ACTA CHEMICA SCANDINAVICA 12 (1958) 1512—1515

Birch Wood Constituents

I. Carbohydrates of Low Molecular Weight

BENGT LINDBERG and LARS SELLEBY

Institutionen för Träkemi, Kungliga Tekniska Högskolan and Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

Myo-inositol, glucose, fructose, sucrose, raffinose, stachyose and verbascose have been isolated from birch wood *(Betula verrucosa)*. The presence of two higher oligosaccharides, probably belonging to the same series as verbascose, was also indicated.

During recent years hardwood has attracted considerable interest as pulp wood. In the Scandinavian countries the birches *(Betula verrucosa* and *B. pubescens)* are the only hardwoods sufficiently abundant to be of general importance. A chemical investigation of the constituents in birch wood is therefore warranted and has been started at this institute. The present communication reports studies on the low molecular weight carbohydrates in the wood of birch *(B. verrucosa)*. The two species *(B. verrucosa* and *B. pubescens)* are closely related and major differences in their chemical composition would not be expected.

A tree was felled in January 1958, and a log cut from it was chopped and milled. The product was treated with acetone as rapidly as possible to inactivate the enzyme systems and thereby to minimise post-mortem changes. The milled wood was then treated with various solvents and the extracts dealt with as described in the experimental part. The carbohydrate fraction was subfractionated by chromatography on carbon-Celite columns and the following substances were isolated (they are listed in the order in which they emerged from one of the columns).

	% of dry wood
Myo-inostiol	0.02
Fructose }	0.56
Glucose }	
Sucrose	0.62
Raffinose	0.04
Stachyose	0.03
Verbascose	0.02

The yields reported are approximate and should be regarded as representative only of the tree in question at the time when it was felled.

Glucose and fructose were not isolated but were identified by their paper chromatographic and electrophoretic behaviour. The other sugars, with the exception of verbascose, were isolated in the crystalline states. Verbascose was obtained as an amorphous powder and was chromatographically and electrophoretically indistinguishable from an authentic sample, and had a specific rotation, +146°, which agreed well with the value recorded in the literature [1].

The three highest oligosaccharides all possessed the structure: *O*-α-D-galactopyranosyl-(1→6)-[*O*-α-D-galactopyranosyl-(1→6)-]$_{n-3}$-*O*-α-D-glucopyranosyl-(1→2)-β-D-fructofuranoside. (In verbascose n = 5.) The chemistry of such oligosaccharides has recently been summarized by French [2] and by Wickström [3]. The two next higher members of the series (n = 6 and n = 7) were chromatographically indicated to be present in a fraction eluted from the column after the verbascose.

All of the oligosaccharides possessed a fructofuranosidic linkage, known to be very easily hydrolysed either by enzymes or by acids. Small amounts of melibiose, manninotriose and verbascotetraose were chromatographically indicated to be present and may have arisen from post-mortem reactions. Their presence does not necessarily imply that they were present in significant amounts in the living tree.

In addition to the carbohydrates described above, a fraction containing a mixture of phenolic substances was obtained, and is now under investigation.

EXPERIMENTAL

Paper chromatography was carried out on Whatman No. 1 filter paper using the follwing solvent systems (v/v): A. Ethyl acetate-acetic acid-water (3:1:3, upper layer); B. *n*-Butanol-ethanol-water (10:3:5); C. Ethyl acetate-pyridine-water (2:1:2, upper layer).

The chromatograms were developed with one of the following spray reagents: silver nitrate in acetone and ethanolic sodium hydroxide, or *p*-anisidine hydrochloride in butanol or resorcinol in hydrochloric acid.

Electrophoresis was carried out on Whatman No. 3 MM filter paper in borate buffer solution (pH 10).

A birch, about 40 years old, was felled and from the trunk a log (100 × 20 cm) was sawn, 1 1/2 – 2 1/2 m from the root end. After one day in the cold, the bark of the log was stripped off. The wood was cut into chips, milled and the wood meal (>30 mesh) covered with acetone and kept at 40°. After 20 h the acetone extract was decanted off and taken to dryness. The residue was dissolved in water (200 ml) and extracted with ether (3 × 100 ml) and the ether layer was taken to dryness. The aqueous layer contained a yellow-brown bulky precipitate, which was centrifuged off. The clear solution was decanted and the precipitate in the centrifuge bottle was washed with water. The aqueous solutions were combined and concentrated to a small volume under reduced pressure at 35°. This solution contained compounds with chromatographic characteristics similar to those of phenols. It was subjected to countercurrent extraction between water and ethyl-methyl-ketone. The extraction was performed in 6 steps with a ratio of water to ethyl-methyl-ketone of 1:3 (v/v). The first two aqueous phases (80 ml) contained most of the carbohydrates. After concentration to dryness it yielded a syrup (20 g), which on chromatograms gave no spots on spraying the papers with diazotised sulphanilic acid.

The airdried wood-meal (2 520 g) from the acetone treatment was continuously extracted in a Soxhlet-type apparatus for 3 days with ether and thereafter once again dried in

the air, and the residue extracted in a similar way with methanol for 4 days. The extract was withdrawn and replaced with fresh methanol every day to minimise the hydrolysis of the extracted carbohydrates. The methanolic extracts were combined and taken to dryness under reduced pressure and the residue after dissolution in water (150 ml), was extracted with chloroform (3 × 50 ml). The chloroform solution contained only traces of material and was discarded. The aqueous phase was centrifuged and the then clear solution on concentration gave a yellow syrup (16 g) which was chromatographically free of phenolic compounds.

Separation of carbohydrates on carbon-Celite columns

The carbohydrate fractions from the acetone and the methanolic extracts were combined (36 g) and, after dissolution in water (150 ml) were added to the top of a carbon-Celite (1:1) column (65 × 7.0 cm). The column was irrigated with the following solvents using the gradient-elution technique:

Water		20 l
Aqueous ethanol	1 %	6 l
» »	1→ 8 %	20 l
» »	8→25 %	20 l
» »	25→35 %	12 l

Fractions (225 ml) were collected automatically and examined on paper chromatograms. Those fractions which were similar were combined and taken to dryness.

Fraction No. 1 (270 mg) contained *myo*-inositol, which crystallised when the solvent was removed. By crystallisation from aqueous ethanol pure *myo*-inositol was obtained. It had m. p. and mixed m. p. 230—233°.

Fraction No. 2 (9.21 g) contained most of the glucose and fructose and a small amount of *myo*-inositol.

Fraction No. 3 (3.35 g) contained glucose and fructose only.

Fraction No. 4 (14.1 g) contained sucrose and traces of melibiose. Crystallisations from aqueous ethanol yielded pure sucrose, $[\alpha]_D^{25}$ +66.6° (*c*, 2.0 in water) and m. p. and mixed m. p. 191—192°.

Fraction No. 5 (187 mg) contained sucrose, raffinose and traces of manninotriose.

Fraction No. 6 (1.43 g) contained raffinose, stachyose and traces of sucrose. This fraction was sub-fractionated on a smaller carbon-Celite (2:1) column (40 × 3.8 cm). The syrup was dissolved in water (50 ml) and added to the top of the column. The column was irrigated with aqueous ethanol the concentration of which was linearly increased from 7 to 15 % (6 l). Fractions (50 ml) were collected and treated as above. Two compounds, later identified as raffinose and stachyose, were obtained in the crystalline state. The former (320 mg) crystallised as the pentahydrate from aqueous ethanol and had $[\alpha]_D^{25}$ +104° (*c*, 1.8 in water). On heating it lost its crystalline properties at 75.5—80°, due to dehydration. The shape of the material was unaffected but examination in polarised light revealed that the material was no longer crystalline; the solid residue collapsed at *ca.* 135°. Authentic raffinose pentahydrate behaved in the same way and no depression was observed on admixture of the two samples. A saturated solution of the other major component in aqueous ethanol on nucleation with crystalline stachyose deposited crystals (240 mg) having $[\alpha]_D^{27}$ +132° (*c*, 1.9 in water) and m. p. and mixed m. p. 153—158°.

Fraction No. 7 (758 mg) contained verbascose, stachyose and raffinose.

Fraction No. 8 (880 mg) contained mainly verbascose and stachyose. This fraction was sub-fractionated on a small carbon-Celite (1:1) column (22 × 3.2 cm). The column was irrigated with aqueous ethanol (9→15 %; 4 l) and fractions (25 ml) were collected and treated as previously described. In this way a compound (217 mg) was obtained which was chromatographically and electrophoretically indistinguishable from verbascose. It was a white, anhydrous, powder which had $[\alpha]_D^{25}$ +146° (*c*, 2.1 in water). The product

was at first believed to be crystalline, but an investigation under the polarizing microscope revealed it to be amorphous. The substance has previously been obtained as a crystalline pentahydrate [1].

This separation also yielded chromatographically pure verbascotetraose (314 mg) which may possibly have been formed from verbascose by hydrolysis by traces of acid on the column. The substance failed to crystallise and was precipitated from an aqueous solution with absolute ethanol. It yielded a white amorphous powder which had $[\alpha]_D^{25}$ +161° (c, 2.0 in water).

Fraction No. 9 (160 mg) contained verbascose and traces of two compounds with lower R_F-values which gave the same colour reactions as did verbascose.

The authors are indebted to Docent A. Wickström, Farmasøytisk Institutt, Oslo, for gifts of authentic stachyose and verbascose.

The Ionization Constant, Solubility Product and Solubility of Abietic and Dehydroabietic Acid

VERA NYRÉN and ERNST BACK

Paper Technology Department, Swedish Forest Products Research Laboratory, Stockholm Ö, Sweden

The ionization constant (K_S), solubility product (K_L) and solubility in water of abietic and dehydroabietic acid at 20°C have been determined simultaneously from potentiometric titrations of their aqueous salt solutions within soap concentrations ranging from below the concentration of limited ion association to above the critical concentration for micelle formation resulting in:

For abietic acid: $pK_S = 6.4$; $pK_L = 11.3$ and L, the solubility of unionized acid: $= 1.2 \times 10^{-5}$ mole/litre.

For dehydroabietic acid: $pK_S = 5.7$; $pK_L = 10.5$ and $L = 1.62 \times 10^{-5}$ mole/litre. Total solubilities at 20°C are presented as a function of pH.

True ionization constants can be determined only below the concentration of limited ion association. This concentration of limited ion association for these acids was estimated from the ionization data.

As our measurements on lauric and myristic acid [1] and those of Ekwall [2] on bile acids have shown that a true ionization constant has to be determined below the limited concentration of ion association, it was decided to reinvestigate data of Back and Steenberg [3] on the electrolytic constants of abietic acid. Dehydroabietic acid was then included in this investigation as it has been indicated that this acid is significantly stronger and more water soluble [4,5].

The method of Back and Steenberg for simultaneous evaluation of the ionization constant, the solubility product and the solubility of the unionized protolyte from single potentiometric titrations has been employed.

EXPERIMENTAL

High purity abietic acid ($[\alpha]_D^{20} = -105.5°$) was prepared by recrystallization as butylamine abietate as described earlier [3]. Dehydroabietic acid of at least 98 % purity ($[\alpha]_D^{20} = 63.0°$) was kindly provided by Hercules Powder Co. The experiments were carried out using the equipment and experimental technique described in the paper on lauric and myristic acid [1], which may be referred to for details. In order to obtain a rapid dissolution of resin acid crystals, sodium resinate solutions for potentiometric titrations had to be prepared with a sodium hydroxide excess of about 10 %.

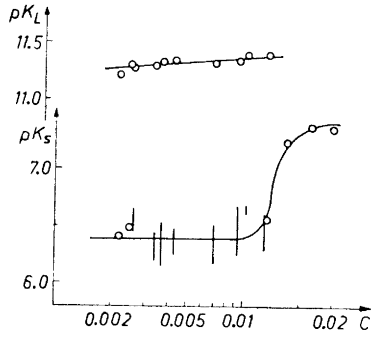

Fig. 1. pK_s and pK_L of abietic acid at 20°C as a function of the total resinate and resin acid concentration, C, in mole/litre at the neutralization point.

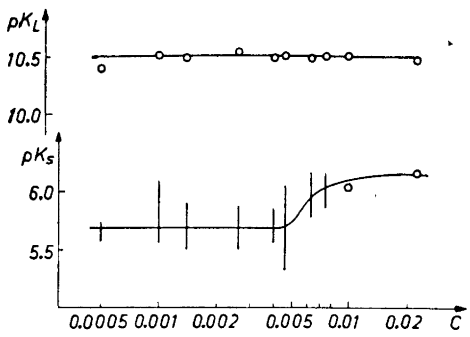

Fig. 2. pK_s and pK_L of dehydroabietic acid at 20°C as a function of the total resinate and resin acid concentration, C, in mole/litre at the neutralization point.

RESULTS

The ionization constant, K_s, the solubility product, K_L, and the solubility of unionized acid, L, were all calculated from single potentiometric titrations and corrected for activity coefficients as earlier described [1,3]. If, due to formation of micelles or associated ions, the presumptions made in these calculations are not valid, the constants calculated naturally represent pseudo-constants only, probably of little interest.

Ionization constants

The ionization constants of abietic and dehydroabietic acid, calculated from the measurements performed, are presented as pK_s values in the lower part of Figs. 1 and 2 as a function of the total resinate and resin acid concentration at the neutralization point. Where necessary, the range of pK_s values within each single titration is indicated by a line.

In agreement with the results obtained for fatty acids [1] and bile acids [2] the data for abietic acid and dehydroabietic acid show true concentration independent ionization constants to be obtained at low resinate concentrations only. The mean values, given together with their 90 % confidence limits, are at 20°C

for abietic acid: $pK_s = 6.4 \pm 0.1$ (6.39 ± 0.08)

$$K_s = 4.1 \times 10^{-7} \text{ mole/litre } (3.4 \times 10^{-7} \text{ to } 4.9 \times 10^{-7})$$

for dehydroabietic acid: $pK_s = 5.7 \pm 0.1$ (5.71 ± 0.05)

$$K_s = 2.0 \times 10^{-6} \text{ mole/litre } (1.7 \times 10^{-6} \text{ to } 2.2 \times 10^{-6})$$

Bruun [5] from monolayer measurements obtained a pK_s value for dehydroabietic acid of 5.84 in good agreement with these direct measurements.

At higher resinate concentrations a pseudo-ionization constant is obtained because of ion association and following micelle formation, not accountable for in evaluating the primary data [1]. Thus, as is seen from Figs 1 and 2 the apparent pK_s value is increasing within a certain concentration range, dominated by limited ion association. Unfortunately the measurements of Back and Steenberg [3] on the ionization constant of abietic acid were carried out within this intermediate concentration range, not accounting for the then little known occurrence of ion association below the critical concentration for micelle formation.

As was also shown for fatty acids [1] and bile acids [2], the pseudo-constant levels off to a constant value, after ion association has reached the stage of micelle formation. Thus, the data of Figs. 1 and 2 permit an estimation of the concentration at which limited ion association becomes obvious, namely

for the abietate anion	10^{-2} mole/litre
for the dehydroabietate anion	6×10^{-3} »

Solubility

The solubility products obtained for abietic and dehydroabietic acid are plotted in the upper part of Figs. 1 and 2 as pK_L values against the total resinate and resin acid concentration at the neutralization point. In both cases the pK_L value obtained can be regarded as independent of concentration (although for abietic acid a very slight change of pK_L with concentration shows up). Also, as pointed out for fatty acids, constant pK_L values occurred, once the acid had coagulated within the system. The following mean solubility products with their 90 % confidence ranges are obtained

for abietic acid	11.31 ± 0.03
for dehydroabietic acid	10.50 ± 0.03

Back and Steenberg earlier obtained within a limited concentration range the pK_L value of 11.4, in reasonable agreement with these data.

The solubility of unionized acids, L, obtained as the quotient of the solubility product and corresponding ionization constant [1,3], given with its 90 % confidence limits, is at 20°C

for abietic acid	1.2×10^{-5} mole/litre	($0{,}9 \times 10^{-5}$ to 1.6×10^{-5})
	3.6 mg/litre	(3 to 5 mg/litre)
for dehydroabietic acid	1.6×10^{-5} mole/litre	(1.4×10^{-5} to 2.0×10^{-5})
	4.9 mg/litre	(4 to 6 mg/litre)

The total solubility, i.e. the sum of the solubilities of ionized and unionized acid at 20°C, determined by L and K_L, respectively, is presented in Fig. 3 as a function of pH. At the equivalence point defined by $a_{H_3O^+} = a_{A^-}$, *i.e.* in a saturated water solution, the mean total solubilities are at 20°C

for abietic acid	1.4×10^{-5} mole/litre = 4.3 mg/litre
for dehydroabietic acid	2.2×10^{-5} mole/litre = 6.6 mg/litre

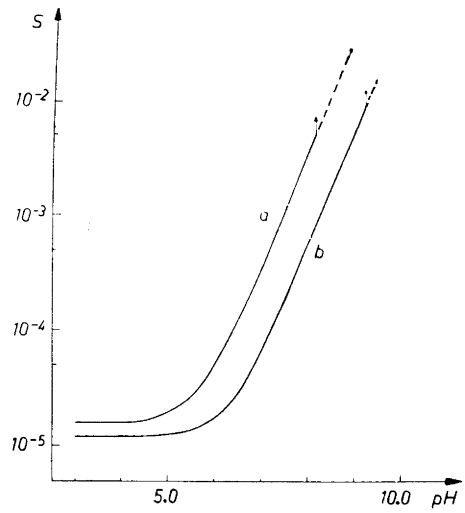

Fig. 3. Total solubility, S, in mole/litre as a function of pH for a) abietic acid b) dehydroabietic acid.

Obviously there is a significant difference in the total solubility of abietic and dehydroabietic acid, which has already found technical applications in the separation of resin acids by fractional acidification [4]. Solubility data, as here presented, make possible more detailed calculations on the efficiency of such a separation.

The solubility curves of Fig. 3 are valid only until the concentration of limited ion association has been reached. Thereafter, the true total solubility might exceed the one to be calculated. In Fig. 3 the corresponding point in the curve is indicated by an arrow. In the following part of the curves calculated dashed lines have been employed to indicate a minimum solubility. The curves are discontinued at a pH-value, where for available anions the critical concentration of micelle formation has been reached. Above this concentration, due to formation of mixed resin acid — resinate ion micelles, a rather rapid increase in total resin acid solubility will occur.

It might be pointed out that in mixtures of several resin acids or of resin and fatty acids the apparent solubility effects mentioned above will all occur at still lower single resinate anion concentrations because of the formation of mixed resinate and soap anion micelles [6], and of mixed associated ions.

Abietic acid *versus* dehydroabietic acid

The differences in solubility between abietic and dehydroabietic acid are in the direction expected. Dehydroabietic acid containing an aromatic ring is more hydrophilic and more water soluble than abietic acid containing a conjugated double bond only. The significant increase in ionization constant

occurring on aromatization of this B-ring (containing the *iso*propylgroup) might be due to steric effects.

Differences obviously also occur in ion association and micelle formation. The ratio of the true ionization constant to the pseudo-constant after micelle formation is considerably larger for abietic acid than for dehydroabietic acid, while limited ion association occurs within a more narrow concentration range. Such differences in micelle formation have also been indicated in the work of Corrin, Klevens and Harkins [7].

Acknowledgement. We are indebted to Hercules Powder Company, Research Dept., for providing a sample of dehydroabietic acid and to *Stiftelsen Pappersbrukens Forsknings-institut (The Research Foundation of the Swedish Paper Mills)* for financial support.

Elution of Alkaloids from Cation Exchangers

A. BERGGREN, C. O. BJÖRLING and B. WILLMAN-JOHNSON

Research Laboratories of Pharmacia Ltd., Uppsala, Sweden

Elution of tertiary and quaternary amines of a high molecular weight from a strong cation exchanger can be performed with 1 N hydrochloric acid if a resin with a very low degree of crosslinking is used. Usually alcohol will considerably improve the elution rate and for some compounds is in fact necessary.

Organic cations of high molecular weight, *e.g.* alkaloidal ions, can usually be adsorbed on strong cation exchange resins. However, once the amines are adsorbed they are often difficult to elute. Bregman [1] states that molecular adsorption is negligible for all univalent organic cations for Dowex 50, all active sites of the exchanger thus being available.

For organic bases the situation is more complicated. Some authors have been able to elute tertiary alkaloidal ions with alcoholic ammonia and Büchi and Furrer [2] also tried aqueous 10 % hydrochloric acid for the elution of quinine but very large eluates were necessary. The difficulties of the elution can be avoided by using an inorganic ion exchanger, *e.g.* Decalso, as suggested by the present authors [3]. Although this method gives good results it is somewhat inconvenient because of the low capacity.

When working on resins with cations of high molecular weight the importance of the degree of crosslinking has been emphasized by Moore and Stein [4], Davey [5], Balenović and Štefanac [6], Jacobs, Work and Kressman [7], Büchi and Furrer [2], van Etten [8], Kunin and Myers [9], Sjöström and Nykänen [10] and Hale, Packham and Pepper [11]. Briefly it may be stated that with a low degree of crosslinking the resin swells to a higher extent and becomes more porous. This causes the resin to take up and give off big ions more easily.

Most experiments performed on ions of moderate size have been restricted to aqueous solutions but with bigger ions it would seem necessary to modify the solvent. Bodamer and Kunin [12] have shown that ion-exchange in non-aqueous media is possible although the rate of the exchange is lower than in water. The main condition is that the resin swells to such an extent that the pores can hold the ions. Gemant [13] investigated ion exchange in hydrocarbons and Drèze and Reith [14] used 20 % alcohol as a solvent. Rückert and Samuelson [15] studied the influence of alcohol on the shrinkage and showed that more glucose is adsorbed from alcohol than from water. Sjöström and Nykänen [10] used alcoholic media at the elution from anion exchangers.

[2] the elution was performed with 1 N sulphuric acid in 10 ml eluate

[3] the elution was performed with 2 N hydrochloric acid

Previously we [16] have found that both tertiary and quaternary amines can easily be eluted with acids if *i.* the degree of crosslinking of the resin is low, *ii.* the solvent contains ethanol, methanol, or acetone in varying amounts.

It was found that 5—50 μ equiv. of the compounds investigated were quantitatively retained by Dowex 50 X1 in a column 20—30 × 4 mm and could not be eluted by the usual solvents. In Table 1 the elution of different substances has been made with 1 N hydrochloric acid in water or alcohol of different strengths. Although some compounds may be eluted with aqueous acid this medium is without effect for papaverine ethyltosylate, benzethonium chloride and DMABF [9-(4-dimethylamino-benzylidene)-fluorene ethyltosylate]. If the acid is made alcoholic its elution capacity is increased. 50—70 % of alcohol seems to be sufficient and generally 15—20 ml eluates gave quantitative recoveries. By taking small eluates of 5 ml this phenomenon can be demonstrated and some typical curves are shown in Fig. 1 and 2. The effect of alcohol is not correlated to the molecular weight of the substance. It is interesting to note that DMABF which is soluble in hot water cannot be eluted by aqueous hydrochloric acid even at 80°.

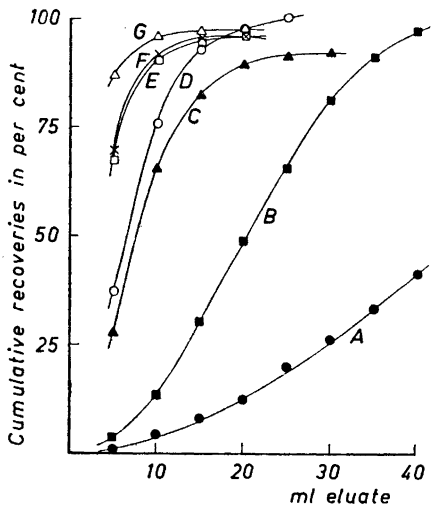

Fig. 1. Elution at different alcohol strengths with 1 N hydrochloric acid.

A Quinine ethiodide in water
B Strychnine ethiodide in water
C DMABF in 50 % alcohol
D Quinine ethiodide in 70 % alcohol
E DMABF in 70 % alcohol
F DMABF in 90 % alcohol

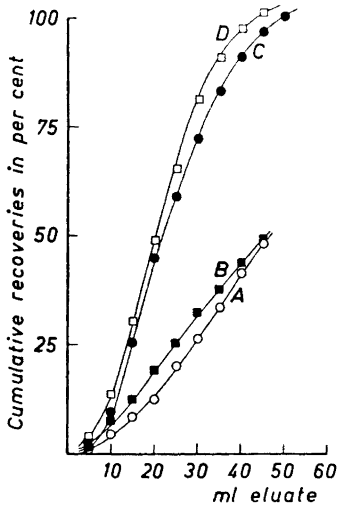

Fig. 2. Elution of tertiary amines and their corresponding quaternary compounds with 1 N hydrochloric acid in water.

A Quinine ethiodide
B Quinine sulphate
C Strychnine nitrate
D Strychnine ethiodide

From Fig. 2 may be seen that there is hardly any difference between the tertiary alkaloid and the corresponding quaternary compound in the two cases investigated. The elution curves were obtained with aqueous 1 N hydrochloric acid as alcoholic acids eluted both types of compounds too rapidly to obtain any reliable values.

In Table 2 perchloric acid solutions of different concentrations and of various alcoholic strengths have been tested for their elution capacity towards DMABF. If the acid concentration is higher than 0.5 N and the alcohol strength more than 50 % the elution is quantitative with 25 ml. Other experiments have shown that hydrochloric acid is somewhat inferior to perchloric acid and that sulphuric acid has a markedly lower elution power. As alcoholic solutions of perchloric acid are disagreable we have chosen 1 N hydrochloric acid as the general elutriant.

Substitution of ethanol for methanol or acetone gave for DMABF the same result. Thus, elution with 1 N hydrochloric acid in 70 % methanol gave 100.6 % recovery in 25 ml eluate and in 70 % acetone 100.3 % recovery.

For a few compounds alcoholic potassium hydroxide is a good elutriant. Thus 0.5 N potassium hydroxide in 90 and 50 % alcohol, respectively, gave quantitative recoveries of papaverine ethyltosylate in 25 ml eluate. On the other hand 1.0 and 0.5 N potassium hydroxide in 70 % alcohol gave only about 70 % recoveries in 25 ml eluate. As many compounds are unstable in alkaline medium and as column blanks are liable to become high these media were not further investigated.

Some experiments have been made with alcoholic solutions of sodium bromide, calcium chloride, barium bromide, and aluminium chloride. In 0.5 M solutions in 50—70 % alcohol the salts will elute DMABF but the elution is rather slow and seems generally to be inferior to that of hydrochloric acid.

In order to investigate the effect of crosslinking, cation exchangers from the same manufacturer with varying degrees of crosslinking were used in the same manner as before. Table 3 shows the results obtained on three different compounds. Of these molecules the ethyl quinolinium bromide is comparati-

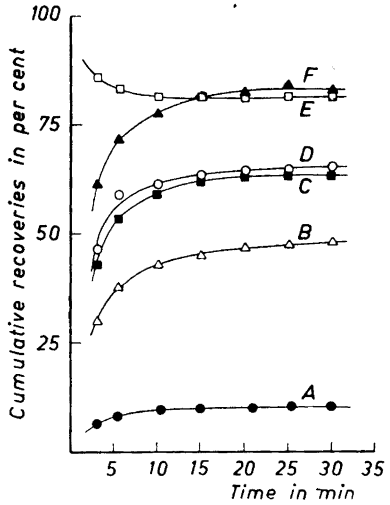

Fig. 3. Equilibrium between DMABF and Dowex 50 X1 at varying concentrations of alcohol and hydrochloric acid.

F 0.1 N hydrochloric acid in 70 % alcohol

ABCD and F: Dowex 50 X1 with DMABF adsorbed was shaken with the corresponding acid.
E: Dowex 50 X1 was shaken with DMABF dissolved in the corresponding acid.

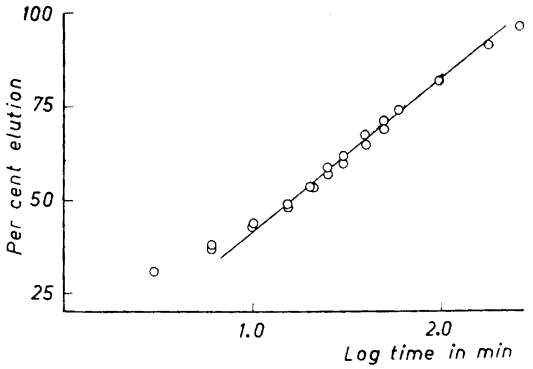

Fig. 4. Equilibrium between DMABF and Dowex 50 X1 with 0.5 M sodium bromide in 70 % alcohol.

vely small, the benzethonium chloride contains a fairly long chain, and the DMABF is rather large. The long-chained benzethonium ion could not be completely adsorbed on ion exchangers with more than 4 % crosslinking. On the ion exchangers X12 and X16 the adsorption from water was very small. Further, there is a tendency towards a slower elution of the amount adsorbed on the more crosslinked resins. For all crosslinkings tried both the small ethyl quinolinium ion and the large DMABF ion are completely adsorbed. The elution rate is, however, greatly decreased if the crosslinking is increased. Further, the large DMABF ion is more strongly retained than the smaller ethyl quinolinium ion. It is interesting to note that the elution rate of DMABF has a pronounced minimum at X8 where the rate is only about 40 % of that of X1 and 60 % of that of X12 and X16.

In Fig. 3 the influence of the concentrations of alcohol and acid is clearly demonstrated from experiments on the equilibrium between DMABF and Dowex 50 X1. The equilibrium is rapidly attained with alcoholic hydrochloric acid. Therefore, the column experiments were most likely performed under equilibrium conditions. With 0.1 N hydrochloric acid in 70 % alcohol the equilibrium was reached from both sides, thus showing that it is a true one. With 0.5 M sodium bromide in 70 % alcohol the process is much slower and here it is possible to apply Langmuir's adsorption isotherm. This is shown in Fig. 4, where the desorption is directly proportional to the logarithm of the time.

EXPERIMENTAL

Column experiments

The ion exchangers (200—400 mesh) used were washed with ammonium citrate solution to remove traces of heavy metals and were then alternately treated several times with aqueous and alcoholic solutions of sodium hydroxide and hydrochloric acid. By this treatment the blanks became negligible.

Unless otherwise stated Dowex 50 X1 in the hydrogen form was used. The columns were 20—30 × 4 mm and could adsorb 15 to 20 mg of substance. When working with resins with a low degree of crosslinking the swelling and shrinking are often cumbersome but with the method used in this work no troubles were encountered. When changing solvents in the columns bubbles are easily formed. They can be avoided by using freshly boiled solvents. The flow rate was kept at about 1 ml/min.

The reagents were of analytical grade and the compounds investigated were of the highest quality available and recrystallized from alcohol and water. Most of the quaternary compounds were synthetized by standard methods and recrystallized from alcohol and water. The equivalent weights and elementary analyses were in good agreement with theory.

For most of the substances a standard curve was drawn at the maximum characteristic for the compound in question in the ultraviolet region and the concentrations of the solutions assayed with its aid. The solvent was usually water or alcohol-water. If acetone was used at the elution it had to be evaporated and the residue dissolved in the appropriate solvent for the final assay. Benzethonium chloride was titrated according to Carkhuff and Boyd [17] and hyoscine methylnitrate was determined either according to Berggren and Nordberg [18] or colorimetrically using bromothymol blue [19].

Procedure 1 to 2 mg of the substance to be investigated — of benzethonium chloride, however, 10 mg and of hyoscine methylnitrate 10—15 mg — dissolved in 10 ml of water or alcohol-water was allowed to flow through the column which was then washed three times with 5 ml of the solvent. The liquids were collected and assayed. The substances on the column were eluted with different solutions, the eluates diluted to the appropriate volume, and assayed. Blanks were always run but their values were usually negligible.

Equilibrium experiments

50 ml of Dowex 50 X1 was mecanically stirred in 400 ml of 50 % alcohol and from a burette a solution of 207.4 mg DMABF in 100 ml of 50 % alcohol was slowly added during 2 h. The resin was transferred to a column and thoroughly washed with 50 % alcohol and finally dried at 50° over night. The resin so prepared contained 4.9 % of moisture determined by the Karl Fischer method.

The resin was assayed by elution with 1 N perchloric acid in 70 % alcohol. Three determinations gave 53.6, 53.1, and 53.9 mg of DMABF per g of resin.

Prior to all experiments an accurately weighed amount, about 50 mg, of the resin was allowed to swell over night in 10.00 ml of water. The rest of the elutriant, about 90.00 g, was added and the mixture shaken. At known intervals 5.00 ml was withdrawn in such a manner that no resin was removed and assayed spectrophotometrically. No special attempts were made to keep the temperature constant.

Short Communications

Hydantoins from Chalcone Oxides

CARL ENEBÄCK

Department of Chemistry, Institute of Technology, Helsingfors, Finland

5-Phenyl-5-benzylhydantoin has been obtained in fair yield by boiling chalcone oxide with ethanolic potassium hydroxide in the presence of urea. This reaction involves a rearrangement of the carbon skeleton of the initial molecule. A range of substituted chalcone oxides has been subjected to the same treatment, and the isolated, weakly acidic reaction products are characterized, by analogy, as the corresponding hydantoins.

It is known that chalcone oxides under similar conditions but without urea yield phenylbenzylglycolic acids, a reaction proceeding *via* the isomeric α-diketone which then undergoes a rearrangement of the benzilic acid type [1]. Recently, Dunnavant and James [2] have presented convincing evidence in favour of a reaction mechanism of the benzilic acid rearrangement type in the well-known formation [3] of 5,5-diphenylhydantoin from benzil with alkali and urea, as well. In conformity with this view *o*-methoxyl groups in the aroyl nucleus of the chalcone oxide should hinder the genesis of a hydantoin about as strongly as they, in the absence of urea, hinder the formation of an α-hydroxy acid through a rearrangement of the benzilic acid type. This seems to be the case judging from the relevant yields of the present work.

Experimental. (All analyses are microanalyses, performed by Dr. A. Bernhardt, Mühlheim, Germany).

3,4-Dimethoxychalcone oxide. To 3,4-dimethoxychalcone (2.68 g) in methanol (25 ml) were added hydrogen peroxide (15 %, 4 ml) and 2 N sodium hydroxide (2.5 ml). The mixture was stirred for 3 h and then cooled in a refrigerator. The crystals separated by filtration were recrystallised from methanol and from chloroform-light petroleum. Yield 2.3 g (81 %), m.p. 89—90°. (Found: C 72.34; H 5.49; $C_{17}H_{16}O_4$ requires C 71.82; H 5.67).

3,3',4,4'-Tetranethoxychalcone oxide. Finely powdered 3,3',4,4'-tetramethoxychalcone, (3.28 g, m.p. 111°), was stirred for 6 h together with a solution of hydrogen peroxide (15 %, 5 ml) and 6 N potassium hydroxide (0.83 ml) in methanol (30 ml). Dissolution came about only partly. Filtration of the reacted mixture gave an almost white powder which was recrystallised from methanol and from chloroform-light petroleum to give 2.75 g (80 %) of the epoxide, m.p. 150—151°. (Found: C 66.44; H 5.91; $C_{19}H_{20}O_6$ requires C 66.27; H 5.85).

5-Phenyl-5-benzylhydantoin. The solution of chalcone oxide (2.24 g, 0.01 mole) in ethanol (20 ml) was kept boiling under reflux. In one operation was added a hot solution of potassium hydroxide (1.23 g, 0.022 mole) and urea (1.32 g, 0.022 mole) in ethanol (20 ml). The refluxing was continued for 2 h and the reaction mixture was then poured into water (400 ml). A tiny precipitate was removed and after that the water solution was saturated with carbon dioxide. The obtained precipitate was collected and recrystallised from dilute ethanol. Yield 2.0 g (75 %), m.p. 210°. Mixing with 5-phenyl-5-benzylhydantoin [4], m.p. 210°, obtained [5] by treating desoxybenzoin with potassium cyanide and ammonium carbonate in dilute ethanol at 60°, did not depress the m.p.

In the same way were obtained:

5-Phenyl-5-(4-methoxybenzyl)-hydantoin, yield 2.55 g (86 %), m.p. 206—208°, (Found: C 68.95; H 5.86; N 9.48; $C_{17}H_{16}O_3N_2$ requires C 68.90; H 5.44; N 9.45) from 4-methoxychalcone oxide (2.54 g), and

5-Phenyl-5-(3,4-dimethoxybenzyl)-hydantoin, yield 2.85 g (87 %), m.p. 211—212°, (Found: C 65.61; H 5.44; N 8.66; $C_{18}H_{18}O_4N_2$ requires C 66.24; H 5.56; N 8.66) from 3,4-dimethoxychalcone oxide (2.84 g).

5-(3,4-Dimethoxyphenyl) -5- (3,4-dimethoxybenzyl)-hydantoin, yield 2.8 g (72 %), m.p. 212—213°, (Found- C 62.05; H 5.84; N 7.48;

$C_{20}H_{22}O_6N_2$ requires C 62.16; H 5.74; N 7.25) was obtained from 3,3',4,4'-tetramethoxychalcone oxide (3.44 g) in the same way with the exception that the main part of the epoxide remained undissolved in the initial boiling ethanolic mixture.

5-Phenyl-5-(1-phenylethyl)-hydantoin. The boiling solution of 2.38 g of dypnone oxide [6], (the crude epoxide containing both of the isomers may be used), in ethanol (20 ml) was treated with ethanolic potassium hydroxide and urea as above. The precipitation of a voluminous potassium salt followed close on the addition of the reagents. After refluxing the mixture for 2 h the precipitate was separated by filtration and washed with a small amount of ethanol. It was then dissolved in water (200 ml) by heating and adding a little sodium hydroxide. The solution thus obtained was saturated with carbon dioxide and the precipitated mass collected and recrystallised from ethanol. Yield 1.0 g (36 %), m.p. 305—307°. (Found: C 72.82; H 5.82; N 10.07; $C_{17}H_{16}O_2N_2$ requires C 72.84; H 5.75; N 9.99). The filtrate from the insoluble potassium salt was poured into water (400 ml). The solution was clarified by filtration and was then saturated with carbon dioxide. The obtained precipitate was collected and recrystallised from ethanol. Yield 1.1 g (39 %) of m.p. 265—266°, (Found: C 72.69; H 5.80; N 10.05; $C_{17}H_{16}O_2N_2$ requires C 72.84; H 5.75; N 9.99). The two products of this preparation are presumably the diastereoisomers of 5-phenyl-5-(1-phenylethyl)-hydantoin.

5-(2-Methoxyphenyl)-5-benzylhydantoin. 2'-Methoxychalcone oxide [7] (2.54 g) was treated with ethanolic potassium hydroxide and urea analogously with the model preparation above. After pouring the reaction mixture in water, the solution, however, was extracted with ether instead of being filtered, by reason of the stickiness of the cloudy precipitate. Saturation of the water phase, from which all the ether had been removed, with carbon dioxide, and repeated recrystallisation of the obtained precipitate from dilute ethanol gave 0.3 g (10 %) of m.p. 224°, (Found: C 69.11; H 5.87; N 9.44; $C_{17}H_{16}O_3N_2$ requires C 68.90; H 5.44; N 9.45).

Benzyl-(2-methoxyphenyl)-glycolic acid. The above procedure was repeated but without urea. The filtrate after precipitating α-hydroxy-2'-methoxychalcone with carbon dioxide was acidified with dilute sulphuric acid and the obtained precipitate recrystallised from dilute ethanol, yielding 0.35 g (13 %) of m.p. 183—184°, (Found: C 70.44; H 5.84; $C_{16}H_{16}O_4$ requires C 70.57; H 5.92).

α-Hydroxy-2',4',6'-trimethoxychalcone[7] but no hydantoin or hydroxy acid was obtained when 2',4',6'-trimethoxychalcone oxide was subjected to the described treatment with or without urea.

Work is in progress to find out suitable conditions for hydrolysis of the present hydantoins.

A Contribution to the Principles of Electrodiffusion

STIG LJUNGGREN

The Royal Institute of Technology, Division of Physical Chemistry, Stockholm, Sweden

Electrodiffusion was suggested by Mysels [1] and Lamm [2] as a method for studying the equilibrium kinetics of certain reactions involving ions. The term refers to the increased diffusion which occurs on the superposition of an electric field in the diffusion direction. The magnitude of this effect is related to the field characteristics and to the kinetics of the system studied. More recently, Giddings [3-5] and Bak and Kauman [6] have contributed to the theory of electrodiffusion.

The theory of Mysels and that of Bak and Kauman refer (although this is not explicitely stated) to the case of selfdiffusion or to the case where a large excess of an electrolyte, which does not partake in the kinetic equilibrium, is added in order to maintain a constant field throughout the diffusion column. In this case the

$C_{20}H_{22}O_6N_2$ requires C 62.16; H 5.74; N 7.25) was obtained from 3,3',4,4'-tetramethoxychalcone oxide (3.44 g) in the same way with the exception that the main part of the epoxide remained undissolved in the initial boiling ethanolic mixture.

A Contribution to the Principles of Electrodiffusion

STIG LJUNGGREN

The Royal Institute of Technology, Division of Physical Chemistry, Stockholm, Sweden

Electrodiffusion was suggested by Mysels [1] and Lamm [2] as a method for studying the equilibrium kinetics of certain reactions involving ions. The term refers to the increased diffusion which occurs on the superposition of an electric field in the diffusion direction. The magnitude of this effect is related to the field characteristics and to the kinetics of the system studied. More recently, Giddings [3-5] and Bak and Kauman [6] have contributed to the theory of electrodiffusion.

The theory of Mysels and that of Bak and Kauman refer (although this is not explicitely stated) to the case of selfdiffusion or to the case where a large excess of an electrolyte, which does not partake in the kinetic equilibrium, is added in order to maintain a constant field throughout the diffusion column. In this case the

Joule heat evolved in the cell may render experiments difficult because of the convection danger. It was evidently this fact which led Lamm [2] to study the possibility of obtaining an electrodiffusion effect of a mutual type with the system

$$\begin{array}{ccccc} AB & \rightleftharpoons & A^+ & + & B^- \\ C(1-a) & & Ca & & Ca \end{array}$$

The theory overlooks, however, the fact that, due to the lack of divergence of the electric current, such an effect will not be obtained in a system that contains only those components which are involved in the dynamic equilibrium. In such a case each ion will migrate with a velocity proportional to its mobility and carry a constant proportion (equal to the transfer number) of the electric current. The latter being constant *, the velocities and also the step-lengths of the ions will be inversely proportional to the ionic concentration, C.

Now, ordinary (mutual) diffusion is the result of an assymmetrical initial condition and a random walk which attempts to smooth out the initial condition. It can, however, be shown that in the case mentioned the variation of the step-lengths has the effect of compensating the skewness of the initial condition. This is most easily realized in the case where a is small. In this case the migration rates are proportional to $1/Ca$. But the "lifetime" of the ions, $T^{\pm}$, is also proportional to $1/Ca$. Hence, the step-lengths are proportional to $1/(Ca)^2$:

$$l \sim 1/C^2a^2$$

Now, according to the law of mass action,

$$Ca^2(1-a) = K$$

so that for small a

$$l \sim 1/C^2a^2 \approx 1/KC$$

i. e. the step-lengths are inversely proportional to the total concentration. In cases where the migration rates of the positive and negative ions are equal, we obtain a simple visualization of electrodiffusion by regarding AB as concentrated in thin layers at a mutual distance equal to the step-length. Each layer will then contain an equal quantity of AB. This is essential, since we may now regard electrodiffusion simply as a random walk of ions, A^+ or B^-, from layer to layer. Hence the ions will change places with one-another giving rise to self-diffusion but not to "ordinary" diffusion, the number of ions and molecules in the layers being unaffected by the random walk. If a is not small, the simple visualization breaks down and the argument becomes more complicated, but the final conclusion still holds.

It should perhaps be stressed that the lack of divergence which is responsible for the difficulties mentioned is a characteristic property of the electric current. In the chromatographic dispersion case treated by Giddings [4] we do not have this difficulty, which can be eliminated by the addition of KCl or some other electrolyte as will be more closely outlined below.

The formulae derived by Lamm [2] for the electrodiffusion coefficient of the positive and negative ions respectively, *i.e.* D^+ and D^-, are good approximations to the truth if the relative concentration change in the cell is small (differential diffusion). However, as already mentioned, the small variation of D^+ and D^- is sufficient to prevent any mutual diffusion from taking place. Since we thus have a case of pure self-diffusion it is obviously without meaning to speak of the diffusion of AB as a whole. Now, by adding a second electrolyte component, it is indeed possible to obtain a sort of mutual type diffusion in which, however, the presence of the additional electrolyte allows A^+ and B^- to diffuse more or less independently of one another.

Generally it will be necessary to use two components also from other reasons, *e. g.* to provide a suitable pH. If the quantity of the second electrolyte component is not too large the Joule heat evolved can be maintained within reasonable limits. It seems possible, in this way, to effect Lamm's original idea of a mutual type electrodiffusion. Another way is, of course, to measure the selfdiffusion of A^+ or B^- in the presence of a mutual gradient between AB and the medium.

Equations valid also for systems of this kind are given below (*cf.* Ref. [6]).

Symbols

a = degree of dissociation.
n = total number of species.
c_j = concentration of the species j in electrochemical equivalents per ml with the sign of the charge included.

* *i. e.* constant with respect to x but not with respect to t.

(If the species is uncharged the sign may be chosen at will).
u_j = ionic mobility of j with the sign of the ionic charge included.
D_j = individual diffusion coefficient of j.
$\varkappa$ = specific conductivity (a function of time and position).
t = time.
t_j = transfer number of j.
x = height coordinate in diffusion cell.
$\mathbf{i}$ = current density (vector). ($\mathbf{i} = \mathbf{i}(t)$).
i = current density in one-dimensional case. ($i = i(t)$).
$\mathbf{X}$ = strength of superposed electric field (vector).
F = Faraday's constant.
$\mathbf{v}_j$ = velocity of the ion j (vector).
$\mathbf{J}_j$ = (electrophoretical) flow of the ionic species j (vector).
J_j = flow of j in one-dimensional case.
Q_j = net reaction rate.

Equations

The current density equals the product of the conductivity and the field strength:

$$\mathbf{i} = \varkappa \mathbf{X} \tag{1}$$

The condition of electroneutrality reads

$$\sum_m c_m = 0 \tag{2}$$

where m denotes summation over ionic species only.
For the conductivity we have

$$\varkappa = F \sum_m c_m u_m \tag{3}$$

The ionic velocity equals the product of the mobility and the field strength

$$\mathbf{v}_j = u_j \mathbf{X} = u_j \mathbf{i}/\varkappa \tag{4}$$

Hence we have for the electrophoretical flow

$$\mathbf{J}_j = c_j \mathbf{v}_j = c_j u_j \mathbf{X} = c_j u_j \mathbf{i}/\varkappa = \frac{\mathbf{i}}{F} \frac{c_j u_j}{\sum_m c_m u_m} \tag{5}$$

Leaving out the terms relating to ordinary diffusion we have

$$(\partial c_j/\partial t) = -\operatorname{div} \mathbf{J}_j + Q_j(c_1, c_2, \cdots, c_n) \tag{6}$$

where Q_j represents the purely chemical rate law, *e. g.*

$$Q_j = \sum_p k_{jp}\, c_1^{r_{1p}} c_2^{r_{2p}} \cdots c_n^{r_{np}}$$

In the one-dimensional case we have

$$J_j = i c_j u_j / F \sum_m c_m u_m \tag{7}$$

and

$$\frac{\partial c_j}{\partial t} = Q_j(c_1, \cdots, c_n) - \frac{i}{F} \frac{\partial}{\partial x} \left(\frac{c_j u_j}{\sum_m c_m u_m} \right) \tag{8}$$

Including additional terms arising from ordinary diffusion, the equation reads

$$\frac{\partial c_j}{\partial t} = Q_j(c_1, \cdots, c_n) - \frac{i}{F} \frac{\partial}{\partial x} \left(\frac{c_j u_j}{\sum_m c_m u_m} \right) + D_j \frac{\partial^2 c_j}{\partial x^2} - \frac{\partial}{\partial x} (c_j u_j X') \tag{9}$$

where

$$X' = \frac{\sum_m D_m (\partial c_m/\partial x)}{\sum_m c_m u_m} \tag{10}$$

is the Nernst ("internal") potential gradient, which depends exclusively on the concentrations and the concentration gradients but not directly on the superposed field.

The quasilinear system (8) of first order partial differential equations will give a complete description of electrodiffusion in all kinds of systems. It may be regarded as a combination of Kohlrausch's differential equation known from electrophoresis with the well-known chemical rate laws. It should not be overlooked that the mathematical difficulties involved in solving these equations may be considerable.

Finally it should be pointed out that the absence of an effect in the case AB follows in a very easy way from these equations. If no other electrolyte is added we have

$$\frac{\partial}{\partial x} \left(\frac{c_j u_j}{\sum_m c_m u_m} \right) = \frac{\partial t_j}{\partial x} = 0$$

where t_j denotes the transfer number.

Note on the Crystal Structure of Ferromagnetic Chromium Dioxide

KARL-AXEL WILHELMI and
OLA JONSSON

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

The formula CrO_2 for the ferromagnetic chromium oxide was established by Michel and Bénard in 1935 [1,2]. They found that this phase is of a rutile type. The compound has subsequently been studied by several investigators [3-6].

The following methods have been used for preparing chromium dioxide:

A) thermal decomposition of CrO_2Cl_2 [1,2,5]
B) thermal decomposition of pure CrO_3 under oxygen pressure [3,4]
C) thermal decomposition of aqueous CrO_3-solution under oxygen pressure [6]

Method A) seems to give a product which is contaminated with Cr_2O_3 and method B) a product contaminated with higher chromium oxides [3] or Cr_2O_3 [3,4]. In Ref.[6] the product (method C) is characterized as "X-ray pure" but no analytical data are given.

Bhatnagar [7] has reported a normal paramagnetic susceptibility corresponding to two unpaired electrons per Cr atom for a substance said to be CrO_2. On the other hand, the ferromagnetism of CrO_2 has been recently confirmed by Glemser [5] and by Ariya *et al.*[4]

This paper gives the results of an X-ray diffraction study of an oxide sample obtained by thermal decomposition of pure CrO_3 (Baker's analyzed, dried over P_2O_5) at 350°C under oxygen pressure (60 atm). The material so obtained consisted of opaque, black, strongly magnetic crystalline aggregates. The sample was dissolved in hot concentrated sulphuric acid and the chromium content determined using Mohr's salt and standard permanganate solution after oxidation by peroxodisulphate in the presence of silver ions. The composition of the sample was found to be $CrO_{2.14}$.

Table 1 lists results reported by previous authors and those obtained in this investigation. The unit cell dimensions of the rutile-type structure were in all cases derived from X-ray powder patterns. Our data were obtained from a Guinier powder photograph taken with CuKa_1 radiation using potassium chloride (a = 6.2919 Å) as an internal standard (*cf.* Table 2). The back-ground fogging caused by the fluorescence radiation from chromium was effectively depressed by means of an aluminium foil (35 μ) covering the photographic film. Even in amply exposed photographs it was not possible to find indications of a doubling of the c axis as

* The presence of this line suggests that the excess oxygen content of the sample over the composition CrO_2 is due to a contamination by the phase $CrO_{2.5}$, the strongest reflexion of which occurs at $\sin^2\theta$ = 0.0558 as calculated from the data given by Schwartz *et al.*[3]

reported by Ariya *et al.*[4] The observed density is in good agreement with the value of 4.89 g/cm³ calculated for a cell content of two formula units of CrO_2.

The axial ratio of chromium dioxide ($c/a = 0.660$) corresponds to a relatively long distance between adjacent Cr atoms and indicates that no attracting forces are acting between these metal atoms in contrast to what is the case in several other compounds of transitions metals with valency states lower than their maximum ones [8]. Of particular interest in this connection is the rutile type phase $(Cr, Mo)O_2$ with its considerably lower values of c/a (down to 0.60) which have been interpreted as caused by the presence of metalmetal bonding [9].

Chemical Synthesis of Oleyl Adenylate

BENGT BORGSTRÖM

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Mixed anhydrides of adenylic acid with short and middle chain fatty acids have been proposed as intermediates in the enzymatic activation of these acids to their CoA derivatives [1-5]. Chemical synthesis of these adenylates has been reported using three different methods: 1) coupling of silver adenylate with the acid chloride (acetyladenylate [1]), 2) the reaction of the acid anhydride with adenylic acid in aqueous pyridine (buturyl and hexanoyl adenylate [2,5]), and 3) the condensation of fatty acid and adenylic acid in the presence of carbodiimides (buturyl adenylate [5]).

For an attempted synthesis of long chain fatty acid adenylates method 2 did not seem practical due to the low solubility of the long chain anhydrides. Of the two other methods the carbodiimide method was found to be the most practical and to give the best yields.

This paper will describe the synthesis of oleyl adenylate by the condensation of oleic acid with adenylic acid in the presence of di*cyclo*hexylcarbodiimide and also includes experiments to show the metabolic activity of this compound with rat liver mitochondria *in vitro*.

EXPERIMENTAL

Materials. Adenylic acid (AMP) was obtained from Sigma Chemical Company and di*cyclo*hexylcarbodiimide (DCC) from Fluka A.G.

Methods. Oleyl adenylate was estimated by the hydroxamic acid-$FeCl_3$ method modified for the acid insoluble hydroxamates of oleic acid [6]. A sample containing approximately 1 mg adenylate in 0.1—0.5 ml was added with 1 ml of a freshly prepared solution of equal volumes of 28 % hydroxylamine and 14 % sodium hydroxide. After 5 min 3 ml of 7 % perchloric acid was added and the insoluble hydroxamates filtered off on a paper filter (Munktell No. 8, diam. 5.5 cm) and washed on the filter two times with each 3 ml of the perchloric acid solution. The hydroxamates were then extracted from the filter with 3 ml of a dilution of Hill's reagent 1:20 in ethanol and the extinction of the solution measured at 530 mμ. With this method 1 μmole hydroxamate gives an extinction of 0.28, the molecular extinction of hydroxamates being around 1 000.

Synthesis of oleyl adenylate. 1 g adenylic acid (= 2.74 mmole) was dissolved in 40 ml pyridine and 8 ml water and 10 ml oleic acid (= 30 mmole) added. This solution was cooled to 0° and was added to an icecold solution of 10 g DCC in 20 ml pyridine. The reaction mixture was allowed to stand for 6 h in an ice-bath and was then added with 32 ml ice-cold

This paper will describe the synthesis of oleyl adenylate by the condensation of oleic acid with adenylic acid in the presence of di*cyclo*hexylcarbodiimide and also includes experiments to show the metabolic activity of this compound with rat liver mitochondria *in vitro*.

EXPERIMENTAL

Materials. Adenylic acid (AMP) was obtained from Sigma Chemical Company and di*cyclo*hexylcarbodiimide (DCC) from Fluka A.G.

Methods. Oleyl adenylate was estimated by the hydroxamic acid-$FeCl_3$ method modified for the acid insoluble hydroxamates of oleic acid [6]. A sample containing approximately 1 mg adenylate in 0.1—0.5 ml was added with 1 ml of a freshly prepared solution of equal volumes of 28 % hydroxylamine and 14 % sodium hydroxide. After 5 min 3 ml of 7 % perchloric acid was added and the insoluble hydroxamates filtered off on a paper filter (Munktell No. 8, diam. 5.5 cm) and washed on the filter two times with each 3 ml of the perchloric acid solution. The hydroxamates were then extracted from the filter with 3 ml of a dilution of Hill's reagent 1:20 in ethanol and the extinction of the solution measured at 530 mμ. With this method 1 μmole hydroxamate gives an extinction of 0.28, the molecular extinction of hydroxamates being around 1 000.

Synthesis of oleyl adenylate. 1 g adenylic acid (= 2.74 mmole) was dissolved in 40 ml pyridine and 8 ml water and 10 ml oleic acid (= 30 mmole) added. This solution was cooled to 0° and was added to an icecold solution of 10 g DCC in 20 ml pyridine. The reaction mixture was allowed to stand for 6 h in an ice-bath and was then added with 32 ml ice-cold

solution containing 66 mg lithium hydroxide (= 2.74 mmole). After 5 min the di-*cyclo*hexylurea was filtered off on a glassfilter and the clear solution extracted with 3 times 200 ml ether to remove excess oleic acid and pyridine. The water phase containing the adenylate was lyophilized and 1.40 g of a slightly yellow powder obtained. When assayed with the hydroxamic acid method this powder contained 1.26 μmoles adenylate per mg corresponding to 0.80 mg oleyl adenylate. The yield was 64 %, calculated on the AMP, and the purity around 80 %. This preparation was further purified by chromatography on a column of Whatman No. 1 paper powder (coarse grade) using *iso*propanol:water 70:30 as solvent [5]. For the purification of 200 mg of the crude preparation a column was prepared from 90 g paper powder (diam. 34 cm). The column was washed with *iso*propanol:water until the effluent was free from substances adsorbing at 259 mμ. 200 mg of the adenylate mixture was dissolved in 10 ml of the 70 % *iso*propanol and applied to the column which was developed with the same solvent. 20 ml fractions were collected and their optical density at 259 mμ determined. A pea kwas obtained between 160 and 240 ml of effluent. These 80 ml were added with 48 ml water and 130 ml ether to extract the *iso*propanol from the water phase and the latter lyophilized. The ultraviolet adsorption spectrum of a solution of this powder showed a single peak at 259 mμ with an optical density at this wavelength of 23.0 per mg as compared to a theoretical figure of 24.4 assuming the oleyl adenylate to have the same molar extinction coefficient as AMP (= 15.4×10^3). The ratio between activated fatty acid as determined by the hydroxamic acid method and the AMP content as derived from the optical density at 259 mμ was 0.96.

A study of the effect of fatty acid to AMP ratio on the yield of adenylate showed that 1, 3 and 9 moles of oleic acid per mole of AMP gave a yield of 45, 69 and 82 %, respectively, of adenylate calculated on the AMP of the reaction. To get the best yield calculated on the fatty acid moiety, as desired in the synthesis of fatty acid labeled adenylate, therefore equimolar amount of AMP and fatty acid should be used.

The method described gave low yields for the synthesis of adenylates with palmitic and stearic acid due to the low solubility of these acids in the solvent mixture used at 0°. If the reaction was allowed to take place at room temperature to facilitate the solution of these acids, the yield of hydroxamic acid forming substances was low most probably due to the formation of polyacylated compounds [5].

Table 1. Oxidation of oleyl adenylate and oleic acid with rat liver mitochondria. The Warburg vessels contained final concentration of 0.01 M phosphate buffer pH 7.4, 0.05 M KCl, 0.005 M $MgCl_2$, 0.0005 M succinate as priming substrate and 10^{-5} M cytochrome c. Mitochondria added in 0.15 M KCl suspension corresponding to 1.5 g liver. Additions according to table. Final volume 2.0 ml; gas phase air. Incubated at 30°: equilibration time 10 min.

Additions	O_2 uptake, μl, 0—20 min.
None	12.8
Oleyl adenylate 0.25 μmole	54.8
» » 0.50 »	58.9
» » 1.0 »	31.6
» » 2.0 »	11.1
ATP 2 μmole	32.8
» 2 + oleic acid 0.25 μmole	65.9
» 2 » » 0.50 »	—
» 2 » » 1.0 »	60.3
» 2 » » 2.0 »	7.2

From Table 1 it appears that rat liver mitochondria can oxidize oleyl adenylate at the same rate as oleic acid in the presence of adenosine triphosphate (ATP) and thus can replace the ATP requirement for the oxidation of oleic acid [7]. The optimal concentration for the oxidation of adenylate in this system is the same as for oleic acid, *i.e.* 2.5×10^{-4} M. At higher substrate concentration both adenylate and oleic acid inhibit respiration.

Diphenyl-picrylhydrazyl as a Standard in Electron Spin Resonance

JOHAN J. LOTHE and GUNNAR EIA

The Central Institute for Industrial Research, Blindern, Oslo, Norway

In the study of free radicals by electron spin resonance α,α-diphenyl-β-picrylhydrazyl (DPH) is widely used as a standard for estimating the number of unpaired electrons present. Recently DPH has become commercially available through Fluka AG. Investigating two separate samples of DPH from this company it was found, that the maximum resonance intensity from one sample was only about one third of that from the other, the line being at the same time correspondingly broader. Subsequent analyses of the samples indicated the presence of substantial amounts of benzene. In view of the importance of DPH as a standard it was thought desireable to investigate the observed effect in some more detail, and especially to ascertain if recrystallization from benzene was responsible for the broadening of the resonance line.

The electron spin resonance spectra were obtained at a frequency of 31.5 Mc/s using a Pound and Knight type spectrometer [1]. The magnetic field produced by a pair of Helmholtz coils was modulated at a frequency of 415 cps, and the signals were displayed on a recorder using a phase-sensitive detector. This technique permits the graphic presentation of the first derivative of the absorption as a function of field. The ordinate in the published spectra was calibrated in number of spin centers according to the resonance intensity from a sample of DPH recrystallized from carbon disulfide.

The existence of a stable (1:1) addition complex between DPH and benzene has been mentioned twice in the literature [2, 3]. We prepared the complex both by recrystallization from a mixture of 3 parts benzene and 2 parts *cyclo*hexane, and by slowly evaporating the solvent at room temperature from a solution of DPH in benzene. Microchemical analysis indicated that the ratio of DPH to benzene in the sample used for the investigation was as 1:0.8.

The resonance line of the DPH-benzene complex (Fig. 1) was extremely broad with a total width of 4.6 ørsted between inflection points of the absorption curve. The peak to peak intensity was only about 1/30th of that observed in a sample of DPH recrystallized from carbon disulfide (Fig. 2), which showed a total width of 0.85 ørsted between inflection points.

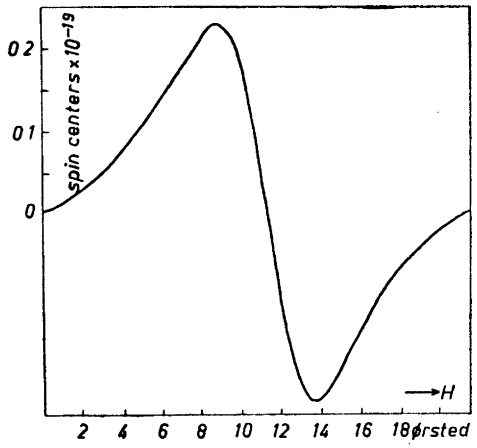

Fig. 1. Electron spin resonance of 60 mg crystalline DPH-benzene complex. (Ordinate is calibrated in spin centers according to resonance intensity from a sample of DPH recrystallized from carbon disulfide.)

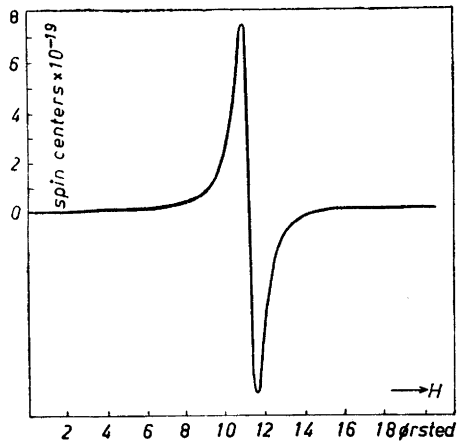

Fig. 2. Electron spin resonance of 50 mg crystalline DPH recrystallized from carbon disulfide.

In accordance with the findings by Müller [3] benzene is only very slowly driven away from the complex. Evacuation of the sample for 24 h at 0.1 mm Hg at room temperature had no effect on the spectrum, and after 10 h of vacuum treatment at 60° the peak-to-peak intensity had increased only by a factor of three. It is interesting to note, however, the ease with which the benzene apparently is dispelled by other organic liquids. Only 2 min after the addition of a small amount of *cyclo*hexane to the DPH-benzene complex the peak-to-peak intensity had increased by a factor of five.

Electron spin resonance spectra of solid free radicals are usually characterized by very narrow absorption lines with a half width of less than 10 ørsted. Large intermolecular exchange interaction of the unpaired electrons is mainly responsible for the sharpening of the lines. Some overlapping of the orbitals should occur in order to have exchange narrowing operating. When the distance between the free radicals in the crystal is increased, one may consequently expect, that the exchange effect will be reduced. It seems likely, that the broadening of the resonance line of the molecular addition complex between DPH and benzene may be ascribed to reduced exchange narrowing. A somewhat similar effect has already been observed by Holden and Kittel [4] in the resonance spectra of di-*p*-anisyl nitric oxide. The resonance lines from this compound was found to have a half width of 15.7 ørsted, whereas a crystalline material in which one part of di-*p*-anisyl nitric oxide was diluted with ten parts of the isomorphous *p,p'*-dimethoxy benzophenone gave a half width of 29.6 ørsted.

It has been pointed out [5], that the line shape, when exchange narrowing is operating should be of the Lorentzian type, whereas for the case of negligible exchange effects a Gaussian line shape is expected. Weidner and Whitmer [6] have previously found a Lorentz type resonance line for DPH. Analysis of the resonance line from the DPH-benzene complex showed, that the line could also in this case be closely reproduced by a Lorentz curve. Even though the line of the DPH-benzene complex is considerably broader than in the sample of DPH recrystallized from carbon disulfide, the line shape indicates thus that the line is still sharpened by exchange narrowing. This is not surprising as according to Holden and Kittel [4], the line width in DPH calculated on the basis of dipole-dipole interaction only should be of the order of 100 ørsted.

Table 1.

Sample	a) ΔH_i ørsted	b) I_p	c) A	d) A
DPH recrystallized from CS_2	0.85	1	1	1
DPH-benzene complex	4.6	0.031	0.9	0.6

a) Distance between inflection points on absorption curve.

b) Peak-to-peak intensity of derivated curve in arbitrary units.

c) Area under absorption curve in arbitrary units, calculated from $(\Delta H_i)^2 \times I_p$.

d) Area under absorption curve in arbitrary units, calculated from the product of the line width and the area under the derivated curve.

It is actually the area under the absorption curve, that is a measure of the number of unpaired electrons present in a sample. This area may be estimated either from the product of the square of the line width and the peak-to-peak intensity, or from the line width times the area under the derivated curve. It is seen from Table 1, that using the first method the areas under the absorption curves of the two samples were found to be nearly equal. The lower results on the DPH-benzene complex obtained using the second method of calculation, is probably due to neglect of the area beyond the limits of integration.

A search was made for a suitable solvent for the recrystallization of DPH. It turned out, that the solvent had a pronounced effect on the resonance line. The highest peak-to-peak intensity in the derivated resonance spectrum was obtained from a sample of DPH recrystallized from carbon disulfide. These observations emphasize that great care should be exercised when using DPH as a standard for estimating the number of unpaired electrons present in a system. DPH should preferably be recrystallized from carbon disulfide, and only the area under the absorption curve should be used for the estimate.

So far the observations on the electron spin resonance spectrum of the DPH-

benzene molecular addition complex have been restricted to the radiofrequency region. It is our hope in the near future to extend the work to the microwave region. Work is in progress on the electron spin resonance spectra of other molecular addition complexes of DPH.

The authors wish to express their gratitude to Mr. H. Hognestad, who constructed the electron spin resonance spectrometer. The microchemical analyses were carried out by Dr. Kirsten, University of Uppsala.

Ligand Field Spectrum of Vanadium(II) Hexaquo Ions

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The absorption spectra of hexaquo ions of divalent metals in the first transition group has been one of the most common subjects for ligand field theory. Cr(II)[1,2], Mn(II)[3], Fe(II)[4,5], Co(II)[6], Ni(II)[7,8] complexes have all been rather much studied. Only the study of vanadium(II) has been very little performed, due to the strongly reducing character of this oxidation state and the interfering colours of the probable vanadium(III) impurities. Kato [9] photographed bands at 820, 760, 560, and 540 mμ of a solution in 3 M HCl. However, measurements on a Cary MS-11 recording spectrophotometer has not confirmed the doublet structure in the green, and it is known that the highly varying sensitivity of most photographic plates in this region may produce spurious maxima. Therefore, Ballhausen and the present author concluded [10] that the three spin-allowed transitions from $^4\Gamma_2$ to $^4\Gamma_5$, $^4\Gamma_4$(F), and $^4\Gamma_4$(P) occur at 820, 555, and 378 mμ, respectively. Similar conclusions were drawn previously by Holmes and McClure [11], but only published recently.

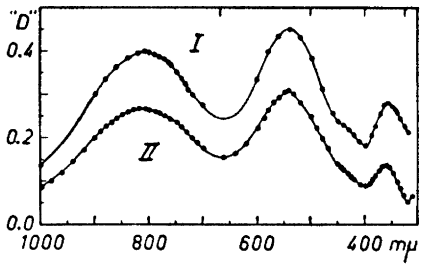

Fig. 1. Reflection spectra of vanadium(II), zinc(II) Tutton salt.

Fig. 1 gives the reflection spectra (as measured on a Beckman DU) of two samples of $(NH_4)_2[Zn(H_2O)_6](SO_4)_2$ into which vanadium(II) is included isomorphically. This happens to be a method of evading the presence of vanadium(III) in the substance. The salt was also dissolved in 2 M H_2SO_4 and measured on the Cary. The band maxima (and shoulders in parentheses) occur at the wavelengths in mμ:

Sample I	Sample II	Solution
810	810	>810
(765)	(760?)	(778)
540	542	563
(430)	(434)	—
355	362	368

The solution has higher wavelengths of all its bands, compared to the solid samples. This may be caused by the presence of sulphate complexes (even though this has relatively little influence on the spectra of other divalent ions), or by partly oxidation to +3 (of which the spectral characteristics is discussed in Ref.[12] p. 79). However, another explanation may be found in the phenomenon [8] that $Ni(H_2O)_6^{++}$ has smaller wavelengths when imbedded in $(NH_4)_2[Ni(H_2O)_6](SO_4)_2$ than in other salts or in solution. Further, the lattice constants of the zinc Tutton salt are so small that $V(H_2O)_6^{++}$ may be compressed to some extent [13].

benzene molecular addition complex have been restricted to the radiofrequency region. It is our hope in the near future to extend the work to the microwave region. Work is in progress on the electron spin resonance spectra of other molecular addition complexes of DPH.

The authors wish to express their gratitude to Mr. H. Hognestad, who constructed the electron spin resonance spectrometer. The microchemical analyses were carried out by Dr. Kirsten, University of Uppsala.

Ligand Field Spectrum of Vanadium(II) Hexaquo Ions

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The absorption spectra of hexaquo ions of divalent metals in the first transition group has been one of the most common subjects for ligand field theory. Cr(II)[1,2], Mn(II)[3], Fe(II)[4,5], Co(II)[6], Ni(II)[7,8] complexes have all been rather much studied. Only the study of vanadium(II) has been very little performed, due to the strongly reducing character of this oxidation state and the interfering colours of the probable vanadium(III) impurities. Kato [9] photographed bands at 820, 760, 560, and 540 mμ of a solution in 3 M HCl. However, measurements on a Cary MS-11 recording spectrophotometer has not confirmed the doublet structure in the green, and it is known that the highly varying sensitivity of most photographic plates in this region may produce spurious maxima. Therefore, Ballhausen and the present author concluded [10] that the three spin-allowed transitions from $^4\Gamma_2$ to $^4\Gamma_5$, $^4\Gamma_4$(F), and $^4\Gamma_4$(P) occur at 820, 555, and 378 mμ, respectively. Similar conclusions were drawn previously by Holmes and McClure [11], but only published recently.

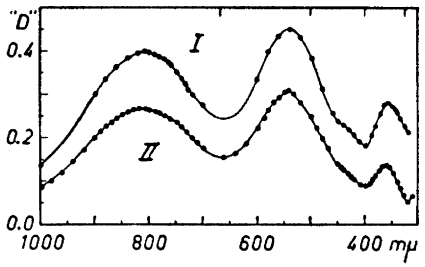

Fig. 1. Reflection spectra of vanadium(II), zinc(II) Tutton salt.

Fig. 1 gives the reflection spectra (as measured on a Beckman DU) of two samples of $(NH_4)_2[Zn(H_2O)_6](SO_4)_2$ into which vanadium(II) is included isomorphically. This happens to be a method of evading the presence of vanadium(III) in the substance. The salt was also dissolved in 2 M H_2SO_4 and measured on the Cary. The band maxima (and shoulders in parentheses) occur at the wavelengths in mμ:

Sample I	Sample II	Solution
810	810	>810
(765)	(760?)	(778)
540	542	563
(430)	(434)	—
355	362	368

The solution has higher wavelengths of all its bands, compared to the solid samples. This may be caused by the presence of sulphate complexes (even though this has relatively little influence on the spectra of other divalent ions), or by partly oxidation to +3 (of which the spectral characteristics is discussed in Ref.[12] p. 79). However, another explanation may be found in the phenomenon [8] that $Ni(H_2O)_6^{++}$ has smaller wavelengths when imbedded in $(NH_4)_2[Ni(H_2O)_6](SO_4)_2$ than in other salts or in solution. Further, the lattice constants of the zinc Tutton salt are so small that $V(H_2O)_6^{++}$ may be compressed to some extent [13].

From the average values of the two solid samples, Δ is seen to be 12 350 K (= cm^{-1}). The parameter of interelectronic repulsion B can be found by the same way [7,8] as in Ni(II), *viz.* from the wavenumbers of all three spin-allowed bands $15B = 18\,500 + 27\,950 - 3 \times 12\,350 = 9\,400$ K, while $15B = 11\,260$ K in gaseous V^{++}. However, as pointed out by Schäffer [13] for the isoelectronic $Cr(H_2O)_6^{+++}$, the third band has undoubtedly too low wavenumber, and it is reasonable to calculate the interelectronic repulsion parameters from the positions of the two first bands alone. In this way, the comparison with isoelectronic species as Mn(IV) in MnF_6^{--} or Mo(III) in $MoCl_6^{-3}$ is also facilitated. From this assumption, $15B$ is found = 10 300 K. The ratio $\beta = 0.92$ between this value and the value for the gaseous V^{++} is comparable with $\beta = 0.93$ in $Mn(H_2O)_6^{++}$ and 0.89 in $Ni(H_2O)_6^{++}$, demonstrating an early position in the nephelauxetic series of central ions (while $\beta = 0.79$ for $Cr(H_2O)_6^{+3}$ and 0.76 for $Fe(H_2O)_6^{+3}$).

For systematical reasons, it would be very valuable, if the spinforbidden transitions from $^4\Gamma_2$ to $^2\Gamma_3$ and $^2\Gamma_4$ (degenerate for pure d-electrons with the sub-shell configuration γ_5^3) could be detected. Even though water has a weak absorption range 740—790 mμ, it is believed that the shoulder $\sim$ 770 mμ actually is this transition (ζ_{3d} is only 169 K in V^{++}, and correspondingly, the spin-forbidden transitions are very weak), which occurs between 700 and 650 mμ in most chromium(III) complexes. The shoulder at 430 mμ in the solid samples may be another spin-forbidden band, or it may be due to superficial oxidation to $V(H_2O)_5OH^{++}$, which has an enormous absorption there [14] (perhaps, it is a dimer $(H_2O)_5\,VOV(H_2O)_5^{+4}$).

It was hoped to prepare other vanadium(II) complexes by dissolving the salt in different complexing agents. Thus, a solution in concentrated aqueous ammonia exhibit bands at $\sim$ 690 and 476 mμ. However, oxidation by traces of air produces a precipitate of $V(OH)_3$, and the possible experiments with other ligands have not yet been successful.

Experimental. 11.7 g (0.1 mole) NH_4VO_3 was mixed with 150 ml water, and 50 ml concentrated sulphuric acid added. The red-brown solution was reduced by zinc foil (Merck p.a.) over dark blue and dark green intermediate colours (of VO^{++} and V(III) sulphato complexes) until a violet solution was formed. This was quickly added to strong solutions (nearly saturated) of $(NH_4)_2SO_4$ in water, and a precipitate was formed of the mixed vanadium(II) and zinc(II) Tutton salt, could be sucked dry on a Büchner funnel. The salt can be kept several months in air without oxidation.

Ligand Field Bands of Hexafluoro Manganate(IV) and Predictions of Band Positions of Transition Group Fluorides

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

Ligand field theory describes the energy levels of central ions with partly filled d-shells in octahedral (O_h) complexes in terms of two parameters: the energy difference Δ (also called $(E_1 - E_2)$ or 10 Dq) between the two equivalent γ_3-orbitals and the three equivalent γ_5-orbitals; and the ratio β between the interelectronic repulsion parameters in the complex and in the corresponding gaseous ion. Even though these parameters are determined by rather unknown mixtures of electrostatic and covalent bonding [1], they are very useful for an empirical classification of the complexes, and Δ (the spectrochemical series) and β (the nephelauxetic series [2]) as function of central ions and of ligands behave very regularly. It is evident, *e.g.* from the many nickel(II) complexes studied [3,4], that the absorption spectrum of an unknown complex often can be precisely interpolated from other, known spectra, even though the parameters of ligand field theory are not accessible for an *a priori* calculation. The present note will discuss the possibilities of predicting the spectra of fluoride complexes which are interesting for many reasons: they are even less nephelauxetic than aquo ions (corresponding to weaker tendency towards covalent bonding) and they represent high and often unusual oxidation states of the metals involved. Further, the Laporte-forbidden ligand field transitions are not so often masked by Laporte-allowed electron transfer bands as in most other complexes. Unfortunately, these fluoride complexes are generally so reactive with glass and with moisture that no reflection spectra have been published (nor absorption spectra of the gaseous fluorides; solutions are not liable to be made in any solvent). It is hoped that this note will draw attention to the spectra and encourage somebody to surmount the large experimental difficulties. It can be remarked that ligand field theory is not especially applicable to fluoride complexes, because they are the least covalent (and therefore the most "electrostatic") complexes of a given central ion; a similar series of predictions might equally well be given for the relatively more covalent chloride or bromide complexes.

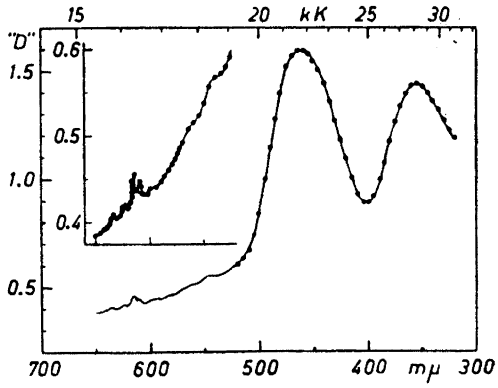

Fig. 1. Reflection spectrum of K_2MnF_6. The optical density "*D*" is indicated on larger scale for the small bands in the red.

The actual knowledge of ligand field parameters of fluoride complexes is mainly derived from CrF_6^{---}, extensively studied by Dr. Claus Schäffer, and from FeF_6^{---}. The latter ion [2] has Δ = 13.9 kK (1 kK = 1 000 cm^{-1}) and β = 0.79, as compared with $Fe(H_2O)_6^{+++}$ Δ = 14.2 kK and β = 0.76. Fig. 1 indicates the reflection spectrum of K_2MnF_6, prepared according to Weinland and Lauenstein [5]. The two spin-allowed bands with maxima at 460 mμ (= 21.75 kK) and 355 mμ (= 28.2 kK) imply Δ = 21.75 kK and the interelectronic repulsion parameter B = 600 K. Since B = 985 K in [6] gaseous Mn^{+4}, β = 0.61 for MnF_6^{--}. This is a surprisingly small value for a fluoride complex, showing that Mn(IV) is placed in the nephelauxetic series of metals even after Rh(III) and Co(III). Previously, it has not been possible to determine β of a Mn(IV) complex, because only the first spin-allowed band of the heteropoly molybdate was observed [7] at 21.4 kK. The latter complex has a narrow, spin-forbidden band at 14.3 kK, as also Mn(IV) heteropolywolframate [8] at 14.5 kK. This is nearly the same position as the transitions from $^4\Gamma_2$ to $^2\Gamma_3$ and $^2\Gamma_4$ in chromium(III) complexes. Kröger [9] found narrow phosphorescence lines of Mn(IV),

surrounded octahedrally by six oxygen atoms, at 15.26 and 15.32 kK. This effect corresponds to the opposite influence on the interelectronic repulsion parameters of increasing ionic charge and increasing covalency, which nearly cancel each other in Mn(II) and Fe(III) complexes [2,10]. Actually, Fig. 1 shows four weak, narrow bands * at 610, 614.5, 622 and 632 mμ. The wavenumbers 15.8—16.4 kK are some 8 % larger than in the oxo complexes of Mn(IV) (corresponding to the larger nephelauxetic effect of O^{--} than of F^-) and indicates a value of $\beta \sim 0.8$. In the molecular orbital theory [11] the wavenumber of $^4\Gamma_2 \rightarrow {}^2\Gamma_3$ is 3K(4,5), representing the interaction between two γ_5-electrons, while the energy difference between $^4\Gamma_5$ and $^4\Gamma_4$ is J(3,4)—J(1,4)—K(3,4) + K(1,4), representing interactions between a γ_5- and a γ_3-electron. If the γ_3-electrons are delocalized more by σ-bonding than the γ_5-electrons are by π-bonding, this difference is intelligible. However, configuration interaction in the complex may disturb this description rather much.

In Table 1 are indicated the positions of ligand field bands of octahedral fluoride complexes, predicted from the general behaviour of Δ and β as function of oxidation state. A few such predicted values have previously been given [12]. Wheeler, Perros and Naeser [14] indicate that PtF_6^{--} has bands at 31.4 and 36.4 kK. Dr. Perros, George Washington University, Wash. D.C., has kindly informed me that these two bands have $\varepsilon = 33$ and 24, respectively, while two weak bands are observed at 22.5 and 24.5 kK with $\varepsilon \sim 4$ and 5. Thus, the spectrum resembles very much that [16] of $IrCl_6^{-3}$, and the excited levels can be identified as $^3\Gamma_4$, $^3\Gamma_5$, $^1\Gamma_4$, and $^1\Gamma_5$. Hepworth, Robinson, and Westland [15] give a band at 31.6 kK of IrF_6^{--}. Since it is known from the chloro complexes of $4d^5$ Ru(III) and $4d^6$ Rh(III) [16] that the first spin-allowed ligand field band occurs nearly at the same wavenumber, a similar analogy may exist between Ir(IV) and Pt(IV). Thus, RhF_6^{--} is expected to have a band $\sim$ 350 mμ. The d^4-systems with $S = 3/2$ might be studied as fluoro complexes for finding the ligand field bands, which are as yet not known [16]. OsF_6^{--} has a band [15] at 32.5 kK, which is expected to be found in IrF_6^- at 36 and in RuF_6^{--} at 29 kK.

Table 1. Predicted positions of ligand field bands of fluoro complexes in kK (= 1 000 cm^{-1}).

There is no doubt that the quinque- and sexavalent metals have very late places in the nephelauxetic series, corresponding to a certain principle of electroneutrality [10]. The parameters of interelectronic repulsion will probably have the same magnitude as in gaseous ions with charges +1 or +2. Further, the orbital energy differences such as Δ assume large values, corresponding to the diamagnetism of NiF_6^{--} and low-spin behaviour of all the $4d^n$- and $5d^n$-fluorides. Nevertheless, a confirmation by measurements would be very valuable, and especially the numerical values of the nephelauxetic effect very interesting. Finally, an interesting stereochemical problem exists by comparison of the green gas RuF_5 with RuF_6^-. If the former is not a double-bridged dimer Ru_2F_{10}, it is one

* When K_2MnF_6 is dissolved in saturated aqueous NH_4F, relatively broad bands are observed in the red at 600, 660, and 702 mμ. Since these bands do not have the same positions as the narrow bands of the solid compound, it must be concluded that it decomposes to hydroxo- or perhaps polymeric oxo-complexes, and a slow evolution of the spectrum is also seen in some ten minutes, before the solution is too opaque of precipitated MnO_2. That hydrolysis products of halide complexes of d^3-systems often have the narrow, spin-forbidden bands highly broadened and somewhat intensified, is known from rhenium(IV)[13]. The bridged compound $W_2Cl_9^{-3}$ has also anomalously high, broad bands in the red at 13.2 and 16.3 kK[12].

of the very rare cases [12] of a d^3-system deviating from octahedral symmetry, and any information about its absorption spectrum will be highly desirable.

Acknowledgments. I thank Dr. Claus E. Schäffer much for many valuable discussions on ligand field theory and its applications. This research was supported by the *European Research Office, U.S. Department of Army* (Frankfurt / Main) under contract no. DA-91-508-EUC-247.

Some Observations on Betaine-Homocysteine-Methyl-Transferases

L.-E. ERICSON

Division of Food Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Experiments carried out in our laboratory suggest that enzymes capable of synthesizing methionine by means of a transfer of a methyl group from betaine (carboxymethyl-trimethyl-ammonium chloride) to homocysteine, are present in appreciable amounts only in the livers of vertebrate animals. Attempts to find such enzymes in microorganisms, plants or invertebrates have so far failed [1]. The apparent pH-optima of the betaine-homocysteine-methyltransferases of all the vertebrate livers tested occur between 7.0 and 7.8. These transferases are strongly inhibited by dimethylglycine, which besides methionine is a product of the enzymic reaction [1,2]. Choline can not replace betaine as the methyl donor with purified enzyme preparations nor does choline act as an inhibitor of the transferases.

In order to study the characteristics of this type of methyl group transfer in more detail, a procedure for the purification of the betaine-homocysteine-methyl-transferase of pig liver was worked out. It comprises the following steps:

1. One part of fresh pig liver is homogenized in three parts of water in a Waring blender. The pH of the homogenate is adjusted to 5.1 at 0°C and the thick "brei" obtained immediately centrifuged at 44 000 $\times$ g for 30 min.

2. The supernatant fluid is adjusted to a pH-value of 7.7 and poured into a series of test tubes which are then placed in a water bath at 80°C for 90 sec. An inactive precipitate is formed and is removed by centrifuging at 44 000 $\times$ g for 30 min.

3. The enzyme which is contained in the supernatant fluid from step 2, is adsorbed on calcium phosphate gel prepared according to Keilin and Hartree [3]. The enzyme is eluted from the gel by means of 0.15 M orthophosphate and 0.1 M pyrophosphate.

4. The eluates from step 3 are pooled and the pH adjusted to 7.2. Acetone is added to a final concentration of 50 %. The precipitate that forms is collected by centrifuging at 5 000 $\times$ g for 10 min, dissolved in water and dialysed against water at pH 8.5.

of the very rare cases [12] of a d^3-system deviating from octahedral symmetry, and any information about its absorption spectrum will be highly desirable.

Some Observations on Betaine-Homocysteine-Methyl-Transferases

L.-E. ERICSON

Division of Food Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Experiments carried out in our laboratory suggest that enzymes capable of synthesizing methionine by means of a transfer of a methyl group from betaine (carboxymethyl-trimethyl-ammonium chloride) to homocysteine, are present in appreciable amounts only in the livers of vertebrate animals. Attempts to find such enzymes in microorganisms, plants or invertebrates have so far failed [1]. The apparent pH-optima of the betaine-homocysteine-methyltransferases of all the vertebrate livers tested occur between 7.0 and 7.8. These transferases are strongly inhibited by dimethylglycine, which besides methionine is a product of the enzymic reaction [1,2]. Choline can not replace betaine as the methyl donor with purified enzyme preparations nor does choline act as an inhibitor of the transferases.

In order to study the characteristics of this type of methyl group transfer in more detail, a procedure for the purification of the betaine-homocysteine-methyl-transferase of pig liver was worked out. It comprises the following steps:

1. One part of fresh pig liver is homogenized in three parts of water in a Waring blender. The pH of the homogenate is adjusted to 5.1 at 0°C and the thick "brei" obtained immediately centrifuged at 44 000 $\times$ g for 30 min.

2. The supernatant fluid is adjusted to a pH-value of 7.7 and poured into a series of test tubes which are then placed in a water bath at 80°C for 90 sec. An inactive precipitate is formed and is removed by centrifuging at 44 000 $\times$ g for 30 min.

3. The enzyme which is contained in the supernatant fluid from step 2, is adsorbed on calcium phosphate gel prepared according to Keilin and Hartree [3]. The enzyme is eluted from the gel by means of 0.15 M orthophosphate and 0.1 M pyrophosphate.

4. The eluates from step 3 are pooled and the pH adjusted to 7.2. Acetone is added to a final concentration of 50 %. The precipitate that forms is collected by centrifuging at 5 000 $\times$ g for 10 min, dissolved in water and dialysed against water at pH 8.5.

5. The pH of the dialysed enzyme preparation is adjusted to 7.50 and acetone is added to a concentration of 50 %. The precipitate is collected by centrifuging at 20 000 × *g* for 10 min and dissolved in 0.005 M phosphate buffer. The pH is adjusted to 6.5 and the solution centrifuged at 20 000 × *g* for 2 min. The supernatant fluid contains the enzyme. The enzyme preparation thus obtained is coloured and has a specific activity approximately 100 times that of the homogenate. The overall yield is of the order of 35 %.

Further purification has been attempted in many different ways. Preparative electrophoresis at pH 9.2 in a density gradient [4] separates the coloured material present in the step 5-preparation from the transferase. Experiments of this type suggest that 60—70 % of the total protein content of the step 5-preparation constitutes an enzyme which is electrophoretically homogeneous at alkaline pH-values. This enzyme can use dimethylpropiothetin as the methyl donor in place of betaine.

Colourless enzyme preparations with a high specific activity have also been obtained using ion-exchange chromatography on triethylaminoethyl cellulose according to Porath [5]. This purification method has also failed to separate betaine-homocysteine-methyl-transferase from material having "thetin homocysteine methylpherase" [6] activity.

Fractionation of the enzyme preparation from step 5 with ethanol has occasionally resulted in crystalline material with a specific activity of about 150 times that of the liver homogenate. Dimethylpropiothetin can replace betaine as the methyl donor both with the crystalline and all other active ethanol fractions obtained. The ratio between the amount of methionine formed with propiothetin and the amount formed with betaine is approximatively ten for these fractions.

If a solution of purified betaine-homocysteine-methyl-transferase is kept at 80°C its ability to transfer methyl groups from betaine is lost at the same rate as its ability to transfer methyl groups from dimethylpropiothetin. — Dimethylglycine, which interferes with the utilization of betaine as the methyl donor also inhibits the methyl transfer from porpiothetin.

A number of compounds were synthesized [7] and tested for their ability to replace betaine as the methyl donor. It was found that the methyl donor specificity of betaine-homocysteine-methyl-transferase is by no means absolute. Not only dimethylpropiothetin and dimethylacetothetin but also carboxymethyl-dimethylethyl-ammonium chloride, carboxymethyl-diethylmethyl-ammonium chloride, 1-carboxyethyl-trimethyl-ammonium chloride and the methyl ester of betaine can more or less efficiently replace betaine as the methyl donor at pH 7.8 in phosphate buffer. However, the enzyme does not seem to be able to transfer ethyl groups.

An interesting property of the purified enzyme is that it is stimulated by some commonly occurring metabolites and inhibited by others. This phenomenon will only be exemplified here with a few remarks on the stimulation by oxalate. An approximately 10 % increase in the activity of the enzyme, as measured by the amount of methionine formed per hour can be obtained with potassium oxalate concentrations of 0.1 mM. The stimulation increases with increasing oxalate concentrations up to about 10 mM. The activity of the stimulated enzyme is then approximately 50 % above that of the control. At still higher concentrations of oxalate the stimulation decreases. Stimulation of the enzyme activity by oxalate is more marked at saturation than at subsaturation levels of either of the substrates. The enzymic formation of methionine is increased by the addition of oxalate also when dimethylpropiothetin serves as the donor of the methyl group.

A full account of the work reported here will be published shortly.

A Shadow Schlieren Method for the Study of Diffusion Boundary Layers at Electrodes

GOSTA WRANGLÉN

Division of Applied Electrochemistry, Royal Institute of Technology, Stockholm 70, Sweden

The Schlieren method described below corresponds to the method developed by Schmidt [1] for the study of temperature boundary layers. It so far seems to have been seldom used for the investigation of concentration boundary layers [2]. Like all Schlieren methods, it is based on the fact that light rays passing through a medium with a continuously changing refractive index are deviated into the optically denser parts of the medium. Since in this case the image is formed by the projection of a shadow without the use of lenses the designation "shadow Schlieren method" seems appropriate [3].

A microscope lamp (Fig. 1) with a small spiral (2 × 2 mm) acts as a point source of light. It is placed at the focus of a condensor lens with a small focal length. This lens gives a beam of approximately parallel light. A high degree of parallelity is achieved by placing two slits at a large distance from each other in the light path. The slits 1 and 2 are 2—3 mm wide and the distance between them is 10 m which means that the deviation from parallelity can be neglected. For qualitative purposes, as in lecture experiments, the distance between the slits can be reduced to about 1 m. The electrolysis cell, consisting of planoparallel plates of optical glass, is placed behind slit 2 in the light path. The light beam passes along and parallel to a copper plate, 1 mm thick, occupying the whole cross section of the cell. A shadow image is obtained on a screen or photographic plate. When no current is flowing, a photograph like the one in Fig. 2 a is obtained.

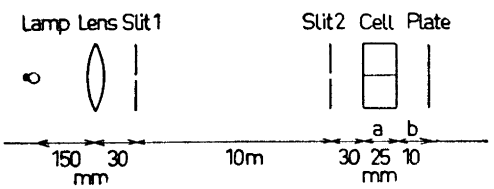

Fig. 1. Optical arrangement for the study of electrode films, viewed from above.

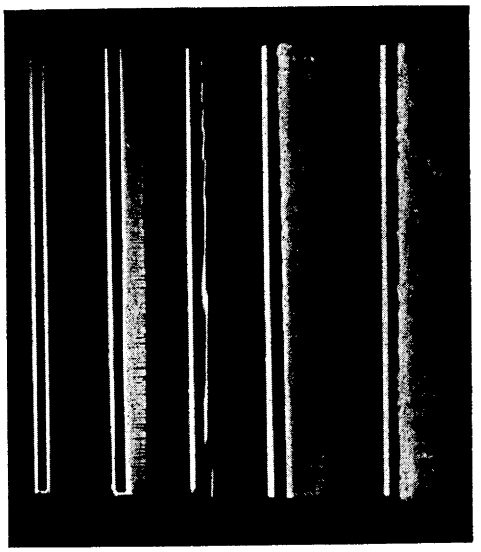

a b c d e

Fig. 2. a) Current shut off b) Cathode with 2 A/dm² on right side c) Anode with 2 A/dm² on right side d) Transition from laminar to turbulent flow at 1.5 A/dm² e) Fully developed turbulence at 4 A/dm². With a), b) and c) slit 2 was 2 mm wide and a = 25 mm, b = 7 mm. With d) and e) slit 2 was 3 mm wide and a = 45 mm, b = 10 mm. In exps. d) and e), the total cathode height was 180 mm, but only the height between 80 and 140 mm from the lower end of the cathode was photographed.

Upon electrolysing, the concentration gradients produced will manifest themselves on the image. In all the cases shown in the photographs here, the electrolyte consisted of 1 M $CuSO_4$ and the temperature was 20°C. If a cathodic current is applied on one side of the copper plate, the photograph in Fig. 2 b is obtained. In the cathode diffusion layer (cathode film), the concentration and refractive index are lower than those in the bulk solution. The light beam is therefore deviated away from the electrode. The deviation is proportional to the refractive index gradient. Since the gradient is greatest close to the cathode surface, the light

rays that enter the solution near the cathode surface will undergo the greatest deviation. The width of the bright band is, therefore, a measure of the concentration gradient on the cathode surface. The deviation may be expected to be proportional to the current density and to the width of the electrode, *i.e.* the length of the light path within the cell. However, this seems to be valid only up to a certain c.d. and electrode width, above which the deviation is constant. This is probably due to the fact that the cathode film is so thin (about 0.5 mm) that the light ray soon enters the bulk solution in which its path is rectilinear. Besides the bright band, a broadening of the cathode shadow is observed, obviously because the light is deviated out of the cathode film. The thickness of this film can therefore be estimated. In the upper part of Fig. 2 b, it seems to be about 0.4 mm.

For photographic purposes, the distance b between the cell and the plate should not be greater than 10 mm, otherwise the shadow image of the cathode will not be sharp. For accuracy in measurement however, this distance should preferably be increased to 100 mm which gives a corresponding increase in the displacement on the screen.

The shadow Schlieren method is less valuable for the investigation of the anode film. The light passing through the boundary layer will be deviated towards and deflected by the electrode. This will result in a broadening of the electrode shadow. There is, however, also an opposing effect, which results in a narrowing of the shadow, due to the light passing close to the rear edge of the electrode. Both these effects seem to appear in Fig. 2 c.

The free convective flow [4] caused by the difference in gravity between the electrode film and the bulk solution is also revealed by the method described, particularly at the cathode. In the case corresponding to Fig. 2 b, horizontal dark lines can be seen in the bright band adjacent to the cathode shadow. These lines move upwards with an increasing speed which seems to correspond to the vertically accelerated laminar flow in the cathode film. Since the velocity of this flow increases with the current density and with the electrode height, the flow will turn turbulent if these variables are increased. The transition from laminar to turbulent flow at a certain distance from the lower edge of the cathode is shown in Fig. 2 d. The diffuse bright band at the upper part of the cathode in Fig. 2 d appears to the naked eye much like the flickering of a flame, obviously due to the formation of eddies. Finally, Fig. 2 e shows fully developed turbulence due to a higher c.d.

While useful information is obtained by this simple method without lenses, it would be of interest to analyse the whole concentration profile in the boundary layer. According to Lamm [5], this could be done by the addition of lenses to the apparatus so as to correspond to Lamm's slit method [6]. The investigation will be continued.

Isotope Effect in the Decomposition of Grignard Compounds by Ordinary Phenol and a Sterically Hindered Phenol

LARS OLOF ASSARSSON

Nobel Institute of Chemistry, Stockholm 50, Sweden

Measurements of the hydrogen isotope effect in the hydrolysis and methanolysis of a number of Grignard compounds in different solvents and under different conditions have been reported in earlier papers [1-4]. Decomposition of Grignard compounds by tritiated phenols has now been carried out. In a series of experiments methylmagnesium iodide and *sec*-butylmagnesium bromide have been decomposed by ordinary phenol, C_6H_5OH, in which tritium has been partially introduced into the hydroxylic position. In another series of experiments the same Grignard compounds have been decomposed by a phenol with steric hindrance, 2,6-di-*tert*-butyl-4-methyl-phenol (called "lonol"), in which tritium has also been partially introduced into the hydroxylic group.

As it seems possible that the reaction mechanism should include a coordination of the hydroxylic compound to the magnesium atom in the Grignard compound (analogous to the coordination of ethers to Grignard compounds), the idea with the present experiments has been to investigate the effect of steric hindrance on this coordination. It is known from v. Braun and Kirschbaum [5] that steric hindrance can render some Grignard reactions impossible. These investigators state that the Grignard compound of [β-chloroethyl] methyl-aniline does not react with ketones though very well with aldehydes. On the other hand a Grignard compound of [γ-halogenopropyl]-methyl-aniline reacts with ketones as well as with aldehydes.

From its reactions it is obvious that 2,6-di-*tert*-butyl-4-methyl-phenol with its branched alkyl groups in the positions *ortho* to the hydroxylic group will offer strong steric hindrance to reactions concerning the latter. For example the compound is not soluble in aqueous sodium hydroxide or potassium hydroxide and it does not give the colour with ferric chloride solution characteristic of phenols [6]. Esterification is also retarded [6]. On the other hand it reacts with Zerewitinoff reagent (methylmagnesium iodide) in the usual manner with formation of methane [6].

The isotope effect in the decompositions by ordinary phenol, given in Table 1, is of the same order of magnitude as those obtained in the hydrolysis and methanolysis.

The isotope effect in the corresponding reactions with lonol, as shown in Table 2, deviates considerably from those obtained with ordinary phenol, methanol and water, but they are not of the same order of magnitude as a "full" hydrogen isotope effect.

The rather large values of k_T/k_H, obtained in the decompositions by phenol, methanol and water, could be explained by a reaction mechanism consisting of a slow coordination of the hydroxylic compound to the Grignard compound followed by a rapid proton transfer with formation of a hydrocarbon (*cf.* Wiberg [7]).

Lonol, on the other hand, could be expected not to be able to be coordinated to the Grignard compounds for steric reasons. If, nevertheless, the coordination takes place, it must be slower than the coordination of ordinary phenol and must consequently give larger ratios k_T/k_H than in the case of ordinary phenol. Actually the experiments give smaller ratios in the case of the phenol with steric hindrance. Therefore the mechanism discussed above can be eliminated, at least for the hindered reaction.

The fact that the reactions with the sterically hindered phenol take place at all (giving about the same ratio k_T/k_H with methylmagnesium iodide and with *sec*-butylmagnesium bromide) indicates, that they are at least partly of dissociative nature. Conseqently the phenol must dissociate off its hydroxylic proton, which in some way later reacts with the Grignard compound or with an alkyl carbanion derived from the Grignard compound with formation of the corresponding hydrocarbon. This seems to be in accordance with one of the mechanisms mentioned by Wiberg [7], who, however, obtained ratios k_D/k_H larger than unity in his methanolysis experiments. If the cleavage of the hydroxylic oxygen-hydrogen bond is supposed to be partly rate determining, it seems natural that the isotope effect should be more pronounced in the case of the hindered phenol than in the ordinary one, since the cleavage is likely to be slower

Table 1. Decomposition of Grignard compounds with phenol-t in *n*-butyl ether at 20°C.

Grignard compound	k_T/k_H	Number of parallel determinations of tritium in combustion water	Mean value (including error in determination of tritium in combustion water from the phenol)
Methyl-Mg iodide	0.757	2	0.78 ± 0.06
	0.814	1	
	0.734	1	
	0.810	2	
Sec-butyl-Mg bromide	0.738	1	0.79 ± 0.06
	0.822	1	
	0.795	1	

and hence more strongly rate-determining in the case of the former.

The Grignard reagents used in the experiments were solutions of the appropriate Grignard compounds in *n*-butyl ether. In the case of *sec*-butylmagnesium bromide part of the solvent plus the "false" butane was distilled off under reduced pressure immediately prior to every decomposition with the phenols[4]. The *n*-butyl ether used as solvent was dried by refluxing over and distillation from metallic sodium. The tritiated phenols were prepared by addition of tritiated water to a solution of the appropriate phenol in an organic solvent. In the case of phenol-t the tritiated water, ethyl ether and ordinary phenol were mixed after which the tritiated phenol was isolated by distilling under reduced pressure. Lonol-t was prepared in an analogous manner with the difference that a mixture of ethyl ether and ethanol was used as solvent, because the tritiated water used in this case had a smaller specific activity than that used in the phenol-t preparation, for which reason a larger amount of water must be used and consequently also a solvent being able to dissolve more water. The lonol-t was isolated by distilling off the solvent and water in vacuum.

As it is known that an exchange between hydrogen in the hydroxylic group and hydrogen in the benzene ring occurs with phenols,

Table 2. Decomposition of Grignard compounds with lonol-t in *n*-butyl ether at 20°C.

Grignard compound	k_T/k_H	Number of parallel determinations of tritium in combustion water	Mean value (including error in determination of tritium in combustion water from the lonol)
Methyl-Mg iodide	0.307	1	0.29 ± 0.03
	0.299	1	
	0.274	1	
Sec.-butyl-Mg bromide	0.306	1	0.33 ± 0.04
	0.322	1	
	0.347	1	

especially at higher temperatures [8], it was necessary to investigate whether and to what extent such an exchange had taken place in the preparations of phenol-t and lonol-t. The possible transition of tritium from the hydroxylic group to the benzene ring should of course give too small tritium activities in the hydrocarbons evolved with the Grignard compounds.

The check of this exchange proceeded in the same manner as described by Kukhtenko [9]. Tritium in the hydroxylic group of the ordinary phenol was washed off by dissolving the phenol in a large volume of 2 % aqueous sodium hydroxide. The phenolate solution was acidified and the phenol was extracted by benzene. The extract was dried with anhydrous calcium chloride and distilled for isolation of phenol free from tritium in the hydroxylic group. In the case of lonol-t, which is not soluble in sodium hydroxide, the method was modified. The tritiated lonol was dissolved in 96 % ethanol, after which ordinary water was added in portions while shaking the mixture until lonol began to precipitate. The precipitated crystals were carefully washed with much water and dried.

The phenols free from hydroxylic tritium were burned over cupric oxide like the initial tritiated phenols, and the radioactivity of the combustion water after reduction to hydrogen was determined by means of a Geiger-Müller counter. The activities thus obtained indicate that the tritiated phenols are practically free from tritium in the benzene rings.

The technique of the Grignard decompositions was the same as the one used earlier, *i. e.* the Grignard reagent in *n*-butyl ether solution was added by means of an injection syringe to a solution of the phenol in the same solvent. The phenols were present in excess over the Grignard compounds.

The tritiated phenols and the hydrocarbons formed in the decompositions were burned over cupric oxide and the radioactivity of the combustion water was determined (after reduction to hydrogen) in the same manner as in the case of the detritiated phenols.

The ratios k_T/k_H in the tables have not been corrected for the change in the isotopic composition of the phenols taking place during the reaction.

Isotope Effect in the Methanolysis of *n*-Butylmagnesium Bromide. A Reinvestigation

LARS OLOF ASSARSSON

Nobel Institute of Chemistry, Stockholm 50, Sweden

In a previous preliminary paper [1] measurements of the hydrogen isotope effect in the methanolysis of *n*-butylmagnesium bromide have been reported. The ratios k_T/k_H obtained in those experiments diverge considerably, the ratio obtained with the freshly prepared Grignard reagent being larger than those obtained with an

Table 1. Results in the decomposition of *n*-butylmagnesium bromide with methanol in *n*-butyl ether at 20°C.

k_T/k_H	Number of parallel determinations of tritium in combustion water	Mean value (including error in determination of tritium in combustion water from the methanol)
1.014	1

especially at higher temperatures [8], it was necessary to investigate whether and to what extent such an exchange had taken place in the preparations of phenol-t and lonol-t. The possible transition of tritium from the hydroxylic group to the benzene ring should of course give too small tritium activities in the hydrocarbons evolved with the Grignard compounds.

The check of this exchange proceeded in the same manner as described by Kukhtenko [9]. Tritium in the hydroxylic group of the ordinary phenol was washed off by dissolving the phenol in a large volume of 2 % aqueous sodium hydroxide. The phenolate solution was acidified and the phenol was extracted by benzene. The extract was dried with anhydrous calcium chloride and distilled for isolation of phenol free from tritium in the hydroxylic group. In the case of lonol-t, which is not soluble in sodium hydroxide, the method was modified. The tritiated lonol was dissolved in 96 % ethanol, after which ordinary water was added in portions while shaking the mixture until lonol began to precipitate. The precipitated crystals were carefully washed with much water and dried.

The phenols free from hydroxylic tritium were burned over cupric oxide like the initial tritiated phenols, and the radioactivity of the combustion water after reduction to hydrogen was determined by means of a Geiger-Müller counter. The activities thus obtained indicate that the tritiated phenols are practically free from tritium in the benzene rings.

The technique of the Grignard decompositions was the same as the one used earlier, *i. e.* the Grignard reagent in *n*-butyl ether solution was added by means of an injection syringe to a solution of the phenol in the same solvent. The phenols were present in excess over the Grignard compounds.

The tritiated phenols and the hydrocarbons formed in the decompositions were burned over cupric oxide and the radioactivity of the combustion water was determined (after reduction to hydrogen) in the same manner as in the case of the detritiated phenols.

The ratios k_T/k_H in the tables have not been corrected for the change in the isotopic composition of the phenols taking place during the reaction.

Isotope Effect in the Methanolysis of *n*-Butylmagnesium Bromide. A Reinvestigation

LARS OLOF ASSARSSON

Nobel Institute of Chemistry, Stockholm 50, Sweden

In a previous preliminary paper [1] measurements of the hydrogen isotope effect in the methanolysis of *n*-butylmagnesium bromide have been reported. The ratios k_T/k_H obtained in those experiments diverge considerably, the ratio obtained with the freshly prepared Grignard reagent being larger than those obtained with an

Table 1. Results in the decomposition of *n*-butylmagnesium bromide with methanol in *n*-butyl ether at 20°C.

0.978	1	

older reagent. This fact was supposed to be due to small amounts of moisture gradually entering the flask containing the Grignard reagent and forming inactive butane. This "false" butane, staying dissolved in the solvent, possibly might also be supposed to be formed by other reactions of the Grignard reagent.

In order to eliminate the "false" butane, part of the solvent *n*-butyl ether was distilled off in vacuum immediately prior to every methanolysis. Owing to the high volatility of butane, its absence then seems warranted. The ratios k_T/k_H obtained in the present experiments show very good reproducibility.

As k_T/k_H is equal to unity the isotopic composition of the methanol does not change during the reaction and hence no correction of the ratio is necessary.

It is interesting to note that the inverse isotope effect obtained by Wiberg [2] has not been confirmed by the present experiments, using tritium instead of deuterium.

The Acid-soluble Nucleotides of *Polyporus squamosus* and *Amanita muscaria*

ROLF BERGKVIST

Institute of Biochemistry, University of Lund, Sweden

The acid-soluble nucleotides of *Polyporus squamosus* and *Amanita muscaria* have been isolated and fractionated by ion exchange chromatography. These substances have been identified by ultraviolet absorption measurements, their chromatographic and ionophoretic behaviour both before and after hydrolysis, and by chemical and enzymic analyses.

In a previous publication from this laboratory [1] a method has been presented for the isolation and analysis of the acid-soluble nucleotides from plant tissues. Methods have also been described for the separation and quantitative analysis of varying amounts of nucleotides using paper chromatography and ionophoresis [2–4], and their application to the nucleotides in wheat, oats and barley [1,5]. It is the purpose of the present paper to extend the previous work on this subject to include the analysis of the acid-soluble nucleotides of two different mushrooms.

The acid-soluble nucleotides were isolated from *P. squamosus* and *A. muscaria* by homogenizing the fruiting bodies in cold perchloric acid. The nucleotides were then freed from interfering substances according to the procedure already described [1]. The separation and quantitative analysis of the nucleotide mixtures were accomplished by ion exchange chromatography on a Dowex 1 column (formate form) as described in the preceding papers. The elution of the nucleotides was followed by the changes in optical densities of the eluate. Figs. 1 and 2 show the effluent curves that were obtained. Since the nucleotide content of both mushrooms were quite similar, the analysis of the two materials are described together.

The eluate fractions from the Dowex column falling under the same peaks were pooled and concentrated by adsorption on charcoal and subsequently eluted with ethanol-ammonia. The isolated nucleotides were identified by their chromatographic and ionophoretic behaviour, both before and after hydrolysis, as compared with authentic nucleotides. The purified samples were then further characterized by the following criteria: (a) ultraviolet ab-

sorption spectra in acid and alkali; (b) total and acid-labile phosphorus content; (c) sugar content; (d) paper chromatographic identification of the sugar components; and (e) ultraviolet absorption curves of the bases obtained after acid hydrolysis. The position of the phosphate groups was confirmed by the action of rattle snake venom and by oxidation with periodate.

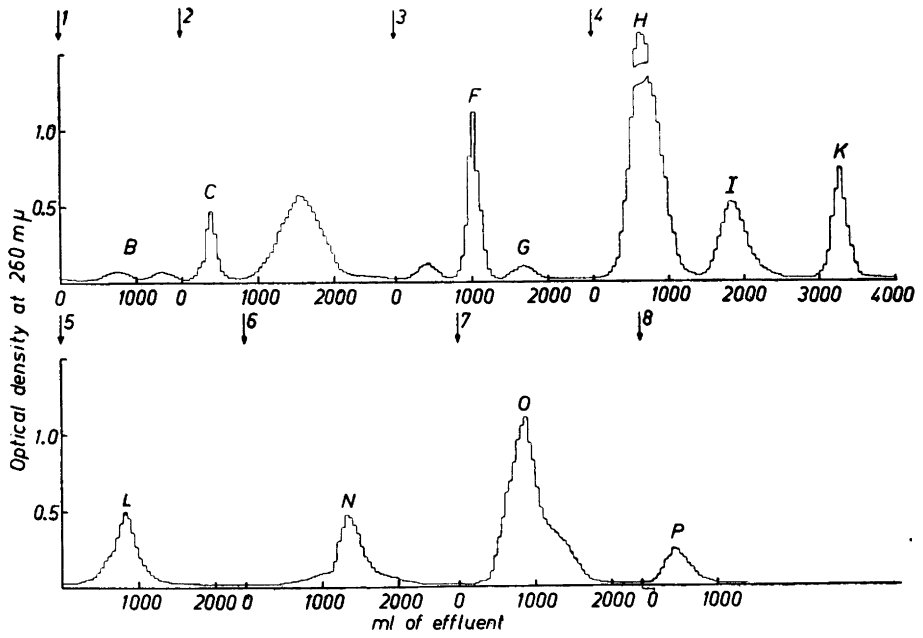

Fig. 2. Ion exchange chromatogram of acid-soluble nucleotides from 500 g of *A. muscaria*. The unmarked peaks contained no nucleotides. Exchanger: Dowex 1, X-10, 200 to 400 mesh, 1.6 × 50 cm, formate form; flow rate 1.5 ml/min. The eluting agents and identity of the peaks are the same as in Fig. 1.

The quantities of the nucleotides in the various column fractions were calculated by using the molecular extinction coefficients previously reported [1]. The results of the analysis are summarized in Table 1.

Peak A was obtained in the wash water or immediately after starting the elution with 0.02 M formic acid. This peak contained non-nucleotide material as the major component in addition to bases, uridine and DPN *.

Among the acid-soluble nucleotides of *P. squamosus*, a cytosine nucleotide is eluted from the resin after 5'-AMP. This compound has been identified as a cytidylic acid-peptide complex [6].

The different nucleotides were obtained as separate fractions with the exception of the peaks G and N. These fractions could be separated by either paper chromatography or ionophoresis. The separation could be made on a larger scale by applying the mixture to the paper as a streak instead of a spot, or by using continuous ionophoresis [5]. Fraction N from *P. squamosus* contained, in addition to the nucleotides, large amounts of a phosphorus-free sub-

Cytidine 5′-phosphates		6.6	2.0

stance with an absorption maximum at 262 mμ. Peak N, from both materials, contained GDP, UTP and an adenosine derivative. The latter compound had an absorption spectrum that was typical for adenosine, but behaved both chromatographically and ionophoretically differently from known adenosine derivatives. The base liberated on acid hydrolysis was adenine, as determined by paper chromatography and spectrophotometry. Three phosphate groups per molecule of adenosine were found, only one of which was acid-labile and could be hydrolyzed in 10 min with 1 N hydrochloric acid at 100°C. Two pentose residues per adenosine were found. No periodate was consumed when the substance was tested by the method of Dixon and Lipkin [7]. The amount of material was not sufficient for a more detailed study of the structure of this adenosine triphosphate.

The chromatography of the nucleotides from these plant materials produced several non-nucleotide peaks. From *A. muscaria* two peaks appeared before the 5′-AMP peak, and from *P. squamosus* a single peak occurred after the 5′-AMP peak.

In addition to the 15 to 18 different nucleotides identified from the acid-soluble nucleotide fraction of these fungi, there are indications of many other nucleotides present in such small concentration that their identifications were not possible.

EXPERIMENTAL

Isolation and separation of acid-soluble nucleotides. Only the fruiting bodies of the mushrooms occurring out of doors under natural field conditions were investigated. 1 000 g of fresh material were homogenized in 1 000 ml of ice cold 10 % perchloric acid in a Waring Blendor and after reextraction with 1 000 ml of 5 % perchloric acid the nucleotides were isolated and freed from disturbing substances according to the method previously reported [1].

Fractionation of the isolated nucleotide mixture was carried out by ion exchange chromatography using Dowex 1, X-10, 200 to 400 mesh, in the formate form. Details about these separations are seen from Figs. 1 and 2. The nucleotides were recovered from the pooled fractions by norite adsorption and elution with 50 % aqueous ethanol containing 0.5 % ammonia.

Analytical methods. The analysis of the different nucleotides has been made using the same methods as described earlier and the same solvent systems have been used for the paper chromatographic identifications [1,5].

The one-dimensional paper ionophoretic separations were carried out with an acetate buffer of ionic strength 0.1 and pH 4.15. For continuous separations the ionic strength was decreased to 0.033. The details of these methods and the apparatus used have been reported in preceding papers [2,3].

The nucleotides used as standard substances were obtained from Sigma Chemical Company or isolated in our laboratory.

The Acid-soluble Nucleotides of Different Mushrooms

ROLF BERGKVIST

Institute of Biochemistry, University of Lund, Sweden

The acid-soluble nucleotides of eight different mushrooms have been separated and their concentrations determined by a combination of ionophoresis and chromatography on paper.

During the development of a scheme for the analysis of the acid-soluble nucleotides of plant materials, different methods have been developed for nucleotide separations. When large amounts of material are available, the use of ion exchange chromatography is most suitable for obtaining a complete resolution and a quantitative recovery of the various components of the nucleotide mixture [1]. Other less time-consuming methods have also been developed. Ionophoresis at pH 4.15 has been found to produce a sufficiently different separation from that obtained with paper chromatography for it to be used in combination with the latter. The nucleotides are fractionated into groups by paper chromatography and then completely separated by one-dimensional ionophoresis [2], or by continuous ionophoresis [3], depending on the quantities to be separated. Preliminary analyses of nucleotide mixtures were carried out by two-dimensional fractionation on a single sheet of filter paper using a combination of ionophoresis and chromatography [4]. This method is especially suitable when only small amounts of material are available, and these analyses can be completed in 24 h.

The latter method has been used for the analysis of the acid-soluble nucleotides of eight different species of mushrooms. The same types of apparatus which have been described earlier were used [4]. For the detailed description of the apparatus and the performance of the analyses the reader is referred to the preceding references.

An aliquot of a concentrated solution of the nucleotide mixture containing about 3 μmoles of nucleotides (calculated from the optical density at 260 mμ) was subjected to paper ionophoresis in a sodium acetate buffer of pH 4.15 and of ionic strength 0.1. The ionophoresis was carried out on a large sheet of Whatman No. 1 paper at 1 000 V for 10 h. The paper was dried at room temperature and then the separation in the second direction was achieved by paper chromatography. The previously described solvent system consisting

of saturated ammonium sulphate solution-*n*-butanol-water (79:0.5:19) was used to get an almost complete separation of the different nucleotides. The various nucleotides were located on the paper photographically in ultraviolet light of 254 mμ, and prints were made with various exposure times to detect components of lower concentration. The spots were cut out from the paper and eluted with 0.1 N hydrochloric acid, and then the concentrations were calculated from the optical densities measured against the appropriate blanks. The uridine diphosphate derivatives, UDPG * and UDPAG, were obtained together as a single spot. To determine the concentrations of these two components an aliquot of the original nucleotide mixture was chromatographed in a solvent composed of 7.5 volumes of 95 % ethanol and 3 volumes of 1 M ammonium acetate of pH 7.5. This solvent separates these nucleotides from each other and from the main bulk of the nucleotide mixture.

To obtain a quantitative indication of the efficiency of this method, the acid-soluble nucleotides of *Polyporus squamosus* and of *Amanita muscaria* were analysed both by this method and by ion exchange chromatography.

The separation and analysis of the nucleotides of these mushrooms by ion exchange chromatography are described in detail in the preceding paper [5]. Fig. 1 shows a map of the positions taken by the various nucleotides after a two-dimensional separation. The results of the analyses are summarized in Table 1.

The amount of each component that could be separated and detected on the filter paper was 0.01—0.50 μmoles. The great variations in the concentration of the different nucleotides in the mixture made the analyses more difficult. High recoveries were obtained for the substances present in high concentrations, while the recovery of nucleotides occurring in lower concentrations was less quantitative. The different monophosphates of the two pyrimidine nucleotides were isolated together, since they are not sufficiently separated by this method. The results of these analyses show that the method is useful for obtaining preliminary analyses of nucleotide mixtures. For more exact analyses of the components present in the lower concentrations, the other methods described must be used [1,2].

The acid-soluble nucleotides of eight different mushrooms were analysed with the method outlined above. The results of these analyses for the various

species are shown in Table 2. Since the uridine diphosphate sugar compounds were obtained as a single spot by the two-dimensional separation described above, they have been further separated by paper chromatography and the results of these analyses are also included in the same table.

There is a striking species variation of the relative nucleotide concentrations among the mushrooms. In all of the species studied the major nucleotide

components are the uridine and adenosine derivatives, as was also observed for wheat, oats and barley. In the mushrooms, however, UDPAG greatly predominates over UDPG while in the cereals UDPG is found in greater amounts than UDPAG.

EXPERIMENTAL

Isolation of acid-soluble nucleotides. The fruiting bodies of the mushrooms occurring out of doors under natural field conditions were investigated. 1 000 g of fresh material were homogenized in 1 000 ml of ice cold 10 % perchloric acid in a Waring Blendor and after reextraction with 1 000 ml of 5 % perchloric acid, the nucleotides were isolated and freed from disturbing substances according to the method previously reported [1].

The nucleotides were readsorbed on norite in order to free them from interfering salts and were eluted by repeated shaking with small volumes of 50 % aqueous ethanol containing 0.5 % ammonia. The combined eluents were neutralized and the volumes reduced to a small volume by blowing air through them.

Analytical methods. The nucleotides were analysed using the apparatus previously described [2,4]. The separations were carried out on Whatman No. 1 paper purified by washing with 1 N hydrochloric acid and water. The mixture to be separated was applied as a line to the dry paper and then the paper was impregnated with sodium acetate buffer of pH 4.15 and of ionic strength 0.1. After an ionophoretic separation at 1 000 V for 10 h, the paper was unfolded and dried at room temperature. The chromatographic separation was made after cutting away the extraneous parts of the paper sheet. Complete separation was obtained in 10 h by descending chromatography with the above mentioned solvent. Spectrophotometric determinations of the different substances were made with a Beckman DU spectrophotometer adapted for use with a volume of 0.6 ml in silica cells with a 10 mm light path.

On the Glycogen in *Escherichia coli B*; Variations in Molecular Weight during Growth. II

T. HOLME, T. LAURENT and H. PALMSTIERNA

Bacteriological Department and Chemical Department I, Karolinska Institutet, Stockholm, Sweden

Previous investigations have shown that the molecular weight of glycogen from *E. coli B* changes during growth. The glycogen has now been fractionated in different molecular weight fractions. It was found that the glycogen consisted mainly of two fractions, one of high molecular weight, $40-90 \times 10^6$, and one of low molecular weight, $<2 \times 10^6$. The high molecular weight fraction is more active in metabolism than is the low molecular one. The changes in the overall molecular weight observed during growth are mainly attributable to changes in this fraction.

In earlier experiments the synthesis and breakdown of the glycogen in cells of *Escherichia coli B* has been investigated [1-3]. Isotopic techniques have been employed in some of these experiments [2]. By the use of these techniques it has been shown that the glycogen was not homogeneous with respect to its metabolic activity. In later experiments variations in the molecular weight of the glycogen were shown to be correlated to the physiological state of the bacterial cells [3].

This paper reports the additional information obtained by the application of isotopic techniques to the study of the metabolic activity of the different molecular weight fractions obtained by ultracentrifugal fractionation of the glycogen.

METHODS

Bacteriological methods. A medium with glucose as the carbon source and ammonium chloride as the sole nitrogen source was used [4] with appropriate modifications for one-factor-starvation [1]. In the nitrogen-deficient media the ammonium chloride concentration was 200 mg/l giving a population density of approximately 380 mg of dry cells per litre of culture upon exhaustion of the nitrogen source.

The cells were cultivated as described earlier [1] in a nitrogen-deficient medium and allowed to enter the "starvation phase" at which time isotopic carbon was added (uniformly labelled ^{14}C-glucose). After this addition, the cells were allowed to metabolize for 45 min. The culture was then rapidly cooled and the cells quantitatively recovered by

Table 1. Isotopic incorporation and molecular weight of glycogen isolated from cells of *E. coli B* during different conditions of growth. For an explanation of the symbols, see the text.

	Glycogen, per cent of dry weight of bacteria	Counts per min per μg glycogen-glucose	Weight average molecular weight of soluble glycogen

II	10.2	133	51×10^6
III	7.2	27	42×10^6

centrifugation. The cells were resuspended in a carbon-free medium, which contained the nitrogen source in excess. After 90 min additional incubation, the cells were spun down. Three samples were taken for analysis; one immediately before the addition of the isotopic carbon (I), the second 45 min after this addition (II), and the third 90 min after the resuspension in the carbon-free, nitrogen-containing medium (III). The dry weight of the cells per litre of culture and their nitrogen and glycogen in per cent of the dry weight was determined.

Chemical methods. The glycogen was isolated as previously described [3]. Light-scattering was used for the molecular weight determinations [3].

Before the molecular weight was determined, the glycogen was fractionated in five fractions by means of centrifugation. The first fraction was obtained as a precipitate after centrifugation in a common laboratory centrifuge at about 2 000 r.p.m. This fraction was insoluble in water and accounted for 10—20 % of the total glycogen. It contained silicate impurities and therefore no estimation of the molecular weight could be made. Three fractions were obtained as precipitates after ultracentrifugation in a Spinco preparative ultracentrifuge at 20 000, 40 000 and 105 000 × *g*. The fifth fraction was the supernatant remaining after these centrifugations.

For the measurements of radioactivity, the samples were spread on aluminium planchets and counted at infinite thinness in a windowless gas flow counter, flushed with a helium-*iso*butane mixture. Since the layer of material did not exceed 0.05 mg per cm^2 no correction was made for self-absorption.

A modification of Dische's carbazol method was used for the quantitative determinations of glucose [5].

RESULTS

The results reported in earlier communications have been confirmed [2, 3]. During a phase in which *E. coli B* cells accumulated glycogen, the molecular weight of the glycogen increased. During a subsequent utilization of the accumulated glycogen, the molecular weight decreased (Table 1).

The results of the fractionation experiments are given in Table 2. On account of the different centrifugation times the experiments E and F are not strictly comparable. In both cases, however, the soluble glycogen was divided into four fractions of quite distinct molecular weight. About 50 % of the soluble glycogen has a very high molecular weight, 40—90 × 10^6. Between 25—40 % was found in the low molecular weight, "supernatant fraction" ($< 2 \times 10^6$). The fractions between these extremes contained a

rather small portion of the total glycogen. The high molecular weight fraction was the one having the highest specific activity at the end of the glycogen accumulation phase (the nitrogen starvation phase). At this time the specific activity in the low molecular weight fraction was considerably lower. At the end of the carbon starvation period the specific activity in the high molecular weight fraction was low. The low molecular weight fraction retained its specific activity to a higher extent than the high molecular one.

DISCUSSION

The results given in Table 1 are in good agreement with our earlier observations [2, 3]. The specific activity of the glucose incorporated in the glycogen during accumulation was the same as that of the medium, indicating that no large pool of intermediary metabolites was present in the bacterial cells. During a subsequent growth period, when the cells had been transferred to a nitrogen-containing and carbon-free medium, the glycogen concentration decreased. Mainly the labelled glucose residues were split off. These facts have been interpreted as depending upon a formation of a peripheral tier of labelled glucose around the glycogen molecules during the starvation phase. This tier was the first one to be split off, when the glycogen was utilized [2]. Furthermore the results might be explained by differing metabolic activities in different glycogen fractions. The present experiments have been performed to determine whether different molecular weight fractions have different metabolic activity.

The fraction with a molecular weight of $40—90 \times 10^6$ contained in all samples about 50 % of the total soluble glycogen. The low molecular weight fraction contained 20—40 % (molecular weight $< 2 \times 10^6$). Thus, the two fractions in between contained only small quantities of glycogen. The polydispersity of the glycogen has thus no Gaussian distribution. Instead there seems to be two different kinds of glycogen, one low molecular weight species and one high molecular weight species.

In an earlier report [3] the weight average molecular weight of the total soluble glycogen was followed during growth. It was found to increase during glycogen synthesis and to decrease during glycogen utilization. For comparison the over all weight average molecular weights were calculated from data in Table 2. They are given in Table 1. These data confirm the earlier results, and it is now obvious that the changes occur mainly in the high molecular weight fraction (Table 2).

The specific activity of the glycogen after nitrogen starvation was higher in the insoluble fraction than in any of the others. In the soluble glycogen the metabolic activity was greater in the high molecular weight fractions than in the low molecular weight ones. During the subsequent breakdown of the glycogen more of the labelled glucose was split off from the highest labelled fractions than from the less labelled fractions. This shows that of the soluble glycogen the high molecular weight fraction had the highest metabolic activity. This result may seem surprising in view of the relatively smaller surface of the large molecules.

Metabolic inhomogeneity of the same kind has been found in rabbit muscle glycogen, but in rat liver the low molecular fraction showed a higher metabolic activity [6].

The authors are grateful for the skilled technical assistance given by Mr. R. Eliasson and Mrs. Berit Edling.

On the Glycogen in *Escherichia coli B*; Variations in Molecular Weight during Growth. III

T. HOLME

Bacteriological Department, Karolinska Institutet, Stockholm, Sweden

The glycogen formed by *Escherichia coli B*, cultivated in continuous culture at different growth rates, has been isolated. This glycogen has been subjected to ultracentrifugal fractionation and the molecular weight of the different fractions has been determined. Of the total glycogen isolated the rapidly dividing cells contained a high percentage of a *low* molecular weight fraction. Slowly dividing cells contained a high percentage of a *high* molecular weight fraction.

In experiments reported in a preceding article ultracentrifugal fractionation was used to obtain fractions of glycogen with different molecular weights [1]. In the present report this method has been applied to glycogen isolated from cells of *E. coli B* grown in continuous culture at different growth rates.

METHODS

The continuous culture methods used have been described earlier [2]. Nitrogen-deficient synthetic medium with sodium lactate as the carbon source was used [3]. The concentration of ammonium chloride (the sole nitrogen source) was 4×10^{-3} M. The data of the experiment reported here are given in Table 1.

Glycogen was isolated from the cells as described earlier [4]. Light-scattering was used for the molecular weight determinations [4]. Fractionation was effected by centrifugation in a Spinco preparative ultracentrifuge. Two fractions were obtained as precipitates after subsequent runs of 20 min at 20 000 *g* and at 105 000 *g*. The supernatant remaining after the last run constituted a third fraction.

A modification of Dische's carbazol method was used for the quantitative determinations of glucose [5].

RESULTS

The molecular weights of the fractions obtained by ultracentrifugal fractionation of the glycogen samples are given in Table 2. Of the three fractions prepared the low molecular weight fraction and the intermediate fraction showed small variations between the different samples. The high molecular weight fraction showed an increase in the molecular weight in rapidly dividing cells.

Nitrogen-limited continuous culture of *E. coli B*. Input concentration of ammonium nitrogen: 56 mg/l.

In a continuous culture steady-state growth can be maintained for long periods of time and the growth rate of the bacteria controlled by the rate of addition of new medium. This "rate of addition" is called the *dilution rate*, defined as f/v, where f is the flow rate of the medium and v is the culture volume. The values given in the last column represent the amount of glycogen synthesized in 1 h per 100 mg bacterial nitrogen.

The glycogen content of these cells was low however, and a large amount of cell material had to be hydrolyzed to obtain the required amount of glycogen. Impurities might have been responsible for the increased molecular weight in these samples.

In Fig. 1 the distribution of glycogen between the different molecular weight fractions is shown. The values are expressed in per cent of the total glycogen of the cells. These values are given in Table 3.

In rapidly dividing cells, at a dilution rate of 0.68 h^{-1}, the amount of glycogen found in the low molecular weight fraction was 50 % of the total glycogen, the high molecular weight fraction contained 45 % and the remainder was found in the intermediate fraction. The glycogen content of these cells was 2.4 % of the dry weight (Table 1).

As reported earlier, the glycogen content of cells cultivated at different growth rates is not uniform [2]. Rapidly dividing cells have a low glycogen content while the reverse is true of slowly dividing cells.

	20 000 *g*	105 000 *g*	supernatant
0.09	61.9	16.3	21.8
0.14	57.4	18.4	24.2
0.27	59.5	14.6	25.9
0.36	58.2	8.7	33.1
0.47	57.7	6.6	35.7
0.68	44.9	5.2	49.9

At a reduced growth rate of the cells, the percentage of glycogen found in the low molecular weight fraction decreased, while the percentage of it in both of the other two fractions increased (Fig. 1). At a dilution rate of 0.09 h^{-1} the low molecular weight fraction accounted for about 22 % of the total glycogen, the intermediate fraction for about 16 % and the high molecular weight fraction for about 62 %. The glycogen content of these cells was about 19 % of the dry weight (Table 1).

DISCUSSION

In the earlier reported experiments [1,4,6] concerned with the synthesis and breakdown of glycogen in *E. coli B*, a special cultivation technique was used involving complete nitrogen starvation. During periods of such starvation, glycogen accumulated in the cells. In the continuous culture, however, nitrogen limitation may be used as a rate-regulating factor and the growth rate of the cells can be varied within a wide range.

As shown earlier [2], the rate of glycogen synthesis increases when the growth rate of the cells is reduced in the nitrogen-limited continuous culture. In the

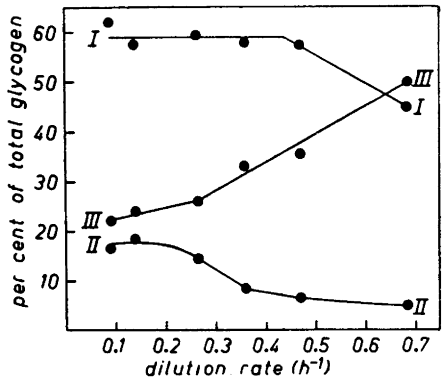

Fig. 1. Distribution of glycogen between different molecular weight fractions. Glycogen samples from *E. coli B* cells grown at different growth rates in continuous culture.

I: high molecular weight fraction.
II: intermediate fraction.
III: low molecular weight fraction.

last column of Table 1 this is confirmed; it can be seen that the rate of glycogen synthesis increases to a maximum at a dilution rate of 0.27 h^{-1}. At lower rates, however, a decrease is noted. This decrease may be the result of such a high content of glycogen in the cells that further formation is inhibited.

In the preceding communication [1] it was shown that there seems to exist two main fractions of glycogen in *E. coli B*, one with a high molecular weight (40—90 $\times$ 10^6) and one with a low molecular weight ($< 2 \times 10^6$). Corresponding fractions are found in the glycogen obtained from continuously cultivated cells, the intermediate fraction never exceeding 20 % of the total glycogen.

From the experiments reported here it can be concluded that the main part of the glycogen that accumulates in slow-growing cells, when their content of glycogen is high, is found in the high molecular weight fraction. When the cells grow at a higher rate, the glycogen content of the cells decreases and at the same time there is an alteration of the distribution ratio of the different molecular weight fractions; half of the total glycogen in these cells may be found in the low molecular weight fraction.

The results are of interest for studies of glycogen metabolism in *Escherichia coli B* since it was previously shown [1], that the different molecular weight fractions have different metabolic activities.

The author is grateful for the skilled technical assistance given by Mr. R. Eliasson and Mrs. Berit Edling. The work has been supported by a grant from the *State Medical Research Council.*

A Combined X-Ray and Neutron Diffraction Investigation of Mercuric Cyanide

JAN HVOSLEF

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway,
Joint Establishment for Nuclear Energy Research, Kjeller, Norway

The precise position of the Hg atom in $Hg(CN)_2$ was found by X-ray methods, while the CN group was localized by means of neutron data. The Hg-C distance is 1.986 ± 0.016 Å and the C-N triple bond is 1.186 ± 0.024 Å. The angle C-Hg-C is 171 ± 2°, while the Hg-C-N angle is 173 ± 2°. The distance between the Hg atom and two N atoms in neighbouring molecules is 2.70 Å. This indicates the existence of an interaction between them.

The space group and approximate Hg positions in $Hg(CN)_2$ were first established by Hassel [1] (1926). Although the light atoms were not detected, he concluded that the lattice must be built up of molecules, and not of separate Hg^{++} and CN^- ions. Later, Hanawolt *et al.*[2] confirmed the proposed structure, and in 1944, Zhdanov and Shugam [3] gave trial parameters for the light atoms, based upon the experimental data of Hanawolt. In a study by infrared spectra of solid $Hg(CN)_2$, Jones [4] was able to confirm the generally accepted opinion that the cyanide group was bound to the Hg atom through the C atom.

The structure was not, however, considered to be firmly established due to the uncertainty of the light atom positions. This uncertainty arises from the dominating influence of Hg *versus* C and N on the scattering of X-rays. For neutron diffraction no such difficulty occurs, as the coherent scattering amplitudes have the following values: $b_{Hg} = 1.30 \times 10^{-12}$ cm, $b_C = 0.66 \times 10^{-12}$ cm, $b_N = 0.94 \times 10^{-12}$ cm.

As no Hg-C distances have been accurately determined it seemed of interest to establish this distance with some precision by means of a neutron diffraction study.

EXPERIMENTAL

Mercuric cyanide crystallizes in the tetragonal space group No. 122 (International tables [5]) D_{2d}^{12}—$I\bar{4}2d$ with eight molecules in the unit cell. The CN groups are in the general 16-fold positions, while the Hg atoms are situated in the 8-fold position (*d*) with one degree of freedom only.

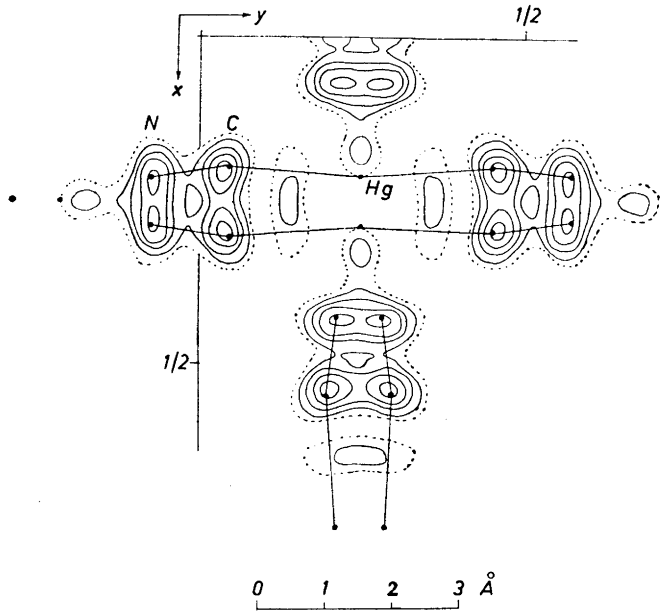

Fig. 1. Fourier projection on (001) of the electron density of the cyanide group in $Hg(CN)_2$, resulting from a synthesis of the coefficients $\{F_{obs}-F_c(Hg)\}$. Final coordinates are indicated by dots. Intervals at arbitrary scale.

The axial lengths were remeasured and found to be $a = 9.643$ Å and $c = 8.880$ Å. Hassel's values were 9.67 Å and 8.92 Å, respectively.

For the X-ray investigation a very small specimen was chosen. The data were recorded on Weissenberg diagrams, using Cu radiation. Multiple film technique and visual estimation was used to obtain the intensities in the $hk0$ zone. No $0kl$ data were recorded.

