDPG, uridine diphosphate glucose; UDPAG, uridine diphosphate acetylglucosamine; DPN, diphosphopyridine nucleotide; TPN, triphosphopyridine nucleotide.

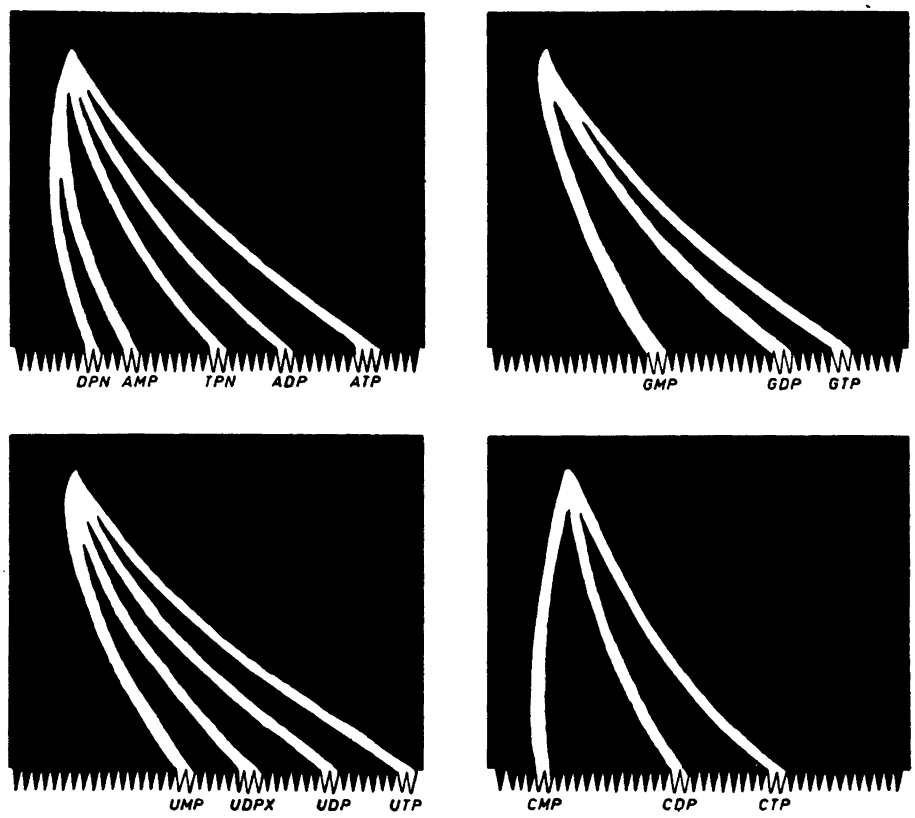

Fig. 1. Contact prints of the paper curtains from separations of groups of nucleotides by continuous ionophoresis. Conditions employed: Whatman No. 1 filter paper; sodium acetate buffer of ionic strength 0.033 and of pH 4.15; 320 V. The cathode was attached to the left edge of the paper curtain and the anode to the right one.

All the actual purine and pyrimidine nucleotides could be quantitatively separated after first fractionating the original mixture by means of paper chromatography [1] into the following groups: (1) AMP, ADP, ATP and DPN; (2) TPN and GMP; (3) GDP and GTP; and (4) CMP, CDP, CTP, UMP, UDP, UTP, UDPG and UDPAG. The different groups were eluted from the paper and concentrated sufficiently for further analysis by adsorption on norite and subsequent elution by ethanol-ammonia.

The concentrated solutions thus obtained could be separated into the different components by continuous ionophoresis. The separation of the different nucleotides was studied measuring the optical densities of the fractions collected from the individual tongues at 250, 260 and 270 mμ with the buffer as the blank. The fraction number and the absorbancy ratios E_{250}/E_{260} and E_{270}/E_{260} could be used for identification of the various nucleotides.

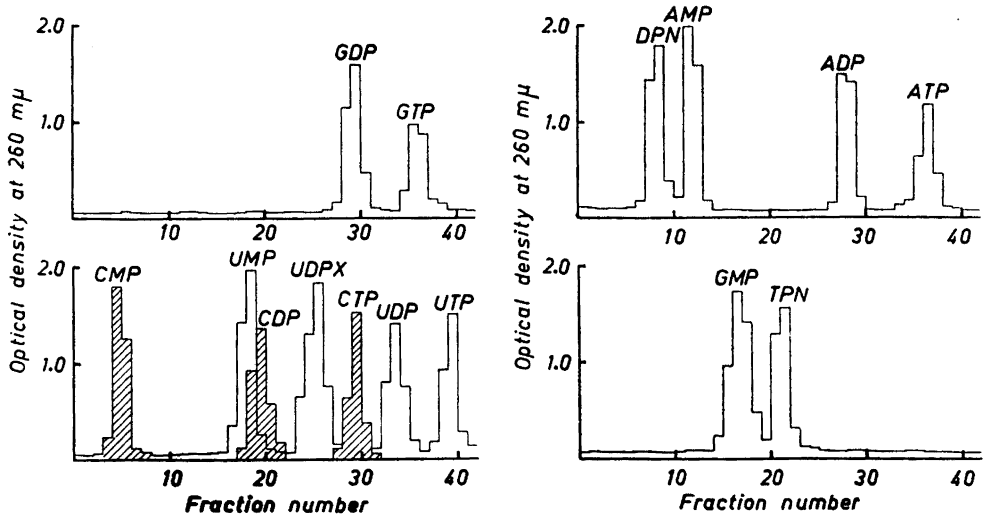

Fig. 2. Separations by continuous ionophoresis of the groups of nucleotides obtained after paper chromatographic fractionation. The same experimental conditions were used as described for Fig. 1. The fraction volumes were adjusted to 3.0 ml with buffer.

To obtain some quantitative measure of the separation efficiency test mixtures of known compositions were analysed by the combination of paper chromatography and continuous ionophoresis. Fig. 2 shows the diagrams obtained by the ionophoretic separation of the groups of nucleotides obtained after paper chromatographic fractionation.

The only components, which were not sufficiently separated, in addition to the uridine diphosphate sugar compounds, were UMP and CDP, but these

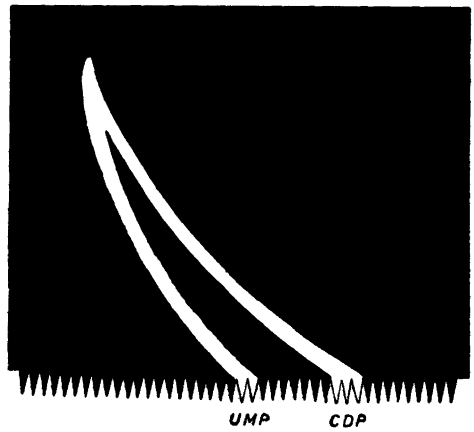

Fig. 3. Contact print of the paper curtain from the separation of UMP and CDP. The same experimental conditions as described for Fig. 1 were used besides that the buffer had a pH of 5.0 and the potential was 340 V.

Table 1. Analysis of a mixture of authentic nucleotides. The concentrations were calculated using the molecular extinction coefficients previously reported [3].

Compound	μmoles of nucleotide		Recovery %
	Calculated	Found	
AMP	3.16	3.13	99
ADP	2.80	2.58	92
ATP	2.32	2.16	93
DPN	2.56	2.25	88

UDP	4.00	3.84	96
UTP	3.68	3.24	88
UDPG	3.36	2.89	86
UDPAG	2.36	2.19	93

substances could easily be separated by paper chromatography or continuous ionophoresis with a buffer of other pH. Fig. 3 shows the separation of these substances with an acetate buffer of pH 5.0 and ionic strength 0.033.

Recoveries of 85—95 % were obtained, as can be seen from Table 1. Because of the number of components which are to be separated and the number end nature of the operations in these analyses, higher recoveries can hardly be expected. Yields of 95—100 % could be obtained for mixtures of nucleotides which could be separated directly on a single paper curtain. DPN was slightly decomposed during the separation but none of the other substances were found to be destroyed.

The earlier described apparatus [1] for one-dimensional ionophoresis with long travelling distances gives a sharper and more rapid separation of nucleotides than is obtainable by continuous ionophoresis. The presently described method is, however, more suitable for separations of larger amounts of material where the capacity of the other apparatus would be exceeded.

EXPERIMENTAL

Continuous ionophoresis. The apparatus consists of a framework holding a trough and the vertical electrode chambers. This frame is placed in a cemented glass case. The dimensions of the paper sheet are 47 × 47 cm, excluding the tongues. A 4 cm portion at the top dips into the trough and the vertical edges are pressed against the electrode chambers, but separated from them by a cellophan membrane. The washing of the electrodes and the constant level control of the solution in the trough is regulated by three Mariotte flasks.

Ionophoresis was carried out on Whatman No. 1 papers purified by washing three times with N hydrochloric acid and finally with water until the pH of the paper was about 7. An acetate buffer of ionic strength 0.033 and of pH 4.15 was used both as background electrolyte and to wash the electrodes. For the separation of UMP and CDP the buffer had a pH of 5.0.

The substance is applied by the insertion of the plunger of a glass syringe by means of a synchronous motor. This apparatus can give 0.020—0.900 ml per hour with different transmissions and syringes. The syringe is fitted with a glass tip joined to the syringe by polyvinyl chloride tubing of 0.6 mm bore. The point of application of the material is 8 cm below the lip of the trough and 9 cm from the cathode. The amount of each component applied per hour varied from 0.03 to 0.50 μmoles. At higher concentrations the zones became a little wider.

The different nucleotides could be identified and their concentrations determined from the optical densities of the fractions using the absorbancy ratios and molar absorbancies reported earlier [3]. The concentrations of the overlapping cytosine and uracil nucleotides could be approximately calculated from the absorbancy ratios.

When using exactly the same experimental conditions substances appeared in the same tubes for different analyses. With care the same paper curtain could be used for many separations.

Paper chromatography. The group separation of the nucleotides was performed as described earlier [1] on large sheets of Whatman No. 1 papers (50 × 110 cm) with the following solvent system: saturated ammonium sulphate-water-*iso*propanol (79:19:2).

The separation of the uridine diphosphate sugar compounds could be attained by paper chromatography in a solvent composed of 7.5 volumes of 95 % ethanol and 3 volumes of 1 M ammonium acetate solution of pH 7.5. UMP and CDP could also be separated in this as well as in many other solvent systems.

Materials. The nucleotides used were obtained from the Sigma Chemical Company. The mixtures to be analysed were obtained by mixing measured volumes of stock solutions of known composition.

The author wishes to express his gratitude to *Sigma Chemical Company* for gifts of many of the nucleotides.

This work has been supported by grants from the *Swedish Natural Science Research Council.*

Synthesis of Phosphopeptides

I. Peptides of DL-Serine and Glycine

GEORG FÖLSCH

Department of Medical Biochemistry, University of Gothenburg, Sweden

The synthesis of unphosphorylated, O-phosphorylated and O-monophenylphosphorylated DL-serylglycine, glycyl-DL-serine and glycyl-DL-serylglycine is described. Infrared absorption spectra of O-phosphorylated peptides are shown.

In 1933 Schmidt [1] as well as Levene and Hill [2] isolated a phosphorus-containing peptide from hydrolysed casein. Posternak and Pollaczek [3] proved that the structure of this peptide was O-phosphoryl-L-seryl-L-glutamic acid. Later, this and other phosphopeptides have been obtained *, particularly in recent years in connection with structural studies on phosphorus-containing proteins [4–11]. Phosphorylated peptides containing glycine have mainly been isolated from hydrolysates of phosphorylated α-chymotrypsin [5–8], but also from an enzymatically synthesized polypeptide [4]. O-Phosphorylserylglycine (Fig. 1., compound Ia) was the phosphopeptide from α-chymotrypsin first described and Shaeffer showed that this peptide was partly converted to glycyl-O-phosphorylserine (Fig. 1., compound IIa) during acid hydrolysis [7]. These two peptides, containing only glycine beside one serine residue are well adepted for model compounds in synthetic studies. As only one asymmetric centrum is present, DL-serine can be used in studies of this kind without the formation of diastereoisomers, a complication that occurs, when other amino acids than glycine are used.

We have prepared synthetic phosphorylated peptides in two different ways **. The most successful route so far has been to synthesize an N-carbobenzoxypeptide benzyl ester first, then introduce a suitable phosphoryl group and finally remove all protecting groups by catalytic hydrogenolysis [13].

* A review of earlier work is given by Perlmann, G. E. *Advances in Protein Chem.* **10** (1955) 1.

** In some cases, mixed anhydrides from N-acylamino acids [12] have been used for N-acylation of O-phosphorylserine. Such N-acylations of phosphorylated serine derivatives, including O-diphenylphosphorylserine [13] and the corresponding benzyl ester [14] will be further investigated.

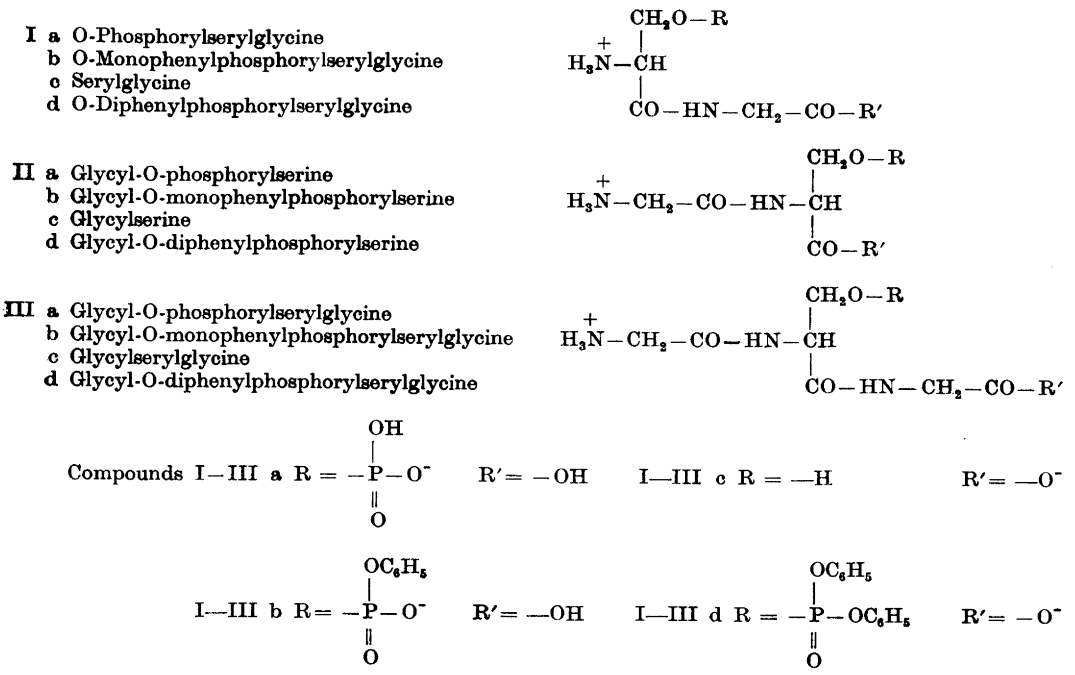

Fig. 1. Structure of serine and glycine peptides.

In the synthesis of N-carbobenzoxypeptide benzyl esters used in this work, the procedure of Sheehan [15] has given equal or better over all yields than with the azide route [16] or with the mixed anhydride technique [12]. The phosphorylation and hydrogenolysis have been performed in this work as described in the synthesis of O-phosphorylserine *, and in the case of peptides it was also possible to isolate diphenylphosphorylated and monophenylphosphorylated intermediates during the hydrogenolysis **. The structure of the compounds is shown in Fig. 1.

Infrared absorption spectra have been recorded and some of them are shown in Fig. 2. The paper chromatographic behaviour of the compounds has been studied, and R_F values are given in Table 1. As in the case of other peptides containing N-terminal glycine, also all the synthesised O-phosphorylated, mono-and diphenylphosphorylated peptides having N-terminal glycine

* For an reaction scheme, see this synthesis (Ref.[13]). Riley *et al.*[14] have recently described the synthesis of O-phosphorylated derivatives of hydroxyamino acids and peptides, for the investigation of which alkaline hydrolysis was used as an alternative for the elimination of phenylic ester groups.

** Bevan *et al.*[17] recently isolated this type of O-monophenylphosphorylated derivatives by hydrogenolytic cleavage of diphenylphosphates.

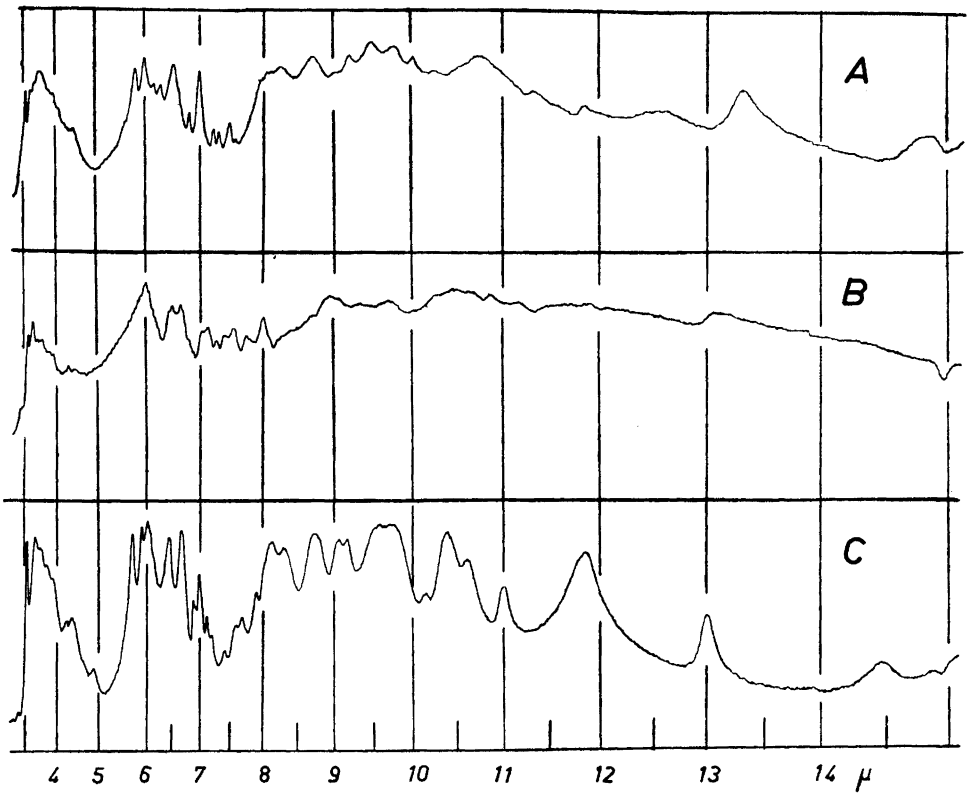

Fig. 2. Infrared absorption spectra of O-phosphoryl-DL-serylglycine (A), glycyl-O-phosphoryl-DL-serine (B) and glycyl-O-phosphoryl-DL-seryl-glycine (C). Compounds (1.4 mg) in potassium bromide (300 mg) pellets.

give an initial yellow colour with ninhydrin spray reagent. After some time (about half an hour) the colour changes slowly to the normal brown-violet tones.

EXPERIMENTAL

Melting or decomposition points, elementary analyses and infrared spectra were all determined as described previously [13]. Solvents in the paper chromatography were also as before: (I) Phenol-water (80/20 v/v), ascending, about 6 h, (II) *n*-Butanol-acetic acid-water (40/10/50 v/v), descending, about 18 h.

N-Carbobenzoxy-DL-serylglycine benzyl ester

a) By the azide route [16]: A vigorously stirred mixture containing 15.6 g (0.1 mole) of DL-serine methyl ester hydrochloride, 5.2 g (0.13 moles) of magnesium oxide, 75 ml of water and 180 ml of chloroform was cooled in an ice-salt mixture, and 23 g of carbobenzoxy chloride [18] was added dropwise within 1/2 h. After continued stirring for 1/2 h,

Compounds numbered according to Fig. 1.

** See Ref.[13], p. 1237, foot note three.

*** The R_F values are calculated from several one-dimensional chromatograms, on which serine had R_F 0.36 in solvent I and 0.18 in solvent II. The three phosphorylated peptides are well separated on two-dimensional chromatograms in solvent I and II.

**** This compound has also been obtained in a low yield by the use of dibenzylphosphoryl chloride as phosphorylating reagent [22]. Riley *et al.*[14] report a m.p. of 150—154° (decomp.) for the compound obtained by alkaline hydrolysis.

5 ml of pyridine was added and the mixture acidified with cold 5 N hydrochloric acid (Congo red). The N-carbobenzoxy-DL-serine methyl ester was taken up in chloroform. The solution was washed with hydrochloric acid, bicarbonate and water, and was finally dried over sodium sulphate. The chloroform was distilled off *in vacuo*, the residue evaporated three times with ethanol and finally dissolved in 100 ml of absolute ethanol. Seven ml of hydrazin hydrate (b.p. 120—121°) was added and the solution left over night. N-carbobenzoxy-DL-seryl hydrazide, 17.2 g (66 %), thus crystallised. M. p. 158—160° (Reported [14] 162—163°). To a solution of 13.2 g (0.05 moles) of the hydrazide in 60 ml of acetic acid, 25 ml of 5 N hydrochloric acid and 250 ml of water was added at −5° a concentrated solution of 3.3 g (0.053 moles) of sodium nitrite. The azide formed, was taken up in 300 ml of cold ether, and the solution was washed and dried in the cold. A cold dry etheral solution of free glycine benzyl ester, freshly prepared from 15.2 g (0.075 moles) of the hydrochloride [19] was added to this solution. The mixture was left for 24 h, whereby a large part of the peptide derivative crystallised out from the solution. The crystals were filtered off, washed with ether, the combined ether solutions were washed with acid, bicarbonate, and water and after drying over sodium sulphate, evaporated to dryness. The residue was crystallised from ethyl acetate and light petroleum (b.p. 20—40°). The total yield of crystalline N-carbobenzoxy-DL-serylglycine benzyl ester was 13.2 g (68 %). M. p. 100—101°. (Found: C 62.7; H 5.8; N 7.3. Calc. for $C_{20}H_{22}O_6N_2$ (386.2): C 62.1; H 5.7; N 7.3).

b) By the mixed anhydride route [12]: 1.95 ml (20 mmoles) of ethyl chlorocarbonate was added to a solution of 4.8 g (20 mmoles) of N-carbobenzoxy-DL-serine [20] and 2.8 ml, (20 mmoles) of triethylamine in 25 ml of anhydrous dimethylformamide at a temperature of 0—5°. Ten minutes later a solution of 4.0 g (20 mmoles) of glycine benzylester hydrochloride [19] and 2.8 ml of triethylamine in 25 ml of dimethylformamide was added, causing a vigorous evolution of carbon dioxide. Next day the mixture was evaporated to dryness *in vacuo* and the residue was extracted in ethyl acetate. The solution was washed and worked up as above, yielding 3.8 g (50 %) crystals from ethyl acetate and light petroleum, m. p. 100—101°.

c) By the carbodiimide procedure [15]: To a solution of 2.4 g (10 mmoles) of N-carbobenzoxy-DL-serine in 25 ml of dimethylformamide was added 1.8 g (15 mmoles) of free glycine benzyl ester [19] and 2.1 g (10 mmoles) of N,N′-di*cyclo*hexylcarbodiimide. The reaction mixture was filtered after 5 h, yielding 2.0 g of N,N′-di*cyclo*hexylurea (m.p. 237—240° decomp.). The solution was evaporated to dryness *in vacuo*, and the residue was dissolved in 75 ml of ethyl acetate. This solution was worked up as above, yielding 2.8 g (72 %) of N-carbobenzoxy-DL-serylglycine benzyl ester m.p. 100—101°.

Carbobenzoxyglycyl-DL-serine benzyl ester

a) By the mixed anhydride route: To the mixed anhydride, prepared as above from 8.4 g (40 mmoles) of carbobenzoxyglycine, 5.6 ml of triethylamine and 3.84 ml of ethyl chlorocarbonate in 40 ml anhydrous dimethylformamide was added a cold mixture of 10.2 g (44 mmoles) of DL-serine benzyl ester hydrochloride [21], 6.2 ml of triethylamine and 40 ml of dimethylformamide. After 5 h at room temperature, the reaction mixture was filtered and evaporated to dryness, and the residue shaken with 100 ml of ethyl acetate and 50 ml of water. The ethyl acetate solution was worked up as in the case of the aforegoing compound, yielding 11.2 g (72 %) of carbobenzoxyglycyl-DL-serine benzyl ester, m. p. 141—142° (from ethanol-ether). (Found: C 62.1; H 5.8; N 7.3. Calc. for $C_{20}H_{22}O_6N_2$ (386.2) C 62.1; H 5.7; N 7.3).

b) By the carbodiimide procedure: From 8.4 g (40 mmoles) of carbobenzoxyglycine, 10.2 g (44 mmoles) of DL-serine benzyl ester hydrochloride, 5.6 ml of triethylamine and 8.4 g of N,N′-dicyclohexylcarbodiimide, a yield of 10.7 g (69 %) m. p. 141—142° was obtained by the same procedure as already described.

Carbobenzoxy glycyl-DL-seryl glycine benzyl ester

To the mixed anhydride prepared as above from 8.4 g of carbobenzoxyglycine, was added a cold solution of 4.4 g (40 mmoles) of DL-serine in 20 ml of 2 N sodium hydroxide. Carbon dioxide was vigorously evolved. After 6 h at room temperature the mixture

was evaporated to dryness *in vacuo*, the residue dissolved in 50 ml of water, washed with ether, and acidified with cold 5 N hydrochloric acid. The oil which separated was taken up with three 50 ml portions of ethyl acetate, the ethyl acetate distilled off at reduced pressure and the residue treated with ether and scratched, resulting in crystals of carbobenzoxyglycyl-DL-serine, 10.5 g (88 %) separating. M. p. 153—154° (recryst. from ethanol-ether). (Found C 52.6; H 5.6; N 9.3. Calc. for $C_{13}H_{16}O_6N_2$ (296.3): C 52.7; H 5.4; N 9.5). To a solution of 5.9 g (20 mmoles) of this compound in 25 ml of dimethylformamide was added 4.4 g (20 mmoles) of glycin benzyl ester hydrochloride, 2.8 ml (20 mmoles) of triethylamine, followed by 4.2 g (20 mmoles) of N,N'-di*cyclo*hexylcarbodiimide. After 6 h, the precipitate of di*cyclo*hexylurea (4.0 g) was filtered off and the solution was evaporated ty dryness *in vacuo*. The remaining oil was brought to crystallisation by shaking and scratching in water and ether. After recrystallisation from ethanol, carbobenzoxyglycyl-DL-serylglycine benzyl ester, 5.8 g (65 %) was obtained. M. p. 169—170°. (Found: C 59.9; H 5.7; N 9.7. Calc. for $C_{22}H_{25}O_7N_3$ (443.4): C 59.6; H 5.7; N 9.5).

Phosphorylation

The procedure previously described [13] was used throughout. To 20 mmoles of carbobenzoxypeptide benzyl ester in 10 to 15 ml of anhydrous pyridine was added 6.4 g (24 mmoles) of diphenylphosphoryl chloride with shaking and moderate cooling. After 4 h 1 ml of water was added, 1/2 h later the reaction mixture was poured into 150 ml of water and 100 ml of chloroform *. The chloroform solution was washed with cold 4 N sulphuric acid, water, 20 % bicarbonate solution, and again with water. After drying over sodium sulphate, the solvent was evaporated *in vacuo*, the residue being the expected diphenylphosphate ester in about 90 % yield. This procedure resulted in O-diphenylphosphoryl-N-carbobenzoxy-DL-serylglycine benzyl ester, colourless oil, $n_D^{21°}$ 1.5642. (Found: N 4.7. Calc. for $C_{32}H_{31}O_9N_3P$ (618.6): N 4.5), O-diphenylphosphoryl-N-(carbobenzoxyglycyl)-DL-serine benzyl ester, colourless oil, $n_D^{20°}$ 1.5620, (Found: N 4.8. Calc. for $C_{32}H_{31}O_9N_3P$ (618.6): N 4.5) and O-diphenylphosphoryl-N-(carbobenzoxyglycyl)-DL-serylglycine benzyl ester, colourless crystals, m. p. 85—86° (from ethanol-light petroleum). (Found: C 60.3; H 5.1; N 6.2; P 4.5. Calc. for $C_{34}H_{34}O_{10}N_3P$ (675.6): C 60.4; H 5.1; N 6.2; P 4.6).

Hydrogenolysis

When monophosphate esters (free phosphorylated peptides) were wanted, the hydrogenation was performed in glacial acetic acid with platinum oxide as catalyst. Water was added after some time to dissolve precipitated material. The time required for complete hydrogenolysis varied between 8 h and 15 h. Paper chromatography was useful for checking the amount of partly hydrogenated derivatives [13]. The residue obtained after filtration and evaporation of the solvent was treated in water solution with Amberlite IR 120 cation exchange resin (H^+ form) to eliminate metal cations, the filtered solutions was evaporated again and the phosphopeptide crystallised from hot water — ethanol.

Diphenylphosphoryl derivatives of the peptides were easily obtained when the hydrogenolysis was performed in ethanol solution with palladium oxide catalyst. Monophenylphosphoryl derivatives were obtained when hydrogenolysis in glacial acetic acid with platinum oxide catalyst was discontinued after a short time. The yields varied with the solubility of the diester **.

The carbobenzoxy peptide benzyl esters and carbobenzoxyglycyl-DL-serine were also hydrogenolysed with palladium catalyst to the free peptides. Analytical data, decomposition points and R_F values of the peptides are shown in Table 1.

* The glycylserine and glycylserylglycine derivatives are only sparingly soluble in ether.

** In a synthesis of O-phosphorylserylleucine (to be published) it vas difficult to isolate the monophenylphosphoryl derivative by hydrogenolysis in acetic acid. This compound, however, crystallised out when an acetic acid-ethanol (1:2) mixture was used.

Acknowledgements. The author wishes to express his sincere thanks to Professor Olof Mellander for his support in this work. He is also much indebted to Mrs. Karin Nilsson, Uppsala, for the infrared absorption spectra, to Miss Ulla-Britt Dahlberg, Uppsala, for the elementary analyses and to Mrs. Birgit Boman for technical assistance.

The work was supported by grants from *Swedish Medical Research Council* to Professor Olof Mellander.

Distribution of Compounds in Polysaccharide Syntheses Using Dextransucrase

BENGT WEIBULL*

Tekniska Forskningscentralen, Svenska Sockerfabriks Aktiebolaget, Arlöv, Sweden

Quantitative results for the synthesis of methyl α-*iso*maltoside and its homologues from methyl α-D-glucoside and sucrose using dextransucrase were recently reported. The distribution of the saccharides can be accounted for if it is assumed that the synthesis proceeds by means of a stepwise transfer of glucosyl groups from sucrose to the primary hydroxyl group of the growing polymer. The rate of the first step is lower than that of the following ones, which seem to be kinetically identical. The reaction thus formally is analogous to the polyaddition of ethylene oxide to water and alcohols. The consequences of these results for the synthesis of dextran are discussed.

Some years ago Hehre [1] put forward the hypothesis that there exists a formal analogy between enzymic polysaccharide syntheses and the formation of polyethylene glycol by polyaddition of ethylene oxide to ethylene glycol. Reactions of the latter type have been studied extensively. The reaction proceeds by means of a stepwise addition of ethylene oxide, the reacting hydroxyl group being regenerated at each step. The distribution of compounds formed was recently studied theoretically and experimentally by Weibull and Nycander [2], and by Weibull [3]. The reaction steps were found to be kinetically identical with the exception of the first one, which generally proceeds at a rate different from the following ones. This accords with the fact that the reacting hydroxyl group is identically bound at every step except the first one. Formulae were derived for the molecular distribution of the polymer product. The following scheme illustrates the reaction:

$$ROH + \underset{\diagdown\,O\,\diagup}{CH_2CH_2} \rightarrow ROCH_2CH_2OH$$

$$ROCH_2CH_2OH + \underset{\diagdown\,O\,\diagup}{CH_2CH_2} \rightarrow ROCH_2CH_2OCH_2CH_2OH \; \textit{etc.}$$

* Present address: Mo och Domsjö AB, Örnsköldsvik, Sweden.

According to Hehre [1] the corresponding scheme for the synthesis of dextran from sucrose should be (Gl = glucose or anhydroglucose, Fr = fructose or anhydrofructose):

$$(\text{Gl-})_n + \text{Gl-Fr} \rightarrow (\text{Gl-})_{n+1} + \text{Fr}$$
dextran sucrose dextran fructose

Unfortunately the initial steps are not known, so it is not possible to apply the distribution formulae derived for the ethylene oxide reactions. A great many other enzymic polysaccharide syntheses have been investigated and also corresponding syntheses of oligosaccharides [4], but practically none of the results published lend themselves to a theoretical interpretation on these lines*. However, results were recently published concerning the synthesis of methyl *α-iso*-maltoside and its homologues from methyl α-D-glucoside and sucrose by means of dextransucrase [5]. The compounds formed were quantitatively separated by means of chromatographic methods as far as the oligosaccharide containing five glucose residues. The data given are well suited to test Hehre's hypothesis and, more specifically, the distribution formulae derived for ethylene oxide reactions. The role of the enzyme will not be considered — it is assumed to act as an ideal catalyst.

THEORETICAL

The derivation of the distribution formulae will not be repeated here. For convenience the final result is reproduced. The following notation accords with that previously used [2].

N_i molecule with i added monomer units (in this case glucose units)
m number of moles of monomer donor (in this case sucrose)
n_{00} » » » » acceptor or starting material (in this case methyl glucoside)
n_i » » » » N_i in the reaction product
c distribution constant = ratio of the equal velocity constants of the higher steps to that of the first step
$v = m/n_{00}$ average degree of polymerisation

The distribution formulae are:

$$v = c \ln \frac{n_{00}}{n_0} - (c - 1)\left(1 - \frac{n_0}{n_{00}}\right) \quad (1)$$

$$\frac{n_i}{n_{00}} = \frac{c^{i-1}}{(c-1)^i}\left\{\frac{n_0}{n_{00}} - \left(\frac{n_0}{n_{00}}\right)^c \sum_{j=0}^{i-1} \frac{1}{j!}\left[(c-1)\ln\frac{n_{00}}{n_0}\right]^j\right\} \quad (2)$$

Calculations

The present calculations are based on the data given in Table II of the paper mentioned [5]. For the sake of convenience this material is reproduced in Table 1 using the notation given above. Further, v_0 is the molar ratio of sucrose

* *Added in proof:* W. J. Whelan and J. M. Bailey (*Biochem. J.* 58 (1954) 560) investigated the molecular distribution of amylose synthesised with potato phosphorylase. They found agreement with the distribution calculated for a stepwise polyaddition.

to methyl glucoside at the beginning of the reaction, N_F, N_G, and N_L represent fructose, glucose and leucrose (5-*O*-α-D-glucopyranosyl-α-D-fructopyranose). Experiments 1, 2, 3, and 5 were carried out on a small scale and the analyses made by quantitative paper chromatography while experiment 4 was made on a preparative scale and the reaction product separated on a carbon-celite column. In experiment 4, 98 % of the total carbohydrate was soluble in 50 % methanol. About 2 % of these solubles contained more than five glucose residues and were not quantitatively determined. The insolubles were more highly polymerised material, presumably dextran.

Table 1. Composition of 50 % methanol-soluble fraction of the glycoside mixture, as glucose in % of total.

Expt. No.	v_0	N_0	N_1	N_2	N_3	N_4	$N_F + N_G$	N_L
1	3.0	11.8	4.6	8.8	10.8	7.2	51.5	5.2
2	1.5	15.5	10.6	11.4	11.4	7.8	40.8	2.4
3	0.75	27.5	12.9	13.5	10.5	5.1	29.9	0.6
4	0.75	26.0	12.7	13.9	10.9	5.1	30.2	1.2
5	0.3	51.0	17.3	10.1	3.5	0.5	17.5	—

Since the data in Table 1 refer to only a part of the reaction product, there is no direct connection between them and the amounts of sucrose and methyl α-glucoside at the beginning of the reaction. These amounts must therefore be indirectly calculated from the material balances. The following set of equations is self-explanatory (n_F, n_G, n_S, and n_L are the number of moles of fructose, glucose, sucrose and leucrose):

$$n_{00} = \sum n_i \quad \text{material balance for the methyl groups} \tag{3}$$

$$m = \sum i n_i \quad \text{» » » » glucose units added to methyl glucoside} \tag{4}$$

$$n_S = n_F + n_L \quad \text{» » » » fructose units} \tag{5}$$

$$n_S = n_{00} v_0 \quad \text{» » » » sucrose} \tag{6}$$

$$v = m/n_{00} \quad \text{definition of } v \tag{7}$$

Eqns. (5) and (6) give:

$$n_F = n_{00} v_0 - n_L \tag{8}$$

In the material balances the amounts of the higher homologues (N_5 *etc.*) could generally not be disregarded. Since they were not experimentally determined, they have been estimated by extrapolation from the amounts of the lower homologues. This was not possible for experiment 1 since the amounts in this case seem to be rather large. Table 2 contains recalculated figures from Table 1 together with extrapolated data (within parentheses) and figures calculated by means of formulae (3), (4), (7), and (8). For simplicity the figures are based on the amounts of N_0 given in Table 1.

The data in Table 2 were used to calculate the molar ratios n_i/n_{00}. Using the values for v and n_0/n_{00}, the distribution constant c' was calculated by means of formula (1). An independent value, c'', was calculated by means

Table 2. Composition of the glycoside mixture, molar proportions.

Expt. No.	v_0	n_0	n_1	n_2	n_3	n_4	n_5	n_6	n_7	n_F+n_G	n_L	n_{00}	m	v	n_F

of formula (2) using the values for n_0/n_{00} and n_1/n_{00}. These figures are given in Table 3. The mean value, $c = 3.80$, was used together with the values for v to calculate theoretical distributions by means of formulae (1) and (2). The results are given in Fig. 1. The experimental figures are indicated as points.

Table 3. Distribution constants for the synthesis of methyl *α-iso*maltoside and its homologues from methyl α-D-glucoside and sucrose using dextransucrase.

Expt. No.	2	3	4	5
c′	3.59	4.07	3.91	3.55
c″	3.29	4.22	4.10	3.69

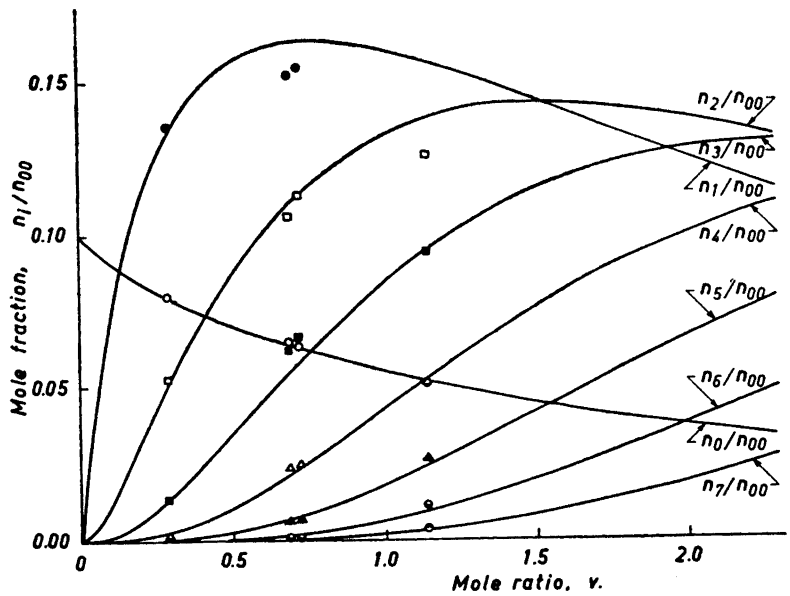

Fig. 1. Distribution of saccharides of the methyl *α-iso*maltoside series, synthesised using dextransucrase; n_i/n_{00} = mole fraction of saccharide with i added glucosyl groups; v = mole ratio of reactants, sucrose to methyl α-glucoside. For convenience, the scale for n_0/n_{00} is ten times smaller than that for the other mole fractions.

DISCUSSION

If all sucrose was used up for the formation of methyl saccharides, the proportion of sucrose to methyl glucoside at the beginning of the experiments, v_0, should equal the corresponding proportion, v, calculated from the analysis of the reaction product. As is seen in Table 2 this is approximately the case in experiments 3, 4, and 5. With the larger amounts of sucrose in experiments 2 and 1, only part of the glucose from the sucrose is bound in the methyl saccharides. Part of the remainder is accounted for as leucrose, but most of it should be bound in the dextran.

The fructose figures in Table 2 reveal a discrepancy in the experimental material. The amounts of fructose calculated from the material balances generally are higher than the experimentally determined sum of fructose and glucose. The discrepancy increases with increasing proportion of sucrose. Since practically all sucrose reacted, there is a loss of fructose which is not accounted for.

Inspection of Table 3 shows that the calculated distribution constants, c' and c'', are rather similar in each experiment. The differences between the constants of the various experiments are also rather small. It thus seems warranted to use a mean value of these figures to calculate the distribution of all the methyl saccharides. As is seen, this calculation gives a rather good picture of the experimental distribution. Of course the experimental material is rather small. It is regrettable that the figures from experiment 1 do not permit an interpretation. However, it seems permissible to state that the reactivity of the primary hydroxyl group of methyl α-D-glucoside is smaller than that of the corresponding groups of at least the next higher homologues, these latter appearing to be of equal reactivity. This conclusion is only a formal one since the details of the enzyme action are not considered.

Unfortunately these conclusions cannot be directly applied to the formation of dextran from sucrose using dextransucrase, in which the initial steps are not known. However, it would be very strange if this reaction was not essentially analogous, *i.e.* a stepwise addition of glucose units to a growing polymer. It seems most simple and natural to assume that sucrose itself is the primary acceptor. The main difficulty is that no intermediates in the form of oligosaccharides have been identified since high molecular dextran is almost the only product even at low degrees of conversion of sucrose [6]. One is then forced to conclude that the enzyme has a very low affinity to sucrose as an acceptor and favours very much the transfer of glucosyl groups to higher saccharides. The significance of branching should not be overlooked in this connection. All natural dextrans are branched but the exact nature of the branching is not settled. However, if a significant part of the branch end groups can function as glucosyl acceptors, the dextran molecule will grow like an avalanche.

Several recent results are in accord with the view that sucrose is the primary acceptor. Hehre [7] has shown one type of natural dextran with a low molecular weight to contain a sucrose unit as end group. Bailey, Barker, Bourne, Stacey, and Theander [8] have synthesised the glucosylsucrose corresponding to the first step of this hypothetical scheme and shown it to be an

excellent acceptor for glucosyl groups transferred from sucrose by dextransucrase. In most experiments described in the literature, crude preparations of dextransucrase were used. In particular, the enzyme was not freed from small amounts of dextran which may act as an acceptor. Recently Bailey, Barker, Bourne, and Stacey [9] have shown that an enzyme preparation with only traces of dextran has a low activity towards sucrose, which can however be increased many times if a suitable acceptor is added. Recent work with the analogous sucrose — levansucrase — levan system is also in accord with the view that sucrose is the primary acceptor in the building up of the polysaccharide.[10-12]

It should be pointed out that formulae (1) and (2) apply only if the amount of acceptor is constant throughout the polymerisation. If the acceptor and monomer donor are identical, as is assumed in the dextran system, very much more complicated formulae are obtained. The occurrence of branching complicates the situation still further. Without more experimental material it seems, however, not worth while to speculate on these problems.

The author would like to thank Svenska Sockerfabriks Aktiebolaget for permission to publish this paper.

Short Communications

Action of Thrombin on Plasmin Digested Fibrinogen

PER WALLÉN and KURT BERGSTRÖM

Kemiska Institutionen II, Karolinska Institutet, Stockholm, Sweden

During the last years convincing evidence has been presented indicating that the effect of thrombin on fibrinogen is a proteolytic reaction [1]. At this proteolysis glycine appears as a new N-terminal residue. The reports concerning the amount of glycine residues, released from one mole fibrinogen, have varied. Recently published investigations [2] carried out by means of Edman's phenyl*iso*thiocyanate method have indicated that 4 moles of glycine appear at the proteolysis of one mole of fibrinogen with thrombin. From the supernatant after clotting Bettelheim and Bailey isolated two peptides, A and B, by electrophoresis [3]. The A peptide contained glutamic acid in N-terminal position and its isoelectric point was lower than that of the B peptide in which no N-terminal amino acid could be demonstrated. Recently Blombäck and Vestermark [4] have been able to isolate the A and B peptides by means of chromatography on 2 % crosslinked Dowex-50.

The purpose of this work was to study the effect of thrombin on the split products from the digestion of fibrinogen by plasmin. One way of doing this is to determine if addition of thrombin to a sample of digested fibrinogen causes any difference in the N-terminal amino-acid composition as compared with a similar sample to which no thrombin had been added. In an earlier work [5] it was shown that Edman's phenyl-*iso*thiocyanate method is very well suited for the study of the fibrinogenolysis.

The fibrinogen used was bovine fraction I-4 of Blombäck and Blombäck [6]. This highly purified fibrinogen contains traces of plasminogen which on activation gives rise to enough plasmin to make the fibrinogen unclottable within a relatively short time. As activator urokinase was used. It was prepared from human urine according to a method described by us earlier [5]. The thrombin used was citrate-activated prothrombin, prepared according to the method of Seegers [7,8]. It contained about 800 NIH units per mg.

The digestion mixture consisted of 1 g of bovine fibrinogen and 15 mg urokinase dissolved in 100 ml 0.02 M phosphate buffer, pH 7.2, containing NaCl to a concentration of 0.15 M. This mixture was incubated at 37°C. Clots obtained by adding 10 NIH units of thrombin to one ml of the reaction mixture dissolved in about 15 min at 37°C. At different times two 10 ml portions were removed from the digestion mixture. To one of them was added 1 ml of a thrombin solution containing 200 NIH units. Both aliquots were incubated for 15 min at 37°C. The enzyme activity was interrupted by adding 10 ml of pyridine containing 0.75 ml phenyl*iso*thiocyanate. The coupling with phenyl*iso*thiocyanate and the conversion of the PTC-amino acids to the corresponding PTH derivates were performed as described by Blombäck and Yamashina [2] and by us in an earlier communication [5]. The PTH-amino acids were identified and quantitatively estimated by the method of Edman and Sjöqvist [9]. The solvents used for the chromatography were those of Edman and Sjöqvist [9] and Sjöqvist [10].

During the fibrinogenolysis quantitative estimations of the following N-terminal amino acids were made: aspartic acid, glutamic acid, glycine, alanine, valine, threonine, tyrosine and lysine. Probably there are some additional N-terminal amino acids, which have not been studied. At least 150 bonds seem to be split by plasmin at maximal digestion.

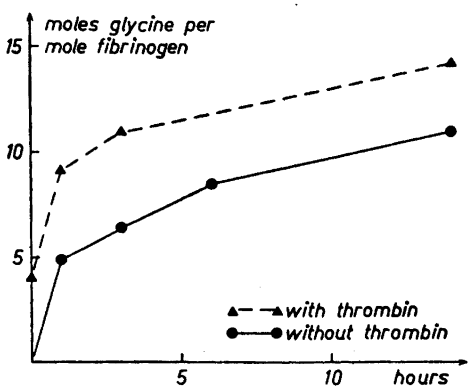

Fig. 1. Increase of N-terminal glycine in a fibrinogenolytic mixture at the addition of thrombin. (The values are corrected for a yield of 80 %.)

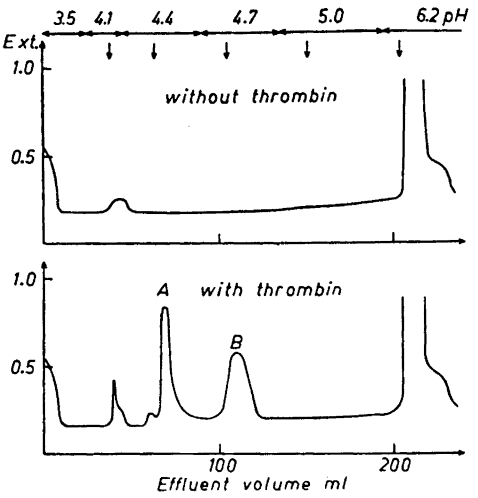

Fig. 2. Release of fibrinopeptides at the addition of thrombin to a fibrinogenolytic mixture. The extinction was read at 700 mμ. The following buffers were used: Na-formate at pH 3.5, Na-acetate at pH 4.1 to 5.0 and Na-phosphate at pH 6.2. The ionic strength of all buffers was 0.1. The vertical arrows indicate the points at which the same pH, as that of the eluting buffer, was obtained.

In the tests to which thrombin was added to the digestion mixture there was an immediate increase in N-terminally bound glycine as compared to the samples taken at the same time but to which no thrombin had been added. This increase in glycine corresponded to nearly 4 moles per mole fibrinogen in the original mixture. This was true even after a digestion time of 14 h when nearly 50 peptide bonds were split (Fig. 1). After still longer digestion times, however, the increase of glycine after the addition of thrombin gradually decreased but seemed to reach the level of about 2 additional moles of glycine at maximal digestion.

In order to determine whether the bonds split by thrombin are the same in the digested as in the intact fibrinogen, an attempt was made to isolate the peptides liberated by the action of thrombin on the digestion mixture described above. The method used was that described by Blombäck and Vestermark [4]. After a digestion time of 5 h two 20 ml samples were removed from the digestion mixture. To one of them 400 NIH units thrombin dissolved in 2 ml were added. Both samples were incubated for 15 min at 37°C. The enzyme action was interrupted by adjusting the pH of the samples to 2 with formic acid. After being kept over night at —20°C they were thawed and the pH adjusted to 4.5. A heavy precipitate formed and was removed by centrifugation. After adjusting the pH of the supernatants to 3.1 they were put on Dowex-50 × 2 columns, 0.9 × 40 cm, previously equilibrated with sodium formate buffer, pH 3.1, of ionic strength 0.1. The columns were eluted with sodium buffers of ionic strength 0.1 with varying pH as seen from Fig. 2. The flow rate of the columns was about 1.5 ml/h. Hourly fractions were collected in a fraction collector. The peptide contents in the fractions were estimated with the colour reaction of Lowry *et al.*[11]

In the chromatograms of peptides from plasmin-digested fibrinogen eluted at pH 4.4 to pH 5.0, *i. e.* in the region where the fibrinopeptides A and B should appear [4], no peptides were found. However, when thrombin was added to the digestion mixture there appeared one peptide at pH 4.4 (A) and another peptide at pH 4.7 (B). With these exceptions the two chromatograms showed an identical pattern. Further it was shown that the first of these peptides (A) contained glutamic acid in N-terminal position, whereas no N-terminal residue could be detected in the second one (B). It is most probable that the peptides A and B, which are released through the action of throm-

bin on the fibrinogenolytic mixture, are identical to the peptides in the supernatant after clotting.

Our results indicate that through the action of thrombin the same peptide bonds are split in fibrinogen irrespective of whether its molecule is intact or has been digested with plasmin. Recently Niewarowski and Kowalski [12] have reported that at the digestion of pure fibrin and fibrinogen by plasmin there appears antithrombin activity in the digestion mixture. It is possible that the protein fragments which are formed during fibrinogenolysis and which are substrates for thrombin can act as competitive inhibitors in the reaction between thrombin and fibrinogen and thus contribute to the antithrombin activity. Work is in progress to study the conditions at maximal plasmin digestion and to isolate the protein fragments, that can be proteolysed by thrombin. A more detailed paper on this subject is to be published in *Arkiv för Kemi*.

Chromic Acid Esters
A Correction

ULRIK KLÄNING

Laboratoriet for Fotokemi, Fotografi og Reproduktionsteknik, Polyteknisk Læreanstalt, Copenhagen, Denmark

In a recent paper evidence for the existence of 1:1 complexes of alcohols or acetaldehyde with acid chromate ion was presented. The equilibrium was written $X + HCrO_4^- = X \cdot HCrO_4^-$, where X stands for methanol, ethanol, propanol, 2-propanol, 2-butanol or acetaldehyde. But the equilibrium constants became incorrect as no allowance was made for the change of the total number of moles per liter with the alcohol or acetaldehyde concentration.

According to Westheimer *et al.*[2,3] the complexes formed in the alcoholic solutions are esters.

$$ROH + HCrO_4^- = ROCrO_3^- + H_2O$$

In solutions containing acetaldehyde the complex formed may be pictured as chromic acid ester of ethylideneglycol.

The equilibrium constant is

$$K_e = \frac{c_e \cdot \gamma_e \cdot c_w \cdot \gamma_w}{c_l \cdot \gamma_l \cdot c_a \cdot \gamma_a} \qquad (1)$$

c_e, c_w, c_l and c_a being molar concentrations of the ester, water, acid chromate and the alcohol, respectively. γ_e, γ_w, γ_l and γ_a are acticity coefficients. For some of the above-mentioned alcohols γ_w and γ_a are known [4,5], but since we do not know γ_e and γ_l we assume that $\gamma_l = \gamma_a \cdot \gamma_l$ and neglect variations in γ_w. This enables us to calculate values of K_e from the reported measurements of $\Delta\varepsilon$[1]. $\Delta\varepsilon$ is the difference between the extinctions at 375 mμ of two solutions both containing 10^{-4} M acid chromate and 10^{-3} M perchloric acid, and one of them also an alcohol or acetaldehyde in varying concentration. Assuming that the extinction coefficients are independent of alcohol or acetaldehyde concentration, we have $\Delta\varepsilon = \Delta\varepsilon_{KI} \cdot l \cdot c_e$, where l is the length of the optical path in cm and $\Delta\varepsilon_{KI}$ the difference between the extinction coefficient of the ester and that of the acid chromate ion at 375 mμ. On introduction of $\Delta\varepsilon$ and the total chromate concentra-

bin on the fibrinogenolytic mixture, are identical to the peptides in the supernatant after clotting.

Our results indicate that through the action of thrombin the same peptide bonds are split in fibrinogen irrespective of whether its molecule is intact or has been digested with plasmin. Recently Niewarowski and Kowalski [12] have reported that at the digestion of pure fibrin and fibrinogen by plasmin there appears antithrombin activity in the digestion mixture. The equilibrium was written $X + HCrO_4^- = X \cdot HCrO_4^-$, where X stands for methanol, ethanol, propanol, 2-propanol, 2-butanol or acetaldehyde. But the equilibrium constants became incorrect as no allowance was made for the change of the total number of moles per liter with the alcohol or acetaldehyde concentration.

According to Westheimer *et al.*[2,3] the complexes formed in the alcoholic solutions are esters.

$$ROH + HCrO_4^- = ROCrO_3^- + H_2O$$

In solutions containing acetaldehyde the complex formed may be pictured as chromic acid ester of ethylideneglycol.

The equilibrium constant is

$$K_e = \frac{c_e \cdot \gamma_e \cdot c_w \cdot \gamma_w}{c_l \cdot \gamma_l \cdot c_a \cdot \gamma_a} \qquad (1)$$

c_e, c_w, c_l and c_a being molar concentrations of the ester, water, acid chromate and the alcohol, respectively. γ_e, γ_w, γ_l and γ_a are acticity coefficients. For some of the above-mentioned alcohols γ_w and γ_a are known [4,5], but since we do not know γ_e and γ_l we assume that $\gamma_l = \gamma_a \cdot \gamma_l$ and neglect variations in γ_w. This enables us to calculate values of K_e from the reported measurements of $\Delta\varepsilon$[1]. $\Delta\varepsilon$ is the difference between the extinctions at 375 mμ of two solutions both containing 10^{-4} M acid chromate and 10^{-3} M perchloric acid, and one of them also an alcohol or acetaldehyde in varying concentration. Assuming that the extinction coefficients are independent of alcohol or acetaldehyde concentration, we have $\Delta\varepsilon = \Delta\varepsilon_{KI} \cdot l \cdot c_e$, where l is the length of the optical path in cm and $\Delta\varepsilon_{KI}$ the difference between the extinction coefficient of the ester and that of the acid chromate ion at 375 mμ. On introduction of $\Delta\varepsilon$ and the total chromate concentra-

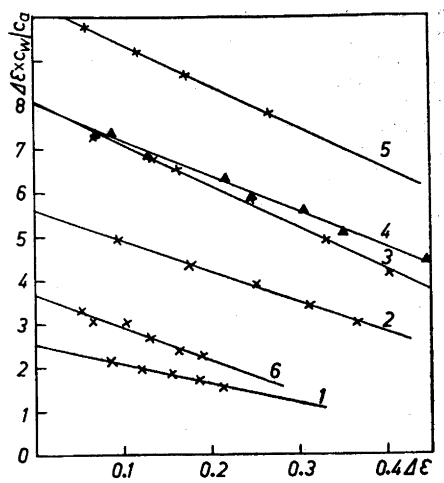

Fig. 1. $\Delta\varepsilon \cdot c_w/c_a$ *versus* $\Delta\varepsilon$ for acid chromate solutions containing 1) methanol, 2) ethanol, 3) *n*-propanol, 4) 2-propanol, 5) 2-butanol and 6) ethylideneglycol.

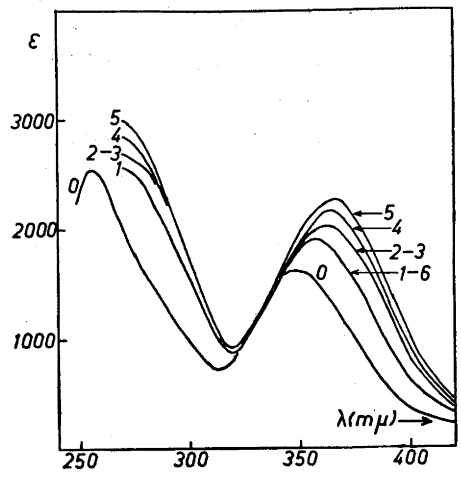

Fig. 2. The absorption spectrum of the acid chromate ion 0), and the absorption spectra of the esters of acid chromate with 1) methanol, 2) ethanol, 3) *n*-propanol, 4) 2-propanol, 5) 2-butanol and 6) ethylideneglycol.

tion c_0 in (1) we obtain the following expression.

$$\frac{\Delta\varepsilon \cdot c_w}{c_a} = \Delta\varepsilon_{KI} \cdot K_e \cdot l \cdot c_0 - K_e \cdot \Delta\varepsilon \quad (2)$$

c_w has been calculated from the densities of the solutions [6]. The concentration of ethylideneglycol has been calculated from the value of the equilibrium constant for formation of ethylideneglycol in dilute aqueous acetaldehyde solutions [7]. Fig. 1. shows $\Delta\varepsilon c_w/c_a$ plotted against $\Delta\varepsilon$. From the slope of the straight lines K_e was calculated. Table 1 shows the values of K_e and the values of the equilibrium constants K, reported in Ref.[1] for the equilibrium $X + HCrO^- = X.HCrO_4^-$. From the measurements of $\Delta\varepsilon$ at varying wavelength the absorption spectra of the esters in the near ultraviolet has been calculated (Fig. 2).

Paramagnetism of Na_2NO_2

Studies in Magnetochemistry 22 *

R. W. ASMUSSEN

The Chemical Laboratory B, Technical University of Denmark, Copenhagen, Denmark

When a solution of sodium nitrite in liquid ammonia is treated with a solution of sodium in liquid ammonia the blue colour of the solution disappears and a yellow compound of the composition Na_2NO_2 is deposited. This substance was first obtained by Maxted [1] and later prepared by Zintl and Kohn [2], who also studied the chemical properties of the salt. The present author investigated the magnetic properties of Na_2NO_2 in 1940 and published in 1941 the qualitative results of the measurements and discussed their chemical significance in the paper [3] "Magnetochemical Studies on Free Radicals" (in Danish). Parts of this article, also that which concerns Na_2NO_2, has been quoted by Selwood [4]. In the present note the quantitative results are reported. Klemm and Pauli [5] published in 1951 a paper on the magnetic properties of the same compound.