For the neutron work, a crystal with the dimensions 4.2 × 3.3 × 1.8 mm^3 was grown from aqueous solution. The crystal was mounted on the goniometer

described by Barstad and Andresen [6]. The neutron source was the Kjeller reactor JEEP, using monochromatic beam with wavelength 1.132 Å. Data for the *hk*0 and 0*kl* zones were recorded.

X-RAY WORK

A very accurate value for the parameter of Hg was derived from the X-ray data by means of Fourier methods. Due to the dominating influence of this atom in the X-ray spectra, a temperature parameter $B_{Hg} = 1.1$ Å^2 could be

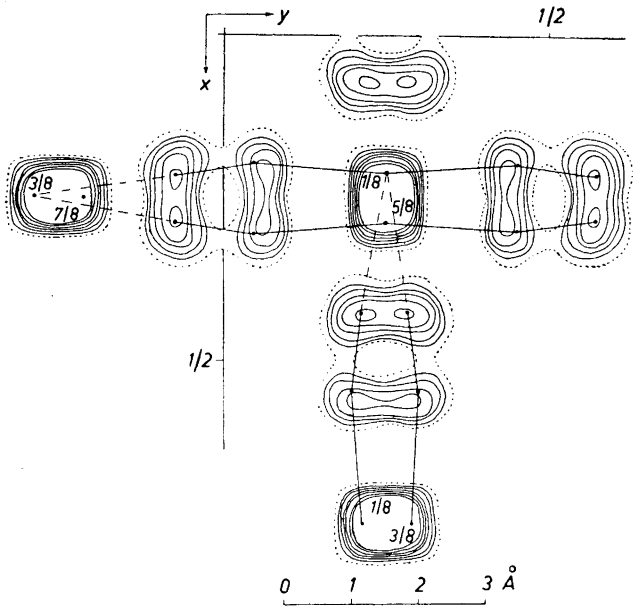

Fig. 2. Fourier projection on (001) by neutron data. Final coordinates are indicated by dots, and *z*-parameters of Hg are given as fractions of the cell edge. Broken lines indicate the Hg..N interactions. Contours are drawn at intervals of 0.33 × 10^{-12} cm/Å^2. The zero level is dotted.

assigned to this atom without knowledge of the precise light atom positions. Hence a difference synthesis with the coefficients (F_{obs}—$F(Hg)_{calc}$) could be made. In the Fourier map (Fig. 1) the light atoms show up, indicating a slight deviation from linearity in the molecule. The parameters are listed in Table 1, and observed and calculated absolute values of the amplitudes are given in Table 2. The *R* index for the X-ray data with final parameters was 8.1 % when reflexions believed to be seriously affected by extinction were omitted.

Significant deviation from linearity in the molecule could, however, not be claimed from the X-ray data.

TREATMENT OF NEUTRON DATA

The approximate light atom positions formed the basis for further work with the neutron data. From the *hk*0 data it became evident that the linear model must be rejected. The Fourier map in Fig. 2 also indicates this, although it suffers severely from series termination errors. Successive (F_o—F_c) syntheses finally lead to the parameters given in Table 2. The *B* value for C and N in this zone was 1.7 Å^2.

In the projection along the *a* axis, the *z* parameters are determined from the inclination of N—C—Hg—C—N with the *c* axis. For this angle, Zhdanov

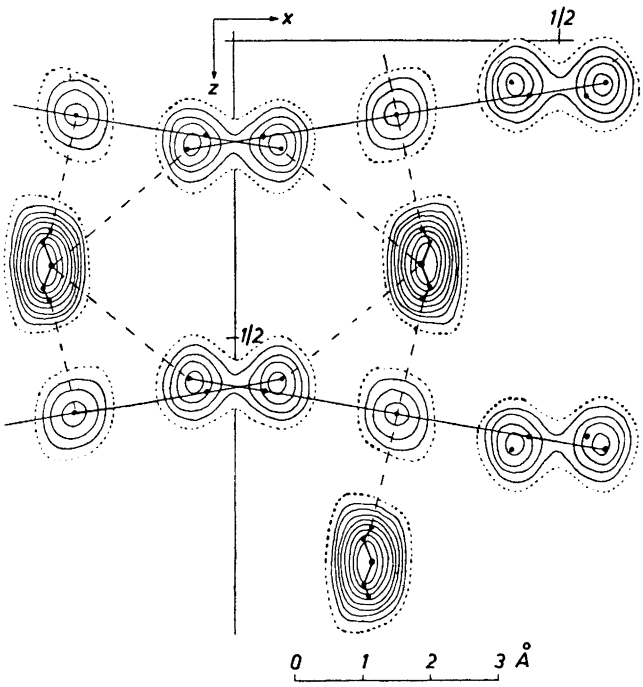

Fig. 3. Fourier projection on (100) by neutron data. Contour intervals are now drawn at intervals of 0.66×10^{-12} cm/Å^2. The interaction between Hg and neighbouring N atoms form zig-zag chains through the lattice, as shown by the broken lines.

and Shugam [3] suggest 76.5° while Jones [4] finds 73°. The treatment of the neutron data for this projection finally lead to the Fourier map shown in Fig. 3. It is unfortunate that most atoms overlap, but as the x and y parameters were known, the z parameters could be determined by a combination of trial-and-error methods and (F_o—F_c) syntheses. During this procedure, the parameters finally converged to the values listed in Table 1. It appeared from these values that the inclination of the molecule to the c axis was 81.2°.

Larger values for the temperature amplitudes were found in this projection. No attempt was made to correct for anisotropy, but it is believed that the higher B values ($B_{Hg} = 2.8$ Å^2, $B_{CN} = 3.3$ Å^2) are significant, indicating higher amplitudes along the c axis.

The over-all R index for the neutron data was 8.9 %, the zero observed reflexions omitted. Absolute values of the neutron amplitudes are listed in Table 2.

RESULTS AND DISCUSSION

The intramolecular distances and their estimated standard deviations (Cruickshank [7] 1949) are as follows: Hg—C = 1.986 ± 0.016 Å, C—N =

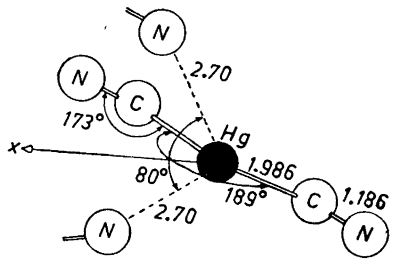

Fig. 4. The atomic arrangement around a Hg atom. The N...Hg...N plane is at an angle of 92° to the plane through the $Hg(CN)_2$ molecule, and the direction from a Hg atom along the x-direction bisects the N..Hg..N and C-Hg-C angles.

1.186 ± 0.024 Å. The angles are: C—Hg—C = 171 ± 2°, Hg—C—N = 173 ± 2°.

From the e.s.d. it must be concluded that the deviation from linearity in N—C—Hg—C—N is significant. In this connection, it is interesting to note that the distance from a mercury atom to two crystallographically equivalent N atoms in neighbouring molecules is 2.70 Å, *i. e.* 0.3—0.4 Å shorter than the van der Waals distance. The N...N distance is 3.44 Å, and the plane N...Hg...N is almost normal to C—Hg—C. Fig. 4 illustrates the atomic arrangement around a Hg atom. All other intermolecular distances have normal values.

These relationships indicate an interaction between Hg and the neighbouring cyanide groups which may be interpreted as due to electrostatic attraction. This attraction is thought to arise from the strong polar properties of the CN group, leaving a small positive charge at the Hg atom and a negative charge at the N atoms. This possibility has also been pointed out by Zhdanov and Shugam, but their N...Hg distance was only 2.52 Å, which would imply a stronger interaction.

Considering the N...Hg interaction as a bond, the $Hg(CN)_2$ molecules are linked together in endless zig-zag chains through the lattice. This is illustrated in Fig. 3.

This investigation was suggested by Dr. G. C. A. Schuit of the Koninklijke/Shell Laboratory, Amsterdam, in connection with the work in progress there in the structure of HgX_4^{--} ions.

The author wants to express his gratitude to Professor O. Hassel, Oslo and to Dr. J. A. Goedkoop, Kjeller for their kind help and many illuminating discussions. *Norges almenvitenskapelige forskningsråd* is acknowledged for financial aid.

ACTA CHEMICA SCANDINAVICA 12 (1958) 1575—1584

Degradation of ^{14}C-Labelled Carolic and Carlosic Acids from *Penicillium Charlesii* G. Smith

SIGVAR LYBING and LEMBITU REIO

Department of Physiological Chemistry, The Wenner-Gren Institute, University of Stockholm, Sweden

From cultures of *Penicillium Charlesii* G. Smith, grown on glucose and ^{14}C-carboxyl-labelled acetate as an additional carbon source, labelled carlosic and carolic acid have been isolated. Itaconic acid, not earlier reported for this species, has also been isolated. Degradation procedures for the two tetronic acids have been worked out and on the basis of the observed isotopic distribution, the synthesis of the tetronic acids is suggested to take place as a condensation between a high labelled 6-carbon unit of β-keto acid type derived directly from acetate by head-to-tail coupling and a low labelled 4-carbon member of the citric acid cycle, the latter being comparatively more diluted by unlabelled carbon from glucose during the incorporation of the acetate added.

It is known from the work of Raistrick and his collaborators [1,2] that *Penicillium Charlesii*, when grown on glucose, produces five closely related acids of the tetronic acid type: carolic, carlosic, carolinic, carlic and γ-methyltetronic acid. From other *Penicillium* species and molds in general a vast number of different organic compounds have been isolated and structurally determined, to a great extent by the work of the Raistrick school, but relatively little is known about the metabolic pathways which lead to the synthesis of these substances. The use of radioactive isotopes, added to the culture medium in the form of labelled glucose, acetate or other intermediary metabolites, is here, as has been the case in the studies on bacterial metabolism, one way of approaching the problem of mold biosynthesis. Among the increasing number of investigations of this kind, the papers by Arnstein and Bentley [3] on the formation of kojic acid, the work by Bentley and Thiessen [4] on itaconic acid biosynthesis and Birch's [5] studies on the synthesis of aromatic compounds can be mentioned.

The study of *Penicillium Charlesii* was suggested by Professor G. Ehrensvärd * as an interesting parallel to a more extensive investigation on the

* Now Professor of Biochemistry, University of Lund, Sweden.

production of phenols and phenol-carbonic acids by *Penicillium* molds belonging to the species *brevi-compactum*, *griseo-fulvum*, *patulum*, *urticae* and *Daleae*. The biosynthesis of aromatic seven- and eight-carbon compounds from glucose by *P. urticae* is discussed in a paper by Ehrensvärd [6].

In order to get a more detailed picture of the metabolic production pattern of *Penicillium Charlesii*, a systematic search for substances in the culture medium was made, using a chromatographic method specially worked out at the laboratory for the study of mold metabolites [7]. With this method new substances could be detected and chromatographically defined, even though their structures were not known.

From the medium of younger cultures grown on glucose (14 days) itaconic acid, not earlier reported for this species, could be isolated in fairly large amounts (0.5 g from six cultures). In older cultures itaconic acid was present in much smaller amounts, for example, only 0.4 g could be isolated from forty-five cultures grown on glucose for a period of 47 days. This suggested that itaconic acid during the incubation period was taken up again from the medium and might be used as an intermediary metabolite in the synthesis of the tetronic acids. To test this possibility ^{14}C-carboxyl-labelled acetate was added to culture medium containing glucose with the expectation of obtaining ^{14}C-labelled itaconic acid. The labelled acid was then intended to be used as an additional carbon source in cultures of the same age as those from which it was to be isolated in order to study its eventual incorporation in the tetronic acids. After two weeks, however, itaconic acid could only be found in very small amounts, while on the other hand carolic and carlosic acid could be isolated, yielding about 0.25 g of each acid from five cultures. The labelled acetate was incorporated in itaconic acid as well as in the two tetronic acids. Addition of acetate apparently increased the formation rate of the tetronic acids, which normally could not be isolated from 2 weeks old cultures.

As itaconic acid could not be isolated in amounts sufficient either for addition to growing cultures, or to permit a complete degradation, no conclusions as to its role in tetronic acid synthesis could be drawn. The purpose of this paper will be to present degradation procedures for carolic and carlosic acid and to report the results of these degradations.

EXPERIMENTAL

Cultivation: Penicillium Charlesii P146, obtained by the courtesy of Professor H. Raistrick at the London School of Hygiene and Medicine, was grown at a temperature of 24°C on a modified Czapek-Dox solution of the following composition: glucose 50.0 g, $NaNO_3$ 2.0 g, KH_2PO_4 1.0 g, KCl 0.5 g, $MgSO_4 . 7H_2O$ 0.5 g, $FeSO_4 . 7H_2O$ 0.005 g, distilled water 1 000 ml and $ZnSO_4 . 7H_2O$ added to give a final concentration of 10^{-6} M of the Zn^{2+}-ion. 1 liter, flat bottom culture flasks, containing 500 ml of the modified Czapek-Dox solution, were inoculated with a spore suspension of about 2×10^6 spores per flask.

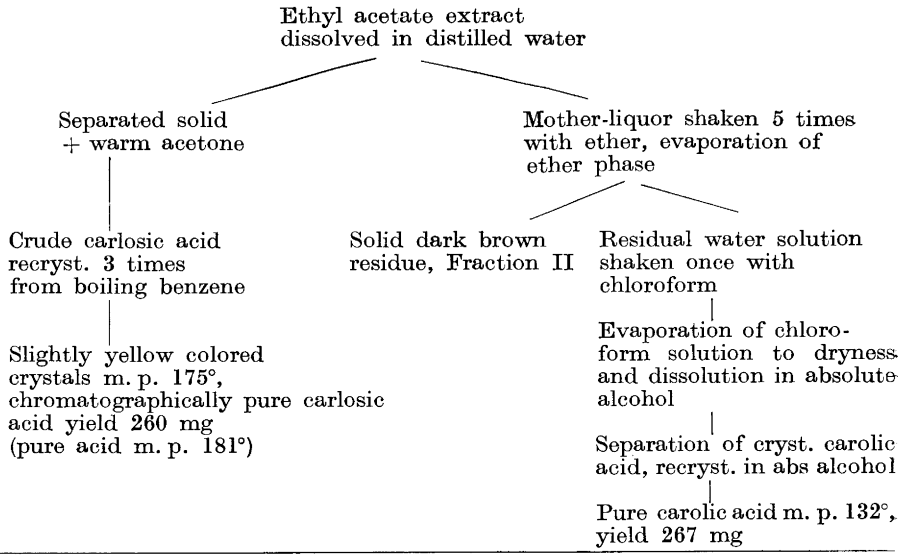
In the isotope experiment 50 mg of ^{14}C-carboxyl-labelled sodium acetate was added on the 3rd and 5th days after inoculation. Altogether 100 mg of labelled acetate (214 000 counts/min/mg carbon in the carboxyl group) was added to each of five culture flasks.

Isolation: After a growing period of two weeks, the culture medium was separated from the mycelium by filtration through cotton wool. The solution from five flasks, about 3 l including 500 ml distilled water used for washing of the mycelia, was evaporated

in vacuo to 200 ml. The solution was then, after acidification with 8 ml of concentrated hydrochloric acid, shaken 5 times with a total of 500 ml ethyl acetate. This extract was evaporated *in vacuo* to 50 ml and upon standing for a couple of days the solution solidified into a sticky mass of dark brown crystals, weighing 7.6 g. From this crude mixture of substances carolic and carlosic acid were isolated according to the procedure outlined in Table 1.

Table 1.

Table 1. Isolation of carolic and carlosic acid.



Both acids were chromatographically tested in six different systems [7], and were found to give R_F values identical with those of the corresponding acids obtained from Professor Raistrick's laboratory and also isolated here from larger cultures.

Chromatography of different fractions during the isolation procedure did reveal the presence of itaconic acid only in the crude mixture called fraction II in Table 1.

This fraction was further purified by repeated crystallisation from chloroform, giving 100 mg of a crystalline substance, by chromatography test found to be a mixture of carlosic and itaconic acids. 50 mg of this mixture was run on a silicic acid column and eluted with chloroform and 5—15 % solutions of butanol in chloroform, according to the scheme worked out by Marvel and Rands [8]. The effluent peak volumes for carlosic and itaconic acid were 200 ml and 290 ml, respectively, identical with the values obtained for a test mixture of the same substances. The eluent was collected in 10 ml fractions, which were titrated with 0.2 N NaOH using phenol red as an indicator. The fractions containing itaconic acid were evaporated to dryness but could not be separated from the indicator substance without losing most of the acid at the same time. The remaining 50 mg of the ^{14}C-labelled carlosic-itaconic acid mixture was run on a silicic acid column in exactly the same way as the first portion with the exception that the collected fractions were not titrated. The fractions known to contain itaconic acid were evaporated to dryness, giving 11.8 mg of practically pure itaconic acid.

Degradation: Hydrolysis of the tetronic acids in 2 N sulphuric acid is known [2] to break up the ring to give carbon dioxide and acetoin, one molecule of each, and a third molecule of a 4-carbon compound formed by the side chain attached to the α-position of the ring.

The side chains of carolic and carlosic acid give one molecule of γ-butyrolactone and butyric acid, respectively.

The common procedure for the different steps worked out for the degradation of carolic and carlosic acid is outlined in the following.

1 mmole of the acid is hydrolyzed for 24 h in 10 ml of 2 N sulphuric acid at a temperature of 140°C. A stream of CO_2-free nitrogen is passed through the hydrolysis solution into a flask with saturated $Ba(OH)_2$ solution to take up the CO_2 formed, on its way passing another flask with 2,4-dinitrophenylhydrazine to trap any acetoin leaving the solution. The CO_2 coming from the ring is easily split off during the first three hours of hydrolysis, while on the other hand the second molecule of CO_2 from the carboxy-methyl group in the γ-position of carlosic acid is more slowly released. By prolonged hydrolysis for 23 h about 60 % of this carboxyl group is recovered as $BaCO_3$ as seen from the values in Table 2. Another 6 h of hydrolysis does not increase the yield. The hydrolysis flask is supplied with an efficient reflux-condenser to decrease the amount of acetoin carried along with the nitrogen stream.

The hydrolysate was then neutralized (to phenolphthalein) with a 33 % solution of NaOH and steam distilled in order to blow over the acetoin. 100 ml of distillate was collected, a large enough volume for all the acetoin to be carried over. The acetoin solution was further treated, according to the method of Clutterbuck and Reuter [9], with 10 ml of 2 N H_2SO_4 and 300 mg (1.3 mmole) of potassium periodate for the oxidation of acetoin to acetaldehyde and acetic acid. Merely keeping the mixture at room temperature for 23 h, as suggested by Clutterbuck and Reuter, was in this case not very effective. A more complete splitting of the molecule was obtained by keeping the solution at 60°C for about 70 h. During this time nitrogen was continuously bubbled through the solution and the acetaldehyde formed was passed *via* an alkaline trap (2 ml 0.01 N NaOH) to take up any acetic acid carried along, into a chromic acid solution (6 N H_2SO_4 + 0.8 N CrO_3) kept at 70°C. The chromic acid solution was later steam distilled and the acetic acid (from acetaldehyde) was titrated with 0.2 N NaOH and put aside for further degradation.

In order to recover the acetic acid split off from acetoin, the reaction mixture was neutralized, evaporated to about 10 ml and after acidification with H_2SO_4 solid sodium sulphite was added in amounts just enough to reduce all the iodine to iodide. The solution could then be steam-distilled and the acetic acid titrated and stored for later Schmidt degradation.

The neutralized hydrolysate contained after steam-distillation sodium butyrate or sodium γ-hydroxybutyrate, depending upon whether carlosic or carolic acid was degraded. Alkaline titration of butyrolactone at a temperature of 80 – 90° did within about 2 h lead to the complete opening of the lactone ring and the formation of sodium γ-hydroxybutyrate. Butyrolactone and butyric acid were separated from the neutralized hydrolysis mixture by steam-distillation after acidification with conc. H_2SO_4.

Butyric acid was after titration with 0.2 N NaOH and evaporation to dryness ready for Schmidt degradation. Butyrolactone on the other hand, or rather Na-γ-hydroxybutyrate obtained after alkaline titration, had to be reduced to butyric acid. This could be done in one operation by heating the sodium γ-hydroxybutyrate (about 0.5 mmole) in a bomb tube containing 1 ml of hydriodic acid, d 1.96, for 5 h at a temperature of 230°C. At this temperature the γ-iodo-butyric acid, formed already at lower temperatures [10], was further converted to butyric acid. The acid was separated from the reaction mixture after dilution to about 20 ml with distilled water and addition of solid sodium sulphite until all the iodine was reduced to iodide. 3 g of silver sulphate dissolved in 3 ml of 85 % H_2SO_4 was then added in order to precipitate the iodide-ions as silver iodide. The precipitate was filtered off, the filtrate steam-distilled and the distillate, containing butyric acid, titrated and evaporated to dryness.

In this manner all the degradation products from carolic and carlosic acid, with the exception of the CO_2 formed during hydrolysis, were obtained in the form of fatty acids suitable for further degradation by the Schmidt procedure [11].

The total ^{14}C-content of the labelled substances was determined by combustion to CO_2 in a stream of oxygen passed through a quartz tube over a platinum gauze heated to 800°C.

RESULTS

The results of the degradations are presented in Tables 2 and 3 and Fig. 1. 1 mmole of each acid was taken for hydrolysis. Carlosic acid was mixed with non-active acid in the proportion 1:1, while carolic acid was degraded without being diluted. The CO_2 formed, either by hydrolysis, by Schmidt degradation or by total combustion, was trapped in a saturated barium hydroxide solution as $BaCO_3$. The ^{14}C-content was determined on 15 mg samples of uniform layers or $BaCO_3$ on 1 cm^2 discs under standard conditions, using a Tracergraph Geiger counter with an automatic sample changer. The ^{14}C-content is given in counts per min per mg carbon counted as $BaCO_3$. The ^{14}C-values of the different carbon atoms of carlosic acid are multiplied by two in order to get values comparable to those obtained for undiluted carolic acid.

Table 2. Degradation of carlosic acid.

Substance formed	time after start of hydrolysis	mmole of CO_2 collected during the diff. time intervals	^{14}C-content counts/min/ mg carbon	amounts in mmole of the degradation products
CO_2:	35 min	0.25	1 600	0.25
	1 h 10 min	0.35	1 564	0.60
	1 h 45 min	0.18	1 598	0.78
	2 h 20 min	0.09	1 278	0.87
	3 h 10 min	0.11	1 080	0.98
	11 h 40 min	0.43	560	1.41
	22 h 55 min	0.17	488	1.58
Acetoin:

* About 0.5 mmole of the butyrolactone was used in order to try the Schmidt degradation on sodium γ-hydroxybutyrate without previous reduction to butyric acid. The yield of the degradation was, however, only about 15 %.

The isotope content of the CO_2 split off from the tetronic acid ring is in the case of carolic acid a mean value of the two determinations made, in the case of carlosic acid a mean value of the first three determinations, containing undiluted CO_2 from the ring. The following fractions, obtained from carlosic acid, have a continuously decreasing isotope content depending upon a mixing with low labeled CO_2 from the carboxy-methyl group at the γ-position. The ^{14}C-content given for this carboxyl carbon might be regarded as a maximum value due to contamination by heavily labelled CO_2 from the ring.

In the above-mentioned paper by Clutterbuck and Reuter [9] it is indicated that by periodate oxidation of acetoin the carbonyl carbon and its adjacent methyl group yield acetic acid and the carbinol group and its adjacent methyl group are split off as acetaldehyde. Whether the symmetrical labelling found for acetoin corresponds to the original isotopic distribution between the β- and γ-carbon atoms in the tetronic acid ring (see Fig. 1) is doubtful. The asymmetrical carbon atom in the carbinol group in the γ-position is responsible for the optical activity of the tetronic acids. As hydrolysis of an ester linkage

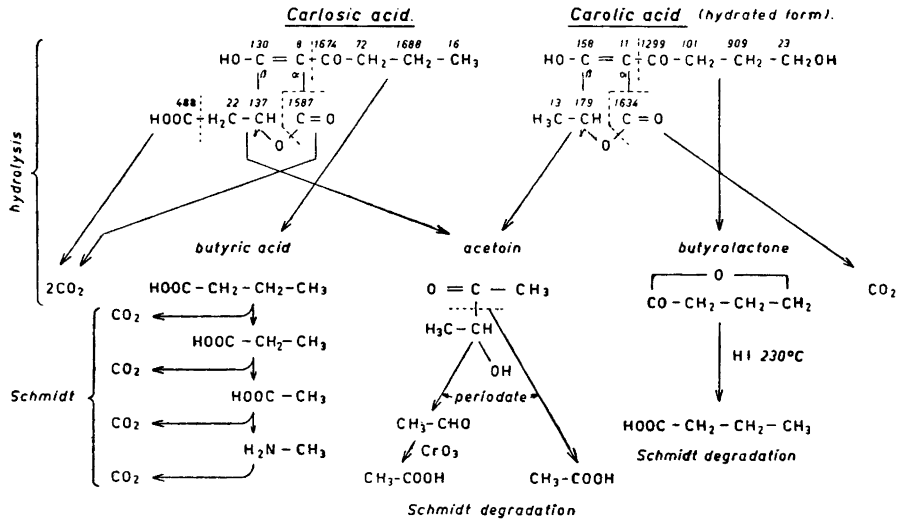

Fig. 1. Degradation scheme for carlosic and carolic acid. The values refer to the isotope content in counts/min/mg C, showing the incorporation of $CH_3{}^{14}COOH$ (214 000 counts/min/mg C in the carboxyl group).

normally does not lead to the rupture of the bond between the carbon atom and the attached hydroxyl group of a secondary alcohol [12], the acetoin formed by hydrolysis would be expected to show optical rotation. The fact that the optical activity of the solutions of carolic and carlosic acid dropped to zero during the hydrolysis, shows, however, that there must have been a change in the configuration of acetoin. As this change is probably not just a stereochemical alteration within the carbinol group [12], an exchange of substituents between the carbinol and carbonyl groups must be assumed to have taken place, with a mixing of the isotope contents as a consequence.

The isotope content found for the β- and γ-carbon atoms might then originally have been built into either one of these two carbon atoms.

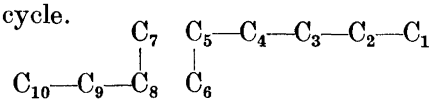
It has also been shown by Juni [13] that in unevenly labelled acetoin, produced by yeast, there occurs some mixing between the carbon atoms, for example by alkaline steam-distillation. In the present investigation it was not necessary to avoid alkaline steam-distillation for the separation of acetoin from the hydrolysis mixture, as at this stage acetoin was already optically inactive.

The only certain information about the ^{14}C-incorporation in itaconic acid was obtained by total combustion. Two determinations gave a mean value of 225 counts/min/mg carbon.

DISCUSSION

From the results of the incorporation of ^{14}C-labelled acetic acid in carolic and carlosic acid it is evident that, in the synthesis of the two acids, a common plan is followed. Considering carlosic acid, the distribution of the ^{14}C-isotope

indicates that the molecule can be regarded to be composed of two differently labelled parts, one 6-carbon and one 4-carbon unit, the former about 10 times as heavily labelled as the latter. The 6-carbon chain seems to be more directly built up from acetyl groups, whereas the lower isotope content of the other part points to a greater dilution with carbon from unlabelled glucose, probably over the citric acid cycle.



If this 4-carbon part, represented by the carbon atoms C_7 to C_{10} in the schematic formula given above (arbitrarily numbered), should at all be considered as a ^{14}C-labelled member of the citric acid cycle, it should have its ^{14}C-carbon mainly in C_7 and C_{10} corresponding to the carboxyl groups of one of the four dicarboxylic acids. The diverging results obtained, *i. e.* an equal distribution of the isotope between C_7 and C_8, can be accounted for, as was discussed earlier, by a change in the configuration of the acetoin molecule formed in the course of the hydrolytic breakdown of the tetronic acids. The isotope content of these two carbon atoms can thus be thought of as originating from C_7. The isotope content of this carbon is thereby increased to 267 counts/min (337 counts/min in the case of carolic acid), a value of the same order of magnitude as that of C_{10}, 488 counts/min.

If the total ^{14}C-content, $5 \times 225 = 1\ 125$ counts/min, obtained for itaconic acid, is assumed to be equally distributed between the two carboxyl groups, a distribution found in itaconic acid from *Aspergillus terreus*, fed carboxyl-labelled acetate [4], the ^{14}C-content of each group will be about 500 counts/min. This value is comparable in magnitude to the isotope contents of C_7 and C_{10}, supposed to originate from the carboxyl groups of a dicarboxylic acid, thus suggesting that itaconic acid in *Penicillium Charlesii* might also be formed over the citric acid cycle.

Even if the results do not suggest a definite scheme for the synthesis of the tetronic acids, they seem, however, to exclude a few pathways along which the acids probably not are formed.

A similar formation mechanism for ascorbic acid and the tetronic acid ring might be anticipated from the structural relationship between the two compounds. The tetronic acid ring would then in accordance with ascorbic acid be synthesized from glucose [14], so that the carbon sequence 6—1 in the glucose molecule would correspond to the carbon sequence 6, 5, 7, 8, 9, 10 in the schematic formula shown above. In glucose labelled by the incorporation of ^{14}C-carboxyl acetate the isotope will appear [15] in carbon atoms 3 and 4. Tetronic acid formed in this way from glucose would thus be labelled in C_7 and C_8. This is in accordance with the results, but the labelling of C_{10} and the high isotope content of C_6 cannot be accounted for by this scheme.

Another route for the formation of the tetronic acids would be a synthetic pathway over acetoin as an intermediary step. Such a mechanism is, however, not consistent with the results obtained, as it does not explain either the origin of the heavily labelled carbon in the carbonyl group in C_6 or the presence of the carboxyl group in C_{10}. Acetoin was furthermore never chromatographically detected in any of the isolated fractions.

Although tracer studies of this kind have their limitations, especially when a number of alternative pathways can be considered for the formation of a certain metabolite, the following speculations on tetronic acid synthesis are cautiously presented as consistent with the observed isotopic distribution.

The formation of the tetronic acids is thought to take place as a condensation between a 6-carbon chain, β-keto-caproyl-coenzyme A, formed *via* acetyl groups in fatty acid synthesis, and a 4-carbon compound of the citric acid cycle. If placed in the schematic formula shown above the β-keto acid will have its carboxyl group in C_6 and the carboxyl groups of the dicarboxylic acid will be in C_7 and C_{10}. The most suitable configuration of the dicarboxylic acid would be that of malic acid with the carbinol group in C_8 and a CoA-linked carboxyl group in C_7. The latter might then take part in a condensation reaction with the methylene group in C_5, activated and having a tendency to give off protons due to the influence of the adjacent carbonyl group and the CoA-linked carboxyl group. The hydroxyl group at C_7 would be formed by enolization, which also would give the double bond between C_5 and C_7. To complete the ring an ester linkage is then assumed to form between C_6 and C_8. Some support for the idea of malic acid as the 4-carbon unit is given by the findings of Larsen and Eimhjellen [16] that malic acid is accumulated with exclusion of itaconic acid in cultures of *Aspergillus terreus*, when the pH of the medium is increased by addition of $CaCO_3$. Whether an increase of the pH-value during the growth period is responsible for the observed accumulation of tetronic acids in preference to itaconic acid in younger cultures of *Penicillium Charlesii* cannot be settled. The pH-value of the culture medium was found to be almost the same before and after an incubation period of 14 days, 4.4 and 4.3 pH-units, respectively. Whatever the cause of the changed production pattern, the accumulation of tetronic acids with the exclusion of itaconic acid might be favored by an increased formation of malic acid. The assumption that malic acid would be present in a CoA-linked form is purely speculative.

The condensation might also take place between β-keto-caproyl-CoA and succinyl-CoA as the activated form of the dicarboxylic acid. It is known that succinyl-CoA by the action of the enzyme thiophorase preferentially gives off its coenzyme A to β-keto acids [17]. For the case that the β-keto acid already is activated by coenzyme A it seems not impossible that a condensation can take place instead. Once the 4-carbon part is attached to the methylene group in C_5, it might then be oxidized and hydrated in order to get a hydroxyl group in C_8, required for an ester linkage to be formed between C_6 and C_8.

Carlosic acid synthesized in this way by condensation of 6-carbon and 4-carbon units might then by decarboxylation of the carboxyl group in C_{10} and oxidation of the methyl group in C_1 to a hydroxy-methyl group be transformed to carolic acid. Oxidation of C_1 in carlosic acid to a hydroxy-methyl group would give carlic acid; decarboxylation of C_{10} together with an oxidation of C_1 to a carboxyl group would lead to the formation of carolinic acid. γ-Methyl-tetronic acid, finally, might be formed by hydrolysis of the bond between C_4 and C_5 from any of the other four tetronic acids, in the case of carlosic and carlic acid a decarboxylation of the carboxyl group in C_{10} would also be required.

γ-Methyltetronic acid might also be considered as the parent substance synthesized by a condensation of acetyl-CoA and activated malic acid or succinyl-CoA.

The authors wish to express their thanks to Professor G. Ehrensvärd for his stimulating interest in this work.

Duodenal Glucuronide Synthesis

I. Identification of Estradiol Glucuronide as a Conjugation Product of Estradiol by the Rat Duodenal Mucosa. Qualitative Studies

ANITA LEHTINEN, V. NURMIKKO and K. HARTIALA

Department of Physiology, University of Turku, Finland

Upon incubating estradiol with slices of duodenum taken from 5 rats a product with the properties of estradiol glucuronide is formed. This product which is extractable from acid solution by ethylacetate gives after hydrolysis with β-glucuronidase chromatographically a qualitative reaction for estradiol and glucuronic acid.

Previous studies by one of us [1,2] have shown that in addition to the liver also mucosal specimens taken from various regions of the gastrointestinal tract are able to conjugate glucuronides *(in vitro)* in the presence of *o*-aminophenol. According to these observations the intestinal glucuronide synthesis participates in the detoxication processes of the organism.

Feeding of another glucurogenic substance, cinchophen, to a dog leads to increased glucuronide contents of portal blood also under conditions when the bile flow into the intestine is prevented [3]. Recently we have also been able to identify phenolphthalein-glucuronide as a conjugation product of the duodenal mucosa [4].

In the present work estradiol is used as the substrate. Its conjugation to a glucuronide by the duodenal mucosa *in vitro* has been demonstrated.

MATERIAL AND METHODS

Tissue specimens. Rats were used in these experiments. The animals were killed by a blow on the head. The tissue specimens were removed immediately, the size of specimens kept equal by means of a starsis. The samples were first placed into the ice cold incubation mixture.

Estradiol. Chrystallized estradiol (Sigma Co., 4.9 mg) was dissolved in 2 ml of propyleneglycol [5].

Incubation. This was carried out in the Warburg apparatus at 37°C over a period of 90 min. The incubation solution (Krebs-Ringer) contained 100 mg glucose and 112 mg sodium lactate per 50 ml of the mixture. Into each Warburg flask were transferred 2.9 ml of this Ringer solution, 0.1 ml of the estradiol propyleneglycol solution (0.9 μmole estradiol) and after this the tissue specimens (approximate dry weight 8—10 mg). Gas phase was 5 % carbon dioxide in oxygen. As controls parallel runs were made with the incubation solution without tissue slices and also with tissue slices but without estradiol.

Sampling. After incubation the contents of 2 Warburg flasks were combined to make one sample for further concentration and chromatographic analysis. The tissue slices were removed from the incubation media and washed with 2 ml Ringer solution (6 ml + 2 ml).

Deproteinization. The incubation mixture was heated at 60°C for 3 min and centrifuged thereafter.

Extraction of free estradiol [5]. The clear protein-free supernatant was extracted with 10 ml of benzene (3 × 10 min). The precipitate left after the previous centrifugation was washed with absolute alcohol (1 ml), centrifuged and the alcohol supernatant added to the benzene solution. This was then evaporated in vacuum.

Extraction of estradiol glucuronide. The water phase left after benzene extraction was made 2 N with HCl and the glucuronide was extracted with ethylacetate (10 ml, 3 × 10 min). The ethylacetate was removed in vacuum.

Hydrolysis. To the ethylacetate residue were added acetate buffer (2 ml, 0.1 M, pH 4.5) and β-glucuronidase enzyme preparation (2 mg, Worthington Biochem. Corp.). The hydrolysis was carried out over a period of 24 h at 37°C.

Extraction of the estradiol liberated by hydrolysis. After the hydrolysis with β-glucuronidase the incubation solution was reextracted with benzene (7 ml, 3 × 10 min). Benzene was removed in vacuum as usual.

Glucuronic acid. The glucuronic acid made free by hydrolysis and after extraction with benzene is left in the water phase. This was evaporated to dryness and subjected for further analysis.

Paper chromatography. 1 ml of a solvent (ethylacetate/benzene) was added to each residue and the solutions were used for chromatographic analyses. These were carried out according to the descending chromatography method. A mixture of butanol, glacial acetic acid and water was used as an irrigant; 24 h, Paper Whatman No. 1. Estradiol spots were identified on the paper by a saturated aqueous solution of *p*-nitrobenzene-azodimethoxy-aniline (Fast Black Salt K, Heftman, 1950). Glucuronic acid was identified with the $AgNO_3$-ammonia reagent (1 vol. 0.1 N $AgNO_3$, 1 vol. 5.0 N NH_3-solution. 1 vol. 2 N NaOH).

RESULTS

From the acidified incubation mixture a compound was extracted with ethylacetate which, on hydrolysis with β-glucuronidase, gave spots for free estradiol and glucuronic acid.

Estradiol glucuronide. The nonhydrolyzed residue after evaporation of the ethylacetate extract failed to give a violet spot on the paper after fixation with Fast Black Salt K (Fig. 2. H, I, J,). This reagent is known to produce such colour with free estradiol [6]. This finding indicates that the estradiol is in a conjugated form in the ethylacetate extract. Spots F and G in Fig. 2 were obtained using 100 μg and 150 μg pure estradiol. From the nonhydrolyzed residue no dark brown spot characteristic for glucuronic acid was formed with the ammonia silver nitrate solution (Fig. 3. A, B, C). The small spots seen at A, B and C are probably caused by some carbohydrate impurities reacting with the potent silver nitrate reagent. The R_F-values of these are distinct from those given by pure glucuronic acid. Spot D corresponds to 150 μg of pure glucuronic acid.

Estradiol and glucuronic acid liberated by hydrolysis. After the hydrolysis a compound dissolved in benzene which on the chromatogram appeared to be estradiol (Fig. 2. A, B, C and D). Spots for pure estradiol are also shown in the same figure (F, G).

Fixation with the ammonia-silver nitrate reagent produced from the hydrolyzed samples spots characteristic for glucuronic acid (Fig. 3. E and F).

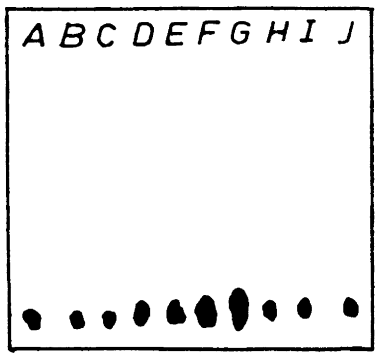

Fig. 1. Unconjugated estradiol. A, B, C, D, H, I, J spots of estradiol left unconjugated during the incubation (in the benzene-alcohol extract). Stained with Fast Black Salt K. G. control solution. E with 100 μg and F with 150 μg of estradiol.

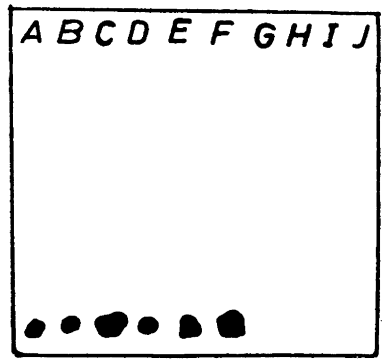

Fig. 2. Estradiol glucuronide. No dark spots characteristic for free estradiol could be obtained from the nonhydrolyzed ethylacetate residue after staining with Fast Black Salt K. (G, H, I, J). Free estradiol. A, B, C, D free estradiol spots after hydrolysis with β-glucuronidase. E and F obtained with 100 μg and 150 μg estradiol.

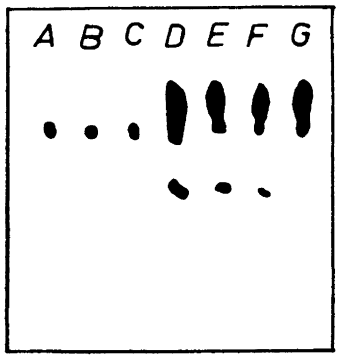

Fig. 3. Free glucuronic acid. E, F, G obtained by hydrolysis with β-glucuronidase; staining with the $AgNO_3$-ammonia reagent. A, B, C nonhydrolyzed samples. D with 100 μg of glucuronic acid.

A spot developed from pure glucuronic acid is shown in the same picture (D). It is to be noted that the spot obtained from the hydrolyzed samples lies higher on the paper than that of pure glucuronic acid. Since this observation was familiar from our previous trials 50 μg pure glucuronic acid was added to the samples of the nonhydrolyzed residue. After the development of the chromatogram the dark spot (Fig. 3. G) appeared at the same point as in the original hydrolyzed samples (Fig. 3. E and F).

Since the spots are formed also with pure glucuronic acid the compound indicated by them apparently is formed during the run. They do not correspond to the R_F-values obtained with glucuronic acid lactone. One possibility is that they are esters formed from glucuronic acid and butanol. The presence of these additional spots does not invalidate the fact that spots representing free glucuronic acid are also produced by hydrolysis of the ethylacetate extract.

Unbound estradiol. The part of the estradiol which remained unconjugated during the incubation and which was extracted with the benzene alcohol extracts appeared very nicely as violet spots in the chromatograms (Fig. 1, A, B, C, D, H, I, J). These were, however, strikingly smaller and weaker than those in the control solutions (Fig. 1, G) in which the incubation procedures were made without any tissue slices. The comparison of spots A, B, C, D, H, I, J with G indicates that pure estradiol has been bound during the incubation. Spots E and F correspond to 100 μg and 150 μg pure estradiol.

Tissue specimens. In order to secure that no agents reacting in the chromatogram similar to estradiol were excreted from the tissue itself during the incubation the following control analyses were performed. Tissue slices were incubated in the usual manner but without the presence of estradiol. The chromatograms produced after this revealed no such spots either from the alcohol-benzene extracts, from the unhydrolyzed samples or from the hydrolysed samples. As a control 100 μg of pure estradiol was run on the same paper.

DISCUSSION

These experimental results indicate that the rat duodenum is capable to conjugate estradiol to the corresponding glucuronide *in vitro*. This conjugate can be hydrolyzed after extraction from acid incubation medium with ethylacetate. These components produced by hydrolysis are estradiol and glucuronic acid. So far these studies have demonstrated only the qualitative formation of estradiol glucuronide. The incubation solution contained 0.9 μmole of estradiol per 8—10 mg of tissue dry weight and a portion of the estradiol has apparently remained unconjugated. Although the exact amounts will be calculated in our later quantitative studies, it seems likely that perhaps some 40—50 % of the estradiol are bound to glucuronic acid. It is worth mentioning that the incubation was performed in a solution in which also sulphate ions were present. It is therefore possible that in addition to the glucuronide conjugation the estradiol has also reacted with sulphate.

These observations are taken as a further evidence to support the previous studies of Hartiala (1954 and 1955) in which *o*-aminophenol under similar conditions as above — with the exception that the incubation solution did not contain sulphate ions — was found to yield a conjugate similar to the *o*-aminophenolglucuronide produced by the liver.

These studies have been supported by the *State Council of Natural Sciences* and *Sigrid Jusélius Stiftelse*, Finland.

Duodenal Glucuronide Synthesis

II. Identification of Estradiol Glucuronide as a Conjugation Product of Estradiol by the Rat Duodenal Mucosa. Quantitative Studies

ANITA LEHTINEN, K. HARTIALA and V. NURMIKKO

Department of Physiology, University of Turku, Finland

Estradiol was incubated in the presence of duodenal mucosal specimens. Free estradiol was extracted with benzene. Thereafter the product, extractable from the supernatant by ethylacetate, was hydrolyzed by β-glucuronidase. The product liberated was then extracted with benzene. Analyses of this product with the Kober reagent revealed that 53 % of the original estradiol appeared as a glucuronide formed during the incubation with duodenal mucosa.

As has been indicated in previous studies [1] estradiol, when incubated with surviving duodenal tissue slices, is conjugated to a compound identified by paper chromatography as estradiol glucuronide. In order to produce further evidence quantitative studies have been performed.

EXPERIMENTAL

The incubation procedures were exactly the same as described in the first part of these experiments. Also the extraction procedures were the same. In order to obtain conditions, comparable to the previous chromatographic procedures, incubates from 2 Warburg flasks were first combined.

First the free estradiol was extracted with benzene. After extraction of the conjugated estradiol-compound with ethylacetate this product was hydrolyzed with β-glucuronidase. The liberated estradiol was then extracted with benzene, the extract was evaporated to dryness and the residue was then transferred to absolute ethanol. From the mixture proteins were removed by centrifugation and the supernatant was transferred to Kober-tubes. The ethanol was then evaporated.

Quantitative estimation of estradiol. This was performed according to the method described by Brown[2], making use of the Kober reaction. To the evaporated residue were added 3 ml of the Kober reagent (2 g chinol/100 ml 60 % H_2SO_4, allowed to stand in the dark for one day before use). The tubes were heated on a boiling water bath for 20 min and brought to room temperature; 0.2 ml aq. dest. was added and the tubes were rewarmed for 10 min and cooled again. The mixture was then diluted for the photometric reading. The brown-yellow colour was read in a spectrophotometer at 518 mμ which was found to be the absorption maximum for pure estradiol and for the experimental samples.

Table 1. Quantitative determination of the amount of estradiol conjugated by duodenal mucosa and hydrolysable by β-glucuronidase. Original amount of free estradiol in the incubation mixture 490 μg.

* Specimens stained brown after the addition of the Kober reagent.

The extinction curve was obtained by preparing a stock solution from estradiol (5 mg/10 ml) and a series of dilutions (containing 15–55 μg estradiol/ml). The colour produced from these samples with the Kober reagent was rectilinear in the 25–50 μg range. According to this a 1:10 dilution was necessary for the later incubation samples. Estradiol was incubated in the Ringer solution but without the tissue slices. This mixture was then treated in the same way as the actual samples. After extraction and hydrolysis these samples should be free of estradiol and serve well as blanks for the Kober reagent readings. The slight colour developed by the blanks was subtracted in the final calculations.

RESULTS

Table 1 presents the results obtained in 5 parallel experiments. The results are expressed as μg of estradiol conjugated per 10 mg of duodenal tissue. The maximum was 353 μg and the minimum 195, mean 256 μg. The amount of estradiol of two Warburg incubates was 490 μg. It appears then that a maximum of 71 and a minimum of 40 % of estradiol was conjugated to glucuronide. Excluding the extreme values the conjugated estradiol amounts to 53 % of the total steroid material.

DISCUSSION

These studies support our previous observations that the duodenal mucosa possesses the ability to carry out active glucuronide synthesis in the presence of suitable material. The chromatographic studies showed no signs of free estradiol in the ethylacetate extract. The present quantitative analyses on the other hand gave high readings for estradiol after hydrolysis of the extracted material with an enzyme specific for the β-glucuronides.

The quantitative studies meet with some technical difficulties. The Kober reaction involves the use of H_2SO_4 which causes a darkening of the samples in the presence of some organic compounds. Therefore the presence of, *e. g.*, glucuronic acid in the conjugated samples does not allow analyses of the non-hydrolyzed material by this method. The results are, however, in good agreement with some of our other similar studies. As shown with phenolphthalein which can be detected by relatively simple chemical means the amount conjugated under similar experimental conditions amounts to 60 % [3].

These studies do not reveal in what form the remaining portion of the original material after the incubation is. Since the incubation mixture contains sulphate ions it is also possible that a certain amount of estradiol-sulphate is formed.

This study has been supported by *The State Council of Natural Sciences* and *Sigrid Jusélius Stiftelse*, Finland.

Duodenal Glucuronide Synthesis

III. Identification of Phenolphthalein Glucuronide as a Conjugation Product of Phenolphthalein in the Intestinal Tract in Rat

ANITA LEHTINEN, P. SAVOLA, M. PULKKINEN and K. HARTIALA

Department of Physiology, University of Turku, Finland

Incubation of phenolphthalein in the presence of surviving duodenal slices resulted in the partial disappearance of the free phenolphthalein from the incubation mixture. The treatment with β-glucuronidase of the ethylacetate extract made from the mixture revealed that some 66 % of the original phenolphthalein appeared as a glucuronide hydrolysable by this enzyme.

Recent studies have indicated that the mucous membrane of the gastrointestinal tract posesses its own defence mechanism against harmful chemical substances. It has been found that the glucuronide conjugation is *in vitro* carried out not only by the liver and the kidney, but also by the gastrointestinal mucous membrane. These observations were made by incubation of the tissue specimens in the presence of *o*-aminophenol [1,2]. This phenomenon has been verified by others using *o*-aminobenzoic acid and *p*-aminobenzoic acid [3]. Most recently we have been able to demonstrate that estradiol glucuronide is formed upon incubation of estradiol with duodenal mucosa in rat [4] and also that the feeding of a glucurogenic substance, cinchophen, leads to increased glucuronide contents in the portal blood in dog [6].

In the present study another glucurogenic substance has been used to confirm these earlier observations. Phenolphthalein was considered to be suitable for this purpose. It is known to be converted into a glucuronide in the organisms, in which form it also is excreted in urine [7]. Phenolphthalein glucuronide is widely used in connection with quantitative determination of β-glucuronidase. This enzyme hydrolyzes the conjugate readily in a linear course to phenolphthalein and glucuronic acid. The quantitative measurement of free phenolphthalein is a simple procedure [8].

MATERIAL AND METHODS

Albino rats (Wistar breed) were used in the experiments.

Incubation. The incubation of free phenolphthalein with duodenal mucosa slices was performed in the Warburg apparatus at 37°C for 90 min. The experimental procedure has been described in detail in previous papers [9,10].

Phenolphthalein concentrations. A stock solution of phenolphthalein was made by dissolving 200 mg of phenolphthalein (Fluka, pro anal.) in 1 ml 10 % NaOH. From this solution 0.02 ml was taken and transferred to 50 ml of the Ringer solution. Thus, this contained 4 mg/50 ml of phenolphthalein or 0.72 mg/9 ml. This 9 ml sample was made by putting the contents of 3 Warburg flasks together, each containing 3 ml of the incubation mixture. The tissue slices from these 3 flasks were removed after the incubation, washed with 1 ml of pure Ringer solution and dried on glass plates for later weighing. The washing solution was added to the combined 9 ml incubation mixture.

Deproteinization. The incubation mixture (10 ml) was made 2 N with hydrochloric acid. By using 4.44 N HCl, the amount used for this was 8.2 ml. This mixture was then heated at 60°C for 2 min and the protein precipitate was separated by centrifugation. The clear supernatant was transferred to an extraction funnel and shaken with 13 ml ethylacetate (2 × 15 min). The precipitant left after the centrifugation was washed with ethanol (1 ml), centrifuged and the alcohol supernatant added to the ethylacetate solution. The ethylacetate was removed in vacuum. The residue was dissolved in 2 ml of an acetate buffer (pH 4.5).

Hydrolysis of phenolphthalein conjugate. 2 mg of β-glucuronidase (Worthington Co) was added to the buffered solution of the residue and this was then incubated together with the separate control samples without β-glucuronidase at 37°C for 4 h. The proteins were removed by heating the mixture at 60°C for 2 min and centrifuging thereafter. The clear supernatant was diluted with 3 ml of distilled water and made alkaline with 3 ml glycine-sodium hydroxide buffer (pH 10.45–10.7). By this means the optimum pH

	Mean		0.60	0.40	0.20				

for the stability of the colour given by phenolphthalein was maintained. After this the mixture was centrifuged. The colour intensity of the clear solutions was measured with a Beckman DU spectrophotometer (540 mμ). This method is a modified Fishman method, originally designed for the determination of β-glucuronidase activity [11]. In our procedure the unknown factor was the amount of free phenolphthalein produced from the conjugate during the incubation with β-glucuronidase.

Calibration curve. This was made by preparing a dilution 0.005 ml/2 ml in 10 % NaOH from the phenolphthalein stock solution and making a dilution series (in Ringer solution) from this. The colour intensity was then measured after mixing the samples with the glycine-sodium hydroxide buffer (3 ml buffer + 3 ml H_2O).

RESULTS AND DISCUSSION

The results are listed in Table 1. First the methodical accuracy can be checked from the values. The measured amount of phenolphthalein in the original incubation mixture was 0.72 mg. The recovery in the triplicate control samples was 0.78, 0.76 and 0.79, mean 0.78. No loss of the original phenolphthalein is indicated. By studying the results it is apparent that a great part of the phenolphthalein present in the mixture is not found in free form after incubation with surviving duodenal tissue. It is also evident that a major portion of this bound glucuronide can be liberated by β-glucuronidase. The calculations indicate that 66 % of the ethylacetate extractable bound phenolphthalein was converted into the glucuronide. The nature of the remaining part (Δ) has not been identified in these studies. There are several possibilities. It might include material conjugated to sulphate and it might also be bound to the protein present in the original mixture.

These studies add to the previous evidence that the duodenal mucosa is able to carry out active glucuronide synthesis. The physiological meaning of this intestinal function is still obscure. In the liver this conjugation serves the purpose of active detoxication. In the intestine it might also serve as a part of the selective absorption mechanism. Our studies now in progress aim at elucidation of some of these points.

This study has been supported by grants from the *State Council for Natural Sciences (Valtion Luonnontieteellinen Toimikunta)* and from the *Sigrid Jusélius Stiftelse.*

The Stability of Metal Halide Complexes in Aqueous Solution

IV. The Fluoride and Chloride Complexes of the Vanadyl Ion, VO^{2+}

STEN AHRLAND and BERTIL NORÉN

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

The stability constants of the fluoride and chloride complexes of the vanadyl ion, VO^{2+}, have been determined. As could be predicted from the position of vanadium in the Periodic Table, the fluoride complexes are much stronger than the chloride ones which are very weak. They are also much stronger than the fluoride complexes formed by divalent ions of similar size but higher symmetry. This is due to the increase of effective charge on the metal atom induced by the strongly electronegative oxygen. On the other hand they are perceptibly weaker than the fluoride complexes of the uranyl ion, UO_2^{2+}, where two oxygen atoms co-operate in increasing the charge on the central uranium atom.

Vanadium is one of the few elements outside the actinide series forming well-established "yl"-ions in acid solutions, *i. e.* ions where a central metal atom is linked to one or two oxygen atoms by strong bonds of a pronouncedly covalent character (*cf.* Refs.[1,2] and refs. quoted therein). Vanadium(IV) thus forms the vanadyl ion, VO^{2+}, and vanadium(V) the vanidol[1] ion, VO_2^+. In connexion with the work on metal halide complexes at present in progress in this laboratory, it seemed worth-while to investigate the tendency of these ions towards halide complex formation, in order to compare them in this respect with the actinide "yl"-ions and also with di- and monovalent ions of higher symmetry.

From the general trends found for the formation of halide complexes by central ions of different positions in the Periodic Table [3], it can be predicted that the stability of the complexes of VO^{2+} and VO_2^+ will decrease in the sequence $F^- \gg Cl^- > Br^- > I^-$. Moreover the complexes formed by the three heavier halides are expected to be very weak, and therefore it might only be possible to determine very approximate values of their stability constants. The fluoride systems therefore seemed to present the most profitable task.

As to experimental methods, the obvious one for the system VO^{2+}—F^- was measurement of $[H^+]$ in acid fluoride solutions by means of the quinhydrone electrode, provided that the electrode functions satisfactorily in the presence of VO^{2+}. This method has been used before for the investigation of several fluoride systems, and a full description of the calculation of stability constants from such data is given in the work [4] on the rather similar system of UO_2^{2+}, *cf.* also Ref.[5] As stated there, the conditions might be complicated by the existence of hydroxo [2] and/or polynuclear complexes in solution besides the postulated simple series of mononuclear fluoride complexes of VO^{2+}; complexes containing HF_2^- as ligand are also conceivable. Such complexes will, however, cause the ligand number $\bar{n}_M$ to be a function not only of the free ligand concentration*, [A], but also of $[H^+]$ and/or the free central ion concentration, [M]. By varying $[H^+]$ and [M], which is brought about by varying the total concentrations of acid and central ion, C_H and C_M, it is therefore possible to decide whether such complexes exist or not [4].

As to VO_2^+, its fluoride complexes cannot be investigated by measurements involving the quinhydrone electrode, as quinhydrone is certainly oxidized by vanadium (V).

Once the constants of the fluoride system of VO^{2+} are known, the weaker complexes of the heavier halides can be investigated by the method of ligand displacement [6]. This has been carried out in the case of chloride.

The measurements were performed at 20°C in a medium of ionic strength 1 M, with $NaClO_4$ as the supplementary salt.

EXPERIMENTAL

Chemicals. Vanadium (IV) perchlorate solutions were prepared in a way similar to that described in Ref.[2] Vanadium(IV) was determined by titration with cerium(IV). The titration was carried out both potentiometrically and with ferroin as indicator. Provided the concentration of sulphuric acid in the solution was kept as low as about 0.5 M, the indication with ferroin was acceptable and gave the same result as was found potentiometrically (*cf.* Ref.[7]). The concentration of V(IV) in the stock solution was 471 mM. In the preparation of the perchlorate solution a slight oxidation to V(V) occurred the amount of which was determined in two ways. First it was calculated from the difference of emf measured in the potentiometric titrations between the solution which was half oxidized and the original solution, before any Ce(IV) had been added. Secondly it was determined by titrating a solution which had previously been completely reduced by SO_2 (the excess of which was removed by boiling the solution). Both methods gave the same value of the amount of V(V), $\approx$0.4 % of that of V(IV). This contamination was considered to be of no importance.

In order to avoid hydrolysis the stock solution was prepared with an excess of free perchloric acid (*cf.* Ref.[2]). The concentration of free acid was determined potentiometrically in the way described for uranyl perchlorate [4]. As certain difficulties (discussed below) were encountered when quinhydrone electrodes were used in vanadium perchlorate solution of low $[H^+]$, glass electrodes were used in this determination. The concentration of perchloric acid in the stock solution was 143 mM.

Sodium fluoride. A stock solution with C_A = 600 mM was prepared from "Merck" *p. a.* material, and sodium perchlorate was added to bring the total ionic strength to 1 M. In order to determine the small amount of foreign basic impurity usually found in fluoride

* Unless stated otherwise, the same symbols are used as in the paper on uranyl fluoride [4].

solutions [4], a small amount of perchloric acid was added to the stock solution which was then titrated with alkali. The present preparation also contained this impurity, buffering around pH = 7 where the hydrofluoric acid was practically neutralized. Its concentration was estimated to about 0.2 % of that of the fluoride. From earlier experience [4] it was evident that this foreign base would have to be suppressed before the fluoride solution could be used in the measurements on complex halides. This was achieved by adjustment of the pH of the solution from the original value of 7.2 to about 6.3. At this lower pH the basic impurity is converted into the corresponding acid while the fluoride ion is still practically unaffected.

Stock solutions close to 1 M were prepared from analytical grade *perchloric acid* and *sodium chloride*. *Sodium perchlorate* was prepared by neutralization of perchloric acid as described before [8].

The behaviour of the quinhydrone electrode in solutions of vanadyl perchlorate. The function of the quinhydrone electrode in the presence of vanadium was checked by measuring the emfs of cells of the type

+ Au	C_H mM $HClO_4$ I = 1 M ($NaClO_4$) quinhydrone(s.)	1 M $NaClO_4$	C_H mM $HClO_4$ C_M mM $VO(ClO_4)_2$ I = 1 M ($NaClO_4$) quinhydrone (s.)	Au —

The measurements were arranged as titrations where C_M was varied and C_H kept constant within a certain series. Series were carried out with C_H = 10, 30 and 100 mM. In this range of pH the hydrolysis of V(IV) is negligible for all values of C_M used [2] and thus $C_H = [H^+]$. If the electrode is working ideally the emf measured should therefore always be = 0. As seen from Table 1, this is very nearly the case for C_H = 30 mM, at least up to C_M = 50 mM. The deviation is also slight for C_H = 100 mM. Its direction and order of magnitude resembles that found for the quinhydrone electrode in uranyl perchlorate solution [9] and the cause might be the same in both cases. For C_H = 10 mM on the other hand, the deviation is much greater and, moreover, goes in the other direction. The potentials at C_H = 10 mM are also much less reproducible than those measured at higher C_H.

Thus, in order to secure an acceptable measurement of $[H^+]$ in vanadyl perchlorate solutions up to a value of C_M = 50 mM by means of the quinhydrone electrode, C_H must be at least 25 mM. The question then arises if the electrode gives the right response for $C_H \geqq 25$ mM also in the presence of fluoride. This was tested by performing the fluoride measurements with several different values of C_H and C_M, *i. e.* by varying those quantities which evidently determine the behaviour of the electrode. The calculation of identical complex formation functions (and hence identical stability constants) from all the experimental values of C_H and C_M implies that the underlying determination of $[H^+]$ was correct and the electrode thus functioning normally.

Table 1. The behaviour of the quinhydrone electrode in vanadyl perchlorate solutions.

$[H^+]\rightarrow$ mM	100	30	10
C_M mM	E mV		
2	0	0	0.7
5	−0.1	0	1.3
10	−0.2	0.2	2.2
20	−0.8	0.3	3.5
30	−1.5	0.4	
50	−3.0	0.4	

As pointed out above such a variation of C_H and C_M was also necessary in order to reveal if the solution contains other complexes than the simple mononuclear series $VOF_n^{(n-2)-}$. Therefore, if no variation with C_H or C_M is found for the complex formation function, this means not only that those other complexes do not exist but also that the determination of the constants of the complexes $VOF_n^{(n-2)-}$ is not impaired by faulty electrode function.

Procedure of the main measurements. The measurements were all arranged as titrations. A cell similar to that written above was connected. The specially prepared fluoride stock solution and an acid perchlorate solution were then added from individual burettes to the right-hand solution so that C_H and C_M were both kept constant during each titration. A plastic vessel was used for this half-cell which had to accomodate acid fluoride solutions. The left hand half-cell, serving as a reference electrode, always had $C_H = 10$ mM in the halide measurements.

In the chloride measurements, the solution of the right-hand cell also contained a certain total chloride concentration C_{Cl} which was also kept constant during a titration.

In the halide titrations, the value of E_H could as a rule be reproduced within ± 0.2 mV. The potentials attained equilibrium practically at once and were stable for hours.

RESULTS

The fluoride system. Corresponding values of [A] and the ligand number $\bar{n}_M$ were calculated according to the equations listed as (1) and (2) of Ref.[5], *i. e.* by using the constants δ_1 and δ_2 of the hydrogen fluoride system. In particular the value of δ_2 is fairly sensitive to the presence of basic impurities in the sodium fluoride solution [4]. As a new stock solution of fluoride, prepared from salt of another source, was used in the present measurements, it seemed advisable to redetermine the constants δ_1 and δ_2. This was done by titrations similar to those described in Ref.[4] Higher values of C_H were however chosen, *viz.* $C_H = 25$, 50 and 100 mM, because the measurements on vanadyl solutions had to be performed at these values of C_H. The present titrations gave $\delta_1 = 850 \pm 30$ M^{-1}, $\delta_2 = 2\,300 \pm 300$ M^{-2}, in good agreement with the values found for the second fluoride preparation used previously.

In order to find E_H of eqn. (1), Ref.[5], it is necessary to know the liquid junctions potentials of the cells used (*cf.* Ref.[4], eqns. (1) and (2). On the reasonable assumption that these potentials depend only on $[H^+]$ they have been previously determined in separate experiments up to $[H^+] = 35$ mM, with reference to the usual quinhydrone electrode of $[H^+]_0 = 10$ mM and $I = 1$ M (Ref.[4], Table 1). For the present investigation the determination of E_d had to be extended to $[H^+] = 100$ mM, Table 2. At such high values of $[H^+]$, E_d is a very substantial correction to the measured values of E.

In the measurements on vanadyl solutions, titrations with $C_H = 100$ and 50 mM were performed with two different values of C_M, *viz.* 50 and 25 mM, while only one value of C_M, 25 mM, was used with $C_H = 25$ mM. The results are given in Tables 3—5, and the complex formation functions giving $\bar{n}_M$ as a function of log [A] are plotted in Fig. 1. Evidently all the combinations of C_H and C_M give identical functions. Thus neither polynuclear complexes nor complexes with HF_2^- as ligand seem to exist in these solutions. Above all no hydrolysis occurs, in spite of the fact that values of pH are reached where the hydrolysis is quite substantial in non-complex perchlorate solutions [2]. Evidently the complex formation with fluoride effectively prevents the formation of soluble hydroxo complexes of V (IV) (*cf.* Ref.[4], p. 706; Ref.[10]). On the other hand the absence of hydrolytic reactions also means that fluoride ions do not displace the oxygen of VO^{2+} within the present range of pH contrary to what

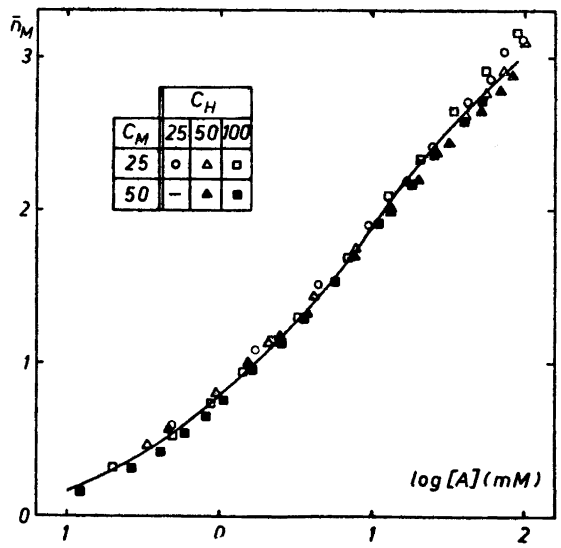

Fig. 1. The complex formation function of the vanadyl fluoride system. The points refer to titrations with different values of C_M and C_H, as indicated by the scheme given in the figure. The curve is calculated from the constants β_n finally found.

has recently * been believed [11]. It might finally also be concluded that the quinhydrone electrode works satisfactorily under the prevailing conditions.

As pointed out in the paper [4] on uranyl fluoride the way of calculating [A] and $\bar{n}_M$ from δ_1 and δ_2 might produce figures at high values of C_A, which are too low for [A] and hence too high for $\bar{n}_M$. A method giving better values of [A] and $\bar{n}_M$ in this region was given and it has also been tried in the present case. However it does not work quite satisfactorily here as $[H^+]$ is so large relative to [HA] and $[HA_2]$ that eqn. (18) of Ref.[4] is no longer a sufficiently close approximation. It can be estimated however that the complex formation curve will only be slightly displaced downwards if calculated according to this method. For the uppermost points at [A] = 100 mM, the difference would be about 0.2 units in $\bar{n}_M$ and it would then decrease rapidly with [A], completely disappearing at [A] $\approx$ 20 mM.

When [A] reached a value of $\approx$100 mM at C_M = 25 mM and $\approx$80 mM at C_M = 50 mM, a precipitate was formed and simultaneously the emf started drifting. The titration series had then to be interrupted. Unfortunately the complex formation curve (Fig. 1) is still steeply rising at these values of [A] and therefore the present measurements could give no reliable information about the coordination number, N, of the vanadyl ion.

For analysis, a larger quantity of the precipitate was prepared in a separate experiment. The filtered substance was washed with small portions of cold water (it is perceptibly soluble) and then dried at 105°C. It could then be heated for 5 h at 180°C without changing its weight. For the determination of vanadium, samples were dissolved in 2 M sulphuric acid and titrated potentiometrically as described above. For the determination of fluorine, another sample was dissolved in 0.05 M hydrochloric acid and the fluoride then precipitated as PbClF (*cf.* Vogel [12], p. 261). In order to achieve a complete precipitation, pH must be kept between 3 and 4. In such a solution, however, the hydrolysis of vanadium(IV) is quite marked, resulting in a coprecipitation of hydrolysed vanadium species. The filtered and washed precipitate therefore cannot be weighed as PbClF. Instead it was dissolved in nitric acid and titrated according to Volhard. At this procedure, no disturbance was observed from the slight amount of vanadium present. Found: V 22.3, 22.0 %, F 40.8 %. Calc. for Na_3VOF_5: V 22.1 %, F 41.1 % (Calc. for Na_2VOF_4: V 27.0 %, F 40.2 %; for Na_4VOF_6: V 18.7 %; F 41.8 %). From the vanadium analysis it thus seems certain that the compound is Na_3VOF_5. The fluorine analysis is in accordance with this, although it cannot decide between several conceivable alternatives with almost the same fluorine content. The ammonium analogue of Na_3VOF_5 has been known since long ago [13]. Unfortunately, neither the structure of this compound, nor that of any other complex vanadyl fluoride seems ever to have been determined. From these solid phases no evidence can therefore be derived about the co-ordination number of the vanadyl ion in its fluoride complexes. As stated above, the complex formation function, valid for aqueous solution, was also inconclusive on this point. The question must therefore be left open for the present.

From the experimental complex formation function the stability constants β_1, β_2 and β_3 of the first three complexes $VOF_n^{(n-2)-}$ are calculated in the usual

* The findings of Ducret [11] might be explained by his use of glass electrodes (and probably glass vessels) for acid fluoride solutions.

Table 6. Computation of the stability constants of the vanadyl fluoride system.

way [14], with a lower integration limit $[A]_0 = 0.1$ mM, Table 6. A very tentative value of β_4 is also given. From these constants the complex formation curve and the composition of the system is calculated according to eqns. (2) and (8) of Ref.[14] The formation curve, fulldrawn in Fig. 1, fits the experimental points well. The composition is presented graphically in Fig. 3.

The Chloride System. As the chloride system could be expected to be weak, a high concentration of chloride $C_{Cl} = 400$ mM was used. The values of δ_1 and δ_2 are however likely to change when such a large amount of the perchlorate is exchanged for chloride. These constants must therefore be determined in the chloride medium also. This was done by titrations at $C_H = 50$ and 100 mM and resulted in $\delta_1 = 800 \pm 30$ M^{-1}; $\delta_2 = 3\,100 \pm 300$ M^{-2}.

Fluoride titrations were then performed with a solution having a vanadium(IV) concentration $C_M = 30$ mM, $C_H = 50$ mM and $C_{Cl} = 400$ mM. The function $\bar{n}_M/[A]$ of the fluoride system obtained from these measurements was very close to that found above for pure fluoride solutions, Fig. 2. An addition of $C_{Cl} = 400$ mM was thus able to repress the complex formation of fluoride only very little, on account of the extreme weakness of the chloride complexes. In fact it was no use to try lower values of C_{Cl}, as these would have

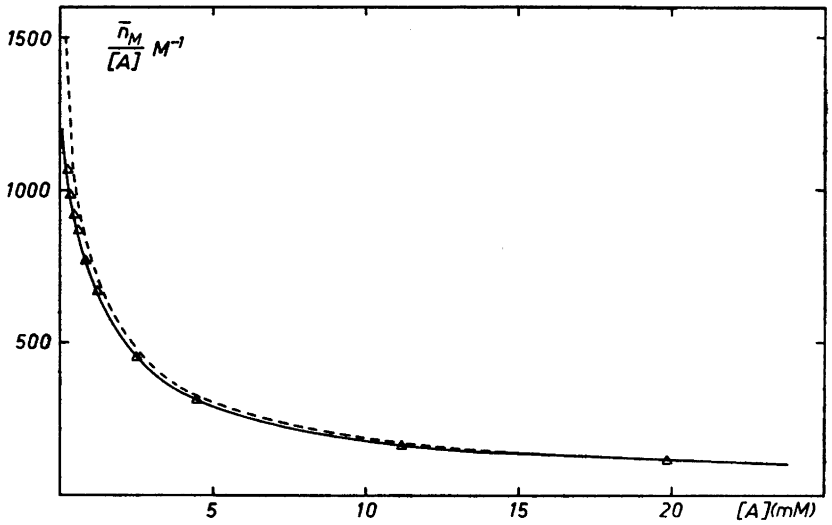

Fig. 2. The function $\bar{n}_M/[A]$ for the vanadyl fluoride system at $I = 1$ M a) in pure perchlorate medium: dashed curve, and b) in the presence of a chloride concentration $C_{Cl} = 400$ mM: triangles, fulldrawn curve.

given functions not significantly separated from the function of $C_{Cl} = 0$. The constant, β_1, of the first chloride complex is therefore calculated from this single value of C_{Cl} under the reasonable assumption that no higher complexes have yet been formed. Using [6] a value of $b = 0.018$ M, the integral $\ln X\,(0.4) = \int_0^b \frac{\bar{n}_M}{[A]} \cdot d[A]$ is graphically found to be $= 0.3625$ giving $\beta_1 = 1.1$ M^{-1}. On account of the possible influence of medium effects *etc.* on the slight difference found between the $\bar{n}_M/[A]$-curves, this value of β_1 can only be considered as showing the order of magnitude. In Fig. 3, the partition of vanadium between VO^{2+} and $VOCl^+$ is shown graphically.

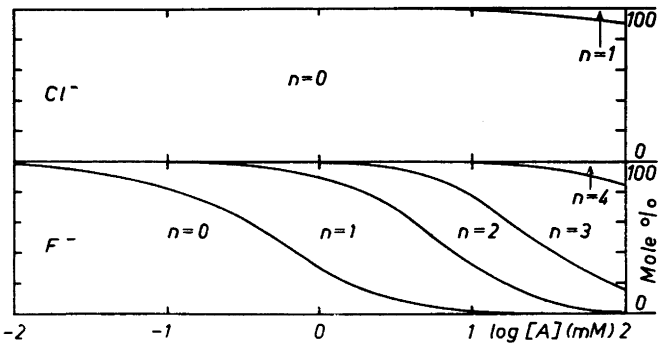

Fig. 3. The distribution of vanadium between the different complexes as a function of log [A].

DISCUSSION

As could be predicted from the position of vanadium in the Periodic Table, the fluoride complexes of VO^{2+} are much stronger than the chloride ones. VO^{2+} is a typical class (a) acceptor [15] and its complex formation with halide ions is thus governed essentially by electrostatic forces [3].

The fluoride complexes of VO^{2+} are much stronger than those of divalent central ions of a similar size, possessing higher symmetry [5], *e. g.* Ni^{2+}, Cu^{2+}, Zn^{2+}. Obviously the effective charge on vanadium in VO^{2+} is greater than +2 due to the high electronegativity of the attached oxygen. On the other hand the fluoride complexes of VO^{2+} is markedly weaker than those [4] of UO_2^{2+}. Certainly two oxygen atoms induce a higher effective charge on uranium in UO_2^{2+} than does one oxygen on vanadium in VO^{2+}. This increase of charge is evidently only partly compensated by the increase of ionic size and the result is a net increase of electrostatic attraction.

A grant from *Statens Naturvetenskapliga Forskningsråd (Swedish Natural Science Research Council)* is gratefully acknowledged. We are further indebted to Dr George Gamlen, I.C.I. Dyestuffs Division, Blackley, Manchester, for his careful linguistic revision of our manuscript.

Aminosugars and Related Compounds

Part V.* 2-Amino-1:6-Anhydro-2-Deoxy-β-D-altropyranose hydrochloride**

A. B. FOSTER, M. STACEY and S. V. VARDHEIM***

Chemistry Department, The University, Edgbaston, Birmingham, England

Treatment of methyl 2:3-anhydro-4:6-*O*-benzylidene-α-D-allopyranoside (IV) with methanolic ammonia (followed by acetylation) yields, as the major product, methyl 2-acetamido-4:6-*O*-benzylidene-2-deoxy-α-D-altropyranoside monohydrate (II) the structure of which is proved. Graded and total acidic hydrolysis of the latter compound yields respectively methyl 2-acetamido-2-deoxy-α-D-altropyranoside and 2-amino-1:6-anhydro-2-deoxy-β-D-altropyranose hydrochloride. The latter compound serves to characterise the parent aminosugar.

Until 1945 the only aminosugars which had been isolated from natural sources were 2-amino-2-deoxy-D-glucose [1] and 2-amino-2-deoxy-D-galactose [2]. Since then a number of other naturally occurring aminosugars have been recognized † and interest in their synthesis has been stimulated ††. In addition to these aminosugars a number of *N*-methylamino [15] and *N*:*N*-dimethylamino sugars [16] are now known. This paper describes work aimed at the synthesis of 2-amino-2-deoxy-D-altrose.

An obvious starting point for a synthesis of 2-amino-2-deoxy-D-altrose is the compound methyl 2-acetamido-3-*O*-acetyl-4:6-*O*-benzylidene-2-deoxy-α-D-altropyranoside (I) reported by Peat and Wiggins [17] to be the major product of the action of methanolic ammonia (followed by acetylation) on methyl 2:3-

† Muramic acid[3], 3-amino-3-deoxy-D-ribose[4], 2-amino-2-deoxy-D-fucose[5], 2-amino-2-deoxy-D-gulose[6], 2-amino-2-deoxy-D-talose[7] and 2-amino-2-deoxy-D-mannose[8].

†† The following D-aminosugars have been synthesized: 2-amino-2-deoxy-D-allose[9], 2-amino-2-deoxy-D-galactose[10], 2-amino-2-deoxy-D-glucose[11], 2-amino-2-deoxy-D-gulose[12], 2-amino-2-deoxy-D-mannose[13] and 2-amino-2-deoxy-D-talose[14], usually isolated as the hydrochloride or *N*-acetate.

anhydro-4:6-*O*-benzylidene-α-D-allopyranoside (IV). Whilst the minor product of this reaction, methyl 3-acetamido-2-*O*-acetyl-4:6-*O*-benzylidene-3-deoxy-α-D-glucopyranoside, was studied in detail [17] the major product apparently was not further examined.

Reinvestigation of this reaction gave methyl 3-acetamido-2-*O*-acetyl-4:6-*O*-benzylidene-3-deoxy-α-D-glucopyranoside in 4.2 % yield with physical constants (m. p. 271°, $[\alpha]_D$ +44.1° in chloroform) in good agreement with those reported [17] (m. p. 270°, $[\alpha]_D$ +44.6° in chloroform) by Peat and Wiggins. The major product *A* (45.7 %) of the reaction was initially assumed to be methyl 2-acetamido-3-*O*-acetyl-4:6-*O*-benzylidene-2-deoxy-α-D-altropyranoside(I) although the physical constants (m. p. 188°, $[M]_D$ +218° in chloroform) were slightly different from those (m. p. 184°, $[M]_D$ +179° in chloroform) reported [17] for this compound. However, failure to release acetate ions by treatment of compound *A* with alkali suggested the absence of *O*-acetyl groups and this was proved by the fact that the infra-red spectrum of compound *A* showed strong absorptions (1 541 and 1 651 cm^{-1}) characteristic [18] of *N*-acetyl groups but no absorption in the region 1 725—1 749 cm^{-1} characteristic [18] of *O*-acetyl groups. The identity of Peat and Wiggins' compound, of which a specimen survived in the chemical collection of the University of Birmingham Chemistry Department, was confirmed when its infra-red spectrum was found to contain strong absorptions at 1 531 and 1 649 cm^{-1} (*N*-acetyl) and at 1 729 cm^{-1} (*O*-acetyl) and on Zemplén deacetylation it gave compound *A*. The latter compound is thus shown to be methyl 2-acetamido-4:6-*O*-benzylidene-2-deoxy-α-D-altropyranoside (II) (isolated as a monohydrate). The infra-red spectra of a series of sugar derivatives containing *O*-acetyl and/or *N*-acetyl groups revealed the range 1 726—1 748 cm^{-1} for *O*-acetyl absorptions and the ranges 1 531—1 555 and 1 634—1 665 cm^{-1} for *N*-acetyl absorptions.

The absence of an *O*-acetyl group from compound *A* is surprising, especially since the minor product isolated from the same reaction mixture was *O*-acetylated. Attempts to *O*-acetylate compound *A* with pyridine and acetic anhydride or acetyl chloride were unsuccessful. The *O*-acetyl group in methyl 2-acetamido-3-*O*-acetyl-4:6-*O*-benzylidene-2-deoxy-α-D-altropyranoside (the product anticipated on *O*-acetylation of compound *A*) was not abnormally labile in that recrystallization could be effected without change under the usual conditions. Since Peat and Wiggins [17] did not give full experimental details further comparison is not possible.

Other evidence was accumulated which substantiated the structure of compound *A*. The presence of a free hydroxyl group was confirmed on treatment of compound *A* with toluene-*p*-sulphonyl chloride in pyridine when methyl 2-acetamido-4:6-*O*-benzylidene-2-deoxy-3-*O*-toluene-*p*-sulphonyl-α-D-altropyranoside (III) was obtained in good yield.

Graded acidic hydrolysis of compound *A* removed the benzylidene residue and yielded methyl 2-acetamido-2-deoxy-α-D-altropyranoside. The ready consumption of approximately one mole of metaperiodate by this latter compound under the usual conditions [19] indicates the presence of a vicinal glycol group and confirms the location of the acetamido residue at C_2 in compound *A*. Assuming normal cleavage of the epoxide ring in methyl 2:3-anhydro-4:6-*O*-benzylidene-α-D-allopyranoside under the action of methanolic ammonia

to give diaxial substituents (Fürst-Platner rule [20]) then compound *A* and the compounds subsequently derived from it must have the D-altrose configuration. The presence of vicinal *cis*-hydroxyl groups in methyl 2-acetamido-2-deoxy-α-D-altropyranoside is indicated by the more rapid consumption of oxidant than in the case of methyl 2-acetamido-2-deoxy-D-glucopyranoside which contains vicinal *trans*-hydroxyl groups.

Total acidic hydrolysis of methyl 2-acetamido-2-deoxy-α-D-altropyranoside or its 4:6-*O*-benzylidene derivative (II) yielded 2-amino-1:6-anhydro-2-deoxy-β-D-altropyranose hydrochloride (V) in low yield (28 % and 33 %, respectively). The highly crystalline nature of this compound recommends it for characterization of the parent aminosugar. That 2-amino-2-deoxy-D-altrose was also produced in the hydrolysis was indicated by the reducing power of the hydrolysate since the 1:6-anhydro compound itself is non-reducing. Examination of the hydrolysate by paper chromatography using the organic phase of a butanol-water-acetic acid (4:5:1) solvent system revealed only a single component. However with the *t*-butanol-water-acetic acid (2:1:1) solvent system [21] two components were observed which had R_F values and chemical properties similar to those of 2-amino-2-deoxy-D-gulose and 2-amino-1:6-anhydro-2-deoxy-β-D-gulopyranose [6]. Attempts to isolate the 2-amino-2-deoxy-D-altrose failed to yield a crystalline product.

The formation of a mixture of the free amino sugar and its 1:6-anhydride on acidic hydrolysis of methyl 2-acetamido-2-deoxy-α-D-altropyranoside and its 4:6-*O*-benzylidene derivative (II) is not surprising since the action of acid on D-altrose is well known [22] to yield an equilibrium mixture of approximately equal proportions of D-altrose and 1:6-anhydro-D-altrose. The $[M]_D$ value —315° (water) of 2-amino-1:6-anhydro-2-deoxy-β-D-altropyranose hydrochloride is similar to those, —339° and —348°, respectively, of 3-amino-1:6-anhydro-3-deoxy-β-D-altropyranose hydrochloride [23] and 1:6-anhydro-β-D-altropyranose [22].

Like 2-amino-1:6-anhydro-2-deoxy-β-D-gulopyranose hydrochloride [6], 2-amino-1:6-anhydro-2-deoxy-β-D-altropyranose hydrochloride readily consumed 2 moles of periodate.

V

EXPERIMENTAL

All m. p. s are uncorrected. Dry pyridine connotes pyridine which has been distilled repeatedly from phosphorus pentoxide.

Action of methanolic ammonia on methyl 2:3-anhydro-4:6-*O*-benzylidene-α-D-allopyranoside

Methyl 2:3-anhydro-4:6-*O*-benzylidene-α-D-allopyranoside [m. p. 198°, $[\alpha]_D$ +140.2° (*c*, 1.0 in $CHCl_3$)] was prepared from methyl 4:6-*O*-benzylidene-2:3-di-*O*-toluene-*p*-sulphonyl-α-D-glucopyranoside by the method of Richtmyer and Hudson [24].

The alloside (5 g) was treated, in a Carius tube, with a cooled (0°) mixture of methanol (60 ml, dried over calcium oxide) and liquid ammonia (21 ml). The tube and contents were cooled in liquid air, the tube sealed and then heated at 140° for 3 days. After cooling in liquid air the tube was opened, the solvents were evaporated at 40° (bath)/14—16 mm, and the residue dried over phosphorus pentoxide *in vacuo*. Acetylation of the residue was effected by addition of dry pyridine (50 ml) and acetic anhydride (7.5 ml). After 12 h the mixture was evaporated at 30° (bath)/0.1 mm, the residue was washed with water then dissolved in chloroform (5 ml) and diluted with ether. On cooling (methanol-solid carbon dioxide mixture) methyl 3-acetamido-4:6-*O*-benzylidene-3-deoxy-α-D-glucopyranoside separated which after recrystallization from chloroform-ether afforded a product (0.3 g, 4.2 %) m. p. 271°, $[\alpha]_D$ +44.1° (*c*, 1.0 in chloroform). (Peat and Wiggins [17] record m. p. 270°, $[\alpha]_D$ +44.6° for this compound). The infra-red spectrum (KBr disc) of this compound showed strong absorptions characteristic of *O*-acetyl (1 726 cm^{-1}) and *N*-acetyl (1 549 and 1 634 cm^{-1}).

From the mother liquors a second product separated and after recrystallization from aqueous-methanol *methyl 2-acetamido-4:6-O-benzylidene-2-deoxy-α-D-altropyranoside hydrate* (2.8 g, 45.7 %) m. p. 188°, $[\alpha]_D$ +64° (*c*, 1.0 in chloroform) was obtained. (Found: C 55.8; H 6.7; N 4.1. $C_{16}H_{20}O_6N \cdot H_2O$ requires C 56.3; H 6.7; N 4.1), $[M]_D$ +218°. The infra-red spectrum (KBr disc) showed strong absorptions characteristic of the *N*-acetyl group (1 541 and 1 651 cm^{-1}) but not for *O*-acetyl.

Attempted *O*-acetylation of the foregoing compound using dry pyridine and acetyl chloride or acetic anhydride was unsuccessful; starting material was recovered unchanged.

Methyl 2-acetamido-4:6-*O*-benzylidene-2-deoxy-3-*O*-toluene-*p*-sulphonyl-α-D-altropyranoside

A solution of methyl 2-acetamido-4:6-*O*-benzylidene-2-deoxy-α-D-altropyranoside (2 g) in dry pyridine (12 ml) was treated with toluene-*p*-sulphonyl chloride (3 g) at 30° for 48 h. On dilution of the reaction mixture with ice water and recrystallization of the precipitate from aqueous-acetone the *product* (1.4 g, 50 %) was obtained m. p. 174° (decomp.), $[\alpha]_D$ +62° (*c*, 1.0 in acetone), $[M]_D$ +296°. (Found: C 58.0; H 5.6; N 3.0; S 7.2. $C_{23}H_{27}O_8NS$ requires C 57.8; H 5.7; N 2.9; S 6.8.)

Acidic hydrolysis of methyl 2-acetamido-4:6-*O*-benzylidene-2-deoxy-α-D-altropyranoside

(a) A solution of methyl 2-acetamido 4:6-*O*-benzylidene-2-deoxy-α-D-altropyranoside (1 g) in 2 N hydrochloric acid (10 ml) was boiled under reflux for 3.5 h. After two extractions with light petroleum (60—80°) the hydrolysate was neutralised with methyl di-*n*-octylamine [25] and then freeze dried. Dissolution of the syrupy residue in 2 *N* hydrochloric acid and dilution with acetone gave *2-amino-1:6-anhydro-2-deoxy-β-D-altropyranose hydrochloride* (0.19 g, 33 % after recrystallization from the same solvent system) which was non-reducing towards Fehling's solution and had m. p. 350° (decomp.), $[\alpha]_D$ −160° (*c*, 0.5 in water) $[M]_D$ −315°. (Found: C 35.7; H 6.0. $C_6H_{10}O_4N \cdot HCl$ requires C 36.4; H 6.1.)

The hydrolysate from which the foregoing compound was isolated was strongly reducing towards Fehling's solution. Examination of the neutralised hydrolysate by paper chromatography using the organic phase of a butanol-water-acetic acid (4:5:1) solvent system gave apparently a single spot which reacted strongly with ninhydrin, aniline hydrogen phthalate [26] and ammoniacal silver nitrate [27]. However with a *t*-butanol-water-acetic acid (2:1:1) solvent system [21] two spots were obtained with mobilities similar to those of 2-amino-2-deoxy-D-gulose and 2-amino-1:6-anhydro-2-deoxy-β-D-gulose [6]. In each case the faster moving component reacted with ninhydrin only and the slower moving component reacted with both ninhydrin and aniline hydrogen phthalate [26]. Attempts to isolate the 2-amino-2-deoxy-D-altrose, presumed present in the hydrolysate, by preparative scale paper chromatography did not yield a crystalline product.

(b) A solution of the altroside (1 g) in 0.5 % methanolic hydrogen chloride (10 ml) was boiled under reflux for 2 h. After two extractions with light petroleum (60 – 80°) the solution was diluted with water and deacidified with methyl di-*n*-octylamine [25] and then evaporated at 30° (bath)/0.1 mm. Methyl 2-acetamido-2-deoxy-α-D-altropyranoside (0.672 g, 92.5 %) was obtained as a syrup showing $[\alpha]_D$ +16.3° (*c*, 1.3 in water), $[M]_D$ +94°.

A solution of methyl 2-acetamido-2-deoxy-α-D-altropyranoside (0.0672 g) in water (5 ml) was treated with 0.25 M sodium metaperiodate solution (15 ml) and the volume rapidly adjusted to 50 ml. The consumption of oxidant was determined by the standard arsenite procedure on aliquots withdrawn at suitable time intervals. In a separate experiment methyl 2-acetamido-2-deoxy-α-D-glucopyranoside (0.0672 g) was oxidised under identical conditions. The consumption of oxidant (moles per mole) was as follows:

Time (h)	0.5	1.0	2.0	3.0	4.5
altroside	0.915	0.950	0.950	0.950	0.950
glucoside	0.710	0.915	0.950	0.994	0.994

A solution of methyl 2-acetamido-2-deoxy-α-D-altropyranoside (0.5 g) in 2 N-hydrochloric acid (10 ml) was boiled under reflux for 3 h. 2-Amino-1:6-anhydro-2-deoxy-β-D-altropyranose hydrochloride (0.118 g, 28 %), m. p. 350° (decomp.), $[\alpha]_D$ −160° (*c*, 0.5 in water) was subsequently isolated as in the foregoing hydrolysis (a).

Periodate oxidation of 2-amino-1:6-anhydro-2-deoxy-β-D-altropyranose hydrochloride

The aminosugar derivative (25 mg) was subjected to periodate oxidation in a manner similar to that described earlier. The consumption of oxidant was as follows:

30 min. 1.85 moles; 1 h. 2.02 moles (final constant value).

Deacetylation of methyl 2-acetamido-3-*O*-acetyl-4:6-*O*-benzylidene-2-deoxy-α-D-altropyranoside

A solution of the altroside derivative [17] (50 mg) in dry methanol (20 ml) was treated with a few mg of metallic sodium. After 12 h the solution was neutralised with carbon dioxide, evaporated and the residue recrystallized from aqueous methanol to yield a product m.p. 188° alone or in admixture with the methyl 2-acetamido-4:6-*O*-benzylidene-2-deoxy-α-D-altropyranoside hydrate described above.

The infra-red spectrum (KBr disc) of methyl 2-acetamido-3-*O*-acetyl-4:6-*O*-benzylidene 2-deoxy-α-D-atropyranoside showed strong absorptions characteristic of *O*-acetyl (1 729 cm^{-1}) and *N*-acetyl (1 531 and 1 649 cm^{-1}).

Acknowledgment. The authors thank Professor E. van Tamelen for samples of 2-amino-2-deoxy-D-gulose and its 1:6-anhydride, and Dr. D. H. Whiffen for the infra-red spectra measurements and for discussion. One of them (S.V.V.) thanks *Papirindustriens Forskningsinstitutt*, Oslo, Norway for a grant.

ACTA CHEMICA SCANDINAVICA 12 (1958) 1611—1621

Die Darstellung von reinen Häminen

K. G. PAUL

Medicinska Nobelinstitutet, Biokemiska avdelningen,
und Wallenbergstiftelsens laboratorium för fysiologisk kemi, Stockholm, Schweden

Drei Methoden für Hämindarstellung werden mit dem Hämochromogenspektrum als Reinheitsprobe verglichen.

1. Rohporphyrin-Porphyrinester-reines Porhyrin-Hämin. Manchmal werden Produkte erhalten, deren Hämochromogenspektra eine erhöhte Absorption im Rot besitzen.

2. Rohporphyrin-Porphyrinester-Häminester-Hämin. Die Hämochromogenspektra der Häminester wiesen auch manchmal die Rotabsorption auf. Der dafür verantwortliche Abkömmling kann durch Chromatographie auf sekundärem Natriumphosphat weggenommen werden. Die molaren Absorptionskoeffizienten für solche Hämine, die nach Verfahren 3. nicht gereinigt werden können, sind dadurch bestimmbar.

3. Kuppelung eines Hämins mit dem Apoprotein eines Häminproteides und Chromatographie auf Anionenaustauscher. Die Hämochromogenspektra der so erhaltenen Häminproteide sind einwandfrei. Auf diesem Weg können 6,7-dikarboxylige Hämine gereinigt werden, möglicherweise auch Monokarboxyhämine.

Bei der Darstellung von Häminen * werden meistens die entsprechenden Porphyrine über ihre Methylester gereinigt. Nach Hydrolyse des Esters wird Eisen in die Porphyrine eingeführt. Die Reinheit der Hämine wird durch Elementaranalyse, Chromatographie auf Säule oder Papier und Spektrophotometrie geprüft. Auf Grund des Darstellungsverfahrens sind als wahrscheinlichste Verunreinigung Abkömmlinge des gewünschten Hämins zu erwarten. Die Elementaranalyse ist daher als Reinheitsprobe nur von beschränktem Wert. Für die spektrophotometrische Reinheitsprüfung muss das Hämin in eine Form gebracht werden, in der die Abkömmlinge gut hervortreten. Bei Häminproteiden kommen bisweilen eine nicht umkehrbare Inaktivierung und eine erhöhte Lichtabsorption im Rot zusammen vor. Diese Erhöhung, die bei Reduktion mit Dithionit in Gegenwart von hämochromogenbildenden Stoffen, z. B. CO, nicht verschwindet (vgl. Hämoglobin-Choleglobin), ist spektrophotometrisch leicht nachweisbar. Weil die Veränderungen in den Hämin-

* Hämin bedeutet in der vorliegenden Arbeit eine Eisen-Porphyrin-Verbindung im allgemeinen. Bluthämin wird Protohämin genannt.

abkömmlingen wahrscheinlich mit denen in den Häminproteiden verwandt sind, dürfte das Hämochromogen eine geeignete Form der Hämine für die spektrophotometrische Reinheitsprüfung sein. Es wurde bald gefunden, dass ein Hämochromogenspektrum ein Plateau oder sogar ein schwaches Maximum bei 600—620 mμ besitzen könnte, ohne dass das Hämin eine Uneinheitlichkeit im Papierchromatogram aufwiese. Messungen des Hämochromogenspektrums wurden deshalb für die zuverlässigste Reinheitsprobe gehalten.

MATERIALIEN UND METHODEN

Alle molaren Lichtabsorptionskoeffizienten (β^*) sind auf Eisenbestimmungen mit Sulphosalicylsäure [1,2] gegründet. Bei unzureichender Verbrennungszeit mit Schwefelsäure-Wasserstoffperoxyd zeigt die Blindprobe eine gelbe Nuance, die der von Eisen verursachten Farbe ähnelt und Werte bis zu $D_{424} = 0{,}1$ gibt. Bei der Verbrennung muss wenigstens 10 Min nach dem letzten Peroxydzusatz gekocht werden [2]. Die Einführung des Eisens in die Porphyrine geschah nach den gewöhnlichen Methoden [3,4].

Für Papierchromatogramme wurde 2,6-Lutidin/Wasser 100/20, Whatman-Papier No. 1 und Zimmertemperatur verwendet, aber kein Ammoniakdampf im Gefäss [5,6].

Die Hämochromogene der freien Hämine mit Pyridin als Base wurden wie gewöhnlich [7] erhalten (Pyridin/0,1 M NaOH 1/3 + Dithionit). Die Häminester wurden in über KOH destilliertem Pyridin gelöst und die Lösung mit einem Volumen von 0,2 M NaOH versetzt.

Meerrettichperoxydase war mit Dowex-2 gereinigt, nicht aber auf Karboxymethylcellulose chromatographiert [8]. Für die Spaltung wurde die Lösung mit 0,2 Vol. von 5 % NaCl und 0,1 M HCl bis an pH 2 versetzt und nach 5 Min in 10 Vol. Azeton von −13° unter Umrühren langsam gegossen. Das Eiweiss wurde in der Kälte abzentrifugiert, ohne Waschen in Wasser aufgelöst und über Nacht gegen kaltes Wasser dialysiert. Ein ähnliches Verfahren ohne Neutralisation wurde früher für Cytochrom c verwendet [9]. Die Peroxydaseaktivität in der Mesidinprobe war mit Protohämin vollständig wiederherstellbar.

Myoglobin I (Mb), von Herrn Å. Åkeson erhalten, wurde wie früher beschrieben [11] gespalten.

Bluthämin wurde nach Chu und Chu [12] oder Fischer [13] erhalten (Tabelle 1). Koproporphyrin III wurde aus *Corynebact. diphteriae*-Bouillon (von Dr. G. Norlin erhalten) isoliert [14] (Fp. des Esters 153 und 178°, korr.). Koproporphyrin I, eine Gabe von Dr. J. J. Scott, enthielt nach Scott höchstens 5 % Koproporphyrin III. Mesoporphyrin I-Ester wurde aus der Fischer-Sammlung durch Professor S. Goldschmidt erhalten. Die übrigen Porphyrine wurden nach Fischer-Orth [15] dargestellt. Zweimal krystallisiertes Cytochrom c wurde von Doz. S. Paléus erhalten.

Tabelle 1. Ausbeute an Protohämin (mg/100 ml Blut) und molare Absorptionskoeffizienten der α-Bande des Pyridinhämochromogens ohne Umkristallisierung.

ERGEBNISSE

Drei Wege für die Darstellung von reinen Häminen wurden probiert. Die Ergebnisse sind in Tabelle 2 gesammelt.

Tabelle 2. Molare Absorptionskoeffizienten der Hämochromogene für Hämine die nach den drei Methoden erhalten sind. Alle Wellenlängen mittels Beckman DU Spektrophotometer erhalten. "Rot" bedeutet die Wellenlänge 50 mμ rotwärts der α-Bande.

[1] Nach Fischer. [2] Nach Chu und Chu. [3] Dasselbe Präparat umkristallisiert. [4] Gewaschene Erythrozyten. [5] In Pyridin-Lauge. [6] Freies Deuterohämin nach Verf. 2 und Verseifung (2,2 μMole, S. 1616).

1. Rohporphyrin — Porphyrinester — reines Porphyrin — Hämin

Mesohämin wird als Beispiel gegeben.

Mesoporphyrin wurde mit Methanol-HCl verestert und durch Chromatographie (Aluminiumoxyd Merck, nach Brockmann, Grad IV, 125 mM Methanol in Chloroform [16]) und Kristallisation bis zum konstanten Schmelzpunkt (216°) gereinigt. Der Ester wurde mit 4 M HCl bei Zimmertemperatur während 48 St verseift und das Porphyrin in Äther getrieben. Es wurde mit 0,02 M HCl gewaschen (geringe Ausbeute, verworfen) und das Porphyrin mit 0,15 M HCl herausgenommen. Gegenstromverteilung [17] zeigte Einheitlichkeit. Der Äther wurde *in vacuo* verjagt, das Porphyrin ausgeflockt, gewaschen, getrocknet und in Hämin überführt.

Ohwohl das Porphyrin also bestimmt rein gewesen war, zeigte das Hämochromogenspektrum erhöhte Absorption bei 600—640 mμ (Abb. 1). Eisen, als

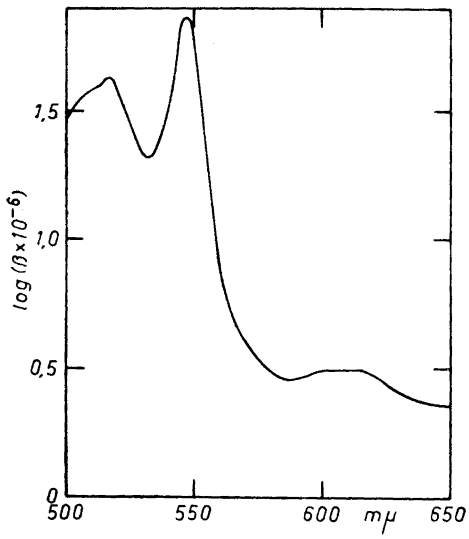

Abb. 1. Pyridinhämochromogen des Mesohämins nach Verfahren 1 erhalten.

Eisen(II)Acetat, gab unter den Bedingungen der Hämochromogenbestimmung $\beta_{600} = 0{,}02 \times 10^7$ cm^2 × Mole^{-1} und ist also als Ursache der Absorption auszuschliessen. Umkristallisation des Hämins aus Pyridin-Eisessig oder einfache Fällung aus alkalischer Lösung mit Überschuss an Säure reduzierte nicht die Absorption im Rot. Freies Porphyrin war in den Mutterlaugen nicht nachweisbar. Versuche, die erhöhte Absorption im Rot zu vermeiden durch Eiseneinführung in N_2- oder CO_2-Atmosphäre mit nachfolgender Oxydation des Ferroeisens mit Cerisulfat oder grossem Überschuss an Ferrichlorid blieben erfolglos. Die erhöhte Absorption im Rot trat auch hier öfters auf.

2. Rohporphyrin — Porphyrinester — Häminester — Hämin

Auch bei Eiseneinführung in Porphyrinester trat die erhöhte Absorption im Rot auf. Die Trennung von reinen Häminestern und ihren Abkömmlingen ging durch Chromatographie auf sekundärem Phosphat [18] glatt.

Deuterohäminester wurde aus Protohämin über Deuteroporphyrinester (Reinigung wie beim Mesoester, Fp. 218°) erhalten und aus Chloroform-Eisessig kristallisiert (Fp. 242—244°). Nach Trocknen *in vacuo* über KOH wurde auf $Na_2HPO_4 \cdot 2H_2O$ / Chloroform (13 × 1 cm) chromatographiert. Der Ester (4,8 μMole nach der Eisenbestimmung) wurde in Chloroform aufgetragen. 15 mM Methanol in Chloroform eluierte eine rote, gut begrenzte Fraktion (3,7 μMole), die sich bei wiederholtem Chromatographieren mit 10 mM Methanol nicht aufteilen liess. Deuterohäminester (Fp. 251°) kristallisierte aus Chloroform und kochsalzgesättigtem Eisessig. Aus der Säule war mit 70 mM Methanol nichts, mit reinem Methanol 0,4 μMole eluierbar; dabei sinterte die Säule.

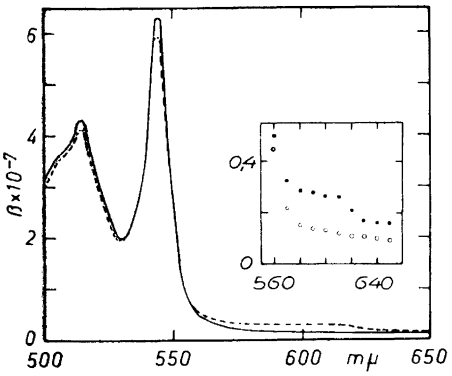

Abb. 2. Pyridinhämochromogen des Deuterohämoinesters vor (----) und nach (——) Chromatographie auf $Na_2HPO_4 \cdot 2H_2O$.

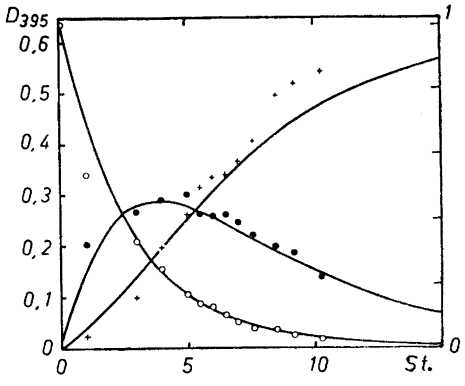

Abb. 3. Verseifung von Mesohämindimethylester mit HCl in Azeton. ○● + bedeuten Absorption der Flecke mit R_F-Werten entsprechend Diester, Monoester und freies Hämin (Ordinate links). Kurven bedeuten Molbrüche (Ordinate rechts), für $k_1 = 0{,}360$ und $k_2 = 0{,}193$ St^{-1} berechnet.

Bei Umchromatographieren mit Gemischen von Chloroform und Methanol erwies sich diese Fraktion als uneinheitlich. Die Hämochromogenspektra des Ausgangsmateriales und der roten Fraktions sind in Abb. 2 gegeben.

In der nachfolgenden Verseifung des Häminesters waren alkalische Lösungen wegen Gefahr der Häminzersetzung zu vermeiden. Die Wahl des Lösungsmittels war bei der sauren Verseifung durch die Anwesenheit von sowohl Ester als freiem Hämin beschränkt. Für Hydrolyse bei Zimmertemperatur, z. B. für die Isolierung des Monoesters, war über Zinn(II)Chlorid gereinigtes Dioxan brauchbar. Bei Temperaturen über 40° trat aber allmählich merkbare Porphyrinfreisetzung und Bildung von Häminabkömmlingen mit niedrigen R_F-Werten auf. Aceton wurde bei mässigen Temperaturen verwandt. Die Geschwindigkeitskonstanten k_1 und k_2 der Verseifung wurden in einem Versuch experimentell bestimmt.

$$\text{Diester} \xrightarrow{k_1} \text{Monoester} \xrightarrow{k_2} \text{freies Hämin}$$

Während einer Verseifung (Abb. 3) wurden Proben entnommen, auf Papier chromatographiert, die Flecke ausgeschnitten und mit kochendem Eisessig eluiert. Die R_F-Werte waren 0,92 (0,87—0,96), 0,80 (0,74—0,84) und 0,68 (0,61—0,77). Diester und freies Hämin als Vergleichungsstoffe gaben den ersten bzw. letzten Wert. Die Konstanten k_1 und k_2 wurden berechnet [19] aus

$\text{Diester}_{t_1} = \text{Diester}_{t_0} \times e^{-k_1 t_1}$

Freies Hämin $= 2\ (1 - e^{-k_2 t_1}) - (1 - e^{-k_1 t_1})$

Diester + Monoester + freies Hämin = 1

Die Molbrüche wurden aus den Lichtabsorptionen erhalten, z. B.

$$\text{Diester} = \frac{\text{Abs. d. Fleckes mit } R_F = 0{,}92}{\text{Summe Abs. d. drei Flecke}}$$

k_1 wurde als 0,360 St^{-1} gefunden. k_2 wurde aus den Messwerten für sowohl freies Hämin als auch Monoester berechnet; beide Möglichkeiten gaben den Wert 0,193 St^{-1}. Wenn Dioxan-10 M HCl, 2:1, für die Verseifung verwendet wurde verschwand der Diester bei 100, 50 und 20° mit den Geschwindigkeiten $t_{\frac{1}{2}}$ 0, 8, 40 und 1 200 Min, was eine scheinbare Aktivierungsenergie von 21 000 cal/Mol entspricht.

4,2 μMole von Deuterohäminester, die auf sekundärem Phosphat (15 mM Methanol in Chloroform) gereinigt waren, wurden bei 50° während 4 St in geschmolzenem Rohr mit 0,8 ml 8 M HCl in 4 ml Aceton verseift. Die Lösung wurde dann mit Chloroform verdünnt und mit Wasser bis zur Neutralität gewaschen. Das dabei ausgefallene freie Hämin (2,2 μMole) war papierchromatographisch einheitlich. Sein Hämochromogen zeigte aber im Vergleich mit dem des Esters erhöhte Absorption im Rot mit einem Maximum bei 602 mμ. Ein Teil der Chloroformlösung wurde getrocknet (Tabelle 2) und auf einer Phosphatsäule ($Na_2HPO_4 \cdot 2\ H_2O/NaH_2PO_4 \cdot 2\ H_2O$ 1/10, 10 × 1 cm, rein Chloroform) chromatographiert, erwies sich aber als uneinheitlich mit niedrigem Quotient α-Bande/Minimum.

3. Kuppelung an das Apoprotein eines Häminproteides und Isolierung des widergebildeten Häminproteides

Eine dritte Möglichkeit wäre, ein Hämin, z. B. nach Methode 1 erhalten, mit einem Ionenaustauscher reagieren zu lassen, aus dem die Abkömmlinge durch reines Hämin völlig verdrängt werden. Ein Ionenaustauscher mit solchen Eigenschaften wäre möglicherweise im Apoprotein eines Häminproteides zu erwarten. Der Arbeitsgang würde demnach, das Apoprotein mit einem — nach dem Gewicht oder der Eisenmenge — so grossen Überschuss an Hämin reagieren zu lassen, dass das molare Verhältnis 1:1 zwischen reinem Hämin und Apoprotein überschritten würde. Der Überschuss an reinem Hämin und die Abkömmlinge wären dann mit einem unspezifischen, starken Anionenaustauscher wegzunehmen.

Meerrettichperoxydase, Pferdeleberkatalase, Methämoglobin, Karboxyhämoglobin, Metmyoglobin und Karboxymyoglobin wanderten auf Dowex-2 (200—400 mesh, 8 % Querbindung, pH 7,4, 0,03—0,15 M Phosphat) mit R_F-Werten $>0{,}9$. Bei niedriger Durchlaufgeschwindigkeit der Flüssigkeit wurde freies Hämin als eine braune Zone am obersten Teil der Säule adsorbiert, bei hoher Geschwindigkeit aber verfärbte sich die ganze Säule braun. Die Reaktion zwischen Hämin * und Austauscher war also nicht momentan. Bei konstanter Durchlaufgeschwindigkeit war die Länge der braunen Zone dem Häminüberschuss proportional. Für die Vermeidung von freiem Hämin im Eluat wurde immer das Chromatographieren während etwa einer halben Stunde unterbrochen sobald die Lösung in der Säule gesunken war; erst dann wurde das Häminproteid eluiert.

Aus Protohämin und Peroxydaseapoprotein rekombinierte Peroxydase war von ungespaltener Peroxydase auf Dowex-2 nicht zu trennen. In qualitativen

* In NaOH-Phosphat, s. unten.

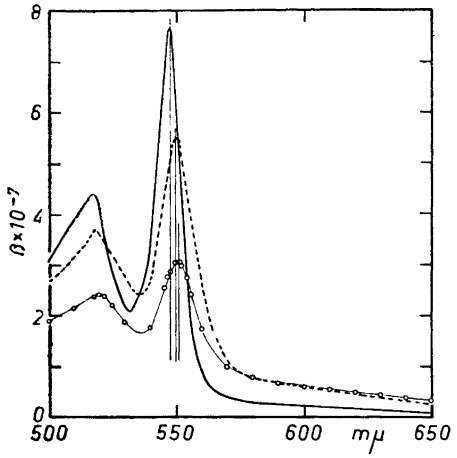

Abb. 4. Pyridinhämochromogen des Hämatohämins vor (---) und nach (———) Kuppelung an Apomyoglobin und Chromatographie auf Dowex-2. —o— ist das Hämochromogenspektrum der mit 1 M HCl eluierten Fraktion. Die Säule war nach der Eluierung mit der Säure nicht häminfrei, weswegen die Kurven nicht ohne weiteres addiert werden können.

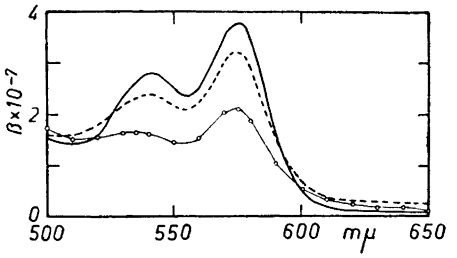

Abb. 5. Pyridinhämochromogen des Diacetyldeuterohämins. Symbolen vgl. Abb. 4.

Versuchen mit einigen Häminen zeigten die Hämochromogenspektra der rekombinierten und chromatographierten Peroxydasen in Vergleich mit den der Ausgangshämine gesteigerte Verhältnisse zwischen Maxima und Minima und Verschwinden der Erhöhung im Rot. Apoprotein "wählt" also reines Hämin aus. Kuppelung ohne Chromatographie von Apoperoxydase mit einer nach dem Eisengehalt äquivalenten Häminmenge beeinflusste nicht das Hämochromogenspektrum.

Bei der Bestimmung der molaren Absorptionskoeffizienten der verschiedenen Hämochromogene wurde wegen des grossen Materialverbrauches in den Eisenbestimmungen Myoglobin I statt Peroxydase verwendet. Rekombiniertes Hämoglobin dürfte mit ungespaltenem Hämoglobin nicht identisch sein [20]. Rekombiniertes und ungespaltenes Myoglobin I zeigen identische Kristallformen, Spektra und elektrophoretische Eigenschaften [11], auch waren sie auf Dowex-2 nicht zu trennen. Es dürfte deshalb gestattet sein, Myoglobin-Apoprotein als "Ionenaustauscher" zu verwenden obwohl die gasbindende Wirkung hier nicht geprüft wurde.

Für jede Kuppelung wurde abgemessen

Mb-Apoprotein	(0,58 μMole/ml)	3,0 ml
Phosphatpuffer	(0,03 M, pH 7,3)	0,2 ml
Hämin	(in M/30 NaOH, NaOH : Hämin = 5)	0,5 ml
Hämin/Protein = 2		

Nach 55 St im Kühlschrank wurden die Lösungen chromatographiert (Dowex-2, 15 × 1 cm, 0,03 M Phosphat, pH 7,3) und Hämochromogen und

Eisen in den Eluaten bestimmt. Die Reinigungen von Hämatohämin und Diacetyldeuterohämin werden als Beispiele gegeben (Abb. 4, 5).

Ausser Apoperoxydase und Apomyoglobin wurde Serumalbumin für die Reinigung probiert. Bei dem Verhältnis 1:1 zwischen Protohämin und Albumin wurde das Hämin von der Säule quantitativ aufgenommen. Bei derselben Durchlaufgeschwindigkeit zog sich aber die braune Farbe weiter hinunter als in Abwesenheit von Eiweiss. Je grösser das Verhältnis von Albumin zu Hämin war je weiter färbte sich die Säule braun, und Hämin trat zuletzt im Eluat auf. Keine Reinigung des Hämins wurde dabei beobachtet. Durch Alter völlig inaktivierte Apoperoxydase verhielt sich wie Serumalbumin.

Verfahren 3 wurde auf einigen anderen Porphyrinverbindungen als 6,7-Dikarboxyl-Häminen geprüft. Apomyoglobin und die oben (S. 1617) gegebenen Bedingungen wurde benutzt. Mesohämin I (6,8-diCOOH) wurde bei dem Verhältnis Hämin/Protein 1:1 von dem Anionenaustauscher zurückgehalten und zwar so, dass der oberste Teil der Säule am stärksten gefärbt wurde mit abwärts abnehmender Verfärbung ohne getrennten Fraktionen. Mit Überschuss an Eiweiss oder schnellem Chromatographieren wurde die ganze Säule braun. Koprohämin III (2,4,6,7-tetraCOOH) gab einen ähnlichen Befund aber ausgeprägter, so dass das Hämin am Anfang der Säule eine scharfe Bande bildete.

Tabelle 3. Chromatogramme auf Dowex-2 Häminisomeren nach Kuppelung an Apoperoxydase. Apoenzym (0,40 ml = 0,72 mg N) und Hämin (0,60 = 0,01 mg N, Hämin:Eiweiss 2,5) während 10 St bei Zimmertemperatur gelassen. Alle Lösungen und Puffern pH 7,6, 0,03 M Phosphat. 0,80 ml der Gemische wurden für Chromatographie genommen. Säulen: Dowex-2, 16 × 0,9 cm.

Hämin	Gesamt-N im Eluat mg	$\frac{D_{400}}{D_{280}}$ im Eluat
MH IX	0,50	2,67
MH I	0,52	1,98
KH III	0,52	0,40
KH I	0,55	0,24
Apoperoxydase	0,54	0,02

Koprohämin I (2,4,6,8-tetraCOOH) benahm sich genau wie sein Isomer. Aus Tabelle 3 geht hervor, dass das Eiweiss bei den drei Häminen fast quantitativ eluiert wurde. Bei Pyrrohämin (7-monoCOOH) war der Befund wegen der niedrigen Lösligkeit dieser Verbindung in Lauge nicht ganz klar. Eine freie, wandernde Bande war aber gut wahrnehmbar; bei Umchromatographieren auf Dowex zeigte sie Einheitlichkeit. Mesoporphyrin IX (6,7-diCOOH) zeigte zwar eine Spektrumänderung bei Zusatz von Apomyoglobin oder Serumalbumin, bei Chromatographieren auf Dowex-2 wurde es aber zurückgehalten, und das Eiweiss trat im Eluat allein auf. Kobalt (III) Mesoporphyrin IX gab denselben Befund wie die 6,7-Dikarboxyl-Hämine. Es wird auch hier daran erinnert, dass die geprüften Eisen(II)Protoporphyrin-Protein-Verbindungen ohne Zerlegung wanderten. Karboxyhämoglobin wanderte schneller als Methämoglobin und Paraperoxydase schneller als Peroxydase; in beiden Fällen waren die relativen R_F-Werte etwa 1:0,9. Diese Beobachtungen stimmen mit denen bei elektrophoretischen Untersuchungen überein.

DISKUSSION

Das übliche Verfahren für Hämindarstellung, hier als Methode 1 bezeichnet, gibt zwar bisweilen Präparate, deren Pyridinhämochromogenspektra niedrige Absorption im Rot zeigen. Meistens aber werden Spektra erhalten, die im Vergleich mit den Hämochromogenspektra von z. B. Erythrocyten oder Cytochrom c gesteigerte Absorption im Rot zeigen. Niedrige Absorption gibt auch aus Blut isoliertes Protohämin. Mit dem beschriebenen Verfahren für die Reinigung von Mesoporphyrin ist es sicher, dass das Porphyrin rein war. Das deutet auf die Eiseneinführung, wahrscheinlicherweise die mit den Redoxverläufen verbundene Bildung von freien Radikalen, als das schädigende Moment. Der geringe Wert [7] der Umkristallisierung aus Pyridin-Eisessig als Reinigungsmethode für schon kristallisierte Hämine wurde bestätigt.

Auch wenn es nicht gelungen ist die Verseifung des Häminesters ohne Nebenreaktionen durchzuführen sind doch die molaren Absorptionskoeffizienten des Hämochromogens des freien Hämins mittels dem Ester erreichbar. Bei der Berechnung der Geschwindigkeitskonstanten k_1 und k_2 der Verseifung wurde dieselbe molare Absorption in Eisessig für Diester, Monoester und freies Hämin angenommen. Dies mag nur annähernd richtig sein, weil eine Auflösung von freiem Hämin in Eisessig nicht stabil ist, und ein Zuwachs der Gesamtabsorption von etwa 10 % während der Verseifung (Abb. 3) wurde in der Tat beobachtet. Dies erklärt warum k_2 etwas grösser als $k_1/2$ gefunden wurde. Die k-Werte zeigen, dass die beiden Karboxylgruppen von einander unabhängig verseift werden.

Die Reinigung mittels Apoprotein gelang bei Proto-, Meso-, Hämato-, Deutero- und Diacetyldeuterohämin, die alle zwei Karboxylgruppen, in 6- und 7-Stellung, besitzen. Die Hämochromogenspektra der vier erstgenannten sind einander sehr ähnlich mit einer engen α-Bande. Aus Abb. 4 geht hervor, dass die Hämatohäminabkömmlinge nicht nur flachere sondern auch langwelligere Hämochromogenbanden als das reine Hämin besitzen. Es war darum von Interesse zu finden, dass Diacetyldeuterohämin, trotz der Ausdehnung und Rotverschiebung seines Hämochromogenspektrums, durch Kuppelung und Anionenaustauscherchromatographie gereinigt werden konnte (Abb. 5). Die relativen Affinitäten der fünf Dikarboxyl-Hämine zu Apoproteinen werden in einer späteren Arbeit näher untersucht; hier wird nur vorläufig erwähnt, dass die Proto-, Meso- und Hämatohäminperoxydasen dieselbe Aktivität in der Mesidinprobe zeigen; Diacetyldeuterohämin dagegen ist völlig inaktiv.

Die fünf genannten 6,7-Dikarboxyl-Hämine (Eisen(III)Porphyrine) ebensowie Kobalt(III)Mesoporphyrin, Eisen(II)Protoporphyrin und Pyrrohämin wanderten, nach Kuppelung an Apoeiweiss, wie gut begrenzte Banden abwärts auf der Säule. Das Eluat konnte mehrmals ohne Aufteilung umchromatographiert werden. Alle anderen geprüften Hämine und Mesoporphyrin IX wurden trotz »Kuppelung» von der Säule adsorbiert. Die Versuche mit verschiedenen Eiweisskörpern — zwei nativen Apoproteinen und zwei unspezifischen Substanzen (Serumalbumin und gealterte Apoperoxydase) — zeigen, dass eine bestimmte Konfiguration im Träger vorhanden sein muss. Es mag angenommen werden, dass die Konfiguration zwei Gruppen umfasst, die imstande sind mit den Häminkarboxylgruppen 6 und 7, oder mit an-

deren Säuregruppen, die ebensoweit von einander getrennt sind, zu reagieren. Gekuppeltes Mesohämin I bekomme dadurch eine freie Karboxylgruppe, die mit Dowex reagieren könnte. Nach dem Befund mit Pyrrohämin genügen Eisen + eine Karboxyäthylgruppe um eine einheitlich wandernde Verbindung zu schaffen. Mesoporphyrin IX zeigt, dass die Karboxylgruppen nicht allein die Bindung Wirkungsgruppe-Eiweiss vermitteln können. Bei pH 7,3 sind die pyrrolischen Stickstoffatomen ungeladen [21], und man muss deshalb schliessen, dass bei den Karboxylgruppen in Mesoporphyrin IX das Apoeiweiss von dem Dowex ersetzt wird. In Kobaltmesoporphyrin gibt es noch eine Bindungsmöglichkeit.

Der Befund bei Koprohämin III wäre verständlich wenn das Hämin, ausser dem Eisen, mit nur einer Karboxylgruppe oder einem "falschen" Paar (2—4, 4—6 oder 2—7, nicht aber 6—7) an dem Eiweiss gebunden wäre oder sonst die Bindung Hämin-Anionenaustauscher stärker als die Bindung Hämin und Protein wäre. Die Frage kann nicht beantwortet werden, weil die möglichen Abstände zwischen Eisen und Karboxylgruppen und die Reihenfolge der vier Dissoziationen unbekannt sind. Aus dem Versuch mit Koprohämin I kann nur geschlossen werden, dass die beiden isomeren Porphyrinen als Hämine unter den hier benutzten Bedingungen nicht zu trennen sind. Bei allen Häminen besteht die Möglichkeit, dass Eisen und Karboxylgruppen in der Bildung von Häminaggregaten teilnehmen. Es ist aber nicht klar warum sich die Koprohämine von den dikarboxyligen Häminen unterscheiden sollten.

Die Stickstoffatome in Dowex sind bei pH 7 positiv geladen, und eine Eisen-Stickstoff-Bindung ist deshalb sehr unwahrscheinlich [22]. Dowex-2 besitzt eine alkoholische Hydroxylgruppe, und Alkohole bilden mit Hämin Komplexe [15]. Eine Esterbildung ist aber unter den gegebenen Bedingungen bei günstigen sterischen Verhältnissen möglich. Es ist auffallend, dass die Reaktion zwischen Dowex und Hämin so viel Zeit braucht und auch, dass adsorbiertes Hämin mit hohen Eiweisskonzentrationen nicht zu eluieren ist.

Die Beobachtung, dass die Abkömmlinge lockerer als die entsprechenden nativen Hämine gebunden sind, steht in Übereinstimmung mit der Auffassung, dass der Hämoglobinabbau am Häminteil beginnt. Die Bindung an Globin würde dabei aufgelockert werden, und die prosthetische Gruppe könnte von anderen Trägern übernommen werden.

Für die freundliche Überlassung von Präparaten werden gedankt Herrn Å. Åkeson (Myoglobin I) und Doz. S. Paléus (Cytochrom c), Medicinska Nobelinstitutets biokemiska avdelning, Stockholm, Dr. G. Norlin (*Corynebact. diphteriae*-Bouillon), Statens bakteriologiska Laboratorium, Stockholm, Prof. S. Goldschmidt (Mesoporphyrin I-Ester), Organisch-chemisches Institut, München und Dr. J. J. Scott (Koproporphyrin I-Ester) National Institute for Medical Research, London.

Fräulein A. Harthoorn hat sehr wertfolle Assistanz geliefert. Die Untersuchung wurde von *Statens naturvetenskapliga forskningsråd* unterstützt.

Studies on Bile Acid Salt Solutions

II. The Solubility of Cholic Acid in Sodium Cholate Solutions and that of Desoxycholic Acid in Sodium Desoxycholate Solutions

PER EKWALL, TORSTEN ROSENDAHL and A. STEN

Institute of Physical Chemistry, Åbo Akademi, Åbo, Finland

The solubility of cholic acid in sodium cholate solutions and that of desoxycholic acid in sodium desoxycholate solutions has been determined by potentiometric titration of solutions of their sodium salts and by measuring the changes in the refractive indexes when the solutions have been saturated with the acids. The former method was found suitable for the determination of the solubilities in dilute solutions where no association has yet occurred; the latter method was more appropriate for solutions containing micellar substance. The solubility product exponent of cholic acid at 20°C was found to be $pK_L = 8.72$ and that of desoxycholic acid $pK_L = 9.15$.

From bile salt solutions saturated with the corresponding acids, the acids separate in pure form. No acid salts were detected in the precipitates. The activity of undissociated cholic acid in sodium cholate solutions saturated with the acid was found to be $a_{HA} = 1.8 \times 10^{-4}$ M. Knowing this value, it has been possible to evaluate the activity of the cholate anion from the pH values of the solutions. The results obtained show that no association takes place in the cholate solutions below a cholate concentration of about 0.01 M. From this concentration up to about 0.03 M, a partial association is observed, but above the latter concentration all the added cholate ions become associated. The activity of undissociated desoxycholic acid in solutions of its sodium salt saturated with the acid is 1.05×10^{-4} M. The evaluation of the activity of the desoxycholate anion in these solutions showed that no association occurs up to a desoxycholate concentration of 0.005—0.006 M. Above the latter concentration a partial association takes place which seems to become complete at least when the desoxycholate concentration exceeds about 0.01 M.

As soon as association sets in, the bile salt solutions begin to dissolve the respective bile acids. The solubilizing power increases stepwise which shows that the micelles have different properties in different concentration ranges. The concentrations delimiting these ranges in solutions saturated with bile acids have been determined.

When an attempt is made to elucidate the structures of aqueous bile salt solutions it is desirable to have exact information about the solubilities of the respective acids in these salt solutions.

As far as the solubilities of bile acids in water are concerned, it is known that the unconjugated acids are sparingly soluble and that their solubilities increase with the number of hydroxyl groups in the molecule. Gillert [1] has reported the solubility of desoxycholic acid as 0.24 g/l and that of cholic acid as 0.28 g/l at 15°C. Also the bile acids conjugated with glycine have relatively low solubilities, whereas the taurine conjugate of desoxycholic acid and especially that of cholic acid are very soluble in water.

The bile acids have a tendency to remain in the colloidal state in solution. Josephson [2] found that when strong acid is slowly added to aqueous bile salt solutions a colloidal solution often results from which the liberated bile acid begins to crystallize out only after some time, frequently after several days. The excess of mineral acid that can be added to solutions of the same concentration of different bile salts before the crystallization begins is observed to vary with the nature of the bile acid. Also foreign salts present in the solution influence the separation of the bile acid. Ekwall and coworkers have confirmed some of these observations [3-5] and have also reported preliminary values for the solubilities of cholic and desoxycholic acids in their respective salt solutions. They have further shown that the solubility increases with the degree of micelle formation.

We have now performed a more detailed investigation of the solubility of cholic acid in sodium cholate solutions and that of desoxycholic acid in sodium desoxycholate solutions. The solubilities have been calculated from the results of potentiometric titrations of the bile salt solutions with hydrochloric acid or have been determined directly by measuring the changes in refractive indices of the saturated solutions. In addition the solubility of cholic acid in pure water has been evaluated.

The bile salts were prepared from the same acids as were employed in the experiments in Part I of this series [5].

THE SOLUBILITY OF CHOLIC ACID IN WATER

The solubility of cholic acid was determined as follows. An excess of cholic acid was added to a volume of boiling conductance water exceeding 2 litres. The resulting mixture was then allowed to stand in a closed flask at 20°C and was shaken from time to time during a period of one week. The undissolved acid was then separated from the solution by filtration and two one-litre aliquots of the solution were evaporated separately to dryness in platinum dishes. The solubilities were found to be 91.9 and 91.4 mg of cholic acid per litre.

Another determination was carried out without heating. The water and excess of cholic acid were mixed in a rocking machine at about 20°C for one week and the mixture was then allowed to stand at 20°C for a further three days. The solubility value was 92.2 mg of cholic acid per litre.

The mean of these three solubility values is 91.8 mg per litre. This value is appreciably lower than the value reported by Gillert.

POTENTIOMETRIC DETERMINATION OF THE SOLUBILITIES OF BILE ACIDS IN BILE SALT SOLUTION

Back and Steenberg [6] have shown that it is possible to determine the solubility of a sparingly soluble weak acid and hence the corresponding solubility product K_L by a potentiometric titration of the solution of the salt of the acid with a strong mineral acid up to a point slightly past that where the acid begins to precipitate. The solubility is calculated directly from the amount of strong acid added and the pH of the solution at the precipitation point where the following equation is in force.

$$L_{HA} = c'_S + c'_{OH^-} - c'_{H_3O^+} \tag{1}$$

In the solution saturated with the weak acid (HA):

$$a_{H_3O^+} \cdot a_{A^-} = K_A \cdot a_{HA} = \text{constant} = K_L \tag{2}$$

$$a_{A^-} = (c_{tot} - c_S - c_{OH^-} + c_{H_3O^+})\, f_{A^-} \tag{3}$$

$$pK_L = pH - \log(c_{tot} - c_S - c_{OH^-} + c_{H_3O^+}) + \frac{0.5\sqrt{\mu}}{1+\sqrt{\mu}} \tag{4}$$

In the equations c_{tot} is the initial salt concentration recalculated with respect to the changed volume of the titration solution, c_S the concentration of free weak acid liberated by adding hydrochloric acid. The primed concentrations, c', refer to those at the precipitation point.

$$L_{HA} = \frac{K_L}{K_A} \cdot \frac{1}{f_{HA}} \simeq \frac{K_L}{K_A} \tag{5}$$

Whereas the calculations based on eqn. 1 should always yield correct values, this is the case for the calculations based on eqns. 4 and 5 only when the activity of the anion of the weak acid can be computed from eqn. 3. In the case of association colloids, *e.g.* bile acid salts, the latter is true only when no micelle formation has taken place. After micelles have been formed eqn. 3 must be replaced by eqn. 3 a.

$$a_{A^-} = (c_{tot} - c_S - c_{OH^-} + c_{H_3O^+} - c_{mic}) \cdot f_{A^-} \tag{3 a}$$

where c_{mic} is the concentration of acid anions bound in the micelles.

If the micelle formation is disregarded, the values obtained for K_L will be too high. As long as the extent of micelle formation is unknown the above method of evaluating the solubility product will not be valid when the salt concentration is so high that micelles are present in the solution. Furthermore, as soon as micelles are formed, the bile acid will be solubilized in the solution; eqn. 5, however, gives only the concentration of unsolubilized bile acid and can hence be applied only when solubilization does not occur. Thus, when micelle formation and solubilization does occur, it is necessary to calculate the solubility with the aid of eqn. 1.

The theory presumes, of course, that the precipitate that separates from the solution when hydrochloric acid is added is actually the weak acid itself and not an acid salt. In order to confirm this in the case of bile acid salts, the precipitates formed on titration of these salts were examined under the

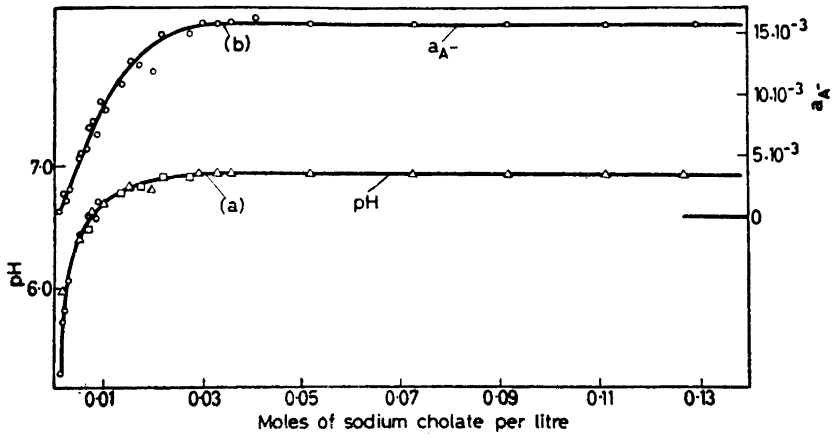

Fig. 1. pH values (curve a) and cholate anion activities, a_{A^-},(curve b) in sodium cholate solutions saturated with cholic acid at 20°C.

microscope, their melting points were determined, and, in a few doubtful cases, an analysis was carried out. All these investigations revealed that the precipitate forming during the titrations consisted only of the bile acid in question.

In titrations of bile salt solutions the applicability and reliability of the potentiometric method are limited by experimental difficulties. It may happen that supersaturated solutions of bile acids in solutions of their salts are readily formed. Sometimes the supersaturation continues also after the appearance of an opalescence or turbidity in the solution or even in solutions containing macroscopically dispersed bile acid precipitate. The calculation of the solubility and solubility product based on pH values for such supersaturated solutions will naturally lead to too high values.

In some cases it may be possible to break off the supersaturation whereupon the pH of the solution will rise abruptly to an appreciably higher value than previously. Probably this higher pH value is the theoretical value for the bile salt solution saturated with bile acid at the point in question in the titration. When no micelle formation has occurred in the solution, the experimental data for this equilibrium state can be used to calculate the solubility product from eqn. 4. It will, however, be less appropriate to use data for such a titration curve to calculate the solubility from eqn. 1 because there will be difficulties in determining at which point in the titration precipitation should have occurred if no supersaturation had taken place. (It is, of course, possible to extend the horizontal part of the curve after the abrupt rise in pH to the left to intersect the descending part of the curve (see Ref.[5], Fig. 1) and consider that part of the curve which is below the horizontal line as being due to supersaturation and to take the point of intersection to represent the saturation point. The solubility value obtained in this way will,

however, be in error and the magnitude of the error will increase with the solubility.)

When calculating the solubilities of the bile acids we have used in addition to the experimental data previously collected in our earlier determination of the dissociation constants of cholic and desoxycholic acids data obtained in new titrations which were continued until precipitation occurred. In the titration of dilute desoxycholate solutions it was in many cases possible to avoid supersaturation and the data could be used directly in the calculation

of the solubility and solubility product. More concentrated desoxycholate solutions containing micelles often yielded highly viscous, supersaturated systems in which the supersaturation could not be broken off and thus the solubility could not be evaluated. In the titration of cholate solutions a supersaturated state usually resulted which, however, could be broken off; in many of these cases the data could be used to calculate the solubility product.

The data obtained are presented in Tables 1 and 2. In the calculation of solubility products only values for solutions in which no micelle formation had occurred were employed. The solubility product exponent (pK_L) for cholic acid in 0.001—0.015 M sodium cholate solutions was found to be 8.72, S.D. 0.07 and that for desoxycholic acid in 0.001—0.004 M sodium descoxycholate solutions 9.15, S.D. 0.025. Using eqn. 5 and the previously determined values of the dissociation constants (cholic acid, $pK_A = 4.98$; desoxycholic acid, $pK_A = 5.17$) the following solubility values were calculated: 77.6 mg of undissociated cholic acid per litre and 43.1 mg of undissociated desoxycholic acid per litre. By direct measurement of pH at the point where precipitation begins and substitution of this value in eqn. 1, the solubility of desoxycholic acid in the above concentration range was found to be 43.1 mg per litre.

The titration method leads to higher solubility values at higher salt concentrations than the above- mentioned. These values are, however, not reliable. Nevertheless, they show that micelle formation and solubilization take plase in these solutions.

DISCUSSION

The solubility products of the bile acids. The value of the solubility of cholic acid in pure water, 91.9 mg/l or 2.15×10^{-4} mole/l, refers to both undissociated and dissociated cholic acid. When the dissociation of the acid is taken into account, the value $K_L = 1.84 \times 10^{-9}$ ($pK_L = 8.73$) is obtained for the solubility product of the acid at 20°C and the value 1.78×10^{-4} M for the activity, a_{HA}, of the undissociated acid in its saturated aqueous solution. When calculating these values it has been assumed that the dissociation equilibrium is not influenced by dissolved carbon dioxide.

This value of the solubility product is in excellent agreement with the mean value, $pK_L = 8.72$, obtained by the potentiometric method. The latter value gives for the activity of undissociated cholic acid in its saturated aqueous solution the value 1.82×10^{-4} M.

The solubility product K_L of desoxycholic acid at 20°C computed from data obtained by potentiometric titration is 7.08×10^{-10} ($pK_L = 9.15$) from which the activity a_{HA} of the undissociated acid in its saturated aqueous solutions is found to be 1.05×10^{-4} M. The direct determination of the solubility from the titrimetric data yielded the same value.

The structure of bile salt solutions saturated with bile acid. Despite the occurrence of micelle formation and solubilization the activity of cholic acid in all sodium cholate solutions saturated with cholic acid should remain constant and equal to 1.82×10^{-4} M. It should therefore be possible to calculate the activity of the cholate ion in these solutions from the data provided by the potentiometric titrations.

Table 1 contains pH values for 0.005—0.015 M cholate solutions at the points in the titration where a precipitate began to form and after equilibrium was attained. As already mentioned, above this point in the titration the titration curve runs parallel to the horizontal axis for some distance. The same is the case also in more concentrated cholate concentrations. Curve a in Fig. 1 shows how the pH at this point and on the horizontal part of the curve varies with the cholate concentration (the abscissa gives the actual cholate concentration at the point in question). In dilute solutions the pH increases with cholate concentration, remains practically constant at the value 6.94 in the 0.03—0.175 M concentration range, but tends to decrease slightly at still higher concentrations (0.3 M, pH 6.88; 0.4 M, pH 6.82; 0.8 M, pH 6.70). The constant value of the pH implies that the activity of the cholate anion is also constant.

The activity of the cholate ion in cholate solutions saturated with cholic acid has been computed from the pH values with the aid of eqns. 2 or 2 a.

$$\log a_{A^-} = \mathrm{pH} - \mathrm{p}K_{\mathrm{I}} \qquad (2\,\mathrm{a})$$

The values of the activity are plotted in curve b of Fig. 1. In the concentration range where the pH is constant the cholate ion activity is 1.57×10^{-2} M. This shows that the major proportion of the cholate ions are bound in micelles at concentrations above 0.03 M. At low concentrations up to approximately 0.01 M cholate the cholate ion activity increases linearly with the cholate concentration, and the activity values are only slightly lower than the concentration values. Between 0.01 and 0.031 M the cholate ion activity increases more slowly as the concentration approaches the upper value. These data show that all the cholate is present in form of single ions up to a concentration of about 0.01 M, but that above this concentration the ions begin to associate more and more until in solutions above 0.03 M in cholate all the added cholate is completely bound to micelles.

The data can also be used to calculate the concentration of unassociated cholate ions and the concentration of the cholate ions bound in the micelles. These calculations, which can be carried out in different ways, are subject to the uncertainties involved when calculating the activity coefficients of ions in solutions where micelle formation has taken place. Our procedure has been as follows. When data obtained for micellar solutions are substituted in eqn. 4 values $\mathrm{p}K_{\mathrm{I,\,exp}}$ are obtained, which differ from the correct values $\mathrm{p}K_{\mathrm{I,\,theor}}$. The correct value $\mathrm{p}K_{\mathrm{I,\,theor}}$ is in these cases obtained only when eqn. 4 is modified by taking into account eqn. 3 a. By combining both these modifications of eqn. 4, eqn. 6 is obtained which permits the calculation of the concentration of micellar substance in the solution.

$$c_{\mathrm{mic}} = (c_{\mathrm{tot}} - c_{\mathrm{S}} - c_{\mathrm{OH^-}} + c_{\mathrm{H_3O^+}}) \left(1 - \frac{K_{\mathrm{I,\,theor}}}{K_{\mathrm{I,\,exp}}} \right) \qquad (6)$$

The results of the calculation are given by the points of curve a in Fig. 2. Micelle formation is seen to begin at the 0.015 M cholate concentration and increases rapidly in extent. (The values in the region immediately above 0.015 M are erratic and it may be that they are slightly too high.)

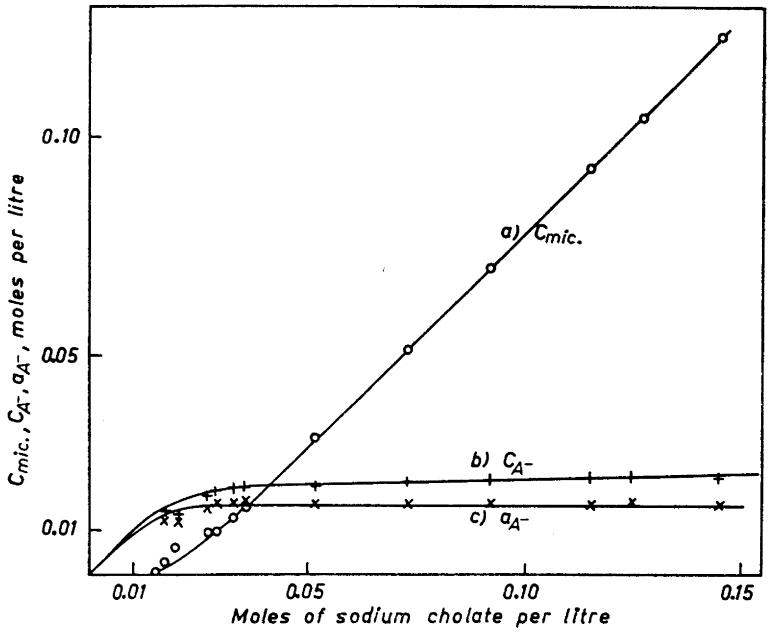

Fig. 2. Micelle formation in sodium cholate solutions saturated with cholic acid at 20°C. The concentration of micellar cholate (a) and of molecular cholate (b), and cholate anion activity (c). The points marked o, × and + have been calculated with the aid of eqn. 6, the curves are based on the activity values given in Fig. 1 b.

On the basis of these values the concentrations of unassociated cholate ions (the points on curve b) and the activity of free cholate ions (the points on curve c) have been calculated (the continuons curves a, b and c have been drawn using values calculated from the activity values in Fig. 1 b). Also these calculations show that the micelle formation begins above 0.01 M (concentration limit 1) is incomplete between 0.01 and 0.03 M, and that all added cholate forms micelles above the latter concentration (concentration limit 2). They give the constant value 1.62×10^{-2} M for the cholate ion activity in the concentration range above about 0.03 M; this value is only slightly higher value than that previously mentioned.

In sodium desoxycholate solutions saturated with desoxycholic acid, also in solutions containing micelles, the activity, a_{HA}, of desoxycholic acid is $1.05 \times 10^{4-}$ M. Using the pK_I value 9.15 we have, as above, calculated the activities of the desoxycholate anion from the pH values of desoxycholate solutions titrated to the precipitation point. It was possible, however, to carry out these calculations with satisfactory accuracy only up to a desoxycholate concentration of about 0.005 M. (At higher desoxycholate concentrations the solutions, as mentioned above, become supersaturated with respect to the acid during the titration and it was not possible to break off the supersaturation; hence exact pH values could not be determined for the saturated solutions.)

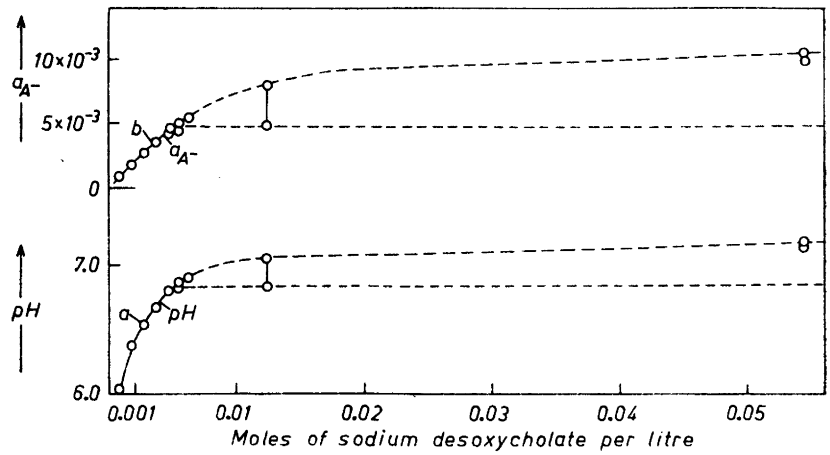

Fig. 3. pH values (curve a) and desoxycholate anion activities, a_{A^-}, (curve b) in sodium desoxycholate solutions saturated with desoxycholic acid at 20°C. In the concentration range above 0.005 M desoxycholate only approximate values lying between the two dashed curves were obtained.

The measured pH values and the respective anion activities are given by curves a and b in Fig. 3. It is possible to state with certainty only that the activity of the desoxycholate anion increases linearly up to a desoxycholate concentration of 0.005 M and that the activities are only slightly lower than the concentration values. This shows that no association takes place up to the mentioned concentration. Above this concentration (concentration limit 1) the activity of the desoxycholate anion seems to remain practically constant or to increase slowly with increasing concentration. In the 0.075 M desoxycholate solution saturated with desoxycholic acid, the anion activity does not seem to be higher than 1.1×10^{-2} M. Association hence begins at the 0.005 M desoxycholate concentration and increases rapidly to such an extent that, at least in solutions above 0.01 M, all the added desoxycholate forms micelles.

DIRECT DETERMINATION OF THE SOLUBILITIES IN BILE SALT SOLUTIONS

In order to obtain reliable information on the solubilities of bile acids in solutions of their salts at concentrations where micelles are formed we have performed a series of direct solubility measurements. In these experiments known weights of cholic and desoxycholic acids were added to measured volumes of solutions of the respective sodium salts in ampoules. After the ampoules had been sealed by fusing, they were placed in a thermostat at 40°C, in some cases at 20°C, and shaken for 5—7 days, during which time either the acid dissolved or the solution became saturated with the acid. The changes in refractive index of the solutions caused by the dissolved acid were measured with a Zeiss — Löwe liquid interferometer. As soon as the solution

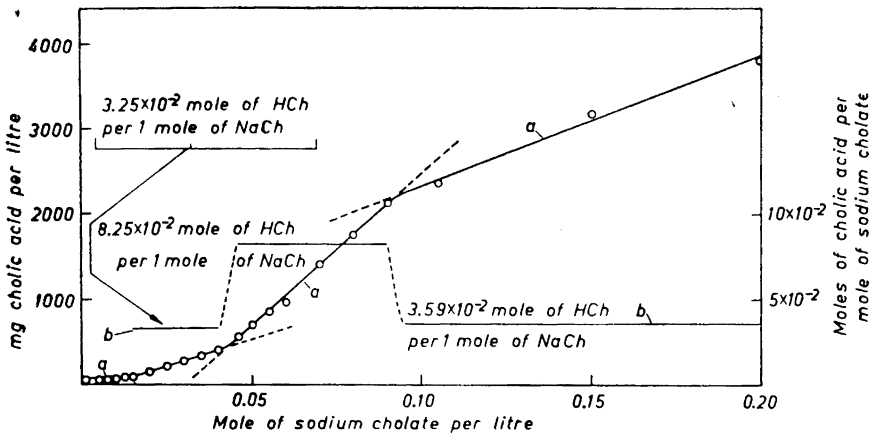

Fig. 4. The solubility of cholic acid in sodium cholate solutions at 40°C determined with the aid of liquid interferometer measurements. The solubility in mg of cholic acid per litre of sodium cholate solution (curve a). The solubility in moles of cholic acid per mole of sodium cholate in the micellar state, *i. e.* the saturation capacity of the cholate micelles (curve b).

became saturated with the acid, no further change in the refractive index was observed. At low bile salt concentrations, where very little acid dissolved, the solubility values were erratic (the maximum deviations from the mean were as large as ± 10 %. With increasing salt concentration and acid solubility more reproducible values (maximum deviations from the mean less

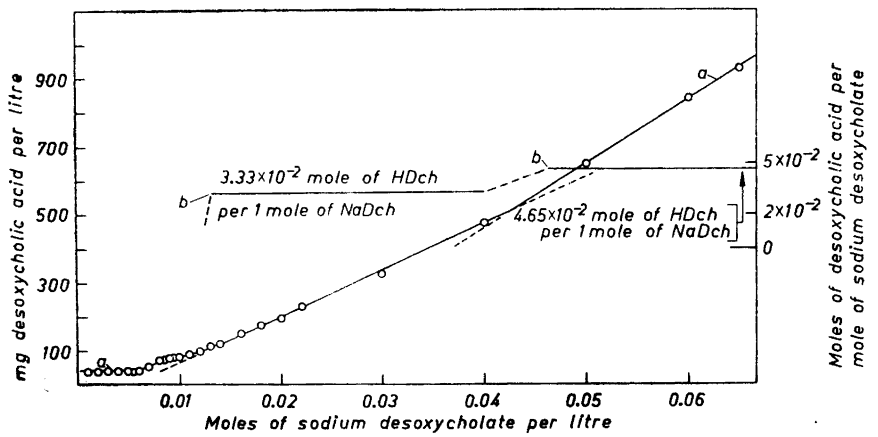

Fig. 5. The solubility of desoxycholic acid in sodium desoxycholate solutions at 40°C determined by the aid of liquid interferometer measurements. The solubility in mg of desoxycholic acid per liter of sodium desoxycholate solution (curve a). The solubility in moles of desoxycholic acid per mole of sodium desoxycholate in the micellar state, *i. e.* the saturation capacity of the desoxycholate micelles (curve b).

than ± 2 %) were recorded. The direct method is thus less suitable for measurement of the solubility in very dilute bile salt solutions than the titration method. In this concentration range the direct method gave somewhat lower solubility values (although they were measured at 40°C) than the titration method. (The values of the solubility products of the bile acids calculated from these values were: for cholic acid in 0.003—0.009 M sodium cholate solutions $pK_L = 8.90$ and in 0.010—0.015 M solutions $pK_L = 8.74—8.69$; for desoxycholic acid in 0.001—0.0055 M sodium desoxycholate solutions $pK_L = 9.23—9.24$.) In bile salt solutions where micelle formation and solubilization occurs the direct method yields more reliable solubility values than the titration method. The results obtained are shown in Figs. 4 and 5, curves a.

SOLUBILIZATION OF BILE ACIDS AND THE PROPERTIES OF THE MICELLES

In sodium cholate solutions (Fig. 4 a) up to 0.015 M in cholate (concentration limit 1) no solubilization of cholic acid could be detected; the solubility in this range is practically constant. Above limit 1 the solubility increases linearly until the cholate concentration rises to 0.04—0.045 M (concentration limit 2). Above this second limit the solubility also increases linearly but more rapidly. Above a cholate concentration of 0.09—0.10 M (limit 3) the increase of the solubility continues but less rapidly than between limits 2 and 3. The ability of cholate to solubilize cholic acid thus varies in different concentration ranges.

It should be noted that the solutions in question were not supersaturated but equilibrium systems in which the cholic acid is solubilized by cholate micelles; thus, they are thermodynamically stable, colloidal systems. Supersaturated solutions may contain appreciably larger amounts of dissolved acid than solutions in which only solubilization occurs. In the potentiometric titrations we have, for instance, encountered clear 0.012 M sodium cholate solutions containing up to 800 mg of cholic acid in one litre (no solubilized acid) and clear 0.03 M cholate solutions containing up to 3 000 mg of the acid per litre (only about 230 mg of cholic acid is solubilized). Also in these cases the cholic acid is colloidally dissolved, but the colloid formed is for the most part unstable and the excess acid will separate from the system sooner or later.

From the solubility curve we have computed the saturation capacity of the micellar cholate, *e.g.* the solubilizing power of the cholate micelles expressed in moles of cholic acid per mole of micellar cholate.

Above concentration limit 2, where all added cholate forms micelles, the slope of the solubility curve directly gives the saturation capacity per mole of micellar substance. Between limits 1 and 2, where all added cholate does not form micelles, we have computed the real saturation capacity of the micellar substance using our previous calculated values of the content of cholate anions in micellar form. The curve b in Fig. 4 shows that the power of the cholate micelles to solubilize cholic acid changes abruptly at the concentration limits but is constant in the concentration ranges between the limits. This implies

that the association leads to the formation of micelles with different properties in the different ranges and that the concentration limits represent cholate concentrations where new types of micelles begin to form in sodium cholate solutions saturated with cholic acid.

In sodium desoxycholate solutions up to about 0.006 M (limit 1) no solubilization of desoxycholic acid could be observed (Fig. 5, curve a); the solubility is practically constant in this range. Above limit 1 the solubility of desoxycholic acid increases rapidly at first, but then somewhat more slowly. Above the 0.010—0.012 M concentration (limit 2) the solubility again increases rapidly, but now practically linearly, up to 0.04—0.05 M concentration (limit 3) above which the solubility curve rises even more rapidly with increasing desoxycholate concentration.

We have shown above that all added desoxycholate forms micelles from the concentration 0.01 M upwards. Above this concentration, the slope of the solubility curve thus gives the saturation capacity of the micellar desoxycholate for desoxycholic acid (curve b in Fig. 5). (Between limits 1 and 2 it is impossible to evaluate the saturation capacity of the micellar substance with certainty because the extent of the micelle formation is not known.) Our calculations show that the solubilization power of the desoxycholate micelles changes at the concentration limits 2 and 3 but remains constant between these limits and in the range above limit 3. Hence micelles with different properties and of different types exist in different concentration ranges also in desoxycholate solutions saturated with desoxycholic acid.

We have previously come to similar conclusions with respect to association and micelle properties in cholate and desoxycholate solutions not saturated with the respective bile acids. The bile acids seem, however, to shift the limits slightly to lower concentrations.

ACTA CHEMICA SCANDINAVICA 12 (1958) 1634—1642

The First Step in the Swelling of Gelatin with Water. III

CHR. WINTHER

Photochemical Laboratory, Technical University of Denmark, Copenhagen, Denmark

The normal content of water in air dried gelatin is shown to be present as a solution of soluble gelatin. On this basis it is possible to give a detailed account of the progress of the watering of the gelatin.

In some earlier treatises [1] I have examined the speed of swelling of the Christensen-interference plate [2] with water. About five different plates were treated with water, each of them going through three successive treatments. It was thereby observed that after drying of the plates the edges of the extinction bands as a whole had shifted towards lower wavelengths.

In order to examine this peculiar phenomenon closer nine other plates were treated with water and dried, each one three separate times, in a single case four times, and the speeds of swelling and of the subsequent drying were examined. Thereby the said phenomenon was confirmed in all cases.

1. THEORY OF THE PHENOMENON

The wavelengths of the two edges of the extinction band (BB) are determined by the formula

$$\lambda_{I} = 263 \left(n_{A} \frac{v_{A}}{100} + n_{G} \right) \tag{1}$$

for the upper edge, and

$$\lambda_{II} = 265 \left(n'_{A} \frac{v'_{A}}{100} + n'_{G} \right) \tag{1a}$$

for the lower edge [3]. Here 263 and 265 are the thicknesses of the gelatin layer plus chromic oxide, n_A and n'_A the indices of refraction for silver bromide, n_G and n'_G the the same values for gelatin, and v_A and v'_A the percentage by volume of silver bromide.

Now, the falling off of the wavelength by subsequent treatment with water cannot be due to a loss of silver bromide as the solubility of this substance is extremely low. As the subsequent calculations show, the loss cannot be due to inorganic components (ashes) because then the found connections between the different amounts of water during the swelling process would be quite meaningless. Therefore the observed falling off must be due to a loss of gelatin.

2. EARLIER MEASUREMENTS

Pouradier [4] has found — using two homogeneous samples of gelatin — that up to 0.13 % of gelatin can be dissolved in cold water without any reduction of the molecular weight. It must be remarked that the examined samples of gelatin had been washed beforehand to remove impurities. Unlike Pouradier earlier investigators [5] had found that the high molecular gelatin had to be split up in smaller molecules in order to be soluble.

The loss of gelatin which I have found is of an entirely different nature. Each watering during two or three days caused a certain loss, and after drying renewed watering resulted in a further, but somewhat smaller, loss, tending against a maximal amount which cannot be exceeded. These maximal values lie between 2.8 and 5.7 % by volume of gelatin.

3. DIRECT MEASUREMENTS

About 1.5 g of Nelson I emulsion gelatin were dried to constant weight over calcium chloride and then for a total of ten days treated with cold water, which was renewed every second day. After removal of the water and spontaneous evaporation for some days the remainder was dried to constant weight over calcium chloride. Thereby were found losses of 16.4 and 16.8 % by volume, on an average 16.6 %.

As the values of G′, the percentage by volume of unhardened gelatin in the interference plates, lie between 31.4 and 22.2 for, respectively, the upper and the lower edge of the BB the values for the interference plates should lie between 3.7 and 5.2 if the densities are the same for the soluble and the insoluble parts of the gelatin.

It is commonly known that commercial gelatin must be regarded as a mixture of molecules of varying size, *e.g.* from 5 000 to 100 000. It may reasonably be taken for granted that only the smallest molecules are directly soluble, whereas the big molecules just swell with water, with the exception of the very small percentage of soluble gelatin which is found among the big molecules, as mentioned before.

4. THE WATER CONTENT OF THE GELATIN

It is commonly known [6] that commercial gelatin contains 10—20 % by weight of water, or 13.6—26.2 % by volume, if the density of completely dry gelatin is taken as 1.42 (see below).

In the course of the swelling experiments the amounts of water, V, which were absorbed during all series of watering were calculated for all values g of dissolved gelatin, from $g = 0$ to $g = g_\infty$. The differences V_0 to V_∞ for the 9 examined plates (18 values) lie between 12.0 and 24.0 % by volume. This leads to the conclusion that the soluble gelatin in air dried gelatin is present as a solution. As the quotient $(V_\infty - V_0):g_\infty$ for the 18 cases varies irregularly between 3.8 and 4.5, average 4.1, the said solution must contain about 25 volumes of gelatin to 100 volumes of water.

The mean value of the 18 values measured here is 17.3. As the mean of 13.6 and 26.2 is a little higher (19.9) I have taken the value 18 as a general mean. The earlier [7] found value of d_G, the density of air dried gelatin, 1.32, consequently must apply to this water content. Therefore, the value of d_G for absolutely dry gelatin and for gelatin with other water contents can be calculated. The results are shown in Table 1.

Table 1.

Water	d_G
0	1.42
12	1.35
18	1.32
24	1.30

The same considerations apply to the values of n_G, the indices of refraction for gelatin, which I have measured on an earlier occasion [7]. Through use of the formula

$$\frac{n_G - 1}{d_G} = \frac{(n_v - 1)\frac{v}{100}}{1} + \frac{(n'_G - 1)\frac{100 - v}{100}}{1.42}$$

where n_v, n_G and n'_G are the indices of refraction for water, gelatin with 18 % by volume of water, and for pure gelatin, respectively, it is possible to calculate the indices of refraction for pure gelatin and afterwards for gelatin with different contents of water. Table 2 shows the results.

Table 2. n_G for different water contents.

λ	0	3	6	9	12	15	18	21	24
700	1.580	1.569	1.558	1.547	1.539	1.529	1.518	1.511	1.504
650	1.585	1.574	1.563	1.552	1.542	1.533	1.525	1.517	1.510
600	1.590	1.579	1.568	1.557	1.547	1.537	1.527	1.520	1.514
500	1.600	1.589	1.578	1.567	1.555	1.546	1.536	1.530	1.524

5. THE LOSS OF GELATIN BY WATERING OF THE INTERFERENCE PLATE

It is now possible to calculate the loss of gelatin. To this end the formula 1 must be altered in the following way:

$$\lambda_I = \left(263—253\,\frac{g}{100}\right)\left(n_A\,\frac{v_A}{100} + n_G\,\frac{100—g}{100}\right)$$

and formula 1a is altered in the same way. Here g is the percent loss of gelatin after each treatment with water for 2 or 3 days, and the number 253 is the thickness of the pure gelatin layer [8]. The values of g are found in Table 3 where the first column shows the number of the plate. Each plate of the size 9 × 12 cm was divided into small pieces, and the small index figure denotes the number of the examined piece of the particular plate. The figures I and II denote the upper and lower edges of the BB. The second column shows the number of days, D, during which the plate was treated with water, the third the successive values of the wavelengths, the fourth the values of v_A, the percentage by volume of silver bromide, the fifth the observed wavelengths after watering for 2 or 3 days. These wavelengths were found to be practically constant for each individual plate and edge. The values here quoted are the averages of the individual measured values. The sixth column shows the values of g.

6. THE MECHANISM OF THE ABSORPTION OF WATER

In the second paper in this series [9] I have found that the first absorption of water, v_0, takes place very rapidly. In the said paper I have also found that the speed of this first diffusion through the plate is 0.69 sec for each μ of thickness. The nine plates now examined have thicknesses from 9.6 to 12.0 μ, and the time for the first diffusion therefore varies from 6.6 to 8.3 sec, a quite negligible value compared with the much longer spaces of time for the following periods of watering.

As the new measurements show the subsequent absorption of water can be divided in two periods, both of which are first order. The first of these periods is ended in about 30 min, whereas the second takes 2 or 3 days.

Assuming, as said before, that the soluble gelatin is present as a series of solutions, situated between the higher molecular gelatin molecules, it is probable that some of these solutions are directly accessible, whereas others are protected by the big molecules. The first ones must therefore be diluted by the water and must hereby give the water the possibility to penetrate into the adjacent cavities between the big molecules. This process then takes about 30 min. Thereafter the dissolved gelatin has to diffuse out into the outer water, and the water in the layer has to force its way between gelatin and silver bromide, and then to fill all accessible cavities. These latter processes are very slow and take a total of about 2 or 3 days.

Furthermore, during the drying the whole network has the possibility of rearranging so that new regions of gelatin solution are made accessible to the next ingress of water. This is going on as long as there is any soluble gelatin available.

Table 3.

7. CALCULATION OF THE AMOUNT OF WATER

The results of the treatment with water were measured spectrographically after 1, 2, 4, 8, 15, 30, 60, 90 and 120 min, and then after 2 or 3 days. Prolonged watering had no further effect.

The wavelengths observed during the treatment with water are all of the second order. In order to convert these values into the corresponding

wavelengths of the first order, I have calculated, with the aid of the indices of refraction for gelatin (with 18 % by volume of water), water and silver bromide, a series of curves which indicate the factor by which the observed wavelength has to be multiplied, for a series of different percentages by volume of water. In each case a probable value is found by a preliminary calculation, and if the finally calculated value for v_v differs too much from the supposed value the calculation is repeated until the supposed and the finally calculated values are practically the same.

The formula for the calculation for the upper edge of the BB is

$$\lambda_v = \left(263—253\frac{g}{100}\right)\left(n_A \frac{v_A}{100} + n_G \frac{100\text{-}g}{100} + n_v v_v\right)$$

and similarly for the lower edge.

For the first series of measurements of the individual plate the value of g is at first zero. During the further treatment with water the available amount of soluble gelatin, g, is dissolved and removed. The final value V therefore must be calculated with this value of g inserted in the formula. The same is the case for all the values in the third period — from 30 min to 2—3 days — when the solution of gelatin is diluted and removed.

I have, therefore, calculated two series of values of v_v, the first one for $g = 0$, the second for $g = g_1$. These two curves are practically parallel. Then I have drawn a curve from the beginning of the lower curve to the upper one in such a way that it coincides with the upper one after about 30 min and thereafter follows this curve to the end. For the next following treatments with water the two curves are calculated for $g = g_1$ and $g = g_2$, and so on.

The results are given in Table 3, where the 7th column contains the values of v_0, the momentary absorption of water, the 8th column the values of v_1, the second step, and the 9th column the values of V, the final amount of water. The 10th column shows the difference $V_\infty—V_0$, which indicates the amount of water in the air dried plate, the 11th column the quotient $\Delta V: \Delta g$ and the 12th and 13th column the two reaction constants of the first order, where the time factors denote minutes and hours, respectively.

The table shows some irregularities. The plates 47_3 and 212_{10} were at first watered as usual. Then they were placed in water for 2 days without measuring the wavelength, only to find the speed of drying. After the drying they were measured again in the normal way during the following treatment with water. For No. 212_{11} it was impossible to measure the values up to 15 min on account of a technical hindrance. Therefore the values of v_0 could not be found in this case.

8. THE VALUES OF g_∞ AND V_∞

These values can be found in two different ways, either graphically, as points of intersection between the two curves which show the variation of

v_0 or v_1 with g, and of V with g, or by calculating the values of g as if varying after the first order, the time factor denoting days, and thereafter calculating the corresponding values of V_∞ as

$$\frac{V_\infty - V_0}{g_\infty - g_0} = 4.1$$

The values of k_g are to be found in Table 3, column 14.

9. THE VALUES OF v_0 AND v_1

If the theory here advanced is correct the values of v_0 must be a little higher than the immediately preceding values of v_1. The values of v_0 have been increased by the cavities, which were made free at the preceding treatment by removal of the soluble gelatin. Furthermore, this soluble gelatin itself has a certain volume, which has to be added to v_1 to give the next value of v_0.

The individual measurements are not accurate enough to allow a test of this kind. The only way is to examine the question in a statistical way. A total of 34 corresponding pairs of v_0 and v_1 have been measured. 22 of them give positive values of the difference $v_0 - v_1$, all of them together making 89.7. The other 12 give negative values, totalling 44.7. The total positive amount is 45.0, on the average 1.32.

The corresponding values of Δg for the 34 cases average 1.26. The two figures are identical.

10. THE SPONTANEOUS DRYING OF THE WET PLATE

In the last paper in this series [10] I have found that the spontaneous drying of the wet interference plate follows the equation

$$v_v = V_\infty \cdot 10^{-k_5 t/D}$$

where D is the thickness of the plate in μ. The thickness of the coating was measured as previously [11] by counting the number of interference lines. The piece of plate glass which was laid on to the edge of the coating was very small, and the distance from the scratched line to the edge of the plate was only 4.4 mm. It was illuminated with the yellow sodium line (589 mμ). Table 4

Table 4.

Plate No.	196_7	196_{11}	196_8	216_9	216_{12}	47_3	47_{10}	212_{10}	212_{11}	mean
D	11.5	11.7	11.0	9.6	12.0	10.3	9.6	10.6	10.6	
k_5 upper	2.33	2.59	2.60	2.51	2.88	2.57	2.27	2.24	2.45	2.48
k_5 lower	2.36	2.65	2.66	2.18	2.55	2.41	2.44	2.37	2.26	2.43

contains the results for the 9 examined plates. The first line of values for k_5 corresponds to the upper edge, the second one to the lower edge of the BB.

The total mean is then 2.46. In the earlier experiments the mean value 2.38 was found for 5 other plates. These two values must be regarded as identical.

11. CONCLUSIONS

1. It is found that by watering of the interference plates some per cent of gelatin is removed. After drying and renewed watering a further, but smaller, portion is removed, and so on, up to a certain limit.

2. The soluble gelatin is shown to be present in the air dried gelatin in the form of a solution of about 25 volumes of gelatin in 100 volumes of water.

3. By the aid of a simple model of the interference plate it is possible to divide the amount of swelling water into three parts which are absorbed with different speeds. It is possible to give a probable explanation of this phenomenon.

The First Step in the Swelling of Gelatin with Water. IV

CHR. WINTHER

Photochemical Laboratory, Technical University of Denmark, Copenhagen, Denmark

By the aid of a simple model of the constitution of the interference plate it is possible to explain the peculiar phenomenon that the lower edge of the extinction band by aftertreatment in some cases takes up more silver bromide than the upper edge. The same model makes it possible to calculate the diameter of the gelatin molecule.

1. AFTERTREATMENT OF THE PLATE

In spite of the very detailed recipe which the late civil engineer Herman Christensen has given for the preparation of his interference gelatin plate [1], and in spite of the practice which I have afterwards developed during the preparation of some 250 plates, it still is a rather delicate job to prepare a really first class plate. Especially the colour is very often too weak.

To overcome this difficulty I have tried to give the finished plates an aftertreatment with silver nitrate and potassium bromide, exactly in the same way as during the original preparation, and it is in this way possible to arrive at much stronger colours and, by varying the concentration of the silver nitrate solution, to obtain any desired colour and, finally, through repetition of the procedure, nearly opaque plates.

By this procedure the concentration of silver bromide is of course increased and, by repeated aftertreatment, the percentage by volume can reach values higher than 60.

In order to get the greatest possible material the original plates (9 × 12 cm) were cut in small pieces (18 × 20 mm) which were indicated by small index figures, *e.g.* 47_3, and examined separately. In this way a total of 30 pieces of 6 different plates have been aftertreated, 13 of them two times and 5 three times, 57 measurements in all of both the upper and the lower edge of the broad band.

The silver nitrate solutions had the concentrations 25:100, 11:100 and 5:100. The first one was applied for 3 or 1 1/4 min with identical results, the second one for 3 min and the third one for 6 min. 24 pieces were treated with the strongest solution, 9 with the intermediate one and 6 with the most diluted solution. The results are shown in Tables 1, 2 and 3.

Table 1. First aftertreatment.

The figures I and II refer to the upper and the lower edge of the broad band. The first column gives the number of the plate, the second the value of v_A, the percentage by volume of silver bromide, and the third the increase in v_A by the aftertreatment.

2. RESULTS OF THE AFTERTREATMENT

With exception of the plates, which have in advance been watered, the increase in v_A is, for each concentration of silver nitrate, independent of the original value of v_A.

Table 2. Second aftertreatment.

196_{11}	26.2	2.6	20.3	0.9

In most cases the increases in v_A are higher for the upper than for the lower edge of the broad band, as could be expected. This is the case for the No. 47 (10 cases), 50 (6 cases), 196 (8 cases and 1 exception), whereas No. 181 (4 cases), 212 (4 cases and 1 exception) and 216 (5 cases) show the opposite phenomenon.

As explained earlier [2] the broad band originates from a series of layers whose percentages by volume of silver bromide are so great and lie

Table 3. Third aftertreatment.

	I		II	
Plate No.	v_A	Δv_A	v_A	Δv_A
212_{11}	42.2	2.7	30.0	4.8
196_{11}	28.8	2.6	21.2	4.8

so near each other, that the individual interference bands merge into one broad band. These layers go from the air side of the coating and into about 2/3 of the whole thickness of the coating. In the next following part of the coating the concentration of silver bromide decreases rapidly so that the individual bands are separated from each other and thereby constitute the so-called fringes.

It appears from this, that v_A is always lower at the lower than at the upper end of the broad band. The most probable explanation why the increase of v_A in a number of cases nevertheless is higher at the lower edge than at the upper edge seems to be that the silver bromide is dispersed in the form of grains, and that these grains at the lower edge are so much smaller than those at the upper edge that the larger surface of these smaller grains more than compensates for the lower concentration.

However, the further development of this explanation leads to great difficulties, especially in respect of the understanding of the different steps of the swelling process [3]. On the other hand, it is possible on the basis of a simple model of the constitution of the plate to give an entirely different explanation of these peculiarities.

3. THE CONSTITUTION OF THE PLATE

In a previous paper [4] I have assumed that the polar groups of the gelatin molecule are found on one side of the molecule, which is therefore hydrophilic, whereas the non-polar groups are found on the other side, which is therefore hydrophobic. The silver bromide is situated between two adjacent hydrophilic surfaces, and the corresponding percentage by volume, G', of unhardened gelatin is therefore divided in two halves.

4. THE COURSE OF THE AFTERTREATMENT

By aftertreatment with silver nitrate, which is terminated already after 1 1/4 min, the solution must at once fill the space v_0 between the adjacent hydrophobic surfaces but has no time for diluting the solutions of soluble gelatin [5], which are distributed throughout the network of gelatin molecules. On the other hand, the silver ions have the possibility of being adsorbed on the already present surfaces of silver bromide.

By the subsequent treatment with potassium bromide (20:100), the silver nitrate, which fills the space v_0, must immediately be converted into silver bromide, and the same is the case with some of the adsorbed silver ions on the surface of the silver bromide.

During the following treatment (6 min) with the mixed solution of potassium bromide and potassium metabisulphite the rest of the adsorbed silver ions are converted into silver bromide, and the molecular silver bromide in the volume v_0 is dissolved by the metabisulphite and then transported to and adsorbed on the surface of the layer of silver bromide, which thereby thickens.

Table 4.

$AgNO_3$ 25:100							
Plate No.	number of pieces	I				II	
		Δv_A mean	v_o mean	ΔS	ΔA	Δv_A mean	ΔA
47	7	13.2	61	2.6	10.6	9.7	7.1
196	6	12.8	90	3.8	9.0	9.8	6.0
212	2	9.0	107	4.5	4.5	10.8	6.3
216	2	8.2	75	3.2	5.0	10.8	7.6

Table 5.

$AgNO_3$ 11:100						
Plate No.	number of pieces	I			II	
		Δv_A mean	ΔS	ΔA	Δv_A mean	ΔA
47	2	7.4	1.3	6.1	5.4	4.3
196	2	5.6	1.9	4.7	5.6	3.7
212	1	6.6	2.2	4.4	8.6	6.4
216	1	8.1	1.6	6.5	8.4	6.8

Table 6.

$AgNO_3$ 5:100						
Plate No.	number of pieces	I			II	
		Δv_A	ΔS	ΔA	Δv_A	ΔA
47	1	4.8	0.5	4.3	3.7	3.2
196	1	3.5	0.8	2.7	4.7	3.9
212	1	5.1	0.9	4.2	4.6	3.7
216	1	4.5	0.7	3.8	5.2	4.5

The increase in v_A through the aftertreatment is therefore made up of two parts, the directly adsorbed quantity ΔA, and the quantity ΔS subsequently transported from v_o.

1. For the silver nitrate solution 25:100 one volume corresponds to the following volume of silver bromide:

$$\frac{25 \times 1.194 \times 1.14}{125 \times 6.46} = 0.0422$$

where 1.194 is the density of the solution, 1.14 the previously [6] found value of the quotient $AgBr:AgNO_3$, and 6.46 the density of silver bromide.

For the solutions 11:100 and 5:100 the figures are 0.0209 and 0.0088, respectively.

2. For the four plates whose values of v_o are experimentally determined [7] the data are collected in Tables 4, 5 and 6.

For the second and third aftertreatment there are fewer observations, and the results therefore are not very exact. See Tables 7 to 11.

47	1	0.7	0.2	0.7	0.2
196	1	2.6	1.8	0.9	0.1
212	1	1.9	1.0	2.6	1.7

Table 10. Third aftertreatment.

$AgNO_3$ 11:100					
		I		II	
Plate No.	number of pieces	Δv_A	ΔA	Δv_A	ΔA
47	1	6.7	5.4	4.3	3.0
216	1	2.8	1.2	6.8	5.2

Table 11.

$AgNO_3$ 5:100					
		I		II	
Plate No.	number of pieces	Δv_A	ΔA	Δv_A	ΔA
196	1	2.6	1.8	4.8	4.0
212	1	2.7	1.8	3.1	2.2

The adsorbed amount of silver bromide ΔA is supposed to form a compact layer the thickness of which can be either the total length of a molecule of silver bromide or — on the average — half this value, if the layer consists of only single silver or bromide ions. The total length of the silver bromide molecule is known to be 0.64 mμ, and it is consequently to be expected that the thickness of the layer is either 0.32 or 0.64 mμ.

If the value of G′, the percentage by volume of unhardened gelatin, is known it must therefore be possible to calculate the diameter of the gelatin molecule because

$$\frac{G'}{2d_G} = \frac{\Delta A}{0.64} \quad \text{or} \quad \frac{G'}{d_G} = \frac{\Delta A}{0.32}$$

where d_G is the diameter of the gelatin molecule. It is multiplied by 2 because the silver bromide is situated between two surfaces of unhardened gelatin, and therefore corresponds to two diameters of gelatin molecules.

From earlier measurements [8] it is known that the values of G′ for the upper edge of the broad band vary from 30.2 to 34.2, with the mean value 31.4, for the lower edge from 21.9 to 22.2 mean 22.2. I assume that these values also are valid for the new measurements. By inserting these values in the equation above we find for the first aftertreatment with the strongest solution of silver nitrate the following values of d_G. (See Table 12).

Table 12.

	I		II		
Plate No.	d_{AgBr}	d_G	d_{AgBr}	d_G	d_G mean
47	0.64	0.93	0.64	0.91	0.92
196	0.64	1.12	0.64	1.18	1.15
212	0.32	1.11	0.64	1.13	1.12
216	0.32	1.00	0.64	0.94	0.97

The table shows that no intermediary values are possible between 0.32 and 0.64, and this fact seems to be the real cause of the peculiar phenomenon that v_A for some plates (212,216) are greater for the lower edge than for the upper edge of the broad band.

The calculated values of d_G agree well with the values 0.8—0.9 mμ which Sheppard, Lambert and Swinehart [9] have assumed earlier.

For the more diluted solutions of silver nitrate and for the second and third aftertreatment the results are scant and not very exact. By using the now known values for d_G we find the corresponding values for the thickness of the silver bromide layer, which are collected in Tables 13 to 15.

Table 13.

Table 15.

Plate No.	$AgNO_3$ 5:100					
	I			II		
	aftertr.			aftertr.		
	1	2	3	1	2	3
47	0.25	0.01	—	0.27	0.02	—
196	0.20	0.13	0.13	0.40	0.00	0.42
212	0.30	0.07	0.13	0.37	0.17	0.22
216	0.24	—	—	0.39	—	—

The figures I and II refer to the upper and the lower edge of the broad band. Column 1 shows the number of the plate, and the following columns the calculated thicknesses of the silver bromide layer for the first, the second and the third aftertreatment, if any.

For the first aftertreatment the values 0.32 and 0.64 seem to be valid for all concentrations of silver nitrate. It is worth noting that also for the concentration 11:100 the lower edge takes up more silver bromide than the upper edge, in the same two cases as before.

The measurements of the following aftertreatments are too scant and uncertain to permit any conclusions.

The First Step in the Swelling of Gelatin with Water. V

CHR. WINTHER

Photochemical Laboratory, Technical University of Denmark, Copenhagen, Denmark

By the aid of a simple model of the constitution of the interference plate it is possible to calculate the thickness of the silver bromide layer and the swelling factor of the gelatin.

In the preceding paper of this series [1] it was shown that the amount of silver bromide which was taken up during the aftertreatment of the interference plate was due to two sources, namely 1) the adsorbed amount of silver ions, and 2) the solution of silver nitrate.

When the original chromated gelatin plate, after exposure, is bathed in the solution of silver nitrate (25:100) a certain amount of silver ions are directly adsorbed [2], and at the same time the solution is filling the network of gelatin molecules for which reason the said amount is determined by 1) the swelling factor f, and 2) the percentage by volume of unhardened gelatin, G′.

1. THE ADSORPTION.

As shown before [3], the adsorption is expressed by the formula

$$\text{ads.} = 0.64 \frac{G'}{2d_G} \qquad (1)$$

where d_G is the diameter of the gelatin molecule.

Table 1 contains, 1) the numbers of the plates, 2) the mean values of v_A, the percentage by volume of silver bromide, for the upper (I) and the lower (II) edge of the broad band. No. 47 comprises 10 cases, No. 196 9, No. 212 5 and No. 216 5 cases. The values of d_G are known from an earlier paper [4], the mean values of G′ are taken as 31.4 and 22.2, respectively [5]. The third column contains the calculated amount of adsorbed silver bromide (ads) and the fourth column the quotients ads:v_A.

From previous measurements [6] it is possible to calculate this quotient for different values of G′, which are taken from Table 7 of the paper just quoted. Table 2 contains the results for three different values of G′, which correspond to the three last values in the said Table 7.

Table 1.

Plate No.	v_A	ads.	ads:v_A	exp.
47 I	27.7	10.9	0.39	0.32
47 II	18.4	7.7	0.42	0.38
196 I	24.7	8.7	0.35	0.32
196 II	16.0	6.2	0.39	0.38
212 I	35.1	9.0	0.26	0.32
212 II	23.6	6.3	0.37	0.38
216 I	30.4	10.4	0.39	0.32
216 II	21.2	7.3	0.42	0.38

The first column shows the number of days which have passed between the coating and the exposure of the plate, the second and the third column show the adsorbed and the total amounts of silver nitrate, and the fourth column the quotient ads: total.

It appears that the behaviour of the plates which have remained only 2 days before the exposure is different from that of plates which have remained 4, 7 or 11 days before the exposure. For these three groups of plates the quotient for each individual value of G′ is nearly constant and markedly greater than for the plates which have had 2 days rest.

All the newly examined plates have only remained 2 days between coating and exposure. It is therefore possible to interpolate graphically the values for G′ = 31.4 and 22.2. These values are shown in Table 1, column 5 under the desingnation exp.

Table 3 contains the corresponding values for the older plates [7].

As the same sort of gelatin (Stoess hard) was used as for No. 212, the value 1.12 for d_G was used for the calculation.

Both Tables 1 and 3 show that the calculated and the experimentally found values of the quotient agree well.

2. THE ABSORPTION OF SILVER NITRATE SOLUTION

In order to calculate the amount of silver nitrate solution which is absorbed by the exposed chromated gelatin plate it is necessary to know the swelling factor f. Earlier measurements [8] have been interpreted under the assumption that — for each sort of gelatin — f should be a constant, independent of the exposure, when it was calculated for 100 % unhardened gelatin. By closer examination of the results this assumption does not seem to hold good. On the contrary, there seems to be an approximate proportionality between f and the amount of swelling water, so that $f = 0.093$ V. It appears from this, that the value of f must be higher at the upper than at the lower edge of the broad band.

The formula for the absorption is now

$$((f—v_o)\frac{G'}{100} + v_o) \times 0.0422$$

or

$$\left[f\frac{G'}{100} + v_o\left(1— \frac{'G'}{100}\right)\right] \times 0.0422 \qquad (2)$$

where v_o is the volume which is filled momentarily with water (or solution), and 0.0422 the volume of silver bromide which corresponds to one volume of silver nitrate solution 25:100.

The experimentally found values of the quotient ads:v_A are only valid for a certain sort of gelatin. They cannot therefore be used for calculating v_A for plates made with other sorts of gelatin. The only possible expedient therefore is to use the experimentally found values of v_A and from them calculate the values of f with the aid of the formulae (1) and (2). Table 4 contains the results for the mean values of the new plates, and Table 5 for the previously examined plates.

3. THE THICKNESS OF THE SILVER BROMIDE LAYER

The silver bromide v_A has one of its surfaces in common with half of the unhardened gelatin G′. Therefore

$$\frac{G'}{2d_G} = \frac{V_A}{d_{AgBr}}$$

where d_{AgBr} is the thickness of the silver bromide layer. The thicknesses d_G of the gelatin molecule are taken from Table 12 in the previous paper in this series [9]. The results are collected in Table 6.

All the values of dAgBr for the lower edge of the broad band are lower than for the upper edge. This is explained by the fact [10] that during the drying of the plate after bathing in silver nitrate solution some of the silver nitrate diffuses deeper into the coating where it constitutes the fringes. This loss is of course greater at the lower than at the upper edge.

4. THE PREPARATION OF THE INTERFERENCE PLATE

This preparation has been thoroughly described in a previous paper [11]. Through the results of the latest experiments it is possible to give some further hints about the procedure.

1. The gelatin should be characterised by the greatest possible swelling factor.

2. After coating the plate should be laid on a plate glass which can be cooled by cold water.

3. The time between the coating and the exposure should not exceed 2 days.

Table 6.

Plate No.	v_A	d_G	G′	d_{AgBr}
47 I	27.7	0.92	31.4	1.62
47 II	18.4	0.92	22.2	1.52
196 I	24.7	1.15	31.4	1.82
196 II	16.6	1.15	22.2	1.66
212 I	35.1	1.12	31.4	2.52
212 II	23.6	1.12	22.2	2.38
216 I	30.4	0.97	31.4	1.88
216 II	22.2	0.97	22.2	1.84

4. The drying of the plate treated with silver nitrate should be accelerated as much as the coating can stand without melting.

5. The treatment with the potassium bromide solution (20:100) which takes about 10—15 sec should be prolonged until the plate shows faint signs of opacity.

5. CONCLUSIONS

1. A scheme for the adsorption and absorption of silver nitrate in the exposed chromated gelatin plate is proposed.

2. The swelling factor f is nearly proportional to the amount of water taken up by the chromated gelatin plate.

3. The calculated values of the quotient ads:v_A agree very well with the experimentally found values.

4. When v_o, the amount of water momentarily absorbed, and d_G, the diameter of the gelatin molecule, are known, it is possible to calculate the swelling factor f.

5. The calculated values of f are smaller when the plate is stored longer than two days between coating and exposure.

6. From the values of unhardened gelatin G′ and of the thickness of the gelatin molecule it is possible to calculate the thickness of the silver bromide layer.

7. The results of the new experiments can give some hints about the preparation of the interference plates.

On the Kinetics of the Decomposition of Cyanic Acid

MOGENS BALLUND JENSEN

The Royal Danish School of Pharmacy, Copenhagen, Denmark

The decomposition of cyanic acid and cyanate into ammonia and carbon dioxide has been investigated kinetically in dilute aqueous solution over the pH-range 0—7 and in strongly basic medium. The experimental results indicate that the decomposition takes place according to three simultaneous reactions, *viz.* $OCNH + H_3O^+ \rightarrow NH_4^+ + CO_2$ (I), $OCNH + H_2O \rightarrow NH_3 + CO_2$ (II), and $OCN^- + 2H_2O \rightarrow NH_3 + HCO_3^-$ (III). The velocity constants for the reactions I and II were found to be 3.61 (l mole^{-1} min^{-1}) and 0.047 (min^{-1}), respectively, at 18°C. The energy of activation was found to be 15.1 kcal mole^{-1} for reaction I and 19.9 kcal mole^{-1} for reaction II. The velocity constant for reaction III was found to be 0.0017 (min^{-1}) at 94°C with an energy of activation of 23.9 kcal mole^{-1}.

Bicarbonate was found to act catalytically on the decomposition.

The acidic dissociation constant of cyanic acid was found to be $10^{-3.54}$ at 18°C.

1. The velocity for the decomposition of cyanate into ammonia and carbon dioxide in aqueous medium has been studied in several cases [1-5]. Most of the investigations have been carried out in strongly acid or basic solution, whereas measurements of the velocity in moderately and weakly acid solution are rather limited.

The present investigation deals with the decomposition of cyanate (meaning cyanic acid and cyanate ion) in dilute solution over the pH range 0—7 and in strongly basic medium.

2. Solutions of potassium cyanate were in most cases prepared by shaking silver cyanate with a solution containing the equivalent amount of potassium iodide. Silver cyanate was prepared by heating 120 g of urea and 68 g of silver nitrate dissolved in about 1 l of water. The needles of silver cyanate, gradually precipitated, were filtered off from time to time and washed until the wash water was almost free from silver ion. The silver cyanate was dried at 60° and stored in a desiccator containing silica gel.

In some experiments solutions prepared from Sodium Cyanate pure (Hopkin and Williams, Ltd.) were used.

0	0	25.00	0.0994
0	0	50.00	0.1001
0	0	50.00	0.1004
0.025	0.075	50.00	0.0999
0.050	0.050	50.00	0.0993
0.075	0.025	50.00	0.0982

3. The experiments were, unless otherwise stated, carried out in such a way that equal volumes of solutions of potassium cyanate and buffers of the temperature in question were mixed and placed in a thermostat. After an appropriate lapse of time the mixture or a sample of the mixture was brought to pH = approx. 5.5 by the addition of sodium acetate or acetic acid and immediately analysed for cyanate or ammonia.

The method of analysis was in the case of cyanate a procedure analogous to the determination of chloride according to Volhard. The cyanate was precipitated as silver cyanate by the addition of silver nitrate whereupon the excess of silver nitrate was titrated back with ammonium thiocyanate in a quota part of the filtrate acidified with nitric acid.

In Table 1 are listed some determinations of the concentration of cyanate in 20.00 ml of a solution of potassium cyanate prepared by shaking a 0.1004 M solution of potassium iodide with silver cyanate, *i.e.* the concentration of cyanate being 0.1004. The cyanate was precipitated with excess silver nitrate in neutral or in weakly acid medium the total volume being 200 ml.

It is seen from Table 1 that a relative great excess of silver nitrate is required in order to precipitate the cyanate quantitatively. It is furthermore seen that if the pH of the solution is less than approx. 5, more or less cyanate remains unprecipitated.

In the case of ammonia the analysis was carried out in such a manner that the cyanate was precipitated as silver cyanate and the content of ammonia in the filtrate was determined in the usual way by distilling off the ammonia.

4. The velocity constants were calculated on the basis of Napierian logarithms and refer to molar concentrations, the unit of time being the minute. The activity coefficient, f, for a monovalent ion was calculated from the expression of Bjerrum: $-\log f = 0.3 \sqrt[3]{c_{ion}}$.

It should be noted that $c_{cyanate}$ means the total concentration of cyanate, *i.e.* the sum of the concentrations of cyanic acid and of cyanate ion.

5. The values 1.44×10^{-3} and 1.82×10^{-5} for the acidic dissociation constants of chloroacetic acid [6] and acetic acid [7], respectively, and the value 4.01×10^{-7} for the first acidic dissociation constant of carbonic acid [8] were used in the calculations at 18°C.

The solubility of carbon dioxide in water at 18°C and at a pressure of 1 atmosphere was calculated from the data of Harned and Davis [8].

In the case of cyanic acid a calculation of the acidic dissociation constant, K_{OCNH}, was carried out on the basis of determinations of the hydrogen ion activity in solutions containing both cyanic acid and cyanate ion. The solutions were prepared by mixing a solution of sodium cyanate with an appropriate

[1] $c_{ClO_4^-} = 0.12$
[2] $c_{Cl^-} = 0.12$
[3] $c_{NO_3^-} = 0.12$

$k_{OCNH \cdot H_3O^+} = 3.61$

volume of hydrochloric acid which in some cases contained sodium nitrate. The temperature of both solutions was 18°C.

By means of a glass electrode the pH of the solution was determined at intervals of one minute and on the basis of the quantity $\Delta pH/\Delta t$ an extrapolation to zero time was made.

In Table 2 are listed the composition of the solutions and the measured and extrapolated values of pH together with the values of K_{OCNH} calculated from the expression

$$K_{OCNH} = \frac{a_{H^+} \cdot a_{OCN^-}}{a_{OCNH}} = \frac{a_{H^+} \cdot c_{OCN^-} \cdot f}{c_{OCNH}}$$

The mean value of K_{OCNH} obtained in this way is $10^{-3.54}$ at 18°C.

ON THE REACTION: $OCNH + H_3O^+ \rightarrow NH_4^+ + CO_2$

In Tables 3 and 4 are listed the experiments which were carried out in strongly acid solutions at 18°C. In most cases nitric acid was used for the experiments just as some of the solutions contained potassium nitrate.

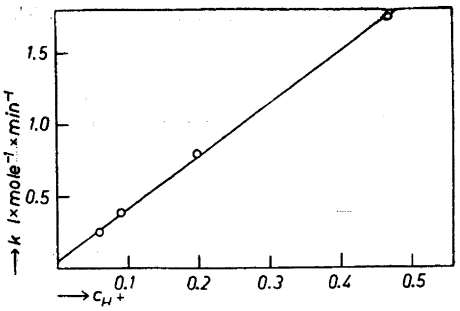

Fig. 1. Velocity constants for the reaction: "cyanic acid → $NH_4^+ + CO_2$" as a function of the hydrogen ion concentration. 18°C.

In runs 10 and 11 perchloric acid and hydrochloric acid, respectively, was used.

It is seen from Table 4 that nitric acid, perchloric acid and hydrochloric acid yield practically the same results.

In run 11 the method of analysis was modified in the following manner. The chloride and the cyanate were precipitated as silver salts at pH = 5.5 upon addition of silver nitrate. The silver chloride and silver cyanate were filtered off, washed, and boiled with excess of 0.1 N hydrochloric acid whereby: $AgNCO + 2HCl + H_2O = AgCl + CO_2 + NH_4Cl$, and back-titration was carried out with 0.1 N sodium hydroxide.

In runs 12 and 13 the decomposition was followed not by determining the concentration of cyanate but by determining the concentration of carbon dioxide and ammonia, respectively. In the case of carbon dioxide the analysis was carried out in such a manner that sodium hydroxide and barium chloride were added and the barium carbonate precipitated was then determined by acidimetric titration.

It is seen from Tables 3 and 4 that good agreement exists between the content of ammonia and carbon dioxide and the content of cyanate the sum being virtually constant, meaning that cyanate decomposes quantitatively into ammonia and carbon dioxide in strongly acid medium.

Tables 3 and 4 also list the velocity constants calculated from the unimolecular expression: $kt = \ln a/a-x$. It is seen that the velocity constants are almost proportional to the hydrogen ion concentration the mean values of which also are listed in Tables 3 and 4. This indicates a bimolecular reaction between cyanic acid and hydrogen ion.

In Fig. 1 the velocity constants listed in Tables 3 and 4 are plotted against the mean values of the hydrogen ion concentration and a straight line is drawn. The slope of this line is 3.61, meaning that the velocity constant, $k_{OCNH \cdot H_3O^+}$, for the reaction:

$$OCNH + H_3O^+ \rightarrow NH_4^+ + CO_2$$

is equal to 3.61 at 18°C. This value is in good agreement with the value 3.75, which was calculated at an ionic strength of 1.0 from the data reported by Lister [3].

Table 5. The temperature dependence of $k_{OCNH \cdot H_3O^+}$

Run	°C	Initial solution				Min.	% cyanate	k	k mean	c_{H^+} mean	$k_{OCNH \cdot H_3O^+}$
		c_{H^+}	$c_{NO_3^-}$	c_{K^+}	$c_{cyanate}$						
56	10.0	0.181	0.20	0.02	0.0197	1.0	73.4	0.311	0.311	0.173	1.71
						2.0	53.8	0.311			
						3.0	39.2	0.313			
						5.0	21.2	0.309			
55	4.0	0.181	0.20	0.02	0.0197	1.0	84.1	0.173	0.173	0.173	0.986
						2.0	70.6	0.175			
						5.0	42.2	0.172			
						9.0	21.2	0.173			

From Fig. 1 can be seen that the straight line intersects the ordinate axis at 0.05 indicating that also another reaction is taking place, *viz.* a reaction between cyanic acid and water, see next section.

In Table 5 are listed some experiments on the temperature dependence of $k_{OCNH \cdot H_3O^+}$. Table 5 contains the velocity constants, k, calculated from the unimolecular expression. k represents a sum of $k_{OCNH \cdot H_3O^+}$ multiplied with the hydrogen ion concentration and k_{OCNH} (see next section), although the contribution of k_{OCNH} to k is small (about 2—5 %). The value of $k_{OCNH \cdot H_3O^+}$ was obtained dividing the difference between k and k_{OCNH} by the mean value of the hydrogen ion concentration. The values of $k_{OCNH \cdot H_3O^+}$ are 1.71 and 0.986 at 10°C and 4°C, respectively. These values give an average of 15.1 kcal . mole^{-1} for the energy of activation, calculated on the basis of the value of $k_{OCNH \cdot H_3O^+}$ at 18°C. Lister [3] has found the energy of activation to be 14.5 kcal mole^{-1}.

ON THE REACTION: $OCNH + H_2O \rightarrow NH_3 + CO_2$

In Table 6 are listed the experiments which were carried out at 18°C in solutions initially being 0.04 N with respect to nitric acid.

The decomposition takes place through the two simultaneous reactions:

$$OCNH + H_3O^+ \rightarrow NH_4^+ + CO_2 \quad (I)$$

and

$$OCNH + H_2O \rightarrow NH_3 + CO_2 \quad (II)$$

fololwed by the instantaneous reaction $NH_3 + H^+ = NH_4^+$. In more acid solution reaction I predominates but in the less acid solutions listed in Table 6 the velocity of reaction II is about a third of that for reaction I.

The velocity constant for reaction II is denoted k_{OCNH}.

Table 6. The velocity constant for the reaction $OCNH + H_2O \rightarrow NH_3 + CO_2$. 18°C.

Run	Initial solution				Min.	$c_{cyanate}$	k_{OCNH}	k_{OCNH} mean

					10.0	0.0043	0.0437	
					15.0	0.0021	0.0484	

$k_{OCNH} = 0.0414$

The concentration of hydrogen ion varies from approx. 0.04 to 0.02 meaning that practically all of the cyanate exists as cyanic acid and the amount being present as cyanate ion has been neglected in the calculations.

Let a denote the initial concentration of cyanic acid and x the amount decomposed at the time t. The initial concentration of hydrogen ion is denoted b. k_1 stands for $k_{OCNH \cdot H_2O^+}$ and k_2 for k_{OCNH}. For the decomposition of the cyanic acid we have: $dx/dt = (k_1 \cdot c_{H^+} + k_2)(a-x)$.

Introducing $c_{H^+} = b-x$ and integrating we get:

$$k_2 = 1/t \left[\ln \frac{a}{a-x} + \ln \frac{k_1(b-x) + k_2}{k_1 b + k_2} \right] - k_1(b-a).$$

Table 7. The temperature dependence of k_{OCNH}

						30.0	0.0067	0.0044	

The values for k_{OCNH} calculated from the above mentioned expression are also listed in Table 6.

In both experiments the mean value 0.041 for k_{OCNH} was obtained at 18°C. This value is in good agreement with the value 0.05 which was found from Fig. 1.

In Table 7 are listed a few experiments on the temperature dependence of k_{OCNH}, the value of which was calculated from the above mentioned expression inserting the value of $k_{OCNH\cdot H_3O^+}$ at the temperature in question. The value of k_{OCNH} is 0.0157 at 10°C corresponding to an anergy of activation of 19.9 kcal mole^{-1}. The value 0.003 found at 4°C is not very accurate since reaction I is by far the predominant at this temperature.

Further experiments on the determination of k_{OCNH} at 18°C were carried out in less acid solutions buffered with a weak acid and its salt. The ionic strength was adjusted to 0.2 by means of sodium nitrate and the samples were analysed for cyanate and ammonia.

For the rate of formation of ammonia we have:

$$dc_{ammonia}/dt = (k_{OCNH\cdot H_3O^+} \cdot c_{H^+} + k_{OCNH}) \cdot c_{OCNH}$$

Introducing $c_{OCNH} = c_{cyanate}/(1 + K_{OCNH}/a_{H^+} \cdot f)$ and $c_{H^+} = a_{H^+}/f$ we get:

$$\frac{dc_{ammonia}}{dt} = \frac{k_{OCNH\cdot H_3O^+} \cdot a_{H^+}/f + k_{OCNH}}{1 + K_{OCNH}/a_{H^+} \cdot f} \cdot c_{cyanate} = k \cdot c_{cyanate}$$

k_{OCNH} was calculated from the experimental value of k inserting the mean value of the hydrogen ion activity and the values 3.61 and $10^{-3.54}$ for $k_{OCNH\cdot H_3O^+}$ and K_{OCNH}, respectively.

The hydrogen ion activity was calculated from the expression $a_{H^+} = K_a/f \cdot c_{HA}/c_{A^-}$, where c_{HA} and c_{A^-} denote the mean value of the concentration of the weak acid and its corresponding base, respectively. K_a is the acidic dissociation constant.

The experiments which were carried out in solutions containing chloroacetic acid and sodium chloroacetate are listed in Table 8. It is seen (runs 15 and 16) that the velocity of the decomposition is practically independent of the total amount of chloroacetic acid if the solutions have the same pH-value, *i.e.* chloroacetic acid shows no appreciable catalytic effect on the decomposition.

It is furthermore observed from Table 8 that the percentages of cyanate and ammonia do not correspond, the sum being less than 100 although the deviations are rather limited. This is probably due to a polymerisation of cyanic acid, *cf.* that a more concentrated solution of sodium cyanate upon addition of acetic acid yields a precipitate of a polymer.

Since the sum of cyanate and ammonia was not constant the value of k could not be calculated from the unimolecular expression but was obtained from $\Delta c_{ammonia} / \Delta t = k \cdot \bar{c}_{cyanate}$, where $\Delta c_{ammonia}$ is the increase in the concentration of ammonia in the time interval Δt and $\bar{c}_{cyanate}$ is the mean value of the cyanate concentration in that interval. In Table 8 are listed the values of k calculated in this way. There is some decrease in the values of

k during a run but this is probably mainly due to the variation in the hydrogen ion activity.

Table 8 also lists the values of k_{OCNH} calculated from the mean values of k.

It should be noted that the velocity of reaction II in the experiments listed in Table 8 is 1.5 to 10 times greater than the velocity of reaction I.

In Table 9 are listed some quite analogous experiments carried out in solutions containing acetic acid and sodium acetate. Also in this case no appreciable catalytic effect of the buffer was observed (runs 19 and 20). The discrepancy between the percentage of cyanate and ammonia is a little more pronounced than in the experiments carried out at pH = 2.3—3.1. The values for k_{OCNH} listed in Table 9 were calculated in the same manner as for those listed in Table 8.

It should be noted that the velocity of reaction I in the experiments listed in Table 9 is less than 1 % of the velocity of reaction II.

Table 10 shows the experiments which were carried out at 18°C with solutions containing sodium cyanate and sodium bicarbonate saturated with carbon dioxide at a pressure of 1 atmosphere. If there was no catalytic effect of the buffer, the rate of the decomposition should be proportional to the hydrogen

Table 9. The decomposition of cyanate at pH = 4.1—4.8. c_{ion} = 0.2. 18°C.

[3]) This run has not been analysed for ammonia.

ion activity, *i.e.* inverse proportional to the concentration of bicarbonate (the concentration of carbon dioxide is constant). The results in Table 10 show that the rate increases with increasing concentration of bicarbonate, *i.e.* bicarbonate acts catalytically on the decomposition of cyanate. The following rate expression is proposed:

$$dc_{cyanate}/dt = -(k' \cdot c_{HCO_3^-} \cdot c_{OCN^-} + k_{OCNH \cdot H_3O^+} \cdot c_{H^+} \cdot c_{OCNH} + k_{OCNH} \cdot c_{OCNH})$$

where k' is the velocity constant for the process catalyzed by bicarbonate.

Introducing $c_{OCNH} = 1/(1 + K_{OCNH}/a_{H^+} \cdot f) \cdot c_{cyanate} \sim a_{H^+} \cdot f/K_{OCNH} \cdot c_{cyanate}$ and neglecting the term $k_{OCNH \cdot H_3O^+} \cdot c_{H^+} \cdot c_{OCNH}$ which plays practically no part in this case, we get:

$$dc_{cyanate}/dt = -(k' \cdot c_{HCO_3^-} + k_{OCNH} \cdot a_{H^+} \cdot f/K_{OCNH}) \cdot c_{cyanate} = -k \cdot c_{cyanate}, \text{ or}$$

$$k \cdot K_{OCNH}/a_{H^+} \cdot f = (k' \cdot K_{OCNH}/a_{H^+} \cdot f) \cdot c_{HCO_3^-} + k_{OCNH} \cdot$$

Table 10. The decomposition of cyanate in carbon dioxide-bicarbonate buffer. pH = 6.5—6.9. c_{ion} = 0.2. 18°C.

					12 657	19.0	76.4	0.000137			

If the quantity $k \cdot K_{OCNH}/a_{H^+} \cdot f$ is plotted against the quantity $(K_{OCNH}/a_{H^+} \cdot f) \cdot c_{HCO_3^-}$ using mean values for the hydrogen ion activity and the bicarbonate ion concentration a straight line can be drawn. The slope of this line gives k' = approx. 0.00060. The line intersects the ordinate axis at 0.062, *i.e.* the value of k_{OCNH} determined in this way is 0.062 which is in relatively good agreement with the value obtained in more acid solution.

It is seen from Table 10 (run 44) that the discrepancy between the percentages of cyanate and ammonia is not so pronounced as in the experiments at pH = 4.1—5.0. The values of k listed in Table 10 were calculated in the same manner as for those listed in Table 8.

The velocity constant, k_{OCNH}, for the reaction:

$$OCNH + H_2O \rightarrow NH_3 + CO_2$$

is 0.047 at 18°, which is the mean value for the determinations in this section.

THE DECOMPOSITION OF CYANATE IN STRONGLY BASIC MEDIUM

In Table 11 are listed the experiments which were carried out with solutions containing sodium cyanate and sodium hydroxide. Upon addition of sodium nitrate the initial ionic strength was adjusted to 0.2.

It is seen from Table 11 that the rate of the decomposition is independent of the hydroxyl ion concentration and identical with the rate of formation of ammonia.

Table 11. The decomposition of cyanate at pH = approx. 13. $c_{ion} = 0.2$.

Run	°C	Initial solution		Min.	% cyanate	% ammonia	k_{OCN^-}	k_{OCN^-} mean

				571		61.8	0.00169	
54	82	0.10	0.020	277	85.3		0.000580	
				578	72.4		0.000562	
				1 346	45.9		0.000578	0.000571
				2 001	31.8		0.000573	
				2 773	20.8		0.000566	
53	70	0.10	0.019	531	91.4		0.000169	
				1 285	80.4		0.000170	
				2 049	71.6		0.000164	0.000170
				2 996	59.4		0.000174	
				4 247	47.8		0.000174	

Table 11 also lists the velocity constant, k_{OCN^-}, for the gross reaction:

$$OCN^- + 2H_2O \rightarrow NH_3 + HCO_3^- \quad \text{(III)}$$

calculated from the expression for an unimolecular reaction. The mean value of k_{OCN^-} is 0.00170 at 94°C, 0.000571 at 82°C and 0.000170 at 70°C.

The mean value of the energy of activation for the reaction is 23.9 kcal mole^{-1} calculated on the basis of the value of k_{OCN^-} at 94°C. The value determined by Lister [3] is 23.4 kcal mole^{-1}.

By extrapolation the value $10^{-6.48}$ for k_{OCN^-} is obtained at 18°C.

It should be added that the reactions I and II are too slow to take any appreciable part in the decomposition in strongly basic medium. On the other hand reaction III can be neglected in the more acid solutions investigated in the preceding sections.

The author wishes to express his sincere thanks to Professor Carl Faurholt, Head of the Department of Inorganic Chemistry, for valuable discussion and advice.

Electron Diffraction Studies of 2,2′-Dithienyl Vapour

A. ALMENNINGEN, O. BASTIANSEN and P. SVENDSÅS

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway;
Institutt for teoretisk kjemi, NTH, Trandheim, Norway

Electron diffraction studies based upon the sector method have been carried out on 2,2′-dithienyl. The obtained structure parameters of the thienyl ring are in good agreement with values obtained by micro-wave investigations for thiophene. The molecule as a whole does not seem to be planar. The angle of twist is found to be 34°.

In a series of earlier papers structure investigations have been carried out on molecules composed of ring systems linked together with single bonds [1-6]. As a member of this series of molecules 2,2′-dithienyl has been included, and an electron diffraction study based upon the sector method has been undertaken.

The sample used in the present investigation was prepared by Siv. Ing. Oddrun Holmboe at the Institute of Organic Chemistry at the Technical University of Norway. The electron diffraction diagrams were taken with the Oslo apparatus at a temperature of 130°C. The photometer curves were read off at an interval of 0.25 s units. Reproducible intensity data were obtained in the s interval ranging from 1.25 Å^{-1} to approximately 45 Å^{-1}. The photometer curves were subjected to the necessary corrections as for the photographic plates, sector corrections, *etc.*[7] To obtain intensity values suited for Fourier transformations the background due to atomic and incoherent scattering has to be subtracted. The theoretical background fitted the experimental intensity curve very well except for a small deviation in the s region beyond $s = 20$ Å^{-1}, where a minor correction had to be made. Difference curves between experimental intensity curves and the background were calculated and multiplied by an artificial damping factor $\exp(-ks^2)$. Radial distribution curves were calculated using k values of 0.0009 and 0.0036. A preliminary model from these curves was used for calculating a theoretical radial distribution curve and the corresponding intensity curve. Experiences thus obtained were used for further corrections of the background. A final intensity curve ready for Fourier transformation is given in Fig. 1. The curve has been multiplied by $\exp(-0.0036\, s^2)$. The upper curve of Fig. 2 is the corresponding Fourier transformation after the subtraction of the envelope [7]. This curve was well suited for the study of the interplanar twist in the molecule.

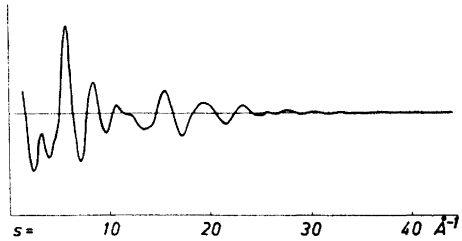

Fig. 1. Experimental intensity curve for Fourier transformation. (k = 0.0036).

A new model was obtained from this improved radial distribution curve. From the position of the peaks corresponding to the distances S—S and C_2—S_{10} (see Fig. 3) it could immediately be concluded that a planar model was improbable. An interplanar angle of approximately 30° had to be assumed.

The new model was used as the starting model for a least square procedure. The structure parameters, listed in the second column of Table 1, are the result of two successive approximations combined with further studies of the radial distribution curve. These values were obtained entirely from our experiment, and it is very satisfactory to compare them with those obtained by Bak *et al.* for thiophene by the micro-wave method [8]. For comparison Bak's two alternative sets of parameters are given in the third and fourth columns of Table 1. It should be pointed out that our values were calculated under the assumption of planar thienyl rings and mirror symmetry in the rings. We have also assumed that the bridge bond between the two rings is in the plane of each of them.

In order to obtain further improvements in the determination of the angle of twist, Bak's parameters for thiophene were used in the thienyl rings. If Bak's model I were used, it would be possible to determine the three additional parameters necessary for elucidating the structure of the 2,2′-dithienyl molecule, namely C_1—C_6, $\angle C_1$—C_6—S_{10}, and the angle of twist φ. The least square

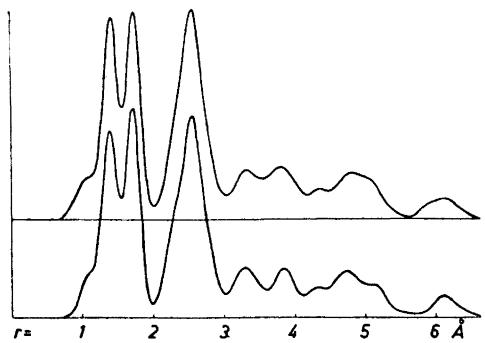

Fig. 2. Upper curve experimental and lower curve theoretical radial distribution curve. (k = 0.0036.)

Table 1. Structure parameters of 2.2'-dithienyl obtained from electron diffraction studies (present work) and structure parameters of thiophene obtained from micro-wave studies (Bak *et al.*[8]).

	E. D. data for 2.2'-dithienyl	M. W. data for thiophene (Bak *et al.*[8]) I	M. W. data for thiophene (Bak *et al.*[8]) II		
C_4-H_4 }	1.08 Å	1.085 Å	1.079 Å		
C_2-H_2 }		1.073 Å	1.079 Å		
C_1-S_5	1.717 Å	1.718 Å	1.723 Å		
C_1-C_2	1.357 Å	1.352 Å	1.360 Å		
C_2-C_3	1.433 Å	1.455 Å	1.430 Å		
$C_1-S_5-C_4$	92.02°	91.30°	91.67°		
C_1-C_6	1.480 Å			1.501 Å	1.476 Å
$C_1-C_6-S_{10}$	120.1°			119.4°	120.0°
	33.8°			34.2°	34.3°

procedure gave as a result for the three additional parameters the values listed in the fifth column of Table 1. In the sixth column the corresponding values obtained from Bak's model II are listed.

The obtained angle of twist of approximately 34° can no doubt be explained by steric difficulties. In the case of a planar molecule the distance between an S atom and the nearest H atom is approximately 2.92 Å. At an angle of 34° the distance increases to 3.09 Å which value should be compared with the van der Waals distance between sulphur and hydrogen of approximately 3.10 Å.

Unfortunately the angle of twist, φ, is not at all determined with an accuracy corresponding to the three values of Table 1. An error estimate based upon least square calculation will lead to a too optimistic result. A more realistic estimate of errors can be carried out by a discussion of the radial distribution curve, including the effects of anharmonic oscillation about the equilibrium angle. In spite of all the sources of error and the small effect upon the decisive distances for the φ determination at small φ values, we feel that the rigid planar model can be excluded. It seems, however, difficult to exclude a more or less free rotation through a certain angle interval. From steric considerations it seems for instance probable that the molecule has a practically free rotation from a φ value corresponding to a contact between H_2 and S_{10} (φ approximately 34°) up to a φ value corresponding to contact in a *cis* like molecule (φ approximately 85°). It is not unlikely that there exist two minima on the energy curve at approximately 34° and 85° with a flat maximum in between. As a matter of fact a better agreement between experimental and theoretical

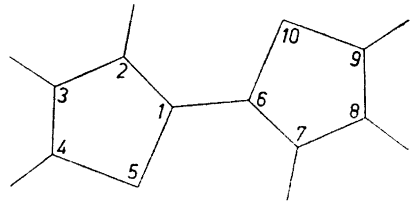

Fig. 3. Numbering of the atoms in the 2,2'-dithienyl molecule.

distribution curves can be obtained if the constancy of φ is abandoned. If, in addition to the molecules with a φ value equal to 34°, there are included a number of other molecules with φ values larger than this value, according to a certain distribution, a nearly complete correspondence can be obtained. Theoretically one might along this line obtain information about the molecular population at various φ values. This is, however, omitted in the present work, as such calculations do not seem to be justified by the present experimental material.

High Molecular Weight Enzyme Inhibitors

III. Polyestradiol Phosphate (P.E.P.), a Long-acting Estrogen

O. FERNÖ, H. FEX, B. HÖGBERG, T. LINDEROT, S. VEIGE

Research Department, AB Leo, Hälsingborg, Sweden, and

E. DICZFALUSY

Hormone Laboratory of the Department of Women's Diseases, Karolinska Sjukhuset, Stockholm, Sweden

The preparation and some of the chemical and pharmacological properties of polyestradiol phosphate, a long-acting water soluble estrogen are described. Data are presented indicating that polyestradiol phosphate is a powerful inhibitor of several enzymes, such as acid and alkaline phosphatases and hyaluronidase.

The preparation of a large number of polymeric phosphoric acid esters and amides of polyphenols, aromatic polyamines and aminophenols has been reported previously [1,2]. These compounds have been found to exert a strong inhibitory effect on certain enzymes, *e.g.* hyaluronidase and acid and alkaline phosphatases. The present investigation deals with the preparation of high molecular weight polyesters of estradiol-17β and phosphoric acid as well as with a study of some chemical and biological properties of these polymers.

PREPARATION AND CHEMICAL PROPERTIES OF P.E.P.

In the Experimental Part a typical experiment on the preparation of polyestradiol phosphate (P.E.P. Standard) is described. The phosporylation was carried out in dry pyridine with phosphoryl chloride (1.1 mole) as phosphorylating agent. This product showed a greatly prolonged duration of estrogenic action, when administered parenterally to spayed mice [15].

In the determination of the molecular weight of P.E.P. Standard (ultracentrifuge) a value of 26 000 was obtained (see Experimental Part) indicating that the molecule contains approximately 80 estradiol moieties. The viscomet-

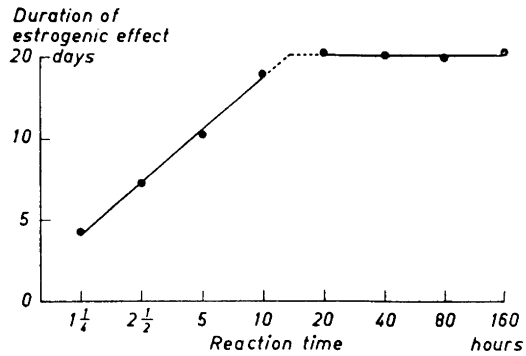

Fig. 1. Correlation between polymerisation time and duration of estrogenic effect of a single subcutaneous injection of 10 μg of polyestradiol phosphate (P.E.P.). Prolonged estrogenic effect was measured by the duration of cornified vaginal smears in spayed mice. The scales are logarithmic but are graduated in true units. Each point corresponds to 30 animals.

ric behavior of this substance is typical for linear polyelectrolytes [3]. The low value of intrinsic viscosity ($[\eta] = 0.04$) may be explained by the hydrophobic character of the estradiol moieties [4].

In order to follow the course of polymerisation, samples were withdrawn at different intervals and the products isolated. After dialysis the non-dialyzable material was investigated. From the data shown in Fig. 1, it appears

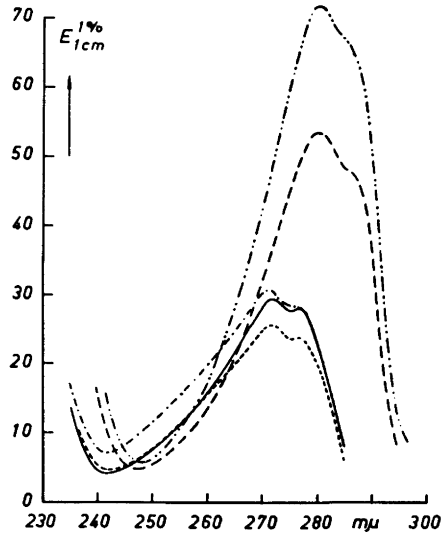

Fig. 2. Ultraviolet absorption spectra of estradiol (—..—..—), estradiol-17-phosphate (— — —), estradiol-3-phosphate (————), estradiol-3,17-diphosphate (. . . . .) and P.E.P. Standard (—.—.—) in 75 % aqueous ethanol.

Table 1. Influence of polymerisation time on the properties of polyestradiol phosphate (P.E.P.).

P.E.P. [a]	Reaction time, hours	% Non-dialyzable $P_{org.}$	% P[b]	% C[b]	% H[bc]	Molar P/Estradiol[d]	% Free hydroxyl groups[e]	λmax.[f] (mμ)
I	1 1/4	37[g]	8.2	—	—	—	26	279
II	2 1/2	42[g]	8.7	—	—	—	22	278
III	5	53[i]	8.8	61.3	7.30	1.00	12	278
III B[h]	5	44[i]	10.9	56.3	6.88	1.35	0	271
IV	10	66	9.3	—	—	—	9	272

VI	40	87	9.6	61.7	6.93	1.08	0	271
VII	80	88	9.6	—	—	—	0	271
VIII	160	90	9.5	60.1	6.98	1.10	0	271
P.E.P.-Standard	70	88—90	9.5	62.2	6.88	1.06	0	271

a) In these experiments the samples were hydrolyzed and worked up in the same way as P.E.P. Standard with the exception that the precipitation with HCl was made without ethanol.
b) Calculated on P.E.P., free from moisture, pyridine and chlorine.
c) % H somewhat higher than the value, which can be calculated (from % C, % free hydroxyl groups and % acid groups) possibly due to small amounts of firmly bound water.
d) Estradiol calculated from % C.
e) According to B. Baggett *et al.*[20] Calculated as % of 'estradiol oxygens'.
f) In 75 % ethanol. P.E.P. was dissolved in a small amount of 0.1 N NaOH, ethanol added, and then neutralized with 0.1 N HCl. Immediate reading.
g) Dialyzed in the presence of pyridine in order to avoid precipitation.
h) "Rephosphorylated" with excess $POCl_3$ in pyridine before hydrolysis and dialysis.
i) If % non-dialyzable is calculated on estradiol, the corresponding figures are, 54 % (III), and 52 % (III B).

that a reaction time of 20 h or more will yield polymers exhibiting maximal duration of estrogenic effect. Likewise it appears from Table 1 that after a reaction time of about 20 h the reaction is nearly complete. After this time practically no free hydroxyl groups could be demonstrated in the non-dialyzable material, while for instance after 75 min, 25 % of the hydroxyl groups originally present were free. In an attempt to assess the relative proportions between free 3-hydroxyl and free 17-hydroxyl groups in the polymer, the ultraviolet absorption spectra were studied.

The ultraviolet absorption spectra of estradiol, estradiol-3-phosphate, estradiol-17-phosphate, estradiol-3,17-diphosphate as well as that of the P.E.P. Standard are given in Fig. 2. When estradiol-3,17-diphosphate and estradiol-17-phosphate were mixed in such a proportion as to give the same percentage of free hydroxyl groups as found in the different polyestradiol phosphates (Table 1), practically identical ultraviolet absorption curves were obtained, indicating that the free hydroxyl groups are predominantly in the 3-position.

In order to investigate the stability of P.E.P., hydrolysis experiments were carried out in aqueous solution at 98° and at various pH values. The rate of hydrolysis was followed by determining the amount of inorganic phosphorus (P_o) liberated. The formation of P_o was most rapid at pH values between

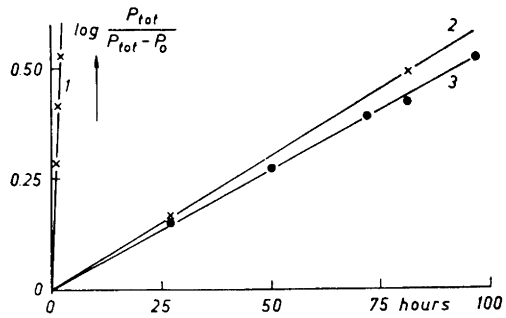

Fig. 3. Hydrolysis of estradiol phosphates in 0.1 M acetate buffer at pH 5.2 (98°). Rates of hydrolysis determined by analysis for liberated phosphoric acid (P_o). 1: Estradiol-3-phosphate ($k = 0.64$ h^{-1}). 2: Estradiol-17-phosphate ($k = 0.014$ h^{-1}). 3: P.E.P. Standard ($k = 0.013$ h^{-1}). As to P.E.P. Standard, 29 % of its phosphorus content is calculated as P_{tot}.

5 and 6; after 50 h 13.5 % of the phosphorus originally present was split off (Fig. 3). In 0.2 N sodium hydroxide solution the formation of P_o took place very slowly (< 1 % P_o, 81 h, 98°).

Furthermore it was found that following hydrolysis at different pH-values (98°, 81 h) the antihyaluronidase activity was practically unchanged within the investigated range (from pH 3.1 to 0.2 N sodium hydroxide solution). In another experiment, using the same conditions (pH 7.1), the duration of estrogenic effect was not changed significantly (potency: 88 % of that of P.E.P. Standard, with fiducial limits ($P = 0.05$) at 75 and 103 %). Under these conditions no free estradiol could be found, not even after a hydrolysis time of 270 h at pH 5.2.

We have also studied the rate of hydrolysis of the different monomeric estradiol phosphates (Fig. 3). In all cases the hydrolysis was found to follow a first order reaction. The period of half life (pH 5.2; 98°) for estradiol-3-phosphate was found to be 1.1 h and for estradiol-17-phosphate 50 h. In case of estradiol-3,17-diphosphate the experimental values were identical with those calculated from the 3- and 17-monophosphate values. The diphosphate is practically stable in 0.1 N sodium hydroxide solution (81 h, 98°) and similarly to the P.E.P. Standard, it has a maximal rate of hydrolysis between pH 5 and 6.

The fact that no free estradiol was found during the hydrolysis of P.E.P. seems to indicate that the liberated P_o is formed from endstanding, primary phosphoric acid esters only.

Even after a very long time (270 h, 98°, pH 5.2) only 28—30 % P_o was found. From Fig. 3 it is evident that the hydrolysis of P.E.P. follows the same course as that of estradiol-17-phosphate. It seems also that the percentage of primary 17-phosphate in P.E.P. lies between 25 and 28 and that the proportion of primary 3-phosphate is small.

From what is said above and from the fact that the free hydroxyl groups found at the beginning of the phosphorylation seem to be in the 3-position,

it seems likely that the first reaction step involves predominantly phosphorylation of the 17-hydroxyl groups yielding estradiol-17-dichlorophosphinate, and thus the polymerisation will take part mainly *via* the 3-hydroxyl groups. In order to confirm this assumption, a phosphorylation was carried out in the same way as described for the P.E.P. Standard, and the reaction mixture hydrolysed after 5 min. The pyridine was removed *in vacuo* (alkalization) and the resulting solution precipitated with hydrochloric acid without dialysis. Analysis of the precipitate and of the filtrate, respectively, showed that 84 % (0.84 mole) of the estradiol had reacted with 79 % (0.87 mole) of the phosphoryl chloride. In titration experiments only primary esters could be demonstrated. The rate of hydrolysis (pH 5.2; 98°) was the same as that of estradiol-17-phosphate. It seems thus very likely that the first step involves a phosphorylation of the 17-hydroxyl group.

Titration experiments with P.E.P. Standard (see Experimental Part) indicate the occurrence of 30 % monoester, 60 % diester and 10 % triester. This latter fact also points to a certain branching of the polymer. The value of 30 % monoester agrees well with that (28—30 %) found in the hydrolysis experiments.

EXPERIMENTAL

A. Preparation of estradiol phosphates

1. Preparation of polyestradiol phosphate. Estradiol-17β (27.2 g) was dissolved in dry pyridine (600 ml) in a flask fitted with a mechanical stirrer, a thermometer, a dropping funnel and a $CaCl_2$-tube. The flask was surrounded by an ice and salt mixture and when the temperature reached $-10°$ to $-12°$ a solution of phosphoryl chloride (10.1 ml) in dry pyridine (80 ml) was added in the course of 25 min. The temperature of the reaction mixture was then allowed to rise to room temperature. The stirring was stopped and the reaction mixture kept at room temperature for another 70 h. (After 30 to 50 h standing the solution may change into a jelly.) 250 g of crushed ice was then added with vigorous stirring and the mixture allowed to stand over night. 2 N NaOH (225 ml) was added and most of the pyridine evaporated *in vacuo*. The rest was made up to a volume of 2 000 ml by water and the pH adjusted to 7.0 to 7.5. The solution was dialyzed against dist. water (cellophane tube, several days). To the content of the tube containing 90 % of the phosphorus originally present, the same volume of ethanol was added and the solution poured with stirring into a mixture of 5 N HCl (200 ml) and ethanol (400 ml). The resulting white precipitate was then filtered and washed with 30 % aqueous ethanol and finally with water. Yield (after drying *in vacuo* over phosphorus pentoxide) about 30 g. Melting range 195—202°. A number of different batches, prepared according to the above mentioned procedure were mixed and the resulting mixture is referred to as P.E.P. Standard *.

Analysis: (P.E.P. Standard)

Moisture: (*in vacuo* 100°) 3.9 %.

Pyridine: (determined spectrophotometrically after alkalization and distillation) 0.3 %.

Chlorine: None.

Phosphorus: (calculated on dried and pyridine free sample) 9.5 %. $[[\alpha]_D = +40°$ ($c = 1$, in pyridine-water 1:1).]

* Samples of this have been distributed to different centra as a reference standard for the bioassay of long-acting estrogens. Such standards can be obtained on request from the Steroid Reference Collection, Postgraduate Medical School, London W 12, and from AB Leo, Hälsingborg, Sweden.

P.E.P. is very soluble in aqueous pyridine, soluble in aqueous alkali and very slightly soluble in ethanol, ethanol-water (1:1), water, dioxane, acetone and chloroform.

Molecular weight. This has been determined on the sodium salt of P.E.P. at pH 7.5 in 0.5 M NaCl solution. The sedimentation constant, determined in a Spinco ultracentrifuge model E with a synthetic boundary cell was found to have the same value at P.E.P. concentrations 1 and 0.5 %, $S_{20} = 2.16 \times 10^{-13}$ *.

The diffusion coefficient (moving boundary method using area and height of diffusion curves) was found to be $D_{20} = 5.8 \times 10^{-7}$ and the partial specific volume $V_{20} = 0.65$. The molecular weight was calculated to be about 26 000.

Viscosity measurements. These were made in an Ubbelohde viscometer at 25° ± 0.01°. The intrinsic viscosity $[\eta]$ has been determined in 0.25 M NaCl solution at pH 7.5. The value of $[\eta] = 0.04$ has been obtained by extrapolating η_{sp}/c to infinite dilution (c in g/100 ml).

Potentiometric titration. P.E.P. Standard was dissolved in an excess of 0.1 N NaOH in the presence of 0.1 M NaCl and titrated with 0.1 N HCl. Inflexion points were found at pH 9.4 and 5.5 respectively. The titrations show 0.90 strongly acid groups and a total number of 1.20 acid groups per phosphorus atom.

The different monomeric estradiol phosphates were dissolved in ethanol-water (1:1) and titrated with 0.02 N NaOH.

2. Preparation of estradiol-3-phosphate. Estradiol-17-acetate (1.5 g) was dissolved in dry pyridine and the solution was added drop by drop with shaking to a solution of phosphorus oxychloride (1.3 ml) in dry pyridine at −10°. After standing for one hour at this temperature the reaction mixture was hydrolyzed with crushed ice. Most of the pyridine was evaporated *in vacuo*. In order to hydrolyze the 17-acetate, 2 N NaOH (50 ml) was added. After standing for 1 h at room temperature the remaining pyridine was removed by shaking several times with ether and the solution poured with stirring into 5 N HCl (50 ml). The resulting precipitate was filtered, washed with 0.2 N HCl and finally with a small quantity of water. Yield after drying in vacuo: 1.6 g. M. p. 212–214°. Found: P 8.9; equiv. wt 177 (as a monobasic acid) and 174 (as a dibasic acid). Calc. for $C_{18}H_{25}O_5$ P: P 8.8; equiv. wt 176.]

3. Estradiol-17-phosphate was prepared in the same way as the 3-phosphate from estradiol-3-acetate (1.5 g). Yield 1.6 g. M. p. 181–183°. [Found: P 9.0; equiv. wt 174 (as a monobasic acid) and 170 (as a dibasic acid). Calc. for $C_{18}H_{25}O_5$ P: P 8.8; equiv. wt 176.]

4. Estradiol-3,17-diphosphate was prepared as above from estradiol (2.5 g) and phosphorus oxychloride (7.5 ml). After 1 h at −10° the mixture was maintained at room temperature for another 3 h. Yield 2.7 g. M. p. 179–181°. [Found: P 13.6; equiv. wt 118 (as a dibasic acid) and 115 (as a tetrabasic acid). Calc. for $C_{18}H_{26}O_8P_2$: P 14.3; equiv. wt 108.] Discrepancy probably due to firmly bound water.

B. Antienzymic properties

The enzymes studied were acid phosphatase, alkaline phosphatase and hyaluronidase.

1. *Acid phosphatase* **. Human seminal acid phosphatase was selected for the purposes of this study in view of its high enzymic activity.

Enzyme. A pool of human seminal fluid was used without purification. Semen was used in a dilution of 1:2 000.

Substrates. a. Phenyl phosphate and *b. p*-nitrophenyl phosphate were used.

Analytical methods. a. Phenol was estimated by Folin's reagent as described by Buch and Buch [5]. Inorganic phosphate was determined according to the method of Martin and Doty [6].

---

* These measurements have been carried out in the Carlsberg Laboratories, Copenhagen, by the courtesy of Professor K. Linderstrøm-Lang.

** The experiments with acid phosphatase using phenyl phosphate as substrate have been carried out in collaboration with Dr. C.-G. Beling. A detailed report of the kinetics and inhibition of this enzyme by different polymeric phosphates will be published elsewhere.

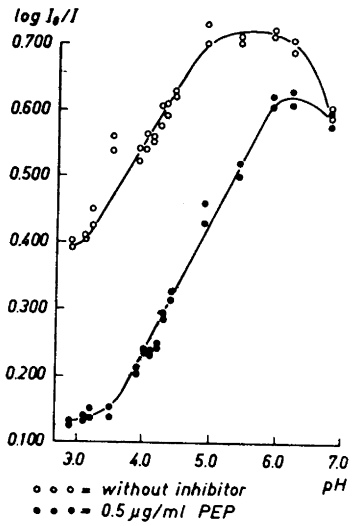

Fig. 4. Relationship between pH and inhibition of human seminal acid phosphatase by 0.5 µg/ml polyestradiol phosphate. 0.15 M acetate buffer, 37°, 8 min. incubation. Substrate: 2×10^{-3} M phenyl phosphate.

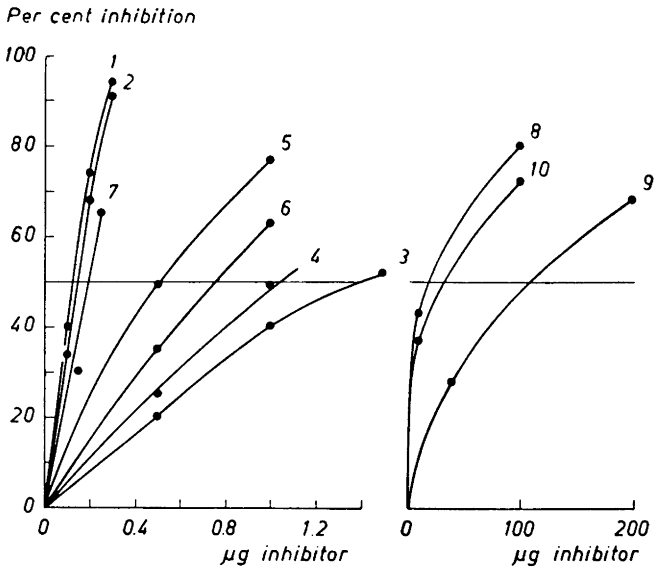

Fig. 5. Inhibition of seminal acid phosphatase by different batches of phosphorylated estradiol at pH 4.5 (acetate buffer). Substrate, *p*-nitrophenyl phosphate. Incubation time 30 min. at 37.5°. 1. P.E.P. Standard, 2. P.E.P. VI + P.E.P. VII (1:1), 3. P.E.P. I, 4. P.E.P. II, 5. P.E.P. III, 6. P.E.P. III B, 7. P.E.P. Standard after hydrolysis (81 h, pH 5.2, 98°), 8. Estradiol-3,17-diphosphate, 9. Estradiol-17-phosphate, 10. Estradiol-3-phosphate.

For further particulars consult Table 1.

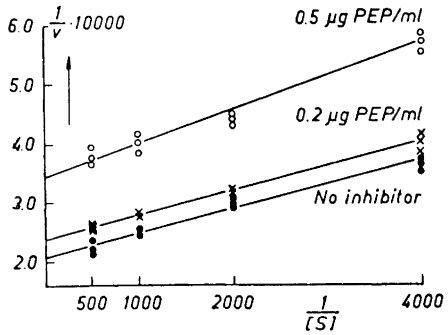

Fig. 6. Relation between acid phosphatase activity and substrate concentration in the presence and absence of polyestradiol phosphate. Activity is expressed as the reciprocal of the amount of phenol liberated in 8 min at 37°. 0.15 M acetate buffer. Substrate: phenyl phosphate, pH 4.5.

b. The method devised by Bessey, Lowry and Brock [7], for the determination of serum alkaline phosphatase was used. The *p*-nitrophenol was determined directly in a spectrophotometer (absorption maximum: 410 mμ).

Conditions of enzyme experiments. a. Enzyme activity was generally estimated within the pH range 3.0 to 6.8, using a 0.15 M acetate buffer, a substrate concentration of 2×10^{-3} M, and a short incubation time (generally 4 or 8 min at 37°).

b. Determinations were carried out at pH 4.5. Reaction volume 1.5 ml (0.5 ml 0.3 M acetate buffer, 0.5 ml 16 mM disodium *p*-nitrophenyl phosphate *, 0.1 ml enzyme). Incubation time 30 min at 37.5°.

Results. The inhibition of seminal acid phosphatase by P.E.P., is shown in Fig. 4. It appears from this figure that the inhibition is most marked on the acid side of the pH-optimum, and that no inhibition occurs at pH 6.8. The inhibition of acid phosphatase at pH 4.5, by different batches of P.E.P. as well as by estradiol-3-phosphate, estradiol-17-phosphate and estradiol-3,17-diphosphate is presented in Fig. 5. It appears from the data of Fig. 5 that estradiol monophosphates and also the diphosphate are much weaker inhibitors than the different P.E.P. preparations.

Reversibility. The enzyme inhibition by P.E.P. could be reversed by small amounts of basic proteins, *e. g.* protamine sulphate.

Type of inhibition. In order to study the type of inhibition, the concentrations of the substrate and inhibitor (P.E.P.) were varied at constant concentration of the enzyme. The typical Lineweaver plots obtained [8] are shown in Fig. 6. The data indicate that the inhibition is not substrate competitive. The same type of inhibition was obtained when *p*-nitrophenyl phosphate was used as a substrate.

2. *Alkaline phosphatase.* Alkaline phosphatase was measured by the method of Bessey, Lowry and Brock [7], using *p*-nitrophenyl phosphate as substrate.

Enzyme. The enzyme was the purified commercial product of Sigma Chemical Co. (St. Louis).

Reagents. 16 mM disodium *p*-nitrophenyl phosphate (Sigma Chemical Co.) in 0.001 N HCl. 0.1 M glycine buffer **. This was prepared from 7.50 g of glycine, 95 mg (0.001 M) of $MgCl_2$, about 80 ml of 1 N NaOH and water to 1 l. Buffered substrate: This consists of equal volumes of the two reagents.

Conditions of enzyme experiments. Determinations were mainly carried out at pH 9.3. The inhibition by the P.E.P. Standard was also investigated within the pH range 7.0—

* This is a 0.42 % solution of the Sigma 104 phosphatase substrate.

** Since it has been suggested that the use of glycine as buffer inhibits the enzyme activity [22], parallel experiments were run using glycine and 2-amino-2-methyl-1-propanol (1 M), respectively. Under our experimental conditions the use of these two buffers gave identical results.

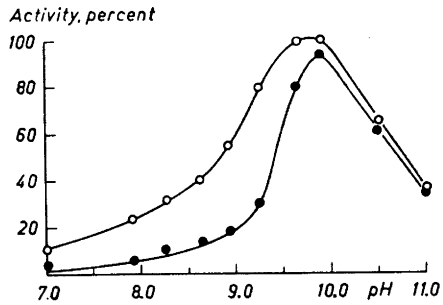

Fig. 7. Relationship between pH and inhibition of the enzymic hydrolysis of *p*-nitrophenyl phosphate by polyestradiol phosphate at 37.5°. 30 min incubation. Substrate concentration 3.3 × 10^{-4} M. Alkaline phosphatase concentration 13.3 μg per ml. O——O——O without inhibitor, ●——●——● 15 μg P.E.P. Standard per ml.

11.0. Reaction volume 1.5 ml (1 ml of the buffered substrate, 0.1 ml enzyme), incubation time 30 min at 37.5°. Enzyme concentration 13.3 μg per ml.

Results. From the relationship between pH and inhibition of the enzymic hydrolysis of *p*-nitrophenyl phosphate by P.E.P., it appears (Fig. 7), that inhibition occurs on the acid side of the pH-optimum only. A similar type of inhibition of alkaline phosphatase by estradiol-3,17-diphosphate, or by polyphloretin phosphate has been reported previously [1,9].

The inhibition of alkaline phosphatase at pH 9.3 by different batches of P.E.P. as well as by estradiol-3-phosphate, estradiol-17-phosphate and estradiol-3,17-diphosphate is presented in Fig. 8. A comparison of the data of Figs. 5 and 8 reveals that estradiol-3,17-diphosphate is a much stronger inhibitor of alkaline phosphatase than of acid phosphatase.

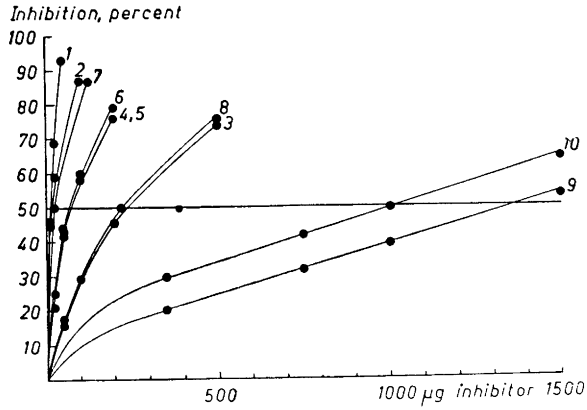

Fig. 8. Per cent inhibition of alkaline phosphatase by different batches of phosphorylated estradiol at pH 9.3. Enzyme concentration 13.3 μg per ml. Substrate, *p*-nitrophenyl phosphate. Glycine buffer with $MgCl_2$, pH 9.3. Incubation time 30 min at 37.5°. 1. P.E.P. Standard. 2. P.E.P. VI + P.E.P. VII (1:1). 3. P.E.P. I. 4. P.E.P. II. 5. P.E.P. III. 6. P.E.P. III B. 7. P.E.P. Standard after hydrolysis. 8. Estradiol-3,17-disphosphate. 9. Estradiol-17-phosphate. 10. Estradiol-3-phosphate.

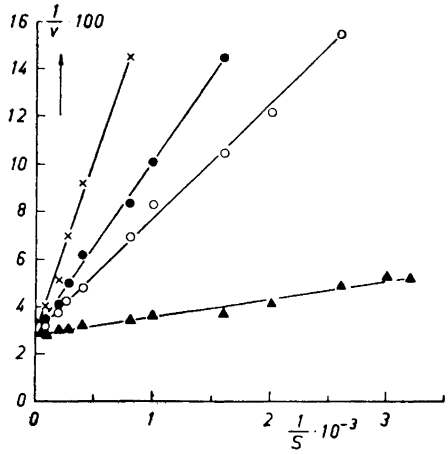

Fig. 9. A double reciprocal plot of the effect of polyestradiol phosphate (P.E.P. Standard) upon the velocity of alkaline phosphatase action at various substrate concentrations. The effect of 3.3 μg (○), 6.6 μg (●), and 10 μg of Polyestradiol phosphate [P.E.P. Standard] (×) upon the action of 13.3 μg alkaline phosphatase at pH 9.3 and 37.5° for 30 min. in the presence of various amounts of *p*-nitrophenyl phosphate. Filled triangles (▲) indicate enzyme activity in the absence of inhibitor.

Reversibility. Similarly to the case of acid phosphatase, the inhibition of alkaline phosphatase could also completely be reversed by basic proteins.

Type of inhibition. 3.3, 6.6 and 10 μg of P.E.P. Standard were added to solutions containing 13.3 μg of enzyme, and 0.27—27 μ moles/ml of *p*-nitrophenyl phosphate. A double reciprocal plot of velocity *versus* substrate concentration is shown in Fig. 9. It appears from the figure that the inhibition is of a competitive nature.

These findings are different from previous observations on polyphloretin phosphate [1], which study, however, was carried out at a lower pH (7.5). Experiments were therefore

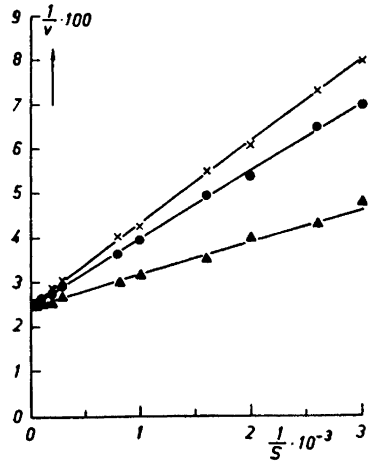

Fig. 10. A double reciprocal plot of the effect of polyphloretin phosphate (P.P.P). upon the velocity of alkaline phosphatase action at various substrate concentrations. The effect of 3.3 μg (●), and 16.7 μg (×) of P.P.P. upon the action of 13.3 μg alkaline phosphatase at pH 9.3 and 37.5° for 30 min. in the presence of various amounts of *p*-nitrophenyl phosphate. Filled triangles (▲) indicate enzyme activity in the absence of inhibitor.

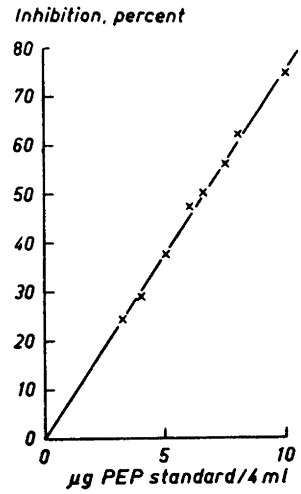

Fig. 11. Inhibition of hyaluronidase by polyestradiol phosphate (P.E.P. Standard). The effect of various amounts of inhibitor upon the action of 5 I.U. hyaluronidase per 4 ml at pH 7.0 and 37.5°.

carried out with polyphloretin phosphate at pH 9.3 and with *p*-nitrophenyl phosphate as substrate. It appears (Fig. 10) that the inhibition under these conditions is substrate-competitive. Further data on this problem will be reported in a forthcoming publication, dealing with polystilboestrol phosphate.

3. *Hyaluronidase.*

Bovine testicular hyaluronidase. The highly purified enzyme was prepared from bull testes according to Högberg [10] and assayed 90 000 I.U./mg nitrogen. Before use the enzyme was dissolved in water and the solution was stabilized with 2 µg methylgelatine (Leo) per I.U. of enzyme. 5 I.U. enzyme was used for the test.

Hyaluronic acid. The substrate, hyaluronic acid, was prepared from human umbilical cords and contained 3.39 % N, 10.3 % acetyl, 42.9 % glucosamine and 46.0 % glucuronic acid. Mc Ilvaine citrate-phosphate buffer, pH 7.0, containing sodium chloride was used

Table 2. The effect of polymerisation time upon the inhibition of phosphatases and of hyaluronidase by different batches of phosphorylated estradiol.

Inhibitor	No. in Figs. 5 and 8	Rel. amount of inhibitor necessary for 50 % inhibition		
		Hyaluronidase	Alkaline phosphatase	Acid phosphatase

* P.E.P. Standard after hydrolysis (81 h, pH 5.2, 98°).

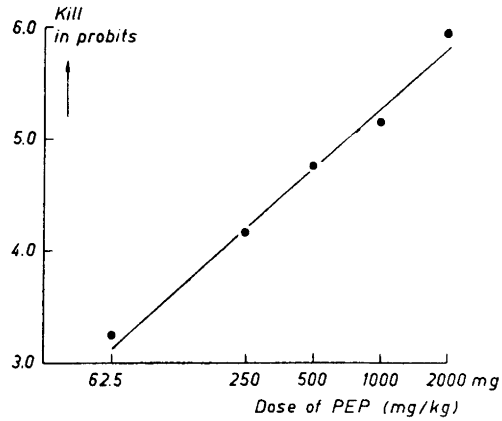

Fig. 12. Relationship between log dose of polyestradiol phosphate and kill (in probits) in a 60-days chronic toxicity test. Each point represents 25 adult male mice.

to dissolve hyaluronic acid (Na_2HPO_4 2 H_2O 16.1 g; citric acid. 2.02 g; NaCl 3.05 g; water to 1 000 ml). The concentration of the substrate was chosen to give a relative viscosity of 4.

Inhibitors. The inhibitors studied were shaken with the buffer and then diluted with buffer to a concentration of 0.1 mg per ml.

Conditions of enzyme experiments. The determination of the antihyaluronidase activity was carried out exactly according to the scheme described previously [1].

Results. Fig. 11 illustrates the inhibition of hyaluronidase at different concentrations of P.E.P. Standard. The influence of polymerisation time on the inhibitory activity of phosphorylated estradiol is demonstrated in Table 2. The inhibition is increased by increased polymerisation time, indicating that the inhibition is depending on the molecular size. An increase in the number of acidic groups (rephosphorylation) or a decrease (hydrolysis) does not change the magnitude of the inhibition (Table 2).

C. Pharmacological properties

Toxicity. The acute toxicity of P.E.P. was estimated in adult male mice. 48 h following a single intravenous injection the L.D.50 was found to be 240 mg/kg, with 95% fiducial limits of error at 212 and 272 mg/kg. It is realized, that in the absence of a toxicity reference standard the calculation of fiducial limits has a rather limited significance.

Chronic toxicity was estimated as follows: groups of 25 adult male mice were injected subcutaneously with P.E.P. in water on every 10th day. On the 60th day of experiment the number of survivors in each group was recorded. No correction has been made for spontaneous mortality. The correlation between the logarithm of dose and mortality in probits [21] is shown in Fig. 12. It appears from the data that under these conditions the L.D.50 is 700 mg/kg. Confidence limits (P = 0.95) were calculated as 350 and 1 400 mg/kg.

Biological activity. The duration of action of P.E.P. depends on the polymerisation time, as demonstrated in Fig. 1. From these data it appears that a polymerisation time less than 20 h will yield P.E.P. preparations with a relatively poor duration of action.

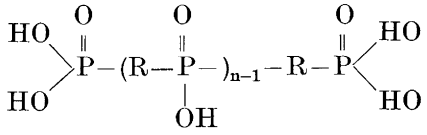
When different preparations of P.E.P. were administered to spayed mice it was found that the logarithm of dose was linearly related to the logarithm of duration of estrogenic action (in days) [11]. On basis of this observation a method of bioassay of long-acting estrogens was worked out [12]. When a mixture of P.E.P. preparations VI and VII (Table 1) was assayed by this method against the P.E.P. Standard, a relative potency of

103 % was obtained (fiducial limits of error: 91 and 117 %, respectively). The index of precision (estimated as Gaddum's λ-criterion [13]) was 0.09, indicating a very satisfactory precision.

It also appears from the data of Table 1 that following "rephosphorylation" with excess $POCl_3$ in pyridine before hydrolysis and dialysis, a P.E.P. preparation (III. B) could be obtained, in which no 'free' hydroxyl groups, but a great number of primary phosphate groups were present. Polymerisation time was only 5 h, which — according to the data of Fig. 1 — is too short for obtaining preparations with an optimal duration of action. When this "rephosphorylated" preparation was bioassayed against the P.E.P. standard, its potency was only 34 % of that of the Standard. This estimate of potency agrees very closely with that (30 %) of another preparation obtained following the same reaction time without "rephosphorylation" (prep. III). It is concluded therefore that the duration of estrogenic effect of P.E.P. does not depend on the relative proportion of acid groups present, but rather on the degree of polymerisation. It is also of interest, that when tested at the dose levels of 7 and 14 μg, respectively, estradiol-3,17-diphosphate did not show any prolonged estrogenic activity. In the same experiment the P.E.P. Standard exhibited a mean duration of 17.9 days (7 μg) and 24.6 days (14 μg), respectively. Finally, when as much as 100 μg of P.E.P. Standard were administered orally to each of 15 spayed mice, in all but one of the animals only negative smears could be obtained, indicating that P.E.P. is inactive when given orally.

DISCUSSION

Assuming that in the P.E.P. molecule the estradiol moieties are linked together by -OPO-bridges and that no free estradiol hydroxyl groups are present, the maximum phosphorus content and some other data can be calculated. The highest possible value of the phosphorus content of a polyestradiol phosphate molecule is dependent on the number of estradiol moieties only and not on possible branchings (one phosphorus being attached to three estradiol moieties). Thus, if the number of estradiol moieties (R) is n, it follows from the formula



that the phosphorus content (per cent) of this molecule is

$$100 \cdot \frac{31\ (n+1)}{334\,n+98} = 9.28 \cdot \frac{n+1}{n+0.29}$$

that the corresponding estradiol (HRH) content is $81.4 \cdot \frac{n}{n+0.29}$

and that the number of acid groups per phosphorus $= \frac{n+3}{n+1}$.

If the molecular weight of P.E.P. Standard is accepted to be 26 000, the n value will be about 80. In the formula above the theoretical percentage of phosphorus will be 9.36 and that of estradiol 81.1. The number of acid groups per phosphorus can be calculated as 1.03. P.E.P. Standard contains 9.5 % phosphorus, 78.2 % estradiol and 1.2 acid groups per phosphorus.

The small discrepancy in the phosphorus and estradiol values may be due to a relatively small proportion of pyrophosphate linkages (formed from small amounts of water in the reaction mixture). The high ratio acid groups to phosphorus, however, seems to speak in favour of a lower molecular weight, as does the low percentage of tertiary phosphate, which does not agree with the amount of primary phosphoric acid esters found. Assuming the molecular weight to lie between 3 000 and 5 000, the high ratio of acid groups to phosphorus as well as the low percentage of tertiary phosphate are easily explained, and if so the ultracentrifuge values may be due to a strong association.

The enzyme experiments reported in this paper indicate that P.E.P. — like most compounds in these series of polymeric phosphates — is a powerful inhibitor of several enzymes.

The results recorded in Tables 1 and 2 seem to indicate that an increase or a decrease in the number of acidic groups present in the inhibitor does not markedly influence the inhibitory effect. From the results obtained with products of different polymerisation time as well as with the monomeric esters, it appears that the degree of condensation is of greater importance.

Interesting is the relatively strong inhibitory effect of estradiol-3, 17-diphosphate upon alkaline phosphatase, as compared to the weak effect of this compound on the other enzymes studied. These findings are in agreement with the results reported previously [9], and indicate that alkaline phosphatases are inhibited by estradiol-3,17-diphosphate. Thus the previous suspicion [15] that the inhibition of kidney alkaline phosphatase by estradiol-3,17-disphosphate might have been due in part to a contamination of this compound by polymeric estradiol phosphates is not supported by the present data.

P.E.P. as well as polyphloretin phosphate have also been found [14] to exert a strong inhibitory effect on the disruption of mast cells produced by compound 48/80 or phospholipase A.

As far as its biological action is concerned, polyestradiol phosphate is a long-acting estrogen when administered parenterally to spayed mice [15], or to human beings [16, 17]. Since P.E.P. is rather resistant to acid or alkaline hydrolysis, as well as to the effect of different phosphatases, it would seem justifiable to assume, that its prolonged duration of action depends on a slow liberation of estradiol in the organism. In fact, experiments, in which P.E.P. labelled with radioactive phosphorus was administered to spayed mice [11] indicate that a definite relationship exists between circulating blood levels and log dose of P.E.P. administered, as well as between the duration of estrous smears and log dose of P.E.P. These correlations suggest that the circulating amount of P.E.P. may be instrumental in maintaining a prolonged estrogenic activity through its slow degradation into estradiol. Furthermore, evidence is also on record indicating that in the human organism substantial amounts of estradiol are liberated from the administered P.E.P. molecule and that this estradiol is metabolized and excreted in the same way as the body's own estrogen. Following the administration of P.E.P. to surgically castrated women, estrone, estradiol-17β and estriol were isolated and identified in their urine [16].

Finally, it is also of interest to note that P.E.P. has found an application in the treatment of prostatic carcinoma [18,19].

Short Communications

On the Biological Methylation of Histamine

KERSTIN M. LINDAHL

Institute of Zoophysiology, University of Uppsala, Sweden

For some time histamine has been known to be methylated and oxidatively deaminated prior to excretion [1]. Recently the postulated intermediary metabolite 1-methyl-4-(β-aminoethyl) imidazole, hereafter referred to as methylhistamine, has been shown to appear in the urine following administration of an amine oxidase inhibitor [2].

In vitro experiments have also demonstrated that the methylation process precedes the deamination [3,4] and may be separated from the following reaction steps [5].

In the above mentioned *in vitro* experiments methionine was added to the enzyme extracts on the assumption that the methyl group is derived from methionine as in many other biological transmethylations. The experiments reported in this communication were undertaken in order to test this hypothesis.

A mouse liver extract, described previously [5] in which methylation of histamine takes place but not deamination, was incubated from 1 to 24 h with nonisotopic histamine and methionine containing radiocarbon in the methyl group. The extract was dialysed prior to use.

Samples were withdrawn at the beginning and the end of the incubation, and analyzed for radioactive methylhistamine according to the isotope dilution method developed by Schayer and co-workers (for a description see Lindell and Schayer [6]).

The method briefly consists of the following steps: carrier methylhistamine * is added to the sample, extracted with chloroform after protein precipitation, and the picrate is recrystallized from water-ethanol using alternately different charcoal adsorbents until constant radioactivity is attained.

The zero-time samples were entirely inactive after two crystallizations, whereas the incubated ones retained a constant activity from the 2nd through the 4th crystallization.

* Methylhistamine was obtained from Dr. R. W. Schayer, Merck Institute for Therapeutic Research, which is hereby gratefully acknowledged.

Table 1.

	15.5 μg ^{14}C histamine, 1.48 mC/mM; 100 μg nonisotopic methionine	100 μg ^{14}C methionine 2.49 mC/mM; 15.5 μg nonisotopic histamine
^{14}C methylhistamine after 2 h incubation, cpm[1]	2 376	1 122
^{14}C histamine at zerotime, cpm	5 816	—
^{14}C histamine after 2h incubation, cpm	3 464	—

[1] The samples were counted in a windowless flow counter, Tracerlab, SC-16, which was made available through the courtesy of Prof. A. Tiselius, Institute of Biochemistry, Uppsala.

In the same manner simultaneous incubates containing only enzyme extract and ^{14}C methionine were assayed for methylhistamine. Now the carrier contained no radioactivity after only two crystallizations. It was thus concluded that carrier methylhistamine can, by repeated crystallization of the dipicrate, be completely freed from contamination by ^{14}C methionine and its possible metabolites.

The destruction of histamine and the formation of methylhistamine was followed by simultaneous incubation of the crude enzyme extract with radiocarbon histamine labelled in the imidazole nucleus. At the end of the incubation remaining histamine and methylhistamine were assayed by isotope dilution technique. It has been shown that by repeated crystallization of the dipicrate carrier amounts of methylhistamine can be freed from contamination by ^{14}C histamine or its metabolic products. By conversion of carrier histamine to its pipsyl derivative the contaminating methylhistamine can be removed [7]. Therefore constant activity of the samples during three successive crystallizations was considered as a sufficient criterion of the purity.

The essential figures from an experiment are given in Table 1. It has been concluded from these results that the methyl group of methylhistamine can be transferred from methionine. Whether methionine is the immediate precursor of the methyl group or an intermediate step is involved cannot be concluded from this type of experiment.

Phosphorus-32 Pentasulfide: Preparation by Isotopic Exchange and Conversion to Thiophosphoryl-32 Chloride and Phosphorus-32 Trichloride

JOHN E. CASIDA*

Department of Entomology, University of Wisconsin, Madison 6, Wisconsin, USA

Certain triesters of phosphoric and thiophosphoric acids are important as pesticides and potential chemical warfare agents. Adequate studies on the metabolism and mode of action of these organophosphorus compounds require their synthesis from high specific activity radiolabeled inorganic intermediates such as phosphorus pentasulfide (P_2S_5), thiophosphoryl chloride ($PSCl_3$), phosphorus trichloride (PCl_3), and phosphoryl chloride ($POCl_3$).

$^{32}POCl_3$ can be readily prepared in high specific activity from the reaction of $H_3{}^{32}PO_4$ with phosphorus pentachloride (PCl_5)[1]. Neutron irradiation is commonly employed to label certain of the other inorganic phosphorus intermediates [2-5]. This method is often inconvenient and the specific activity of the organophosphorus compounds prepared from these irradiated intermediates is usually not greater than 5 mC/g. $^{32}PSCl_3$ can also be prepared from $H_3{}^{32}PO_4$ *via* $^{32}POCl_3$ and $^{32}PCl_3$[6,7] or by an inefficient isotope exchange reaction [8].

Various procedures were tried to achieve isotope exchange between $H_3{}^{32}PO_4$ or $Na_2H{}^{32}PO_4$ and red phosphorus, $PSCl_3$ or P_2S_5. The products from each attempt were reacted with ethanol [9] or converted to other known organic derivatives [4] and then separated by paper and ion-exchange chromatography [10] to determine the degree of exchange. After correction for the radioactivity remaining on the glassware, the

Phosphorus-32 Pentasulfide: Preparation by Isotopic Exchange and Conversion to Thiophosphoryl-32 Chloride and Phosphorus-32 Trichloride

JOHN E. CASIDA*

Department of Entomology, University of Wisconsin, Madison 6, Wisconsin, USA

Certain triesters of phosphoric and thiophosphoric acids are important as pesticides and potential chemical warfare agents. Adequate studies on the metabolism and mode of action of these organophosphorus compounds require their synthesis from high specific activity radiolabeled inorganic intermediates such as phosphorus pentasulfide (P_2S_5), thiophosphoryl chloride ($PSCl_3$), phosphorus trichloride (PCl_3), and phosphoryl chloride ($POCl_3$).

$^{32}POCl_3$ can be readily prepared in high specific activity from the reaction of $H_3{}^{32}PO_4$ with phosphorus pentachloride (PCl_5)[1]. Neutron irradiation is commonly employed to label certain of the other inorganic phosphorus intermediates [2-5]. This method is often inconvenient and the specific activity of the organophosphorus compounds prepared from these irradiated intermediates is usually not greater than 5 mC/g. $^{32}PSCl_3$ can also be prepared from $H_3{}^{32}PO_4$ *via* $^{32}POCl_3$ and $^{32}PCl_3$[6,7] or by an inefficient isotope exchange reaction [8].

Various procedures were tried to achieve isotope exchange between $H_3{}^{32}PO_4$ or $Na_2H{}^{32}PO_4$ and red phosphorus, $PSCl_3$ or P_2S_5. The products from each attempt were reacted with ethanol [9] or converted to other known organic derivatives [4] and then separated by paper and ion-exchange chromatography [10] to determine the degree of exchange. After correction for the radioactivity remaining on the glassware, the

* Current address: Institute of Organic Chemistry and Biochemistry, University of Stockholm, Stockholm, Sweden.

only significant exchange occurred with the sulfur-containing compounds. The percentage exchange was low with $PSCl_3$ but almost complete with P_2S_5.

For preparation of $^{32}P_2S_5$, carrier-free $H_3{}^{32}PO_4$ or $Na_2H{}^{32}PO_4$ was evaporated in a reaction flask. The acid was preferable when the residue after evaporation was high and the salt when the residue was no more than a few milligrams. Red phosphorus and sulfur were then added in a 2 to 5 molar ratio with a combined weight of 0.20 to 2.0 g. While gassing the flask with dry carbon dioxide, the mixture was heated in one spot with a weak flame to initiate the vigorous reaction [11] that liquified the mixture and formed P_2S_5. When the mixture was then boiled for 10 min the exchange reaction was over 98 % complete. Similar exchange (95—98 %) resulted by slowly melting P_2S_5 in a reaction flask and then boiling for 10 min while gassing with carbon dioxide, and by heating the P_2S_5 for 2 h at 300—500°C in sealed ampules. The specific activity of the $^{32}P_2S_5$ thusly formed remained constant through repeated recrystallizations from carbon disulfide. When this $H_3{}^{32}PO_4$—P_2S_5 exchange reaction was run in the presence of varying amounts of non-labeled H_3PO_4, the percentage of the radioactivity recovered as $H_3{}^{32}PO_4$ closely approximated the percentage of the total phosphorus in the reaction mixture contributed by the H_3PO_4.

$^{32}PSCl_3$ was prepared in 73 % yield from $^{32}P_2S_5$ by reaction with 3 molar equivalents of PCl_5 [12,13] in the presence of anhydrous aluminium chloride comparable to 1.5 times the weight of the sulfur. The reaction was carried out in a closed all-glass system for 1.5 h at 160°C. $^{32}PCl_3$ was then formed in 91 % yield by reaction of the $^{32}PSCl_3$ with 1.1 molar equivalents of triphenyl phosphine at 130—140°C for 2 h according to a known type reaction [14] for obtaining sulfur migration from $PSCl_3$.

$^{32}P_2S_5$ prepared by this isotope exchange reaction has been used in the preparation of 15 different organic phosphate and phosphorothioate insecticides. Yields of the chromatographically-pure insecticides varied from 20—90 % based both on total phosphorus and radioactivity. The specific activities ranged from 2 to 340 mC/g. A more detailed report on the conversion of the $^{32}P_2S_5$ to various labeled insecticides and the characterization of the radioactive products will be published elsewhere.

Approved for publication by the Director of the Wisconsin Agricultural Experiment Station. This investigation was supported in part by a research contract with the *U. S. Atomic Energy Commission* (Contract No. AT (11—1)-64, Project No. 14). The author gratefully acknowledges the kind advice of Drs. G. Schrader and R. Mühlmann of *Farbenfabriken Bayer*, Elberfeld, Germany, and Dr. C. Simon of *J. R. Geigy*, Basle, Switzerland, and the skilled technical assistance of Mr. T. K. Knoke and Mr. K. Bürgin.

*iso*Thiocyanates XXXIII. * An *iso*Thiocyanate Glucoside (Glucobarbarin) of *Reseda luteola* L.

ANDERS KJÆR and ROLF GMELIN

Organic Chemical Laboratory of The Royal Veterinary and Agricultural College, Copenhagen V, Denmark

Phylogenists are agreed that the family *Resedaceae*, comprising six genera and about 70 species, belongs in the order *Rhoeadales*. Within the latter its close affinity to the *Cruciferae* and, particularly, the *Capparidaceae* has been generally accepted. Hence, it is not surprising that several literature references can be found to the occurrence of mustard oils in species of the genus *Reseda*.

Reseda luteola L. (dyer's weed, weld) was once grown as a source of the flavonoid dye luteolin. In 1871, Hirschberg [1] reported on the appearance of a smell similar to that of horse-radish in disintegrated root material of *R. luteola* and *R. odorata*. This observation was confirmed by Spatzier [2] who further demonstrated the presence of myrosinase in seeds and epidermic tissue of various *Reseda* species.

Pietschmann [3] later adduced microchemical evidence for the occurrence of an unidentified mustard oil in the leaf, stem, root and seed of *R.luteola*. In their paper-chromatographic survey of *iso*thiocyanate glucosides in numerous plants, Schultz and Gmelin [4] recorded the presence in roots, as well as other parts of fresh plants, of *R. luteola* of a single, unidentified glucoside travelling on paper at a rate (R_F 0.20) considerably lower than that of glucotropaeolin (R_F 0.31), the glucoside of *Tropaeolum majus*.

A closer study of the mustard oil glucoside in leaves and inflorescences of *Reseda luteola* L. has now resulted in the isolation of (−)-5-phenyl-2-oxazolidinethione as a product of enzymic fission. Paper chromatography in two solvent systems revealed the presence of only one glucoside in the employed material, migrating at a rate similar to that of glucotropaeolin.

Leaves and inflorescences of *Reseda luteola* (fresh weight 300 g) were added to hot methanol (3 l) and the mixture was refluxed for 1 h. After filtration, the pressed filter cake was extracted with hot 50 % methanol (3 l) and the filtrate collected and combined with the first extract. The solution was stripped of methanol, and water (1 l) was added to the residue. The precipitate was removed by filtration through Celite and 10 % lead acetate solution was added to the filtrate until no further precipitation took place. Excess lead ions were removed as lead phosphate by adding excess of 1/15 M phosphate buffer (pH 6.5) to the filtrate. After filtration, a cell-free myrosinase preparation (10 ml) was added and the buffered mixture set aside at room temperature for 3 h. The solution was then extracted with three 200 ml portions of chloroform. The chloroform extract was washed thrice with a 5 % $NaHCO_3$-solution and then shaken with about 10 g of acid-washed alumina in order to remove traces of flavonoid impurities. On evaporation of the dried chloroform extract a crystalline fraction remained which was recrystallized from ethyl acetate to give well-formed prisms. An additional recrystallization from 70 % ethanol afforded a pure specimen of colourless material (496 mg), m. p. 126—127° (capillary tube, uncorrected), $[\alpha]_D^{23}$ −69.3° ± 1.5° (c=2.0, MeOH).

The identity of the isolated compound with (−)-5-phenyl-2-oxazolidinethione (I) was suggested through the above physical constants and established beyond doubt upon comparison with an authentic specimen of the latter, previously synthesized in this laboratory [5]. Undepressed mixed melting point along with coinciding infra-red spectra served to establish the identity of the compound isolated from *Reseda luteola* and (I).

The formation of (I) upon enzymic hydrolysis suggests the presence in *R. luteola* of glucobarbarin, formerly encountered in seeds of *Barbarea vulgaris* R.Br.[5] As briefly pointed out previously [5], (I) depicts the absolute configuration of the naturally derived, *levo*rotatory heterocyclic compound as a consequence of its synthesis from (−)-2-amino-1-phenylethanol, accomplished in the following way.

(−)-2-Amino-1-phenylethanol (2.0 g) (m. p. 62—3°, $[\alpha]_D^{23}$ −43.5° (c = 2.0, abs. EtOH)), prepared by $LiAlH_4$ reduction of (−)-mandelamide as described by Pratesi and Grassi [6], was dissolved in anhydrous dioxane (6 ml), con-

II

taining triethylamine (1.55 g), and the solution was cooled to —10°. CS_2 (0.90 ml) was added with stirring, and the solution was allowed to come to room temperature. After cooling again to —10°, ethyl chloroformate (1.78 g) was introduced, resulting in separation of triethylammonium chloride. Chloroform (12 ml) and triethylamine (1.50) were added and the stirred reaction mixture was allowed to come to room temperature. After the evolution of COS had ceased, HCl (1 N) was added to acid reaction, and the aqueous phase was extracted thrice with chloroform. On evaporation of the dried chloroform solution a partly crystalline product resulted, which could be recrystallized from a mixture of ethyl acetate and hexane to give prisms of (—)-5-phenyl-2-oxazolidinethione (I) (1.48 g), m. p. 125°. An analytical specimen was produced by two additional recrystallizations from 50 % ethanol as colourless prisms, m. p. 126° (uncorr.), $[\alpha]_D^{23}$ —71.0° ± 1.5° (c = 2.0, MeOH). (Found: C 60.10; H 4.84; N 7.68. Calc. for C_9H_9NOS: C 60.31; H 5.06; N 7.82).

Similarly processed, (+)-2-amino-1-phenylethanol (m. p. 63°, $[\alpha]_D^{23}$ +44.2° (c = 2.0, abs. EtOH)) afforded the enantiomeric (+)-5-phenyl-2-oxazolidinethione (II), m. p. 126° (uncorr.), $[\alpha]_D^{23}$ +71° ± 1.5° (c = 2.0, MeOH) (Found: C 60.00; H 5.00; N 7.66).

A solution of equal amounts of the antipodes in hot aqueous ethanol crystallized on cooling and seeding as the racemic compound, m. p. 139° (uncorr.), undepressed on admixture with an authentic specimen [5].

The employed synthesis procedure represents an extension of the method developed by Hodgkins and Ettlinger [7] for the synthesis of *iso*thiocyanates *.

Glucobarbarin appears to be a glucoside of the general structural type [8], containing a 2-hydroxy-2-phenylethyl-side chain. The configuration of the latter is likely to be the same as that established above for (—)-5-phenyl-2-oxazolidinethione (I), which results from spontaneous cyclization of the primarily formed 2-hydroxy-2-phenylethyl *iso*thiocyanate without participation of bonds extending from the asymmetric carbon atom.

Paper chromatography and spectrophometric assays have disclosed the presence of glucobarbarin also in seeds of *R. luteola* L. The results of further investigations of *Resedaceae* species will form the subject of a forthcoming communication.

The work is part of investigations supported by *The Danish State Research Foundation* and *The Carlsberg Foundation*. A special grant from *Kai Hansen's Fond* is gratefully acknowledged.

A Note on the Substrate Specificity of Horse Liver Alcohol Dehydrogenase

ALFRED D. WINER*

Biochemical Department, Nobel Medical Institute, Stockholm, Sweden

During the course of a kinetic study of various aldehydes on the DPNH–ADH** compound with the aid of a fluorescence recorder [1], it was found that several hitherto unreported aldehydes and alcohols would function as substrates for horse liver ADH. The substrate specificity of ADH has been previously studied by several investigators [2-4]. Lutwak-Mann using impure ADH found that the relative order of reactivity was ethanol>propanol> amyl alcohol>methanol. Zatman with ADH prepared according to Lutwak-Mann found methanol to be oxidized at about one ninth of the rate for ethanol. Theorell and Bonnichsen using pure ADH found that the Michaelis constants of some higher aliphatic alcohols (allyl, *n*-propanol and *n*-butanol) were lower than for ethanol and stated that higher homologues of ethanol are substrates if they contain the group $-C-CH_2OH$. Bliss [5] has reported that Vitamin A alcohol is converted to retinene using an enzyme prepared according to Bonnichsen and Wassén [6], and Bonnichsen and Hubbard [7] confirmed this observation with pure ADH + DPNH + retinene. In the present study it was found that not only do a number of aliphatic aldehydes and alcohols show greater initial reaction velocities than the physiological substrates acetaldehyde and ethanol under the experimental conditions employed but also that benzyl alcohol, furfuryl alcohol and *cyclo*hexanol are reversibly oxidized by pure ADH.

Experimental part. Pure crystalline ADH was prepared by a modification procedure of Bonnichsen and Brink [8] as described by Dalziel [9]. All final determinations were made with the main component of the resolved enzyme as obtained by chromatography on carboxymethylcellulose. DPN and DPNH were commercial products from Sigma Chemical Company. Yeast ADH was a C. F. Boehringer Company product. All substrates were reagent grade chemicals further purified by distillation under suitable pressures. Rate determinations of the oxido-reduction of DPN(H) were made either in phosphate buffer, ionic strength 0.1, pH 6.95 or in glycine-NaOH buffer, 0.1 M, pH 9.50, at 23.5°, and initial velocities are expressed as moles per liter per min per mole of ADH ***. Details of the fluorescence characteristics of DPNH have been previously described [11,12].

Discussion. ADH appears to have a very broad specificity toward aliphatic carbinol compounds and acts as well on some aromatic and cyclic alcohols and aldehydes (see Table 1). As previously reported by Theorell and Bonnichsen [4], and confirmed in the present studies, pure ADH does not react with methanol + DPN to any observable extent, nor do the alcohols *tert*-butanol, *tert*-amyl or *iso*propyl. Methanol, furthermore, does not effect the activity toward ethanol or other alcohols. That Merritt [13], employing a rat liver acetone powder preparation, found *cyclo*hexanol to be reversibly oxidized to *cyclo*hexanone is probably due to the ADH present in the preparation. The K_m for *cyclo*hexanol was determined to be 1.3×10^{-3} M and for furfuryl alcohol 1.4×10^{-4} M (K_m for ethanol 5.3×10^{-4} M). Furfural was found to have a K_m of 7.7×10^{-6} M and *cyclo*hexanone of 1.9×10^{-3} M (K_m for acetaldehyde 2.1×10^{-4} M) ****. It is easily possible in the case of some alcohols and aldehydes listed in Table 1 to determine quantitative amounts of these substrates in concentrations of 10^{-7} M.

The reactivity of these substrates on yeast ADH are, however, quite different. *Cyclo*hexanol and *cyclo*hexanone will not react with the yeast enzyme and furfural acts at about one sixth of the rate for acetaldehyde while furfuryl alcohol reacts at about one-two hundredth of the rate for ethanol.

Formation of Particulate Ribonucleoprotein with Enzymatic Activities *in vitro*

AGNAR P. NYGAARD

Johan Throne Holst's Institutt for Ernæringsforskning, University of Oslo, Norway

During the purification of lactic dehydrogenase from baker's yeast [1] a particulate ribonucleoprotein was observed to be formed in a soluble preparation of proteins and ribonucleic acid. The solution was obtained from the mechanically extracted cells by acetone precipitation, calcium phosphate adsorption/elution and ammonium sulfate precipitation. The nucleoprotein precipitated on storage at 6°C from the saltfree solution which had been concentrated by lyophilization.

The precipitate contained about equal amounts of nucleic acid and protein. Adenine, guanine, cytosine and uracil were all present. The nucleoprotein (nucleic acid and protein) was insoluble in water and in different salt solutions (*e. g.* 1 M sodium chloride), but dissolved in 0.04 M sodium hydroxide. In some preparations the particles settled easily in a low centrifugal field, in others a clear solution was not obtained even after 30 min centrifugation at 30 000 × *g*.

The original solution contained 10 % ribonucleic acid, 5—10 % each of lactic-, malic-, alcohol- and triosephosphate dehydrogenase, and had proteolytic and nucleolytic activities. The well-washed particles had malic dehydrogenase activity. None of the other dehydrogenases were present. The particles digested the particulate ribonucleic acid. Thus, on incubation in phosphate buffer purine and pyrimidine material appeared in the supernatent. This material was not liberated by boiling of the particulate ribonucleoprotein.

Malic dehydrogenase was measured spectrophotometrically at 340 mμ, with oxalacetic acid and DPNH at pH 8.4, with malic acid and DPN at pH 9.6. The rate was 40 μmoles oxalacetic acid reduced per mg particulate protein per hour. Highly purified malic dehydrogenase has been obtained from the original ammonium sulfate precipitate by zone electrophoresis on cellulose. This soluble preparation did not contain ribonucleic acid and had an activity of 8 500 μmoles oxalacetic acid reduced per mg protein per hour.

The results indicate that particulate ribonucleoproteins isolated from bacterial cells may not necessarily represent original particles of the cell. Particles may be formed in a haphazard manner during extraction and purification.

Standard Deviations of Interatomic Distances in Completely Deuterated Benzene

S. J. CYVIN

Institutt for teoretisk kjemi, Norges tekniske høgskole, Trondheim, Norway

In a previous communication the calculation of standard deviations of interatomic distances in the benzene molecule has been reported [1]. The calculated values have been compared with values obtained from electron diffraction data [2].

Similar calculations from spectroscopic data have been performed for the benzene-d_6 molecule with the result given in Table 1. The experimental fundamental

Table 1. Standard deviations for interatomic distances in benzene-d_6.