The preparation of Na_2NO_2 was carried out according to the method given by Zintl and Kohn [2] using an apparatus and a technique similar to those applied by these authors. The samples were extracted with liquid ammonia in order to remove $NaNO_2$ with which the preparations were contaminated. Seven independent specimens were prepared but the magnetic measurements are given for four only. Two preparations (Nos. 1 and 2) possessed very small paramagnetic susceptibilities. The analyses proved that 1 and 2 were rather impure. One preparation (No. 5) exploded in the magnetic measuring tube.

In trying to prepare $LiNaNO_2$ we did not succeed in getting sufficiently pure substances.

The determination of the magnetic susceptibilities were performed by the Gouy-method as described by Christiansen and Asmussen [6]. The substances were transferred to the magnetic measuring tubes protected by an atmosphere of dry nitrogen. The results of the magnetic measurements and the chemical analyses are given in Table 1. The molar susceptibilities (column 5) were corrected for the diamagnetic contribution of the electron system of the ions Na^+ and O^{-2}. The gram ionic susceptibilities used for these ions are -3.7×10^{-6} and -11.3×10^{-6}, respectively. The total diamagnetic correction is then -30×10^{-6} neglecting the correction for N^{+2}, which doubtless is very small since the value for N^{+5} is about -0.1×10^{-6}.

Na_2NO_2 is formed in a reaction similar to that of the metal ketyls and may be considered as an inorganic ketyl. If the crystal contains Na^+ and NO_2^{-2} ions only, the molar magnetic susceptibility should be $1\,271 \times 10^{-6}$ (spin only; at 20°C). The observed small susceptibility values may be interpreted as being due to a certain dissociation in the crystal of the dimer $Na_4N_2O_4$, the sodium salt of a hypothetical tetraoxyhydrazine:

$$\underset{\mu = 0}{Na_4N_2O_4} \rightleftharpoons \underset{\mu = 1.73\ \mu_B}{2Na_2NO_2}$$

* No. 21 appeared in *Acta Chem. Scand.* **12** (1958) 24.

Table 1. Analyses, paramagnetic susceptibilities and degrees of dissociation for four independent preparations of Na_2NO_2.

Prep. No.	% Na Calc.	% Na Found	Temp. °K	$\chi_g \times 10^6$	$\chi_M \times 10^6$ for Na_2NO_2	$\chi_M \times 10^6$ for Na_2NO_2 Corr.	$\chi_M \times 10^6$ for $Na_4N_2O_4$ Corr.	$\chi_M \times 10^6$ for 100 % dis. $Na_4N_2O_4$	Degree of dissociation
3	49.98	49.4	294	2.0	184	214	428	2 524	0.17
4	49.98	49.8	292	2.4	221	251	502	2 542	0.20
6	49.98	49.7	292	2.1	193	223	446	2 542	0.18
7	49.98	49.2	293	1.9	175	205	410	2 534	0.16

The degrees of dissociation at room temperature calculated by means of the data in columns Nos. 7 and 8 are in column 9. The mean value is 0.18. Klemm and Pauli [5] report 0.23 at 20°C. Their susceptibility values at two lower temperatures may be interpreted as indicating a decrease in the degree of dissociation with decreasing temperature.

Isolation of an Anti-*Sclerotinia* Factor, 7-Hydroxy-4′-methoxy-*iso*flavone from Red Clover

ARTTURI I. VIRTANEN and PENTTI K. HIETALA

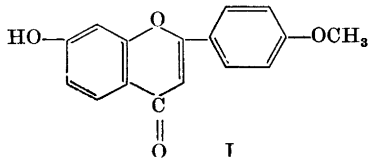
Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

When investigating the antifungal substances in red clover, we isolated a new compound (A 1) the characteristics of which we have earlier reported [1,2]. The structure elucidation of this compound is still in progress. When isolating this compound, we also came to isolate an other substance (A 2) which is found in comparatively large amounts in the leaves and the stems of red clover. From fresh clover plants the isolation and separation of the two substances in pure form was difficult, since on paper chromatograms both substances behaved in much the same way in different solvent systems. The separation succeeded, however, using O'Keeffe fractionation. 2.69 g (m.p. 217°C) of A 1 was obtained in crystalline form from 10.75 kg of fresh red clover and 4.6 g (m.p. 262°C) of A 2, likewise in crystalline form. A large amount of the latter remained in the motherliquor, however. The total amount of A 2 was calculated on the basis of paper chromatography from the fluorescence of the spots to about 10 g per 10 kg fresh clover harvested 26.7. Since A 1 disappears on drying of the clover, the isolation of A 2 from dried clover is easy (ether extraction, extraction of the ether residue by petroleum ether and sublimation of the undissolved residue *in vacuo* at 260 to 280°C).

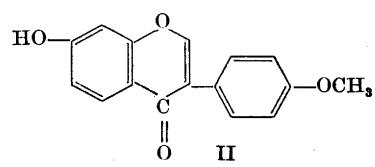
The structure of A 2. Elementary analysis: C 71.89; H 4.66; Calc. for $C_{16}H_{12}O_4$: C 71.63; H 4.51. The substance contained one hydroxy and one methoxy group. The content of the methoxy group in the substance was 11.1 %, determined by the method of Vieböck and Brecher, calculated for the compound $(C_{15}H_9O_3)$-OCH_3 11.57 %.

Using Rossman's method the substance in 30 min took up an amount of bromine corresponding to one double bond. In the alkali melt (131 mg of A 2, 2.74 g of solid KOH, 230–250°C, 2 h) 2,4-dihydroxybenzoic acid and *p*-hydroxybenzoic acid were formed. When heated in $BaOH_2$ solution anisic acid was formed. The structure of the A 2 compound accordingly is I or II.

On heating 400 mg of the substance in NaOH solution on a water bath for 20 min a substance was obtained after neutralisation with hydrochloric acid, acidification with acidic sodium phosphate and extraction by ether. This substance crystallized in flaky crystals and melted at 164°C. The yield was 285 mg. The elementary analysis of the substance was C 69.36; H 5.61; O 24.62. If the compound formed had been a chalcone $(C_{16}H_{12}O_4 + H_2O)$ corresponding to A 2, the calculated values



I



II

The degrees of dissociation at room temperature calculated by means of the data in columns Nos. 7 and 8 are in column 9. The mean value is 0.18. Klemm and Pauli [5] report 0.23 at 20°C. Their susceptibility values at two lower temperatures may be interpreted as indicating a decrease in the degree of dissociation with decreasing temperature.

Isolation of an Anti-*Sclerotinia* Factor, 7-Hydroxy-4′-methoxy-*iso*flavone from Red Clover

ARTTURI I. VIRTANEN and PENTTI K. HIETALA

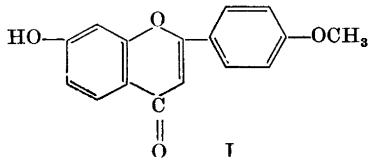
Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

When investigating the antifungal substances in red clover, we isolated a new compound (A 1) the characteristics of which we have earlier reported [1,2]. The structure elucidation of this compound is still in progress. When isolating this compound, we also came to isolate an other substance (A 2) which is found in comparatively large amounts in the leaves and the stems of red clover. From fresh clover plants the isolation and separation of the two substances in pure form was difficult, since on paper chromatograms both substances behaved in much the same way in different solvent systems. The separation succeeded, however, using O'Keeffe fractionation. 2.69 g (m.p. 217°C) of A 1 was obtained in crystalline form from 10.75 kg of fresh red clover and 4.6 g (m.p. 262°C) of A 2, likewise in crystalline form. A large amount of the latter remained in the motherliquor, however. The total amount of A 2 was calculated on the basis of paper chromatography from the fluorescence of the spots to about 10 g per 10 kg fresh clover harvested 26.7. Since A 1 disappears on drying of the clover, the isolation of A 2 from dried clover is easy (ether extraction, extraction of the ether residue by petroleum ether and sublimation of the undissolved residue *in vacuo* at 260 to 280°C).

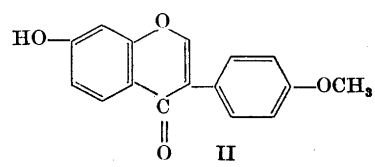
The structure of A 2. Elementary analysis: C 71.89; H 4.66; Calc. for $C_{16}H_{12}O_4$: C 71.63; H 4.51. The substance contained one hydroxy and one methoxy group. The content of the methoxy group in the substance was 11.1 %, determined by the method of Vieböck and Brecher, calculated for the compound $(C_{15}H_9O_3)$-OCH_3 11.57 %.

Using Rossman's method the substance in 30 min took up an amount of bromine corresponding to one double bond. In the alkali melt (131 mg of A 2, 2.74 g of solid KOH, 230–250°C, 2 h) 2,4-dihydroxybenzoic acid and *p*-hydroxybenzoic acid were formed. When heated in $BaOH_2$ solution anisic acid was formed. The structure of the A 2 compound accordingly is I or II.

On heating 400 mg of the substance in NaOH solution on a water bath for 20 min a substance was obtained after neutralisation with hydrochloric acid, acidification with acidic sodium phosphate and extraction by ether. This substance crystallized in flaky crystals and melted at 164°C. The yield was 285 mg. The elementary analysis of the substance was C 69.36; H 5.61; O 24.62. If the compound formed had been a chalcone $(C_{16}H_{12}O_4 + H_2O)$ corresponding to A 2, the calculated values



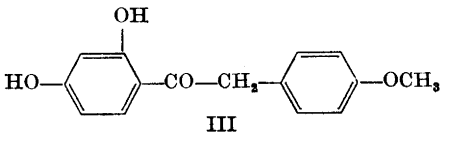
I



II

had been: C 67.11; H 4.95; O 27.94. The values found do not agree with the calculated ones. The CO group had thus apparently split off as formic acid on the alkali treatment, why the composition of the compound was $C_{15}H_{14}O_4$, for which the calculated values are: C 69.77; H 5.44; O 24.79. The determination of the methoxy group gave a value corresponding to this. (Found: 11.71 %-OCH_3; calc. for ($C_{14}H_{11}O_3$)-OCH_3: 12.02 %.)

The compound reacted with 2,4-dinitrophenylhydrazine. The structure of the compound is, on the basis of the results obtained, the following (III)



III

This can be formed only if compound A 2 has an *iso*flavone structure (*i.e.* structure II). The substance isolated by us is thus 7-hydroxy-4'-methoxy*iso*flavone.

By methylation a methoxy compound is obtained from the ketone III. The m.p. of this compund is 102—104°C. The methoxy determination gave values which correspond to the formula ($C_{14}H_{10}O_2$)·(-OCH_3)$_2$ (Found: 22.6 % -OCH_3; calc. 22.8 %).

In an investigation by Power and Salway [3] a compound $C_{16}H_{12}O_4$, m.p. 253°C, was isolated from flowers of red clover. This substance, called pratol, is clearly identical with the substance isolated by us. Structure I has been proposed for it, *i.e.* a flavone structure. On the basis of our investigations this concept has to be corrected. By the method of Robinson and Venkatamaran [4] we synthesized 7-hydroxy-4'-methoxyflavone and found that it differs from the A 2 substance isolated from clover, both with regard to the melting point and to the UV-spectrum.

The isolated antifungal substances A 1 and A 2 are active against *Sclerotinia trifoliorum* and *Fusarium nivale*. A 1 has a higher activity against *Fusarium* than *Sclerotinia*, A 2 again is much more active against the latter.

This is a preliminary report of our results and further details will be published in a more comprehensive article.

Added in proof: F. Wessely (*Monatshefte Chem.* **57** (1931) 395) has synthesized an *iso*flavone, formononetin, which has the same structure as our substance isolated from red clover. Professor Wessely (Vienna) was kind enough to send us a sample of his substance and we could identify it with our substance.

In literature we have found a paper by Cheng *et al.* (*Science* **120** (1954) 575) where determinations of the estrogenic effect of some synthetic *iso*flavones are presented. Formononetin has also been found to have such an effect.

Mr. P. O. Karvonen has actively taken part in this work, among other things in the determination of the methoxy groups.

The support given by the *Rockefeller Foundation* is gratefully acknowledged.

The Transfer of L-5-Vinyl-2-thiooxazolidone (oxazolidinethione) to Milk

ARTTURI I. VIRTANEN, MATTI KREULA and MARTTI KIESVAARA

Laboratory of Valio, Biochemical Institute, Helsinki, Finland

From the seeds of *Brassica* plants Astwood *et al.*[1] have isolated a strongly antithyroid substance which they established as L-5-vinyl-2-thiooxazolidone. In the edible portions of *Brassica* vegetables, such as cabbage, kale, cauliflower, broccoli, mustardgreens, and horseradish root, they did not find this substance. In this laboratory Kreula and Kiesvaara [2] developed a chromatographic-spectrophotometric method by which vinyl-thiooxazolidone can be determined in green plants in a concentration of 1 μg/g fresh plants and 5 μg/litre milk. Contrary to the findings by Astwood *et al.* the present authors found

had been: C 67.11; H 4.95; O 27.94. The values found do not agree with the calculated ones. The CO group had thus apparently split off as formic acid on the alkali treatment, why the composition of the compound was $C_{15}H_{14}O_4$, for which the calculated values are: C 69.77; H 5.44; O 24.79. The Transfer of L-5-Vinyl-2-thiooxazolidone (oxazolidinethione) to Milk

ARTTURI I. VIRTANEN, MATTI KREULA and MARTTI KIESVAARA

Laboratory of Valio, Biochemical Institute, Helsinki, Finland

From the seeds of *Brassica* plants Astwood *et al.*[1] have isolated a strongly antithyroid substance which they established as L-5-vinyl-2-thiooxazolidone. In the edible portions of *Brassica* vegetables, such as cabbage, kale, cauliflower, broccoli, mustardgreens, and horseradish root, they did not find this substance. In this laboratory Kreula and Kiesvaara [2] developed a chromatographic-spectrophotometric method by which vinyl-thiooxazolidone can be determined in green plants in a concentration of 1 μg/g fresh plants and 5 μg/litre milk. Contrary to the findings by Astwood *et al.* the present authors found

considerable amounts of vinyl-thiooxazolidone in cabbage, kale, rape, *etc.*, in cabbage for instance 5-40 μg/g fresh weight.

In the literature there has lately occurred information about the antithyroid effect of milk when cruciferous plants are used as fodder [3]. In order to find out to what extent vinyl-thiooxazolidone is possibly transferred to milk, a feeding experiment was performed with a cow, the daily production of which was 8.2 kg of milk. At 7 o'clock p.m. on the 3rd of March the cow was fed with 0.5 kg of finely ground moistened rape seeds which according to analysis contained 4.5 g of vinyl-thiooxazolidone. The active substance is formed from a glycoside found in the seeds by enzymatic action. In the moistened seeds the liberation takes place rapidly, and this presumably happens in the rumen too. A milk sample was taken before feeding, 12 h after feeding, and then every 12 h for 6 days.

Not even a trace of vinyl-thiooxazolidone, which has a strong absorption maximum at 240 mμ, was found in any milk sample. On the other hand, a small amount of a substance with a strong absorption maximum at 255 mμ was found in the milk 12 h after feeding (after 24 h the amount was already very small). After 48 h there were only traces of it in the milk (Fig. 1).

Since strong reductive processes take place in the rumen — among other things unsaturated fatty acids are largely reduced to saturated ones — it is possible that vinyl-thiooxazolidone is reduced to the corresponding 5-ethyl-2-thiooxazolidone in the rumen. The substance excreted into milk could thus be this compound. According to Astwood *et al.* the spectra of 5,5-dimethyl-2-thiooxazolidone and 2-thiooxazolidone are nearly identical with the spectrum of 5-vinyl-2-thiooxazolidone. On the basis of this, the side chain would have no greater influence on the spectrum of compounds of this type, and the substance found in milk would accordingly not be ethyl-thiooxazolidone. The amount of the substance excreted into milk was minimal, about 0.1 % of the vinyl-thiooxazolidone given to the cow, provided that the specific absorption of the substances at 240 and 255 mμ, respectively, is approximately the same. The investigations concerning the substance found in milk continue.

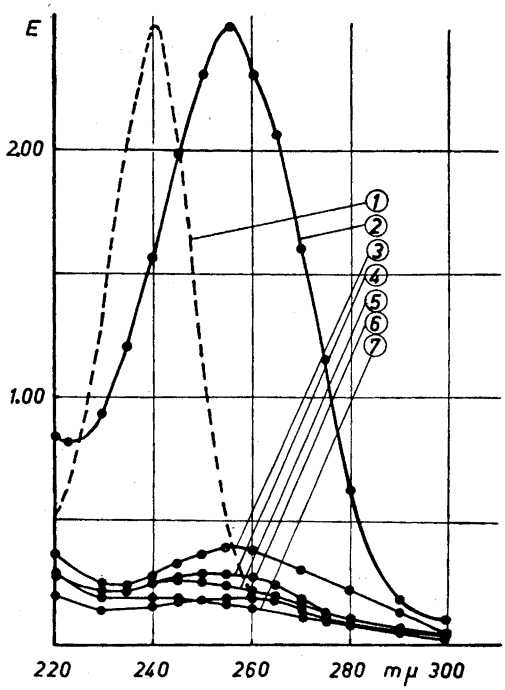

Fig. 1. UV-spectra of the compound which appears in cow's milk after feeding of 0.5 kg of finely ground moistened rape seeds containing 4.5 g of L-5-vinyl-2-thiooxazolidone (2—7). The curves show the relative values after 12 h (2), 30 h (3), 54 h (4), 78 h (5), 102 h (6), and 126 h (7). The dashed curve (1) shows the spectrum of L-5-vinyl-2-thiooxazolidone.

A new Synthesis of 6-Selenoctic Acid and a Related Compound

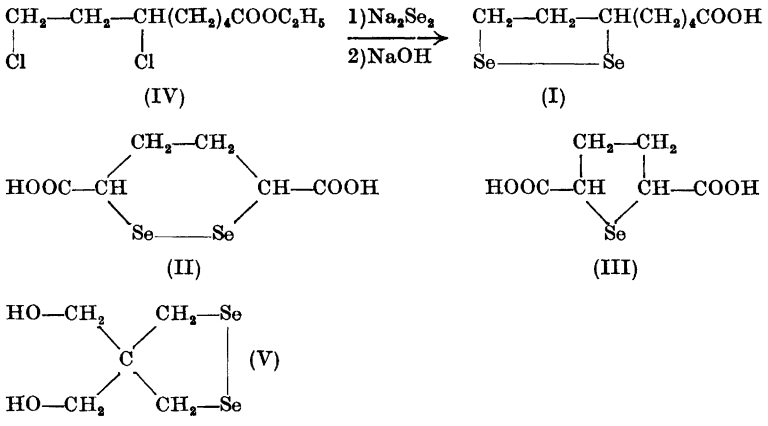
GÖRAN BERGSON

Chemical Institute, University of Uppsala, Sweden

Recently the author described the synthesis of 6-selenoctic acid (I) in this journal [1]. As this substance had not been characterized before and since operations with cyclic selenium compounds are not easy, the author then applied a method of synthesis analogous to one used in the preparation of 6-thioctic acid [2]. The method involved the synthesis of 6,8-dibenzylselenoloctanoic acid from ethyl 6,8-dichlorooctanoate followed by reductive cleavage with sodium in liquid ammonia and oxidation with air. In this way 6-selenoctic acid was obtained in fair yield, and some of its properties could be determined. It now seemed advisable to look for other synthetic methods.

The simplest of all methods for preparing organic diselenides is the alkylation of alkali diselenides. As pointed out by Fredga [3], however, this method fails to give the six-membered cyclic diselenide 1,2-diselenane-3,6-dicarboxylic acid (II) when α,α'-dibromoadipic acid is treated with potassium diselenide. In this case the reaction leads to the five-membered cyclic monoselenide tetrahydroselenophene-2,5-dicarboxylic acid (III) and elementary selenium. When ethyl 6,8-dichlorooctanoate (IV) is treated with sodium diselenide, however, only a small amount of elementary selenium remains after the reaction, and ring closure takes place to form 6-selenoctic acid. In a similar way reaction between 2,2-(bisiodomethyl)-propanediol-1,3 and sodium diselenide gives the cyclic compound 4,4-(bishydroxymethyl)-1,2-diselenolane (V).

From the point of view of steric strain in the cyclic diselenides it seems difficult to explain why the fivemembered rings seem to form more easily than the six-membered. The presence of the carboxylic groups in the vicinity of the bromine atoms in dibromoadipic acid possibly complicates the reaction. A preliminary experiment with dibromoglutaric acid and sodium diselenide points in this direction. It must be borne in mind that α-halogen substituted carboxylic acids (contrary to other halogen compounds) completely oxidize sodium ditelluride to elementary tellurium, the acid being reduced to the unsubstituted fatty acid [4]. In view of the possible oxidative action of the halogen compounds towards the alkali diselenide it seems advisable to use chlorine compounds whenever possible. It must be pointed out that 6-selenoctic acid is obtained in better yield than 4,4-(bishydroxymethyl)-1,2-diselenolane, which may be due to the fact that a chlorine compound was used in the preparation of the former and an iodine compound for the latter. Backer and Winter also got only a low yield of 4-phenyl-4-methyl-1,2-diselenolane when phenyl methyldibromopropane was treated with potassium diselenide. The chief products were elementary selenium and a hydrocarbon.[5] When complications of these kinds occur the second method worked out by



Fredga, *viz.* hydrolysis of selenocyanates must be recommended [3]. In this way, Fredga obtained 1,2-diselenane-3,6-dicarboxylic acid, and Backer and Winter 4-phenyl-4-methyl-1,2-diselenolane and 4,4-dimethyl-1,2-diselenolane [5].

6-Selenoctic acid has its characteristic UV-peak at 442 mμ as can be seen from Fig. 1, curve 1. The spectrum of 4,4-(bishydroxymethyl)-1,2-diselenolane is closely related as well as that of 1,2-diselenolane itself [6]. Non-cyclic diselenides absorb at about 310 mμ [7]. Whether the shoulder at about 300 mμ in the spectra of the five-membered ring compounds is due to the presence of a small amount of polymer in the solution or to a hitherto unrecognized band cannot be answered at present. After standing over night the spectrum of the solution of 6-selenoctic acid did not change significantly. When 6-selenoctic acid was treated with $NaBH_4$, the absorption band at 442 mμ disappeared, indicating complete reduction to the selenol (Fig. 1 curve 2). 1,2-Dithiolane derivatives are said not to be reduced by sodium borohydride [8]. When the reduced solution was allowed to stand in the air for about one hour, oxidation to 6-selenoctic acid occurred, as seen from Fig. 1 curve 3. A complete report of the UV and IR spectra of diselenides is to be published in *Arkiv Kemi*. Preparation of optically active 6-selenoctic acid is planned.

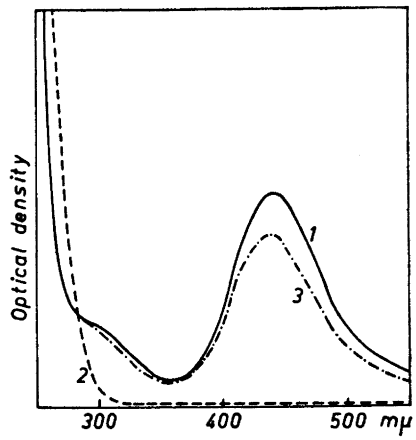


Fig. 1. Light absorption of 1) 6-selenoctic acid in ethanol, 2) 6-selenoctic acid reduced with $NaBH_4$, 3) the reduced solution after 1 h exposure to air.

Experimental: 6-Selenoctic acid. Sodium diselenide solution was prepared by dissolving 2.17 g of sodium formaldehydesulphoxylate (Rongalite C), 1.47 g of sodium hydroxide and 2.91 g of selenium in 30 ml of water in a nitrogen atmosphere. 4.43 g of ethyl 6,8-dichlorooctanoate dissolved in 30 ml of ethanol was added dropwise and the reaction mixture stirred for 90 min, the temperature being kept at 60—70°. 1.47 g of sodium hydroxide in 25 ml of water was added and stirring and warming continued for 5 h. After standing over night the mixture was acidified with 6 N hydrochloric acid. The product was taken up in 50 ml of chloroform. This extract was dried with sodium sulphate and the solvent removed in vacuum. The residue was extracted with boiling *n*-hexane, and when this solution cooled, the crude 6-selenoctic acid separated (m. p. 86—89°). The yield was about 25 % but it seems possible to increase it. After recrystallization from *n*-hexane, the product melted at 89—90.5°.

4,4 - (Bishydroxymethyl) - 1,2 - diselenolane. The sodium diselenide solution was prepared as above, and the calculated quantity of 2,2-(bisiodomethyl)-propanediol-1,3 dissolved in ethanol was added. After 5 h reflux, the mixture was extracted with 3 × 50 ml of ether. The extract was dried with sodium sulphate and the ether evaporated. The residue was boiled with some petroleum ether to remove impurities and then recrystallized twice from benzene. The product crystallized in long dark red needles m. p. 133—135°. (Found: Se 59.8. Calc. 60.6.) Yield 8 %.

I wish to express my gratitude to Professor Arne Fredga for much helpful advice. I am also indebted to Dr. Lennart Schotte for his interest in this work. A grant from the *Swedish Natural Science Research Council* is gratefully acknowledged.

Studies of the Hydrogen Bond

IV. Theoretical Determination of Electronic Polarization Energies

INGA FISCHER-HJALMARS
and RAGNAR GRAHN

Institute of Theoretical Physics, University of Stockholm, Stockholm, Sweden

The problem why some molecules associate by aid of hydrogen bonds (H bonds) while others seem to have no disposition for the formation of such bonds has been thoroughly discussed for many years but has not yet been solved in a completely satisfactory way. The main factors, which cooperate in the formation of an H bond, are supposed to be: 1) electrostatic interaction, 2) covalent binding, 3) polarization. In many investigations of the H bond only the two first factors have been taken into consideration. The factor 3) seems, however, to be of the same importance as the other two. It has been discussed previously by, *e.g.*, Bauer and Magat [1] and by Ehrenberg and Fischer [2-4] (Studies of the Hydrogen Bond I, II, III). Bauer and Magat [1] have calculated the energy of an H bond between water molecules with due consideration to polarization effects. This calculation was carried out in a classical way by use of the experimental value of the polarizability of the whole molecule. Ehrenberg and Fischer [2,3] have pointed out that certain organic compounds with a less polarizable hetero-atom are less soluble in water than others with a more polarizable hetero-atom. They proposed quantum mechanical calculations to clarify the rôle of polarization for H bond formation, and a very rough calculation of this kind was carried out [4].

The influence from the above-mentioned three factors upon an H bond cannot be strictly separated. It would therefore have been desirable to make a complete, quantum mechanical calculation of the total energy of H-bonded systems. Because of the complexity of such systems we have chosen to investigate primarily the electronic polarization effects and less rigorously the other two factors. Even this simplified programme must be further reduced to make the computational work tolerable.

Hitherto we have studied the association of H_2O, where there is a strong H bond, and of H_2S, where there is no H bond. Calculations on the association of HF and of HCl are going on but will not be reported here. They will be published later by one of us (R.G.) together with a more detailed description of the calculations on H_2O and H_2S.

In the study of the H bond between H_2O molecules we have considered the following system:  We have used the intermolecular distances given by the ice-structure, proposed by Bernal and Fowler [5]. For the description of the electron distribution of a free H_2O molecule we have used the molecular orbitals (MO's), calculated by Ellison and Shull [6]. Our investigation includes a study of i) the strengthening of the H bond, caused by the electronic polarization of the whole H_2O in the field from the net positive charge on H′ and ii) the strengthening of the H bond, caused by the polarization of H′ in the field from the adjacent H_2O.

The energy gain from the effect i) has been obtained from a computation of the change of the original MO's of H_2O, caused by the potential from H′. Now, the O atom of the free H_2O has two filled lone-pair MO's. When expressing the electron distribution by aid of equivalent orbitals, it is seen that already in the free H_2O these MO's are almost completely localized at the "back" of the O atom. Thus, the computed electron density at the back of the O atom cannot increase as a result of the H′ potential, unless excited atomic orbitals (AO's) are included in the changed MO's. However, for computational reasons, we have assumed the changed MO's to be linear combinations of the same AO's as the original MO's. Consequently, our calculation can only take into account that part of the effect from H′, which consists in moving the electrons of the O—H bonds closer towards the O atom. The energy gain from this movement is found to be comparatively small, only 0.2 kcal/mole. However, the sign of this energy change indicates that the effect i) would give a much larger energy gain, if excited AO's of the O atom were included.

The effect ii) has been computed by replacing the 1s AO of H′ by a hybrid of the three AO's 1s, $2p\sigma$ and $2p\pi$. The coefficients of this hybrid have been determined by a variation method. The energy

gain from this polarization of H′ has been found to be about 1.5 kcal/mole.

Summing up, the total computed energy gain from polarization effects is 0.2 + 1.5 = 1.7 kcal/mole. This value is, however, not very definite. There are several factors, which could modify it in one direction or the other. One factor, which would increase it, is the fact that 0.2 and 1.5 kcal/mole should be considered as lower limits of the effects i) and ii). Another, which would diminish it, is the fact that the effect ii) should cause a slight weakening of the O′—H′ bond. Although the value 1.7 kcal/mole is rather approximate, it is interesting to compare it with the purely electrostatic interaction energy. Using the point charge model, discussed by Bauer and Magat [1], this energy is computed to 5.1 kcal/mole. Thus, it is seen that the polarization energy is not a negligible part of the total H bond energy.

For comparison with H_2O we have also studied the association of H_2S, which has an electronic structure similar to that of H_2O. H_2S solidifies at −82.9°C, but it does not seem to have a definite crystalline form. We have studied the interaction of two H_2S molecules, $S'-H'....S\begin{matrix}H\\H\end{matrix}$, assuming the atoms S′H′S to be on a straight line. In the case of H_2S we have only computed the above-mentioned polarization effect ii). We have found a small energy gain, about 0.05 kcal/mole. Since the effect ii) is giving the main contribution to the polarization energy in the H_2O case, it is reasonable to assume the total polarization energy in the association of H_2S to be of the order of magnitude of 0.05 kcal/mole. The purely electrostatic interaction energy is in this case computed to be 0.25 kcal/mole, when a point charge model is used.

The numerical results of the present investigation are collected in Table 1.

Table 1. Effects contributing to H bond formation. Energies in kcal/mole.

Molecule	Polarization energy			Electrostatic energy	Exptl. H bond energy
	i)	ii)	total		
H_2O	0.2	1.5	1.7	5.1	5.8
H_2S	—	0.05	~0.05	0.25	—

From Table 1 it is seen that the polarization effects are important for the H bond formation in the H_2O case, whereas they cannot have any influence in the H_2S case.

Some Advantages of Using a Mercury Cathode in the Kolbe Electro-synthesis

NGUYEN DINH-NGUYEN

Department of Medical Biochemistry, University of Gothenburg, Sweden

When the anodic reaction $2\ -\overset{|}{\underset{|}{C}}-COO^- \xrightarrow{-2e} -\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}- + 2\ CO_2$, named after Hermann Kolbe [1], is used for the preparation of alkali-sensitive substances such as esters, present practice usually avoids hydrolysis by electrolysing free carboxylic acids in the presence of only a few per cent of their sodium salts, the reaction being stopped when the electrolyte turns neutral. The solvent is generally methanol and the electrodes smooth platinum sheets.

In an attempt to prepare dimethyl adipate from methyl hydrogen succinate using this technique, a yield of only 38 % was obtained, in contrast to the 70 % reported by Bouveault [2]. He electrolysed equivalent amounts of succinic anhydride and sodium in methanol, using a water-cooled platinum-tube anode and a mercury cathode. New runs were therefore made with mercury as cathode at the bottom of a beaker, and a platinum-sheet anode

gain from this polarization of H′ has been found to be about 1.5 kcal/mole.

Summing up, the total computed energy gain from polarization effects is 0.2 + 1.5 = 1.7 kcal/mole. This value is, however, not very definite. There are several factors, which could modify it in one direction or the other. One factor, which would increase it, is the fact that 0.2 and 1.5 kcal/mole should be considered as lower limits of the effects i) and ii). Another, which would diminish it, is the fact that the effect ii) should cause a slight weakening of the O′—H′ bond. Although the value 1.7 kcal/mole is rather approximate, it is interesting to compare it with the purely electrostatic interaction energy. Using the point charge model, discussed by Bauer and Magat [1], this energy is computed to 5.1 kcal/mole. Thus, it is seen that the polarization energy is not a negligible part of the total H bond energy.

For comparison with H_2O we have also studied the association of H_2S, which has an electronic structure similar to that of H_2O. H_2S solidifies at −82.9°C, but it does not seem to have a definite crystalline form. We have studied the interaction of two H_2S molecules, $S'-H'....S\begin{matrix}H\\H\end{matrix}$, assuming the atoms S′H′S to be on a straight line. In the case of H_2S we have only computed the above-mentioned polarization effect ii). We have found a small energy gain, about 0.05 kcal/mole. Since the effect ii) is giving the main contribution to the polarization energy in the H_2O case, it is reasonable to assume the total polarization energy in the association of H_2S to be of the order of magnitude of 0.05 kcal/mole. The purely electrostatic interaction energy is in this case computed to be 0.25 kcal/mole, when a point charge model is used.

The numerical results of the present investigation are collected in Table 1.

Table 1. Effects contributing to H bond formation. Energies in kcal/mole.

Molecule	Polarization energy			Electrostatic energy	Exptl. H bond energy
	i)	ii)	total		
H_2O	0.2	1.5	1.7	5.1	5.8
H_2S	—	0.05	~0.05	0.25	—

From Table 1 it is seen that the polarization effects are important for the H bond formation in the H_2O case, whereas they cannot have any influence in the H_2S case.

Some Advantages of Using a Mercury Cathode in the Kolbe Electro-synthesis

NGUYEN DINH-NGUYEN

Department of Medical Biochemistry, University of Gothenburg, Sweden

When the anodic reaction $2\ -\overset{|}{\underset{|}{C}}-COO^- \xrightarrow{-2e} -\overset{|}{\underset{|}{C}}-\overset{|}{\underset{|}{C}}- + 2\ CO_2$, named after Hermann Kolbe [1], is used for the preparation of alkali-sensitive substances such as esters, present practice usually avoids hydrolysis by electrolysing free carboxylic acids in the presence of only a few per cent of their sodium salts, the reaction being stopped when the electrolyte turns neutral. The solvent is generally methanol and the electrodes smooth platinum sheets.

In an attempt to prepare dimethyl adipate from methyl hydrogen succinate using this technique, a yield of only 38 % was obtained, in contrast to the 70 % reported by Bouveault [2]. He electrolysed equivalent amounts of succinic anhydride and sodium in methanol, using a water-cooled platinum-tube anode and a mercury cathode. New runs were therefore made with mercury as cathode at the bottom of a beaker, and a platinum-sheet anode

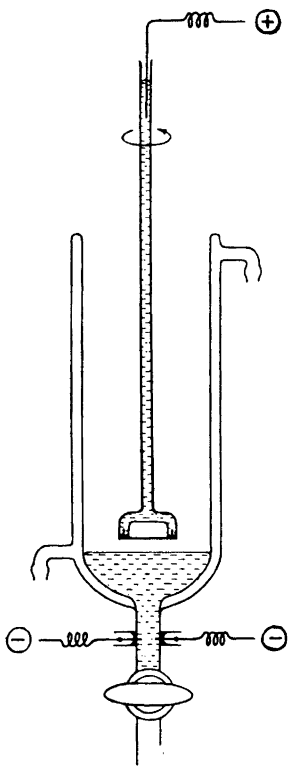

Fig. 1. Apparatus for Kolbe electro-synthesis with mercury as cathode.

was mounted horizontally 1 cm above the surface of the mercury. 50 to 100 % of the half-ester in methanol was neutralized with sodium, and the beaker was cooled in running water as before. In this way the yield of dimethyl adipate rose to 55 %, and finally reached 68 % when the anode was rotated at a speed high enough to bring about efficient stirring.

Apart from the improved yield in this particular case, the use of a mercury cathode has several other advantages. The mercury amalgamates the excess of discharged sodium ions, and the electrolyte does not turn alkaline as long as the voltage is applied. As much sodium as is practical may therefore be added, with the advantage of increased current density and consequently reduced reaction time. The current drops during the electrolysis, and the necessity of watching the pH is eliminated, as the ammeter indicates when the reaction should be interrupted. The electrolysis may probably be run for any length of time without harm, however, and is thus easily fitted into other work going on.

To facilitate separation of the electrolyte from the mercury without first stopping the electrolysis, the simple apparatus shown in Fig. 1 was devised. It is a beaker with double walls for water cooling, and with an outlet at the bottom. The outlet stem has a stopcock, and between this and the bottom of the beaker are two platinum threads melted through the stem wall, to connect the mercury with the negative pole. The platinum-sheet anode has short platinum threads melted into the stirrer tube, which is filled with mercury connected with the positive pole through the open upper end of the tube.

This work was made possible by grants from *Statens naturvetenskapliga forskningsråd* to S. Ställberg-Stenhagen. The hospitality of *Hässle-Tika AB* is gratefully acknowledged.

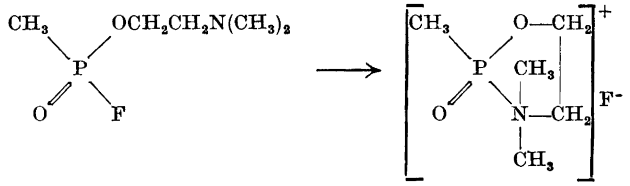
Infra-red Spectroscopic Evidence on the Structure of Isomerized Dimethylaminoethoxy-methyl-phosphoryl Fluoride

LENNART LARSSON

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

It was found by Tammelin [1] that, when dimethylaminoethoxy-methyl-phosphoryl fluoride is stored at room temperature, the liquid is transformed in a few days into a solid compound with the same per cent composition as the initial liquid. In contrast to the liquid isomer, the solid one is not easily hydrolyzed in alkaline solutions but is in acid solutions and apparently yields the same products of hydrolysis as the liquid compound. Moreover, the solid isomer gives no Schönemann reaction whereas the liquid one does. On the basis of these results Tammelin has postulated the following rearrangement for dimethylaminoethoxy-methyl-phosphoryl fluoride (I).

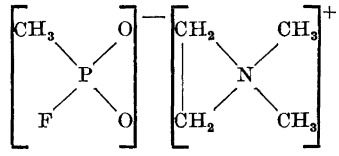


I

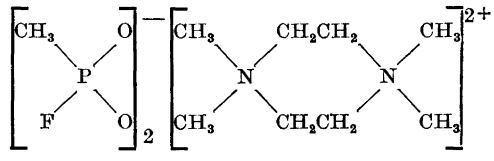
When *iso*propoxy-methyl-phosphoryl fluoride (Sarin) was mixed with triethylamine in mole ratio 1:1, no reaction seemed to occur. This observation is not consistent with the rearrangement proposed above.

Another conceivable rearrangement analogous to that described by Fukuto and Stafford [2] for the isomerization of diethoxy-diethylaminoethoxy-thionophosphate to the thiolo-isomer is that the liquid is transformed to an ethylene-immonium salt (II) or to the more stable piperazinium salt (III).

It was thus of interest to make an infra-red spectroscopic study of the rearranged product to elucidate its structure. As appears from Fig. 1, the infra-red spectrum of the solid isomer (1) shows mainly the same pattern as that of the quaternized derivative of the liquid compound, methyl-fluoro-phosphorylcholine iodide (2), with two fundamental exceptions: in the spectra of the solid isomer the strong absorption band at 11.79 μ (848 cm^{-1}), assigned to the vibration of the P—F bond [3], is absent and at 13.52 μ (740 cm^{-1}) a band appears which can probably be attributed to the vibration of a P—N bond [3]. The spectrum of the solid isomer adheres closely also to that of ethoxy-methyl-phosphorylcholine iodide (3) with the exception of the absorption band at 13.52 μ mentioned above. The absorption bands at about 3 μ and 6 μ in all the



II



III

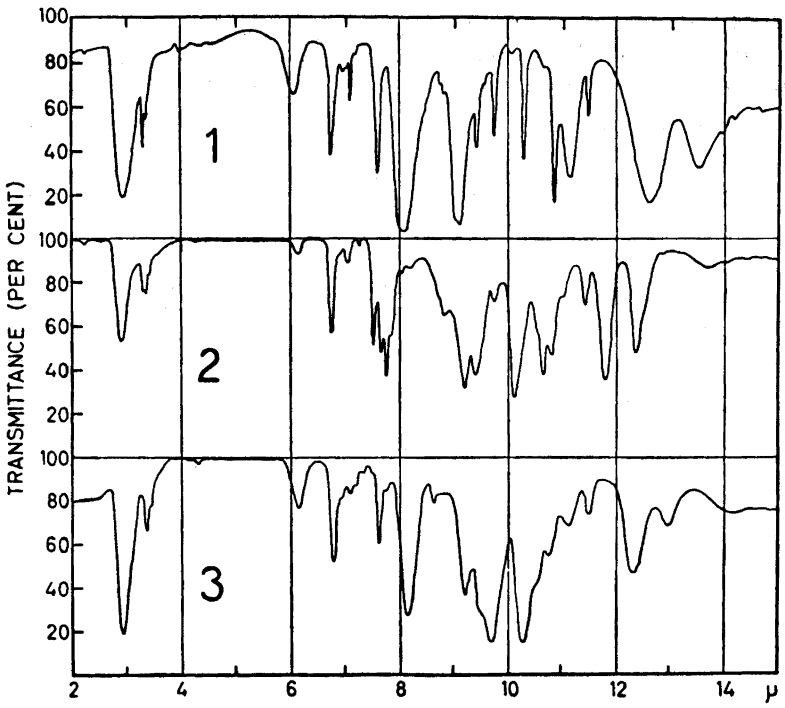


Fig. 1. The infra-red spectra of the solid isomer of dimethyl-aminoethoxy-methyl-phosphoryl fluoride (1) and the iodides of methyl-fluoro-phosphorylcholine (2) and of ethoxy-methyl-phosphorylcholine (3).

spectra are probably caused by moisture, picked up during the preparation of the potassium bromide disks. The remaining absorption bands agree well with those usually obtained in the infra-red spectra of organic phosphorus compounds. The results obtained from the infra-red measurements are thus entirely in accordance with the structure that Tammelin has suggested for the solid isomer of dimethyl-aminoethoxy-methyl-phosphoryl fluoride, and they exclude structures like II and III.

It has been shown that thiosulphate ion reacts with ethylene-immonium ion [5]. From a study, performed in the same manner as described by Fukuto and Stafford [2], it has been found that the solid isomer does not react with thiosulphate ion indicating that there is no immonium ion present in the solid isomer. This result is a further argument against structure II.

Experimental. The compounds studied were synthesized by Tammelin [1,4] at this institute. The infra-red spectra were recorded by means of a Perkin-Elmer spectrometer, Model 21, equipped with a rock salt prism, and the following settings were used: Resolution 927; response 2:1170; gain 6; suppression 3; speed about 1 μ/min; scale 5 cm/μ. The potassium bromide disk technique was employed, and 1 mg of sample was mechanically ground together with 300 mg of potassium bromide.

My sincere thanks are due to Professor G. Ljunggren, Director of this Institute, for the kind interest he has shown in this work.

The Effect of Nitrous Oxide on Biological Nitrogen Fixation and the Uptake of Combined Nitrogen

SINIKKA LUNDBOM

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

Some years ago it was found in this laboratory [1] in long time growth experiments with *Azotobacter vinelandii* that N_2O inhibits not only the fixation of molecular nitrogen but also the utilization of nitrate nitrogen. The utilization of ammonium nitrogen was not inhibited. Later Mozen *et al.*[2] observed in short time experiments with the same strain of *A. vinelandii*, using nitrate labelled with ^{15}N, that the utilization of nitrate nitrogen was not inhibited by N_2O. In the last mentioned experiments the cells were harvested 3—24 h after inoculation. The reason for this difference between long time and short time experiments is unexplained. I have controlled the previous results from long time growth experiments with *A. vinelandii* harvesting the cells 48 and 144 h after inoculation. The results of the experiments are presented in this paper. The experiments were performed with the same strain

of *A. vinelandii* as earlier. Similar experiments were also performed with *Clostridium pasteurianum.*

Azotobacter was incubated at 30°C in Burk's medium containing 10 p.p.m. Mo, and *Clostridium* was incubated at 37°C in synthetic nutrient solution containing the essential vitamins [3].

The inocula for *Azotobacter* were grown for 24 h, aerating the culture very heavily. The inocula for nitrate culture were adapted thrice in the basal nutrient solution containing 500 p.p.m. nitrate nitrogen as KNO_3.

The inocula for *Clostridium* were grown for 36 h and the culture was enriched with nitrogen, bubbling a nitrogen-stream continually through the culture. The nitrate inocula were adapted in a similar way as by *Azotobacter.*

The experiments were carried out in six vacuum desiccators each of 8 l. Each desiccator contained 4 bottles of 100 ml each containing 25 ml nutrient solution. Gas-mixtures: *Azotobacter:* 0.2 atm. N_2 and 0.2 atm. O_2, 0.2 atm. N_2, 0.2 atm. O_2 and 0.6 atm. N_2O, and 0.2 atm. O_2 and 0.8 atm. N_2O. *Clostridium:* 1.0 atm. N_2, 0.4 atm. N_2 and 0.6 atm. N_2O, and 1.0 atm. N_2O.

In order to get the gas-mixtures into the desiccators the treatment of *Azotobacter* desiccators was: vacuum, flushing with air, filling with the required gas-mixture; and of *Clostridium* desiccators: vacuum, flushing with nitrogen twice, filling with required gas-mixtures.

48 and 144 h after inoculation two bottles from each desiccator were taken for analyses. The samples were immediately put on ice, centrifuged and the supernatant was used for nitrate analysis (bottles with nitrate). The

cells were washed once with distilled water and a Kjeldahl-analysis was made from the washed cells. The increase of nitrogen in the cell mass and the decrease of nitrate in the solution correspond well with each other in the *Azotobacter* experiments, wherefore analytical errors have not influenced the results essentially. In *Clostridium* experiments the increase of nitrogen in the cells is somewhat larger than the decrease of nitrate in the solution, and hence a slight N_2 fixation might have occurred even when nitrate formed the source of nitrogen.

Tables 1 and 2 and Fig. 1 present nitrogen fixation and the utilization of nitrate nitrogen by *Azotobacter*. During 48 h practically no N_2 fixation could be found in *Azotobacter* cultures with 0.6 atm. N_2O. After 144 h some N_2 fixation was, strangely enough, found under these conditions (Fig. 1, curves 1, and 2). The inhibition of the utilization of nitrate nitrogen is clear already 48 h after inoculation and especially after 144 h at both N_2O concentrations (Fig. 1, curves 4, 5, and 6).

The results with *Clostridium* are presented in Tables 3 and 4, and in Fig. 2. In *Clostridium* cultures 1.0 atm. N_2O totally prevented nitrate utilization after 48 h. 48 h after inoculation the utilization of NO_3-N was about 1 mg/55 ml nutrient solution (Tables 3 and 4). The inhibiting effect of nitrous oxide on the utilization of nitrate in long time growth experiments is difficult to explain. Since it is not met with in short time experiments, as is the case with molecular nitrogen fixation, in long time growth experiments we probably have to do with some secondary influence which is not known more closely.

The experimental part of the work was performed in the autumn of 1954.

On the Rearrangement Products of Humulone

L.-O. SPETSIG

Forskningslaboratoriet LKB, Äppelviken, Sweden

The main bitter substances of beer are the *iso*humulones formed by rearrangement of the humulone, cohumulone and adhumulone of hops during the wort boiling. They have been isolated from trimethylpentane extracts of beer by countercurrent distribution [1]. According to Windisch *et al*, however, two products were formed from humulone when rearranged in a buffer solution, as the preformed *iso*humulone (Harzkörper A) was in part degraded to a second compound of similar properties (Harzkörper B)[2]. The latter compound and its analogues have not been observed in beer. When treated with boiling alkaline ethanol humulone is stated to give *iso*humulone only[3].

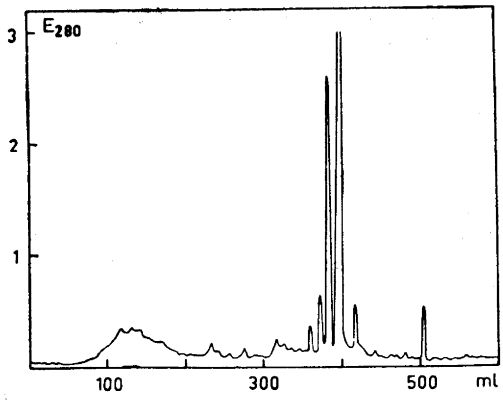

Fig. 1. Distribution diagram for rearrangement products of humulone in an acetate buffer of pH 5.1. The last peak is unreacted humulone.

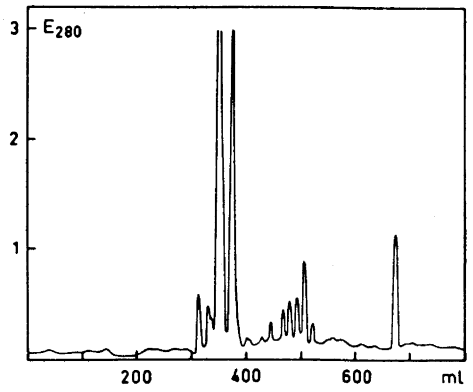

Fig. 2. Chromatographic pattern of the rearrangement products of humulone from alkaline ethanol.

We have now tried to study humulone rearrangement products of different origins by reversed-phase partition chromatography. The separations were performed on 800 × 8 mm columns of hydrophobic Hyflo Super Cel with chloroform as the stationary solvent. Gradient elution was accomplished with a buffer solution containing 25% methanol, the pH-value of which was steadily increased. The optical density of the elute was measured continuously by a spectrophotometer connected to a recorder [4].

When humulone was rearranged at 100°C in a number of buffer solutions of medium pH-value two principal components were always found, which were eluted at pH 5.8—6.0 (Fig. 1). Their ultraviolet absorption spectra were similar to that of the *iso*humulones of beer and to that of humulinic acid. It has been shown earlier [4] that the chromatographic pattern of the bitter substances of beer was predominated by a five (or six) peaks appearing at pH 5.6—6.2. It seemed probable that the group consisted of six components, two from each of the three humulones.

These results have led us to assume that the two same principal compounds are formed from humulone in beer and in buffer solutions of medium pH-value. A detailed study of the humulone rearrangements in buffer solutions thus is to be desired.

These results have led us to assume that the two same principal compounds are formed from humulone in beer and in buffer solutions of medium pH-value. A detailed study of the humulone rearrangements in buffer solutions thus is to be desired.

An attempt was also made to prepare *iso*humulone by treating humulone with boiling alcoholic alkali [3]. However, a rather complex reaction mixture resulted, as was also found by Carson [5] and by Howard [6] (Fig. 2). Moreover, none of the main compounds could be identical with the *iso*humulone of beer, though they had ressembling ultraviolet absorption curves, as they were eluted already at pH 4.5 and 4.7, respectively. Some minor components only appeared at pH ~ 6 where the *iso*-humulones of beer are normally found. The last peak in the chromatogram was formed by unreacted humulone.

A Stirrer for Flasks Totally Enclosed

OLOV E. ÖHRN

Institute of Physical Chemistry, University of Uppsala, Uppsala, Sweden

In connection with some fractionation work[1] a stirrer for flasks totally enclosed has been constructed. The design is based on the principle that if one end of a rod, the middle of which is connected to a ball joint, is driven in a circle the other end will also describe a circle, whereas the middle remains fixed. The middle can of course be connected to a flexible membrane instead of a ball joint. In this way it is possible to get a perfect seal. The stirrer is shown in Fig. 1.

It is designed to be used in flasks with joints of Standard Taper 29. The stopper, made of teflon, has been machined so that we have a relatively thin-walled cylinder, closed in the center with a plate only 0.5 mm thick, through the middle of which runs a tube that fits tightly around the stirring rod. To obtain a better seal the teflon tube may be pressed against the rod with a thick rubber bushing and in this way we also avoid a slow rotation of the stirrer in the direction opposite to that of the motor. The connection of the motor to the rod, *via* a bearing eccentric to the motor axle, will be clear from the figure. A length of 30 cm for the rod with a maximum amplitude of 2 cm is adequate.

The simple shape of the rod has proved most satisfactory for fractionate work since very little precipitate becomes attached to the stirrer.

Received April 3, 1958.

An attempt was also made to prepare *iso*humulone by treating humulone with boiling alcoholic alkali [3]. However, a rather complex reaction mixture resulted, as was also found by Carson [5] and by Howard [6] (Fig. 2). Moreover, none of the main compounds could be identical with the *iso*humulone of beer, though they had ressembling ultraviolet absorption curves, as they were eluted already at pH 4.5 and 4.7, respectively. Some minor components only appeared at pH ~ 6 where the *iso*-humulones of beer are normally found. The last peak in the chromatogram was formed by unreacted humulone.

A Stirrer for Flasks Totally Enclosed

OLOV E. ÖHRN

Institute of Physical Chemistry, University of Uppsala, Uppsala, Sweden

In connection with some fractionation work[1] a stirrer for flasks totally enclosed has been constructed. The design is based on the principle that if one end of a rod, the middle of which is connected to a ball joint, is driven in a circle the other end will also describe a circle, whereas the middle remains fixed. The middle can of course be connected to a flexible membrane instead of a ball joint. In this way it is possible to get a perfect seal. The stirrer is shown in Fig. 1.

It is designed to be used in flasks with joints of Standard Taper 29. The stopper, made of teflon, has been machined so that we have a relatively thin-walled cylinder, closed in the center with a plate only 0.5 mm thick, through the middle of which runs a tube that fits tightly around the stirring rod. To obtain a better seal the teflon tube may be pressed against the rod with a thick rubber bushing and in this way we also avoid a slow rotation of the stirrer in the direction opposite to that of the motor. The connection of the motor to the rod, *via* a bearing eccentric to the motor axle, will be clear from the figure. A length of 30 cm for the rod with a maximum amplitude of 2 cm is adequate.

The simple shape of the rod has proved most satisfactory for fractionate work since very little precipitate becomes attached to the stirrer.

Mean Amplitudes of Vibration in Certain Four-Atomic Molecules

J. BAKKEN

Institutt for teoretisk kjemi, Norges tekniske høgskole, Trondheim, Norway

Mean amplitudes of vibration (u) for the interatomic distances in certain four-atomic molecules have been calculated from spectroscopic data (Table 1). When the instantaneous interatomic distance is denoted by R and R_e is the equilibrium distance, then u is defined by

$$u = [\overline{(R - R_e)^2}]^{\frac{1}{2}}$$

The average is taken over the molecules in the gaseous state by thermodynamic equilibrium at a given temperature T. The calculations are based on the assumption of small harmonic vibrations, the method being described by Morino *et al.*[1]

Informations concerning u-values from spectroscopic data are of great interest for electron diffraction investigations. As to studies of mean amplitudes both from electron diffraction data and spectroscopic calculations, references are made to Karle and Karle [2], Kimura *et al.*[3] and Bastiansen *et al.*[4-6]. Electron diffraction investigations of the molecules studied in this work would contribute appreciably to our knowledge of mean amplitudes and are under consideration.

Soluble Diaphorase in Animal Tissues

Lars Ernster and Franco Navazio*

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

The soluble fraction obtained upon centrifugation of rat liver homogenates made in 0.25 M sucrose-3 % polyvinylpyrrolidone at 105 000 *g* for 60 min exhibits a high diaphorase activity as revealed by measuring the rate of reduction of 2,6-dichlorophenolindophenol by reduced di- or triphosphopyridine nucleotide (DPNH of TPNH). As emerges from the typical data shown in Table 1, this activity is, in contrast to those found in mitochondria and microsomes, virtually equally high with DPNH and TPNH, and it exceeds, in terms of total protein content, the diaphorase activities of the particulate fractions more than twice in the case of DPNH and about twenty times in the case of TPNH. The soluble diaphorase resembles the particulate one in that it reacts with methylene blue at about half the rate obtained with 2,6-dichlorophenolindophenol, but differs from the latter in being inactive towards cytochrome c or ferricyanide; treatment of the enzyme with ferric chloride according to Mahler and Elowe [1] did not alter this state of affairs. The following findings indicate that the soluble DPNH- and TPNH-diaphorase reactions are catalyzed by one common enzyme: 1) the two activities are not additive; 2) they are equally sensitive to various inhibitors such as *p*-chloromercuribenzoate, atebrine, or flavin adenine dinucleotide (flavin mononucleotide is not inhibitory); 3) they show no tendency to separate upon ammonium sulphate fractionation of the soluble fraction. Preliminary data indicate that this type of soluble diaphorase is ubiquitous as to its occurrence among animal tissues, although the highest activity hitherto found is that present in rat liver.

Table 1. Cytoplasmic distribution of diaphorase activities in rat liver.

Homogenates of rat liver were made in 0.25 M sucrose solution containing 3 % polyvinylpyrrolidone (pH adjusted to 7). 100 ml homogenate, containing 10 g wet weight liver, was centrifuged *a*) at 1 600 *g* for 10 min, *b*) at 4 100 *g* for 15 min, and *c*) at 105 000 *g* for 60 min. The denotions, mitochondrial, microsomal and soluble fractions, refer to the pellets obtained in *b* and *c*, and the supernatant obtained in *c*, respectively. The mitochondrial pellet was washed, and the microsomal pellet rinsed, twice with 0.25 M sucrose, and both pellets were suspended in 0.25 M sucrose. The test system contained 0.5 ml 0.3 M tris buffer (pH 7.5), 2.3 ml 0.25 M sucrose (containing, in the case of the soluble fraction, 3 % polyvinylpyrrolidone, pH adjusted to 7), 0.1 ml 3 mM DPNH or TPNH, 0.1 ml 1.7 mM 2,6-dichlorophenolindophenol, and 0.1 ml of the fraction to be tested, containing 5 mg wet weight liver equivalent in the case of mitochondria or microsomes, and 0.5 mg in the case of the soluble fraction. The decolorization of the dye was recorded in a Beckman DK2 spectrophotometer at 600 mμ, using glass cuvettes of 1 cm light path. The reaction was started by the addition of the reduced pyridine nucleotides, and followed for 4—6 min at room temperature. The values are expressed in terms of 1 g wet weight liver equivalent.

Fraction	Total protein content, mg	Diaphorase activity (μmoles dye reduced per min) DPNH	TPNH
Mitochondrial	23.3	4.3	1.0
Microsomal	31.1	13.1	1.9
Soluble	29.2	39.0	35.0

On the Relation of Mitochondrial ATPase to Diaphorase Flavin

Hans Löw

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

Recent studies [1,2] of the relationship between oxidative phosphorylation and 2,4-dinitrophenol (DNP) stimulated adenosinetriphosphatase (ATPase) have indicated that the mitochondrial enzyme sequence which can be stimulated by DNP to break down ATP includes one link which is a part of the electron transport chain, *viz.* the diaphorase flavoenzyme. Further support for this conclusion could be obtained by showing that atebrin, a drug known to interfere with flavins probably in a competetive manner [3], stimulates the DNP-activated ATPase by about 40 % in low concentrations, while in higher concentrations it almost completely inhibits this reaction. Typical data are shown in Table 1. Due to a certain structural

Table 1. The effect of atebrin and promazines on DNP-ATPase

Compounds	Concentration, mM	Relative activity %
None	—	100
Atebrin	1.5	149
Atebrin	8.0	11
Promazine	0.1	135
Promazine	0.5	11
Chloropromazine	0.05	142
Chloropromazine	0.2	15
Acetylpromazine	0.2	134
Acetylpromazine	1.0	6

Each incubation tube contained the following: 5 mM ATP, 5 mM tris buffer pH 7.5, 0.1 mM DNP and 0.25 M sucrose. Final volume 2.0 ml. The tubes were incubated at 30° C for 20 min.

relationship between atebrin and promazine derivatives and to the fact that these are known to influence oxidative phosphorylation in isolated mitochondria [4] the effect of a series of promazine compounds was also tested. As is shown in Table 1 these gave an effect similar to that of atebrin.

The significance of these findings will be discussed.

The Potency of the Microsomal Material to Metabolize and Bind Carcinogens during Liver Regeneration

Tore Hultin and Alexandra von der Decken

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

As a result of partial hepatectomy pronounced modifications are induced in the microsomal material of liver cytoplasm [1]. After a lag period of about 12—14 h there is a fairly rapid increase of the RNA/protein ratio. About simultaneously the activity of the microsomes in amino acid incorporating systems shows a rapid increase. The culmination generally occurs about 30 h after the operation.

Concurrently with this activation other components of the microsomal material decrease. The activity of glucose-6-phosphatase, measured per mg microsomal protein, is reduced by approximately 15 %. The concentration of DPNH-cytochrome c reductase is reduced to approximately the same degree. Liver microsomes are capable of demethylating the carcinogenic azo dye methylaminoazobenzene in the presence of TPNH under aerobic conditions [2]. The capacity of the microsomal material for carrying out this oxygen transfer, is reduced during regeneration, usually by about 20 %. Under the same conditions of oxygen transfer, reactive metabolites of the azo dye are produced. When ^{14}C-labeled azo compounds are used in the system, the isotope becomes bound to the microsomal proteins. Microsomes from regenerating liver have a considerably reduced capacity for producing reactive metabolites from ^{14}C-labeled azo dyes. This effect is most easily demonstrated by adding soluble proteins to the microsomal systems metabolizing ^{14}C-labeled carcinogenic azo compounds. Reactive metabolites are secondarily emitted from the microsomes, and became trapped by the soluble proteins. Subsequently the specific activities of the soluble proteins may be determined. Similar experiments have been carried out with 2-aminofluorene-9-^{14}C. In the regenerating livers, finally, the concentration of cytochrome b_5

(determined on deoxycholate extracts by dithionite reduction) is diminished by about 30%.

It is generally considered that the endoplasmic reticulum of the cytoplasm is the main origin of the microsomal material. Since RNA is concentrated to the nucleoprotein granules, which are attached to the delicate membranes of this network, while the enzymes and cytochrome b_5 apparently are associated with the membranes, the experiments suggest a richer attachment of nucleoprotein granules to the membranes during liver regeneration. Apparently, however, the composition of the membranes may become modified at the same time.

On Submitochondrial Particles with High DPNH-oxidase * and Low Succinic Oxidase Activity

Herrick Baltscheffsky**

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

A new method for obtaining submitochondrial particles capable of respiration and oxidative phosphorylation has been briefly reported [1]. After grinding liver mitochondria from rat or guinea pig with Al_2O_3 and centrifuging the ground material at 25 000 × *g* for 10 min, in order to get down the alumina and heavier mitochondrial structural fragments the particles are in the supernatant. After centrifugation for 1 h at 100 000 × *g* practically all the DPNH-oxidase activity of this supernatant is in the sediment, which is then suspended in a suitable medium.

Two slightly different methods of preparation (I and II) have been used. In I the medium for the last centrifugation before grinding and for the subsequent operations is 30 mM phosphate buffer of pH 7.0, in II 0.25 M sucrose. Significant differences between the preparations so obtained are: II gives a several fold higher final yield and the stimulation of its DPNH-oxidase by added cytochrome c is lower (usually less than 50 %, compared to more than 200 % for I). In II the supernatant after the 25 000 × *g* centrifugation consists of two separate layers, the bottom one being small in volume and red-colored.

2 mM amytal inhibits practically all the DPNH-oxidase activity in the absence of added cytochrome c, which eliminates the possibility that a significant part of this respiration is due to microsomal contamination.

The submitochondrial particles have a high DPNH-oxidase activity compared to their succinic oxidase activity [1]. Also, the DPNH-cytochrome c reductase activity is much higher than the succinate-cytochrome c reductase activity. The ratio for five different preparations varied between 7.7 and 17, mean value 10 (I gave somewhat higher ratios than II). In the heavier structural fragments the ratio is much lower. The almost complete separation obtained, of the system responsible for the oxidation of DPNH from that responsible for the oxidation of succinate is thus possibly due to a tighter binding of the latter to these fragments.

The rate of oxidation of DPNH is stimulated by $Na_4P_2O_7$, EDTA and ATP, active where ADP and AMP are not. ITP also stimulates this respiration, but only in higher concentration and to a lesser degree than ATP. These stimulations are inhibited by amytal.

The TPNH-oxidase and the TPNH-cytochrome c reductase activities of the particles are low compared to the corresponding DPNH-activities, but are several fold increased by addition of DPN.

The particles have ATP-ase activity. It is increased up to 100-fold by added Mg^{++} whereas 2,4-dinitrophenol only has a slight (about 2-fold) stimulating effect.

Activity of Amino Acid Activating Enzyme Systems during Liver Regeneration

Alexandra von der Decken and Tore Hultin

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

In order to attain an incorporation of labeled amino acids into proteins by cell-free liver preparations, microsomal material and certain

soluble cytoplasmic components have to be included in the system [1]. It has been shown previously that microsomes, isolated from regenerating rat liver, work more effectively in incorporation systems of this kind than normal microsomes [2,3]. The present report is concerned with the effects of regenerative growth induction on the soluble components of the incorporation system. As is well known, these components are required for the initial activation of the labeled amino acids at the expense of high-energy phosphates [4]. The complete soluble system used in these experiments contained the following essential components: (1) a mechanism for ATP-generation (in the present experiments composed of phosphoenolpyruvate, pyruvate kinase and adenylate kinase), (2) guanosine triphosphate [5], (3) amino acid activating enzymes, associated in an hitherto unknown way with soluble RNA.

With standard amounts of liver microsomes as acceptor for activated amino acids, cell fluid from regenerating livers effected, per mg protein, a more rapid incorporation of ^{14}C-L-leucine into protein than cell fluid from normal liver. The increase was preceded by a lag period of 12—14 h and culminated about 30 h after hepatectomy. As a rule, the activity then was 60—80 % higher in the case of regenerating livers.

In order to elucidate which of the components of the activation chain were affected by the regeneration, some of these components were studied separately. The higher efficiency of the cell fluid from regenerating liver was not due to increased contents of phosphoenolpyruvate, ATP or guanosine triphosphate, since these compounds were added separately to the incorporation system in adequate amounts. The concentrations of pyruvate kinase and adenylate kinase were not significantly higher in the preparations from regenerating liver. In several experiments, moreover, these enzymes (prepared from rabbit muscle) were added in excess to the incubation samples without influencing the regeneration effects. The amounts of amino acid activating enzymes were determined in dialyzed cell fluid from normal and regenerating livers by measuring the rate of ^{32}P-exchange between ^{32}P-pyrophosphate and ATP in the presence of L-leucine or an amino acid mixture. An increase of nearly 40 % was observed in the regenerating livers. The RNA-content showed a slight increase at the same time.

It is concluded, therefore, that the higher efficiency of the amino acid activating system, observed in regenerating liver, was primarily due to a higher activity of the amino acid activating enzymes proper.

The Initial Reactions Involved in Respiratory Chain Phosphorylations

O. Lindberg, B. Grabe, H. Löw, P. Siekevitz* and L. Ernster

Wenner-Gren Institute and Institute of Theoretical Physics, University of Stockholm, Stockholm, Sweden

Recent studies have indicated that the mitochondrial PO_4-ATP ** exchange and DNP-activated ATPase reactions involve a reversible electron transport through the diaphorase-FAD of the respiratory chain [1,2]. On the basis of these conclusions and of certain quantum-chemical considerations [3,4] pointing to a possible participation of phosphorylated quinoid structures as intermediates in respiratory chain phosphorylations the following reaction sequence appears to be a satisfactory formulation of the mechanism of the first of the three phosphorylations occurring along the mitochondrial oxidation of DPNH by oxygen:

1) DPNH is oxidized by the diaphorase-FAD with the simultaneous cleavage of one of the P—O bonds of a molecule of inorganic phosphate and the attachment of the phosphoryl radical to the 2-keto group of the *iso*-alloxazine ring:

---

* On leave of absence from The Rockefeller Institute for Medical Research and the recipient of a travel grant from the National Research Council, U.S.A.

** Abbreviations: PO_4, inorganic phosphate; ATP, adenosine triphosphate; ADP, adenosine diphosphate; DPNH, reduced diphosphopyridine nucleotide; FAD, flavin adenine dinucleotide; DNP, 2,4-dinitrophenol.

(determined on deoxycholate extracts by dithionite reduction) is diminished by about 30%.

It is generally considered that the endoplasmic reticulum of the cytoplasm is the main origin of the microsomal material. Since RNA is concentrated to the nucleoprotein granules, which are attached to the delicate membranes of this network, while the enzymes and cytochrome b_5 apparently are associated with the membranes, the experiments suggest a richer attachment of nucleoprotein granules to the membranes during liver regeneration. Apparently, however, the composition of the membranes may become modified at the same time.

On Submitochondrial Particles with High DPNH-oxidase * and Low Succinic Oxidase Activity

Herrick Baltscheffsky**

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

A new method for obtaining submitochondrial particles capable of respiration and oxidative phosphorylation has been briefly reported [1]. After grinding liver mitochondria from rat or guinea pig with Al_2O_3 and centrifuging the ground material at 25 000 × *g* for 10 min, in order to get down the alumina and heavier mitochondrial structural fragments the particles are in the supernatant. After centrifugation for 1 h at 100 000 × *g* practically all the DPNH-oxidase activity of this supernatant is in the sediment, which is then suspended in a suitable medium.

Two slightly different methods of preparation (I and II) have been used. In I the medium for the last centrifugation before grinding and for the subsequent operations is 30 mM phosphate buffer of pH 7.0, in II 0.25 M sucrose. Significant differences between the preparations so obtained are: II gives a several fold higher final yield and the stimulation of its DPNH-oxidase by added cytochrome c is lower (usually less than 50 %, compared to more than 200 % for I). In II the supernatant after the 25 000 × *g* centrifugation consists of two separate layers, the bottom one being small in volume and red-colored.

2 mM amytal inhibits practically all the DPNH-oxidase activity in the absence of added cytochrome c, which eliminates the possibility that a significant part of this respiration is due to microsomal contamination.

The submitochondrial particles have a high DPNH-oxidase activity compared to their succinic oxidase activity [1]. Also, the DPNH-cytochrome c reductase activity is much higher than the succinate-cytochrome c reductase activity. The ratio for five different preparations varied between 7.7 and 17, mean value 10 (I gave somewhat higher ratios than II). In the heavier structural fragments the ratio is much lower. The almost complete separation obtained, of the system responsible for the oxidation of DPNH from that responsible for the oxidation of succinate is thus possibly due to a tighter binding of the latter to these fragments.

The rate of oxidation of DPNH is stimulated by $Na_4P_2O_7$, EDTA and ATP, active where ADP and AMP are not. ITP also stimulates this respiration, but only in higher concentration and to a lesser degree than ATP. These stimulations are inhibited by amytal.

The TPNH-oxidase and the TPNH-cytochrome c reductase activities of the particles are low compared to the corresponding DPNH-activities, but are several fold increased by addition of DPN.

The particles have ATP-ase activity. It is increased up to 100-fold by added Mg^{++} whereas 2,4-dinitrophenol only has a slight (about 2-fold) stimulating effect.

Activity of Amino Acid Activating Enzyme Systems during Liver Regeneration

Alexandra von der Decken and Tore Hultin

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

In order to attain an incorporation of labeled amino acids into proteins by cell-free liver preparations, microsomal material and certain

soluble cytoplasmic components have to be included in the system [1]. It has been shown previously that microsomes, isolated from regenerating rat liver, work more effectively in incorporation systems of this kind than normal microsomes [2,3]. The present report is concerned with the effects of regenerative growth induction on the soluble components of the incorporation system. As is well known, these components are required for the initial activation of the labeled amino acids at the expense of high-energy phosphates [4]. The complete soluble system used in these experiments contained the following essential components: (1) a mechanism for ATP-generation (in the present experiments composed of phosphoenolpyruvate, pyruvate kinase and adenylate kinase), (2) guanosine triphosphate [5], (3) amino acid activating enzymes, associated in an hitherto unknown way with soluble RNA.

With standard amounts of liver microsomes as acceptor for activated amino acids, cell fluid from regenerating livers effected, per mg protein, a more rapid incorporation of ^{14}C-L-leucine into protein than cell fluid from normal liver. The increase was preceded by a lag period of 12—14 h and culminated about 30 h after hepatectomy. As a rule, the activity then was 60—80 % higher in the case of regenerating livers.

In order to elucidate which of the components of the activation chain were affected by the regeneration, some of these components were studied separately. The higher efficiency of the cell fluid from regenerating liver was not due to increased contents of phosphoenolpyruvate, ATP or guanosine triphosphate, since these compounds were added separately to the incorporation system in adequate amounts. The concentrations of pyruvate kinase and adenylate kinase were not significantly higher in the preparations from regenerating liver. In several experiments, moreover, these enzymes (prepared from rabbit muscle) were added in excess to the incubation samples without influencing the regeneration effects. The amounts of amino acid activating enzymes were determined in dialyzed cell fluid from normal and regenerating livers by measuring the rate of ^{32}P-exchange between ^{32}P-pyrophosphate and ATP in the presence of L-leucine or an amino acid mixture. An increase of nearly 40 % was observed in the regenerating livers. The RNA-content showed a slight increase at the same time.

It is concluded, therefore, that the higher efficiency of the amino acid activating system, observed in regenerating liver, was primarily due to a higher activity of the amino acid activating enzymes proper.

The Initial Reactions Involved in Respiratory Chain Phosphorylations

O. Lindberg, B. Grabe, H. Löw, P. Siekevitz* and L. Ernster

Wenner-Gren Institute and Institute of Theoretical Physics, University of Stockholm, Stockholm, Sweden

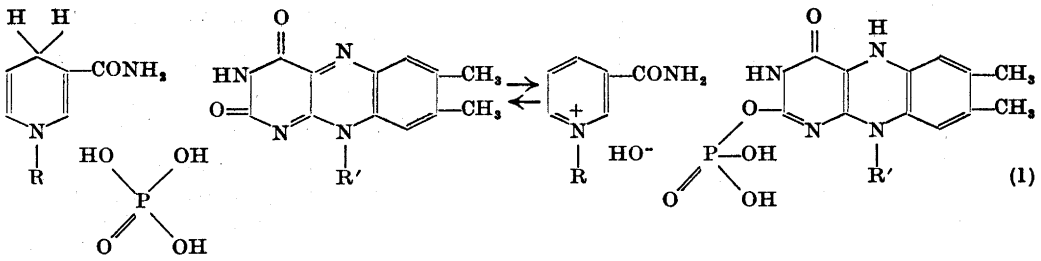
Recent studies have indicated that the mitochondrial PO_4-ATP ** exchange and DNP-activated ATPase reactions involve a reversible electron transport through the diaphorase-FAD of the respiratory chain [1,2]. On the basis of these conclusions and of certain quantum-chemical considerations [3,4] pointing to a possible participation of phosphorylated quinoid structures as intermediates in respiratory chain phosphorylations the following reaction sequence appears to be a satisfactory formulation of the mechanism of the first of the three phosphorylations occurring along the mitochondrial oxidation of DPNH by oxygen:

1) DPNH is oxidized by the diaphorase-FAD with the simultaneous cleavage of one of the P—O bonds of a molecule of inorganic phosphate and the attachment of the phosphoryl radical to the 2-keto group of the *iso*-alloxazine ring:

---

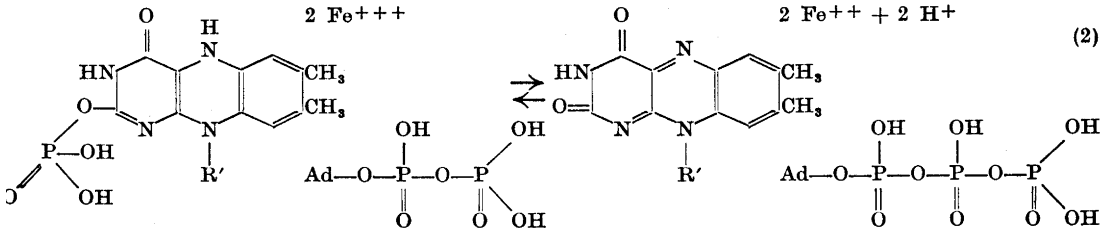
* On leave of absence from The Rockefeller Institute for Medical Research and the recipient of a travel grant from the National Research Council, U.S.A.

** Abbreviations: PO_4, inorganic phosphate; ATP, adenosine triphosphate; ADP, adenosine diphosphate; DPNH, reduced diphosphopyridine nucleotide; FAD, flavin adenine dinucleotide; DNP, 2,4-dinitrophenol.



(1)

2) The reduced phosphoryl-FAD is reoxidized by the subsequent carrier along the respiratory chain, with the simultaneous transfer of the phosphoryl group to ADP:



(2)

Reaction (1) is dependent on the spatial arrangement of the reactants. It requires that the pyridine ring of DPNH and the *iso*alloxazine ring of FAD be oriented in two parallel planes close enough to be bridged over by a phosphate ion, the latter being an obligatory component of the reaction; one of the OH-groups of the phosphate may be attracted by the amide group of DPNH.

Reaction (1) is thought to be sensitive to amytal *, which blocks both electron trans fer and the concomitant attachment of phosphate, and to DNP, which interferes with the attachment of phosphate in the left-to-right reaction, thus rendering the electron transfer uncoupled from, and independent of, the activation of inorganic phosphate.

By assuming that Reaction (1) is more rapid than Reaction (2) in the intact mitochondria the proposed mechanism can be visualized to account for the known [5] discrepancy between the rates of H_2O—$P^{18}O_4$ and $^{32}PO_4$—ATP exchange during oxidative phosphorylation.

The possibility to generalize the present type of mechanism to be valid also for the two other instances of respiratory chain phosphorylation will be discussed.

Toxic Liver Injury: Some Biochemical Changes in the Liver caused by Dimethylnitrosamine

P. N. Magee **

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

Dimethylnitrosamine (N-nitrosodimethylamine) is used industrially as a solvent and as an intermediate in synthetic processes. It has been shown to cause acute haemorrhagic centrilobular necrosis of the liver in the rat and other laboratory animals when administered in doses of the order of 25 mg pr kg body weight [1]. The acute liver lesions may be accompanied by bleeding into the gut and haemorrhagic peritoneal effusion, but there is little evidence of damage to other tissues and organs.

Toxic Liver Injury: Some Biochemical Changes in the Liver caused by Dimethylnitrosamine

P. N. Magee **

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

Dimethylnitrosamine (N-nitrosodimethylamine) is used industrially as a solvent and as an intermediate in synthetic processes. It has been shown to cause acute haemorrhagic centrilobular necrosis of the liver in the rat and other laboratory animals when administered in doses of the order of 25 mg pr kg body weight [1]. The acute liver lesions may be accompanied by bleeding into the gut and haemorrhagic peritoneal effusion, but there is little evidence of damage to other tissues and organs.

** On leave of absence from Medical Research Council Toxicology Research Unit, Carshalton, England.

When dimethylnitrosamine was added to the normal diet of rats at a level of 50 parts per million a high incidence of malignant tumours of the liver was found between the 26th and 40th weeks [2]. Dimethylnitrosamine is a useful agent for the experimental study of toxic liver injury because its acute effects are regular and reproducible and also it can be readily estimated in tissues and body fluids by the polarographic method of Heath and Jarvis [3]. The compound is rapidly metabolised *in vivo*, mainly, and perhaps exclusively by the liver [4,5]. It is distributed almost uniformly in the different tissues and organs with no preferential accumulation in the liver, and there is evidence that it becomes uniformly distributed in the body water soon after administration [5]. Metabolism occurs *in vitro* by liver slices and broken-cell preparations, but not to a significant extent with other tissues with the possible exception of kidney. There is a strong requirement for oxygen and complete inhibition by anaerobiosis. Metabolic activity of broken-cell preparations can be removed by dialysis and partially restored by the addition of TPN and to a less extent DPN. All the activity occurs in the microsome+cell sap fraction of the liver with negligible metabolism by the nuclear+mitochondrial fraction [6].

Incorporation of labelled amino acids into rat liver protein *in vivo* is markedly reduced 3 h after the animal has received a necrotising dose of dimethylnitrosamine but incorporation into kidney and spleen protein is not altered significantly nor is the labelling of the free amino acids in the liver. Incorporation of ^{32}P into acid-soluble, lipid and residual phosphorus fractions of the liver is not significantly changed 6 h after the same dose of dimethylnitrosamine, but incorporation into a partially purified RNA fraction is reduced at this time [7].

Some histochemical and biochemical changes found in the liver during the development of the necrosis will be described, also some recent work on the metabolism of ^{14}C-dimethylnitrosamine and on the effect of the compound on rat liver slices *in vitro*.

Structural Factors Involved in the Diaphorase and Cytochrome c-Reductase Activities of Mitochondria and Microsomes

Lars Ernster

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

As indicated by previous studies [1,2], the low activity at which TPNH * is oxidized by way of the cytochrome system may constitute a limiting factor for the function of TPN-dependent oxidations in liver tissue. The great discrepancy in activity, known to prevail between the liver TPNH- and DPNH-cytochrome c reductase systems [3], and recent evidence reported in the literature [4,5] that the former may be selectively regulated by metabolic control mechanisms, prompted a comparative study of the two systems with respect to their catalytic components. Interest was in the first place focused on the diaphorase components, since these are believed to constitute the first catalytic links of the cytochrome c-reductase systems with the reduced pyridine nucleotides.

While the TPNH- and DPNH-cytochrome c reductases are located exclusively in the particulate elements of the cytoplasm [3,6,7], recent studies [8] revealed the occurrence of a considerable diaphorase activity in the soluble cytoplasm. This activity was found to be equally high with DPNH and TPNH, in contrast to those present in mitochondria and microsomes, which are 3—7 times higher with DPNH than with TPNH. Since there are indications that the TPNH- and DPNH-diaphorase activities of the soluble cytoplasm are catalyzed by one common enzyme [8] it appeared to be of interest to investigate whether the same could be valid for the particulate DPNH- and TPNH diaphorases, their discrepancy in activity being due to secondary factors, connected with the organized nature of the structures in which they are located. The data collected in Tables 1 and 2 seem to support this concept.

As emerges from Table 1, precipitation of a suspension of mitochondria or microsomes with acetone resulted in a selective stimulation of the TPNH-diaphorase activity, with a shift of the TPNH/DPNH activity ratio towards unity. A similar effect ensued if mitochondria or microsomes were exposed to a hypotonic

* The symbols, DPNH and TPNH, stand for the reduced forms of di- and triphosphopyridine nucleotide, respectively.

When dimethylnitrosamine was added to the normal diet of rats at a level of 50 parts per million a high incidence of malignant tumours of the liver was found between the 26th and 40th weeks [2]. Structural Factors Involved in the Diaphorase and Cytochrome c-Reductase Activities of Mitochondria and Microsomes

Lars Ernster

Wenner-Gren Institute, University of Stockholm, Stockholm, Sweden

As indicated by previous studies [1,2], the low activity at which TPNH * is oxidized by way of the cytochrome system may constitute a limiting factor for the function of TPN-dependent oxidations in liver tissue. The great discrepancy in activity, known to prevail between the liver TPNH- and DPNH-cytochrome c reductase systems [3], and recent evidence reported in the literature [4,5] that the former may be selectively regulated by metabolic control mechanisms, prompted a comparative study of the two systems with respect to their catalytic components. Interest was in the first place focused on the diaphorase components, since these are believed to constitute the first catalytic links of the cytochrome c-reductase systems with the reduced pyridine nucleotides.

While the TPNH- and DPNH-cytochrome c reductases are located exclusively in the particulate elements of the cytoplasm [3,6,7], recent studies [8] revealed the occurrence of a considerable diaphorase activity in the soluble cytoplasm. This activity was found to be equally high with DPNH and TPNH, in contrast to those present in mitochondria and microsomes, which are 3—7 times higher with DPNH than with TPNH. Since there are indications that the TPNH- and DPNH-diaphorase activities of the soluble cytoplasm are catalyzed by one common enzyme [8] it appeared to be of interest to investigate whether the same could be valid for the particulate DPNH- and TPNH diaphorases, their discrepancy in activity being due to secondary factors, connected with the organized nature of the structures in which they are located. The data collected in Tables 1 and 2 seem to support this concept.

As emerges from Table 1, precipitation of a suspension of mitochondria or microsomes with acetone resulted in a selective stimulation of the TPNH-diaphorase activity, with a shift of the TPNH/DPNH activity ratio towards unity. A similar effect ensued if mitochondria or microsomes were exposed to a hypotonic

* The symbols, DPNH and TPNH, stand for the reduced forms of di- and triphosphopyridine nucleotide, respectively.

Table 1. Effects of acetone treatment and hypotonicity on the activities of particulate liver diaphorases.

Homogenates of rat liver were made in 0.25 M sucrose solution. 100 ml homogenate, containing 10 g wet weight liver, was centrifuged *a*) at 1 600 *g* for 10 min, *b*) at 4 100 *g* for 15 min, and *c*) at 105 000 *g* for 60 min. The denotions, mitochondria and microsomes, refer to the pellets obtained in *b* and *c*, respectively. The mitochondrial pellet was washed, and the microsomal pellet rinsed, twice with 0.25 M sucrose, and both pellets were suspended in 10 ml 0.25 M sucrose. 4 ml aliquots of both suspensions were added to 36 ml cold (—12°C) acetone, the precipitates separated by centrifugation at 0°C, and dried in a desiccator. The dry precipitates were suspended in 4 ml 0.25 M sucrose. Another aliquot of the mitochondrial and microsomal suspensions was diluted with 9 volumes of distilled water and allowed to stand at 0°C for 30 min before test. The test system contained 0.5 ml 0.3 M tris buffer (pH 7.5), 2.3 ml 0.25 M sucrose, 0.1 ml 3 mM DPNH or TPNH, 0.1 ml 1.7 mM 2,6-dichlorophenolindophenol, and 10 mg wet weight liver equivalent mitochondria or 5 mg equivalent microsomes in a volume of 0.1 ml 0.25 M sucrose. When indicated, ATP was added in a final concentration of 3 mM and Mn++ in a final concentration of 0.3 mM. The decolorization of the dye was recorded in a Beckman DK2 spectrophotometer at 600 mμ, using glass cuvettes of 1 cm light path. The reaction was started by the addition of the reduced pyridine nucleotides, and followed for 4—6 min at room temperature. The values are expressed in terms of 1 g wet weight liver equivalent.

Treatment	*Mitochondria*			*Microsomes*		
	Diaphorase activities (μmoles dye reduced/min)					
	TPNH	DPNH	$\frac{\text{TPNH}}{\text{DPNH}}$	TPNH	DPNH	$\frac{\text{TPNH}}{\text{DPNH}}$
None	1.0	4.3	0.23	1.9	10.2	0.15
Acetone	1.9	3.0	0.65	3.5	3.4	1.03
Hypotonicity	2.8	4.5	0.61	2.9	10.8	0.27
» + ATP	1.5	4.3	0.34			
» + ATP + Mn++	0.9	4.3	0.21			

medium (0.05 M sucrose) at 0°C for 30 min; in this case the effect on the mitochondria could be counteracted by ATP and Mn++, which are known protectors of the mitochondrial structure [9].

Since deoxycholate has previously proved to be a useful tool in studying the biochemical organization of mitochondria [10-12] and microsomes [13] the effect of this agent was investigated in greater detail. Table 2 illustrates the effects of increasing concentrations of deoxycholate on the mitochondrial and microsomal diaphorase and cytochrome c reductase activities. Again, the structural destruction was accompanied by an increase of the TPNH/DPNH activity ratio in both instances and with both types of activities measured. However, whereas in the case of mitochondria this increase was mainly due to an absolute increase of the TPNH-diaphorase and cytochrome c-reductase activities, in the case of microsomes these activities remained virtually constant and the increase of the activity ratios could entirely be accounted for by a decrease of the DPNH-linked activities; yet, the mitochondrial DPNH-cytochrome c-reductase was also strongly inhibited by deoxycholate. Whether the different behaviors of the mitochondrial and microsomal TPNH-diaphorase and cytochrome c-reductase activities towards deoxycholate are related to the known difference existing between the actions of deoxycholate on the mitochondrial [10,11] and microsomal [13] membranes is the subject of continued studies. The data as yet available point to the possibility that the great difference prevailing between the cellular activities of the TPNH- and DPNH-cytochrome c-reductase systems is primarily due to different locations within, or relations to, the cytoplasmic structures rather than to different catalytic compositions.

Table 2. Effects of varying concentrations of deoxycholate on the diaphorase and cytochrome c-reductase activities of rat liver mitochondria and microsomes.

Diaphorase activities were tested as described in Table 1. The test system used for the determination of the cytochrome c-reductase activity contained the following: 0.5 ml 0.3 M tris buffer (pH 7.5), 2.2 ml 0.25 M sucrose, 0.1 ml 10 mM KCN, 0.1 ml 3 mM DPNH or TPNH, and 0.1 ml 1.5 mM cytochrome c. The reaction was started by the addition of the reduced pyridine nucleotides, and followed by recording the increase in optical density at 550 mμ, due to the reduction of cytochrome c. The amounts of enzyme used in the different tests, expressed in mg wet weight liver equivalents, were as follows: *Mitochondria:* TPNH- or DPNH-diaphorase, 10; TPNH-cytochrome c-reductase, 33; DPNH-cytochrome c-reductase, 3.3. *Microsomes:* TPNH- or DPNH-diaphorase, 3.3; TPNH-cytochrome c-reductase, 17; DPNH-cytochrome c-reductase, 1.7. Deoxycholate was included in the test systems in concentrations as indicated. The values below are expressed in relative terms, giving the value 100 to the activity obtained with DPNH as substrate in the absence of deoxycholate within each individual type of test.

Fungus Pigments

VIII *. The Structure of Cinnabarin and Cinnabarinic Acid

JARL GRIPENBERG

Department of Chemistry, Finland Institute of Technology Helsingfors, Finland

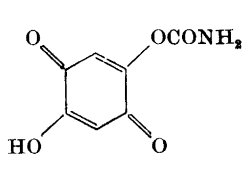
Hydrolysis of cinnabarin with alkali gives cinnaquinone, $C_7H_5NO_5$, which upon further hydrolysis gives 2,5-dihydroxybenzoquinone. The formation of these compounds and the results of reductive acetylation of cinnabarin and its derivatives has led to the conclusion that cinnabarin is 2-amino-9-hydroxymethylphenoxazin-3-one-1-carboxylic acid (IX). Cinnabarinic acid is formulated as 2-aminophenoxazin-3-one-1,9-dicarboxylic acid (XV), and it is identical with a compound obtained earlier by oxidation of 3-hydroxyanthranilic acid.

Since cinnabarin was first isolated, it has been known that alkaline hydrolysis gives one molecule of ammonia, but no other definite product could be isolated from this reaction [1-3]. It has now been found that on hydrolysis with a small volume of 2 N sodium hydroxide at room temperature for a short time a sparingly soluble sodium salt is precipitated. Acidification yields an orange-red crystalline compound, $C_7H_5NO_5$, which we have called cinnaquinone. Further hydrolysis of cinnaquinone gives 2,5-dihydroxybenzoquinone, ammonia and carbon dioxide [5].

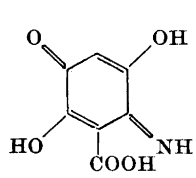
In view of the mild conditions for this further hydrolysis and the similarity of the U.V.-spectra of cinnaquinone and of 2,5-dihydroxybenzoquinone (Fig. 1) it is assumed that the reaction is not accompanied by any deepseated changes in structure. The structures I—VI therefore represent the theoretical possibilities for the structure of cinnaquinone.

Of these, I can be dismissed at once because cinnaquinone has peaks at 1 683 and 1 613 cm^{-1} in the carbonyl region, whereas I should have a peak at $\sim$ 1 725 cm^{-1} typical of carbamates [4]. It is more difficult to decide between the other possible structures. VI, incorporating the carboxamide group suspected in cinnabarin [3,6] is the structure most likely to have been formed under the conditions used, and was considered the most probable alternative [5].

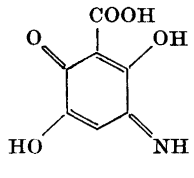
* The paper in *Proc. Chem. Soc.* **1957** 233 is regarded as Part VII of this series. Part VI *Suomen Kemistilehti B* **30** (1957) 134.



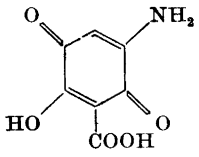
I



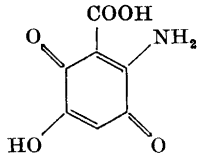
II



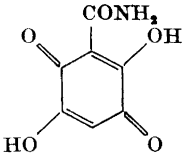
III



IV

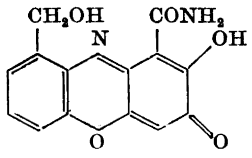


V

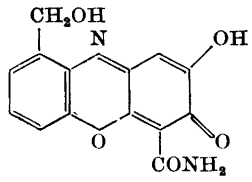


VI

The formation of a hydroxybenzoquinone derivative on alkaline hydrolysis of cinnabarin is in complete accordance with its formulation as a phenoxazin-3-one derivative [7,8] because phenoxazin-3-ones are known to give hydroxybenzoquinones, although more drastic conditions have usually been employed [9,10]. Cinnabarin was accordingly formulated [5] as VII or VIII



VII



VIII

Both these formulae, however, suffer from the disadvantage that they do not permit any rational formulation of the products of reductive acetylation of cinnabarin and its derivatives.

The first paper in this series [1] described the formation of two substances by reductive acetylation of cinnabarin. They were designated as cinnabarin leucoacetate A and cinnabarin leucoacetate B, respectively. The former was given the composition $C_{16}H_{16}N_2O_6$ and the latter $C_{18}H_{16}N_2O_6$ and it was shown that leucoacetate A upon further acetylation gives leucoacetate B. Cavill *et al.*[3] also prepared leucoacetate B, but assigned it the composition $C_{20}H_{16}N_2O_7$. More recent analytical evidence is also more consistent with this formula, and we therefore regard it as correct. Cinnabarin leucoacetate B is thus triacetylanhydrodihydrocinnabarin. Cavill *et al*[3] also prepared a triacetyl-O-methyldihydrocinnabarin. Since no anhydro compound was formed in this case they drew the natural conclusion that the hydroxylgroup, which is methylated is that involved in the formation of the anhydro compound.

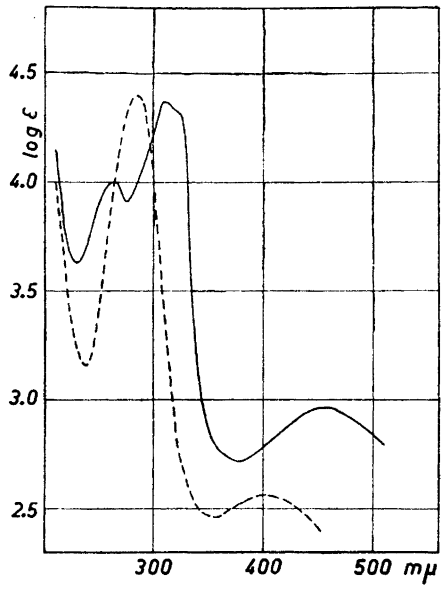


Fig. 1. Absorption curves for cinnaquinone (———). and 2,5-dihydroxybenzoquinone (– – – –). Both in alcohol.

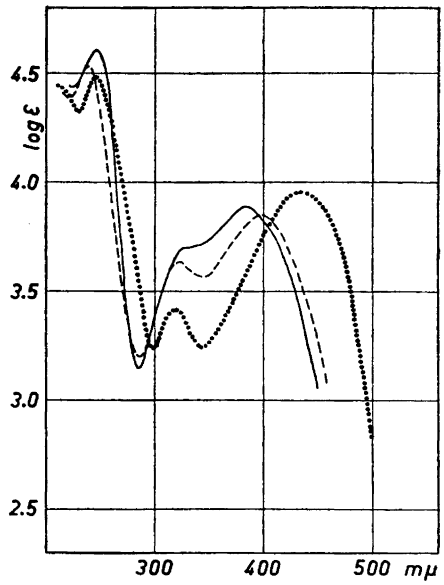

Fig. 2. Absorption curves for triacetyldihydrocinnabarin (XI) (————), triacetyldihydrocinnabarin methyl ester (XII) (– – – –) and triacetylanhydrodihydrocinnabarin (XIII) (·····). All in alcohol.

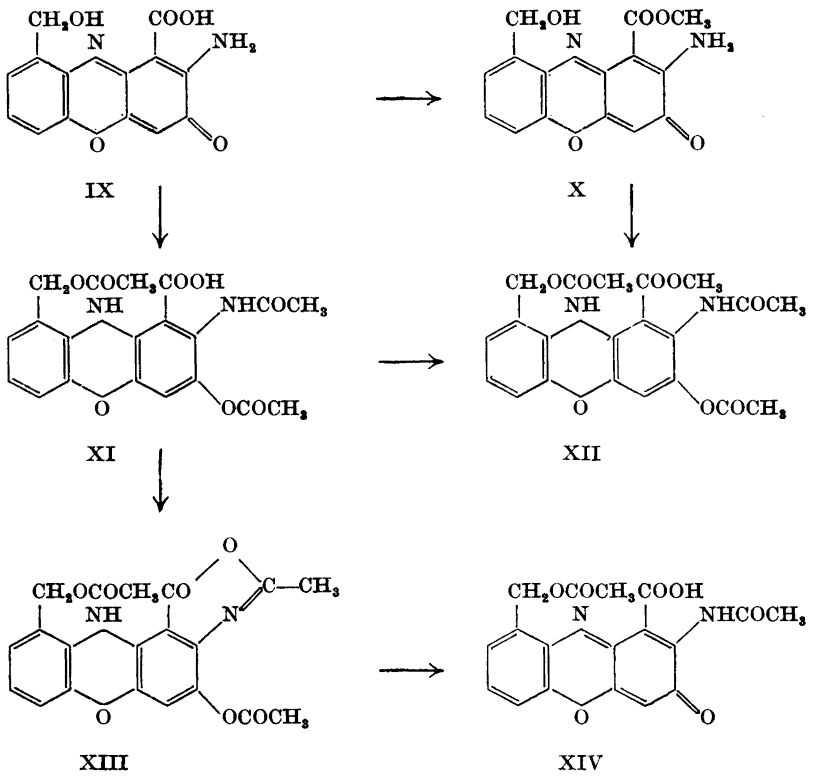
A comparison of the U.V.-spectra of cinnabarin leucoacetate A and triacetyl-O-methyldihydrocinnabarin indicated a close relationship between them (Fig. 2). This was also established by methylation of leucoacetate A with diazomethane, which gave triacetyl-O-methyldihydrocinnabarin. In our hands this substance had m.p. 173.5—174.5°, whether prepared by methylation of cinnabarin leucoacetate A or by reductive acetylation of O-methyl cinnabarin, whereas Cavill *et al.*[3] report 156°. This difference is probably due to dimorphism. Cinnabarin leucoacetate A must thus be triacetyldihydrocinnabarin with a composition $C_{20}H_{18}N_2O_8$, although the nitrogen value (8.42 %) is much higher than that required by the above formula (6.76 %). The carbon and hydrogen values (C 57.63; H 4.93) fit this formula reasonably well (Calc. C 57.97; H 4.38).

All attempts to repeat the preparation of leucoacetate A have given only very minute amounts of material insufficient for further analysis.

The results of reductive acetylation show that the hydroxyl group in triacetyldihydrocinnabarin, which is responsible for the acidity [1], is also present in cinnabarin, and is that which is methylated in the formation of O-methylcinnabarin. This hydroxyl group also takes part in the reaction leading to the formation of triacetylanhydrodihydrocinnabarin.

Formulae VII or VIII for cinnabarin do not give a satisfactory explanation of the behaviour of cinnabarin.

If, however, cinnabarin has the structure IX these reactions can be formulated as shown below,



O-Methylcinnabarin (X) is, on this basis, more properly named cinnabarin methyl ester. Triacetyldihydrocinnabarin (leucoacetate A) is XI, triacetyldihydrocinnabarin methyl ester (triacetyl-O-methyldihydrocinnabarin) is XII and triacetylanhydrodihydrocinnabarin (leucoacetate B) is XIII. The conversion of XI into XIII is a well known reaction [11]. That the NH-group of the phenoxazine ring cannot be acetylated can be ascribed to steric hindrance.

These structures are also supported by the I.R.-spectra (Our I.R.-spectra differ in some respects from these reported by Cavill *et al.*[3], but these differences are probably due to the difference in technique employed [12], and in the case of triacetyldihydrocinnabarin methyl ester also to different crystalline forms.) The bands at 1 672 and 1 653 cm^{-1} in the spectrum of cinnabarin, which were originally assigned to the carboxamide group [3], can equally well be due to strongly chelated carboxyl and the carbonyl of the phenoxazin-3-one [13]. Cinnabarin methyl ester has a single much stronger band at 1 657 cm^{-1} in this region [3]. The strong, partly resolved absorption just below 1 600 cm^{-1} is typical of phenoxazin-3-ones [13] and disappears on reductive acetylation. Instead there are a number of bands above 1 650 cm^{-1}. In the spectrum

of XI the bands at 1 770 and 1 740 cm^{-1} can be assigned to the aromatic acetate and the aliphatic acetate, and those at 1 690 and 1 677 cm^{-1} to the carboxyl and the N-acetyl-group, or *vice versa*. In XII the corresponding bands occurs at 1 760, 1 740, 1 682 and 1 657 cm^{-1}. XIII has, as expected, a third band above 1 700 cm^{-1}, due to the carbonyl group of the oxazinone ring [11]. The band at 1 775 cm^{-1} can be assigned to the aromatic acetate and the band at 1 750 cm^{-1} to the oxazinone carbonyl or vice versa and the one at 1 732 cm^{-1} to the aliphatic acetate. The band at 1 655 cm^{-1} is probably due to the C = N-bond in the oxazinone ring [11].

One objection that could be raised against these formulations for the leucoderivatives of cinnabarin is, that the transformation of XI into XIII causes a large bathochromic shift in the spectrum (see Fig. 2) while the change from N-acetylanthranilic acid into 2-methylbenzoxazin-4-one is accompanied by a slight hypsochromic shift [11]. It is, however, doubtful whether any significant conclusion can be put on a comparison of systems that are as different as these.

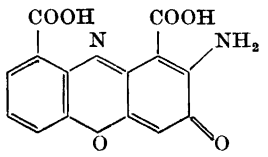
These leucoderivatives of cinnabarin are quite stable, unlike the leucoacetate of actinomycin, which according to Brockmann and Franck [14] can be readily partially hydrolysed and reoxidised to N-acetylactinomycin. Such a hydrolysis appears to take place with triacetylanhydrodihydrocinnabarin (XIII) only in the presence of an oxidant, *e.g.* nitrous acid. Cavill *et al.*[15] who discovered this reaction called their product diacetyl*iso*polystictin (in our nomenclature diacetyl*iso*cinnabarin) but it might just as well be diacetylcinnabarin (XIV). Their assumption that this product should be identical with our leucoacetate A is incorrect, as shown by the completely different U.V.- and I.R.-spectra for the two compounds and by the strong mixed m.p. depression.

The formulation of cinnabarin as IX and not as VII or VIII finds further support in a colour reaction. Brockmann and Franck [16] have observed that actinomycin, which has an amino-group in the 2-position of the phenoxazin-3-one ring gives a yellow colour with stannous chloride, while desaminoactinomycin, with a hydroxyl group in the 2-position gives a green colour. This difference between 2-amino- and 2-hydroxyphenoxazin-3-ones is even more pronounced in the parent compounds; 2-aminophenoxazin-3-one gives with stannous chloride a colourless solution and 2-hydroxyphenoxazin-3-one a blue colour [9]. Cinnabarin gives in accordance with its formulation as a 2-aminoderivative only a yellow colour.

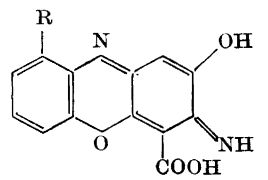
If cinnabarin is IX it means that cinnaquinone must be V. Its properties agree equally well with this structure, although it is somewhat surprising that such a compound is stable under alkaline conditions. The formation of oxamic acid on oxidation of cinnabarin under slightly alkaline conditions [6] can of course also be explained on the basis of structure IX for cinnabarin.

In a previous paper [6] we described the isolation of cinnabarinic acid, which accompanies cinnabarin. The assumed close similarity of cinnabarinic acid and cinnabarin, which was inferred from their almost identical U.V.-absorption in pyridine solution has now found further support in that both show the same characteristic shift of absorption maximum in strongly acidic solution (see below) and both give the same yellow colour reaction with stannous chloride.

Cinnabarinic acid has the composition $C_{14}H_8N_2O_6$, having two hydrogen atoms less and one oxygen atom more than cinnabarin. It was therefore very tempting to speculate that cinnabarinic acid differs from cinnabarin in having a carboxyl group instead of the primary hydroxyl group. The presence of a second carboxyl group in cinnabarinic acid, which finds strong support in a band at 1 727 cm^{-1} also explains the greater acidity of cinnabarinic acid [6]. If cinnabarin has structure IX, cinnabarinic acid should be XV.



XV



XVI R = COOH
XVII R = CH_2OH

XV has been proposed by Butenandt *et al.*[10] as an alternative structure for the product obtained by oxidation of 3-hydroxyanthranilic acid, the other being XVI. Through the kindness of Professor Butenandt we received a sample of his »Farbstoff IV». Although the I.R.-spectrum of »Farbstoff IV» is not quite as sharp as that of cinnabarinic acid, there can be no doubt that the two substances are identical (Fig. 3). The identity of the U.V.-spectra both in neutral and strongly acidic solution [10] confirms this identity further.

One remarkable difference between cinnabarin and cinnabarinic acid is in their behaviour towards alkali. Cinnabarin, as has been shown above, splits off cinnaquinone, while cinnabarinic acid is converted into 2-hydroxyphenoxazin-3-one-9-carboxylic acid [10]. Attempts to obtain cinnaquinone from cinnabarinic acid gave only a minute amount of a substance, which showed the characteristic U.V. spectrum of cinnaquinone but the amount available was not sufficient for further purification.

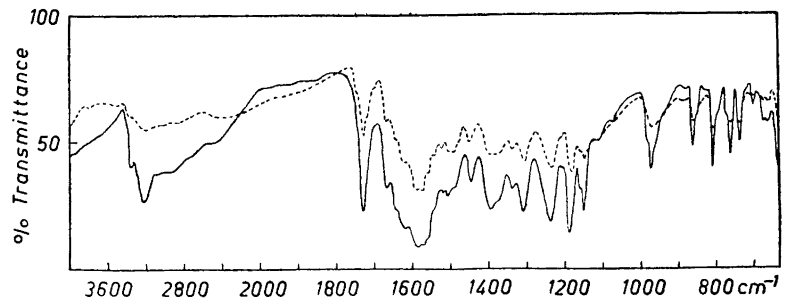


Fig. 3. Infrared absorption curves for natural cinnabarinic acid (————) and synthetic cinnabarinic acid (— — — — —). In KBr-discs.

In spite of this difference, which can be accounted for by the influence of the 9-carboxylic group on the rate of hydrolysis of the C = N-bond, it is considered that cinnabarin and cinnabarinic acid have analogous structures. This definitely excludes structures VII and VIII for cinnabarin. The possibility that cinnabarinic acid has structure XVI and cinnabarin XVII is highly improbable because XVII ought to form a dimethyl derivative. The formation of phenoxazin-3-one (or more probably 9-methylphenoxazin-3-one) on zinc dust distillation [6,7] and oxamic acid on oxidation of cinnabarin [6] is also difficult to reconcile with structure XVII.

IX and XV thus appear to be the most probable structures for cinnabarin and cinnabarinic acid, respectively.

After this paper had been written a paper by Cavill, Clezy and Tetaz [17] appeared, in which the structure IX is also suggested for cinnabarin.

EXPERIMENTAL

(The analyses are by Dr. A. Bernhardt, Mühlheim, and the I.R.-spectra by Mr. B. C. Fogelberg, Ab Centrallaboratorium, Helsingfors.)

Cinnaquinone. Cinnabarin (400 mg) was added to 2 N sodium hydroxide (2 ml) and the mixture was stirred with a glass rod. The cinnabarin dissolved in a few minutes and a brown crystalline precipitate soon formed. This was at once filtered off. A second crop of crystals forming in the filtrate was also filtered off and usually a third crop of crystals could also be obtained. The combined precipitates were dissolved in the minimum amount of water and the solution was acidified. Brown-yellow crystals of cinnaquinone, mixed with some dark-brown amorphous material were obtained. The precipitate was filtered off and treated with ethyl acetate which leaves the amorphous material undissolved. The filtrate which still contained a considerable amount of cinnaquinone was extracted with ethyl acetate. The combined ethyl acetate extracts were evaporated under reduced pressure and the crystalline residue recrystallised from dioxan giving orange-brown needles (70 mg), decomp. above 200° without melting. (Found: C 45.78; H 2.95; N 7.39; $C_7H_5NO_5$ requires C 45.91; H 2.75; N 7.65). I.R. maxima (KBr): 3 375 (m), 3 230 (m), 1 683 (m), 1 613 (m), 1 580 (s), 1 490 (m), 1 422 (m), 1 395 (s), 1 332 (s), 1 302 (m), 1 247 (m), 1 212 (w), 1 167 (m), 955 (w), 882 (w), 865 (w), 820 (w), 763 (w), 742 (w) cm^{-1}.

2,5-Dihydroxybenzoquinone. Cinnaquinone (10 mg) was added to 20 % sodium hydroxide (0.5 ml) and warmed slightly. In a few minutes a red precipitate was formed and was filtered off, treated with acid and extracted with ethyl acetate. The residue from the ethyl acetate extract was sublimed at 90°/0.005 mm. The red sublimate had an I.R.-spectrum indistinguishable from that of 2,5-dihydroxybenzoquinone prepared according to Jones and Shonle [18].

Triacetyldihydrocinnabarin methyl ester. a) Cinnabarin methyl ester [3] (30 mg) was suspended in acetic anhydride (2 ml). A few drops of pyridine and zinc dust were added and the mixture was warmed giving a yellow solution. This was filtered hot to remove unreacted zinc and then poured into water. The yellow precipitate was filtered off and recrystallised from benzene, small yellow needles m. p. 173.5—174.5° (Found: C 59.49; H 4.64; $C_{21}H_{20}N_2O_8$ requires C 58.87; H 4.71). I.R. maxima (KBr): 3 330 (w), 3 250 (w), 1 760 (s), 1 740 (s), 1 682 (s), 1 657 (s), 1 612 (w), 1 582 (w), 1 513 (s), 1 475 (s), 1 437 (m), 1 375 (m), 1 349 (w), 1 312 (m), 1 290 (s), 1 254 (s), 1 240 (s), 1 207 (s), 1 116 (m), 1 020 (m), 965 (w), 912 (w), 875 (w), 847 (w), 789 (w), 771 (m), 720 (w) cm^{-1}.

b) Triacetyldihydrocinnabarin [1] (10 mg) was suspended in ether and an ethereal solution of diazomethane was added. The clear solution which formed after some time was evaporated leaving fine yellow needles, m. p. 173—174°. No depression of m. p. when mixed with material prepared according to a).

Triacetylanhydrodihydrocinnabarin was prepared as described before [1]. (Found: C 60.24; H 4.39; N 7.03; O 28.29; $C_{20}H_{16}N_2O_7$ requires C 60.60; H 4.07; N 7.07; O 28.26). I.R. maxima (KBr): 3 340 (m), 1 775 (s), 1 750 (s), 1 732 (s), 1 655 (s), 1 619 (w), 1 589

(w), 1 519 (s), 1 481 (s), 1 465 (s), 1 432 (m), 1 405 (m), 1 375 (s), 1 351 (m), 1 317 (s), 1 292 (s), 1 260 (m), 1 230 (s), 1 198 (s), 1 163 (m), 1 131 (s), 1 063 (s), 1 027 (m), 1 009 (m), 999 (m), 970 (m), 914 (m), 883 (m), 790 (m), 780 (s), 716 (w), 685 (m) cm^{-1}.

Triacetyldihydrocinnabarin [1] has I.R. maxima (KBr): 3 380 (m), 1 770 (s), 1 740 (m), 1 690 (s), 1 677 (s), 1 630 (m), 1 587 (m), 1 508 (s), 1 480 (s), 1 435 (m), 1 381 (m), 1 295 (s), 1 260 (s), 1 237 (s), 1 198 (s), 1 120 (w), 1 022 (m), 993 (w), 955 (w), 938 (w), 920 (w), 878 (m), 847 (w), 796 (w), 779 (m), 768 (w), 745 (w), 730 (m), 715 (w), 695 (w) cm^{-1}.

Cinnabarinic acid [6] was purified further by extractive crystallisation, first from dioxan and then from acetone. I.R. maxima (KBr); 3 370 (m), 3 240 (s), 1 727 (s), 1 662 (m), 1 615 (s), 1 587 (s), 1 570 (s), 1 516 (m), 1 507 (m), 1 448 (m), 1 395 (s), 1 338 (m), 1 310 (s), 1 237 (s), 1 184 (s), 1 150 (s), 973 (m), 860 (m), 807 (m), 761 (m), 736 (m), 701 (w), 670 (w), 663 (w), 633 (m) cm^{-1}.

This investigation has been supported by a grant from *Statens Naturvetenskapliga Kommission*, which is gratefully acknowledged. The author also wishes to thank Professor A. Butenandt, München, for kindly providing a reference sample.

The Solubility of Argon and Ethane in Perfluoro-*n*-Heptane and Carbon Disulfide

J. CHR. GJALDBÆK and H. NIEMANN

Department of Inorganic Chemistry, The Royal Danish School of Pharmacy, Copenhagen Denmark

Solubility experiments carried out at 25°C resulted in the following values expressed as Bunsen coefficients: Argon in perfluoro-*n*-heptane 0.528, argon in carbon disulfide 0.180; ethane in perfluoro-*n*-heptane 2.03, ethane in carbon disulfide 3.94. From these values together with existing data in other solvents the solubility parameters for argon and ethane have been calculated to 5.43 and 7.55, respectively.

For a subsequent investigation of the solubility of gases in alcohols and water we needed values for the solubility parameters of argon and ethane. Concerning the concept "solubility parameter" the reader is referred to Hildebrand and Scott's monograph [1, p. 129].

Preliminary values for these parameters (argon 5.4 and ethane 6.45) have been published in an earlier paper [2, p. 56]. These values were considered to be rather inaccurate since the calculation was based on only two solvents for each gas. For the new experiments we have chosen a solvent with a very low and one with a very high solubility parameter, *viz.* perfluoro-*n*-heptane (5.85) and carbon disulfide (10.0).

EXPERIMENTAL AND RESULTS

The solubility determinations of argon were carried out in an apparatus and by a procedure described in an earlier paper [3]. The solubility determinations of ethane were carried out in an analogous apparatus having a 20 ml container for both the solvent and the gas.

Argon (from "L'air liquide") was identified by its emission spectrum. A sample of the gas was filled in a Geissler tube and the wave lengths of about fifty lines in the red and the blue spectrum were measured and found to be in accordance with values given in the literature. The gas was dried over phosphorus pentoxide and proved to contain less than 0.05 % water.

Ethane (Research Grade from Phillips Petroleum-Company) was analyzed in a gas-chromatograph; 25 ml of the gas (measured at 20°C and 1 atm) was adsorbed on a column of silica gel. The length of the column was 25 cm and the cross section about 0.8 cm^2.

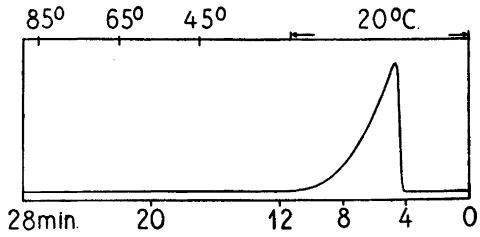

Fig. 1.

The speed of the supporting gas, hydrogen, was about 50 ml per minute. The detector was a thermal conductivity cell. The resulting curve is reproduced in Fig. 1, where the abscissa is the time in minutes. The first part of the analysis was carried out at 20°C. The sharp front after about 4 min shows that the gas contains no methane. 11 min after the beginning of the experimert the temperature was gradually increased to 85°C as shown in Fig. 1. Butane and higher hydrocarbons must be absent, since the curve shows only one peak.

To prove that lower hydrocarbons were absent the gas was analyzed in a Beckman spectrograph; the length of the cuvette was 10 cm and the pressure about 530 mm; the wave length was varied from 15 to 3 μ corresponding to wave numbers from 670 to 3 300 cm^{-1}.

The curve showed three characteristic bands for ethane at about 820, 1 450 and 2 934 cm^{-1}. A weak band at 949 cm^{-1} was interpreted as originating from ethene, the content of which was estimated to be less than 0.5 and possibly as low as 0.1 %. A very weak band at about 1 250 cm^{-1} was not identified.

By combustion analysis in an apparatus, as described by Christiansen and Wulff [4], we found results between 99.6 and 100.4 % ethane.

Perfluoro-n-heptane was fractionated in a 35-plate column (boiling point from 82.44 to 82.53°C at 760 mm). The fractions were analyzed in a Beckman spectrophotometer DU and showed a strong absorption in ultraviolet with maximum at about 216 mμ. Using the purification method of Glew and Reeves [5] we passed the fluoroheptane through a column of dry silica gel. After this purification we found the extinction coefficient to be about 0.02 at 216 mμ. The boiling point was now 82.55−82.56° ± 0.02 at 760 mm.

Carbon disulfide (analytical reagent) was fractionated in the distillation column and showed a boiling point of 46.03°C (760 mm).

The experimental results are given in Table 1 and expressed as Bunsen coefficients. The calculated means are considered to be reliable to within one per cent. The experiments were finished in June 1956. Since then Reeves and Hildebrand [6] have published a value for the solubility of argon in carbon disulfide; their value differs less than 1 % from our value.

CALULCATION OF THE SOLUBILITY PARAMETERS FOR ARGON AND ETHANE

The solubilities of argon and ethane are given in Tables 2 and 3 together with existing values for the solubilities in other solvents; the values are given in mole fractions ($x_2 \times 10^4$).

The solubility parameter (δ_2) for argon has been calculated from the equation

$$-\log x_2 = -\log x_2^i + 0.4343 \frac{\overline{V}_2}{RT}(\delta_1 - \delta_2)^2 + \log \frac{\overline{V}_2}{V_1} + 0.4343\left(1 - \frac{\overline{V}_2}{V_1}\right) \quad (1)$$

Table 1. Solubilities of argon and ethane expressed in Bunsen coefficients at 25°C.

	Argon		Ethane	
	singel determi-nations	mean	singel determi-nations	mean
CS_2	0.1815 0.179 0.1796	0.180	3.927 3.944	3.94
n-C_7F_{16}	0.5286 0.5275	0.528	(1.922) * 2.032 2.027	2.03

* this result is regarded to be too low.

in such a way that the equation reproduces the experimental values as closely as possible. With regard to the derivation of eqn. (1) reference should be made to Hildebrand and Scott [1, p. 131]. The ideal solubility, x_2^i, of argon has been calculated from

$$-\log x_2^i = -\frac{\Delta H \cdot 0.4343}{R}\left(\frac{1}{T} - \frac{1}{T_b}\right)$$

using $\Delta H = 1\,500$ cal/mole (*Int. Crit. Tables* V, p. 135) at the boiling point for argon $T_b = 87°K$. The result is $x_2^i = 21.6 \times 10^{-4}$ at $T = 298.1°K$. Since the partial molal volume ($\bar{V}_2$) of argon is not determined we have used the value for oxygen ($\bar{V}_2 = 46$ ml), see *Gjaldbœk* [2, p. 57].