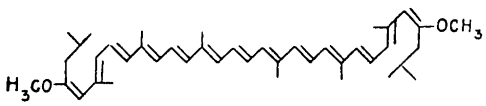
Two New Naturally Occurring Methoxyl-Containing Carotenoids

SYNNØVE LIAAEN JENSEN

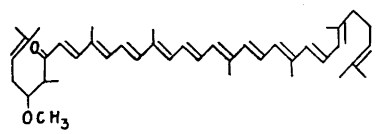
Institutt for Organisk Kjemi, Norges tekniske høgskole, Trondheim, Norway

Methoxyl-containing carotenoids have so far been restricted to the photosynthetic bacteria. Carotenoids hitherto known to contain methoxyl groups are:

1) Spirilloxanthin, isolated by van Niel *et al.*[1] in 1935 from old cultures of *Rhodospirillum rubrum*, and shown by comparision of analythical data [2] to be identical with rhodoviolascin, isolated the same year by Karrer *et al.*[3] from mixed cultures of *Rhodovibrio* species. Karrer *et al.* have proposed the formula for spirilloxanthin [4].



2) Pigment Y (Yellow) and Pigment R (Red), isolated from *Rhodopseudomonas spheroides*, and both shown by Goodwin *et al.*[5] to contain one methoxyl group. For Pigment R Goodwin *et al.* have proposed the formula



and renamed it spheroidenone [5].

Kinetic experiments performed by Stanier *et al*[6]. to establish the route of carotenoid synthesis in the photosynthetic, nonsulphur purple bacterium *Rhodospirillum rubrum*, showed that the following transformation occurs quantitatively during growth:

lycopene → P481 → spirilloxanthin
OH-lycopene → OH-P481 → OH-spirilloxanthin

The structures of the carotenoids P481 and OH-P481 are not known. The designation Pigment 481 was given by Goodwin *et al.*[7] from the main absorption band in petroleum ether.

During endogenous carotenoid synthesis (anaerobically in light) washed cells of *Rhodospirillum rubrum* previously grown in the presence of diphenylamine, produced considerable amounts of P481 and OH-P481, whereas only a limited synthesis of spirilloxanthin normally was observed. This observation led to the assumption that P481 and OH-P481 were carotenoids with the same C_{40} skeleton as lycopene, and that lack of intracellular methyl donators limited the endogenous spirilloxanthin synthesis [8].

In the investigation now reported the presence of methoxyl groups in crystalline, chromatographically pure P481 and OH-P481 was indicated by IR-absorption bands at 1 078 cm^{-1} (KBr discs).

Quantitative methoxyl determinations were carried out according to the modified method of Inglis [8], and gave the following results:

Carotenoid	% OCH_3 found	% OCH_3 calculated	based on formula
P481	5.51	5.48	$C_{40}H_{55}(OCH_3)$
OH-P481	5.33	5.31	$C_{40}H_{54}(OH)(OCH_3)$

These results establish the presence of one methoxyl group in both P481 and OH-P481.

The fact that P481 and OH-P481 are C_{41} compounds is not in accordance with our previous suggestion. However, this finding fits well the role that has been ascribed to these two carotenoids as biosynthetic intermediates between lycopene ($C_{40}H_{56}$) and spirilloxanthin ($C_{42}H_{60}O_2$)[6].

Work on the chemical structure of P481 and OH-P481 is in progress.

The author is indebted to prof. R. Y. Stanier, Dept. of Bacteriology, University of California, Berkeley, for providing facilities for the cultivation of mass cultures of *Rhodospirillum rubrum* in his laboratory, to Mr. Charles E. Spotts for skilled assistance, and to prof. N. A. Sørensen, NTH, for inspiring interest in this work.

Notiz über α-Phenoxyhydrozimtsäure

H. SEBELIUS*

Vor etwa vierzig Jahren hat der Verf. am Chemischen Institut der Universität Lund auf Veranlassung von Professor J. M. Lovén die α-Phenoxyhydrozimtsäure mit Hilfe der aktiven α-Phenäthylamine [1] in ihre optisch aktiven Komponenten gespalten und einige vorläufige Ergebnisse darüber publiziert [2]. Ehe die Untersuchung für andere Arbeiten unterbrochen wurde, lagen noch einige Resultate vor, die sich unter anderem auf die Säureamide bezogen. Für ihre Darstellung wurde ein Verfahren erprobt, das einfach und mit vorzüglicher Ausbeute zu so gut wie analysenreinen Substanzen direkt führte und wahrscheinlich auch für andere α-Phenoxykarbonsäuren verwendbar ist. Verschiedene Derivate dieser Säuren haben ja in der letzten Zeit als Pflanzenwachstumsregulatoren bedeutendes Interesse erreicht, und in diesem Zusammenhang verdienen die hierauf bezüglichen Säureamide Aufmerksamkeit.

Das Verfahren zur Darstellung der Säureamide war folgendes: Die Äthylester der Säuren wurden in der etwa zehnfachen Menge mit Ammoniak bei −10°C gesättigten Äthylalkohols aufgelöst und in gut verschlossenen, starkwändigen Gefässen rund zehn Tage bei Zimmertemperatur aufbewahrt. Nach dieser Zeit hatten sich die gebildeten Amide in centimeterlange, gut entwickelte Prismen ausgeschieden.

Das Amid der Racemsäure schmolz bei 145°C und war in Wasser, Alkohol und Aether schwer löslich. Stickstoffbestimmung nach Kjeldahl gab 5,7 % N, ber. 5,8 %.

Der für die Darstellung des Amids der linksdrehenden α-Phenoxyhydrozimtsäure verwendete Äthylester hatte bei 14 mm Hg den Siedepunkt 198°C und die spezifische Drehung in Alkohol $[\alpha]_D^{18}$ −20°, in Chloroform $[\alpha]_D^{18}$ −24°. Das nach dem oben angegebenen Verfahren erhaltene Amid kristallisierte sehr schön, gab bei der Analyse den berechneten Stickstoffgehalt von 5,8 % N und schmolz bei 147°C, also unbedeutend höher als das Amid der Racemsäure. Wegen der Schwerlöslichkeit des Amids in Alkohol wurde die Drehung in Aceton bestimmt: $[\alpha]_D^{18}$ −11°. Auffallenderweise zeigte es in Chloroform entgegengesetzte Drehungsrichtung, $[\alpha]_D^{18}$ +26°. Die Drehungsveränderung wurde damals als Resultat einer relativ festen Anlagerung von Chloroform an die Amidgruppe gedeutet. In Eisessig, wo man eine derartige selektive Solvatisierung vermuten konnte, war die Drehung ebenfalls positiv, nämlich $[\alpha]_D^{18}$ rund +11°. Die Drehungsmessungen wurden mit einem alten, wenig empfindlichen Polarimeter und ziemlich bescheidenen Substanzmengen ausgeführt und machen daher keinen Anspruch auf Präcision.

Notiz über α-Phenoxyhydrozimtsäure

H. SEBELIUS*

Vor etwa vierzig Jahren hat der Verf. am Chemischen Institut der Universität Lund auf Veranlassung von Professor J. M. Lovén die α-Phenoxyhydrozimtsäure mit Hilfe der aktiven α-Phenäthylamine [1] in ihre optisch aktiven Komponenten gespalten und einige vorläufige Ergebnisse darüber publiziert [2]. Ehe die Untersuchung für andere Arbeiten unterbrochen wurde, lagen noch einige Resultate vor, die sich unter anderem auf die Säureamide bezogen. Für ihre Darstellung wurde ein Verfahren erprobt, das einfach und mit vorzüglicher Ausbeute zu so gut wie analysenreinen Substanzen direkt führte und wahrscheinlich auch für andere α-Phenoxykarbonsäuren verwendbar ist. Verschiedene Derivate dieser Säuren haben ja in der letzten Zeit als Pflanzenwachstumsregulatoren bedeutendes Interesse erreicht, und in diesem Zusammenhang verdienen die hierauf bezüglichen Säureamide Aufmerksamkeit.

Das Verfahren zur Darstellung der Säureamide war folgendes: Die Äthylester der Säuren wurden in der etwa zehnfachen Menge mit Ammoniak bei −10°C gesättigten Äthylalkohols aufgelöst und in gut verschlossenen, starkwändigen Gefässen rund zehn Tage bei Zimmertemperatur aufbewahrt. Nach dieser Zeit hatten sich die gebildeten Amide in centimeterlange, gut entwickelte Prismen ausgeschieden.

Das Amid der Racemsäure schmolz bei 145°C und war in Wasser, Alkohol und Aether schwer löslich. Stickstoffbestimmung nach Kjeldahl gab 5,7 % N, ber. 5,8 %.

Der für die Darstellung des Amids der linksdrehenden α-Phenoxyhydrozimtsäure verwendete Äthylester hatte bei 14 mm Hg den Siedepunkt 198°C und die spezifische Drehung in Alkohol $[\alpha]_D^{18}$ −20°, in Chloroform $[\alpha]_D^{18}$ −24°. Das nach dem oben angegebenen Verfahren erhaltene Amid kristallisierte sehr schön, gab bei der Analyse den berechneten Stickstoffgehalt von 5,8 % N und schmolz bei 147°C, also unbedeutend höher als das Amid der Racemsäure. Wegen der Schwerlöslichkeit des Amids in Alkohol wurde die Drehung in Aceton bestimmt: $[\alpha]_D^{18}$ −11°. Auffallenderweise zeigte es in Chloroform entgegengesetzte Drehungsrichtung, $[\alpha]_D^{18}$ +26°. Die Drehungsveränderung wurde damals als Resultat einer relativ festen Anlagerung von Chloroform an die Amidgruppe gedeutet. In Eisessig, wo man eine derartige selektive Solvatisierung vermuten konnte, war die Drehung ebenfalls positiv, nämlich $[\alpha]_D^{18}$ rund +11°. Die Drehungsmessungen wurden mit einem alten, wenig empfindlichen Polarimeter und ziemlich bescheidenen Substanzmengen ausgeführt und machen daher keinen Anspruch auf Präcision.

Structure of the Tetrathionate Ion in the Sodium Salt

OLAV FOSS and ASBJØRN HORDVIK

Chemical Institute, University of Bergen, Bergen, Norway

A crystal structure analysis of barium tetrathionate dihydrate five years ago [1] led to an unbranched, non-planar structure for the sulphur chain of the tetrathionate ion, and gave the following values (±0.03 Å and ± 2°) for bond lengths and angles: $S_1-S_2 = 2.10$ Å, $S_2-S_3 = 2.02$ Å, $S_3-S_4 = 2.13$ Å, $\angle S_1-S_2-S_3 = 104°$, $\angle S_2-S_3-S_4 = 102°$. The dihedral angle, $S_1S_2S_3/S_2S_3S_4$, was found to be 90°. These results have now been confirmed through a more accurate structure analysis of sodium tetrathionate dihydrate, $Na_2S_4O_6 \cdot 2H_2O$.

This salt is monoclinic [2], with $a = 14.50$ Å, $b = 6.37$ Å, $c = 5.47$ Å, $\beta = 105.6°$, and two formula units per unit cell. The space group is C_2^3-C2, which requires that the tetrathionate ion lies on a twofold axis of symmetry. The b and c-axis projections were solved through Patterson and Fourier syntheses and refined through repeated difference syntheses, based on 81 observed $h0l$ reflections and 56 observed $hk0$ reflections out of 90 and 61, respectively, accessible with Cu$K\alpha$ radiation. The intensities were estimated visually from zero-layer Weissenberg photographs of an approximately spherical crystal with a diameter of 0.12 mm. Individual temperature corrections, anisotropic for some atoms, were applied in calculating $h0l$ structure factors, whereas an overall, isotropic temperature correction was used for the $hk0$ data. The final atomic coordinates are listed in Table 1; the reliability index R is 0.076 for both zones.

Table 1. Atomic coordinates for sodium tetrathionate dihydrate, in fractions of monoclinic cell edges. Origin on a twofold axis.

	x	y	z
S_2	0.0234	0	0.342
S_1	0.1340	0.227	0.420
O_1	0.090	0.435	0.379
O_2	0.180	0.169	0.223
O_3	0.192	0.193	0.678
Na	0.271	0.406	0.020
H_2O	0.123	0.619	—0.088

These coordinates give a length of 2.019 Å for the middle S—S bond across the twofold axis, and 2.116 Å for the end S—S bonds, with estimated standard deviations of 0.01 Å. There is thus no doubt that the middle bond, between the two divalent sulphur atoms of the tetrathionate ion, is shorter than the two other S—S bonds. The S—S—S bond angles are 103.8° ± 0.5° and the dihedral angle SSS/SSS is 90.4° ± 1°.

The SO_3 groups have trigonal symmetry within the accuracy of the analysis, with S—O bond lengths of 1.45, 1.46 and 1.46 Å (± 0.02 Å) and O—S—O angles of 112.6°, 113.5° and 114.8° (± 1.5°). The axis of the trigonal pyramid does not coincide with the direction of the O_3S-S bond, the O—S—S angles being 108.1°, 98.6° and 107.6° (± 1°).

Details of the structure will be published later.

ACTA CHEMICA SCANDINAVICA 12 (1958) 1701—1714

The Crystal Structure of $Mo(OH)_3PO_4$

PEDER KIERKEGAARD

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

$Mo(OH)_3PO_4$ has a monoclinic unit cell containing two formula units and with the dimensions

$a = (6.731 \pm 0.005)$ Å
$b = (6.319 \pm 0.005)$ Å
$c = (7.034 \pm 0.005)$ Å
$\beta = (110.16 \pm 0.05)°$
$V = 280._8$ Å^3

A structure is proposed with atomic positions in the space group No. 11, $P2_1/m$. The positions of the molybdenum and phosphorus atoms in the unit cell were determined by Fourier methods. The parameters of the oxygen atoms were determined partly from electron density projections and partly from geometrical considerations, interatomic distances from previously determined structures being used. The crystals are built up of double chains parallel to the y-axis and formed by MoO_6 octahedra, coupled together by PO_4 groups so that every MoO_6 octahedron is sharing edges with three phosphate tetrahedra and every PO_4 tetrahedron with three MoO_6 octahedra. The double chains are then held together by the hydrogen atoms situated between adjacent oxygen atoms from different chains.

In connection with an X-ray investigation of oxygen-phosphorus compounds of molybdenum and wolfram undertaken at this institute a crystal structure determination of a molybdenum(VI)-phosphate, $2\ MoO_3 \cdot P_2O_5 \cdot 3\ H_2O$, has been made. The existence of a crystalline compound of this composition was reported by Schulz [1]. The crystals were described as slightly soluble in cold water but dissolving easily in warm water, giving a strongly acid solution, yellow when warm but colourless at room temperature. The compound did not lose water until it was heated to a temperature above 225°C and, as a water-free final product $2\ MoO_3 \cdot P_2O_5$ was formed. From this and some other experiments it was concluded by Schulz that the first compound was an orthophosphate with the formula $MoO_2HPO_4 \cdot H_2O$ and the second was a pyrophosphate, $(MoO_2)_2P_2O_7$. A structure determination of the latter has been started but here we shall deal only with the first-mentioned compound.

PREPARATION OF THE CRYSTALS

A viscous solution of MoO_3 (15 g) in concentrated (14.5 M) H_3PO_4 (45 ml) was prepared at about 180°C. On cooling the solution was diluted with 400 ml of concentrated (15.5 M) HNO_3 and then evaporated, during which time small crystals were obtained. The evaporation was continued to a volume of 200 ml after which the crystals were filtered off, washed with cold water and dried in air. (The method according to Schulz [1].)

The crystals were small colourless rods. However, the yield was low and the crystals obtained were too small for X-ray work and therefore the synthesis was repeated several times, resulting in sufficient amounts of the small crystals. The biggest single crystal obtained after growth in hot solution was one of about 0.1 mm in length and 0.03 mm in diameter.

Analysis. A sample was dissolved in hot water. From an ammoniacal solution the *phosphorus* was precipitated (according to Kolthoff and Sandell [2]) with a magnesium solution. The precipitate of magnesium phosphate was filtered off, washed with water, dissolved in hot 1 M HNO_3 and from this solution the phosphorus finally was precipitated with ammonium molybdate and weighed as $(NH_4)_3PO_4 \cdot 12\ MoO_3$. The amount of *molybdenum* in the filtrate was determined gravimetrically by precipitation with 8-hydroxyquinoline [3,4] from a solution slightly acid with acetic acid. The precipitate was filtered off, washed with water, dried at 140°C and weighed as molybdenum hydroxyquinolate. The *water* was determined by Hartwig-Bendig's [5] modification of Brush's [6] and Penfield's [7] methods.

The *density* of the crystals was determined from the apparent loss of weight in benzene.

	Calculated for $2\ MoO_3 \cdot P_2O_5 \cdot 3\ H_2O$	Found
% MoO_3	59.48	59.7
% P_2O_5	29.35	29.5
% H_2O	11.17	10.7
Density	2.862	2.82

The density is calculated for one formula unit per unit cell.

UNIT CELL AND SPACE GROUP

From rotation photographs (around [010] and [100]) and the corresponding Weissenberg photographs (zero, first and second layer lines), taken with CuK radiation it was concluded that the crystals are monoclinic with $a = 6.8$ Å, $b = 6.4$ Å, $c = 7.1$ Å and $\beta = 110°$ (the b-axis coincides with the needle axis of the crystal).

The reflections were recorded photographically with multiple film techniques and the relative intensities were estimated visually by comparison with an intensity scale obtained by photographing a reflection with different exposure times. However, the accuracy in the intensity estimations was rather low since the photographs were fairly poor owing to the smallness of the crystals prepared. The values of F^2 were then calculated from the relative intensities using the polarization and Lorentz' factor given by Lu[8]. No correction was applied for absorption.

More accurate values for the unit cell dimensions were calculated from a powder photograph taken with monochromatized Cu$K\alpha_1$ radiation in a focusing camera of Guinier type. KCl was used as an internal standard substance (see Table 1).

$$a = (6.731 \pm 0.005)\ \text{Å}$$
$$b = (6.319 \pm 0.005)\ \text{Å}$$
$$c = (7.034 \pm 0.005)\ \text{Å}$$
$$\beta = (110.1_6 \pm 0.05)^\circ$$
$$V = 280._8\ \text{Å}^3$$

The value (2.82) found for the density gives $0.99 \approx 1$ formula unit in the unit cell.

The reflections systematically absent are

$$0k0 \text{ with } k = \text{odd}$$

This is characteristic of the two space groups No. 4, $P2_1$, and No. 11, $P2_1/m$. The investigation was started by examining whether the structure was consistent with the latter space group, having the highest symmetry. In No. 11, $P2_1/m$, the following point positions are possible.

$2(a)$: 000; $0\frac{1}{2}0$; $2(b)$: $\frac{1}{2}00$; $\frac{1}{2}\frac{1}{2}0$; $2(c)$: $00\frac{1}{2}$;$0\frac{1}{2}\frac{1}{2}$
$2(d)$: $\frac{1}{2}0\frac{1}{2}$; $\frac{1}{2}\frac{1}{2}\frac{1}{2}$; $2(e)$: $\pm(x\frac{1}{4}z)$
$4(f)$: $\pm(xyz)$; $\pm(x,\frac{1}{2}\text{-}y,z)$

Table 1. Powder photograph of $Mo(OH)_3PO_4$. CuK_{α_1}-radiation. $\lambda_{CuK_{\alpha_1}} = 1.54050$ Å.

The powder photograph was measured and interpreted to $\sin^2\Theta = 0.41$.
Reflections systematically absent in space group $P2_1/m$ have been omitted.
KCl ($a = 6.2930$ Å) has been used as an internal standard substance.

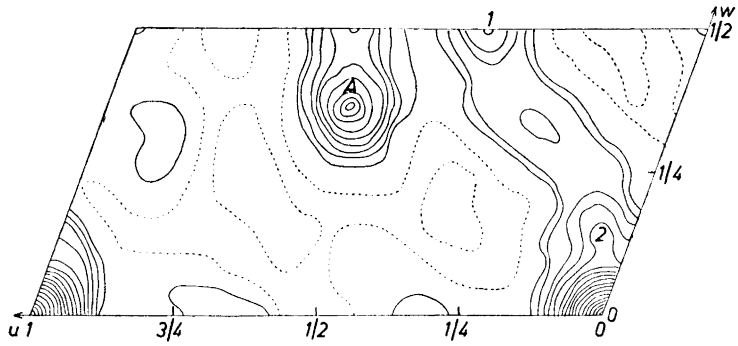

Fig. 1. The Patterson function $P(upw)$ for $Mo(OH)_3PO_4$. Dashed lines indicate negative values.

POSITIONS OF THE MOLYBDENUM AND PHOSPHORUS ATOMS

In order to find the positions of the two molybdenum atoms the Patterson projections, $P(upw)$ and $P(pvw)$, were calculated (Figs. 1 and 2). Those atoms must occupy one of the twofold positions, *i.e.* 2(*a*)—(*e*). Now, in the Patterson projections on the *uw* and *vw* plane there are high peaks (besides the origin maxima) at $u = 0.57_0$, $w = 0.36_2$ in $P(upw)$ (A in Fig. 1), and at $v = \frac{1}{2}$, $w = 0.35_2$ in $P(pvw)$ (B in Fig. 2). (All maxima have been located by the interpolation table given by Booth [9].) Thus, in the half-cell there is a high peak at $u = 0.57$, $v = \frac{1}{2}$, $w = 0.36$ and this maximum certainly corresponds to the Mo—Mo vector. The molybdenum atoms thus must occupy the point position 2(*e*), as the other twofold point positions would require the Mo—Mo vector to have the specialized coordinates $u = \frac{1}{2}$, $v = 0$, $w = \frac{1}{2}$. From the coordinates given above we get

2 Mo in $P2_1/m$ 2(*e*) with $x \approx 0.285$, $y = 1/4$, $z \approx 0.180$

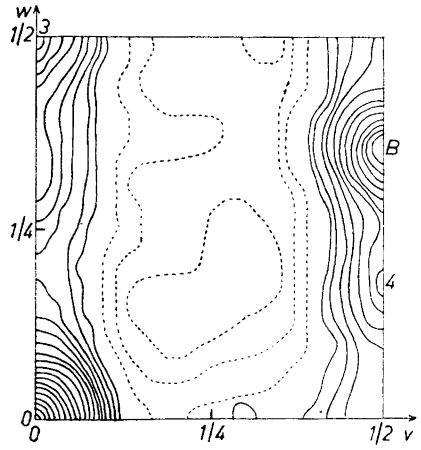

Fig. 2. The Patterson function $P(pvw)$ for $Mo(OH)_3PO_4$. Dashed lines indicate negative values.

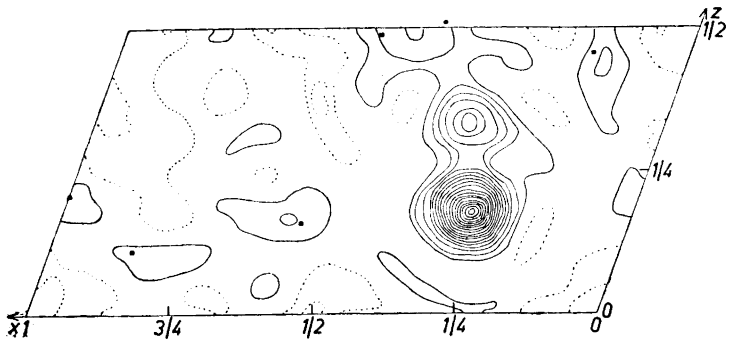

Fig. 3. Electron density of $Mo(OH)_3PO_4$ projected on the *xz* plane. The positions of the oxygen atoms O_2-O_6 (■) have been marked. Dashed lines indicate negative values.

In addition to the peak corresponding to the Mo—Mo vector the Patterson projections also show maxima, the heights of which suggest that they can be ascribed to the Mo—P distances. Thus, the peaks 1 ($u = 0.38$, $w = 0.50$) and 2 ($u = 0.06$, $w = 0.15$) in $P(upw)$ (Fig. 1) and 3 ($v = 0$, $w = 0.50$) and 4 ($v = \frac{1}{2}$, $w = 0.16$) in $P(pvw)$ (Fig. 2) define two maxima in the Patterson function, *viz.* at $u = 0.38$, $v = 0$, $w = 0.50$ and at $u = 0.06$, $v = \frac{1}{2}$, $w = 0.15$. These Mo—P vectors are only in accordance with the two phosphorus atoms occupying the point position 2(*e*) with the approximate coordinates

$$x_P = x_{Mo} + 0.38 = 0.67$$
$$y_P = 1/4$$
$$z_P = z_{Mo} + 0.50 = 0.68$$

POSITIONS OF THE OXYGEN ATOMS

Electron density projections. In order to obtain more accurate values of the molybdenum and phosphorus coordinates the electron density projec-

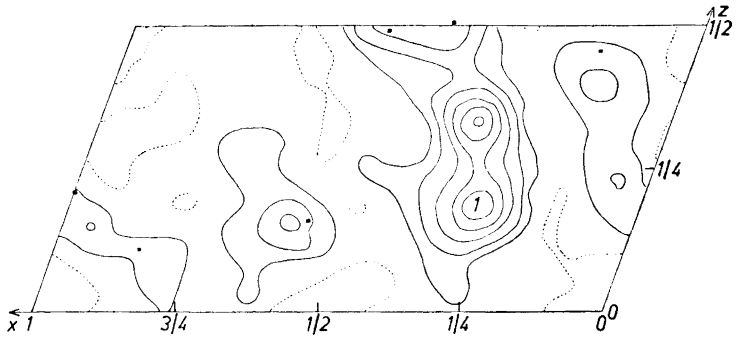

Fig. 4. Electron density of $Mo(OH)_3PO_4$ projected on the *xz* plane and with the molybdenum atom substracted. The positions of the oxygen atoms have been indicated as in Fig. 3. Dashed lines indicate negative values.

tion on the *xz* and *yz* planes were calculated. The signs of all structure factors $F(h0l)$ and $F(0kl)$ were determined from the contributions given by the molybdenum atoms. The results are given in Figs. 3 and 5.

From Fig. 3 we see that the molybdenum and the phosphorus atoms are clearly indicated at $x = 0.282$, $z = 0.176$ and at $x = 0.34$, $z = 0.34$. However, the "phosphorus" peak might be a little displaced from the correct phosphorus position by diffraction effects caused by the heavy molybdenum atom. In order to get, probably more reliable, coordinates for the phosphorus atoms the molybdenum atom was subtracted from the Fourier image in Fig. 3. — The contributions of the Mo atoms to the structure factors were multiplied by a "temperature" factor of $10^{-0.315 \sin^2\Theta}$, obtained in the ordinary way for the determination of temperature factors.

From Fig. 4, which shows this new electron density projection, we see the phosphorus atom at $x = 0.32_7$, $z = 0.33_8$. However, there is yet another maximum (1 in Fig. 4, with $x = 0.28_7$, $z = 0.18_8$) with nearly the same positions as the molybdenum atom. The height of the peak is about the same as the maximum corresponding to the phosphorus position and if it is a real one the only atoms which could give a maximum of this height are two overlapping oxygen atoms, which will occur if four oxygen atoms occupy the point position 4(*f*). Now, from Fig. 5 showing the electron density projected on the *yz* plane, we see that there are two peaks (1') outside (*i.e.* $y = 0.54$ and 0.96) the mirror planes ($y = \pm 1/4$) and with the *z* parameter ($z = 0.18_9$) in close agreement with the *z* parameter found above for peak 1 in Fig. 4. It seems therefore very probable that peak 1 is a real maximum and that four oxygen atoms are situated in the point position 4(*f*). (The accuracy of the *x*-coordinate of these oxygen atoms might be reduced owing to inadequate subtraction of the overlapping Mo atom [10].)

The molybdenum and phosphorus atoms stand out very clearly in $\varrho(pyz)$ (Fig. 5), the molybdenum at $y = 1/4$, $z = 0.177$ and the phosphorus at $y = 3/4$,

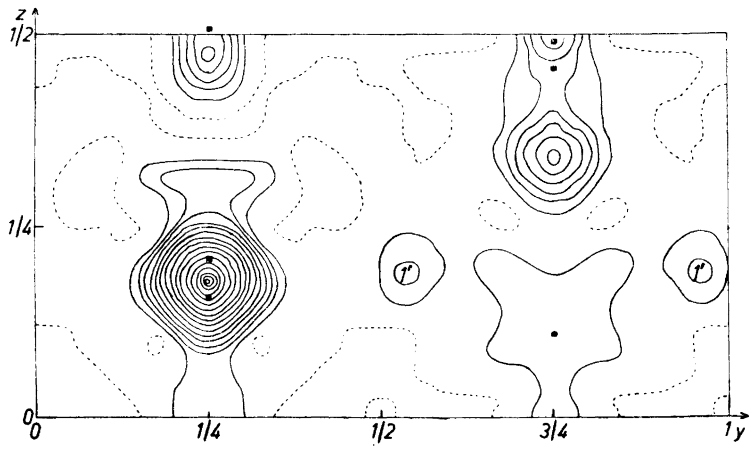

Fig. 5. Electron density of $Mo(OH)_3PO_4$ projected on the *yz* plane. The positions of the oxygen atoms have been indicated as in Fig. 3. Dashed lines indicate negative values.

$z = 0.34_0$, the z parameters being in good agreement with those obtained from $\varrho(xpz)$. The values obtained from $\varrho(xpz)$ should, however, be more correct, since in the calculation of this projection more F-values were used. Thus from the electron density projections the following parameters could be obtained:

2 Mo	in	$P2_1/m$	2(*e*)	with:	$x = 0.282$,	$y = 1/4$,	$z = 0.176$
2 P	in	»	»	»	$x = 0.67_3$,	$y = 1/4$,	$z = 0.66_2$
4 O_1	in	»	4(*f*)	»	$x = 0.71_3$,	$y = 0.46_0$	$z = 0.81_1$

The remaining maxima in the electron density projections were, at this state of the investigation, not considered as they are rather diffuse and of about the same height as the false maxima [11]. However, as will be seen (see p. 1708) they were found to correspond to oxygen positions.

Geometrical considerations. The four oxygen atoms (O_1), the positions of which have been found from the electron density projections, are situated close to phosphorus atoms with the distances P—2 $O_1 = 1.6_5$ Å. These distances are in good agreement with P—O distances found in previously described structures [12–14] (*viz.* P—O = 1.4_5—1.6_5 Å). Assuming that the coordination figure around the phosphorus atoms is a fairly regular tetrahedron, which seems to be very probable, it is then possible to calculate the parameters of the remaining oxygen atoms (O_2 and O_3) in the PO_4 tetrahedron. If we assume the bond lengths P—O_2 = P—O_3 = 1.5_5 Å and O_2—O_3 = 2.5_3 Å (these distances are mean values of those published [12–14]) the coordinates of the oxygen atoms O_2 and O_3 follow immediately. Thus we obtain

2 O_2	in	$P2_1/m$	2(*e*)	with:	$x = 0.44_3$,	$y = 1/4$,	$z = 0.50_9$
2 O_3	in	»	»	»	$x = 0.83_0$,	$y = 1/4$,	$z = 0.54_4$

Now we have to find the positions of the remaining six oxygen atoms in the unit cell. They must occupy three of the twofold or one of the twofold and one of the fourfold positions, if the arrangement of these atoms also has the symmetry $P2_1/m$. Assuming that the distances between these oxygen atoms and the oxygens already located (*i.e.* O_1—O_3) are not less than 2.6_0 Å, the twofold positions 2(*a*)—2(*d*) can at once be eliminated and thus the remaining oxygen atoms are situated in 4 × 2(*e*) or 2(*e*) + 4(*f*). Of these point positions, 4(*f*) seems to be improbable since nothing indicates this in the electron density projections. (Figs. 3—5.) Moreover, with the oxygen parameters found above, we have three oxygen atoms (2 O_1 and O_2) in contact with one molybdenum atom (*viz.* Mo—2 $O_1 = 1.8_3$ Å and Mo—$O_2 = 2.2_2$ Å, in good agreement with Mo—O distances found in previously determined structures of oxygen compounds of molybdenum [15–18] and these four atoms are situated in the same plane. Now, if we have four oxygens in 4(*f*) these oxygens cannot be in contact with the molybdenum atoms since all O—O distances ought to be $\geq 2.6_0$ Å and thus we would obtain a very improbable coordination, quite different from previously known arrangements [16–18]. For these reasons we conclude that the remaining six oxygen atoms must occupy the point positions 2(*e*).

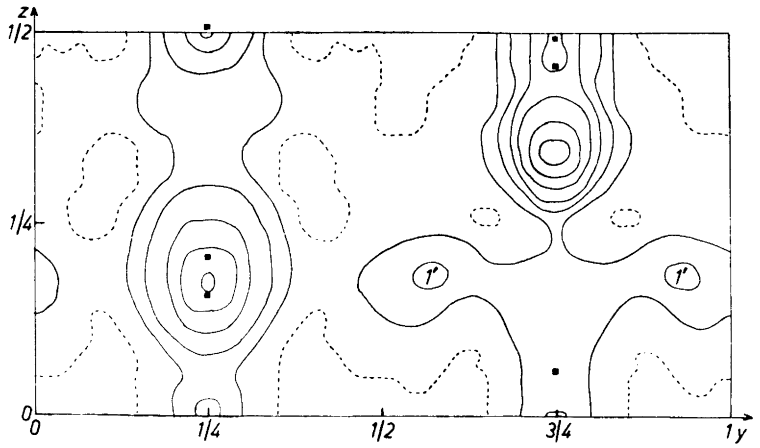

Fig. 6. Electron density of $Mo(OH)_3PO_4$ projected on the *yz* plane and with the molybdenum atom substracted. The positions of the oxygen atoms have been indicated as in Fig. 3. Dashed lines indicate negative values.

Now, with the assumption made above for the O—O distances and assuming the distance Mo—O to be not less than that found [15] in MoO_3, *i.e.* 1.8_0 Å, reasonable interatomic distances were only obtained assuming

2 O_4	in	$P2_1/m$	2(*e*)	with	$x = 0.15_0$,	$y = 1/4$,	$z = 0.89_0$
2 O_5	»	»	»	»	$x = 0.57_3$,	$y = 1/4$,	$z = 0.15_8$
2 O_6	»	»	»	»	$x = 0.99_6$,	$y = 1/4$,	$z = 0.20_8$

When the coordinates of all oxygen atoms have been determined the positions of these atoms were checked against the electron density projections (Figs. 3—5). The positions of the oxygen atoms O_2—O_6 have been denoted in these figures and, as we see, they are situated in positive areas and in most cases nearly coinciding with small peaks. However, these maxima are spread over a rather wide area, probably because of inadequate intensity material owing to the smallness of the crystal, so it is not possible to obtain any coordinates from the positions of these peaks. From Fig. 5 we see that the oxygen atoms O_5 and O_6 coincide with the molybdenum atom in this projection. In order to check if these oxygen atoms can be distinguished, the molybdenum atom was also subtracted from this Fourier image (in the same way as with Fig. 3, see p. 1706). The result is given in Fig. 6 and we see the phosphorus and oxygen (1') peaks with the same positions as in Fig. 5. The remaining maxima in Fig. 6 are well explained since they correspond to oxygen positions.

ARRANGEMENT OF THE HYDROGEN ATOMS

In the unit cell there are also six hydrogen atoms, which should be situated close to some of the oxygen atoms. Now, the oxygen atoms are not all equivalent in the sense that they have not the same environment. Thus the oxygen

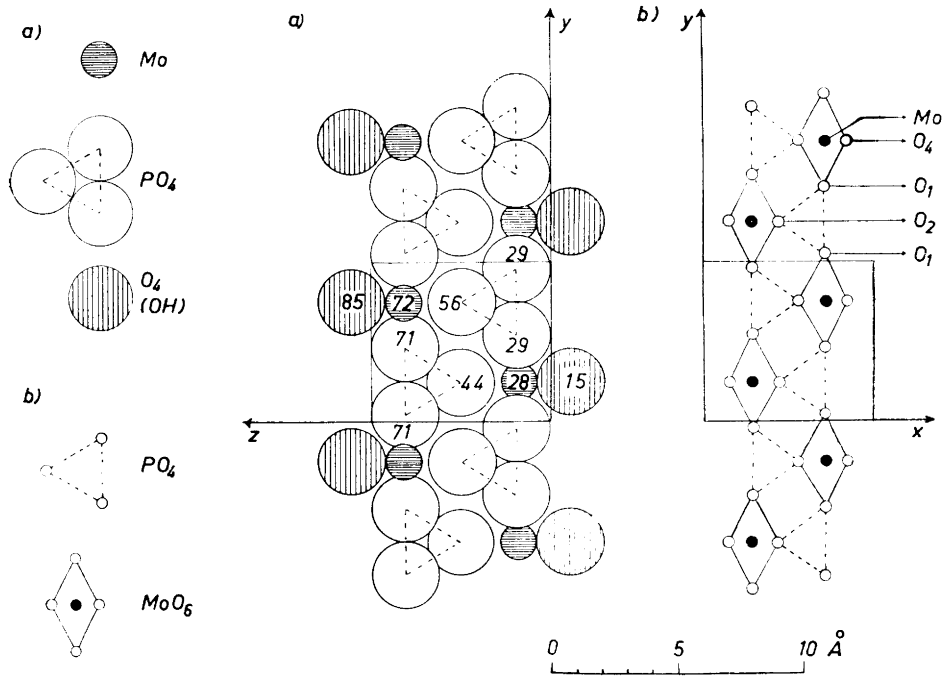

Fig. 7. The contacts between MoO_6-octahedra and PO_4-tetrahedra showing the double chains in $Mo(OH)_3PO_4$. The oxygen atoms O_5 and O_6 in the MoO_6-octahedra are situated over or below the molybdenum atoms and have not been indicated. a) Projection of the *yz* plane. The figures denote the height of the atoms in percentages of *a*. b) Projection of the *xy* plane.

atoms O_1 and O_2 are in contact with phosphorus and also with molybdenum atoms, while the oxygen atom O_3 is in contact only with one phosphorus atom and the oxygen atoms O_4—O_6 only with one molybdenum atom (*cf.* Fig. 7). It seems therefore much more probable that the hydrogen atoms are situated close to six of the oxygen atoms O_3—O_6. Now, as the proton affinity of O^{2-} is greater than that of PO_4^{3-}, it seems much more likely that the hydrogen atoms are situated close to all or some of the oxygen atoms O_4—O_6 than to the phosphate oxygen atom O_3 and some of the oxygen O_4—O_6. Thus, the six oxygen atoms O_4—O_6 exist either as six OH^- or as three O^{2-} and three H_2O, of which the first alternative seems to be the most plausible. As the interatomic distances between the oxygen atoms O_4—O_6 and neighbouring oxygen atoms are about 2.7_5 Å, the hydroxyl ions almost certainly form hydroxyl bonds (Ref.[13], p. 413) with neighbouring oxygen atoms. However, in this investigation it has not been possible to determine the parameters of the hydrogen atoms.

With the arrangement proposed for the hydrogen atoms there are no water molecules present in the crystals — which may also be supported by

the fact that the crystals do not lose water until it is heated to above 225°C [1] — but they contain three hydroxyl groups for one molybdenum atom. Their formula should then be written $Mo(OH)_3PO_4$ rather than $2\ MoO_3 \cdot P_2O_5 \cdot 3\ H_2O$ or $MoO_2HPO_4H_2O$.

FINAL STRUCTURE PROPOSITION

The following structure is thus proposed for $Mo(OH)_3PO_4$. Space group: No. 11, $P2_1/m$. Two formula units per unit cell.

		x	y	z
2 Mo	in 2(*e*)	0.282 ± 0.003	1/4	0.176 ± 0.003
2 P	in 2(*e*)	0.673 ± 0.006	1/4	0.662 ± 0.006
4 O_1	in 4(*f*)	0.71	0.46	0.81
2 O_2	in 2(*e*)	0.44	1/4	0.51
2 O_3	in 2(*e*)	0.83	1/4	0.54
2 O_4	in 2(*e*)	0.15	1/4	0.89
2 O_5	in 2(*e*)	0.57	1/4	0.16
2 O_6	in 2(*e*)	0.00	1/4	0.21

2(*e*): $\pm(x,\ 1/4,\ z)$
4(*f*): $\pm(x,y,z);\ \pm(x,\frac{1}{2}-y,z)$

The accuracy of the oxygen parameters is estimated to be about ±0.01. The structure factors were calculated with these parameters, multiplied by the exponential factor $10^{-0.315\ \sin^2\Theta}$ (*cf.* above) and compared with the observed structure factors from the corresponding Weissenberg photographs (Table 2). Taking into account that, particularly in 0*kl* and 1*kl* dependent on the shape of the crystals, there is an absorption effect [11] in the reflections, the agreement between observed and calculated intensities is quite good. The reliability index, *R*, valculated according to Booth (*cf.* Ref.[9], p. 101), was found to be 0.17 for *h*0*l* and 0.19 for 0*kl* (absent reflections not included).

DESCRIPTION OF STRUCTURE

In the structure, the molybdenum atoms are surrounded by six oxygen atoms in an octahedral arrangement. These MoO_6 octahedra are linked together by phosphate tetrahedra so that every molybdenum atom is in contact with three PO_4 tetrahedra and every PO_4 tetrahedron with three molybdenum atoms so that the cyrstals are built up of double chains extending to [010] and containing alternately MoO_6 and PO_4 groups (*cf.* Fig. 7). These double chains with the composition $(Mo_2O_6(PO_4)_2^{6-})_n$ are then held together by the hydrogen atoms, situated between adjacent oxygen atoms (O_3—O_6) from different chains.

The *xz* projection of the structure is shown in Fig. 8.

The distances between adjacent atoms in the structure will be (*in* Å)

Table 2. Comparison between calculated and observed structure factors from Weissenberg photographs of $Mo(OH)_3PO_4$. Cu*K*-radiation.

P —O_3 ;	O_3—P	$= 1.5_5$	O_3—O_5;	O_5—O_3	$= 2.6_7$
O_1—O_1		$= 2.6_5$	O_3—O_6;	O_6—O_3	$= 3.0_8$
O_1—2 O_2;	O_2—4 O_1	$= 2.7_0$; 2.8_1	O_4—O_5;	O_5—O_4	$= 2.8_2$
O_1—O_3 ;	O_3—2 O_1	$= 2.6_3$	O_4—2 O_6;	O_6— $2O_4$	$= 2.7_7$; 3.4_5
O_1—2 O_4;	O_4—4 O_1	$= 2.7_0$; 3.1_0	O_5—O_6;	O_6—O_5	$= 2.7_4$

The O—O distances are all within the normal range, showing that the lattice is also supported by O—O contacts. However, the distances may be in error by a few tenths of an Ångström unit, because the oxygen positions could not be determined very accurately.

This investigation forms part of a research program on metal oxides and related compounds supported by the *Swedish Natural Science Research Council.*

The author wishes to thank Professor Arne Ölander for his kind interest and Dr. Arne Magnéli for his encouraging interest and for many valuable discussions. The author is also indebted to Fil.lic. Georg Lundgren for his helpful interest and to Mr. Rolf Norin for valuable help with the preparation work and for drawing some of the figures. Thanks are also due to the Swedish Board for Computing Machinery for making the Calculator BESK available for considerable part of the calculating work involved in this investigation.

The Crystal Structure of WOP_2O_7

PEDER KIERKEGAARD

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

WOP_2O_7 has a monoclinic unit cell containing four formula units and with the dimensions

$$a = (15.170 \pm 0.005)\ \text{Å}$$
$$b = (5.162 \pm 0.005)\ \text{Å}$$
$$c = (6.917 \pm 0.005)\ \text{Å}$$
$$\beta = (102.41 \pm 0.05)^\circ$$
$$V = 547.9\ \text{Å}^3$$

A structure is proposed with the symmetry No. 12, $C2/m$. The positions of the wolfram and phosphorus atoms in the unit cell were determined by Fourier methods. The parameters of the oxygen atoms were derived partly from electron density projections and partly from geometrical considerations, interatomic P—O and O—O distances from previously determined structures being used. The crystals are built up of layers parallel to the yz plane and formed of fairly regular WO_6 octahedra coupled together by P_2O_7 groups. The layers are held together by van der Waals' forces and the crystals show pronounced basal cleavage resulting from this layer structure.

In the system WO_3—P_2O_5 the existence of two crystalline compounds with the compositions $2WO_3 \cdot P_2O_5$ and $WO_3 \cdot P_2O_5$ was reported by Schulz [1]. The crystals were insoluble in water, acids and dilute ammonia and difficultly soluble in hot dilute sodium hydroxide. In solutions of $WO_3 \cdot P_2O_5$ only ortho- and diphosphate ion could be proved. Polyphosphate ions were not found. In connection with an X-ray investigation of oxides undertaken at this institute a crystal structure determination of these compounds was started and this paper gives the structure of $WO_3 \cdot P_2O_5$.

PREPARATION OF THE CRYSTALS

A mixture of 4 g WO_3 and 4.8 g P_2O_5, in a platinum crucible, was heated in an autoclave at 550°C for about a week, when crystals good for X-ray work were obtained. (The method according to Schulz [1].) After being cooled the crystals were washed with hot water and dried in air. Under the microscope they showed to be colourless, elongated plates, which cleft very easily into long, thin plates of various widths.

Analysis. A sample was fused with sodium potassium carbonate in a platinum crucible and the cake dissolved in boiling water. From an ammoniacal solution the *phosphorus*

was precipitated (according to Kolthoff and Sandell [2]) with a magnesium solution. The precipitate was filtered off, washed with water, dissolved in hot 1 M HNO_3 and from this solution the phosphorus was finally precipitated with ammonium molybdate and weighed as $(NH_4)_3PO_4 \cdot 12MoO_3$. The amount of *wolfram* in the filtrate — made neutral — was determined gravimetrically by precipitation with mercury(I)nitrate according to Cumming and Kay [3] and weighed, after ignition, as WO_3. The methods of analysis were tested carefully on samples with known various compositions and this examination showed very low errors.

The *density* of the crystals was determined from the apparent loss of weight in benzene.

	Calculated for $WO_3 \cdot P_2O_5$	Found
% WO_3	62.02	62.0 ± 0.2
% P_2O_5	37.98	38.0 ± 0.2
Density	4.54	4.46 ± 0.01

The density is calculated for 4 formula units per cell.

UNIT CELL AND SPACE GROUP

Two small single crystals of different shape were split from larger ones. For the taking of rotation and Weissenberg photographs (zero, first and second layer) with CuK radiation, one, a needle about 0.2 mm in length and about 0.01 mm in diameter, was rotated around the needle axis [010] and the other, a plate only about 0.04 mm thick, 0.03 mm wide, and 0.2 mm long, was rotated round a diagonal in the plane of the plate [001]. It was concluded that the crystals are monoclinic and that the dimensions of the unit cell are about 15.7_4 Å, 5.0_9 Å, 6.8_4 Å and the monoclinic angle is about 102°.

The reflections were recorded photographically with the multiple film technique and the relative intensities were estimated visually by comparison with an intensity scale obtained by photographing a reflection with different exposure times. The F^2 values were then calculated using the polarization and Lorentz' factor given by Lu [4]. No correction was applied for the absorption.

More accurate values for the unit cell dimensions were calculated from a powder photograph, taken with strictly monochromatized Cu$K\alpha_1$ radiation in a focusing camera of Guinier type. KCl was used as an internal standard substance (see Table 1).

$$a = (15.710 \pm 0.005)\ \text{Å} \qquad \beta = (102.41 \pm 0.05)^\circ$$
$$b = (5.162 \pm 0.005)\ \text{Å} \qquad V = 547.9\ \text{Å}^3$$
$$c = (6.917 \pm 0.005)\ \text{Å}$$

The value (4.46) found for the density gives 3.93 ≈ 4 formula units in the unit cell.

The reflections systematically absent are

hkl	with	$h+k$	= odd
$h0l$	»	h	= odd
$0k0$	»	k	= odd

This is characteristic of the three space groups No. 5,$C2$, No. 8,Cm and No. 12,$C2/m$. The investigation was started by examining whether the

structure was consistent with the last space-group, that having the highest symmetry.

In No. 12,$C2/m$ the following point positions are possible

$$(000,\ \tfrac{1}{2}\tfrac{1}{2}0) +$$

2(a): 000; 2(b): $0\frac{1}{2}0$; 2(c): $00\frac{1}{2}$; 2(d): $0\frac{1}{2}\frac{1}{2}$
4(e): $\frac{1}{4}\frac{1}{4}0$; $\frac{1}{4}\frac{3}{4}0$; 4(f): $\frac{1}{4}\frac{1}{4}\frac{1}{2}$; $\frac{1}{4}\frac{3}{4}\frac{1}{2}$
4(g): $\pm(0,y,0)$; 4(h): $\pm(0,y,\frac{1}{2})$; 4(i): $\pm(x,0,z)$
8(j): $\pm(x,y,z)$; $\pm(x,\bar{y},z)$

POSITIONS OF THE WOLFRAM ATOMS

In order to find the four wolfram positions, the Patterson projections $P(uvp)$ and $P(upw)$ were calculated (Figs. 1 and 2).

The four wolfram atoms in the unit cell must occupy two of the twofold, or one of the fourfold, positions. Now $P(upw)$ has no maximum at $u = 0$, $w = \frac{1}{2}$ or at $u = \frac{1}{2}$, $w = \frac{1}{2}$ and $P(uvp)$ has no maximum at $u = 0$, $v = \frac{1}{2}$ or at $u = \frac{1}{2}$, $v = 0$ so this will exclude the possibility of the wolfram atoms being situated in combinations of the twofold positions or in 4(e)—(h). Thus the

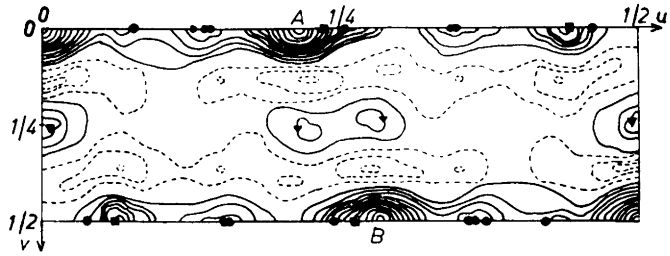

Fig. 1. The Patterson function $P(uvp)$. The W—P (■), W—O_{1-2} (▲) and W—O_{3-6} (●) vectors have been indicated. For the largest maxima (00) and ($\frac{1}{2}\frac{1}{2}$), only every second contour has been marked. Dashed lines indicate negative values.

wolfram atoms must be situated in 4(*i*) and the W—W distances should be

$$\pm(\tfrac{1}{2},\tfrac{1}{2},0); \qquad \pm(2x,0,2z); \qquad \pm(\tfrac{1}{2}+2x\,\tfrac{1}{2},2z)$$

The Patterson projections on the *uv* and *uw* plane should therefore show (besides the origin maxima) the following maxima

in the *uv* plane		in the *uw* plane	
I. $(\frac{1}{2},\frac{1}{2})$	weight 4	IV. $(\frac{1}{2},0)$	weight 4
II. $\pm(2x,0)$	weight 2	V. $\pm(2x,2z)$	weight 2
III. $\pm(\frac{1}{2}+2x,\frac{1}{2})$	weight 2	VI. $\pm(\frac{1}{2}+2x,2z)$	weight 2

There are two high peaks in $P(uvp)$ at $u = 0.21_2$, $v = 0$ (A in Fig. 1) and at $u = 0.28_8$, $v = \frac{1}{2}$ (B in Fig. 1) and one peak at $u = \frac{1}{2}$, $v = \frac{1}{2}$, whose height is about double that of the other two. (All maxima have been located by the interpolation table given by Booth [5].) These maxima certainly correspond to the W—W vectors I, II, and III so that peak A corresponds to the vector II above (and B to III) and thus we get $x_W = 0.10_6$. (It is sufficient to consider the range $0 \leq x \leq 1/4$, $0 \leq z \leq \frac{1}{2}$.)

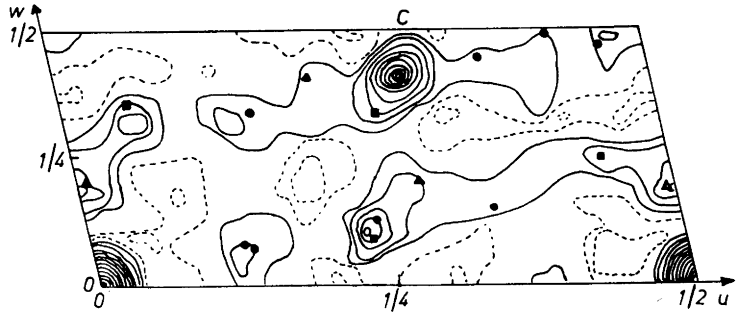

Fig. 2. The Patterson function $P(upw)$. The positions of the vectors have been marked as in Fig. 1. For the largest maxima (00) and ($\frac{1}{2}$0), only every second contour has been marked. Dashed lines indicate negative values.

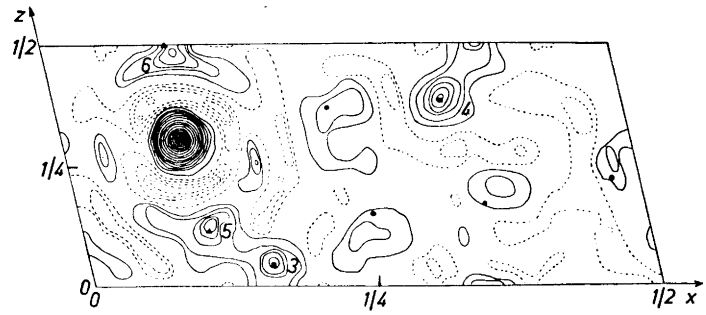

Fig. 3. Electron density projected on the *xz* plane. The positions of the phosphorus atoms (■), oxygen atoms O_{1-2} (▲) and oxygen atoms O_{3-6} (●) have been marked. In the wolfram peak only every second contour has been marked. Dashed lines indicate negative values.

The projection $P(upw)$ should therefore have one high peak at $u = \frac{1}{2}$, $w = 0$ (corresponding to the vector IV above) and two peaks with the u coordinates equal to $\pm 0.21_2$ and ± 0.712 (corresponding to the vectors V and VI above). Now the projection $P(upw)$ has a pronounced peak at $u = \frac{1}{2}$, $w = 0$ and two peaks (the heights of which are about half that of the first one) at $u = 0.20_8$, $w = 0.60_0$ and at $u = 0.29_2$, $w = 0.40_0$ (C in Fig. 2). Since the height and positions of these peaks correspond to the calculated values we conclude:

4 W in $C2/m$ $4(i)$ with $x = 0.10_5$, $y = 0$, $z = 0.30_0$.

POSITIONS OF THE LIGHT ATOMS

Electron density projections. In the Patterson projections in Figs. 1 and 2 there are, in addition to peaks corresponding to the W—W vectors, several lower maxima which perhaps could be ascribed to the W—P, and maybe also to some W—O, distances. From these small maxima, if real, it would be possible to determine the positions of the phosphorus atoms in the unit

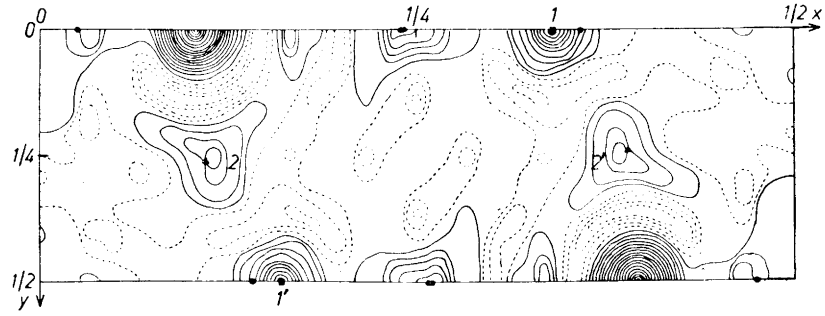

Fig. 4. Electron density projected on the *xy* plane. The positions of the atoms have been indicated as in Fig. 3. In the wolfram peak only every second contour has been marked. Dashed lines indicate negative values.

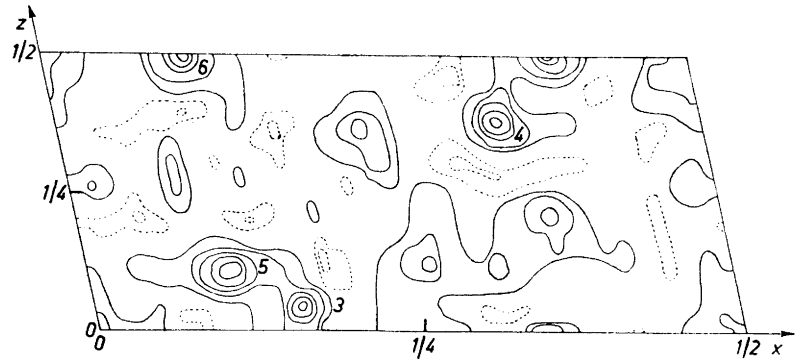

Fig. 5. Electron density projected on the *xz* plane with the wolfram atom subtracted. Dashed lines indicate negative values.

cell. It would, however, be more favourable to determine their sites from a map giving electron density, as such a map gives maxima that are sharper and less in number than those of the corresponding vector map.

For a compound of this type the electron density projections can easily be calculated since the signs of all the F-values can be determined from the contributions given by the wolfram atoms because of their dominant scattering factors. In this way $\varrho\ (xpz)$ and $\varrho\ (xyp)$ were calculated and the results are given in Figs. 3 and 4. We see that the wolfram atoms are clearly indicated at $x = 0.103$, $z = 0.295$ in $\varrho(xpz)$ (Fig. 3) and at $x = 0.103$, $y = 0$ in $\varrho\ (xyp)$ (Fig. 4) and from these values we thus obtain the final parameters of the wolfram atoms: $x = 0.103$, $y = 0$, $z = 0.295$.

Besides the very high wolfram peaks in the calculated electron density projections there are lower peaks in $\varrho\ (xyp)$ (Fig. 4) at $x = 0.34$ (0.16), $y = 0$ ($\frac{1}{2}$) (1 and 1' in Fig. 4) and at $x = 0.11$ (0.39), $y = 0.25$ (2 and 2' in Fig. 4). The electron density projected on the *xz* plane (Fig. 3) also shows lower maxima (all of about the same heights) with the following sets of parameters

3.	$x = 0.16$	$z = 0.05$
4.	$x = 0.34$	$z = 0.38$
5.	$x = 0.11$	$z = 0.12$
6.	$x = 0.11$	$z = 0.47$

If these lower peaks in the projections are real maxima, and not false ones formed by errors — diffraction effects or errors in the observed intensities due to absorption within the crystal [6] — the only atoms, which could give peaks of this height are the phosphorus atoms or overlapping oxygen atoms.

In order to find out if the lower maxima from $\varrho\ (xpz)$ and $\varrho\ (xyp)$ really correspond to atom positions in the unit cell, the wolfram atoms were subtracted from these projections and the results are given in Figs. 5 and 6. (The effect of the temperature factor, calculated by the ordinary procedure was found to be negligible; probably it roughly cancels out with the absorption effect.)

From Fig. 5, which shows ϱ (xpz) with the wolfram atoms subtracted, we see that we still have four distinct maxima of about the same height and with the following sets of parameters

3.	$x = 0.160$	$z = 0.044$
4.	$x = 0.340$	$z = 0.380$
5.	$x = 0.111$	$z = 0.113$
6.	$x = 0.109$	$z = 0.499$

from which it should be possible to get the positions of the phosphorus atoms. Now, in the unit cell we have eight phosphorus and thirty-two oxygen atoms. In the xz projection never more than two oxygen atoms can overlap (the b-axis is only 5.16 Å). Since the parameters given above are not special, the eight phosphorus atoms must occupy the point positions 8(j) or 4(i). Moreover, if they are situated in 8(j) two phosphorus maxima should overlap in the xz projection and thus we should get only one pronounced maximum in the quadrant of the projection represented in Fig. 5, and the height of this peak should have been at least double that of the other maxima in this quadrant. Now, as mentioned above, we have four distinct maxima, which all have nearly the same height. So we conclude that the phosphorus atoms are situated in two point positions 4(i), which will give two peaks in ϱ (xpz). The remaining two maxima should correspond to two sets of oxygen atoms in point positions 8(j) each giving a maximum from two superimposed oxygen atoms.

From Fig. 6, which shows ϱ (xyp) with the wolfram atoms subtracted, we see that the wolfram atoms and most of their diffraction effects have disappeared but there are, however, two pronounced maxima at $x = 0.339$ (0.161), $y = 0$ ($\frac{1}{2}$) (1 and 1′ in Fig. 6) and two small peaks at $x = 0.11_3$, $y = 0.24_0$ and at $x = 0.38_7$, $y = 0.26_0$ (2 and 2′ in Fig. 6). According to the conclusions given above the first two maxima (1 and 1′) correspond to the phosphorus positions and the peaks 2 and 2′ will correspond to the oxygen positions in the point position 8(j). Thus we conclude that the maxima 3 and 4 in Fig. 5 will give the parameters of the phosphorus atoms and with these coordinates we find that two phosphorus maxima overlap in the xy-projection. This is in good agreement with observed heights in this projection. Finally the posi-

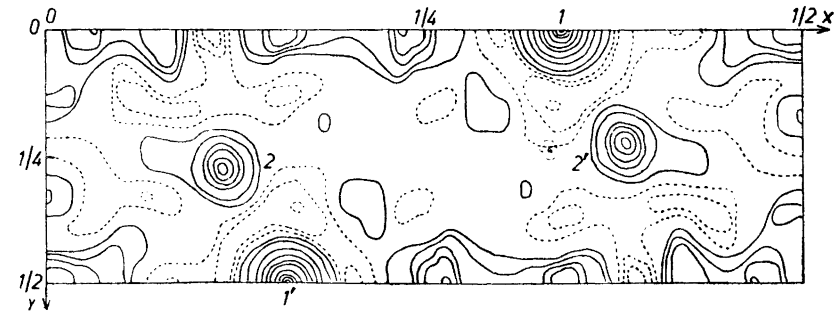

Fig. 6. Electron density projected on the xy plane with the wolfram atoms subtracted. Dashed lines indicate negative values.

tions of the sixteen oxygen atoms in the position 8(*j*) follow immediately from the maxima 5 and 6 in Fig. 5 and 2 and 2' in Fig. 6. The values obtained from ϱ (*xpz*) should be more correct, since in the calculation of this projection more *F*-values were used.

Thus, from the electron density projections the following parameters could be obtained:

4	W	in	*C*2/*m*	4(*i*)	with	$x = 0.103$	$y = 0$ $z = 0.295$
4	P_1	»	»	»	»	$x = 0.34_0$	$y = 0$ $z = 0.38_0$
4	P_2	»	»	»	»	$x = 0.34_0$	$y = 0$ $z = 0.95_6$
8	O_1	»	»	8(*j*)	»	$x = 0.39_0$	$y = 0.24_0$ $z = 0.50_1$
8	O_2	»	»	»	»	$x = 0.39_0$	$y = 0.24_0$ $z = 0.88_7$

Using these parameters W—P and W—O distances were calculated and the maxima in the Patterson projections (Figs. 1—2) were compared with these W—P and W—O vectors. All of these vectors were found to correspond to maxima (*cf.* Figs. 1 and 2) in *P*(*uvp*) and *P*(*upw*) and moreover the heights of the peaks also corresponded to the calculated weights.

The remaining maxima in the Patterson and electron density projections may correspond to W—O vectors or oxygen atom positions but at this stage of the investigation they were not considered, since these peaks are of about the same height as the false maxima [6].

Geometrical considerations. The sixteen oxygen atoms, the positions of which have been found from electron density projections, are situated close to phosphorus atoms with the distances P_1—2 $O_1 = 1.6_0$ Å and P_2—2 $O_2 = 1.6_0$ Å. These distances are in good agreement with P—O distances in previously described structures [7-9] (*i.e.* P—O = 1.45—1.65 Å). Assuming that the coordination figure around the phosphorus atoms is a tetrahedron, which seems to be very probable, it is then possible to calculate the parameters of the remaining oxygen atoms in the PO_4 tetrahedra. If we assume the bond lengths P—O = 1.5_5 Å and O—O = 2.5_3 Å (these distances are mean values of those published [7-9]) the coordinates of the oxygen atoms O_3—O_5 follow immediately. Thus we obtain

4	O_3	in	*C*2/*m*	4(*i*)	with	$x = 0.24_0$	$y = 0$ $z = 0.36_5$
4	O_4	»	»	»	»	$x = 0.35_8$	$y = 0$ $z = 0.16_8$
4	O_5	»	»	»	»	$x = 0.24_2$	$y = 0$ $z = 0.85_2$

Now we have to find the position of the remaining four oxygen atoms in the unit cell. They must occupy two of the twofold, or one of the fourfold, positions. Assuming that the distances between these oxygen atoms and the oxygens already located (*i.e.* O_1—O_5) are not less than 2.6_0 Å, the twofold (2(*a*)—(*d*)) and the fourfold (4(*e*)—(*h*)) point positions at once can be eliminated and thus we must have four oxygen atoms (O_6) in 4(*i*). In order to determine the coordinates, the section $y = 0$ in the unit cell was drawn and regions forbidden to oxygen atoms were marked out (Fig. 7). From the figure we see that there are only very small areas left free for the centres of these oxygen atoms. The coordinates of the oxygen atoms O_6 would then be

4 O_6 in *C*2/*m* 4(*i*) with $x = 0.97_5$ $y = 0$ $z = 0.21_7$

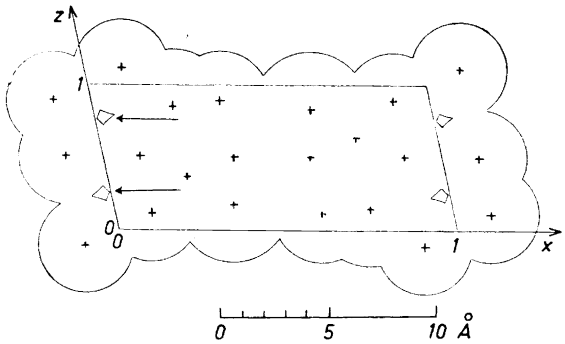

Fig. 7. Section at $y = 0$ through the unit cell showing the areas forbidden to the oxygen atoms, O_6, in this plane. The circles enclose domains forbidden around the oxygen atoms O_{1-5}. The arrows point out the only areas left free for the centres of O_6. + = centre of oxygen.

Using these oxygen coordinates the remaining W—O distances were calculated and these vectors have been indicated in Figs. 1 and 2. The positions of the oxygen atoms O_3—O_6 have also been marked in the electron density projections (Figs. 3—4). From the figures we see that these vectors or oxygen positions are situated in positive areas and, in fact, in most cases they coincide fairly well with small peaks in the Patterson and electron density projections. This seems to indicate the coordinate values to be plausible. Moreover with the coordinates found above we obtain contacts W—6O with a coordination figure, within the errors, a regular octahedron, which has been found in previously determined crystal structures of wolfram compounds [11–13]. For the coordination figure around the phosphorus we have presumed a tetrahedron with two P—O distances equal to 1.5_5 Å and one O—O distance equal to 2.5_3 Å. This will give P_2O_7-groups (*i.e.* two PO_4 tetrahedra sharing an oxygen) with a P—O—P angle at the central oxygen of 142°, which can be compared with 134° found in $Na_4P_2O_7.10H_2O$ [9] and 180° found in the curious series of SiP_2O_7 and related compounds [14]. Thus, the assumptions made above to get the coordinates, give an arrangement of the atoms, which seems to be very probable.

FINAL STRUCTURE PROPOSITION

The following structure is thus proposed for $WO_3.P_2O_5$. Space group: No. 12, $C2/m$. 4 formula units per unit cell

Using these parameters the F values were calculated for the reflexions and compared with the observed ones. They are given in Table 2 for $hk0$, $h0l$, $hk1$ and $h1l$. Table 3 gives the details for some reflexions which have more pronounced phosphorus and oxygen contributions to the magnitudes of the structure factors. The reliability index, R, calculated according to Booth (see Ref.[5], p. 101), was found to be 0.14 for $hk0$ and 0.13 for $h0l$ (absent reflexions not included) and 0.34 or 0.24 for the same reflexions calculated *without* the phosphorus and oxygen atoms, and 0.24 or 0.19 calculated without the oxygen atoms, showing that the structure should be essentially correct as regards the heavy atoms and also indicating that the proposed coordinates of the phosphorus and the oxygen atoms will give much better agreement between observed and calculated intensities.

In the structure determination described above we have assumed that the structure is consistent with the space group $C2/m$ having the highest symmetry. This will give that the y coordinates for W, P, O_3—O_6 must be equal to 0 or $\frac{1}{2}$. From the Patterson projection $P(uvp)$ we see that these atoms at least will be situated close to these planes. In fact it does not seem possible to get any essential difference for the atom arrangement even if the less symmetrical space groups are considered but this will increase the errors in the parameters, as most of the coordinates will be obtained from overlapping peaks [10]. Moreover, since the electron density projections show distinct

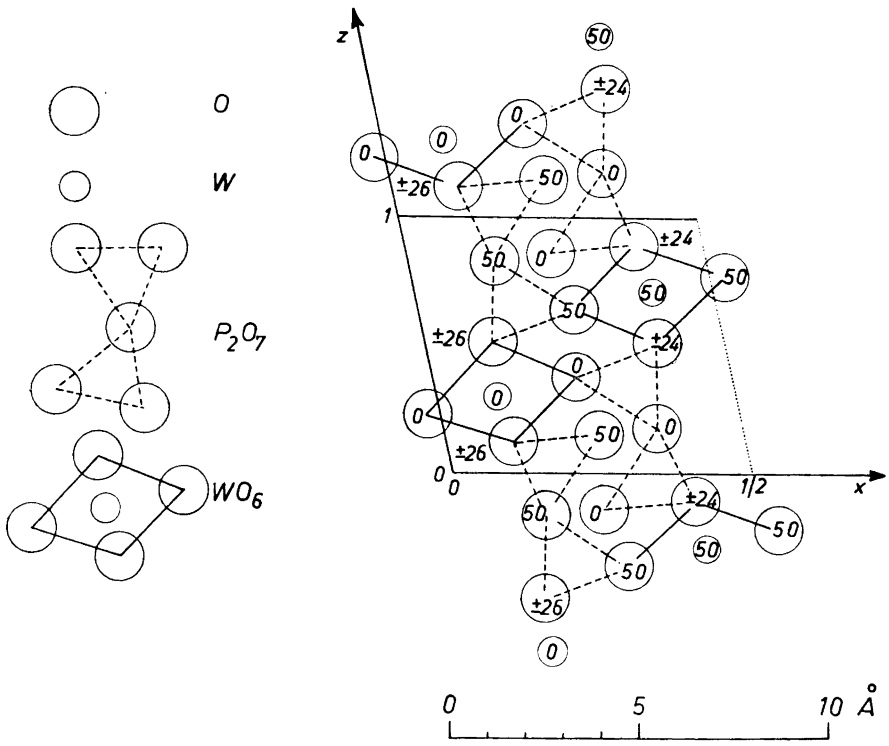

Fig. 8. The layer of WOP_2O_7. Only one layer has been indicated (*i. e.* wolfram and oxygen atoms with x parameters within the limits $-0.02 \leq x \leq 0.52$). The figures denote the height of the atoms in percentages of b.

maxima and the electron density projected on two different planes (xy and xz) show mutual agreement, it seems very probable that the atoms belong to the space group $C2/m$.

DESCRIPTION OF THE STRUCTURE

The structure of $WO_3.P_2O_5$ may be described as built up of WO_6-octahedra and P_2O_7-groups. Every wolfram atom is in contact with five P_2O_7-groups and every P_2O_7-group with five wolfram atoms. Every wolfram atom is also in contact with one oxygen atom (O_6), which is bonded only to this wolfram atom, so that the crystals are built up of WOP_2O_7-layers parallel to the yz plane (Fig. 8). The layers are thus electrically neutral, so that in the crystals there are only feeble attractive forces between neighbouring layers, which will explain the pronounced basal cleavage along the yz plane. The building principle might be expressed by the formula WOP_2O_7 and the compound should then be written according to this rather than $WO_3.P_2O_5$.

The xz projection of the structure is shown in Fig. 9.

On the Determination of Thiosulphate by the Silver Thiocyanate Method

NILS-HERMAN SCHÖÖN

Department of Engineering Chemistry, Chalmers Tekniska Högskola, Göteborg, Sweden

The silver thiocyanate method for the colorimetric determination of thiosulphate has been studied. The relation between the amount of thiosulphate added and the amount of silver thiocyanate dissolved was calculated at the ionic strengths, $I = 0$ and $I = 4$, with the aid of available data on silver thiosulphate complexes. The influence of hydrogen sulphite was also calculated.

Experiments were performed at 20°C for the thiosulphate concentration interval $2.5 \times 10^{-5} - 1.5 \times 10^{-3}$ M and for the sulphite concentrations 0.01 M and 0.1 M. The amount of silver thiocyanate dissolved was determined both colorimetrically and by measuring the radioactivity of the solution, ^{110}Ag being used as tracer. In the colorimetric method, the absorbance gives the total thiocyanate concentration in the solution since complexes of silver and thiocyanate and mixed complexes of silver, thiosulphate and thiocyanate can be neglected.

The dissolved amount of silver thiocyanate was shown to be constant when shaking for 10—40 min. With longer reaction times, the concentration of thiocyanate increased owing to the formation of silver sulphide.

At low ionic strengths, the relationship between thiosulphate added and silver thiocyanate dissolved was linear for $c_{S_2O_3} > 2 \times 10^{-4}$, while, for lower thiosulphate concentrations, a nonlinear relationship was valid. An addition of 0.1 M hydrogen sulphite did not increase the solubility of the silver thiocyanate.

At $I = 4$, the relationship between thiosulphate added and silver thiocyanate dissolved was linear within the whole range of concentration investigated ($c_{S_2O_3} < 5 \times 10^{-4}$). It was found that hydrogen sulphite decreased the solubility of silver thiocyanate at this ionic strength. This decrease was almost completely eliminated by the addition of an excess of formaldehyde.

The use of silver azide instead of silver thiocyanate for the determination of thiosulphate in coloured solutions was also studied.

If a solution of thiosulphate is shaken with a solid silver halogenide, the halogenide is dissolved owing to the formation of stable complexes containing silver and thiosulphate ions. This phenomenon is well-known from the

photographic fixing process and many investigations have been published on the dissolution of silver halogenides in complex-forming solutions. On the basis of the photographic fixing reaction, Utsumi [1] has worked out a colorimetric method for the determination of thiosulphate. According to Utsumi, the thiosulphate solution is shaken for some minutes with an excess of solid silver thiocyanate. After separating the solid phase, the amount of thiocyanate dissolved is colorimetrically determined as iron(III)thiocyanate. Utsumi observed that, within the concentration range examined (3×10^{-6}—1.8×10^{-4} M thiosulphate), the relationship between the thiocyanate and thiosulphate concentrations was linear. Utsumi supposed that the dissolution occurred according to the reaction

$$3\ S_2O_3^{2-} + 2\ AgSCN_{(s)} \rightleftharpoons Ag_2(S_2O_3)_3^{4-} + 2\ SCN^-$$

In the present paper, this method has been studied more particularly with regard to the determination of thiosulphate in solutions containing hydrogen sulphite. The method is especially designed for analysing thiosulphate in spent liquor from sulphite cellulose cooking. The determination of thiosulphate can be done, in this case, either before or after the separation of high polymer compounds by ion exchange. In the latter case, the low polymer anions are eluted from the anion exchanger with a large amount of 4 M sodium perchlorate. For this reason, the dissolution of silver thiocyanate in thiosulphate has been investigated both for solutions at low ionic strength and for solutions containing 4 M sodium perchlorate.

From investigations published on the thiosulphate in sulphite spent liquor [2], it can be seen that the thiosulphate concentration amounts to about 10^{-3} M. In the present paper, the silver thiocyanate method has, therefore, been primarily tested for a corresponding concentration range. In solutions containing 4 M sodium perchlorate, a lower concentration range has, however, been of greater interest.

EXPERIMENTAL

Chemicals. Part of the investigation was performed with silver thiocyanate containing ^{110}Ag. The neutron radiation of a silver wire (puriss) was carried out by AB Atomenergi. The chemicals used were of analytical quality, except for iron(III)nitrate which was puriss grade.

Shaking- and filtration procedure. The solution was vigorously shaken (15 min at about 1 500 shakes per min) at (20 ± 0.5)°C with a laboratory "Microid flaskshaker" from Griffin & George Ltd. In the experiments with a longer time of reaction (8—9 h), the solution was rotated (25 r.p.m.) in an air thermostat. When inactive silver thiocyanate was used, 70 mg precipitate was added to 30 ml solution. In the experiments with radioactive silver thiocyanate, the precipitate was dispersed in water or in 4 M sodium perchlorate. A certain volume, 10 or 15 ml, of this mixture was added to the solution. The amount of radioactive precipitate was 15—20 mg per 30 ml solution shaken. The shaking, as well as the other operations, was performed in dark coloured flasks. After shaking, the solutions were immediately filtered through an ultra colloid filter according to Zsigmondy (average pore size 150 mμ) under a pressure of 2—3 atm nitrogen in a Thiessen apparatus.

The colorimetric determination. In the experiments at high ionic strength ($I = 4$), 5 ml iron(III)nitrate solution containing 0.5 M iron(III)nitrate and 0.5 M nitric acid was added to 10 ml of the filtrate. In the experiments at the same ionic strength but in the

presence of hydrogen sulphite, 5 ml 1 M formaldehyde and 5 ml iron(III)nitrate solution were added to 15 ml of the filtrate. The formaldehyde was added in order to bind the hydrogen sulphite. In the experiments at low ionic strengths, the procedure was for $c_{S_2O_3} < 2 \times 10^{-4}$ the same as that described above, while, for a thiosulphate concentration of $2 \times 10^{-4} - 1.5 \times 10^{-3}$ M, 5 ml iron(III)nitrate solution was added to 10 ml of the filtrate. This latter solution was diluted to 50 ml before the colorimetric determination. In the experiments with hydrogen sulphite, 10 ml 1 M formaldehyde was added before the dilution. The concentration of the iron(III)thiocyanate complexes formed was determined at the wavelength 460 mμ using a spectrophotometer Beckman Model DU. The slit width was 0.02–0.03 mm and a 1 cm cell was used. In each series of experiments, a calibration was performed with potassium thiocyanate in order to determine the relationship between the absorbance and the concentration of thiocyanate. Sodium thiocyanate was used in solutions containing 4 M sodium perchlorate.

The flame photometric measurements. In some of the experiments at low ionic strengths, the concentration of sodium was determined by means of a spectrophotometer Beckman Model DU with a flame photometry attachment. The intensity of flame emission was measured at 589 mμ.

The radioactivity determination. The activity of 10 ml filtrate was measured with a G.M. tube for liquids, supplied by Mullard Ltd. The radioactivity of the silver thiocyanate was chosen to give about 700 c.p.m./10^{-4} M silver. Corrections had to be applied for the difference between the radioactive absorptions of solutions of low and high ionic strengths and for the radioactive decay. The scaler was an Electronic Counter PW 4035 from Philips.

The potentiometric measurements. The silver electrode was made according to Brown [3], but with thicker platinum wires in order to obtain larger electrode surfaces. A mercury-(I)sulphate electrode, consisting of a 4 M sodium perchlorate solution saturated with mercury(I)sulphate, served as reference electrode. The potentiometer equipment was obtained from Rubicon Co., Philadelphia and the galvanometer from Leeds & Northrup Co. The measurements were carried out at (20 ± 0.05)°C.

THEORY

For the quantitative analysis it is of interest to calculate the relation between the total concentrations of thiosulphate and thiocyanate. This calculation has been done on the assumption that solid silver thiocyanate is in equilibrium with the silver thiosulphate complexes in the solution. At the ionic strength $I = 0$, the calculation has only been performed for mononuclear complexes since no constants for polynuclear complexes are available in the literature at this ionic strength. The influence of hydrogen sulphite has also been studied. At the ionic strength $I = 4$, the calculations can be done more exactly since, in this case, the constants for the polynuclear complexes are known. At this ionic strength, the calculation is divided into two cases. In the first case, the solution is assumed to be supersaturated with $NaAgS_2O_3 \cdot H_2O$ whereas, in the second case, this salt is presumed to be in equilibrium with the solution. Whether $NaAgS_2O_3 \cdot H_2O$ could precipitate at the lower ionic strength cannot be decided from the literature data [4].

Solubility of silver thiocyanate at $I = 0$

Chateau and Pouradier [5] determined potentiometrically the mononuclear dissociation constants at 20°C for silver thiosulphate complexes. The constants

were recalculated by the authors to the ionic strength $I = 0$. From these values, the following complexity constants can be obtained

$$\beta_{1,1} = 6.7 \times 10^8,\ \beta_{1,2} = 2.9 \times 10^{13} \text{ and } \beta_{1,3} = 1.4 \times 10^{14}.$$

The constants are defined as

$$\beta_{1,n} = \frac{[Ag(S_2O_3)_n^{(2n-1)-}]}{[Ag^+]\ [S_2O_3^{2-}]^n}$$

(All concentrations in the present article are given in mole/litre).

Silver sulphite complexes were studied potentiometrically at 25°C by Chateau, Duranté and Hervier [6]. At the ionic strength $I = 0$, the complexity constants can be calculated to be $\gamma_{1,1} = 4 \times 10^5$, $\gamma_{1,2} = 4.8 \times 10^8$ and $\gamma_{1,3} = 10^9$. Chateau *et al.* also showed that the formation of silver sulphite complexes was low in a hydrogen sulphite solution owing to the low concentration of free sulphite. Consequently, all complexes except $AgSO_3^-$ can be neglected even in a rather concentrated hydrogen sulphite solution. From the constants for the silver thiosulphate complexes, it is clear that the complex with three ligands is not formed within the actual concentration range $c_{S_2O_3} < 1.5 \times 10^{-3}$. The concentration of uncomplexed silver ion and the concentrations of silver thiocyanate complexes [7], mixed silver thiosulphate-thiocyanate complexes (*cf.* under F), the ion pair $NaS_2O_3^-$ and $HS_2O_3^-$ can also be neglected [8]. All these ions can in addition be neglected in the calculations for the ionic strength $I = 4$. For the solubility product $L_R = [Ag^+][SCN^-]$, the value 1.08×10^{-12} has been used [9].

With these simplifications, the total thiosulphate content is

$$c_{S_2O_3} = [S_2O_3^{2-}] + [Ag^+]\ (\beta_{1,1}[S_2O_3^{2-}] + 2\beta_{1,2}[S_2O_3^{2-}]^2) \tag{1}$$

and the total sulphite content

$$c_{SO_3} = [SO_3^{2-}] + \frac{[H^+][SO_3^{2-}]}{k_2} + \frac{[H^+]^2[SO_3^{2-}]}{k_1 k_2} + [Ag^+]\,\gamma_{1,1}[SO_3^{2-}] \tag{2}$$

where

$$k_1 = \frac{[H^+]\ [HSO_3^-]}{[H_2SO_3]} \text{ and } k_2 = \frac{[H^+]\ [SO_3^{2-}]}{[HSO_3^-]}$$

The total thiocyanate content is

$$c_{SCN} = c_{Ag} = [Ag^+]\ (\beta_{1,1}[S_2O_3^{2-}] + \beta_{1,2}[S_2O_3^{2-}]^2 + \gamma_{1,1}[SO_3^{2-}]) \tag{3}$$

Since $c_{SCN} = [SCN^-]$, the following relations can be derived from eqns. (1) and (3)

$$c_{S_2O_3} = 2[SCN^-] - \frac{2\gamma_{1,1}L_R}{[SCN^-]}\ [SO_3^{2-}] + \left(1 - \frac{L_R\beta_{1,1}}{[SCN^-]}\right)\left\{\left[\left(\frac{\beta_{1,1}}{2\beta_{1,2}}\right)^2 + \right.\right.$$
$$\left.\left. + \frac{1}{\beta_{1,2}}\left(\frac{[SCN^-]^2}{L_R} - \gamma_{1,1}[SO_3^{2-}]\right)\right]^{\frac{1}{2}} - \frac{\beta_{1,1}}{2\beta_{1,2}}\right\} \tag{4}$$

and from (2)

$$[SO_3^{2-}] = \frac{c_{SO_3}}{1 + \frac{[H^+]}{k_2} + \frac{[H^+]^2}{k_1 k_2} + \gamma_{1,1} \frac{L_R}{[SCN^-]}} \quad (5)$$

On inserting the values of the constants, eqn. (4) becomes

$$c_{S_2O_3} = 2[SCN^-] - 8.64 \times 10^{-7} \frac{[SO_3^{2-}]}{[SCN^-]} + \left(1 - \frac{7.24 \times 10^{-4}}{[SCN^-]}\right)[(1.33 \times 10^{-10} + 0.0319\ [SCN^-]^2 - 1.38 \times 10^{-8}\ [SO_3^{2-}])^{\frac{1}{2}} - 1.16 \times 10^{-5}] \quad (6)$$

The relation $[SCN^-] = f(c_{S_2O_3})$, which is of interest here, was calculated numerically from eqn. (6) (*cf.* Fig. 2). It will be discussed later in connection with the results of the experiments. The solubility function was also calculated for the ionic strengths $I = 10^{-3}$ and $I = 10^{-4}$. It was found that the solubility at these ionic strengths was only a little higher than that at $I = 0$. For this calculation, a correction was introduced for the activity factors. The activity factors were calculated according to Debye-Hückel's approximation $-\log f_i = \frac{0.5\ z_i^2 \sqrt{I}}{1 + \sqrt{I}}$.

The influence of hydrogen sulphite was also estimated from eqn. (6). An addition of 0.1 M hydrogen sulphite, which corresponds to $[SO_3^{2-}] \sim 10^{-4}$, was found not to increase the solubility at the thiosulphate concentration 10^{-3} M while, at 10^{-4} M, the increase in the solubility amounted to 0.7 %. The comparison is made at the same ionic strength. However, if the increase in ionic strength is taken into consideration, then it is found that the solubility will be decreased by the addition of 0.1 M hydrogen sulphite.

Solubility of silver thiocyanate at $I = 4$

The dissolution of silver thiocyanate in thiosulphate, with 4 M sodium perchlorate as an additional salt, is somewhat different to that at the ionic strength $I = 0$, because of the formation of insoluble $NaAgS_2O_3 \cdot H_2O$. In a solution saturated with $NaAgS_2O_3 \cdot H_2O$, Nilsson [10] found the product $L_T = [Ag^+]\,[S_2O_3^{2-}] = 5.7 \times 10^{-14}$ at $I = 4$. At this ionic strength, the solubility product of silver thiocyanate is $L_R = 7.76 \times 10^{-13}$ according to Leden and Nilsson [9]. A comparison of these values shows that sodium silver thiosulphate is the more insoluble one. It can, however, be seen from Nilsson's work that $NaAgS_2O_3 \cdot H_2O$ precipitates slowly and therefore the calculations must also include the case in which a supersaturated solution is obtained.

No formation of $NaAgS_2O_3 \cdot H_2O$

The complexity constants for silver thiosulphate ions were determined by Nilsson [11] at $I = 4$ and 25°C. He found that the measurements could not be explained only by the formation of the mononuclear complexes $Ag(S_2O_3)_n^{(2n-1)-}$

but also the formation of polynuclear complexes had to be taken into consideration. The best agreement with the experimental results was obtained if the complexes $Ag_2(S_2O_3)_4^{6-}$ and $Ag_{3z}(S_2O_3)_{3z+2}^{(3z+4)-}$ were assumed to exist. From the complexity constants $\beta_{m,n}$ given by Nilsson (*cf.* Ref.[11], Table 5), it can be calculated that the ions Ag^+, $Ag(S_2O_3)_3^{5-}$, $Ag_2(S_2O_3)_4^{6-}$ and $Ag_3(S_2O_3)_5^{7-}$ can be neglected in the concentration range studied here ($c_{S_2O_3} < 5 \times 10^{-4}$). The concentration of $AgS_2O_3^-$ is also low but this ion can only be neglected in the upper part of the interval.

If the solution is supersaturated with $NaAgS_2O_3 \cdot H_2O$, then, using the above simplifications, the total silver and thiosulphate contents of the solution can be written:

$$c_{Ag} = [Ag^+] \sum_{n=1}^{2} \beta_{1,n} [S_2O_3^{2-}]^n + \sum_{z=2}^{\infty} 3z\beta_{3z,3z+2}[Ag^+]^{3z} [S_2O_3^{2-}]^{(3z+2)} \quad (7)$$

$$c_{S_2O_3} = [S_2O_3^{2-}] + [Ag^+] \sum_{n=1}^{2} n\beta_{1,n}[S_2O_3^{2-}]^n + \sum_{z=2}^{\infty} (3z+2)\beta_{3z,3z+2}[Ag^+]^{3z}[S_2O_3^{2-}]^{(3z+2)} \quad (8)$$

Since the sum of the polynuclear terms converges very slowly, the whole series must be summed. This summation was performed in Ref.[11] [*cf.* particularly eqns. (48)—(54)] where the constants h_0 and h where also defined. Upon summation, eqns. (7) and (8) become:

$$c_{Ag} = \beta_{1,1} [Ag^+] [S_2O_3^{2-}] + \beta_{1,2} [Ag^+] [S_2O_3^{2-}]^2 + \beta_{6,8} [Ag^+]^6 [S_2O_3^{2-}]^8 \times$$
$$\times \left[6 + h_0 \beta_{3,5} [Ag^+]^3 [S_2O_3^{2-}]^3 \frac{(9 - 6h \beta_{3,5} [Ag^+]^3 [S_2O_3^{2-}]^3)}{(1 - h \beta_{3,5} [Ag^+]^3 [S_2O_3^{2-}]^3)^2} \right] \quad (9)$$

$$c_{S_2O_3} = [S_2O_3^{2-}] + \beta_{1,1} [Ag^+] [S_2O_3^{2-}] + 2\beta_{1,2} [Ag^+] [S_2O_3^{2-}]^2 + \beta_{6,8} [Ag^+]^6 [S_2O_3^{2-}]^8 \times$$
$$\times \left[8 + h_0 \beta_{3,5} [Ag^+]^3 [S_2O_3^{2-}]^3 \frac{(11 - 8h \beta_{3,5} [Ag^+]^3 [S_2O_3^{2-}]^3)}{(1 - h \beta_{3,5} [Ag^+]^3 [S_2O_3^{2-}]^3)^2} \right] \quad (10)$$

Since the complexes are in equilibrium with solid silver thiocyanate, the concentration of free silver ions is $[Ag^+] = L_R [SCN^-]^{-1}$. For the thiocyanate, it is also valid that $c_{SCN} = [SCN^-] = c_{Ag}$. The function $[SCN^-] = f(c_{S_2O_3})$ can be calculated from these four relations by the trial and error method. The results of this calculation are given in Fig. 4 and are discussed below in connection with the results of the experiments.

Formation of $NaAgS_2O_3 \cdot H_2O$

If $NaAgS_2O_3 \cdot H_2O$ precipitates and if this salt is in equilibrium with the solution, then the system will be described by the following two material balances:

$$c_{Ag} = [SCN^-] = [Ag^+] \sum_{n=0}^{3} \beta_{1,n} [S_2O_3^{2-}]^n + 2\beta_{2,4} [Ag^+]^2 [S_2O_3^{2-}]^4 + \\ + 3\beta_{3,5} [Ag^+]^3 [S_2O_3^{2-}]^5 + \sum_{z=2}^{\infty} 3z\, \beta_{3z,3z+2} [Ag^+]^{3z} [S_2O_3^{2-}]^{(3z+2)} + c_s \qquad (11)$$

$$c_{S_2O_3} = [S_2O_3^{2-}] + [Ag^+] \sum_{n=1}^{3} n\beta_{1,n} [S_2O_3^{2-}]^n + 4\beta_{2,4} [Ag^+]^2 [S_2O_3^{2-}]^4 + \\ + 5\beta_{3,5} [Ag^+]^3 [S_2O_3^{2-}]^5 + \sum_{z=2}^{\infty} (3z+2)\, \beta_{3z,3z+2} [Ag^+]^{3z} [S_2O_3^{2-}]^{(3z+2)} + c_s \qquad (12)$$

Since in this case a general function $c_{S_2O_3} = f([SCN^-])$ can easily be derived, the equations will not be simplified as in the calculation for the supersaturated solution. In eqns. (11) and (12), c_s denotes the amount of $NaAgS_2O_3 \cdot H_2O$ formed by the reaction. Since the solution is in equilibrium with both solid silver thiocyanate and solid sodium silver thiosulphate, the concentration of free silver is $[Ag^+] = L_R[SCN^-]^{-1} = L_T[S_2O_3^{2-}]^{-1}$ and the concentration of free thiosulphate is $[S_2O_3^{2-}] = L_T\, L_R^{-1}\, [SCN^-]$.

After summation and elimination of c_s, $[Ag^+]$ and $[S_2O_3^{2-}]$, the following relation is obtained

$$c_{S_2O_3} = \left(1 + \frac{L_T}{L_R} + \beta_{1,2} \frac{L_T^2}{L_R} - \frac{L_R}{[SCN^-]^2}\right) [SCN^-] + 2\left(\frac{L_T}{L_R}\right)^2 \left[\beta_{1,3}\, L_T + \beta_{2,4}\, L_T^2 + \right. \\ \left. + \beta_{3,5}\, L_T^3 + \beta_{6,8}\, L_T^6 \left(1 + \frac{h_0 \beta_{3,5}\, L_T^3}{1 - h\, \beta_{3,5}\, L_T^3}\right)\right] [SCN^-]^2 \qquad (13)$$

and, on inserting the values of the constants:

$$c_{S_2O_3} = 0.0429\, [SCN^-]^2 + 1.096\, [SCN^-] - \frac{7.76 \times 10^{-13}}{[SCN^-]}$$

For the concentration range studied, the first and third term can be neglected and the simple relation $[SCN^-] = 0.91\, c_{S_2O_3}$ is obtained.

Whether an addition of hydrogen sulphite will increase the solubility of silver thiocyanate at $I = 4$ has not been calculated since no complexity constants for this system are available. The influence of this addition was very small at low ionic strengths and is assumed to be of the same order at high ionic strengths.

RESULTS AND DISCUSSION

A. *Stability of the colour.* On adding the acidic iron(III)solution to the filtrate, there is a risk that the silver thiosulphate complexes will decompose and hence silver thiocyanate will precipitate again. This problem has been studied by measuring the absorbance as a function of time. To 10 ml filtrate ($c_{S_2O_3} \sim 5 \times 10^{-4}$), 10 ml iron(III)solution was added. The solution was diluted to 50 ml before the colorimetric determination was performed.

Table 1. Stability of the colour.

Sample	Absorbance, after			
	10 min	30 min	50 min	90 min
$I \sim 0$	0.232	0.233	0.233	—
$I = 4$	0.250	0.250	0.250	0.253

The time values in Table 1 refer to the time passed since the addition of the iron(III)solution. As can be seen from the table, the colour is sufficiently stable to allow a reliable determination of the absorbance. After about 2—3 h, the colour intensity becomes smaller and the solution turns gradually turbid. In solutions containing hydrogen sulphite, a stable colour can only be obtained after the addition of an excess of formaldehyde.

In the following experiments it has been studied whether the measured absorbance really corresponds to the total thiocyanate content in the solution. Two solutions were investigated in this case. One of these consisted of 10 ml silver thiosulphate solution (containing 0.5 mM silver and 1 mM thiosulphate) and 10 ml 0.45 mM potassium thiocyanate, while in the other solution the silver thiosulphate was replaced by 10 ml water. To both solutions 10 ml iron(III)nitrate solution was added. The solutions were diluted to 50 ml and the absorbance was measured. The result of these measurements showed that the absorbance was exactly the same for the two solutions. This means that the colorimetric method gives the total thiocyanate content of the solutions, *i.e.* complexes of silver and thiocyanate and mixed complexes of silver, thiosulphate and thiocyanate can be neglected.

B. *Influence of the shaking time.* The influence of the shaking time has been studied by shaking 10^{-4} M thiosulphate with inactive silver thiocyanate. The results of these experiments (Fig. 1) show that the dissolved amount of thiocyanate remains constant in an interval from 10 to 40 min. Further shaking gives an increased dissolution and, after 8—9 h of rotation, the concentration of thiocyanate reaches a limit $c_{SCN} = 2\ c_{S_2O_3}$.

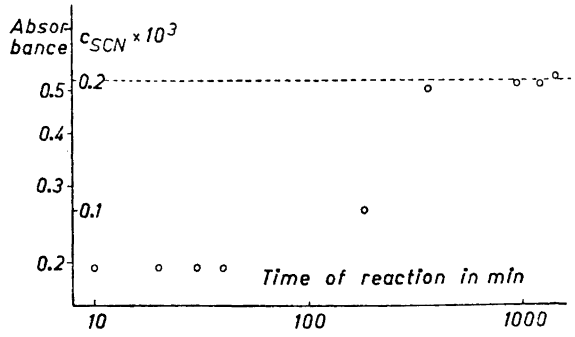

Fig. 1. Dissolution of silver thiocyanate as a function of time of reaction.

The precipitate turns gradually dark during the rotation, indicating a formation of silver sulphide. The dissolution reaction can in this case be written: $2\ AgSCN_{(s)} + S_2O_3^{2-} + H_2O \rightarrow Ag_2S_{(s)} + SO_4^{2-} + 2SCN^- + 2H^+$. Whether the experimentally found relation $c_{SCN} = 2c_{S_2O_3}$ is due to a complete transformation of thiosulphate into sulphide and sulphate according to this reaction has not yet been studied. — Similar observations were made by Dickinson [12], and by Chateau and Pouradier [13] for the dissolution of silver bromide in sodium thiosulphate. — From an analytical point of view, the sample can either be shaken for 10—40 min or rotated for about 8 h. In the latter case, a higher absorbance is obtained and, also, it is probable that the dissolution can be better reproduced. As will be reported in a forthcoming paper [14], this long time of reaction is not suitable for the determination of thiosulphate in solutions containing polythionates.

C. *Formation of* $NaAgS_2O_3 \cdot H_2O$ *at* $I \sim 0$. The precipitation of $NaAgS_2O_3 \cdot H_2O$ at $I \sim 0$ was investigated by measuring the sodium content before and after shaking. The determination of sodium was made flame photometrically. The experiments were carried out with 2×10^{-4} M thiosulphate. Parallel determinations of the thiocyanate concentration were performed colorimetrically.

Table 2. Determination of sodium content. Measuring-conditions: O_2-pressure 15 psi, C_2H_2-pressure 4 psi. Slit width 0.01 mm, sensitivity 3.

Time of shaking min	Sodium concentration		Thiocyanate concentration	
	Scale divisions	10^{-3} M	Absorbance	10^{-3} M
0	2.80	0.40	—	—
10	2.75	0.39	0.377	0.142
20	2.63	0.38	0.377	0.142
30	2.56	0.37	0.380	0.144
40	2.60	0.37	0.377	0.142

As is seen from Table 2, the sodium concentration decreases when the reaction time is increased from 10 to 40 min. This decrease cannot be due to an increased formation of $NaAgS_2O_3 \cdot H_2O$ since the thiocyanate concentration is constant during this interval of time. The sodium concentration of the filtrate is about 5 % less than that of the original solution. Because this decrease is probably partly caused by an adsorption of sodium ions on the solid silver thiocyanate, the formation of $NaAgS_2O_3 \cdot H_2O$ can be considered to be very small. Hence the dissolution of silver thiocyanate at this ionic strength must be due to a formation of complexes with silver ions.

D. *Determination of thiosulphate at low ionic strengths.* The investigations were performed for the thiosulphate concentration interval 2.5×10^{-5}—1.5×10^{-3} M. In Figs. 2 a and 2 b, the results with inactive silver and active silver are compared. The calculated relation $[SCN^-] = f(c_{S_2O_3})$ is also given in both figures. Fig. 2 a shows the solubility for $c_{S_2O_3} < 1.5 \times 10^{-3}$ while, in Fig. 2 b,

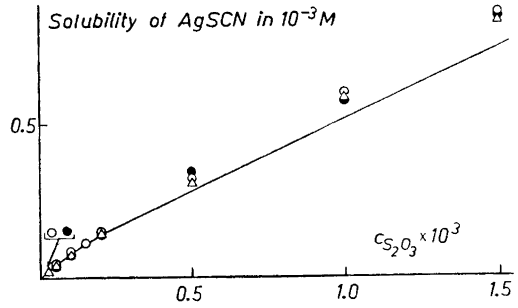

Fig. 2 a. Solubility of silver thiocyanate at low ionic strengths.
O c_{SCN}, inactive silver thiocyanate
● c_{SCN}, radioactive silver thiocyanate
△ c_{Ag}
— calculated solubility

the solubility for $c_{S_2O_3} < 2 \times 10^{-4}$ is shown on an enlarged scale. From Fig. 2 a, it is seen that both the calculated and found relationships between the thiocyanate content and the thiosulphate content are linear within a large interval. This linearity does not, however, extend over the whole concentration range investigated.

It can furthermore be seen from the figures that the experiments with inactive and active silver gave the same results despite the fact that these experiments were performed with different amounts of silver thiocyanate. This means that the method is reproducible even if the amount of silver thiocyanate added is varied. This result, as well as the fact that the solubility is independent of the time of shaking, shows that the solid phase is in equilib-

rium with the solution. It is also seen that the silver content is equal to the thiocyanate content, which indicates that no solid phase containing silver is formed. The experimentally found curve deviates from the calculated one for $c_{S_2O_3} > 1.5 \times 10^{-4}$ (*cf.* Fig. 2 b). The calculated values are lower than those found experimentally and the deviation amounts to about 10 %. This deviation is probably due to the formation of polynuclear complexes. These complexes are partly included in the calculated function since the mononuclear dissociation constants [5] were determined without any corrections for polynuclear complexes.

Fig. 3 shows the results of the shaking experiments with thiosulphate and 0.1 M hydrogen sulphite. The curve obtained from the experiments without an addition of hydrogen sulphite is also drawn. It can be seen that the addition of hydrogen sulphite has only a slight influence, as already predicted by the theory. The solubility of silver thiocyanate in a neutral or alkaline sulphite solution is on the other hand considerable. This can be seen from Table 3 which contains the results of the experiments with solutions containing only sulphite.

Table 3. Solubility of silver thiocyanate in sulphite solutions.

c_{SO_3}	c_{Ag}
0.1	1.2×10^{-3}
0.01	4.7×10^{-4}

Summarizing this examination of the silver thiocyanate method at low ionic strengths, it can be said that thiosulphate can be determined in solutions with an excess of hydrogen sulphite but cannot be determined in solutions containing alkaline sulphite. The determination can be performed either colorimetrically or with a method using active silver thiocyanate. For the concentration interval $c_{S_2O_3} > 2 \times 10^{-4}$ the standard curve $[SCN^-] = f(c_{S_2O_3})$ can be approximated by the straight line $[SCN^-] = 0.53\ c_{S_2O_3} + 0.05 \times 10^{-3}$ which means that the solubility of silver thiocyanate does not increase proportional to the concentration of thiosulphate. For $c_{S_2O_3} < 2 \times 10^{-4}$ the standard curve deviates considerably from this straight line.

E. *Determination of thiosulphate at high ionic strengths.* A calculation of the function $[SCN^-] = f(c_{S_2O_3})$ at ionic strengths up to $I = 0.1$ indicates that the solubility decreases with increasing ionic strengths. The calculation of this function at higher ionic strengths is, however, difficult with the data available at the present for the complexity constants. In order to investigate the circumstances at various ionic strengths, some experiments with 10^{-3} M thiosulphate were performed. Sodium perchlorate was added to the thiosulphate solution in order to obtain the desired ionic strength (Table 4).

Table 4. Solubility of silver thiocyanate at various ionic strengths.

I	$c_{Ag} \times 10^3$	$c_{SCN} \times 10^3$
0.001	0.58	0.57
0.01	0.59	0.57
0.1	0.60	0.58
1	0.59	0.59

Contrary to the calculated results, the values found experimentally show that the solubility is independent of the ionic strength up to $I = 1$.

Particular interest is given in this paper to the course of the dissolution at $I = 4$. The investigation at this ionic strength was confined to the concentration range $c_{S_2O_3} < 5 \times 10^{-4}$. As in the investigations at the low ionic

Table 5. Solubility of silver thiocyanate at $I \sim 4$.

strength the influence of hydrogen sulphite was also studied. The results obtained from these investigations are given in Table 5. The table also contains the absorption coefficients obtained from the experiments with sodium thiocyanate solutions. The unit for the absorption coefficient values is $10^3\,M^{-1}\,cm^{-1}$. The results in Table 5 obtained without hydrogen sulphite are plotted in Fig. 4. As is seen from the results, the solubility of silver thiocyanate is considerably decreased by an addition of hydrogen sulphite. This effect can almost be eliminated by adding an excess of formaldehyde. For the analytical application, however, it must be pointed out that, in this case, the relation between the absorbance and the concentration of thiocyanate is not the same as that obtained for solutions without hydrogen sulphite and formaldehyde since a large excess of formaldehyde must be added before the colorimetric determination in order to obtain a stable colour. A corresponding change in the relationship between the absorbance and concentration of thiocyanate is also obtained at low ionic strengths.

In Fig. 4, the calculated solubility functions $[SCN^-] = f(c_{S_2O_3})$ are shown. The corresponding relation for the amount of silver, bound as mononuclear complexes in the supersaturated solution, is also presented in the figure. From this relation it can be seen that the amount of silver, bound as polynuclear complexes, is about 50 % of the total silver content. In solutions

saturated with $NaAgS_2O_3 \cdot H_2O$, the silver content is on the other hand very low and follows the equation, $c_{Ag} = 0.02\ c_{S_2O_3} + 1.3 \times 10^{-6}$, when $c_{S_2O_3} < 5 \times 10^{-4}$. All the silver is in this case bound as mononuclear complexes. The calculated solubility function, for saturated and supersaturated solutions, can in both cases be approximated by straight lines in the concentration range in question. As already shown in the theory, the relation $[SCN^-] = 0.91\ c_{S_2O_3}$ holds for the saturated solution.

A comparison between the experimentally found values and the calculated ones indicates that the solution is supersaturated with $NaAgS_2O_3 \cdot H_2O$. A small amount of precipitate is, however, formed since the silver content is lower than the thiocyanate content. The agreement between the calculated values and the experimental ones is considered to be acceptable. The calculated values are somewhat lower than the found ones. The experimentally found values also show that the solubility of silver thiocyanate is proportional to the concentration of thiosulphate which can also be seen from the results given in Table 6.

F. *Formation of mixed complexes.* In the investigations reported in literature, the dissolution of silver halogenides in thiosulphate solutions is assumed to occur by the formation of mononuclear silver thiosulphate complexes with various numbers of ligand ions. Yatsimirskii and Panova [15], however, are of the opinion that the formation of $AgS_2O_3^-$ and $Ag(S_2O_3)_2^{3-}$ is not so probable. They discuss the problem on the basis of experiments performed by Valenta [16] and consider that the results indicate the formation of the complex $AgXS_2O_3^{2-}$, where X is the halogenide. Valenta's experiments have also been discussed by Chateau and Pouradier [5]. They determined the mononuclear dissociation constants for $Ag(S_2O_3)_n^{(2n-1)-}$ and showed, with the aid of these values, that the solubility of the silver halogenides investigated by Valenta is mainly due to the formation of $Ag(S_2O_3)_2^{3-}$ and $Ag(S_2O_3)_3^{5-}$. Whether or not mixed complexes are formed is not discussed by Chateau and Pouradier.

From the results given under A in this work, it is seen that the formation of complexes between silver, thiosulphate and thiocyanate is negligible in solutions containing a large excess of iron(III)ion. The question whether mixed complexes exist in the filtrates from the shaking experiments (before the addition of iron(III)nitrate) has been studied in the present work by measuring the concentration of free silver ion $[Ag^+]$ and the total content of thiocyanate. The experiments were performed at the ionic strength $I = 4$ using inactive silver thiocyanate. For the potentiometric determination of the concentration of free silver ion, the cell can be written:

$$- \text{Ag} \mid \underset{I=4}{\text{filtrate}} \mid 4\ \text{M}\ NaClO_4 \mid Hg_2SO_4,\ \text{Hg} +$$

The emf (in mV) of this cell is at 20°C

$$E = E_0 - 58.17\ \log\ [Ag^+] = -81.3 - 58.17\ \log\ [Ag^+]$$

The value of E_0 was determined in a cell where the filtrate was replaced by silver perchlorate solutions of known concentrations. Sodium perchlorate was added to these solutions to make ionic strength $I = 4$. This determination

also gave a check that the electrodes followed Nernst's law. No corrections for the diffusion potentials were made since the ionic mobilities of the complexes formed were not known. The results are given in Table 6. Two series are reported — in the first, the experiments were performed with an aged precipitate while, in the latter, the precipitate was freshly prepared.

Table 6. Determination of [Ag+].

$c_{S_2O_3} \times 10^4$	$c_{SCN} \times 10^4$	E	$[Ag^+] \times 10^9$	$[Ag^+]\, c_{SCN} \times 10^{13}$	$c_{SCN} / c_{S_2O_3}$
1.00	0.59	375.5	14.0	8.3	0.59
2.00	1.17	397.1	5.97	7.0	0.59
5.00	2.97	423.8	2.08	6.2	0.59
1.00	0.61	376.9	13.3	8.1	0.61
2.00	1.17	398.1	5.74	6.7	0.59
3.50	2.11	414.9	2.95	6.2	0.60

If mixed complexes exist in the filtrate the product $c_{SCN}\,[Ag^+]$ will be higher than the solubility product of silver thiocyanate. The product $c_{SCN}[Ag^+]$ will in addition increase with the concentration of thiosulphate and thiocyanate, since the formation of the mixed complexes also increase. From Table 6 it is seen that the calculated product decreases with increasing thiosulphate concentration. In comparison with the value for the solubility product $L_R = 7.76 \times 10^{-13}$ given by Leden and Nilsson, all the calculated values are too low except those for the lowest concentration of thiosulphate. Consequently it cannot be shown by these experiments whether or not mixed complexes are formed. On the other hand, the potentiometric measurements and the experiments performed with radioactive silver indicate that the concentration of mixed complexes in the filtrate is considerably lower than predicted by Yatsimirskii and Panova.

From Table 6 it is seen that the dissolution is independent of the age of the precipitate. The calculated ratio $c_{SCN}/c_{S_2O_3}$ shows the linearity of the dissolution function.

G. *Determination of thiosulphate using other insoluble salts than silver thiocyanate.* The determination of thiosulphate as reported above is not limited to the use of silver thiocyanate. Utsumi [17] has also used copper(I)thiocyanate for the determination. In this case, Utsumi suggests an addition of 0.3 ml 6 N nitric acid to 10 ml of the sample before the shaking procedure in order to obtain a higher solubility. In the present investigation it was shown that, with such an addition, the solubility was very high even without the addition of thiosulphate. In a neutral thiosulphate solution, the solubility of the copper(I)thiocyanate was found to be lower than the solubility of silver thiocyanate at a corresponding thiosulphate concentration.

By using radioactive silver salts, the analytical method is not limited to those compounds where the solubility can be determined colorimetrically. Silver chloride, bromide and iodide can be employed. The solubility of silver

iodide is, however, too low from an analytical point of view. For dark coloured solutions, the method with radioactive silver is of course the only suitable one. In certain cases, a colorimetric method is available for dark coloured solutions if silver azide is used as solid salt. In this case, the filtrate is steam distilled in a Parnas [18] apparatus after addition of sulphuric acid. The volatile hydrazoic acid is driven off by the distillation and is subsequently absorbed in a receiver containing acidic iron(III)nitrate solution. Like thiocyanate, the azide ion forms coloured complexes with the iron(III)ion. These complexes have an absorption maximum at the wave-length 460 mμ. Since the hydrazoic acid is a weak acid ($K_s = 2.6 \times 10^{-5}$) and since the silver azide is comparatively soluble ($L = 2.6 \times 10^{-9}$), the use of silver azide is limited to weakly alkaline solutions which do not contain sulphite. The distillation procedure was tested in the present work. It was found that hydrazoic acid was completely driven off by passing 50 g steam through 30 ml 1 mM azide solution to which 2 ml 5 N sulphuric acid had been added. The relationship between added thiosulphate and dissolved silver azide was found to be nonlinear.

The author wishes to thank Docent I. Leden and Dr. R. O. Nilsson for valuable discussions and Mr. E. Seyfarth for assistance with the laboratory work. *Statens Tekniska Forskningsråd* and *Chalmerska Forskningsfonden* have supported the research financially, which support is gratefully acknowledged.

*iso*Thiocyanates XXXII.* Synthesis and Reactions of 3-Benzoyloxypropyl *iso*Thiocyanate, Enzymically Liberated from Glucomalcolmiin, and some Compounds of Related Structure

ANDERS KJÆR and ROALD BOE JENSEN

Organic Chemical Laboratory, Royal Veterinary and Agricultural College, Copenhagen, Denmark

Observations resulting in the discovery of a new mustard oil glucoside, *glucomalcolmiin*, in seeds of *Malcolmia maritima* R. Br. *(Cruciferae)* are discussed. Preliminarily reported evidence [1] for the structure of the corresponding *iso*thiocyanate, *malcolmiin*, has been supplemented by unequivocal proof of its structure. 3-Benzoyloxypropyl *iso*thiocyanate has been synthesized and its identity with malcolmiin definitely established. A structural expression for glucomalcolmiin is proposed.

The additional presence in *M. maritima* seeds of glucocheirolin is rigorously proved.

The complex picture observed on ammonia treatment of an enzymically hydrolyzed seed extract of *M. maritima* has been interpreted and the formation of tetrahydro-1,3-oxazine-2-thione corroborated by synthesis. Additional representatives of this little known class of heterocyclic compounds have been synthesized by base-induced ring-closure of the corresponding 3-hydroxyalkyl *iso*thiocyanates. The diminished cyclization tendency of these relative to the 2-hydroxyalkyl mustard oils is pointed out. The biogenesis of glucomalcolmiin is briefly discussed.

A preliminary communication of this series [1] announced the detection in Nature of a new *iso*thiocyanate glucoside, *glucomalcolmiin*, characterized by undergoing enzymic hydrolysis to glucose, sulphate and a mustard oil, tentatively formulated as 3-benzoyloxypropyl *iso*thiocyanate. It is the purpose of the present paper to describe in more detail the experimental data supporting the proposed structure, including the synthesis of the new mustard oil, as well as to expand on the chemistry of some structurally related compounds.

* Part XXXI of this series: *Botan. Tidsskr.* **54** (1958) 36.

The cruciferous genus *Malcolmia* comprises about 25 herbaceous species indigenous to the Mediterranean region. A few of these have attained horticultural significance, *e.g. Malcolmia maritima* (L.) R.Br.* which is easily procurable as seed material from commercial sources **. It is only recently, however, that its contents of *iso*thiocyanate-producing glucosides has been recognized. Thus, an earlier paper of this series [2], surveying the results of paperchromatographic analyses of volatile mustard oils in numerous seed samples, listed *Cheiranthus maritimus* as a species furnishing methyl *iso*thiocyanate on enzymic hydrolysis. This assignment proved untenable when authentic methyl mustard oil glucoside (glucocapparin) was encountered in our laboratory as a natural compound, occurring in several species belonging to the family *Capparidaceae* [3,4]. Schultz and Wagner [5,6], in a communication on paperchromatographic analysis of mustard oil glucosides in numerous plant species, reported the occurrence in seeds of *M. maritima* R.Br. of three partly unidentified glucosides, one of which was found to be present in small amounts only. Essentially the same pattern was observed independently in our laboratory on chromatography of the glucosides in a crude methanolic seed extract [1]. Conspicuous spots, possessing R_B-values [5] of 0.34 and 1.36, were noticed on chromatograms run with the upper layer of the solvent system: *n*-butanol: ethanol: water (4:1:4) as the mobile phase, whereas a minor, and still unidentified glucoside appeared as a weak spot with an R_B-value of 1.03.

Enzymic hydrolysis of a homogeneous preparation of the fastest moving glucoside (R_B 1.36), provided by elution of the appropriate zone from a band paper chromatogram with phosphate buffer, furnished a mustard oil possessing absorption characteristics in the ultra-violet region indicative of aromatic structure. A high-extinction maximum at 232 mμ, together with an auxiliary band of much lower intensity at about 270 mμ, suggested the presence in the *iso*thiocyanate of a conjugated aromatic system, possibly of the benzoyl-type. This pattern, in conjunction with the R_B-value of the parent glucoside, clearly demonstrated this to be different from all heretofore recorded mustard oil glucosides. In accord with common usage within this field the designation *glucomalcolmiin* was therefore introduced for the new natural product [1], affording the corresponding *iso*thiocyanate, *malcolmiin*, on enzymic hydrolysis.

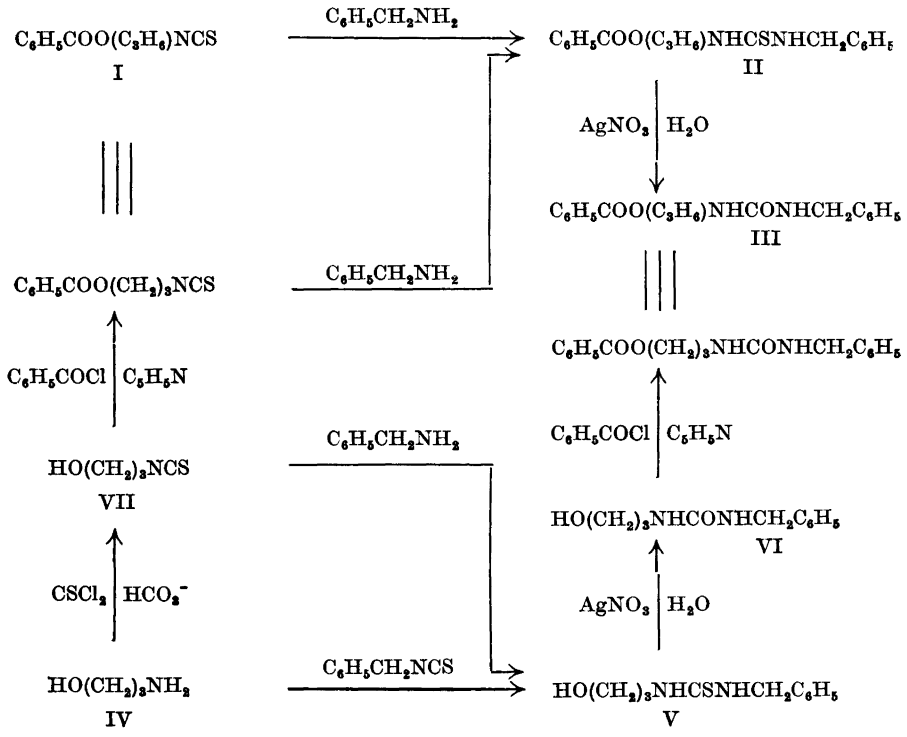
Efforts were first directed towards the isolation of a crystalline thiourea-derivative of malcolmiin. When a purified glucoside extract, prepared from a larger amount of *Malcolmia maritima* seeds, was subjected to enzymic hydrolysis in a buffered solution at pH 6.8, an ether-soluble, optically inactive mustard oil fraction was produced. Subsequent treatment of this with methanolic ammonia resulted in the formation of crystalline malcolmiin-thiourea, $C_{11}H_{14}O_2N_2S$, devoid of optical activity and displaying UV-data in alcoholic solution [1] interpretable as ordinary thiourea-absorption (λ_{max}^{EtOH} 243 mμ) superimposed upon a benzoyl pattern (λ_{max}^{EtOH} 228 mμ, 270—280 mμ). Infrared absorption data [1] provided further evidence for the presence of a benzoate grouping in the thiourea, eventually established beyond doubt by the isola-

* *Nomen conservandum* over *Cheiranthus maritimus* L.

** The seed material employed in the present investigations was obtained from the company *J. E. Ohlsen's Enke*, Copenhagen K., Denmark.

tion of benzoic acid subsequent to alkaline hydrolysis. In water-saturated chloroform malcolmiin-thiourea migrated at a rate corresponding to an R_{Ph}-value [7] of 1.07. Several structural possibilities for malcolmiin, $C_6H_5COO(C_3H_6)NCS$, were discussed in the preliminary paper [1] and evidence adduced in favour of 3-benzoyloxypropyl *iso*thiocyanate, $C_6H_5COO(CH_2)_3NCS$, being the correct formulation.

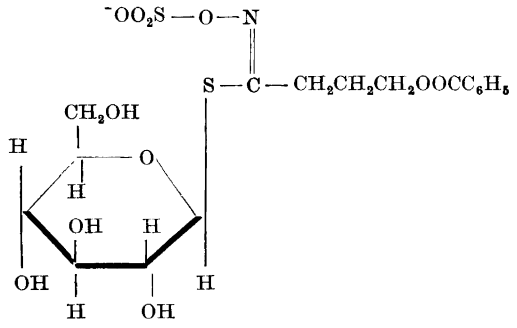
This conclusion has now been verified by various synthetic approaches. Thus, malcolmiin (I) reacted with benzylamine to give the crystalline benzylthiourea (II) which could be smoothly transformed into the corresponding benzylurea (III) on treatment with a solution of silver nitrate in aqueous ethanol. The identity of (III) as 1-(3-benzoyloxypropyl)-3-benzylurea was ascertained by an unequivocal synthesis of the latter starting with 3-aminopropanol (IV).



Reaction of this amino-alcohol with one molecular equivalent of benzyl *iso*thiocyanate afforded 1-benzyl-3-(3-hydroxypropyl)-thiourea (V), smoothly transformed by means of silver nitrate into the corresponding, syrupy benzylurea (VI). When benzoylated in pyridine solution the latter yielded 1-(3-benzoyloxypropyl)-3-benzylurea which proved identical with (III) on critical comparison.

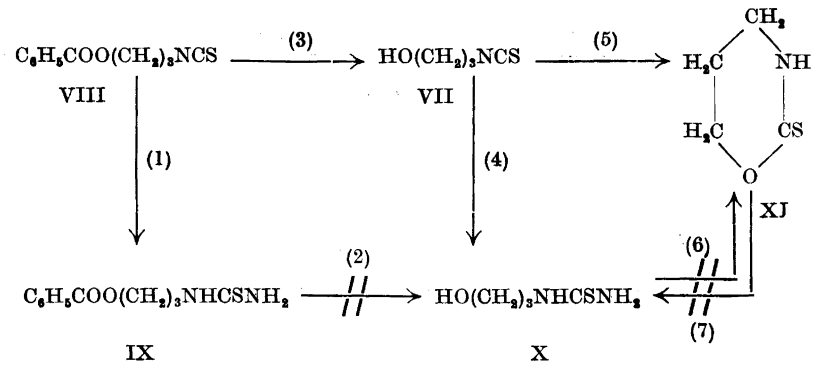
A more direct structure proof for malcolmiin (I) was achieved by its synthesis. After several alternative routes had been unsuccessfully explored it was found that the bifunctional 3-aminopropanol (IV) on treatment with thiocarbonyl chloride in bicarbonate solution afforded a moderate yield of the distillable 3-hydroxypropyl *iso*thiocyanate (VII), the identity of which appeared from its reaction with benzylamine to give a benzylthiourea (V) indistinguishable from the specimen prepared as described above. Benzoylation of (VII) in pyridine solution proceeded easily to give 3-benzoyloxypropyl *iso*thiocyanate as a distillable, colourless oil with correct analytical figures. The identity of the synthetic mustard oil and malcolmiin (I) appeared from the fact that the former reacted with benzylamine to give 1-(3-benzoyloxypropyl)-3-benzylthiourea (II), identical with the benzylthiourea derivative of malcolmiin.

Glucomalcolmiin is a mustard oil glucoside of the ordinary type, furnishing glucose and sulphate in addition to malcolmiin on enzymic hydrolysis. Liberation of sulphate was demonstrated by reaction with barium ions, whereas the formation of glucose was established by paper chromatography in two solvent systems. Again, strong acid treatment of glucomalcolmiin produced hydroxylamine, a characteristic fission product as pointed out by Ettlinger and Lundeen [8] in support of the revised general structure for the *iso*thiocyanate glucosides advanced by these authors. Although conclusive evidence for the stereochemical details are lacking in the present case, it appears very likely that the glucomalcolmiin ion possesses the following structure:



The accessibility of the new mustard oil (I) by synthesis prompted a closer study of its behaviour towards ammonia. The ester linkage and *iso*thiocyanate-grouping both constitute possible sites for nucleophilic attack by the base. In fact, several reaction products were encountered resulting from competing reactions at the vulnerable centers. The following scheme represents the predictable reaction products, the mutual relationships of which were established by paper chromatography.

Upon treatment of synthetic malcolmiin (VIII) with 0.5 N ethanolic ammonia for 40 min. at room temperature, a maximum yield of the corresponding 1-(3-benzoyloxypropyl)-thiourea (IX) was produced together with



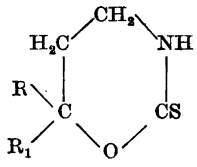
traces of 1-(3-hydroxypropyl)-thiourea (X). Prolonged exposure of (VIII) to ammonia resulted in an increase of the relative amounts of (X), whereas the benzoate-thiourea (IX) proved almost inert towards ammonia under the same conditions. Hence, the route (3)-(4) is the preferred path of reaction rather than (1)-(2) under the present circumstances, indicating an enhanced susceptibility to ammonolysis of the ester mustard oil compared to the ester thiourea. A solution of (VIII), which had been treated for 24 h with ammonia, afforded on paper chromatography in water-saturated chloroform a weak spot with a violet-blue Grote-reaction in addition to those of the thioureas (IX) and (X) and located intermediate between these. The same spot appeared, yet to a much larger extent and supplementary to the expected spot of (X), upon treatment of 3-hydroxypropyl mustard oil (VII) with ammonia. It therefore seemed reasonable to consider the unexpected by-product to be tetrahydro-1,3-oxazine-2-thione (XI), competitively formed by base-induced cyclization of (VII). This assumption was further strengthened by a synthesis of the previously unknown ring-compound (XI)[1] which on paper chromatography afforded a spot indistinguishable from that observed in the ammonia-treated reaction mixture. That the ring compound was produced by the direct route (5) rather than *via* the path (4)-(6) followed from the established inertness of (X) to excess ammonia. Again, the remote possibility of (X) being formed *via* the heterocyclic compound was ruled out on basis of the established stability of (XI) towards ammonia under the conditions employed.

The above conclusions provide a logical interpretation of the complex pattern observed on paper chromatography of crude thiourea fractions of enzymically hydrolyzed seed extracts of *Malcolmia maritima*, as presented and discussed in a preliminary communication [1].

Appropriate processing of a larger seed portion of *M. maritima* disclosed its content of a substantial amount of glucocheirolin, enzymically hydrolyzed to cheirolin (3-methylsulphonylpropyl *iso*thiocyanate) which was characterized as crystalline derivatives formed upon reaction with aniline and benzylamine [1]. The finding of glucocheirolin in *M.maritima* is not surprising in view of the long established occurrence of this glucoside in several *Cheiranthus* species (for a review *cf.* Ref.[9]), closely related botanically to the genus *Malcolmia*. As pointed out previously [1] one of the two spots reported by Schultz and

Wagner [5,6] in thiourea-chromatograms of *M.maritima* extracts was correctly attributed to cheirolin-thiourea whereas the second component, assigned by the same authors to a new, naturally occurring mustard oil, undoubtedly represents 1-(3-hydroxypropyl)-thiourea (X) the artifact character of which in the present case was demonstrated in our preliminary note [1].

The unexpected appearance of the heterocyclic compound (XI) during the present studies rendered a closer investigation of this ring-system desirable. Only one tetrahydro-1,3-oxazine-2-thione seems to have been previously recorded, *viz.* the 4,4,6-trimethyl-derivative prepared by Rosen [10] from 4-amino-4-methyl-2-pentanol. In the course of the current studies (±)-6-methyl- (XII) and 6,6-dimethyl-tetrahydro-1,3-oxazine-2-thione (XIII) were synthesized by treating the appropriate γ-amino-alcohols, *viz.* (±)-4-amino-2-butanol and 4-amino-2-methyl-2-butanol, respectively, with thiocarbonyl chloride in bicarbonate solution to give the corresponding (±)-3-hydroxybutyl (XIV) and 3-methyl-3-hydroxybutyl *iso*thiocyanate (XV) both of which could be cyclized in alkaline solution to the ring compounds (XII) and (XIII), respectively. The distillable mustard oils, (XIV) and (XV), were further characterized as crystalline thioureas formed on reaction with ammonia in chloroform solution. In addition, the benzylthiourea derivative of (XV) was prepared by reaction of 4-amino-2-methyl-2-butanol with benzyl *iso*thiocyanate.



$R = H$, $R_1 = CH_3$: XII
$R = R_1 = CH_3$: XIII

$CH_3CHOHCH_2CH_2NCS$ XIV

$(CH_3)_2C(OH)CH_2CH_2NCS$ XV

In general, it appears that 3-hydroxysubstituted *iso*thiocyanates readily undergo intramolecular cyclization to tetrahydro-1,3-oxazine-2-thiones in alkaline solution, a reaction which is comparable to the analogous and well-established cyclization of 2-hydroxy-alkyl mustard oils to 2-oxazolidinethiones (XVI) [10–15] *. In connexion with the present studies a new representative of the latter class of heterocyclic compounds was synthesized, *viz.* (±)-5-ethyl-5-methyl-2-oxazolidinethione (XVII) derivable from (±)-1-amino-2-methyl-2-butanol which was, in turn, produced by reduction of 2-hydroxy-2-methyl-butyronitrile with lithium aluminium hydride.

* For references to earlier papers *cf.* Ref.[11]

Infra-red spectra of the six-membered heterocyclic compounds, (XI)—(XIII), in the solid state or neutral solutions, indicated their character of tetrahydrooxazinethiones rather than dihydrooxazinethiols. In a detailed study, Ettlinger [16] formerly demonstrated several representative compounds of the five-membered class (XVI) to exist entirely in the thione form under comparable conditions.

Contrary to γ-hydroxysubstituted *iso*thiocyanates the tetrahydro-1,3-oxazine-2-thiones, (XI)—(XIII), exert a high-extinction band at 243 mμ in aqueous solution, displaced to 250 mμ in 96 % ethanol. Apart from a minor hyperchromic shift virtually no change of the absorption pattern occurs on addition of alkali provided prolonged exposure to strong base is avoided; if not, a slow but irreversible cleavage of the ring system takes place. Hence, spectrophotometric assays provide a convenient means of following the intramolecular cyclization under varying conditions. From such experiments it was concluded that: (i) a very rapid ring-closure occurs at pH 12 or above in ethanol solution, whereas at pH 10 or below the cyclization is extremely slow, (ii) hydrogen ions are without any promoting effect on the cyclization rate, (iii) a slow ring-closure occurs in boiling ethanol, and (iv) heating to a temperature as high as 125° without solvent does not result in appreciable ring formation. A less striking, but definite promoting effect was demonstrable with triethylamine although paperchromatographic controls indicated that with this base the ring-closure did not proceed to completion. Under standardized conditions there seemed to be a slight increase in the cyclization rate parallel to the increasing number of carbon atoms in the mustard oils. The above observations are consistent with the view that cyclization proceeds by nucleophilic attack of the deprotonized hydroxy substituent on the carbon atom of the *iso*thiocyanate grouping. Hence, the acid strength of the hydroxy-group as well as the intrinsic cyclization tendency may be expected to influence the over-all reaction rate, which, however, appears to be generally less than that prevailing in the corresponding 2-hydroxysubstituted *iso*thiocyanates under comparable conditions. Thus far, all syntheses designed to yield the latter compounds have invariably resulted in cyclized products.

Although no experimental evidence is yet available it appears reasonable to envisage glucomalcolmiin as biogenetically derived from *des*benzoylglucomalcolmiin containing the 3-hydroxypropyl-side chain. Furthermore, it may be of interest to consider a possible generic relationship of the latter with other well-established glucosides containing a 3-carbon unit in their side-chains, such as sinigrin, with the allyl-grouping, and glucoibervirin [17] possessing the methylthiopropyl radical as its side-chain. Glucoiberin and glucocheirolin may tentatively be regarded as secondarily formed oxidation products of glucoibervirin. Several examples of enzymic transformations between analogously substituted compounds can be adduced from modern biochemistry and suggest a common biogenetic pathway for these glucosides, a possibility which will be submitted to experimental trial in forthcoming studies.

EXPERIMENTAL

Melting points are uncorrected and determined in capillary tubes in a slowly heated bath. Analytical specimens have been dried *in vacuo* over calcium chloride at room temperature.

Most of the synthetic compounds described in the sequel have been prepared with no special view to establishing the optimal conditions for the reactions involved. Hence, in many cases the reported yields most likely can be improved considerably.

Spectroscopic detection of glucomalcolmiin. A concentrated methanolic extract of finely ground seeds of *Malcolmia maritima* was applied as a narrow band to the starting line of a 15 cm broad strip of prewashed Whatman paper No. 1. After descending chromatography for 24 h with the upper layer of the system *n*-BuOH:EtOH:H_2O (4:1:4) as the mobile phase, two edge cuts were employed for locating the band of the fastest moving glucoside by means of a silver nitrate spray. The appropriate area of the paper was cut out, eluted with dilute phosphate buffer (pH 6.8), and the resulting solution subjected to enzymic hydrolysis on addition of a drop of a cell-free myrosinase preparation [18]. After extraction of the liberated mustard oil (malcolmiin) with ether and displacement of the solvent by water, the ultra-violet absorption spectrum was determined. A sharp peak at 232 mμ and an inflexion of much lower extinction near 275 mμ were characteristic features, suggesting aromatic character of malcolmiin.

Isolation of malcolmiin and cheirolin as thiourea-derivatives. Finely ground seeds (500 g) of *M. maritima* were defatted with a total of 4 l of boiling carbon tetrachloride and then thoroughly extracted with 70 % methanol (2.5 l). After removal of the solvent *in vacuo*, the residue was taken up in water, treated with excess lead acetate and the white precipitate filtered off and discarded. Lead ions in the filtrate were precipitated by hydrogen sulphide and after repeated filtrations the solution was buffered with phosphates to pH 6.8, adjusted to a total volume of 2 l with water and subjected to enzymic hydrolysis by addition of a cell-free myrosinase preparation (15 ml). At the end of 12 h the mixture was extracted, first with three 300-ml portions of ether and then thrice with the same volumes of chloroform. In order to remove some coloured impurities both extracts were briefly washed with cold 1 N NaOH and then with water. The dried and concentrated extracts were now processed separately.

The chloroform fraction was treated with benzylamine (1 ml), resulting in the separation of a crystalline product (470 mg). Two recrystallizations from 10 % ethanol afforded *1-benzyl-3-(3-methylsulphonylpropyl)-thiourea* (cheirolin-benzylthiourea) (390 mg) as colourless, rhombic plates, m. p. 116°, identified on comparison with an authentic, synthetic specimen (m. p. 116°), prepared from cheirolin [19] and benzylamine (analyses previously published [1]).

The ether extract was divided into two halves. To the first was added aniline (1 ml), and the resulting crystalline precipitate (84 mg) was recrystallized twice from water to yield *1-(3-methylsulphonylpropyl)-3-phenylthiourea* (cheirolin-phenylthiourea) (54 mg), m. p. 138°, undepressed on admixture with a previously prepared synthetic specimen [19].

The remaining half of the ether extract was kept overnight in ammonia-containing methanol. Next day, the solvent was removed and the residue treated with hot ethyl acetate, leaving a slight amount of cheirolin-thiourea undissolved. Concentration of the filtrate resulted in separation of an oily fraction, paperchromatographically proved to be a mixture of 3-hydroxypropylthiourea (X) and tetrahydro-1,3-oxazine-2-thione (XI). Further concentration of the supernatant yielded a solid product which proved homogeneous on paper chromatography after one recrystallization from aqueous methanol (78 mg), m. p. 159°. Additional recrystallizations, first from ethyl acetate and then from 30 % ethanol, afforded *malcolmiin-thiourea* (23 mg) as colourless, dense, optically inactive crystals, m. p. 162° (analyses, UV- and IR-data as well as the R_{Ph}-value have been previously published [1]), undepressed on admixture with a specimen of synthetic 1-(3-benzoyloxypropyl)-thiourea (IX) described in the following.

A separate preparation of an ether extract, procured as just described, was treated with benzylamine to yield crystalline *malcolmiin-benzylthiourea* (101 mg), separating from a mixture of ethyl acetate and hexane as colourless crystals, m. p. 80.5°. Mixed melting point determination and coinciding infra-red spectra served to establish the identity of this derivative with a synthetic sample of 1-benzyl-3-(3-benzoyloxypropyl)-thiourea described in the sequel.

Desulphurization of malcolmiin-benzylthiourea (II). The benzylthiourea of natural malcolmiin (II) (100 mg), dissolved in 90 % ethanol (2 ml), was treated with silver nitrate (214 mg) in water (2 ml), and the solution was heated on a water-bath for 0.5 h. pH was kept at 7 by gradual addition of 0.5 N NaOH during the heating process. Precipitated Ag_2S was filtered off and the reaction product (15 mg) caused to separate by addition of water. Three recrystallizations from 80 % ethanol yielded a pure specimen (3 mg) of a compound, m. p. 145°, identified as 1-(3-benzoyloxypropyl)-3-benzyl-urea (III). No depression of the melting point was observed on admixture with an authentic specimen of the latter, prepared as described below. Furthermore, coinciding infra-red spectra served to confirm the identity.

Degradation of malcolmiin-thiourea. A sample of partly purified malcolmiin-thiourea (73 mg), secured as described above, was dissolved in ethanol containing excess of 0.1 N NaOH and left at room temperature for 48 h. The acidified solution was then extracted with ether and the extract concentrated to dryness. The residue (40 mg) was treated with charcoal in hot hexane, recrystallized once from water and finally sublimed to give pure benzoic acid (17 mg), m. p. 123°, undepressed on admixture with an authentic sample.

The aqueous solution was concentrated to dryness, dissolved in a few drops of water and chromatographed on paper, both in water-saturated chloroform and *n*-butanol: ethanol:water, together with synthetic 3-hydroxypropylthiourea *(vide infra)* from which it could not be distinguished. Both remained on the starting line in chloroform but travelled corresponding to an R_F-value of *ca.* 0.52 in the alcoholic system.

Degradation of glucomalcolmiin. A glucomalcolmiin fraction, prepared by elution of the appropriate zones from several band chromatograms, was subjected to enzymic cleavage in the usual way. After removal of malcolmiin by ether extraction, the concentrated aqueous phase was assayed for glucose by paper chromatography in *n*-butanol-ethanol:water (4:1:4) and pyridine:amyl alcohol:water (35:30:30). R_F-values of 0.16 and 0.34 were determined, respectively, the same as for simultaneously run reference samples of authentic D-glucose.

A separate sample of the aqueous phase yielded a positive sulphate reaction when tested with barium chloride. In both cases, appropriate blanks were checked in order to exclude positive reactions from possible trace constituents of the paper or enzyme preparation.

The dry residue from a similarly prepared solution of glucomalcolmiin was left overnight with excess of conc. HCl at room temperature. The liberation of hydroxylamine was demonstrated paperchromatographically by the method employed by Ettlinger and Lundeen [8].