From eqn. (1) we have calculated $\delta_2 = 5.43$. The accuracy with which this value represents the experimental data appears from Table 2.

The ideal solubility of ethane has been calculated from

$$x_2^i = \frac{1}{41.37} = 0.0242$$

where 41.37 atm is the vapour pressure of ethane at 25°C, confer Beattie et al.[9]

The density 0.338 of liquid ethane at 25°C has been interpolated using densities given in *Int. Crit. Tables* (III, p. 230); from this density we calculated the molal volume of liquid ethane to be 88 ml.

The accuracy with which the empirical value $\delta_2 = 7.55$ represents the experimental data appears in Table 3.

McDaniel [11] has measured the solubilities of ethane in n-hexane and n-heptane. If we recalculate his values into mole fractions we get 0.0177 and 0.0266, respectively. From equation (1) we calculate 0.026 and 0.0268.

Acknowledgements. The analyses of ethane were carried out in the Chemical Laboratory of the University, Copenhagen. We wish to express our gratitude to civil engineer Daniel Christensen and mag.scient. Flemming Andersen for their kind help with the analyses and interpretation of the results. We also thank Professor Carl Faurholt, director of the laboratory, for his kind interest in the investigations. The financial support from *Statens almindelige Videnskabsfond* is gratefully acknowledged.

Separation of Acetylated Sugars and Related Compounds by Paper Chromatography in Organic Two-phase Solvent Systems

BÖRJE WICKBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The paper chromatography of acetates of sugars, sugar alcohols, cyclitols and glycosides using two-phase organic solvent systems has been investigated. Dimethyl sulphoxide, formamide and dimethyl formamide have been used as polar solvents but though all of them gave about the same resolution, dimethyl sulphoxide was preferred for practical reasons. The mobilities were found to be very dependent on the structure of the compounds but were little influenced by the molecular weight. Exceptionally great differences in mobilities were observed with the sugar alcohol derivatives. Of the fully acetylated sugars and glycosides of the D-series which were investigated, all α-anomers travelled faster than the corresponding β-anomers. The 2,3,6-tri-*O*-methyl derivatives of D-glucose and D-mannose which are difficult to distinguish by ordinary paper chromatography and by electrophoresis were easily separated as their acetates. This method should be of general value for the separation and characterisation of *O*-methyl sugars.

In the paper chromatography of carbohydrates the relative R_F values in the aqueous solvent systems commonly used generally vary little with the solvent composition. This is a serious limitation of the method as there is usually little hope of radically improving a poor resolution by changing solvents and further, the characterisation of carbohydrate compounds by paper chromatography only may be misleading. Sometimes these difficulties are overcome in indirect ways as is the case with the sugar alcohols. These may be converted into anhydrides which are then characterised by R_F values and colour reactions [1] but the method is time-consuming and leaves the problem of isolating the original alcohols unsolved.

In connection with work on the carbohydrate constituents of some lichens and algae which contain complicated mixtures of sugar alcohols, cyclitols and glycosides, some attempts were made to find a complementary method for the paper chromatographic separation and characterisation of such compounds.

As further search for suitable aqueous mixtures seemed unprofitable recourse was made to two-phase organic solvent systems, such as have been

successfully employed for the separation of various lipophilic compounds, *e.g.*[2–6]. In addition to formamide (FA) and dimethyl formamide (DMF) which have been used earlier, dimethyl sulphoxide (DMS) also was tried as the polar stationary phase. Attempts were first made to separate some hexoses using 25 % v/v solutions of FA or DMS in ethyl acetate as solvents but as the relative R_F values were about the same as in the usual aqueous solvents and the spots produced in the case of DMS rather trailing, the experiments were continued with acetylated sugars.

A method for the separation of sugar acetates by reversed phase chromatography on acetylated paper has been described by Micheel and Schweppe [7] but though monosaccharide acetates were well separated from disaccharide acetates the resolution within each of these groups was generally rather poor.

Preliminary experiments were made using FA, DMF and DMS as stationary solvents and light petroleum, *iso*propyl ether, ethyl ether and benzene as mobile solvents (Table 1). No precautions were taken against atmospheric moisture in the chromatogram tanks.

It is evident that despite significant differences in some cases the stationary phases give on the whole about the same resolution. FA has the advantage of being sparingly soluble in all the mobile solvents and is thus strongly retained by the paper but on the other hand the silver nitrate spray (see Experimental part) cannot be used in this case for detection of the spots. DMF and DMS do not interfere with any of the spray reagents but they are less firmly held by the paper. DMS gives distinct spots in combination with light petroleum, *iso*propyl ether and slightly moist ethyl ether but elongated spots and very diffuse solvent fronts with sodium-dried ethyl ether and with benzene. DMF gave trailing spots with both light petroleum and *iso*propyl ether and was partly washed off the paper by the latter solvent.

As spraying with silver nitrate — sodium hydroxide is the most convenient way of detecting the spots, DMS is the most satisfactory of the stationary solvents tried. It is cheap and sufficiently stable when stored in glass bottles and as far as is known to the author toxic effects have not been observed. However, it should be handled with some care as when inhaled or absorbed through the skin it may produce a somewhat annoying sensation of taste.

In the following the discussion of the chromatographic technique is based mainly upon experience from work with DMS, but the same conclusions will most probably be valid for other solvents of the same type.

Before use it was necessary to impregnate the papers with the stationary solvent by dipping in a solution of the latter, blotting and drying. In order to minimise the effect of accidental irregularities in the process two such treatments with a dilute solution were preferred to one treatment with a more concentrated.

It was found that a suitable loading with DMS was obtained by using a ca 25 % v/v solution in toluene. If the concentration was below 20 % the spots became elongated or trailed and if it was above 30 % the paper had a wet and spotted appearance and the solvent front tended to be uneven. When drying the papers after impregnation DMS tended to evaporate faster along the edges, causing a faster flow through these parts during development. The drying time should therefore not be prolonged unduly.

In view of the hygroscopicity of the stationary solvents it is necessary to take precautions against atmospheric moisture when handling the impregnated chromatograms as otherwise the R_F values and resolution will vary with the weather. As is to be expected the R_F values increase with the moisture content of the solvents and with the polarity of the mobile phase. With rising R_F values the resolution generally decreases and maximum selectivity was therefore obtained by running the chromatograms in light petroleum in the presence of silica gel as a desiccant.

Because of the low solubility of DMS and its strong affinity to the paper, light petroleum and *iso*propyl ether were used as developing agents without being saturated with the stationary phase. With moist ethyl ether, 2 % v/v of DMS was added if the chromatograms were to be developed for several hours with this solvent. The resulting impoverishment of the stationary phase in the upper parts of the paper will of course affect the migration of the spots but this occurs only to a small extent. When α- and β-glucose pentaacetates were run on chromatograms in DMS — light petroleum the average R_{GA} values

(*cf.* Table 1, note *a*) for the β-acetate were 0.43, 0.47 and 0.49 when the α-acetate had travelled 3, 5 and 11 cm, respectively. Using the method described above the reproducibility was tolerably good. However, when chromatograms were run for several hours it was often found that the distance travelled by a compound might vary considerably across the paper even if the solvent front not had been perceptibly oblique before leaving the paper. This error can be detected and corrected for by adding a reference compound at short intervals along the starting line. If this compound has a slightly higher R_F value than the components of the samples it may be spotted on the paper at the same points as the samples to keep down the size of paper needed. The resolution is checked by running two reference compounds, the relative movements of which should be constant. Tables 2 and 3 list the R_F or R_{GA} values of a number of acetylated sugar derivatives run in light petroleum or *iso*propyl ether on DMS treated paper.

As is apparent especially from the behaviour of the sugar alcohol acetates the mobilities of isomeric compounds show differences which could not be obtained previously in the paper chromatography of carbohydrates while the influence of the molecular weight is of secondary importance. This makes the new method a useful complement to the standard methods for paper chromatography in aqueous solvents where the opposite usually applies. The pyranosidic acetates and acetylated glycosides investigated should all have a C 1 conformation, and it is interesting to note that in all cases the derivatives carrying an axial substituent on carbon atom 1 have much higher R_{GA} values than their respective anomers. This effect is more pronounced for the anomeric glycoside acetates of galactose than for the corresponding pentaacetyl deriva-

1-L-Glycerol D-galactopyranoside	0.45	0.07	0.20	0.06

tives and the difference also seems to increase with the bulk of the aglycon group. Although axial substitution in the 2- or 4-position usually seems to reduce the rate of migration, some α-D-galactopyranose derivatives investigated do not obey this rule and so far the experimental material is too small for definite conclusions to be drawn.

Disadvantages of the method are that in some cases the procedures for detection of the spots are rather complicated and sometimes insensitive and also that the samples may have to be acetylated before chromatography. However, the difficulty of detecting a compound is often compensated by the fairly large quantities of material which can be run as a single spot. The acetylation is easily carried out on a micro scale and the low viscosity of the mobile solvents in combination with the high power of resolution usually allows the development to be completed within a few hours.

An important case where the standard method fails is in the separation of arabitol and adonitol as their acetates, since the relative rates of the spots are 1 : 0.96, respectively, in the system DMS — light petroleum. Substitution of FA or even better, a mixture of FA and DMF for the DMS gave complete resolution of the acetates, the relative rates of the components now being 1 : 0.86—0.88.

Treatment of sugar alcohols with formic acid and phosphorous pentoxide gives the corresponding fully formylated esters in fair yield [10], and these may be run on paper chromatograms using DMS and ethyl or *iso*propyl ether as solvents. The mobilities are rather low, adonitol pentaformate travels about 1 cm/h in *iso*propyl ether, and the relative rates for the adonitol, arabitol, xylitol and sorbitol derivatives were found to be 1.00 : 0.74 : 0.40 :

Table 4. R_F and R_{GA} values of 1,4-di-*O*-acetyl-2,3,6-tri-*O*-methyl derivatives of D-glucose and D-mannose. Stationary phase: DMS.

Mobile phase:	Light petroleum R_{GA} values	*Iso*propyl ether R_F values
Parent compound:		
α-D-Glucose	6.1	0.45
β-D-Glucose	4.9	0.42
α-D-Mannose	1.8	0.25
β-D-Mannose	0.57	0.12

0.28 in the same solvent. Unfortunately the formates are not easily prepared on a micro scale, they are not very stable and some of them, *e.g.* those of mannitol, dulcitol and erythritol are unsuitable for paper chromatography because of their very low solubility.

Detailed experiments on the separation of methylated sugars in these solvents have not been carried out, but there are indications that DMS and ethyl or *iso*propyl ether may be used for chromatography of hexose tetramethyl ethers. Dr. I. Croon, Svenska Träforskningsinstitutet, has found that 2,3,6-tri-*O*-methyl D-glucose and 2,3,6-tri-*O*-methyl D-mannose can be separated on DMS treated paper by developing with an ethyl ether — DMS (19 : 1) mixture. This separation is not easily accomplished with the usual aqueous solvent systems. However, while the mannose derivative gave mainly one spot (rate: 5.4 cm/6 h) the glucose derivative gave two (rates: 6.2 and 8.0 cm/6 h), the relative intensities of which changed on storing the sample solution. Probably the mutarotation in this case was slow enough to allow the separation of the α- and β-anomers. A similar phenomenon was observed for 2,3,4,6-tetra-*O*-acetyl D-glucose (see Table 1). To avoid this complication and to obtain derivatives with higher mobilities, milligram samples of the trimethyl ethers were acetylated with pyridine, sulphuric acid or sodium acetate as catalyst. The resulting products were subjected to paper chromatography using DMS as the stationary phase (Table 4). The spots were detected by spraying with anisidine hydrochloride (see Experimental part). Since the acetyl derivatives are somewhat volatile the chromatograms were not dried before spraying with hexamethylene diamine solution. The structures were assigned on the assumption that the catalysts directed the formation of α- and β-acetates in the usual way. In the presence of sulphuric acid or pyridine the mannose derivative yielded the α-acetate almost exclusively and even with sodium acetate as catalyst the same anomer was still the major product. In the case of the glucose trimethyl ether the β-acetate was the more favoured anomer.

The very different R_{GA} values found for the glucose and mannose derivatives (Table 4) shows that paper chromatography of acetylated sugar methyl ethers may be a useful method for both identification and isolation.

Separation on a preparative scale of closely related compounds may occasionally be effected by a simple counter-current extraction technique as is illustrated by the preparation of *o*-cresyl α- and β-D-galactopyranoside tetraacetate. From the mixture of acetylated galactosides which is formed on heating

penta-*O*-acetyl β-D-galactopyranose with *o*-cresol in the presence of zinc chloride Helferich *et al.*[11] isolated the pyranosidic α- and β-derivatives by fractional crystallisation, but this separation was now found to be very unpredictable. As calculated from the R_F values of the α- and β-compounds using DMS and moist ethyl ether as solvents (R_F *ca.* 0.9 and 0.8, resp.) the corresponding partition coefficients (C_{ether}/C_{DMS}) were in the approximate ratio 2.3 : 1. Separation of the mixture by counter-current extraction was therefore attempted using ethyl ether and DMS containing 5 % v/v of water as solvents. The process was followed on paper chromatograms and by a suitable withdrawal of enriched fractions only six separating funnels were required. The pure components could finally be isolated in a good yield.

EXPERIMENTAL

Paper. Whatman No. 1 filter paper was used throughout.

Solvents. All solvents were of reagent grade. Formamide (FA), dimethyl formamide (DMF) and dimethyl sulphoxide (DMS)* were distilled under reduced pressure; other solvents were used without purification. The light petroleum had b.p. 60—71° (Skellysolve B).

Impregnation with the stationary phase. In the standard procedure for impregnation with DMS the chromatogram papers were passed at an even rate through a 25 % v/v solution of DMS in toluene, uniformly blotted between layers of filter paper and then dried at 60° for 1 min to remove the toluene. This process was repeated once and after the second drying the papers were immediately placed between glass plates leaving only the starting line and paper above it uncovered. After application of the spots the papers were transferred to the chromatogram tank in such a manner that absorption of atmospheric moisture was avoided.

When the reproducibility is of secondary importance the above procedure may be simplified, *e. g.* by blowing off the toluene from the papers with hot air. If the papers are to be handled without protection from moisture it is advisable to impregnate with a more dilute DMS solution, *e. g.* 20 %.

In the preliminary experiments on acetylated compounds (Table 1) the following impregnating solutions were used: 20 % v/v FA in ethyl acetate; 20 % v/v DMF in benzene; 20 % v/v DMS in benzene. Each paper was dipped in the impregnating solution, blotted and dried at 60° for 30 sec. After a second impregnation in the same manner the papers were dried at 60° for 1 min and then covered with glass slides while the samples were applied.

For separation of the pentaacetates of arabitol and adonitol using FA as the stationary phase the papers were impregnated twice with a 20 % v/v solution of FA in ethyl acetate analogous to the DMS treatment described above. To obtain a mixed FA—DMF phase the second impregnation was made with a 20 % v/v solution of DMF in benzene.

Application of samples. The samples were usually applied as 2 % solutions in ethyl ether or chloroform but provided that no crystallisation occurred upon drying the concentration could be raised to 5 or even 10 %.

Development. All chromatograms were run by the descending technique. In view of the fire hazard and for general convenience, small glass tanks were used for development with benzene, *iso*propyl ether or ethyl ether, the papers being ca 23 cm long with the starting line 5 cm from the upper end. Where not otherwise stated, separations in light petroleum were made on papers ca 46 cm long with the starting line 7 cm from the upper end and with silica gel present as a desiccant in the chromatogram tank. The solvent reached the lower end in 25—35 min for the short papers and 60—90 min for the long ones.

Detection of spots. a) *Silver nitrate — sodium hydroxide spray* [8]. After drying for 5—10 min at 120° the chromatograms were sprayed with aqueous silver nitrate (saturated aqueous solution — water 1:100 v/v) and dried in a current of hot air, excessive heating

* Purchased from Nitroglycerin AB, Gyttorp, Sweden.

being avoided. (While the paper was still wet some compounds appeared as greasy spots.) The chromatograms were then sprayed on both sides with an alcoholic sodium hydroxide solution prepared from 1 part of an aqueous solution (40 g NaOH in 100 ml water) and 9 parts of ethanol. Some compounds, *e. g.* acetates of reducing sugars reacted quickly while others like acetylated alkyl glycosides gave spots very slowly. In the latter case it was found favourable to keep the wet chromatograms after spraying with alkali between glass slides to prevent evaporation of ethanol. As soon as possible and before the background had become too dark the papers were washed successively with dilute ammonia and water and finally treated with aqueous hydrogen sulphide. (Prolonged treatment with ammonia or hydrogen sulphide has a bleaching action.) This method could not be used for chromatograms impregnated with FA.

b) *Hexamethylene diamine.* Commercial 70 % aqueous hexamethylenediamine solution was distilled under reduced pressure and the distillate was diluted with 4 parts of ethanol. When chromatograms were sprayed with this reagent and then heated at 120° over a period of 5—10 min the acetates of reducing sugars showed up as faint yellowish spots which were strongly fluorescent in ultraviolet light. Usually the chromatograms were dried for 5—10 min at 120° before spraying, but in the case of DMS this was found to be unnecessary.

c) p-*Anisidine hydrochloride.* After treatment as in b) to remove the acetate groups the chromatograms were sprayed with a solution of *p*-anisidine (2.3 g) in a mixture of concentrated hydrochloric acid (5 ml), ethanol (30 ml) and butanol (60 ml). After a few minutes heating at 120° the chromatograms were inspected by visible and ultraviolet light. The acetates of the 2,3,6-trimethyl ethers of glucose and mannose showed up as bright red-violet spots and glucose pentaacetates as light brown spots. The chromatograms were then rinsed with water.

d) *Sodium periodate*[9]. After treatment as in b) the chromatograms were dipped in 90 % aqueous acetone containing 10 % phthalic acid, dried and then sprayed with 0.2 % aqueous sodium metaperiodate. After ca 5 min they were sprayed with a reagent prepared by mixing equal parts of 5 % aqueous manganese sulphate and 5 % 4,4-methylenebis (N,N-dimethyl aniline) in 2 N aqueous formic acid. On drying in a current of hot air, white spots appeared against a blue-green background. The spots were unstable to prolonged heating and disappeared after a few days at room temperature. Insufficient acidification with phthalic acid was found to give rise to an uneven background, the colour partly appearing before the chromatograms were dried. Acetates of sugar alcohols and their glycosides were easily detected but in the case of acetylated alkyl glycosides and cyclitols the sensitivity was less satisfactory.

Acetylation of O-methyl sugars. a) *Acetic anhydride — pyridine.* A sample (1—2 mg) of the sugar was dissolved in acetic anhydride (30 μl) and pyridine (30 μl) in a capillary tube and the solution was heated to 100—105° for 5 min. After decomposition of unreacted acetic anhydride with a few drops of water the product was extracted with chloroform (0.2 ml) and the extract successively washed with dilute sulphuric acid, aqueous sodium bicarbonate and water and finally dried with magnesium sulphate. When applied to paper chromatograms 5—10 μl of this solution were put on the same spot.

b) *Acetic anhydride — sulphuric acid.* The sample (1—2 mg) dissolved in acetic anhydride (40 μl) containing 1 % v/v of sulphuric acid was heated to 100° for 1 min. The solution especially in the case of 2,3,6-tri-*O*-methyl D-mannose turned very dark. After cooling and adding 2 drops of pyridine the mixture was worked up as under a).

c) *Acetic anhydride — sodium acetate.* A mixture of the sample (1—2 mg), acetic anhydride (40 μl) and a few crystals of anhydrous sodium acetate was heated to 110° for 1 h. Pyridine (2 drops) was added after cooling and the product isolated as above.

Separation of anomeric o-cresyl D-galactopyranoside tetraacetates by counter-current extraction. β-pentaacetyl D-galactose (93 g) was added with stirring to a mixture of *o*-cresol (85 g) and anhydrous zinc chloride (5 g) kept at 120°. The temperature was then raised to 135—140° for 40 mins. After cooling the reaction mixture was dissolved in benzene and the solution was washed with 2 N aqueous sodium hydroxide and water, dried with sodium sulphate and concentrated to dryness. The residue, dissolved in dilute ethanol gave a crude crystalline mixture of the anomeric *o*-cresyl D-galactopyranoside tetraacetates.

The above acetate mixture was added to No. 1 of a series of six separating funnels each of which contained ethyl ether (300 ml) saturated with DMS containing 5 % v/v

of water. Successive 75 ml portions of DMS, containing 5 % of water and saturated with ether, were used for the extraction. At the stage at which DMS portion No. 1 had reached funnel No. 6, funnel No. 1 contained DMS portion No. 6, *etc.* The separation was followed by chromatograms of the ether phase. The chromatograms were run for about 5 mins in DMS-*iso*propyl ether. When ether phase No. 1 was sufficiently free from the β-anomer (after seven extractions) it was withdrawn and the funnel after being refilled with fresh ether phase placed as No. 7 in the series of funnels and the extraction continued. When possible the number of funnels was reduced one by one. When only one remained the contents of this were discarded. Altogether 18 portions of ether and 35 of DMS were required. The combined ether solutions were freed from DMS by washing with water, concentrated and the residue was recrystallised yielding crude *o*-cresyl α-D-galactopyranoside tetraacetate (43 g), m. p.* 80–90°, $[\alpha]_D$ +160° (chloroform, $c = 2$). By paper chromatography it was shown to contain traces of the β-anomer. The pure compound with m. p. 90–92° and $[\alpha]_D$ +176° was obtained by treating the crude product with 2 N aqueous sodium hydroxide (1 400 ml) at 100° for 16 h and reacetylating the hydrolysed material (yield 31 g).

The combined DMS solutions were diluted with water and extracted with ether. The ether solution was concentrated and the residue recrystallised giving pure *o*-cresyl β-D-galactopyranoside tetraacetate (22 g), m. p. 114–116°, $[\alpha]_D$ ±0.

The Preparation of Formate Esters of Polyols

LARS SELLEBY and BÖRJE WICKBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Treatment of polyols with formic acid and phosphorus pentoxide has been found to yield the fully formylated esters in a good yield. These formates show a strong tendency to crystallise, and should be suitable as derivatives. The formylation of D-glucose by the same method has been investigated by chromatographic methods.

A previous communication [1] on the paper chromatography of sugar acetates and related compounds, also described the separation of some fully formylated polyols. These compounds have not been reported earlier in the literature and as they crystallised with great ease and should be of potential value as derivatives, their synthesis was investigated more thoroughly. Their preparation is complicated by the fact that formic acid does not form a stable anhydride or stable halides except the fluoride.

The method first used for the formylation of polyols was simply a repeated treatment of the alcohols with anhydrous formic acid, and ethylene glycol diformate [2], glycerol triformate [3] and erythritol tetraformate [4] have been prepared in this way. Formic acid forms a fairly stable mixed anhydride with acetic acid [5] and from the reaction of this anhydride with erythritol Freudenberg and Jacob [6] obtained the corresponding tetraformate in 60 % yield. However, no definite products could be isolated when D-mannitol and D-glucitol were subjected to the same treatment.

Wolf *et al.*[7] found that a mean maximum of 2.3 hydroxyl groups per glucose unit were esterified when starch was treated with formic acid at room temperature. Attempts to remove water from the reaction mixture by distilling with benzene or by adding anhydrous calcium sulphate had almost no effect.

The reaction between D-glucose and formic acid has been investigated by Tarkow and Stamm [8] who found that formylation took place preferentially at the primary hydroxyl group, though the hydroxyl group in the 4-position would react also. Richtzenhain and Lidman [9] have shown that β- but not α-acetates of pyranosidic D-sugars react with formic acid at room temperature. The reaction products were not investigated further.

Experiments with some pentitols and hexitols showed that fully formylated products could be isolated in 20-30 % yield if the alcohols were repeatedly treated with anhydrous formic acid at 100°. Formyl fluoride [10] and the mixed anhydride from formic and acetic acid were tried as formylating agents but unfortunately both compounds decomposed in the presence of catalysts like sulphuric acid or pyridine. Preliminary attempts to formylate D-glucitol or D-glucose with formyl fluoride in dimethyl formamide solution failed and when D-glucose was allowed to react with the mixed anhydride, paper chromatograms indicated that the formates formed initially (17 h reaction time) reacted further, probably with the introduction of acetyl groups. As some experiments with transesterification reactions also were unsuccessful, the possibility of continuously removing the water formed in the reaction between formic acid and the alcohol component was considered.

Aqueous formic acid may be concentrated by azeotropic distillation with propyl formate [11] or various amines, [12,13] but attempts to use propyl formate in an esterification reaction gave negative results. According to Jones [14] a 99.5 % formic acid is obtained from dilute acid by adding phosphorus pentoxide with efficient cooling and subsequently distilling the mixture. A similar procedure is described by Schlesinger and Martin [15] who use boron trioxide as drying agent. Because of complex formation between boric acid and polyols, boron trioxide is probably less suitable for the preparation of formates; this was confirmed by experiments with D-mannitol. On the other hand addition of phosphorus pentoxide to a mixture of 99 % formic acid and D-mannitol was found to raise the yield of mannitol hexaformate considerably, and experiments were now made with D-mannitol, D-glucitol and galactitol to find the best conditions for the reaction (see Table 1). The formates of the pentitols and of *myo*-inositol were prepared under the conditions giving the highest yields of the hexitol derivatives.

All the polyol formates crystallised with unusual ease, even the xylitol derivative. Both xylitol and most of its previously known derivatives are notoriously difficult to obtain in a crystalline state. At room temperature the D-mannitol and galactitol derivatives were almost insoluble in common solvents and only slightly soluble (0.1-0.2 %) in dimethyl formamide or dimethyl sulphoxide. They were recrystallised from large volumes of boiling pyridine or acetonitrile. The low-melting formates are unfortunately rather unstable and after exposure for a few days to atmospheric moisture at room temperature they often gave a smell of formic acid. The analytical values for carbon and hydrogen were not entirely satisfactory and a more suitable method of analysis was found to be alkaline hydrolysis and titration. Paper chromatographic data for the compounds are given in a previous paper [1].

The formylation of D-glucose by the same method was investigated qualitatively by a chromatographic technique. To obtain mild reaction conditions a pyrophosphoric acid mixture with the average composition $H_3PO_4.2P_2O_5$ was substituted for the phosphorus pentoxide. On chromatograms run in a benzene - dimethyl sulphoxide system, the reaction product gave mainly 3 fairly fast spots. In addition to these there were also a few weak and very slow spots. When a sample was deformylated with ethanol containing catalytic amounts of sodium ethoxide, the product gave a spot only for glucose on paper

Table 1 *. Esterification of some hexitols with formic acid in the presence of phosphorus pentoxide.

Hexitol	HCOOH ml	P_2O_5 g	Time h	Yield of hexaformate %

»	10.0	2.5	20	91
D-Glucitol	10.0	2.2	1	17
»	10.0	2.2	2	37
»	10.0	2.2	3.5	51
»	10.0	2.2	20	71

* All yields refer to crude crystalline products. The phosphorus pentoxide was added over a period of 10 min to a solution of the hexitol (1.00 g) in 99 % formic acid with cooling in ice-water. The reaction was then allowed to proceed at room temperature.

chromatograms run in an ethyl acetate - acetic acid - water system. The formate mixture was then separated on a cellulose column using a light petroleum - benzene - dimethyl sulphoxide mixture as solvent. The fastest component (Fraction 1) was obtained in a chromatographically pure state but did not crystallise. No separation was observed with the following two components (Fraction 2), but this behaviour could be expected if they were an anomeric pair with a moderately slow interconversion.

Fraction 1 was acetylated with acetic anhydride and pyridine, but the product showed the same R_F value as the starting material. This indicated that Fraction 1 was penta-*O*-formyl D-glucose, either as a single compound or as an inseparable mixture. Acetylation of Fraction 2 in the same way gave a product which gave two spots both of which were much faster than those observed before acetylation. When sodium acetate was substituted for pyridine in the acetylation of Fraction 2 only the faster of the acetate spots was observed on paper chromatograms. This result indicates that Fraction 2 was most probably an anomeric mixture of D-glucose tetraformates with a free hydroxyl group on carbon atom 1. The β-acetate, assuming that this is as usual the anomer formed preferentially with sodium acetate as a catalyst, has, contrary to earlier experience [1], a higher R_F value than the α-anomer. Attempts to obtain the acetylated formates in a crystalline state after separation on a cellulose column were unsuccessful.

EXPERIMENTAL*

Formylation of polyols. The polyol (1 g) was dissolved in commercial *ca.* 99 % formic acid (10 ml), if necessary with slight warming and phosphorus pentoxide (2.2 g) was added gradually with shaking and efficient cooling in ice-water. At the beginning, the addition of phosphorus pentoxide caused a rather vigorous evolution of gas but the reaction soon subsided. After 10 min the cooling bath was removed and the reaction was allowed to proceed at room temperature for 20 h. If the formate crystallised during the reaction (this occurred with the D-mannitol, D-glucitol, galactitol, D-arabitol and erythritol derivatives) the mixture was stirred mechanically with crushed ice and water (10 ml) and the crystals were then filtered off as quickly as possible. If the formate was more soluble the formic acid solution was diluted with ice and water (15 ml), extracted with ethyl acetate and the extract washed with cold aqueous sodium bicarbonate and water. The ethyl acetate solution was dried over ignited magnesium sulphate and concentrated under reduced pressure yielding the crude formate. Because of the low stability of the formates the last procedure was later modified by adding pyridine (20 ml) to the formic acid solution before dilution with ice-water.

D-*Mannitol hexaformate* was obtained in 90 % yield. Recrystallisation from large volumes of boiling pyridine gave a product with m. p. 208—210° (decomp.). When it was recrystallised from acetonitrile the melting point fell, even when a small quantity of pyridine was added to the solvent. $[\alpha]_D^{22}$ +60° (dimethyl sulphoxide, c = 0.1). (Found: C 40.9; H 4.37; HCO_2 76.0. Calc. for $C_{12}H_{14}O_{12}$: C 41.2; H 4.03; HCO_2 77.2.)

Galactitol hexaformate was obtained in 90 % yield. It was slightly more soluble than the mannitol derivative and after recrystallisation from boiling pyridine it had m. p. 200—202° (decomp.). (Found: C 42.2; H 4.27; HCO_2 77.7. Calc. for $C_{12}H_{14}O_{12}$: C 41.2; H 4.03; HCO_2 77.2.)

D-*Glucitol hexaformate* was obtained in 76 % yield and was recrystallised from acetone. M. p. 164—166.5°, $[\alpha]_D^{22}$ +19° (dimethyl formamide, c = 2.0). (Found: C 41.0; H 4.03; HCO_2 78.7. Calc. for $C_{12}H_{14}O_{12}$: C 41.2; H 4.03; HCO_2 77.2.)

D-*Arabitol pentaformate* was obtained in 76 % yield. It was recrystallised from aqueous acetone. M. p. 142.5—143.5°, $[\alpha]_D^{22}$ +48° (dimethyl formamide, c = 2.0). (Found: HCO_2 76.8. Calc. for $C_{10}H_{12}O_{10}$: HCO_2 77.0.)

Ribitol pentaformate was isolated by diluting the reaction mixture with pyridine (20 ml) and ice-water (15 ml) and extracting with ethyl acetate as described above. The crude product crystallised from chloroform — ethyl ether in 68 % yield. It was recrystallised from aqueous acetone, m. p. 63—64°. (Found: HCO_2 75.7. Calc. for $C_{10}H_{12}O_{10}$: HCO_2 77.0.)

Xylitol pentaformate. Part of the formate (0.48 g) crystallised when the reaction mixture was diluted with ice-water (15 ml). Immediately after filtration the mother liquors were combined with the aqueous washings and extracted with ethyl acetate. The extract phase was washed, dried and concentrated. The residue (0.47 g) was crystallised from aqueous methanol giving a further quantity of formate (0.15 g). The total yield of the crude product was thus only 35 % of theory. The m. p., after recrystallising from water, was 88—90.5°. (Found: HCO_2 76.2. Calc. for $C_{10}H_{12}O_{10}$: HCO_2 77.0.)

Erythritol tetraformate was obtained in 93 % yield and was recrystallised from acetone. M. p. 155.5—158°. (Found: HCO_2 76.7. Calc. for $C_8H_{10}O_8$: HCO_2 76.9.)

(From a solution of erythritol (1 g) in formic acid (10 ml) the tetraformate slowly crystallised in 44 % yield.)

myo-*Inositol hexaformate* was isolated as described for adonitol pentaformate. The syrup remaining after concentration of the ethyl acetate extract was dissolved in acetone and the solution was saturated with ethyl ether. The crude formate crystallised overnight. Yield 41 %. After recrystallisation from aqueous acetone it had m. p. 183—185°. (Found: HCO_2 77.5. Calc. for $C_{12}H_{12}O_{12}$: HCO_2 77.6.)

Determination of ester groups by saponification. The sample (ca 100 mg) was dissolved in 0.25 N ethanolic potassium hydroxide solution (10 ml). After 24 h an excess of 0.25 M hydrochloric acid was added, and after a few hours the acid was back-titrated with 0.1 M sodium hydroxide using phenolphthalein as indicator. A blank was run simultaneously.

* All melting points are corrected.

Formylation of D-*glucose.* The pyrophosphoric acid used in the formylation of glucose had the average composition $H_3PO_4 . 2P_2O_5$ and was prepared by dropping 85 % phosphoric acid onto phosphorus pentoxide with vigorous shaking. It formed granules 2 – 4 mm in diameter.

Pyrophosphoric acid (2.5 g) was added to a solution of D-glucose (1 g) in 99 % formic acid (10 ml) with cooling in ice-water and mechanical stirring. After all the granules had dissolved the mixture was left at room temperature overnight. A slight evolution of gas was observed. The solution was then stirred into ice-water and the mixture was extracted with ethyl acetate (3 × 25 ml). The extract was washed with aqueous sodium bicarbonate and water, dried over magnesium sulphate and concentrated at 15 mm pressure and 35 – 40° bath temperature. The yield of syrup was 0.55 g (31 % of the theoretical yield of pentaformate).

The product was chromatographed on paper using the technique previously described[1]. Before adding the sample the chromatogram was impregnated with a 25 % v/v solution of dimethyl sulphoxide in toluene, blotted and dried for 2 min at 60°. After a second impregnation the toluene was allowed to evaporate at room temperature and the sample was put on the paper as a 3 % solution in chloroform. Benzene containing 4 % v/v of dimethyl sulphoxide and 1 % v/v of water (Solvent 1) or benzene – light petroleum (3:1, v/v) with 4 % v/v of dimethyl sulphoxide and 1 % v/v of water added (Solvent 2) were used as developing solutions. The spots were detected by spraying the chromatograms with aqueous silver nitrate and ethanolic sodium hydroxide. The main spots had R_F 0.45, 0.25 and 0.16 (Solvent 1) and R_F 0.13, 0.05 and 0.00 (Solvent 2).

The main part of the syrup (500 mg) was dissolved in a 4:1, v/v benzene – light petroleum mixture (25 ml) by adding the minimum quantity of dimethyl sulphoxide. The solution was added to the top of a cellulose column (36 × 2.2 cm) which had been prewashed with benzene – light petroleum (4:1, v/v) containing 5 % v/v of dimethyl sulphoxide. The column was then irrigated with the same solvent. The first part of the eluate gave a spot for the fastest component only. It was concentrated and the residue was dissolved in ethyl acetate. The solution was washed repeatedly with water, dried and concentrated yielding Fraction 1 as a syrup (110 mg). After a small empty fraction the next two compounds appeared simultaneously in the eluate. The mixture was isolated as before yielding Fraction 2 (140 mg).

Samples of Fraction 1 and 2 were acetylated by heating to 100° for 5 min with acetic anhydride and pyridine, and the products were run on paper chromatograms. According to these Fraction 1 had been recovered unchanged, but Fraction 2 had been acetylated to give two spots with R_F 0.77 and 0.65 in Solvent 1 and R_F 0.47 and 0.28 in Solvent 2. Fraction 2 when heated with acetic anhydride and sodium acetate at 100° for 1 h gave a product which showed mainly a single spot with R_F 0.77 in Solvent 1 and R_F 0.47 in Solvent 2.

A second lot of D-glucose (1.5 g) was formylated as before using formic acid (15 ml) and pyrophosphoric acid (3.8 g). After standing overnight the reaction mixture was stirred into pyridine (50 ml), ethyl acetate was added and the upper phase was washed repeatedly with water and aqueous sodium bicarbonate. It was dried and concentrated under reduced pressure to give a syrup (2.6 g) which still contained traces of pyridine. The product was shown by paper chromatography to be similar to that obtained in the first formylation, but the fastest spot was a little fainter. Treatment with acetic anhydride and sodium acetate (1 h at 100°) yielded a syrup which gave spots with R_F 0.77, 0.65 and 0.45 (Solvent 1) and R_F 0.47, 0.28 and 0.13 (Solvent 2).

Part of the acetylated formate mixture (480 mg) was separated on a cellulose column as before, using Solvent 2 as eluant. The two fastest components were obtained in separate fractions which were worked up in the usual way. However, these preparations did not crystallise. As only a part (160 mg) of the material added to the column was recovered in this way, the column was afterwards stripped with ethyl acetate. The washings were extracted with water to remove dimethyl sulphoxide, dried and concentrated. The residue (270 mg), which gave rather faint spots with R_F 0.65 and 0.45 on chromatograms run in Solvent 1, was deformylated in cold absolute ethanol containing catalytic amounts of sodium ethoxide. To prevent the hydrolysis of any orthoesters, the mixture was afterwards diluted with a small quantity of water and neutralised by saturation with carbon dioxide. On chromatograms run in ethyl acetate – acetic acid – water (3:1:1) the deformylated product gave a single spot, indistinguishable from that of D-glucose. This was also the only product detected on paper chromatograms after deformylation in the same way of a freshly prepared D-glucose formate mixture.

The Heats of Hydrolysis of Some Alkyl Acetates

INGEMAR WADSÖ

Thermochemistry Laboratory, University of Lund, Sweden

The heats of hydrolysis of some alkyl acetates have been determined at 25°C. For the idealized, isothermal hydrolysis reactions

$$ROAc(l) + H_2O(l) \rightarrow ROH(l) + HOAc(l)$$

the enthalpy changes were found as follows:
0.89 ± 0.04 kcal/mole for R = Et; 0.80 ± 0.05 kcal/mole for R = *n*-Bu; 0.54 ± 0.05 kcal/mole for R = *i*-Pr. These data have been compared with the corresponding values for the hydrolysis of thiolesters.

In previous papers the heats of hydrolysis of thiolacetic acid [1] and of some alkyl thiol acetates [2] have been reported. In continuing the study of the thermochemistry of acyl derivatives and transacylation processes of biochemical interest it was felt important to determine heats of hydrolysis for some simple alkyl acetates.

EXPERIMENTAL

Materials. The esters were commercially available preparations. They were purified by distillation through a 10-plate column. Purities were found to be 99.9 % or better as judged by measurements of equivalent weights. These were determined after alkaline hydrolysis by titration of acetic acid. The hydrolysis was carried out in alcohol—water solution containing 2 moles of NaOH per mole of ester. After 12 h the sample was titrated potentiometrically with 0.1 N HCl.

Table 1. Equivalent weight, density and refractive index for the esters ROAc.

R	Equivalent weight		d_4^{25}	n_D^{25}
	Found	Theoretical		
Et	88.15	88.10	0.8950	1.3707
n-Bu	116.16	116.16	0.8758	1.3928
i-Pr	102.20	102.13	0.8709	1.3757

Auxiliary substances. Alcohols used for heats of solution measurements were thoroughly dried and distilled. Acetic acid was purified by freezing out 4 times. Its purity was found to be 100.0 % (potentiometric titration with NaOH).

Apparatus. The reactions were carried out in an isothermal calorimeter, which will be described in detail elsewhere [3]. The calorimeter consisted of a steel reaction vessel with stirrer, heating element, and a thermistor (Stantel U 236120) for measuring the temperature changes.

Calibration. The heat capacity of the calorimeter was determined electrically by passing a known current for a given time (240—315 sec) through the heating element. The calibrations were carried out on the system after the hydrolysis. In the runs, corrections were made for the small differences in heat capacity of the ampoule and its content.

Heat of reaction measurements. The calorimeter was charged with 90 ml of 0.8 N sodium hydroxide solution in water-ethanol (2:3). The sealed glass ampoule contained about 3 mmoles of ester (alcohol, acetic acid or water). The reaction was completed within 5 min, the duration of the reaction period was 8 min *. The initial and final thermistor resistance (R_i and R_f, respectively) could therefore be obtained graphically without introducing significant errors.

Corrections to standard states. The ideal isothermal hydrolysis reaction V is obtained from eqns. I to IV, corresponding to the reactions taking place under actual experimental conditions.

I	$ROAc(l) + H_2O(soln) \rightarrow ROH(soln) + HOAc(soln)$	ΔH_1
II	$ROH(l) \rightarrow ROH(soln)$	ΔH_2
III	$HOAc(l) \rightarrow HOAc(soln)$	ΔH_3
IV	$H_2O(l) \rightarrow H_2O(soln)$	ΔH_4
V	$ROAc(l) + H_2O(l) \rightarrow ROH(l) + HOAc(l)$	$\Delta H°$
	$\Delta H° = \Delta H_1 - \Delta H_2 - \Delta H_3 + \Delta H_4$	

Units of measurement. The results of the calorimetry experiments are expressed in terms of the defined calorie equal to 4.1840 abs. joules and refer to the isothermal process at 25° and to the true mass.

The molecular weights were computed from the 1951 table of international atomic weights [4].

RESULTS

The experimental results are summarised in Tables 2 to 5. Table 2 gives the results of a series of calibration experiments. The following symbols have been used:

q input of electrical energy

$\log R_i/R_f$ the expression proportional to the temperature change; R_i and R_f are the thermistor resistance values at the start and the end, respectively, of the main period

ε the heat capacity of the calorimetric system in calories per unit of $\log R_i/R_f$

Table 2. Calibration experiments.

q, cal	$10^4 \times \log R_i/R_f$	$\varepsilon \times 10^{-2}$
37.28	64.42	57.87
37.25	64.34	57.90
48.85	84.63	57.72
41.89	72.45	57.82
		57.83 ± 0.04 **

* Attempts to determine the heat of hydrolysis of *t*-BuOAc with this apparatus failed due to the slowness of the hydrolysis.

** All the uncertainties are given as the standard deviation of the mean.

In Table 3, the first column identifies R in ROAc, the second gives the amount of ester hydrolyzed, the fourth gives the amount of heat evolved during the experiment, and the last column gives the enthalpy change.

i-Pr	10.57	−0.31	11.61	0.19	−0.54 ± 0.05

DISCUSSION

Previously the heat of hydrolysis of EtOAc has been determined by Berenger-Calvet [5]. The value obtained by her is in resonably good agreement with that obtained in the present work. No other calorimetric determination of heats of hydrolysis of alkyl acetates has been found in the literature.

Unfortunately, there is an appreciable uncertainty in the heat of formation value for acetic acid [1]. Therefore, heat of hydrolysis values derived from heat of formation data cannot be calculated with the desired accuracy at the present time.

Table 6. Comparison between values of heats of hydrolysis of ROAc and RSAc in the liquid state.

R	$\Delta H°$, kcal/mole		Difference
	ROAc	RSAc	
Et	0.89	−0.95	1.84
n-Bu	0.80	−1.09	1.89
i-Pr	0.54	−1.39	1.93

As has been stated before [2], there is only a small difference between the standard heats of hydrolysis for alkyl thiolesters and alkyl O-esters in the liquid state. Table 6 shows that this difference for Et, *n*-Bu and *i*-Pr amounts to less than 2 kcal/mole. However, if the reactions are compared in the gaseous state (Table 7) there is a much greater difference, depending on the high heats of vaporisation of alcohols compared with those of the corresponding thiols. The heats of vaporisation of esters, alcohols and thiols were calculated from the equations given by Klages [6]. The heat of vaporisation of acetic acid [7] (monomeric vapor) and water [8] were taken to 12.5 and 10.5 kcal/mole, respectively.

Table 7. Comparison between heats of hydrolysis of ROAc and RSAc in the gaseous state.

R	$\Delta H°$, kcal/mole		Difference
	ROAc	RSAc	
Et	5.0	−1.7	6.7
n-Bu	5.0	−1.5	6.5
i-Pr	4.4	−2.0	6.4

The Heats of Aminolysis of *n*-Butyl Thiolacetate and Acetic Anhydride

INGEMAR WADSÖ

Thermochemistry Laboratory, University of Lund, Sweden

The heat of aminolysis of *n*-butyl thiolacetate by *n*-butylamine was determined at 25°C. For the idealized, isothermal aminolysis reaction

n-BuSAc (l) + *n*-$BuNH_2$ (l) → *n*-BuSH (l) + *n*-BuNHAc (l)

the enthalpy change was found to be -13.7 ± 0.2 kcal/mole. The heat of aminolysis of acetic anhydride was also determined and from the obtained value and known values of the heats of hydrolysis of acetic anhydride and *n*-butyl thiolacetate a value of -13.80 ± 0.15 kcal/mole was derived for the heat of aminolysis of *n*-butyl thiolacetate.

The heat of hydrolysis of *n*-butyl acetamide was calculated to be 12.69 ± 0.10 kcal/mole.

Recently much interest has been directed towards S-acyl compounds as acetylating agents in biochemical systems. It is known that a thiolester of an aminoacid easily forms a peptide by aminolysis [1]. In connection with previous work [2] on energy relationships of S-acylated compounds it seemed of interest to determine the enthalpy change of the reaction

$$RCOSR' + R''NH_2 \longrightarrow R'SH + RCONHR''$$

The reaction can be looked upon as an model for peptide formation, where RCOSR' corresponds to a S-acyl activated amino acid and $R''NH_2$ to an amino acid.

In the simplified system investigated here, R was methyl and R', R'' were *n*-butyl. Thus the thiol ester was *n*-BuSAc and the amine was *n*-$BuNH_2$. However, the value obtained might be significantly in error. It was therefore checked by an indirect determination, by measuring the heat of aminolysis of acetic anhydride and combining this with known values for the heats of hydrolysis of Ac_2O and *n*-BuSAc, from which the heat of aminolysis of *n*-BuSAc could then be calculated.

PART I. AMINOLYSIS OF *n*-BUTYL THIOLACETATE

Experimental

Materials. *n*-BuSAc was prepared and purified according to Ref.[2] The equivalent weight was determined by iodometric titration of the thiol formed by alkaline hydrolysis [2].

The equivalent weight indicated 100.0 % purity. $n^{25}_D = 1.4584$ $d_4^{25} = 0.9385$. n-$BuNH_2$ (purum grade) was dried by refluxing with NaOH-pellets. The amine was distilled through an efficient column and a fraction boiling at 76.2°C (760 mm Hg) was collected. Potentiometric titration gave an equivalent weight corresponding to 99.6 % purity.

Auxiliary substances. n-BuSH was freshly distilled and its purity as checked by iodometric titration was found to be 100.0 %. n-BuNHAc was prepared from n-BuSAc and n-$BuNH_2$. The synthesis and physical data of the substance are described below.

Chemistry of the process. In order to secure a rapid reaction and to avoid side reactions the aminolysis was carried out in butyl amine. However, the thiol formed was extremely rapidly oxidised by air in the alkaline medium. The rate of oxidation was studied by exposing to air solutions of n-BuSH in n-$BuNH_2$. After a given time the solution (5 ml of a 3 % solution in a 100 ml conical flask) was cooled with dry ice, acidified with glacial acetic acid and titrated with iodine. The experiments showed that *ca.* 10 % of the thiol was oxidised within 30 min.

In order to check that the reaction products of the aminolysis reaction were as expected, the following synthesis was carried out. 20.0 g of n-BuSAc were added rapidly to 150 ml of n-$BuNH_2$. After 30 min at room temperature the excess of amine and the thiol formed were driven off by distillation at atmospheric pressure. The presence of thiol in the distillate was confirmed by the nitroprusside reaction. The remaining product was distilled at reduced pressure. n-BuNHAc was collected at 140–141°C and 21 mm Hg. Yield 16.6 g or 95 %. After further distillation the physical data of the substance were in good agreement with those given in the literature [3]. B. p. 230°C at 760 mm Hg, $n_D^{25} = 1.4391$, $d_4^{25} = 0.8951$.

Apparatus. The reactions were carried out in an isothermal calorimeter which will be described in a forthcoming paper [4].

Calibration. The heat capacity of the system was determined electrically by passing a known current for a known time (20 min) through the heating element. Thermal leakage was calculated by the Regnault-Pfaundler's method. The calibration experiments was carried out after the aminolysis experiments. In the runs, corrections were made for the small differences in heat capacity of the ampoule and its content.

Procedure. As stated above, it was not possible to avoid air oxidation of the thiol formed during an experiment. In order to suppress the influence of this exothermic reaction a small amount of butanethiol was added to the solution prior to the reaction. The heat of oxidation increased much less than expected from the increase in thiol concentration due to aminolysis. However, a significant error was introduced, which could be seen from the values of the thermal leakage constant, K. If thiol was added prior to the reaction the value of K was only 10 % lower than in calibration experiments whereas the value of K was found to be negative when butanethiol was not added.

The calorimeter was charged with 90 ml of n-$BuNH_2$ to which 9 mmoles of n-BuSH were added. The sealed glass ampoule contained *ca.* 3 mmoles of n-BuSAc. After equilibration the reaction was started by breaking the ampoule. The duration of the reaction period was 45 min, so that the thermal leakage had to be calculated by the Regnault-Pfaundler method. As the K-values obtained from the runs were abnormally low, the mean of those from the calibration experiments was used in the calculations. The small systematic error introduced by the oxidation of the thiol formed during the aminolysis cancels out to a great extent by the error in the heat of solution experiment of butanethiol — the only difference between the two series of experiments being the slow appearance of thiol in the aminolysis and the momentary mixing of thiol and solvent in the solution experiment.

Heat of solution measurements. n-BuSH: In order to obtain a close similarity between the solution measurements and the aminolysis experiments, the reactino period was kept at 45 min. n-BuNHAc: The reaction period was 5 min and R_i and R_f were obtained graphically.

Corrections to standard state. The idealised aminolysis reaction IV is obtained from reactions I to III, which correspond to the actual experiments.

I	n-$BuNH_2$ (l) + n-BuSAc (l) → n-BuSH (soln) + n-BuNHAc (soln)	ΔH_1
II	n-BuSH (l) → n-BuSH (soln)	ΔH_2
III	n-BuNHAc (l) → n-BuNHAc (soln)	ΔH_3
IV	n-$BuNH_2$ (l) + n-BuSAc (l) → n-BuSH (l) + n-BuNHAc (l)	$\Delta H°_4$

$$\Delta H°_4 = \Delta H_1 - \Delta H_2 - \Delta H_3 \quad (1)$$

Units of measurement. The results of the calorimetric experiments are expressed in terms of the defined calorie equal to 4.1840 abs. joules and refer to the isothermal process at 25°C and to the true mass. The molecular weights were computed from the 1951 Table of international atomic weights [5].

Results

The experimental results are summarised in Tables 1 to 3. In Table 1 the results from the calibration experiments are given. The first column shows the input of electrical energy, the second the expression proportional to the temperature increase and the third the value of the heat capacity in calories per unit of log (R_i/R_f). Uncertainties are given as the standard deviation of the mean.

Table 1. Calibration experiments.

	3.105	13.05	4.57		1.47
				Mean	1.42 ± 0.04

From eqn. (1) ΔH_4^0 is calculated to be 13.73 ± 0.09 kcal/mole. However, uncertainty in the K-value used is estimated to be 2 %. This will cause an uncertainty in ΔH_1 amounting to 0.1 kcal/mole. Therefore, the best value that can be obtained from these experiments is believed to be

$$\Delta H_4^0 = -13.7 \pm 0.2 \text{ kcal/mole.}$$

PART II. AMINOLYSIS OF ACETIC ANHYDRIDE

Materials. Ac_2O was freshly distilled immediately before the experiments. Its equivalent weight (determined by potentiometric titration of the acetic acid formed by hydrolysis) indicated 99.9 % purity. n-$BuNH_2$ was treated as given in part I.

Auxiliary substances. HOAc was purified by freezing out 4 times. The equivalent weight corresponded to 100.0 % purity. n-BuNHAc was prepared from Ac_2O and n-$BuNH_2$. Details of the method of synthesis and physical data of the substance are given below. Benzene, free from thiophene was dried with KOH-pellets and distilled.

Chemistry of the process. Ac_2O reacts vigorously with pure n-$BuNH_2$. In the calorimetric experiments the reaction rate was moderated by performing the aminolysis in benzene solution. The reaction products were soluble in this medium at the concentrations used. To confirm that n-BuNHAc was obtained in the reaction, the following experiment was carried out.

0.3 mole of Ac_2O was added rapidly to a solution of 1.2 moles of n-$BuNH_2$ in 150 ml benzene. The temperature of the mixture was kept below 30°C by cooling with ice water. After *ca.* 10 min the benzene and the excess of amine was distilled off. To the residue, 50 ml of water were added and the solution was extracted three times with ether. The product was dried with anhydrous $CaCl_2$ and the ether distilled off. The residue was distilled under reduced pressure through an efficient column. 28.6 g (83 %) n-BuNHAc was collected at 92.5°C (1 mm Hg). The physical data of the substance were in good agreement with those given in the literature [3]. B.p. 230°C at 760 mm Hg, $n_D^{25} = 1.4393$, $d_4^{25} = 0.8950$.

Apparatus. See Part I.

Calibration experiments. The calorimeter was calibrated as in Part I, except that the heat was supplied for 4 min only. The main period lasted for 7 min and R_i and R_f were obtained graphically.

Correction to standard state. The idealized aminolysis reaction IX is obtained from reactions V to VIII which correspond to the reactions taken place under actual experimental conditions.

V	Ac_2O (l) + n-$BuNH_2$ (soln) → n-BuNHAc (soln) + HOAc (soln)	ΔH_5
VI	HOAc (l) → HOAc (soln)	ΔH_6
VII	n-BuNHAc (l) → n-BuNHAc (soln)	ΔH_7
VIII	n-$BuNH_2$ (l) → n-$BuNH_2$ (soln)	ΔH_8
IX	Ac_2O (l) + n-$BuNH_2$ (l) → n-BuNHAc (l) + HOAc (l)	ΔH_9^0

$$\Delta H_9^0 = \Delta H_5 - \Delta H_6 - \Delta H_7 + \Delta H_8 \quad (2)$$

The experimental results are summarized in Tables 4 to 6.

X *n*-BuSAc (l) + H_2O (l) → *n*-BuSH (l) + HOAc (l) ΔH_{10}^0

XI Ac_2O (l) + H_2O (l) → 2 HOAc (l) ΔH_{11}^0

IV *n*-BuSAc (l) + *n*-$BuNH_2$ (l) → *n*-BuNHAc (l) + *n*-BuSH (l) ΔH_4^0

$$\Delta H_4^0 = \Delta H_9^0 + \Delta H_{10}^0 - \Delta H_{11}^0 \quad (3)$$

Thus we find ΔH_4^0 to be −13.82 ± 0.11 kcal/mole. This value is in good agreement with the value given in Part I. Taken into consideration the more favourable experimental conditions of the indirect determination $\Delta H_4^0 =$ −13.80 ± 0.15 kcal/mole seems at present to be the best value that can be given.

Calculation of the heat of hydrolysis of *n*-BuNHAc

It is well known that N-alkyl acetamides do not easily hydrolyze at room temperature. It is therefore difficult to obtain a good value for the heat of hydrolysis from direct measurements. However, by subtracting reaction IX from reaction XI we get the idealized hydrolysis reaction XII

XII $\quad n\text{-BuNHAc(l)} + H_2O(l) \rightarrow n\text{-BuNH}_2(l) + HOAc(l) \qquad \Delta H_{12}^0$

$$\Delta H_{12}^0 = \Delta H_{11}^0 - \Delta H_9^0 \qquad (4)$$

Thus the heat of hydrolysis of *n*-BuNHAc is calculated to be 12.73 ± 0.10 kcal/mole.

The Fractionation of Rat Liver Supernatant by Salt Gradient Elution from Triethylaminoethyl Cellulose Columns

JOHN GLOMSET

Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

Gradient elution from triethylaminoethyl cellulose columns has been employed for the separation of fractions from rat liver containing proteins and nucleotides. The method has proved to be useful for the chromatographic separation of each of these types of compound.

The experiments of Sober and Peterson and others [1-3] successfully employing acidic and basic cellulose derivatives for the chromatographic separation of proteins have aroused a great deal of interest. Many papers describing the utilization of various types of cellulose ion exchange columns have appeared in the literature. Not infrequently columns of DEAE * cellulose prepared according to Peterson and Sober [4] have been employed. Recently Porath [5] has described the preparation of triethylaminoethyl cellulose, and reports of the successful use of this material have appeared [6,7]. In an earlier paper [8] the present author described some experiments utilizing stepwise elution chromatography with columns of TEAE cellulose. The main object of these experiments was to separate and purify phosphoproteins present in the supernatant fraction of rat liver as obtained by centrifugation according to Schneider and Hogeboom [9]. In the present paper the use of a simple saline gradient at constant pH for the fractionation of the same starting material will be described. To further characterize the salt gradient system employed here as a preliminary to later experiments nucleotide extracts have also been chromatographed.

EXPERIMENTAL

Rat liver supernatant was prepared as before [8] except that 0.01 M sodium EDTA, pH 7.4 was included in the initial perfusion saline and omitted from the sucrose. In experiments in which the whole supernatant fraction was to be chromatographed the material was applied to the column immediately after the final centrifugation. When the

* The following abbreviations will be used: DEAE cellulose, diethylaminoethyl cellulose; TEAE cellulose, triethylaminoethyl cellulose; EDTA, ethylenediaminetetraacetic acid; Tris, Tris (hydroxymethyl)-aminomethane; TCA, trichloroacetic acid; ATP, adenosine triphosphate; ADP, adenosinediphosphate.

acetone precipitated proteins of the supernatant were to be chromatographed the pH of the supernatant was first adjusted to 6.5 with 0.1 N acetic acid. Analytical grade acetone which had been pre-cooled to −14°C was then added dropwise with continuous stirring in an alcohol-dry ice bath at −14°C. Precipitates were collected by centrifugation in refrigerated centrifuges at −14°C after addition of acetone to concentrations of 50 and 70 % by volume. The precipitates were washed twice, dissolved in 0.01 N Tris-HCl, pH 7.4, combined, and immediately applied to the ion exchange column.

In one type of experiment a mixture of radioactive mitochondrial nucleotides was prepared in the course of the preparation of the supernatant fraction. The method described by Beyer *et al.*[10] was used except that the sucrose did not contain EDTA and the radioactive phosphate was added to a sucrose suspension of the washed mitochondria. The reaction was stopped after 10 min. at 0°C by the addition of TCA.

TEAE was prepared from DEAE according to Porath [5]. It contained 24.3 mg N per g dry powder. It was used in the chloride form after equilibration with 0.01 N Tris-Cl buffer, pH 7.4. All chromatographic separations were performed at +4°C. The gradient system comprised two steps. The first extended from 0 to 0.2 N NaCl. The second extended from 0.2 to 1.0 N NaCl. The entire system was buffered throughout with 0.01 N Tris-HCl, pH 7.4. The gradients were established as described by Boman [11]. A beaker was used as the mixing flask, and an Erlenmeyer flask of the same volume as the reservoir flask. All that was required in addition was a magnetic stirrer and some plastic tubing. In the different experiments two flask sizes were used, 500 ml or 1 000 ml, depending on whether the column contained 15 or 35 g of the ion exchanger, respectively.