1-Benzyl-3-(3-hydroxypropyl)-thiourea (V). 3-Aminopropanol (1.0 g) and benzyl *iso*thiocyanate (2.0 g) were mixed in ether (25 ml) and left at room temperature for 24 h. After removal of the solvent, the crystalline product was recrystallized twice from aqueous ethanol to yield the pure thiourea (2.84 g), m. p. 99° (Found: C 58.90; H 7.06; N 12.41. Calc. for $C_{11}H_{16}N_2OS$: C 58.89; H 7.19; N 12.49).

1-Benzyl-3-(3-hydroxypropyl)-urea (VI). The above thiourea (V) (2.0 g) was dissolved in ethanol (35 ml) and a solution of silver nitrate (3.0 g) in water (5 ml) was added. The mixture was heated on a water-bath for 20 min., and 0.5 N NaOH was gradually added to maintain pH 7. The solvents were removed in vacuum after filtration, and the reaction product dissolved in abs. ethanol and thus separated from $NaNO_3$. On concentration a colourless syrup separated which showed no signs of crystallization by various treatments.

1-(3-Benzoyloxypropyl)-3-benzyl-urea (III). To a solution of the syrupy urea (VI) (1.76 g) in dry pyridine (20 ml) freshly distilled benzoyl chloride (1.30 g) was added, and the mixture was set aside for 24 h. The brown solution was then diluted with ice-water (50 ml) when the oily precipitate readily crystallized. Three recrystallizations from 80 % ethanol afforded a pure specimen (686 mg) of the benzoylurea as glistening needles, m. p. 146°, alone or in admixture with the preparation above, derived from 'natural' malcolmiin-benzylthiourea. (Found: C 69.10; H 6.60; N 8.89. Calc. for $C_{18}H_{20}N_2O_3$: C 69.20; H 6.45; N 8.97). The infra-red spectrum (in KBr) displayed a strong benzoate C=O-band at 1 722 cm^{-1}.

3-Hydroxypropyl iso*thiocyanate* (VII). A mixture of 3-aminopropanol (16 g) in 5 % $NaHCO_3$-solution (270 ml) and thiocarbonyl chloride (25 g) in chloroform (350 ml) was vigorously stirred until the thiophosgene colour had disappeared. The dried chloroform

solution was concentrated and the yellow, pungent oil was distilled *in vacuo*. A small fore-run was followed by a constant boiling fraction (6.5 g), b. p. 80°/2 mm, of almost colourless 3-hydroxypropyl mustard oil, n_D^{25} 1.5432. A center-cut sample was analyzed. (Found: C 41.20; H 6.08; N 11.90. Calc. for C_4H_7NOS: C 40.98; H 6.02; N 11.95). A residue (2—3 g) of a very viscous product remained in the distilling flask. After a few weeks a distilled sample had changed into a similar product, probably of polymeric nature (polythiourethanes).

In order to prove the identity of the distilled mustard oil, a small sample was allowed to react with benzylamine in ether to give a quantitative yield of 1-benzyl-3-(3-hydroxypropyl)-thiourea (V) which, recrystallized from aqueous ethanol, had the m. p. 99°, undepressed on admixture with the product described above, prepared from 3-aminopropanol and benzyl *iso*thiocyanate.

3-Benzoyloxypropyl iso*thiocyanate (malcolmiin)* (I). In a typical experiment freshly distilled 3-hydroxypropyl mustard oil (1.56 g) was dissolved in dry pyridine (7 ml) and freshly distilled benzoyl chloride (2.5 g) was added. After 14 h at room temperature excess dilute HCl was added. When all benzoyl chloride was hydrolyzed, the solution was extracted with ether. The organic layer was washed with 5 % $NaHCO_3$-solution and water, and dried. The new *iso*thiocyanate distilled as a colourless oil (1.20 g), b. p. 144°/0.4 mm, n_D^{25} 1.5687. (Found: C 59.60; H 4.93; N 6.43. Calc. for $C_{11}H_{11}NO_2S$: C 59.73; H 5.01; N 6.33.)

1-(3-Benzoyloxypropyl)-thiourea (IX). Synthetic malcolmiin (150 mg) was dissolved in abs. ethanol (10 ml) and a 6 N solution of ammonia in the same solvent (1 ml) was added. After 40 min. at room temperature, the solvent and excess ammonia was removed *in vacuo*, leaving the thiourea (156 mg) as a colourless solid. This was recrystallized once from 30 % ethanol and once from ethyl acetate to give pure malcolmiin-thiourea (76 mg), m. p. 162°. Mixed melting point determination and coinciding infra-red spectra served to establish the identity of the product with the thiourea prepared from 'natural' malcolmiin and described above.

1-(3-Benzoyloxypropyl)-3-benzyl-thiourea (II). When synthetic malcolmiin (150 mg) was mixed with benzylamine (150 mg) in ether (5 ml), and the solution left overnight at room temperature, (II) (210 mg) crystallized on removal of the solvent and trituration of the residue with a few drops of dilute acid. Recrystallization, first from aqueous ethanol and thence from a mixture of ethyl acetate and hexane, afforded a colourless specimen for analysis, m. p. 80.5°, alone or in admixture with the above preparation from 'natural' malcolmiin. (Found: C 65.80; H 6.10; N 8.39. Calc. for $C_{18}H_{20}N_2O_2S$: C 65.82; H 6.14; N 8.53.)

1-(3-Hydroxypropyl)-thiourea (X). A solution of freshly distilled 3-hydroxypropyl *iso*thiocyanate (VII) (600 mg) in chloroform (100 ml), saturated with dry ammonia, deposited after 12 h at room temperature a crop (572 mg) of colourless crystals. An analytical specimen was produced by three recrystallizations from nitromethane, m. p. 131°. (Found: C 35.70; H 7.47; N 20.82. Calc. for $C_4H_{10}N_2OS$: C 35.80; H 7.51; N 20.89.) The thiourea (X) travels on paper chromatography in *n*-butanol-ethanol:water (4:1:4) at a rate corresponding to an R_F-value of 0.52.

Tetrahydro-1,3-oxazine-2-thione (XI). 3-Aminopropanol was subjected to mustard oil synthesis under non-aqueous conditions, according to the directions given by Hodgkins and Ettlinger [20]. The solution of the reaction product in triethylamine-containing chloroform was concentrated to a small volume, acidified with HCl and thoroughly extracted with ether. The turbid, dry ether extract contained a greenish oil which was refluxed in benzene solution for 0.5 h. Evaporation of the solvent resulted in the separation of a partly crystalline product which was purified by charcoal treatment in chloroform solution. Two recrystallizations from chloroform-pentane mixtures yielded the pure ring-compound as colourless plates, m. p. 129°. (Analyses previously published [1].) Yields were of the order of 20 % but could undoubtedly be improved. The ultra-violet spectrum in 96 % ethanol had λ_{max} 250 mμ (ε 14 200), in water: λ_{max} 243 mμ (ε 13 700). Addition of NaOH resulted in an increased molecular extinction (ε 16 300), yet at the same wavelength.

The infra-red spectrum (in KBr), though reminiscent of that of 2-oxazolidinethione, possessed several characteristic, individual features. Conspicuous bands were observed

at: 765 (m, broad), 810 (s), 914 (s), 964 (s), 1 052 (vs), 1 130 (s), 1 168 (vs), 1 210 (m), 1 238 (vs), 1 315 (vs), 1 374 (m), 1 478 (m), 1 578 (vs) and 3 200 (s) cm^{-1}.

In water-saturated chloroform the heterocyclic compound travelled at a rate corresponding to an R_{Ph}-value of 0.78.

(±)-3-Hydroxybutyronitrile. Propylene chlorohydrin (200 g), prepared from propylene oxide and HCl[21], was refluxed for 5 h with slightly more than one molecular equivalent of KCN dissolved in ethanol, and a trace of KI. The solvent was then distilled off and the residue fractionated *in vacuo* to give racemic 3-hydroxybutyronitrile (185 g) as a colourless liquid, b. p. 103°/13 mm. A similar procedure has been previously employed by Bruylants and Castille [22].

(±)-4-Amino-2-butanol. This amino-alcohol has previously been synthesized either by aluminium amalgam reduction of 2-hydroxybutyraldoxime [23,24] or, in 48 % over-all yield, by a two-step process from 1,3-butanediol cyclic sulphate [25]. In the present work, however, reduction of 3-hydroxybutyronitrile (8.5 g) with lithium aluminium hydride (10 g) in dry ether (300 ml), carried out in the usual way, proceeded satisfactorily to give 5.4 g of distilled amino-alcohol, b. p. 74—82°/10 mm. The broad boiling point range, noticed also by other workers [25], is undoubtedly ascribable to hydrate formation. The picrate melted at 122° (literature values [23,25] 122°.)

(±)-3-Hydroxybutyl iso*thiocyanate* (XIV). The above amine (3.6 g), dissolved in saturated $NaHCO_3$-solution (150 ml), was vigorously stirred with a solution of thiocarbonyl chloride (4.73 g) in chloroform (100 ml), until the red colour had disappeared. The chloroform layer was washed with dilute HCl and water, dried and distilled to remove the solvent. The residual oil was fractionated *in vacuo* to give a pure preparation (1.08 g) of the almost colourless mustard oil, b. p. 89°/0.5 mm, n_D^{25} 1.5267. (Found: C 45.95; H 6.96; N 10.50. Calc. for C_5H_9NOS: C 45.77; H 6.92; N 10.68.)

(±)-1-(3-Hydroxybutyl)-thiourea. A solution of the mustard oil (XIV) (150 mg) was kept in ammonia-saturated chloroform (75 ml) for 12 h. Removal of the solvent left a syrup which crystallized in contact with nitromethane to give the colourless thiourea (37 mg), which was recrystallized from the same solvent before analysis, m. p. 115°. (Found: C 40.49; H 8.09; N 18.80. Calc. for $C_5H_{12}N_2OS$: C 40.53. H 8.17; N 18.91.) In *n*-butanol-ethanol:water (4:1:4) the thiourea travels with an R_F-value of 0.64.

(±)-6-Methyl-tetrahydro-1,3-oxazine-2-thione (XII). A chloroform solution of 3-hydroxybutyl mustard oil, prepared from 3.78 g of 4-amino-2-butanol, as described above, was stirred with 1 N NaOH for 2 h at room temperature. After acidification, the organic phase was separated, dried and concentrated to yield a crystalline crop, embedded in an oil. The latter was removed by ether treatment and subsequently demonstrated to consist essentially of non-cyclized mustard oil.

The crystalline fraction (1.15 g) was purified by repeated recrystallizations from chloroform-pentane mixtures to give colourless needles, m. p. 142°. (Found: C 45.55; H 6.85; N 10.50. Calc. for C_5H_9NOS: C 45.77; H 6.92; N 10.68.) λ_{max}^{EtOH} 250 mμ (ε 15 500). The ring-compound travels in chloroform with an R_F-value of 0.82 (R_{Ph} 1.05).

3-Hydroxy-3-methyl-butyronitrile. 1-Chloro-2-methyl-2-propanol [26] (33 g) was dissolved in ethanol and placed together with excess NaCN in a round-bottomed flask, equipped with a reflux condenser, and heated locally to start an exothermic reaction. After this had ceased the mixture was gently refluxed for 1 h. The solvent was then removed, water was added and the reaction products extracted with ether. Distillation gave the pure cyanohydrin (21 g), b. p. 114°/30 mm, n_D^{25} 1.4277. (Found: C 60.80; H 9.08; N 13.90. Calc. for C_5H_9NO: C 60.59; H 9.15; N 14.14.)

The hydroxynitrile has been previously reported, yet with a deviating b. p., *viz.* 130—132°/30 mm (n_D 1.42911) [27].

4-Amino-2-methyl-2-butanol. Reduction of the above hydroxynitrile (10 g) with $LiAlH_4$ (7.6 g) in the usual way gave, after two distillations, the colourless amine as a viscous oil (5.3 g), b. p. 71.5°/10 mm, n_D^{25} 1.4484. (Found: C 58.20; H 12.65; N 13.63. Calc. for $C_5H_{13}NO$: C 58.19; H 12.70; N 13.58.)

A poorly characterized specimen of the same amine was reported by Barger and White [28] as a hydrolysis product of hydroxydihydrogalegin and also as a product resulting from the reaction between 4-amino-2-methyl-2-butene and dilute sulphuric acid.

1-Benzyl-3-(3-hydroxy-3-methyl-butyl)-thiourea. A solution of the above amine (300 mg) and benzyl *iso*thiocyanate (420 mg) in dry ether (20 ml) deposited after 0.5 h at room temperature a crop (594 mg) of almost pure thiourea. An analytical specimen was secured by two recrystallizations from aqueous ethanol, m. p. 127°. (Found: C 61.93; H 7.86; N 10.92. Calc. for $C_{13}H_{20}N_2OS$: C 61.86; H 7.99; N 11.05.)

3-Hydroxy-3-methyl-butyl iso*thiocyanate* (XV). 4-Amino-2-methyl-2-butanol (3.10 g) was treated with thiocarbonyl chloride (3.45 g) in bicarbonate solution exactly as described above for the lower homologue, to give 1.73 g of redistilled mustard oil, b. p. 77°/0.3 mm, n_D^{25} 1.5220. (Found: C 49.70; H 7.49; N 9.58. Calc. for $C_6H_{11}NOS$: C 49.63; H 7.64; N 9.65.)

1-(3-Hydroxy-3-methyl-butyl)-thiourea. This derivative was prepared from the above mustard oil (200 mg) and ammonia-saturated chloroform as described above for the lower homologue. The pure thiourea (150 mg) was obtained after two recrystallizations from nitromethane, m. p. 99°. (Found: C 44.54; H 8.60; N 17.14. Calc. for $C_6H_{14}N_2OS$: C 44.39; H 8.69; N 17.26.) On paper chromatography in *n*-butanol:ethanol:water (4:1:4) the R_F-value 0.69 was determined.

6,6-Dimethyl-tetrahydro-1,3-oxazine-2-thione (XIII). When 3-hydroxy-3-methyl-butyl *iso*thiocyanate (200 mg) was treated for 15 min. in ethanol (2 ml) with 0.1 N NaOH (15 ml) and then brought to pH 7 with acid, ether extraction yielded the cyclized product in crystalline form. An analytical specimen (40 mg) separated from ethyl acetate-hexane mixtures as colourless, nacreous plates, m. p. 136°. (Found: C 49.56; H 7.69; N 9.56. Calc. for $C_6H_{11}NOS$: C 49.63; H 7.64; N 9.65.) λ_{max}^{EtOH} 251 mμ (ε 14 500). R_F in chloroform 0.90 (R_{Ph} 1.15).

(±)-1-Amino-2-methyl-2-butanol. Methyl ethyl ketone cyanohydrin (7.6 g) was smoothly reduced with lithium aluminium hydride (5.3 g) in anhydrous ether (200 ml) under the usual conditions. The resulting amino-alcohol was obtained after distillation as a viscous, colourless oil (3.2 g), b. p. 69°/12 mm. It was characterized as the *neutral oxalate*, separating from hot ethanol in nacreous plates, m. p. 193°. (Found: C 48.58; H 9.50; N 9.43. Calc. for 2 $C_5H_{13}ON$, $C_2H_2O_4$: C 48.62; H 9.52; N 9.45.)

The amino-alcohol has formerly been characterized as its nitrate [30] and its hygroscopic hydrochloride, the latter though with varying melting points [29,30].

(±)-5-Ethyl-5-methyl-2-oxazolidinethione (XVII). The above amine (2.5 g) was subjected to the general conditions designed by Hodgkins and Ettlinger [20] for mustard oil synthesis under non-aqueous conditions. The oily reaction product crystallized in a desiccator to the cyclic compound (1.20 g) of which an analytical specimen separated slowly from water as compact, colourless rhombs, m. p. 52–53°. (Found: C 49.15; H 7.57; N 9.58. Calc. for $C_6H_{11}NOS$: C 49.63; H 7.64; N 9.65.)

The valuable assistance of Dr. R. Gmelin in the preliminary phases of the present work is gratefully acknowledged. Microanalyses have been performed by Mr. P. Hansen at the Chemical Laboratory of the University of Copenhagen.

The work is part of investigations supported by *Statens Almindelige Videnskabsfond (The Danish State Research Foundation)* and *Carlsbergfondet (The Carlsberg Foundation)*. A special grant from *Kai Hansen's Fond* is also gratefully acknowledged.

Approximate Calculations of Mean Amplitudes of Vibration

S. J. CYVIN and J. BAKKEN

Institutt for teoretisk kjemi, Norges tekniske høgskole, Trondheim, Norway

The mean amplitudes of vibration for the interatomic distances in several four-atomic molecules are calculated by an approximate method, and the results are compared to the rigorously calculated values. The method is based on a four-constant approximation for the hyperbolic cotangent and gives the mean amplitudes with about 1/2 percent accuracy.

Morino *et al.*[1] have developed an approximate formula for calculating mean square amplitudes of vibration, assuming $\coth t = 1/t + t/4$. This approximation is applicable only for frequencies below 1 200 cm^{-1} and may give as much as 4 % error in the mean amplitude. In the present investigation, a four-constant approximation, *viz.*

$$\coth t = -\Theta_{-3}t^{-3} + \Theta_{-1}t^{-1} + \Theta_1 t - \Theta_3 t^3$$

has been applied. The resulting formula for the mean square amplitude may be written

$$\overline{R_i^2} = -\delta\ (\mathrm{FGF})^{-1}_{ii} + \gamma\ \mathrm{F}^{-1}_{ii} + \alpha\ \mathrm{G}_{ii} - \beta\ (\mathrm{GFG})_{ii}$$

where F and G denote the energy matrices introduced by Wilson [2], and

$$\alpha = h^2\Theta_1/16\pi^2 kT;\quad \beta = h^4\Theta_3/256\pi^4(kT)^3$$

$$\gamma = \Theta_{-1}kT\ :\quad \delta = 16\Theta_{-3}\pi^2(kT)^3/h^2$$

The contants Θ may be adjusted by a least-squares technique for a given interval of t. It has been possible to construct functions with at the most about 1 % deviation from the hyperbolic cotangent in the following intervals:

I	$t = 0.5$—4.0	(207—1 658 cm^{-1})
II	$t = 1.0$—5.5	(414—2 279 cm^{-1})
III	$t = 1.5$—6.5	(622—2 694 cm^{-1})
IV	$t = 2.0$—7.5	(829—3 108 cm^{-1})

Table 1. Calculated mean square amplitudes.

* Based upon the atomic weight units for masses and mdyne/Å for force constants.

The proper one of the alternatives I to IV should be selected according to the magnitude of the fundamentals contributing to the desired mean amplitude. The corresponding intervals of frequencies, referring to the temperature 298 °K, are included above. Thus the present formula will give not more than

Table 2. Mean amplitudes of vibration in Å units at 298 °K.

Molecule	Distance	Approximation I	II	III	IV	Rigorous
P_4	P–P	0.0534				0.0533 [8]
ND_3	N–D			0.0619		0.0618
	D–D			0.1042		0.1040
PH_3	P–H			0.0866	0.0862	0.0862 [8]
	H–H			0.1512	0.1514	0.1521 [8]

CH_3O	C–H				0.0798	0.0801 [8]
	C–O				0.0375	0.0372 [8]
	H–H				0.1201	0.1170 [8]
	O–H				0.0944	0.0912 [8]

about 0.5 % error in the mean amplitude for vibrational frequencies within the indicated intervals.

The method has been applied to several molecules with the results given in Table 1, which also includes the actual intervals of frequencies with references to the experimental data. The mean amplitudes calculated by the approximate method are given in Table 2. In accordance with the prediction, it is seen that most of the present results deviate less than 0.5 % from the rigorously calculated values. The mean amplitudes for NH_3 are not included in Table 2, because the extremely high frequency 3 337 cm^{-1} falls outside the chosen intervals. The approximation IV gives 0.0715 Å for N—H and 0.1227 Å for the H—H mean amplitude. When compared with the rigorously calculated values 0.0727 and 0.1236 Å, the errors 1.7 and 0.7 % are found for the N—H and H—H amplitudes, respectively.

Further details concerning the method and development of the formula is to be published later.

Fungus Pigments

X.* The Ultra-violet Absorption of Some Substituted 2,5-Diphenylbenzoquinones and their Leucoacetates

JARL GRIPENBERG

Department of Chemistry, Finland Institute of Technology, Helsingfors, Finland

The ultra-violet absorption spectra of a number of substituted 2,5-diphenylbenzoquinones and their leucoacetates have been determined. These spectra and their significance in structure determination are discussed.

During the investigation of aurantiacin, the most recently isolated member of the diphenylbenzoquinone pigments found in fungi, the ultra-violet absorption spectrum was of considerable help in the structure determination [1].

It was felt that a knowledge of the spectra of other substituted diphenylbenzoquinones might be of value in future work. The spectra of a number of such compounds were therefore measured in dioxan solution and the results are given in Table 1.

Dioxan was selected because it is the only suitable solvent which is not too polar in which all the compounds are sufficiently soluble. The spectrum of 2,5-diphenylbenzoquinone (I) in carbon tetrachloride has been published by Flaig *et al.*[2] and it agrees well with that obtained here. Murray [3] reported maxima at 388 and 494 mμ for polyporic acid (II) in pyridine; in this solvent, however, polyporic acid is present at least partly as an anion, and the absorption is therefore not comparable with the data given here.

All the spectra have two maxima, that at shorter wave-length being always the stronger. The spectra are divided clearly into two distinct groups by the position of the second maximum. In the first, substances I—VIII, this maximum lies between 330 and 350 mμ. In substances IX—XVI forming the second group, this maximum is at 380—405 mμ. On inspecting the structural features of the compounds in the two groups, it is obvious, that in all those belonging to the first group, R is either hydrogen or an acylated hydroxyl, while in the second group R is hydroxyl or methoxyl. The nature of the substituent

* In addition an inflexion at 260 mμ (4.45)

R′, on the other hand, seems to be much less important because both types of substituents occur in both groups.

A hydroxyl or methoxyl group in the *p*-position of the aromatic ring thus has a bathochromic effect, which disappears on acylation. A hydroxyl or methoxyl group attached directly to the quinone ring has no such effect and in fact a slight hypsochromic effect can be observed (Compare: II with I; VIII with VII; XI, XII, XIII and XIV with IX and X).

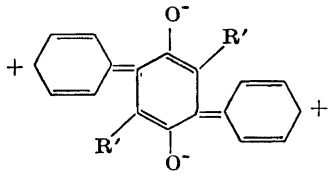
The effect of different substituents on the short wave maximum is more difficult to determine because in the substances with a benzoyl group the absorption of this group will appear in the same region and may thus mask the absorption of the parent substance. The contribution of the benzoyl group to the absorption is seen clearly in the higher extinction coefficient for the benzoates. The substance VIII forms a special case. In addition to the maximum at 242 mμ there is an inflexion at ~ 260 mμ (The complete absorption curve of this substance is reproduced in Part IV [1]). It is assumed that the maximum at 242 mμ is due to the benzoyl group and that the absorption of the other part of the molecule is responsible for the inflexion.

Hydroxyl or methoxyl groups in the *p*-positions have a bathochromic effect as is shown by comparison of IX and X with I and of XI and XIII with II. An apparent exception is formed by XV and XVI which show no bathochromic shift in the short-wave band in spite of a hydroxyl or methoxyl group in

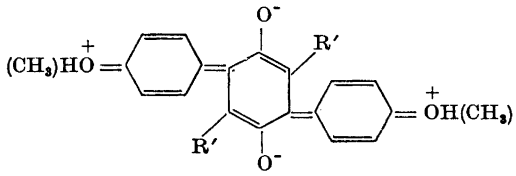
the *p*-position. This is probably the result of overlapping of the absorption referred to above.

Hydroxyl groups and to a lesser extent methoxyl groups in the quinone ring have a definite bathochromic affect on the short-wave band as is readily seen by a comparison of II with I, and of XI, XII, XIII and XIV with IX and X. The inflexion in VIII will also be due to such an effect. This bathochromic effect is at least partly removed by acylation (see III, XV and XVI).

The effect of the substituents in the *p*-positions on the long wave absorption maximum is readily understood, on the assumption that this absorption is the result of an electronic transition leading to excited forms such as A and B



A



B

that is, that the chromophore is composed of two benzylideneketone systems.

Table 2.

	max_1		max_2	
	mμ	log ε	mμ	log ε
	220.5	4.08	286	4.37
	234	4.01	323	4.37
	232	4.02	318	4.39
	223	4.06	290	4.36

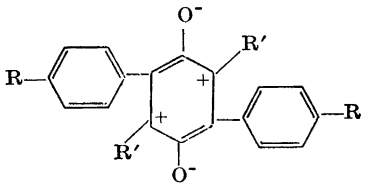
As can be seen from the figures reported in Table 2, which are taken from the work of Wilds *et al.*[4], the effect of a substituent in the aromatic ring in benzylideneacetone on the second maximum is of the same relative magnitude as in the diphenylbenzoquinones. The fact that the maximum in the diphenylbenzoquinones is at much longer waver-lengths than in similarly substituted benzylideneacetones shows clearly that the two benzylideneketone systems

which formally exist in the diphenylbenzoquinones are not independent of another, although they are neither conjugated nor cross-conjugated in the ordinary sense [5]. They are, however, both cross-conjugated with the same vinylketone system forming a kind of double cross-conjugated system, similar to that found for instance in benzil and vinylogous benzils [6,7].

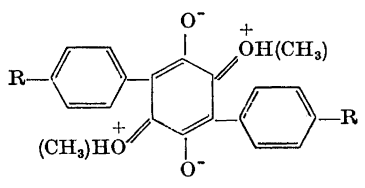
A possible explanation for the slight hypsochromic shift of the long-wave maximum observed when R′ is hydroxyl or methoxyl is given below.

For the maximum at shorter wavelenghts there are two obvious explanations: it may correspond either to the shortwave absorption of the benzylideneketone system or to that of the quinone ring. As can be seen from Table 2, the effect of the substitutes in the *p*-position on this band in the benzylideneacetones is the same as on the long-wave band, just as is observed in the diphenylbenzoquinones. It should, however, be noted that the shortwave maximum in the benzylideneacetones is weaker than the long-wave maximum, while the opposite is true for the diphenylbenzoquinones. Further the observed bathochromic effect of the hydroxyl or methoxyl groups in the quinone ring finds no obvious explanation in this way.

The second possibility referred to above, however, offer a ready explanation of this. According to Braude [8] the short-wave band of benzoquinone has its origin in an electronic transition leading to an excited state, which in the present cases would be C and D with a consequent bathochromic shift



C



D

when R′ is hydroxyl or methoxyl. Actually the bathochromic shift is smaller than expected on this assumption. For instance 2,5-dihydroxybenzoquinone has maxima at ~277 and 285 mμ and 2,5-dihydroxythymoquinone has a maximum at ~295 mμ [2]. One explanation for this would be that the electronic transition leading to D is in the opposite direction to that leading to A and B and may thus require more energy than in 2,5-dihydroxybenzoquinone and its homologues.

The bathochromic shift when R is hydroxyl or methoxyl is not readily explained in this way; the opposite effect, due to the counteraction of the two systems, would have been expected.

This counteraction of the two systems could, however, explain the hypsochromic effect on the second maximum, which is observed when R′ is hydroxyl or methoxyl.

It is obvious that neither of the two alternative explanations alone is quite satisfactory, and it may well be that both contribute to the formation of the short-wave band.

Brockmann and Budde [9] have devised a method by which the parent ring system of a polycyclic quinone is fixed by comparison of the UV-spectrum of the acetylated hydroquinone with that of the corresponding hydrocarbon. These usually differ only by a small bathochromic shift caused by the acetoxyl groups. It was of interest to see whether this method was applicable also to the diphenylbenzoquinones.

Table 3.

		max	
		mμ	log ε
XVII	R = $OCOCH_3$; R′ = R″ = H	260	4.40
XVIII	R = $OCOCH_3$; R′ = H; R″ = $OCOCH_3$	263	4.40
XIX	R = R′ = $OCOCH_3$; R″ = H	245	4.27
XX	R = R′ = R″ = $OCOCH_3$	249	4.35

Table 3 gives absorption maxima of the leuco-acetates of some of the diphenylbenzoquinones listed in Table 1. They are all at shorter wavelengths than that of terphenyl [10] (276 mμ). This hypsochromic shift instead of the expected bathochromic shift is by no means surprising. It is well known that substituents *ortho* to the central bond in diphenyl have a hypsochromic effect which has been attributed to non-coplanarity of the two rings due to steric hindrance [11]. Even a single methyl group is enough to produce this effect [12]. The same should also apply to derivatives of terphenyl, although very little is known about their spectra. Erdtman *et al.*[13] have shown that the spectrum of 2,5,2′,5′,2″,5″-hexa-acetoxy-*p*-terphenyl, an isomer of (XX), has a strong inflexion at ~250 mμ, and is thus in good agreement with that of XX, although this has a definite maximum.

The difference between those substances having only a single substituent adjacent to the connecting bonds between the aromatic rings and those having two substituents is also clerly revealed by the figures of Table 3.

In the spectra of aurantiacin leuco-acetate and the acetate of dihydroaurantiacin dibenzoate, recorded in a previous paper [14], the maximum due to the terphenyl system is covered by the strong absorption of the benzoyl group and occurs only as a weak inflexion at 260—270 mμ.

When allowance is made for this hypsochromic effect due to restricted rotation, it should be possible to identify diphenylbenzoquinones by the spectra of their leuco-acetates, and it is definitely possible to distinguish them from quinones derived from condensed hydrocarbons.

EXPERIMENTAL

All the quinones used in this investigation have been described before. The compounds V, VI, VII, VIII, XI, XV and XVI were obtained during work on the structure of aurantiacin [1]. XII, XIII and XIV were obtained from atromentin (XI) according to Kögl and Becker[15]. I, IX and X were synthesised according to the method of Pummerer and Prell[16] and II according to Frank and coworkers [17]. III and IV were obtained by acetylation of II and IX, respectively. All substances prepared in the present work had m. p. s in agreement with those given in the literature, except 3,6-dibromo-2,5-diphenylbenzoquinone, used as an intermediate in the synthesis of polyporic acid (II). Our sample had m. p. 232–233°, whereas Frank *et al.*[17] as well as Schildneck and Adams [18] report 223–224°. Dr. Frank has kindly informed us that the m. p. of his sample, determined now, is 233–234° and that he regards the earlier statement as a misprint.

The leuco-acetates were prepared by reductive acetylation of the corresponding quinones in the presence of pyridine. XVIII and XX have been described before [1,16]. XVII had m. p. 193–194°. (Found: C 76.28; H 5.24. $C_{22}H_{18}O_4$ requires C 75.85; H 5.29 %) and XIX m. p. 266–267°. (Found: C 66.60; H 4.72. $C_{26}H_{22}O_8$ requires C 67.52; H 4.80 %.) Both substances were recrystallised from acetic acid.

The spectra were measured with a Beckman Model DU Spectrophotometer. The dioxan, used as solvent, was purified by distillation over sodium.

The author wishes to thank Prof. R. Adams and Dr. R. L. Frank for their help in settling the reason for the differences in m. p. referred to above.

The Crystal Structure of Acetaldehyde-ammonia

EINAR WANG LUND

Kjemisk Institutt, Universitetet i Oslo, Blindern, Norway

In the solid state acetaldehyde-ammonia is found to be the trihydrate of trimethyl-hexahydrotriazine. The methyl groups are bonded equatorially to the carbon atoms of the hydrogenated triazine ring. The C—C and C—N distances are normal. Oxygen atoms of the waters of crystallization are interconnected by hydrogen bonds of length 2.70 Å to form a six-membered puckered ring. Hydrogen bonds probably exist between oxygen atoms and nitrogen atoms of adjacent rings.

In a previous short communication [1] a preliminary account of the crystal structure of acetaldehyde-ammonia has been given. This article is a more complete description of the structure.

The general tendency of aldehydes to polymerize has led several authors to the assumption that acetaldehyde-ammonia is a trimer. Among others Delépine [2] presented the idea that acetaldehyde-ammonia in the solid state actually is a trihydrate of 2,4,6-trimethyl-hexahydro-1,3,5-triazine. Delépine based this assumption mainly on the fact that the compound is easily dehydrated *in vacuo* over concentrated sulphuric acid. The anhydrous product formed under such conditions has been found by the author to cyrstallize in the cubic space group $Pa3$ with the lattice constant $a = 14.56$ Å.

The molecular structure proposed by Delépine was also the main result of an X-ray crystallographic determination made by Moerman [3]. The structure reported by Moerman was, however, rather improbable with respect to interatomic distances and bond angles. Therefore a re-investigation of the structure using Fourier methods has been carried out.

Crystals of acetaldehyde-ammonia in the form of rhombohedra were obtained by adding gaseous ammonia to an ice-cold solution of acetaldehyde in dry ether. Rotation and Weissenberg photographs showed that the Laue symmetry of the crystals is $D3d$- $3m$ and that the unit cell with hexagonal axes has the dimensions: $a = 11.29$ Å, $c = 15.87$ Å. With the value of the density reported by Moerman $d = 1.06$ gcm^{-3} these dimensions led to a number of 18 units of $CH_3CHO{\cdot}NH_3$ in the hexagonal unit cell. Inspection of Weissenberg diagrams showed no systematic extinctions of reflexions other than those given by a rhombohedral structure based on a hexagonal

unit cell. Therefore the possible space groups are D_{3d}^5—$R\bar{3}m$, D_3^7—$R32$ or C_{3v}^5—$R3m$. Of these only D_{3v}^5—$R\bar{3}m$ contains a center of symmetry.

The first X-ray study of acetaldehyde-ammonia was made by Hassel and Mark [4] who determined the cell dimensions and the space group. They based the space group determination on the statement made by Groth [5] that acetaldehyde-ammonia belongs to the ditrigonal scalenohedral class D_{3d}—$\bar{3}m$. Hassel and Mark found therefore unambigously from the sets of reflexions present that the only possible space group is D_{3d}^5—$R\bar{3}m$.

In order to support the crystal class determination, investigation was made for the presence of piezoelectricity. This was kindly undertaken by Mr. Erik Blomgren at the Chemistry Department of the University of Uppsala, Sweden. Mr. Blomgren could state very positively that no piezoeffect was present. This negative result together with the statement of Groth and the fact that the space group $R\bar{3}m$ is the only of the three groups mentioned that has a 36-fold general position led to the choice of this space group as the most probable. The final result is considered to be a confirmation of the correctness of this choice.

The arrangement of symmetry elements in this space group is such that any Fourier projection will give considerable amount of overlap of nonequivalent atoms and no resolved peaks suitable for determination of atomic coordinates. Therefore the computation of a Fourier section was considered necessary in order to get details of the structure. The asymmetric part of the "monomer" contains (apart from the hydrogen atoms) two carbon atoms, one nitrogen atom and one oxygen atom which have to be placed in one of the special 18-fold positions. The only possible one from steric considerations is that which involves a plane of symmetry. This plane with the equation $y = -x$ then contains all the important atoms in the asymmetric unit and is therefore highly suitable as the plane for a Fourier section.

In order to obtain the necessary intensities double sets of equi-inclination Weissenberg photographs were taken with Cu-K radiation. With rotation about c sets of photographs were from $l = 0$ to $l = 7$ and with rotation about a sets were taken for $h = 0$ to $h = 3$. Intensities of reflexions were estimated visually using a standard scale with known relative values. After correction for Lorentz and polarization factors the intensities were interrelated and brought to the same relative scale. Later the observed values of the structure factors were normalized to the set of calculated values.

The trial structure used in order to obtain signs of the structure factors was partly based on the main features of the structure of Moerman, *viz.* a hydrogenated, methyl substituted triazine ring with center in (0,0,z), the nitrogen atoms of the ring being loosely connected to oxygen atoms by means of hydrogen bonds. A satisfactory agreement between absolute values of observed and calculated structure factors was obtained with the parameter z having a value about 1/4 and oxygen atoms forming a puckered six-membered ring with center in $z = \frac{1}{2}$.

After some refinement, including the introduction of the effect of hydrogen atoms in the calculated structure factors, a final Fourier map was obtained which is reproduced in Fig. 1. In this map contour lines are drawn for arbitrary equidistant values of the function ϱ (x,$\bar{x}$,z). The peaks corresponding

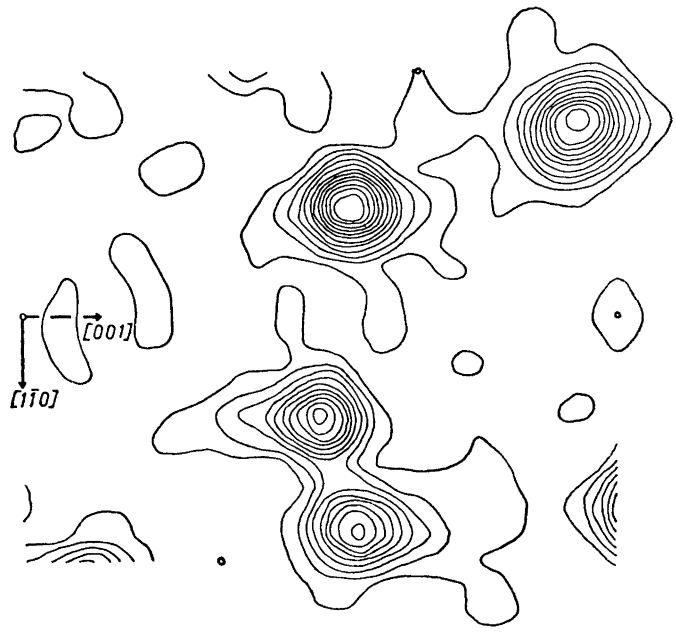

Fig. 1. Fourier section in the plane $y = -x$. Contour lines are drawn at arbitrary equidistant values of the function $\varrho\ (x,\bar{x},z)$.

to nitrogen, oxygen and two carbon atoms are well resolved and the positions of the maxima are assumed to determine atomic coordinates of these atoms which are listed in Table 1.

The main features of the structure formed by carbon, nitrogen and oxygen atoms can be described as follows. Alternating carbon and nitrogen atoms form a six-membered puckered ring of the *cyclo*hexane type. The N—C distance is found to be 1.47 Å. The angles in the ring, ∠NCN and ∠CNC are 114.6° and 109.0°, respectively. To each carbon atom of the ring is linked a methyl group in equatorial position. The C—C distance found is 1.53 Å. The angle between the C—C direction and the threefold axis (negative *c*-axis for the molecule in question) is found to be 109.1° whereas the angle ∠NCC amounts to 109.5°. The oxygen atoms closest to the substituted triazine ring are situated at a distance 2.87 Å from the nitrogen atoms. A hydrogen bond is probably established between these atoms. The angle between the N—O direction and the threefold axis is 115.5°. The N—O direction is thus not far from that corresponding to a bond directed equatorially away from the nitrogen atom.

Oxygen atoms more distant from the triazine ring in question lie at 3.20Å from the nitrogen atoms in a direction making 19° with the threefold axis. These oxygen atoms are, however, at the shorter distance of 2.87 Å from nitrogen atoms of other substituted triazine rings. On account of the symmetry

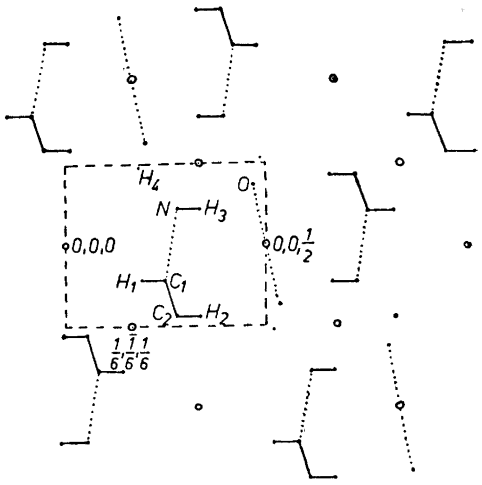

Fig. 2. General survey of positions of atoms and symmetry centers in the plane of the Fourier section. C—C, C—H and N—H bonds lying in the plane are shown by full lines. Nitrogen and carbon atoms belonging to the same hydrotriazine ring are interconnected by dotted lines; the same applies to oxygen atoms of one oxygen ring. The asymmetric unit of Fig. 1 is outlined by a broken line.

six oxygen atoms form a puckered ring. In this ring the O—O distance found is 2.70 Å and the angle ∠OOO is 106.3°. These oxygen atoms are therefore assumed to be interconnected by hydrogen bonds.

Introduction of hydrogen atoms in the calculation of structure factors improved the correspondence with the observed values. The positions of the hydrogen atoms were chosen from chemical facts using reasonable bond distances and valency angles. In spite of the trimerization of the molecule it is highly reasonable that the arrangement $CH_3 \cdot CH \cdot NH$ is retained whereas the remaining two hydrogen atoms of the monomer are probably connected to oxygen. For the methyl groups there are two equilibrium positions consistent with the presence of a symmetry plane through the C—C bond. The one which makes van der Waals' distances most favourable has a C—H bond parallel to the threefold axis. For steric reasons free rotation of methyl groups is improbable. The hydrogen atoms connected to carbon and nitrogen atoms of the ring are assumed to be in axial positions with C—H and N—H distances equal to 1.09 Å and 1.00 Å, respectively. These two hydrogen atoms and one of the methyl hydrogen atoms are thus assumed to lie in the plane of the Fourier section and the extensions of the peaks may indicate their presence.

Between two adjacent oxygen atoms of the oxygen ring one hydrogen atom is assumed to be located. The space group symmetry requires this hydrogen atom either to be located half way between the oxygen atoms or to be disor-

H_6	0.037	−0.173	0.509

derly distributed over two symmetrically located positions equidistant from the two oxygen atoms. The latter alternative was chosen, with O—H distance equal to 0.96 Å. For the calculation of structure factors this arrangement corresponds to placing half a hydrogen atoms in a general 36-fold position.

The position of the other hydrogen atom connected to oxygen was assumed to be equatorial to the oxygen ring with an angle ∠OOH equal to 109°. This hydrogen atom will then be located about 0.7 Å from the line of length 2.87 Å connecting the oxygen atom and the nearest nitrogen atom.

The coordinates thus chosen for hydrogen atoms and used in the calculation of structure factors are listed in Table 2. In Fig. 2 is shown the arrangement of atoms and symmetry centers over a greater area of the plane of the Fourier section with the inclusion of hydrogen atoms.

The atomic scattering factors used for carbon, nitrogen and oxygen are those calculated by Berghuis *et al* [6]. For hydrogen the scattering factor given by McWeeny [7] was applied. The calculated structure factors were corrected with an isotropic temperature factor $\exp(-B \sin^2\Theta/\lambda^2)$ with $B = 4.14$ Å^2. A test for an expected anisotropic vibration with the trigonal axis as a preferred direction had no positive result.

In Table 3 a list of observed and calculated structure factors is given. Calculated values for all 415 reflexions with $\sin\Theta/\lambda$ less than 0.6 are included. That only 136 reflecions are observed is partly due to too short exposure of Weissenberg diagrams of higher layer lines. Of the observed structure factors 96 % have a value greater than 10. It is assumed that the value 8 is an average lower limit of the values of structure factors which are observable from the diagrams taken. For unobserved reflexions only that part of a calculated structure factor which exceeds 8 is considered as an error in computing the R-factor.

The over all R-factor with the limit of 8 as observable is found to be 0.24. To this value the contribution from five of the strongest reflexions with $|F_{calc}| > 90$ is 0.04. These strongest reflexions are assumed to be affected by extinction and to be less accurately observed due to the difficulty in estimating their intensities visually. The R-factor for $hk0$-reflexions only is 0.10, for $0kl$-reflexions 0.24. To the latter value the strong reflexions mentioned contribute 0.07. The R-factor including only reflexions with $F_{obs} \neq 0$ is 0.16.

It is believed that the structure is more accurate than an over all R-factor of 0.24 generally would imply. The reasons for this are the difficulty in obtain-

ing reliable estimated values of intensities for higher layer lines, too short exposure time for some of the diagrams and extinction effects on five of the strongest reflexions.

The values of interatomic distances and bond angles given above and listed in Table 4 are assumed to be accurate to about one per cent. It is seen that the C—C and C—N bond lengths found are normal. The O—O distance and the shortest N—O distance are assumed to correspond to hydrogen bonds. In comparison with an ideal *cyclo*hexane ring the hydrotriazine ring does not have a center of symmetry geometrically, the angles at N and at C being somewhat different.

It may be of interest to point out that the six-membered ring formed by oxygen atoms in this structure is very similar to the structure element in

Intra- and Intermolecular Hydrogen Bonds in Nitro- and Nitrosophenols

PER M. BOLL

Department of Organic Chemistry, The Royal Danish School of Pharmacy, Copenhagen, Denmark

Nitro- and nitrosophenols are examined in the infrared part of the spectrum in the solid state as well as in solution in order to gain information on the relationship between molecular structure and intra- and intermolecular hydrogen bond formation.

2-Nitrophenols show intramolecular hydrogen bonding, whereas 3- and 4-nitrophenols show intermolecular hydrogen bonding, which is ruptured by solution. 2-Nitrosophenols (4-nitrosoresorcinol, 1-nitroso-2-naphthol) lack fundamental bands of hydroxyl absorption indicating that these compounds exist exclusively in the condition of a completely chelated system.

Additional evidence of the derivative formed by reacting morphine hydrochloride with nitrous fumes being 2-nitromorphine hydrochloride is given.

There has been some doubt about the derivative prepared when reacting morphine hydrochloride with nitrous fumes was a *nitroso* or a *nitro* compound. By chemical means Baggesgaard Rasmussen and Boll [1] found the compound to be 2-*nitro*morphine. Spectroscopically, in the infrared part of the spectrum a *nitroso* compound (N←→O) is characterized by only one absorption band whereas a *nitro* compound due to both symmetrical stretching (—N(→O)↙) and unsymmetrical stretching (N(→O)↖) is characterized by two absorption bands. All these bands have to be strong. The spectrum of the compound considered to be 2-*nitro*morphine hydrochloride has indeed such two bands at 1 525 and 1 530 cm^{-1}. These frequencies correspond closely to the frequencies expected for a *nitro* compound. A *nitroso* compound, on the other hand, should have given one band at 1 525 cm^{-1}.

The present work was planned in order to gain information on the relationship between molecular structure and intra- and intermolecular hydrogen formation in *nitro* and *nitroso*phenols. It was hoped that such information should give conclusive spectroscopic evidence of the aforementioned compound being 2-*nitro*morphine hydrochloride.

Since the infrared spectrum affords a picture of the molecule in its ground state it seemed that the infrared examination of the strength of chelation in *nitro*- and *nitroso*phenols through the hydroxyl band shift might afford the desired information. The hydroxyl bands in the 3 000—3 500 cm^{-1} region have been measured for some *nitro*- and *nitroso*phenols in solid state and in chloroform solution. The high frequency band is due to the free hydroxyl group and the low frequency band is due to the bonded hydroxyl group.

DISCUSSION

It has been known for a long time that 2-*nitro*phenol differs from its 3- and 4-isomers in many of its physical properties. The explanation has been that the former compound is chelated and not associated. The vibration corresponding essentially to the hydroxyl bond stretching for molecules containing this group gives absorption in the 3 000—3 500 cm^{-1} region and its

Table 1. Fundamental bands of hydroxyl and amine absorption in the infrared part of the spectrum.

Compound	Hydroxyl and Amine Band (cm^{-1}) Solid (KBr)	In $CHCl_3$	Conc.	Interpretation

2,4,6-Trinitrophenol	broad band	3 190 (weak)	0.025 M	intramolecular H-bond
1-Methyl-4,6-dinitrophenol	3 240	3 240	0.025 M	intramolecular H-bond

first overtone is found at about 7 000 cm^{-1}. Hilbert *et al.*[2] have studied the hydrogen bonding in the 7 000 cm^{-1} region for a large number of compounds containing phenolic hydroxyl groups and found that such a group forms a strong hydrogen bond with an oxygen atom of an adjacent *nitro* group. For example, 2-*nitro*phenol does not absorb radiation in this region indicating that the steric conditions for forming strong hydrogen bonds are satisfied, whereas 3-*nitro*phenol as well as 4-*nitro*phenol present strong absorption indicating absence of intramolecular hydrogen bonding.

The same conclusion can be drawn from Table 1. The position of the hydroxyl band of 2-*nitro*phenol does not shift by dissolving the compound, whereas those of both 3- and 4-*nitro*phenol shift. This observation can only be explained by intramolecular hydrogen bonding in 2-*nitro*phenol. The values recorded for 3-and 4-*nitro*phenol are close to the values given by Ginetti [3] who for both compounds found the hydroxyl band at 3 330 cm^{-1} and 3 520 cm^{-1} in chloroform and in solid state, respectively.

Furthermore, the finding of Amstutz *et al.*[4] that the fundamental band of hydroxyl absorption is lacking for 1-*nitroso*-2-naphthol, whereas 1-*nitro*-2-naphthol has a definite, although weak, band at approximately 3 250 cm^{-1}, has been confirmed. Besides, it was found that 4-*nitroso*-resorcinol only showed one band of hydroxyl absorption at 3 270 cm^{-1} corresponding to an intermolecular type of hydrogen bonding which was ruptured by solution and shifted to 3 580 cm^{-1}. 4-*Nitro*resorcinol, on the other hand, gave two bands of hydroxyl absorption corresponding to intermolecular as well as intramolecular hydrogen bonding. The lack of a fundamental band of hydroxyl absorption for 1-*nitroso*-2-naphthol and the presence of only one band of hydroxyl absorption for 4-*nitroso*resorcinol corresponding to intermolecular hydrogen bonding appears to be conclusive evidence that the phenolic hydroxyl group adjacent to the nitroso group is not free. This lack of hydroxyl absorption indicates that 1-*nitroso*-2-naphthol exists exclusively in the condition of a completely chelated system, whereas 4-*nitroso*resorcinol, besides possessing a completely chelated system, also is di- or polymerized. The existence of a resonance possibility with the corresponding quinone monoxime only tends to stabilize the chelated system:

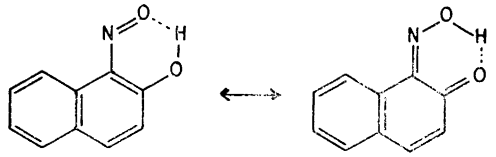

Fig. 1.

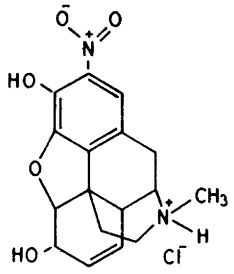
From the above mentioned observations it should now be possible to give additional evidence of the derivative prepared by reacting morphine hydrochloride with nitrous fumes being in fact 2-*nitro*morphine hydrochloride. If the compound had been 2-*nitroso*morphine hydrochloride, the infrared spectrum of the compound should only give two bands, namely from the alcoholic hydroxyl group and the substituted amino group, respectively. On the other hand, the infrared spectrum of 2-*nitro*morphine hydrochloride should, besides



2-Nitromorphine hydrochloride

Fig. 2.

showing the two aforementioned absorption bands, give a third band originating from a not completely chelated system consisting of the *ortho*-situated *nitro* and phenolic hydroxyl groups. From Table 1 is clearly seen that the compound which is thought to be 2-*nitro*morphine hydrochloride, indeed gives the three expected absorption bands. At this place it has to be mentioned that this conclusion is only valid if it be assumed that the alcoholic hydroxyl group and the substituted amino group in 2-*nitro*morphine hydrochloride each only gives one band of absorption.

Finally it can be seen from Table 1 that a *para*-substituted *nitroso*phenol gave the same type of intermolecular hydrogen bonding as the *para*-substituted *nitro*phenol, just as three different poly*nitro*phenols with the phenolic hydroxyl group *ortho* to the *nitro* group all showed intramolecular hydrogen bonding.

EXPERIMENTAL

The measurements were carried out with a Perkin-Elmer model 21 double beam spectrophotometer equipped with a rock salt prism.

For the bands due to unassociated molecules, solutions were made up to 0.025 M in chloroform *Merck* grade *pro analysi*. However, in some cases the components were not soluble to this extent and saturated solutions of the compounds in chloroform were used. The solutions were measured in 1 mm cells. In the reference beam chloroform was placed to compensate for the bands originating from the solvent.

Commercially available chemicals recrystallized from ethanol-water mixtures were used with the exception of the following compounds:

1-Nitro-*2-naphthol*. 1-*Nitroso*-2-naphthol was oxidized with nitric acid following the procedure of Fierz-David and Ischer [5]. Subjected to distillation with superheated steam the compound distilled over as orange-yellow crystals, which after recrystallization melted at 100—102°C (Lit. value [5] 102°C).

4-Nitroso*resorcinol*. Resorcinol was reacted with *iso*amyl nitrite in alkaline alcoholic solution according to Henrich [6]. After recrystallization from water the compound began to decompose at 110°C and turned black at 145°C.

4-Nitro*resorcinol*. The potassium salt of 4-*nitroso*resorcinol was oxidized with 3 % hydrogen peroxide according to Gilbert *et al.*[7] The reaction mixture was acidified and extracted with ethyl ether. After evaporation of the ether, the compound was recrystallized from water. Its melting point, after quick dehydration, was 112—115°C (Lit. value [7] 115°C).

2-Nitro*morphine hydrochloride*. Morphine hydrochloride was reacted with nitrous fumes at −2 to −3°C using the modified procedure described by Baggesgaard Rasmussen and Boll [1]. The compound was recrystallized from N hydrochloric acid.

Acknowledgement. My sincere thanks are due to Professor Børge Bak, University of Copenhagen, for valuable advice.

The Constitution of the Formamidinium Disulphide Ion, from the Crystal Structures of the Diiodide and Dibromide

OLAV FOSS, JONAS JOHNSEN and OLE TVEDTEN

Chemical Institute, University of Bergen, Bergen, Norway

The unit cells of formamidinium disulphide diiodide (I) and dibromide (II) monohydrates, $[(H_2N)_2C-S-S-C(NH_2)_2]X_2 \cdot H_2O$, are: I, $a = 5.15$ Å, $b = 16.52$ Å, $c = 13.39$ Å; space group, D_{2h}^{10}-$Pccn$ with $Z = 4$. II, $a = 8.61$ Å, $b = 5.12$ Å, $c = 12.40$ Å, $\beta = 99\frac{1}{2}°$; space group, $C_{2h}^{4}-P2/c$ with $Z = 2$. The structures have been determined by two-dimensional X-ray methods.

The crystals are built up of formamidinium disulphide cations and halide anions, and water of crystallization; the cation possesses, by space group requirements, a twofold axis of symmetry in both salts. The disulphide group has normal configuration and dimensions, with S—S = 2.04 Å, and ∠S—S—C = 99° and 104°, CSS/SSC dihedral angle = 105° and 89°, in I and II, respectively. The dimensions of the thiourea groups are as in the thiourea molecule before oxidation to formamidinium disulphide cation, but for a slight lengthening of the C—S bond. There is a small but not significant deviation from planarity of the thiourea groups, and no significant difference between the lengths of the two C—N bonds of a group. In both salts the water molecules lie on twofold axes, and each participates in hydrogen bonds with two halide ions and two nitrogen atoms.

Salts of formamidinium disulphide are formed from thiourea by the action of oxidizing agents such as chlorine [1], bromine [1–5], iodine [6–13], cupric ion [14,15], hydrogen peroxide [7,11,15,16], peroxydisulphate ion [8], peroxyacetic acid [15], sulphonyl chlorides [6], sulphuryl chloride [10], permanganate [7], and by anodic oxidation [17,18]:

$$2\ (H_2N)_2CS = [(H_2N)_2C—S—S—C(NH_2)_2]^{++} + 2\ e \qquad (1)$$

Conversely, the disulphide may be reduced to thiourea by means of sodium amalgam [1], hydrogen sulphide [2], nascent hydrogen [10], or cathodically [18]. The reaction of thiourea with iodine:

$$2\ (H_2N)_2CS + I_3^- = [(H_2N)_2C—S—S—C(NH_2)_2]^{++} + 3\ I^- \qquad (2)$$

leads to an equilibrium which can be readily approached from either side [6–13]. Thus, in dilute solutions thiourea may be titrated quantitatively with iodine [9], whereas on dissolving crystals of formamidinium disulphide diiodide in water [6,8,10], on addition of potassium iodide to a solution of the dichloride or other salts [6,8,10], or on addition of solvents of low ionizing power such as methanol, ethanol or acetone to an aqueous solution of the diiodide [8,10,13], iodine is liberated. From potentiometric measurements, Preisler and Berger [16] found the oxidation-reduction potential of the reversible thiourea-formamidinium disulphide system (1) to be 0.42 V at 30°C, referred to the normal hydrogen electrode, for solutions at constant ionic strength containing 0.05 N to 1 N hydrochloric acid. The results of Preisler and Berger have later been confirmed by Freedman and Corwin [19]. Together with the potential, 0.54 V, of the iodide-triiodide system, this gives $K = 10^4$ for the equilibrium constant of reaction (2), in close agreement with the value obtained by Mahr [12] from spectrophotometric measurements of iodine concentration in equilibrium mixtures.

A number of salts of formamidinium disulphide have been isolated and characterized. The sparingly soluble dinitrate [5-8,10,11,17] separates on addition of nitric acid or nitrates to solutions of other salts, or on oxidation of thiourea in presence of nitrate ions.

The salts show normal disulphide reactivity. Typical heterolytic cleavage of the S–S bond takes place in the reaction with cysteine (RSH) to produce [11] in the first step a mixed disulphide:

$$[(H_2N)_2C-S-S-C(NH_2)_2]^{++} + RS^- = [RS-S-C(NH_2)_2]^+ + (H_2N)_2CS \qquad (3)$$

and in the second step cystine:

$$[RS-S-C(NH_2)_2]^+ + RS^- = RS-SR + (H_2N)_2CS \qquad (4)$$

The hydrolysis of the disulphide [1,6], to give thiourea, sulphur and cyanamide, has been formulated thus [11]:

$$[(H_2N)_2C-S-S-C(NH_2)_2]^{++} + OH^- = [(H_2N)_2C-S-OH]^+ + (H_2N)_2CS \qquad (5)$$

with subsequent decomposition of the sulphenyl hydroxide, although it appears that an alternative mechanism involving a nucleophilic attack on carbon instead of sulphur cannot be excluded. Likewise, the reaction with cyanide ion [2], which leads to the same products as the hydrolysis reaction except for the formation of thiocyanate ion instead of sulphur, may be interpreted in terms of a nucleophilic attack of cyanide ion on sulphur, to give the species

$$[(H_2N)_2C-SCN]^+$$

as an intermediate. Heterolytic fission of the disulphide link has been considered [20] as a possible first step in the reaction of the disulphide with secondary and primary amines. The reaction of the disulphide with acetone and other ketones to give substituted 2-aminothiazoles [4] is likely to involve a first step analogous to halogenation reactions of ketones, to produce

$$[(H_2N)_2C-S-CH_2-\underset{\underset{O}{\|}}{C}-CH_3]^+$$

with subsequent ring closure under elimination of water.

The tetramethyl analogue of formamidinium disulphide has been isolated as the perchlorate by Lecher *et al.*[21], from the reaction of tetramethylthiourea with bromine. Sahasrabudhey [22,23] prepared also the chloride and bromide, and demonstrated the reactions:

$$[(Me_2N)_2C-S-S-C(NMe_2)_2]^{++} + 2\ S_2O_3^{--} = (S_2O_3)_2^{--} + 2\ (Me_2N)_2CS \qquad (6)$$

$$[(Me_2N)_2C-S-S-C(NMe_2)_2]^{++} + 2\ (H_2N)_2CS = [(H_2N)_2C-S-S-C(NH_2)_2]^{++} + 2\ (Me_2N)_2CS \qquad (7)$$

Eqn. (7) represents a readily displaceable equilibrium. Although quite different explanations are implicit in Sahasrabudhey's arguments, reactions (6) and (7) have the appearance of typical two-step nucleophilic displacements, involving heterolysis of the S—S bond of the original disulphide in the first step, and of the S—S bond of a mixed disulphide in the second step, like the two steps of the formamidinium disulphide-cysteine reaction given by Eqs. (3) and (4) above.

The disulphide nature of the salts is well established, and has indeed not been questioned until Sahasrabudhey [5,13,22,23] in 1951—53 argued that they were not disulphides, but monomeric compounds derived from a single thiourea molecule. His experimental results, of which some are referred to above, are in fact in complete accord with the disulphide formula, but were by Sahasrabudhey construed to imply a "rather unusual type of link" [23] between the oxidized thiourea residue and the anion, something like "a free radical, Weitz's or Wurster's salt" structure. His cryscopic measurements in glacial acetic acid [22,23] gave values of 190—220 for the molecular weight of the tetramethyl derivative of the dibromide, as compared with 212 required for the monomeric formula Me_2NCSBr; however, the results agree equally well with the double formula for a salt composed of three ions.

The present X-ray crystallographic work serves to establish the disulphide nature of the salts in the crystalline state. There should be no reason to suspect that the disulphide bond is not preserved in solution, insofar as cleavage through ordinary chemical interactions does not take place.

CRYSTAL DATA

Unit cell and space group data were derived from oscillation and Weissenberg photographs of single-crystal specimens. The axial lengths are based on $\lambda(\mathrm{Cu}K\alpha) = 1.542$ Å and are probably accurate to within 0.5 %. Densities were determined by flotation in mixtures of carbon tetrachloride with benzene or bromoform.

Formamidinium disulphide dichloride, $[(H_2N)_2CS]_2Cl_2$. Orthorhombic bipyramidal, $a = 10.54$ Å, $b = 19.75$ Å, $c = 8.85$ Å. There are eight formula units per unit cell; density, calc. 1.61, found 1.57 g/cm³. The space group, from systematic absences, is $D_{2h}^{15} - Pbca$. The crystals occurred as long prisms {021}.

Formamidinium disulphide dibromide monohydrate, $[(H_2N)_2CS]_2Br_2 \cdot H_2O$. Monoclinic, $a = 8.61$ Å, $b = 5.12$ Å, $c = 12.40$ Å, $\beta = 99\frac{1}{2}°$. Two formula units per unit cell; density, calc. 2.04, found 2.04 g/cm³. Systematic absences, $h0l$ when l is odd. These are characteristic of the space groups, $C_{2h}^4 - P2/c$ and $C_s^2 - P/c$, of which the former would require that the formamidinium disulphide ion possess a centre or a twofold axis of symmetry.

The crystals were obtained as plates {100}, or as flat prisms bounded by {100} and, less developed, {001}.

Formamidinium disulphide diiodide monohydrate, $[(H_2N)_2CS]_2I_2 \cdot H_2O$. Orthorhombic bipyramidal, $a = 5.15$ Å, $b = 16.52$ Å, $c = 13.39$ Å. Four formula units per unit cell; density, calc. 2.47, found 2.47 g/cm³. The space group, from systematic absences, is $D_{2h}^{10} - Pccn$, which has eightfold general positions, and centres of symmetry and twofold axes as special, fourfold positions.

The crystals were well developed prisms, elongated along the *a* axis and in most cases flattened along the *c* axis.

The diiodide (I) and later the dibromide (II) were chosen for further study. The results on II indicate that the centrosymmetric space group, C_{2h}^4 — $P2/c$, is the correct one. Twofold symmetry of the disulphide ion is thereby crystallographically required in both salts; of the two possibilities the molecular symmetry element was found to be a twofold axis and not a symmetry centre. The latter would have led to a planar, *trans* disulphide group; the only planar disulphide group yet found is the *cis* group occurring in thiuret hydroiodide [24].

A preliminary account of the structure of the diiodide has been published [25].

EXPERIMENTAL

The dichloride was prepared from thiourea in hydrochloric acid solution by oxidation with hydrogen peroxide as described by Preisler and Berger [16], the dibromide by slowly adding the equivalent amount of bromine to a 20 % aqueous solution of thiourea, under cooling in ice water, and the diiodide as described by Marshall [8], by gradually adding 5 parts of iodine crystals to 3 parts of powdered thiourea in 25 parts of water, and subsequent cooling.

The measured densities as compared with the X-ray densities, and the occurrence of peaks of reasonable height on the twofold axes in the electron density maps, leave no doubt that the crystals of I and II are monohydrates, although no mentioning of water of crystallization in these salts is found in literature. However, the analyses by McGowan [6] and Werner [10] of I and by Hunter and Jones [3] of II agree better with monohydrates than anhydrous salts. Boeseken [15] obtained the dichloride as a pentahydrate, whereas the present crystals, and preparations analyzed by earlier workers [6,18], were anhydrous.

For the structure determinations, the intensities of the $0kl$ and $hk0$ reflections of I and the $h0l$ and $0kl$ reflections of II were estimated visually from zero-layer Weissenberg photographs. Copper radiation was used, and crystals with cross-sections of 0.04 × 0.05 mm and 0.07 × 0.05 mm, respectively, for the *a*- and *c*-axis photographs of I, and 0.11 × 0.09 mm and about 0.1 × 0.1 mm, respectively, for the *b*- and *a*-axis photographs of II. The absorption coefficient for Cu$K\alpha$ radiation is 499 and 130 cm^{-1} for I and II, respectively. No corrections for absorption were made, and absorption effects are undoubtedly reflected in the temperature corrections later applied to the calculated structure factors. In the case of I, 98 out of 144 $0kl$ reflections and 48 out of 60 $hk0$ reflections within the range $\sin\Theta < 0.985$ were recorded with measurable intensity, the corresponding figures for II being 124 out of 130 $h0l$ reflections and 71 out of 81 $0kl$ reflections. They were converted to relative structure amplitudes in the usual way, and eventually put to an approximately absolute scale by comparison with the calculated values.

Viervoll and Ögrim's [26] atomic scattering curve for sulphur was used in the calculation of structure factors, and the curves of Berghuis *et al.*[27] for oxygen, nitrogen and carbon. The hydrogen contributions were ignored in both structures. For the iodide and bromide ions, curves were constructed based on the Thomas-Fermi values for xenon and krypton, respectively, at small scattering angles and for electroneutral iodine and bromine at intermediate and larger scattering angles.

Summations were made by means of Beevers-Lipson strips, at 12° intervals along the *a* axis of I and the *a* and *b* axes of II, and at 6° intervals along the other axes.

THE STRUCTURE ANALYSES

The structures were solved by use of the heavy atom method, the positions of the iodide and bromide ions being found from Patterson projections. Although the vector maps gave also the position of the one sulphur atom of the asymmetric unit, the signs used in the first F_o synthesis were in each case

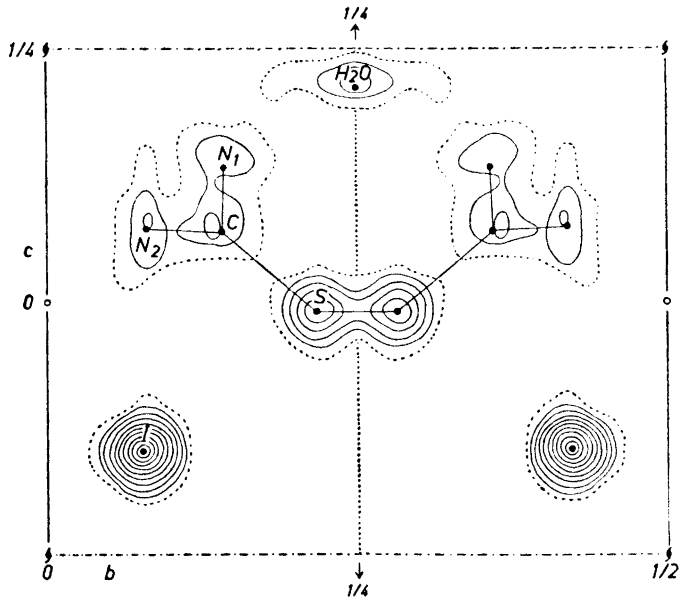

Fig. 1. Electron density projection of formamidinium disulphide diiodide monohydrate (I) along the *a* axis. The figure shows two asymmetric units. Contours at intervals of 10 e · Å^{-2} for the iodide ion, 5 e · Å^{-2} for sulphur, 4 e · Å^{-2} for oxygen and 3 e · Å^{-2} for the carbon and nitrogen atoms. The 3-electron line is dashed. The final atomic positions are marked with dots, and lines drawn to indicate the outline of the disulphide cation.

based on the contributions of the heavy atom alone, and the location of the sulphur peak appearing in the first electron density map was then checked against the coordinates derived from the vector map. In the projec-

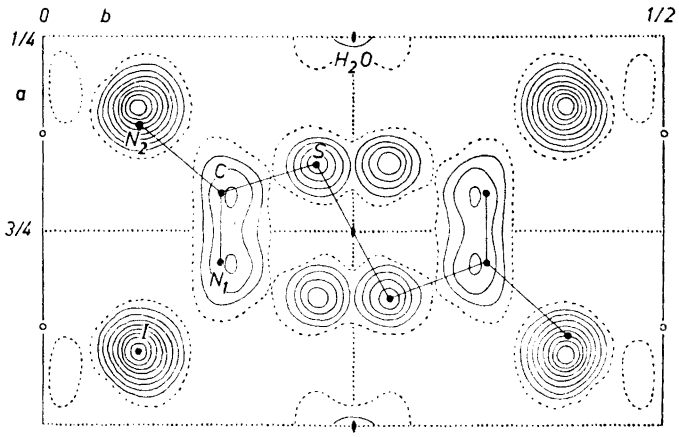

Fig. 2. Electron density projection of I along the *c* axis, showing four asymmetric units. The 6-electron line is dashed, and contours are at intervals of 10 e · Å^{-2} for the iodide ion and 5 e · Å^{-2} for the other atoms.

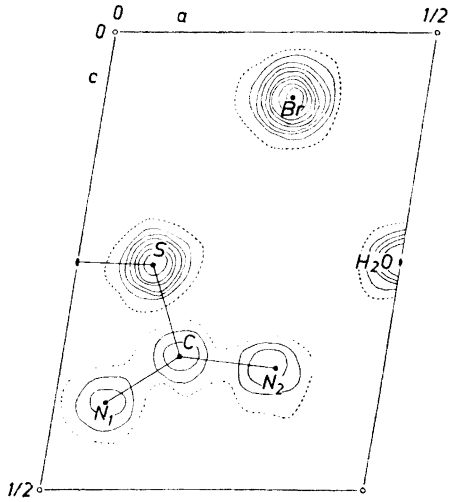

Fig. 3. Electron density projection of the asymmetric unit of formamidinium disulphide dibromide monohydrate (II) along the *b* axis. The 3-electron line is dashed, and contours are at intervals of 6 e · Å^{-2} for the bromide ion, 3 e · Å^{-2} for sulphur and oxygen and 2 e · Å^{-2} for carbon and nitrogen. The final atomic positions are marked with dots, and the outline of one thiourea group is drawn; the other thiourea group (not shown) of the disulphide cation lies on the other side of the twofold axis.

tion along the short axis of each salt, the approximate positions of also the lighter atoms could be determined from the first electron density map, whereas in the projection along the second longest axis, overlapping occurred, of iodine and nitrogen and of carbon and nitrogen in the *c*-axis projection of I, and of carbon and nitrogen and of sulphur and oxygen in the *a*-axis projection of II. The *y* coordinates in the case of I, and *z* coordinates in the case of II, of the overlapped lighter atoms were at first put equal to those determined from the better resolved short-axis projections, and preliminary *x* and *y* coordinates, respectively, were assigned on the basis of assumed bond lengths and angles. When F_o refinement had led to the determination of the sign of all but a few very weak reflections of a zone, further refinement was carried out by means of repeated $(F_o - F_c)$ syntheses.

The two electron density projections of the diiodide are shown in Figs. 1 and 2, and those of the dibromide in Figs. 3 and 4. The atomic coordinates are given in Tables 1 and 2. In the case of II, Table 2, the coordinates used for the last structure-factor calculations were corrected on the basis of the gradients still present at some atomic positions in the last difference map for each zone. Two sets of *z* coordinates for II were obtained, one from each zone; where the corrected values differed the final value was taken as the mean of the two, weighted according to their apparent reliability. The two sets of *y* coordinates for I, used together with the *x* and *z* coordinates of Table 1 for the last structure-factor calculations, were: $y(\mathrm{I}) = 0.0782$ and 0.0785, $y(\mathrm{S}) = 0.2195$ and 0.2185, $y(\mathrm{C}) = 0.139$ and 0.144, $y(\mathrm{N_1}) = 0.140$ and 0.145, $y(\mathrm{N_2}) = 0.080$

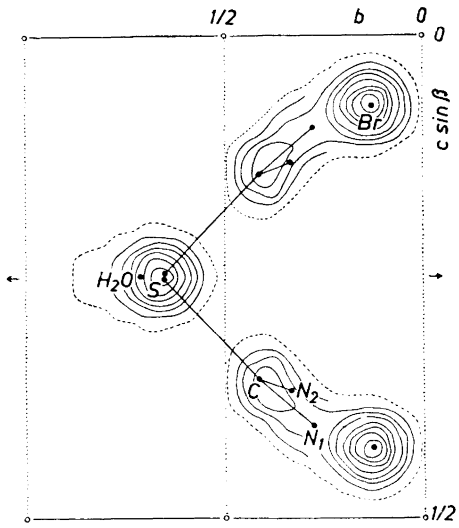

Fig. 4. Electron density projection of II along the *a* axis. One disulphide cation (two asymmetric units) is shown. The 6-electron line is dashed, and contours are at intervals of 6 e . Å^{-2} for bromine, sulphur and oxygen, and 3 e . Å^{-2} for carbon and nitrogen. The map shows that the final atomic positions (marked with dots) correspond to not quite planar thiourea groups, and that the best plane of a group is nearly parallel to the projection axis.

and 0.079, from the 0*kl* and *hk*0 data, respectively. The *y* values of Table 1 are in the case of C, N_1 and N_2 from the 0*kl* data; for I and S they are weighted means.

Table 1. Atomic coordinates for formamidinium disulphide diiodide monohydrate, in fractions of cell edges. Origin at a centre of symmetry.

	x	*y*	*z*
I	0.428	0.0783	0.3547
S	0.578	0.2192	−0.008
C	0.665	0.139	0.071
N_1	0.850	0.140	0.136
N_2	0.481	0.080	0.076
H_2O	0.250	0.250	0.214

In Tables 3 and 4, observed and calculated structure factors are listed for the 0*kl* zone of I and the *h*0*l* zone of II. In the temperature factor exp $[-B(\sin^2\Theta/\lambda^2)]$ applied to the calculated structure factors, the final values of B were chosen on the basis of the difference maps, and were as follows, in Å^2 units: In the 0*kl* zone of I, $B = 2.4$ for iodine, 2.2 for sulphur, and 2.6 for the lighter atoms, while in the *hk*0 zone, $B = 2.0$ for sulphur, 2.8 for the lighter atoms, and $2.4 + 1.4 \cos^2\varphi$ for iodine, where φ is the angle between the normal of the reflectiong plane and the direction of maximum

vibration of the atom, the a axis. In the $h0l$ zone of II, $B = 3.2$ for all atoms except bromine, where $B = 3.0 + 0.8 \cos^2\varphi$. Here, the direction of maximum vibration made an angle of about 44° with the a axis in the acute angle. In the $0kl$ zone of II, $B = 4.5$ for bromine, 2.0 for carbon and 4.0 for the other atoms.

The strong reflections, 060 of I and 200 and 302 of II have $|F_o|$ values markedly lower than the calculated ones. The two last reflections were omitted from the difference syntheses and the calculations of scale factor for the zone while the first one was, rather arbitrarily, included in the difference syntheses with half weight.

H_2O	0.500	0.711	0.250

The reliability index, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, with non-observed reflections included when $|F_c|$ exceeds the observable limit, is 0.089 and 0.097, respectively, for the $0kl$ and $hk0$ zones of the diiodide, and 0.068 for the $h0l$ zone (0.076 if the above-mentioned 200 and 302 reflections with low observed values are included) and 0.098 for the $0kl$ zone of the dibromide.

In the space group $Pccn$ of the diiodide, there is an uncertainty of $z = \frac{1}{4}$ with respect to location of symmetry centres which cannot be resolved from projections alone. That is because in the projection along the a as well as the b axis, symmetry centres, and twofold screw axes parallel to the projection axis and thus apparent symmetry centres, alternate at $c/4$ intervals along the c axis. Another uncertainty is that, once a set of coordinates for atoms of the disulphide cation has been chosen, there are two symmetry-related possibilities for the third coordinate of an iodide ion chosen in one projection. Both ambiguities can be resolved only by reference to hkl reflections with l

odd. In each case a choise was first made on the basis of calculated I—I and I—S distances, and the choise was later confirmed through comparison of calculated structure factors with rough intensity observations for a few representative *hkl* reflections.

ESTIMATE OF ERRORS

The standard deviations of atomic coordinates were estimated from the root-mean-square gradient of the difference maps and the curvature of the electron density peaks [28,29]. Where overlapping occurred, the s.d. was taken as about twice that which would otherwise have applied. In this way the following s.d. were obtained. In the diiodide, $\sigma(x) = 0.005$ Å, $\sigma(y) = \sigma(z) = 0.002$ Å for iodine; $\sigma(x) = \sigma(y) = \sigma(z) = 0.010$—0.012 Å for sulphur; $\sigma(x) = 0.04$—0.05 Å, $\sigma(y) = \sigma(z) = 0.02$—0.03 Å for carbon and nitrogen. In the dibromide, $\sigma(x) = \sigma(y) = 0.002$ Å, $\sigma(z) = 0.003$ Å for bromine; $\sigma(x) = \sigma(z) = 0.005$ Å, $\sigma(y) = 0.01$ Å for sulphur; $\sigma(x) = \sigma(z) = 0.015$—0.020 Å, $\sigma(y) = 0.03$—0.04 Å for carbon and nitrogen.

These values give standard deviations of 0.01 Å for the S—S bond length in the dibromide, and about 0.03 Å for S—C and C—N bond lengths. In the diiodide the corresponding figures are 0.02 Å and about 0.04 Å, respectively. For the S—S—C bond angle, $\sigma = 1°$ and 1—2°, and for S—C—N and N—C—N bond angles, about 2° and 3°, in the dibromide and diiodide, respectively. In both salts the S—S bond lies across a twofold axis, and the length is independent of the sulphur coordinate along the axis.

THE FORMAMIDINIUM DISULPHIDE ION

The salts are built up of disulphide cations and halide anions, and water of crystallization. The dimensions of the cation are listed in Table 5.

Table 5. Bond lengths and angles in the formamidinium disulphide ion.

	Diiodide	Dibromide		Diiodide	Dibromide
S—S	2.044 Å	2.044 Å	∠S—S—C	98.9°	104.0°
S—C	1.75	1.78	∠S—C—N_1	122.9°	121.2°
C—N_1	1.33	1.33	∠S—C—N_2	113.1°	118.3°
C—N_2	1.36	1.33	∠N_1—C—N_2	116.3°	119.0°
			Dihedral angle CSS/SSC	104.8°	89.2°

The S—S bond length is the same as in four other open-chain disulphides X—S—S—X for which data of comparable accuracy are available, namely 2.05 ± 0.02 Å in hydrogen disulphide [30], 2.04 ± 0.03 Å in dimethyl disulphide [30], 2.05 ± 0.02 Å in *bis*(trifluoromethyl) disulphide [31] and 2.04 ± 0.005 Å in N,N'-diglycyl-L-cystine dihydrate [32]. Also, the sulphur valency angle and the dihedral angle of the disulphide group lie in the normal range, *cf.* the recent review by Abrahams [33].

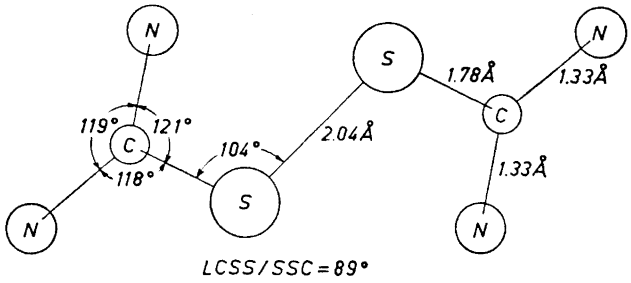

Fig. 5. The formamidinium disulphide cation as seen along the *b* axis of the dibromide.

The thiourea groups are planar within the accuracy of the atomic coordinates. Least squares planes through the four atoms of the group, with the sulphur coordinates given three times the weight of the carbon and nitrogen coordinates, have the equations

$$0.5340\ X - 0.4554\ Y - 0.7124\ Z = 0.023 \quad \text{(Diiodide)}$$
$$0.0573\ X + 0.6852\ Y + 0.7261\ Z = 4.582 \quad \text{(Dibromide)}$$

where X, Y and Z are in Å, in the case of the dibromide not referring to the axes of the monoclinic unit cell but to orthogonal axes a, b and c' where c' is normal to a and b. The planes pass at shortest distances of —0.006 Å from S, +0.083 Å from C, —0.036 Å from N_1 and —0.027 Å from N_2 in the diiodide, and at —0.007 Å from S, +0.068 Å from C, —0.022 Å from N_1 and —0.020 Å from N_2 in the dibromide. In view of the relatively large standard deviations of the coordinates of the lighter atoms, the displacements of the atoms from the planes can hardly be considered significant. On the other hand, it is known [34] that packing forces in crystals may cause distortions from planarity, of molecules or groups otherwise planar. As pointed out by Wheatley [35] with reference to ethylenethiourea, "distortions by crystal forces of molecules placed in unsymmetrical surroundings should be quite common". A decision is not possible in the present cases, although in the diiodide there is an indication that the distortion is real: As discussed later, the CN_1N_2 plane, $0.5548\ X - 0.6803\ Y - 0.5953\ Z = 0.001$, passes nearly equidistant between two iodide ions, and appears to allow a more reasonable location of amino hydrogen atoms than does the least-squares thiourea plane.

The two C—N bonds of a thiourea group have the same length, the slightly larger value for C—N_2 (1.36 Å) in the diiodide relative to the three other values of 1.33 Å being well within the experimental uncertainty. In fact, the thiourea groups are as in the thiourea molecule before oxidation of formamidinium disulphide, but for a slight but probably significant lengthening of the C—S bond relative to thiourea. According to a recent redetermination of the crystal structure of thiourea by Truter[36] the thiourea molecule is planar, with C—S = 1.710 ± 0.01 Å, C—N = 1.332 ± 0.01 Å, and ∠ N—C—N = 115°. The C and S atoms lie in a mirror plane which passes midway between the N atoms. Wheatley [35] found the same length, 1.708 ± 0.01 Å, for the C—S bond in

ethylenethiourea, and deduced a value of 22 % double-bond character for a C—S bond of this length. Abrahams' bond length-bond order curve [33], based on 1.61 Å for a double and 1.82 Å for a single C—S bond, gives about 65 %. Although thus the bond order data are conflicting it seems certain that the C—S bond of thiourea possesses a considerable degree of double-bond character; whether or not some is retained in formamidinium disulphide cannot be decided on the basis of the rather inaccurate values of 1.75 Å and 1.78 Å for the bond, but appears probable since interaction of the lone electrons of sulphur (a $p\pi$ pair or one of two sp^3 π pairs) with the $p\pi$ orbital of the sp^2-hybridized carbon atom is still possible. The concerned sulphur and carbon π orbitals are approximately parallel, the normal of the SSC plane making an angle of 14° with the normal of the least-squares plane of the thiourea group in the diiodide, and 6° in the dibromide.

The relative orientation of the two thiourea groups of a formamidinium disulphide cation is slightly different in the two salts. Such differences may be expected to arise, from different packing forces in the crystals, and they manifest themselves in three ways: The sulphur valency angle is 99 ± 1—2° in the diiodide and 104 ± 1° in the dibromide. Although on the basis of the standard deviations the difference may not be real, the statistically more accurate S—S—G angles, where G is the centre of gravity of the thiourea group (the sulphur coordinates given three times the weight of those of the lighter atoms) are also different, namely 101° in the diiodide and 104° in the dibromide. Furthermore, a difference in the degree of rotation about the

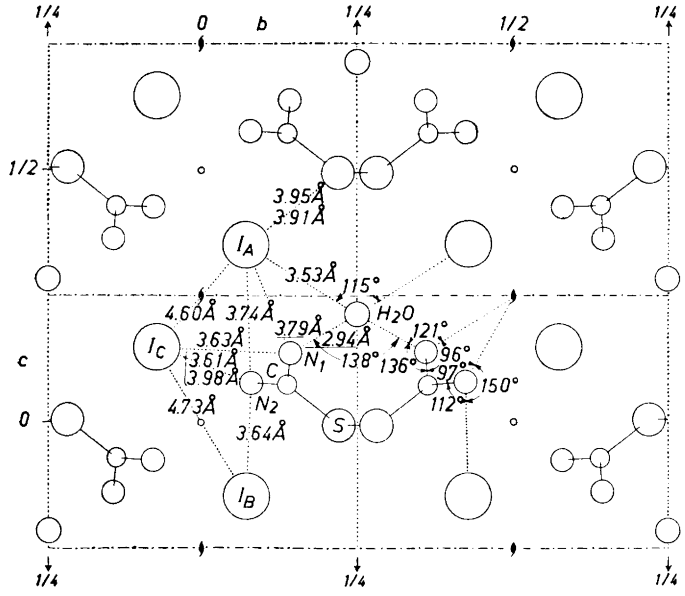

Fig. 6. The atomic arrangement in formamidinium disulphide diiodide monohydrate as seen along the *a* axis. Some non-bonded approaches and distances and angles relevant to the location of the hydrogen atoms are indicated.

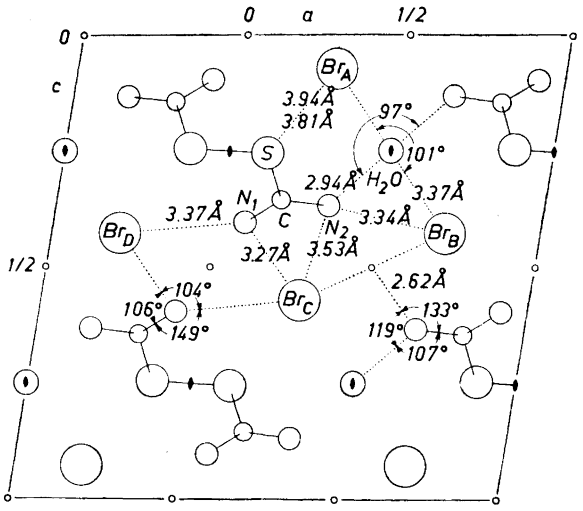

Fig. 7. A view along the *b* axis of the dibromide (one and a half unit cell) with interatomic approaches indicated as in Fig. 6.

S—S bond occurs, as expressed in the dihedral angles CSS/SSC which are 105° in the diiodide and 89° in the dibromide. Third, the sulphur atom of one thiourea group lies 0.48 Å from the least-squares plane of the other thiourea group in the diiodide and 0.22 Å in the dibromide, corresponding to different degrees of rotation, about the S—C bond, of the sulphur atom out of the plane.

THE PACKING IN THE CRYSTALS

The standard deviations of electron density, evaluated as the root-mean-square of the figures in the difference maps, are 0.46 and 0.65 e.Å^{-2}, respectively, for the *h*0*l* and 0*kl* zones of the dibromide, and 0.84 and 1.5 e.Å^{-2}, respectively, for the 0*kl* and *hk*0 zones of the diiodide. Any peak in the difference maps which might indicate positions of hydrogen atoms would therefore not be significant. In the following, the amino hydrogen atoms are assumed to be located in or not too far from positions corresponding to planar sp^2-hybridized nitrogen, as in urea and thiourea. They will be discussed with reference to the least-squares plane of the thiourea group in the dibromide, and to the CN_1N_2 plane in the diiodide, since this leads to slightly more reasonable hydrogen positions is some cases.

The atomic arrangements as seen along the shortest axis of each crystal are shown in Figs. 6 and 7.

Diiodide. The water molecule, located on a twofold axis at $\frac{1}{4},\frac{1}{4},z$ with $z = 0.214$, lies 3.53 Å from iodide ion I_A and the corresponding iodide ion on the other side of the twofold axis. The angle I—H_2O—I is 115°, and it seems probable that the water molecule forms hydrogen bonds to these iodide ions. Jellinek [37] reports a length of 3.57 Å for a O—H···I hydrogen bond in

muscarine iodide. The same water molecule participates with its two lone electron pairs in N—H···O hydrogen bonding from two nitrogen atoms, at a distance of 2.94 Å and a N—H_2O—N angle of 138°. These nitrogen atoms are $N_{1(\bar{1}00)}$, in an adjacent unit cell along the a axis, and N_1', in the same unit cell but on the other side of the twofold axis, and belong to different formamidinium disulphide cations. This leads to the occurrence in the crystal of infinite helical chains parallel to the a axis, of alternating formamidinium disulphide cations and water molecules, with one of each per turn of the helix, and $a = 5.15$ Å as repeat distance. The C—N—H_2O angle is 136° and the oxygen atom lies 10°, as seen from the nitrogen atom, out of the CN_1N_2 plane. Each oxygen atom thus participates in four hydrogen bonds, with atoms which form a distorted tetrahedron about it; two of the relevant angles are given above and the other four are I—H_2O—N_1' = 120°, I—H_2O—$N_{1(\bar{1}00)}$ = 71°, and a corresponding pair on the other side of the twofold axis.

Each of the two iodide ions forms, in directions 87° and 67° away from the water molecule, close contacts (3.91 Å and 3.95 Å) with two sulphur atoms ($\angle$S—I—S = 82°) of an adjacent helix, related to the first through the operation of the glide plane c normal to the a axis. The sulphur atoms belong to different disulphide cations, in adjacent unit cell along the a axis. Four such I—S contacts occur per turn of the helix, one of each length on each side of the twofold axis. Each iodide ion also forms two fairly close contacts with other iodide ions, in directions away from the helixes, namely 4.60 Å over the nearest screw axis parallel to the a axis, and 4.73 Å over the nearest symmetry centre.

One of the four amino hydrogen atoms of each thiourea group has so far been accounted for, through hydrogen bonding to water. There are short approaches between the nitrogen atoms and the iodide ions I_A and I_C (at $\frac{1}{2} + x, \bar{y}, \frac{1}{2}-z$; related to I_A through the operation of the screw axis at $x,0,\frac{1}{4}$): N_1—I_A = 3.79 Å, N_1—I_C = 3.63 Å, N_2—I_A = 3.74 Å, N_2—I_C = 3.61 Å. Expected length of a N—H···I hydrogen bond would be in this range, judging from values listed for N—H···Cl bonds [38]. However, I_A lies — 2.36 Å and I_C lies + 2.24 Å out of the CN_1N_2 plane, so that linear hydrogen bonds are improbable *. Now, the line joining I_A and I_C is normal to the CN_1N_2 plane (I_A—I_C = 4.60 Å), and the midpoint P between I_A and I_C, on the screw axis, is only —0.06 Å out of the plane, and 2.91 Å from N_1 and 2.86 Å from N_2. It appears likely that one N_1—H and one N_2—H bond are directed, not towards I_A or I_C but towards their midpoint, or nearly so. The relevant angles at N_1 and N_2 are: C—N_1—P = 96°, $H_2O_{(100)}$—N_1—P = 121°, C—N_2—P = 97°. With a N—H bond length of 1.0 Å the hydrogen atoms would lie 2.9—3.0 Å from the iodide ions, each hydrogen atom forming two such contacts.

It remains to account for one N_2 hydrogen atom. N_2 lies 3.64 Å from I_B (at $\frac{1}{2}-x, y, z-\frac{1}{2}$, related to I_A through the glide plane c at $x = \frac{1}{4}$) and 3.98 Å from $I_{C(\bar{1}00)}$. These two iodide ions are 4.73 Å apart, and are related through the symmetry centre at the origin. Both lie 0.62 Å out of the CN_1N_2 plane, their midpoint Q (the origin) lies in the plane and 2.99 Å from N_2. There are

* The distances from I_A and I_C to the least-squares plane of the thiourea group are —2.82 Å and +1.73 Å. The midpoint between I_A and I_C lies —0.54 Å out of the least-squares plane.

then two directions of the second N_2—H bond to consider, namely, towards I_B or towards the midpoint Q between I_B and $I_{C(\bar{1}\,0\,0)}$. The angles, C—N_2—I_B = 112°, P—N_2—I_B = 150°, C—N_2—Q = 112°. It appears that a direction intermediate between these two would give reasonable valency angles at N_2.

Dibromide. The expected lengths of N—H···Br and O—H···Br hydrogen bonds, from analogous bonds involving chloride, are about 3.3 Å.

The environment of the water molecule is as in the diiodide. The molecule lies on a twofold axis, at $\frac{1}{2},y,\frac{1}{4}$ with $y = 0.711$, and participates in hydrogen bonding to two bromide ions, above, and from two amino nitrogen atoms, below as seen down the twofold axis, one of each kind on each side of the axis, and in an approximately tetrahedral arrangement. The bromide ions are $Br_{A(010)}$, in an adjacent cell along the *b* axis, and $Br_{B(010)}$, related to the first through the twofold axis. The coordinates of Br_A are those listed in Table 2. The distances O—H···Br = 3.37 Å and N_2—H···O = 2.94 Å, and the angles, Br—H_2O—Br = 101°, N_2—H_2O—N_2 = 97°, $Br_{A(010)}$-H_2O-N_2 = 120° and $Br_{B(010)}$—H_2O—N_2 = 110°. The angle C—N_2—H_2O is 107°, and the water molecule is 0.35 Å out of the least-squares plane of the thiourea group, or 7° as seen from N_2. Again the N—H···O hydrogen bonds lead to the occurrence of an infinite chain, parallel to the *a* axis, of alternating water molecules and formamidinium disulphide cations. The water molecules and the sulphur atoms of the cations lie approximately on a straight line, at $y = 0.65$—0.71 and $z = \frac{1}{4}$, with the N_2 atoms below at $y = 0.332$ and the bromide ions above at $y = 1.131$, on both sides of $z = \frac{1}{4}$. The distances from Br_A and $Br_{A(010)}$ to the sulphur atom of the thiourea group to which N_2 belongs are 3.94 Å and 3.81 Å, respectively.

The nitrogen atom N_2 lies 3.34 Å and 3.53 Å, respectively, from the bromide ions Br_B and Br_C, these two ions are 4.46 Å apart and are related through the symmetry centre P at $\frac{1}{2},0,\frac{1}{2}$, they lie —0.03 Å and + 0.12 Å, respectively, out of the least-squares plane of the thiourea group. The geometry is, however, not favourable for N—H···Br hydrogen bonding, the angle C—N_2—Br_B being 173°, H_2O—N_2—Br_B = 77°, C—N_2—Br_C = 94° and H_2O—N_2—Br_C = 156°. The symmetry centre P, midway between the bromide ions, is 2.62 Å from N_2 and 0.05 Å out of the least-squares plane, and the angle C—N_2—P = 133° and H_2O—N_2—P = 119°. It appears probable that a N_2—H bond is directed towards the symmetry centre, the hydrogen atom would then lie about 2.75 Å from both bromide ions.

The other nitrogen atom of the thiourea group, N_1, lies 3.27 Å and 3.37 Å, respectively, from the bromide ions Br_C and Br_D, related to each other through a symmetry centre at $0,0,\frac{1}{2}$. They are 0.12 Å and — 0.54 Å, respectively, out of the least-squares plane, or 2° and 9° as seen from N_1. The angles, C—N_1—Br_C = 106°, Br_C—N_1—Br_D = 104°, C—N_1—Br_D = 150°, are not quite satisfactory for hydrogen bonding; the valency angles at N_1 would become more equal if the two N_1—H bonds are directed not towards the bromide ions but slightly aside of the ions.

A hydrate structure analogous to the two present ones occurs in adenine hydrochloride hemihydrate [39], where the water molecule lies on a twofold axis with two chloride ions (O—H···Cl = 3.12 Å) and two nitrogen atoms (O···H—N = 2.87 Å) in a distorted tetrahedral arrangement about it.

The Crystal and Molecular Structure of Thiuret Hydroiodide

OLAV FOSS and OLAV TJOMSLAND

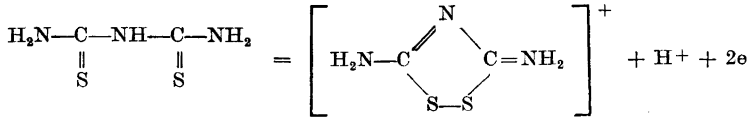
Chemical Institute, University of Bergen, Bergen, Norway

The crystal structure of the five-membered cyclic disulphide, thiuret hydroiodide, a 3,5-diamino derivative of 1,2,4-dithiazole, has been determined by two-dimensional X-ray methods. The disulphide group lies across a crystallographic mirror plane and is therefore planar, and the thiuret ion as a whole is planar or nearly so.

The crystals have four $[S_2(C-NH_2)_2N]I$ units in a cell based on the space group, D_{2h}^{16}-*Pnma*, with $a = 5.38$ Å, $b = 9.24$ Å, $c = 13.98$ Å. The dimensions of the thiuret ring were found to be, S—S = 2.09 ± 0.012 Å, S—C = 1.73 ± 0.03 Å, C—N = 1.31 ± 0.03 Å, ∠S—S—C = 92.4 ± 1°, ∠S—C—N = 118 ± 2°, ∠C—N—C = 117 ± 2°, and the exocyclic C—NH_2 bond, 1.36 ± 0.03 Å. Within the experimental accuracy the carbon valencies are trigonal planar.

Thiourea reacts with numerous oxidizing agents to give salts of formamidinium disulphide, which according to recent crystal structure determinations of the diiodide and dibromide monohydrates [1], contains a normal, non-planar disulphide group. Similarly, the formal condensation product of two moles of thiourea, dithiobiuret, undergoes reversible oxidation by such reagents as hydrogen peroxide, iodine, ceric salts, thallic salts, or formamidinium disulphide salts, to give compounds which are regarded as salts of the base, thiuret, or 3,5-diimino-1,2,4-dithiazolidine [2–5]. This is a five-membered cyclic disulphide.

Fromm [6] in 1893 first assigned the name, thiuret, and a disulphide formula, to an oxidation product of a dithiobiuret. Although a number of derivatives of dithiobiuret and thiuret were studied by Fromm and later workers [5], the synthesis of dithiobiuret itself was not achieved until 1943 [7], and its oxidation product (thiuret hydrochloride and hydroiodide) described in 1947 [2,3]. In this year, Preisler and Bateman [2] published a potentiometric study of the reversible dithiobiuret-thiuret system:



They found a value of + 0.25 V for the oxidation-reduction potential at pH = 0 and 30°C, referred to the normal hydrogen electrode, as compared with + 0.42 V for the potential of the thiourea-formamidinium disulphide system measured earlier by Preisler and Berger [8]:

$$2\ (H_2N)_2CS = [(H_2N)_2C—S—S—C(NH_2)_2]^{++} + 2e$$

Dithiobiuret is thus a markedly stronger reducing agent than thiourea. The acid dissociation constant of the monovalent thiuret cation was measured [2] as 4×10^{-8}. The free thiuret base has not been isolated, the salts being rapidly decomposed by alkalies with elimination of sulphur.

A survey [9] of unit cells and space groups of some 1,2,4-dithiazolidine derivatives, including thiuret hydrohalides, indicated the occurrence in the hydroiodide of a molecular mirror plane of symmetry and thereby of a planar *cis* disulphide group. This would be the first example of a planar disulphide group, all previous structure determinations of compounds of the type X—S—S—X having given a dihedral angle XSS/SSX of about 90°. The barrier towards rotation about the S—S bond, through the planar *cis* form with zero dihedral angle, has been estimated [10,11] as 10—14 kcal/mole. A preliminary account of the crystal structure of the hydroiodide was published at the same time [12].

CRYSTAL DATA

The salt was prepared by addition of an excess of aqueous potassium iodide to a warm aqueous solution of thiuret hydrochloride, and was recrystallized from water. The crystals are faintly yellow, m. p. (reported [3]) 247°C. They occurred as prisms extended along the *a* axis and bounded by {001} and {011}. There is perfect cleavage along the *c* plane, and a rather pronounced tendency of irregular growth and twinning, but crystals were found which gave satisfactory intensity photographs.

The crystals are orthorhombic, with the unit cell dimensions [9]: $a = 5.38$ Å, $b = 9.24$ Å, $c = 13.98$ Å (± 0.5 %). There are four $[S_2(C—NH_2)_2N]I$ units in the cell; density, calc. 2.50, found 2.49 g/cm^3. From the systematic absences, $0kl$ when $k + l$ is odd and $hk0$ when h is odd, and the subsequent structure analysis, the space group is D_{2h}^{16} — *Pnma*. The iodide ion and the ring nitrogen atom of the cation lie in the mirror plane of this space group, the other atoms are in general, eightfold positions. There are thus 13 positional parameters to be determined, excluding the hydrogen atoms.

THE STRUCTURE ANALYSIS

The intensities of the reflections of the three principal zones were estimated visually from zero-layer Weissenberg photographs. Copper radiation was used ($\mu = 438$ cm^{-1}) and crystals with cross-sections of 0.07 × 0.07 mm for the $0kl$ and $hk0$ zones and 0.07 × 0.03 mm for the $h0l$ zone. Out of 88 $0kl$, 93 $h0l$ and 33 $hk0$ reflections within the range $\sin \Theta < 0.985$, 83, 86 and 29, respectively, were observed and measured. The intensities were corrected for the Lorenz and polarization factors in the usual way, but not for absorp-

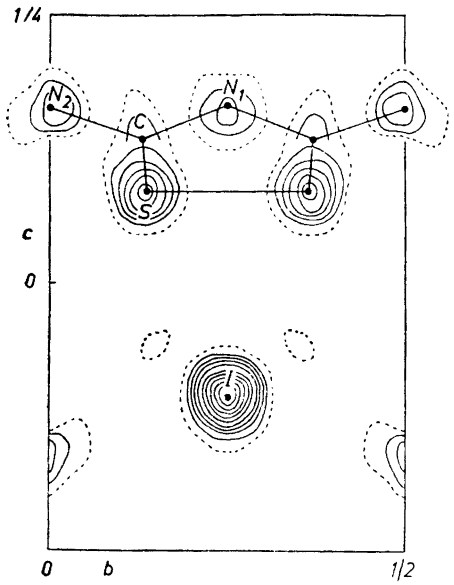


Fig. 1. Electron density projection of thiuret hydroiodide along the *a* axis. Contours at intervals of 10 e · Å^{-2} for iodine, 4 e · Å^{-2} for sulphur, 2 e · Å^{-2} for carbon and nitrogen, beginning with 4 e · Å^{-2} (dashed). The mirror plane is normal to the plane of the paper and passes through I and N_1.

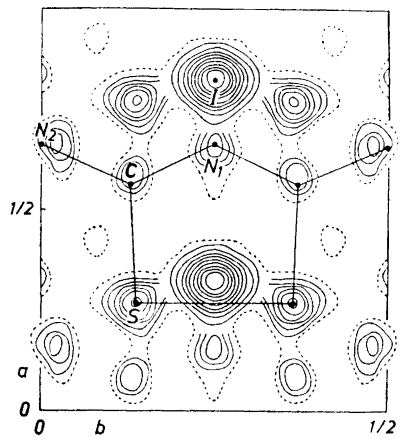

Fig. 2. Electron density projection of thiuret hydroiodide along the *c* axis. The contour interval is 3 e · Å^{-2} for carbon and nitrogen, and the 8-electron line is dashed; otherwise as in Fig. 1.

tion, and were converted to relative structure amplitudes and ultimately brought to an approximately absolute scale by comparison with the calculated values.

The coordinates of the iodide ion were found from Patterson projections, and the structure was solved by use of the heavy atom method and refined through successive Fourier and Fourier difference syntheses. Summations were made by means of Beevers-Lipson strips, at 12° intervals along the *a* axis and 6° intervals along the *b* and *c* axes. The 0*kl* zone was refined first, and the *h*0*l* zone next considered, but here extensive overlapping occurred, so that attention was shifted to the *hk*0 zone. The five *x* coordinates are thus based on the 29 observed *hk*0 reflections; together with the five thermal parameters employed for this zone the number of variables is fairly large relative to the number of observations.

The 0*kl* and *hk*0 electron density maps are shown in Figs. 1 and 2, and the final atomic coordinates are listed in Table 1. The positions corresponding to these coordinates are marked with dots in Figs. 1 and 2. It is seen that particularly in the *hk*0 projection the maxima of the electron density peaks differ markedly from the final positions, apparently because of series termination effects corrected for through the difference refinement.

Table 1. Atomic coordinates for thiuret hydroiodide, in fractions of cell edges. Origin at a centre of symmetry.

	x	y	z
I	0.8235	0.250	−0.1075
N_1	0.665	0.250	0.165
S	0.270	0.1370	0.0845
C	0.565	0.129	0.134
N_2	0.662	0.000	0.163

The observed and calculated values of the 0*kl* and *hk*0 structure factors are listed in Table 2. The calculated values are based on the atomic scattering curves of Berghuis *et al.*[13] for carbon and nitrogen, of Viervoll and Ögrim [14] for sulphur, and an iodine curve constructed from the Thomas-Fermi values for xenon at small scattering angles and electroneutral iodine at intermediate and large angles. In the temperature factor exp $[-B(\sin^2\Theta/\lambda^2)]$ the following values of B were finally adopted, mainly on the basis of the difference maps: In the 0*kl* zone, $B = (2.3 + 0.8 \cos^2\varphi)$ Å^2 for iodine, where φ is the angle between the normal of the reflecting plane and the c axis, and $B = 2.6$ Å for the other atoms. In the *hk*0 zone, $B = (2.0 + 0.5 \cos^2\varphi)$ Å^2 for iodine and $(1.8 + 0.8 \cos^2\varphi)$ Å^2 for sulphur, where φ is the angle between the normal of the reflecting plane and the b axis, and $B = 2.3$ Å^2 for carbon and nitrogen. No significance in terms of anisotropic thermal vibrations should be attached to the B values, as they may reflect absorption and other errors in the observed structure factors.

In the case of the C and N_2 atoms the y coordinates used for the final structure factor calculations were, $y(C) = 0.126$ and 0.132, $y(N_2) = -0.002$ and $+0.002$, respectively, for the 0*kl* and *hk*0 zones. The values of Table 1 are weighted means.

The reliability index, $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, with non-observed reflections included when $|F_c|$ is larger than the observable limit, is 0.073 for the 0*kl* zone and 0.061 for the *hk*0 zone. The strong reflections 004 and 033 have calculated values relatively much larger than the observed ones, and were omitted from the calculation of R index and scale factors for the zone, and from the difference syntheses. A calculation of structure factors for the *h*0*l* zone, using the x and z coordinates derived from the 0*kl* and *hk*0 zones and an approximate temperature correction with $B = 4.0$ Å^2, gave a R index of 0.15 for this zone.

ASSESSMENT OF ACCURACY

The standard deviation of electron density, evaluated from the difference maps, is 0.7 e.Å^{-2} for the 0*kl* zone and 1.2 e.Å^{-2} for the *hk*0 zone. The s.d. of the atomic coordinates were estimated from the root-mean-square of the gradients in the difference maps and the curvatures of the electron density peaks [15,16], and the following values were found: $\sigma(x) = 0.003$ Å, $\sigma(z) = 0.002$ Å for iodine, $\sigma(x) = 0.010$ Å, $\sigma(y) = 0.006$ Å, $\sigma(z) = 0.009$ Å for sulphur, and $\sigma = 0.02$ Å for the carbon and nitrogen coordinates, except $\sigma(z)$ for carbon

Table 2. Observed and calculated 0*kl* and *hk*0 structure factors for thiuret hydroiodide.

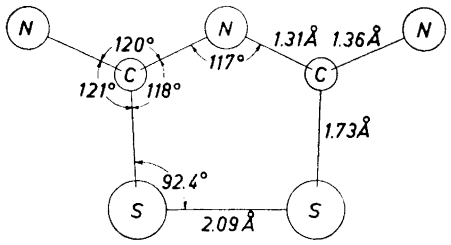

Fig. 3. The thiuret ion, with bond lengths and angles.

which is larger because of overlapping. y for iodine and N_1 are fixed by symmetry relations. This gives $\sigma = 0.012$ Å for the S—S bond length across the mirror plane, about 0.03 Å for S—C and C—N bond lengths, 1° for the S—S—C angle and 2° for other bond angles in the cation.

THE THIURET ION

The bond lengths, as calculated from the atomic coordinates of Table 1, are as follows: S—S = 2.088 Å, S—C = 1.73 Å, C—N_1 (cyclic) = 1.31 Å, C—N_2 (exocyclic) = 1.36 Å, and the angles, S—S—C = 92.4°, S—C—N_1 = 118.1°, C—N_1—C = 116.9°, N_2—C—S = 120.5°, N_2—C—N_1 = 119.5°. The cation as seen in projection along the c crystal axis is shown in Fig. 3.

The S—S bond appears to be significantly longer than 2.04—2.05 Å normally found in non-cyclic disulphides, *e.g.*, 2.044 ± 0.01 Å in formamidinium disulphide dibromide monohydrate [1]. Within the accuracy of the results the carbon valencies are trigonal planar, and although the rather large s.d. do not permit definite conclusions, the found lengths for the three bonds from carbon indicate that they possess some double-bond character. If the lengths of single and double bonds between the atoms in the appropriate hybridization states are taken to be [17-19], C—N = 1.47 Å, C=N = 1.27 Å, C—S = 1.80 Å, C=S = 1.60 Å, Pauling's expression relating bond length and bond order [20] gives about 55 % double-bond character for the C—N_1 bond, 30 % for the C—N_2 bond and 15 % for the C—S bond. Although to discuss bond orders when the experimental uncertainty is 0.03 Å seems rather naive, the results are reasonable.

The shortness of the ring C—N bond thus indicates that the ring N_1 atom has a π orbital available for overlap with the carbon π orbital. Since mirror plane symmetry of the thiuret ion is crystallographically required, it follows that of the four hydrogen atoms of the ion, two are bonded to each of the exocyclic N_2 nitrogen atoms. The other mirror plane-symmetric alternative, one hydrogen atom on each N_2 atom and two on the ring N_1 atom, would make N_1 quaternary and leave no available π orbital. The C—N_1 bond should then be expected to be considerably longer than the C—N_2 bond, and the C—N_1—C angle should be closer to tetrahedral. The found value for the angle (117°) is in agreement with the observation [21,22] that in heterocyclic rings containing nitrogen atoms, the bond angle of the (mainly sp^2-hybridized) nitrogen is less than 120°. A diamino as contrasted with a diimino structure

should correspond to higher stability as a result of conjugation across the ring nitrogen atom, of the two sp^2-hybridized carbon atoms. A similar nitrogen bridge between carbon atoms each bonded to an amino group occurs in melamine, 2,4,6-triamino-*s*-triazine [23].

The N_2—C—N_1—C—N_2 grouping is planar. A least-squares plane through the atoms:

$$0.6209\ X - 0.7839\ Z = 0.419$$

(X and Z in Å) passes through C and at —0.006 Å from N_1 and +0.006 Å from N_2. This plane makes an angle of 15° with the C—S—S—C plane. A least-squares plane through all the atoms of the cation, with the sulphur coordinates given three times the weight of the carbon and nitrogen coordinates:

$$0.4544\ X - 0.8908\ Z = -0.384$$

passes at a shortest distance of —0.008 Å from S, +0.097 Å from C, —0.046 Å from N_1 and —0.027 Å from N_2. The distances are particularly dependent on the z coordinates, and since the z coordinate of C probably has a larger s.d. than the other light atom coordinates (0.02 Å) the apparent deviation from planarity of the thiuret ion as a whole can hardly be considered significant. However, distortions from planarity do sometimes occur in crystals of molecules which on the basis of hybridization and resonance considerations should be expected to be planar [17,24].

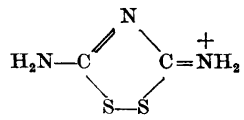
The thiuret ion contains two thiourea groups, and is formally derived from the formamidinium disulphide ion through ring closure under elimination of an ammonium ion. Neither in the structure analyses of formamidinium disulphide diiodide and dibromide monohydrates [1] do the experimental results permit a decision whether the thiourea groups are quite planar or not. The difference between the C—S bond lengths in the dibromide [1] (1.78 Å) and in thiuret hydroiodide (1.73 Å) is within the limits of error. Thiourea itself is planar in the crystals [25], with C—S = 1.71 ± 0.01 Å.

THE PLANARITY OF THE DISULPHIDE GROUP

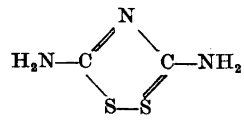
The disulphide group lies across a crystallographic mirror plane. Therefore, unless the mirror plane symmetry is statistical, the disulphide group is exactly planar. Such groups are normally non-planar, with a dihedral angle of about 90° between the planes of the valencies of the two sulphur atoms [19], there being a barrier of 10—14 kcal/mole [10,11] towards rotation about the S—S bond, through the planar *cis* and *trans* forms. This barrier can be explained [26,27] as arising principally from the mutual repulsion of the unshared $p\pi$ electron pairs, one on each sulphur atom. The σ-bonding orbitals of sulphur are thereby assumed to be nearly pure p in character. The possibility exists that extra stability is conferred upon the S—S bond in the non-planar form with about 90° dihedral angle, through overlap of the sulphur $p\pi$ electron pair with an available d orbital of the bond partner; the S—S bond would then have some pd π-bond character. The S—S bond of about 2.04 Å in non-cyclic

disulphides and the short bonds of the same length in the tetra- and pentathionate ions would, on the basis of the present knowledge about length-order relations for S—S bonds [19,28], correspond to about 20 % π-bonding.

In the relatively stable thiuret hydroiodide, with planar disulphide group, the S—S rotation barrier, if it exists also there, must be compensated through other effects, such as favourable lattice conditions in the mirror-plane arrangement, and through resonance stabilization of the ring. The most probable resonance forms of the supposedly correct tautomer of the thiuret ion are



(A)



(B)

and their mirror images. Form A would seem to be the more important one, and confer considerable stability on the ion. Form B involves a π electron pair of sulphur.

The incorporation of the disulphide group in a five-membered ring will, for strain reasons, not allow a normal dihedral angle of about 90°; however, in the saturated five-membered cyclic disulphide, 1,2-dithiolane-4-carboxylic acid [29,30], the dihedral angle is not zero but 27 $\pm$ 1°, and the dithiolane ring is rather unstable. It appears that the unsaturated character of the thiuret ring system is responsible for the planarity of the disulphide group and the stability of the ion. The presence of an unsaturated carbon atom (sp^2-hybridized, with an available $p\pi$ orbital) adjacent to each sulphur atom is not a sufficient requisite for planarity of a disulphide group; in the non-cyclic formamidinium disulphide ion, where the carbon atoms are in the same state of hybridization as in the thiuret ion and also there bonded to a sulphur and two nitrogen atoms, the disulphide group is non-planar, with a dihedral angle of 105° in the diiodide and 89° in the dibromide [1]. The question arises whether the planarity of the disulphide group in unsaturated cyclic disulphides of the thiuret type is due in some degree to π-electron conjugation over the ring as a whole, with participation of sulphur π orbitals; in cyclic conjugated systems such as thiophen and thiazole, a sulphur atom replaces a —CH=CH— group and contributes two π electrons to the aromatic sextet. From the observed S—S bond length in thiuret hydroiodide, conjugation across the S—S bond does not appear to be very strong. In a crystal structure analysis of another unsaturated five-membered cyclic disulphide, 4-methyl-1,2-dithia-4-*cyclo*pentene-3-thione, Kehl and Jeffrey [31] have found that the molecule lies approximately in a plane. They state that "From the observed bond lengths the five-membered ring has some aromatic character. — This π-bonding does not, however, appear to include the S_1—S_2 link, which has a normal single bond length (2.03 Å)." The bond is thus shorter than the S—S bond in thiuret hydroiodide; on the basis of the available length-order data [19,28] the length does indicate 20—30 % π character. It is noteworthy that the ring atoms in the thiuret ion have a sextet of π electrons, as have the ring atoms in the tri-

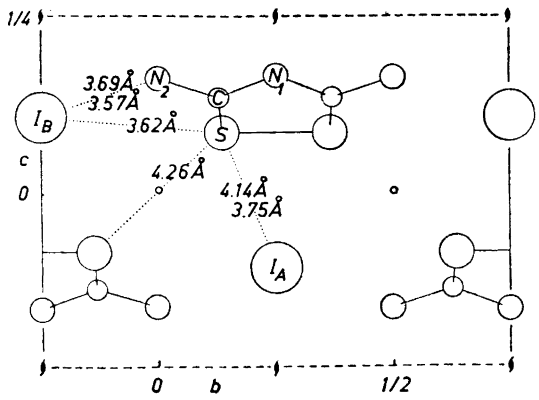


Fig. 4. The ionic arrangement as seen along the *a* axis. Half a unit cell is shown.

thiones of which the above 4-methyl derivative is an example. Lüttringhaus [32,33] has emphasized the aromatic, thiophen-like character of the trithione ring in the thiocarbonyl polarized form, and pointed out that in this ring system the planar form of the disulphide group appears to be stable.

THE IONIC ENVIRONMENT

The arrangement of thiuret ions and iodide ions as seen along the *a* crystal axis is shown in Fig. 4.

The crystals have a layer structure, there being no bonds and only weak non-bonded contacts across the glide plane *a* normal to the *c* axis at $z = \frac{1}{4}$ and $-\frac{1}{4}$. This accounts for the perfect cleavage along the *c* plane. The shortest distances across the glide plane are, N_1—N_1 = 3.55 Å, N_2—N_2 = 3.63 Å, N_2—N_1 = 4.30 and 4.31 Å, N_2—I = 3.95 Å and I—I = 4.81 Å. The N—N approaches are not close enough for van der Waals contacts or hydrogen bonds between the atoms, and the I—I distance is longer than twice the ionic radius of iodine, 2.16 Å [20]. If the hydrogen atoms are trigonally bonded to N_2 and lie in or not too far removed from the least-squares plane of the thiuret ion, then one of the N_2—H bonds is directed approximately toward the related nitrogen atom (N_2') across the glide plane, at an angle of about 60° with the plane of the thiuret ion to which N_2' belongs. N_2' lies 15° out of the plane of the first thiuret ion, as seen from N_2, and the C—N_2—N_2' angle is 119°. With a N—H bond length of 1.0 Å and van der Waals radii for hydrogen and nitrogen of 1.2 and 1.5 Å, respectively [20], the N_2—N_2' distance of 3.63 Å may indicate a weak contact between hydrogen and N_2'.

There are several close non-bonded approaches within a layer. In Fig. 4, the iodide ion I_B is related to I_A through the symmetry centre in $\frac{1}{2}$,0,0; the coordinates of I_A are those listed in Table 1. N_2 lies 3.57 Å from I_B and 3.69 Å from $I_{B(100)}$; these iodide ions are —0.52 Å and + 1.92 Å, respectively, out of the plane of the thiuret ion. A trigonal N_2—H bond located in this plane

would be directed about 20° away from I_B, as seen from N_2, and the hydrogen atom would lie about 2.8 Å from I_B.

Each sulphur atom forms close contacts with two iodide ions and a weaker one with a third. If the coordinates of the reference sulphur atom are those listed in Table 1, the contacts are S—I_A = 4.14 Å, S—$I_{A(\bar{1}00)}$ = 3.75 Å and S—I_B = 3.62 Å. In formamidinium disulphide diiodide monohydrate [1] the closest S—I approaches are 3.91 and 3.95 Å, and in 2,2′-diiododiethyltrisulphide [34], with covalent iodine, 3.74, 3.80 and 3.85 Å. It appears that the value, 1.60 Å proposed by Donohue [34] for the van der Waals radius of sulphur fits the experimental data, at least for S—I contacts, better than does the Pauling value [20] of 1.85 Å.

The environment of an iodide ion is as follows. Located in a mirror plane, it has on each side of the plane two nitrogen atoms at 3.57 and 3.69 Å and three sulphur atoms at 3.62, 3.75 and 4.14 Å, and in the plane a nitrogen atom at 3.90 Å; these approaches are all within the layer. In the adjacent layer there is a nitrogen atom at 3.95 Å on each side of the mirror plane, and two iodide ions in the plane, both at 4.81 Å.

The shortest non-bonded S—S distance in the crystals is 4.26 Å over a centre of symmetry.

The work has been supported financially by *Norges Almenvitenskapelige Forskningsråd*. A sample of thiuret hydrochloride was generously provided by American Cyanamid Company, New York.

The Crystal and Molecular Structure of 1,2-Dithiolane-4-carboxylic Acid

OLAV FOSS and OLAV TJOMSLAND

Chemical Institute, University of Bergen, Bergen, Norway

The crystals of 1,2-dithiolane-4-carboxylic acid are triclinic, with $a = 5.34$ Å, $b = 5.85$ Å, $c = 10.75$ Å, $\alpha = 93\frac{1}{2}°$, $\beta = 89\frac{1}{2}°$, $\gamma = 109\frac{1}{2}°$, and two molecules per unit cell. The space group is $C_i^1-P\bar{1}$. A structure analysis based on 268 observed $0kl$ and $h0l$ reflections has shown that the 1,2-dithiolane ring is not planar, the dihedral angle CSS/SSC being $26.6 \pm 1°$.

The bond lengths in the ring were found to be, $S_1-S_2 = 2.096 \pm 0.009$ Å, $S_2-C_3 = 1.85$ Å, $C_3-C_4 = 1.48$ Å, $C_4-C_5 = 1.55$ Å, $C_5-S_1 = 1.83$ Å, and the angles, $C_5-S_1-S_2 = 92.6 \pm 0.7°$, $S_1-S_2-C_3 = 96.6 \pm 0.6°$, $S_2-C_3-C_4 = 111°$, $C_3-C_4-C_5 = 114°$, $C_4-C_5-S_1 = 104°$. The carboxyl group is planar and has normal dimensions. The molecules are arranged into dimers about centres of symmetry, through O—H···O hydrogen bonds between carboxyl groups.

The 1,2-dithiolane ring has attracted considerable interest in the later years [1-4] because of its presence in 6-thioctic acid (α-lipoic acid) [5]. From a viewpoint of sulphur stereochemistry the importance of the 1,2-dithiolane ring lies in the circumstance that, due to the geometrical requirements of the five-membered ring, the disulphide group cannot maintain the normal dihedral angle of about 90° [6-9] between the planes of the valencies of the sulphur atoms.

1,2-Dithiolane itself is an unstable yellow substance which readily undergoes polymerization [1,4,10], but beside 6-thioctic acid, some substituted 1,2-dithiolanes have been prepared which are more stable, *e.g.*, the 4,4′-dimethyl, 4,4′-dihydroxymethyl, 3,3′-dimethyl and 3,3′,5,5′-tetramethyl derivatives [11,12,4] and the 3,5-dicarboxylic [13] and 3- and 4-carboxylic [14,15] acids. The crystal structure of the last acid is described in this paper.

1,2-Dithiolane-4-carboxylic acid was first isolated by Schotte and Ström [15] in 1956, as yellow prisms with m.p. 76.5—77.5°C, although the corresponding dithiol, β,β'-dithiol*iso*butyric acid, was obtained in 1948 by Jansen [16] on reduction of a sulphur-containing polymeric material isolated from asparagus juice. The UV absorption was measured by Schotte [3] and found to be closely related to that of 1,2-dithiolane itself [1,10]. The unit cell and space group has been published [17], and also a preliminary report on the crystal structure [18].

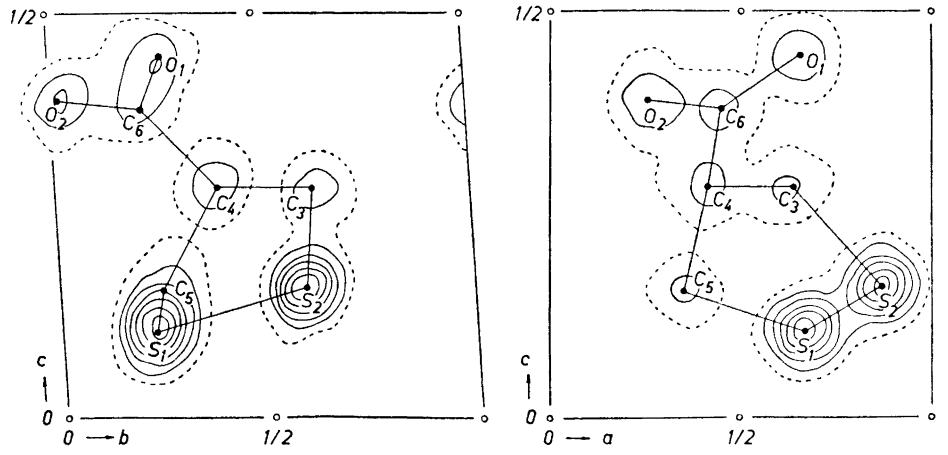
CRYSTAL DATA

From oscillation and Weissenberg photographs about the three axes and about [1$\bar{1}$0] (of length 6.46 Å) the lattice parameters are, to within 0.5 %: $a = 5.34$ Å, $b = 5.85$ Å, $c = 10.75$ Å, $\alpha = 93\frac{1}{2}°$, $\beta = 89\frac{1}{2}°$, $\gamma = 109\frac{1}{2}°$. There are two molecules per unit cell; density, calc. 1.58, found 1.54 g/cm^3. On the basis of the subsequent structure analysis, the space group is C_i^1—$P\bar{1}$. The asymmetric unit is thus one molecule.

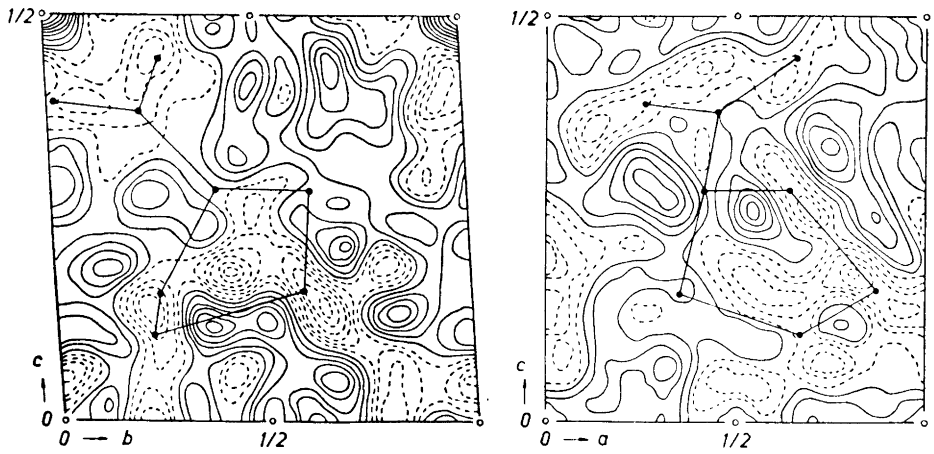
The intensities of the 0*kl* and *h*0*l* reflections were estimated visually from zero-layer Weissenberg photographs taken with copper radiation. The crystals used for the photographs had cross-sections of about 0.1 × 0.1 mm or smaller. During the exposures they changed slowly, from the surface inwards, into an oily, presumably polymeric material. Out of 146 0*kl* reflections within the range sin $\Theta < 0.985$, 136 were observed, the corresponding figures for the *h*0*l* zone being 132 out of 137. Although the absorption is not negligible ($\mu = 70$ cm^{-1} for Cu$K\alpha$ X-rays) no correction was applied. The intensities were corrected for the Lorentz and polarization factors and converted into relative structure amplitudes in the usual way.

DETERMINATION AND REFINEMENT OF THE STRUCTURE

The approximate y and z coordinates of the sulphur atoms ($y = 0.224$, $z = 0.107$ for S_1 and $y = 0.576$, $z = 0.165$ for S_2) were determined from a Patterson projection along the a axis. A subsequent Fourier synthesis of 77 of the strongest 0*kl* reflections, with signs based on the sulphur contributions, gave the approximate positions of the lighter atoms and allowed refinement by Fourier and Fourier difference methods to be carried out. The b-axis projection was afterwards solved and refined in the same way. Nine cycles



Figs. 1 and 2. Electron density projection of 1,2-dithiolane-4-carboxylic acid along the a axis (left) and along the b axis (right). Contours at intervals of 3 e · Å^{-2}, beginning with 3 e · Å^{-2} (dashed). The final atomic positions are marked with dots.



Figs. 3 and 4. Difference projection along the *a* axis (left) and along the *b* axis (right). Contours at intervals of 0.15 e · Å^{-2}, with negative dashed, zero and positive fully drawn. The final atomic positions are marked with dots.

of difference refinement were made for the 0*kl* zone and six for the *h*0*l* zone. The summations were made by means of Beevers-Lipson strips, using axial subdivisions equal to *a*/30 (0.18 Å), *b*/30 (0.20 Å) and *c*/60 (0.18 Å).

The electron density projections along the *a* and *b* axes are shown in Figs. 1 and 2, and the final difference maps in Figs. 3 and 4. The atomic coordinates are listed in Table 1. The two independent sets of *z* coordinates obtained, one from each zone, differed for the following atoms: $z(S_1) = 0.1060$ and 0.1055, $z(S_2) = 0.1610$ and 0.1605, $z(C_3) = 0.284$ and 0.283, $z(C_4) = 0.286$ and 0.284, $z(C_5) = 0.157$ and 0.156, from the 0*kl* and *h*0*l* data, respectively.

Table 1. Atomic coordinates for 1,2-dithiolane-4-carboxylic acid, in fractions of the triclinic axes, and relating to a centre of symmetry.

The observed and calculated values of the 0*kl* and *h*0*l* structure factors are listed in Table 2. The calculated values are based on the atomic scattering curve of Viervoll and Ögrim for sulphur [19] and of Berghuis *et al.*[20] for carbon and oxygen. It was not thought worth while to attempt a location of the hydrogen atoms from the X-ray data, although some of the peaks in the

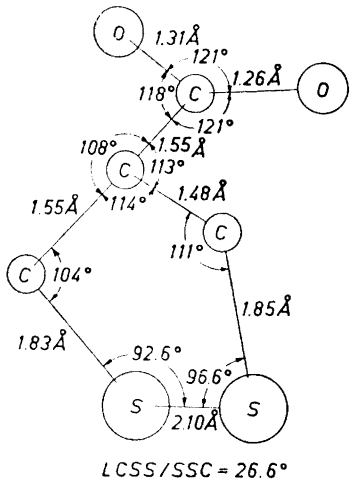

Fig. 5. 1,2-Dithiolane-4-carboxylic acid as seen along the *b* axis.

difference maps (the standard deviation of electron density is about 0.3 e.$Å^{-2}$ for both zones) are in the approximate positions expected for hydrogen atoms. In the temperature factor exp $[-B(\sin^2\Theta/\lambda^2)]$ applied in the calculation of structure factors, B (in $Å^2$) is 4.5 for sulphur and oxygen and 3.5 for carbon in the $0kl$ zone, and 5.2 for sulphur, 5.5 for oxygen and 4.8 for carbon in the $h0l$ zone. The reliability index $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$, with non-observed reflections included when $|F_c|$ exceeds the observeable limit, is 0.122 for the $0kl$ zone and 0.105 for the $h0l$ zone.

Standard deviations of atomic coordinates were estimated from the root-mean-square gradients in the final difference maps and the curvatures of the peaks in the electron density maps [21,22]. Where overlapping occurred, the s.d. was taken as up to twice that which would otherwise have applied. In this way the following values were obtained and used for calculation of the s.d. of bond lengths and angles: For the sulphur coordinates $\sigma = 0.005$ Å except $\sigma(y)$ for S_1 which was put equal to 0.008 Å. For the light atoms $\sigma = 0.015$ Å for x of C_5 and O_1, y of C_3 and C_4 and z of C_3, C_4 and C_5; 0.02 Å for x of C_3, C_4 and O_2 and for y and z of C_6, O_1 and O_2; 0.025 Å for x of C_6 and 0.03 Å for y of C_5.

CONFIGURATION AND DIMENSIONS OF THE 1,2-DITHIOLANE RING

The bond lengths and angles in the molecule, calculated from the coordinates of Table 1, are listed in Table 3, together with estimated standard deviations. A drawing of the molecule as seen in projection along the *b* crystal axis is shown in Fig. 5.

The data show that the disulphide group differs from non-cyclic disulphides in three distinct ways: The bond angles are smaller and the S—S bond slightly longer, and there is a large decrease in dihedral angle.

Table 3. Dimensions of 1,2-dithiolane-4-carboxylic acid.

$S_1-S_2 = 2.096 \pm 0.009$ Å	$\angle S_1-S_2-C_3 = 96.6 \pm 0.6°$
$S_1-C_5 = 1.83 \pm 0.02$	$\angle S_2-S_1-C_5 = 92.6 \pm 0.7$
$S_2-C_3 = 1.85 \pm 0.02$	$\angle S_1-C_5-C_4 = 104.2 \pm 1.3$
$C_3-C_4 = 1.48 \pm 0.025$	$\angle S_2-C_3-C_4 = 110.6 \pm 1.2$
$C_4-C_5 = 1.55 \pm 0.03$	$\angle C_3-C_4-C_5 = 114.1 \pm 1.6$
$C_4-C_6 = 1.55$ $C_6-O_1 = 1.26$ } ± 0.03 Å $C_6-O_2 = 1.31$	$\angle O_1-C_6-O_2 = 121.0$ $\angle C_4-C_6-O_1 = 121.2$ } $\pm 2°$ $\angle C_4-C_6-O_2 = 117.8$
$\angle C_5-C_4-C_6 = 107.5 \pm 1.5°$	$\angle C_3-C_4-C_6 = 113.1 \pm 1.5°$

Dihedral angle $C_5S_1S_2/S_1S_2C_3 = 26.6 \pm 1°$

The bond angles of the two sulphur atoms, although they appear to differ significantly, are both smaller than the angle of 107 ± 3° in dimethyl disulphide [23], 105.4 ± 3° in *bis*(trifluoromethyl) disulphide [24], 103 ± 1° in N,N'-diglycyl-L-cystine dihydrate [25], and 104 ± 1° and 99 ± 2°, respectively, in formamidinium disulphide dibromide and diiodide monohydrates [26]. For all but the last example the angles lie in the range 103—107°.

The observed S—C and C—C bond lengths do not differ significantly from the normal single-bond lengths, 1.82 Å [8] and 1.54 Å. The S—S bond appears to be significantly longer than in non-cyclic disulphides. In the five examples referred to above the mean of the observed lengths is 2.044 Å, with an average deviation of 0.004 Å. In orthorhombic sulphur [27], S—S = 2.037 ± 0.005 Å. The longest bonds between two divalent sulphur atoms, measured with any accuracy, appear to be the two long bonds of 2.10 and 2.13 ± 0.03 Å in cesium hexasulphide [28], and that of 2.088 ± 0.012 Å in the planar thiuret ion, an unsaturated five-membered cyclic disulphide [29]. It has been suggested [8,28,30] that the bonds of length about 2.04 Å possess some double-bond character, and that the single-bond length is in the neighbourhood of 2.08—2.10 Å, as found here. Another view [31] is that the observed variations in S—S bond lengths are due to different degrees of *s* and *p* character in the hybrid σ-bond orbitals of sulphur. A smaller bond angle at sulphur would then lead to less *s* character and a longer bond.

The major change in the disulphide group induced by the geometrical requirements of the ring is the decrease in dihedral angle, from the normal value [8] of about 90° to 26.6 ± 1° in the 1,2-dithiolane ring. The barrier to rotation about the bond between two divalent sulphur atoms, through the planar *cis* and *trans* forms with zero and 180° dihedral angles, has been estimated as 10—14 kcal/mole [32,33]. With the barrier a twofold cosine type the observed dihedral angle in 1,2-dithiolane-4-carboxylic acid corresponds to a S—S torsion energy equal to 80 % of the barrier height. A smaller dihedral angle occurs in thiuret hydroiodide [29] where the angle is zero, and probably in 4-methyl-1,2-dithia-4-*cyclo*pentene-3-thione which according to a short report [34] is approximately planar; these are five-membered cyclic disulphides, but conditions are presumably different because of the unsaturated character of the rings. It appears likely that the decrease in dihedral angle has a bearing on

the increase in S—S bond length, through the increased repulsion between the unshared $p\pi$ electron pairs of sulphur which are thought to be the principal cause of the barrier [6,9], and possibly through less favourable conditions for pd π-bonding.

The 1,2-dithiolane ring is not symmetrical about the disulphide group. Of the bond angles at carbon, that at C_5 appears to be significantly smaller than tetrahedral, and that at C_4 is larger, but not significantly. Here, at C_4, a widening of the angle would result from torsion and bending strain in the disulphide group, the distance between the carbon atoms C_3 and C_5 bonded to sulphur being about 0.2 Å larger in non-cyclic disulphides than the distance, 3.54 Å, observed here. The dihedral angles in the ring, beside that of the disulphide group, are $S_1S_2C_3/S_2C_3C_4 = 20°$, $S_2C_3C_4/C_3C_4C_5 = 26°$, $C_3C_4C_5/C_4C_5S_1 = 54°$, $C_4C_5S_1/C_5S_1S_2 = 49°$. The two large dihedral angles are associated with the carbon atom, C_5, which has the smallest bond angle.

Bergson and Schotte have [35], on the basis of the present structural data, made a conformation analysis of the 1,2-dithiolane ring, and concluded that the total strain in the ring is at least 16 kcal/mole.

The 4-carboxyl group is planar, the maximum deviation of an atom from the least-squares plane through the group being 0.002 Å, in the case of C_6. This carbon atom lies 3.17 Å from S_1 and 3.57 Å from S_2. The dimensions of the group agree reasonably well with values reported for other aliphatic carboxylic acids [36,37]. The carboxyl group is directed towards the symmetry centre at $\frac{1}{2},0,\frac{1}{2}$, which lies 0.11 Å from the plane of the group. Two molecules, one on each side of the symmetry centre, are arranged into dimers through O—H···O hydrogen bonds of length 2.61 Å between the carboxyl groups. This is the structure normally found in monocarboxylic acids [38,39].

A van der Waals contact of length 3.41 Å occurs between two S_1 sulphur atoms across the symmetry centre at $\frac{1}{2},0,0$. In orthorhombic sulphur [27] the shortest intermolecular contact is 3.69 Å and thus longer, but a van der Waals radius for sulphur of about 1.60 Å is indicated in two compounds containing iodine [28,39].

The authors are indebted to Docent Lennart Schotte, University of Uppsala, for providing the sample of 1,2-dithiolane-4-carboxylic acid used in this study. A grant from *L. Meltzers Høyskolefond* to one of us (O. F.) is gratefully acknowledged.

The Action of Alkali on Methyl 2:3-Anhydro-α-D-allopyranoside and 1:5-Anhydro-2-deoxy-3-*O*-toluene-*p*-sulphonyl-D-arabinohexitol

A. B. FOSTER, M. STACEY and S. V. VARDHEIM*

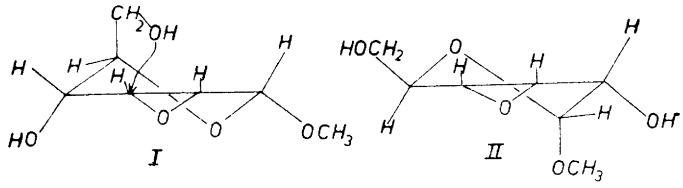
Chemistry Department, The University, Edgbaston, Birmingham, England

Treatment of methyl 2:3-anhydro-α-D-allopyranoside with alkali yields methyl 3:6-anhydro-α-D-glucopyranoside as the only isolable product. Under similar reaction conditions 1:5-anhydro-2-deoxy-3-*O*-toluene-*p*-sulphonyl-D-*arabino*hexitol (the synthesis of which is described) rapidly loses the toluene-*p*-sulphonyloxy residue apparently without the formation of a 3:6-anhydro derivative. The relationship of these observations to those noted by Peat and Wiggins [1], following the treatment of methyl 2:4:6-tri-*O*-acetyl-3-*O*-toluene-*p*-sulphonyl-β-D-glucopyranoside with alkali, is discussed.