The effluent from the columns was collected in 3−5 ml portions. The chromatographic separation was followed by spectrophotometric readings in the Beckman model DU apparatus, employing cuvettes of 1 cm light path at 260 and 280 mμ. Radioactivity determinations were made on aliquots which had been dried on glass planchets. The chloride content of the effluent was followed by a modification of the method of Bergman and Senik [12] worked out by the Analytical laboratory of AB Pharmacia, Uppsala.

RESULTS AND DISCUSSION

Three different types of experiment were performed. In the first the fresh supernatant, obtained directly after centrifugation of the liver homogenate, was immediately filtered into a column containing 35 g of TEAE, previously equilibrated with 0.01 N Tris-HCl, pH 7.4. After washing the column with the same buffer elution was carried out as described in the Experimental section. Fig. 1 shows the type of chromatogram obtained with this procedure. The first peak consists of compounds not adsorbed to the ion exchanger under these conditions. The succeeding peaks comprise both proteins and nucleotides as will be seen by comparing the relative absorption at 260 and 280 mμ in Fig. 1 with that of Fig. 3. The last peak in Fig. 1 contains most of the RNA of the supernatant. As noted previously [8], however, a significant percentage of the RNA of the supernatant (about 20 %) cannot be eluted from the column under these conditions nor by increasing the salt concentration or reducing the pH. It can be removed, however, using 1 % NaOH. With these reservations this method should be a convenient way to prepare soluble RNA from rat liver homogenates. A cardinal advantage of the method is that no preliminary precipitation steps or lengthy dialysis are needed.

In order to obtain a clearer conception of the behaviour of nucleotide material when chromatographed by salt gradient elution using columns of TEAE cellulose a second type of experiment was performed. Here, various types of nucleotide extracts were chromatographed. Fig. 2 shows a chromatogram of a TCA extract of rat liver mitochondria.

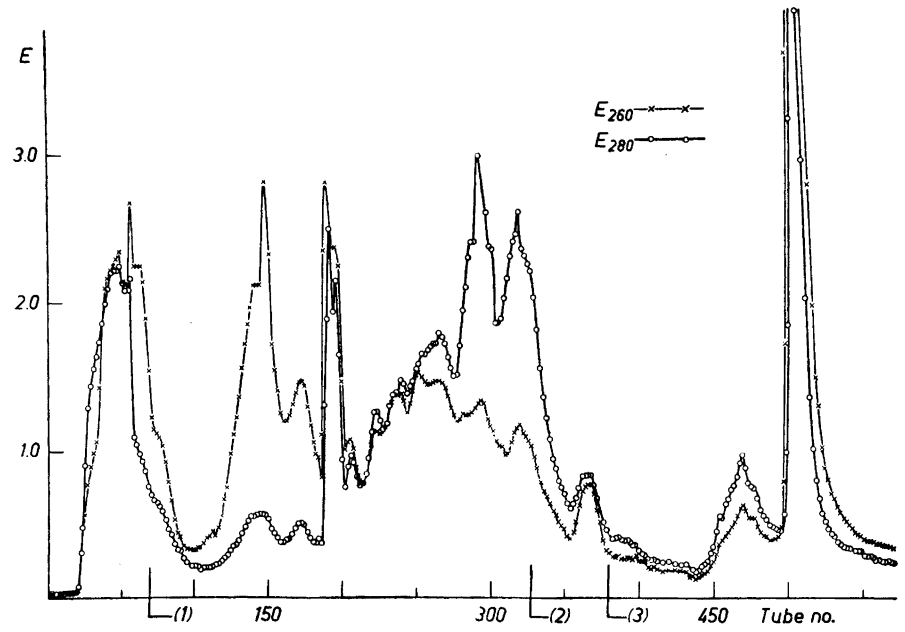

Fig. 1. Chromatogram of whole rat liver supernatant on TEAE cellulose. 4 livers used. The column contained 35 g TEAE cellulose. 1 000 ml vessels used to obtain the gradient. The first marker on the abscissa indicates the beginning of the first step of the gradient. From the second to the third marker, 0.2 N NaCl in 0.01 N Tris-HCl, pH 7.4 was filtered through the column. The third marker indicates the beginning of the second step of the gradient.

It will be seen that a satisfactory fractionation has been obtained, comparable with that obtained earlier [10] using a formic acid gradient system on Dowex 1. It was of primary interest for subsequent experiments (to be published) to determine the positions of inorganic phosphate, ADP, and ATP on the chromatogram. These are peaks IV, VIII, and IX, respectivly, and are the only radioactive peaks obtained under the conditions of the experiment. The successful use of TEAE cellulose for nucleotide chromatography would appear to be of value as a complement to those ion exchange methods already available, especially with compounds containing labile groups which might otherwise be destroyed by the lower pHs generally used in conventional nucleotide chromatography.

The third type of experiment was performed with acetone-precipitated liver supernatant protein. The precipitation was performed as quickly as possible to reduce the risk of denaturation. The combined precipitates were dissolved in buffer and chromatographed in the same way as in Fig. 1 without, however, having attempted to remove the small amount of residual acetone present. This explains the absorption properties of the first peak in Fig. 3, a typical chromatogram from this type of experiment.

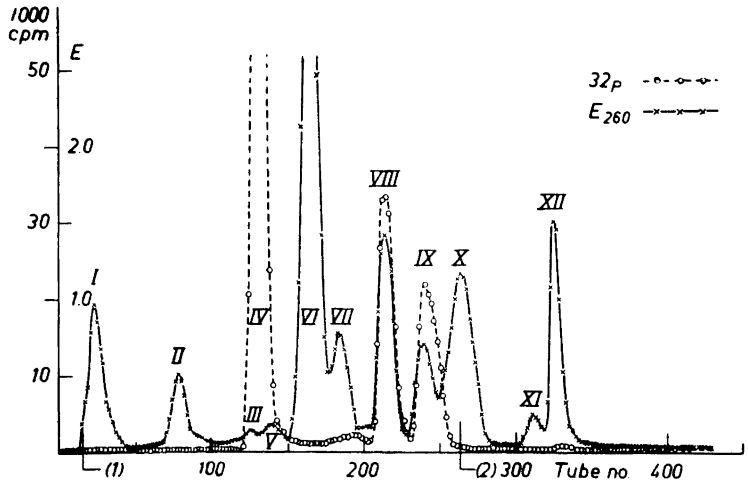

Fig. 2. Chromatogram of radioactive TCA extract of rat liver mitochondria on TEAE cellulose. Mitochondria from 4 rat livers used. 15 g of TEAE cellulose. 500 ml gradient vessels. The first and second markers on the abscissa indicate the beginning of steps 1 and 2 of the gradient, respectively.

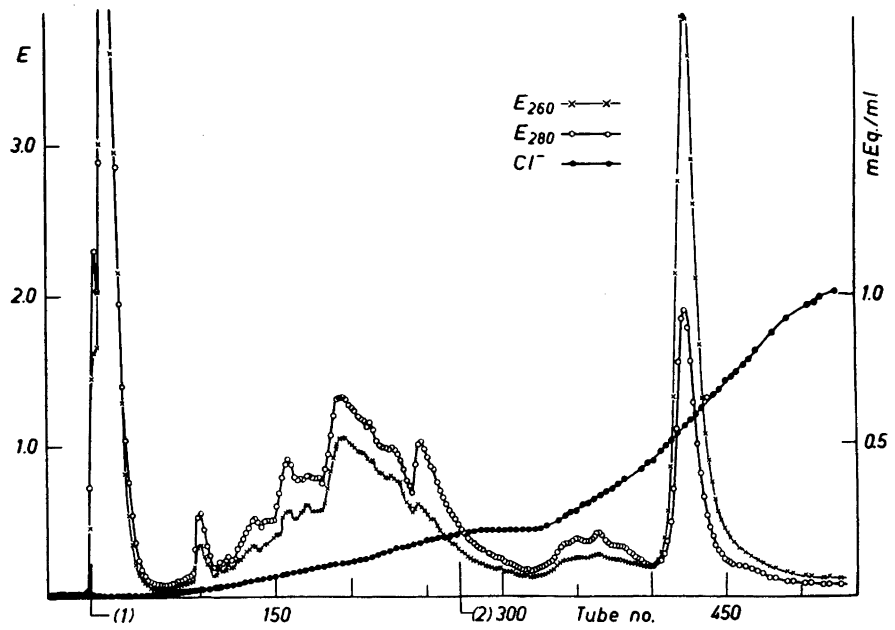

Fig. 3. Chromatogram of acetone-precipitated protein of rat liver supernatant on TEAE cellulose. 4 livers. 35 g of TEAE cellulose. 1 000 ml gradient vessels. The first and second markers on the abscissa indicate the beginning of steps 1 and 2 of the gradient, respectively. The chloride concentration in the effluent in mequiv. per ml may be determined from the ordinate at the right.

In this experiment the chloride concentration of the effluent was followed in order to indicate the nature of the gradient obtained. It will be seen that the nucleotide material present in the experiment reproduced in Fig. 1 has been removed and that the only two peaks with a high relative absorption at 260 mμ are the first and last, respectively. The first owes its absorption properties to the acetone present, while the last peak, as in Fig. 1, contains RNA. Although the chromatogram shown in Fig. 3 is of interest in that it gives a picture of the normal pattern of soluble rat liver proteins (and as such may profitably be compared with the electropherograms of soluble liver protein fractions obtained previously [8]) the identity of the remaining peaks has not been investigated further at this time. The object of the present experiments has been to study the chromatographic behaviour of nucleotide extracts and the soluble proteins of rat liver on gradient elution from columns of TEAE cellulose. The use of this method for the separation of the phosphoproteins of rat liver supernatant will be described in a subsequent paper.

Acknowledgments. This investigation was supported by a grant from the *Medical Faculty of the University of Uppsala.* The author is indebted to Dr. J. Porath for a generous gift of DEAE cellulose. He is also grateful to Dr. W. Kirsten for making available the chloride determination method.

Formation of Trehalose during Dissimilation of Glucose by *Propionibacterium* *

RUNE STJERNHOLM**

Department of Biochemistry, Western Reserve University, School of Medicine, Cleveland 6, Ohio, USA

A non-reducing carbohydrate has been isolated and purified from media and cells of three species of *Propionibacterium* fermenting glucose. This sugar was identified as trehalose after crystallization and preparation of its octaacetate derivative. Further criteria used were mixed melting points, paper chromatography and optical rotation.

A non-reducing carbohydrate has been observed in the media from fermentations of glucose by three species of *Propionibacterium* [1,2]. With proliferating cells 9 % of the fermented glucose was converted to a non-reducing sugar [1], and with resting cells [2] as much as 30 %. After the glucose had been utilized there was a subsequent conversion of the non-reducing carbohydrate to CO_2 and propionic, acetic and succinic acids [1]. The present report deals with the isolation and identification of this non-reducing sugar.

METHODS AND EXPERIMENTAL

The three species of *Propionibacterium* used in this investigation were *P. arabinosum* strain 34W, *P. shermanii* strain 52W and *P. pentosaceum* strain 49W. All fermentations were carried out anaerobically with washed cell suspensions. The bacteria had previously been carried through three transfers, grown for 4 to 5 days each, on the following medium which contained, per liter, glucose (5.0 g), yeast extract (5.0 g), K-phosphate buffer (0.5 M, pH 6.8), and 1 mg of each of the following vitamins: calcium-pantothenate, thiamine-HCl and biotine. The cells from the last transfer were collected by centrifugation and washed twice by resuspension in distilled water followed by centrifugation.

In a typical experiment 120 ml of a reaction mixture containing glucose (0.05 M), K-phosphate buffer (0.15 M, pH 7.2), and washed cells (2.5 % w/v) in a 300 ml round bottom flask was shaken and continuously gassed with nitrogen. After a variable period of time (6 to 22 h) the fermentation was stopped by the addition of sulfuric acid to pH 1, and the cells were then removed by centrifugation and washed twice with distilled water. The combined supernatant solutions (about 140 ml) were extracted with ether for 48 h

* This investigation was supported in part by a grant from the U.S. Public Health Service, No. E-1003 (C-2).

** DuPont Fellow, 1956—1958.

and the aqueous residue was then deionized by successive passage through a column containing Dowex-50 H^+ ($\times 12$, 200 mesh) and Duolite A4. The deionized solution was concentrated to 5 ml at 80° under an air jet, and placed on a celite-charcoal column [3] (30 mm × 500 mm if the total amount of carbohydrate did not exceed 300 mg). Water with an increasing concentration of ethanol was used for development of and elution from the column. The total carbohydrate in each fraction of eluate was determined by the anthrone method [4].

Table 1. Chromatography of fermentation residue on celite-charcoal.

Fraction	Eluant	Volume	Compound eluted
1	Water	100 ml	nil
2	1 % EtOH	100 »	»
3	2 » »	100 »	hexoses
4	3 » »	100 »	»
5	4 » »	100 »	nil
6	5 » »	100 »	»
7	6 » »	100 »	non-red. sugar
8	7 » »	100 »	» » »
9	8 » »	100 »	nil
10	9 » »	100 »	»
11	95 » »	500 »	»

A non-reducing sugar appeared in the fraction eluted with 6 and 7 % ethanol (Table 1). This elution behavior is typical of disaccharides [3], and when this substance was hydrolyzed with H_2SO_4 (1 M, 30 min, 100°) in a sealed tube glucose was the sole product. These preliminary data suggested that the non-reducing sugar might be trehalose [1-(α-D-glucopyranosido)-α-D-glucopyranoside].

Paper chromatography of the non-reducing material in four different solvent systems (Table 2) showed in each case a single spot, which could be detected when sprayed with reagents such as $AgNO_3$—NaOH [5] and HIO_4—KI-starch that react with non-reducing compounds [6]. The spot could not be detected when sprayed with aniline-phthalate [7] or *p*-anisidine-HCl [8] reagents which are specific for aldoses and reducing sugar in general. The R_F values of the non-reducing material were identical with that of known trehalose in the four solvent systems (Table 2).

Table 2. Paper chromatography of non-reducing compound and trehalose.

Solvent-system	R_F of non-red. compound	R_F of trehalose
Phenol-water	0.26	0.26
Collidine-water	0.28	0.28
n-BuOH-water	0.04	0.04
Ethylacetate-pyridine-water	0.09	0.09

When the non-reducing compound and known trehalose were mixed and chromatographed in each solvent system no separation took place.

Crystallization of the eluted non-reducing material from 80 % ethanol gave colorless rhombic crystals [m. p. 98°, $[\alpha]_D^{25}$ +179 (*c* 2, H_2O)]. The mixed melting point with a recrystallized commercial preparation of α,α′-trehalose-dihydrate [m. p. 98°, $[\alpha]_D^{20}$ +178 (*c* 2, H_2O)] showed no depression.

An acetate of the isolated material was prepared by reaction with excess acetic anhydride in pyridine [9] (12 h, 25°). Crystallization from 60 % ethanol gave colorless

needles [m. p. 100—102°, $[\alpha]_D^{25}$ +164.5 (*c.* 1.16, $CHCl_3$)]. The mixed melting point with a known sample of trehalose octa-acetate [9] (m. p. 100—102°, $[\alpha]_D^{20}$ +162.5, $CHCl_3$) showed no depression.

That trehalose is the only non-reducing sugar in the media was revealed from balance studies of several fermentations (Table 3). However, intracellularly a glycogen-like substance has been found in addition to trehalose.

Table 3. Balance studies on the aqueous residue after ether extraction of fermentation media.

Fermentation 1		
Total carbohydrate (anthrone method) [4]		141 mg *
Reducing sugar (Somogyi analysis) [10]		105 mg
Non-reducing sugar (calc.)		36 mg
Individual fractions from charcoal-celite column (anthrone method)	hexoses	118 mg
	trehalose	29 mg
Fermentation 2		
Total carbohydrate (anthrone method)		190 mg
Individual fractions from charcoal-celite column (anthrone method)	hexoses	129 mg
	trehalose	70 mg

* All values calculated as glucose.

Three species of *Propionibacterium* were analyzed for their cellular content of trehalose (Table 4). Cells of 34W, 52W and 49W, grown for two days on the above described glucose, yeast extract, phosphate and vitamin medium, were centrifuged, washed twice with water, lyophilized, and then treated according to the method given by Myrbäck [11] and Stewart *et al.*[12] for the isolation of trehalose from baker's yeast. By paper chromatographic assay (*cf.* Table 2), these preparations were found to contain trehalose and no other carbohydrates. Anthrone analysis of these fractions gave the trehalose content of the three species as shown in Table 4.

Table 4. Anthrone analysis of the trehalose content in the cells of *Propionibacterium*.

34W	5.3 %	trehalose (as glucose) *
52W	1.9 %	trehalose (as glucose) *
49W	0.7 %	trehalose (as glucose) *

* Calculated on dry weight of cells.

DISCUSSION

The findings of trehalose inside the cells of three species of *Propionibacterium*, and the production of the disaccharide in their media, may indicate that the presence of this sugar is characteristic of the entire genus.

Trehalose has earlier been identified or isolated from human tubercle bacilli [13], *Mycobacterium phlei* [14], mushrooms [15], brewer's yeast [16], lichens [17], algae [18] and insects [19]. The enzymatic synthesis of trehalose has been postulated to proceed *via* trehalose-6-phosphate, formed from UDPG and glucose-6-phosphate [20].

Trehalose samples, obtained from fermentation of glucose-1-^{14}C, -2-^{14}C, 3,4-^{14}C and -6-^{14}C by *P. arabinosum* and *P. shermanii*, after hydrolysis to glucose have been degraded by the method of Bernstein *et al.*[21], to determine the

isotopic distribution of the individual carbon atoms in order to study the mechanism of trehalose formation in these organisms. The results of these investigations will be published elsewhere.

Acknowledgement. The author wishes to express his sincere appreciation to Dr. H. G. Wood for suggesting this problem, and for helpful discussion during the progress of the work and the preparation of the manuscript.

Phenolic Compounds in Brown Algae
I. The Presence of Reducing Compounds in *Ascophyllum nodosum* (L.) Le Jol.

ARNE HAUG and BJØRN LARSEN

Norwegian Institute of Seaweed Research, N.T.H., Trondheim, Norway

The brown alga *Ascophyllum nodosum* contains amounts of reducing compounds varying from 0.4 to 2.25 mequiv. per g dry matter depending on place of growth. Evidence is presented which indicates that the reducing compounds show reactions characteristic of phenols, and that they are identical with the compounds giving the color reaction of the physodes ("fucosan").

It has been known for more than sixty years that the cells of brown algae often contain a large number of highly refractive, colorless vesicles which are usually termed physodes. In 1893 Crato [1] showed that the physodes could reduce silver nitrate, and that they could be stained by vanillin hydrochloric acid. From this and other evidence he concluded that the physodes contained phenols, and that these phenols consisted partly, at least, of phloroglucinol. His results were later confirmed by several authors, among them Kylin [2,3] who described the contents of the physodes as compounds related to tannins. He noticed that these tannin-like compounds were rapidly oxidised to brown colored substances under alkaline conditions. In a note from this laboratory [4] it was shown that a diazo reagent could be used to distinguish between *Laminaria hyperborea* (Gunn.) Foslie and *Laminaria digitata* (Huds.) Lamour., and later, unpublished work showed that the diazo reagent colored specifically the physodes.

In 1943 Rönnerstrand [5] reported that brown algae contained a compound that interfered in the titration of vitamin C with dichlorophenol-indophenol, and he assumed that this reducing component ("fucosan") was contained in the physodes. He also attempted a quantitative estimation of the "fucosan" content by titration with dichlorophenol-indophenol in dilute metaphosphoric acid after vitamin C was destroyed by means of ascorbinase. In *Ascophyllum nodosum* he found a "fucosan" content corresponding to 18—32 mg ascorbic acid per 100 g fresh algae.

In 1957, Esping [6] reported that the enzyme inhibitory effect of extracts from *Fucus vesiculosus* L. probably was due to a polyphenol.

It was observed in this laboratory that the acid extracts of d r i e d *Ascophyllum nodosum* contained considerable amounts of reducing compounds, while the reducing power of similar extracts of d r i e d *Laminaria* species was insignificant. It was shown that it was possible in this way to distinguish between meal produced from Fucaceae and Laminariaceae species. Extracts of f r e s h *Laminaria* species, on the other hand, showed a considerable reducing power. The difference is thus due to a loss of reducing power during drying of *Laminaria* species, and will be subject to further investigation.

The present investigation is confined to the reducing compounds of *Ascophyllum nodosum*.

EXPERIMENTAL

Extraction. Extracts of fresh material were prepared in the following way: 40 g fresh algae was disintegrated with 200 ml 0.2 N sulfuric acid in a Waring blendor. Solid particles were removed by centrifuging.

When dry material was used, 1 g ground algae was extracted with 50 ml 0.2 N sulfuric acid overnight, and the extract was filtered.

Potentiometric titration. 10 ml extract was neutralised with approximately 1 ml 2 N sodium hydroxide. After addition of 10 ml 0.5 N sodium hydroxide, the extract was titrated by batchwise addition of 0.01 N potassium ferricyanide solution in 0.25 N sodium hydroxide. The solution was stirred vigorously throughout the titration. Near the endpoint of the titration, the reaction proceeds slowly, and the solution must be allowed to stand for about 5 min before the equilibrium potential is reached. The potential was measured against a saturated calomel electrode.

The relation between the potential and pH was determined in the following way: 10 ml extract was made alkaline with 2 ml 2 N sodium hydroxide. A 0.05 N solution of potassium ferricyanide in water was added in a quantity sufficient to oxidise half the amount of reducing components present. After 5 min 1 ml 2 N hydrochloric acid and 10 ml buffer solution of the desired pH were added and the potential was measured.

Color reactions. The vanillin reagent was prepared by dissolving 5 g vanillin in a mixture of 20 ml conc. sulfuric acid and 10 ml water. 1 ml extract and 5 ml reagent were thoroughly mixed and after about half an hour the red color was measured in a Beckman DU spectrophotometer at 515 mμ. Extracts with a high content of phenolic compounds formed a colored precipitate with the reagent, and such extracts were therefore diluted before the reagent was added.

The diazo reagent was prepared by dissolving 100 mg diazosulfanilic acid in 20 ml 3 % sodium carbonate solution. 2 ml reagent was then mixed with 2 ml extract diluted with sufficient 3 % (w/v) sodium carbonate solution to give a color intensity which could be measured directly. The optical density at 470 mμ was then determined. As a blank was used 2 ml reagent mixed with 2 ml 3 % sodium carbonate solution. The reagent is unstable and the measurements must be carried out as fast as possible.

The brown color in alkaline solution was obtained by mixing 1 ml extract with 4 ml 3 % sodium carbonate solution and heating the mixture for 15 min at 120°C. The color was measured at 420 mμ.

Determinations with hide powder. 20 g dried seaweed sample was extracted with 1 000 ml 40 % (v/v) aqueous acetone overnight. The acetone was removed *in vacuo*, and water was added to give 1 000 ml. 50 ml of this extract was used for determination of dry matter and ash. To 200 ml extract acidified with 5 drops conc. hydrochloric acid was added 100 g hide powder *. After 24 h 50 ml of the filtered solution was used for determination of ash and dry matter. The amount of "tannins" is taken as the organic dry matter removed by the hide powder treatment.

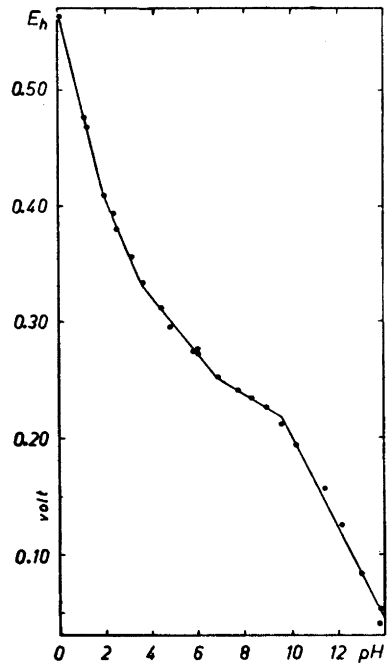

Fig. 1. pH dependence of the potential of extracts from *Ascophyllum nodosum.*

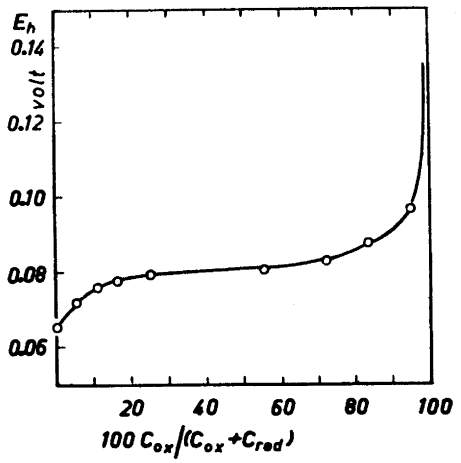

Fig. 2. Titration curve for *Ascophyllum* extracts.

RESULTS

Paper chromatography. Extracts from fresh and dried *Ascophyllum* were subjected to paper chromatography (S & S 2043 b). The solvent system used was butanol:pyridine:saturated sodium chloride solution, 1:1:2 [7]. Bisdiazotised benzidine was used as spray reagent. The extracts from both fresh and dried weed showed two major spots with R_F values of approximately 0.18 and 0.95. In addition a weak spot with an R_F value of 0.70 and traces of other components were observed. The major spots observed using the diazo reagent could also be demonstrated by spraying with ammoniacal silver nitrate.

Potentiometric titration. In Fig. 1 the potential (E_h) of an extract of fresh *Ascophyllum* is plotted as a function of pH. It will be seen that the reducing power increases with increasing pH. The curve is of a complex shape, indicating a number of dissociation steps.

Experiments have been carried out with several oxidising agents, such as potassium ferricyanide, Fremy's salt, ceric ammonium sulfate, sodium nitroprusside and dichlorophenol-indophenol. Potassium ferricyanide in alkaline solution was found to be the most convenient oxidising agent and has been

Table 1. Reducing power, mequiv. per g dry matter.

Locality	Fresh	Dried
1. Tarva	2.25	2.20
2. Garten	1.56	1.70

4. Munkaunet	0.94	0.86
5. Korsvika	0.40	0.31
6. Leangen	0.67	0.73
7. Være	1.11	1.00
8. Midtsannan	1.27	1.46
9. Muruvik	0.63	0.67

used throughout this work. Satisfactory results were also obtained with Fremy's salt, while ceric ammonium sulfate, sodium nitroprusside and dichlorophenol-indophenol gave no satisfactory endpoint.

Fig. 2 shows a titration curve of an *Ascophyllum* extract. The index potential is low, indicating that a considerable number of electrons are involved in the reaction [8].

Ascophyllum nodosum was collected at nine different localities in the Trondheimsfjord area in the first week of July 1957. The reducing power of fresh and dried material was determined. The results (Table 1) are given as milliequiv. per g dry matter.

It will be seen that there is no systematic difference between the reducing power of fresh and dried weed. The differences observed are probably due to incomplete extraction. Dried samples showed no loss of reducing power after three months of storage.

According to Rönnerstrand the vitamin C content of *Ascophyllum* corresponds to less than 0.02 mequiv. per g dry matter. Vitamin C makes therefore only a very small contribution to the reducing power of the extracts.

The reducing power of the *Ascophyllum* extracts varied from 0.4 to 2.25 mequiv. per g dry alga between the different localities. Localities Nos. 1, 2 and 3 are outside or in the outer parts of the Trondheimsfjord, localities Nos. 4, 5 and 6 are in the immediate neighbourhood of Trondheim, and localities Nos. 7, 8 and 9 are east of Trondheim, towards the inner parts of the fjord. Low reducing power was observed at localities where the salinity was lowered due to contamination with fresh water from river outlets. A more detailed study of these variations with place of growth will be published later.

Color reactions. In order to determine if the reducing compounds were identical with the substances responsible for the color reactions of the physodes, the nine *Ascophyllum* samples were extracted with dilute acid and the extracts subjected to color tests. As we wanted to include in the series an extract with a very low reducing power, a tenth sample was prepared in the following way: Water was added to the ground and dried material from locality No. 1 to reduce the dry matter content to 60 %. The sample was then heated to 120°C for 30 min. After this treatment the reducing power of the sample had decreased to 0.05 mequiv. per g dry matter. A detailed study of the

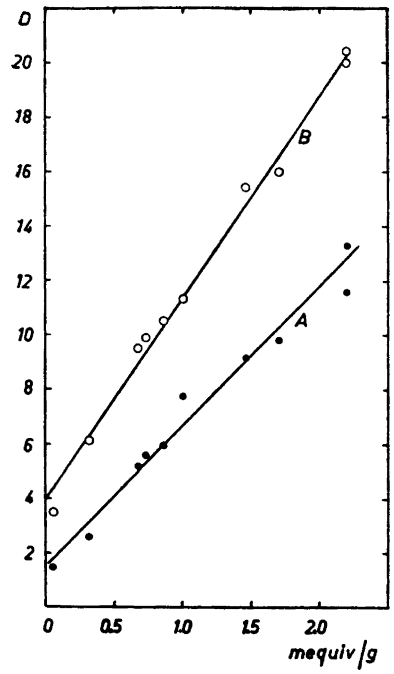

Fig. 3. Correlation between reducing power (mequiv. per g) and color with vanillin sulfuric acid (A) and diazosulfanilic acid (B) (optical density corrected for dilution).

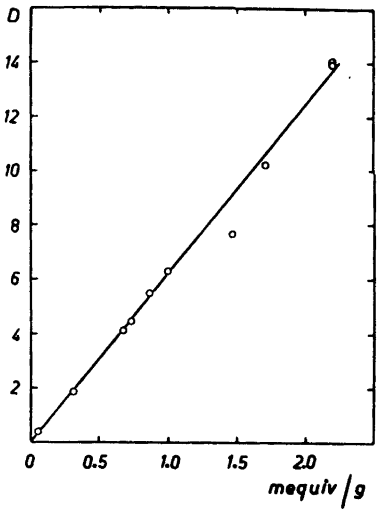

Fig. 4. Correlation between reducing power (mequiv. per g) and color of extracts after heating for 15 min at 120°C in alkali (optical density corrected for dilution).

effect of heat on the reducing power of the extracts will be published later.

In Fig. 3, curve A, the intensity of the red color of the extracts after addition of vanillin sulfuric acid is plotted as a function of the reducing power. The distinct correlation between the amount of reducing compounds and the red color given with vanillin sulfuric acid indicates that the substance in the physodes responsible for this reaction is identical with the reducing compounds.

Curve B in Fig. 3 shows the relation between the reducing power of the extracts and the color produced by diazotised sulfanilic acid in alkaline solution. Also in this case the correlation is pronounced and indicates that the reducing compounds and the compounds colored by diazo reagent are identical.

Fig. 4 shows the relation between the reducing power and the color obtained by heating the extracts for 15 min at 120°C after addition of alkali. The curve indicates that the reducing compounds are responsible for the formation of brown-colored substances in alkaline seaweed extracts.

It will be seen that the curve in Fig. 4 passes through the origin, while the curves in Fig. 3 pass through a point on the ordinate axis. This may be explained by assuming that the seaweed extracts contained a small amount

of a non-reducing substance that gave color reactions with diazotised sulfanilic acid and vanillin sulfuric acid, but which did not form brown colored substances when heated in alkaline solution.

The reaction of formaldehyde, gelatin and hide powder on the reducing compounds. When fresh *Ascophyllum* is treated with formaldehyde, the physodes become resistant to drying, freezing and boiling, while such treatment otherwise completely destroys the structureof the physodes. If an *Ascophyllum* sample treated with formaldehyde was extracted in the usual manner after careful removal of the formaldehyde *in vacuo*, the extract showed no reducing was not colored by the addition of diazo reagents or vanillin sulfuric acid power, was and furthermore no brown color was formed when the extract heated after addition of alkali.

It is known that tannins are precipitated by gelatin. When a solution of gelatin was added to an *Ascophyllum* extract adjusted to pH 3, a precipitate was formed. When the precipitate was removed by centrifugation, the supernatant became only slightly colored on adding vanillin sulfuric acid or diazo reagent, or when the extract was heated with alkali. It could also be shown that only traces of reducing compounds were present.

Similar results were obtained when we used hide powder instead of gelatin as the protein component of the reaction. It was then possible to carry out the reaction quantitatively by determining the amount of dry matter removed from the extracts by the hide powder treatment [9]. For practical reasons, the extraction was in this case carried out with 40 % (v/v) aqueous acetone solution. It was shown that this solvent extracted approximately the same amount of reducing compounds as the dilute acid used in the other determinations. The results are presented in Fig. 5 as a function of the reducing power of the acetone extracts. The curve can be extrapolated to a point on the ordinate axis corresponding to 4 g "tannins" per 100 g dry alga, indicating that the hide powder also reacted with non-reducing compounds in the extracts.

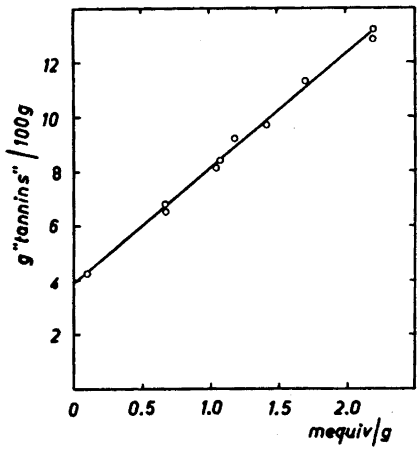

Fig. 5. Correlation between reducing power (mequiv. per g) and organic matter removed by hide powder treatment (g per 100 g dry matter).

The nature of these compounds is not known. If we assume that the content of interfering, non-reducing compounds is approximately the same in all samples, independent of the place of growth, the samples with the highest reducing power contain approximately 9 g reducing compounds per 100 g dry matter, which is in agreement with the result obtained when an equivalent weight of 40 is postulated.

DISCUSSION AND CONCLUSIONS

Extracts of *Ascophyllum nodosum* contain compounds which show a reducing potential measured against a saturated calomel electrode at pH values above 7. The relative amounts of these compounds can be estimated by potentiometric titration with potassium ferricyanide in alkaline solution. Plants from the outer parts of the Trondheimsfjord were found to contain about six times as much reducing compounds as a sample from a locality in the neighbourhood of Trondheim. Even the lowest reducing power observed corresponds to about ten times the "fucosan" content reported by Rönnerstrand. This is probably due to the fact that Rönnerstrand carried out his titrations in an acid medium, where the difference in potential between the seaweed extracts and the oxidising agent is small and a clear endpoint could not be obtained.

The pronounced correlation between the reducing power and the color reactions characteristic of the physodes strongly indicates that the reducing compounds are located in the physodes. This assumption is also supported by the fact that formaldehyde leads to a structural change in the physodes with the result that extracts of material treated with formaldehyde show no reducing power. Unpublished work by E. Baardseth of this institute indicated that the number of physodes per g fresh alga is positively correlated to the amount of reducing compounds in the plants.

The reactions of the reducing compounds with formaldehyde, gelatin, hide powder and color reagents are reactions characteristic of phenols. It is therefore probable that the physodes of *Ascophyllum* contain reducing, phenolic compounds. The results from the potentiometric titration and the analyses with hide powder showed that the reducing compounds occurred in considerable quantities, amounting to about 9 g per 100 g dry matter in the samples from the outer parts of the Trondheimsfjord.

So far the exact chemical nature of these compounds is not known. The results of this investigation indicate that the equivalent weight of the compound is low, that a number of electrons are involved in the reduction (Fig. 2) and furthermore that dissociation of the reducing groups occurs in several steps as the pH is increased.

Crystal Structure of Ni_3B and Co_3B

STIG RUNDQVIST

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

Ni_3B and Co_3B are isostructural with cementite (Fe_3C). A single-crystal structure determination of Ni_3B has been made. Some properties of the cementite structure are discussed.

X-Ray investigations of the Co-B and Ni-B systems have revealed the existence of two isomorphous borides Co_3B and Ni_3B. Co_3B has not been reported in earlier work on the Co-B system [1-3]. Ni_3B has previously been found by Andersson and Kiessling [4] but no X-ray data were published. The powder diffraction lines of Co_3B and Ni_3B, which could be indexed with orthorhombic unit cells (Table 1), showed close resemblance to the cementite (Fe_3C) powder pattern [5].

The first X-ray investigation of cementite was carried out by Westgren and Phragmén [6,7], who determined the orthorhombic unit cell using powder and single-crystal methods. From Westgren's and Phragmén's data Hendricks [8] deduced the space group ($P\,b\,n\,m$) and the iron positions. Different positions of the carbon atoms were proposed by Hendricks and by Westgren [9]. Westgren's structure proposal was later confirmed by Lipson and Petch [10] who settled the carbon positions with threedimensional Fourier methods using accurate intensity measurements from powder photographs. However, Lipson's and Petch's intensity material was rather limited (26 independent reflexions, in four cases with overlaps) and since no actual single-crystal determination of the cementite structure has been made, it seemed desirable to determine the structure of Co_3B or Ni_3B with the single-crystal technique.

EXPERIMENTAL

The borides were prepared from elementary boron (97.5 %), nickel powder (99.8 %) and cobalt powder (99.2 %, containing 0.45 % nickel) either by arcmelting or by sintering at 900°—1 000°C in evacuated and sealed silica tubes. X-Ray powder photographs were taken in Guinier-type focusing cameras with Cr-$K\alpha$ or Cu-$K\alpha$ radiation, using CaF_2 as standard. Ni_3B was chosen for the single-crystal work, and small crystal fragments were picked from crushed melts. The zero-layer line around the b-axis and the layer-lines 0—8 around the c-axis were recorded with Mo-K radiation in a multiple-film Weissenberg camera with thin iron foils between successive films. About 250 nonequivalent intensities were visually estimated by comparison with a standard intensity scale. Relative $|F|^2$.

values were calculated with the aid of Lu's curves [11]. An empirical correction for thermal movement and Θ-dependent absorption was obtained by plotting log F_o/F_c against $\sin^2\Theta$. Fourier summations were made on the Hägg-Laurent machine [12].

DETERMINATION OF THE STRUCTURE

All reflexions were consistent with space group $P\,b\,n\,m$. Starting with the assumption that the signs of the corresponding structure factors in Fe_3C and Ni_3B were the same, correct signs of all Ni_3B reflexions were determined by successive refinements of the electron density projections $\varrho\,(xz)$ and $\varrho\,(xy)$. The nickel positions obtained from the projections were further refined with electron density maps in the $(x\ y\ 1/4)$ plane using the entire intensity material. By difference synthesis in the same plane the positions of the boron atoms were found. After the last refinement, the reliability index was 0.11.

The result of the structure determination is collected in Table 2. Interatomic distances are listed in Table 3.

DESCRIPTION OF THE STRUCTURE AND DISCUSSION

The cementite structure has been discussed by several authors [8-10,13,14]. The packing of the metal atoms is rather complicated and attempts have been made to interpret the structure in terms of deformed austenite or martensite structures. In view of the result of the Ni_3B structure determination, a comparison of the cementite structure with boride structures might also be justified.

As pointed out by Lipson and Petch, the cementite structure is built up of successive metal atom layers parallel with {103}. The layers are composed of a slightly corrugated array of interconnected squares and triangles with

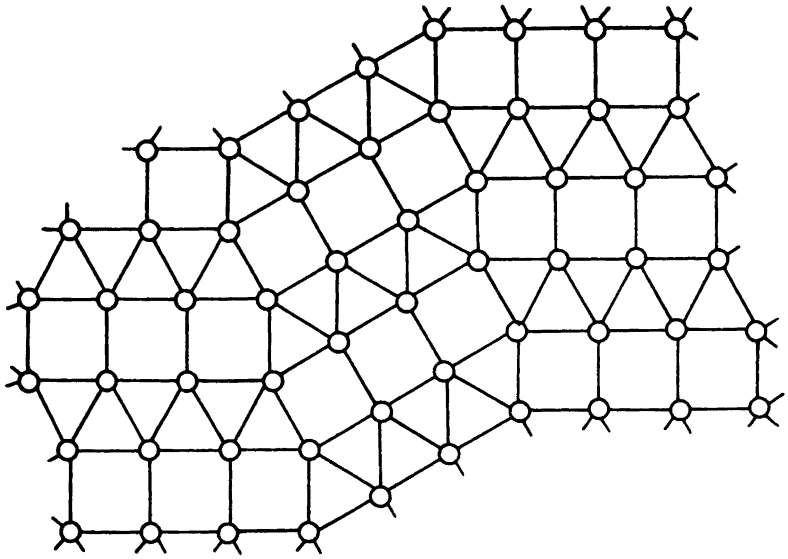

Fig. 1. Nickel atom layers parallel with {103} in Ni_3B.

metal atoms in the corners (Fig. 1). It is seen From Figs. 1, 2 and 3, that these layers may be regarded as an intermediate between the slightly corrugated atom layers parallel with $\{10\bar{1}1\}$ in hexagonal close-packed structures and the metal atom layers parallel with {001} in Ni_2B and Co_2B. These borides both have the $CuAl_2$ structure, which has been discussed by Black [15].

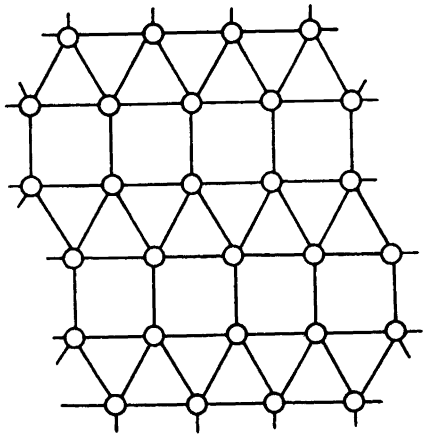

Fig. 2. Atom layers parallel with $\{10\bar{1}1\}$ in hexagonal close-packed structures.

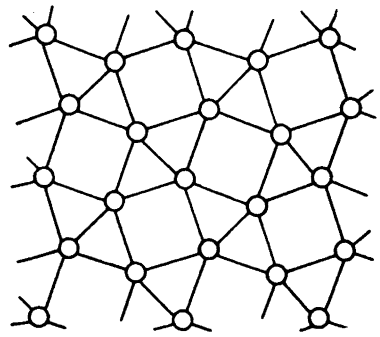

Fig. 3. Metal atom layers parallel with {001} in Me_2B-borides with the $CuAl_2$ structure.

The resemblance to other boride structures becomes more evident when the environment of the boron atoms in Ni_3B is considered. As seen from Table 3, the boron atoms are surrounded by nine nickel atoms. The six closest neighbours are situated in the corners of a triangular prism, the remaining three are situated at larger distances outside the rectangular sides of the prism. The triangular prismatic coordination around the boron atoms has been found in several types of transition metal borides [16]. The mean distance between the boron atoms and the six closest nickel atoms is 2.04 Å. Assuming the nickel radius to be 1.25 Å, the boron atom radius is only 0.79 Å, approaching the value 0.77 Å of the carbon atom radius in cementite. According to Kiessling [16] the normal boron radius is 0.86 Å.

Besides Fe_3C, very few compounds with the cementite structure have hitherto been reported. Meyer and Kohlhaas [17,18] claimed the existence of cobalt cementite and nickel cementite, but Jacobson and Westgren [19] could not confirm the cementite structure of Ni_3C. Kuo and Persson [20] have prepared manganese cementite (Mn_3C).

The possibility of substituting some other element for carbon in Fe_3C while retaining the structure was discussed by Petch [13] from size-factor considerations. Since the atomic radii of B, C and N are, respectively, 0.86, 0.76 and 0.71 Å it might be expected that nitrogen should replace carbon easily whereas boron should experience difficulties. Analogously, carbon should replace boron in Co_3B and Ni_3B. In fact, it has been found that Co_3B dissolves carbon to a limited extent, probably less than 20 % at 1 000° as found from measurements of the contraction of the Co_3B unit cell in ternary Co-B-C alloys. The solubility of carbon in Ni_3B is probably very small, since no significant contraction of the Ni_3B unit cell in ternary Ni-B-C alloys has been detected.

However, in Fe_3C, no solubility of nitrogen has been found [21] whereas an extended solubility of boron exists [22,23]. The boron solubility limit in Fe_3C has been determined by Nicholson [23] who found it possible to replace up to 80 % of the carbon by boron at 1 000°C. Recently, Aronsson (private communication) has prepared a ternary phase $Fe_3(B, Si)$ with cementite structure.

From the foregoing it is evident that simple size-factor considerations cannot be used to predict the existence of new compounds with the cementite structure. An attempt to explain the stability of boron-substituted Fe_3C has been made by Massalski [24] and Nicholson. They assume that the cementite structure is critically adjusted to the electronic environment produced by carbon atoms in interstitial positions. When boron is substituting for carbon in these positions, a similar electronic environment can be maintained if one electron is donated from the 3d shell of iron. This theory is supported by the results of magnetic measurements made by Nicholson.

Cocarboxylase Activity of Thiamine Triphosphate in Yeast Transketolase

KARL-HEINZ KIESSLING

Institute of Zoophysiology, University of Uppsala, Sweden

The ability of thiamine tri- and monophosphate to replace thiamine diphosphate (cocarboxylase) in transketolase isolated from baker's yeast has been studied.

Neither the tri- nor the monophosphate showed any remarkable cocarboxylase activity in this system. Only when thiamine triphosphate was transformed into thiamine diphosphate by means of phosphatases cocarboxylase activity was obtained.

Thiamine triphosphate * has been found in rat liver [1] and in baker's yeast [2,3]. Isolated from yeast this compound was shown to be identical with synthetic thiamine triphosphate with regard to the arrangement of the phosphate groups [3].

Very little is known about the action of TTP and its localization. On the basis of the observed action of TTP on the frog's heart Plotka *et al.* [4] put forward the hypothesis that TTP plays a role in the special metabolism related to nerve impulse transmission.

The ability of synthetic TTP to replace TDP in an isolated carboxylase from baker's yeast has been studied by de la Fuente and Diaz-Cadavieco [5], Kiessling [3], and Rossi-Fanelli *et al.*[6] In this system TTP was found to be inactive. This was also the case with TTP isolated from yeast [3]. Cocarboxylase activity was obtained from TTP only after pre-incubation with a potato apyrase at 0°C, when γ-P is split off [3].

An entirely different explanation of the above negative results has been put forward by Bartos [7] who suggests the existence in yeast of two distinct apoenzymes, one combining with TDP, the other with TTP. Thus only the former should have been isolated in the experiments referred to above [5,3,6].

The turnover rate of the different phosphate groups of TTP in baker's yeast has been studied with glucose as a substrate and in the presence of

* Abbreviations: TTP, thiamine triphosphate; TDP, thiamine diphosphate (cocarboxylase); TMP, thiamine monophosphate; EDTA, ethylenediaminetetraacetate (Versene); DPNH, reduced diphosphopyridine nucleotide; AMP, adenosine-5-phosphate.

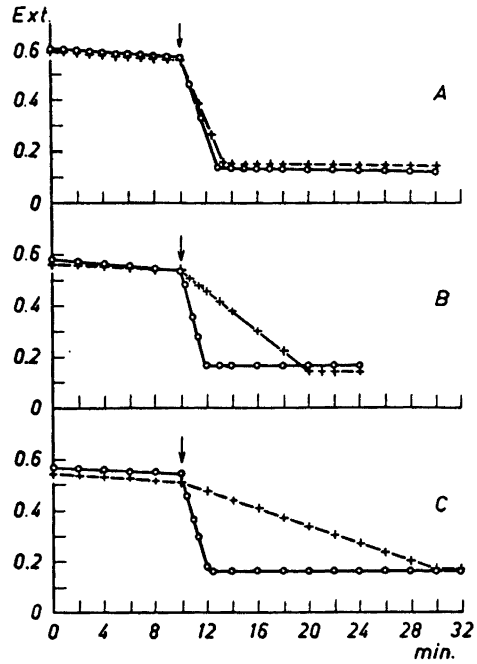

Fig. 1. The necessity of TDP by transketolase after dialysis.
The isolation of the enzyme was performed according to de la Haba *et al.*[12], and carried on to the protamine step.

+———+ no synthetic TDP present
O———O 0.05 ml 0.1 % TDP present

radioactive inorganic phosphate [8]. The terminal phosphate group became radioactive more rapidly than the β- and α-P. Synthetic TTP added to rat liver mitochondria did, however, not exchange its phosphate groups [9].

In homogenates and in protein fractions from rat liver, however, Greiling and Kiesow [10] found, in the absence of ATP, an enzymatic transfer of phosphate from TTP to glucose.

From yeast an enzyme, named transketolase, has been crystallized [11,12] which transforms ribose-5-phosphate and ribulose-5-phosphate into a mixture of heptulose-7-phosphate and glyceraldehyde-3-phosphate:

Ribose-5-phosphate + ribulose-5-phosphate $\rightleftharpoons$
$\rightleftharpoons$ heptulose-7-phosphate + glyceraldehyde-3-phosphate

This reaction has been shown to be conditioned by TDP and magnesium [11]. As TTP occurs in yeast and the concentration can be considerably increased by suitable pre-incubation of the yeast [2,3], the ability of TTP to replace TDP in a transketolase isolated from baker's yeast has been investigated in this paper.

EXPERIMENTAL

Transketolase. The transketolase has been isolated from baker's yeast * according to de la Haba *et al.*[12] The isolation was carried on to the protamine treatment. At this stage transketolase is stable for weeks if kept at 5°C. The enzyme shows no need of TDP and magnesium (Fig. 1 A). Only after prolonged dialysis against a solution [11] of 0.6 % EDTA-0.9 % KCl, pH 7.4, reduction and eventual loss of transketolase activity was obtained. This was, however, restored by the addition of magnesium and TDP (Figs. 1 B and 1 C).

Ribose-5-phosphate was prepared by boiling adenosine-5-phosphate for ten minutes in 1 N HCl, removal of insoluble barium salts, and precipitation of the barium salt of ribose-5-phosphate with four volumes of ethyl alcohol [13].

Isomerase, free of transketolase, was isolated from baker's yeast as described by de la Haba *et al.*[12]

Isomerase product. The equilibrium mixture of ribose-5-phosphate and ribulose-5-phosphate (isomerase product) was prepared from ribose-5-phosphate by incubation for 3 h with dialyzed isomerase [12]. The resulting product was kept in the form of the barium salt at 2°C, and transformed into the ammonium salt before use [12].

α-Glycerophosphate dehydrogenase from rabbit muscle was prepared according to Racker [13].

TTP, TDP, TMP. A mixture of thiamine phosphates was prepared according to Viscontini *et al.*[14], and TTP, TDP and TMP were isolated according to Kiessling [15]. As, however, the samples obtained in this way were poisonous when added to the transketolase, the solvent impurities were removed by re-chromatography of the isolated compounds in a second non-poisonous solvent (*n*-propanol-H_2O-1 M acetate buffer pH 5, 70:20:10) described by Siliprandi and Siliprandi [16].

DPNH and crystalline *AMP*, both from yeast, were obtained from Sigma Chemical Company. The extinction was measured in a Beckman spectrophotometer at 340 mμ.

Composition of samples. The incubation was performed mainly according to de la Haba *et al.*[12] Into a quartz cell (holding 4 ml) were pipetted: 0.05 ml of 0.5 M glycylglycine buffer, pH 7.6, 0.05 ml of 0.002 M DPNH, 0.05 ml of crude glycerophosphate dehydrogenase, 0.05 ml of the ammonium salt of isomerase product solution, 0.05 ml of 0.06 M $MgCl_2$, 0.1 ml of a transketolase solution containing about 1 000 units per ml **, samples of TTP, TDP or TMP (see below), and water to make 4 ml.

RESULTS

Dialysis of the transketolase preparation for 48 h gives an enzyme which, without addition of TDP, is inactive (Fig. 2A). Addition of TDP rapidly gives rise to an oxidation of DPNH. The same amount of TTP is less active (Fig. 2A). That TTP is active at all may be explained in different ways. Either TTP, to a certain degree, can replace TDP, or it is decomposed to TDP by phosphatases. The possibility that the added TTP is initially contaminated with TDP is excluded by the paper chromatographic controls. In order to find out if TDP is formed from TTP by phosphatases, samples were taken after different incubation intervals, and analyzed by paper chromatography according to Kiessling[15]. The chromatograms showed that TTP was rapidly transformed into TDP and TMP. After 15 min only about 30 % remained as TTP.

When, on the other hand, TTP and TDP are added later during the incubation (Fig. 2B), the oxidation of DPNH in the TTP incubation is considerably retarded, whereas in the TDP incubation the oxidation starts almost immedia-

* The baker's yeast was from Uppsala Ångkvarn Ltd., Sweden.

** A unit of enzyme is defined according to de la Haba *et al.*[12] as the amount of enzyme which gives an extinction change of 0.001 per min under the conditions of the assay.

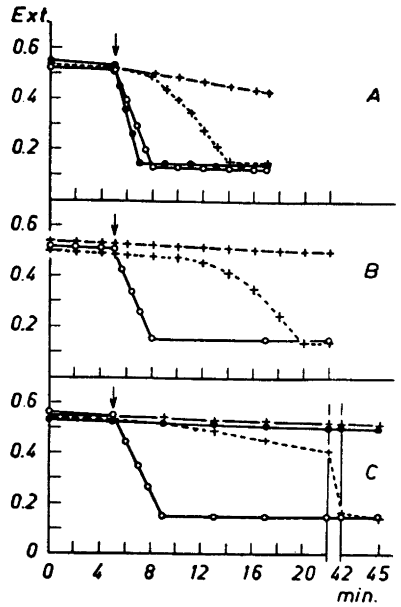

Fig. 2A. Effect of TDP and TTP on transketolase dialyzed for 48 h. The arrow indicates the addition of transketolase. TDP and TTP have been purified by paper chromatography as described in "Experimental".

+————+ no thiamine phosphate added
+– – – –+ 0.36 ml TTP (100 μg)
○————○ 0.11 ml TDP (100 μg)
●————● 0.36 ml TDP (327 μg)

B. Effect of the later addition of TTP and TDP. Transketolase is present from the beginning. The arrow indicates the point, when the thiamine phosphates are added. The designations of the curves are the same as in Fig. 2 A.

C. Effect of TTP, TDP and TMP on transketolase in the presence of thiamine. The arrow indicates the addition of the thiamine phosphates. 300 μg thiamine were added to each sample at the beginning of the incubation.

+————+ no thiamine phosphate added
+– – – –+ 0.36 ml TTP (100 μg)
●————● 0.30 ml TMP (100 μg)
○————○ 0.11 ml TDP (100 μg)

tely after the addition of TDP. This result gives further evidence for TTP being inactive as coenzyme in transketolase, and becoming active only after phosphatases have transformed it into TDP.

Westenbrink and van Dorp [17] have shown that yeast phosphatases acting on thiamine phosphates are strongly inhibited by thiamine. Thus addition of thiamine to the incubation mixture might prevent the decomposition of TTP to TDP. The results from an experiment are shown in Fig. 2C. It is seen that the complete oxidation of DPNH is effected at a much slower rate in

the presence of thiamine than in its absence when phosphatase activity is not inhibited. The oxidation rate in the presence of TDP is not noticeably affected by thiamine.

Fig. 2C also shows that TMP has no ability to replace TDP in this system.

Acknowledgements. I am indebted to Mrs. Margot Persson for skilful technical assistance in preparing the enzymes and performing the incubations. This work is part of investigations made possible by grants from the *Swedish Natural Science Research Council.*

The Crystal Structure of Piperazinium Di-dichloroiodide

CHRISTIAN RØMMING

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

The crystal structure of piperazinium di-dichloroiodide, $C_4H_{10}N_2 \cdot 2(HCl \cdot ICl)$, has been determined by X-ray methods. The ICl_2^- ion, being linear but not symmetrical, has the configuration $Cl^- — I — Cl$ with the $Cl^- — I$ distance 2.69 Å and the $I — Cl$ distance 2.47 Å. The Cl^- is coordinated to three positive groups and one iodine atom in a distorted tetrahedral arrangement, the three $N^+ — Cl^-$ distances being 3.23 Å.

It has been known for a long time that addition compounds between an amine and one halogen molecule form compounds with one molecule hydrogen halide. In the course of an investigation carried out in this department of the former type of addition compounds [1] it was thought to be of interest to examine one of the hydrogen halide compounds. The choice of the present compound, piperazine with two molecules ICl and two molecules HCl added to it, was made because of its centrosymmetrical configuration.

Earlier structure determinations of this type of compounds include $NH_4 \cdot I_3$ [2], $NH_4 \cdot ClIBr$ [3] and $(CH_3)_4N \cdot ICl_2$ [4]. The structure of the trihalide ions is discussed by Hach and Rundle [5].

EXPERIMENTAL

Piperazinium di-dichloroiodide was prepared by adding a solution of iodine monochloride in hydrochloric acid to a hot solution of piperazine in water. After slow cooling to room temperature small yellow needle-formed crystals of the compound separated from the solution. Oscillation and Weissenberg photographs about two crystallographic axes were taken in order to determine the unit cell dimensions. The (0*kl*)-intensities were estimated visually from a set of Weissenberg films while the (*hk*0)-intensities were measured microphotometrically from photographs taken with a Wiebenga integrating Weissenberg camera. The crystals used had a cross-section of 0.10 × 0.10 mm. Copper $K\alpha$ radiation was employed (λ = 1.542 Å). 103 (0*kl*)-reflections out of 114 obtainable with this radiation and 113 (*hk*0)-reflections out of 131 possible were recorded. Absorbtion corrections were not applied.

CRYSTAL DATA

The crystals were found to be triclinic with the unit cell dimensions:

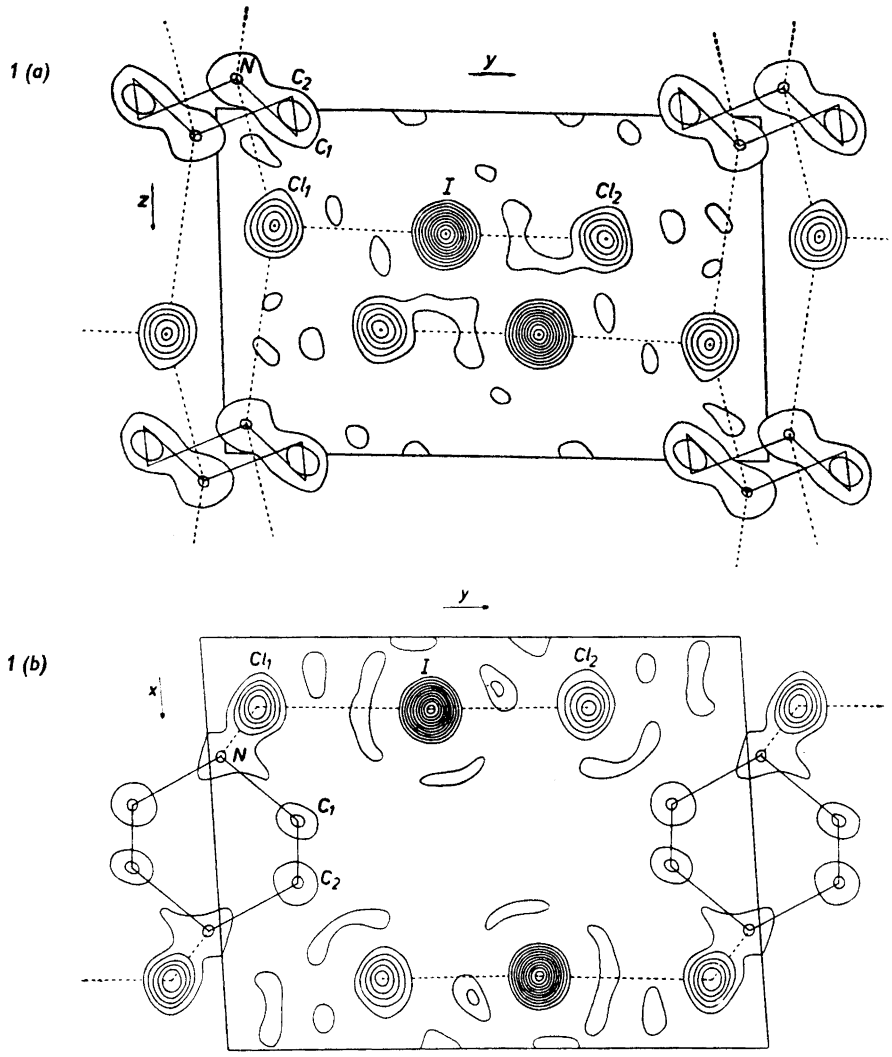

Fig. 1. Electron density projection along the *a*-axis (a) and c-axis (b). Contours at intervals of 5 e·Å^{-2}. Every second contour in the iodine peak is omitted.

a = 7.55 Å	b = 8.45 Å	c = 6.25 Å
α = 87.6°	β = 121.8°	γ = 84.4°

The figures given are believed to be accurate to within 0.5 % for the axial lengths and 0.5° for the angles.

The density was determined from flotation experiments and was found equal to 2.33 g/cm^3. With one molecule in the unit cell the calculated density is 2.38 g/cm^3.

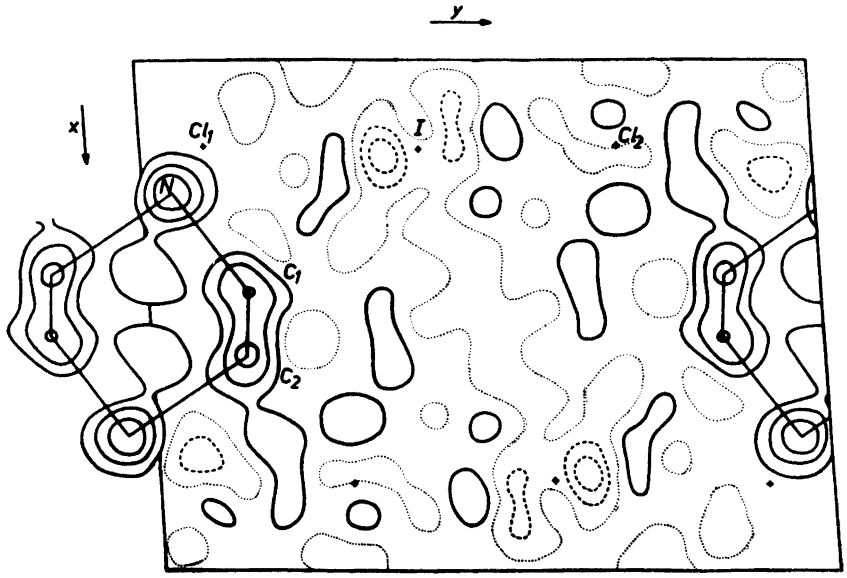

Fig. 2. ($F_o - F_{hal}$) projection along the *c*-axis. Contours at intervals of 2 e.Å^{-2}. Negative contours are broken and zero contour dotted. The halogen positions are indicated by crosses.

The space group P$\bar{1}$ was assumed to be the correct one as a centre of symmetry has previously been observed to exist in the piperazine ring, suggesting a symmetrical distribution of the (HCl.ICl) groups with respect to the two nitrogen atoms.

THE STRUCTURE DETERMINATION

Projection along the c-axis. Approximate x and y parameters for the iodine atom were determined by inspection of the (h00)- and (0k0)-reflections, and the signs for the structure factors based on these parameters were evaluated. A preliminary Fourier synthesis resulted in an electron density map showing well separated peaks for the iodine and the two chlorine atoms in the asymmetric unit. The position of the piperazine ring around the symmetry centre in (0,0) was also roughly indicated. After two refinements the electron density map of Fig. 1(a) was obtained, showing the halogen and nitrogen positions, whereas the two carbon atoms are too close together to be resolved as separate peaks.

Projection along the a-axis. The determination of this projection was carried out independently, using the same methods. The Fourier map obtained after three refinements is given in Fig. 1(b), showing all the atoms as separate peaks. The termination of series error introduces positive areas around the heavy atoms, and this effect is seen to have some influence on the position of the nitrogen peak. In order to find more precise parameters for this atom

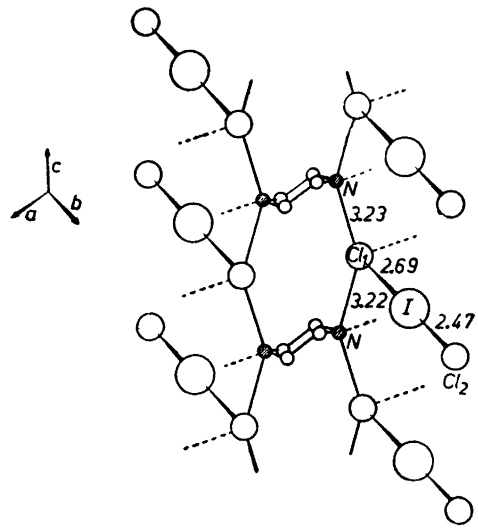

Fig. 3. Structure of piperazinium di-dichloroiodide. The figure shows a few of the units in a chain of piperazinium ions and ICl_2^- ions along the *c*-axis. The broken lines indicate the bonds between neighbouring chains. Bond lengths are in Å units.

a (F_0—F_{hal}) synthesis [6] was carried out, F_0 is the observed structure factor and F_{hal} is the contribution to the calculated structure factor from the halogen atoms alone. The difference map is given in Fig. 2. The nitrogen atom is now closer to the Cl_1 atom, but the positions of the carbon atoms remain nearly the same as before. The gradients at the halogen positions are too small to indicate any adjustments of the parameters.

The *y* parameters found for the halogen atoms in the two projections agree to within 0.001 of the axial length. For the nitrogen atom the difference is 0.006. The *z* parameters for the carbon atoms were calculated using *x* and *y* parameters found in the (F_0—F_{hal}) synthesis and assuming the carbon-carbon distance across the ring through the symmetry centre to be 1.90 Å. The atomic coordinates are given in Table 1.

Table 1. Atomic coordinates as fractions of the cell edges.

Atom	*x*	*y*	*z*
I	0.177	0.416	0.362
Cl_1	0.169	0.099	0.341
Cl_2	0.168	0.709	0.366
N	0.277	0.040	−0.086
C_1	0.455	0.148 *	0.082 *
C_2	0.582	0.140 *	−0.036 *

* The mean value of the *y* and calculated *z* parameters are 0.144 and 0.023, respectively, whereas the common maximum in the *a*-projection has the parameters 0.140 and 0.017.

Table 2. Bond lengths in trihalide ions.

Compound	Bond type	Bond length	Sum of covalent radii	Reference
NH_4ClIBr	I—Cl	2.38 Å	2.32 Å	3
	I—Br	2.50 Å	2.47 Å	3
$(CH_3)_4NICl_2$	$I—Cl_1$	2.34 Å	2.32 Å	4
	$I—Cl_2$	2.34 Å	2.32 Å	4
$PICl_6$	$I—Cl_1$	2.36 Å	2.32 Å	10
	$I—Cl_2$	2.36 Å	2.32 Å	10
NH_4I_3	$I_1—I_2$	3.10 Å	2.66 Å	2
	$I_2—I_3$	2.82 Å	2.66 Å	2
CsI_3	$I_1—I_2$	3.04 Å	2.66 Å	11
	$I_2—I_3$	2.86 Å	2.66 Å	11
$C_4H_{12}N_2 \cdot 2ICl_2$	$I—Cl_1$	2.69 Å	2.32 Å	Present examination
	$I—Cl_2$	2.47 Å	2.32 Å	

Observed and calculated structure factors are listed in Table 3. For the 12 largest (marked with an asterisk) the observed values are seen to be considerably lower than the calculated ones. This effect is thought to be mainly due to extinction, and these reflections are therefore disregarded in the calculation of the reliability index and the (F_0—F_{hal}) synthesis. They are, however, included in the estimations of the standard deviations.

For the different atoms the following B values in the temperature factor exp ($-B \sin^2\Theta / \lambda^2$) were used:

($0kl$)- reflections: $B_I = 2{\cdot}0$ Å^2; $B_{Cl} = 2.5$ Å^2; $B_{N \text{ and } C} = 3.0$ Å^2
($hk0$)-reflections: $B_I = 1{\cdot}5$ Å^2; $B_{Cl} = 2.0$ Å^2; $B_{N \text{ and } C} = 2.5$ Å^2

The atomic scattering factors given in *Internationale Tabellen* [7] were used in the calculations. The reliability index R is 0.11 for the ($0kl$)-reflections and 0.12 for the ($hk0$)-reflections.

Estimates of the standard deviations [8] for the halogen positions were as follows:

I: $\sigma(x) = 0.002$ Å; $\sigma(y) = 0.003$ Å; $\sigma(z) = 0.003$ Å
Cl: $\sigma(x) = 0.008$ Å; $\sigma(y) = 0.012$ Å; $\sigma(z) = 0.010$ Å

The standard deviation for the nitrogen coordinates is 0.06 Å.

DESCRIPTION AND DISCUSSION OF THE STRUCTURE

The crystal may be regarded as being built up of chains running parallel to the c-axis, as shown in Fig. 3. In every chain piperazinium ions alternate with ICl_2^- ions. In such a chain a chlorine atom like Cl_1 is coordinated to *two* equivalent nitrogens. The nitrogen and Cl_1 atoms in one chain are coordinated to Cl_1, respectively nitrogen atoms in a neighbouring chain to form a net paral-

Table 3. Observed and calculated structure factors. The given values are one half of the absolute values. F_0's suffering from extinction are marked with an asterisk.

lel to the *a*-*c* plane. The bonds between the chains are indicated in Fig. 3 by broken lines. The ICl_2^- ions are linear and their direction approximately normal to the net. In Fig. 4 is shown a projection of the structure along the chain axis (*c*-axis), the broken lines here too indicating the bonds between the chains.

Cl_1 is surrounded by three nitrogens and one iodine atom in a distorted tetrahedral arrangement. The distance to the nitrogen atoms are 3.22 Å, 3.23 Å and 3.25 Å, respectively, as indicated in the figures. The angles N-Cl_1-N are 152°, 122° and 122° and the angles N-Cl_1-I are 102°, 95° and 120°. The Cl_1-N distances are somewhat shorter than the distance found in ammonium chloride (3.35 Å), but are equal to the shortest Cl-N distance observed in ammonium chlorobromoiodide [3].

As may be seen from Fig. 4 the distance between the Cl_2 atom in one net and the Cl_1 atom in the next one is only 3.29 Å and the shortest I—I separation is 4.06 Å while the sum of the van der Waals radii as given by Pauling [9] are 3.60 Å and 4.30 Å, respectively. These short intermolecular distances indicate a comparatively strong interaction between the nets, and the forces here are probably mainly responsible for the packing of the nets along the *b*-axis into the three dimensional lattice. All other intermolecular distances are found to be larger than the sums of the van der Waals radii.

The N—N′ distance across the piperazine ring as calculated from the coordinates given above is 2.94 Å which is close to the expected value.

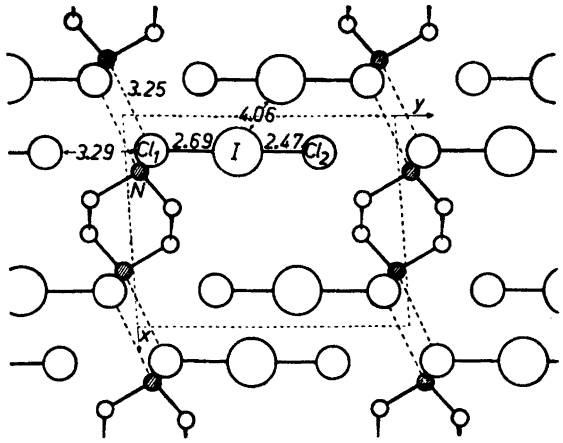

Fig. 4. The structure as seen along the chain axis. The broken lines denote the connection between the chains as in Fig. 3. Distances are in Å units.

The three halogen atoms form a linear $(Cl—I—Cl)^-$ ion which, however, is unsymmetrical, the Cl_1-I distance being 2.69 Å and the I-Cl_2 distance 2.47 Å. Since the standard deviation for the Cl-I distance is only 0.012 Å the difference between the two distances is certainly significant. Both of the I-Cl distances are substantially larger than the sum of the covalent radii [9] (2.32 Å), and also larger than the distances found in earlier examinations of the ICl_2^- ion. The halogen-halogen distances so far determined in X-ray examinations of trihalides are listed in Table 2.

Since the Cl_1 atom is surrounded closely by the positive ammonium groups while the distance from Cl_2 to the nearest nitrogen is 4.30 Å it seems very probable that Cl_1 carries a negative charge. The present ion is more analogous to the I_3^- ion than to the earlier examined ICl_2^- and $ClIBr^-$ ions as may be seen from Table 2.

It appears natural to describe the present ion as an addition complex between an electron donor (Cl^-) and an electron acceptor (ICl) and to suggest that the bond is of the same type as in the addition compounds between amines and halogens [1]. The I-Cl distance in pyridine · ICl is thus very nearly the same as in the present Cl^--I-Cl ion, and it may also be mentioned that the I-I distance found in the addition compound between benzyl sulphide and I_2 [1] corresponds closely to the shorter one in the I_3^- ion.

The author wishes to express his sincere thanks to professor Odd Hassel for his help and very kind interest in this work. The investigation has been supported by *The Rockefeller Foundation.*

On the Photo-transformation of Ergot Alkaloids
II. Lumilysergic Acids

HANS HELLBERG

Chemical Department, State Pharmaceutical Laboratory, Stockholm, Sweden

The preparation of the four theoretically possible lumilysergic acids is here reported together with a description of the physical properties of these substances such as the appearance of crystals, optical rotation, light absorption, pK_a-values. A scheme for the identification of the acids by paper chromatography has been elaborated. Finally the stereochemical connections between the lumiacids on one hand and the lumialkaloids and the dihydroalkaloids on the other have been discussed and established with rather great probability.

Several series of lumiergot alkaloids are known today and there are good reasons for assuming that all their members derive from the four theoretically possible lumilysergic acids, which differ stereochemically at the atoms C_8 and C_{10} [1,2]. Stoll and Schlientz [1] have described the preparation of lumilysergic acid I, and — as preliminarily reported [3] — we have now succeeded in preparing all four acids.

Paper chromatography was used for the identification of the lumilysergic acids. The first method was taken over from our previous work on the lumiergometrins [2]. It works with an acetic acidic aqueous phase and is here called "the acidic method". The main feature of the second method is the ammoniacal water phase, and it is therefore referred to as "the ammoniacal method".

Already in experiments on a micro scale, the products being identified only by paper chromatography, did we find four lumilysergic acids (Table 1). For a logical discussion we may provisionally denote them as A, B, C and D. In the acidic method the acids B and C do not differ in R_F-values, and in the ammoniacal method the difference between the R_F-values for A and D is too small to be of use for the purpose of identification. But used in combination the two methods give a fairly reliable identification of the lumilysergic acids.

The preparation of the lumiacids took place both by irradiation of lysergic and *iso*lysergic acids in acidic solution, and by alkaline hydrolysis of lumialkaloids. The products were separated by partition chromatography on kieselguhr (celite) with the solvents from the methods on paper but in somewhat changed proportions. Details are given in the experimental part, but the results may be summarized as follows: —

Irradiation (acidic solution)

Lysergic acid → A + C (traces)
*Iso*lysergic acid → B + A (small quantity) + C (small quantity) + D (traces).

Hydrolysis (KOH in 50 % ethanol, boiling 1 $^1/_2$ h)

Lumiergocristine I → A + B
Lumiergocristinine II → C + D

Thus the irradiation of lysergic acid gave an almost pure lumiacid in conformity with the behaviour of the alkaloids derived from lysergic acid. However, also *iso*lysergic acid gave one strongly dominating product, unlike its alkaloidal derivatives, which on irradiation give the two possible C_{10}-alternatives in measurable yields. The appearance here of the acids A + C in small quantities may at least partly be attributed to a transformation of *iso*lysergic acid into lysergic acid in the strongly acidic solution which was irradiated.

At the alkaline hydrolysis of both lumiergocristine I and lumiergocristinine II two acids were obtained in yields of comparable magnitude. However, the treatment of pure lumiacids with ethanolic KOH under the conditions of hydrolysis used did not cause any transformation detectable even by paper chromatography, and so the transformation occurring during the hydrolysis of the lumialkaloids must be coupled with the hydrolytic cleavage. Very probably it is an epimerization at C_8. According to Stoll *et al.*[4] the same treatment of the analogous dihydroalkaloids leads to only one acid in each case. In the main this could be confirmed by us on paper chromatograms for dihydroergotamine I and dihydroergocristine I. Thus there seems to be a distinct difference between lumialkaloids and dihydroalkaloids in their ability to epimerize at C_8 on alkaline hydrolysis.

The stereochemical connections of the lumilysergic acids to lumialkaloids and dihydroalkaloids can, to begin with, be discussed on the basis of the preparative experiments made. If we postulate that the hydrolytic decomposition leads to an epimerization at C_8, the lumiacids A and B must be denoted as I while C and D must be assigned the figure II. From the results of the irradiation of lysergic acid it may be concluded that A is lumilysergic acid I. Then B must be lumi*iso*lysergic acid I, which is not contrary to the results of the irradiation of *iso*lysergic acid. The appearance of C and D, respectively, at the irradiation of lysergic and *iso*lysergic acid, respectively, indicates that C is lumilysergic acid II and D lumi*iso*lysergic acid II.

The connections thus made probable are corroborated by a comparison of the R_F-values obtained by the acidic methods for lumialkaloids in the first paper of this series [2] and for lumiacids in this paper (Table 1). Using the same provisional nomenclature as in Ref.[2] * the scheme given there may be extended as follows:

* α denotes the slower and β the faster component of a pair of substances, probably having the same steric configuration at C_8.

Table 1. Paper chromatography of lumilysergic acids (see experimental part).

	R_F	
	Acidic method	Ammoniacal method
Lumilysergic acid I (= substance A)	0.39	0.16
Lumi*iso*lysergic acid I (= substance B)	0.32	0.41
Lumilysergic acid II (= substance C)	0.32	0.06
Lumi*iso*lysergic acid II (= substance D)	0.48	0.18

α-lumi-ine = lumi-ine II ; lumilys.acid II = α-lumilys.acid.
β-lumi-ine = lumi-ine I ; lumilys.acid I = β-lumilys.acid.
α-lumi-inine = lumi-inine I ; lumi*iso*lys.acid I = α-lumi*iso*lys.acid
β-lumi-inine = lumi-inine II; lumi*iso*lys.acid II = β-lumi*iso*lys.acid

Also a glance at those lumialkaloid and lumiacid pairs which are supposed here to be sterically similar at C_{10} reveals a corresponding regularity, possibly with one weak point, *viz.* the lumiergometrine I and the lumiergometrinine I, which show approximately identical R_F-values.

Finally reference may be made to the tentative discussion of the same sterical connections which appeared in the former paper of this series [2], where from an argument entirely different from those of this paper the same allotment of configurations was obtained.

EXPERIMENTAL

A. Paper chromatography

The acetic acid method has been described in the first paper of this series [2].

The ammoniacal method was performed in a very similar way, the main difference being that the acetic acid was exchanged for ammonia. The solvent mixture had the following definite composition: Benzene, butanol, 2 M ammonia (1:3:4).

In Table 1 there are collected the average R_F-values of the lumilysergic acids, obtained with both methods.

B. Preparation of the lumilysergic acids

Irradiation of lysergic acid. A solution of 0.75 g of crystallized lysergic acid ($[\alpha]_D^{20}$ = +43°; c = 1 in pyridine) in 30 ml of 0.2 M HCl, kept air-free by a stream of N_2, was irradiated in a quartz flask until transformation ceased. (Time: ca. 3 h with a Hanovia S-4 U.V.-lamp). The dark blue solution was made alkaline with 3 ml of 5 M ammonia and saturated with a stream of CO_2. Gradually a crystalline substance, corresponding paper-chromatographically to lumilysergic acid I (substance A) was precipitated. The crystallization was completed over-night in the refrigerator. The precipitate was redissolved in 50 ml of 0.2 M ammonia and precipitated again with CO_2. Yield: 0.25 g of a light grey substance. Before the determination of physical constants (Tables 1, 2 and 3)

Table 2. Summary of appearance and some physical properties of the lumilysergic acids (constants corrected to dry basis).

	Appearance	Heating on Kofler block	Optical rotation $[\alpha]_D^{20}$ $c = 0.5$ in 0.5 M HCl	Light Absorption E (1 %, 1 cm) in 0.1 M HCl
Lumilysergic acid I (substance A)	From water: Short pillars From methanol: Long needles, breaking up to short rods	Decomposition at 240°C	+ 38°	224 at 283 mμ (max.)
Lumi*iso*lysergic acid I (substance B)	From water: Conglomerate of thin plates	Melting and decomp. 185°–190°C	+ 47°	230 at 283 mμ (max.)
Lumilysergic acid II (substance C)	From water: Rectangular plates	Melting and decomp. ca. 190°C	+ 10°	228 at 284 mμ (max.)
Lumi*iso*lysergic acid II (substance D)	From methanol: Conglomerate of small apparently irregular crystals	Decomposition at 210°C	− 13°	205 at 281 mμ (max.)

and elementary composition the lumilysergic acid I was recrystallized from a great quantity of methanol. (Substance dried in a high vacuum at 140°C. Found: C 65.85; H 6.44; N 9.54; O 16.88. Calc. for $C_{16}H_{18}O_3N_2$ (286.34): C 67.12; H 6.34; N 9.78; O 16.76).

In the mother liquor of the first crystallization lumilysergic acid II (substance C) was identified by paper chromatography.

Irradiation of iso*lysergic acid.* 0.5 g of crystallized isolysergic acid ($[\alpha]_D^{20}$ between +260° and +270°; $c = 1$ in pyridine) dissolved in 7.5 ml of acetic acid and 20 ml of water was treated as the solution of lysergic acid. The irradiated solution was neutralized to pH 7 with ammonia and evaporated to dryness in a CO_2-atmosphere under reduced pres-

Table 3. Estimated pK_a-values for lysergic and lumilysergic acids. Water Solution. 22°C. (See experimental part.)

	pK_1	pK_2
Lysergic acid *	3.22	7.93
*Iso*lysergic acid *	3.12	8.57
Lumilysergic acid I	3.38	9.00
Lumi*iso*lysergic acid I	3.94	9.17
Lumilysergic acid II	3.42	8.33
Lumi*iso*lysergic acid II	3.38	9.20

* Ref.[5] reports the following figures (24°C): Lysergic acid $pK_1 = 3.19$. 3.44; $pK_2 = 7.96$, 7.68. *Iso*lysergic acid $pK_1 = 3.21$, 3.44; $pK_2 = 8.31$, 8.61.

sure. The residue, freed from the ammonium salts by sublimation at 60°C in a high vacuum, was subjected to partition chromatography. Column: 38 × 3.4 cm; 120 g of celite. Solvent mixture at the start: benzene, butanol, 2 M ammonia (1:1:2). The dominating fraction, lumi*iso*lysergic acid I (substance B) came out as the second peak. After changing the elutrient to the organic phase of the mixture benzene, butanol, 2 M ammonia (1:3:4) there were obtained two more small fractions. From the first of these ca. 20 mg of lumilysergic acid I (substance A) and from the second a few mg of lumilysergic acid II (substance C) were isolated. Lumi*iso*lysergic acid II (substance D) was identified paper-chromatographically in the liquid fraction containing lumilysergic acid I.

The main fraction, containing lumi*iso*lysergic acid I was evaporated in a vacuum (N_2-atmosphere). The residue, dissolved in 20 ml of 0.4 M ammonia, was filtered, neutralized with CO_2 and evaporated in a CO_2-atmosphere to a volume of ca. 2 ml. The lumi*iso*lysergic acid crystallized from the solution. The yield, 120 mg, was recrystallized once from water. Physical properties in Tables 1, 2 and 3. (Substance dried in a high vacuum at 80°C. Found: C; 67.00 H 6.44; N 9.83; O 16.52. Calc. for $C_{16}H_{18}O_3N_2$ (286.34): C 67.12; H 6.34; N 9.78; O 16.76).

Hydrolysis of lumiergocristine I. A solution of 1 g of crystallized lumiergocristine I ($[\alpha]_D^{20} = +17°$; $c = 1$ in pyridine) in 16 ml of M KOH in 50 % ethanol was boiled under reflux in an N_2-atmosphere for 1 1/2 h. After cooling most of the ethanol was evaporated in an N_2-atmosphere, and then the solution was saturated with CO_2 and evaporated to dryness in a CO_2-atmosphere, both distillations being made under reduced pressure. The residue was chromatographed as described in the former section, the elutrient being changed after lumi*iso*lysergic acid I *(v. supra)*. The second and the third fractions were dominating and contained lumi*iso*lysergic acid I (substance B) and lumilysergic acid I (substance A), respectively. After the removal of the solvent the residues were treated as described under the headlines "irradiation of isolysergic acid" and "irradiation of lysergic acid". The yields of crude crystalline material were 50 mg of lumi*iso*lysergic acid I and 95 mg of lumilysergic acid I. The recrystallized products were identified through the physical properties given in Tables 1, 2 and 3. They were not submitted to elementary analysis.

Hydrolysis of lumiergocristinine II. 0.45 g of lumiergocristinine II (pure according to the criteria given in Part I of this series; Ref.[2]) was hydrolyzed as described for lumiergocristine I. The reaction mixture was neutralized with CO_2 and evaporated under reduced pressure in a CO_2-atmosphere. The residue was extracted with 100 + 50 + 50 ml of absolute ethanol, the filtered extracts evaporated to dryness in an N_2-atmosphere under reduced pressure and submitted to partition chromatography. Column: 40 × 3.4 cm; 140 g of celite. Solvent mixture at the start: benzene, butanol and 20 % acetic acid (1:1:2). Two main fractions were obtained, the first one containing lumi*iso*lysergic acid II (substance D) and the second lumilysergic acid II (substance C). The fractions were evaporated to dryness.

The residue containing lumilysergic acid II was dissolved in 20 ml of 0.4 M ammonia. The solution was filtered, neutralized with CO_2 and evaporated in a CO_2-atmosphere to ca. 2 ml. The substance crystallized from this solution in a yield of 45 mg, and after recrystallization from water the material had the physical properties given in Tables 1, 2 and 3. (Substance dried in a high vacuum at 100°C. Found: C 67.20; H 6.36; N 9.51; O 16.56. Calc. for $C_{16}H_{18}O_3N_2$ (286.34): C 67.12; H 6.34; N 9.78; O 16.76).

The residue containing lumi*iso*lysergic acid II having been dissolved in a few ml of methanol, the substance crystallized. The yield was 55 mg. After recrystallization from methanol lumi*iso*lysergic acid II showed the physical properties given in Tables 1, 2 and 3. (Substance dried in a high vacum at 80°C. Found: C 66.63; H 6.59; N 9.90; O 16.90. Calc. for $C_{16}H_{18}O_3N_2$ (286.34): C 67.12; H 6.34; N 9.78; O 16.76).

C. Determination of protolytic constants

About 6 mg of the substance, dissolved in ca. 5 ml of CO_2-free water by the addition of ca. 0.25 ml of 0.1 N hydrochloric or methanesulphonic acid, were titrated potentiometrically with 0.02 N CO_2-free sodium hydroxide. The measuring system used (glass-electrode, calomel electrode, Radiometer PHM 3) was constantly and carefully calibrated by means

of pH-standards (M/20 potassium hydrogen phthalate and M/20 sodium borate). The temperature was 22°C. The first equivalence point of the acids could be fixed by a sufficient pH-change. From this value the volumes for half-neutralization in either direction were calculated, using the weight of substance taken, the molecular weight of the acids and the normality of the sodium hydroxide. Then the pK_a-values were read from the titration curve without further correction. The individual results obtained did not as a rule differ more than ± 0.05 pH-units from the averages given in Table 3. pK_a-values for the lysergic acids in aqueous solution have been determined by Craig *et al.*[5] Their figures, which do not seem to be very accurate, are not inconsistent with ours.

Acknowledgements. The elementary analyses were performed by Dr. Alfred Bernhardt, Max-Planck-Institut für Kohlenforschung, Mühlheim (Ruhr), which is gratefully acknowledged. My thanks are also due to *Statens Medicinska Forskningsråd* for financial support, and to Mrs M. Spilsbury, who revised the English.

Interferometric Studies of Boundary Formation and Deviations from Ideality in Diffusion Experiments

OLOF BRYNGDAHL

Institute of Optical Reseach, The Royal Institute of Technology, Stockholm 70, Sweden

Various types of diffusion cells have been studied by means of the birefringence interference method especially with regard to the methods used for producing a sharp interface. This method, which is very sensitive to small concentration differences, was found to give valuable information concerning the beginning of the diffusion process. Thus, the boundary formation has been compared for different types of cells. The small influence of convection, in spite of the small concentration differences used, was quite remarkable. The various factors influencing ideality in diffusion experiments using the birefringence interference method on very dilute solutions have been discussed in some detail.

STUDIES ON BOUNDARY FORMATION IN DIFFUSION CELLS

Optical methods are of great value in the study of liquid diffusion because of their precision and the great amount of information which they yield. One of the main problems in arranging diffusion experiments is the formation of an initially sharp interface.

This problem has been solved in many different ways. Diffusion cells belonging to the types mentioned below have been designed specially for registration by optical methods.

The diffusion equation is usually solved using the initial condition that the solution and solvent are separated by a sharp interface in an infinitely long tube at $t = 0$. Turbulence and other disturbing phenomena arising from the boundary formation process must therefore be suppressed. Thus, the way in which the boundary is formed has proved to be of great importance, since this is decisive for the magnitude of the zero-time correction and the lapse of time after which the first measurements can be taken.

The magnitude of the concentration difference influences the ideality of the initial gradient. With decreasing concentration difference, the density gradient decreases and the disturbances arising from the formation process disappear more slowly. On working with very dilute solutions it is consequently important that the disturbing phenomena be minimized. It will be shown below that sharp interfaces can be formed using the boundary-sharpening technique [1] even with very small concentration differences.

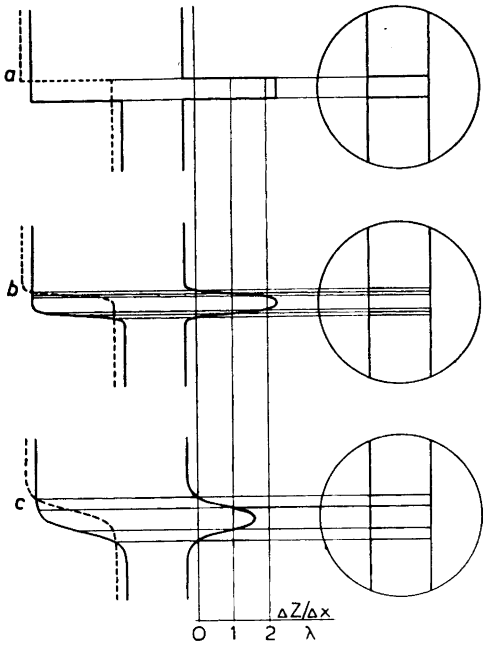

Fig. 1. (Left) The refractive index as a function of x for the concentration gradient. (Middle) The corresponding difference graph for the path differences between the two wave fronts produced by the Savart plate. (Right) The appearance of destructive interference in the object plane.

a) An ideal initial boundary gives rise to a concentration step which in this method is represented by a fringe pair.

b) At the beginning of the diffusion run, a record of the refractive index instead of its gradient is obtained because of the steepness of the concentration gradient.

c) As a rule, however, the photograph gives the derivative dn/dx directly due to the doubling of the wave front and no correction is necessary.

I. OPTICAL METHOD

The shearing interferometer utilizing birefringence interferences [2-4] and giving an image of the whole diffusion column is very sensitive to small concentration differences and is also suitable for the registration of rapid processes. Studies of the beginning of the diffusion process have been performed with this recording interferometric method, the optical arrangement of which has been described in an earlier paper [4].

By placing a birefringent double crystal plate (Savart plate) in parallel light behind the cell in the optical arrangement, a doubling of the wave front (representing the concentration curve) is effected (Fig. 1). If the crossed polarizers have their oscillation planes at 45° with respect to the principal planes of the Savart plate, the light is extinguished at those points where the optical path difference between the wave fronts is a whole number of wave lengths [4]. From Fig. 1a it is evident that an ideal boundary formation is represented

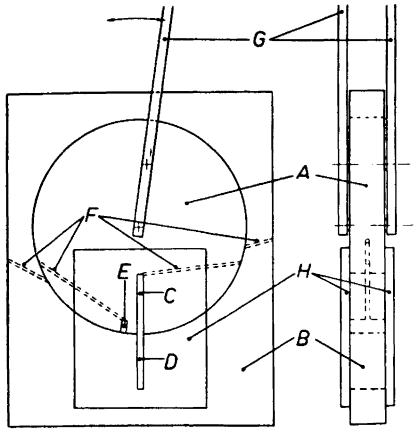

Fig. 2. Diffusion cell. By means of a lever *G* it is possible to turn the inner disk *A* until the two halves of the diffusion column *C* and *D* coincide. In this way the boundary will be formed and the diffusion started. The cell is tightened with silica lubricant at the glass plates *H* forming the walls of the diffusion cell.

by one horizontal fringe pair with a distance between the fringes equal to the displacement between the wavefronts. In Fig. 1 it is seen that at first the optical method gives a doubling of the integral curve and that later, when the refractive index gradient becomes broader, the method gives a record of the derivative dn/dx. Actually, the measurements give $\Delta n/\Delta x$ but the correction for obtaining the derivative can be easily calculated [2-4]. The correction is as a rule very small and can be neglected [2]. Only at the start of the diffusion has one to pay attention to the correction term. Hence, if no measurements are made at the beginning, the method becomes quite convenient.

II. DIFFUSION CELLS

In optical methods the following demands are made upon the diffusion cells:

a) plane parallel, transparent, homogeneous walls in the light direction,

b) a rectangular cross section to eliminate optical distortions,

c) uniformly thick diffusion column forming no wedge.

Thanks to Prof. O. Lamm and Dr. H. Svensson who kindly put diffusion cells at our disposal, a fairly complete examination could be performed and the different ways of producing boundary layers compared.

The types of cells commonly used and examined here can be classified in three groups according to the technique of boundary formation:

I "Draw-slide cell" — usually referred to as the Lamm cell. A slide separating solution and solvent is drawn out — two cells of this type [5] with thicknesses of 1 cm (*Ia*) and 5 cm (*Ib*) were studied.

II "Flowing-junction cell". The boundary is formed by allowing solution and solvent to flow out together through a narrow horizontal exit slit in the side wall of the cell [6-9]. The cell [6] examined here was 5 cm thick.

III "Sliding-solvent cell". In this cell the interface is formed by sliding the solvent over the solution [10-12].

After some unsuccessful experiments with cells of type *III* built according to descriptions found in the literature, the author decided to design a new cell of this type (Fig. 2). The material used was perspex, 1.2 cm thick. A circular disk *A* (diameter = 10 cm) was fitted into a corresponding hole in a plate *B*. Narrow slits *C* and *D* (3 mm) were cut and used as a diffusion column. A slit *E* was also cut for pouring in the bottom solution. Small channels *F* are bored to permit filling by means of a syringe. The boundary layer is formed by turning the disk until the slits *C* and *D* coincide.

III. REGISTRATION

In order to get a complete mapping of the phenomena arising from the boundary formation process, two different photographic registration methods have been used.

1. A registration of the whole of the cell plane was performed at equal time intervals. The time of exposure was about 1 sec.

2. A continuous registration of the interference pattern gives much information about the symmetry and various disturbing phenomena and their influence. A narrow vertical strip of the image plane was reproduced on a film attached to a continuously moving drum. A film speed of 3 cm/min was employed.

Ilford HPS film was used to attain a minimum of exposure.

IV. EXPERIMENTS

Monochromatic light (5 461 Å) was used in all experiments. The solutions, always with distilled water as solvent, were carefully thermostated at a temperature of about 21°C.

The following experiments were carried out:

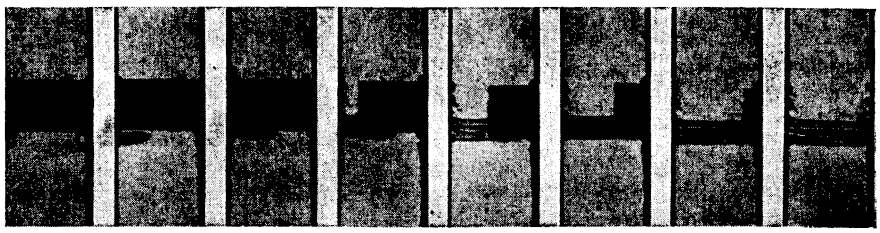
Run	Solution diffusing against water	g/100 ml	Cell thickness in cm	Zero-time correction in sec	
Ia, 1 *	glycine	0.0942	1.0	29	Draw-slide cell
Ib, 1	sucrose	0.0503	5.0	22	
Ib, 2	sucrose	0.0503	5.0	18 (20)	
II, 1	sucrose	0.0500	5.0	4	Flowing-junction cell
II, 2	sucrose	0.0500	5.0	3	
III, 1	sucrose	0.2508	1.2	20	Sliding-solvent cell

V. RESULTS

In all cases the concentration was chosen so as to give rise to 3—5 fringe pairs at the beginning of the run.

* The first figure refers to the cell types described in Section II, and the last figure to the registration methods listed in Section III.

Run I a, 1



I. "Draw-slide cell"

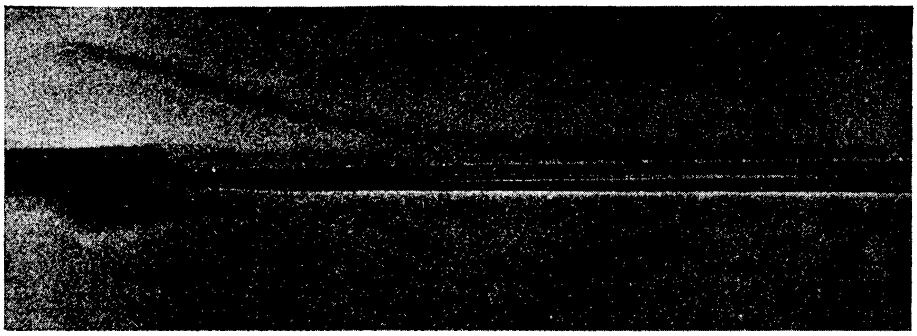
Ia, 1. The registrations were performed at 6 sec intervals. From the recordings it is seen how a region of mixing is developed below the slide. If the dividing wall is withdrawn at a uniform speed, a sucking effect acts upon the liquid so that a sharp boundary is formed. It should be added that the zero-time point (starting point of the diffusion run) will generally occur in the period between when the slide starts to leave the cell wall and when it is completely removed from the diffusion column. The slide was 2 mm thick.

Ib, 1. The slide thickness here was 1 mm. A turbulent motion under the slide is also visible in this run. However, another phenomenon occurs - at the instant the slide leaves the cell wall a narrow beam of solution is forced up into the solvent layer. It spreads out at a definite height but sinks and disappears with time (*cf. Ib, 2*).

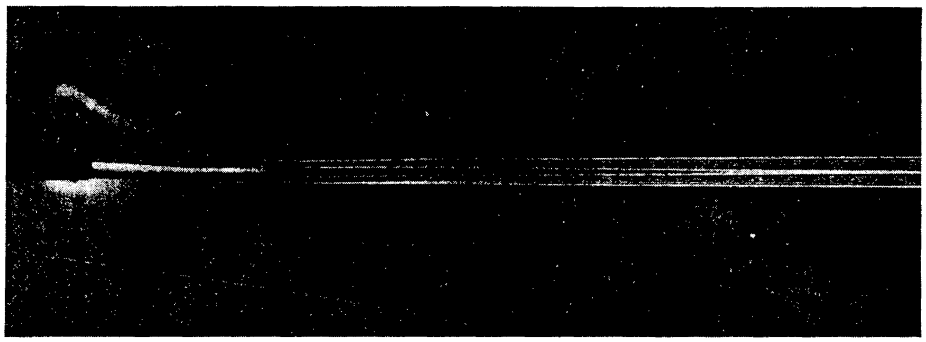
The influence of the slide velocity on the boundary formed has been examined. In the case of the 2 mm slide (*Ia*), only slow speeds (less than 0.2 mm/sec) are possible since turbulence sets in at higher speeds. A speed of 0.1 mm/sec gave a smooth symmetrical gradient and was found to be the

I b, 1

Run I b, 2



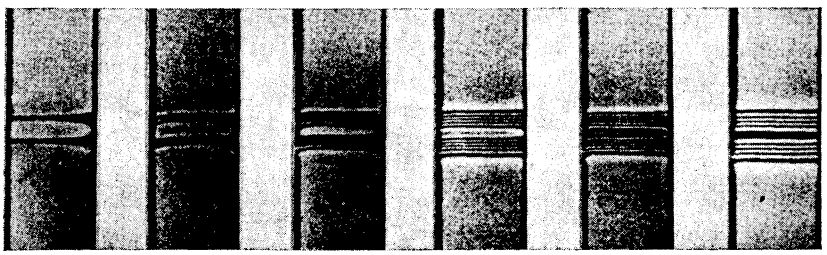
Run I b, 2



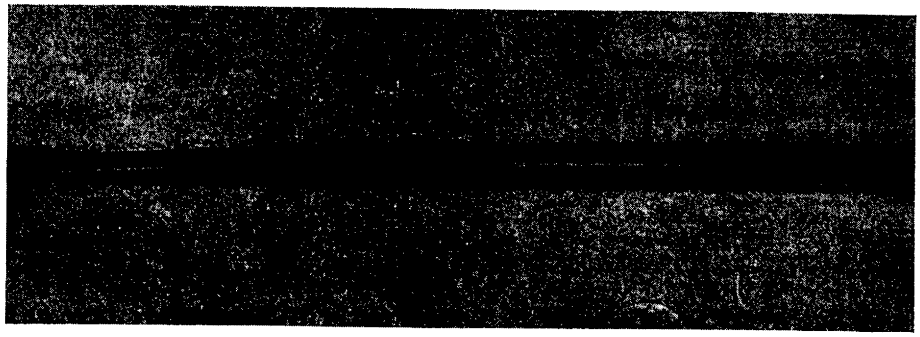
most suitable value. The cell with the 1 mm slide (*Ib*) gave a sharp boundary with a slide speed of 1 mm/sec. However, at this speed disturbing vibrations of the boundary occurred. The most satisfactory results were obtained with a value of about 0.2 mm/sec. The slide speed must not be too slow in order to avoid lateral skewness of the gradient.

Ib, 2. Two records showing the change in the interference pattern with time. Here the vanishing of the disturbing processes in clearly seen. The sharpness of the gradient is also apparent.

Run II, 1



Run II, 2



II. "Flowing-junction cell"

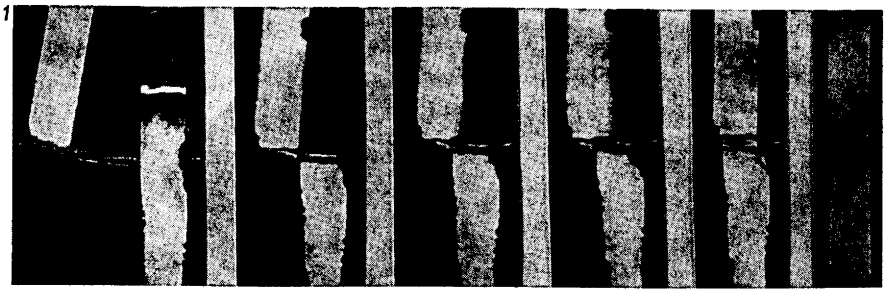
II, 1. The sharp gradient is obtained as a state of equilibrium. As is seen from the photographs, the boundary is sharper near the exit slit. The outflow rate considerably influences the symmetry of the gradient. The outflow was about one drop every two seconds. However, a continuous flow was obtained by placing the capillary outlet in a beaker of water. Different concentrations required different sized capillaries.

II, 2. No disturbances can be observed in this photograph. This cell gave the most ideal boundary obtained in this work. However, there is asymmetry due to incorrect focusing. This skewness of the gradient disappears if the camera is focused on a plane 1/3 of the cell thickness from the front wall [13].

III. "Sliding-solvent cell"

III, 1. This cell resembles cell type *I* but here the displacement of the upper column of liquid has been eliminated. The liquid column was moved with a speed of 0.3 mm/sec which was found to be the best one for this cell. Only small asymmetries along the gradient have been observed. Sharp boundaries were also obtained for very dilute solutions.

Run III, 1



These experiments confirm the possibility of forming sharp interfaces between solutions with very small density differences. The boundary-sharpening technique works well without leaving any disturbing convections and no superimposed thermal gradient is necessary to increase the density gradient. As is seen from the photographs of the formation of the interfaces, *all* the cells examined work very well and can be used for precise measurements at the smallest concentration differences.

It would perhaps be worth while investigating the possibility of improving the boundary-sharpening technique further by equipping the cell with two outflow slits opposite each other. By varying the outflows through the two slits, the optimum conditions could be obtained (*i.e.* the outflows need not necessarely be equal).

DIGRESSION ON DEVIATIONS FROM IDEALITY IN DIFFUSION EXPERIMENTS

VI. THE EFFECT OF THE MAGNITUDE OF THE DENSITY DIFFERENCE ON THE FORMATION OF IDEAL GRADIENTS

It is possible to sharpen the boundary using a transient, superimposed thermal gradient. This procedure cannot be used when working with very dilute solutions since the time for the disappearance of the thermal gradient is comparable to the length of the run.

The values of the parameters, *e.g.* slide speed, outflow rate and pressure difference, have proved to be very critical when working with small concentration differences. The adjustment of the different parameters is easiest with the flowing-junction cell. Initially sharp boundary layers have been observed with the flowing-junction cell down to a concentration difference (sucrose solution) corresponding to an optical path decrement of about 1 000 Å.

One may ask how great a concentration difference is necessary to form a sharp interface. Convection caused by transient temperature gradients, which cannot be totally eliminated by good thermostating, must be prevented by a sufficiently large concentration gradient.

An estimate of the amount of convection produced can be obtained from Grashof's number * (Gr_1) and another dimensionless number (Gr_2) specifying the convection caused by a density gradient.

$$Gr_1 = \frac{l^3 g \gamma \Theta}{\nu^2}$$

$$Gr_2 = \frac{l^3 g \frac{1}{V}\left(\frac{\partial V}{\partial c}\right) \Delta c}{\nu^2 d}$$

The influence of the various parameters (l — characteristic length, Θ — temperature difference, Δc — concentration difference, ν — kinematic viscosity) on the convection can be obtained using these numbers.

* See, *e. g.*, *Lexikon der Physik*, H. Franke, Stuttgart 1950, p. 593.

The following notations are used: g — gravity, γ — thermal expansion coefficient, V — volume, c — concentration, ϱ — density of the solution.

$Gr_1 = Gr_2$ gives the concentration gradient necessary to counteract a transient thermal gradient (Θ).

$$\frac{\Theta}{\Delta c} = \frac{\partial V/\partial c}{V\gamma} = \frac{1}{\gamma}\frac{\partial \ln V}{\partial c} = -\frac{1}{\gamma}\frac{\partial \ln \varrho}{\partial c} \tag{1}$$

A rather trivial fact also apparent from Grashof's number is that the cell should be as narrow as possible if the convection is to be a minimum.

VII. ADVANTAGES OF PERFORMING DIFFUSION EXPERIMENTS WITH SMALL CONCENTRATION DIFFERENCES

Working with small concentration differences diminishes most of the problems pertaining to the non-linear relation between refractive index and concentration as well as to the concentration dependance of the diffusion coefficient.

The time necessary for performing a diffusion run by the birefringence interference method is greatly dependant upon the concentration difference. Small concentration differences make possible a saving of time and the use of smaller amounts of materials which may be difficult to obtain or purify.

With systems having a density maximum or minimum at a certain concentration, it is necessary to work in a range where the density-concentration curve is monotonic and this can always be achieved by working with very small concentration differences.

VIII. FACTORS DECISIVE FOR THE LENGTH OF TIME BEFORE MEASUREMENTS CAN BE PERFORMED

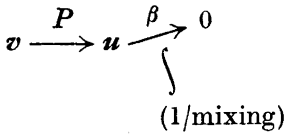
No measurements can be performed before the lapse of a sufficient period of time to allow:

1) disturbing processes arising from the shearing procedure to die out (see Section X, a),

2) the aberrations to decrease to 1/50 of a light wavelength (the critical time of diffusion of Svensson) [14].

However, even working with such low concentration differences as those here, the critical time is surprisingly small, about a few seconds, and can be left out of consideration. What sets a limit to measurements at the beginning of the diffusion process are consequently the disturbances arising from the formation of the boundary. It is difficult to give a strict mathematical treatment of this.

An intuitive conception may be conveyed by the following picture:



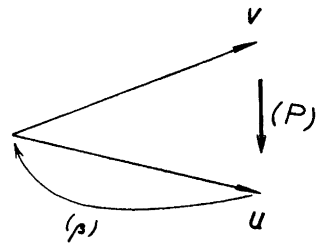


Fig. 3. Velocity field representation in *Hilbert space* l^2 (projected in two dimensions).

where v represents the velocity field of the liquid during the formation process, u the velocity field after closing the outflow or removing the slide and β = damping factor of the liquid. The extent of mixing is inversely proportional to β. P indicates a transformation (operator) of the velocity field in function space and β is related to the decay of the vector field u *. A "projection" of function space (Hilbert space) on the twodimensional subspace represented by the plane of the paper (Fig. 3) shows that the question — "How long will the decay of the turbulent field take?" — is answered as soon as the operator P and β can be formulated. A more detailed study of this question would be of great value in suggesting new ways for the further improvement of the cell construction.

* Let us denote the velocity of flow at a single point by v. v, which is a vector function of the position vector, can be expanded in an infinite series of mutually orthogonal vector functions $\bar{\varphi}_i$, satisfying the same boundary conditions as v:

$$v = \sum_{i=1}^{\infty} a_i \bar{\varphi}_i$$

Now, the functions v and $\bar{\varphi}_i$ can be regarded as elements of a so called Hilbert space. The infinite sequence

$$v = \{a_i\}_1^{\infty} \ (= \{a_1, a_2, a_3, \ldots, a_i, \ldots\}),$$

where the a_i are the same as above, is an element of another Hilbert space (l^2 called). It can be shown that there is a one to one correspondence between the two Hilbert spaces mentioned. In this way the whole of the velocity field v can be represented by a single point in Hilbert space. With the use of these concepts the kinetical energy of the streaming liquid may be regarded as a so called functional of points in Hilbert space:

$$\Phi = \Phi(v)$$

If on closing the outflow the velocity field v goes over into another velocity field, u, with the same energy,

then

$$\Phi(u) = \Phi(v),$$

and the transformation from v to u may be thought of as effected by an *operator*, P:

$$u = P\,v.$$

Thus, by an operator, a point of one Hilbert space is assigned to each point of another Hilbert space in a one to one fashion in exactly the same manner as an ordinary function $y = f(x)$ assigns a point on the y-axis to each point of the x-axis.

IX. ZERO-TIME CORRECTION

From the registrations it is evident that the smallest zero-time correction is obtained with the flowing-junction cell. Two principles for determining the zero-time correction are possible, namely

1) insertion of the real initial condition into Fick's law, and

2) extrapolation to zero time from the points obtained.

Our findings prove that the second method is the most reliable since all cell types show deviations from the ideal process during the first part of the run. Methods for obtaining the zero-time correction in these experiments are found in Ref.[4]

X. THE INFLUENCE OF DEVIATIONS FROM IDEALITY ON THE MEASUREMENTS

When studying free diffusion by measuring the refractive index gradient in the diffusion cell as a function of time, one has to take the following factors into consideration in order to obtain accurate measurements:

1) occasional skewness arising from the boundary formation process,

2) the Wiener skewness (an optical effect),

3) deviations from the linear relation between refractive index and solute concentration,

4) the concentration dependance of the diffusion coefficient,

5) deviations from ideality due to polydispersity or impure preparations.

a. Solution of Fick's equation with an asymmetrical initial condition. A skew gradient caused by the mechanical boundary formation process (occasional skewness) leads to the problem of solving Fick's second equation with an asymmetrical initial condition, *e.g.* of the form $c(\xi,0) = c_0(1-e^{-\xi/a})$ for $\xi>0$ and $c(\xi,0) = 0$ for $\xi<0$, where ξ is the coordinate in the diffusion direction and a is a parameter proportional to the amount of asymmetry.

The influence of the skewness on the measurements can be estimated by the solution of the diffusion equation with an unsymmetrical initial condition. The solution has the following form [15]

$$c(x,t) = \int_{-\infty}^{+\infty} \frac{1}{2\sqrt{\pi Dt}}\, e^{-\frac{(x-\xi)^2}{4Dt}}\, c(\xi,0)\, d\xi \qquad (2)$$

With $c(\xi,0) = c_0(1-e^{-\xi/a})\ U(\xi)$, where U is the "unit step function"

$$U(\xi) = \begin{cases} 1 \text{ for } \xi > 0 \\ 1/2 \text{ for } \xi = 0 \\ 0 \text{ for } \xi < 0 \end{cases}$$

we get

$$c(x,t) = \int_{0}^{\infty} \frac{c_0}{2\sqrt{\pi Dt}}\, e^{-\frac{(x-\xi)^2}{4Dt}}\, (1-e^{-\xi/a})\, d\xi \qquad (3)$$

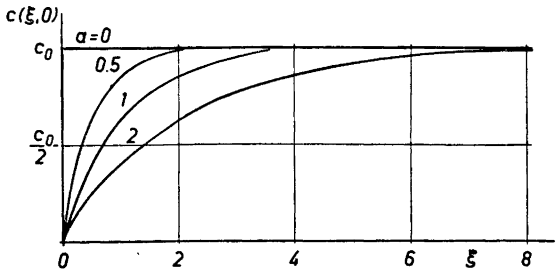

Fig. 4. Initially skew concentration distribution with the asymmetry parameter $a = 0$ (ideal distribution), 0.5, 1, and 2, respectively.

The solution can be written in the form

$$c(x,t) = \frac{c_0}{2}\left\{1 + \operatorname{erf}\left(\frac{x}{\sqrt{4Dt}}\right)\right\} - \frac{c_0}{2}\exp\left(\frac{Dt}{a^2} - \frac{x}{a}\right)\left\{1 - \operatorname{erf}\left(\frac{\sqrt{Dt}}{a} - \frac{x}{\sqrt{4Dt}}\right)\right\} \quad (4)$$

where the first term is the ordinary solution (for $c(\xi,0) = U(\xi)$) and the second term is the correction due to the skewness.

An asymptotic expansion of the expression for the correction term in (4) shows that the correction will approach zero for large values of t.

A quantitative estimation of the influence of an occasional skewness on the diffusion coefficient determined by the present method can be obtained as follows.

Derivation of (4) gives

$$\frac{\partial c(x,t)}{\partial x} = \frac{c_0}{2a}\exp\left(\frac{Dt}{a^2} - \frac{x}{a}\right)\left\{1 - \operatorname{erf}\left(\frac{\sqrt{Dt}}{a} - \frac{x}{\sqrt{4Dt}}\right)\right\} \quad (5)$$

In Fig. 4 the initial concentration distributions are shown for some values of the asymmetry parameter a. Fig. 5 shows the derivative curve for the same values of a.

In the method of evaluation described in Ref. [4] an unsymmetrical gradient will cause a small error in the measured value of $2x$ and accordingly in the diffusion coefficient *. Now a theoretical explanation of the appearance of the experimental curves in Figs. 8 and 11 of Ref.[4] is possible. In the neighbourhood of the inflexion point (see Fig. 5) an asymmetrical gradient will give too small a value of $2x$ while, on the other hand, measurements on the outermost fringe pairs correspond to the lower part of the Gaussian curve. Fig. 8 refers to measurements near the inflexion points and it is seen that the curves break down for small values of $(2x)^2$. In Fig. 11 too high a value for the

* The distances $2x$ between corresponding fringes in the interference pattern are measured. Following a definite fringe pair with time, we may plot $(2x)^2$ *vs.* t and the diffusion coefficient is then obtained from a value of $(2x)^2$ and its corresponding times t_1 and t_2 by the equation

$$D = \frac{(2x)^2(1/t_1 - 1/t_2)}{8 \ln t_2/t_1}$$

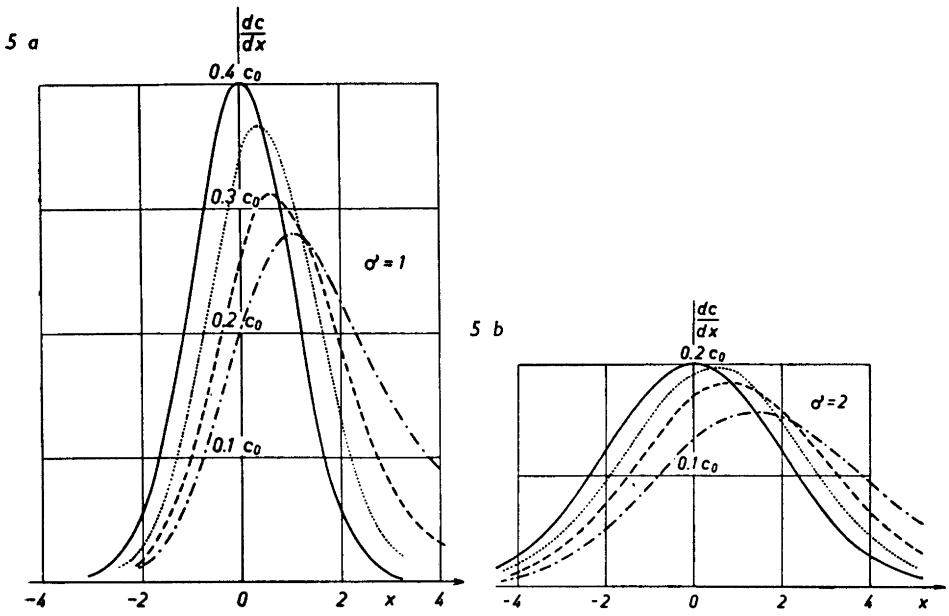

Fig. 5. dn/dx curves corresponding to the curves of Fig. 4 plotted for $\sigma = 1$ and 2, respectively ($\sigma = \sqrt{2Dt}$). —.—.— $a = 2$; — — — $a = 1$; . . . . . $a = 0.5$; ——— $a = 0$.

diffusion coefficient is obtained; here however, the corrections are not so large owing to a more ideal boundary formation, (*i.e.* a smaller zero-time correction).

Generally, measurements are performed in the neighbourhood of the inflexion points of the Gaussian curve, where $x = \sigma = \sqrt{2Dt}$. Knowing the slope at the inflexion points it is possible to estimate the error in the determination of $2x$, and from this an estimation of the error in D can be made, *viz.* $\Delta D/D = 2\Delta(2x)/2x$.

From Fig. 6 it is possible to obtain a convenient expression for the displacement (δ_+) of the fringes from the ideal curve.

With the notation of Fig. 6 we conclude

$$f(x_a) = f_0(x_i) \approx f(x_i) + (x_a - x_i)\ f'_0(x_i)$$

$$\text{and hence} \quad \delta_+ = x_a - x_i \approx \frac{f_0(x_i) - f(x_i)}{f'_0(x_i)} \tag{6}$$

for positive x-values and correspondingly for negative values of x.

$$\Delta(2x) = \delta_+ - \delta_- \text{ and hence} \qquad \frac{\Delta D}{D} = \frac{\delta_+ - \delta_-}{x}$$

From Fig. 7 $\Delta D/D$ can be read as a function of a and σ.