The action of alkali on methyl 2:4:6-tri-*O*-acetyl-3-*O*-toluene-*p*-sulphonyl-β-D-glucopyranoside has been found[1] to yield a mixture of methyl 2:3-anhydro- and 3:4-anhydro-β-D-allopyranosides and methyl 3:6-anhydro-β-D-glucopyranoside. These compounds were isolated as derivatives in which the anhydro-rings were preserved; the sensitivity of the latter compound towards acidic reagents resulted in its conversion to methyl 3:6-anhydro-β-D-glucofuranoside during the isolation procedure [2]. Initially it was thought that the methyl 3:6-anhydro-β-D-glucopyranoside had arisen by direct intramolecular attack of the C_6-hydroxyl group on the C_3-toluene-*p*-sulphonyloxy residue but it was later realised [3] that the first products of reaction were the two epoxide derivatives and that the 3:6-anhydro-compound resulted from intramolecular attack of the C_6-hydroxyl group on C_3in either or both of the 2:3- and 3:4-anhydro compounds. That the 2:3-anhydrocompound was involved in such a reaction was suggested by Ohle *et al.*[3], presumably on analogy with reactions in the furanose series [3]; the formation of a 3:4-anhydro-compound is, however, precluded in this case. No experimental evidence has been obtained which would indicate the true course of reaction.

Methyl 2:3-anhydro- and 3:4-anhydro-α- and β-D-allopyranoside would be expected [4] to adopt half-chair in preference to half-boat conformations.

* Present address (S.V.V.): Papirindustriens Forskningsinstitutt, Boks 250, Vinderen, Oslo, Norway.



(The presence of the epoxide ring requires that C_1:C_2:C_3:C_4 and C_2:C_3:C_4:C_5 be coplanar in the 2:3- and 3:4-epoxide compounds, respectively). An examination of accurate scale models reveals that in the half-chair conformation (I) of methyl 2:3-anhydro-α-D-allopyranoside the C_6-hydroxyl group is well situated for nucleophilic attack on C_3 to yield a 3:6-anhydro-D-glucopyranoside and that this is not the case in either of the half-chair conformations (*e.g.* II) of methyl 3:4-anhydro-α-D-allopyranoside. Normal scission of the epoxide ring would be predicted in the latter case. Experimental evidence has been obtained which confirms these predictions.

Graded acidic hydrolysis of methyl 4:6-*O*-benzylidene-2:3-anhydro-α-D-allopyranoside [5] yielded methyl 2:3-anhydro-α-D-allopyranoside (III) in good yield. The latter compound was only slowly attacked ($[\alpha]_D$ + 149° → + 142.5° in 6 days) on treatment with N sodium hydroxide at room temperature. Elevation of the temperature to 50° resulted in completion of reaction within 3 days. ($[\alpha]_D$ + 142.5° → + 37.8°). Quantitative analysis of the reaction products was not possible because of the occurrence of some decomposition but methyl 3:6-anhydro-α-D-glucopyranoside (IV) was the only isolable compound. Although some decomposition occurred the fall in $[\alpha]_D$ during the reaction indicated that methyl 3:6-anhydro-α-D-glucopyranoside was the major, if not the sole product since the alternative products (methyl α-D-glucopyranoside and methyl α-D-altropyranoside) which would result from normal scission of the epoxide are strongly dextrorotatory ($[\alpha]_D$ + 158° and + 125°, respectively). These compounds could not be detected in the products of reaction. The known [2] sensitivity of methyl 3:6-anhydro-α-D-glucopyranoside towards acid is further illustrated by its conversion to methyl 3:6-anhydro-α-D-glucofuranoside on short contact with the resin Amberlite IR-120 (H^+ form).

The slow conversion of methyl 2:3-anhydro-α-D-allopyranoside to methyl 3:6-anhydro-α-D-glucopyranoside probably accounts for the low yield of 3:6-anhydro compound isolated in the reaction studied by Peat and Wiggins [1]. Further, a close analogy may be drawn with the conversion [6] of 1:2-anhydro-α-D-glucopyranose to 1:6-anhydro-β-D-glucopyranose under similar reaction conditions.

Since methyl 3:4-anhydro-α or β-D-allopyranoside is apparently unknown and inaccessible a synthesis of a suitable 3:4-epoxide derived from 1:5-anhydro-2-deoxy-D-*arabino*hexitol (V) (1:2-dideoxy-D-"glucose") was examined. 1:5-Anhydro-2-deoxy-D-*arabino*hexitol (V) was obtained by sequential application of platinum catalysed hydrogenation and saponification to 3:4:6-tri-*O*-acetyl-D-glucal. Reaction of 1:5-anhydro-2-deoxy-D-*arabino*hexitol (V) with benzaldehyde at 115° yielded a 4:6-*O*-benzylidene derivative (VI) which was readily converted to 1:5-anhydro-4:6-*O*-benzylidene-2-deoxy-3-*O*-toluene-*p*-

sulphonyl-D-*arabino*hexitol (VII). Graded acidic hydrolysis of the latter compound yielded 1:5-anhydro-2-deoxy-3-*O*-toluene-*p*-sulphonyl-D-*arabino*hexitol (VIII) (3-*O*-toluene-*p*-sulphonyl-1:2-dideoxy-D-"glucose"). Allocation of structures to these compounds was based on the following arguments. The 3-*O*-toluene-*p*-sulphonate (VIII) was different to the mono-*O*-toluene-*p*-sulphonate obtained by selective toluene-*p*-sulphonylation of 1:5-anhydro-2-deoxy-D-*arabino*hexitol (III). The structure of the latter compound was shown to be 1:5-anhydro-2-deoxy-6-*O*-toluene-*p*-sulphonyl-D-*arabino*hexitol (IX) by its ready consumption of approximately 1 mol. of metaperiodate. The formation of a seven membered 3:6-*O*-benzylidene ring in the reaction of 1:5-anhydro-2-deoxy-D-*arabino*hexitol (III) with benzaldehyde would seem very improbable in view of the fact that an alternative product is the six-membered 4:6-*O*-benzylidene compound the structure of which is related to *trans*-decalin. Whilst 3:6-*O*-benzylidene-D-glucopyranose derivatives are unknown a wealth of examples of 4:6-*O*-benzylidene-D-glucopyranose derivatives is provided in carbohydrate chemistry. Seven-membered alkylidene rings, however, have been observed [7], thus D-mannitol reacts with acetaldehyde to yield 1:3-2:5-4:6-tri-*O*-ethylidene-D-mannitol. Although this example is not strictly analogous to the case being considered it may be noted that formation of the 1:3- and 4:6-rings precedes formation of the 2:5-ring and that the six-membered cyclic acetals are more stable towards acid than the seven-membered cyclic acetal [8]. Thus compound (VI) is allocated the structure 1:5-anhydro-4:6-*O*-benzylidene-2-deoxy-D-*arabino*hexitol.

Treatment of 1:5-anhydro-2-deoxy-3-*O*-toluene-*p*-sulphonyl-D-*arabino*hexitol (VIII) with sodium hydroxide at 50° resulted in ready elimination of the toluene-*p*-sulphonyloxy group. Direct hydrolysis of the 3-*O*-toluene-*p*-sulphonate is ruled out since Peat has pointed out [9] that, unless anhydro ring formation can occur, direct hydrolysis of carbohydrate toluene-*p*-sulphonates occurs slowly. Examination of the products of reaction revealed that the major product(s) were susceptible to attack by periodate. Further, on zone electrophoresis (ionophoresis) on paper in a borate buffer (pH 10) using the enclosed strip technique [10], two components, detectable by the periodate-permanganate reagent [11] were observed. The major component had an M_G value [10] and properties identical with those of 1:5-anhydro-2-deoxy-D-*arabino*hexitol (III); the minor component had a higher M_G value. These observations are entirely consistent with the formation and reaction of 1:5-2:3-dianhydro-2-deoxy-D-*ribo*hexitol (X) to yield a mixture of 1:5-anhydro-2-deoxy-D-*arabo* (III) and D-*xylo*hexitols (XI) following the action of alkali on 1:5-anhydro-2-deoxy-3-*O*-toluene-*p*-sulphonyl-D-*arabino*hexitol. Since the above products (III) and (XI) are susceptible to attack by metaperiodate and because 3:6-anhydro-D-glucopyranosides are resistant, it may be inferred that 1:5-3:6-dianhydro-2-deoxy-D-*arabino*hexitol must be formed to an insignificant extent, if at all, as a consequence of the action of alkali on 1:5-anhydro-2-deoxy-3-*O*-toluene-*p*-sulphonyl-D-*arabino*hexitol.

Thus in the original experiments of Peat and Wiggins [1] it is most probable that of methyl 2:3-anhydro-β-D-allopyranoside and methyl 3:4-anhydro-β-D-allopyranoside, the first products of the action of alkali on methyl 2:4:6-tri-*O*-acetyl-3-*O*-toluene-*p*-sulphonyl β-D-glucopyranoside, the former but not

the latter yields methyl 3:6-anhydro-β-D-glucopyranoside on further action of alkali.

EXPERIMENTAL

Methyl 2:3-anhydro-α-D-allopyranoside. The method adopted was a modification of that reported by Gut and Prins [12].

A solution of methyl 2:3-anhydro-4:6-*O*-benzylidene-α-D-allopyranoside [5] (1.75 g, m. p. 198°, $[\alpha]_D$ +140.2° in chloroform) in 0.05 N hydrochloric acid (20 ml) and methanol (70 ml) was boiled under reflux for 2 h. After cooling and dilution with water (50 ml) the solution was concentrated at 35°, (bath)/16 mm, and deacidified with methyl di-*n*-octylamine [13]. After extraction with ether the neutral hydrolysate was concentrated at 60° (bath)/14—16 mm and the residue decolorized by dissolution in ethanol and treatment with charcoal. Concentration of the solution gave methyl 2:3-anhydro-α-D-allopyranoside (0.9 g, 77.5 %), m. p. 105°, $[\alpha]_D$ + 152° (*c*, 1.0 in methanol). Gut and Prins [12] quote m. p. 104—107°, $[\alpha]_D$ + 152° in methanol.

Action of alkali on methyl 2:3-anhydro-α-D-allopyranoside. (a) A solution of methyl 2:3-anhydro-α-D-allopyranoside (0.5 g) in N sodium hydroxide (5 ml) was stored at room temperature; $[\alpha]_D$ changed from 149° → 142.5° during 6 days. Elevation of the temperature to 50° caused a change in $[\alpha]_D$ +142.5° → +37.8° (final constant value) during 3 days. Some decomposition occurred during this process. Calculated final value for complete conversion to methyl 3:6-anhydro-α-D-glucopyranoside was *ca.* +55°. After neutralisation of the reaction mixture with carbon dioxide and evaporation at 60°, (bath)/14—16 mm, the residue was extracted with boiling acetone during 30 min (acidic hydrolysis of the residue produced no substances reducing toward Fehling's solution). The extract was decolorized with charcoal and evaporated at 40° (bath)/14—16 mm. Crystallization of the residue from ethyl acetate gave methyl 3:6-anhydro-α-D-glucopyranoside (0.28 g, 56 %) m. p. 108°, $[\alpha]_D$ +56.5° (*c*, 0.5 in water). Haworth *et al.*[2] record m. p. 108°, $[\alpha]_D$ +56° in water for this compound.

(b) In a second experiment methyl 2:3-anhydro-*α*-D-allopyranoside (0.3 g) was treated with alkali at 50° as described in (a). The reaction mixture was freed from cations by passage down a column of Amberlite IR-120 (H^+ form). Evaporation of the eluate at 60°, (bath)/14 — 16 mm, gave a syrupy residue which crystallized slowly. Methyl 3:6-anhydro-*α*-D-glucofuranoside (0.16 g, 53.3 %) was subsequently isolated with m. p. 67°, $[\alpha]_D$ +164.5° (*c*, 0.5 in water). Haworth *et al.*[2] record m. p. 68°, $[\alpha]_D$ +164° in water for this compound. The infra-red spectrum (KBr disc) of the furanoside showed absorptions at 795 and 882 cm^{-1} indicative [14] of the furanose structure.

Treatment of an aqueous solution of methyl 3:6-anhydro-*α*-D-glucopyranoside with sodium metaperiodate using the conditions described elsewhere [15] resulted in zero consumption of oxidant during 24 h.

1:5-Anhydro-2-deoxy-D-arabino*hexitol (1:2-dideoxy*-D-*"glucose")*. A solution of amorphous 3:4:6-tri-*O*-acetyl-1:5-anhydro-2-deoxy-D-*arabino*hexitol (15 g, prepared by hydrogenation of an ethanolic solution of 3:4:6-tri-*O*-acetyl-D-glucal [16] in the presence of platinum oxide [17]) in dry methanol (50 ml) was treated with a small amount of metallic sodium. [18] After 12 h the solution was diluted with water (10 ml) concentrated to small volume (*ca.* 5 — 10 ml) and then deionized by passage down a column of Amberlite IR-120 (H^+ form). Evaporation of the eluate and recrystallization of the residue from chloroform-light petroleum (60 — 80°) gave 1:5-anhydro-2-deoxy-D-*arabino*hexitol (6.1 g, 75 %) m. p. 88°, $[\alpha]_D$ +16° (*c*, 2.0 in water). Fischer[16] records m. p. 86 — 87°, $[\alpha]_D$ +16.3° in water for the same compound prepared by a different method.

*1:5-Anhydro-4:6-*O*-benzylidene-2-deoxy*-D-arabino*hexitol (4:6-*O*-benzylidene-1:2-dideoxy*-D-*"glucose")*. A solution of 1:5-anhydro-2-deoxy-D-*arabino*hexitol (1 g) in freshly distilled benzaldehyde (5 ml) was maintained at 115° for 45 min [19], a stream of carbon dioxide being passed continuously through the mixture during this period. The cooled mixture was diluted with light petroleum (60 — 80°) and the crude product collected and washed with light petroleum (60 — 80°). Recrystallization from ether-light petroleum (60 — 80°) afforded *1:5-anhydro-4:6-*O*-benzylidene-2-deoxy*-D-arabino*hexitol* (1.1 g, 69 %) m. p. 98°, $[\alpha]_D$ −54.6° (*c*, 0.4 in ethanol). (Found: C 66.0; H 6.8. $C_{13}H_{16}O_4$ requires C 66.1; H 6.8.)

*1:5-Anhydro-4:6-*O*-benzylidene-2-deoxy-3-*O*-toluene*-p-*sulphonyl*-D-arabino*hexitol (4:6-*O*-benzylidene-3-*O*-toluene*-p-*sulphonyl-1:2-dideoxy*-D-*"glucose")*. A solution of 1:5-anhydro-4:6-*O*-benzylidene-2-deoxy-D-*arabino*hexitol (2 g) in dry pyridine (10 ml) was treated with a solution of toluene-*p*-sulphonyl chloride (2 g) also in dry pyridine (5 ml) at 35° for 48 h. The crude product which separated on dilution of the reaction mixture with water was collected, washed with water and recrystallized from ethanol to yield *1:5-anhydro-4:6-*O*-benzylidene-2-deoxy-3-*O*-toluene*-p-*sulphonyl*-D-arabino*hexitol* (2.2 g, 66.5 %), m. p. 167°, $[\alpha]_D$ −31.7° (*c*, 0.44 in chloroform). (Found: C 61.55; H 5.6; S 8.4. $C_{20}H_{22}O_6S$ requires C 61.5; H 5.6; S 8.2).

*1:5-Anhydro-2-deoxy-3-*O*-toluene*-p-*sulphonyl*-D-arabino*hexitol (3-*O*-toluene*-p-*sulphonyl-1:2-dideoxy*-D-*"glucose")*. A solution of 1:5-anhydro-4:6-*O*-benzylidene-2-deoxy-3-*O*-toluene-*p*-sulphonyl-D-*arabino*hexitol (1 g) in methanolic hydrogen chloride (5 ml, 0.5 % w/v) was boiled under reflux for 2 h. After cooling and dilution with water (10 ml) the solution was neutralised with sodium hydrogen carbonate, concentrated to small volume at 40°, (bath)/14 — 16 mm, and finally freeze-dried. Recrystallization of the residue from chloroform-light petroleum (60 — 80°) afforded *1:5-anhydro-2-deoxy-3-*O*-toluene*-p-*sulphonyl*-D-arabino*hexitol* (0.51 g, 65.8 %), m. p. 111°, $[\alpha]_D$ +23.4° (*c*, 0.51 in chloroform). (Found: C 51.7; H 6.3; S 10.6. $C_{13}H_{18}O_6S$ requires C 51.65; H 6.0; S 10.6).

*Action of alkali on 1:5-anhydro-2-deoxy-3-*O*-toluene*-p-*sulphonyl*-D-arabino*hexitol.* (a) A solution of 1:5-anhydro-2-deoxy-3-*O*-toluene-*p*-sulphonyl-D-*arabino*hexitol (60.4 mg, 0.2 mmole) in ethanol (2.5 ml) and N sodium hydroxide (5 ml) was stirred at 50° for 3 days. After neutralisation with N hydrochloric acid, aqueous sodium metaperiodate solution (15 ml, 0.25 M) was added and the volume rapidly adjusted to 50 ml. The consumption of periodate was determined by the standard procedure [20] of addition of excess arsenite solution and back titration with standard iodine solution using the appropriate blank solutions. A final constant uptake of 0.955 mole of periodate was observed after 30 min.

(b) A solution of 1:5-anhydro-2-deoxy-3-*O*-toluene-*p*-sulphonyl-D-*arabino*hexitol (0.15 g) in ethanol (5 ml) and N sodium hydroxide (10 ml) was stored at 50° for 3 days, and then deionized by passage successively through Amberlite resins IR-120 (H^+ form) and CG-400 (HO^- form). After concentration of the eluate to small volume (*ca.* 1 ml)

zone electrophoresis (ionophoresis) was carried out on Whatman No. 3 paper, using a borate buffer [21] (pH 10) and the enclosed strip technique [10] at a potential gradient of 20 —25 V/cm for 1.5 h. Using the periodate-permanganate reagent [11] for detection, two zones were located; the major zone had a mobility and detection properties identical with that of 1:5-anhydro 2-deoxy-D-*arabino*hexitol whilst the minor zone had a higher mobility.

*1:5-Anhydro-2-deoxy-6-*O*-toluene*-p-*sulphonyl*-D-arabino*hexitol (6-*O*-toluene*-p-*sulphonyl-1:2-dideoxy*-D-*"glucose")*. To a cooled (0°) solution of 1:5-anhydro-2-deoxy-D-*arabino*hexitol (1 g) in dry pyridine (20 ml) a solution of toluene-*p*-sulphonyl chloride (1.3 g) also in dry pyridine (3 ml) was added. After storage at 0° for 2 h and then at room temperature overnight the mixture was diluted with water (50 ml) and extracted with chloroform (4 × 25 ml). The combined and dried ($MgSO_4$) extracts were concentrated at 35°, (bath)/14—16 mm, and, after drying over P_2O_5 *in vacuo*, the residue was dissolved in the minimum volume of chloroform and diluted with continual stirring with light petroleum (60—80°) to turbidity. *1:5-Anhydro-2-deoxy-6-*O*-toluene*-p-*sulphonyl*-D-arabino*hexitol* (1.1 g, 54 %), m. p. 104°, $[\alpha]_D$ +8.5° (*c*, 1.0 in chloroform) was obtained. (Found: C 51.6; H 6.0; S 10.5. $C_{13}H_{18}O_6S$ requires C 51.65; H 6.0; S 10.6.)

A solution of the above compound (60.4 mg, 0.2 mmole) in water (15 ml) was treated with aqueous sodium periodate (15 ml, 0.25 M) and the solution rapidly adjusted to 50 ml. The consumption of periodate was determined as described above and was as follows:

Time (h)	0.5	1.0	2.5	4.0	5.0
Oxidant consumed (mole)	0.816	0.864	0.912	0.960	0.960

Adsorption of Plasminogen Activator to Fibrin

MOGENS LASSEN

From the Biological Institute of the Carlsberg Foundation and the University Institute of Physical Chemistry, Copenhagen, Denmark

The plasminogen activator formed by reaction between streptokinase and human proactivator is quantitatively adsorbed on human fibrin clots. Separation of fibrin from adsorbed activator was not accomplished, but dilute neutral solutions suitable for estimation of activator could be prepared. The proactivator obtained by heat inactivation of acid solutions of fibrin and adsorbed activator was separated from the fibrin. It was extremely labile in neutralized solutions.

According to present knowledge [1,2], the effect of streptokinase in the activation of fibrinolysis can be described by the following schemes:

$$\text{streptokinase} + \text{proactivator} \rightleftharpoons \text{activator}$$

$$\text{plasminogen} \xrightarrow{\text{activator}} \text{plasmin}$$

A purified preparation of the plasminogen activator would be of interest for many reasons. Its properties could be studied and it could be compared with other components of the fibrinolytic system. It would also be valuable in clinical research. Müllertz [3,4] has found the activator to be adsorbed on fibrin. The present work describes the preparation of acid solutions of fibrin containing adsorbed activator, and the estimation of the content of activator in such solutions. With the procedure described, the yield of activator was nearly quantitative.

MATERIALS AND METHODS

Barbital buffer. Diethyl barbiturate (Michaelis), pH 7.8, to which was added NaCl to give a final ionic strength of 0.15.

Phosphate buffer (Sørensen) pH 7.6.

Streptokinase. "Varidase" was kindly supplied by the Lederle Laboratories Division, American Cyanamid Company. The units are those stated on the packages and determined according to Christensen [5].

Proactivator. Human plasma obtained from out-dated citrated bank blood was used without further purification.

Thrombin. A preparation of bovine thrombin containing about 20 000 NIH units (National Institute of Health) per g was kindly supplied by Løvens kemiske Fabrik, Copenhagen.

Measuring methods: Activator and proactivator were determined by the modified lysis time method described by Lassen [6].

RESULTS

1. *Adsorption of activator to fibrin.* The following procedure was found to give the best yield:

Streptokinase dissolved in 1 ml of phosphate buffer, pH 7.6, 0.1 mg of thrombin dissolved in 50 μl of the same buffer, and 1 ml of human plasma were cooled in an ice bath and mixed in the order mentioned. In general, 5 000 units of streptokinase were used, since this amount was found to be nearly equivalent to the content of proactivator in 1 ml human plasma, and thus ensured the best utilization of both precursors. After standing for 4 h at 0° the clot was finely divided with a glass rod and collected by centrifuging for 10 min in a high speed centrifuge (20 000 rev/min) at 0°. The precipitate was washed thoroughly with 5 ml of icecold phosphate buffer and again centrifuged. This washing procedure was repeated twice, first with buffer as before, and then with 5 ml of icecold distilled water. Finally, the fibrin was dissolved at 0° in 2 ml 0.05 M acetic acid, and cleared by centrifuging. It is important to keep the temperature at 0°, since even at this temperature the activator was found to deteriorate in acid solutions (5 — 10 % were lost per hour and the temperature coefficient was high).

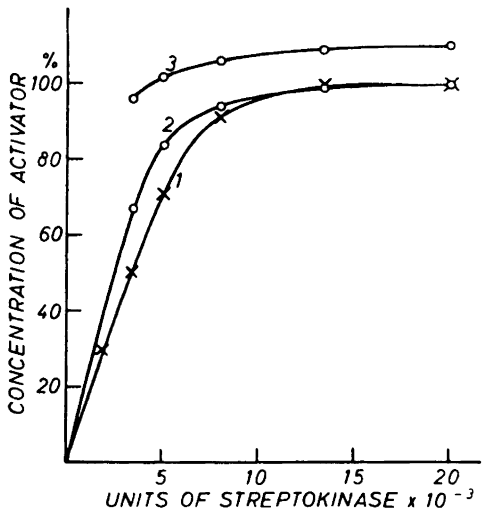

Fig. 1. Adsorption of activator to fibrin. 1 ml of streptokinase solutions in phosphate buffer, pH 7.6, containing the amounts of streptokinase stated on the abscissa were mixed with 50 μl thrombin solution at 0°. 1 ml plasma was then added and the clotted mixtures were stored overnight at 0°. Acid solutions of fibrin were then prepared as described in the text. The activator was estimated in the following solutions: Curve 2, 50 μl fibrin solution + 10 ml barbital buffer. Curve 3, 50 μl fibrin solution + 10 ml barbital buffer containing 500 units of streptokinase. Curve 1, the original mixtures of streptokinase and plasma were prepared without addition of thrombin and incubated for 10 min at room temperature. The activator was then estimated in 50 μl of these solutions diluted with 10 ml barbital buffer.

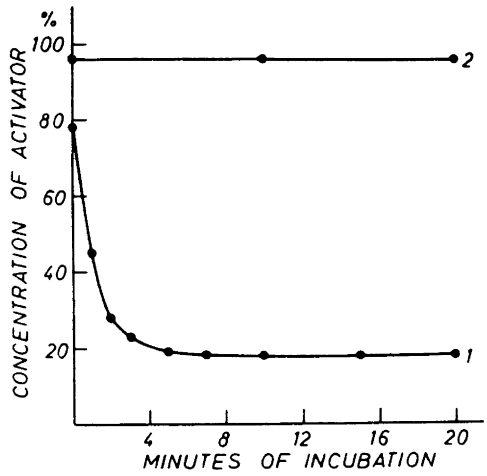

Fig. 2. Inactivation of activator at acid reaction. A solution of fibrin and activator in 0.05 M acetic acid, pH 3.5, was prepared as described. The solution was incubated at 37° and the activator (curve 1) and the sum of activator and proactivator (curve 2) were determined at different times. For the estimations of activator 50 μl of the acid solution were diluted with 10 ml of barbital buffer. For the estimations of activator + proactivator 250 units of streptokinase were added. 1 000 units of streptokinase dissolved in 1 ml of the heated solution of fibrin was found to be stable for 2 h at 37°.

After diluting 50 μl of the acid solution with 10 ml barbital buffer the activator could be measured as described [6]. This was possible since precipitation of fibrin is a very slow process at this high dilution. In four experiments in which 5 000 units of streptokinase per ml of plasma were used, the amounts of activator obtained constituted 110, 135, 140 and 150 %, respectively, of the amounts obtained when the same amount of streptokinase and proactivator (human plasma) were incubated for 10 min at room temperature. In all experiments the amount of activator which remained in serum constituted less than 0.5 %. The apparent excess over 100 % in "yields" can perhaps be ascribed to an influence of fibrin on the formation and stability of the activator.

In many experiments it was found more convenient to leave the clotted solutions overnight at 0°. This was investigated in the next experiment with different concentrations of streptokinase (Fig. 1, curve 2). Curve 1 shows the amounts of activator formed after incubation of the unclotted streptokinase-plasma mixtures for 10 min at room temperature. This curve is in full agreement with the results obtained by Müllertz [2] on the basis of which the reaction between streptokinase and proactivator was proposed to be stoichiometric. The similarity between curves 1 and 2 shows the adsorption of the activator to be nearly quantitative for all concentrations of streptokinase employed. Furthermore, the sum of activator and proactivator in the acid solutions of fibrin was estimated by adding an excess of streptokinase to the buffer used for the dilution (curve 3). The higher values obtained in curve 3 as compared

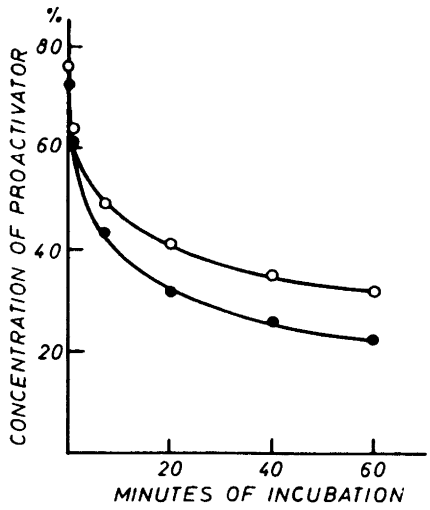

Fig. 3. Lability of proactivator prepared from two different solutions of fibrin plus activator. These solutions were stored overnight at −20°, thawed and centrifuged. The supernatants were neutralized at room temperature with equal volumes of 0.2 M Na_2HPO_4 and the proactivator was estimated at different time intervals.

with curve 2 indicate the presence of an excess of proactivator in the acid solutions of fibrin.

Attempts at separating fibrin and activator have been performed as follows: Precipitation with sodium chloride, or with ethanol at low temperature, or with sodium tungstate, or by neutralization in the presence of phosphate buffer at different concentrations and in the presence of L-lysine ethylester, benzoyl-L-arginine ethylester, amino acids, proteins (including casein, gelatin, Witte peptone, or bovine fibrin hydrolysed with trypsin or chymotrypsin), nucleic acid, sodium sulphosalicylate or sodium tungstate. The best yield (5 %) was obtained with bovine fibrin hydrolysed by trypsin. By precipitation at neutral reaction most of the activator was recovered in the fibrin, while the precipitations at acid reactions were accompanied by deterioration of activator. Furthermore, selective adsorption to barium sulphate and Amberlite IRC 50 from the acid solutions was studied, but these procedures caused either inactivation or irreversible adsorption of activator. An attempt to hydrolyse fibrin in acid solution with pepsin resulted in rapid inactivation of activator. Fibrin made by thrombin coagulation of the citrated plasma used was found to be insoluble in dilute acetic acid. An attempt was made to produce insoluble fibrin from the mixture of plasma and streptokinase by centrifuging immediately after formation of the clot, but some of the fibrin dissolved and the yield of activator was low.

2. *Inactivation of activator in acid solutions.* Troll and Sherry [1] inactivated the activator at acid pH under rather drastic conditions (100° for 15 min at pH 2). They found that most of the original amount of proactivator was

still present in the heated solutions, since reactivation could be obtained by addition of streptokinase to the neutralized solutions. They assumed the acid inactivation to result from destruction of streptokinase and concluded that the activator was formed through a reversible reaction between streptokinase and proactivator:

$$\text{Streptokinase} + \text{proactivator} \rightleftharpoons \text{activator}$$

The inactivation at acid reaction was explained by a displacement of this reaction towards the left, due to removal of streptokinase. The activator present in the acid solution of fibrin (pH about 3.5) was found to be extremely labile at 37°, as well as at room temperature, although complete inactivation could never be achieved (Fig. 2, curve 1). During inactivation equivalent amounts of proactivator were apparently formed (Fig. 2, curve 2). These results are in accordance with Troll and Sherry [1]. However, streptokinase was found to be stable under the experimental conditions (legend to Fig. 2). The assumption that the inactivation of activator at acid reaction is caused by destruction of the orginal streptokinase therefore appears questionable.

3. *Separation of proactivator and fibrin.* Several attempts to isolate the proactivator produced by acid inactivation have been made. Of many experiments the following procedure was found to give the nearest approach to a separation: Acid solutions of fibrin and adsorbed activator were prepared as described. The solutions were placed overnight at —20° and thawed the next day. This procedure caused irreversible precipitation of the fibrin. The centrifuged solutions contained very little activator and about 75 % of the theoretical amount of proactivator. However, proactivator produced in this manner was found to be extremely labile in the neutralized solutions (Fig. 3). In this respect this "proactivator" apparently differs from the genuine proactivator.

Acknowledgements. The author is indebted to Dr. Tage Astrup for his interest and helpful advice. The investigation was made possible by a grant from *Statens almindelige Videnskabsfond*, Denmark. It forms part of the investigations on fibrinolysis for which Dr. Astrup receives support from *The Josiah Macy, Jr. Foundation*, New York, and the *National Danish Association against Rheumatic Diseases*.

Synthesis of Compounds Related to Muscarufin

IV.* 2,5-Bis-(2-carbomethoxyphenyl)-veratraldehyde

MARTIN NILSSON

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The preparation of the title compound (II) from 2,5-di-iodovanillin is reported.

Recently Bohlmann and Kritzler [1] described an approach to the synthesis of muscarufin starting with the preparation of 3-(4-carboxy-$\Delta^{1,3}$-butadienyl)-6-methoxybenzoquinone-(1,4) from *iso*vanillin. However, due to the poor solubility of the quinone they were unable to attach the 2-carboxyphenyl residues.

A somewhat similar approach has been investigated in this laboratory aimed at the preparation of a *p*-terphenylaldehyde, the aldehyde group of which could be the starting point for the attachment of a side chain by methods similar to those of Bohlmann and Kritzler.

The Ullmann reaction is often a convenient route to *p*-terphenyl derivatives [2,3] and as the aldehyde group might be difficult to introduce at a later stage a di-iodoaldehyde was chosen as the starting material. Aldehyde groups generally survive under the conditions of the Ullmann reaction (*cf.* review by Fanta [4]), but preliminary experiments on the reactions of 2-iodo- and 5-iodoveratraldehydes with copper indicated that some oxidation was likely to occur in the first case.

Acetalisation was therefore chosen for protection of the aldehyde group. No acetal of vanillin appears to be described in literature and early comments [5] indicate that *o*- and *p*-hydroxybenzaldehydes fail to give acetals under standard conditions.

Vanillin when treated with ethylene glycol and boron trifluoride at room temperature gave a blue solution, from which only starting material was recovered. 2,5-Di-iodovanillin [6] under the same treatment gave a colourless solution from which 2,5-di-iodovanillin ethylene acetal was obtained (30—40

* Part III. *Acta Chem. Scand.* **12** (1958) 537.

% yield); a faint pink coloration appeared at the very beginning but soon faded. Better yield (64 %) was obtained when the reaction was carried out at higher temperature with continuous removal of water.

The failure of vanillin to give an acetal may be ascribed to the stability of the "quinoid" vanillin-boron trifluoride complex. As judged from the faint colour the corresponding complex of 2,5-di-iodovanillin is not as stable and this is presumably due to steric interference of the iodine atom(s).

Treatment of 2,5-di-iodovanillin ethylene acetal with diazomethane gave 2,5-di-iodoveratraldehyde ethylene acetal in good yield. The alkaline methylation of 2,5-di-iodovanillin gave poor yields.

The Ullmann reaction with 2,5-di-iodoveratraldehyde ethylene acetal and methyl 2-bromobenzoate gave 2,5-bis-(2-carbomethoxyphenyl)-veratraldehyde ethylene acetal (I) in fair yield.

Mild acid hydrolysis of I gave 2,5-bis-(2-carbomethoxyphenyl)-veratraldehyde (II) which, however, did not give crystalline derivatives.

Demethylation of II (or I) with hydrobromic acid gave a high-melting, sparingly soluble product, which was difficult to purify and gave a poor analysis. Its resemblance to the stable dilactones described in previous communications [2,3] and infrared data indicate it to be the dilactone of 2,5-bis-(2-carboxyphenyl)-protocatechualdehyde (III).

Attempts to use the Reformatsky reaction with methyl γ-bromocrotonate [1,7], the Wittig reaction using the triphenylphosphonium salt from the same ester [7], and the acid-catalysed condensation with diethyl ethylidenemalonate [8] for the introduction of the muscarufin side-chain on 2,5-(2-carbomethoxyphenyl)-veratraldehyde (II) have so far been unsuccessful.

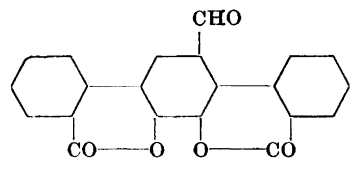
II R = — CHO



III

EXPERIMENTAL

The melting points were determined on a Kofler block. The infrared spectra (potassium bromide discs) were recorded on a Perkin Elmer No. 21 instrument with a sodium chloride prism.

Ullmann coupling of iodoveratraldehydes. 2-Iodoveratraldehyde [6] (0.8 g) and copper bronze (2 g) were mixed in a test tube and heated to 250° for 15 min. The cooled mixture was extracted with chloroform, the opaque greenish solution was evaporated and the residue was distilled at 10 mm to give an oil (0.2 g, 45 %), which solidified and was recrystallised from methanol to give *5,5',6,6'-tetramethoxy-2,2'-diformyldiphenyl* as prisms, m. p. 136—137°. (Found: C 65.1; H 5.6. Calc. for $C_{18}H_{18}O_6$: C 65.4; H 5.5.)

5-Iodoveratraldehyde [9] by the same procedure gave *5,5',6,6'-tetramethoxy-3,3'-diformyldiphenyl* (65 %), m. p. 138–140°, undepressed by the product obtained by methylation of "dehydrodivanillin" [10] (*cf.* Ref.[9]). There were no obvious signs of oxidation in this experiment.

The mixed m. p. of the synthetic products gave a marked depression (115–135°).

2,5-Di-iodovanillin ethylene acetal. 2,5-Di-iodovanillin (45 g) prepared in 35 % overall yield from vanillin [6], ethylene glycol (40 ml) and boron trifluoride-ether complex (47 %, 10 ml) were heated in trichloroethylene (250 ml) under reflux with continuous removal of water from the condensate for 16 h. After cooling the glycol phase was separated and extracted with trichloroethylene. The combined trichloroethylene solution was washed quickly with water and sodium hydrogen carbonate solution and dried over sodium sulphate. Evaporation of the solvent gave a solid (32 g, 64 %, m. p. 110–125°), which was recrystallised from dry methyl *cyclo*hexane to give 2,5-di-iodovanillin ethylene acetal as elongated plates, m. p. 127–128°, occasionally resolidifying and finally melting at 135–137°. (Found: C 27.1; H 2.1; I 56.4. Calc. for $C_{10}H_{10}I_2O_4$: C 26.8; H 2.3; I 56.7.) The acetal was rather sensitive to water; recrystallisation from ethanol-water mixtures and even from moist light petroleum caused extensive hydrolysis.

2,5-Di-iodoveratraldehyde ethylene acetal. Crude 2,5-di-iodovanillin ethylene acetal was suspended in ether and treated with a moderate excess of diazomethane. After 1 h the nitrogen evolution ceased, the solvent was removed and the solid product was recrystallised from small volumes of methanol, m. p. 80–81° (70 % yield). (Found: C 28.2; H 2.6; 55.1. Calc. for $C_{11}H_{12}I_2O_4$: C 28.6; H 2.6; I 54.9.)

2,5-Bis-(2-carbomethoxyphenyl)-veratraldehyde ethylene acetal (I). 2,5-Di-iodoveratraldehyde ethylene acetal (4.3 g, 0.009 mole), methyl 2-bromobenzoate (17 g, 0.08 mole) and copper bronze (50 g) were allowed to react at 250°. The oil obtained by extraction with chloroform was distilled giving methyl benzoate, dimethyl diphenate and a fraction, b. p. 240–260°, 1 mm (2.5 g, yellow oil), which was dissolved in benzene and passed through a column of alumina. The solvent was removed and the residue was dissolved in a small volume of methanol and after keeping in the refrigerator gave I as compact prisms, m. p. 124–126° (1.0 g). (Found: C 67.9; H 5.8. Calc. for $C_{27}H_{26}O_8$: C 67.8; H 5.5.)

The infrared spectrum showed an ester carbonyl band at 1 730 cm^{-1}.

Mild acid hydrolysis of the material in the mother liquors gave a further quantity of crystalline material (II, 0.5 g, m. p. 135–137°; see below) bringing the total yield for the Ullmann coupling to 35 %.

2,5-Bis-(2-carbomethoxyphenyl)-veratraldehyde (II). The acetal I was heated on the water bath for 0.5 h in aqueous acetic acid containing a trace of *p*-toluenesulphonic acid. On cooling the aldehyde II separated in quantitative yield and was recrystallised from methanol to give prisms, m. p. 140–141°. (Found: C 68.8; H 5.3. Calc. for $C_{25}H_{22}O_7$: C 69.1; H 5.1.)

The infrared spectrum showed ester carbonyl (1 730 cm^{-1}), aldehyde carbonyl (1 695 cm^{-1}) and aldehyde C–H stretching band (2 760 cm^{-1}).

Attempts to prepare the 2,4-dinitrophenylhydrazone and the semicarbazone gave only amorphous material.

Demethylation. The aldehyde II (0.20 g), hydrobromic acid (*d* 1.48, 1 ml) and acetic acid (2 ml) were heated under reflux for 0.5 h. After cooling the precipitate was collected and was recrystallised from large volumes of acetic acid to give small needles, which were always somewhat brownish, m. p. *ca.* 360° (decomp.). (Found: C 72.8; H 2.9. Calc. for $C_{21}H_{10}O_5$: C 73.7; H 2.9.)

The infrared spectrum showed a very strong band at 1 755 cm^{-1}, which may be ascribed to a six-membered ring lactone, and bands due to an aldehyde group (1 695 and 2 760 cm^{-1}). The dilactone of 2,5-dihydroxy-1,4-bis-(2-carboxyphenyl)-benzene [2] gave a very strong band at 1 750 cm^{-1}.

The author is indebted to *Statens Tekniska Forskningsråd* for a fellowship and to Dr. B. R. Thomas for linguistic criticism.

A Relaxation Method for the Determination of Moderately Rapid Reaction Rates near Chemical Equilibrium

STIG LJUNGGREN and OLE LAMM

The Royal Institute of Technology, Division of Physical Chemistry, Stockholm 70, Sweden

A new relaxation method, based on the equilibrium displacement produced by a *rapid pressure rise*, is described. Using the present technique, the pressure was raised from 1 to 150 atmospheres in about one twentieth of a second. The relaxation to equilibrium was followed by a continuous registration of the conductivity of the sample solution. This technique was employed to study the kinetics near equilibrium of the carbon dioxide-water system. It was also found possible to calculate the true dissociation constant of carbonic acid.

SYMBOLS

b_{rs} = constants defined in text
C_p = specific heat
C = total concentration
c^o = equilibrium concentration
c_o = concentration of undissociated constituent
c_+ = concentration of positive ion
c_- = concentration of negative ion
H^o = partial molar enthalpy of standard state (referred to infinite dilution)
J = cell constant
K = equilibrium constant in general
K_s = true dissociation constant of CO_2
K_h = hydration constant of CO_2
K_{sh} = apparent dissociation constant of CO_2
k_f = forward rate constant
k_r = reverse rate constant
l = eqivalent ionic conductance
p = pressure; algebraic expression defined in the text
q = algebraic expression defined in the text
R = gas constant; cell resistance
S = entropy
T = absolute temperature

t = time
V° = partial molar volume of standard state (referred to infinite dilution)
$V^{\neq}$ = partial molar volume of activated state
y = recorder deflexion
α = degree of dissociation
α_0 = equilibrium degree of dissociation
β = relative change in K on compression from p_1 to p_2
γ = volume compression ratio
Δ = finite difference operator; perturbation from equilibrium concentration
ε = constant of integration
Θ = perturbation measure
$\varkappa$ = specific conductance of solution
λ = eigenvalues of matrix
τ = relaxation time

INTRODUCTION

In connection with other investigations at this Institute there arose a need for a method suitable for the study of the kinetics of certain reactions with half-times ranging from 0.05 sec up to a few minutes. All reactions which were studied involved ionic species. For this reason it seemed most convenient to utilize the conductivity of the solutions. Of the existing methods [1] for studying fast reactions, only the rapid flow method of Hartridge and Roughton [2] seemed to be applicable in the region of rates mentioned. An estimation showed, however, that it would be difficult to adapt the flow method successfully to conductivity registration without sacrificing the low liquid consumption which is characteristic of certain modifications of this method. From the point of view of general experimental simplicity, a relaxation method seemed most attractive. This led the authors to the development of what might be called *a pressure jump method.* By recording the variation of conductivity following the application of a rapid pressure rise, the rate at which the new equilibrium was approached could be studied. There is a simple relation between the relaxation time (time lag) and the reaction rates (*cf.* Refs.[3,4]). A rather similar method, the temperature jump method, has been indicated by Eigen [5].

A still simpler relaxation method, which to the authors' knowledge, has not been tried as yet, would be a rapid dilution of the sample solution followed by, for example, conductivity registration.

The pressure jump method is not confined to solutions having an electric conductivity. The variation of colour, temperature or dielectric constant of the solution may be used as well. In addition to the relaxation process, the pressure dependence of the equilibrium constant can be studied by the same experimental arrangement.

The original flow method[2,2a] requires large quantities of liquid. In later modifications [2], *e. g. the stopped flow and accelerated flow methods,* this drawback has been overcome. The flow method has hitherto been applied mainly to biological systems, *e. g.* enzyme reactions. The rate of hydration and dehydration of carbon dioxide and the rate of the conversion $Cr_2O_7^{2-} - HCrO_4^-$ have, however, also been determined in this way[6].

Relaxation methods[1] have attracted much attention in recent years. In addition to the *pressure jump method* described in this paper and the *remperature jump method* already mentioned, we have, for example, the method utilizing the equilibrium displacement caused by a strong electric field, the so called *dissociation field effect* (or second Wien effect) [1,3]. Owing to the enormous production of Joule heat per unit time, this method can only be used for very fast reactions. The same thing is true for the *sound absorption method* [1].

Proton magnetic resonance has been applied, for example, to the study of the extremely rapid protolysis of ammonia and various amines [1,7].

A *dielectric dispersion method* has recently been used to study the dissociation rate of boric acid [8].

Polarographic and related methods [9-14] are applicable in cases where the electrode process is preceded by the reaction to be studied. As an example of a successful application of this technique, the determination of the dissociation rate of the complex ion $[Cd(CN)_4]^{2-}$ may be mentioned [15].

BASIC THEORY

The effects of pressure on the conductivity of an electrolyte are twofold. First, the ionic mobilities are changed, due in the first place to the change in viscosity of the solvent. Second, there is a displacement of the equilibrium position (*i.e.* a change in the equilibrium degree of dissociation) which we utilize to study the rate of approach to the new equilibrium at the higher pressure. The equilibrium perturbation is to be ascribed partly to the change in the equilibrium constant and partly to the pure volume effect, *i.e.* the increase of the concentrations due to the volume compression.

1. The pressure effect on the equilibrium constant

For the variation of the equilibrium constant, K, with pressure, p, under adiabatic conditions we have

$$(\partial \ \ln K/\partial p)_S = (\partial \ \ln K/\partial p)_T + (\partial \ \ln K/\partial T)_p \ \ (\partial T/\partial p)_S ,$$

where T is the absolute temperature and S the entropy of the solution. Now, from thermodynamics we know that

$$(\partial \ \ln K/\partial p)_T = -\Delta V^\circ/RT$$

$$(\partial \ \ln K/\partial T)_p = \Delta H^\circ/RT^2$$

$$(\partial T/\partial p)_S = T(\partial V/\partial T)_p/C_p$$

where V° and H° are the volume and enthalpy of the standard states (referred to infinite dilution).

$$(\partial \ \ln K/\partial p)_S = \frac{1}{RT} \cdot \left[-\Delta V^\circ + \Delta H^\circ \ (\partial V/\partial T)_p/C_p \right]$$

Realizing that

$$\ln \ (K_2/K_1) = \int_{p_1}^{p_2} (\partial \ \ln K/\partial p)_S \mathrm{d}p$$

and introducing the ratio

$$\beta = K_2/K_1$$

we have

$$\beta = \exp\left[\int_{p_1}^{p_2} (\partial \ln K/\partial p)_S \mathrm{d}p\right] =$$

$$= \exp\left[\int_{p_1}^{p_2} \frac{-\Delta V^\circ + \Delta H^\circ (\partial V/\partial T)_p/C_p}{RT} \cdot \mathrm{d}p\right]$$

When working with dilute aqueous solutions, we may disregard the second term within the bracket in the expression for $(\partial \ln K/\partial p)_S$ since $(\partial V/\partial T)_p$ is very small for water at room temperature (and zero at the temperature of maximum density). If the equilibrium involves ionic species, the change in K is accompanied by a corresponding change in the conductivity of the solution.

As to the magnitude of the pressure effect, we find that if $\Delta V^\circ = 1$ cm^3 per mole, then a change of p from 1 to 100 atm will produce a change in K of 4×10^{-3}. This is sufficient to permit registration of the relaxation process.

2. The volume effect

The volume effect is of course much smaller in a solution than in a gas mixture, but it is comparable in magnitude to the change in K (*i.e.* β) given above. As an example let us study the dissociation equilibrium

$$\underset{c_0}{AB} \rightleftharpoons \underset{c_+}{A^+} + \underset{c_-}{B^-}$$

According to the law of mass action we have

$$c_+ c_-/c_0 = K$$

If, now, the pressure is rapidly raised, say, from 1 to 100 atm, all concentrations are instantaneously increased in the same ratio, γ, as the volume decrease of the solution.

$$c_0' = \gamma c_0$$

$$c_+' = \gamma c_+$$

$$c_-' = \gamma c_-$$

γ can be calculated if the compressibility of the solution is known. As c changes to c', K will simultaneously change to K'

$$K' = \beta K$$

where β can be calculated using the equation deduced in the foregoing section.

The equilibrium is perturbed as a result of the changes in c and K. As a measure for the perturbation, we introduce a quantity Θ, defined by the relation

$$c_+' c_-'/c_o' = (1 + \Theta)\ K'$$

Thus

$$\gamma c_+ \gamma c_-/\gamma c_o = (1 + \Theta)\beta K$$

i.e.

$$\Theta = (\gamma - \beta)/\beta$$

Obviously, the two effects, γ and β, may occasionally cancel. On the other hand, it is possible to obtain a measurable effect even in such cases where β is very small or equal to zero. It is hard to make any predictions since ΔV° varies appreciably from case to case. (*cf.* Ref.[16]).

3. The change in the ionic mobilities

As discussed by Bridgman [17], the ionic mobilities are themselves functions of the pressure. However, this effect, being instantaneous, has no influence on the relaxation time.

4. The relaxation

In order to get an idea of the relaxation process we will study the case of a weak binary electrolyte * which dissociates according to the formula

$$AB \underset{k_r}{\overset{k_f}{\rightleftharpoons}} A^+ + B^-$$

$$C(1-\alpha) \qquad C\alpha \qquad C\alpha$$

Then

$$\frac{C\,\alpha_o^2}{1-\alpha_o} = K$$

where α_o is the equilibrium degree of dissociation and α the actual degree of dissociation. k_f and k_r are the forward and reverse rate constants respectively. The rate equation of the system is

$$\frac{d\alpha}{dt} = k_f\left(1-\alpha-\frac{C\alpha^2}{K}\right)$$

On integration (*cf.* Ref.[4]) at constant K and k_f we obtain

$$\frac{\alpha-\alpha_o}{\alpha+\dfrac{\alpha_o}{1-\alpha_o}} = \varepsilon e^{-t/\tau}$$

* An example of a more complicated case will be encountered below in connection with the system carbon dioxide-water.

where s is a constant and

$$\tau = \frac{1-\alpha_o}{k_r C(2-\alpha_o)\alpha_o}$$

τ is the so-called Langevin time lag. The expression may be rewritten in the form

$$\tau = \frac{\alpha_o}{k_f (2-\alpha_o)}$$

If $\alpha-\alpha_o = \Delta\alpha$ is small in comparison with α_o, the integrated rate equation becomes approximately

$$\Delta \alpha = (\Delta\alpha)_o \, e^{-t/\tau}$$

where $(\Delta\alpha)_o$ refers to $t = 0$.

The specific conductance of the relaxing solution is proportional to α:

$$\varkappa = 10^{-3} \, C\alpha \, (l_{A+} + l_{B-})$$

where l_{A+} and l_{B-} denote the equivalent conductances of A^+ and B^- respectively at the elevated pressure.

Hence

$$\Delta\varkappa = (\Delta\varkappa)_o e^{-t/\tau}$$

Using this expression, τ may be determined by following the variation of $\varkappa$.

The expression for τ shows that it depends on α_o. Since α_o depends in turn on C and K, a suitable *concentration* range must be chosen in each particular case in order that τ may assume a value suitable for measurement.

Having determined τ, the question arises as to whether the value obtained agrees with the reaction rate at atmospheric pressure. For the variation of the rate constants with pressure we have [18]

$$\left(\frac{\partial \ln k}{\partial p}\right)_T = \frac{\Delta V^{\neq}}{RT}$$

where $\Delta V^{\neq}$ refers to the activated state. Obviously this effect is of the same order of magnitude as the change in K, *i.e.* about 1 % for a pressure variation of 100 atm. As a rule this is within the limit of errors in the determination of τ and k.

THE APPARATUS

A conductivity cell, two types of which are shown in Figs. 1 and 2 *, was enclosed in a pressure vessel of stainless steel, Fig. 3. The pressure was transmitted from the pressure medium (water or paraffin oil) to the solution in the cell by means of a flexible polythene tube, Fig. 1. This simple arrangement proved completely satisfactory in practice. When water was used as pressure

* The cell in Fig. 2 has the advantage of giving a constant current density in every part of the electrode surfaces.

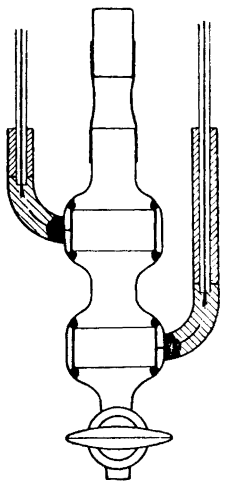

Fig. 1. Conductivity cell. The polythene tube on top of the cell transmits the pressure.

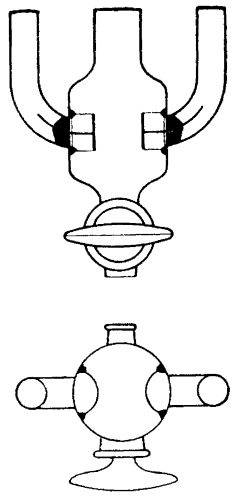

Fig. 2. Conductivity cell. The electrodes are curved (harmonic circles) so that the current density is nearly constant over the whole electrode surface.

medium, the knurled screws inside the vessel and the connections to the insulated leads were completely embedded in picein in order to avoid conduction through the water. The rapid pressure rise was achieved simply by connecting the pressure vessel to a 150 atm nitrogen cylinder and rapidly opening the

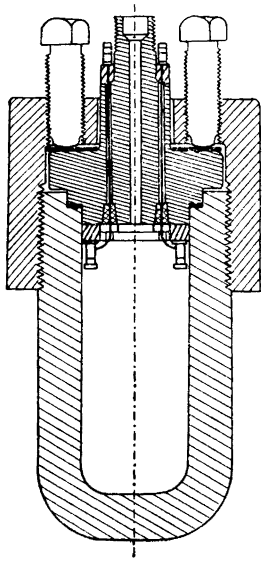

Fig. 3. Pressure vessel. The electrode leads pass through teflon cones tightening according to the "principle of the unsupported area" [17].

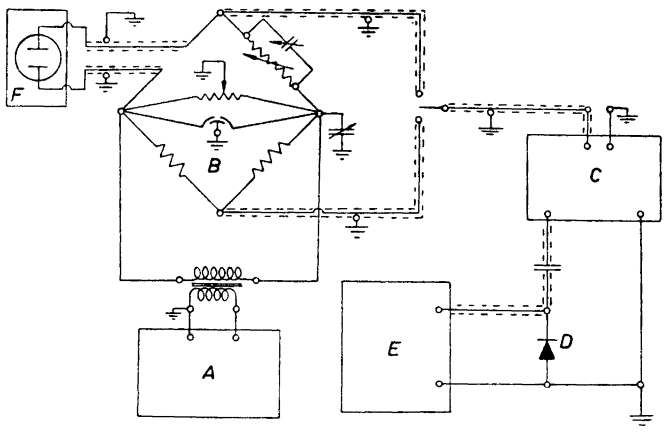

Fig. 4. Recording system. A, oscillator; B, Wheatstone bridge (separately balanced against earth); C, amplifier; D, rectifier; E, recorder; F, conductivity cell.

stopcock. In this way the pressure variation could be obtained without shock or vibration in less than one twentieth of a second. This sets the lower limit to the range of time-lags that can be determined. However, it should possible to improve the present form of the method.

The recording system is shown schematically in Fig. 4. The cell, the isolated leads of which passed through the cover of the pressure vessel, forms one branch of a Wheatstone bridge fed from an audio frequency oscillator *. The detector signal, which at low degress of unbalance is approximately proportional to the relative variation of the resistance of the cell, was amplified ** and rectified. The DC voltage from the copper rectifier was then recorded ***. The working conditions have to be chosen in such a way that, as far as possible, the recording system is linear in the whole range used.

Fig. 5 shows an actual registration with 0.01 M KCl in the cell and *paraffin oil* as pressure medium. In this case, the whole of the change in conductivity is due to the change in ionic mobilities and to the pure volume effect.

Fig. 6 shows a registration from an experiment with a carbon dioxide solution. The instantaneous change, AB, is due to the same reasons as those for KCl and also to a displacement of the rapid equilibrium: $H_2CO_3 \rightleftharpoons H^+ + HCO^-_3$. The slow change, BC, on the other hand, reflects the relaxation of the hydration reaction of CO_2. The theory of this will be given below.

* At frequencies above 5 000 cycles/sec, the mass of the recorder galvanometer prevents the superimposed AC component (ripple) from being recorded.

** In order to avoid transient distortion (from the building-up process), the band width of the amplifier must not be too small. (*cf.* Ref.[18a]). For this reason, an untuned amplifier was used.

*** A direct writing recorder, the Mingograph, manufactured by the Elema Co., Stockholm, Sweden, was used. The ink is sprayed on to the recording paper by a small, light nozzle. This eliminates the friction between pen and paper and enables rapid processes to be recorded on ordinary paper. The instrument was originally designed for medical purposes.

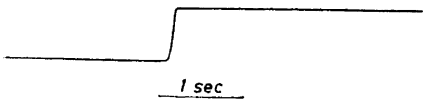

Fig. 5. Record obtained with 0.01 M KCl.

Fig. 6. Record obtained with a CO_2 solution. AB, rapid change; BC, slow change (relaxation curve).

Fig. 6 also illustrates the method of evaluation used. We have

$$y = y_0 \, e^{-t/\tau}$$

Hence, if y is plotted in a logarithmic scale *versus* time, then $-1/\tau$ is obtained as the slope of the line.

Theoretically there should be no *lower* limit for the rates of reactions which can be determined by the method. The following facts have, however, to be considered. On compression to a hundred atmospheres, the temperature of the *medium* may rise by several degrees.* Thus heat is slowly transferred to the conductivity vessel, changing the conductivity of the electrolyte. This may mask the change in conductivity if the reaction studied is slow (large τ)**. If the reaction is fast the heat of the compression is less disturbing ***. However, the advantage of using a pressure medium at the temperature of its density maximum (if it has one), *e.g.* water at 4°C, becomes apparent. For fast

* The adiabatic heat of compression obeys the equation already stated:

$$(\partial T/\partial p)_S = (T/C_p)(\partial V/\partial T)_p$$

Assuming that $(\partial T/\partial p)_S$ remains constant, we may easily calculate the temperature rise on compression to a hundred atmospheres. Approximate values for some common substances are (at room temperature):

Substance	*Temperature rise (°C/100 atm)*	
Pentane	3.5	
Ethyl ether	3.15	
Benzene	2.45	
Rubber	0.84	
Paraffin	0.84	
Glycerol	0.49	
Mercury	0.28	
2.5 % KCl in aq.	0.16	
Water	0.07	(20°C)
»	0	(4°C)
Brass	0.10	
Glass	0.03	
Porcelain	0.007	
Nitrogen gas	77.5	(calcd. in a different way)

** In experiments with solutions having a high conductivity, the Joule heat evolved in the cell must also be considered.

*** For such rapid reactions where the heat conduction can be neglected, the *temperature jump method* may have an advantage over the present one, since it permits a more rapid application of the perturbation. However, the rate of application of the pressure might be considerably increased using, for example, »a bursting membrane» technique (compare *e.g.* [19,20]).

processes, paraffin oil is superior since the turbulence resulting from the application of pressure is damped much more rapidly in paraffin oil than in water. In addition, paraffin oil is a superior electrical insulator. It was found practical to use *agar* in the water to increase its viscosity to approximately that of paraffin oil.

The electrodes of the cell were treated with HNO_3/HCl and then carefully washed before each run. In the experiments with carbon dioxide solutions, unplatinized electrodes were used in order to prevent adsorption on the electrode surfaces.

THE SYSTEM CARBON DIOXIDE-WATER

a. *Relaxation time.* The system carbon dioxide-water is an example of a case which is more complicated than the simple binary electrolyte case treated above. In this system, there is an intermediate stage, the hydration of CO_2, so that the dissociation proceeds according to the formula

$$CO_2 + H_2O \underset{k_2}{\overset{k_1}{\rightleftharpoons}} H_2CO_3 \underset{k_4}{\overset{k_3}{\rightleftharpoons}} H^+ + HCO^-_3$$

There is also a competing reaction path

$$CO_2 + OH^- \rightleftharpoons HCO^-_3$$

which, however, does not become important unless p H$>$8 (*cf.* Ref.[21]). Hence, the system will obey the following rate equations

$$\begin{cases} \dfrac{dc_{CO_2}}{dt} = -k_1 c_{CO_2} + k_2 c_{H_2CO_3} \\ \dfrac{dc_{H_2CO_3}}{dt} = k_1 c_{CO_2} - k_2 c_{H_2CO_3} - k_3 c_{H_2CO_3} + k_4 c_{\pm}^2 \\ \dfrac{dc_{\pm}}{dt} = k_3 c_{H_2CO_3} - k_4 c_{\pm}^2 \end{cases}$$

where

$$c_{\pm} = c_{H^+} = c_{HCO^-_3}$$

We will now introduce

$$\begin{cases} c_{CO_2} = c^\circ_{CO_2} + \Delta_1 \\ c_{H_2CO_3} = c^\circ_{H_2C_3O} + \Delta_2 \\ c_{\pm} = c^\circ_{\pm} + \Delta_3 \end{cases}$$

where Δ_1, Δ_2, and Δ_3 denote small deviations from the equilibrium concentrations (denoted c°).

$$\begin{cases} 0 = k_1 c^\circ_{CO_2} + k_2 c^\circ_{H_2CO_3} \\ 0 = k_1 c^\circ_{CO_2} - k_2 c^\circ_{H_2CO_3} - k_3 c^\circ_{H_2CO_3} + k_4 (c^\circ_{\pm})^2 \\ 0 = k_3 c^\circ_{H_2CO_3} - k_4 (c^\circ_{\pm})^2 \end{cases}$$

For small Δ we may put

$$c_{\pm}^2 \approx (c_{\pm}^\circ)^2 + 2c_{\pm}^\circ \Delta_3 = (c_{\pm}^\circ)^2 + k_5\Delta_3/k_4$$

where $k_5 = 2c_{\pm}^\circ k_4$
In this case there results

$$\begin{cases} \dfrac{d\Delta_1}{dt} = -k_1\Delta_1 + k_2\Delta_2 \\ \dfrac{d\Delta_2}{dt} = k_1\Delta_1 - k_2\Delta_2 - k_3\Delta_2 + k_5\Delta_3 \\ \dfrac{d\Delta_3}{dt} = k_3\Delta_2 - k_5\Delta_3 \end{cases}$$

or written in matrix notation

$$\frac{d\Delta}{dt} + A\Delta = 0$$

where

$$A = \begin{pmatrix} k_1 & -k_2 & 0 \\ -k_1 & k_2 + k_5 & -k_5 \\ 0 & -k_3 & k_5 \end{pmatrix}; \quad \Delta = \begin{pmatrix} \Delta_1 \\ \Delta_2 \\ \Delta_3 \end{pmatrix}$$

The general solution of this system, which is easily obtained on diagonalization of the matrix (*cf. e.g.* Frost and Pearson [22] or Matsen and Franklin [23]), can be written as linear combinations of exponential functions

$$\Delta = e^{-At}\,\Delta_0 \quad \text{or} \quad \Delta_r = \sum_{s=1}^{3} b_{rs}\, e^{-\lambda_s}$$

where b_{rs} are constants (components of the eigenvectors) and λ_s are the eigenvalues of the matrix, or solutions of the secular equation:

$$\begin{vmatrix} k_1 - \lambda & -k_2 & 0 \\ -k_1 & k_2 + k_3 - \lambda & -k_5 \\ 0 & -k_3 & k_5 - \lambda \end{vmatrix} = 0$$

This equation has three solutions

$$\lambda_1 = 0$$
$$\lambda_2 = \tfrac{1}{2}(p+q)$$
$$\lambda_3 = \tfrac{1}{2}(p-q)$$

where

$$p = k_1 + k_2 + k_3 + k_5$$
$$q = [p^2 - 4(k_1k_3 + k_2k_5 + k_1k_5)]^{1/2}$$

Now $\lim_{t\to\infty} \Delta_r = 0, \qquad r = 1,2,3.$

Hence $b_{r1} = 0, \qquad r = 1,2,3.$

The second term in the expression for Δ_r, *i.e.* $b_{r2}\ e^{-\lambda_2 t}$, becomes negligible very quickly since λ_2 is large ($k_3,k_5 \rangle\rangle k_1,k_2$). Thus the relaxation is approximately described by

$$\Delta_r = b_{r3}\ e^{-\lambda_3 t}$$

and we have for the relaxation time

$$\tau = 1/\lambda_3$$

or, since $(k_1k_3 + k_2k_5 + k_1k_5) \langle\langle\ p^2$, we may approximate

$$\frac{1}{\tau} = \lambda_3 = \tfrac{1}{2}\ p\left(1 - \sqrt{1 - 4\cdot\frac{k_1k_3 + k_2k_5 + k_1k_5}{p^2}}\right) \approx$$
$$\approx \frac{k_1k_3 + k_2k_5 + k_1k_5}{p} = \frac{k_1k_3 + k_2k_5 + k_1k_5}{k_1 + k_2 + k_3 + k_5}$$

Utilizing the fact that $k_1,k_2 \langle\langle k_3,k_5$, we may approximate further

$$\frac{1}{\tau} \approx \frac{k_1k_3 + k_2k_5 + k_1k_5}{k_3 + k_5} = k_1 + \frac{k_2k_5}{k_3 + k_5}$$

Resubstituting

$$k_5 = 2k_4c_\pm^\circ$$

we obtain

$$\frac{1}{\tau} \approx k_1 + \frac{2k_4c_\pm^\circ k_2}{2k_4c_\pm^\circ + k_3}$$

Denoting the true dissociation constant of H_2CO_3 by $K_s = k_3/k_4$, we finally obtain

$$\frac{1}{\tau} \approx k_1 + \frac{2c_\pm^\circ k_2}{2c_\pm^\circ + K_s}$$

This expression agrees asymptotically with those given by Eigen [24] for the two limiting cases *, $2c_\pm^\circ \rangle\rangle\ K_s$ and $2c_\pm^\circ \rangle\rangle\ K_s$. The former is equivalent to the simple case treated in the preceding section.

* $2c_\pm^\circ \langle\langle K_s$ means that the dissociation of H_2CO_3 is practically complete, *i. e.* we are concerned with the reaction: $CO_2 + H_2O \rightleftharpoons H^+ + HCO_3^-$. In this case we have

$$1/\tau = k_1 + 2k_2c_\pm/K_s.$$

$2c_\pm^\circ \rangle\rangle K_s$ means that the dissociation of H_2CO_3 is very small, *i. e.* we would have the reaction $CO_2 + H_2O \rightleftharpoons H_2CO_3$, with the rate of relaxation determined by $1/\tau = k_1 + k_2$.

b. Experimental. In view of the theoretical considerations given above, it is now possible by carrying out experiments at various concentrations to determine the rate constants k_1, k_2 and the true dissociation constant K_s as well as the hydration constant K_h. For, utilizing the fact known from earlier investigations that $k_1 \ll k_2$ *, the equation

$$\frac{1}{\tau} = k_1 + \frac{2c_{\pm}^{\circ} k_2}{2c_{\pm}^{\circ} + K_s}$$

may in our case be replaced by

$$\tau = \frac{1}{k_2}\left(1 + \frac{K_s}{2c_{\pm}^{\circ}}\right)$$

Denoting the equivalent ionic conductances by l, we have for the conductivity (neglecting the difference between the actual equivalent conductivities and those at infinite dilution):

$$\varkappa = 10^{-3} c_{\pm}^{\circ} \; (l_{H+}^{\circ} + l_{HCO_3^-}^{\circ})$$

Now

$$J = R \; \varkappa$$

where J is the cell constant and R the resistance of the cell. Hence

$$1/c_{\pm}^{\circ} = 10^{-3} \; (l_{\pm+}^{\circ} + l_{HCO_3^-}^{\circ}) \; R/J$$

If this is inserted in the expression for τ we obtain

$$\tau = 1/k_2 + 10^{-3} K_s \; (l_{H+}^{\circ} + l_{HCO_3^-}^{\circ}) \; R/2Jk_2$$

Consequently we may plot τ *versus* R to obtain a straight line.

The results of the experiments are given in Table 1 and shown in Fig. 7.

Table 1. Chemical relaxation time for aqueous solutions ** of CO_2 at 4°C and 150 atm pressure.

R	R_{corr} ***	τ
5.24 kΩ	5.20 kΩ	0.76 sec
5.24	5.20	0.77
5.98	5.93	0.62
5.98	5.93	0.61
9.13	9.06	0.75
9.13	9.06	0.72
9.13	9.06	0.83
13.7	13.6	0.92
13.7	13.6	0.95
16.4	16.2	1.30
16.4	16.2	1.19

* *cf.* Table 2.

** The carbon dioxide solutions were prepared by bubbling CO_2 through conductivity water and then diluting to the desired concentration. Since losses of CO_2 were difficult to avoid, it is more reliable to use the conductivity for the concentration determination throughout.

*** R_{corr} denotes the values corrected for the volume change on compression to 150 atm.

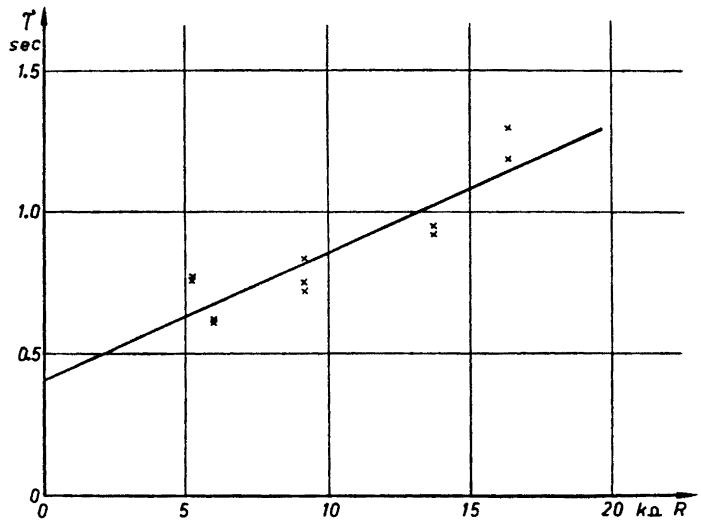

Fig. 7. Plot of τ *versus* R from experiments with CO_2-H_2O at 4°C.

A straight line has been fitted to the points in Fig. 7 using the method of least squares. The equation of this line is

$$\tau = aR + b$$

where

$$a = (0.045 \pm 0.006)10^{-3} \text{ sec ohm}^{-1}$$

$$b = (0.409 \pm 0.025)\text{sec}$$

Thus

$$k_2 = 1/b = 2.4 \text{ sec}^{-1}$$

and with

$$K_s = 2 \times 10^3 \, Jk_2a/(l^{\circ}_{H+} + l^{\circ}_{HCO_3^-})$$

insertion of the various quantities yields

$$K_s = 1.6 \times 10^{-4}$$

In these experiments, a cell with $J = 0.21$ cm^{-1} was used.

If we denote the hydration constant of carbon dioxide by K_h:

$$K_h = c_{H_2CO_3}/c_{CO_2} = k_1/k_2$$

and the apparent primary dissociation constant of carbonic acid by K_{sh}:

$$K_{sh} = \frac{c_{H+} \cdot c_{HCO_3^-}}{c_{CO_2} + c_{H_2CO_3}}$$

it is well known that

$$K_{sh} = \frac{K_s K_h}{1 + K_h}$$

Inserting our values for K_s and k_2 and the known [25] value of K_{sh} (interpolation yields $K_{sh} \approx 2.94 \times 10^{-7}$ at 4°C) we obtain

$$K_h = 1.8 \times 10^{-3}$$
$$k_1 = 4.4 \times 10^{-3} \text{ sec}^{-1} \text{ mole}^{-1} \text{ l}$$

c. *Discussion.* The results of our present investigation at 4°C and 150 atm are *

$k_1 = 4.4 \times 10^{-3}$ sec^{-1} mole^{-1} l
$k_2 = 2.4$ sec^{-1}
$K_h = 1.8 \times 10^{-3}$
$K_s = 1.6 \times 10^{-4}$

Some previous results are given in Table 2 for comparison.

Table 2. Previous results for k_1, k_2, K_s and K_h.

* It was observed that curves corresponding to a much shorter relaxation time were obtained at 18°C consistent with the temperature dependence of the rate constants. However, no quantitative experiments were carried out at this temperature.

By carrying out experiments at two different temperatures, it would, however, be possible to determine the activation energies of the various steps of the reaction between CO_2 and water.

The dispersion of the points in Fig. 7 indicates that the precision of the method is not yet very great. There are two imperfections in the electric circuit which should be mentioned. One is the deviation from linearity of the rectifier. Although the recording system was calibrated before each run, a certain loss of accuracy is always obtained. The other is the "overshoot" effect produced by the resonance compensating arrangement of the recorder. This imperfection is present in all mechanical oscillographs and cannot be avoided unless very particular measures are taken. These systematic erros together with the accidental errors of the recording system and errors in the evaluation of the relaxation curves cause an error in the τ values obtained of an order of magnitude from 10 % to 20 % in unfavourable cases. It seems however that, using more elaborate components in the electric system, it will be possible to increase the accuracy.

The low ionic concentrations in the experiments with the volatile CO_2-water system makes these determinations particularly difficult.

In the experiments it was observed that the balancing capacitance of the cell had to be changed when the pressure was applied. This was considered to be without influence on the determinations. It would be possible, by the use of a phase sensitive rectifier, to study this effect which is, at least in part, of a purely mechanical nature (a change in the capacitance of the leads).

Acknowledgement. A pressure method for the determination of micelle formation rates was independently proposed several years ago by G. Aniansson of this Institute.

Electrophoretic and Ultracentrifugal Study of Plaice Myogen

J. W. JEBSEN* and G. HAMOIR**

Laboratory of General Biology, University of Liège, Belgium

The protein composition of water extracts and myogen of plaice muscle has been investigated by electrophoresis and ultracentrifugation. Plaice myogen has been fractionated with neutral ammonium sulphate in the whole range of saturation and the different fractions analysed by both methods. The salting-out range of the various electrophoretic and ultracentrifugal gradients has been determined. Usually the components precipitating at a higher salt concentration sediment more slowly and migrate more rapidly in the electrical field. Some properties of two crystalline albumins have been described. The isolation of a third component by preparative electrophoresis has allowed to show that the protein of abnormal amino acid composition discovered in carp myogen also occurs in plaice. Although the muscle extracts of low ionic strength present a high specificity from the electrophoretic point of view, their more detailed study will make the common properties of their protein constituents more conspicuous.

Fish muscle extracts of low ionic strength have been investigated electrophoretically in several laboratories. Carp [1–7] and cod [8,9] have been examined fairly extensively while general surveys of about 25 species including *Gadidae*, *Pleuronectidae*, *Selachii* and fresh-water fishes have been carried out by *Connell* [10] and by Nikkilä and Linko [11]. These surveys have, however, been limited to the electrophoretic analysis of whole extracts. A fractionation scheme with ethanol at low temperature has been described [11] but applied only on a small scale and to pike muscle extracts, the fractions obtained being characterized by paper electrophoresis. The separation of the albumins and globulins of the whole extracts by dialysis against water and the electrophoretic analysis of the myogens isolated in this way have been carried out on cod [8], carp [1–4] and plaice [12]. The fractionation of the carp myogen with neutral ammonium sulphate has been investigated in Liège by Henrotte [5–7] who crystallized two carp albumins and described some of their properties (*cf.* also Hamoir [13]). Preliminary experiments have also been done on plaice myogen resulting in the crystallization of another muscle albumin [12,14].

A systematic study of the fractionation of fish myogens is thus still lacking. We have thought it therefore of interest to investigate more completely the electrophoretic and ultracentrifugal behaviour of plaice muscle extracts of low ionic strength, of plaice myogen and of fractions isolated from it with neutral ammonium sulphate in the whole range of saturation. A preliminary report of a part of this work has already been published [15].

METHODS

Plaice *(Pleuronectes platessa* L.) was caught on the Belgian coast, immediately eviscerated and kept in ice for about 20 h before filleting. The muscles are cut into small blocks and stored at −20°C for 1 to 30 days in closed containers in order to avoid evaporation. All operations are carried out at 0°C. Muscles fragments are cut in slices 40 μ thick with an automatic freezing microtome [16]. The muscle pulp is mixed with one volume of water and gently stirred for one hour. The extract is sometimes dialyzed for 48 h against 2 l of a phosphate buffer of μ 0.05 and pH 7.5 renewed once (0.0156 M Na_2HPO_4 + 0.0035 M KH_2PO_4). The precipitate formed is spun down and the supernatant examined by electrophoresis or ultracentrifugation. Usually the dialysis is carried out against the same volume of distilled water renewed several times for three days in order to remove completely the globulins. The myogen is then fractionated with neutral ammonium sulphate or dialyzed against the usual buffer of μ 0.05 and pH 7.5 before electrophoretic or ultracentrifugal analysis.

For fractionation, a mixture of solid ammonium sulphate and disodium phosphate (0.71 g $Na_2HPO_4 \cdot 12\ H_2O$/100 g ammonium sulphate) is added to the rapidly stirred solution. The precipitate formed is removed immediately except in the case of the last fraction (90 − 100 % saturation) which is left overnight in the cold room before centrifugation. In the calculation of the degree of saturation, we have admitted that the total amount of salt added correspond only to ammonium sulphate and we have taken account of the variations of volume occurring: the degree of saturation used corresponds to the percentage of the salt concentration of the saturated solution at 0°C (*cf.* Brenner-Holzach and Staehelin [17]). After dialysis the protein content of the solutions is determined with a dipping refractometer. Samples of the protein solution and of the dialysis fluid are placed in a water bath of constant temperature (25°C) and illuminated with a sodium lamp (589 mμ). The refractive increment corresponding to a concentration of 1 g/100 ml has been taken equal to 182×10^{-5} according to determinations by Hamoir [3] on carp myogen.

Electrophoresis is conducted at 1°C in a Tiselius apparatus slightly modified [18], the recording of the patterns beeing made according to the Longsworth's procedure [19,20]. The mobilities are calculated from the mean conductivity of the buffer and the protein solution and from the maximum ordinate of the gradients. At the low ionic strength used, the ascending mobilities notably exceed the descending ones and depend on the protein concentration. A correction according to Longsworth and Mac-Innes [21] has however not been applied. We will thus consider mainly the descending values. The relative concentrations of the different gradients have been determined according to the perpendicular extrapolation method of Tiselius and Kabat [22]. At the low ionic strength used, an overestimation of the quick gradients at the expense of the slow ones may occur particularly on the ascending side [23]. Our surface determinations did not, however, disclose notable discrepancies between the ascending and the descending values (*cf.* Table 3). This anomaly appears thus usually not very pronounced here. A further check of its importance by use of higher ionic strength has not been made.

The ultracentrifugations are carried out with an ultracentrifuge Spinco Model E in the department of Physical Chemistry (Prof. V. Desreux). The rates of sedimentation are corrected for water and 20°C, use being made of the mean partial specific volume given in Svedberg and Pedersen's [24] Appendix II. The relative concentrations are also calculated according to Tiselius and Kabat [22]. No account is taken of the decrease of concentration of the slower components occurring at the different boundaries observed which lead to an overestimation of the slow components at the expense of the quick ones [25].

Some measurements of absorption in the ultraviolet have been made with a D. U. Beckman spectrophotometer.

RESULTS

A. The protein composition of whole extracts and myogen

a) *Content in albumins and globulins.* The amounts of proteins isolated after one or several extractions with water and subsequent dialysis against a phosphate buffer of μ 0.05 and pH 7.5 or water are given in Table 1. Although each extract was made from about 10 fishes, notable variations occur from one extraction to the other reminiscent of those observed on the carp [3]. The amounts of globulin X and myogen obtained after exhaustive extraction are definitely lower than the values given for the carp [3]. The content of myogen of plaice muscle is lower than the ones of carp white or red muscles; if one assumes a protein content of 16 %, it would represent only 13 % of the muscle proteins. In the case of globulin X, the difference is perhaps not significant owing to the lower ionic strength used in the present experiments.

b) *Electrophoretic analysis.* The electrophoretic pattern of the whole extract at μ 0.05 and pH 7.5 is given in Fig. 1 a. Its peaks are numbered according to Connell's nomenclature. Four gradients are visible on the ascending side. The quickest small ascending peak of Connell [10] is not observable here. It is not always present in the electrophoretic patterns. The quickest fraction of Fig. 1 a is heterogeneous and corresponds to the component 1 a of Connell [10]. Peak 2 is well defined on the ascending and descending sides; it is separated

from the main peak 4 by a heterogeneous fraction numbered 3. The slowest ascending gradient appears fairly symmetrical; prolonged electrophoresis reveals, however, that it splits into two gradients on the descending side. As some fractionations have shown that a component of intermediate mobility occurs between gradient 4 and this slow peak, it has been represented by the numbers 6 and 7 instead of 5 and 6 previously used [10].

If the extract of Fig. 1 a is dialysed against water, the globulin X fraction precipitates. The supernatant obtained after centrifugation gives a somewhat different electrophoretic pattern (Fig. 1 b). The components 1 and 1 a disappear. The relative proportion of peak 4 increases definitely. The following slow ascending peak is notably reduced and the two gradients corresponding to numbers 6 and 7 separate now clearly on both limbs.

The mobilities of these different gradients are given in Table 2 together with the data obtained by Connell [10] in a single experiment. Connell's values are much lower. In view of the larger number of experiments and of the good agreement of our results, our data are probably more correct. The percentages of the different gradients are given in Table 3. They are similar to the ones given earlier [10]. The measurements made on myogen and the determinations of the proportion of globulin X in these extracts allow to estimate the amount of globulin X corresponding to each peak (*cf.* Table 1). As the total content in globulins varies notably from one extract to the other (*cf.* Table 1), these evaluations are approximate. They show nevertheless that the peaks 3 and 4

of whole extracts are entirely soluble in water while a partial precipitation of peak 2 occurs. Globulin X is formed mainly by the slow moving components 5, 6 and 7 and by the quick ones 1 and 1 a.

c) *Ultracentrifugal analysis.* Two ultracentrifugations of plaice myogen made by Henrotte [12] have shown that the three components sedimenting with rates of about 7, 5 and 1.5 *S* observed in carp myogen [3,4] are also present in this case. We have carried out further experiments on myogen and have examined whole extracts similar to those analysed by electrophoresis too.

The whole extract (Fig. 2 a) does not differ qualitatively from myogen (Fig. 2 b); it includes the three peaks already mentioned. Their corrected rates of sedimentation and relative concentrations are given in Table 4, together with similar data relative to the myogen. Notable variations occur in the rate of sedimentation of each peak. Two of the experiments of myogen carried out on two different concentrations and the surface measurements show that these variations cannot be due to changes in concentration. They also obviously exceed the experimental errors, particularly in the case of the slow and the median peaks. Several components of close rates of sedimentation are present in these two gradients. The comparison of the surface determinations relative to whole extracts and myogen allows also to estimate the amount of globulins occurring in each peak of the whole extract. After dialysis against water the slow peak remains entirely in solution, the medium one precipitates in the proportion of about 25 % (*cf.* Table 1) and the third one about 50 %. Fish muscle extracts of low ionic strength appear thus to behave very similarly in the ultracentrifuge. They seem to contain generally the slow sedimenting components first observed by Deuticke [26] on frog muscle extracts which do not occur in rabbit muscles and therefore not in muscles of warm-blooded animals. They differ only from each other in the proportions of the different gradients observed.

B. The fractionation of myogen with neutral ammonium sulphate

The range of salt fractionation up to 65 % has already been briefly examined by Henrotte [12,14]. He has considered the fractions corresponding to 0—40, 40—48, 48—55 and 55—65 % of saturation at pH 6.5 and analysed the fractions 40—48 and 48—55 by ultracentrifugation. The first one sediments as a single peak of about 7 *S*; the second one is a mixture of the previous component and of another one of about 5 *S* which could be crystallized [12,14].

We have fractionated plaice myogen at neutral pH in the whole range of saturation. In order to avoid arbitrariness in the determination of the zones of fractionation, a salting-out curve has first been measured by ultraviolet absorption up to 65 % saturation. The precipitation starts at 35 % saturation and increases progressively without definite break of the curve. There was therefore no reason to change the earlier zones of fractionation. The main fractions examined are 0—40, 40—48, 48—55, 55—65, 70—80, 80—90 and 90—100 %. The amount of protein isolated in each of these fractions is given in Table 5. Two major ranges of precipitation appear clearly separated by the small zone 65—70 % of lower precipitation.

a) *Electrophoretic analysis of the fractions.* All the fractions considered except fraction 65—70 % have been isolated several times in order to check the reproducibility of the electrophoretic results. Many overlapping fractions have also been considered such as 40—55, 48—65, 65—80, 70—100, 80—100 whose results are mainly confirmatory of the previous ones and will therefore usually not be described here. The relative positions of some peaks pertaining to different fractions have been controlled by mixing some fractions and examining the elctrophoretic pattern of the mixture. The results obtained are summarized in Fig. 3.

The fractionation discloses some new peaks which are not observed in plaice myogen. Small quick heterogeneous gradients are visible on the ascending side in the fractions isolated up to 65 % saturation (Fig. 3a, b, c, d); the only ones which appear more or less homogeneous migrate at the level of 1a in fractions 0—40 and 55—65 %. Component 2 remains soluble up to

Table 5. Partition of myogen by ammonium sulphate fractionation at neutral pH.

Migration to the right. Conditions of electrophoresis: μ 0.05; pH 7.5; electrical field 6.4—6.7 V/cm. a) 0—40 % saturation: 1 %, 260 min., b) 40—48 % saturation: 1.5 %, 140 min., c) 48—55 % saturation: 2.25 %, 236 min., d) 55—65 % saturation: 1.5 %, 217 min., e) 70—80 % saturation: 1.5 %, 222 min., f) 80—90 % saturation: 1.5 %, 243 min., g) 90—100 % saturation: 1.39 %, 203 min.

70 % saturation; it precipitates mainly in the fractions 80—90 % and 90—100 %. Component 3 which does not appear clearly in whole myogen is somewhat better defined in Fig. 3d, e and f. The proportion of component 4 in the different fractions varies suprisingly: it decreases up to 55—65 % and increases again in fractions 70—80 and 80—90 %. This behaviour suggests that this peak corresponds to at least two components of different solubilities. Component 5 separates from component 6 after prolonged electrophoresis on the ascending side in fractions 48—55 and 55—65 % (Fig. 3c and d) as a sometimes important peak although it is not visible in myogen. It corresponds probably to a rapid portion of the gradient 6 of myogen which does not clearly resolve from this gradient because of its low concentration in myogen. Component 7 is fairly soluble and precipitates in the range 70—100 % (Fig. 3e, f, g). The analysis of these electrophoretic patterns is given in Tables 2 and 3.

Our results differ somewhat from those obtained by fractionation of pike muscle extracts with ethanol [11]. It was found in this case that the solubility of the various components increases with the electrophoretic mobility. The

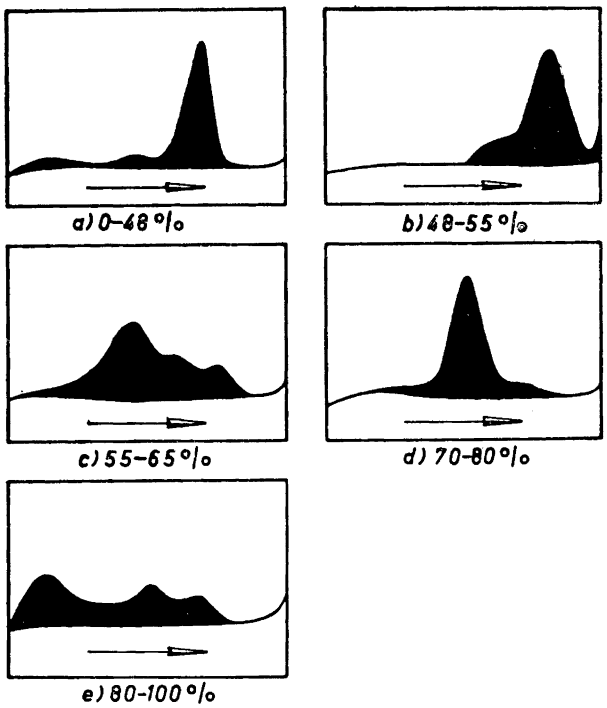

Fig. 4. Ultracentrifugal patterns of some fractions of plaice myogen isolated with neutral ammonium sulphate. Direction of migration: from left to right. Protein conc. 1 %; μ 0.05; pH 7.5. a) 0—48 % saturation, 56 min., b) 48—55 % saturation, 48 min., c) 55—65 % saturation, 56 min., d) 70—80 % saturation, 64 min., e) 80—100 % saturation, 76 min.

behaviour of components 7 and 4 of plaice myogen are in disagreement with these results. The quicker electrophoretic components are apparently generally more soluble but it is clear that this regularity has many exceptions.

b) *Ultracentrifugal analysis of the fractions.* Henrotte [12,14] has already shown that a single component of about 7 *S* is present in fraction 40—48 % while two of about 5 and 7 *S* are observed in the fraction 48—55 %. We have extended this analytical work to the various fractions described in the preceding paragraph. The main results obtained are summarized in Fig. 4.

The three ultracentrifugal gradients of plaice myogen precipitate on ammonium sulphate fractionation in very different ranges. The fractions 0—40 and 40—48 % contain nearly exclusively the quick peak (Fig. 4a). The median ones begin to precipitate in significant amounts in the range 48—55 % (Fig. 4b *) and occur as a single peak in the fraction 70—80 (Fig. 4d) with sometimes a slight admixture of the quick peak. The intermediate fraction 55—65 % is a mixture of the quick and the median components. It reveals also the occurrence of a new gradient sedimenting more quickly than the quick one of whole myogen. The slow gradient is present as an impurity in fraction 0—48 % and is the major component of the fraction 80—100 %. A nearly complete isolation of the quick and the median gradients and a considerable increase in concentration of the slow gradient are thus obtained by ammonium sulphate fractionation at neutral pH. The corrected rates of sedimentation and the relative amounts of the different peaks are given in Table 4. The surface determinations are somewhat inaccurate because of the difficulty in determining the exact position of the base line. In the case of the small gradients, a quick spreading is also usually observed which makes the determinations of the rates of sedimentation less precise. Some conclusions are nevertheless possible. The slow peak of plaice myogen precipitates in a small proportion in the range 35—48 % and mainly in the range 80—100 %. The two other peaks are more heterogeneous; they precipitate in the whole range. The rates of sedimentation are of the same order of magnitude for the fractions as for the total myogen. The higher variations observed are apparently due to the quick spreading of some gradients and to changes in concentration except perhaps for the quick peak which shows a progressive decrease of the rate when higher salting-out ranges are considered.

The comparison of the ultracentrifugal results with the electrophoretic patterns obtained with the same preparations is very instructive. It shows that the main parts of the fractions 0—48 % and 70—80 % which sediment so differently, migrate with the mobility of peak 4. The wide range of precipitation of this peak is due to the successive salting-out of two different types of molecules. The electrophoresis of a fraction 70—80 % which appeared pure by ultracentrifugation has shown that few percent of the median ultracentrifugal gradient migrate in the electrical field more slowly than peak 4.

The major part of the slow sedimenting component of plaice myogen precipitates in the range 80—100 % as the electrophoretic gradient 2. This gradient isolated by preparative electrophoresis sediments effectively at the rate of

* The apparently higher rates of sedimentation observed in this picture are due to the incomplete filling of the cell.

about 1.5 *S* (*cf.* following paragraph). The higher proportion of the slow ultracentrifugal peak (*cf.* Tables 3 and 4) in fraction 80—100 % suggests however the occurrence in this peak of proteins migrating more slowly in the electrical field.

C. Isolation of some components

The electrophoretic and ultracentrifugal analyses just described have shown the occurrence of some fractions which are fairly homogeneous under the conditions of our experiments. The precipitates which separate between 0—48 % and between 70—80 % contain relatively low percentages of impurities. Further experiments would, however, be necessary to determine their degree of homogeneity. A first step has been made in this direction by isolating crystalline components sedimenting with the rate of these two fractions. Henrotte and Dresse [14] have crystallized from plaice myogen a component of a rate of sedimentation of about 5 *S*. We have reproduced these results and made a preliminary examination of two other components.

1. *Crystalline component of 5.5 S.* Our method of preparation differs somewhat from the one described earlier [12,14]. Myogen is brought to 48 % saturation and about pH 6.5 by addition of solid ammonium sulphate. A saturated solution of ammonium sulphate at neutral pH is then added up to 55 % saturation. This second precipitate is also removed. The fraction precipitating between 55 % and 62 % saturation is redissolved in a minimum amount of water. Rhombohedra similar to those obtained by Henrotte [12,14] separate usually within a day (Fig. 5). They have also been prepared from fractions precipitating with neutral saturated ammonium sulphate in the range of 59—65 or 65—70 % saturation. The slight acidity of 6.5 recommended by Henrotte probably favours the crystallization but seems not very critical.

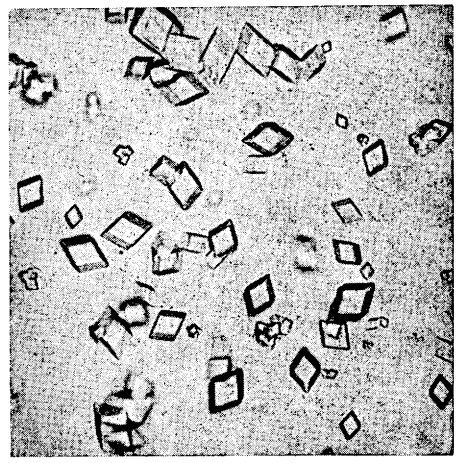

Fig. 5. Crystalline component of 5.5 *S*. Magnification: × 190.

Fig. 6. Crystalline component of 7.1 *S*. Magnification: × 1 800.

Three preparations have been examined by ultracentrifugation. An impurity sedimenting more quickly than the main peak and amounting to less than 5 % of the total protein content is observed. The corrected rates of sedimentation of the main peak at a concentration of 1 % are of 5.48 *S*, 5.48 *S* and 5.46 *S* and at 0.5 % of 5.54 *S* (one determination). The corresponding values of the impurity have been measured on a single preparation at a total concentration of 1 and 0.5 %; they are, respectively, of 8.11 and 8.31 *S*. The values for the main peak are in agreement with the determinations made on the corresponding fractions (Table 4). They are somewhat higher than the rates of the median peak of myogen. This crystalline component seems to correspond to a quick fraction of this median peak. In the electrical field, this crystalline material migrates at μ 0.05 and pH 7.5 as a single peak, moving at the rate of peak 4. A good degree of purity has therefore been achieved in this preparation.

2. *Crystalline component of 7.1 S.* In the course of the previous preparation, another crystalline material could be isolated. This result was first observed by Henrotte [12]. The method of preparation of this new type of crystals differs only slightly from the preceding one. The same fraction 55—62 % redissolved in a minimum amount of water sometimes gives rise to bunches of needles instead of rhombohedra. An important amorphous precipitate appears also at about the same speed. The aspect of the preparations is shown in the Fig. 6. Needles could also been obtained from precipitates isolated in the ranges 48—53 and 53—59 %. We have also been able recently to prepare these crystals in an easier way: myogen has been precipitated at neutral pH with our usual mixture of solid ammonium sulphate and disodium phosphate up to 55 % saturation. The precipitate is partially redissolved with water and the supernatent is separated by centrifugation. Bunches of needles soon appear in the solution together with an amorphous precipitate. The formation

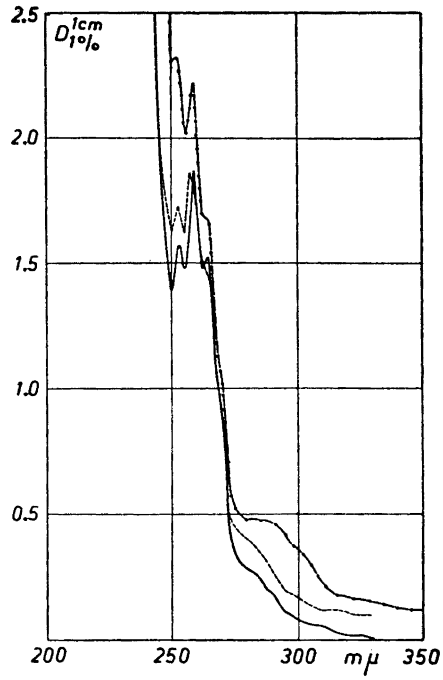

Fig. 7. Ultraviolet absorption spectra of the component of 1.5 *S* at neutral pH (——) and in presence of 0.1 N NaOH (—·—·—) and 0.1 N HCl (— — —).

of these crystals occurs therefore at neutral pH. This protein has a lower range of precipitation than the preceding one. The mixture of crystals and amorphous material shown in Fig. 6 has been separated by centrifugation, redissolved and examined by ultracentrifugation. A single peak has been observed on four different preparations sedimenting at a concentration of 1 % with corrected rates of 6.92 *S*, 7.24 *S*, 7.1 *S* and 7.17 *S*. The last preparation has also been examined at a concentration of 0.5 %; a somewhat higher corrected rate of 7.37 *S* was observed. These values are in agreement with those obtained for the quick component of myogen (Table 4) but somewhat smaller than those of the corresponding fractions.

A preliminary electrophoresis on the other hand suggests that this mixture of crystals and amorphous material is still fairly heterogeneous. A further fractionation should be necessary to isolate this crystalline material in a satisfactory degree of purity.

3. *Component of 1.5 S.* The myogens of cold-vertebrates appear to contain generally a fraction sedimenting very slowly in the ultracentrifuge. A crystalline component of this fraction has been isolated from carp muscles [7]. It precipitates with ammonium sulphate at very high salt concentration, contains about 15 % phenylalanine and no tyrosine and tryptophane [7,13]. This abnormal amino acid composition allowed to determine if a similar protein exists also in plaice myogen. In the fraction precipitating with neutral ammonium sulphate between 90 and 100 % saturation, a sharp ascending peak

(*cf.* Fig. 3g) migrates much quicker than the other gradients. We have been unable to isolate this component by zone electrophoresis on starch columns but small amounts could be obtained by preparative electrophoresis. They have been examined by ultracentrifugation and spectrophotometry. A preliminary report on this part of our work has already been published [15].

a. *Ultracentrifugal behaviour:* A single peak is observed which sediments with a corrected rate of 1.4—1.5 *S*. The values obtained with three different preparations are 1.45 *S* at 0.88 %, 1.52 *S* at 0.5 % and 1.43 *S* at 0.4 %. They do not differ essentially from those obtained previously for the slow peak (Table 4).

b. *Ultraviolet spectrum:* This component presents the abnormal amino acid composition of the corresponding component of carp muscle. Several preparations have been examined at pH 7.5. The three maxima of phenylalanine at 252, 257 and 263 mμ are observed at 253, 259 and 265 mμ and a small absorption which varies from one preparation to the other occurs at higher wave length suggesting the presence of an impurity containing tyrosine, tryptophane or cystine (Fig. 7). In presence of 0.1 N NaOH, the absorption due to this impurity is notably increased. We are therefore not dealing with tryptophane but possibly with tyrosine or cystine. The absence of a definite maximum at about 295 mμ suggests the presence of cystine. In 0.1 N HCl, the spectrum does not differ notably from the one observed at neutral pH.

The content in phenylalanine has been evaluated spectrophotometrically: if the absorption at 259 mμ is attributed exclusively to phenylalanine and if use is made of Fromageot and Schneck's data [27] for the absorption of this amino acid, it amounts to 16 % and is therefore approximatively equal to the one of the carp component. The comparison of the electrophoretic data on the other hand suggests a notable difference in charge: its descending mobility at μ 0.05 and pH 7.5 is -6.5×10^{-5} cm^2 volt^{-1} sec^{-1} while that of the carp protein at μ 0.075 (0.05 phosphate and 0.025 NaCl) and pH 7.3, is -3.2×10^{-5} cm^2 volt^{-1} sec^{-1}. The content in basic and acid amino acids appears thus variable according to the origin.

DISCUSSION

The present investigation has attempted a general survey of the protein composition of plaice myogen by electrophoresis and ultracentrifugation. In order to increase the resolution, the electrophoresis has been carried out at low ionic strength. The resulting improvement of the qualitative analysis, however, increases the boundary anomalies and decreases the precision of the quantitative data. Although myogen contains about 50 different enzymes according to several authors [28,29], the resolution obtained by electrophoresis at pH 7.5 is particularly poor in this case. Five components are observed in the whole extracts instead of 7 in the cod [8] and 6 in the carp [12] and the major one represents a particularly high percentage of the total amount: 50 to 55 % instead of about 40 % in the two other fishes. Electrophoresis carried out at different pH values would perhaps give a better separation but this point has not been investigated. On the other hand, the resolution obtained by

ultracentrifugation is small and similar to the one previously obtained with the carp [3,4].

The fractionation of plaice myogen with neutral ammonium sulphate has made possible an improvement of this analysis: peaks could be observed which were initially too small to be visible and some components could be separated. The examination of the different fractions by electrophoresis und ultracentrifugation shows the occurrence of a general trend: when the degree of saturation of the range considered increases, the electrophoretic mobilities of the components isolated increase and the ultracentrifugal ones decrease. A similar electrophoretic result has already been observed after ethanol fractionation of a pike muscle extract [11]. The range of fractionation suitable to the isolation of a component identified by ultracentrifugation or electrophoresis can thus bee foreseen. This paper shows, however, that discrepancies are not uncommon neither from the electrophoretic nor from the ultracentrifugal point of view.

The comparative electrophoretic studies of Connell [10] and Nikkilä and Linko [11] have shown the great heterogeneity of fish muscle extracts of low ionic strength. This heterogeneity has not been observed so far by ultracentrifugation. Furthermore, when a protein such as the component of S 1.5 can be characterized by some peculiar properties, it seems to occur generally but with different electrophoretic mobilities according to its origin. The charge of these proteins seems to play a secondary role and not to be related to their function in the cell. The further comparative study of the muscle albumins will certainly show more clearly the properties of these proteins which are directly related to their enzymatic functions and must not differ according to their origin.

We are much indebted to *Fiskeribedriftens Forskningsfond*, Norway (J. W. Jebsen) and to the *Fonds National de la Recherche Scientifique* (G. Hamoir) for financial support of this investigation, and wish to thank Prof. Dubuisson and Desreux for facilities put at our disposal. One of us (J. W. J.) expresses his sincere gratitude to Prof. Dubuisson for his kind hospitality, and to Director Eirik Heen, *Norwegian Fisheries Research Institute*, for making this study possible.

Hexosamine and Ester Sulphate Content of the Human *Nucleus Pulposus* at Different Ages

ANUND HALLÉN

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

The hexosamine and sulphate content of adult human *nucleus pulposus* (central part of the intervertebral disc) has been determined. Equimolar quantities of hexosamine and ester sulphate were found. An increase could be noted in the ratio of glucosamine/galactosamine, from about 0.5 at 15 years of age to 1.5 at 90 years. It is concluded that, with rising age, a change takes place in the mucopolysaccharide pattern, in the form of an increase in the ratio of keratosulphate/chondroitin sulphate.

The *nucleus pulposus* (*N.P.*), the central part of the intervertebral disc, is a form of connective tissue that contains unusually large quantities of carbohydrate. It has been shown to contain chondroitin sulphate by Malmgren and Sylvén [1], and keratosulphate by Gardell and Rastgeldi [2]. A method for partial separation of the two polysaccharides has been described by Gardell [3].

The object of the present investigation was to determine whether there are any age differences in the mucopolysaccharide pattern of *N.P.*, and whether it has a high hyaluronic acid content, as claimed by Meyer [4] and by Hall *et al.*[5] Since keratosulphate contains equimolar quantities of glucosamine and ester sulphate, chondroitin sulphate equimolar quantities of galactosamine and ester sulphate, and hyaluronic acid hexosamine but no sulphate, this can be done by comparing the quantities of the hexosamines and ester sulphates at different ages.

EXPERIMENTAL

Non-pathologic lumbar and lower thoracic intervertebral discs were taken from autopsy cases. The *N. P.* was dissected free from the surrounding *annulus fibrosus*, freeze-dried and ground in a mortar. About 4 mg were analyzed for amino sugars according to Gardell [6]. Hydrolysis was performed in sealed tubes with 0.5 ml of 6 N hydrochloric acid for 8 h in a boiling water bath. After desiccation the hydrolysate was put on the top of a Dowex-50 column; the hexosamines were eluted with 0.3 N hydrochloric acid, and determined with the Elson-Morgan method.

About 50—100 mg of the *N. P.* powder were taken for determination of the sulphate content. The powder was hydrolyzed in 4 ml of 6 N hydrochloric acid for 4 h in a boiling

Table 1. Hexosamine and sulphate-sulphur content of freeze-dried *N. P.* from subjects of different ages.

Age, years	% Hexosamine	% Sulphur	Mole hexosamine / Mole sulphur
19	11.3	2.85	0.7
22	10.5	2.48	0.7
27	12.2	2.72	0.8
38	10.0	2.44	0.7
43	8.1	1.13	1.3
50	12.0	2.07	1.0
60	8.5	1.84	0.8
68	7.0	0.98	1.3
74	5.5	1.01	1.0
79	5.5	1.77	0.6
86	6.4	1.07	1.1

water bath, and filtered. Barium sulphate was precipitated from hot solution by the addition of barium chloride. On the following morning, the precipitate was collected on a platinum-iridium Gooch filter, dried and weighed.

To remove free sulphate ions, which might have interfered to some extent with the ester sulphate determinations, the *N. P.* was digested with proteolytic enzymes according to Gardell [7], and run down an anion exchange column according to Boström and Månsson [8]. One g of *N. P.*, both from subjects aged 20—60 years and aged 70 years, was denatured in boiling water; the pH was adjusted to 8.5, and glycerol extracts from pig pancreas and intestinal mucosa were added. The mixtures were digested at 40°C for 2—3 weeks, the pH being controlled and, when necessary, adjusted by the addition of dilute sodium hydroxide. After some particles had been centrifuged off and discarded, the solutions were allowed to pass Dowex-2×8 20—40 mesh columns in chloride form. No barium sulphate opalescence could then be detected on addition of barium chloride. The materials were freeze-dried, and about 10 mg were taken for hexosamine determination and 100—150 mg for sulphate determination.

RESULTS

The results of the analyses are presented in Tables 1—3. As can be seen in Table 1, the hexosamine and sulphate content of dry *N.P.* decreases with rising age. The values were only roughly reproducible, since the powders were not sufficiently homogenized. The values are, however, of the order of magnitude expected for equimolar quantities of hexosamine and ester sulphate being present

Table 2. Hexosamine and sulphate-sulphur content of *N. P.* digested with proteolytic enzymes and devoid of free sulphate ions.

N. P.	% Hexosamine *	% Sulphur	Mole hexosamine / Mole sulphur
20—60 years	6.1	1.24	0.9
70 years	3.5	0.72	0.9

* The ratio of glucosamine/galactosamine remained essentially unchanged during digestion; 0.9 for subjects aged 20—60 years, and 1.2 for 70 years.

Table 3. Hexosamine content and ratio of glucosamine/galactosamine of freeze-dried *N. P.* from subjects of different ages.

Age years	No. of cases	% Hexosamine Mean	Range	% Glucosamine Mean	Range	% Galactosamine Mean	Range	Glucosamine / Galactosamine Mean	Range
11–20	6	14.7	11.3–16.8	4.8	4.3–5.6	9.9	6.9–12.0	0.50	0.41–0.64
21–30	6	11.2	10.3–12.7	4.5	3.2–5.3	6.4	5.4– 8.0	0.75	0.60–0.90
31–40	4	10.6	9.5–11.9	5.2	4.6–6.3	5.4	4.9– 5.9	0.96	0.89–1.13
41–50	4	9.5	7.6–12.0	4.4	3.8–5.5	5.1	3.8– 6.5	0.89	0.66–1.05
51–60	12	8.3	6.1–11.0	4.0	2.8–5.5	4.3	2.8– 5.6	0.96	0.69–1.33
61–70	9	7.8	4.2–11.5	4.1	2.4–5.9	3.7	1.7– 6.1	1.13	0.90–1.38
71–80	5	6.7	5.5– 8.1	3.7	3.1–4.2	3.0	2.4– 3.8	1.25	1.10–1.45
81–90	3	6.6	6.4– 6.8	3.8	3.6–3.9	2.9	2.5– 3.1	1.42	1.17–1.53
91–	1	3.3	–	2.1	–	1.2	–	1.79	–

Table 2 shows the hexosamine and sulphate content of freeze-dried *N.P.*, digested with proteolytic enzymes and devoid of free sulphates. Within errors of method equimolar quantities of hexosamine and ester sulphate were found with no excess of hexosamine. The figures are lower than could be expected from the values in Table 1, probably depending on a higher water content.

It can be inferred from Table 3 that a fairly consistent change in the hexosamine pattern of *N.P.* takes place during aging. Not only does the hexosamine content decrease from about 14 % of dry weight at 15 years of age to 6 % at 90 years, but the ratio of glycosamine/galactosamine increases from about 0.5 to 1.5.

DISCUSSION

The presence of equimolar quantities of hexosamine and ester sulphate suggests that hyaluronic acid contributes very little to the amount of the human *N.P.* mucopolysaccharides. This is in agreement with the findings of Gardell and Rastgeldi [2], who concluded that the glucosamine in *N.P.* belongs to keratosulphate and the galactosamine to chondroitin sulphate. The changes observed in the hexosamine pattern of *N.P.* with age thus reflect an increase in the ratio keratosulphate/chondroitin sulphate.

Hirsch *et al.*[9] studied the sulphate content of human *N.P.* They found that although in the dry substance it diminished with age, as also observed in the present investigation, it was practically constant per volume native tissue.

It is probable that a similar change in the mucopolysaccharide pattern with rising age occurs in other tissues as well. Hass [10] studied the reducing power and sulphate content of dried costal cartilage, and noted a slight increase up to the third and fourth decades of life, and a slight decrease thereafter. Loewi [11] found equimolar amounts of hexosamine, as determined with the Elson-Morgan method, and ester sulphate. With age the values slightly decreased. Shetlar and Masters [12], on the other hand, who determined uronic acid with the carbazole method of Dische, and hexosamine with the Elson-Morgan

method, found that uronic acid had a maximal value at birth and then diminished markedly. Moreover, with increasing age, there was much more hexosamine than could be expected from the uronic acid content. Kuhn and Leppelmann [13] studied the hexosamines of joint cartilage, using paper chromatography for the separation of glucosamine and galactosamine, and found that the ratio of glucosamine/galactosamine increased with rising age, in a similar manner as found for *N.P.* in the present investigation.

Acknowledgements. Iam greatly indebted to Professor Erik Jorpes and Docent Sven Gardell for valuable discussions, and to Docent Harry Boström and Docent Lennart Rodén for help with the ester sulphate determinations.

The investigation has been aided by grants from *Karolinska Institutets reservationsanslag.*

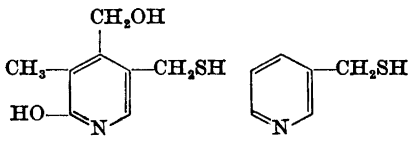
Vor kurzem beschrieben wir den Strahlenschutzeffekt eines sulfhydrylhaltigen Pyridoxinderivates bei der Maus [1]. Der Beobachtung kommt insofern sowohl praktische als auch theoretische Bedeutung zu, als wir selbst früher ausführlich dargestellt haben [2-4], dass offenbar nur Sulfhydrylkörper der sogenannten Cystein-Cysteaminreihe beim Tier in der Lage seien gegen eine Einwirkung energiereicher Strahlen zu schützen. Die Körper dieser Reihe haben die allgemeine Struktur:

$$HS-(CH_2)_x-N\begin{matrix}R_1\\R_2\end{matrix}$$

dazu gehören alle entsprechenden α-Aminosäuren. Auf die Bedeutung von x, R_1 und R_2 soll hier nicht eingegangen werden; wir verweisen auf unsere früheren Arbeiten. Unter cyclischen Verbindungen mit freier SH-Gruppe sind mit Sicherheit bisher keine strahlenschützenden gefunden worden. Das sulfhydrylhaltige Pyridoxinderivat stellt die erste Ausnahme dar. Es handelt sich um das 3-Mercaptomethyl-4-hydroxymethyl-5-hydroxy-6-methylpyridin **, ein echtes Derivat (I) des Vitamin B_6 (kurz B_6-SH genannt):



I II

Es lassen sich, wie wir früher ausgeführt haben [1], keine Unterlagen gewinnen, dass Pyridoxin selbst in der Lage ist eine Strahlenschutzwirkung zu entfalten. — Wie im Falle anderer Schutzstoffe [5,6] ist zu prüfen, ob auch nach peroraler Applikation ein Effekt zu erzielen ist. Ferner interessiert, ob die Wirkung an das unversehrte Mercapto-Pyridoxinmolekül gebunden ist.

Experimenteller Teil. Material und Methode: Weibliche 120—150 g schwere Ratten im Falle des B_6-SH-Fütterungsversuches und weibliche 20 g schwere Mäuse bei der Prüfung des 3-Mercaptomethylpyridins werden einer Röntgenganzkörperbestrahlung unterworfen. Beide Tierarten entstammen institutseigenen Inzuchtstämmen. Die Fütterung erfolgt bei den Ratten mit Latz-Rattenkeksen und Wasser *ad libitum*, bei den Mäusen mit Hafer/Weizen und einem Milchgriespudding. B_6-SH wird morgens nach 12 stündigem Fasten 100 mg/120 g Ratte per Schlundsonde und 60 min vor der Bestrahlung als wässrige Lösung appliziert. Diese B_6-SH-Dosis wird sehr gut vertragen. Wir richten uns in der Dosierung nach anderen Versuchen mit Homocysteinthiolacton [5] und β-Aminoäthyl-isothiuronium-Br-HBr (AET)[6]. — Die Mäuse erhalten 5 min vor dem Strahleninsult 3 mg 3-Mercaptomethylpyridin (wiss. Abt. Fa. E. Merck A.G./Darmstadt)/20 g Maus intraperitoneal. Es handelt sich ebenfalls um eine wässrige Lösung. Die Dosis entspricht etwa dem in früheren Versuchen injizierten B_6-SH und wird von den Mäusen gerade noch vertragen. D.h. es treten keine Todesfälle auf, jedoch schon die ersten Intoxikationserscheinungen.

---

* Herrn Professor Philipp/Freiburg zum 65. Geburtstag gewidmet.

** Die Substanz, die von der Fa. E. Merck A.G./Darmstadt (Deutschland) zum Patent angemeldet ist, wurde uns von dieser in liebenswürdigerweise zur Verfügung gestellt. Herrn Dr. O. Zima danken wir für seine Hilfe.

Die Bestrahlungsbedingungen sind folgende: Apparatur der Fa. C. H. F. Müller/Hamburg, M.G. 300, 200 kV, 15 mA, HWS: 0,57 mm Cu, 306 r/min, Fokus-Tierabstand 30 cm. Jeweils 3 Ratten bzw. 6 Mäuse werden in einem dafür konstruierten Celluloidbehälter bestrahlt. Kontrolltiere erhalten nur eine Röntgenbestrahlung und keinerlei Behandlung.

Die Ergebnisse des B_6-SH-Versuches sind in Tabelle 1 zusammengestellt. Hieraus ergibt

Tabelle 1.

Dosis in r	Zahl d. Tiere B_6—SH	Prozent tot	Zahl d. Tiere Kontrolle	Prozent tot
300	—	—	50	10
400	25	4	50	22
500	50	12	50	58
550	75	21,3	150	47,4
600	50	32	50	80
700	75	84	—	—

sich nach der Probit-Analyse die Regressionsgleichung für:

B_6—SH: $y = 13{,}34\ x - 32{,}27$
Kontrolle: $y = 5{,}91\ x - 11{,}04$
DL 50 = 622,1 ± 20,1 r
DL 50 = 517,6 ± 29,6 r

Zwischen den beiden DL 50-Werten besteht eine gesicherte Differenz (P = 0,01—0,001). In Figur 1 sind die Regressionslinien aufgezeichnet. Sie vermitteln uns deutlich das Bild des Schutzeffektes.

Durch die verschiedenartige Neigung beider Kurven ist der Unterschied im Bereich der höheren Strahlendosen nicht so ausgeprägt wie bei niederen, z. B. 300 r, 400 r oder 500 r. Eine eventuelle Parallelität beider Kurven kann ausgeschlossen werden (P = <0,001).

Nachdem sowohl nach parenteraler als peroraler Applikation des B_6-SH ein Strahlenschutzeffekt bei Maus und Ratte auftritt, erhebt sich die Frage, ob derselbe streng an die Pyridoxinkonfiguration gebunden ist. Wir untersuchen daher entsprechend unseren ersten B_6-SH-Versuchen die Wirkung des 3-Mercaptomethylpyridins (II), eines Körpers, dem 3 Substituenten des Pyridinringes im Vergleich zum Pyridoxin fehlen. Die Ergebnisse sind in Tabelle 2 zusammengestellt.

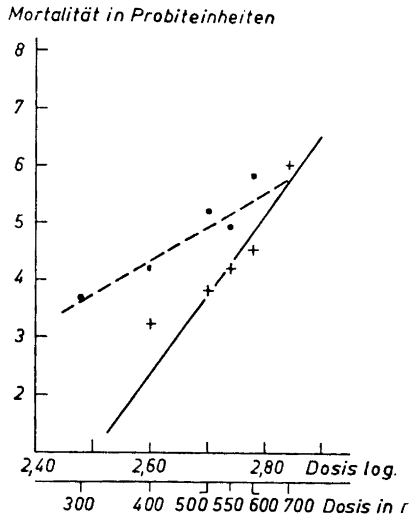


Fig. 1. Dosis-Wirkungskungskurve bei Ganzkörperbestrahlung.
•———• : Kontrollen
+——+ : B_6—S
Abszisse: log. der in r gemessenen Dosis, darunter die regelrechten r-Werte.
Ordinate: Prozent der gestorbenen Tiere in Probiteinheiten.

Tabelle 2.

Dosis in r	Zahl d. Tiere Mercaptomethylpyridin	Prozent tot	Zahl d. Tiere Kontrolle	Prozent tot
500	50	18	50	8
550	50	22	—	—
575	—	—	50	22
600	50	74	—	—
620	—	—	50	64
700	50	94	50	92

Aus ihnen ergeben sich die Regressionsgleichungen für:

3-Mercaptomethylpyridin:
$y = 18{,}31\ x - 45{,}54$; DL 50 = 575,7 ± 14,8 r

Kontrolle:
$y = 20{,}19\ x - 51{,}16$; DL 50 = 604,8 ± 7,2 r

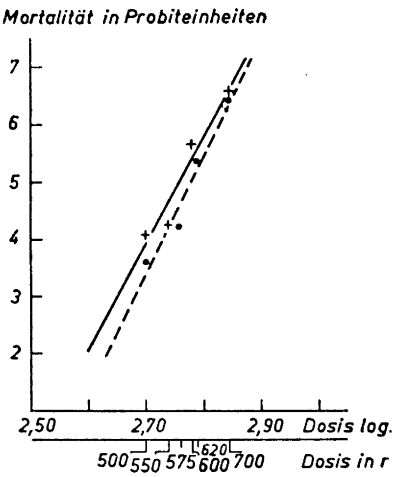

Fig. 2. Dosis-Wirkungskurven bei Ganzkörperbestrahlung.
•———•: Kontrollen.
+——+: 3-Mercaptomethylpyridin.
Abszisse: log. der in r gemessener Dosen, darunter die regelrechten r-Werte.
Ordinate: Prozent der gestorbenen Tiere in Probiteinheiten.

Zwischen den beiden DL 50-Werten besteht keine gesicherte Differenz (P = 0,8—0,9). Eine weitere Prüfung gibt die Gewähr, dass beide Regressionslinien parallel verlaufen (für Nicht-Parallelität: P = 0,9—0,8). Figur 2 zeigt die Verhältnisse graphisch. Die leichte Linksverschiebung der 3-Mercaptomethylpyridin-Kurve ist sehr wahrscheinlich auf eine gewisse Giftwirkung des Mercaptans zu beziehen und auf keinen Fall im Sinne einer Sensibilisierung zu deuten.

Diskussion. Die vorliegenden Ergebnisse bestätigen unsere ersten Beobachtungen, dass im Mercapto-Pyridoxin ein Schutzköper gegenüber energiereichen Strahlen vorliegt. Derselbe tritt sowohl nach parenteraler als auch peroraler Applikation auf und entspricht damit den Schutzstoffen der Cystein-Cysteaminreihe. Der perorale Schutz lässt sich mit dem nach Homocysteinthiolacton oder AET vergleichen. Mit diesem Befund lässt sich die Vorstellung einer spezifischen Strahlenschutzwirkung der Sulfhydrylkörper der Cystein-Cysteaminreihe nicht mehr aufrecht erhalten.

Entsprechend unseren Untersuchungen im Bereich der Cysteaminreihe prüfen wir auch beim Mercapto-Pyridoxin, welche Bedeutung den einzelenen Substituenten des Pyridinringes zukommt. Dabei zeigt sich, dass das einfache 3-Mercaptomethylpyridin vollkommen unwirksam ist.

Wie im Falle der Schutzwirkung der Cystein-Cysteaminkörper ist auch im vorliegenden eine Deutung des Schutzmechanismus nicht möglich.

Die Untersuchungen wurden mit Unterstützung der Deutschen Forschungsgemeinschaft ausgeführt.

On the Significance of the Release of two Different Peptides from Fibrinogen during Clotting

TORVARD C. LAURENT and BIRGER BLOMBÄCK

Department of Chemistry, Karolinska Institutet, Stockholm, Sweden

The first step in the clotting process when fibrinogen is incubated with thrombin is a release of two different peptides, A and B [1,2]. It has been shown that clotting also occurs after incubation with reptilase when only peptide A is released [3,4]. This raises the question of the biological significance of the release of peptide B.

The second step in the clotting process with thrombin has been shown to be a formation of an intermediate polymer with a varying length and a width corresponding to two parallel fibrinogen molecules [5]. Casassa [6] showed that it is possible by means of light-scattering to obtain the ratio of the molecular weight and molecular length (M/L) of this polymer. The second

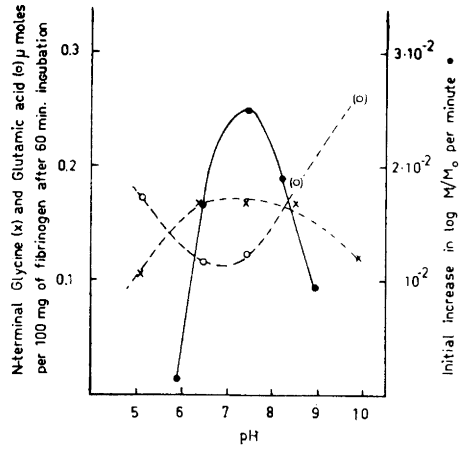

Fig. 1. N-Terminal analysis on glycine and glutamic acid after incubation of 0.17 % fibrinogen with 0.024 NIH-units/ml of reptilase for 60 min. The initial polymerization rate of the protein has been plotted for comparison. M is the weight-average molecular weight of the polymer and M_0 is the molecular weight of fibrinogen.

step of the clotting can conveniently be studied in urea solutions, where step three, the visible clotting, is inhibited [7].

The aim of the present investigation, of which this is a preliminary report, was to see whether an intermediate polymer could be formed even by reptilase as the coagulating agent.

The first experiment was planned to determine the pH-optimum of the action of reptilase as well as to assure that only peptide A was split off within the working range of the pH. The experimental conditions were described earlier [4]. N-Terminal glycine, glutamic acid and tyrosine were determined after incubation of fibrinogen with reptilase for 1 h and 17.5 h at room temperature. The protein concentration was 0.17 %, the reptilase concentration 0.024 NIH-units/ml and the medium was tris-imidazole buffer and sodium chloride, ionic strength 0.2. The values for glycine and glutamic acid were corrected with respect to the tyrosine values [8]. The initial polymerization rate was followed by light-scattering [4]. Fig. 1 shows that the decrease of glutamic acid, the increase of glycine and the initial polymerization rate all had pH-optima at pH 6—8. Within the error of the method, the disappearance of one N-terminal glutamic acid corresponded to the appearance of one N-terminal glycine. After 17.5 h incubation the ratio of N-terminal glycine to N-terminal tyrosine (Table 1) was, within the experimental errors, 1:1, indicating that most of the fibrinogen had been transformed to fibrin at all pH's studied and that only one peptide, A, had been split off.

Table 1. Ratio of N-terminal glycine and tyrosine after incubation of fibrinogen with reptilase for 17.5 h. The experimental conditions are described in the text.

pH	5.1	6.35	7.4	8.5	9.9
Glycine / Tyrosine	1.12	0.81	0.97	0.97	0.95

In the second experiment, thrombin and reptilase were added in a concentration of 0.03 NIH-units/ml to different solutions of 1 % fibrinogen containing 0.02 M tris-imidazole buffer pH 6.35 and 0.38 M sodium chloride. The solutions were incubated in dialysis bags for 9 h at 37°C. The clots formed were then dissolved by dialysis for 6 h against 2 M urea containing 0.01 M tris-imidazole buffer pH 7.45 and 0.22 M

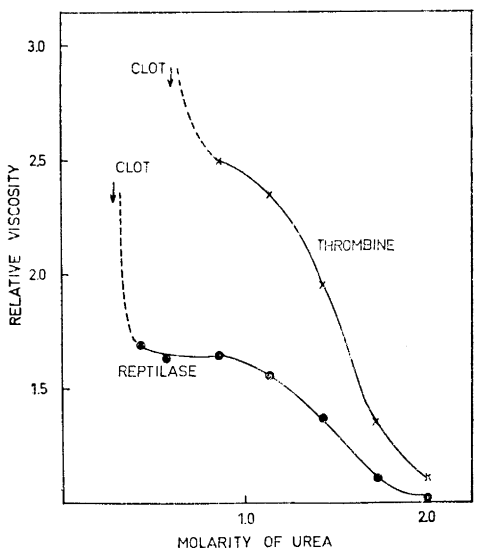

Fig. 2. Relative viscosity at different urea concentrations of fibrin formed by the action of thrombin and reptilase. Protein concentration 0.14 %.

sodium chloride. The solutions were diluted, the protein concentration being 0.14 %, keeping the ionic concentration constant, at varying urea concentrations. The viscosities of the solutions were measured in an Ostwald viscometer at 20°C, 18—24 h after dilution. No correction for non-Newtonian flow was applied. The result is shown in Fig. 2. The increase in the range of 0.4—2 M urea of the viscosity of fibrin formed by reptilase and in the range of 0.7—2 M urea of the viscosity of fibrin formed by thrombin is most probably an indication of the formation of urea soluble fibrin polymers.

In order to compare the two intermediate polymers by light-scattering a third experiment was performed identical with the second except that the enzyme concentration was now kept at 0.06 NIH-units/ml in the original incubation mixture and the incubation time was 18 h. The N-terminal analysis in the first experiment indicates that during this incubation time, all

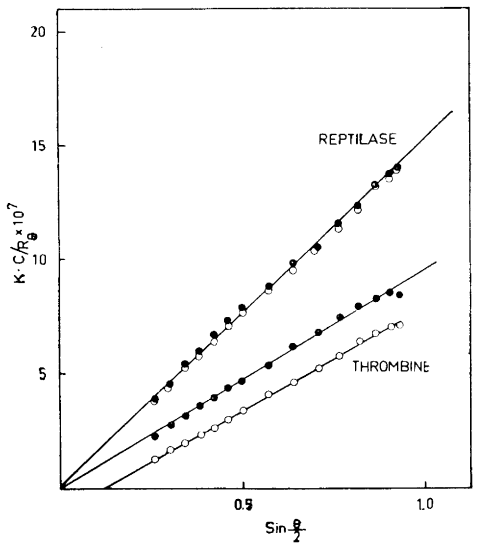

Fig. 3. Evaluation of light-scattering data according to Casassa. ($K = 2\pi^2 n^2 (dn/dc)^2 / N\lambda^4$, where n is the refractive index of the solvent; dn/dc the refractive increment, 0.197 ml/g; N, Avogadros number and λ the wavelength of the light. c is the concentration of protein in g/ml and R_Θ is the reduced angular intensity measured at the angle Θ.) ● = protein concentration 0.07 %; ○ = protein concentration 0.14 %.

fibrinogen is converted to fibrin. The intermediate polymers formed were studied in 1 M urea at protein concentrations of 0.07 and 0.14 % 18—24 h after the dilutions were made. The angular distribution of the scattered light at a wavelength of 4 360 Å was measured at 35°—135° in a Brice-Phoenix light-scattering photometer using a cylindrical glasscell [8]. The solutions had been cleaned from dust in the usual way [4]. The results were evaluated according to Casassa [5] (Fig. 3). The slope of the line $K \cdot c/R_\Theta$ *vs.* sin $\Theta/2$ is related to the weight-average of M/L. For reptilase formed fibrin at 0.14 % concentration, the slope in four experiments was $1.50 - 1.78 \times 10^{-6}$ and for thrombin formed fibrin $0.87 - 1.16 \times 10^{-6}$. The averages correspond to M/L values of 0.73×10^{11} and 1.16×10^{11}, respectively. If calculated according to Casassa, this should mean polymers 1.1 and 1.8 times wider than fibrinogen. At l ast at the present conditions, it seems as if reptilase formed fibrin was polymerized mainly end-to-end while thrombin formed fibrin had a tendency for lateral aggregation.

Note added in proof. The reptilase was obtained from AB Pentapharm, Basel. A new batch of this enzyme, obtained from the same firm, after this note was submitted for publication, had the same activity as thrombin, *i.e.* it splitted off both peptide A and B. Light-scattering data of fibrin obtained with this enzyme were identical with data of thrombin formed fibrin. This is in agreement with the observation that a lateral aggregation occurs when peptide B is split off. The reason for the different activities of the two reptilase batches is unknown.

Note on the Purification of Human Antihemophilic Globulin

BIRGER BLOMBÄCK, MARGARETA BLOMBÄCK and INGA MARIE NILSSON

Chemistry Department II, Karolinska Institutet, Stockholm, Sweden

Purification of the antihemophilic globulin in Cohn's fraction I (human) by different procedures in the presence of glycine has been reported earlier [1,2]. A fraction, denoted as I-1-A, was obtained by these procedures. The yield of antihemophilic globulin in this fraction was about 80 % of that in fraction I, and the activity per mg of protein was about 200 times that of plasma. The antihemophilic factor of fraction I-1-A probably forms a complex with fibrinogen. Approximately two-thirds of the fraction are coagulable with thrombin. Attempts to dissociate this complex by fractionation with organic solvents were unsuccessful.

It was, however, found that in contrast to the behaviour of the antihemophilic activity in plasma (*cf.* Ref.[3]), the antihemophilic activity in the purified fraction I-1-A could easily be adsorbed on barium sulphate, aluminium oxide and calcium phosphate (di- and tribasic) as well as on kaolin and bentonite. Barium sulphate adsorbed (from a 0.05 M sodium citrate solution) not only the antihemophilic activity, but also considerable amounts of fibrinogen. The other salts adsorbed more or less selectively the antihemophilic activity, leaving fibrinogen and other proteins in the supernatant. Attempts to elute the activity from all these salts were unsuccessful.

It was also found that the antihemophilic activity could conveniently be adsorbed on tricalcium citrate. Thus, 25 mg of tricalcium citrate adsorbed about 90 % of the antihemophilic factor from 1 ml of a 0.3 % protein solution of fraction I-1-A dissolved in 0.05 M sodium citrate, pH 6.8. After centrifugation and washing of the precipitate with 0.05 M sodium citrate, pH 6.8, the activity could be eluted by dissolving the tricalcium citrate precipitate in 2.0 ml of 0.1 M sodium-EDTA, pH 6.8.

Table 1.

Fraction	Protein		Activity	
	total, mg	yield, % of fr. I-1-A	yield, % of fr. I-1-A	relative, per mg prot.
I-1-A (10 ml)	33.1	100	100	1.0
Supernatant	30.0	90.6	7.3	0.08
			3.9 *	—
EDTA-eluate	3.0	8.5	99.0	11.0
			106.0	

* Values obtained in another experiment, using a different sample of fr. I-1-A.

It can be inferred from Table 1 that less than 10 % of the total protein in the solution of fraction I-1-A is adsorbed on tricalcium citrate. The fibrinogen in fraction I-1-A remained in the supernatant after adsorbtion. As judged by the protein determination procedure used [4], the antihemophilic activity per mg protein in the EDTA eluate is about 10 times higher than in the original fraction. Thus, purification of the antihemophilic factor as compared with plasma is about 2000 times on the protein basis.

Work is now in progress to recover and further study the antihemophilic factor in the EDTA solution. A complete report will be given in *Arkiv Kemi*.

The pS-Activity Curve of a Serum Fraction IV-6-3 Studied with Butyrylcholine at pS above 3

EDITH HEILBRONN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

Studies on the butyrylcholinesterase (BuChE) catalyzed hydrolysis of thiocholine esters [1] performed in 0.1 M potassium chloride, with the aid of an automatic recording titrator [2] and using fraction IV-6-3 obtained from retroplacentar serum (AB Kabi, Stockholm), gave results, which apparently did not follow the Michaelis-Menten law. In no case could straight lines be obtained when, for example, according to Hofstee's [3] variation of the Michaelis-Menten equation

$$v = -\frac{v}{S} \times K_M + V_m \qquad (1)$$

enzyme activity (v) was plotted against v/S (S = conc. of the substrate). All pS-activity curves showed a kind of S-shape, but the activity did not approach zero around substrate concentrations of 0.5×10^{-3} M, as one would expect. The unexpected high reaction velocities at low substrate concentrations were shown not to depend upon spontaneous hydrolysis of the substrates or upon accelerating effects of potassium iodide (Fig. 1).

In order to find out, if the reason for the deviation from the Michaelis-Menten law was to be found in the enzyme preparation, it was decided to study a pS-activity curve with the same enzyme preparation and a wellknown substrate such as butyrylcholine iodide (BuChI). This was done at constant ionic strength $\mu = 0.20$, pH = 8.00 and 25°C. By means of introducing a second syringe in the automatic recording titrator, driven synchronously with the syringe containing the titrator (sodium hydroxide) and containing a BuChI solution of exactly the same concentration as the titrator (each mole of hydrolysed BuChI consumes one mole of sodium hydroxide), it was possible to keep the substrate concentration constant during the course of hydrolysis and thus to change a pseudo-first order reaction to a pseudo-zero order reaction. This method allowed studies of the hydrolysis down to about 10^{-6} M solutions of substrate. The small amounts of solutions from the syringes caused only insignificant changes in the ionic strength of the solution during the course of hydrolysis.

Enzyme: 25 mg of serumfraction IV-6-3 were dissolved in 100 ml of 0.1 M potassium chloride. *Titrator:* 0.025 M sodium hydroxide. *Substrate solution:* The second syringe contained a 0.025 M solution of butyrylcholine iodide in distilled water. *Substrate concentration and ionic strength*: A substrate concentration range from 10^{-1} M to 10^{-6} M (in final solution) was studied. The ionic strength of the final

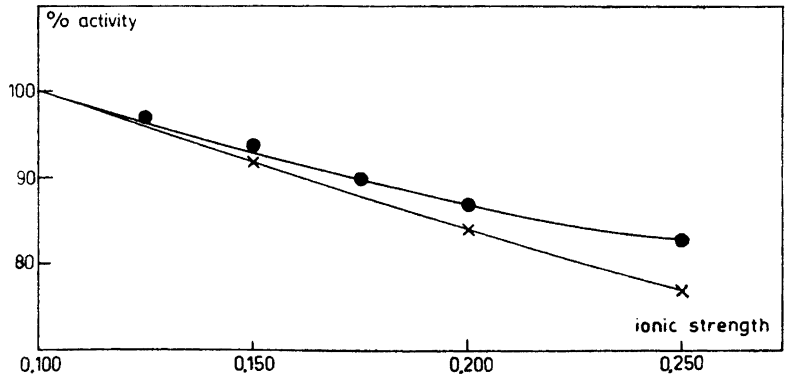

Fig. 1. Dependence of enzyme activity on ionic strength for the system potassium chloride —IV-6-3—acetylthiocholine iodide (●) and potassium iodide—IV-6-3—acetylthiocholine iodide (×). Concentration of acetylthiocholine iodide 0.001 M.

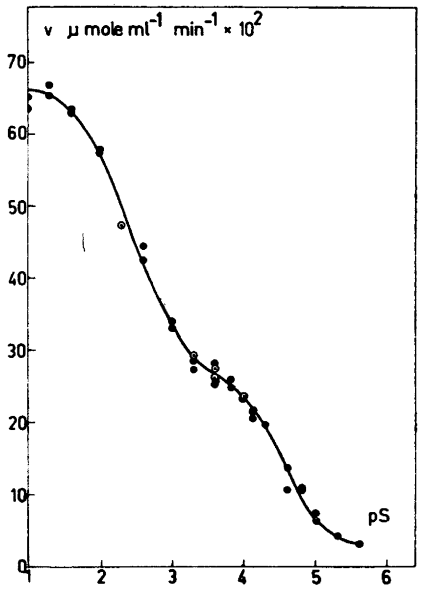

Fig. 2. pS-Activity curve for the system serum fraction IV-6-3—BuChI at $t = 25°C$, ionic strength $\mu = 0.20$, pH = 8.00. Substrate concentration kept constant by means of "double syringe" method.

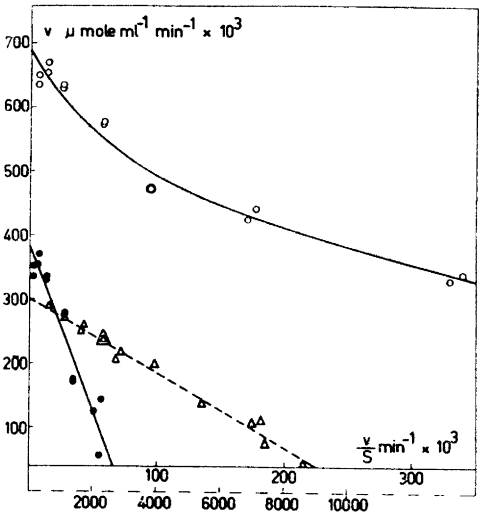

Fig. 3. Michaelis-Menten plot according to Hofstee. O, experimentally obtained curve; ●, first part of the curve minus maximum activity for the second part of the curve; △, second part of the curve. Straight lines calculated by method of least squares.

solutions was kept at 0.20 by dissolving additional amounts of potassium iodide. *Method:* 37 ml of 0.10 M potassium chloride were added to the vessel. Substrate and potassium iodide were dissolved in this solution. The syringe containing the titrator was put into place and pH was adjusted to 8.00. 3 ml of enzyme solution were administered and pH was immediately again adjusted to 8.00. The second syringe was put into place and hydrolysis was recorded during about 10 min. Initial values were used for calculations.

Fig. 2 shows the curve obtained which gives the impression of 2 enzymes able to split BuChI. The second enzyme seems to have a very low substrate maximum, about 0.5×10^{-3} M. Assuming that the second enzyme is of the BuChE type, thus not inhibited by excess of substrate, it was possible to obtain two straight lines, according to Hofstee's equation, as shown in Fig. 3. The lines were calculated by the method of least squares. From the line representing the second enzyme, the maximum activity for the second enzyme, 0.3 μmole ml^{-1} min^{-1}, was calculated. This value was subtracted from the activity values of the first part of the experimentally obtained pS-activity curve. The last values belonging to the first part of this curve were subtracted by 0.29 μmole ml^{-1} min^{-1}, as maximum activity does not seem to be reached at this point.

The possibility of two enzymes occurring in the preparation used is also indicated by earlier electrophoretic and chromatographic studies[4] on fraction IV-6-3. Chromatograms on calcium phosphate showed always two peaks with cholinesterase activity.

My sincere thanks are due to Professor G. Ljunggren, Director of the Research Institute of National Defence, Dept. 1, for his kind interest in this work.

Alkaline Incineration of Iodine-Containing Organic Material

GÖSTA WIDSTRÖM and MONICA BJÖRKMAN

Clinical Laboratories, Centrallasarettet, Stocksund, Sweden

Methods for alkaline incineration of organic material have been extensively studied as an important step in the estimation of iodine content. Alkaline incineration for analysis of protein-bound iodine, as suggested by Barker, Humphrey and Soley[1], has become generally accepted as a very useful method for estimation of circulating thyroid hormone.

In order to obtain reproducible results, all conditions in the several steps of this analysis must be kept constant within narrow limits. One reason is that it is difficult to avoid considerable losses of iodine during the ashing procedure. Difficulties are encountered both in keeping this loss constant, and in compensating for it. In experiments with radioactive iodine, van Middlesworth [2] found the recovery of iodine with the method of Barker *et al.* to range from 68 to 86 %. Skanse and Hedenskog,[3] using a slightly modified technique, claimed a recovery of not better than 86 %. Since the iodine recovery is evidently unsatisfactory with the incineration method in question, an attempt to reduce the losses is motivated. In the present experiments, the iodine losses were studied on dry ashing of iodine-containing substances, both protein-bound and in the iodide form, labelled with ^{131}I.

General procedure. A working solution of $Na^{131}I$, with an activity of about 0.06 μC/ml was prepared by 500-fold dilution of a stock solution of $Na^{131}I$ in very dilute sulphite. Dilution was performed with 0.04 N NaOH, and NaI added as a carrier to a concentration of 20 μg/100 ml.

Protein-bound ^{131}I ($PB^{131}I$) was obtained from patients treated for thyroid disease. The $PB^{131}I$ serum was diluted with normal serum to an activity convenient for measurements and treated with small charges of Dowex 2 × 8, 40 mesh, for elimination of inorganic iodine.

One ml of either of these dilute solutions and various amounts of other substances were collected in Pyrex tubes, dried overnight at 100°C, and ashed in a muffle furnace at 600°C for 3 h.

Table 1. Recovery of iodine in % after incineration at 600°C for 3 and 24 h, respectively, with various amounts of different alkalis added to the incineration mixture. Each value is the mean of 2—5 experiments.

Alkali added	Without Somogyi's reagent $Na^{131}I$		$PB^{131}I$		With Somogyi's reagent $Na^{131}I$		Precipitated with Somogyi's reagent $PB^{131}I$

Acetate added	Metal iodide m.p.°C	b.p.°C	Recovery, % 1 h	2 h	6 h	24 h
1 ml 4 N KAc	723	1 420	—	78	68	60
1 ml 4 N NaAc	651	1 300	70	66	38	20
2 ml 4 N $BaAc_2$	740 d		15	8	1	0
2 ml 4 N $CaAc_2$	575	718	5	2	0	0

After incineration and cooling, the ashes were dissolved in 5 ml of 1 N HCl by stirring with a glass rod, and the tubes centrifuged. Three ml of each centrifugate were taken for activity measurements, and compared with the activity of the corresponding working solution or $PB^{131}I$ serum. An LKB scintillation counter was used for the measurements, and the activity of the samples was adjusted to give about 10 000 counts/min.

Results. Experiments in which inorganic ^{131}I and protein-bound ^{131}I, respectively, were incinerated with and without Somogyi's reagent are recorded in Table 1. When the serum protein-bound ^{131}I was incinerated together with Somogyi's reagent and 1 ml of 4 N Na_2CO_3 (method of Barker *et al.*), the mean recovery was 76 %. When K_2CO_3 was used instead of Na_2CO_3, the recovery increased to 96 %. Substitution of K_2CO_3 for Na_2CO_3 in the incineration mixture therefore seems to be a practical means of reducing the losses of iodine during incineration *.

Table 1 shows large differences in the recovery of added iodine on incineration with various alkalis. An explanation might be provided by taking into account the melting and boiling points of the corresponding iodides. They decrease in the following order: K,Na,Ba and Ca. It is, however, difficult to predict the vapour pressure of the iodides in these somewhat complicated mixtures of salts.

The following experiments were made to demonstrate the correlation between losses of iodides and their melting points on alkaline incineration. Nickel crucibles were each charged with 1 ml of $Na^{131}I$ working solution, after which an equimolar amount of the alkali acetate of K, Na, Ca and Ba, respectively, was added. The crucibles were dried at 100°C for 24 h, and then incinerated at 600°C for 1, 2, 6 and 24 h, respectively. The ashes were brought into solution, and their activity measured as described. The results are summarized in Table 2. The correlation between the physical constants of the iodides and the losses on incineration, increasing with time, is clearly apparent.

A similar experiment, recorded in Table 3, confirms the considerable reduction in these losses when K_2CO_3 is substituted for Na_2CO_3, as used in the alkaline incineration method of Barker *et al.* It is also fully evident that the losses were much greater in the wideopen crucibles than in the test tubes heated in an almost horizontal position.

The practical consequences of the large loss of iodide on incineration with Ca must also be taken into account. This is because the presence of Ca in normal serum might decrease the iodide recovery on incineration with Na_2CO_3 or even with K_2CO_3. The following experiment was therefore made. One ml of $Na^{131}I$ working solution was mixed in Pyrex tubes with 1 ml of 2 N Na_2CO_3 or K_2CO_3, and 1 ml of $CaAc_2$ solution in various concentrations was added, as shown in Table 4. All the tubes were dried at 100°C for 24 h, and then incinerated at 600°C for 3 h. It can be inferred from the table that the amount of Ca present in normal serum may influence the iodide loss. The losses were considerably smaller in the K_2CO_3 than in the Na_2CO_3 series. The effect of Ca was found to be

* Vilkki (pers. comm. and Ref.[4]) has published a modification of Baker and Humphrey's method using KOH instead of Na_2CO_3 for the incineration, as the experience is that KOH is better than NaOH for collecting iodine in the distillation procedure. Kingsley *et al.*[5] has substituted Na_2CO_3 for K_2CO_3 in the B. & H. incineration method because of the better purity of the potassium reagent (pers. comm.).

about the same in the physiologic range, but in higher concentrations the loss was much more pronounced in the Na_2CO_3 series.

It is obvious that the presence of greater concentrations of cations, the iodides of which have low meltingpoints, may result in considerable errors in the quantitative determination of iodine in organic material. The use of K_2CO_3 instead of Na_2CO_3 on incineration will result in a more complete recovery of iodine.

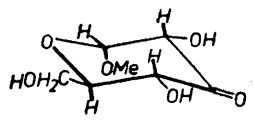
** These figures are more accurate than those previously [4] given.

with sodium amalgam. The *myo*-inosose-2, having no axial hydroxyl groups, gave a large proportion of the axial epimer on catalytic hydrogenation, and a ratio of axial to equatorial epimers of about 4:3 on reduction with borohydride and sodium amalgam. The second compound (II), in which the oxo group is hindered by an axial hydroxyl group in β-position, gave the axial epimer only, on catalytic hydrogenation or borohydride reduction and an axial to equatorial ratio of about 6:2 on reduction with sodium amalgam. The results obtained with compound II show that the axial hydroxyl group β to the oxo group has a considerable effect on the approach of the borohydride ion.

In the present investigation methyl β-D-2-oxo-glucopyranoside (III), methyl β-D-3-oxo-glucopyranoside (IV) and methyl α-D-3-oxo-glucopyranoside (V) were reduced catalytically with Pt- and Raney nickel-catalyst, with sodium amalgam and with borohydride and the proportions of the methyl glycosides obtained were estimated. It was shown by paper chromatography that the resulting glycosides contained only small amounts of unreacted oxo-glucoside and only traces of other compounds. The ratios of epimeric glycosides obtained were determined by quantitative analysis of the sugars obtained on hydrolysis of the reduction product. The analytical figures (Table 1) were corrected for sugar decomposition during hydrolysis and for the formation of 1,6-anhydro-D-allose [3].

In comparing the four types of reducing agents, it must be borne in mind that one of them (Raney nickel) was used at a higher temperature and one (borohydride) at a higher pH than the others. As in the case of the two inososes none of these reducing agents gave products in which the most stable, equatorial isomer (the methyl glucoside) predominated. In general the effect of hindrance was most marked in the Pt-catalysed reduction and least using sodium amalgam. The reduction with Raney nickel catalyst gave ratios of the methyl glycoside epimers closer to those obtained with sodium amalgam and borohydride than to those obtained using H_2/Pt. Methyl α-3-oxo-glucoside (V), with an axial, bulky methoxyl group β to the oxo-group, was similar to *epi*-inosose-2, and gave a large proportion of the axial isomer on reduction with borohydride, as was expected, and also with Raney nickel.

Experimental. The oxo-glucosides were prepared as described previously [5,6] and 20 mg samples of the compounds were reduced in 1 % solution. Reduction over platinum catalyst was done in unbuffered aqueous solution at pH 6 for 4 h using Adams catalyst and with Raney nickel according to the procedure of Karabinos



Methyl-α-D-3-oxo-glucopyranoside.

and Ballun [7], by refluxing the oxo-glucoside for 3 h in unbuffered aqueous ethanol (30 % water) at pH 6. They were reduced with sodium amalgam (2.5 % sodium) for 4 h in aqueous solution buffered to pH 6. The amalgam was added at intervals over 4 h and the pH was kept at 6 by the addition of small amounts of acetic acid, the product was then deionised. The borohydride reduction was done in aqueous solution buffered to pH 9.5 for 5 h and the product was then deionised.

The reduction products were hydrolysed with 0.5 N sulphuric acid for 16 h at 100°, neutralised with Amberlite IR-4B (free base) and the solution obtained was concentrated. The sugars were separated by paper chromatography and a quantitative quadruple estimation was made using the procedure of Saeman *et al.*[8]. Schleicher and Schüll No. 2043a papers were used and the chromatograms were eluted with ethyl acetate-acetic acid-water, 3:1:3 (upper phase).

Some Remarks about the Shape of Gaussian Error Curve of Absorption Bands

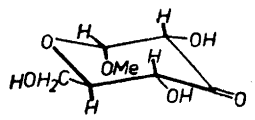
LECH STOLARCZYK

Chemistry Department A, Technical University of Denmark, Copenhagen; Electrochemical Department, Institute of Physical Chemistry, Polish Academy of Science, Warsaw, Poland

As it is well known in literature, the Gaussian error curve is often a good approximation of absorption band shape for transition group complexes [1]. In the theory of electronic transitions in molecules [2] this behaviour can be understood as the projection of the (squared) vibrational wavefunction of the electronic groundstate on the potential curve of the excited electronic state. If the electronic groundstate has a parabolic potential curve as function of the internuclear distance, and if the temperature is so low that only the groundstate ($n=0$ in $E=(n+{}^1/_2)h\nu_0$) of the harmonic oscillator is populated, the Gaussian shaped wavefunction will produce a nearly Gaussian shaped absorption band (by projection on a linear potential curve of the excited electronic state) viz.

$$\varepsilon = \frac{\sigma}{\sigma_s}\,\varepsilon_0 \exp\left[-\frac{(\sigma-\sigma_0)^2}{\delta^2}\right] \ln 2 \qquad (I)$$

where the indices zero on the wavenumber σ and extinction coefficient ε refer to a point near to the band maximum. The factor $\frac{\sigma}{\sigma_0}$ explains partly that fact [1] that $\delta(-)<\delta<\delta(+)$, where $\delta(-)$ and $\delta(+)$ are the halfwidths of two halves of non-corrected Gaussian curves towards smaller and larger σ. Dr. Klixbüll Jørgensen has pointed out that in this approximation, the maximum occurs at $\sigma = \sigma_0 + \frac{\delta^2}{\sigma_0 2\ln 2}$ and the ratio between the two half-widths is $\frac{\delta(+)}{\delta(-)} \simeq 1 + \frac{\delta}{\sigma_0 \ln 2}$. Reasonable values for the slope of the excited state's potential curve, as implied from ligand field theory [3-5], agree well with the observed values of δ.



Methyl-α-D-3-oxo-glucopyranoside.

Some Remarks about the Shape of Gaussian Error Curve of Absorption Bands

LECH STOLARCZYK

Chemistry Department A, Technical University of Denmark, Copenhagen; Electrochemical Department, Institute of Physical Chemistry, Polish Academy of Science, Warsaw, Poland

As it is well known in literature, the Gaussian error curve is often a good approximation of absorption band shape for transition group complexes [1]. In the theory of electronic transitions in molecules [2] this behaviour can be understood as the projection of the (squared) vibrational wavefunction of the electronic groundstate on the potential curve of the excited electronic state. If the electronic groundstate has a parabolic potential curve as function of the internuclear distance, and if the temperature is so low that only the groundstate ($n=0$ in $E=(n+{}^1/_2)h\nu_0$) of the harmonic oscillator is populated, the Gaussian shaped wavefunction will produce a nearly Gaussian shaped absorption band (by projection on a linear potential curve of the excited electronic state) viz.

$$\varepsilon = \frac{\sigma}{\sigma_s}\,\varepsilon_0 \exp\left[-\frac{(\sigma-\sigma_0)^2}{\delta^2}\right] \ln 2 \qquad (I)$$

where the indices zero on the wavenumber σ and extinction coefficient ε refer to a point near to the band maximum. The factor $\frac{\sigma}{\sigma_0}$ explains partly that fact [1] that $\delta(-)<\delta<\delta(+)$, where $\delta(-)$ and $\delta(+)$ are the halfwidths of two halves of non-corrected Gaussian curves towards smaller and larger σ. Dr. Klixbüll Jørgensen has pointed out that in this approximation, the maximum occurs at $\sigma = \sigma_0 + \frac{\delta^2}{\sigma_0 2\ln 2}$ and the ratio between the two half-widths is $\frac{\delta(+)}{\delta(-)} \simeq 1 + \frac{\delta}{\sigma_0 \ln 2}$. Reasonable values for the slope of the excited state's potential curve, as implied from ligand field theory [3-5], agree well with the observed values of δ.

It is obvious that for a mixture, where the electronic groundstate is populated *e.g.* ~75 % ($n=0$), 20 % ($n=1$), 4 % ($n=2$), 1 % ($n=3$), a Gaussian shape cannot be obtained of the absorption band. On the other hand, the present note will draw attention to the fact that high temperature and Maxwell-Boltzmann distribution also produces a Gaussian probability distribution in the harmonic oscillator, and thus, a nearly Gaussian-shaped band (I) will also be expected here. We have three cases, which can be experimentally distinguished, *viz*:

1. $kT \ll h\nu_0$ Nearly Gaussian-shaped band, independent of T for a small heating, δ proportional to $(fm)^{-1/4}$, f is the force constant and m the effective mass.
2. $kT \sim h\nu_0$ The band is not Gaussian-shaped to any good approximation.
3. $kT \gg h\nu_0$ Nearly Gaussian-shaped band, proportional to $\sqrt{T}$ and to $f^{-1/4}$, independent of m.

The proof of the third case is the following: The Maxwell-Boltzmann probability of oscillation with amplitude from a to $a + da$ in a system of harmonic oscillators is given by

$$P_{(a,da)} = \frac{f}{kT} \exp\left(-\frac{fa^2}{2kT}\right) a\, da$$

Probability of finding a classical harmonic oscillator vibrating with the amplitude a in a position from x to $x + dx$ is given by:

$$P_{a(x,dx)} = \frac{dx}{\pi \sqrt{a^2 - x^2}}$$

Total probability of position from x to $x + dx$ in a system of oscillators vibrating with various amplitudes in thermal equilibrium is given by:

$$P_{(x,dx)} = \int_{a=x}^{\infty} P_{(a,da)}\, P_{a(x,dx)} =$$

$$= \frac{f}{\pi kT}\, dx \int_{a=x}^{\infty} \frac{\exp\left(-\frac{fa^2}{2kT}\right)}{\sqrt{a^2 - x^2}}\, a\, da = \quad \text{(II)}$$

$$= \frac{\sqrt{f}}{\sqrt{2\pi kT}} \exp\left(-\frac{fx^2}{2kT}\right) dx$$

It is seen from (II) that the half width for Gaussian error curve based on the assumption of ligands high vibrational excitement should be proportional to $\sqrt{f/T}$ and unrelated to mass of ligands. Measurements seem to show the half width of absorption bands being nearly unchanged by exchange of ligands in spite of great differences in their masses. Small effects can easily be related to force constants. In such a manner the assumption of high vibrational excitement seems to be more probable. Further confirmations are to be searched by examining the temperature dependande of absorption band half width.

The Oxidation of Glycosides

VIII.* The Degradation of Methyl α-D-3-oxo-glucopyranoside, Methyl β-D-3-oxo-glucopyranoside and Methyl β-D-2-oxo-glucopyranoside by Lime-water **

OLOF THEANDER

Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

On treatment with lime-water methyl α-D-3-oxo-glucopyranoside, methyl β-D-3-oxo-glucopyranoside and methyl β-D-2-oxo-glucopyranoside were very rapidly degraded. The principal route involved the elimination of the methoxyl group and, in all cases, led initially to the formation of a dicarbonyl intermediate which then gave acids. The dicarbonyl intermediate was proved to be 1,5-anhydro-2,3-dioxo-D-glucitol. On reduction it gave all four expected 1,5-anhydro-D-glycitols including the hitherto unknown 1,5-anhydro-D-allitol.

It is commonly believed that the pronounced sensitivity of oxidised cellulose to alkali depends upon the presence of oxo-glucose residues. The alkaline degradation of carbohydrates to saccharinic acids has recently been reviewed by Sowden [1]. A probable ionic mechanism for those transformations, which has been advanced by Isbell [2], involves the following successive steps: (i) the formation and ionisation of an enediol; (ii) the β-elimination of a hydroxyl, alkoxyl or glycosyl group; (iii) a rearrangement to an α-dicarbonyl intermediate; and (iv) a benzilic acid type of rearrangement to give a saccharinic acid. In Fig. 1 this mechanism is shown applied to the alkaline degradation of those oxo-glucosides studied in the present investigation. Haskins and Hogsed [3] were the first to suggest that it was probable that the alkaline degradation of oxidised cellulose involved the scission of β-glucosylcarbonylresidues.

Oxo-glucosides are now available [4,5] and these were used as models simulating oxo-glucose residues in oxidised cellulose or in oxidised starch. Alkaline treatment with lime-water was used to enable a comparison to be made with the results obtained by Kenner *et al.*[1], who used oxygen-free, saturated lime-

** A preliminary report was given at the XVth International Congress of Pure and Applied Chemistry, Paris, in July 1957.

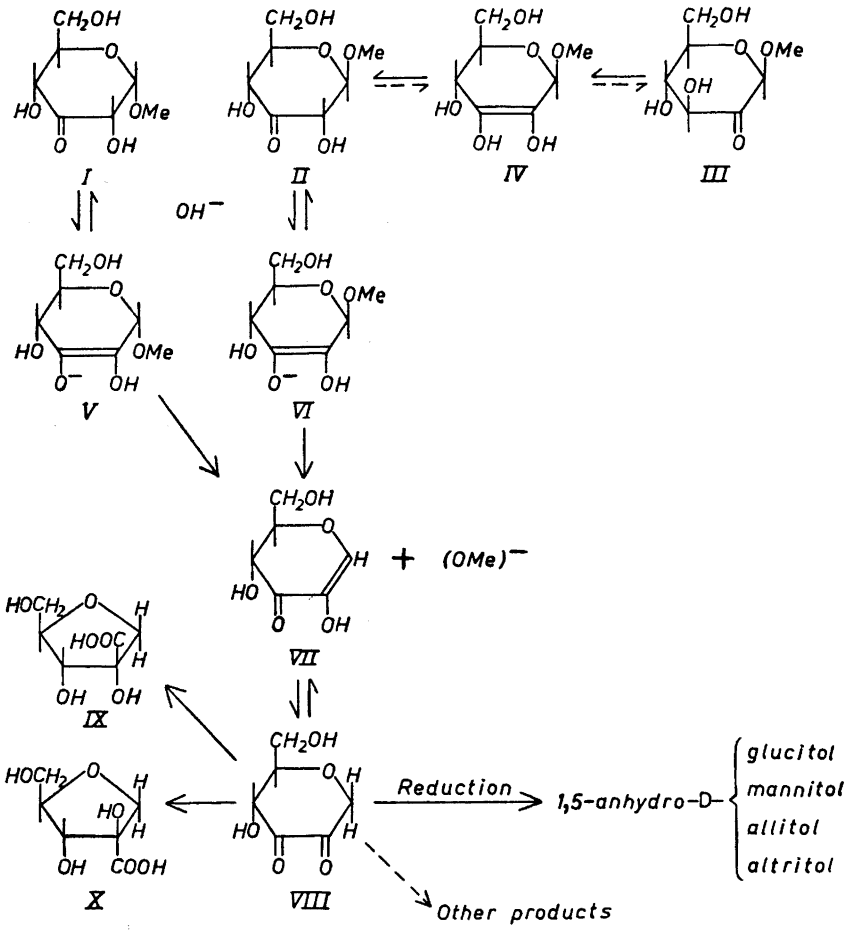

Fig. 1. Treatment of methyl α-3-oxo-glucoside (I), methyl β-3-oxo-glucoside (II) and methyl β-2-oxo-glucoside (III) with lime-water and reduction of 1,5-anhydro-2,3-dioxo-glucitol(VIII).

water (at 25°) in their extensive studies of the role played by substituents during the alkaline degradation of monosaccharides, oligosaccharides or polysaccharides.

When methyl β-D-3-oxo-glucopyranoside (II) was treated with saturated lime-water (at 25°) the optical rotation altered very rapidly from a negative to a high positive value. Fractions were withdrawn after short periods of treatment and immediately acidified and then examined on paper chromatograms. It was found that, associated with a rapid decrease of II, there was an increase in the amounts of the acids. A considerable quantity of a compound, giving distinctive colorations with the various spray reagents, was

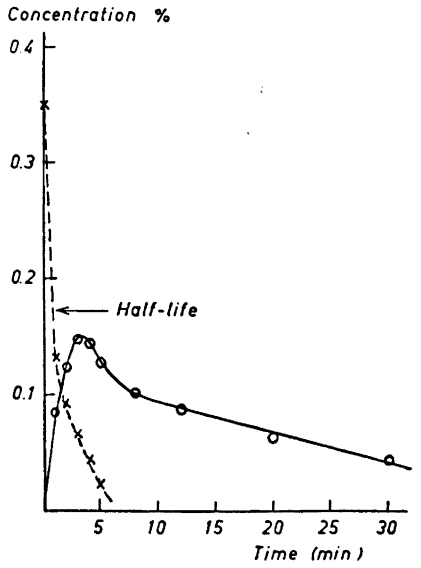

Fig. 2. Formation of 1,5-anhydro-2,3-dioxo-glucitol (—O—O—) on treatment of methyl β-3-oxo-glucoside (– – × – – × – –) with lime-water (0.042 N) at 25°.

observed. It was shown to be the α-dicarbonyl intermediate (VIII) that would be expected to be formed if the degradation involved scission of the glycosidic ether linkage. Both II and VIII were semi-quantitatively determined throughout the reaction period (Fig. 2). The extremely short half-life of II (about one minute) is roughly one hundreth of those of the most alkali-labile sugars previously studied (laminaribiose and turanose [6]) and is about 2 000 times less than that of cellobiose [7].

Dilute lime-water (0.02 N) was used to enable the optical rotation to be followed during the degradation of methyl α-D-3-oxo-glucopyranoside (I), methyl β-D-3-oxo-glucopyranoside (II) and methyl β-D-2-oxo-glucopyranoside (III). All three oxo-glucosides gave a maximum positive rotation which was correlated, by paper chromatographic examination, with the presence of the principal component (compound VIII). The 2-oxo-glucoside (III) was degraded more slowly than were the two anomers of 3-oxo-glucoside, and by the paper chromatographic examination, it was shown that it was first transformed into a compound having the same R_F-values as II. There was also a component present which gave a pink spot with resorcinol, and which had an R_F-value between those of the two oxo-glucosides. This spot may have been due to the enediol IV. But no epimerisation of II to III was detected when the former was treated with alkali (Fig. 3).

In several experiments compound VIII (prepared from II) was isolated. The amorphous product, in aqueous solution at pH 5, had $[\alpha]_D^{22}$ + 155° and ε_{max} 3 100 at 293 mμ (methyl β-3-oxo-glucoside: $\varepsilon_{max.}$ 90 at 285 mμ). Small amounts were obtained crystalline (m.p. 53—55°). The amorphous and crystalline products gave single clearly defined spots which were both chromatographically and electrophoretically indistinguishable from one another.

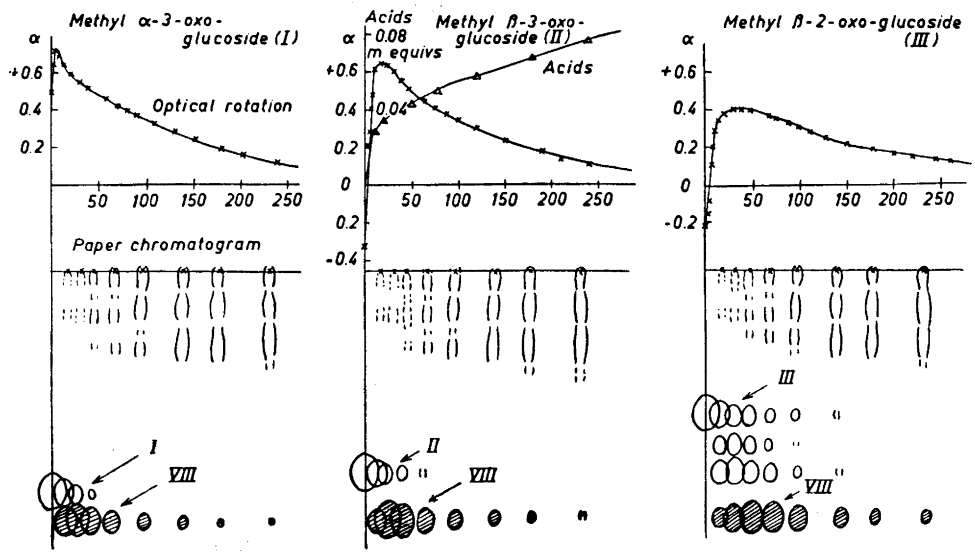

Fig. 3. Diagram of paper chromatograms (irrigant B) showing spots observed and relating them to the fall in optical rotation when methyl α-3-oxo-glucoside, methyl β-3-oxo-glucoside and methyl β-2-oxo-glucoside were separately treated with lime-water (0.02 N) at 22°. Abscissa = time in minutes.

The dicarbonyl compound rapidly formed a precipitate with 2,4-dinitrophenylhydrazine, but did not give a satisfactory crystalline derivative with this reagent or with *o*-phenylenediamine. It carried no methoxyl group, but carbonyl determination, by the borohydride method, indicated the presence of two carbonyl groups (assuming M.W. 160).

The mixture of products obtained on the reduction of the dicarbonyl intermediate with Raney nickel or with borohydride was separated. The four products obtained were: amorphous 1,5-anhydro-D-altritol (characterised as its crystalline tetra-acetate) and crystalline 1,5-anhydro-D-glucitol, 1,5-anhydro-D-mannitol and a substance having m.p. 147—148°, $[\alpha]_D^{22}$ + 26° (in water). This last substance gave an analysis consistent with the formula $C_6H_{12}O_5$ and, from the evidence presented below, it was concluded to be 1,5-anhydro-D-allitol. Its specific rotation, +26°, accords reasonably well with those calculated from the specific rotations of methyl β-D-alloside and the methyl β-D-glycosides and 1,5-anhydro-D-glycitol derivatives of glucose, altrose and gulose ($[\alpha]_D$ = +20°, 22° and 28°). The values calculated from the rotations of the corresponding derivatives of mannose and galactose however were markedly different. Foster [8] has shown that 1,5-anhydro-glycitols and the corresponding methyl-glycosides behave similarly on electrophoresis. The M_G value of the above unknown compound was similar to that of methyl β-alloside (Table 1); a strong indication of the former being 1,5-anhydro-D-allitol. No 1,5-anhydro-galactitol could be detected among the reduction products.

Table 1. Paper electrophoretic mobilities in borate (M_G-values) of methyl D-glycopyranosides and 1,5-anhydro-D-glycitols.

	M_G
Methyl β-alloside	0.49
1,5-Anhydro-allitol	0.48
1,5-Anhydro-altritol	0.63
Methyl α-glucoside	0.10
Methyl β-glucoside	0.16
1,5-Anhydro-glucitol	0.18
Methyl α-mannoside	0.39
Methyl β-mannoside	0.30
1,5-Anhydro-mannitol	0.38
Methyl α-galactoside	0.35
Methyl β-galactoside	0.37
1,5-Anhydro-galactitol	0.36

It is of interest to note that the proportions of the four reduction products varied with the choice of reducing conditions. When Raney nickel was used (at pH 5) there was a much higher yield of anhydro-mannitol than of anhydro-glucitol but this order was reversed when borohydride was used (at pH 9.5). There was no marked difference in the relative yields of anhydro-allitol, but that of anhydro-altritol decreased to traces when borohydride was used. The difference might be due both to the nature of the reductants as such, and to a preferential formation of the dioxo form (VIII) at pH 5 and of the enolic form (VII) at pH 9.5. At pH 5, the dicarbonyl intermediate gave no coloration with ferric chloride. UV spectroscopic studies at different pH values strongly indicate that at pH 9.5 a keto-enol equilibrium exists (Fig. 4). At that pH the UV absorption is compounded of a contribution given by the absorption peak noted at 290 mμ at pH 5 and of the peak noted at *ca.* 340 mμ at pH 12 (a ketone having an αβ-ethylenic bond exhibits an absorption peak at *ca.* 330 mμ [9]). A compatible observation was made when II was treated with lime-water and the reaction stopped, by acidification of the mixture, at that time at which VIII was present in maximum amount. The peak initially observed in the UV spectra at 320 mμ then vanished and a new peak appeared at 280 mμ; simultaneously the optical rotation fell by about 50 %. The UV absorption reverted to the former type on making the solution alkaline.

The isolation of the four 1,5-anhydro-glycitols (in the relatively high yield of 60 %) proves that the structure of the intermediate is 1,5-anhydro-2,3-dioxo-D-glucitol. This is the first case reported of isolation and identification of a dicarbonyl intermediate in the alkaline degradation of carbohydrates.

Recently Blears, Machell and Richards [10] reported that when 4-*O*-substituted glucose derivatives were degraded by dilute sodium hydroxide solution, an intermediate was formed which was believed to be a dicarbonyl derivative. It was not pure, although it gave a crystalline osazone. Evidence was also obtained of the presence of fragmentation products, possibly formed from dicarbonyl intermediates.

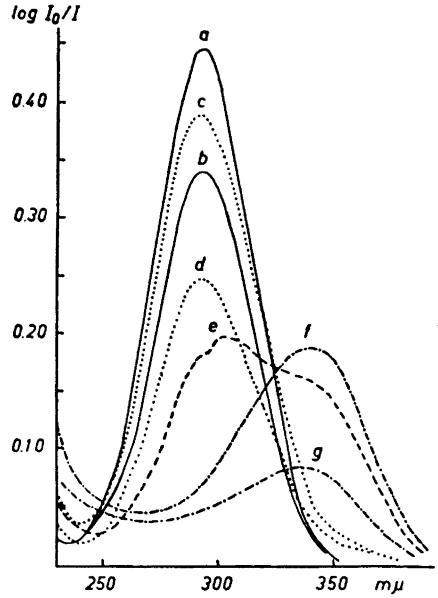

Fig. 4. Ultraviolet absorption spectra of 1,5-anhydro-2,3-dioxo-glucitol in aqueous solutions at different pH-values at 22°. (All four solutions were made from the same stock solution by diluting it to $1.5 \cdot 10^{-4}$ M).

From the reaction-mixture produced when methyl 3-oxo-glucoside was treated with lime-water the various neutral products were isolated at that time at which the product VIII was present in maximum amount. The overall yield of neutral products was 65 % and of this three fifths were VIII, one fifth was unreacted methyl 3-oxo-glucoside and one fifth a complex mixture of components. Scission of a carbon-oxygen bond could take place at three sites in β-position to the oxo-group, namely at the two ring-oxygen linkages or at the glycosidic link (see Fig. 1). It is apparent that the reaction proceeded, to a very large extent by elimination of the glycosidic methoxyl to give the intermediate VIII. This view is supported by the fact that the acids were present in roughly the same proportions as were those obtained when a sample of VIII was treated with lime-water; in both cases the mixtures of acids were electrophoretically similar. They have not yet been studied in detail. On treatment of VIII with lime-water also some neutral products were formed. The dicarbonyl compound VIII was unstable over the entire pH range investi-

gated (1.5—12) but most labile on the alkaline side. The reaction-mixtures were studied by paper chromatography and by UV spectroscopy (Fig. 4). These studies indicated that different types of reactions take place under acidic and under basic conditions.

The mixture of neutral products obtained on treating II with lime-water would be expected to be highly complex as numerous reactions will have taken place. In addition to the principal reaction discussed, there may be, for instance, reactions involving epimerisation, molecular fragmentation or the scission of ring-oxygen linkage. From the mixture small amounts of a compound were isolated, which were chromatographically and electrophoretically indistinguishable from methyl β-D-4-oxo-glucopyranoside. On reduction and subsequent hydrolysis it gave glucose and galactose, indicating that epimerisation had taken place at C_4. Two other compounds were isolated having higher R_F-values than VIII. One had a methoxyl group, while the other did not. The latter compound crystallised (m.p. 157—159°) and gave a violet coloration with ferric chloride.

Investigations are continuing on the alkaline degradation of oxo-glucosides. Experiments now in progress show that the degradation of II and III via VIII is of importance even under slightly acidic conditions.

EXPERIMENTAL

Melting points are corrected. The ultraviolet spectra were determined in aqueous solution with a Beckman DU instrument. All solvents were removed by distillation under reduced pressure. Whatman No. 1 paper was normally used for paper chromatography and electrophoresis. Preparative separations were carried out on Whatman No. 3 MM or 31 paper. The following reagents were used in sprays: (a) silver nitrate-sodium hydroxide, (b) *p*-anisidine hydrogen chloride, (c) resorcinol-hydrochloric acid, (d) bromocresol green and (e) ferric chloride.

The irrigants and buffers used were:
A. Ethyl acetate-acetic acid-water, 3:1:3 (upper phase).
B. Butanol-ethanol-water, 10:3:5.
C. Hydrogen sulphite buffer pH 4.7, 0.1 M. (used at 50°) [11].
D. Borate buffer pH 10.0, 0.1 M.
E. Acetate buffer pH 4.0, 0.1 M.

Kinetic studies of the action of lime-water on methyl α-D-3-oxo-glucopyranoside (I), methyl β-D-3-oxo-glucopyranoside (II) and methyl β-D-2-oxo-glucopyranoside (III)

The oxo-glucosides were prepared as previously [4,5] described. The lime-water used was freed from oxygen by bubbling a stream of nitrogen through it.

A sample (35 mg) of II was treated with saturated lime-water (50 ml; 0.042 N; pH 12.3) at 25°. The pH remained practically constant throughout the treatment and fractions were withdrawn at short intervals and immediately shaken with an excess of Amberlite resin IR-120 (H^+) to form the free acids from the calcium salts of the reaction products. Samples of the fractions were placed, with cold air drying of the solutions, on paper chromatograms, some of which were then run in irrigant A and some in irrigant B. One paper of each was treated with spray *a* and one with spray *c* and quantitative estimations were made by visual comparison of the area of the spots produced with those, produced by a series of reference spots corresponding to known amounts of II and of VIII. The

average values obtained are given in Fig. 2. The sample of VIII used for the preparation of the reference solution was freshly isolated from a pure fraction on thick paper chromatograms. The concentration in an aliquot of the stock solution was determined gravimetrically following evaporation of the solvent. The amount of contaminating decomposition products formed between the time of elution of VIII and that of its application to the chromatograms was probably < 5 %.

In another series of experiments samples (63 mg of each) of I, II and III were treated with dilute lime-water (25 ml; 0.019 N, pH 12.1) at 22°. The change in optical rotation was noted (2 dm tube) and samples were withdrawn from time to time and, after acidification (by treatment with Amberlite IR-120, see above), were examined on paper chromatograms. The number of equivalents of acids formed during the alkaline treatment of II was estimated in a separate experiment by back-titration after the addition of an excess of sulphuric acid. The results are given in Fig. 3.

In all three cases the solution became pale yellow and turned cloudy shortly after the maximum optical rotations were observed. This cloudiness may have been due to sparingly soluble calcium salts. The precipitated material was filtered off and nitrogen again passed through the solution. The optical rotations taken before and after the development of the cloudiness all lay on a smooth continuous curve.

Action of lime-water on methyl β-D-3-oxo-glucopyranoside (II) and fractionation of the products

Methyl β-3-oxo-glucoside was treated batchwise (0.2—1.0 g) with oxygen-free lime-water (40 ml 0.02 N/0.1 g of II) at 25° and the products were then fractionated. The course of the reaction was followed polarimetrically and when the maximum rotation was observed the degradation was normally stopped by acidification as previously, giving a pH of *ca.* 4. In a few cases before paper chromatographic separation the solution was rapidly passed through a column containing an excess of Amberlite IR-4 B (free base) from which the acids could then be recovered as ammonium salts. It was found that a better yield of VIII could be obtained if the last ion exchange step was omitted. The acidic products accounted for 25 % and the neutral products for 65 % of the starting material. The solution was concentrated to a volume small enough to be suitable for application to chromatographic papers (the last step of this concentration was by lyophilisation). The separation was carried out on Whatman No. 31 papers by irrigating them with A for 1 3/4 h. After drying the sheets, the positions of the various components were determined in the usual way and they were then eluted. The total time for those procedures was *ca.* 1 h. Four fractions were obtained:

A. A complex mixture of compounds, principally acids, having R_F-values less than that of II.
B. Unreacted II (*ca.* 20 % of the neutral products).
C. Chromatographically pure VIII (*ca.* 60 % of the neutral products).
D. A mixture of compounds having R_F-values higher than that of VIII and containing two major components. (Two minor components giving brown spots were noted on unsprayed chromatograms on which this fraction was examined.)

From fraction A a small amount of a component, indistinguishable from methyl β-D-4-oxo-glucopyranoside, was separated by paper chromatography (irrigant A). On reduction with borohydride and subsequent hydrolysis it gave compounds chromatographically indistinguishable from glucose and galactose.

From fraction D the two principal neutral products were chromatographically separated (each representing about 5 % of the starting II) on Whatman No. 3 MM paper (irrigant A). One of them, which contained no methoxyl gave a strong violet coloration with spray *e*, crystallised (m.p. 157—159°) from aqueous ethanol and the other contained *ca.* 15 % OCH_3.

Characterisation and properties of 1,5-anhydro-2,3-dioxo-D-glucitol (VIII)

Fraction C was slightly contaminated by traces of acetic acid (pH of solution 3—4). Generally the solution was used directly in order to minimize the danger of decomposition. The concentration was determined gravimetrically after evaporating the solvent from an aliquot and drying the amorphous material over P_2O_5. The optical rotations and UV-absorptions of the fresh eluates were determined in several cases (the pH was adjusted to 5). The average values obtained were $[\alpha]_D^{22}$ +155° and $\varepsilon_{max.}$ 3 100 at 293 mμ. In three experiments the solutions were lyophilised in a flask externally cooled to −10°. The syrup obtained, partly crystallised. By treatment of aqueous slurries of this material with either acetone, *n*-propanol or methyl ethyl ketone and acetic acid, small amounts of chromatographically and electrophoretically pure crystalline material (m.p. 53—55°) were obtained. The compound decomposed so readily that it was not possible to crystallise it in the usual way from warmed solvents (even at 0° the crystals decomposed).

Assuming the molecular weight of VIII to be 160, the compound was estimated, by borohydride reduction [12], to contain 1.84 carbonyl groups. It had no methoxyl groups. On paper chromatographic examination it was found to react with silver nitrate, even in the absence of sodium hydroxide, and to give distinctive yellow spots with sprays *b* or *c* but no coloration with sprays *d* or *e*. The compound has $R_{Glucose}$ 4.42 and 2.31 (irrigants A and B, resp.); M_V, 1.62 (buffer C); M_G, 0.63 and 0 (buffers D and E, resp.).

The results of UV-studies on VIII at different pH-values are given in Fig. 4. Products formed from VIII on treating it for various times and at different pH-values (1.5—12) were examined paper chromatographically. A sample of VIII was treated for 30 min with lime-water (0.02 N) and the ammonium salts of the acids formed were compared on electrophoretograms (buffer E) with the ammonium salts mentioned earlier (those obtained on the alkaline treatment of II). The two mixtures were electrophoretically similar, and contained one component which predominated in each case and which had $M_{Gluconic\ acid}$, 1.30.

Reduction of 1,5-anhydro-2,3-dioxo-D-glucitol and fractionation of the products

Samples of VIII (present in freshly isolated eluates) were reduced either by boiling them under reflux with Raney nickel in 70 % ethanol (pH 5) for 3 h, or by treating them with borohydride (pH 9.5) at room temperature for 6 h. After deionisation and evaporation of the solvents the products were chromatographically fractionated (irrigant A) on Whatman No. 3 MM paper (previously washed with water).

Two fractions (1 and 2) were obtained (60 % yield from VIII). The first one was subfractionated by chromatography (irrigant A) and the second one by electrophoresis in borate buffer to give four fractions (1a, 1b, 2a and 2b).

Fraction 1a was treated with charcoal and then crystallised from aqueous ethanol. It was chromatographically and electrophoretically indistinguishable from 1,5-anhydro-D-glucitol and had m.p. and mixed m.p. 141—142° and $[\alpha]_D^{22}$ +43° (*c*, 0.5 in water).

Fraction 1b was crystallised in the same way as above. The product was chromatographically and electrophoretically indistinguishable from 1,5-anhydro-D-mannitol and had m.p. and mixed m.p. 156—157° and $[\alpha]_D^{22}$ −54° (*c*, 0.5 in water).

Fraction 2a was amorphous. The product was chromatographically and electrophoretically indistinguishable from 1,5-anhydro-D-altritol. It had $[\alpha]_D^{22}$ +25 (*c*, 0.5 in water) (Ref.[13] +28.4). The product was acetylated and then gave 2,3,4,6-tetra-*O*-acetyl-1,5-anhydro-D-altritol which had m.p. and mixed m.p. 102—103°.

Fraction 2b was crystallised from aqueous ethanol. The product had m.p. 147—148° $[\alpha]_D^{22}$ +26 (*c*, 0.5 in water) and C 43.8; H 7.28. Calc. for $C_6H_{12}O_5$: C 43.9; H 7.37.

The author is indebted to Mr. A. Assarsson for his skilful assistance and to Dr. N. K. Richtmyer, Bethesda, U.S.A., for a gift of 1,5-anhydro-D-altritol and of 1,5-anhydro-D-galactitol.

The Oxidation of Glycosides

IX. Acidic and Alkaline Degradation of Methyl β-D-2-Oxo-glucopyranoside and Methyl β-D-3-Oxo-glucopyranoside

OLOF THEANDER

Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

An investigation has been made of the acidic and alkaline degradation of methyl β-D-2-oxo-glucopyranoside (I) and methyl β-D-3-oxo-glucopyranoside (II). Under acidic conditions both gave reductic acid while I also gave D-glucosone and II gave D-ribulose. The degradation of I and II in aqueous solution at pH 4 and pH 7 at 100° was rapid and followed the alkaline type of degradation with elimination of the methoxyl group and formation of the dicarbonyl intermediate, 1,5-anhydro-2,3-dioxo-D-glucitol. The reaction products of I also contained II and D-ribulose. No fundamental differences in the type and pattern of the reaction products from those obtained by degradation of II with either lime-water or sodium hydroxide were detected but the rate of reaction of the dicarbonyl intermediate was much slower when sodium hydroxide was used.

Part VIII [1] described the degradation of some oxo-glucosides by lime-water. The present investigation was undertaken to study the degradation of methyl β-D-2-oxo-glucopyranoside (I) and of methyl β-D-3-oxo-glucopyranoside (II) at other pH values and to compare the effect of using sodium hydroxide as the base instead of lime-water.

When the oxo-glucosides were treated with sulphuric acid (0.5 N at 100°) the solution rapidly developed a yellow coloration, then gradually turned brownish and formed a dark coloured precipitate. The hydrolysate had a smell similar to that of furfural. Under similar conditions methyl β-D-glucopyranoside turned only slightly yellow. A semi-quantitative determination (Fig. 1) showed that the rates of hydrolysis of I, II and the unsubstituted methyl glucoside were rather similar and followed the sequence: methyl 3-oxo-glucoside > methyl 2-oxo-glucoside > methyl glucoside. The dioxo sugars formed by hydrolysis of I and II would be expected to be much more reactive than glucose. The oxo-glucosides were not hydrolysable with β-glucosidase.

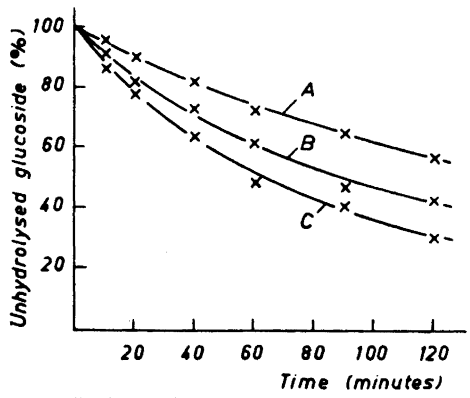

Fig. 1. Treatment of methyl β-D-glucopyranoside (A), methyl β-D-2-oxo-glucopyranoside (B) and methyl β-D-3-oxo-glucopyranoside (C) with 0.5 N sulphuric acid at 100°.

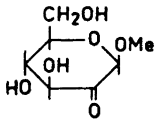
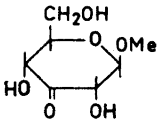
Under hydrolytic conditions that gave mostly glucose and only small amounts of further degradation products from methyl β-glucoside, there was formed from the oxo-glucosides a very complex mixture of compounds that gave positive and very characteristic reactions with silver nitrate-sodium hydroxide, *p*-anisidine hydrochloride, resorcinol-hydrochloric acid and 2,4-dinitrophenylhydrazine reagents. Electrophoresis in hydrogen sulphite buffer [2] was found to be particularly useful in studying the products and gave good separations and round, well-defined spots. Some compounds were present in the hydrolysates from both I and II, some were present only when shorter reaction times were used.

From the degradation of both I and II there was isolated an acidic, strongly reducing crystalline compound that was shown to be reductic acid (III). This substance was obtained by Reichstein and Oppenauer [3] by acid treatment of monomeric uronic acids or polyuronides in a yield of 7 % and in small amounts from xylose. Sohn [4] has recorded its formation in small amount on acid treatment of oxidised cellulose. The acid treatment of oxo-glucosides in the present investigation seems to give a higher yield of this substance than has been obtained previously from other carbohydrates and in this case it is probably an intermediate in the main path of degradation. It was isolated in 22 % yield from the degradation of methyl 3-oxo-glucoside. Other compounds that were obviously associated with the occurrence of reductic acid were also present such as furfural which was isolated in small amounts and has previously[3] been shown to be formed by acid treatment of III, oxidation products of the easily oxidisable III and a product that did not migrate an electrophoresis in hydrogen sulphite but gave the same characteristic reactions as III with several different reagents.

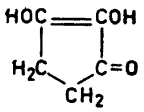
A liquid compound was formed from both I and II (ca. 5 %) which had a relatively high mobility in electrophoresis in hydrogen sulphite ($M_{Vanillin}$ = 1.70), did not reduce a neutral silver solution, gave a characteristic colour reaction with *p*-anisidine hydrochloride and with resorcinol-hydrochloric acid and rapidly gave a precipitate with 2,4-dinitrophenylhydrazine. In addition



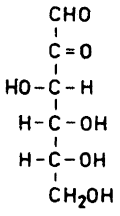
I



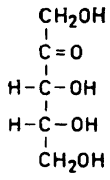
II



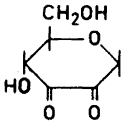
III



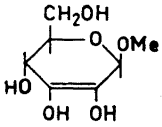
IV



V



VI



VII

to these compounds there were a few other very minor components that were present in the products from both I and II.

D-Glucosone (IV) was isolated in about 20 % yield from the product obtained from I*. Attempts to isolate a corresponding 3-oxo-glucose from the product from II were unsuccessful. This sugar is probably more reactive than IV. However a small amount of D-ribulose (V, 1.5 %) which might have arisen from cleavage of 3-oxo-glucose was isolated from a hydrolysate of II. Ribulose could not be detected in the hydrolysate from I.

In the preceding paper [1] it was shown that both I and II are degraded very rapidly at room temperature by lime-water and that the principal course of the degradation involves elimination of the methoxyl group and the formation of 1,5-anhydro-2,3-dioxo-D-glucitol (VI) which then gives rise to acids, probably by a benzilic acid type rearrangement. Blears, Machell and Richards [5] have reported that the alkaline degradation of 4-*O*-substituted glucose derivatives gives greater amounts of the dicarbonyl intermediate and that the fragmentation of this intermediate was favoured at the expense of saccharinic acid formation when dilute sodium hydroxide solution was used instead of lime-water. In the present investigation a comparison was made of the results of treatment of methyl β-3-oxo-glucoside (II) with lime water and with sodium

* *Addeed in proof:* No reductic acid was detected on treatment of D-glucosone under acid conditions in the same way as methyl 2-oxo-glucoside (I). This indicates that formation of the five-membered ring might not be preceded by hydrolysis of I.

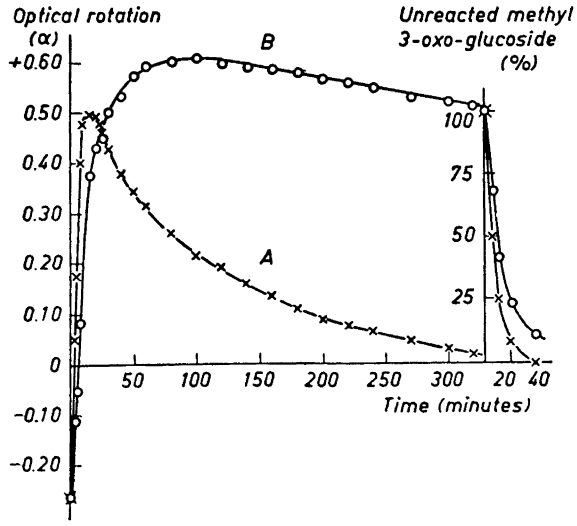


Fig. 2. Treatment of methyl β-D-3-oxo-glucopyranoside with A. lime water (— × — × —) and B sodium hydroxide (—O—O—), 0.018 N at 23°.

hydroxide. The degradation was followed by the optical rotation, by semi-quantitative determination of II (Fig. 2) and by paper chromatographic examination. The dicarbonyl intermediate (VI) reacted much more slowly in sodium hydroxide solutions than in lime-water; II was also degraded somewhat more slowly by sodium hydroxide. The only difference which was detected between samples taken from the two reaction mixtures when the rotation was a maximum was a somewhat lower amount of II and a larger amount of VI in the sodium hydroxide product. No other difference was detected in either the neutral or the acid products which could indicate that the reactions with sodium hydroxide were any different from those with lime-water.

The stability of the oxo-glucosides at the neutral point and at a pH value (pH 4) near that at which carbohydrates are known to be most stable was also of interest.

On treatment of either I or II at pH 7 (at 100°) the solution turned yellow in a few minutes just as in alkaline treatment at room temperature paper chromatographic examination showed that they underwent the same degradation *via* the dicarbonyl intermediate VI as when treated with alkali. In a large scale experiment with the methyl 2-oxo-glucoside (I) at pH 7 for 10 min, methyl 3-oxo-glucoside (18 %) and D-ribulose (3 %) were isolated; most of the remainder of the product was made up of compounds similar to those formed in the alkaline degradation. No methyl 3-oxo-mannoside (an epimerisation product that would be expected together with II) could be isolated and if present it was probably only in much smaller amount than II.

In a large scale experiment with the methyl 3-oxo-glucoside (II) at pH 7 the dicarbonyl intermediate VI and the neutral, unidentified crystalline com-

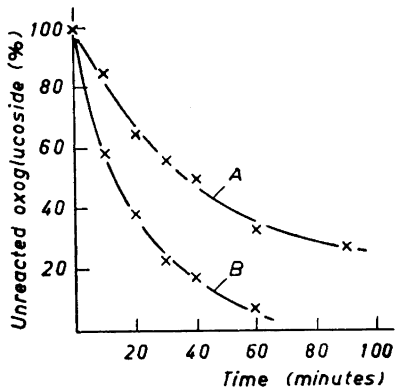

Fig. 3. Treatment of methyl β-D-2-oxo-glucopyranoside and methyl β-D-3-oxo-glucopyranoside at pH 4 and 100°. A. Methyl 3-oxo-glucoside. B. Methyl 2-oxo-glucoside.

pound that had been obtained by alkaline treatment were isolated; traces of I were also detected. The acids obtained showed a similar paper electrophoretic pattern to those from the product of alkaline treatment.

The principal neutral products obtained at pH 4 were the same as those obtained at pH 7 but the rate of degradation was slower. Semi-quantitative determinations of I and II were made throughout the course of the reaction (Fig. 3). The 2-oxo-glucoside was rapidly converted to the 3-oxo-glucoside which then underwent a further change *via* VI. This compound was isolated and identified chromatographically and was shown electrophoretically to give the expected products on reduction with Raney nickel and with borohydride. These results show that the mechanism of the alkaline degradation of oxo-glucosides involving epimerisation, the elimination of the methoxyl group and the formation of a dicarbonyl intermediate is also operative under slightly acid conditions. Whether the further transformation of the dicarbonyl intermediate follows the benzilic acid type rearrangement at this low pH value is, however, uncertain since preliminary results have shown [1] that VI is transformed in different ways at low and high pH values.

Among the products obtained by treatment of I and II at pH 4 there was found in small amount a compound with the same chromatographic behaviour and giving the same reactions with the reagents used as the possible enediol VII, that was suggested [1] as an intermediate in the formation of II on alkaline treatmetnt of I.

In an aqueous solution of methyl β-2-oxo-glucoside in contact with an excess of a weakly basic resin (Amberlite IR-4B: free base) for 4 h at room temperature there was formed about 10 % of methyl β-3-oxo-glucoside. However, when the latter was treated in the same way only traces of transformation products were detected. The 3-oxo-glucoside as well as the possible enediol (VII) mentioned above were detected in a solution of the 2-oxo-glucoside in distilled water after keeping at 4° for a few months but no transformation products were found in a solution of the 3-oxo-glucoside kept under similar conditions.

EXPERIMENTAL

Melting points are corrected. All solvents were removed either by distillation under reduced pressure or by lyophilisation. Paper chromatograms were normally run on Schleicher and Schüll No. 2043 a paper; preparative chromatographic separations were done on Whatman 3MM (after thorough washing) or 31 papers; paper electrophoreses were run on Whatman 3MM paper.

The spray reagents used were: (a) silver nitrate-sodium hydroxide, (b) *p*-anisidine hydrochloride, (c) resorcinol-hydrochloric acid, (d) 2,4-dinitrophenylhydrazine-hydrochloric acid and (e) ferric chloride.

The eluting solvents and buffers used were:

A Ethyl acetate-acetic acid-water, 3:1:3 (upper phase)
B Butanol-ethanol-water, 10:3:5
C Hydrogen sulphite buffer pH 4.7, 0.1 M[2] (used at 50°, M_V = migration relative to that of vanillin)
D Borate buffer, pH 10.0, 0.1 M
E Acetate buffer pH 4.0, 0.1 M
F Phosphate buffer pH 7.0, 0.1 M

Reaction of methyl β-2-oxo-glucopyranoside (I) and methyl β-3-oxo-glucopyranoside (II) with sulphuric acid

Solutions of I, II (prepared as previously [6] described) and methyl β-D-glucopyranoside (0.5 ml, 1 %) in 0.5 N sulphuric acid in sealed glass tubes were kept in a water bath at 100° for different times. After cooling, water (1 ml) was added and the pH was adjusted to 5 by the addition of dry Amberlite resin IR 4B (free base). Aliquots of these solutions were paper chromatographed using solvent A and semi-quantitative determinations were made of the components present by visual estimation on three runs as described previously [1]. For comparison, the amounts of unhydrolysed glucoside in the products from the methyl glucoside were calculated from determinations of glucose by the method of Saeman [7]; the two methods gave good agreement. The kinetic results are shown in Fig. 1.

Paper chromatographic and electrophoretic (buffer C) studies showed that the products obtained from I and II were quite complicated mixtures but there were only a few main components.

Separation of the degradation products obtained from II. In a preliminary large scale experiment, a solution of II (1.00 g) in sulphuric acid (100 ml, 0.5 N) was kept in a water bath at 100° for 2 h. The brownish hydrolysate after cooling was filtered to remove the small amounts of brown precipitate and then extracted continuously with ether for 24 h. The semi-solid dark brown product obtained on evaporation of the ethereal solution contained two main components, A and B, with M_V-values of 1.07 and 1.70 respectively (buffer C) and a considerable amount of material which did not migrate in this buffer. Some minor products were also present which had high migration values in buffers E and F. The product was distilled in a vacuum (ca. 0.06 mm of Hg). A colourless oil distilled at 85° which contained largely B together with traces of other compounds. At 125° a colourless product sublimed which was found to be pure A. It was recrystallised from methanol-methyl ethyl ketone and identified as reductic acid (III). The principal component remaining in the ether-extracted aqueous solution was unchanged II (0.228 g).

Since the hydrolysates from the kinetic investigation showed that some components of the products of the degradation were more rapidly destroyed than others, a solution of II (0.50 g) in 0.5 N sulphuric acid was heated in a water bath at 100° for only 30 min. Chromatography on thick filter paper gave about 60 per cent of II together with a mixture containing principally A and B and, in addition, small amounts (1.5 %) of a compound which was isolated and shown to be D-ribulose (V).

To give a better idea of the proportions of the different components present a further large scale run was made omitting the somewhat drastic distillation step. II (1.00 g) was heated in 0.5 N sulphuric acid (100 ml) for 3 h in a water bath at 100°. The hydrolysate (which had a smell of furfural) was diluted with water (100 ml) and distilled at ordinary pressure until 100 ml had been distilled off. Furfural only was detected in this fraction (by electrophoresis using buffer C); estimation by colorometric analysis showed that 15 mg was present. The hydrolysate, which was now free of the smell of furfural, was continuously extracted with ether for 4 days. The aqueous phase was treated with barium carbonate, deionised on Amberlite IR-120 (H^+) and taken to dryness (0.24 g). The ether extract was evaporated (0.43 g) and on crystallisation gave reductic acid (85 mg) in an electrophoretically pure state; the mother liquor was fractionated by electrophoresis on thick filter paper using buffer C. The strips containing separate fractions were eluted with water and the resultant solutions treated with barium carbonate to a pH 5—6, filtered, passed through an Amberlite IR-4B (free base) column and taken to dryness by lyophilisation. Before evaporation the fraction containing reductic acid was given a short treatment with hydrogen sulphide to reduce any tri-oxo-pentane which might have been present [8]. The material not extracted by ether contained some B but only small amounts of reductic acid; it was fractionated by paper chromatography on thick filter paper using solvent A. The two fractionations gave unreacted II (165 mg) reductic acid (90 mg) and B (45 mg).

Separation of the degradation products from I. Methyl β-2-oxo-glucoside (I, 200 mg) was heated in sulphuric acid solution (0.5 N, 20 ml) for 3 h in a water bath at 100°. Chromatography on thick filter paper (solvent A) gave: unreacted I (35 mg), D-glucosone (30 mg) and reductic acid (20 mg). The substance B that had been isolated from the product of acid treatment of II was present but no trace of ribulose could be detected.

Reductic acid (II). Recrystallisation from a methanol-methyl ethyl ketone mixture gave reductic acid, m.p. 211—212°, undepressed on admixture with an authentic sample, $R_F = 0.65$ (solvent A), $M_V = 1.07$ (buffer C). The infrared spectrum was identical with that of authentic material. It reduced a neutral silver solution immediately at room temperature and gave a characteristic green-yellow coloration with spray reagent *b*. These two characteristic spray reactions were also given by small amounts of material with $M_V = 0$ on an electrophoretogram (buffer C) of the ether extract from II. The product of oxidation of the reductic acid with iodine, as described by Reichstein and Oppenauer [8] in their preparation of trioxo-pentane from reductic acid, gave two spots on electrophoretograms (buffer C) with M_V-values 2.03 and 2.12, respectively, and a single elongated spot $R_F = 0.31$ on paper chromatograms (solvent A). These spots were detected by reduction of a neutral silver solution at room temperature or by a red brown coloration with spray reagent *b*. It was found that the same substances were also present in smaller amounts in the ether extract from II and were formed in a few days when the easily oxidisable reductic acid was kept in aqueous solution at room temperature.

Furfural. It was electrophoretically shown to be indistinguishable from an authentic sample and characterised as its 2,4-dinitro-phenylhydrazone, m.p. and mixed m.p. 228°.

Compound B. This was not identified. It distilled at 85—90°/ca 0.06 mm; $R_F = 0.56$ (solvent A), $M_V = 1.70$ (buffer C), $M_V = 0$ (buffer F). It reduced alkaline silver solution immediately, gave on orange colour with spray reagent *b* and pink colour with spray reagent *c*. It gave an orange precipitate immediately with 2,4-dihitrophenylhydrazine. It did not give reductic acid on acid treatment.

D-*Ribulose* (V). The amorphous compound, $[\alpha]_D^{24}$ ca. −15°, (*c*, 0.5 in water), paper chromatographically and electrophoretically indinstinguishable from authentic material. The gray colour with spray reagent *c* was particularly characteristic and sensitive. Part of the product was converted to the *o*-nitrophenylhydrazone, m.p. and mixed m.p. 167—168°. Part of the product was reduced with borohydride, deionised and acetylated (acetic anhydride-pyridine). The two acetates obtained were indistinguishable from the authentic acetates of ribitol and D-arabitol by paper chromatography using the method of Wickberg [9] with formamide + dimethyl formamide as stationary phase and eluting with light petroleum (b.p. 60—70°).

D-*Glucosone* (IV). The amorphous compound was paper chromatographically and electrophoretically (buffer C; M_V = 1.24) indistinguishable from authentic D-glucosone. It was characterised by the formation at room temperature of D-glucose phenylosazone, m.p. and mixed m.p. 205–207°.

Reaction of methyl β-D-3-oxo-glucopyranoside (II) with lime-water and with sodium hydroxide

Two series of experiments were made on the reactions of II (50 mg) in lime-water (25 ml, 0.018 N) and in aqueous sodium hydroxide solution (25 ml, 0.018 N) at 23°. At intervals the change in optical rotation was determined and samples were withdrawn, acidified with Amberlite IR-120 and examined by paper chromatography and electrophoresis; a semi-quantitative estimation of the amount of unreacted II present was also made using the method previously[1] described. The results are shown in Fig. 2. Oxygen was removed from the basic solutions by bubbling nitrogen through the solutions, but later experiments showed that degradation proceeded at the same rate without this treatment.

Reaction of methyl β-D-2-oxo-glucopyranoside (I) and methyl β-D-3-oxo-glucopyranoside (II) at pH 7

Methyl β-3-oxo-glucoside (II, 500 mg) in 0.2 N phosphate buffer (50 ml) was kept in a water bath at 100° for 30 min. A yellow colour appeared after a few minutes and gradually increased in strength. After cooling the solution was stirred with Amberlite IR-120 (H+) and then with Amberlite IR-4B (free base), the pH was adjusted to 5 and the solution was concentrated to a small volume and separated on Whatman No. 31 paper (solvent A). The neutral product (240 mg) gave unreacted II (85 mg), 1,5-anhydro-2,3-dioxo-D-glucitol (VI) (65 mg) and the unidentified crystalline compound previously[1] obtained from the alkaline treatment of II (5 mg), m.p. and mixed m.p. 156–158°. Traces of I were detected but no ribulose was present. The acids were recovered as the ammonium salts from the Amberlite IR-4B resin; electrophoresis showed a similar pattern to that given by the corresponding product from the alkaline treatment.

Methyl β-2-oxo-glucoside (I, 250 mg) was treated in the same way as above for 10 min. After deionisation the product was fractionated on a carbon-Celite column (2.5 × 22 cm) using gradient elution and gave unreacted I (20 mg), D-ribulose (15 mg) and II (70 mg); other minor compounds were also present. D-Ribulose was characterised as above. The methyl β-3-oxo-glucoside (II), m.p. and mixed m.p. 130–131°, $[\alpha]_D^{22}$ −61° (*c*, 2 in water) was chromatographically and electrophoretically identical with an authentic sample.

Treatment of methyl β-D-2-oxo-glucopyranoside (I) and methyl β-D-3-oxo-glucopyranoside (II) at pH 4

Two series of experiments were made with I and II, respectively. Solutions of the substance in 0.2 N acetate buffer (0.5 ml, 1 %) in sealed glass tubes were kept in a water bath at 100° for different times. After cooling. the samples were diluted with water (1 ml), excess Amberlite IR-120 (H+) was added and semi-quantitative determinations were made of unreacted I and II present as described previously. The results are shown in Fig. 2.

In one experiment, II (250 mg) in 0.2 N acetate buffer (25 ml) was kept in a water bath at 100° for 45 min. After cooling and deionisation the product was separated on Whatman No. 31 paper (solvent A) giving: unreacted II (90 mg), VI (15 mg); the unidentified crystalline product (m.p. 156–158°) mentioned above was detected by paper chromatography. A part of VI was reduced with borohydride and with Raney nickel and the four 1,5-anhydroglycitols obtained were characterised by paper electrophoresis (buffer D) as described previously[1].

The author is indebted to Mr. A. Assarsson for his skilful assistance and to Professor T. Reichstein, Basel, Switzerland, for a gift of reductic acid.

On the Reaction between Substituted Cyanoacetic Esters and Methylene Bromide. The Preparation of α,α′-Di-(*tert.*-butyl)-glutaric Acid

LENNART EBERSON

Department of Organic Chemistry, Chemical Institute, University of Lund, Sweden

Ethyl methyl-, ethyl-, *iso*propyl-, and *tert.*-butylcyanoacetate, in the form of their sodium compounds, react with methylene bromide with the formation of 1,3-dialkyl-1-carbethoxyglutaronitriles, *i.e.*, one carbethoxy group is eliminated during the reaction. These compounds on hydrolysis and decarboxylation give the diastereoisomers of the corresponding α,α′-dialkylsubstituted glutaric acids.

A monoalkylsubstituted malonic ester, in the form of its sodium compound, reacts with methylene bromide with the formation of a 1,3-dialkyl-1,1,3-tricarbethoxypropane [1,2]. One carbethoxy group is eliminated as diethyl carbonate. The yields of the products were dependent on the nature of the alkyl substituent in the way shown in Table 1.

Table 1. Yields of 1,3-dialkyl-1,1,3-tricarbethoxypropanes.

Alkyl group	Yield of product in %
CH_3 [1]	83
C_2H_5 [1]	61
n-C_3H_7 [1]	68
iso-C_3H_7 [1]	39 [a]
n-C_4H_9 [1]	74
iso-C_4H_9 [1]	51
tert.-C_4H_9 [1]	0 [a,b]
n-C_5H_{11} [1]	77
neo-C_5H_{11} [1]	0 [c]
$(CH_3)_3SiCH_2$ [2]	62
$C_6H_5CH_2$ [1]	77

a. The reaction was carried out in ethanol-toluene solution to attain an increased reflux temperature. b. Only unchanged starting material was obtained. c. The product was mainly ethyl α-*neo*pentylacrylate.

Thus branching at the α- or β-position in the alkyl group retards or, as for the *tert.*-butyl and *neo*pentyl derivatives, completely inhibits the reaction. It was suggested that the unreactivity of diethyl *tert.*-butylmalonate was due to its considerably reduced CH-acidity rather than the presence of the bulky *tert.*-butyl group. For the *neo*pentyl derivative the situation is another, as this compound is readily alkylated with alkyl halogenides in ethanolic solution [3] and apparently has an acidity comparable with that of *n*-alkylmalonic esters. In the reaction with methylene bromide diethyl bromomethyl-*neo*pentylmalonate consequently is formed and then split by sodium ethoxide into ethyl α-*neo*pentylacrylate, diethyl carbonate, and sodium bromide. This acrylic ester has been found to be very resistant to addition reagents and thus the reaction will stop at this stage. The unreactivity probably depends on the steric influence of the *neo*pentyl group. The difference between the rates of bromine addition to *tert.*-butylethylene and *neo*pentylethylene has been explained in the same way [4]. The great difference between the *neo*pentyl group and its silicon analogue, the trimethylsilylmethyl group [5], also manifests itself in this reaction.

As the cyano group is known to have a greater acid-strengthening effect than the carbethoxy group, the reaction between ethyl *tert.*-butylcyanoacetate and methylene bromide was studied in order to test the above hypothesis. In fact the reaction product consisted of I, R = *tert.*-butyl, formed according to the formula:

$$2\ \mathrm{R.CH(CN)COOEt} + \mathrm{CH_2Br_2} + 2\ \mathrm{OEt^-} \longrightarrow$$

$$\mathrm{R.C(CN)COOEt}\ (\mathrm{R.CH.CN}\ \text{—}\ \mathrm{CH_2}) + \mathrm{EtOH} + (\mathrm{EtO})_2\mathrm{CO} + 2\ \mathrm{Br^-}$$

I

with the elimination of one carbethoxy group, in close analogy with the behaviour of monosubstituted malonic esters. In ethanolic solution the yield was 19 %, whereas addition of toluene to the reaction mixture in order to increase the reflux temperature gave 52 % yield. Ethyl methyl-, ethyl-, and *iso*propylcyanoacetate in ethanolic solution similarly gave I, R = CH_3, C_2H_5, and *iso*-C_3H_7 in 70, 77, and 58 % yield, respectively.

I, R = *tert.*-C_4H_9 was purified by distillation *in vacuo* and then solidified on standing, m.p. 75—80°. Recrystallization from 80 % methanol gave m.p. 79—81°. The small change in m.p. indicates that the substance which is capable of existing in two diastereoisomeric forms either is produced in preponderantly one form or that the solid consists of the eutectic mixture. The formation of both forms of α,α'-di-(*tert.*-butyl)-glutaric acid is no conclusive evidence, as the drastic conditions necessary for hydrolysis are likely to affect the asymmetric centra. Recrystallization from several solvents and solvent pairs had no effect upon the m.p.

Zelinsky [6] and Auwers and Thorpe [7] carried out the same reaction with ethyl methylcyanoacetate and methylene iodide and claimed that 1,3-dimethyl-

1,3-dicarbethoxyglutaronitrile was formed in about 50 % yield. However, as their analyses did not agree well with this formula and the substance was stated to be difficult to purify owing to decomposition during distillation, it seems probable that their compound actually was I, R = CH_3. This is also indicated by the b.p. reported, 165—170°/12 mm. For comparison it should be mentioned that 1,3-dicarbethoxyglutaronitrile has b.p. 195°/20 mm [8].

I, R = *tert.*-C_4H_9, was very resistant to hydrolysis in acid or alkaline solution. Sulphuric acid of various strengths was either without effect or caused decomposition due to oxidation. Boiling ethanolic potassium hydroxide also left the substance unchanged. However, boiling with excess potassium hydroxide in ethylene glycol containing some water (boiling temperature about 175°) converted it into a mixture of the monoamides of α,α'-di-(*tert.*-butyl)-glutaric acid, which could be separated by fractionated crystallization from acetic acid, m.p. 242—243° and 214—216°, respectively. Apparently the carbethoxy group (or one of the cyano groups) was eliminated directly during this procedure, as evidenced by the evolution of large amounts of carbon dioxide on acidification. In order to hydrolyze the remaining amide group the monoamides were dissolved in a mixture of concentrated hydrochloric acid and acetic acid and treated with sodium nitrite. This method gave the two forms of α,α'-di-(*tert.*-butyl)-glutaric acid in almost quantitative yields, m.p. 221—222° and 213—214°. The eutectic m.p. was 189°. The amide with m.p. 242—243° corresponded to the acid with m.p. 213—214°.

1,3-Dimethyl-, 1,3-diethyl-, and 1,3-di*iso*propyl-1-carbethoxyglutaronitrile (I, R = CH_3, C_2H_5, and *iso*-C_3H_7) were hydrolyzed and decarboxylated in acid media as described in the experimental part. The acid mixtures obtained were separated into diastereoisomers according to known procedures. [1,9,10]

EXPERIMENTAL

The preparation of 1,3-di-(tert.-*butyl*)*-1-carbethoxyglutaronitrile (I, R =* tert.-C_4H_9*) in ethanolic solution.* Sodium, 4.6 g (0.2 mole), was dissolved in 70 ml of absolute ethanol, and 33.8 g (0.2 mole) of ethyl *tert.*-butylcyanoacetate were added followed by 17.4 g (0.1 mole) of methylene bromide. The reaction mixture was allowed to boil for 24 h after which time it reacted almost neutrally. After neutralization with acetic acid the ethanol was distilled off and the residue treated with water. The organic layer was taken up in ether and the ether solution washed with water and finally dried with anhydrous magnesium sulphate. Fractionation yielded besides unchanged starting material 5.7 g of I, R = *tert.*-C_4H_9, b.p. 113—114°/1 mm, which solidified upon standing, m.p. 75—80°. After recrystallization from 80 % aqueous methanol 5.2 g of the pure compound were obtained, m.p. 79—81°. Further recrystallizations from 80 % aqueous methanol, 80 % aqueous ethanol, petroleum ether, benzene-petroleum ether, or ethyl acetate-petroleum ether did not change the m.p. (Found: C 68.9; H 9.3; N 10.0. Calc. for $C_{16}H_{26}O_2N_2$: C 69.0; H 9.4; N 10.1). The yield was 19 %.

The preparation of I, R = tert.-C_4H_9*, in ethanol-toluene solution.* Sodium, 11.5 g (0.5 mole), was heated under 200 ml of toluene until the metal had melted. A mixture of 40 ml of absolute ethanol and 84.5 g (0.5 mole) of ethyl *tert.*-butylcyanoacetate was added during a period of 10 min whereby a vigorous reaction occurred. To the resulting yellow solution were added 43.5 g (0.25 mole) of methylene bromide, and the mixture was kept at reflux temperature for 36 h, after which time it reacted neutrally. Water was added and the product was isolated and purified as above, b.p. 150—152°/4 mm, m.p. after recrystallization from 80 % aqueous methanol 79—81°. The yield was 29.8 g (52 %), based on unrecovered starting material (69.3 g).

The monoamides of a,a'-di-(tert.-*butyl*)-*glutaric acid.* 1,3-di-(*tert.*-butyl)-1-carbethoxyglutaronitrile, 13.9 g (0.05 mole), was slowly heated together with 28.0 g (0.5 mole) of potassium hydroxide, 80 ml of ethylene glycol, and 5 ml of water. A vigorous reaction occurred, and when it had subsided the solution was refluxed for 20 h. After cooling it was poured into 150 ml of water. On acidification with concentrated hydrochloric acid large amounts of carbon dioxide were evolved and a solid was obtained. The latter was very difficult to filter owing to contamination with silicon dioxide from the reaction vessel. After drying it weighed 15.7 g. A small amount was treated with boiling ethyl acetate, filtered from insoluble matter, and the solution allowed to cool slowly. Crystals with m.p. 235—240° separated, m.p. after another recrystallization from ethyl acetate 242—243°. The mother liquor from the first filtration was freed from solvent and the residue recrystallized twice from aqueous acetic acid, m.p. 214—216°. (Found for the monoamide with m.p. 242—243°: C 64.0; H 10.2; N 5.8; equiv. wt. 243.5. Found for the monomide with m.p. 214—216°: C 64.2; H 10.4; N 5.8; equiv. wt. 242.3. Calc. for $C_{13}H_{25}O_3N$: C 64.2; H 10.4; N 5.8; equiv. wt. 243.3).

a,a'-Di-(tert.-*butyl*)-*glutaric acid.* Crude mixture of the monoamides, 3.0 g, was dissolved in 50 ml of glacial acetic acid and filtered from insoluble matter. Concentrated hydrochloric acid, 10 ml, was added and the solution cooled in an ice-bath. When the temperature was below 5°, a solution of 3.0 g of sodium nitrite in a few ml of water was added slowly. The mixture was cautiously heated in a water-bath whereby evolution of nitrogen began at about 40°. When the gas evolution had ceased, the solution was boiled for 10 min and then diluted with 300 ml of water. The solid was filtered and dried (1.4 g). It was dissolved in a mixture of ethyl acetate and benzene (1:1) and the solution allowed to cool. The crystals were filtered, m.p. 220—222°, and recrystallized once from glacial acetic acid, m.p. 221—222° (0.5 g). The mother liquor was evaporated to dryness and the residue recrystallized twice from aqueous acetic acid, m.p. 213—214° (0.45 g). The eutectic mixture melted at 189°. (Found for the acid with m.p. 221—222°: C 63.8; H 9.9; equiv. wt. 121.8. Found for the acid with m.p. 213—214°: C 63.7; H 9.9: equiv. wt. 122.7. Calc. for $C_{13}H_{24}O_4$: C 63.9; H 9.9; equiv. wt. 122.2).

When small amounts of the pure monoamides were treated in the same way, almost quantitative yields of the respective acids were obtained. The amide with m.p. 242—243° corresponded to the acid with m.p. 213—214°.

1,3-Dimethyl-1-carbethoxyglutaronitrile (*I*, $R = CH_3$). This compound was prepared from 0.2 mole of sodium dissolved in 70 ml of ethanol, 0.2 mole of ethyl methylcyanoacetate, and 0.1 mole of methylene bromide. The reflux time was 24 h. The product was isolated as above, b.p. 137—138°/4 mm, n_D^{20} 1.4438, d_4^{20} 1.0354, yield 70 %. (Found: C 61.4; H 7.3; N 14.0; r_D 0.2564. Calc. for $C_{10}H_{14}O_2N_2$: C 61.8; H 7.3; N 14.4; r_D 0.2560).

a,a'-Dimethylglutaric acid. 1,3-Dimethyl-1-carbethoxyglutaronitrile was hydrolyzed and decarboxylated by boiling with concentrated hydrochloric acid for 20 h. The yield of crude acid mixture was almost quantitative and it was separated into the diastereoisomers according to Möller [9], m.p. 140—141° and 125—127°, respectively.

1,3-Diethyl-1-carbethoxyglutaronitrile (*I*, $R = C_2H_5$). This compound was prepared in the same way as the methyl derivative in a 0.2 mole run, b.p. 151—153°/4 mm, n_D^{20} 1.4468, d_4^{20} 1.0088, yield 77 %. (Found: C 64.6; H 8.1; N 12.5; r_D 0.2648. Calc. for $C_{12}H_{18}O_2N_2$: C 64.8; H 8.2; N 12.6; r_D 0.2655).

a,a'-Diethylglutaric acid. 1,3-Diethyl-1-carbethoxyglutaronitrile was hydrolyzed and decarboxylated by boiling with 50 % sulphuric acid for 12 h. The yield of crude acid mixture was almost quantitative and it was separated into the diastereoisomers according to Berner and Landmark [10], m.p. 119—121° and 92—94°, respectively.

*1,3-Di*iso*propyl-1-carbethoxyglutaronitrile* (*I*, R = iso-C_3H_7). This compound was prepared in the same way as the methyl derivative in a 0.5 mole run, b.p. 136—142°/2 mm, n_D^{20} 1.4523, d_4^{20} 0.9992, yield 58 %. (Found: C 67.0; H 8.9; N 11.3; r_D 0.2701. Calc. for $C_{14}H_{22}O_2N_2$: C 67.2; H 8.9; N 11.2; r_D 0.2728).

*a,a'-Di*iso*propylglutaric acid.* 1,3-Di*iso*propyl-1-carbethoxyglutaronitrile was hydrolyzed and decarboxylated by boiling with 80 % sulphuric acid for 20 min. The yield of crude acid mixture was 90 %, and it was separated into diastereoisomers according to Eberson [1], m.p. 141—142° and 119—120°, respectively.

The author wishes to express his sincere gratitude to Professor Erik Larsson for his kind interest in this work. A grant from the *Kungliga Fysiografiska Sällskapet* is gratefully acknowledged.

Studies on Hemicelluloses from Pine (*Pinus silvestris* L.)

HANS MEIER

Wood Chemistry Department, Swedish Forest Products Research Laboratory, Stockholm Ö, Sweden

A number of glucomannan fractions and an araboxylan fraction have been isolated from pine (*Pinus silvestris* L.) holocellulose. The ratio glucose:mannose varied from 1:3.1 to 1:3.7 in the different glucomannans. All fractions contained a few per cent of galactose residues and the possible presence of galactoglucomannans cannot be excluded. The ratio arabinose:xylose in the isolated araboxylan was 1:7.4 and the uronic acid content 18.6 %.

The average degree of polymerisation ($\overline{DP}_n$) increased from about 70 for the most easily extractable glucomannan fractions up to about 115 for the most resistant. The $\overline{DP}_n$ value for the araboxylan was 121.

It seems probable that the glucomannans in a holocellulose are partly bound to the remaining lignin even when the holocellulose in question has a very low Klason-lignin content.

Studies were earlier reported [1] on the physical properties of glucomannans from Norwegian spruce (*Picea Abies* Karst.). Similar investigations have now been carried out on glucomannans and on an araboxylan from pine (*Pinus silvestris* L.).

ISOLATION OF THE CRUDE HEMICELLULOSES

The crude hemicelluloses were isolated by successive treatments of a chlorite-holocellulose with dimethyl sulphoxide, hot water, potassium hydroxide and finally with potassium hydroxide and boric acid. The xylans were practically completely extracted, but about 25 % of the glucomannans present in the holocellulose were resistant to those treatments. They could, however, be extracted, in part at least, after having destroyed the cellular structure of the residue by dissolving it in cupri-ethylene diamine and regenerating it by reprecipitation with acetic acid.

Table 1. Carbohydrate analyses of the crude hemicellulose extracts and of the residues.

Sample		Yield g	Galactose/Glucose %		Mannose %	Arabinose %	Xylose %
K_2	Holocellulose (yield with respect to acetone-treated wood: 69 %. Klason-lignin: 1 %)	147.1	1.6	71.8	15.6	1.7	9.3
$K_2GM_1X_1$	$(CH_3)_2SO$-extract	1.1	26.7		16.4	6.8	50.0
$K_2GM_2X_2$	H_2O-extract	2.9	24.4		72.6	1.2	1.8
$K_2GM_3X_3$	14 % KOH-extract	22.1	15.5		28.0	6.8	49.8
$K_2GM_4X_4$	(14 % KOH+3 % H_3BO_3)-extract	3.5	23.0		63.5	2.5	11.0
$K_2GM_5X_5$	(24 % KOH+3 % H_3BO_3)-extract	2.3	24.7		70.3	2.3	2.7
K_3	Residue after the previous extractions		92.9		7.1	trace	trace
$K_3GM_6X_6$	(24 % KOH+3 % H_3BO_3)-extract from the cupri-ethylene diamine-regenerate of K_3	2.5	29.0		65.3	2.1	3.6
K_4	Residue after the extraction of the cupri-ethylene diamine-regenerate of K_3		95.1		4.9	trace	trace

The composition of the different fractions is shown in Table 1. The dimethyl sulphoxide extracted principally xylans but only in small amounts. Hot water extracts contained an almost pure glucomannan having only 1.8 % of xylose residues while two samples of spruce holocellulose under similar conditions contained 16.5 and 11 % of xylose residues [1]. About a quarter of the material extracted by 14 % potassium hydroxide consisted of mannose residues while the rest of the fraction contained most of the xylans that could be extracted from the holocellulose. Relatively pure glucomannans were isolated in later extractions by a solution of potassium hydroxide and boric acid.

FRACTIONATION AND PURIFICATION OF THE CRUDE HEMICELLULOSES

The hemicelluloses extracted by hot water and by potassium hydroxide and boric acid contained primarily glucose and mannose residues. The contaminating araboxylans could to a large extent be removed by fractionation of the samples with Fehling's solution and then with barium hydroxide. Barium hydroxide has been shown [2] to be a good reagent for the selective precipitation of polysaccharides containing mannose residues. Xylans do not precipitate under the conditions employed, but in certain cases do so at higher concentrations of barium hydroxide. As will be seen in Table 2, glucomannans were obtained having only 1.2 to 2.8 % of xylose residues. Unlike the glucomannans isolated from spruce [1] they contained 2.8 to 4.7 % of galactose residues and normally also a low proportion of arabinose residues.

Table 2. Carbohydrate analyses and degree of polymerisation of the glucomannans and of an araboxylan obtained by fractionation using Fehling's solution and barium hydroxide.

Sample	Origin (*cf.* Table 1)	Galactose %	Glucose %	Mannose %	Arabinose %	Xylose %	Glucose: Mannose	$[\alpha]_D^{20}$ [a]	$\overline{DP}_n$	$\overline{DP}_w$	Nitrogen[b] %

[a] In 2.5 N NaOH.
[b] Nitrogen content of the nitrated samples used in DP-determinations.

The material extracted by 14 % potassium hydroxide was sub-fractionated from an aqueous alkaline solution by the addition of Fehling's solution and then yielded a precipitate (A) enriched in glucomannan, and a supernatant (B) enriched in xylan. No significant reduction in the proportion of xylose residues in the glucomannan-rich fraction (A) was obtained when the material was again treated with Fehling's solution, but the xylose residues were reduced from 19.6 to 8.3 % in the precipitate obtained when barium hydroxide was added to a solution of the material (K_2GM_3, Table 2). The xylan-rich supernatant (B) contained 10.8 % of mannose residues but this was reduced to 1.2 % by the preferential precipitation with barium hydroxide solution of a fraction enriched in mannose residues. In this way an araboxylan (K_2X_3, Table 2) was obtained having a uronic acid content of 18.6 % and a ratio of arabinose to xylose residues of 1:7.4. (This ratio refers only to those xylose residues in the xylan which have no uronic acid residues bound to them since the latter, under the hydrolytic conditions used, are present in aldobiuronic acids.)

Although cetyltrimethylammonium bromide (CTA-Br) has been used [3] to separate acidic and neutral polysaccharides, its use in the present work did not result in any significant reduction in the proportion of xylose residues in fraction K_2GM_3.

Table 3. Carbohydrate- and lignin-analyses of two fractions from K_2GM_3 precipitated with cetavlon hydroxide in the presence of boric acid. (Carbohydrate content is assumed to be 100 %.)

Sample	Lignin %	Galactose %	Glucose %	Mannose %	Arabinose %	Xylose %
F_2	5.8	4.2	18.9	64.0	2.3	10.6
F_4	trace	2.5	18.5	77.0	trace	2.0

Finally K_2GM_3 was divided into five fractions (F_{1-5}) by adding boric acid and then making successive additons of cetyltrimethylammonium hydroxide (CTA-OH). This method has been used at this laboratory [4] to fractionate arabogalactans. The first three fractions (F_{1-3}), which accounted for about 80 % of the recovered material, were similar to one another but were still heterogeneous (*cf.* Table 3). The next two fractions ($F_{4,5}$), on the other hand, contained glucose and mannose residues almost exclusively.

Recent studies by Lindgren[5] strongly indicate that in coniferous woods the hemicelluloses are in part chemically bound to lignin. It is, therefore, possible that the major component, F_{1-3}, is a hemicellulose-lignin complex with one or more types of hemicelluloses bound to lignin. By spectral analysis the lignin content in F_{1-3} was determined to be about 6 %; F_4 and F_5, on the other hand, contained no lignin (the Klason-lignin in the starting holocellulose was less than 1 %). On electrophoresis of a sample of F_2 on glass-fibre sheets wet with 0.05 N sodium hydroxide, it gave a single spot with a migration distinct from that of the glucomannan sample F_5. This indicated that in F_2 there was no glucomannan similar to that in F_5 and that the mannose residues present in the former fraction must either have been present in a different type of molecule, or be in a glucomannan chemically bound to some other species. There were two items indicating that a lignin-hemicellulose complex was present. Firstly, Lindgren [5] has noted that when lignin-free hemicelluloses are chromatographed on glass-fibre paper, using 0.05 N sodium hydroxide as irrigant, then the hemicelluloses migrate with the solvent front; lignin-hemicellulose complexes, on the other hand, have R_F values below 1. F_2 and F_5 had R_F 0.3—0.4 and 1, respectively, indicating that the former was a lignin-hemicellulose complex. Secondly, a sample of K_2GM_3 (lignin content 5 %) was delignified by chlorination and by extraction with ethanolic ethanolamine, and the product, in solution, was afterwards treated with barium hydroxide. The precipitate then obtained (K_2GM_3*) contained a much smaller amount of xylose residues than did K_2GM_3 (see Table 2). This indicated that, prior to delignification, the xylose residues had been present in some molecular species other than the glucomannan but that both species were probably bound to lignin molecules. The mobility of K_2GM_3* on an electrophoretogram was similar to that of the glucomannan F_5.

The samples K_2X_3, K_2GM_4 and K_2GM_6 contained, respectively, 1.1, 3.6 and 5 % lignin. By chromatographic examination on glass-fibre paper a sample of K_2X_3 was found to contain two components; one having an R_F of 0.3, the other of 1, indicative, it is believed, of their having been produced by a hemicellulose-lignin complex and a hemicellulose, respectively. The spot produced by the former was very weak, and that by the latter strong, while K_2GM_4 and K_2GM_6 gave two spots each of about equal intensity. It seems, therefore, that in the latter two samples also a considerable part of the glucomannan was bound to the lignin.

DP-DETERMINATIONS

The degrees of polymerisation based on number-average molecular weights ($\overline{DP}_n$), were determined osmometrically on the nitrates in butyl acetate [1]. The results are shown in Table 2. The $\overline{DP}_n$ value for the glucomannan extracted by water was *ca.* 70 and was practically identical to that of the corresponding fraction from spruce holocellulose [1]. The value for K_2GM_3 was relatively high (89.9) probably due to the presence, as a contaminant, of an araboxylan of higher molecular weight. The fractions that had been extracted with potassium hydroxide/boric acid differed but little from one another. The fraction extracted from the regenerated cellulose (K_2GM_6) had a $\overline{DP}_n$ of *ca.* 115, a value rather lower than that given by the corresponding fraction from spruce [1].

The $\overline{DP}_n$ value of the sodium salt of the acidic araboxylan (K_2X_3) was determined in 0.1 N sodium chloride (*cf.* Ref.[7]) to be *ca.* 120.

The problem had to be considered of whether these $\overline{DP}_n$ values related to hemicelluloses or to lignin-hemicellulose complexes. Lignin was, however, found to be absent from the nitrated samples, and this indicated that delignification had taken place during nitration and that, in consequence, the $\overline{DP}_n$ values were those of hemicelluloses and not of lignin-hemicellulose complexes.

The degrees of polymerisation based on weight-average molecular weight ($\overline{DP}_w$), were determined viscometrically on the nitrates in butyl acetate. $K\eta$ in the equation of Schulz and Blaschke

$$Z\eta = \frac{\eta_{sp}}{c(1 + K_\eta \cdot \eta_{sp})}$$

was determined to be 0.29 and the $\overline{DP}_w$ values were then obtained by application of the equation derived by Marx [8]:

$$Z_{\eta \text{ acetone}} = 1.5 \times 10^{-3} \overline{DP}_w{}^{0.9}$$

In a separate experiment $Z_{\eta \text{ butyl acetate}}$ was determined to be $1.13 \times Z_{\eta \text{ acetone}}$.

The derivation of Marx' equation was based on measurements carried out on cellulose nitrates which contained *ca.* 13.6 % nitrogen. The calculation of the $\overline{DP}_w$ values of the nitrated glucomannans was based on the average weight of the residues, allowance being made for their incomplete nitration. It must, however, be stressed that the $\overline{DP}_w$ values in Table 2 are of necessity highly uncertain as it is very doubtful if the formula of Marx can legitimately be applied to nitrated glucomannans of low molecular weight. The $\overline{DP}_n$ and $\overline{DP}_w$ values of the various fractions both increase in the same order; the lowest values being given by the most readily extracted glucomannans and the highest values by those most difficult to extract. This indicates that all of the molecular species probably possess a similar degree of branching.

DISCUSSION

The mannose residues in the holocellulose of *Pinus silverstris* are present in glucomannans as was also earlier found in work on *Picea Abies* [1]. The ratio of glucose to mannose appears, however, to be rather higher in the former (*ca.* 1:3.5 as compared to *ca.* 1:4 in *Picea Abies*).

From the various fractions glucomannans were precipitated by the addition of Fehling's solution and those precipitates were dissolved in water and fractionated by the addition of barium hydroxide. The glucomannan then precipitated generally contained about 2 % xylose, 2 % arabinose, and up to 4.2 % galactose residues. The material extracted by the 14 % potassium hydroxide ($K_2GM_3X_3$) did not yield a similar polysaccharide when treated in like manner but from its mannose-rich sub-fraction, K_2GM_3, by fractional precipitation with cetavlon hydroxide and boric acid there was obtained a small amount of a polysaccharide containing principally glucose and mannose residues. The major part of the K_2GM_3 sub-fraction contained xylose and galactose residues in addition to glucose and mannose residues. As the xylose residues could largely be removed after delignification of the material, it seems probable that they and the glucomannan were bound independently to the lignin. It is uncertain whether or not the galactose residues were present as part of the glucomannan. The galactose residues may be present in contaminating polysaccharides as arabogalactans or pectic galactans.

The various glucomannans had optical rotations differing relatively widely from one another. This variation may have been due to varying amounts of lignin and to differences in the proportions of the different sugar residues.

The $\overline{DP}_n$ values of the different purified glucomannans were similar to those given by the corresponding fractions from spruce. The araboxylan K_2X_3 had a $\overline{DP}_n$ of 121, that is a value even higher than that given by the least readily extracted glucomannan (K_2GM_6).

EXPERIMENTAL

Quantitative paper chromatography. The hydrolyses and the quantitative sugar analyses of the hemicelluloses were carried out by the method of Saeman *et al.*[9] using the chromatographic irrigants ethyl acetate — acetic acid — water (3:1:3), and, for the separation of glucose and galactose, ethyl acetate — pyridine — water (2:1:2).

Electrophoresis. The electrophoresis was carried out on glass-fibre sheets [5]. The spray-reagent was a mixture of *a*-naphthol (1 g), conc. sulfuric acid (5 ml) and *n*-butanol (100 ml).

Fractional extraction of the hemicellulose. Wood meal (18—35 mesh) of *Pinus silvestris* L. was treated in a Soxhlet-type extractor with acetone and the residue was then delignified by the chlorite method [10]. The product remaining after delignification was 68.9 % of the acetone-treated wood. The holocellulose (147 g) was thoroughly washed with water and was then mechanically shaken, at room temperature, with dimethyl sulphoxide (1.5 l) in an atmosphere of nitrogen. Three such treatments were carried out over a total period of 24 h. Then the residual material was washed with cold water. The combined extracts were slightly acidified by the addition of a little hydrochloric acid and the hemicelluloses were precipitated from the solution by the addition of twice its volume of ethanol. The precipitate was centrifuged down and, after washing with *ca.* 65 % aqueous ethanol, was suspended in water. The remaining ethanol was distilled off, and the solution then freezedried. The residual material from the dimethyl sulphoxide

treatment was then treated successively, and in a similar way, with boiling water (giving extract $K_2GM_2X_2$), 14 % potassium hydroxide (giving extract $K_2GM_3X_3$), 14 % potassium hydroxide and 3 % boric acid (giving extract $K_2GM_5X_5$), and 24 % potassium hydroxide and 3 % boric acid (giving extract $K_2GM_4X_4$). In all cases a total of 4.5 l of liquid was employed over three treatments. A sample of the final residue (K_3) was dissolved in cupriethylene diamine and precipitation was effected by the addition of acetic acid. The precipitate was treated once with 24 % potassium hydroxide + 3 % boric acid (giving extract $K_2GM_6X_6$). All extractions were carried out in an atmosphere of nitrogen. The extracts were sligthly acidified and the hemicelluloses precipitated, washed, and dried as described earlier. Those precipitates contaminated by borate were washed also with warm methanol to remove the boric salts.

Isolation and purification of the glucomannans and of an araboxylan. The various crude hemicellulose fractions were suspended in fifty times their weight of water and the mixture was homogenized in a Turmix blender. After boiling the mixture for a few minutes, then cooling, it remained turbid, but complete dissolution was effected on the addition of a little dilute sodium hydroxide. To these solutions Fehling's solution was added, and the resultant precipitate was centrifuged down and washed once with water. The centrifugate from the $K_2GM_3X_3$ fraction, after acidification with hydrochloric acid, was passed through a column of cation-exchange resin (IR 120). The hemicelluloses were then precipitated by the addition of ethanol and the precipitates, after washing, were dried. As this product still contained *ca.* 10 % mannose residues it was redissolved in water and was treated with barium hydroxide and the precipitate centrifuged down. The centrifugate, after acidification with acetic acid, was treated with ethanol and a relatively pure araboxylan (K_2X_3) was obtained.

Those precipitates that had been obtained from the crude hemicelluloses with Fehling's solution were dissolved in N hydrochloric acid and glucomannans were precipitated by the addition of ethanol. The precipitates were separated and washed until neutral. They were then suspended in water, and, after distilling off the remaining ethanol, were freeze-dried. As some samples were still obviously heterogeneous all were redissolved in water and were precipitated by the addition of saturated barium hydroxide solution. The precipitates were dissolved in either 2 N acetic acid or in N hydrochloric acid. The glucomannans were precipitated with ethanol, then washed and dried.

Fractionation of the sample K_2GM_3 *with cetyltrimethylammonium hydroxide* (CTA-OH). A sample (500 mg) of the K_2GM_3 fraction was dissolved in water (25 ml) and CTA-OH (0.3 mmole) was added. The precipitate was separated and dissolved in N sodium chloride. From this solution the CTA was precipitated by potassium iodide and was centrifuged down and washed with potassium iodide solution. The centrifugate and the washings were combined and acidified and the hemicelluloses, after precipitation with ethanol, were washed and dried (yield 175 mg). The material was hydrolysed and the hydrolysate examined chromatographically. The sugars were all present in amounts similar to those found in a hydrolysate of the starting material. The hemicelluloses, left in the supernatant after the cetavlon precipitation, were precipitated by the addition of ethanol. This material (180 mg) on hydrolysis was found to contain all of the sugars noted in the hydrolysate of the previous precipitate, but the galactose and xylose were present in somewhat lower amounts.

In another experiment a sample (1 g) of K_2GM_3 was dissolved in water (100 ml) and boric acid (6.2 mmole) was added. To this solution there were added four successive portions of both sodium hydroxide and cetavlon hydroxide with intermediate separation of the precipitate formed on each addition (fractions: F_{1-4}). A total of 4 mmole of each reagent was added. The precipitates were dissolved in 6 % acetic acid and the hemicelluloses precipitated by the addition of ten times the volume of ethanol. After centrifugation the samples were washed and dried. The solution remaining after the final precipitation was passed successively through columns of cation-, and anion-exchange resins (IR 120 and IR 4B), then the solvent was distilled off from the eluate and a further fraction (F_5) was obtained. Samples of the first three fractions (F_{1-3}), after hydrolysis, were found to contain similar amounts of the same sugars as found in the hydrolysate of the non-fractionated material. F_4 and F_5 accounted for about 20 % of the weight of F_{1-5} and contained glucose and mannose residues almost exclusively.

Delignification of K_2GM_3. A 1 % aqueous solution of K_2GM_3 was treated with chlorine by passing the gas for 5 min through the solution which was kept at 6° [11]. The hemicellu-

loses were then precipitated by the addition of four times the volume of ethanol. After washing the precipitate, it was suspended in a 3 % solution of ethanolamine in ethanol and the mixture was boiled for 5 min. The residue was separated and, after treating it again in the same way with ethanolic ethanolamine, it was redissolved in water and the above procedure repeated twice from the chlorination stage. By those treatments the amount of lignin was reduced from *ca.* 5 % in K_2GM_3 to 0.4 % in K_2GM_3*.

Lignin analyses. Samples (0.5 g/l) of the hemicellulose fractions were dissolved in 0.5 N sodium hydroxide and the absorption curves from 250—320 mμ were determined with a Beckman spectrophotometer. A lignin-free ivory nut mannan was used as reference substance. Those samples which contained lignin had a sharp absorption maximum at 280—285 mμ (*cf.* Ref.[6]) whereas in the chlorinated sample the corresponding maximum was at *ca.* 295 mμ. From the height of the maximum the lignin content was calculated using the equation:

$$\log \frac{I_o}{I} = \varepsilon \cdot c \cdot d$$

in which $\log \frac{I_o}{I}$ is the determined absorption value. ε is the "molar" extinction coefficient, c is the "molar" concentration of lignin, and d is the thickness of the liquid layer in cm. The "molarity" of lignin solutions is arbitrarily based upon the methoxyl content of the lignin, which, is taken to be 15 %. A "molar" solution of lignin then contains 206 g (*i.e.* $\frac{1 \text{ mole } OCH_3}{15} \times 100$ g) of lignin per litre. The value of ε used, *viz.* 3 200, was that determined for native lignin by Aulin-Erdtman [6]. Our determinations are therefore only valid if we are justified in assuming that no changes took place in the lignin structure during the various treatments.

Osmotic determinations. The osmotic determinations were carried out on the nitrated glucomannans as described in an earlier paper [1].

An aqueous solution of the acidic araboxylan (K_2X_3) was passed through a column of the cation-exchange resin IR 120 (Na^+) and the osmotic pressure was then determined on the sodium salt of the araboxylan dissolved in 0.1 N sodium chloride (cf. Ref[7].). The semipermeable membranes used were "Ultracellafilter allerfeinst" supplied by "Membranfiltergesellschaft Göttingen".

Viscometric determinations. The relative viscosity was determined on the nitrated samples in butyl acetate in an Ostwald viscometer at 25°.

Acknowledgement. The author wishes to express his thanks to Miss Barbro Enström for her skilful assistance.

Effect of Benzoic Acid on the Metabolic Conjugations of *p*-Aminobenzoic Acid in the Rat

MARTTI KOIVUSALO, TAPANI LUUKKAINEN, TATU MIETTINEN and JAAKKO PISPA

Department of Medical Chemistry, University of Helsinki, Finland

The excretion of *p*-aminobenzoic acid and its conjugates is determined by the counter current distribution technique in rat urine after the administration of *p*-aminobenzoic acid alone and with the addition of benzoate.

It has been found that *p*-aminobenzoic acid is excreted also in rat urine as glucuronide in addition to acetyl and glycine conjugates.

After administration of benzoate with *p*-aminobenzoic acid the amounts of glycine and glucuronide conjugates decreased whereas the amount of acetyl-*p*-aminobenzoic acid increased.

Only a small fraction of the administered *p*-aminobenzoic acid was excreted as such and this was unaffected by benzoate.

Most of the administered *p*-aminobenzoic acid is rapidly excreted by the mammal in the urine as different conjugates and only a small part is excreted as free *p*-aminobenzoic acid [1–3]. In man most of the administered *p*-aminobenzoic acid is conjugated with glycine to *p*-aminohippurate, but also appreciable amounts of acetyl-*p*-aminobenzoate and of the glucuronides of *p*-aminobenzoic acid and acetyl-*p*-aminobenzoic acid are excreted with small amounts of free *p*-aminobenzoic acid and acetyl-*p*-aminohippurate [3,4]. Similar results have been obtained in rabbits [5–7]. In rat urine Riggs and Christensen [8] found *p*-aminohippurate, *p*-aminobenzoate and their acetyl derivatives after administration of *p*-aminobenzoic acid. Simultaneous administration of benzoic acid increased the amount of acetyl-*p*-aminobenzoate and decreased the amount of glycine conjugates excreted [8].

In the present paper results are reported from studies by the counter current distribution technique on the excretion pattern of *p*-aminobenzoic acid and its metabolites in rat urine. It was found that also in rats there was an appreciable excretion of glucuronide conjugates, as had been found earlier in man and in rabbits. Simultaneous administration of benzoic acid abolished almost totally the excretion of conjugates other than acetyl-*p*-aminobenzoate whose excretion increased correspondingly. The excretion of unconjugated *p*-aminobenzoate was unaffected by the administration of benzoate.

EXPERIMENTAL

The experimental animals were 40 white rats of Wistar strain weighing 180—220 g. The diet during the experiments was the usual stock diet of this Department.

The dosage of *p*-aminobenzoic acid was 15 μmoles per rat and it was given in 5 ml of water by stomach tube. Urine was collected without preservative during a period of 4 h after the administration of *p*-aminobenzoic acid and the urine samples of all rats were pooled. After five days the same rats were given 300 μmoles of sodium benzoate and 15 μmoles of *p*-aminobenzoic acid in 5 ml of water and the urines collected as above.

The counter current distribution technique of Craig [9] was used. The solvent system was amyl alcohol and 0.1 M acetate buffer pH 3.4, 24 transfers were made in an all-glass apparatus.

The glucuronides were determined in the aqueous phase by the modified naphthoresorcinol method of Miettinen *et al.*[10] Before analysis the samples were extracted three times with ether to remove the traces of amyl alcohol present.

The diazotisable amines were determined by the method of Bratton and Marshall [11] before and after acid hydrolysis. The determinations were made from both phases. *p*-Aminobenzoic acid and its derivatives were extracted from the organic phase with 0.1 N NaOH.

The distribution coefficients of authentic samples of *p*-aminobenzoic acid, *p*-aminohippuric acid and acetyl-*p*-aminobenzoic acid were determined in the solvent system used, and compared with those obtained from the peaks of the experimental distribution curves uring the formula presented by Rauen and Stamm [12]. These values are presented in Table 1 and the identification of the peaks in the distribution curves is based on them.

Table 1. Distribution coefficients of *p*-aminobenzoic acid and its conjugates in amyl alcohol/acetate buffer.

	Determined	Calculated from the curves
p-Aminobenzoic acid	10.80	11.00
Acetyl-*p*-aminobenzoic acid	14.00	15.67
p-Aminohippuric acid	0.36	0.35
Acetyl-*p*-aminohippuric acid	—	1.00

RESULTS AND DISCUSSION

The results are presented in Fig. 1 and 2. It is seen from Fig. 1 that in the normal rat most of the *p*-aminobenzoic acid excreted in the urine is conjugated with glycine to form *p*-aminohippurate and acetyl-*p*-aminohippurate. An appreciable amount of acetyl-*p*-aminobenzoate is also excreted but the amount of free *p*-aminobenzoate is rather small. The *p*-aminobenzoic acid glucuronides excreted are mostly unconjugated as regards the amino group, only negligible amounts of acetyl-*p*-aminobenzoic acid glucuronide were found. The glucuronide peak apparently contains also other glucuronides besides those of *p*-aminobenzoic acid and its derivatives, as is seen when the total amount of amines in the first plates is compared with the amount of total glucuronide in the same plates.

Conversely, when benzoate was also administered, the excretion of the glycine conjugates of *p*-aminobenzoic acid fell to very low values, but was not totally abolished. No acetyl-*p*-aminobenzoic acid glucuronide was found and the amount of *p*-aminobenzoic acid glucuronide was also much diminished. The

The curves and peak numbers as in Fig. 1.

total amount of glucuronides was increased probably due to the excretion of benzoic acid glucuronide. The excretion of acetyl-*p*-aminobenzoic acid was correspondingly increased, it was in fact the only metabolite of *p*-aminobenzoic acid excreted in the urine in noteworthy amounts after administration of benzoate. The low excretion of unconjugated *p*-aminobenzoic acid was not affected by benzoate.

The appreciable amounts of *p*-aminobenzoic acid glucuronides excreted by the rat makes it necessary to determine also these conjugates in addition to

glycine and acetyl conjugates when the pattern of the *p*-aminobenzoic acid conjugates is determined in the urine. If this is not done, the amounts of free *p*-aminobenzoic acid and *p*-aminohippuric acid in particular will be estimated too high.

The relative amount of acetyl conjugates calculated as a percentage of the total *p*-aminobenzoic acid excretion increased after administration of benzoate from 53 to 85%. This rise is not due to any activation of the acetylation processes but presumably to the inhibition of the glycine conjugation, which in turn leads to diminished excretion of total *p*-aminobenzoic acid as shown by the experiments on the acetylation of aromatic amines by Luukkainen [13].

An interesting observation is that, although the excretion pattern of all the conjugates is changed after the administration of benzoate, the amount of unconjugated *p*-aminobenzoic acid excreted remained constant.

Electrophoretic Behaviour of Pea Formic Dehydrogenase

MARTTI KOIVUSALO and JAAKKO PISPA

Department of Medical Chemistry, University of Helsinki, Finland

Zone electrophoresis of partially purified formic dehydrogenase from green peas was carried out in polyvinyl chloride resin blocks.

The enzyme activity moved as a single symmetrical peak in all the preparations and was located between the two principal protein peaks, which presumably were vicilin and legumin. When normal human serum was run in the same block with formic dehydrogenase, the enzyme activity was found to have approximately the same mobility as the β-globulins.

A plant formic dehydrogenase was first discovered by Thunberg [1-3] in bean seeds. Pea seeds contain the same enzyme, which differs from the bacterial formic dehydrogenase requiring diphosphopyridine nucleotide as coenzyme [4-7]. The enzyme has been partially purified from peas and beans but has resisted many efforts for further purification [8-10]. During attempts in this laboratory to develop a reliable and sensitive enzymic micromethod for the determination of formic acid in blood and other biological materials, the pea formic dehydrogenase was taken under further study. In the present paper the results of studies on the electrophoretic behaviour of green pea formic dehydrogenase during various stages of purification are reported. Both the enzymic activity and the protein content of the electrophoretic fractions of the partially purified preparations were determined.

METHODS

The source of the enzyme preparations was green pea seeds (*Pisum sativum*, var. *Celvedon*).

The purification of the formic dehydrogenase was made principally by the methods of Nason and Little [10] and Davison [9] with only minor modifications. The purification steps mentioned in the present paper refer to the steps of Nason and Little [10].

Diphosphopyridine nucleotide was purchased from Boehringer und Söhne (DPN, reinst). Calcium phosphate gel and alumina C_γ gel were prepared after instructions given by Colowick [11].

The preparative zone electrophoresis * was carried out using a rectangular perspex trough packed with polyvinyl chloride resin, Geon 426 (G. F. Goodrich Co.) moistened

* We are grateful to Dr. Rainer Pesola from this Institute for introducing this technique to us.

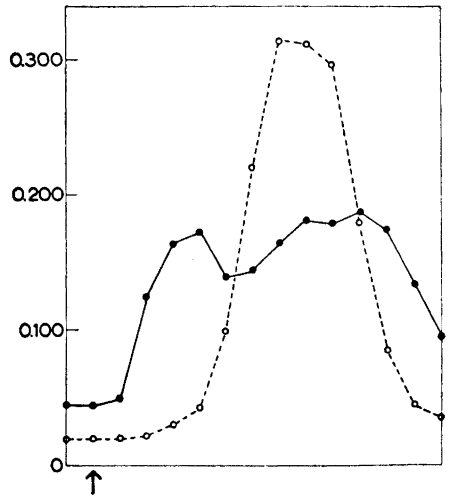

Fig. 1. Electropherogram of pea formic dehydrogenase preparation. Step 7. O———O enzyme activity, ●———● protein. Fractions of 0.8 cm. Place of application marked with arrow.

with barbital buffer, pH 8.6, ionic strength 0.05. To prevent evaporation melted paraffin was poured on the block and allowed to solidify. The substance under analysis was applied to the block trough a narrow cut in the paraffin cover. The contact to the buffer vessels was effected from the ends of the block with strips of filter paper. During the run the block was in a vertical position in a perspex chamber [12].

The time of electrophoresis ranged from 48 to 72 h; a voltage of 400 V and a current of 10 mA were used per block. After the run the resin block was cut in 0.4 or 0.8 cm fractions, and each fraction was divided into two parts, from which the enzyme activity and the protein content, respectively, were determined.

The protein content of the fractions was determined by the method of Kunkel and Tiselius [13] after elution by shaking for 30 min with 3 ml of 0.1 N NaOH.

The other part of each fraction was eluted with 3 ml of 0.5 M potassium phosphate buffer pH 6.5 and the formic dehydrogenase activity of the eluates was assayed in the following system: 1 ml of eluate, 1 ml of 0.5 M potassium phosphate buffer, pH 6.5, and 1 ml of assay mixture. The assay mixture consisted of 30 ml of 0.5 sodium formate, neutralised with hydrochloric acid, 10 ml of diphosphopyridine nucleotide solution (2 mg per ml) and 0.5 M potassium phosphate buffer pH 6.5 and 100 ml. The assay was carried out in test tubes which were held at room temperature for 2 h, after which the optical densities were read with a Beckman DU spectrophotometer at 340 mμ in 1 cm silica cuvettes.

Paper electrophoresis was run in the conventional apparatus using Whatman No. 1 filter paper strips. The time of the run was 6 h using a voltage of 500 V. Barbital buffer pH 8.6 and ionic strength 0.05 was used. After the run the proteins were stained with Lissamin Green and the papers were cut in fragments of 3 mm, which were eluted with 4 ml of 0.1 N NaOH each. The optical densities of the eluates were determined with Beckman B spectrophotometer at 635 mμ.

The free electrophoresis was carried out in the conventional Tiselius apparatus at pH 8.6.

RESULTS AND DISCUSSION

Typical electrophoresis curves obtained are presented in Figs. 1 and 2.

The protein curve did not change much during the purification of the enzyme. There were two main peaks in all the curves obtained in various

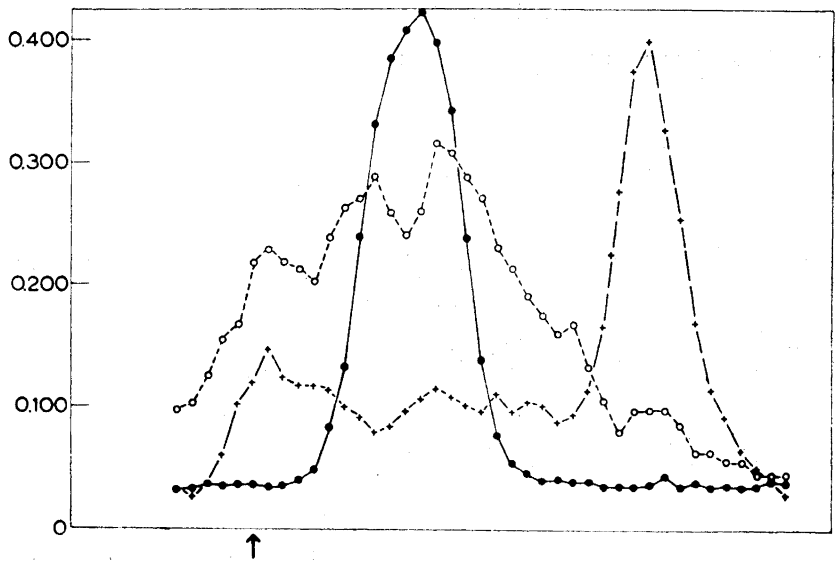

Fig. 2. Electropherograms of pea formic dehydrogenase and human serum run in the same block. +----+ serum protein. O----O enzyme protein, ●----● enzyme activity. Step 7. Place of application marked with arrow.

stages of purification. These peaks are most probably due to the two pea globulins, legumin and vicilin. Legumin and vicilin are two proteins differing in sulphur content, amino acid composition and molecular weight as determined by ultracentrifugation, and probably function principally as reserve proteins [14–19].

With free Tiselius electrophoresis and paper electrophoresis similar protein curves with two peaks were also obtained.

The enzyme activity moved as a single symmetrical peak in all the electrophoretic runs made. It was always localised between the two protein peaks, a little nearer to the faster moving one. No clear peak was found in the protein curves to correspond to the enzyme activity even at the later stages of purification. However, all the preparations used were still rather crude.

To obtain some information of the relative electrophoretic mobility of formic dehydrogenase, normal human serum was run in the same block. When the curves obtained (Fig. 2) are compared, it is seen that the pea formic dehydrogenase activity has about the same mobility as the β-globulins.

Further purification was attempted with a technique in which the active fractions from several electrophoretic runs were pooled and lyophilised and submitted once again to electrophoresis. No increase in the purification was achieved, however, due to partial inactivation of the enzyme during lyophilisation.

The Isolation of Protein-Bound Phosphorylmuramic Acid from *Lactobacillus casei*

GUNNAR ÅGREN and CARL-HENRIC DE VERDIER

Institute of Medical Chemistry, University of Uppsala, Sweden

A new phosphorylated amino acid has been isolated from a hydrolysate of the protein residue of *L. casei*. It has been identified as phosphorylated muramic acid. The position of the phosphate group must probably be in the primary alcoholic group. The yield of crystalline material was about 150 mg from 1 kg fresh bacteria.

In earlier communications it was demonstrated that acid hydrolysates of protein from *L. casei* mainly contained a phosphorylated amino acid [1,2] which was not identical with the phosphorylated amino acids isolated with a similar procedure from animal proteins [3]. The amino acid contained one nitrogen atom per phosphoryl group and ionophoretically behaved as a neutral amino acid. The rate of ^{32}P-incorporation into this amino acid was compared with that of other phosphorus compounds such as free and RNA-bond nucleotides. By preparing large amounts of the phosphorylated compound it could be shown that it contained about 50 % oxygen and behaved as an amino sugar. Later, the dephosphorylated compound was found to be identical with 3-O-α-carboxyethyl-D-glucosamine [4] which also has been named muramic acid (Mur)*.

PREPARATION OF PHOSPHORYLMURAMIC ACID

Lactobacillus casei (7461) was cultivated in a medium with the following composition: 10 g of Dextropur **, 10 g of $NaOCOCH_3 \cdot 3\ H_2O$, 10 g of Bactopeptone ***, 1 g of yeast extract ****, 25.4 ml of liver extract §, 0.5 ml of

* The following abbreviations are used: Mur = muramic acid; MurP = O-phosphorylmuramic acid; SerP = O-phosphorylserine.

** Glucose manufactured by Corn Products Co., New York.

*** Parke, Davis and Co.

**** Difco Laboratories.

§ 100 g of Difco Liver was dissolved in 1 330 ml water and kept at 50°C for one hour and subsequently at 80° for 5 min. After filtration and concentration the filtrate was lyophilized This material was dissolved to contain 15 mg per ml.

salt mixture * per 1 000 ml of medium at pH 6.8. For large scale cultivation (90 l) the necessary ingredients were first dissolved in 5 l water and heated at 100°C for about 15 min. After cooling a dark precipitate was removed by filtration. The filtrate was evenly distributed in thirty 6 liter Erlenmayer flasks and subsequently water was added to a final volume of 3 l per flask. After adjusting the pH to 6.8 sterilization was accomplished by autoclaving the flasks 15 min at 118°C.

Inocula for large scale cultivations was prepared by transferring a small amount of growth from a stab culture [5] to two 10 ml flasks, each containing 5 ml of medium. The amount of inocula was increased in the four subsequent steps (2, 3, 4, and 5) according to Table 1. 300 ml of suspension from step

Table 1. Increase of inocula for large scale cultivation.

Step No.	Ml of inocula to ml of culture		Incubation time, h
1	0.1	2 × 5	24
2	8 × 0.5	8 × 5	24
3	30 × 1	30 × 20	17
4	30 × 20	30 × 100	17
5	30 × 100	30 × 300	17
6	30 × 300	30 × 3 000	

5 was then added to each 6 l flask containing 3 l sterilized medium. 1 mC radioactive phosphate per liter medium was added at the same time. Previously it had been shown that the presence of as much as 100 mC per liter had no demonstrable effect on growth or acid production over a period of 72 h [6]. Incubation was carried out in an air incubator for 17 h at 37°C. In order to increase the utilization of ^{32}P added to the medium inorganic phosphate was excluded from the salt mixture, since preliminary experiments had shown that the phosphorus present in Bactopeptone and liver furnished sufficient total phosphorus (0.003 %) for normal growth.

At the end of the cultivation the bacteria were separated from the medium in Sharples centrifuges. The usual yield of fresh bacteria from a single cultivation of 90 l was about 400—500 g. This material was washed two times with cold 10 % TCA. Lipids were extracted by treatment two times with a mixture of ethanol and ether in the ratio 3:1 at 40 to 50°C for 15 min and then with ether. Nucleic acids were extracted according to Schneider [7] for 15 min at 90°C with 5 % TCA. The residue was then treated with ethanol-ether (3:1) and ether and taken as the Schneider protein fraction. The normal yield was between 75—90 g.

After hydrolysis with 10 volumes of 2 N HCl per g dry protein for 20 h at 100°C insoluble humin was removed by centrifugation. The centrifugate was evaporated to dryness *in vacuo* three times with intermittent addition of water. The dissolved hydrolysate was usually mixed with the hydrolyzed

* 4 g of $MgSO_4 \cdot H_2O$, 1 g $FeSO_4 \cdot 7\ H_2O$, 1 g of NaCl, 0.1 g of $MnSO_4 \cdot H_2O$ were dissolved to 100 ml.

protein from an unlabeled batch of cells. Each half of the mixed hydrolysates was applied to a Dowex 50 column. The diameter was 6.5 and column length about 50 cm. Elution was carried out with 0.01 N HCl. A typical elution curve is given in a previous paper [1]. Irrespective of column dimensions MurP was obtained in the third column volume of eluate.

Excess of HCl was removed as described above and the residue, about 0.5 g by weight, was dissolved in a small volume of water and applied to a Dowex 1 formate (2 % DVB) column. (Dimensions 2 cm × 45 cm). Elution was carried out with a gradient 0→1 M formic acid and with a volume of 200 ml in the mixer. When the acidity in the eluate reached a value which corresponded to 0.60 M formic acid MurP appeared. For rechromatography a constant concentration of 0.5 M formic acid was sometimes used. With this system MurP appeared after 4.0 column volumes when it was chromatographed in a 1.0 cm × 43 cm column of Dowex 1. The usual yield of MurP from the two batches of cells was about 150 mg. For the following analysis about 1 g of MurP was prepared.

Dephosphorylation of MurP was at first performed in sealed glasstubes with 2 N HCl at 120°C and for 20 h. In this procedure a considerable part of Mur was destructed. It was found that MurP like O-phosphorylserine was hydrolyzed by prostate phosphatase. For that purpose an enzyme was used which had been purified according to Boman [8]. The digestion was performed in a 1.6 % solution of the substrate after pH was adjusted to 5.0 with trimethylamine. The reaction was followed by ionophoresis runs at pH 5 in a 0.1 M solution of pyridine-acetic acid. With the amounts of enzyme used it was found to be complete after 5 h of digestion at room temperature.

Crystalline phosphorylmuramic acid was obtained by slow evaporation of water solutions and from ethanol-water solutions as small needleshaped crystals. It was not possible to get crystals large enough for single crystal X-ray analysis. Under similar conditions Mur gave relatively large rods.

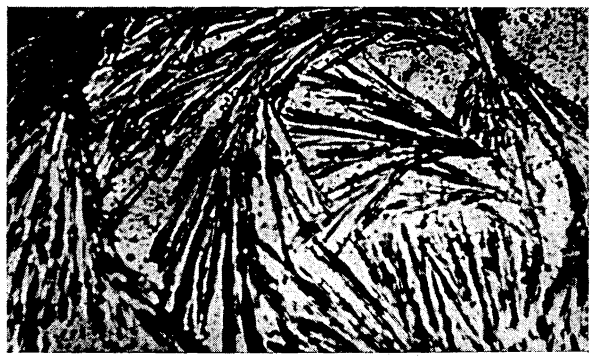

Fig. 1. A photograph of phosphorylmuramic acid isolated from the "protein fraction" of *L. casei*. Crystallized from a weak formic acid solution.

IDENTIFICATION AND CHARACTERIZATION

The elementary analysis first obtained showed that the compound must be a carbohydrate derivative containing nine carbon atoms. Sialic acid [9] and muramic acid are the most well known compounds with such a constitution. Different colour reactions described below were in favour of muramic acid. Against identity with sialic acid also was the high acid stability of our isolated compound. The following different methods were used for identification of the compound with muramic acid.

Elementary analysis

The data obtained are given in Table 2. The determinations of C, H, O, N were made by Mr. W. Kirsten at this institute and by Dr. A. Bernhardt, Mikroanalytisches Laboratorium im Max-Planck-Institut für Kohlenforschung, Mühlheim (Ruhr), Western Germany. Phosphorus was analysed according to a modification of Martin and Doty [10].

Paper ionophoresis and paper chromatography

For ionophoresis Whatman paper No. 3 was used and for chromatography mostly No. 1. The ionophoretic migration of MurP in comparison to SerP is shown in Table 3. The dephosphorylated compound showed the same mobility as glycine by ionophoresis at pH 5. The solvents for the paper chromatographic identification of this compound are listed in the preceding paper [1]. The second solvent mentioned there was not used. Fig. 2 is a photograph of

Table 3. The ionophoretic mobility of MurP at pH 3 and 5 compared with SerP. + and − indicate that the substances move toward the anode and the cathode, respectively. Figures are given in cm.

	MurP	SerP
Sodium citrate − citric acid, pH 3	−4.0	+1.8
Pyridine acetate − acetic acid, pH 5	+14.0	+18.3

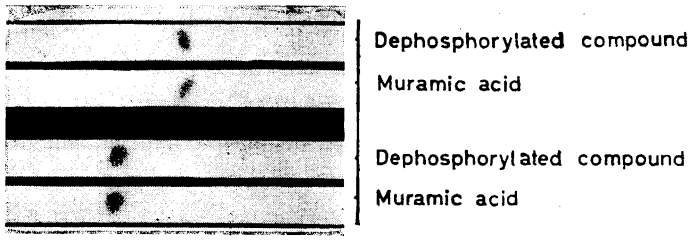

Fig. 2. Two one-dimensional chromatograms run with *iso*-butyric acid-NH_3-water (below) and *n*-butanol-acetic acid-water (above) showing that the dephosphorylated compound gives a spot identical with muramic acid.

a chromatogram with the dephosphorylated compound and Mur * running parallely. In the four solvents identical R_F values for the two compounds were obtained.

X-Ray diffraction studies

X-Ray powder diagram of MurP was obtained with a Debye-Scherrer camera but for the dephosphorylated compound a Guinier camera was used. Single crystal studies of Mur was done at the Department of Inorganic Chemistry, University of Uppsala **. The diagram of Mur supplied by Dr. Dark was identical with that obtained by enzymatic dephosphorylation of the phosphorus compound from the rest protein fraction (Fig. 3).

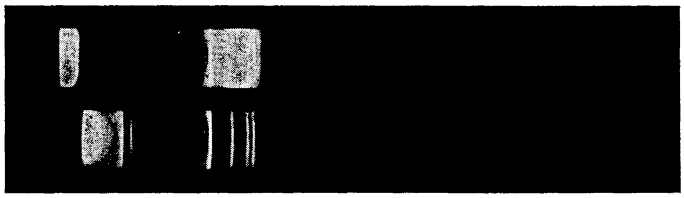

Fig. 3. X-Ray powder diagram of the dephosphorylated compound (below) is identical with that of muramic acid (above). (Some impurity in muramic acid has given a few additional weak bands.)

The density of the small crystals obtained was determined with the flotation method. Table 4 gives the spacings obtained for the phosphorylated and dephorsphorylated substances. The crystals of Mur belonged to the orthorhombic system with the cell dimensions: $a = 5.406$ Å; $b = 10.40$ Å, $c = 20.48$ Å. The density was 1.41. Calculated for four molecules per unit cell the formula weight will be 244.5 (calc. for $C_9H_{17}O_7N$ 251.24).

* The authors want to express their gratitude to Dr. F. A. Dark, the Microbiological Research Establishment, Porton, England, for the gift of a sample of muramic acid.

** The authors want to express their thanks to Dr. Abrahamsson who carried out this study.

Electrometric titration

The dissociation constants of MurP were determined by titration with 1.0 N sodium hydroxide added with an Agla micro burette. pH was measured with a direct reading pH meter (Electronic Instruments Ltd, Richmond, England Model 23 A). 38.05 mg MurP was titrated. The pK_s-values for the different steps can be seen from the following formula (Fig. 4). The corresponding values for L-O-phosphorylserine and L-O-phosphorylthreonine were 2.1; 5.7; 9.7; and 2.8; 6.1; 10.1. The dissociation constants of DL-phosphorylserine were determined by Österberg [11] with somewhat divergent values. The titration gives a molecular weight of 355 for MurP.

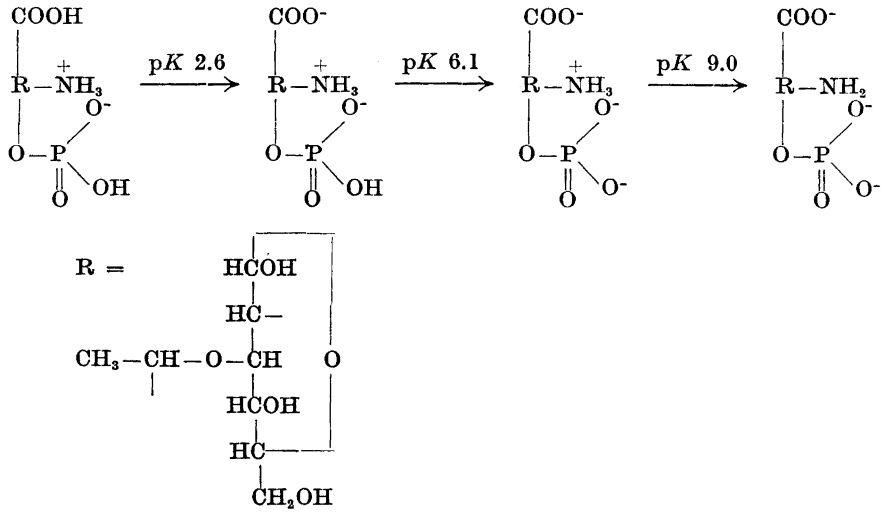

Fig. 4. The different steps of the protolysis of phosphorylated muramic acid.

Optical rotation

For MurP the following value was obtained: $\alpha_D^{25} + 3.43°$ (water; *l*,1; *c*, 4.21) which corresponds to

$$[\alpha]_D^{25} + 81.5°; [M]_D^{25} + 285°$$

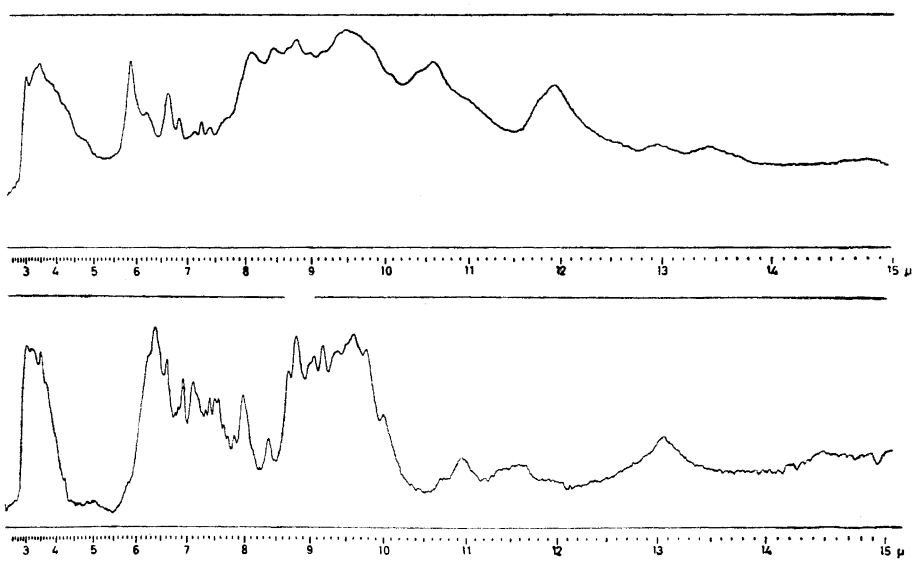

Fig. 5. Infrared absorption curves for MurP (above) and Mur.

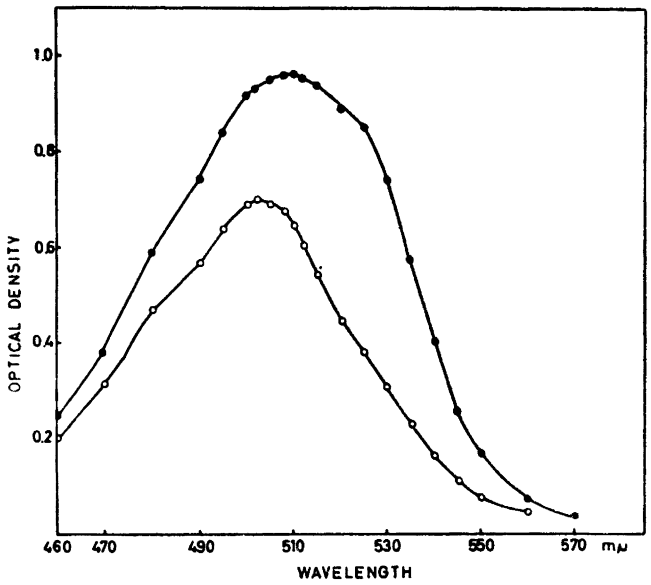

Fig. 6. Absorption curves of the colours obtained from Mur and MurP with the Elson-Morgan reaction. For -●-●- 1.94 μmole of MurP, for -O-O- 2.8 μmoles of Mur.

Infrared absorption analyses of the dephosphorylated compound and Mur were performed and showed identity. The absorption curves of Mur and MurP are shown in Fig. 5 *.

Colour reactions

The Elson-Morgan reaction was performed according to Blix' modification [12]. Absorption curves were drawn for both Mur and MurP after determinations with a Beckman DU spectrophotometer (Fig. 6). The displacement of the absorption maximum below 510 mμ is characteristic for a 3-substituted hexosamine [13]. On paper chromatograms MurP gave a positive reaction with ammoniacal $AgNO_3$ and also with anilinhydrogenphthalate a positive reaction was obtained [14]. Likewise on paper chromatograms both MurP and Mur were detected in very small amounts (2 and 1 μg, respectively) with ninhydrin reagent, 0.4 % solution in *iso*propanol-water (10:90).

DISCUSSION

To our knowledge protein-bound or free MurP has not been described. The exact position of the phosphorus linkage in MurP has not been certainly proved but according to all observations described in the previous sections

* The authors are indebted to Dr. Ingrid Fischmeister at this Institute for these analyses.

(acid stability and ninhydrin reaction) the phosphorus ought to be bound to the sixth carbon atom of the glucosamine moiety. The half life times of glucose-1-phosphate and glucosamine-1-phosphate in 1 N HCl at 100°C are about 1 and 4 min, respectively. For glucose-6-phosphate the corresponding figure is 1 300 min [15].

Mur is a major constituent of the bacterial cell wall [16] and according to theories put forward by Park and Strominger [17], uridine diphosphate-Mur and uridine diphosphate-Mur-peptides accumulate in consequences of the interference by penicillin with the biosynthesis of the cell wall. An alternative hypothesis has been put forward by Trucco and Pardee[18]. It was suggested that penicillin causes formation of an enzyme that attacks the cell membrane rather than the cell wall and that disruption of the membrane results in the escape of the cell content.

The observations of Park and Strominger were carried out with *Staphylococcus aureus* and in the microorganism an uridine diphosphate-Mur-peptide had the same amino acid composition as the cell wall. In *L. casei* the amino acid pattern is more complicated [16]. Possibly in line with this observation we have found a series of uridine diphosphate-Mur-peptides from *L. casei* inhibited by penicillin. These will be described in a following paper where the isolation of some Mur-P-peptides from the protein residue also will be given.

Regarding the role of MurP phosphorus in the phosphoproteins of *L. casei* it is possible that it has the structural function to cross-link peptide chains. Mur may also represent the active site in transphosphorylating enzymes [19] located either to cell plasma or cell walls. The relatively low turnover reported earlier makes it probable that most of the phosphorus atoms have a structural function. The mechanism for the synthesis of protein bound MurP has not been investigated more closely. It has so far not been possible to isolate free MurP. It cannot be excluded that uridine diphosphate-MurP may be an intermediate in the biosynthesis of protein-bound MurP. In this connection it must be mentioned that Strominger [20] recently isolated uridine diphosphate acetylglucosamine phosphate from oviduct of laying hen. He also suggested that uridine nucleotides of similar types may be activated intermediates in the biosynthesis of glycoproteins and mucopolysaccharides. A preliminary note has been published that galactosamine phosphate should be present in the hydrolysate of bone tissue [21]. More recently hexosamine phosphate has also been isolated in the hydrolysate of protein residue form *E. coli* [22].

On the Complex Chemistry of the Tervalent Rare Earth Ions

II. The Acetate Systems of Praseodymium, Samarium, Dysprosium, Holmium, Erbium and Ytterbium

ARTUR SONESSON

Department of Inorganic and Physical Chemistry, Chemical Institute, University of Lund, Lund, Sweden

Six rare earth acetate systems have been examined potentiometrically and one of these moreover extinctiometrically. The complexity constants are listed in Table 13 and the stability constants in Table 14 (together with four systems reported in Part I [1]). All measurements have been performed in perchlorate medium of ionic strength 2 M at 20°C.

The extinctiometric investigation of the $Er^{3+}-Ac^{-}-$ system* shows that the formation of the acetate complexes is accompanied by the appearance of new peaks close to the original absorption bands at about 380 mμ and 525 mμ. The new peaks, one at every band, have a somewhat shorter wavelength than the original peaks. The agreement between the potentiometrically and the extinctiometrically obtained complexity constants is good.

The stability constant of the first complex, b_1, increases with the atomic number from La to Sm. Then it decreases for Gd and Dy and remains approximately constant for Dy, Ho, Er and Yb. To begin with, b_2 and b_3 also increase with the atomic number of the rare earth. For the heaviest rare earths, however, b_2 and b_3 decrease slightly.