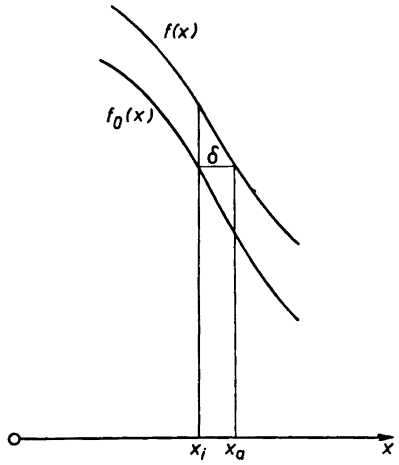

Fig. 6. Illustration of the method used for calculating δ in the neighbourhood of an inflexion point of the ideal curve (f_0 (x)) and the actual curve (f (x)).

From the character of the curves in Fig. 7 it is seen, following a horizontal line, how fast the corrections due to an asymmetrical initial condition die out. The great amount of asymmetry which can be tolerated is surprising.

It is obvious, however, when working with very dilute solutions and thus rapid diffusion experiments, that the initial skewness must be minimized if satisfactory results are to be obtained. In fact the demands on the symmetry are nearly inversely proportional to the time of experiment.

From Fig. 7 the impossibility of using the beginning of a diffusion run for extrapolation to zero-time is apparent. For a run with an occasional skewness (fixed a in Fig. 7), an estimation of the correction as a function of time can be obtained. Since this function is non-linear for small time values, the extrapolation to zero-time fails, as can be seen from the appearance of the curve (increasing correction on going to smaller time values). In practice this must be taken into account, especially when working with very dilute solutions.

b. Elimination of the Wiener skewness. Svensson [13,16] has shown that the aberration causing the Wiener skewness disappears if the camera is focused on a plane 1/3 of the cell thickness from the front wall.

c. The influence of the concentration dependance of the diffusion coefficient. In order to obtain a better interpretation of the data from optical interferometers, attempts have been made to solve the second equation of Fick in the case of a concentration dependant diffusion coefficient using a series expansion method [17]. For sucrose, *e.g.*, there is a variation of 2 % in D between 1.5 % solution and infinite dilution [18].

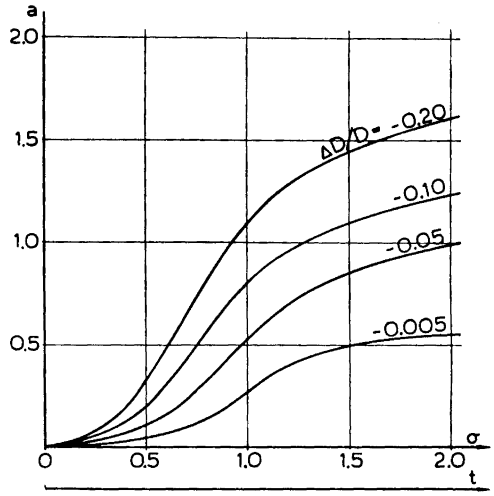

Fig. 7. Illustration of the influence of an asymmetrical initial condition on the diffusion coefficient measured.

In order to examine the influence of a concentration-dependant diffusion coefficient on the appearance of the interference pattern in *this method*, the solution of Fick's equation for the case of an exponential variation of the diffusion coefficient with concentration was studied.
If we put

$$D(c) = D_0 \, e^{\alpha c} \tag{7}$$

for the diffusion coefficient, then the Fick equation takes on the following form

$$\frac{\partial c}{\partial t} = \frac{\partial}{\partial x}(D_0 \, e^{\alpha c} \frac{\partial c}{\partial x}) \tag{8}$$

An approximate solution of this equation has been derived by Clarke [19]. Of interest here is the solution for small concentration differences

$$\left(\frac{\partial c}{\partial x}\right)_{\Delta c \text{ small}} \approx \frac{\Delta c}{2\sqrt{\pi D_0 t}} e^{-\frac{x^2}{4D_0 t}} \left\{1 - \alpha \bar{c}\left(\frac{1}{2} - \frac{x^2}{4D_0 t}\right) + \right.$$
$$\left. + \frac{\alpha^2 \bar{c}^2}{8}\left[7 - 8\frac{x^2}{4D_0 t} + 4\left(\frac{x^2}{4D_0 t}\right)^2\right]\right\} \tag{9}$$

where $\bar{c} = \frac{c_I + c_{II}}{2}$ (the arithmetic mean of the concentrations of the upper and the lower solution).

It should be noted that according to this expression, the position of the maximum point is the same as for the ideal case with a constant diffusion coefficient.

In the neighbourhood of the inflexion points ($x = \sigma = \sqrt{2Dt}$) we have

$$\frac{\partial c}{\partial x} = \frac{\Delta c}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}} \left\{1 + \frac{\alpha^2\bar{c}^2}{2}\right\} \tag{10}$$

Using (6) we obtain the following expression for the error in $(2x)$

$$\Delta(2x) = 2\delta = \frac{\sigma\alpha^2\bar{c}^2}{2} \tag{11}$$

and consequently

$$\frac{\Delta D}{D} = 2\frac{\Delta(2x)}{2x} = \frac{\alpha^2\bar{c}^2}{2} \tag{12}$$

In Ref.[4] diffusion runs with sucrose are described with concentration differences from 0.01 to 0.1 % sucrose. From eqn. (12) we conclude the corresponding values of $(\Delta D/D)$ to be from 0.0001 to 0.01 %, which can be left out of consideration.

A number of mathematical methods has been devised to compensate for effects 3 and 4 which cause rather large deviations if the experiments are performed with large concentration differences. Effects 3 and 4 give rise to a skew deviation of the refractive index gradient curve from the ideal Gaussian curve. These two sources of skewness may occasionally cancel [17] but there are also systems in which these effects act in the same direction and in such cases the resulting effect cannot be neglected.

The possibility of using quite small concentration differences in experiments with the birefringence interference method [4] reduces the magnitude of these errors substantially. The corrections necessary are much smaller and the mathematical difficulties correspondingly less.

XI. REMARKS ON SOME TECHNICAL DETAILS

A very great advantage of the flowing-junction cell over the other cell types is that no moving mechanical parts are situated in the optical field. Thus, the optical field is clear and the tightening problems are simplified. The flowing-junction cell is very convenient for volatile organic solutions since it can easily be tightened with teflon packings [9] (there are indeed sparingly soluble lubricants but no ideal ones).

Another advantage of the flowing-junction cell is that one is in control of the formation of the boundary and can study the interface before starting the diffusion run. On the other hand, the flowing-junction cell is more sensitive to impurities in the liquids, but by inserting sintered glass filters in the input tubes to remove grease and other impurities, this disadvantage can probably be eliminated.

A disadvantage of the draw-slide cell is the trace of lubricant which is always left on the glass walls at the position where the slide is drawn out. The same criticism applies to the sliding-solvent cell.

The adsorption danger must be taken into account in diffusion experiments. In Ref.[4] the difficulty of performing diffusion runs with glycine in

cell *Ia* (a stainless steel cell) was pointed out. Lamm [5] describes an apparent downward drift of the diffusion coefficient of pentaerythrite during a run which he ascribes to the adsorption of pentaerythrite on the elastolite side walls of the cell used.

XII. RECOMMENDATION FOR FUTURE INVESTIGATIONS

In addition to the present method there are numerous others, the most important of which are the scale- and schlieren methods of Lamm, the Gouy-interferometer, the Rayleigh-Calvet-Philpot interferometer, the Jamin interferometer and a modified schlieren method utilizing a Wolter phase plate [20] instead of a slit or an edge. All these methods are used side by side and so far no really satisfactory attempt has been made to compare the accuracy attainable by various methods. There is, however, indication that the present method should be superior to at least some of the earlier ones. There are two reasons for this. Firstly the method employs interferences with only a few wave-length differences. The advantage of this has been pointed out elsewhere [2]. Secondly it is caracterised by what Wolter calls "Minimistrahlkennzeichnung" [21] which is advantageous from a measuring point of view. (Wolter ascribes the advantage of the "Minimistrahlkennzeichnung" to the so called wave uncertainty principle, the application of which is questionable).

It seems to the author that a satisfactory theory, which permits a quantitative calculation of the accuracy attainable by various methods would be highly desirable.

Oxidation of Metals: Determination of Activation Energies

PER KOFSTAD

Central Institute for Industrial Research, Blindern, Oslo, Norway

A new method is proposed for the determination of energies of activation of oxidation of metals and alloys. Metals are oxidized under conditions of linearly increasing temperature, and the activation energy may be determined from one single oxidation run. In addition the method also gives the approximate temperature regions in which different rate laws of oxidation are found.

The described method has been applied to high-temperature oxidation of nickel, zirconium, copper, and titanium.

In the study of oxidation of metals and alloys the activation energies are of fundamental importance in the consideration of oxidation mechanisms. Hitherto, however, the reported values often show large mutual disagreements for the same metal. A good example is the oxidation of copper, where activation energies ranging from 29.4 to 42 kcal have been reported in the temperature region 500—1 000°C by different investigators.[1–6]

An accurate determination of activation energies involves a large number of isothermal runs at different temperatures. In this communication a faster method is proposed for the determination of activation energies. The metals are oxidized under conditions of linearly increasing temperature, and the method gives the activation energy of oxidation from one single oxidation run, and in addition gives the approximate temperature regions in which different rate laws are found. Although the proposal of oxidizing metals under such conditions is not new,[7] it is believed that the present treatment of the results provides a new approach for a simple and rapid method for studies of oxidation of metals and alloys.

OXIDATION OF METALS

The oxidation of metals follows different rate laws depending upon the metal, the nature and semi-conducting properties of the oxide formed, and the temperature. At high temperatures (generally greater than 200—300°C) we usually have 1) linear, 2) parabolic, or 3) cubic rate laws, which may be expressed as,

$$\frac{d(m/A)}{dt} = k_1 \qquad \text{(Linear)} \qquad (1)$$

$$m/A \frac{d(m/A)}{dt} = k_2 \qquad \text{(Parabolic)} \qquad (2)$$

$$(m/A)^2 \frac{d(m/A)}{dt} = k_3 \qquad \text{(Cubic)} \qquad (3)$$

In these equations m/A represent gain in weight per unit area at time t, and k_1, k_2, and k_3 are the oxidation rate constants for the linear, parabolic, and cubic rate laws, respectively.

The temperature dependence of oxidation reactions may be expressed by the empirical Arrhenius equation

$$k = B \exp(-Q/RT) \qquad (4)$$

where k is the rate constant for the oxidation at temperature T, B is a parameter whose dimensions depend on units for k, and Q is the activation energy.

In order to provide a more complete interpretation of B, Gulbransen [8] applied the absolute reaction rate theory to oxidation reactions obeying parabolic rate laws. The rate constant was accordingly expressed in terms of the entropy and heat of activation and with a preexponential factor proportional to T.

In as much as oxidation processes obey the Arrhenius equation and as also non-parabolic rate laws are included in this treatment, the following approach will be confined to the use of eqn. 4.

Eqns. 1, 2, and 3 may be written as

$$(m/A)^n \frac{d(m/A)}{dt} = k \qquad (5)$$

where n is a constant having values of 0, 1, and 2 for the linear, parabolic, and cubic rate laws, respectively.

Oxidizing under conditions with linear increase of temperature, we have

$$T = at + b \text{ or } dT = adt \qquad (6)$$

Substituting (4) and (6) in eqn. 5, we get

$$(m/A)^n \frac{d(m/A)}{dT} = (B/a) \exp(-Q/RT) \qquad (7)$$

Taking the logarithm and rearranging, eqn. 7 may be written

$$(n + 1)\ln(m/A) + \ln \frac{d\ln(m/A)}{dT} = \ln B/a - Q/RT \qquad (8)$$

According to eqn. 8 a plot of $(n + 1) \ln (m/A) + \ln \frac{d\ln(m/A)}{dT}$ *versus* $1/T$ should yield a straight line whose slope is equal to $(-Q/R)$ and which permits calculation of the activation energy, Q. The value of the parameter B in eqn. 4 may also be determined by introducing corresponding experimental values of (m/A), T, and a.

The use of eqn. 8 necessitates the evaluation of $\frac{\mathrm{d}\ln(m/A)}{\mathrm{d}T}$, and the approximate values for this differential quotient were calculated as

$$\left(\frac{\mathrm{d}\ln(m/A)}{\mathrm{d}T}\right)_{T=T_j} = \frac{\ln(m/A)_{j+1} - \ln(m/A)_{j-1}}{T_{+1} - T_{j-1}} \qquad \text{(a)}$$

Temperature intervals of 25°K were found suitable in the described runs, and a table of the following type was used for each oxidation run:

T°C	$1/T$	$x = m/A$	$\ln x$	$(n+1)\,2\ln x$	$\frac{\Delta \ln x}{\Delta T}$	$\ln \frac{\Delta \ln x}{\Delta T}$
Intervals of 25°K		x_1	$\ln x_1$			
		x_2	$\ln x_2$	z_2	y_2	$\ln y_2$
		x_3	$\ln x_3$	z_3	y_3	$\ln y_3$
		x_4	$\ln x_4$	z_4	y_4	$\ln y_4$

where $z_j = \ln x_{j+1} - \ln x_{j-1}$
and $y_j = z_j/50$

In applying this approach to metals oxidizing according to linear rate laws, it is necessary to plot $\ln(m/A) + \ln \frac{\ln(m/A)}{T}$ *versus* $1/T$, in the case of parabolic rate laws $2\ln(m/A) + \ln \frac{\ln(m/A)}{T}$ *versus* $1/T$, and cubic rate laws $3\ln(m/A) + \ln \frac{\ln(m/A)}{T}$ *versus* 1/T. This treatment of the data should yield straight lines for the particular rate laws in the corresponding temperature regions. If the oxidation of a metal follows different rate laws in different temperature regions, one should also obtain distinct breaks in the curves at the temperature regions where the oxidation changes rate laws. For example if the oxidation of a metal follows the cubic, parabolic, and linear rate laws successively with increasing temperature, the plotted curve will be a straight line only in the temperature regions where the assumed rate law is valid, while the plotted curve should show a curvature in the temperature regions where the other rate laws are valid. Thus in addition to the activation energy, such a treatment would also give approximate values as to the temperature regions in which the different rate laws may be found.

It should be emphasized that eqn. 8 is valid only under conditions of cubic, parabolic, and linear rate laws. The described approach is thus not applicable for oxidation of metals at low temperatures or at the very beginning of the oxidation at higher temperatures, at which conditions logarithmic and reciprocal logarithmic rate laws are generally obeyed. These latter rate laws may, however, also be treated in the same manner as described above.

EXPERIMENTAL RESULTS

The described method was tried on Ni, Zr, Cu, and Ti, and the experimental results gave activation energies in satisfactory agreement with previously published values obtained from isothermal runs.

The metals were oxidized under conditions with linearly increasing temperature from 400°C to 1 100°C with a temperature increase of either 3.86 or 2.22°C/min. Owing to the small weight gain before 600—700°C during these runs, activation energies could only be determined for temperature regions 700—1 100°C.

The oxidation of titanium has previously been found to obey the cubic (400—600°), the parabolic (600—900°C), an linear rate law (900—1 000°C) in the indicated temperature regions.[9] With the above mentioned experimental conditions one should consequently obtain a break in the curve corresponding to a transition from the parabolic to the linear rate law region.

In Fig. 1 are shown the data for unannealed van Arkel titanium oxidized under linear temperature increase of 3.86°C/min plotted under the assumption of linear and parabolic rate laws. As seen the parabolic rate law plot yields a straight line between 700°C and 900°C, while the linear rate law plot gives a straight line above 900°C, thus confirming the results obtained from isotherm-

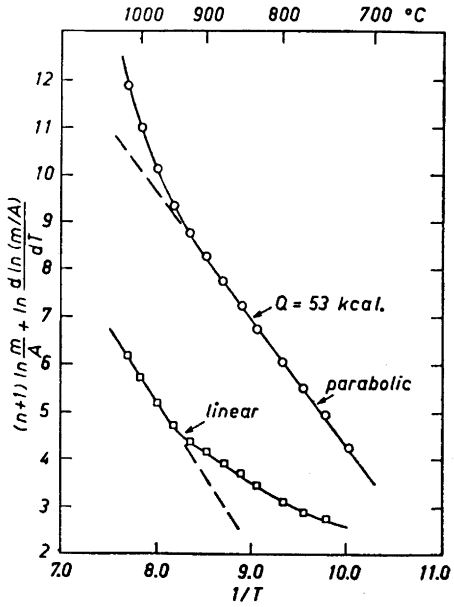

Fig. 1. Oxidation of van Arkel titanium with temperature increase of 3.86°C/min. Data plotted under assumption of linear and parabolic rate laws.

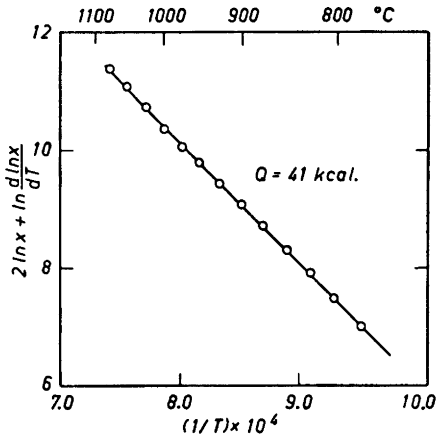

Fig. 3. Oxidation of nickel (2.22°C/min).

al runs. Furthermore, the activation energy in the parabolic rate law region amounts to 53 kcal, which is in excellent agreement with the value of 52 ± 2 kcal, which was obtained by isothermal oxidation of the same metal in this laboratory.

Fig. 2 shows the results on oxidation of zirconium (2.22°C/min) plotted under the assumption of linear, parabolic, and cubic rate laws. As seen the cubic rate law plot yields a straight line between 650 and 950°C giving an activation energy of 48 kcal in agreement with the results of Belle and Mallett,[10] who found that the oxidation of zirconium conformed with a cubic rate law between 400 and 1 000°C and with an activation energy of 47.2 kcal. Furthermore, the plots in Fig. 2 also indicate that the cubic rate law is not conformed with between 950 and 1 100°C, but in this region the parabolic rate law plot yields a straight line and an activation energy of approximately 60 kcal, and thus indicating conformity with the parabolic rate law in this temperature region. Two runs with a temperature increase of 3.86°C/min showed conformity with the cubic rate law between 700 and 1 050°C, and with an activation energy of 46 kcal.

Isothermal oxidation of zirconium by both Cubicciotti [11] and Gulbransen [12] has previously been found to obey a parabolic rate law, and the disagreement between these data and those of Belle and Mallett cannot be explained at present. A tentative explanation may be that the amount and type of impurities may have a decisive effect on the rate law observed, as Mallett and Albrecht [13] showed that 1.5 and 2.5 wt. % Zn—Zr alloys oxidize according to cubic and parabolic rate laws, respectively.

Isothermal oxidation of nickel has previously been found to follow a parabolic rate law at high temperatures, and in accordance with this a parabolic rate law plot yields a straight line between 750 and 1 050°C, as shown in Fig. 3. The activation energy was found to be 41 kcal. As a comparison previously published values range from 34 to 51 kcal [14–17].

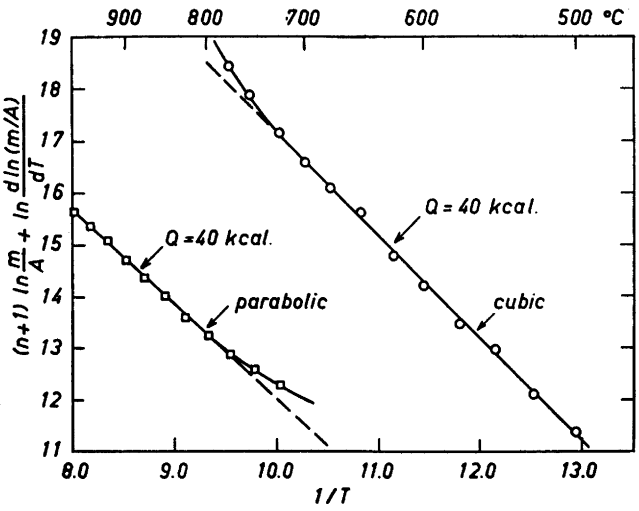

Fig. 4. Oxidation of copper (2.22°C/min). Data plotted assuming parabolic and cubic rate laws.

The results for oxidation of copper for a temperature increase of 2.22°C/min are given in Fig. 4. According to the plots the assumption of a parabolic rate law is only valid in the temperature region 750—1 000°C, while it may be inferred that the oxidation obeys a cubic rate law between 500 and 750°C. The activation energies for the parabolic and the cubic rate law regions was found to be 35 and 40 kcal, respectively. As a comparison previously published values for the parabolic rate law region range from 29.2 to 42.0 kcal [1–6].

DISCUSSION

The described results indicate that activation energies determined under conditions of linearly increasing temperature are in agreement with corresponding values determined from isothermal runs. Furthermore, the method also gives approximate temperature regions in which different rate laws are found.

While the activation energy found should be independent of the heating rate, it is to be expected that the appearance of different rate law regions are somewhat dependent on the rate of temperature increase, which is also apparent from the present results. The rate law observed in isothermal runs may be dependent upon the thickness of the oxide scale, and a certain rate law may thus be found to extend to higher temperatures for a fast than for a slow rate of temperature increase. This is indicated by the results on zirconium, in which case the cubic rate law was conformed with up to 1 050°C for a temperature increase of 3.86°C/min, but only up to 950°C for a temperature increase

of 2.22°C/min. In the case of oxidation of copper it might seem surprising, when comparing to the isothermal studies, that the cubic rate law is valid up to a temperature of about 700°C. However, in addition to the effect of the relationship between rate of temperature increase, film thickness, and rate law observed, this may be due to the fact that the oxide formed consists both of CuO and Cu_2O, and that their relative amounts changes with temperature. At 500°C the oxide scale consists mainly of CuO, and the relative amounts of CuO decreases with increasing temperature until it at 900°C only accounts for 10 % of the oxide scale [6]. The oxidation of Cu_2O to CuO has previously been [18] found to obey a cubic rate law between 600 and 1 000°C, and it does not therefore seem unreasonable that the cubic rate law is obeyed up to 700°C under the described experimental conditions.

Studies on Cobaltammines

II. Association of Ammonia with the Hexammine Cobalt(III) Ion in Aqueous Solution

RAGNAR LARSSON

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The solubilities of $Co(NH_3)_6(ClO_4)_3$ and $Ba(IO_3)_2$ in 1 M NH_4ClO_4 are reported for mixed solvents, the non-aqueous component being ammonia, methanol, ethanol, acetone, glycerol and dioxane. Using these measurements, a method is devised for the calculation of the association constants when ammonia is associated with the $Co(NH_3)_6^{3+}$ ion. The first constant is reported. Evidence for an association of acetone with the $Co(NH_3)_6^{3+}$ ion is discussed. A spectrophotometric method is used which confirms the results from the solubility measurements.

From a solution containing some ammonium nitrate a solid phase has been isolated, having the composition $(Co(NH_3)_6 . NH_3)(ClO_4)_2NO_3$.

The hexammine cobalt(III) ion, a complex seemingly saturated with respect to further coordination, has been the subject of several investigations on ion association. For example, the association of sulphate or thiosulphate ions has been investigated conductometrically [1] and spectrophotometrically [2,3], by measurements of solubility [4,5] and dialysis [6] as well as by a polarographic method [7]. Association of halide and pseudohalide ions has been studied both conductometrically [8] and spectrophotometrically [9–11], whereas oxalate ion association has been studied by measurements of conductivity [12] and dialysis [6].

It must be noted, however, that some of the interpretations of these experimental data are not generally accepted.

It seemed to be of interest to investigate the association of an uncharged, polar molecule with the $Co(NH_3)_6^{3+}$ ion. No such measurements have apparently been made though several authors [13,14] have pointed out the importance of such an association in determining the velocity of inner-sphere substitutions.

In the first part [15] of this series it was reported that there is an increase in the solubility of $Co(NH_3)_6(ClO_4)_3$ in 1 M NH_4ClO_4 as the concentration of ammonia is increased. This fact was then explained as the result of an outer-

sphere ammine formation. In this work those solubility measurements have been extended in an effort to make possible the calculation of association constants.

As a check of the results obtained, an extinctiometric method has also been used.

THEORY OF THE SOLUBILITY MEASUREMENTS

The notations will be those of the preceding paper [15] except when otherwise stated.

The reactions under investigation may be written in the general form:

$$MA_6 \cdot mH_2O + n\ A \rightleftharpoons (MA_6)A_n \cdot (m\text{-}n)H_2O + n\ H_2O \quad (1)$$

Excluding the solvating water, the conrresponding association constant is defined by

$$\beta_n = \frac{[(MA_6)A_n] f_{(MA_6)A_n} \cdot a_{aq}{}^n}{[MA_6] \cdot f_{MA_6} \cdot [A]^n \cdot f_A{}^n} \quad (2)$$

where brackets mean free concentrations and f the activity coefficients of the species in question. a_{aq} is the activity of water. Now, $f_{(MA_6)A_n}$ and f_{MA_6} may be considered as almost equal, as they are related to ions of the same charge and almost nearly the same size. Thus eqn. (2) may be rewritten as

$$\beta_n = \frac{[(MA_6)A_n] a_{aq}{}^n}{[MA_6] \cdot a_A{}^n} \quad (3)$$

where $a_A = [A] \cdot f_A$

We define $X = \sum_{n=1}^{N} \beta_n \cdot a_A^n / a_{aq}^n$ (4)

Thus $C_M = [MA_6]\ (1 + X)$ (5)

In a solution saturated with $MA_6(ClO_4)_3$, we have

$$[MA_6]\ [ClO_4]^3 = L \quad (6)$$

and in the case when $C_A = 0$, *i.e.*, $C_M = [MA_6]_0$, we have

$$[MA_6]_0\ [ClO_4]_0^3 = L_0 \quad (7)$$

If, as is the case in the present investigation, only the concentration of ammonia is changed, the salt medium being constantly kept 1 M NH_4ClO_4, and if C_M is low, we can put

$$[ClO_4] = [ClO_4]_0 \quad (8)$$

Combining eqns. (6)—(8) we get

$$[MA_6]/[MA_6]_0 = L/L_0 \quad (9)$$

Inserting eqn. [9] into eqn. [5] we get

$$1 + X = \frac{C_M}{[MA_6]_0} \cdot \frac{L_0}{L} \quad (10)$$

Knowledge of L/L_0 as a function of [A] would enable us to calculate X.

The evaluation of L/L_0

With this purpose in mind we will consider the effects on the solubility of a sparingly soluble salt in an aqueous solution of high ionic strength when a part of the water is exchanged for another solvent, *e.g.*, ammonia. This other solvent will be called here, for the sake of brevity, an "aquo-substitute".

The following items may be considered important:

1. The aquo-substitute may form complexes with the cation — or the anion — of the sparingly soluble salt.

2. A change in solvation conditions may result in a change in the "distance of closest approach" and thus cause activity changes of the ions in question.

3. The change in the dielectric constant of the solvent will cause a change in the activity coefficients of the ions. According to Owen [16], two effects are operating: the primary and the secondary medium effects. The first one, arising from changes in ion-solvent interaction, is more or less correctly described by the theoretical equation of Born [17] or by the empirical equation of Davies and Ricci [18]. However, it must be emphasized that none of those equations is generally valid. (*Cf.* Mayper, Clever and Verhoek [19].) The secondary effect, connected with ion-ion interactions, is dependent on the ionic strength and is implied in the Debye-Hückel-Gronwall-LaMer equation.

One way to estimate the quotient L/L_0 for $Co(NH_3)_6(ClO_4)_3$ in aqueous ammonia would be to use an ion of reference that does not form ammine complexes and is solvated as the $Co(NH_3)_6^{3+}$ ion. It should preferably be of the same size and have the same charge as this ion.

An ion fulfilling these demands is not easy to find, as most tervalent positive ions are hydrolyzed in aqueous ammonia, even at a high ammonium ion concentration.

As a reference ion Ba^{2+} has therefore been chosen. The measurements of Bjerrum [20, p. 145] indicate that this ion has a very low tendency of ammine formation.

However, the change of the solubilities of $MA_6(ClO_4)_3$ and a barium salt are not directly comparable for obvious reasons.

To overcome this difficulty, we might try to find another aquo-substitute, call it B, that does not form complexes with either $Co(NH_3)_6^{3+}$ or Ba^{2+} ions. Through a comparison of the solubility decrease of a barium salt in solutions of ammonia and in solutions of the aquo-substitute B, information might be obtained on the function $(L/L_0)_{MA_6}$. We now make the following definitions:

The formal solubility product * of $Co(NH_3)_6(ClO_4)_3$ is given by $l_{MA_6} = C_{MA_6} \cdot C^3_{ClO_4}$. The formal solubility product of the barium salt to be used (BaX_2) is given by $l_{Ba} = C_{Ba} \cdot C_x^2$.

What we set out to measure is then the relative change of these formal quantities, l/l_0, where l_0 $(= L_0)$ means l in solutions having C_B $(C_A) = 0$.

The reasoning will proceed as follows: If no MA_6-B nor any Ba^{2+}-A or Ba^{2+}-B complexes are formed and if the solvation effects can be ignored, the quotients $(l/l_0)_{MA_6}$ and $(l/l_0)_{Ba}$ in the different solvents will depend only

* Note the difference between the usage of the symbol l in this paper and in the preceding one [15].

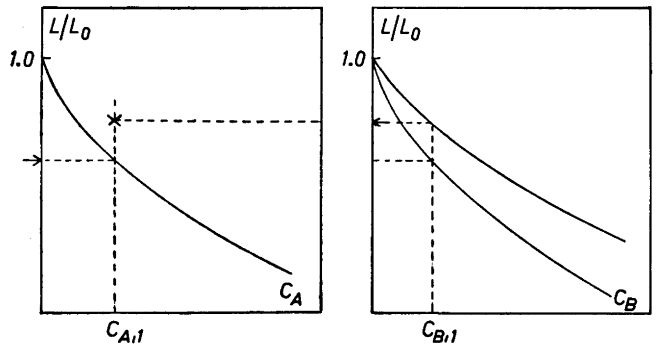

Fig. 1. Expected appearance of $(L/L_0)_{Ba}$ plotted against C_A (left figure) and $(L/L_0)_{MA_4}$ (right figure, upper curve) and $(L/L_0)_{Ba}$ (right figure, lower curve) plotted against C_B

on the dielectric constant of the solvent, as pointed out in item 3 previously mentioned. If now the quotients l/l_0, which in these special cases turn into L/L_0, are plotted against C_B — or C_A in the relevant case — we may expect curves of the form indicated in Fig. 1. For a certain value of L/L_0, indicated by an arrow in the left diagram, we find the concentrations C_{A_1} and C_{B_1} for which the solubility product of the barium salt is decreased to the same amount. According to the assumptions made, these solutions must then have the same dielectric constant. At $C_B = C_{B_1}$ we can read the value of L/L_0 of $Co(NH_3)_6(ClO_4)_3$ from the upper curve in the right diagram, indicated there by an arrow. This value of L/L_0, however, must be that of $Co(NH_3)_6(ClO_4)_3$ at the concentration C_{A_1}; this point is indicated by a cross in the left diagram.

Thus we may construct a set of points and from these draw a curve, describing the change of the solubility product of $Co(NH_3)_6(ClO_4)_3$ in ammonia solution. This curve represents the function L/L_0 of eqn. (10) and insertion in this equation thus gives X, from which function the complexity constants may be obtained according to eqn. (4).

Calculation of f_A/a_{aq}

The standard state of the ammonia activity has been chosen so that $f_{NH_3} = 1$ in 1 M NH_4ClO_4, $C_A = 0$. The activity of water is put = 1 in that same solution.

Following Bjerrum (Ref. [20], p. 143) we assume that f_A as a function of C_A when $C_{NH_4ClO_4} = 1$ M will run approximately parallel to f_A when $C_{NH_4ClO_4} = 0$.

Thus the vapour pressure data of Perman [21] at zero ionic strength and 20°C can be used. From these it is found, if $C_A < 5$ M,

$$f_A = 1 + 0.066_3 C_A + 0.00106\ C_A^2 \qquad (11\,a)$$

$$a_{aq} = 1 - 0.0244\ C_A \qquad (11\,b)$$

EXPERIMENTAL

As the sparingly soluble barium salt *$Ba(IO_3)_2$ was chosen.* In order to make the best possible choice of the aquo-substitute B, the formal solubility products, l, for $Co(NH_3)_6(ClO_4)_3$ and $Ba(IO_3)_2$ were determined in 1 M NH_4ClO_4 at 20°C in aqueous solutions containing varying amounts of the following solvents: Methanol, ethanol, glycerol, acetone and dioxane.

For all these solvent mixtures the dielectric constant is known from the measurements of Åkerlöf [22].

Chemicals used. The radioactive preparation of $Co(NH_3)_6(ClO_4)_3$ was the same as in Part I [15].

The *barium iodate* was prepared from solutions of reagent quality barium chloride and potassium iodate.

The *ammonium perchlorate* and *ammonia* solutions were prepared as in Part I [15]. The solutions of *methanol, ethanol, glycerol* and *acetone* were made from weighed amounts of absolute, acetone-free methanol, absolute ethanol, glycerol, p.a., heated to 180°C to expel water, and acetone, p.a., respectively. The *dioxane*, Eastman 2144, was purified according to Eigenberger [23], and distilled at the constant boiling point 101.2°C. The melting point was found to be 11.5°C. The small amounts of impurities present certainly do not seriously affect the general features of the solubility curves.

Procedure. Solutions of 1 M NH_4ClO_4, C_B M B (or C_A M A) were shaken with $Co^*(NH_3)_6(ClO_4)_3$ or $Ba(IO_3)_2$ in 100 ml flasks at 20°C in a thermostatically controlled room for two days to ensure saturation. The method of separation and measuring of the cobalt solutions was the same as in Part I [15]. The saturated solution of barium iodate was withdrawn with a 10 ml pipette provided with a filter-stick. The iodate content was determined iodometrically. The solubility product, l_{Ba}, was then easily calculated. As acetone and dioxane interfere in iodometric titrations, the solutions containing these solvents were freed from them before titration of the iodate content. The acetone solutions were made alkaline and boiled until all traces of ammonia were gone; it was then considered to be free from acetone also. The dioxane solutions were evaporated to dryness on the steambath. The quotient l/l_0 could be determined within ±1 % for $Ba(IO_3)_2$ and ±2 % for $Co(NH_3)_6(ClO_4)_3$.

RESULTS

The quotients l/l_0 found are reported in Tables 1 and 2. Along with these are given values, $(D)_{I=0}$, of the dielectric constants of the solvent mixtures that should be valid if the ionic strength, I, was zero. They are arrived at from density determinations of the stock solutions employed and linear interpolation from the data of Åkerlöf [22]. As the curves given by Åkerlöf describing D as a function of the concentration of aquo-substitute (given as weight-percent) are not exactly linear, the values of Tables 1 and 2 are not quite accurate, but they will serve well enough to give a rough picture of the dependency of l/l_0 on D. It must also be remembered that these values of D are certainly not those of the actual solutions having an ionic strength I = 1 M. $(D)_{I=1}$ may be some 10 % lower than $(D)_{I=0}$, (*cf.* Hasted, Ritson and Collie [24]). However, the quotient $(D_0/D)_{I=0} - D_0$ being the dielectric constant for $C_B = 0$ — will perhaps be more directly comparable to $(D_0/D)_{I=1}$ and has been used in Figs. 2 and 3.

It is seen that the curves of solubility of $Ba(IO_3)_2$ show the same relative positions as reported by Monk [25] at zero ionic strength.

Now, if the curves l/l_0 *versus* $(D_0/D)_{I=0}$ for different aquo-substitutes coincide, it might be inferred that the assumptions made on the exclusive dependency of l/l_0 on D are fulfilled. For $MA_6(ClO_4)_3$ this is the case in the

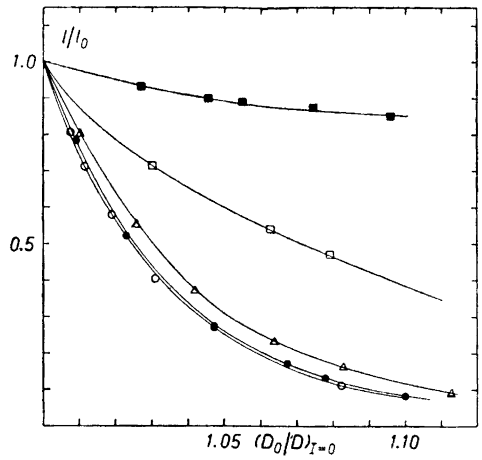

Fig. 2. The $Ba(IO_3)_2$ solubility curves; l/l_0 plotted against $(D_0/D)_{I=0}$. The symbols refer to the following aquo-substitutes: methanol (○); ethanol (●); acetone (△); dioxane (□); glycerol (■).

ethanol and methanol systems; for $Ba(IO_3)_2$ the ethanol, methanol and acetone curves lie rather close.

For these systems l/l_0 thus equals or nearly equals L/L_0 and the procedure indicated in Fig. 1 may be applied.

The measurements of Monk [25], also including the propanols, show that as the aquo-substitute molecule is made smaller, the solubility curves seem to converge to a common limit.

Thus, as ammonia, for which aquo-substitute we seek an analoque, is a small molecule, and as methanol is the smallest molecule of the reference aquo-substitutes investigated and also fulfills the demands stated, methanol will be chosen as the aquo-substitute to be used in the following calculations.

Discussion of anomalies

The l/l_0-curves in dioxane and glycerol media do not coincide with the curves of the primary alcohol media (Figs. 2 and 3). Thus the change of the formal solubility products of the salts in question is not exclusively dependent on the dielectric constant of these solvents. Other factors must operate, such as an incorporation of the aquo-substitute in the solvation sheath of the ions (item 2 in the foregoing) or a complex formation (item 1). If a pure electrostatic attraction is operating, we should expect this effect to be greater for the Ba^{2+} ion than for the larger $Co(NH_3)_6^{3+}$ ion. The different courses of the curves of glycerol and dioxane media indicate that several factors are of importance, such as, *e.g.*, the degree of selective solvation and the dimensions of the aquo-substitute molecules. This latter effect may perhaps be accounted for by assuming the operation of London dispersion forces as discussed by Bockris, Bowler-Reed and Kitchener [26].

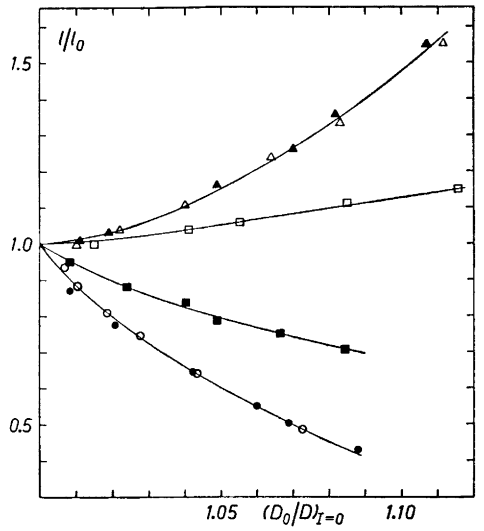

Fig. 3. The $MA_6(ClO_4)_3$ solubility curves; l/l_0 plotted against $(D_0/D)_{I=0}$. The symbols refer to the following aquo-substitutes: methanol (○); ethanol (●); glycerol (■); dioxane (□); acetone, when a small amount of chloride ions is present in the solutions (△); acetone, when perchlorate ions are the only anions in the solutions (▲).

Of course a distinction between a strongly selective solvation and complex formation is very difficult to make. In this connection reference [27] may be made to the well-known glycerol compounds of the alkaline earth metals.

The solubility curves in the acetone medium, however, exhibit a different picture. The $Ba(IO_3)_2$-curve lies quite close to those of the primary alcohol media. The $Co(NH_3)_6(ClO_4)_3$-curve, on the other hand, indicates an increase of solubility. If we attribute the solubility increase of $Co(NH_3)_6(ClO_4)_3$ in ammonia solutions to an ammonia complex formation, we must for the sake of consequence infer a complex formation between acetone and the $Co(NH_3)_6^{3+}$ ion. This is not entirely inconceivable as examples of ketonic complexes are known, *e.g.*, from the chemistry of the actinides (*cf.* Rydberg [28] and references quoted there).

In a recent review Katzin [29] has advanced the opinion that the increase in solubility found for salts in acetone-water solutions originates solely from an increased complex formation between the metal ion and the anions of the salt in question; this should be related to the small affinity of acetone for hydrogen ions and thus — according to Katzin — its small ability to compete with the anions for coordination sites when the water activity is diminished. However, it must be remembered that the parallel between complex formation and base strength, underlying that reasoning, holds true only for ligands of similar structure yielding pure σ-bonds; other factors would invalidate that parallelism.

Now, for practical reasons, the cobalt stock solution of the present work holds a certain amount of chloride ions, which are introduced in the solutions considered in concentrations of about 5 mM. Are these chloride ions responsible for the observed increase in solubility? The decisive experiment is, of course, to determine the solubility in solutions containing only perchlorate ions as anions — tacitly assuming that perchlorate ions do

Table 3. Corresponding values of C_A and C_B (B = methanol) yielding corresponding values of $(L/L_0)_{MA_6}$ and $(L/L_0)_{Ba}$. Calculation of $1 + X$.

not form any complexes. Such measurements are reported in Fig. 2. The increase of solubility is not less than for the solutions containing chloride ions. Thus, in this case, an explanation as that proposed by Katzin [29] must be ruled out.

Calculations

In the first two columns of Table 3 are given some values of C_A and the corresponding relative decrease of the solubility product of $Ba(IO_3)_2$ in ammonia solution, obtained by graphical interpolation from the data of Table 2. The third column contains the methanol concentrations that give the same relative decrease of L_{Ba}, also obtained by graphical interpolation form Table 2. The relative decrease of L_{MA_6}, as obtained from the values of Table 1, for these values of C_B is given in column 4 of Table 3. This column thus gives L/L_0 of $MA_6(ClO_4)_3$ for the values of C_A in column 1 (*Cf.* Fig. 1). From the values of $(L/L_0)_{MA_6}$ thus obtained and the corresponding values of C_M/C_{M_0} given in column 5, $1 + X_A$ has been calculated from eqn. (10).

In the definition of β_n (eqn. (2)) we have used the free ligand concentration [A]. However, as C_A is large, C_M very small and the complexity very weak, the approximation $[A] = C_A$ is not an improper one and will be used in the following.

In the last column of Table 3 a_A/a_{aq} is calculated from eqn. (11). In Fig. 4 $X \cdot (a_{aq}/a_A)$ is plotted against a_A/a_{aq}. It is seen that there exists a linear relation between these two quantities.

If we take only the first two terms of eqn. (4) into consideration, it may be transformed to

$$\frac{a_{aq}}{a_A} X = \beta_1 + \beta_2 \cdot \frac{a_A}{a_{aq}} \qquad (12)$$

Thus, from the above-mentioned linear relation the first two complexity constants may be obtained.

$$\beta_1 = 0.24 \pm 0.05 \text{ M}^{-1}; \ \beta_2 \approx 0.05 \text{ M}^{-2}$$

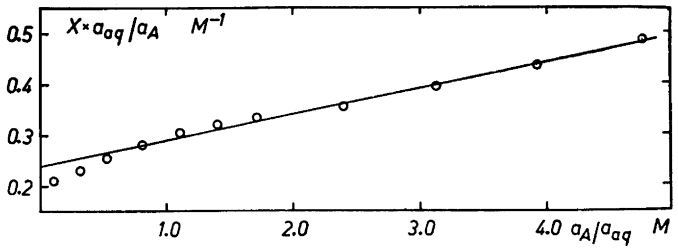

Fig. 4. $X \cdot \frac{a_{aq}}{a_A}$ as a function of a_A/a_{aq}.

However, if we assume the existence of the first complex only but take into consideration the increase of the complexity constant as the dielectric constant of the solvent diminishes (*cf.* Ref.[30]), we also obtain a linear relation between $\frac{a_{aq}}{a_A} X$ and $\frac{a_A}{a_{aq}}$:

Making the simplifying assumptions of linear dependency of D on C_A and of β_1 on D_0/D, valid at not too large values of D_0/D, we may write

$$D = D_0 - k\,C_A \tag{13 a}$$

which equation becomes

$$D_0/D = 1 + k'C_A \tag{13 b}$$

and

$$\beta_1 = (\beta_1)_0\ (1 + k''D_0/D) \tag{14}$$

where k, k' and k'' are constants. Combining eqns. (13 b) and (14) we obtain the linear relation

$$\beta_1 = (\beta_1)_0\ (1 + k'' + k'k''C_A) \tag{15}$$

Thus

$$\frac{a_{aq}}{a_A} X = \beta_1 = (\beta_1)_0(1 + k'') + k'k''(\beta_1)_0C_A \tag{16}$$

Or, as C_A is approximately proportional to a_A/a_{aq} (*cf.* eqns. (11)), $\frac{a_{aq}}{a_A} X$ will be a linear function of a_A/a_{aq}, as in Fig. 4.

It is difficult to see how to distinguish between the effects of eqns. (12) and (16). At least we can say that a value of β_2 calculated from eqn. (12) must be a maximum value.

FORMATION OF THE SOLID PHASE $[Co(NH_3)_5NH_3](ClO_4)_2NO_3$

Some solubility measurements have also been carried out in a salt medium consisting of 0.150 M NH_4NO_3 and 0.850 M NH_4ClO_4.

The solubility curve then obtained is presented in Fig. 5. It is seen that at a certain value of the ammonia concentration the curve exhibits a distinct break, indicating that a new solid phase is formed. As the appearance of this

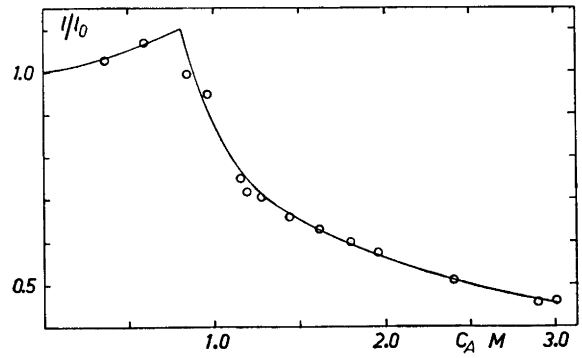

Fig. 5. $(I/I_0)_{MA_6}$ as a function of C_A in a salt medium of the composition 0.850 M NH_4ClO_4, 0.150 M NH_4NO_3.

new phase is obviously dependent on the presence of both nitrate ions and ammonia, we may expect it to be of the general composition $(Co(NH_3)_6)(NH_3)_x(ClO_4)_{3-y}(NO_3)_y$

Analysis of the solid phase. Some $Co(NH_3)_6(ClO_4)_3$ — unlabelled — was shaken with 100 ml of a solution of the following composition: 2.4 M NH_3, 0.15 M NH_4NO_3 and 0.85 M NH_4ClO_4. After a day the solid phase was separated and washed with alcohol until no ammonia could be detected, then washed with ether and air-dried. The substance thus obtained lost ammonia slowly on storage in open vessels at room temperature and rapidly at 100°C. The dried substance was analyzed for nitrate content according to Lindo [31] and for cobalt by a colorimetric determination of the $Co(NH_3)_6^{3+}$ ion at 472 mμ. (NO_3^-: Calc. for $Co(NH_3)_6(ClO_4)_2NO_3$ 14.7 %; Found 14.8 %, Co: Calc. 13.97 %; Found 13.96 %.)

If the ether-dried substance was rapidly weighed and thereafter dried at 100°C, it lost 3.7 % of its weight. (Calc. for $[Co(NH_3)_6NH_3](ClO_4)_2NO_3$ 3.9 %.) This result is in agreement with solid phase studies of Ephraim [32] and of Spacu and Voishescu [33], which indicate that $[Co(NH_3)_6NH_3]Cl_3$, though not stable, may be isolated at room temperature.

Thus we may conclude that the new solid phase is $[Co(NH_3)_6NH_3](ClO_4)_2NO_3$. However, as the composition of the solid phase gives no direct information on the composition of the ionic species in solution, no further investigation was made.

THE LIGHT ABSORPTION MEASUREMENTS

The absorption spectrum of the $Co(NH_3)_6^{3+}$ ion in ammonia solutions has been investigated once by Nakatsuka [34] who, however, reports no perceptible change with increasing ammonia concentration.

The low solubility of $Co(NH_3)_6(ClO_4)_3$ and the weak complexity under consideration render a complete extinctiometric investigation impossible. However, an approximate method has been attempted, under the assumption that only the first complex is present in appreciable amounts. (For a complete theory see, *e.g.*, Ahrland [35].) In order to reach higher values of C_M, the measurements have been performed at ionic strength 0.1 M.

The following notations are used:

ε_0 = extinction coefficient of the MA_6^{3+} ion
ε_1 = » » » » $(MA_6)A^{3+}$ ion
E = measured optical density
d = cell thickness (cm)

The quantity ε_M is defined by

$$E = d\varepsilon_M C_M \tag{17}$$

Hence,

$$\varepsilon_M C_M = \varepsilon_0[MA_6] + \varepsilon_1[(MA_6)A] \tag{18}$$

Introducing the complexity constant β_1 from eqn. (3) we can rewrite eqn. (18)

$$\varepsilon_M - \varepsilon_0 = \frac{(\varepsilon_1 - \varepsilon_0)\beta_1 \cdot [A] \cdot f_A/a_{aq}}{1 + \beta_1 \cdot [A] \cdot f_A/a_{aq}} \tag{19}$$

If $q = \dfrac{\varepsilon'_M - \varepsilon_0}{\varepsilon''_M - \varepsilon_0}$ where ε'_M and ε''_M are measured at $C_A = C_A'$ and C_A'' respectively, and if we put $C_A' = [A]'$ and $C_A'' = [A]''$ we obtain from eqn. (19)

$$\beta_1 = \frac{qC_A''f_A''/a''_{aq} - C_A'f_A'/a'_{aq}}{C_A'f_A'/a'_{aq} \cdot C_A''f_A''/a''_{aq}(1-q)} \tag{20}$$

Here f'_A and a'_{aq} denote the activity coefficient of A and water activity at $C_A = C'_A$, etc.

These quantities are calculated from eqns. (11 a) and (11 b) under the same assumption as before, *i.e.*, that f_A and a_{aq} are functions dependent only on C_A. This means that f_A and a_{aq} are now determined by the condition that $f_A = 1$ and $a_{aq} = 1$ in solutions 0.1 M NH_4ClO_4, $C_A = 0$.

From the paper [35] referred to it follows that if other complexes than the first one also exist, the value of β_1 will be too small.

On the other hand, if only the first complex exists, as assumed here, but the determination is performed at a rather high ammonia concentration, the value of β_1 thus found will be greater than that valid at zero ammonia concentration, as follows from eqn. (15).

From these measurements we can thus expect only an indication of the order of magnitude of β_1.

Experimental. The measurements were performed in the ultraviolet wave length region, where outer-sphere association has previously been found to cause the greatest change in the absorption spectrum of the cobalt hexammine ion (Refs. [2,3,9-11]). The apparatus used was a Beckman Quartz Spectrophotometer (Model DU), changed as described by Adell [36].

The solutions were all 5.00 mM with respect to $Co(NH_3)_6(ClO_4)_3$. The ionic strength was kept 0.1 M by adding NH_4ClO_4. Four sets of measurements were made, with $C_A = 0$, 0.320, 0.640 and 0.960 M. The reference cell contained ammonia at the same concentration and so much of NH_4ClO_4 that the perchlorate concentration was equal to that in the other cell.

For $E > 0.1$ the reproducibility was ± 2 %, which may be accepted in view of the great systematic errors of the method.

Table 4. Calculation of the quotient q and β_1 from the experimental values of ε_M and ε_0.

$C'_A = 0.320$ M; $q_1 = \frac{\varepsilon'_M - \varepsilon_0}{\varepsilon'''_M - \varepsilon_0}$		$C''_A = 0.640$ M;		$C'''_A = 0.960$ M $q_2 = \frac{\varepsilon''_M - \varepsilon_0}{\varepsilon'''_M - \varepsilon_0}$		
mμ	$\log \varepsilon_0$	$\log \varepsilon'_M$	$\log \varepsilon''_M$	$\log \varepsilon'''_M$	q_1	q_2
255	0.765	0.925	1.00	1.075	0.43	0.69
250	1.105	1.235	1.305	1.37	0.42	0.70
248	1.27	1.38	1.445	1.505	0.40	0.69
246	1.455	1.55	1.605	1.66	0.41	0.69
244	1.645	1.72	1.765	1.815	0.39	0.67
242	1.85	1.91	1.95	1.99	0.39	0.68
240	2.06	2.105	2.135	2.17	0.38	0.65
238	2.265	2.30	2.33	2.355	0.37	0.71
236	2.465	2.495	2.515	2.535	0.41	0.69
234	2.66	2.68	2.70	2.715	0.36	0.71
233	2.75	2.77	2.785	2.805	0.35	0.63
232	2.84	2.865	2.88	2.895	0.44	0.72
231	2.93	2.95	2.965	2.98	0.38	0.69
				Mean	0.39	0.69
					β_1 M^{-1}	
					0.38	0.20
					0.3 ± 0.2	

If we attribute the second-order term in a_A/a_{aq}, that was found from the solubility measurements, exclusively to the change in the dielectric constant we can introduce in eqn. (19) the correction:

$$\beta_1 = (\beta_1)_0 + 0.05\ a_A/a_{aq}$$

This gives us a second-order equation in $(\beta_1)_0$ which renders $(\beta_1)_0 = 0.44$ and 0.32, valid at $C_A = 0$ and $I = 0.1$ M and corresponding to the two values of q of Table 4.
This correction thus reduces the relative spreading appreciably.

Results. In Table 4 the calculations are shown for those wave lengths where the shift of the extinction coefficients is large enough to permit calculations of some degree of accuracy.

COMPARISON BETWEEN THE SOLUBILITY AND THE LIGHT ABSORPTION METHODS

As different standard states have been used for f_A in the solubility measurements and in the light absorption measurements, the constants obtained are not directly comparable.

However, from theoretical considerations Bjerrum (Ref.[20], p. 129) presents the formula,

$$\log \beta = \log \beta_0 + 0.03\ C_{NH_4^+} \qquad (21)$$

where β denotes the association constant for the association of one ammonia to a metal ion. Experimentally he finds very different values of the coefficient, both positive and negative ones, and especially for the reaction

$$MA_5H_2O + A \rightleftharpoons MA_6 + H_2O$$

he finds (Ref.[20], p. 281) for the equilibrium constant β

$$\log \beta = \log \beta_0 + 0.18\ C_{NH_4^+} \qquad (22)$$

If this surprisingly great coefficient is assumed to apply also for the very similar reaction considered here,

$$MA_6 + A \rightleftharpoons (MA_6)A$$

we must conclude that β_1 at ionic strength 1 M should be about 40 % greater than at ionic strength 0.1 M.

Thus for ionic strength 1 M we have:

$\beta_1 = 0.24 \pm 0.05\ M^{-1}$ (solubility method)
$\beta_1 = 0.4 \pm 0.3\ M^{-1}$ (light abs. method)

If we prefer to make the "salt effect" correction with the help of eqn. (21), we obtain a smaller value $\beta_1 = 0.3 \pm 0.2\ M^{-1}$ (light abs. method).

Furthermore, if there exists a slight barium-ammonia complexity, which we have assumed not to be the case, the value of β_1 calculated from the solubility measurements should be somewhat greater. (The curve in the left diagram of Fig. 1 should be steeper and for a given value of C_A we should obtain a greater X than that reported.)

To sum up, we can state that the results of the two methods are not inconsistent.

The author is indebted to Prof. S. Bodforss, Dr. B. Adell, Dr. S. Ahrland and Dr. S. Fronæus for their kind interest that has promoted this work.

A Kinetic Study of the Reaction of *iso*Propoxy-methyl-phosphoryl Fluoride (Sarin) with Hydrogen Peroxide

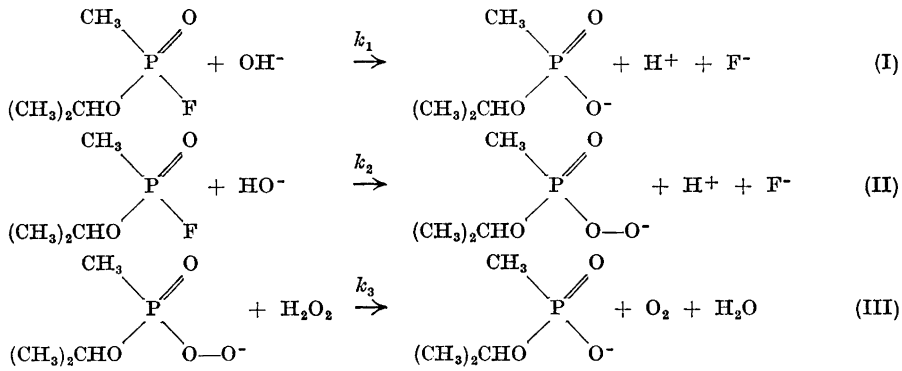
LENNART LARSSON

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The reaction of *iso*propoxy-methyl-phosphoryl fluoride (Sarin) and hydrogen peroxide has been investigated and the bimolecular rate constant and energy and entropy of activation of the formation of *iso*propoxy-methyl-perhydroxy-phosphine oxide have been calculated. It has been suggested that the reaction involves a nucleophilic attack of the perhydroxyl ion on the phosphorus atom, and that the transition state is stabilized by the formation of a hydrogen bond between the perhydroxyl ion and the oxygen atom of the phosphoryl group. It has been shown that the decomposition of the peroxy acid proceeds by two competitive reactions, the rate constants of which have been calculated.

The reaction of organic phosphorus compounds with hydrogen peroxide plays an important role in the Schönemann reaction. The principle of this reaction is the oxidation of amines, such as benzidine, to coloured products by hydrogen peroxide in the presence of various phosphorus compounds [1]. The reaction has been made the basis of a sensitive method for the quantitative determination of nerve gases [2,3].

In this connection it was of interest to study the reaction between Sarin and alkaline solutions of hydrogen peroxide in the absence of an oxidizable amine. Gehauf *et al.*[2] have discussed the mechanism of this reaction and have postulated the following scheme for the formation and decomposition of *iso*propoxy-methyl-perhydroxy-phosphine oxide. In the same scheme the alkaline hydrolysis of Sarin (I) is also given.



The same mechanism has also been proposed by Epstein *et al.*[4] in the study of the reaction between diethyl *p*-nitrophenyl phosphate (Paraoxon) and hydrogen peroxide. The present report is an attempt to make a detailed investigation of the reaction of Sarin with hydrogen peroxide at various pH-values and temperatures.

EXPERIMENTAL

Materials. Sarin was synthesized in this institute and freshly distilled before use[5]. A stock solution of Sarin in dioxane, E. Merck c.p. purified from peroxides and redistilled over sodium, was prepared. The concentration of Sarin in this solution was 8.0 mM.

Hydrogen peroxide (about 30 %), E. Merck anal. reagent. The exact concentration was determined by titration with 0.1 N solution of potassium permanganate.

Paper chromatographic technique. The final products of the reaction were analyzed by means of paper chromatographic technique. A solution containing 0.5 % Sarin and 0.5 % hydrogen peroxide in 0.1 M ammonium hydroxide was prepared. At this pH the reaction is almost instantaneously completed. By means of a micropipette 5 μl of this solution were placed on a filter paper, Whatman No. 1, and the spot was dried in hot air. Ascending technique was used, and the chromatogram was run at 25°C. An acid solvent with the following composition was used: *n*-butanol:ethanol:acetic acid:water (8:2:1:3)[6]. After the drying, phosphorus was developed by spraying the paper with an acid solution of ammonium molybdate and treating the dried paper with hydrogen sulfide[7].

Kinetic measurements. The kinetics of the reaction were studied in a manner similar to that described for the hydrolysis of Sarin and its analogues by means of an automatic recording titrator[5]. Two types of experiments were performed.

Procedure I. In the first series of experiments the reaction rate constant, k_2 (Reaction II), was determined by excess of hydrogen peroxide at 25°C at the pH-values 7.70, 8.00 and 8.50, and at 35°C at the pH-values 7.70 and 8.00. A solution containing 38.00 ml of 0.10 M potassium chloride and 1.00 ml of appropriately diluted hydrogen peroxide was adjusted by the titrator to a preselected pH-value, after which 1.00 ml of the stock solution of Sarin was added. The initial concentration of Sarin was 0.20 mM in every run and the initial concentration of hydrogen peroxide varied between 2.50 and 10.00 mM. The reaction was allowed to terminate, and the concentrations of Sarin at different times were calculated from the recorded amount of alkali consumed in the reaction. Such a calculation presupposes that the *iso*propoxy-methyl-hydroxy-phosphine oxide as well as the *iso*propoxy-methyl-perhydroxy-phosphine oxide formed in the reaction is totally ionized in the prevailing pH range.

Procedure II. In a second series of experiments which were performed at 25°C and pH 8.50, the initial concentration of Sarin was the same as mentioned above but that of the hydrogen peroxide was 0.50 mM. The initial and final concentrations of hydrogen peroxide were determined colorimetrically with titanium sulphate[8]. In other respects the same experimental technique was used as described under I. The spontaneous decomposition of hydrogen peroxide was checked during 2 h in a separate run and was found to be insignificant.

In two runs 1.00 ml of sample was withdrawn from the reaction vessel at intervals and added to 2.00 ml of a 1.25 % solution of *o*-tolidine in acetone and 2.00 ml of water. The optical density of the mixture was determined after 2 min in a 5 cm absorption cell at 4 250 Å with a Beckmann spectrophotometer, Type B. From these measurements it was possible to determine at which time during the reaction the concentration of the "peroxyphosphorus acid" attained its maximum value. A determination of the actual concentration of the peroxy acid, however, would be very difficult, because the rate of the colour reaction is unknown.

Determination of dissociation constants. The mixed dissociation constant, K_a', of *iso*propoxy-methyl-hydroxy-phosphine oxide was determined by potentiometric titration of a 5 mM hydrolysate of *iso*propoxy-methyl-phosphoryl chloride in 0.10 M potassium chloride solution with 0.1 M sodium hydroxide. The details of the procedure and the calculations are described in an earlier paper[9]. Two runs at 25°C gave $pK_a' = 2.10 \pm 0.05$.

Owing to the instability of the "peroxyphosphorus acid" formed it has not been possible to determine its dissociation constant. However, presuming that the relationship

between the dissociation constants of the "phosphorus acid" and the peroxy acid is the same as that between those of a carboxylic acid and the corresponding peroxy acid [10], pK'_a of the "peroxyphosphorus acid" may be estimated at 5—6.

RESULTS AND DISCUSSION

Formation of *iso*propoxy-methyl-perhydroxy-phosphine oxide

The formation of a "peroxyphosphorus acid" as an intermediate in the reaction of Sarin with hydrogen peroxide has been supported by the fact that the reaction mixture oxidizes thiosulphate ion to sulphate ion [2]. According to Feigl this anomalous oxidation of thiosulphate has been attributed to peroxy acids [11]. Also the oxidation of certain amines by hydrogen peroxide in the presence of organic phosphorus compounds indicates the formation of this intermediate. Furthermore the fluorine atom is split off more rapidly than the oxygen molecule is formed [2].

In the reaction two equivalents of acid were formed. On the basis of the estimated value of the dissociation constant of the "peroxyphosphorus acid", this acid was considered as totally ionized in the pH range in question. The subsequent decomposition of the peroxy acid according to Reaction III will then not cause any further consumption of alkali. The concentration of Sarin at different times was therefore calculated from the amount of alkali consumed. When hydrogen peroxide is in excess, the reaction can be treated as a pseudo first-order reaction. When the logarithm of the concentration of Sarin (c_{PF}) was plotted against the time a straight line was obtained as appears in Fig. 1. It is also shown in the figure that at low concentrations of hydrogen peroxide the curve deviates from the straight line at the end of the reaction, indicating that the decrease of the hydrogen peroxide concentration can only be neglected in the first part of the reaction.

From the curves obtained the observed rate constants, k_{obs}, were calculated. It is obvious from Table 1 that, at the lower pH-values, where sponta-

neous hydrolysis is negligible, k_{obs}, at constant pH, is proportional to the concentration of hydrogen peroxide, which indicates a bimolecular reaction mechanism. The variation of rate with pH shows that the perhydroxyl ion is the active component in the reaction.

The true second-order rate constant, k_2, was calculated from the expression:

$$k_2 = \frac{k_{obs} - k_1}{c_{HO_2^-}} \tag{1}$$

where the observed rate constant is corrected for the rate constant of the spontaneous hydrolysis, k_1, found from earlier experiments [5]. According to the law of mass action the perhydroxyl ion concentration is:

$$c_{HO_2^-} = \frac{K'_{H_2O_2} \cdot c^\circ_{H_2O_2}}{a_{H+} + K'_{H_2O_2}} \tag{2}$$

where $c^\circ_{H_2O_2}$ is the total concentration of hydrogen peroxide and $K'_{H_2O_2}$, the mixed dissociation constant. The values of $K'_{H_2O_2}$ at 25°C and 35°C in 0.10 M potassium chloride solution were estimated at 2.92×10^{-12} and 4.66×10^{-12}, respectively, from the thermodynamic constants given by Evans and Uri [12]. When $a_{H+} \gg K'_{H_2O_2}$ which is valid in the present pH range, eqn. (2) is reduced to:

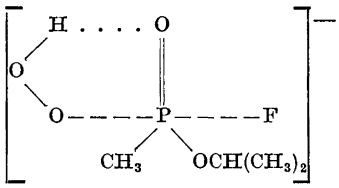
$$c_{HO_2^-} = \frac{K'_{H_2O_2} \cdot c^\circ_{H_2O_2}}{a_{H+}} \tag{3}$$

The values of k_2 at 25°C and 35°C are given in Table 1 and their mean values were found to be $k_2^{25} = (1.34 \pm 0.06) \times 10^3$ l mole^{-1} sec^{-1} and $k_2^{35} = (2.04 \pm 0.09) \times 10^3$ l mole^{-1} sec^{-1}. From these rate constants the energy of activation

was calculated as 7.7 ± 1.6 kcal mole^{-1} and the entropy of activation as -20 ± 5 E.U.

The facts that straight line plots are obtained from the experiments and that k_2 is independent of pH, support the hypothesis that *iso*propoxy-methyl-perhydroxy-phosphine oxide is totally ionized in the present pH range.

The mechanism of the reaction of Sarin with perhydroxyl ions may be considered to be analogous to that of the alkaline hydrolysis of Sarin, *i.e.* it involves a nucleophilic attack of the perhydroxyl ion on the phosphorus atom. The rate of this reaction has been shown to be about 50 times greater than that of the alkaline hydrolysis. This difference may be due to perhydroxyl ion being more nucleophilic than hydroxyl ion in spite of the greater basicity of the latter. Another reason for the greater rate of reaction is that perhydroxyl ion will contribute to the stabilization of the transition state by the formation of a hydrogen bond such as



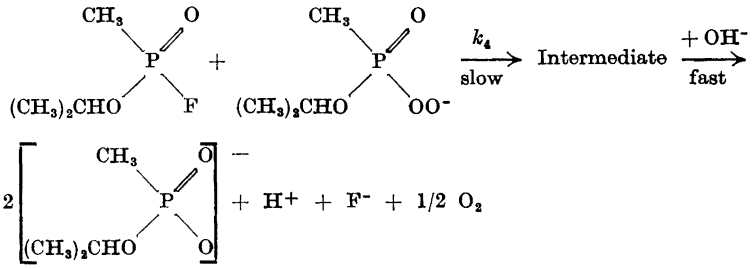
The formation of a hydrogen bond in the association of phenol with Sarin has been demonstrated in an infra-red spectroscopic study [13]. It has also been shown in this study that the absorption band of the P=O group shifts to lower frequency corresponding to a bond weakening, and that of the P—F group shifts to higher frequency corresponding to a bond strengthening. These results indicate that a hydrogen bond to the oxygen atom in the P=O group is formed. Thus it seems very probable that such a hydrogen bond also will be formed between the perhydroxyl ion and the oxygen atom in the P=O group in the transition state as suggested above.

Decomposition of *iso*propoxy-methyl-perhydroxy-phosphine oxide

The decomposition of the "peroxyphosphorus acid" shown in Reaction III has been supported by the consumption of two moles of hydrogen peroxide and the evolution of one mole of oxygen per mole of Sarin [2] when excess of hydrogen peroxide was used. By means of paper chromatography only a single final product containing phosphorus was found, and this was identified from its R_F value as *iso*propoxy-methyl-hydroxy-phosphine oxide, *i.e.* the same product as was formed in the spontaneous hydrolysis [5].

For the detailed kinetic study of the decomposition only a slight excess of hydrogen peroxide was used. In this case the spontaneous hydrolysis of Sarin was obvious, and it was necessary to take it into consideration in the calculations. To get a conception of the magnitude of the rate constant k_3, two separate calculations of the constant k_2 were made. In one case it was assumed that $k_3 \gg k_2$ and in the other that $k_3 \ll k_2$. The differential equations obtained

were evaluated by means of graphical integration analogously to the method described by Wideqvist [14]. The constant k_2 for the two cases was calculated after various times of reaction. For a value of k_3 between these extreme values, k_2 might increase with time when the calculations are based on the first assumption, and decrease when the calculations are based on the second one. It was, however, found that in both alternatives k_2 was increasing which indicates that Sarin reacts in an additional way to the one which was postulated before. A supplementary reaction such as the following is probable:



(IV)

For the Reactions I—IV the following differential equations can be set up:

$$\frac{dc_{PF}}{dt} = -k_1 c_{PF} - k_2 c_{PF} c_{HO_2^-} - k_4 c_{PF} c_{POO^-} \tag{4}$$

$$\frac{dc_{H_2O_2}}{dt} = -k_2 c_{PF} c_{HO_2^-} - k_3 c_{POO^-} c_{H_2O_2} \tag{5}$$

$$\frac{dc_{POO^-}}{dt} = k_2 c_{PF} c_{HO_2^-} - k_3 c_{POO^-} c_{H_2O_2} - k_4 c_{PF} c_{POO^-} \tag{6}$$

The differential equations were treated by means of a recording electronic computer (Precision Analog Computing Equipment, Electronic Associates, Inc.). The known values of c°_{PF}, $c^\circ_{H_2O_2}$, $c^\circ_{POO^-}$, k_1 and k_2 were put into the equations and k_3 and k_4 were varied until the recorded curve of the function c_{PF} against t coincided with the experimental one. The best agreement was obtained when $k_3 = 3.0$ l mole^{-1} sec^{-1} and $k_4 = 3.5$ l mole^{-1} sec^{-1} as appears from Fig. 2. For comparison the curves obtained from some other values of the constants k_3 and k_4 are given in the same figure.

In Fig. 3 the functions c_{PF}, c_{POO^-} and $c_{H_2O_2}$ against t are given with the values of k_3 and k_4 found above. From the c_{POO^-} curve it is shown that the maximum concentration of "peroxyphosphorus acid" is reached after 900 sec. From the colorimetric determination the maximum concentration was found to be between 800 and 900 sec which agrees fairly well with the calculated value. From the $c_{H_2O_2}$ curve the amount of hydrogen peroxide consumed in the reaction after 7 000 sec was estimated as 1.30 moles per mole of Sarin. The corresponding value from the determinations of the concentrations of hydrogen peroxide at the start and at the end of the reaction (after 4 h) was found to be 1.42. It is possible that the discrepancy between the found

1.0	0.10	— + — +

The experimental values are designed O.

and calculated consumption of hydrogen peroxide depends upon the spontaneous decomposition of hydrogen peroxide which has been neglected in the calculations.

In the determination of the rate constant, k_2, the influence of Reaction IV is practically negligible, because in those experiments the concentration of hydrogen peroxide was so high that Reaction III predominated over Reaction IV.

From the experimental data obtained no conclusions concerning the mechanisms of Reaction III can be drawn. Reaction IV probably proceeds over a peroxypyrophosphate formed by a nucleophilic attack of the peroxy acid on the phosphorus atom of the Sarin molecule. The hydrolysis of the intermediate is certainly very fast. There is a possibility that the intermediate is hydrolysed to one molecule "peroxyhosphorus acid" and one molecule "phosphorus acid" in contrast to what is stated in Reaction IV. However, the good agreement obtained between the experimental and calculated curves argues against the latter hypothesis and favours the process given in Reaction IV.

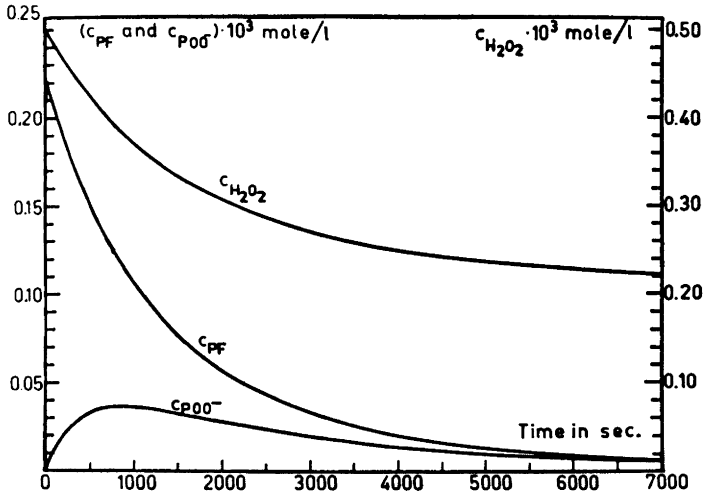

Fig. 3. The computed curves for the functions c_{PF}, c_{POO^-} and $c_{H_2O_2}$ against t at pH 8.50 and 25°C. $k_1 = 0.106 \times 10^{-3}$ sec^{-1}, $k_2 = 1.34 \times 10^3$ l mole^{-1} sec^{-1}, $k_3 = 3.0$ l mole^{-1} sec^{-1} and $k_4 = 3.5$ l mole^{-1} sec^{-1}.

My sincere thanks are due to Professor G. Ljunggren, Director of this Institute, for the kind interest he has shown in this work. The author wishes also to express his sincere thanks to Docent L. Melander, Nobel Institute of Chemistry, for stimulating criticism and discussions, and to Fil.kand. J. Prawitz for his kind assistance in programming the computor.

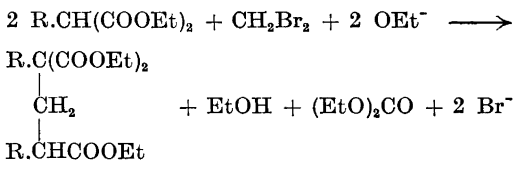
On the Reaction between Substituted Malonic Esters and Methylene Bromide. II

LENNART EBERSON

Department of Organic Chemistry, Chemical Institute, University of Lund, Sweden

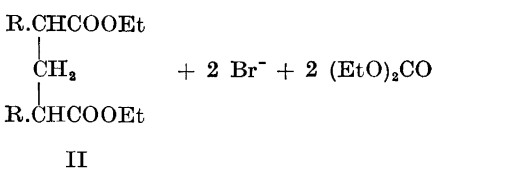
$\alpha,\alpha,\omega,\omega$-Tetracarbethoxyalkanes of the type III with n = 0, 2, 3, in the form of their disodium compounds, react with methylene bromide in ethanolic solution with the formation of the tetraesters IV, n = 0, 2, 3. With III, n = 1, the reaction takes another course and mainly pentaethyl 1,1,3,3,5-pentacarboxylate (VI) is formed.

The reaction between the sodium compound of a monosubstituted malonic ester and methylene bromide in ethanolic solution has been found to proceed according to the formula [1,2]:



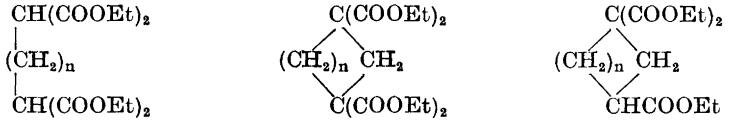
I

for R = methyl, ethyl, *n*-propyl, *iso*propyl, *n*-butyl, *iso*butyl-, *n*-amyl, benzyl, trimethylsilylmethyl, and acetamino, *i.e.*, one carbethoxy group is eliminated and a tricarboxylic ester (I) is formed. When R is an electronegative group, such as phenyl or carbethoxy, an $\alpha\alpha'$-disubstituted glutaric ester (II) is formed directly with the elimination of two carbethoxy groups.



II

The investigation now has been extended to the study of the reaction between an $\alpha,\alpha,\omega,\omega$,-tetracarbethoxyalkane (III, n = 0—3) and methylene bromide.



III IV V

Various examples of this reaction leading to cyclic compounds of the type IV are found in the literature. Kötz and Stalmann [3] investigated the reaction between the disodium compound of 1,1,2,2,-tetracarbethoxyethane and methylene iodide at 130° in absolute ethanol. They claimed that one solid (m. p. 43°) and one liquid form of tetraethyl *cyclo*propane-1,1,2,2-tetracarboxylate (IV, n = 0) were formed. They also stated that no reaction took place at temperatures below 130° and that the exchange of methylene iodide for the corresponding chloride led to very poor yields.

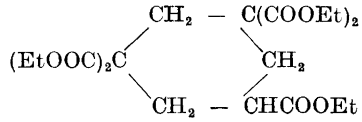
Guthzeit and Dressel [4] claimed that the main product from the reaction between 1,1,3,3-tetracarbethoxypropane (III, n = 1) and methylene iodide was tetraethyl *cyclo*butane-1,1,3,3-tetracarboxylate (IV, n = 1). However no proof of structure was given. Furthermore the same reaction with 1,1,4,4-tetracarbethoxybutane (III, n = 2) [5–8] and 1,1,5,5-tetracarbethoxypentane (III, n = 3) [9] has been shown to yield IV, n = 2 and 3, respectively.

In view of the above results for alkylmalonic esters it seemed worth while to reinvestigate the cited reactions to establish whether a similar elimination of a carbethoxy group with the formation of V occurs parallel to the formation of IV.

1. The reaction between 1,1,2,2-tetracarbethoxyethane and methylene bromide (iodide). This reaction took place in boiling ethanolic solution both with the bromide and the iodide, contrary to the statement of Kötz and Stalmann [3] that temperatures above 130° were required to obtain reasonable yields. The product was distillable and consisted exclusively of tetraethyl *cyclo*propane-1,1,2,2-tetracarboxylate with m. p. 41—43°. No trace of diethyl carbonate, which would have resulted if a carbethoxy group had been eliminated, could be detected.

2. The reaction between 1,1,3,3-tetracarbethoxypropane and methylene bromide (iodide). If this reaction was carried out in boiling ethanolic solution (about 80°) with methylene bromide or iodide a very viscous oil was obtained. When distilled *in vacuo* it decomposed and the decomposition products smelt very strongly of diethyl methylenemalonate. Apparently the crude reaction product consisted of polymeric diethyl methylenemalonate to a great extent. On alkaline or acid hydrolysis only tarry products were obtained. However, if the reaction temperature was raised to 100°, the product was distillable and a main fraction boiling at 210—215°/4 mm was obtained. On acid hydrolysis it yielded an acid with m.p. 212—215°, which was identified as *cyclo*hexane-1,3,5-tricarboxylic acid. On alkaline hydrolysis an acid with m.p. 180—184° (decomp.) was obtained, which lost carbon dioxide upon boiling with dilute

hydrochloric acid and gave *cyclo*hexane-1,3,5-tricarboxylic acid. The analyses indicated that the original ester was pentaethyl *cyclo*hexane-1,1,3,3,5-pentacarboxylate (VI) and that the acid with m. p. 180—184° was *cyclo*hexane-1,1,3,3,5-pentacarboxylic acid.



VI

A small amount of diethyl carbonate was isolated. No compound belonging to the *cyclo*butane series could be found.

3. The reaction between 1,1,4,4-tetracarbethoxybutane and methylene bromide. The investigation of this reaction confirmed the results of Pospischill [5], Thole and Thorpe [6], Perkin and Scarborough [7], and Guha and Ranganathan [8]. The yield of IV, n = 2, was poor and considerable amounts of tarry by-products were obtained as the above authors also have found. A small amount of diethyl carbonate, which probably resulted from the reaction between 1,1,4,4-tetracarbethoxybutane and ethoxide ion [10], was isolated. IV, n = 2, has been found to be stable under the reaction conditions employed [6].

4. The reaction between 1,1,5,5-tetracarbethoxypentane and methylene bromide. Perkin's [9] results were fully confirmed and only IV, n = 3, could be isolated. No diethyl carbonate was found.

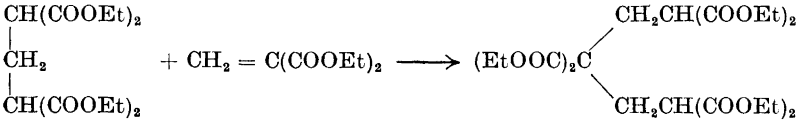
DISCUSSION

At first the reaction between 1,1,3,3-tetracarbethoxypropane and a methylene halide will be considered, as it deviates from the normal behaviour. Meerwein and Schürmann [11] have shown that 1,1,3,3-carbomethoxypropane reacts with sodium methylate in methanol in a complex manner with the formation of a bi*cyclo*nonane derivative. They were also able to demonstrate the intermediate steps of the reaction and that the same products were obtained irrespective of whether the starting materials were sodium methoxide and 1,1,3,3-tetracarbomethoxypropane, sodium methoxide, 1,1,3,3-tetracarbomethoxypropane, and dimethyl methylenemalonate or sodium methoxide, methylene iodide, and dimethyl malonate.

The formation of pentaethyl *cyclo*hexane-1,1,3,3,5-pentacarboxylate can be easily explained on the basis of Meerwein and Schürmann's investigations in the following way: In an alkaline medium 1,1,3,3-tetracarbethoxypropane is in equilibrium with a mixture of diethyl methylenemalonate and diethyl malonate.

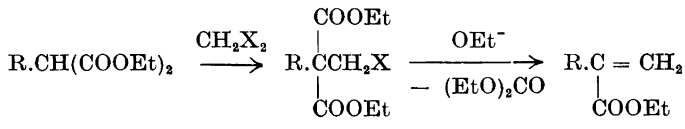
$$(EtOOC)_2CHCH_2CH(COOEt)_2 \rightleftharpoons CH_2 = C(COOEt)_2 + CH_2(COOEt)_2$$

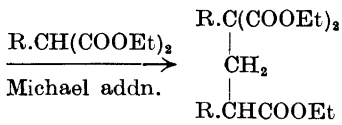
Diethyl methylenemalonate then reacts with 1,1,3,3-tetracarbethoxypropane (a Michael addition) according to the formula:



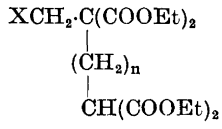
1,1,3,3,5,5-hexacarbethoxypentane is formed as has been proved by Meerwein and Schürmann in the case of the methyl derivative and is cyclized with the excess of methylene halide with the formation of VI and the elimination of one carbethoxy group as diethyl carbonate.

In the previous paper dealing with this subject [2], a reaction scheme for the reaction between a monosubstituted malonic ester and a methylene halide was proposed. It can be summarized in the following way:





Apparently this mechanism is not always valid when the two malonic ester residues are situated within the same molecule. However, the first step must be the formation of a bromomethyl-substituted compound VII.



VII

The second step may take place either according to the above mechanism *via* an unsaturated compound (elimination of one carbethoxy group to form V) or the halogen atom may be displaced directly by reaction with the second anionic center. Actually both situations have been observed (formation of compound VI and compound IV, n = 0, 2, 3), but it is difficult to draw any conclusions from the above data regarding the structural features which determine the course of the reaction. The second mechanism is rather remarkable as it involves displacement of a halogen atom under normal conditions in a structure analogous to the *neo*pentyl halides [12]. Probably this is a manifestation of the well known but not entirely understood effect, that accommodation of substituents at the ends of a closing carbon chain facilitates ring formation.

EXPERIMENTAL

Tetraethyl cyclo*propane-1,1,2,2-tetracarboxylate.* Sodium, 9.2 g (0.4 mole), was dissolved in 150 ml of absolute ethanol, and 63.6 g (0.2 mole) of 1,1,2,2-tetracarbethoxyethane were added whereby a stiff porridge of its disodium compound was obtained. Methylene bromide, 34.8 g (0.2 mole), was added and the mixture was held at reflux temperature for 20 h. After this time the mixture was thinly fluid and almost neutral. It was neutralized with a few drops of glacial acetic acid and the ethanol was distilled off

through a short column. Water was added and the semi-solid mass was taken up in ether, the ether solution dried with anhydrous magnesium sulphate, and finally the ether distilled off. Distillation of the residue yielded 48.5 g (71 %) of tetraethyl *cyclo*propane-1,1,2,2-tetracarboxylate, which soon solidified. It could eventually be recrystallized from a mixture of absolute ether and petroleum ether and then melted at 41–43° *. No diethyl carbonate could be detected in the fore-runs.

When the same procedure was repeated with methylene iodide instead of the bromide the reaction mixture became entirely clear after refluxing over night. After neutralization with a few drops of glacial acetic acid, the ethanol was distilled off and water was added. In this case the reaction product solidified completely and could be filtered off. After drying in a vacuum-desiccator it was recrystallized from a mixture of absolute ether and petroleum ether, m. p. 41–43°. The yield was 72 %. (Found: C 54.2; H 6.7. Calc. for $C_{15}H_{22}O_8$: C 54.5; H 6.7). Kötz and Stalmann [3] reported m. p. 43°. Guthzeit and Dressel [4] also reported m. p. 43° for a specimen prepared from 1,1,3,3-tetracarbethoxypropane and bromine.

The tetraethyl ester was hydrolyzed by boiling with 10 % ethanolic potassium hydroxide over night. The ethanol was evaporated on the water-bath and the residue treated with dilute hydrochloric acid. The resulting solution was evaporated to dryness on the water-bath (the tetraacid is sufficiently stable to permit this operation) and the residue repeatedly extracted with boiling acetone. The combined acetone extracts were concentrated to a small volume and left to crystallize. An 81 % yield of rather pure tetraacid was obtained. After recrystallization from acetone it melted at 205–210° (decomp.). (Found: C 38.7; H 2.8. Calc. for $C_7H_6O_8$: C 38.5; H 2.8). Guthzeit and Dressel [4] reported m. p. 200° (decomp.).

Pentaethyl cyclo*hexane-1,1,3,3,5-pentacarboxylate.* Sodium, 11.5 g (0.5 mole), was dissolved in 180 ml of absolute ethanol and the solution poured into a soda-water bottle together with 83.0 g (0.25 mole) of 1,1,3,3-tetracarbethoxypropane and 67.0 g (0.25 mole) of methylene iodide. When the first reaction had subsided (after about 5 min) the bottle was sealed and heated in a water-bath at 100° for 30 h. The reaction mixture, which was almost neutral was worked up as in the foregoing experiment. Distillation *in vacuo* yielded one fraction (2.8 g) boiling at 50–60°/50 mm, which consisted of diethyl carbonate, one fraction boiling up to 210°/4 mm, and one main fraction at 210–215°/4 mm. The second fraction, which weighed 19.5 g, boiled inconstantly through the whole interval and gave on acid hydrolysis a small amount of a substance with m. p. 235–240°. It was readily oxidized with alkaline potassium permanganate but was not further investigated. No other definite compounds were found among the hydrolysis products.

The third fraction (33.8 g) consisted of pentaethyl *cyclo*hexane-1,1,3,3,5-pentacarboxylate, as indicated by the analysis and its behaviour upon hydrolysis. (Found: C 56.4; H 7.3. Calc. for $C_{21}H_{32}O_{10}$: C 56.7; H 7.3.)

The pentaethyl ester, 20.0 g, was hydrolyzed by boiling over night with 10 % ethanolic potassium hydroxide. The ethanol was removed on the water-bath and the residue was treated with dilute hydrochloric acid. The solution was then continuously extracted with ether for two days. The ether solution, which gradually deposited large amounts of crystals, was filtered and the mother liquor was evaporated to dryness, whereby a second crop of crystals was obtained. The total yield of crude product was 12.1 g (88 %). The crystals were somewhat sticky. A pure product was obtained after recrystallization from hot (80°) glacial acetic acid, though with considerable loss of substance. The m. p. was 180–184° (decomp.). The substance had to be dried at 110° for 2 h before analysis. (Found: C 43.6; H 4.2. Calc. for $C_{11}H_{12}O_{10}$: C 43.4; H 4.0.) When boiled with dilute hydrochloric acid for some hours, carbon dioxide was evolved and the pentacarboxylic acid converted to *cyclo*hexane-1,3,5-tricarboxylic acid, m. p. 208–213° (see below).

The pentaethyl ester, 5.0 g, was boiled over night with concentrated hydrochloric acid. The solution was evaporated to dryness on a water-bath and an almost quantitative yield of crude *cyclo*hexane-1,3,5-tricarboxylic acid was obtained, m. p. 205–210°. It was recrystallized twice from a mixture of benzene and acetone and then melted at 212–215°. Before analysis it had to be dried at 110° for 2 h in order to remove traces of solvent, which was held firmly by the crystals. (Found: C 49.9; H 5.7; equiv. wt. 73.0. Calc. for $C_9H_{12}O_6$: C 50.0; H 5.6; equiv. wt. 72.1.) The acid was converted into its triamide accord-

* The melting points were determined with a Kofler apparatus.

ing to Newman and Lowrie [13], m. p. 286–289° (decomp.) after recrystallization from water, and to its trimethyl ester by esterification with methanol, m. p. 43–45° after recrystallization from petroleum ether. Newman and Lowrie reported for the acid m. p. 216–218°, the amide 287.5–288.5° (decomp.), and the methyl ester 48–49°.

If methylene bromide was used instead of the iodide and the reaction carried out at 100° for 30 h, the same products were obtained.

Tetraethyl cyclo*pentane-1,1,3,3-tetracarboxylate.* Sodium, 4.6 g (0.2 mole), was dissolved in 70 ml of absolute ethanol and 34.6 g (0.1 mole) of 1,1,4,4-tetracarbethoxybutane together with 17.4 g (0.1 mole) of methylene bromide were added during a few minutes. The mixture was boiled under reflux for 20 h, after which time it was almost neutral. It was worked up as usual. The crude product was not distillable even at low pressures without extensive decomposition, and therefore it was hydrolyzed directly. However a small amount (1.2 g) of diethyl carbonate was distilled off, b. p. 50–60°/ca. 50 mm.

The crude ester (30.2 g) was boiled with 10 % ethanolic potassium hydroxide over night. The ethanol was distilled off and dilute hydrochloric acid was added. The solution was continuously extracted with ether for 36 h. The ether solution gradually deposited crystals which were filtered and dried, m. p. 185–190° (decomp.). The substance (4.3 g) was *cyclo*pentane-1,1,3,3-tetracarboxylic acid as indicated by analysis. (Found: C 44.0; H 4.2. Calc. for $C_9H_{10}O_8$: C 43.9; H 4.1). Pospischill [5] reported m. p. 186–188° (decomp.). From the mother liquor of the above filtration a dark viscous oil was obtained. No definite compounds could be isolated from this oil.

Tetraethyl cyclo*hexane-1,1,3,3-tetracarboxylate.* Sodium, 9.2 g (0.4 mole), was dissolved in 150 ml of absolute ethanol. To the solution were added 72.0 g (0.2 mole) of 1,1,5,5-tetracarbethoxypentane and then dropwise 34.8 g (0.2 mole) of methylene bromide. A vigorous reaction soon set in and when it had subsided the mixture was boiled under reflux for 20 h. The mixture then was almost neutral and was worked up in the usual manner. The crude product (68.3 g) which did not contain any detectable amounts of diethyl carbonate, could not be distilled without decomposition, even at low pressures. It was therefore directly hydrolyzed with 10 % potassium hydroxide over night and the tetraacid was isolated by means of continuous ether-extraction as above. A yield of 16.4 g of a rather pure product was obtained. It was recrystallized from hot (80°) water and then melted at 210–220° (decomp.). (Found: C 46.3; H 4.7. Calc. for $C_{10}H_{12}O_8$: C 46.2; H 4.7.) Perkin [9] reported m. p. 218–220°. The mother liquors were examined for other compounds but without success.

The author wishes to express his sincere gratitude to Professor Erik Larsson for his kind interest in this work. A grant from *Kungliga Fysiografiska Sällskapet* is gratefully acknowledged.

Studies of Allergens from Alder Pollen (*Alnus Glutinosa*)

STIG HERBERTSON and JERKER PORATH

Institute of Biochemistry, University of Uppsala, Sweden

and

HELGE COLLDAHL

Medical Clinic II, Allergy Department, S:t Göran's Hospital, Stockholm, Sweden

An alder-pollen (*Alnus glutinosa*) extract has been fractionated and examined for allergenic activity by skin tests.

The activity was found in a non dialysable fraction. No decrease in activity was observed when this fraction was heated to 100°C for 1 hour. Treatment with pepsin, trypsin and chymotrypsin did not cause any significant inactivation.

Further fractionation by zone electrophoresis and chromatography on cellulose ion exchangers yielded a peptide-like fraction, 300 times as potent as the crude extract. This fraction contained at least 11 different amino acids.

The chemical and immunological properties of pollen allergens have been studied for about fifty years. Although much work has been done to isolate and to characterize active components in pollen, a chemically pure allergen has not yet been isolated. The activity appears, at least in some pollen species, to be shared by several substances. This circumstance, together with the lack of accurate test methods and methods for quantitative studies, has often led to contradictory reports. In spite of these facts, it can be concluded that allergens from different pollen have some characteristics in common. Chiefly ragweed and grass pollen have been studied. It is therefore appropriate to mention something about the methods that have been used for the fractionation of extracts of these pollen species and to point to some conclusions that have been drawn about the nature of the allergens.

The allergens of ragweed and grass pollen are generally found to be non-dialysable when ordinary dialysis membranes are used.[1,2] Weakly active components sometimes found in the dialysate have been referred to as break-down products formed during the procedures [16].

Abramson *et al.*[3] employed Tiselius' moving boundary electrophoresis technique for the separation of components in crude extracts of ragweed

pollen. An active colourless fraction contained subtances with molecular weights of about 5 000, as determined by ultracentrifugation.

Fractionations by chromatography on ion exchange resins have been preliminary described by Bookman and Wax [4]. Using crude water extracts of ragweed pollen, they found that the best results were obtained when a sulfonic acid resin (Dowex-50) was used. However, only a small part of the initial activity was recovered.

From results obtained by using different precipitating agents, such as ammonium sulfate [5–8, 9–11], alcohols [12–15], acetone [16], lead acetate [17], acids [18–20], and bases [8,13] for fractionations of extracts, it has been suggested that the active substances in ragweed pollen are carbohydrate-protein complexes, proteins or carbohydrates.

Augustin has published preliminary reports on fractionations of grass pollen [21–23]. Salt fractionations of the extracts yielded a number of active proteins associated with carbohydrate-pigment complexes which could not be removed from the protein moiety by prolonged dialysis. Diffusion and ultracentrifuge studies on the active fraction indicated a molecular weight of 14 000.

Critical summaries of chemical and immunological studies in pollen allergy have recently been written by Augustin [23,24].

The present study is an attempt to apply modern fractionation techniques to the isolation of allergens and to quantitate the procedures involved. Zone electrophoresis and chromatography on cellulose ion exchangers are methods that would be suitable for problems of this kind. Alder pollen (*Alnus glutinosa*) are used in this work because large samples of this species were available. The general chemical composition of alder pollen *(Alnus glutinosa, Alnus incana)* has been studied by Nielsen *et al.*[25], but no reports on the purification of alder pollen allergens are found in the literature.

MATERIALS AND METHODS

Pollen. The pollen used in this investigation have been collected from the alder tree, *Alnus glutinosa,* in 1954 by A.B. Cernelle, Vegeholm, Sweden. Immediately after collection, the pollen samples were dried to a moisture content of 5—6 % and were kept cool and dry. The quantity of other pollen species amounted only to about 0.1 % [25].

Proteolytic enzymes. Pepsin was obtained from Parke, Davis and Co., London; *Trypsin* was obtained from Worthington Biochemical Corp., Freehold, New Jersey; *Chymotrypsin* was obtained from the Armour laboratories, Armour and Co., Chicago, Ill.

Ion exchangers. Triethylaminoethylcellulose anion exchange powder (TEAE-cellulose) was prepared as described by Porath [27]. The nitrogen content of the preparation was 5.1 mg per g of dry powder.

Sulfoethylcellulose ion exchange powder (SE-cellulose) was prepared as described by Porath [27]. The SE-cellulose contained 0.45 mequiv. sulfur per gram dry powder.

Zone electrophoresis. Zone electrophoresis was performed in externally cooled columns, using the technique described by Porath [31]. In one experiment ethanolised cellulose was used as supporting medium. In two other experiments a gel B 196* was used instead of cellulose.

Biological test. The biological activity was measured by intradermal tests on alder-sensitive patients.

A standard test solution is made up by dissolving material from 1 g pollen in 10 ml of a 0.5 % phenol solution (1:10). Before the testing there are made tenfold serial dilutions

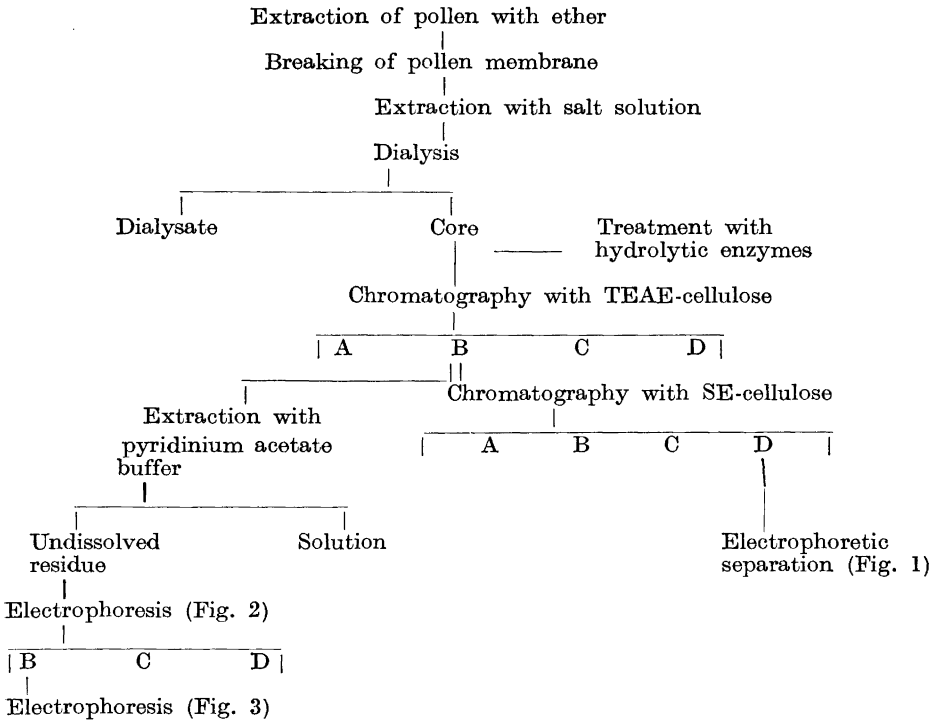
* Obtained from AB Pharmacia, Uppsala.

of the standard test solution up to 1: 10^6 (*i. e.* 1: 10^2, 1: 10^3, ... 1: 10^6). Physiologic salt solution containing 0.5 % phenol is used for the dilution.

A control is made by injection salt-phenol solution in the skin of the patient. With the same syringe the different antigen containing dilutions are injected. The highest dilution is first injected, and this is followed by the next lower until a dilution is found which just gives a positive skin reaction. More or less strong responses are indicated by ‡ resp. ±. If a reaction is found only for the dilution 1: 10^2, this response can not with certainty be regarded as positive because nonspecific factors will interfere with the reaction at such a low dilution. This effect is more pronounced for crude extracts.

EXPERIMENTAL

Flow sheet



Sampling for activity assays

If a fractionation had been made in an experiment and a certain fraction was to be tested, there was taken the portion of 1 g pollen that was recovered in the fraction (*i. e.* if say 500 g of pollen have been fractionated, one should take 1/500 of the material in the fraction to be tested). This portion was made up to standard condition by being dissolved in 10 ml of 0.5 % phenol solution and then prepared for testing. The dilution (1: 10 ×) which gave a positive skin reaction was marked as the activity. Consequently the activity value of this solution will never exceed that of the standard test solution from crude extract.

A. Pretreatment of pollen

1. *Ether extraction.* The pollen grains were defatted by extraction with ether in the following way. A sample of pollen (500 g) was suspended in peroxide free diethylether (1 l) and transferred to a glass tube of the type used for chromatography. Fresh ether was slowly percolated through the column. After 24 h when no more material went into the solution the extracted pollen sample was poured out and the residual ether was removed in vacuum.

13 % of the original pollen weight was thus removed by the extraction.

2. *Breaking of the pollen membranes.* In order to facilitate a subsequent extraction of active material the pollen membranes were ruptured as follows. A sample of pollen (100 g) was suspended in a small amount (200 ml) of extracting fluid (see below). The suspension was frozen to −70°C and was then thawed. The procedure was repeated three times or till nearly all of the pollen grains were ruptured (checked by observation in a microscope).

B. Extraction of active material

1. *Extraction with salt solution.* The active material was extracted from the ruptured pollen by using the same procedure as for the ether extraction, but the extracting fluid was composed of 0.9 % sodium chloride and 0.5 % phenol dissolved in boiled distilled water. A sample corresponding to 1 000 g of fresh pollen was extracted during 36 h at 4°C with 3 600 ml of fluid. Extract exceeding 3 600 ml was collected separately in one experiment, but was not used for preparations because the activity in this fraction was only about one hundredth of that in the first collected fraction.

Each gram pollen yielded 251 mg of dry material and 18.2 mg of nitrogen (Kjeldahl). The activity of the extract was determined to ‡ 1: 10^4 ± 1: 10^5 (Patient L.F.).

2. *Extraction with sulfuric acid.* For comparison an extraction was made under condition where proteolytic activity in the extract is supposed to be prevented. A small scale extraction of 10 g pollen was made with 0.25 N sulfuric acid in the same way as indicated above. 50 ml of extract was collected during 24 h. 10 ml of the extract was dialysed in a cellophane sac for 1 h against water. The dialysed residue was neutralized to pH 7 with sodium bicarbonate (sample E). Another 10 ml of the initial extract was dialysed against 0.25 N sulfuric acid for 20 h. The residue (sample R) and the dialysate (sample D) were neutralized to pH 7. Results of the testing in Table 1.

Table 1.

Sample	Activity Patient L.F.
E	‡ 1: 10^4
R	+ 1: 10^4
D	+ 1: 10^2

Reference: Extract (NaCl) (‡ 1: 10^4 ± 1: 10^5)

The sulfuric acid extract was not used for the subsequent fractionations.

C. Dialysis of the salt extract obtained as described under B 1

The phenol-sodium chloride extract was dialysed in Visking cellophane sacs of 4 cm diameter. The extract inside the sacs was stirred with a rotating glass rod. During the first 24 h the extract was dialysed twice against 0.5 % phenol in water. The dialysis was continued for another 24 h but the residue in the sacs was now dialysed twice against boiled water. The whole procedure was performed in a cold room at 4°C. The liquid inside the sacs was centrifuged in order to remove a precipitate formed during the dialysis.

The precipitate which was dissolved in sodium chloride solution was inactive. The centrifuged liquid (referred to as "Core" in Table 2) had the same activity as the extract. The pooled outside liquids (dialysate) had no activity.

Table 2.

Sample	Nitrogen, mg per g pollen	Weight, mg per g pollen	Activity Patients L.F.	J.U.
Core	2.1	35	$+1:10^4$	$\pm 1:10^5$
Dialysate	10.2		$+1:10^2$	
Precipitate	3.0	18	$+1:10^2$	
Extract	18.2	251	$+1:10^4$	$\pm 1:10^5$

The active material did not pass the dialysis membrane. The extract was purified sevenfold by weight.

D. Properties of preparation "Core".

1. *Stability to heating.* 35 mg of preparation "Core" (Table 2) was dissolved in distilled water and heated in a closed glass tube at 100°C during 1 h. Results from testing in Table 3.

Table 3.

Sample	Activity (Patient L.F.)
Core	$+1:10^5$
Heated Core	$+1:10^5$

2. *Treatment with proteolytic enzymes.* The procedures used in the following experiments are similar to those described by Li *et al.*[26]

Pepsin. 35 mg of preparation "Core" (Table 2) and 25 mg of cryst. pepsin (1:3 000 U.S.P.) were dissolved in 45 ml of 0.01 N hydrochloric acid solution. A standard was prepared by dissolving 35 mg of preparation "Core" in 45 ml of hydrochloric acid. For comparison a solution was prepared by dissolving 25 mg pepsin in 0.01 N hydrochloric acid solution (sample "pepsin"). To all solutions were added a few drops of toluene. When all the solutions had been kept at 37°C for 4 h they were placed in a boiling water-bath for 2 min to terminate the enzymatic activity. The results from the testing are given in Table 4.

Table 4.

Sample	Activity Patient L.F.		Patient J.U.		Patient A.N.
Core	$+1:10^4$	$\pm 1:10^5$	$+1:10^4$	$\pm 1:10^5$	$+1:10^3$
Digest	$+1:10^4$	$\pm 1:10^5$	$+1:10^4$	$\pm 1:10^5$	neg.
Pepsin	$+1:10^2$	$\pm 1:10^3$	$+1:10^2$		neg.

Trypsin. 35 mg of preparation "Core" (Table 2) and 10 mg of cryst. trypsin were dissolved in 50 ml of water. pH was adjusted to 9.3 by dropwise addition of 2 % ammonia solution. A standard was prepared by dissolving 35 mg of preparation "Core" in ammonia solution. For comparison a solution was prepared by dissolving 10 mg trypsin in 50 ml ammonia solution. After the mixtures had been kept at 37°C for 6 h the enzymatic activity was terminated by heating to 100°C for 2 min. The results from the testing are compiled in Table 5.

Table 5.

Sample	Activity Patient L.F.		Patient J.U.		Patient A.N.
Core	$+1:10^4$	$\pm 1:10^5$	$+1:10^4$	$\pm 1:10^5$	$+1:10^3$
Digest	$+1:10^5$		$+1:10^4$		$\pm 1:10^3$
Trypsin	neg.		neg.		neg.

Chymotrypsin. 35 mg of preparation "Core" (Table 2) and 10 mg chymotrypsin were dissolved in 0.2 N ammonium acetate buffer of pH 8.2. A standard solution was prepared by dissolving 35 mg of preparation "Core" in ammonium acetate buffer. For comparison a solution was prepared by dissolving 10 mg chymotrypsin in the buffer. The mixtures were kept at 38°C for 5 h and then the enzymatic activity was terminated at 100°C for two min. The results from the testing are shown in Table 6.

Table 6.

Sample	Activity Patient L.F.		Patient J.U.		Patient A.B.
Core	$+1:10^4$	$\pm 1:10^5$	$+1:10^4$	$\pm 1:10^5$	$+1:10^3$
Digest	$+1:10^4$		$+1:10^4$		$+1:10^3$
Chymotrypsin	$+1:10^3$		$\pm 1:10^2$		$\pm 1:10^2$

E. Fractionation of preparation "Core" by chromatography on triethylaminoethyl cellulose.

100 g of TEAE-cellulose ion exchanger containing 5.1 mg nitrogen per g was prepared as free base. The TEAE-cellulose was suspended in distilled water and packed in a Büchner funnel (19 cm in diameter) which was placed on a vacuum flask. 2 000 ml of preparation "Core" (Table 2) (corresponding to 435 g of pollen) were gently sucked through the ion exchanger during 1 h. Unadsorbed material was washed out with 1 l of water. The adsorbed material was displaced with three different solutions in the following order:

1) 2 l of 0.1 N pyridinium acetate (PyAc) buffer of pH 5.0.
2) 1 l of 1.0 N pyridinium acetate buffer of pH 5.0.
3) 0.5 l of 1 N acetic acid (HAc).

The collected fractions were freed from buffer and acid by vacuum distillation and finally lyophilized. The results obtained in one experiment is found in Table 7.

Table 7.

Sample	Fraction	Weight (mg)	Nitrogen (mg)	Activity Patient L.F. (2 measurements)	
TEAE–A	Eluate	6.6		$+1:10^2$	$+1:10^3$
TEAE–B	0.1 N PyAc	4.6	441	$+1:10^4$	$+1:10^5$
TEAE–C	1 N PyAc	3.2		$+1:10^2$ $\pm 1:10^3$	-------
TEAE–D	1 N HAc	0.1		neg	-------
	Total	14.6			
Core		15.2	929	$+1:10^4$	$+1:10^5$

The total loss of material amounted to 4 %, provided that material from the ion exchanger itself was not eluted during the process. The activity in preparation TEAE—B was the same as in preparation "Core". Preparation "Core" was purified threefold by weight and twofold by nitrogen. The experiment was easily reproduced. The ion exchange powder was packed in a wide funnel. If a column with a small diameter is used the elution easily stops because of the strong accumulation of material at the top of the column.

F. Fractionation of preparation TEAE-B on sulfoethyl cellulose

SE-cellulose, which contained 0.45 mequiv. sulfur per g dry powder was worked up as free acid. The powder was suspended in dist. water and was packed in a glass tube under pressure. Preparation TEAE-B (Table 7) was dissolved in distilled water and was applied to the column. The chromatogram was developed first with dist. water followed by a three step displacement with different solvents in the following order:

1) 0.1 N triethylammonium acetate buffer of pH 5.0
2) 1.0 N triethylammonium acetate buffer of pH 5.0
3) 0.1 N triethylamine.

Fig. 1 shows an experiment where 374 mg of preparation TEAE-B has been chromatographed on 25 g of SE-cellulose which was packed to a column of 2 cm diameter. Fractions of 7 ml were collected every 10 min.

Aliquots of 0.25 ml were taken from each fraction in the fraction range 1—85 and aliquots of 0.1 ml from each fraction in the fraction range 86—170 and were then analysed with ninhydrin [28]. Aliquots of 0.5 ml were taken for orcinol analysis [29]. 0.1 ml samples were used for turbidimetric determination of proteins with trichloroacetic acid [30]. No turbidity was observed. The distribution of yellow pigments is indicated in Fig. 1 (visually observed).

Fractions were pooled as indicated in Table 8 and were freed from buffer. After lyophilization the activity was determined.

Table 8.

Sample	Fraction range in Fig. 1	Weight (mg)	Activity Patient	Activity M.C.
SE—A	0— 15	0.1	$\pm 1:10^2$	$\pm 1:10^3$
SE—B	16— 85	67.4	$+ 1:10^3$	$\pm 1:10^4$
SE—C	86—100	238.4	$+ 1:10^2$	
SE—D	101—170	68.2	$\ddagger 1:10^4$	$\pm 1:10^5$
	Total	374.1		
TEAE—B		374.0	$\ddagger 1:10^4$	$\pm 1:10^5$

By the fractionation Preparation TEAE—B was purified fivefold by weight.

G. Electrophoretic separation of preparation SE-D.

In order to study the heterogeneity of preparation SE—D (Table 8) this fraction was investigated by zone electrophoresis using the technique described by Porath [31]. The column which had a length of 150 cm and a diameter of 3 cm was washed with 0.1 N triethylammonium acetate buffer of pH 5.0.

60.2 mg of preparation SE—D was dissolved in 3.0 ml of 0.1 N triethylammonium acetate buffer of pH 5.0. Undissolved material (sample SE—P) was removed by centrifugation. The brownish yellow solution, containing 47.0 mg of dissolved material, was

placed on the top of the column and was slowly forced into it by gravity to a position 10 cm from the top. 1 200—1 300 V were applied giving a current of 85 mA. After 52 h the electrophoresis was stopped and the liquid in the column was displaced at a rate of 60 ml per h. 6.7 ml fractions were collected.

From every second fraction 0.5 ml was taken for ninhydrin analysis. The ultraviolet absorption at 280 mμ was also measured on undiluted fractions. 0.5 ml samples from every other fraction were hydrolysed in 4.5 N hydrochloric acid at 110°C for 15 h and then subjected to ninhydrin analysis [32]. The values from the measurements are recorded in Fig. 2. Fractions were pooled according to Table 9 and freed from buffer, lyophilized and tested. A correction is made in the weight values because samples had been withdrawn for analysis.

Table 9.

Sample	Fraction range in Fig. 2	Weight (mg)	Activity Patient	Activity L.F.
E—1A	0— 55	1.0	$\pm 1:10^2$	
E—1B	56— 75	7.2	$+1:10^2$	$\pm 1:10^3$
E—1C	76—100	10.1	$+1:10^2$	
E—1D	101—120	7.1	$+1:10^2$	
E—1E	121—170	10.8	$+1:10^2$	
	Total	36.2

H. Extraction of preparation TEAE-B with buffer

A considerable purification of the active material was achieved by extraction of preparation TEAE—B (Table 7) with buffer as described below. The procedure was not always reproducible. However, the following experiment gave data about the allergen(s).

500 mg of preparation TEAE—B (Table 7) was thoroughly mixed with 2 ml of 0.1 N pyridinium acetate buffer of pH 5.0. Undissolved material was treated again with 1 ml of buffer. Still undissolved material (sample TEAE—BP) was separated by centrifugation. The solutions were pooled (TEAE—BP). Preparation TEAE—BP was freed from buffer and lyophilized. The test results are shown in Table 10.

Table 10.

Sample	Weight (mg)	Activity Patient L.F.	Activity Patient J.U.	
TEAE—B	500	$\ddagger 1:10^4$	$+1:10^4$	
TEAE—BP	70	$+1:10^4$	$+1:10^3$	$\pm 1:10^4$
TEAE—BS		$+1:10^2$	neg	

By the extraction preparation TEAE—B was purified about sevenfold.

I. Electrophoresis of preparation TEAE-BP

The electrophoresis was performed in an externally cooled column 90 cm long and with a diameter of 1.6 cm. Gel B 196 was used as supporting medium. 0.05 N triethylammonium carbonate buffer of pH 8.6 was used [33].

69 mg of preparation TEAE—BP (Table 10) was dissolved in 4 ml of triethylammonium carbonate buffer of pH 8.6. The brownish yellow solution was applied on the column

and by gravity forced 26 cm down into the column. 600 V were applied yielding a current of 15 mA. After 15 h the electrophoresis was stopped and the liquid in the column was displaced at a rate of 40 ml per h. 3 ml fractions were collected.

From every second fraction 0.1 ml was taken for ninhydrin analysis. The measured values are recorded in Fig. 3. The fractions were pooled according to Table 11, freed from buffer, lyophilized and tested. The brownish yellow colour was concentrated in fraction E−2B.

Table 11.

Sample	Fraction range	Weight (mg)	Activity Patient U.B.		Patient G.J.M.		Patient Y.N.	
E−2A	0−11	1.1						
E−2B	12−18	33.6	‡1: 10^2	±1: 10^3	‡1: 10^2	±1: 10^3	+1: 10^3	±1: 10^4
E−2C	19−29	21.9	neg		±1: 10^2		±1: 10^3	
E−2D	30−50	7.6	±1: 10^2		±1: 10^2		±1: 10^3	
TEAE−BP			+1: 10^3		±1: 10^3		±1: 10^4	

Preparation TEAE−BP was purified about twofold by the procedure, and had now about 300 times as high specific activity as the initial extract. The nitrogen value of preparation E−2B was 1.19 mg.

A too big amount of material from preparation E−2B is required for detection on paper. Therefore a new zone electrophoresis experiment was made instead of using paper electrophoresis.

Electrophoresis. The same column (90 × 1.6) was used but the buffer was now 0.05 N triethylammonium carbonate buffer of pH 9.0.

30 mg of preparation E−2B (Table 11) was dissolved in 2 ml of buffer and was forced 25 cm into the column. The electrophoresis was run for 39 h using 700 V and a current of 25 mA. To make it possible to run the electrophoresis during 39 h and still keep the substances in the column, the liquid in the column was slowly forced in the opposite direction to that in which the substances migrated. This was arranged by keeping the buffer in the two electrode vessels at different levels.

The liquid in the column was displaced at a rate of 40 ml per h. 2.5 ml fractions were collected.

0.1 ml samples from every second fraction were used for ninhydrin analysis.

0.05 ml samples were hydrolysed in 4.5 N hydrochloric acid at 110°C during 15 h and the ninhydrin values determined. Absorption at 275 mμ was measured. The measured values are shown in Fig. 4. The highest ninhydrin value and the strongest colour (yellow) was found in the same tube. 25 mg of material was found in the fraction range 26−120.

The material in the fraction range 28−43 was preliminarily examined. One sample was hydrolysed with 6 N hydrochloric acid at 110°C for 15 h. The hydrolysate was studied by means of paper electrophoresis and paper chromatography. Both acid, basic and neutral amino acids were present (at least 11 different spots). The same amount of unhydrolysed material did not give any colour with ninhydrin on paper. When enough of unhydrolysed material had been chromatographed on paper, using 80 % phenol in borate buffer of pH 9.3 as solvent system, the yellow pigment stayed at the starting point and a 'ninhydrin spot' was found with an R_F-value of about 0.5.

DISCUSSION

From the results of the semi-quantitative skin test method used in this study it is not always possible to conclude whether one of several active components has lost its activity during the fractionation procedure. This is the main reason why methods as mild as possible have been applied. The tests were performed with the same patient (Patient L.F.) except in the experi-

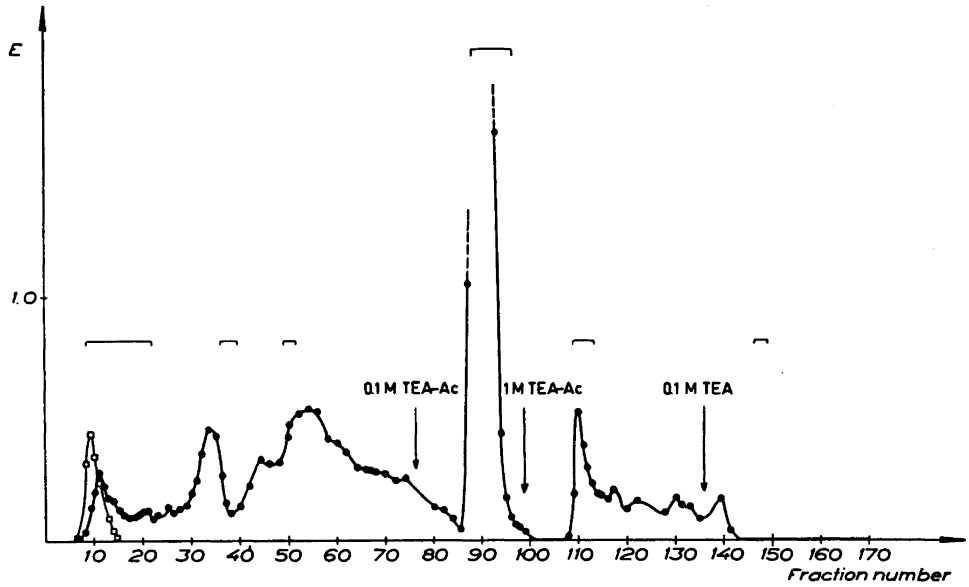

Fig. 1. Chromatographic separation of 374 mg of preparation TEAE—B on 25 g of SM-cellulose (column diameter: 2 cm). Fractions of 7 ml were collected.

ment described in passages F and I. Patient M.C. (passage F) and Patient L.F. gave about equal response to preparation TEAE-B.