The heavier rare earths (Gd—Yb) seem to form polynuclear complexes which, however, are rather weak.

In Part I[1] the complexity constants of the acetate systems of La, Ce, Nd, and Gd were reported. The first three ions belong to the lightest rare earths, whilst Gd is situated in the middle of the series. In the present paper the investigation of the acetate systems of two light rare earths (Pr and Sm) and four heavy ones (Dy, Ho, Er, and Yb) is reported.

* Ac^{-} = acetate ion.

CHEMICALS USED

Rare earth perchlorates. Praseodymium and samarium perchlorates were prepared from the nitrates (> 98 % pure) by repeated evaporations with perchloric acid. In the preparations of the other rare earth perchlorates oxides with purity > 99 % were dissolved in perchloric acid.

The concentrations of the stock solutions were determined by gravimetric analysis. Pr and Sm were precipitated as oxalates, Dy, Ho, Er, and Yb as hydroxides. Moreover, the concentrations of the stock solutions were controlled by means of a cation exchanger column.

The concentration of free perchloric acid of the stock solutions was determined by electrometric titration with sodium hydroxide.

The *other chemicals* used were of analytical grade as in Part I. The concentrations of the stock solutions of NaAc and $NaClO_4$ were checked by means of a cation exchanger column.

A. THE POTENTIOMETRIC INVESTIGATION

Notations and general formulae (for deductions of the formulae the reader is referred to Part I and to Fronæus [2]).

$[H^+]'$, $[H^+]$ = the hydrogen ion concentration of the buffer solution and the complex solution, respectively.

C_H° = the concentration of free perchloric acid of the rare earth perchlorate solution before buffer is added. Thus $C_H^\circ = \nu \cdot C_M^\circ$, ν being a constant and C_M° the starting concentration of the rare earth perchlorate.

C_H = $\nu . C_M$, C_M being the total concentration of rare earth of the complex solution.

C'_{HA}, C'_A = the stoichiometric concentrations of acid HA and salt NaA, calculated from the amount of buffer added to the complex solution.

δ = C'_{HA}/C'_A

C_A = the actual total concentration of the ligand A, thus $C_A = C'_A + [H^+] - C_H$.

[M], [A] = the concentrations of free central ion and free ligand respectively.

E_A = $E' - E$ = the difference between the emfs (in mV) of two elements according to I(15)*, which have $C_M = 0$ and $C_M \neq 0$, respectively.

ΔE_A = a correction term applied to E_A to correct for the increase of emf caused by the reduction of the ionic strength through the complex formation. ΔE_A is computed according to the eqns. I(16) and I(17).

β_n, β'_n = the complexity constants of the mononuclear and the dinuclear complexes, respectively.

b_n = the stability constants: $b_1 = \beta_1$, $b_n = \beta_n/\beta_{n-1}$ $(n = 2, 3, \ldots)$.

$\bar{n}$ = the ligand number.

$\bar{n}_I$ = the ligand number of the mononuclear complexes.

$\bar{n}_c$ = the ligand number of the mononuclear complexes, calculated by means of the complexity constants.

$$\beta_n = \frac{[MA_n]}{[M] \cdot [A]^n} \tag{1a}$$

$$\beta'_n = \frac{[M_2A_n]}{[M]^2 \cdot [A]^n} \tag{1b}$$

* Formulae in Part I are referred to in this way.

$$[A] = \frac{[H^+]'}{[H^+]} \cdot \frac{(C_A' + [H^+]')\ (\delta C_A' + C_H - [H^+])}{\delta C_A' - [H^+]'} \tag{2}$$

$$E_A - \Delta E_A = 58.16 \log \frac{[H^+]}{[H^+]'} \tag{3}$$

$$\bar{n} = \frac{C_A' + [H^+] - C_H - [A]}{C_M} \tag{4}$$

$$\bar{n}_I = [A] \cdot \frac{X'}{X} = \frac{\sum_{n=1}^{N} n\beta_n[A]^n}{1 + \sum_{n=1}^{N} \beta_n[A]^n} \tag{4a}$$ *

$$X = 1 + \sum_{n=1}^{N} \beta_n \cdot [A]^n \tag{5}$$

$$X = \frac{C_M}{[M]}\text{, if only mononuclear complexes are formed} \tag{5a}$$

$$Y = \sum_{n=1}^{L} \beta_n' \cdot [A]^n \tag{6}$$

$$\ln X([A]_j) = \int_0^{[A]_j} \frac{\bar{n}_I}{[A]} \cdot d[A] \tag{7}$$

$$X_1 = (X-1)/[A]\ ;\ X_n = (X_{n-1} - \beta_{n-1})/[A]\ (n = 2, 3, \ldots) \tag{8}$$

Experimental. The experimental procedure has been the same as that described in Part I. The quinhydrone elements measured have had the composition shown in I(15).

As was shown in Part I, the hydrolysis of the lower rare earths caused by the addition of acetate buffer can be neglected. However, the hydrolysis increases considerably with the atomic number of the rare earth, and therefore the $Yb^{3+}-Ac^-$—system has been examined by use of buffers with different concentrations of acetic acid (δ = 0.5, 2.0 and 5.0; C_M = 25 mM). As seen in Table 8A—C and Fig. 2 the buffer ½HAc:1 NaAc gives somewhat higher values of $\bar{n}/[A]$ at low [A] than the other buffers. This indicates formation of OH-complexes. Hydrolytic reactions, *e.g.*

$$Yb(H_2O)_n^{3+} + H_2O \rightarrow Yb(OH)(H_2O)_{n-1}^{2+} + H_3O^+$$

$$Yb(Ac)(H_2O)_m^{2+} + H_2O \rightarrow Yb(Ac)(OH)(H_2O)_{m-1}^{1+} + H_3O^+$$

produce hydrogen ions, which then combine with acetate ions ($H_3O^+ + Ac^- \rightleftharpoons HAc + H_2O$) until equilibrium has been reached. The result will be a decrease of $[Ac^-]$ in the same way as if rare earth acetate complexes were formed, and the ligand number $\bar{n}$ obtained by the potentiometric measurements will include also the OH-complexes.

* This formula is a correction of eqn. I (7), which has been written in an erroneous form.

However, the hydroxide complexes are formed in competition with the acetate complexes and therefore the tendency of forming hydroxide complexes must decrease when the acetate concentration is increased. Moreover, the hydrolytic reactions must be depressed if the hydrogen ion concentration of the complex solution is increased, *i.e.* if a more acid buffer solution is used.

From the investigation of the Yb^{3+}—Ac^-—system it is evident that the hydrolysis of the ytterbium ions is rather weak, as the $\bar{n}$/[A]-functions obtained with the different buffers approach each other rapidly when [A] is increased. Besides, the buffers with $\delta = 2$ and 5 give approximately the same $\bar{n}$/[A]-functions even at the lowest values of [A]. Therefore it seems certain that the formation of Yb^{3+}—OH^-—complexes by the addition of the buffer 2 HAc:1 NaAc is so slight that it can be neglected.

In the discussion above the possibility of complex formation between Yb^{3+} and unprotolyzed HAc has been excluded, as extinctiometric measurements have shown that two solutions with the composition

80 mM $Ho(ClO_4)_3$ + 100 mM $HClO_4$ + 1420 mM $NaClO_4$ + x mM HAc

and having $x = 0$ and 990, respectively, show the same extinction curve within the limits of the random errors.

THE SYSTEMS INVESTIGATED

The praseodymium acetate system. The E_A-values obtained experimentally and the values of [A] and $\bar{n}$/[A], calculated by means of eqns. (2)—(4), are collected in Table 1. The coincidence between the two $\bar{n}$/[A]-functions is so good that formation of polynuclear complexes to a detectable amount can be excluded.

The complexity constants have been computed by means of eqns. (5), (7) and (8). The X-functions of the system are to be found in Table 3A.

complexes. When both mono- and dinuclear complexes are formed, the connection between $\bar{n}/[A]$ and [M] is given by the equation

$$\frac{\bar{n}}{[A]} = \frac{X' + [M] \cdot Y'}{X + 2[M] \cdot Y} \tag{9}$$

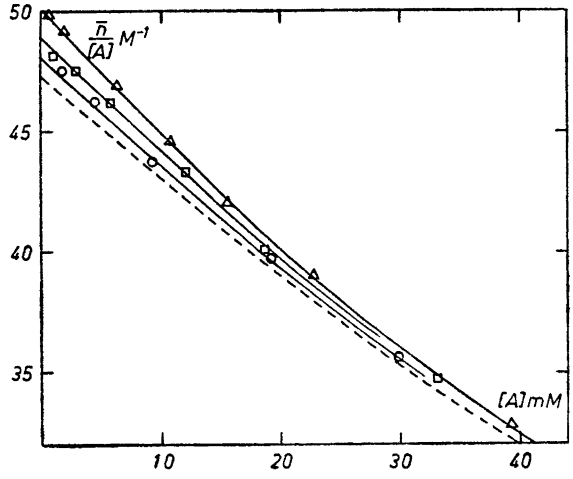

Fig. 1. The function $\frac{\bar{n}}{[A]} = f([A])$ of the dysprosium acetate system. The signs refer to the different values of C_M given in Table 4. The broken curve is the function obtained by extrapolation to $C_M = 0$.

(*cf. eqn.* I(8)). From the theory given by Fronæus [2] and confirmed experimentally, it appears that the $\bar{n}$/[A]-functions of series with different C_M will approach each other when [A] is increased. Finally the functions will meet at a point, and after that they will diverge again but in the reversed order. For the Dy^{3+}-Ac^--system the $\bar{n}$/[A]-curves meet at [A] ≈ 60 mM, but the curves seem to coincide at higher [A]-values.

As [M] = 0 at $C_M = 0$ we can deduce from (9)

$$\lim_{C_M \to 0} \frac{\bar{n}}{[A]} = \left(\frac{\bar{n}}{[A]}\right)_{C_M=0} = \frac{X'}{X} = \frac{\bar{n}_I}{[A]} \tag{10}$$

The function $(\bar{n}/[A])_{C_M=0} = f([A])$ is listed in Table 6A and represented by the broken curve in Fig. 1. The function has been used for the computation of the X-functions in Table 6A according to eqns. (7) and (8). In this way it is possible to calculate the complexity constants of the mononuclear complexes.

From eqn. (9) it can be deduced

$$\lim_{C_A \to 0} \frac{\bar{n}}{[A]} = \beta_1 + C_M \cdot \beta_1' \tag{11}$$

According to this formula $\beta_1' \approx 40$ M^{-2}.

The holmium acetate system. The results of the measurements on the Ho^{3+}-Ac^--system are shown in Tables 5 and 6B. Also for this system the series with $C_M = 40$ mM gives somewhat higher $\bar{n}$/[A] at low [A] than the series with $C_M = 20$ mM. In calculating the X-functions in Table 6B the $\bar{n}$/[A]-curve was drawn in accordance to the values of $(\bar{n}/[A])_{C_M=0}$ given in Table 6B.

Table 5. The corresponding values of [A] and $\bar{n}$/[A] for the holmium acetate system.

The erbium acetate system. From the $\bar{n}$/[A]-values in Table 7 it must be inferred that polynuclear complexes are present also in this system. β_1' can be estimated to $\approx$ 30 M^{-2}. In the computation of the X-functions in Table 9A, the values of $(\bar{n}/[A])_{C_M=0}$ have been used.

Table 7. The corresponding values of [A] and $\bar{n}$/[A] for the erbium acetate system.

The ytterbium acetate system. As mentioned before the hydrolysis of Yb^{3+} has been examined by means of acetate buffers with different δ. Table 8A—C and Fig. 2 show that the hydrolysis can be neglected when the buffer 2 HAc: 1 NaAc is added.

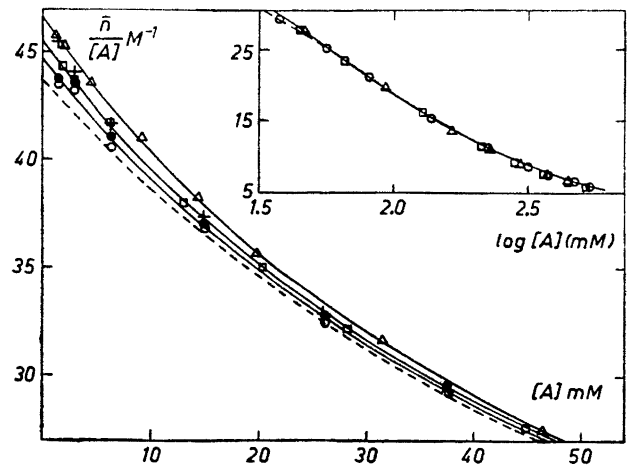

Fig. 2. $\frac{\bar{n}}{[A]}$ as a function of [A] for the ytterbium acetate system at different values of C_M and δ, according to the titration series in Table 8. The broken curve is obtained by extrapolation to $C_M = 0$.

It is seen from Table 8B, D, E and Fig. 2 that polynuclear complexes probably are formed. β_1' can be estimated to about 30 M^{-2}. The X-functions in Table 9B are computed from $(\bar{n}/[A])_{C_M=0}$.

B. THE EXTINCTIOMETRIC INVESTIGATION

In order to check the potentiometrically determined complexity constants of the acetate systems of the higher rare earths, an extinctiometric examination of the erbium acetate system has been performed. This method of investigation has been examined theoretically by Fronæus [2,p. 87], who has shown that only systems of exclusively mononuclear complexes are suitable for extinctiometric investigation. However, we can in favourable cases get an approximate value of at least β_1 also for systems with dinuclear complexes (*cf.* the extinctiometric investigation of the copper(II) acetate system performed by Fronæus [2]).

As to the erbium acetate system it is indicated by the potentiometric investigation that polynuclear complexes are probably formed ($\beta_1' \approx 30$ M^{-2}, if the presence of only mono- and dinuclear complexes is assumed). However, the concentration of the first dinuclear complex, calculated from β_1', is very low (*cf.* Table 10), and it might therefore be possible to get at least some idea of the constants of the mononuclear complexes by extinctiometric measurements.

Calculation of the complexity constants from extinctiometric data

In addition to the notations already given, it is denoted by

E the total extinction of the solution, measured with water in the reference cell,

d the thickness of the absorbing layer in cm,

e the quotient E/d,

ε_M°, ε_A° the molar extinctions of M and A,

ε_n, ε_n' the molar extinctions of the mononuclear complexes MA_n and the dinuclear complexes M_2A_n, respectively.

In the case where both mono- and dinuclear complexes are formed, the following is valid

$$e = \varepsilon_M^\circ \cdot [M] + \sum_{n=1}^{N} \varepsilon_n \cdot [MA_n] + \sum_{n=1}^{L} \varepsilon_n' \cdot [M_2A_n] + \varepsilon_A^\circ \cdot [A] \qquad (12)$$

Table 10. The concentrations of the first dinuclear (a) and the first mononuclear (b) erbium acetate complexes at some values of C_M and [A], chosen from the extinctiometric measurements. The potentiometrically obtained values of β_1 and β_1' have been used in the calculations.

C_M mM	37.3	36.6	35.8	14.9	14.8	14.6	7.5	7.4	7.3
[Ac^-] mM	2	10	20	2	10	20	2	10	20
a mM	0.07	0.18	0.17	0.011	0.03	0.03	0.003	0.008	0.007
b mM	2.8	9.9	13.6	1.1	4.0	5.6	0.56	2.0	2.8
$\frac{a}{b} \cdot 10^{+2}$	2.5	1.8	1.3	1.0	0.8	0.5	0.5	0.4	0.3

After having expressed $[MA_n]$ and $[M_2A_n]$ by means of [A], β_n and β_n', and introduced the abbreviations

$$\varepsilon = \frac{e - \varepsilon_M^\circ \cdot C_M - \varepsilon_A^\circ \cdot C_A}{C_M}$$

$$\xi = \sum_{n=1}^{N} (\varepsilon_n - \varepsilon_M^\circ - n \cdot \varepsilon_A^\circ)\, \beta_n [A]^n$$

$$\eta = \sum_{n=1}^{L} (\varepsilon_n' - 2\varepsilon_M^\circ - n\varepsilon_A^\circ)\, \beta_n' [A]^n$$

we get the expression

$$\varepsilon = \frac{\xi + [M] \cdot \eta}{X + 2[M] \cdot Y} \tag{13}$$

$\varepsilon = \xi/X$ in the case where *only mononuclear* complexes are formed, as $\eta = 0$ and $Y = 0$. Thus $\varepsilon = f([A])$, independent of [M], and consequently solutions with the same value of ε must have the same value of [A]. In this case we have

$$\left(\frac{\partial C_A}{\partial C_M}\right)_\varepsilon = \bar{n}_I \text{ (Constant } \varepsilon) \tag{14}$$

By extrapolating the straight line $(C_A)_\varepsilon = [A] + \bar{n}_I \times (C_M)_\varepsilon$ obtained from eqn. (14) to $C_M = 0$, we get [A] of all solutions with the same value of ε.

If *both mono- and dinuclear* complexes are present, eqn. (14) is not valid, as $\varepsilon = f([A], [M])$. However, using eqn. (13) (ε being constant) and the expressions of C_M and C_A at the bottom of page 167 in Part I, we can deduce for $C_M = 0$

$$\left(\frac{\partial C_A}{\partial C_M}\right)_{\substack{\varepsilon \\ C_M=0}} = k_\varepsilon = \bar{n}_I + \frac{2\,Y \cdot \xi - X \cdot \eta}{X(X \cdot \xi' - X' \cdot \xi)} \tag{15}$$

The determination of k_ε can be performed in the following way. The function $\varepsilon = f(C_A)$ is determined experimentally for some values of C_M. By cutting the curves with lines ε = constant, we obtain the pairs of corresponding values $(C_A, C_M)_\varepsilon$. Then, k_ε for every value of ε is determined from the slope of the function $(C_A)_\varepsilon = f(C_M)_\varepsilon$ at $C_M = 0$. This function, however, is not necessarily a straight line as seen from eqn. (15), and therefore the calculation of k_ε can be rather uncertain.

For the Er^{3+}-Ac^--system, $[M_2A_n]$ is very low and decreases much more rapidly than $[MA_n]$ when $[M] \to 0$, as seen in Table 10 (calculated with the use of eqns. 1a, 1b, 5 and 5a). Therefore it is probable that the values of $(C_A)_{C_M=0} = [A]$, obtained by extrapolations of the function $(C_A)_\varepsilon = f(C_M)_\varepsilon$ to $C_M = 0$, represent approximately the concentration of free ligand also in solutions with low $C_M \neq 0$. Therefore, the function $(C_A)_\varepsilon = f(C_M)_\varepsilon$

ought to be a straight line at low values of C_M, indicating that $k_\varepsilon \approx \bar{n}_I$ at low C_M. Then, if the second term of eqn. (15) can be neglected, we can compute the complexity constants of the mononuclear complexes by use of $k_\varepsilon/[A]$ and eqn. (7). However, the constants may contain a systematic error that we cannot estimate.

From eqn. (15) it can be deduced

$$\lim_{[A]\to 0} \frac{k_\varepsilon}{[A]} = \beta_1 - \frac{\Delta\varepsilon_1'\cdot\beta_1'}{\Delta\varepsilon_1\cdot\beta_1}, \text{ with } \begin{cases}\Delta\varepsilon_1' = \varepsilon_1' - 2\varepsilon_M^\circ - \varepsilon_A^\circ \\ \Delta\varepsilon_1 = \varepsilon_1 - \varepsilon_M^\circ - \varepsilon_A^\circ\end{cases} \quad (16)$$

Thus, we get directly an approximate value of β_1 if we can compute k_ε at so low [A] that it is possible to extrapolate $k_\varepsilon/[A]$ to $[A] = 0$, and if the last term of (16) can be neglected.

Measurements

The extinctiometric measurements have been carried out at 20°C with a Beckman Recording Quartz Spectrophotometer Model DK 1. Except in obtaining the survey in Fig. 3, the spectrophotometer was constantly adjusted to the wavelength 378 mμ. As the absorption bands are very narrow, it is necessary to use a very narrow band width. Therefore the apparatus was set at a high sensitivity (80), which resulted in a very narrow slit and an effective band width of only ≈ 5 Å.

According the Fronæus [2,p.95] the experimental error caused by the imperfect monochromaticity of the light is reduced if the measurements are carried out in a wavelength range where the extinction curve has a horizontal tangent. This is not possible in the case of the Er^{3+}-Ac^--system, owing to the narrow peaks and to the fact that the positions of the peaks are shifted when the complexes are formed. At 378 mμ, however, the extinction curve has about the same slope at all values of $[Ac^-]$.

Another systematic error is caused by the partial reflection of the light at the end plates of the absorption cells. This error is reduced if the corresponding solutions, used at the calculation of k_ε (*i.e.*, solutions with the same ε), have the same value of E. This condition is fulfilled approximately if solutions with the same value of C_A' also have the same value of $d.C_M$ (*cf.* Table 11).

The solutions measured have been prepared by mixing different volumes of two solutions,

S_1: $\frac{75}{d}$ mM $Er(ClO_4)_3$ + (2 000 − 6.$\frac{75}{d}$) mM $NaClO_4$

S_2: 2 000 mM HAc + 1 000 mM NaAc + 1 000 mM $NaClO_4$

Thus, the connection between C_M and C_A' is

$$C_M = \frac{75}{d}(1 - C_A' \times 10^{-3}), \; C_M \text{ and } C_A' \text{ in mM} \quad (17)$$

In the calculation of the true ligand concentration $C_A = C_A' + [H^+] - C_H$ of the complex solution, the potentiometrically obtained values of the correction terms $[H^+]$ and C_H have been used.

As one absorption cell has been filled with the complex solution and the other with a buffer solution with the same C_A', the value of $E - d \cdot \varepsilon_A^\circ \cdot C_A'$ has been determined directly.

It was controlled that Beer's law is valid for erbium perchlorate solutions with low C_M. At 378 mμ it was found $\varepsilon_M^\circ = 2.15 \pm 0.03$ for $C_M \leq 40$ mM.

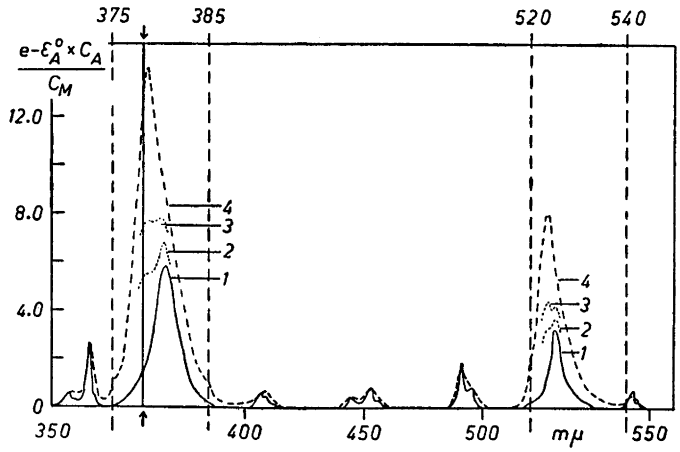

Fig. 3. Extinction curves of one erbium perchlorate solution (curve 1) and three erbium perchlorate solutions with various amounts of the buffer 2 HAc:1 NaAc; $\bar{n} \approx 0.9$ (curve 2), $\bar{n} \approx 1.4$ (curve 3) and $\bar{n} \approx 4$ (curve 4), $\bar{n}$ according to the potentiometric measurements. The arrows and the line indicate the wavelength 378 mμ at which the extinctiometric investigation has been performed. - - - - The erbium ion has still another absorption band in the visible range at about 660 mμ. The height of the peak is nearly independent of C_{Ac} ($\varepsilon_M^0 \approx 1.5$). — — — The two ranges 375—385 mμ and 520—540 mμ have been enlarged.

Fig. 3 shows the extinction curves of one erbium perchlorate solution and three complex solutions with different values of [A]. The addition of acetate buffer results in the appearance of a new peak of somewhat shorter wavelength in the band at 380 mμ as also in the band at 525 mμ. At high acetate concentration the new peak dominates and incorporates the original peak. It is evident that ε of the new peak is a function of [A]. Otherwise, of course, the extinc-

tiometric method of investigation of the complexity system were not applicable. The peak at 380 mμ has been chosen for the measurements as solutions with lower C_M can be used.

Complex rare earth systems have been examined extinctiometrically before, *e.g.*, by Moeller and Brantley [3] and by Vickery [4], who have examined solutions of the EDTA-complexes. They, too, observed that in some cases the dominating bands of the rare earth were split when the complexing agent was added. However, no attempts of computing the complexity constants of the systems were made.

The function $\varepsilon = f(C_A)$ of three series with different C_M is shown in Fig. 4. Table 11 gives the corresponding values of C_A and C_M at some values of ε. The function $(C_A)_\varepsilon = f(C_M)_\varepsilon$ proves to be approximately linear for $\varepsilon > 2.0$. Thus it is possible to extrapolate the function to $C_M = 0$ and to calculate

the values of k_ε and [A] given in Table 11. As seen in the table the agreement between $k_\varepsilon/[A]$ and $\bar{n}_I/[A]$, potentiometrically obtained, is surprisingly good, especially for $[A] > 25$ mM.

The function $k_\varepsilon/[A] = f([A])$ has been extrapolated to $[A] = 0$ and after that the complexity constants have been computed in the same way as before (Table 12). The constants obtained extinctiometrically are in good agreement with those determined potentiometrically (Table 13). Therefore it seems plausible to assume that the approximations made are permissible, *i.e.*, that the concentration of polynuclear complexes in erbium acetate solutions with low C_M is so low that $k_\varepsilon \approx \bar{n}_I$.

Table 14. The stability constants of the rare earth acetate systems reported in Parts I and II, the ionic radii and the numbers of electrons in the 4f-orbitals of the tervalent rare earth ions.

* Templeton, D. H. and Dauben, C. H. *J. Am. Chem. Soc.* **76** (1954) 5237.

At low [A], k_ε/[A] seems to be somewhat higher than $\bar{n}_I$/[A]. As seen in eqn. (16) this is possible if $\Delta\varepsilon_1 < 0$, or, perhaps more likely, if $\Delta\varepsilon_1' < 0$. When [A] < 15 mM, [A] and k_ε will be very uncertain, as the values of $(C_A, C_M)_\varepsilon$ no longer represent a straight line.

DISCUSSION OF THE RESULTS

As seen in Table 14, the stability constant b_1 of the first mononuclear complex increase strongly from La to Sm. This increase is expected as the ionic radius decreases in the same direction. However, from Sm to Dy b_1 decreases strongly and then b_1 remains approximately constant at Dy, Ho, Er and Yb, although the ionic radius decreases incessantly. Thus it seems as if the possibility of forming the first acetate complex is rendered more difficult after the 4f-orbitals have been half-filled with electrons.

To begin with, the stability constant of the second complex increases when the ionic radius of the rare earth decreases, but from Dy to Yb also b_2 shows a decided tendency to decrease. The maximum stability of the third complex is reached at Ho. Thus the tendency to form higher complexes does not decrease as rapidly as the tendency to form the first complex.

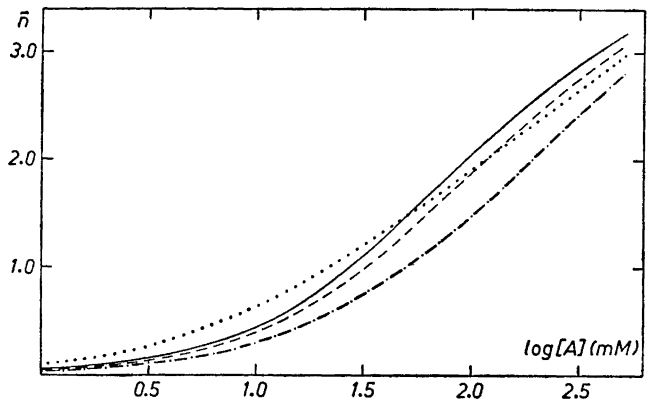

Fig. 5. The complex formation curves of some rare earth acetate systems: ——— the Dy^{3+}-Ac^--system; — — — the Yb^{3+}-Ac^--system; · · · · · the Sm^{3+}-Ac^--system; — · — · — the La^{3+}-Ac^--system.

Fig. 5 shows how the ligand number $\bar{n}_I$ of some rare earth acetate systems varies with the concentration of free ligand of the solution.

As was discussed in Part I, it is doubtful whether the fourth complexity constant has a real meaning, as anionic acetate complexes of the rare earths cannot be proved by anion exchange experiments (Fronæus [5]).

As to the formation of polynuclear complexes, β_1' is 30 à 40 M^{-2} for Gd, Dy, Er and Yb and probably also for Ho. For the acetate systems of the

lighter rare earths the presence of polynuclear complexes is not so evident (perhaps because the $\bar{n}$/[A]-curves are rather steep at the lowest values of [A]).

Finally I wish to express my gratitude to Professor Sven Bodforss for the facilities he has kindly placed at my disposal.

My thanks are also due to Professor Sture Fronæus and Dr. Sten Ahrland for kind advice and criticism.

This work is a part of an investigation supported by *Statens Naturvetenskapliga Forskningsråd (Swedish Natural Science Research Council)*.

Studies on Histidyl Peptides. I

Imidazole Protected Histidine in the Synthesis of C-Terminal and N-Terminal Histidyl Peptides

DIMITRIOS THEODOROPOULOS* and GEORG FÖLSCH

Department of Medical Biochemistry, University of Gothenburg, Sweden

Carbobenzoxy-*im*.benzyl-L-histidine and *im*.benzyl-L-histidine benzyl ester have been used as starting materials in the synthesis of C-terminal and N-terminal histidyl peptides.

It has been suggested during the last few years that histidine probably constitutes a portion of the active center of various hydrolytic enzymes. This suggestion is strongly supported by the evidence that photo-oxidation of the residues of histidine in ribonuclease, trypsin, lysozyme, etc., is accompanied by the loss of enzymic activity. The esteratic properties of various imidazole compounds have been extensively studied [1], but whether the histidine residue is the primary site of reaction of the various organophosphorus enzyme inhibitors, remains a subject of intense controversy [2–4]. The tempting hypothesis that a phosphoryl group is transferred from the imidazole group of histidine to a hydroxyl group of an adjacent residue of serine, needs to be established on the basis of experimental evidence.

We therefore consider it worth while to undertake the synthesis of various peptides containing histidine and serine for two reasons. Primarily to study their behavior towards organophosphorus enzyme inhibitors, and secondly, to study the sensitivity of various proteolytic enzymes towards these peptides when phosphorylated at different functional groups. This is a part of the study of the biological importance of phosphorylated peptides [5,6] which is carried out in this laboratory.

A report of the synthesis of such peptides, involving the sequences histidylserine and serylhistidine, as well as several other C-terminal and N-terminal histidyl peptides will be presented in this paper. During this synthetic work, the recently reported procedure [7] *, employing imidazole-benzyl-L-histidine,

* *Footnote added in proof.* A preliminary note appeared in *J. Org. Chem.* **21** (1956) 1550 and it is noteworthy that Schwyzer has successfully employed imidazole protected histidine in the recent synthesis of a pentapeptide, [*Nature* **182** (1958) 1669].

was exclusively used. The potentialities of this procedure have also been investigated in detail in the course of this work.

DISCUSSION AND RESULTS

The use of carbobenzoxy-*im*.benzyl-L-histidine in the synthesis of N-terminal histidyl peptides.

The basic nature of the imidazole group of histidine has presented formidable problems during the incorporation of an histidine residue into synthetic polypeptides.

Recently, Katchalski *et al.*[8] reported the synthesis of 1,N-dicarbobenzoxy-L-histidine, but it has since been noted, that this compound decarbobenzoxylates readily to produce N-carbobenzoxy-L-histidine.

Akabori *et al.*[9], employing 1,N-dicarbobenzoxy-L-histidine as starting material, have synthesized a number of histidyl dipeptide ester derivatives. It is, however, evident from the work of Katchalski, that any attempt to extend the peptide chain of these dicarbobenzoxy histidyl peptide esters on either the carboxyl or the amino end, will be complicated due to the elimination of the 1-carbobenzoxy group.

It is noteworthy that although a number of synthetic procedures are currently available for the synthesis of histidyl peptides [9–11], no synthesis of dipeptide L-histidyl-L-histidine in optically pure form has yet been reported.

Fischer and Suzuki [12] in 1905 prepared histidyl-histidine by alkaline hydrolysis of L-histidine anhydride, but this hydrolysis was accompanied by racemization. Almost thirty years later, Abderhalden and Leinert [13] hydrolysed L-histidine anhydride with acid, thinking that they could avoid racemization, but no product was isolated.

In this connection, we have succeeded in producing an unequivocal synthesis of an L-histidyl-L-histidine derivative by employing *im*.benzyl-L-histidine [14] as starting material.

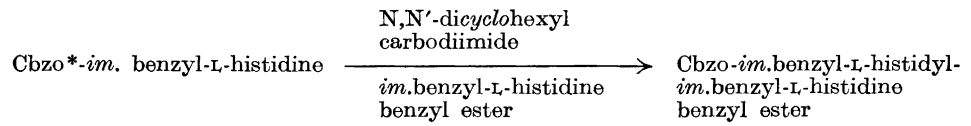
Coupling *im*.benzyl-L-histidine with one mole of benzyl chloroformate [15] in aqueous solution at 0°, at pH alkaline by addition of lithium hydroxide *, followed by acidification, resulted in the synthesis of carbobenzoxy-*im*. benzyl-L-histidine [7]. This compound is sparingly soluble in various organic solvents, such as chloroform, dioxane, ethylacetate, tetrahydrofuran, *etc.*, a fact which appeared to be a stumbling block in its usefulness in peptide synthesis. An attempt to convert carbobenzoxy-*im*.benzyl-L-histidine into its chloride hydrochloride on treatment with thionyl chloride, resulted in a crystalline product. Further work is in progress to identify the composition of this product.

Although the condensation of carbobenzoxy-*im*.benzyl-L-histidine with amino acid and peptide esters, employing the tetraethyl pyrophosphite procedure [16], holds promise due to its well established capacity to deal with

* Lithium hydroxide was chosen instead of sodium or potassium hydroxide since the latter forms less soluble salts with carbobenzoxy-*im*. benzyl-L-histidine which precipitated during the coupling, thus forming a mass.

amino acid and peptide derivatives of low solubility [17], we did not persist in pursuing this procedure since the carbodiimide method [18] operated with excellent results in our case.

A slight modification was, however, enforced due to the afore mentioned solubility properties of carbobenzoxy-*im*.benzyl-L-histidine in organic solvents. Carbobenzoxy-*im*.benzyl-L-histidine was therefore dissolved in dimethylformamide upon heating, and when the solution standing at room temperature had cooled to 40—50°, it was mixed with amino acid esters and carbodiimide. Condensation of carbobenzoxy-*im*.benzyl-L-histidine, with *im*.benzyl-L-histidine benzyl ester thus resulted in the production of carbobenzoxy-*im*.benzyl-L-histidyl-*im*.benzyl-L-histidine benzyl ester.



The conversion of the latter in to L-histidyl-L-histidine will be reported in a later communication.

In the investigated cases, reported below, the peptide ester derivatives thus formed were easily isolated in crystalline form from the dimethylformamide solution by addition of water.

Carbobenzoxy-*im*.benzyl-L-histidyl peptide esters can be extended on either the carboxyl or the amino end by hydrolysis of the ester group, or selective splitting of the N-carbobenzoxy group by hydrogen bromide [16,19] or catalytic hydrogenation [15].

The use of *im*.benzyl-L-histidine benzyl ester in the synthesis of histidine peptides

All the amino acid benzyl esters used in the course of this work were prepared in accordance with the directions of Cipera and Nicholls [20]. Following their method, we also conveniently esterified *im*.benzyl-L-histidine to give the *im*.benzyl-L-histidine benzyl ester dibenzenesulfonate. The latter ester was obtained in crystalline form in about 80 % yield. It can readily recrystallize and remain unchanged for several days in the open. In contrast, *im*.benzyl-L-histidine methyl ester dihydrochloride[7], obtained by the Fischer procedure, appears to be extremely hygroscopic.

Condensation of carbobenzoxy-L-phenylalanine with L-histidine methyl ester employing the carboxylic-carbonic anhydride procedure has been recently reported [21]. This procedure, however, does not always produce satisfactory results, probably due to the undesired side-reaction with the imidazole group of histidine.

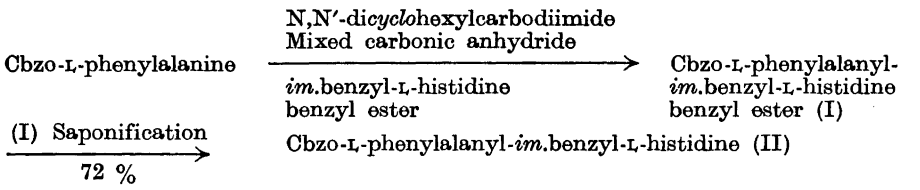
When carbobenzoxy amino acids were condensed with *im*.benzyl-L-histidine benzyl ester *via* the mixed carboxylic-carbonic anhydride [22,23] or the

* Cbzo stands for Carbobenzoxy.

carbodiimide procedure for peptide bond formation, the desired derivatives were obtained in good yield and in crystalline form. Carbobenzoxy-L-serine [24] was thus coupled with *im*.benzyl-L-histidine benzyl ester, employing the carbodiimide prodedure to give the product carbobenzoxy-L-seryl-*im*.benzyl-L-histidine benzyl ester * in crystalline form.

Merrifield and Woolley [25], during their synthetic studies with peptides possessing strepogeny activity, attempted the synthesis of carbobenzoxy-L-seryl-L-histidine methyl ester, to this end employing the azide and carbodiimide methods to condense carbobenzoxy-L-serine with histidine methyl ester. As the authors state, the oily product obtained was not homogeneous, and crystallized only after it had been purified by countercurrent distribution.

When carbobenzoxy-L-phenylalanine was condensed with *im*.benzyl-L-histidine benzyl ester by either of the aforementioned condensing methods, the product carbobenzoxy-L-phenylalanyl-*im*.benzyl-L-histidine benzyl ester (I) was obtained in good yield. Compound (I) was saponified, with no difficulty, with the equivalent amount of sodium hydroxide, and upon acidification with acetic acid, carbobenzoxy-L-phenylalanyl-*im*.benzyl-L-histidine (II) was obtained, after recrystallization, at a 72 % yield.



Hydrolysis of the ester (I) provides the carboxyl group of the *im*.benzyl-L-histidine residue free to link with other amino acids and peptides. Compound (II) was consequently condensed with L-leucine benzyl ester and L-aspartic acid dibenzyl ester by the carbodiimide procedure to produce carbobenzoxy-L-phenylalanyl-*im*.benzyl-L-histidyl-L-leucine benzyl ester (III) as well as the corresponding aspartate derivative.

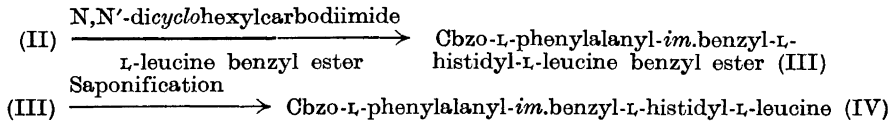
Unreacted compound (II) was separated from (III), not by the usual procedure consisting in extraction with sodium or potassium bicarbonate solution [26]. Compound (II) and the corresponding derivatives reported here, form sparingly soluble salts in water with alkalies, triethylamine, dimethylamine, and ammonia.

Taking advantage of the widely different solubilities of (II) and (III) in ethylacetate, we were able to separate them by dissolving the residue in the above-mentioned solvent. Compound (II) is sparingly soluble in ethylacetate, precipitates and can be removed by filtration. Complete removal of (II) is accomplished by washing the ethylacetate layer thoroughly with 5 % sodium carbonate solution.

---

* The sequence serylhistidine has been identified in the B chain of insulin [Ryle A., Sanger F., Smith L. and Kitai R. *Biochem. J.* **60** (1955) 541] and it is rather interesting to note that the reverse sequence histidylserine occurs in glucagon [Bromer W., Sinn L. and Behrens O. *J. Am. Chem. Soc.* **79** (1957) 2807].

Compound (III) upon saponification, followed by acidification with acetic acid, produced carbobenzoxy-L-phenylalanyl-*im*.benzyl-L-histidyl-L-leucine (IV) in good yield.



Condensation of carbobenzoxy-L-phenylalanyl-*im*.benzyl-L-histidine azide with leucine benzyl ester does not always give satisfactory results due to the tendency of the azide to rearrange. A similar tendency has been observed in the case of carbobenzoxy-L-seryl-L-histidine azide by Merrifield and Wolley [25].

Compound (IV), dissolved in absolute ethanol, was selectively decarbobenzoxylated by catalytic hydrogenation in the presence of palladium black. The so formed L-phenylalanyl-*im*.benzyl-L-histidyl-L-leucine(V), being insoluble in absolute ethanol, precipitates during the hydrogenation. Selective splitting of the N-carbobenzoxy group frees the amino end for extension of the peptide chain, using conventional methods.

Compound (IV), dissolved in 50 % ethanol and hydrogenated for 24 h in the presence of palladium black, afforded the peptide L-phenylalanyl-L-histidyl-L-leucine with an $[\alpha]_D^{24}$ value of +30.5° as a 1.08 % solution in glacial acetic acid.

Since it is a well-known fact that *im*.benzyl-L-histidine easily splits by reduction with sodium in liquid ammonia [14] to produce free histidine, compound (IV) was reduced by this procedure. The tripeptide L-phenylalanyl-L-histidyl-L-leucine * thus obtained showed an optical rotation of $[\alpha]_D^{24}$ +29.5° as a 1 % solution in glacial acetic acid.

EXPERIMENTAL

Carbobenzoxy-im.*benzyl-L-histidine*. A solution of 1.22 g (0.005 mole) of *im*.benzyl-L-histidine in 5 ml of N LiOH was cooled in an ice-bath, and 1 ml of carbobenzoxy chloride, diluted in 3 ml of dioxane, was added in four portions while stirring. During the addition of the carbobenzoxy chloride the solution was kept alkaline by addition of N LiOH. When the last portion of the carbobenzoxy chloride was added, the solution was permitted to remain at room temperature for about 15 min. Addition of 20—30 ml of water, and acidification with acetic acid, caused the desired product to precipitate. It was then filtered off, washed well with water and finally with ether. It was recrystallized by dissolving in dimethylformamide and precipitating with ether. Yield 1.3 g (70 %), m.p. 210—213° (reported [7] 210—213°), $[\alpha]_D^{21}$ + 5.2° (*c* 5 in glacial acetic acid).

im.*Benzyl-L-histidine benzyl ester dibenzenesulfonate*. Into a 150 ml round-bottomed flask were placed 2.45 g (0.01 mole) of *im*.benzyl-L-histidine, 3.87 g (10 % excess) of benzenesulfonic acid monohydrate, 10 ml of benzyl alcohol and 20 ml of carbon tetrachloride. The mixture was then heated under reflux, the liberated water being removed azeotropically. A clear solution was obtained after reflux began. When water no longer

* The C-terminal sequence in valine-hypertensin has been shown to be phenylalanylhistidyl-leucine [Elliot, D. and Peart, W. *Nature* **177** (1956) 527].

distilled off (about the seventh addition of carbon tetrachloride), the reaction mixture was permitted to cool down to room temperature. Through addition of dry ether, the ester precipitated. It was then filtered and washed several times with ether, after which it was dried in a desiccator and then recrystallized by dissolving in *iso*propyl alcohol or dioxane, and precipitating by ether, yield 5.1 g (80 %), m.p. 174—177°, $[\alpha]_D^{18}$ + 8.0° (*c* 1.5 in dimethylformamide). (Found: N 6.50. Calc.for $C_{32}H_{33}O_8N_3S_2$: N 6.45).

Carbobenzoxy-im.*benzyl*-L-*histidyl*-L-*serine benzyl ester.* A suspension of 1.89 g (0.005 mole) of carbobenzoxy-*im*.benzyl-L-histidine in 30 ml of dimethylformamide was dissolved upon heating and then left to cool to 40—45°. This solution was mixed with a previously prepared solution of 1.76 g (0.005 mole) of L-serine benzyl ester benzenesulfonate, and 0.5 g (0.005 mole) of triethylamine in 10 ml of dimethylformamide. Di*cyclo*hexyl-carbodiimide (0.98 g, 0.005 mole) was immediately added and the solution was stirred overnight at room temperature. Di*cyclo*hexylurea was removed by filtration, and the solution was diluted by with 400—500 ml of water *. The ensuing oil crystallized upon scratching with a glass rod. It was cooled, filtered and washed several times with water, then recrystallized by dissolving in ethanol and precipitating with ether. Yield 1.7 g (60 %), m.p. 149—151°, $[\alpha]_D^{21}$ + 2.9° (*c* 5.8 in glacial acetic acid). When recrystallized again from ethylacetate, the m.p. remained the same. (Found: C 66.70; H 5.98; N 10.05. Calc. for $C_{31}H_{32}O_6N_4$: C 66.89; H 5.79; N 10.07).

Carbobenzoxy-im.*benzyl*-L-*histidyl*-im.*benzyl*-L-*histidine benzyl ester.* To 10 ml of dimethylformamide were added 3.25 g (0.005 mole of *im*.benzyl-L-histidine benzyl ester dibenzenesulfonate and 1.01 g (0.01 mole) of triethylamine. This solution was mixed with 1.86 g (0.005 mole) of cbzo-*im*.benzyl-L-histidine, dissolved in 30 ml of dimethylformamide (heated at 40—45°) and 1 g (about 0.005 mole) of di*cyclo*hexylcarbodiimide. The solution was stirred overninght at room temperature. The di*cyclo*hexylurea was then filtered off, washed twice with tetrahydrofuran, and the combined filtrates were diluted with 400 ml of water. Upon cooling and scratching with a glass rod, the desired product crystallized. It was filtered off, washed with water several times, and recrystallized from ethanol-ether. Yield 1.9 g (54 %) m.p. 137°, $[\alpha]_D^{21}$ —22.3° (*c* 5.3 in glacial acetic acid). A further 200 mg of the compound was obtained from the mother-liquor on addition of petroleum ether, m.p. 135°. (Found: C 70.50; H 5.77; N 11.95. Calc for $C_{51}H_{50}O_5N_6$: C 70.68; H 5.78; N 12.06).

Carbobenzoxy-im.*benzyl*-L-*histidylglycine benzyl ester.* A solution of 1.68 g (0.005 mole) of glycine benzyl ester *p*-toluenesulfonate in 10 ml of dimethylformamide was neutralized by addition of 0.5 g (0.005 mole) of triethylamine. It was then mixed with a hot solution (40—45°) of 1.86 g (0.005 mole) of cbzo-*im*.benzyl-L-histidine in 30 ml of dimethylformamide, and 0.98 g (0.005 mole) of di*cyclo*hexylcarbodiimide. The mixture was stirred overnight at room temperature. Di*cyclo*hexylurea was removed by filtration, and the solution was diluted by addition of 500 ml of water. On standing in the refrigerator, the oily product crystallized. It was recrystallized from ethanol-ether, yield 1.1 g (40 %), m.p. 111—112°. (Found: N 10.71. Calc. for $C_{30}H_{30}O_5N_4$: N 10.64).

Carbobenzoxy-im.*benzyl*-L-*histidylglycine.* To a solution of 1 g of the above ester in 15 ml of acetone, 2 ml of N NaOH was added. 5 min later, the product that far saponified, precipitated. Water (5 ml) was then added, and the precipitate was completely dissolved. The solution thus obtained was then allowed to remain for another 15 min at room temperature, and was then diluted with 150 ml of water. Acidification with acetic acid made the desired product precipitate, yield 0.75 g (90 %), m.p. 235—240°, $[\alpha]_D^{20}$ —5.5° (*c* 2.1 in glacial acetic acid). (Found: C 62.80; H 5.85; N 12.75. Calc. for $C_{23}H_{24}O_5N_4$: C 63.20; H 5.54; N 12.85).

Carbobenzoxy-im.*benzyl*-L-*histidyl*-L-*glutamic acid dibenzyl ester.* A solution of 2.49 g (0.005 mole) of L-glutamic acid dibenzyl ester *p*-toluenesulfonate and 0.5 g (0.005 mole) of triethylamine in 10 ml of dimethylformamide was mixed with a solution of 1.89 g

* Alternatively the dimethylformamide was distilled off *in vacuo* (1 mm pressure) at 50° and the remaining residue taken up in ethylacetate or chloroform. The solution was then washed successively with 5 % lithium carbonate and water, and dried over sodium sulphate. The solvent was evaporated *in vacuo*, and the remaining residue was treated as above.

(0.005 mole) of cbzo-*im*.benzyl-L-histidine pro-heated at 40—45°. Di*cyclo*hexylcarbodiimide (0.98 g, 0.005 mole) was immediately added, and the solution was stirred overnight at room temperature. Then di*cyclo*hexylurea was filtered off, and the solution was diluted with 400—500 ml of water. On standing overnight in the refrigerator, the desired product crystallized. Yield 2.8 g. It was recrystallized from ethylacetate-ether, yield 1.8 g (50 %), m.p. 89—91°. (Found: N 8.24. Calc. for $C_{40}H_{40}O_7N_4$: N 8.13).

Carbobenzoxy-im.*benzyl*-L-*histidyl*-L-*glutamic acid.* A solution of 1.72 g (2.5 mmole) of the above ester, and 5 ml of N NaOH in 10 ml of acetone, was stirred for 30 min at room temperature. At the end of that time, 10 ml of water was added, and the solution was filtered and diluted with further 200 ml of water. Upon acidification with acetic acid and cooling in the refrigerator, the product precipitated. Yield 1.15 g (90 %), m.p. 95—97° (recrystallized from ethanol-water). (Found: N 11.10. Calc for $C_{26}H_{28}O_7N_4$: N 11.19).

Carbobenzoxy-L-*phenylalanyl*-im.*benzyl*-L-*histidine. A. By the mixed anhydride procedure.* A solution containing 1.48 g (0.005 mole) of carbobenzoxy-L-phenylalanine, 10 ml of tetrahydrofuran and 0.5 g (0.005 mole) of triethylamine, was cooled to 0°, and 0.5 g (0.005 mole) of ethylchlorocarbonate was then added. After 5 min, 3.25 g (0.005 mole) of *im*.benzyl-L-histidine benzyl ester dibenzenesulfonate and 1.01 g. (0.01 mole) of triethylamine, dissolved in 20 ml of tetrahydrofuran, were added. Coupling was ensured by evolution of carbon dioxide. After 30 min the reaction mixture was diluted with 250—300 ml of water and the desired ester precipitated. The ester was filtered off, washed several times with bicarbonate solution and finally with water. It was then recrystallized by dissolving in ethanol and precipitating with ether, yield 1.9 g (61 %), m.p. 106—107°. (Found: N 8.90. Calc. for $C_{37}H_{36}O_5N_4$: N 9.08).

B. By the carbodiimide method. To a solution of 10 ml of tetrahydrofuran were added 3.25 g (0.005 mole) of *im*.benzyl-L-histidine benzyl ester dibenzenesulfonate, 1.01 g (0.01 mole) of triethylamine, 1.48 g (0.005 mole) of carbobenzoxy-L-phenylalanine and 0.98 g (0.005 mole) of di*cyclo*hexylcarbodiimide. After 15 min di*cyclo*hexylurea began to precipitate. The mixture was stirred at room temperature for 5—6 h and then acidified with a few drops of acetic acid. After 30 min the di*cyclo*hexylurea was removed by filtration, and the solution was diluted with water as described above. Alternatively, the tetrahydrofuran was evaporated *in vacuo* at 40° and the residue was taken up in chloroform. The chloroform layer was washed successively with bicarbonate solution and water. It was dried over sodium sulphate, and the solvent evaporated *in vacuo*. The solid residue was recrystallized from ethanol-ether in a manner similar to that described above, yield 2.1 g (70 %), m.p. 106—107°.

Saponification of the ester. The above ester (6.16 g, 0.01 mole) was dissolved in 20 ml of acetone, 11 ml (10 % excess) of N NaOH was added and the mixture was stirred at room temperature for 30 min. The thus formed sodium salt of the dipeptide derivative which precipitated in the meantime, was dissolved upon gentle heating, and the solution was quickly filtered and diluted with 300 ml of water. This made the slightly soluble sodium salt of the dipeptide precipitate and form a white mass. Upon acidification with acetic acid, the desired compound crystallized. After cooling, the product was filtered, washed several times with water and recrystallized by dissolving in 80 % ethanol, and precipitating with ether. Yield 3.7 g (72 %), m.p. 139—140° (reported [7] 140—141°), $[\alpha]_D^{12}$ + 28° (*c* 1 in glacial acetic acid).

Carbobenzoxy-L-*phenylalanyl*-im.*benzyl*-L-*histidyl*-L-*aspartic acid.* A solution of 1.21 g (2.5 mmole) of L-aspartic acid dibenzyl ester *p*-toluenesulfonate in 10 ml of dimethylformamide was neutralized by addition of 0.25 g (250 mmole) of triethylamine. This solution was mixed with 1.31 g (250 mmole) of cbzo-L-phenylalanyl-*im*.benzyl-L-histidine, and when the latter was completely dissolved, 0.49 g (2.5 mmole) of di*cyclo*hexylcarbodiimide was added. Di*cyclo*hexylurea was filtered off 6 h later and the solvent was evaporated to dryness at 1 mm pressure at 50°. Ethylacetate was added to the residue and concentrated *in vacuo*. This process was repeated four times. The residue was then taken up in ethylacetate (50 ml), cooled for one hour, and filtered. Afterwards the filtrate was washed twice with 5 % sodium carbonate solution, and dried over sodium sulphate. The solvent was evaporated *in vacuo* and the remaining residue solidified upon treatment with ether. Yield 1.5 g. The ester thus obtained was further saponified as follows:

The ester (2.04 g, 2.5 mmole) was suspended in 20 ml of acetone-ethanol (1:1) and 5 ml of N NaOH were added. Stirring for 30 min at room temperature, with gentle

heating at the end of this period, brought about the solution of the hydrolyzed ester. The solution was immediately filtered to remove traces of insoluble compound and then diluted with 200 ml of water, when the tripeptide sodium salt precipitated. The precipitate was acidified with acetic acid, filtered, washed several times with water and recrystallized from 60 % ethanol. Yield 1.2 g (80 %), m.p. 193—196° (reported [7] 193—196°), $[\alpha]_D^{12}$ +20° (*c* 1 in glacial acetic acid).

*Carbobenzoxy-*L*-phenylalanyl-*im.*benzyl-*L*-histidyl-*L*-leucine.* This compound was prepared in a manner similar to that used in the synthesis of the carbobenzoxy-L-phenylalanyl-*im.*benzyl-L-histidyl-L-aspartic acid. When carbobenzoxy-L-phenylalanyl-*im.*benzyl-L-histidine was coupled with leucine methyl or benzyl esters, an oily product was obtained. Saponification produced the desired product in an overall yield of 50 %, m.p. 96°. A sample of the product was recrystallized by dissolution in *iso*propyl alcohol and by precipitation with *iso*propyl ether, m.p. 160—165° (not sharp, reported [7] 163—165°).

L-*Phenylalanyl-*im.*benzyl-*L*-histidyl-*L*-leucine.* A solution of 1.55 g (2.5 mmole) of carbobenzoxy-L-phenylalanyl-*im.*benzyl-L-leucine (m.p. 96°) in absolute ethanol was hydrogenated in the presence of 300 mg of palladium black. Hydrogenation was carride out for half-an-hour during which time the desired product precipitated. The precipitate was dissolved by addition of water and heating. The catalyst was filtered off and the solution evaporated to dryness *in vacuo*. The residue was filtered by addition of ether, yield 1.09 g (90 %). Paper chromatography revealed besides the main product another faint ninhydrin-positive spot at the region of the free peptide phenylalanylhistidylleucine. Recrystallization from 50 % alcohol gave a homogeneous product, as was indicated by paper chromatography and paper electrophoresis, m.p. 162—164° (decomp.), $[\alpha]_D^{21}$ +23.3°; (*c* 1.03 in glacial acetic acid). (Found: C 66.10; H 6.80. Calc. for $C_{28}H_{35}O_4N_5$: C 66.51° H 6.97).

L-*Phenylalanyl-*L*-histidyl-*L*-leucine.* Carbobenzoxy-L-phenylalanyl-*im.*benzyl-L-histidyl-L-leucine (1.59 g, 2.5 mmole) was suspended in 50 ml of liquid ammonia and 0.34 g (100 % excess) of sodium was added in pieces. The blue color remained for about 20 min and then the excess of sodium was neutralized by addition of ammonium acetate. Ammonia was allowed to evaporate and the residue was taken up in 15 ml of water. The water layer was washed twice with ether and evaporated *in vacuo* at 40°. To the residue 5 ml of water was added and the solution reconcentrated. This process was repeated several times. At the end, the residue was treated with 3 ml of water and cooled in the refrigerator. The precipitated peptide was filtered off and washed with 1 ml of cold water. Yield 0.5 g (50 %), $[\alpha]_D^{24}$ +29.5° (*c* 1 in glacial acetic acid), [reported [7] $[\alpha]_D^{24}$ +30.5° (*c* 1.08 in glacial acetic acid)].

*Carbobenzoxy-*L*-seryl-*im.*benzyl-*L*-histidine benzyl ester.* A suspension of 3.25 g (0.005 mole) of *im.*benzyl-L-histidine benzyl ester dibenzenesulfonate in 30 ml of tetrahydrofuran was neutralized by addition of 1.01 g (0.01 mole) of triethylamine. 5 min later 1.19 g (0.005 mole) of carbobenzoxy-L-serine and 0.98 g (0.005 mole) of di*cyclo*hexylcarbodiimide were added while stirring. The mixture was permitted to remain overnight at room temperature and di*cyclo*hexylurea was then removed by filtration. The solution was diluted with 300 ml of water, causing the desired product to precipitate. The product was filtered off, washed several times with water, and purified by dissolution in hot ethylacetate and precipitated by addition of petroleum ether. Yield 2.2 g. Further recrystallization from ethanol-ether gave a product with a sharp m.p. 138.5—139.5°, yield 1.6 g (57 %), $[\alpha]_D^{21}$ −26.3° (*c* 8.4 in glacial acetic acid). (Found: C 66.70; H 5.92; N 10.01. Calc. for $C_{31}H_{32}O_6N_4$: C 66.89; H 5.79; N 10.07).

*N-Tritylglycyl-*im.*benzyl-*L*-histidine.* Coupling of tritylglycine [27] with *im.*benzyl-L-histidine benzyl ester was accomplished either by the mixed carboxylic-carbonic anhydride procedure, or the carbodiimide method, in a manner similar to that described for the preparation of carbobenzoxy-L-phenylalanyl-*im.*benzyl-L-histidine. At the end of the reaction the tetrahydrofuran was evaporated *in vacuo* and the residue was taken up in ethylacetate. The ethylacetate layer was then washed thoroughly with 5 % sodium carbonate solution and water. It was dried over sodium sulphate and the solvent evaporated *in vacuo*. No attempt was made to crystallize the remaining residue which was further hydrolyzed in the same way as described for the carbobenzoxy-L-phenylalanyl-*im.*benzyl-

L-histidine derivative. The product was recrystallized from ethanol-water, yield 60 %, $[\alpha]_D^{21}$ +24.2° (*c* 2.7 in tetrahydrofuran), m.p. 198—201° (reported [7] 198—201°).

*Carbobenzoxy-L-isoleucyl-*im.*benzyl-L-histidine benzyl ester.* This compound was prepared in a manner similar to that used in the synthesis of carbobenzoxy-L-phenylalanyl-*im.* benzyl-L-histidine. Thus 2.65 g (0.01 mole) of carbobenzoxy-L-*iso*leucine [21] was coupled with *im.*benzyl-L-histidine benzyl ester, employing either the mixed carboxylic-carbonic anhydride procedure or the carbodiimide method. After recrystallization from 70 % ethanol, 3.5 g (60 %), and 4 g (70 %), respectively, were obtained, m.p. 132—134°, $[\alpha]_D^{21}$ −21.8° (*c* 10.1 in glacial acetic acid). (Found: N 9.76. Calc. for $C_{34}H_{38}O_5N_4$: N 9.61).

im.*Benzyl-L-histidine methyl ester dihydrochloride.* A fast stream of hydrogen chloride was bubbled for 15 min into a suspension of 2.45 g (0.01 mole) of *im.*benzyl-L-histidine in 20 ml of absolute methanol. The obtained solution was then evaporated *in vacuo* and the residue dissolved by addition of a new portion of methanol. Hydrogen chloride was bubbled in again. After removal of the solvent *in vacuo*, the remaining oily residue was dried *in vacuo* for 3—4 h at 40°, making thus the oily product solidify. The product (3.1 g), being extremely hygroscopic, was further dried before use in a desiccator (P_2O_5) for 24 h. The ester obtained is pure enough for peptide synthesis. A sample of it was dissolved in the minimal amount of methanol, concentrated with hydrogen chloride, and upon addition of dry ether precipitated. The solvent was decanted and the precipitate was washed with ether and dried in a desiccator (P_2O_5). The thus recrystallized ester melted at 111—115°, (reported [7] 111—115°), when heated quickly.

*Carbobenzoxy-L-phenylalanyl-*im.*benzyl-L-histidine hydrazide.* A solution containing 2.99 g (0.01 mole) of carbobenzoxy-L-phenylalanine and 1.01 g (0.01 mole) of triethylamine in 20 ml of chloroform was cooled to 5° and treated with 1.08 g (0.01 mole) of ethylchlorocarbonate. After 5 min it was mixed with a solution of 3.30 g (0.01 mole) of *im.*benzyl-L-histidine methyl ester dihydrochloride, and 2.02 g (0.02 mole) of triethylamine in 30 ml of chloroform. Coupling was ensured by evolution of carbon dioxide. After 30 min the solution was washed with dilute bicarbonate solution and water. It was then dried over sodium sulphate and the solvent evaporated *in vacuo* at 40°. To the residue ethanol was added and concentrated again. The remaining oily residue (3.8 g, 70 %) was dissolved in 20 ml of hot ethanol and mixed with 1 g (200 % excess) of hydrazine monohydrate. The mixture was kept overnight at room temperature, and by addition of water the hydrazide precipitated completely. It was filtered off and recrystallized from 80 % ethanol, yield 2.8 g (75 %), m.p. 183—186° (reported [7] 183—186°).

Acknowledgements. The authors wish to express their sincere thanks to Professor Olof Mellander for his support in this work.

Aid from the *Medical Faculty of the University of Gothenburg* and *AB. Marabou, Sundbyberg*, for a research fellowship to one of us (D. Th.) is gratefully acknowledged.

Thanks are also due to *Hässle-Tika AB.* for placing laboratory facilities at our disposal.

The work was supported by grants from the *Swedish Medical Research Council* to Professor Olof Mellander.

The Crystal Structure of KCr_3O_8

KARL-AXEL WILHELMI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

KCr_3O_8 crystallizes in the monoclinic system, space group No. 12 $C2/m$, with the unit-cell dimensions $a = 8.593$ Å, $b = 5.466$ Å, $c = 7.641$ Å, $\beta = 96°39'$ and two formula units in the unit cell. The structure is formed by CrO_6 octahedra and CrO_4 tetrahedra arranged in layers by sharing corners. The layers are held together by K ions. The bond distances are briefly compared with those found in some other chromium compounds. KCr_3O_8 is stoichiometric. The structure differs considerably in character from those of the non-stoichiometric vanadium and wolfram bronzes of similar composition.

In connection with work on the thermal decomposition of CrO_3, the compound KCr_3O_8 was obtained by melting CrO_3 with $K_2Cr_2O_7$ [1]. The same procedure was described by Suchow *et al.*[2] for preparing compounds MCr_3O_8 (M = Li, Na, K, Rb). The X-ray study performed by these authors indicated that two of the six chromium atoms in the unit cell occupy positions which are not equivalent to the positions occupied by the other four. This suggested the possibility of the former chromium atoms being trivalent and the latter hexavalent.

EXPERIMENTAL

A complete elucidation of the crystal structure had to be based on single-crystal data. The previous investigators failed in preparing material for such techniques. A satisfactory procedure for obtaining good crystals was, however, to heat a mixture of composition $K_2Cr_2O_7 + 2\ CrO_3$ at 350°C at oxygen pressures up to 55 atm for 2 h.

The reagents used were potassium dichromate (analytical grade, Hopkins and Williams Ltd.) and chromium trioxide (Baker's analyzed, dried over P_2O_5). The materials were powdered, intimately mixed and transferred to a silica crucible. The crucible was then placed in an autoclave consisting of a thickwalled steel tube welded at one end. A lid, containing a small copper tube attached to an oxygen cylinder, was bolted to the open end, a silver gasket being placed between the tube and the lid. A commercial pressure-reducing valve was used to measure the pressure. The autoclave was flushed several

times with oxygen before heating it in an electrical oven. After 2 h the autoclave was allowed to cool slowly.

The excess potassium dichromate was extracted with water, leaving a residue of rod-shaped prisms. After drying in an oven at 120°C, the sample was dissolved in hot concentrated sulphuric acid and the chromium determined using Mohr's salt and standard permanganate solution after oxidation by peroxodisulphate in the presence of silver ions. The potassium was determined gravimetrically as potassium perchlorate in samples dissolved in hot 65 % perchloric acid [3]. The reproducibility of the analyses was found to be good and the results in fair agreement with the values calculated for KCr_3O_8.

Chromium, %		Potassium, %	
Found	Calcd	Found	Calcd
48.30 ± 0.05	48.29	12.0 ± 0.2	12.10

The density of the crystals was determined from the loss of weight in benzene (*cf.* Table 1).

A single crystal (*ca.* 0.1 × 0.05 × 0.03 mm^3) was selected. Rotation photographs around [010] and [100] and Weissenberg photographs (*h*0*l*, *h*1*l*, *h*2*l*, *h*3*l* and 0*kl*) were taken with Cu-*K* radiation. The crystals proved to be monoclinic with the *b*-axis along the prism axis and with unit cell dimensions in good agreement with the values given by Suchow *et al.*[2]. More accurate values for the lattice parameters were calculated from a powder photograph obtained in a Guinier type focusing camera of 80 mm diameter (transmission position) with strictly monochromatized Cu$K\alpha_1$ radiation. Potassium chloride (Analar, British Drug Houses, a = 6.2919 Å at 20°C [4]) was added to the specimen as an internal standard (Table 2). The measurement of the reflexions was made on the very sharp high-angle edge of the lines, a procedure introduced by Österlöf [5].

The only reflexions systematically absent were *hkl* with $h+k$ odd, which is characteristic of the space groups No. 12 $C2/m$, No. 8 Cm and No. 5 $C2$. Since it was found possible to derive a plausible structure assuming the highest symmetry $C2/m$, the space groups Cm and $C2$ were not considered. A test for piezoelectricity accordingly did not show any effect. (Experiment carried out by J. Baecklund, University of Uppsala.) Suchow *et al.* on prolonged exposure obtained several weak extra powder lines, incompatible with the unit cell and symmetry found here. Such lines were not observed in the present investigation even after ample exposure nor did they show up in the Weissenberg photographs. In this connection it is worth mentioning that the density, 3.15, found by Suchow *et al.* differs considerably from the calculated value, 3.01, which might indicate that the preparation studied by them is not identical with the one used in the present investigation.

The crystallographic data obtained in this investigation are summarized in Table 1.

The Weissenberg reflexions were recorded photographically using multiple film techniques and their intensities were estimated visually. The F^2 values were then calculated using nomograms given by Lu [6]. No correction was applied for absorption. The maxima in the Fourier syntheses were located by an interpolation table given by Booth [7]. The analytical representation of atomic scattering factors given by Vand, Eiland and Pepinsky [8] for chromium, potassium and oxygen atoms were used when calculating the F values.

Table 1. Crystallographic data for KCr_3O_8.

Laue symmetry: $2/m$.
Unit-cell dimensions: a = 8.593 ± 0.001 Å
b = 5.466 ± 0.001 Å
c = 7.641 ± 0.001 Å
β = 96°39′ ± 20′.

Absent spectra: hkl with $h+k \neq 2n$
Space group: No. 12 $C2/m$
Density: 3.02 (observed)
Density: 3.01 (calculated for $K_2Cr_6O_{16}$)

DERIVATION OF THE STRUCTURE

In $C2/m$ the following point positions exist:

$(0,0,0;\ \frac{1}{2},\frac{1}{2},0)+$
$2(a)$: $(0,0,0)$; $2(b)$: $(0,\frac{1}{2},0)$; $2(c)$: $(0,0,\frac{1}{2})$; $2(d)$: $(0,\frac{1}{2},\frac{1}{2})$
$4(e)$: $(\frac{1}{4},\frac{1}{4},0;\ \frac{1}{4},\frac{3}{4},0)$; $4(f)$: $(\frac{1}{4},\frac{1}{4},\frac{1}{2};\ \frac{1}{4},\frac{3}{4},\frac{1}{2})$
$4(g)$: $(0,y,0;\ 0,\bar{y},0)$; $4(h)$: $(0,y,\frac{1}{2};\ 0,\bar{y},\frac{1}{2})$; $4(i)$: $(x,0,z;\ \bar{x},0,\bar{z})$
$8(j)$: $(x,y,z;\ x,\bar{y},z;\ \bar{x},y,\bar{z};\ \bar{x},\bar{y},\bar{z})$

The two potassium atoms may be assumed arbitrarily to occupy the twofold position $2(a)$.

In order to determine the positions of the six chromium atoms, the projection $P(upw)$ of the Patterson function was calculated (Fig. 1). All the chromium atoms cannot occupy two-fold positions as this would require maxima in this function only at $u = 0$ or $\frac{1}{2}$ and $w = 0$ or $\frac{1}{2}$. Actually $P(upw)$ in addition to such maxima (A and B of Fig. 1) also shows three further high maxima (C, D and E). Of the six chromium atoms, two must thus be accomodated in a two-fold position and four in a four-fold position. The position $2(b)$ is not probable since it would give the far too short K-Cr distance of $b/2 = 2.733$ Å. The positions $4(e)$—$4(h)$ would only require maxima at $u = 0$ or $\frac{1}{4}$ and $w = 0$ or $\frac{1}{2}$. Thus it is concluded that the six chromium atoms occupy $2(c)$ or $2(d)$ and $4(i)$. To decide between $2(c)$ and $2(d)$, the linear Harker section $P(0v\frac{1}{2})$

Table 2. Powder photograph of KCr_3O_8. CuKa_1 radiation. Reflexions systematically absent in space group $C2/m$ have been omitted. The intensities were calculated from the expression $\frac{p}{100}(F_{calc})^2$ where p is the number of equivalent reflexions.

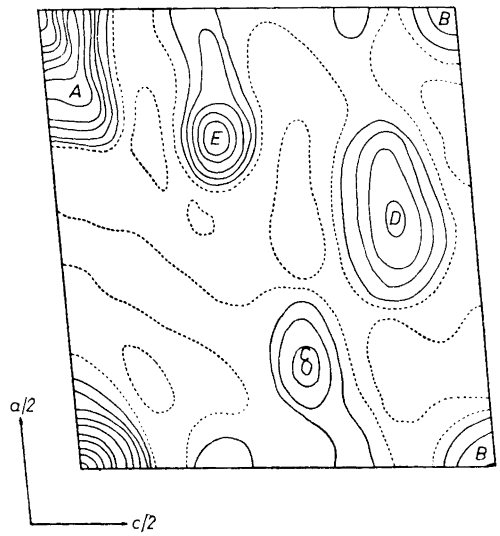

Fig. 1. Projection of the Patterson function *P(upw)*. Dashed lines indicate negative values.

was calculated and found to have only one high maximum, *viz.* at $v = 0$. This locates these two chromium atoms at the point position 2(*c*) and thus we conclude the following arrangement of the metal atoms: 2 K in 2(*a*), 2 Cr_I in 2(*c*) and 4 Cr_{II} in 4(*i*).

The projections in *P(upw)* of the interatomic vectors corresponding to the metal atoms are given in Table 3 (*cf.* Fig. 1). Reasonable Cr_I—Cr_{II} distances are only obtained if it is assumed that the maximum C is caused by a K—Cr_{II} vector $(\frac{1}{2}+x,z)$ and thus the x and z parameters for the Cr_{II} atoms are 0.62 and 0.29, respectively. These values require further peaks in *P(upw)* in perfect agreement with the observed data (*cf.* Table 3 and Fig. 1).

Table 3. Observed and calculated metal-metal peaks in *P(upw)*.

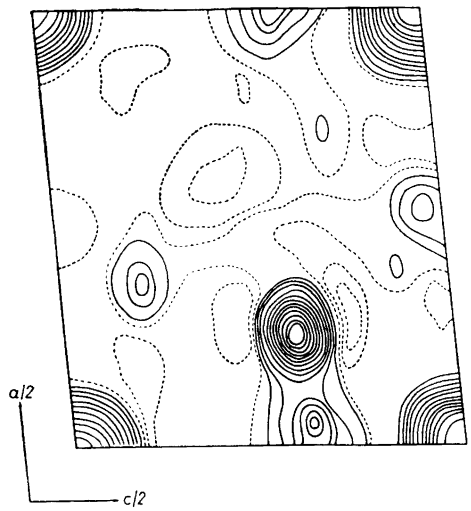

Fig. 2a. Electron density projection $\varrho_2(xpz)$. Dashed lines indicate negative values.

Since the *b* axis is rather short, the *xz* projection of the electron density should show little or no overlapping. At first this projection was calculated using only those *F* values whose signs could be derived from the potassium and chromium contributions. Three pronounced maxima were found giving the positions of the potassium (height 1 165) and chromium atoms (height

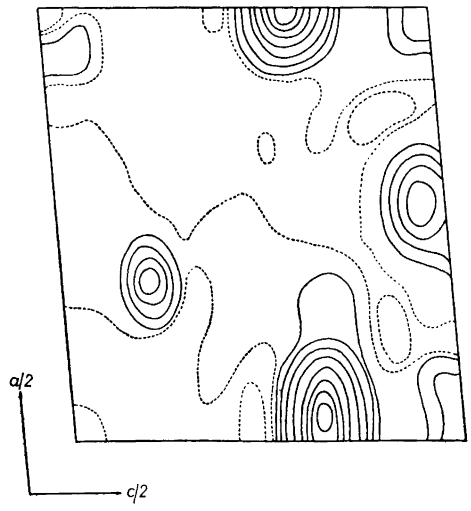

Fig. 2b. Electron density projection $\varrho_3(xpz)$ with the potassium and chromium atoms (Cr_1 and Cr_2) subtracted. Dashed lines indicate negative values.

1 230 and 1 350). (The heights are given on an arbitrary scale.) In addition there were five further maxima:

I.	$x = 0$,	$z = 0.33$	(Height 470);
II.	$x = 0.25$,	$z = 0.50$	(» 270);
III.	$x = 0.18$,	$z = 0.08$	(» 180);
IV.	$x = 0.13$,	$z = 0.47$	(» 180);
V.	$x = 0.22$,	$z = 0.25$	(» 130);

Of these maxima, I and II were assumed to correspond to oxygen atoms in the positions 8(*j*) and 4(*i*) in conformity with their relative heights.

The electron density projection obtained after including these twelve oxygen atoms in the calculations (Fig. 2a) showed no displacements of the positions of the potassium and chromium atoms. The oxygen maxima (I) and (II) had moved and were considerably sharpened and their relative heights were in better agreement with the K and Cr maxima. The maxima IV and V had vanished while III now appeared with the same height as II indicating maximum III to correspond to the remaining four oxygen atoms in a fourfold position 4(*i*). Including all the atoms in the calculations improved the agreement between observed and calculated F values but did not change the sign of any structure factor. Fig. 2b shows the appearance of the projection $\varrho(xpz)$ after subtracting the metal atom contributions. The parameter values thus derived are given in Table 4.

There was only one y parameter to be determined, *viz.* that of the O_{III} atom. In order to find it, the electron density projection $\varrho(pyz)$ was calculated (Fig. 3). Here the potassium and chromium atoms appear very distinctly. The value obtained for $z(Cr_{II})$ is 0.292, in almost perfect agreement with the value found above. The O_I atom is overlapped by Cr_I. The z parameter of the O_{II} atom is somewhat changed from the value obtained from $\varrho(xpz)$. The latter should, however, be more reliable since more F values were used in the calculation of this projection. Also the close vicinity to the high maximum in 0,0 might have contributed to this displacement.

The remaining maximum in $\varrho(pyz)$ is due to two superimposed O_{II} atoms and gives the parameter values $y = 0.250$ and $z = 0.317$, the latter being in fair agreement with the value obtained above.

A careful inspection of the Weissenberg photographs shows a very close agreement between all pairs of structure factors $F(h1l)$ and $F(h3l)$, which supports the reliability of the values for the y parameters.

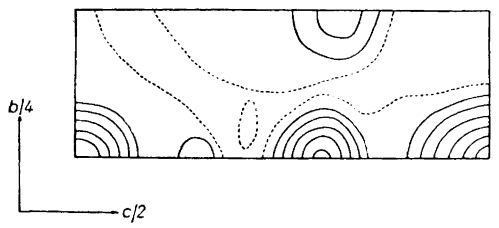

Fig. 3. Electron density projection $\varrho(pyz)$. Dashed lines indicate negative values.

Table 4. Atomic parameters for KCr_3O_8.

(Space-group No. 12 $C2/m$)

Atoms	Point position	x	y	z
2 K	2(*a*)	0	0	0
2 Cr_I	2(*c*)	0	0	½
4 Cr_{II}	4(*i*)	0.625	0	0.293
4 O_I	4(*i*)	0.225	0	0.551
4 O_{II}	4(*i*)	0.682	0	0.108
8 O_{III}	8(*j*)	0.024	0.250	0.315

DESCRIPTION AND DISCUSSION OF THE STRUCTURE

The atomic arrangement thus derived for KCr_3O_8 is summarized in Table 4

Using these parameters, the F values were calculated for the reflexions $h0l$, $h1l$ (identical with $h3l$) and $0kl$ and compared with the observed ones (Table 5). The F_{calc} values were modified by an isotropic temperature factor $B = 0.35$ Å^2 obtained experimentally for $F(h0l)$, $F(h1l)$ and $F(0kl)$. The "reliability" index R calculated according to Booth (1948) was found to be 0.14 for $h0l$, 0.12 for $h1l$ and 0.15 for $0kl$, when the reflexions with vanishingly small amplitudes were taken as having structure amplitudes equal to half the minimum value that it was found possible to observe at the corresponding angle. If only observed reflexions were considered, then the index values for the three groups of reflexions were 0.12, 0.12 and 0.15, respectively. The good agreement between observed and calculated structure factors and the low R values suggest that the coordinates proposed above are essentially correct. The accuracy of the parameters is estimated to be $\pm$ 0.002 for Cr_{II} and $\pm$ 0.004 for the oxygen atoms.

The structure of KCr_3O_8 is shown in Fig. 4 in which it can be seen that the chromium coordination is of two kinds. The first type (Cr_I) forms six bonds with oxygen atoms, *viz.* four with O_{III} atoms and two with O_I atoms. The arrangement of these oxygen atoms is very nearly perfectly octahedral. On the other hand, the coordination around the Cr_{II} atoms consists of a tetrahedron of four oxygen atoms, *viz.* one O_I atom, one O_{II} atom and two O_{III} atoms. The octahedra and tetrahedra are linked together by having corners in common forming continuous layers || the *ab*-plane. All the oxygen atoms except O_{II} belong simultaneously to one CrO_6 octahedron and one CrO_4 tetrahedron. The O_{II} atoms belong only to CrO_4 tetrahedra. The layers are held together by K ions which have ten nearest oxygen neighbours.

Interatomic distances and bond angles are given in Table 6. The accuracy of the Cr-O distance is estimated to be $\pm$ 0.04 Å, while the K-O and O-O distances may be in error by $\pm$ 0.10 Å and $\pm$ 0.10 Å respectively. The distances are of reasonable length throughout.

There is a significant difference between the Cr_I-O and Cr_{II}-O distances. The average of the former (1.97 Å) coincides with that recently found by Douglass [9] in $HCrO_2$ (average value of six Cr^{3+}-O distances 1.97 $\pm$ 0.04 Å).

Table 5. Comparison between calulated and observed structure factors from Weissenberg photographs of KCr_3O_8. Cu$K\alpha$-radiation. Intensities only observed as β-reflexions are marked with an asterisk.

The Cr_{II}-O distances of 1.55—1.65 Å agree well with values around 1.60 Å reported for the $Cr^{6+}O_4$ groups in K_2CrO_4 [10], $CaCrO_4$ [11], Na_2CrO_4 [12] and $CuCrO_4$ [13]. Thus the coordination numbers as well as the interatomic distances indicate that the Cr_I atoms are essentially trivalent and the Cr_{II} atoms hexavalent. While the unsymmetrical Cr_I^{3+}—O—Cr_{II}^{6+} bridges of KCr_3O_8 thus differ completely from the symmetrical bridges Cr^{6+}—O—Cr^{6+} in CrO_3 [14] and $(NH_4)_2Cr_2O_7$ [15] with Cr-O distances of 1.8_0 and 1.9_0 Å, respectively, the

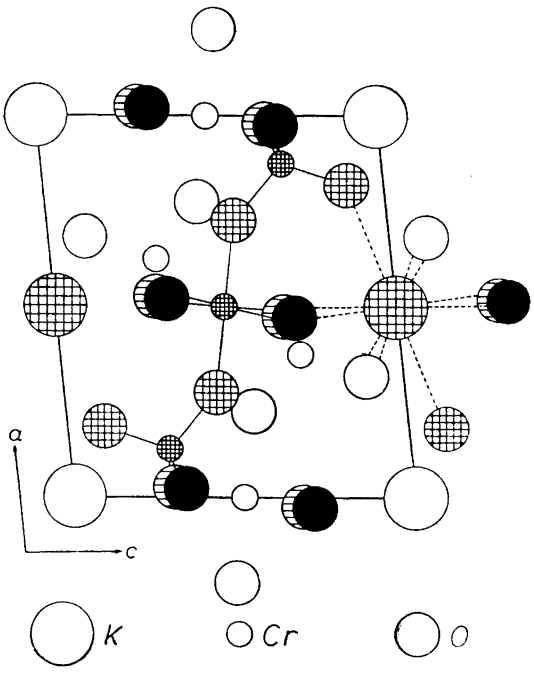

Fig. 4. The unit cell content of KCr_3O_8 projected on (010). Atoms at $y = 0$ open circles, atoms at $y = \frac{1}{4}$ shaded horizontally, atoms at $y = \frac{1}{2}$ shaded horizontally and vertically and atoms at $y = \frac{3}{4}$ black. Bonds between the atoms in a $Cr_3O_8^-$ unit with the chromium atoms at $y = \frac{1}{2}$ are shown with lines. The broken lines represent the K—O bonds.

2(O_{III} — Cr_I — O_{III})	86°	O_{II} — Cr_{II} — O_{III}	109°

bond angles Cr—O—Cr have similar values in all three substances, *viz.* 138° and 146° (KCr_3O_8), 136° (CrO_3) and 115° ($(NH_4)_2Cr_2O_7$). The O_2 atom which belongs to one Cr atom only (Cr^{6+}) is in slightly closer contact with the latter than are the shared O atoms.

Wadsley recently determined the structures of two vanadium compounds with formulae similar to that of KCr_3O_8, *viz.* the so-called vanadium bronzes $Na_{2-x}V_6O_{15}$ [16] and $Li_{1+x}V_3O_8$ [17]. These phases are intensely coloured, chemically very inert and electric semiconductors as are also the earlier well known wolfram bronzes [18–20]. The present investigation has revealed a fundamental difference in structural character between KCr_3O_8 and these compounds. In the bronzes, all vanadium or wolfram atoms occupy positions which are energetically equivalent or probably nearly so. This is likely to facilitate an electron transfer between the metal atoms which is reflected in the considerable electric conductivity of these compounds. In KCr_3O_8, on the other hand, the chromium atoms of fourfold and sixfold coordination must differ very much in energy and hence electron transport between these atoms must be considerably hindered. This view is supported by the recent observation by Wadsley (private communication) that KCr_3O_8 has a very high electrical resistance. The black colour of KCr_3O_8 might possibly indicate a very slight electron transfer between the Cr^{3+} and Cr^{6+} atoms but it might also be caused by the character of the Cr—O bonds. Accurate determinations of Cr—O distances in other chromates would be of great interest. Determinations of the structures of $Rb_2Cr_2O_7$ ($C2/c$ and $P2_1/n$) are in progress and will be published elsewhere. It is planned to reinvestigate the crystal structure of $(NH_4)_2Cr_3O_{10}$ [21].

A comparison between the structures of KCr_3O_8 and $KAl(SO_4)_2$ [22] reveals a certain structural relationship between these compounds, a fact which was first suggested by Professor J. Zemann (Göttingen).

Acknowledgement. This investigation forms part of a research programme on the crystal chemistry of chromium compounds, which is financially supported by the *Swedish Natural Science Research Council.* Part of the calculations involved in this structure determination has been carried out on the BESK, for the use of which the author is indebted to the *Swedish Board for Computing Machinery.*

The author is indebted to the head of this Institute, Professor Arne Ölander, for his kind interest and for the provision of laboratory facilities. Thanks are also due to Dr. Arne Magnéli for stimulating discussions and criticism in connection with this work, to Dr. A. D. Wadsley (C.S.I.R.O., Melbourne) for helpful discussion and permission to quote data as yet unpublished, and to Dr. J. Baecklund for carrying out the piezoelectric test.

Studies on Arabogalactans

II. Fractionation of the Arabogalactan from *Larix occidentalis* Nutt. A Methylation Study of one of the Components

HANS O. BOUVENG and BENGT LINDBERG

Träkemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The arabogalactan from Western Larch (*Larix occidentalis* Nutt.) heartwood has been separated into two components by fractional precipitation of their borate complexes with cetyl-trimethylammoniumhydroxide. These differ in electrophoretic mobility in borate buffer and in sedimentation velocity but have about the same composition and optical rotation. Methylation and hydrolysis of the component with the higher molecular weight afforded 2-*O*-methyl-D-galactose, 2,4-di-*O*-methyl-D-galactose, 2,6-di-*O*-methyl-D-galactose, 2,3,4-tri-*O*-methyl-D-galatose, 2,4,6-tri-*O*-methyl-D-galactose, 2,3,4,6-tetra-*O*-methyl-D-galactose, 2,5-di-*O*-methyl-L-arabinose, 2,3,4-tri-*O*-methyl-L-arabinose and 2,3,5-tri-*O*-methyl-L-arabinose, which were separated, characterised and estimated quantitatively.

FRACTIONATION OF THE ARABOGALACTAN

The homogeneity of the arabogalactans from the *Larix* genus has long been under discussion. In ultracentrifuge studies of a larchwood arabogalactan (species not stated) Mosimann and Svedberg [1] found two components with approximate molecular weights of 16 000 and 100 000. In Western Larch arabogalactan Lystad-Borgin [2] found only one component in the heartwood but two in the sapwood. The molecular weight of these components seemed to be of the same order as those calculated by Mosimann and Svedberg, the heartwood component having the higher molecular weight. Fractional precipitation of the polysaccharide, either directly or after methylation or acetylation has given opposite results (*cf.* Ref.[3]). In a recent publication Aspinall *et al.*[4] concluded that the arabogalactan from European Larch, *L. decidua* Miller, was homogeneous, since no proof of heterogeneity could be found. The heterogeneity of the arabogalactan from Western Larch (*L. occidentalis* Nutt.) heartwood which was left undecided in a previous communication [5] has now been investigated. Electrophoresis of the polysaccharide on glass fibre sheets using borate buffer showed the presence of two components (A and B), which gave two distinct spots on development of the electrophoretograms.

Cetyl-trimethylammonium bromide and similar quaternary ammonium salts have been used succesfully by Scott [6] and others for the fractionation of acidic polysaccharides. Barker *et al.*[7] recently showed that the method could also be applied to neutral polysaccharides capable of forming borate complexes. When this method was used for the fractionation of larch arabogalactan, only part of one component (A), the more mobile on electrophoresis, could be precipitated. The incompleteness of the fractionation was probably caused by to high an ionic strength in the solution. The method was therefore modified by using the corresponding base, cetyl-trimethylammoniumhydroxide, together with boric acid and this gave almost complete precipitation of the polysaccharide. The addition of a small amount of sodium hydroxide had a favourable coagulating effect. The fractionations were made in 4—5 steps at pH 7—8; usually only one of the fractions contained both components. As the mixed fractions were easily refractionated by the same procedure, the original material could be separated completely into the two components.

The proportion of A to B was about 2:1. A, $[\alpha]_D^{20}$ +7° (in water), contained 19 % (molar) arabinose and B, $[\alpha]_D^{20}$ +10°, 21 % arabinose. Sedimentation analysis, made by courtesy of Prof. S. Claesson, Dept. of Physical Chemistry, Uppsala University, gave sedimentation constants 4.3 and 1.4, resp., for A and B in good agreement with the values previously reported [1,2]; the components appeared in the approximate proportion of 2:1. The molecular weights of A and B are therefore of the same magnitude, 100 000 and 16 000, as those calculated for the two components in the sample studied by Mosimann and Svedberg.

A METHYLATION STUDY OF ARABOGALACTAN A

Arabogalactan A was methylated first with methyl sulphate and sodium hydroxide and then with methyl iodide and silver oxide in dimethyl formamide. The latter procedure, devised by Kuhn *et al.*[8] for carbohydrates of low molecular weight, proved to be valuable for polysaccharides also. It was, however, necessary to modify the method of isolation of the methylated product in order to improve the yield. After four methylations in dimethyl formamide the product had a methoxyl content of 44.4 % (theoretical value 44.7 %). The usual methods of estimating the completeness of the methylation of a polysaccharide are not unambiguous; those using methoxyl analyses and infrared spectrophotometry are both open to criticism. Besides the methoxyl analysis a good criterion of the completeness of methylation in the present case was also found in the absence of even traces of unmethylated monomers in the hydrolysate of the methylated polysaccharide.

The hydrolysate from the methylated polysaccharide was fractionated by chromatography on carbon and cellulose columns and on thick filter papers. Carbon columns, in some cases combined with filter paper chromatography, proved most satisfactory for the separation of ethers with at least one free alcoholic hydroxyl; separation on cellulose columns gave better results for highly methylated ethers. The results from the fractionation of the hydrolysate are summarised in Table 1. The ethers were either obtained crystalline or characterised as crystalline derivatives.

Table 1. Galactose and arabinose methyl ethers isolated from the hydrolysate of 0.96 g of methylated arabogalactan A.

Methyl Ethers	mmoles	molar %
2-Methylgalactose	0.14	3.7
2,4-Dimethylgalactose	1.42	37.5
2,6-Dimethylgalactose	0.11	2.9
2,3,4-Trimethylgalactose	0.52	13.7
2,4,6-Trimethylgalactose	0.16	4.2
2,3,4,6-Tetramethylgalactose 2,3,5-Trimethylarabinose	1.22	32.2
2,5-Dimethylarabinose	0.12	3.2
2,3,4-Trimethylarabinose	0.10	2.6

As is often found in this type of investigation, the number of end groups, represented by the tetramethyl galactose and trimethyl arabinose, was smaller than that required by the number of branching points as determined by the amount of mono- and dimethyl galactoses. Incomplete methylation, possibly demethylation during the acid hydrolysis and losses due to the volatility of the fully methylated monomers will all contribute to this discrepancy. A recent publication of Gardiner and Percival [9] has emphasised the last possibility. In the present investigation it was found that about 5 % of a sample of tetramethyl galactose was lost on concentration of an aqueous solution under the conditions used in the quantitative estimation of the ether. Further, if 2,3,4-tri-*O*-methyl-L-arabinose and 2,5-di-*O*-methyl-L-arabinose are derived entirely from 3-*O*-β-L-arabopyranosyl-L-arabofuranose units [10,5], the difference in the amounts of these ethers gives a measure of the deficiences of the methods used.

It is difficult to decide whether the occurrence of 2-*O*-methyl-D-galactose and 2,6-di-*O*-methyl-D-galactose has any structural significance as an indication of the presence of 1,4-linkages. As the hydroxyl group at $C_{(4)}$ in a galactose residue is axial, it is presumably less reactive in the methylation (*cf.* Ref.[11]). The results of a partial methylation of 6-trityl-β-methyl-D-galactoside also indicated that this hydroxyl group is less reactive [12]; in this case, however, steric interaction from the trityl group might be of some importance. If 2-*O*-methyl-D-galactose and 2,6-di-*O*-methyl-D-galactose were the results of demethylation of 2,4-di-*O*-methyl-D-galactose and 2,4,6-tri-*O*-methyl-D-galactose or incomplete methylation of residues, corresponding to these ethers, it would be expected that these pairs of methyl ethers would be formed in about same proportion. However, the proportions actually found are 1.3:1 and 8.8:1. Therefore, and in view of the virtual absence of other monomethyl and dimethyl ethers of galactose, this strongly supports the structural significance of 2-*O*-methyl-D-galactose and 2,6-di-*O*-methyl-D-galactose.

2,3,5-Tri-*O*-methyl-L-arabinose and 2,3,4,6-tetra-*O*-methyl-D-galactose did not separate on the carbon column; separation of the corresponding fraction on thick filter paper afforded the arabinose ether but this was impure and in insufficient quantity for proper characterisation. A larger amount of methylated polysaccharide was therefore subjected to a mild hydrolysis and the low-molecular part of the hydrolysate was hydrolysed further and then frac-

tionated on a cellulose column. The first fraction afforded 4.5 % (molar) of pure 2,3,5-tri-*O*-methyl-L-arabinose; a further quantity of this ether appeared in the following fraction which contained mainly 2,3,4,6-tetra-*O*-methyl-D-galactose. As the hydrolysis of the arabinose residues was not taken to completion, this figure does not represent the total amount of terminal arabofuranosidic units.

It was therefore not possible to make a quantitative estimation of the relative amounts of 2,3,5-tri-*O*-methyl-L-arabinose and 2,3,4,6-tetra-*O*-methyl-D-galactose. In view of the proportion of arabinose to 3-*O*-β-L-arabopyranosyl-L-arabinose (5.9:2) formed on partial hydrolysis [5], it seems reasonable to assume that about 2/3 of the arabinose is present as terminal arabofuranose units and 1/3 as 3-*O*-β-L-arabopyranosyl-L-arabofuranose. Therefore, taking the values for 2,5-di-*O*-methyl-L-arabinose and 2,3,4-tri-*O*-methyl-L-arabinose also into consideration, the arabinose content of the original polysaccharide could be estimated as 18—19 % (molar), in good agreement with the value 18.7 %, found by quantitative paper chromatography.

The relatively low percentage of galactose trimethyl ethers indicates that the arabogalactan A has a more branched structure than previously investigated polysaccharides of similar type; the isolation of 2-*O*-methyl-D-galactose suggests a small number of doubly branched units. The galactose residues are substituted in the 3- and 6-positions to about the same extent with linkages of the β-pyranoside type. A small number of 1,4-linkages seems to be present. There is 18—19 % (molar) of arabinose, about one third of which is combined as 3-*O*-β-L-arabopyranosyl-L-arabofuranose and the remainder as terminal L-arabofuranose residues.

The results previously reported of a partial hydrolysis of the arabogalactan strongly indicated the presence of galactofuranosidic residues in the polysaccharide. An additional, chromatographic investigation of A and B separately revealed no fundamental differences between the two components in this respect. However, no furanoside methyl ethers of galactose were found in the present investigation. This does not necessarily imply that galactofuranosidic residues are not present in arabogalactan A, since the experimental methods used were inadequate for the isolation of the corresponding ethers in the presence of large amounts of other ethers. This problem therefore requires further examination.

A comparison of the results of the present investigation with those of previous studies of related polysaccharides is of interest but must await the structure investigation of arabogalactan B.

EXPERIMENTAL

Melting points are corrected. All evaporations were carried out under reduced pressure.

Chromatography. Papers: Whatman No. 1 and 3 MM and Schleicher and Schüll 602 hP. Solvent: Butanol, ethanol, water, 10:3:5. Developer: Anisidine hydrochloride.

Paper electrophoresis. Paper: Schleicher and Schüll Glass Fibre Paper. Developer: α-Naphthol/sulphuric acid in butanol.

Preparation of larch arabogalactan. The polysaccharide was prepared mainly as described in part I[5]. It was purified further by filtering through ion exchange columns

(Amberlite IR-120 and IR-4B) and treatment with Floridin before being concentrated. It was obtained as a light-coloured powder on precipitation from ethanol. The arabinose content was 16.3 %, determined according to Saeman *et al* [13].

Electrophoresis of arabogalactan. The electrophoretograms (14 × 50 cm) were run in borate buffer at pH 10 for 30—45 min at 2 000 V and 30—50 mA. To allow for electroosmosis, which is very pronounced on glass fibre papers, the non-complexforming ω-hydroxymethylfurfural was used as reference substance. On development the electrophoretograms gave two distinct spots, the denser one (A) moving about 30 % faster than the other (B).

Sedimentation analysis of arabogalactan. Sedimentation analysis revealed two components with sedimentation constants (S_{20}) of 4.3 (A) and 1.4 (B) in the proportion 2:1. Determination on the pure components, prepared as described below, gave the same sedimentation constants (4.3 and 1.4). Both components showed considerable polymolecularity but were found to be essentially free of the other component.

Fractionation of arabogalactan. In a typical experiment the polysaccharide (40 g = 0.25 mole anhydrosugar) was dissolved in water (1 000 ml) and 0.6 M boric acid (415 ml). Cetyltrimethylammonium hydroxide (CTA-OH) was prepared by filtering an aqueous solution of the corresponding bromide through a hydroxyl-saturated column of Dowex 2 ion exchange resin. A portion of this solution (0.095 N) was added to the polysaccharide solution which became cloudy but formed no precipitate until a small amount of sodium hydroxide was added. The sticky precipitate thus obtained was collected on a glass filter and washed thoroughly with water. A further portion of CTA-OH and of sodium hydroxide was added to the filtrate and the fresh precipitate collected. The residual solution was deionised, concentrated and the remaining boric acid was removed by evaporation with methanol, giving a small quantity of polysaccharide which was isolated in the usual manner by precipitation with ethanol. To regenerate the polysaccharides, the precipitates obtained above were dissolved in the miniumum amount of 6 % acetic acid and poured into ethanol; the different fractions were obtained as white powders after filtering and drying. The results of the fractionation are summarised in Table 2. The mixed fraction was dissolved in water (500 ml) and 0.6 M boric acid (120 ml); 0.095 N CTA-OH (52 ml) and 0.5 N sodium hydroxide (5 ml) were added, the precipitate formed was collected and the polysaccharide was isolated as desribed above. 8.0 g of pure arabogalactan A was obtained; the residual solution afforded 3.2 g of mixed material. The arabogalactan fractions thus obtained were electrophoretically pure.

Table 2. Fractionation of 40 g of larch arabogalactan.

0.095 N CTA-OH added (ml)	0.50 N NaOH added (ml)	Weight of fraction (g)	Components
105	5	14.6	A
105	10	11.6	A + B
105	10	5.9	B
52	20	1.5	B
Residue	—	2.1	B

Methylation of arabogalactan A. The polysaccharide (5.70 g) was dissolved in 22.5 % sodium hydroxide (60 ml) under a nitrogen atmosphere. Methyl sulphate (30 ml) was added in small portions over 6 h while the solution was stirred vigorously and cooled with ice water. After a further 2 h the reaction mixture was neutralised with dilute sulphuric acid, dialysed over night against running tap water and then de-ionised by filtering through columns of Amberlite resins IR-120 and IR-4B. After concentration to dryness, the polysaccharide was dissolved in chloroform and precipitated in light petroleum. Yield 6.07 g (93 %); OCH_3 = 26.7 %.

The premethylated polysaccharide (6.05 g) was dissolved in 60 ml of freshly distilled dimethyl formamide (DMFA) and dry methyl iodide (25 ml). The solution was stirred vigorously and cooled while silver oxide (20 g) was added in portions over one hour. After

a reaction time of 20 h the polysaccharide was isolated as described by Kuhn *et al.*[9] for the isolation of fully methylated low-molecular weight carbohydrates. Precipitation in light petroleum gave 5.39 g (82 %), OCH_3 = 41.7 %.

This product (5.29 g) was methylated 20 h with methyl iodide (8 ml) and silver oxide (6 g) in DMFA (50 ml). The reaction mixture was centrifuged and the solid material was thoroughly washed with DMFA and chloroform. The combined centrifugates were concentrated almost to dryness and benzene (150 ml) was added. The precipitated silver salts were filtered off. The precipitate was treated with a small volume of hot DMFA, poured into benzene and filtered. The combined filtrates were concentrated and, if necessary, filtered again. The product was isolated either as a glass or by precipitation in light petroleum as a yellowish powder. This methylation was repeated twice. The final methylation gave 4.15 g of methylated arabogalactan A; OCH_3 = 44.4 % (theoretical value 44.7 %), $[\alpha]_D^{20}$ −37° (*c*, 1.0 in ethanol). The average yield for each methylation was thus 92 %. No trace was found of unmethylated arabinose and galactose on hydrolysis of the methylated polysaccharide.

Separation of methyl ethers from hydrolysed, methylated arabogalactan A. Methylated arabogalactan A (0.96 g) was heated in formic acid (60 ml) at 100° for 6 h. The formyl esters obtained on concentration were hydrolysed by heating in hydrochloric acid (100 ml, 0.5 N) at 100° for 10 h. After neutralising by filtration through an ion exchange column (IR-4B) and concentration of the solution, the hydrolysate was added to the top of a carbon-Celite column (3.5 × 43 cm) and eluted, using the gradient elution technique[14], with 5 l 6—24 % ethanol + 2.5 l 24—50 % ethanol + 1 l 60 % acetone. Table 3 shows how the fractions (25 ml each) were combined; the amount of sugar present was estimated by hypoiodite oxidation[15] and weighing.

A similar preparative separation was made using 2.0 g of methylated polysaccharide and gave crystalline 2-*O*-methyl-D-galactose, 2,4-di-*O*-methyl-D-galactose and 2,6-di-*O*-methyl-D-galactose; the other ethers, except 2,3,5-tri-*O*-methyl-L-arabinose were obtained in quantities sufficient for the preparation of derivatives. Except for the identifications, this separation will not be described in detail.

Fractions 146—159 contained about 50 % each of 2,3,4-trimethylgalactose and 2,5-dimethylarabinose, as estimated by paper chromatograms. Fractions 95—106, 107—119

	2,5-dimethylarabinose	1.35	48.3	0.094

and 120—145 were analysed in the following way. A suitable quantity (7—9 mg) of each fraction was separated on thick filter paper (Schleicher and Schüll 602 hP). The substances were located in the usual way, eluted from the corresponding strips with water and a quantitative estimation was made by hypoiodite oxidation. The following results were obtained (Table 4). Combination of these analytical data gives the values shown in Table 1.

Partial hydrolysis of methylated arabogalactan A. Exhaustively methylated polysaccharide (6.3 g) was boiled for six days in 0.02 N sulphuric acid containing 30 % ethanol. The solution was neutralised with barium carbonate and concentrated to dryness; the hydrolysate was dissolved in benzene, precipitated in light petroleum and filtered. The solid material was re-precipitated twice and the combined filtrates concentrated to a lightcoloured syrup (1.74 g), which was further hydrolysed in 0.5 N hydrochloric acid to split the methylated oligosaccharides present.

*Isolation of 2,3,5-tri-O-methyl-*L*-arabinose.* This product was added to the top of a cellulose column and eluted with butanol saturated with water. The top fraction afforded 282 mg of 2,3,5-tri-*O*-methyl-L-arabinose (4.5 % calculated on the original material). The following fraction contained mainly 2,3,4,6-tetra-*O*-methyl-D-galactose and a lesser quantity of the arabinose ether.

Characterisation of the methyl ethers

*2-O-Methyl-*D*-galactose.* The ether was crystallised from ethanol, m.p. and mixed m.p. 150—152°. On chromatography and electrophoresis, the ether was indistinguishable from an authentic sample of 2-*O*-methyl-D-galactose.

*2,4-Di-O-methyl-*D*-galactose.* The ether was crystallised from moist ethyl acetate, m.p. 103°, sintering at 80°; m.p. of the corresponding aniline derivative 216—219°. The ether was converted to the osazone, m.p. 146—149°, undepressed on admixture with an authentic sample of 4-*O*-methyl-D-galactosazone. On electrophoresis in borate buffer the ether, as expected, was immobile.

*2,6-Di-O-methyl-*D*-galactose.* The ether was recrystallised from ethyl acetate, m.p. 120—122°, undepressed on admixture with a synthetic sample. On electrophoresis in borate buffer, it moved somewhat more slowly than 2-*O*-methyl-D-galactose but decidedly faster than 4-*O*-methyl-D-galactose, as would be expected for a galactose derivative, capable of forming a complex only between $C_{(3)}$ and $C_{(4)}$ [12].

*2,3,4-Tri-O-methyl-*D*-galactose.* The ether was converted to the aniline derivative, m.p. 170—171°, undepressed on admixture with an authentic specimen.

*2,4,6-Tri-O-methyl-*D*-galactose.* The ether was converted to the aniline derivative, m.p. 179—180°. For further characterisation, a portion of the ether was reduced with

sodium borohydride. The trimethylgalactitol thus obtained consumed no periodate. This is in agreement with a 2,4,6-tri-*O*-methyl-D-galactose structure for the original ether which is the only pyranosidic trimethylgalactose of which the corresponding galactitol derivative is not oxidised by periodate.

2,3,4,6-Tetra-O-methyl-D-galactose. The ether was converted to the aniline derivative, m.p. 198—200°, undepressed on admixture with an authentic sample.

2,5-Di-O-methyl-L-arabinose. This was somewhat faster on paper chromatogram than 2,3,4-tri-*O*-methyl-L-arabinose and yielded arabinose only on demethylation. It was converted to the corresponding amide, m.p. 132—133°, in good agreement with values previously reported [16].

2,3,4-Tri-O-methyl-L-arabinose. The ether was converted to the corresponding phenylhydrazide, m.p. 157—158°, undepressed on admixture with an authentic specimen.

2,3,5-Tri-O-methyl-L-arabinose. The ether was faster on paper chromatogram than 2,3,4,6-tetra-*O*-methyl-D-galactose and gave arabinose on demethylation. It was converted to the corresponding arabonamide, m.p. 139—140°, in good agreement with values previously reported [16].

The authors are indebted to Miss Rose-Marie Karlsson and Miss Anita Myhrman for skilful assistance and to *Fonden för Skoglig Forskning* for financial support.

ACTA CHEMICA SCANDINAVICA 12 (1958) 1985—1989

Incorporation of ^{14}C-Acetate in the Phenolic Substances in *Penicillium Islandicum* Sopp

STEN GATENBECK

Institute of Biochemistry, University of Lund, Sweden

The ^{14}C-distribution in 3-hydroxyphthalic acid, isolated from *P. islandicum*, grown on $CH_3{}^{14}COONa$, has been investigated. It was shown that the phthalic acid molecule is built up according to the acetate hypothesis. A new phenolic metabolite was studied and the anthraquinone content of the mycelium investigated which resulted in the identification of catenarin and emodin and the isolation of islandicin.

From previous studies [1,2] it is well known that acetate is the starting material for the formation of several aromatic compounds. The anthraquinone, emodin, belongs to those [3] and the present work will give evidence for an acetate coupling in other anthraquinones too.

In order to study the biosynthesis of anthraquinones a UV-mutant of *Penicillium islandicum*, strain N.R.R.L. 1036, was used, and the incorporation of ^{14}C-labelled acetate in the phenolic substances produced has been studied in the hope to find a precursor to the anthraquinone molecule among them. This special mutant shows a larger production of 3-hydroxyphthalic acid [4] and islandicin [5] than the wild type and it does not produce erythroskyrine [6] which in the wild type disturbs the localization of the anthraquinones on the paper chromatogram.

The culture medium contained very few appreciably labelled compounds. By developing an ether extract of the culture medium on paper chromatogram only three radioactive peaks could be detected by scanning the paper chromatogram with a G.M.-counter (Fig. 1). Two of these peaks were identified by chemical reagents as 3-hydroxyphthalic acid and a mixture of anthraquinones.

3-Hydroxyphthalic acid was isolated and its ^{14}C distribution investigated according to Fig. 2. The radioactive pattern of 3-hydroxyphthalic acid shows a strict conformity to the acetate theory.

The third radioactive peak contained a phenolic substance that has not previously been shown in *P. islandicum*. This substance which for the sake of brevity will be called compound A was isolated and its chemical properties

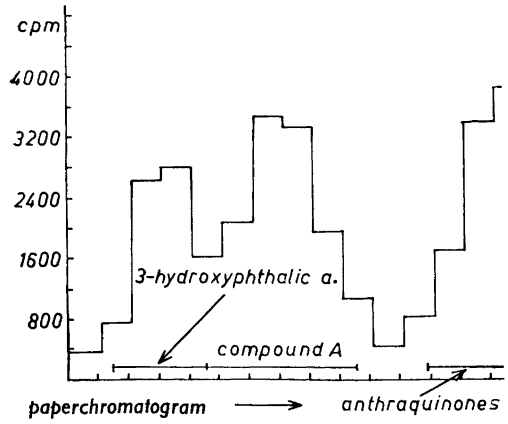

Fig. 1.

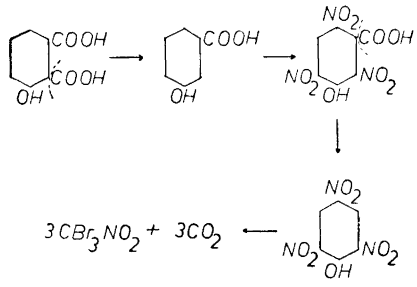

Fig. 2.

studied. It is very soluble in ethanol and acetone, slightly soluble in ether and water. It dissolves readily in 0.5 N $NaHCO_3$ with a slight yellow color and gives a gray brown coloration with ferric chloride solution. It has a strong reducing power indicating a hydroquinone structure. An interesting property of compound A is its behavior in concentrated sulfuric acid. By gentle warming it forms a new compound which shows all the reactions of an anthraquinone. It is orange in color and sublimes at 155—160°C in vacuum. It dissolves readily in 1 N NaOH and in 1 N Na_2CO_3 with a blue violet color. A pure blue color is obtained with alcoholic magnesium acetate. The anthraquinone has the following absorption maxima in ethanol, λ_{max} (mμ): 237.5, 258, 284, 301, 490, 515, 463—468 (inflexion). The solubility of the anthraquinone in 1 N Na_2CO_3 indicates that it has a β-hydroxyl group and the absorption spectrum points to a 1,4-position of two hydroxyl groups. The small amount of the sample has not allowed further analysis of the anthraquinone.

The compound A has a very sharp decomposition point at 212°C and shows no optical activity. Dithionite solution does not alter the compound and no anthraquinone is formed by thermal decomposition excluding any relationship to the hydrated anthraquinones rubroskyrin [6] and luteoskyrin [7].

The radioactive compound A was added to spores from *P. islandicum* suspended in a Czapek-Dox-agar medium. The culture was harvested after fourteen days. It was extracted with acetone and the extract put on a thick paper chromatogram. Two radioactive peaks were obtained by scanning the paper chromatogram with a G.M.-counter. One of them represented the unaltered compound A, the other one a yellow pigment with no anthraquinone properties. This pigment has not been further investigated.

The radioactive 3-hydroxyphthalic acid was tested in the same way as above in a spore suspension. No radioactive substance other than 3-hydroxyphthalic acid could be detected on the paper chromatogram under the experimental conditions employed.

The mycelium, cultivated on labelled acetate, was extracted with chloroform and the chloroform extract fractionated on a silica gel column. From one fraction, orange in UV-light, islandicin was isolated. The specific radioactivity of islandicin was compared with that of 3-hydroxyphthalic acid. The following values were obtained: islandicin, 10.1×10^4 counts min^{-1} $mmole^{-1}$ C-$atom^{-1}$; 3-hydroxyphthalic acid, 9.6×10^4 counts min^{-1} $mmole^{-1}$ C-$atom^{-1}$; *i. e.* they have about the same specific radioactivity indicating a similar acetate coupling in islandicin as there is in 3-hydroxyphthalic acid.

From a second fraction, violet in UV-light, small amounts of two further anthraquinones could be isolated after repeated running on thick paper chromatogram. One of them was catenarin which has recently been found by Shibata *et al.*[7] in *P. islandicum*. It was identified by the absorption spectrum and the melting point 246°C. The other anthraquinone was emodin, which was recognized by its R_F value on the paper chromatogram. Extraction of the emodin from the paper and adding unlabelled emodin as a carrier to the extract resulted in substantial amount of this compound. It could then be recrystallized to constant radioactivity. Emodin has earlier been found in higher plants and in higher fungi.

EXPERIMENTAL

Culture conditions. Four flasks, each containing 500 ml of Czapek-Dox medium, were cultivated according to Howard and Raistrick [5] for thirteen days. At that time a solution of 1 mC of $CH_3{}^{14}COONa$ was equally distributed to the four flasks and the growth was allowed to continue for further eight days. The mycelium was filtered off and washed with distilled water.

Culture medium. The culture medium was neutralized with solid Na_2CO_3 and concentrated in vacuum to about 600 ml. It was acidified with concentrated HCl and extracted four times with ether. The ether phases were extracted with 0.5 N $NaHCO_3$. The ether solution did not contain any radioactivity after the extraction. The hydrogen carbonate solution was acidified with HCl and extracted with ether. After drying the ether solution with anhydrous Na_2SO_4 it was evaporated to a small volume. The residue was placed on Whatman paper No. 3 and the chromatogram developed in a solvent containing chloroform-methanol-formic acid (4 %) (10 : 1 : 1). The 3-hydroxyphthalic acid (R_F about 0.15) was cut out and eluted with ethanol. The strongly colored ethanol extract was put on a silica gel column with water as the solvent. The 3-hydroxyphthalic acid fraction was collected and extracted with ether. The ether extract was then further purified by paper chromatography as described above. The ethanol solution was concentrated in vacuum and the concentrate evaporated to dryness at room temperature and atmospheric pressure. The substance isolated melted at 155—157°C and the melting point was not depressed on admixture with authe tic 3-hydroxyphthalic acid.

The compound A that was detected by its aborption in UV-light was cut out of the paper chromatogram and purified in the same way as 3-hydroxyphtalic acid.

Degradation of 3-hydroxyphthalic acid. (All radioactive measurements are listed in Table 1.) 311 mg of unlabelled, synthetic 3-hydroxyphthalic acid were added to the radioactive 3-hydroxyphthalic acid, isolated from the culture medium, and the mixture dissolved in acetone. The acetone solution was evaporated to dryness at room temperature. A portion of the substance was totally combusted according to van Slyke and Folch [8]. The carbon dioxide was trapped in a barium hydroxide solution. The barium carbonate was isolated and its radioactivity measured. Throughout the work the same amount of barium carbonate (15 mg) has been used for the measurements of the radioactivity and with the same apparatus as reported earlier.

Decarboxylation of 3-hydroxyphtalic acid. 100.9 mg of 3-hydroxyphthalic acid were dissolved in 20 ml of diluted H_2SO_4 (1:1). The solution was refluxed for 25 min. The

Table 1. ^{14}C-Distribution in 3-hydroxyphthalic acid.

COOH-Group (2-position)	1	1 495	1 495	1	1
m-Hydroxybenzoic acid (total comb.)	7	644	4 508	3.01	3
COOH-Group (1-position)	1	79	79	0.05	0
Picric acid (total) comb.)	6	734	4 404	2.95	3
Bromopicrin (C-atoms from 2,4,6-positions)	3	2	6	0	0
CO_2 from the hypo-bromite degradation (C-atoms from 1,3,5-positions)	3	1 361	4 083	2.74	3

The numbers of the COOH-groups in column 5 are obtained by taking the radioactivity of the COOH-group from 2-position as the basis for the calculations. This COOH-group is supposed to derive directly from the COOH-group in acetic acid.

top of the condensor was connected with a barium hydroxide solution. A stream of carbon dioxide free nitrogen was flushed through the system to force the evolved carbon dioxide into the barium hydroxide solution. The barium carbonate was isolated and its radioactivity measured. The sulfuric acid solution was diluted with water and then extracted four times with ether. The residue from the ether extract was recrystallized twice from water yielding 52.7 mg of *m*-hydroxybenzoic acid, m. p. 200°C. A part of the *m*-hydroxybenzoic acid was combusted as above while the remaining acid was diluted 5.22 times with nonradioactive *m*-hydroxybenzoic acid by recrystallization from 3.5 ml of water. All radioactive values listed have been corrected to correspond to the most diluted state.

Nitration of m-hydroxybenzoic acid. The nitration was made according to Wolffenstein and Paar [9]. 0.78 ml of HNO_3 (*d* 1.52) was added to 208 mg of *m*-hydroxybenzoic acid and the mixture evaporated to dryness on a steam bath. This procedure was repeated with the same amount of HNO_3. After extracting the residue three times with boiling benzene, 2,4,6-trinitro-*m*-hydroxybenzoic acid crystallized from the benzene solution. Yield 203 mg, m. p. 180°C.

Decarboxylation of 2,4,6-trinitro-m-*hydroxybenzoic acid.* 203 mg of trinitro-*m*-hydroxybenzoic acid were suspended in 5 ml of glycerol and the mixture refluxed for 20 min. The carbon dioxide was trapped in barium hydroxide solution and the radioactivity measured as above. The glycerol solution was diluted with water, acidified with HCl and extracted five times with ether. The ether solution was evaporated to dryness and the picric acid recrystallized from diluted sulfuric acid. Yield 130 mg, m. p. 120°C. About 10 mg of the picric acid were combusted and the radioactivity measured.

Hypobromite degradation of picric acid. 70 mg of picric acid were added at 0°C to a carbonate free solution of barium hypobromite (from 2.8 mg of barium hydroxide and 0.38 ml of bromine in 60 ml of water). After keeping the mixture at room temperature for 30 min, the bromopicrin was isolated by steam distillation, washed with diluted HCl and water, combusted as above and the radioactivity of the barium carbonate measured. The barium carbonate formed during the reaction was filtered off and washed with water. It was purified by recycling the carbon dioxide into a fresh solution of barium hydroxide. The barium carbonate was isolated and the radioactivity measured.

The mycelium. The mycelium was air dried and extracted with chloroform in a Soxhlet apparatus. The chloroform solution was concentrated to a small volume on the steam bath and then dried at room temperature. Islandicin, catenarin and emodin were isolated as described above. After sublimation and recrystallization from glacial acetic acid the yield of islandicin was 600 mg, m. p. 218°C.

The fractions from the silica gel column containing catenarin and emodin were developed on paper chromatogram (Whatman No. 3) in a solvent consisting of benzene-formic acid (2 %) (10 : 1). Catenarin has R_F 0.45 and emodin R_F 0.50. The anthraquinones were extracted from the paper with acetone and identified as already mentioned in this paper.

The author wishes to thank Professor G. Ehrensvärd for many helpful discussions. Thanks are also due to Cand.Mag. P. Barbesgaard for preparing the mutant used in this work.

On the Metabolism of Thiosulfate Esters

BO SÖRBO

Research Institute of National Defense, Medical Dept., and Nobel Medical Institute, Biochemical Dept., Stockholm, Sweden

An enzyme has been demonstrated in rat liver, which converts sulfocysteine to thiosulfate, ammonia and pyruvate. No thiosulfate is formed from aminoethylthiosulfuric acid. Sulfite is formed from both these thiosulfate esters when they are incubated with liver homogenate under anaerobic conditions, and the reaction is augmented by heat denaturation of the homogenate. The reaction is attributed to a nonenzymic reaction with protein bound thiol groups. A possible use of thiosulfate esters as protective substances against ionizing radiation is suggested.

Thiosulfate esters have so far not attracted much interest from a biochemical point of view. One ester, sulfocysteine * [$COOHCH(NH_2)CH_2S_2O_3H$], was demonstrated by Clarke [1] to be a reaction product from cystine and sulfite, but was apparently not considered as a possible normal metabolite. Later work with mould mutants [3,4] has, however, suggested that in these moulds, sulfocysteine may be an intermediate in the metabolic pathway leading from sulfate to cysteine. Recently Cavallini and Stirpe [5] administered sulfocysteine to rats and observed an increased excretion of thiosulfate. They suggested that the compound was deminated to ammonia, pyruvate and thiosulfate and that sulfocysteine was a precursor of the thiosulfate normally excreted in the urine from higher animals.

The present work was undertaken in order to study possible transformations of sulfocysteine and its decarboxylated analogue, β-aminoethylthiosulfuric acid (AETA) in the presence of rat liver and rat kidney. These two compounds were chosen for study as they are more stable than simple aliphatic thiosulfate esters. A preliminary report of the present work has appeared in this journal [6].

* Clarke originally proposed the name cysteine-S-sulfonate, but this could erroneously imply a thiosulfonate structure (RSO_2SH) instead of a thiosulfate ester structure (RS_2O_3H) for the compound. Recently [2] the name S-sulfocysteine has been suggested and it is used in the present paper.

MATERIALS

Attempts were first made to prepare sodium sulfocysteine according to Clarke [1], but in confirmation of the original report it was found that the product obtained was contaminated with copper ions. These could not be removed by cation exchangers; presumeably the copper ions were complexed by sulfocysteine. Attempts to remove the copper by treating the sample with H_2S led to immediate decomposition of the sulfocysteine. The following improved method for the preparation of the compound, giving a copper free product, was then worked out. To 2.4 g cystine (10 mmole) dissolved in 80 ml water and 5 ml 25 % ammonia was added 12.6 g $Na_2SO_3 \cdot 7H_2O$ (50 mmole) and the solution left for 1 h. 30 % H_2O_2 was then added dropwise with efficient stirring until no free cysteine could be detected with phosphotungstic acid [7]. About 3 ml H_2O_2 were required. The solution was then neutralized with 2.4 ml anhydrous acetic acid, and 15 ml 2 M barium acetate solution was added. Barium sulfate was centrifuged off and the supernatant taken to dryness *in vacuo*. The residue was treated successively with 50, 25 and 15 ml hot 95 % ethanol in order to remove sodium acetate, and the ethanol insoluble residue was then dissolved in 6 ml H_2O. By addition of one volume of 95 % ethanol the sodium sulfocysteine was precipitated as crystals which were collected after one night in the refrigerator. 1.74 g of the compound (containing 3 moles of water per 2 moles of salt [1]) was obtained, corresponding to 34 % of the theoretical yield. Recrystallization from ethanol-water (1:1) gave 1.54 g of pure product.

AETA [8] was a gift from Dr. B. Hansen.

METHODS

Thiosulfate was determined colorimetrically as previously described [9]. Sulfate was determined by a turbidimetric method modified from that of Gassner and Friedel [10]. To 3 ml of the sample was added 0.3 ml 2 M trichloroacetic acid and 5.7 ml water, and precipitated proteins centrifuged off. To 3 ml of supernatant was then added 0.4 ml gelatine reagent followed by 0.4 ml of barium chloride reagent [10]. The turbidity was measured in a 1 cm cuvette at 400 mμ against a blank, obtained by adding 0.8 ml gelatine reagent to another 3 ml aliquot of the supernatant. Sulfite was determined by a colorimetric procedure, based on that of West and Gaeke [11]. To the sample was added an equal volume of 0.2 M $HgCl_2$ and the precipitate was centrifuged off. To 0.5 ml of supernatant was then added 2.0 ml of 0.04 % *p*-rosaniline hydrochloride in 0.72 M HCl and 2.0 ml of 0.2 % formaldehyde, and after 3—7 min. the absorbance of 570 mμ was determined. A blank value was obtained by adding $HgCl_2$ to the test system before the thiosulfate ester. Pyruvic acid and ammonia were determined in trichloroacetic acid filtrates, the former according to Friedemann and Haugen [12] and the latter by nesslerization following aeration.

Paper chromatography was carried out with ascending development on Whatman paper No. 1 and either 75 % acetone-water or 80 % phenol-water as solvents. The samples were deproteinized either by trichloroacetic acid or by heating at 100°C for 2 min. The chromatograms were sprayed with ninhydrine or iodoplatinate [13] (the latter reagent demonstrated compounds containing oxidizable sulfur). The presence of disulfides on the chromatograms was in some cases verified by spraying with phosphotungstic acid-sulfite [14]. The identity of the pyruvate formed from sulfocysteine was also established by paper chromatography according to Wieland and Fisher [15].

RESULTS

When sulfocysteine was incubated with rat liver or kidney slices, small amounts of thiosulfate were formed (Table 1). With a rat liver homogenate instead of slices, the yield of thiosulfate was increased. The formation of thiosulfate was not dependent upon the presence of oxygen and the active system was heat labile (Table 1). No thiosulfate was formed from AETA under otherwise similar conditions. Further experiments demonstrated that the formation

heated 2 min. at 100°C	Air	0

of thiosulfate from sulfocysteine was a zero order reaction (under the conditions indicated in Table 1). Active extracts could be prepared from acetone dried rat liver powder and they were not significantly inactivated by dialysis against 0.01 M sodium acetate at 4°C. When such dialyzed extracts were incubated with sulfocysteine the formation of pyruvate and ammonia besides thiosulfate could be easily demonstrated. When the three reaction products were quantitatively determined the results shown in Table 2 were obtained. The somewhat low yields of pyruvate and ammonia can be attributed to a conversion of these compounds to other products by the liver extract [16], and consequently the stoichiometry of the reaction is best represented by

$$-S_2O_3CH_2 \cdot CHNH_2 \cdot COOH + H_2O \rightarrow CH_3 \cdot CO \cdot COO^- + S_2O_3^{2-} + NH_4^+ + H^+$$

However, not only thiosulfate, but also sulfate was formed, when a rat liver homogenate was incubated with sulfocysteine while about the same amount of sulfate was obtained when sulfocysteine was replaced by AETA (Table 3). The responsible system was heat labile. As no sulfate was formed under anaerobic conditions a simple hydrolysis of the thiosulfate ester to sulfate could be excluded and it was then suspected that sulfate was formed through oxidation of another primary reaction product. (The possibility that thiosulfate was this primary product in case of sulfocysteine was excluded by the fact that thiosulfate is not oxidized to sulfate by liver homogenates [17]). A possible sulfate precursor would be sulfite, and this was in fact formed, when sulfocysteine or AETA was incubated with liver homogenates under

anaerobic conditions. No sulfite could be detected when the incubation was carried out in air as the sulfite was rapidly oxidized to sulfate, presumably through the action of the sulfite oxidase system [18]. It was somewhat unexpectedly found that heating of the homogenate did not destroy, but on the contrary stimulated sulfite formation (Table 4) and this could only in part be attributed to an inactivation of the heat labile sulfite oxidase, as this "activation" was observed also under anaerobic conditions (Table 4). Further experiments demonstrated that the sulfite formation was completely inhibited by 0.001 M *p*-chloromercuribenzoate, a sulfhydryl group reagent, which suggested that sulfite was formed through a reaction between the thiosulfate ester and a sulfhydryl group. As it is well known that heat denaturation liberates "masked" sulfhydryl groups in proteins, the effect of heat treatment on the homogenate indicated that the active sulfhydryl groups were mainly protein bound. This was also supported by the fact that dialysis of a heat denatured homogenate gave only a 25 % decrease of the sulfite forming activity. (The dialysis was carried out in a nitrogen atmosphere, as otherwise a large decrease of activity was obtained.) Of interest was also that sulfite was formed from sulfocysteine and heat denatured ovalbumin, a protein containing SH-groups, but not from sulfocysteine and the native protein. The

reaction between a thiosulfate ester and a sulfhydryl compound gives sulfite and a mixed disulfide according to Ref.[2]

$$R_1SSO_3H + R_2SH \rightarrow R_1SSR_2 + H_2SO_3$$

In the present case the mixed disulfide should be protein bound. Indirect evidence for a formation of a protein bound disulfide from the thiosulfate ester and liver homogenate could in fact be obtained. When the reaction mixtures were deproteinized with trichloroacetic acid, paper chromatography did not reveal any reaction products containing amino groups or sulfur in the supernatant (except thiosulfate in the case of sulfocysteine), but when deproteinization was carried out by heat denaturation, cystine and cystamine were detected in the sulfocysteine and AETA system, respectively. The formation of these symmetrical disulfides could be attributed to a rearrangement of the primary formed mixed disulfide by the heating steps according to 2 PSSR → $(PS)_2 + (RS)_2$ (where P indicates protein).

The formation of sulfite with a simple sulfhydryl compound, glutathione, was also studied for comparative purposes (Fig. 1). It is evident that the reaction stops, when an equilibrium point is reached, as already demonstrated by Stricks and Kolthoff [19] in similar systems by a polarographic technique. The reaction between the thiosulfate esters and inorganic sulfide was also studied, but in this case the reaction was more complicated, as not only sulfide but also thiosulfate was formed. The time course of these reactions in shown in Fig. 2. The results can be explained by a primary formation of sulfite and a persulfide, followed by a slower transsulfuration according to

$$RSSO_3^- + HS^- \rightarrow RSSH + SO_3^{2-} \rightarrow RSH + S_2O_3^{2-}$$

as already suggested by Gutman [20]. Under the reaction conditions used in

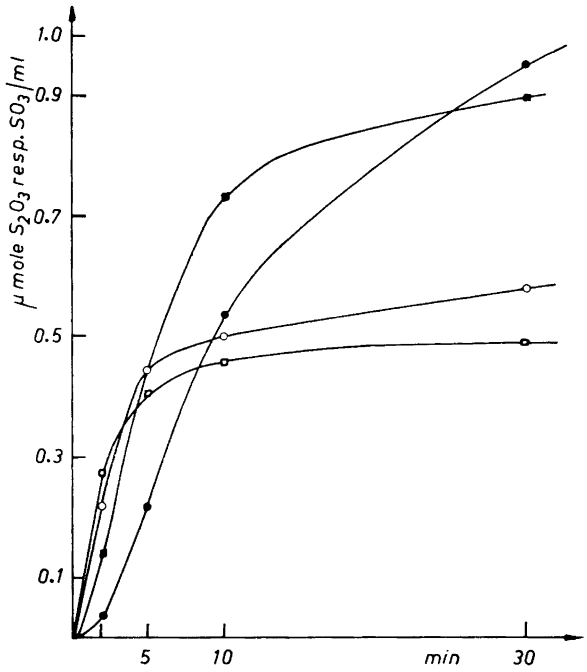

Fig. 2. Relation between inorganic sulfide and thiosulfate esters. Conditions as in Fig. I except that glutathione was replaced by Na_2S, 0.99 μmole/ml.

□ □ □ □ Sulfite from AETA

this work the thiosulfate ester was present in excess, and consequently the following reaction also occurred

$$RSSO_3^- + RSH \rightarrow (RS)_2 + HSO_3^-$$

as is evident from the fact that the molar yield of sulfite plus thiosulfate was in excess over the sulfide added to the system (*cf.* Fig. 2). The formation of cystine and cystamine, respectively, in the systems was confirmed by paper chromatography, but no persulfide was detected, presumably due to the instability of the latter. The results obtained have a certain resemblance to those obtained in a study of the reaction between a thiosulfonate ester (disulfoxide) and inorganic sulfide [21]. The reaction products were here found to be sulfinate, as expected, but a disulfide and thiosulfonate instead of the expected persulfide.

DISCUSSION

The present work has demonstrated an enzymic formation of thiosulfate from sulfocysteine, with pyruvate and ammonia as the other reaction products, thus confirming the suggestion of Cavallini and Stirpe [5]. This reaction shows a resemblance to the cysteine desulfhydrase reaction [22], where hydrogen sulfide,

pyruvate and ammonia are formed from cysteine, when the latter is incubated with liver. As sulfocysteine is structurally related to cysteine, the same enzyme system may be responsible for both these reactions. It is of interest here that the thiosulfate formation from sulfocysteine in the presence of liver homogenate was strongly inhibited by semicarbazide (87 % inhibition at 0.001 M inhibitor conc.) and thus also in this respect similar to cysteine desulfhydrase [21]. Concerning the possibility that sulfocysteine is a precursor for thiosulfate in higher animals, the available data do not indicate that sulfocysteine is of importance in this respect. It was previously [2] demonstrated that thiosulfate is rapidly formed from β-mercaptopyruvate and sulfite in the presence of liver, and the ability of a liver homogenate to form thiosulfate by this reaction is about 10^4 times higher than its catalytic activity on sulfocysteine.

The ability of thiosulfate esters to form mixed disulfides is of interest in connection with chemical protection against ionizing radiation. Eldjarn and Pihl [23] have attributed the protecting properties of certain sulfhydryl and disulfide compounds (for instance cysteamine) to their ability to form mixed disulfides with proteins. If this theory is valid one should expect that also thiosulfate esters have radiation protective properties and this has, as a matter of fact, been experimentally verified for AETA in connection with the present work [24]. Experiments with other thiosulfate esters are now in progress.

The valuable technical assistance of Mrs. E. Ekblom is gratefully acknowledged.

Cellular Localisation, Solubilization and Separation of Intestinal Glycosidases

BENGT BORGSTRÖM and ARNE DAHLQVIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Invertase, maltase and trehalase activities of hog small intestinal mucosa are localized in the microsome fraction obtained from a homogenate on differential centrifugation.

Trypsin causes a solubilization of the glycosidases from the microsomes. During specified conditions the invertase and maltase activities are not affected by trypsin, and trehalase activity only to a minor extent. A method for preparation of soluble glycosidases based on this finding is described.

Trehalase activity of this soluble preparation in contrast to invertase and maltase activities, is destroyed by exposure to ethanol at +4°C. Intestinal trehalase, therefore, must be an enzyme separate from maltase and invertase.

Trehalase activity is also obtained as a separate peak by column chromatography on substituted cellulose (DEAE-cellulose), while invertase and maltase activities could not be completely separated. A change in the ratio of maltase to invertase activity during elution from 1.0 to 6.4, however, indicates the separate identity also of these two enzymes.

The disaccharide hydrolases of mammalian intestine are usually described as maltase, invertase and lactase. According to the specificity theory of Weidenhagen, intestinal invertase and maltase should only be two activities of one and the same enzyme, an α-D-glucopyranosidase, capable of hydrolyzing all α-D-glucopyranosides [1]. With the same nomenclature, lactase, which is well known to be a separate enzyme [2], should be a β-D-galactopyranosidase.

That intestinal extracts from certain mammals are also able to hydrolyze trehalose (1-*O*-α-D-glucopyranosyl-α-D-glucopyranoside) has been known for a long time [3], but it has never been shown if intestinal trehalase is a separate enzyme, or if it is identical with the α-D-glucopyranosidase supposed by Weidenhagen. In many lower organisms, trehalase has been found to be a special enzyme, separable from maltase [3].

Experimental results have been reported, which make the assumption of one single intestinal α-D-glucopyranosidase questionable. Intestinal extracts cannot hydrolyze methyl-α-D-glucopyranoside, which shows that not all α-D-

glucopyranosides can be hydrolyzed [4,5]. Recently it has been reported that activities against nigerose (3-*O*-α-D-glucopyranosyl-D-glucose) and *iso*maltose (6-*O*-α-D-glucopyranosyl-D-glucose) in intestinal extracts from swine have been partially separated from maltase activity [6–8]. All α-D-glucopyranosides which can be hydrolyzed by intestinal enzyme preparations therefore do not seem to be hydrolyzed by the same enzyme.

In the present paper are reported studies of glycosidases from swine small intestinal mucosa: invertase, maltase, trehalase and lactase. These glycosidase activities were found to be particle-bound in intestinal mucosa preparations, and their solubilization from the particles has been studied. Chromatography of the solubilized enzyme solution on substituted cellulose (DEAE-cellulose) according to Peterson and Sober [9] has indicated the presence therein of three separate α-D-glucopyranosidases, *i. e.* trehalase, invertase and maltase.

RESULTS AND DISCUSSION

Differential centrifugation of mucosa homogenate. Freshly prepared intestinal mucosa from swine was homogenized with 4 parts (volume/weight) of 0.25 M sucrose, previously chilled to prevent its enzymatic hydrolysis. In the first experiments a homogenizer of the Potter-Elvehjem type [10] with a plastic pestle was used. This was, however, found to give incomplete homogenization, with a great part of the enzymes remaining in intact cells. Later an "Ultra Turrax" homogenizer was used with a homogenization time of 2 min and a volume of about 100 ml. After homogenization, the sample was centrifuged at 600 *g* for 10 min to remove whole cells and nuclei. The supernatant from this centrifugation is henceforth named total homogenate.

In the experiments where the "Ultra Turrax" homogenizer was used, the total homogenate was more enzyme-rich, but both homogenization techniques gave the same results in the subsequent fractionation.

The total homogenate obtained contained 20—30 units of invertase per ml. The other glycosidases were determined in homogenates made with buffer instead of sucrose solution, or in homogenates from which the sucrose had been removed by dialysis against distilled water (this procedure does not affect the glycosidase activity). The ratios of the other glycosidase activities to invertase activity were relatively constant, being about 2.0 for maltase, 0.5 for trehalase, and 0.2 for lactase.

The total homogenate was fractionated in a "Spinco" preparative ultracentrifuge [11]. The mitochondria were first sedimented at 7 000 *g* for 20 min (rotor 40, 10 000 RPM). The sediment was resuspended in 0.25 M sucrose and centrifuged once more at 7 000 *g*. The combined supernatants were centrifuged at 100 000 *g* for 45 min (rotor 40, 40 000 RPM) to give the microsome fraction and the particle-free supernatant. The invertase activity was found to be mainly localized in the microsome fraction (Table 1).

The microsomes were washed with distilled water, and the remaining sucrose removed by dialysis before determination of maltase, trehalase, and lactase activities. The microsomes were found to have the same ratios of action upon maltose, trehalose, and lactose as the total homogenate. These activities

Microsomes (100 000 *g* for 45 min.)	276	83.7	72.0	3.83
Particle-free supernatant	36	10.9	210.0	0.17

must therefore also be localized in the microsomes. (Of the small amounts of amylase present, less than 25 % was localized in the microsome fraction.)

Solubilization of the glycosidases from the microsome fraction. Different methods were tried to solubilize the glycosidases. Treatment with distilled water or repeated freezing and thawing, which has been found to release some particle-bound enzymes [12], were without effect in the present case. Larner and Gillespie, who had found intestinal maltase and oligo-1,6-glucosidase localized in the microsomes, used acetone powder extracts for fractionation [13]. They have not, however, reported any criterion that the enzymes really were brought into solution by the acetone treatment. We have found the glycosidase activities in acetone powder extracts from intestinal mucosa readily sedimentable in the ultracentrifuge at 100 000 *g* for 45 min (rotor 40, 40 000 RPM), which shows that no solubilization occurs with this method. Treatment with *n*-butanol according to Morton [12], resulted in a partial inactivation of the enzymes, without any solubilization. Nor did snake venom [14] give any solubilization (0.2 mg *Crotalus adamanteus* venom/ml in 0.1 M acetate buffer pH 6.5, incubated for 5 h at 37°C).

Sodium desoxycholate has been found to solubilize most of the proteins from isolated liver microsomes [15]. When intestinal microsomes were treated with 0.5 % sodium desoxycholate in 0.1 M phosphate buffer pH 7.5, the glycosidases remained in a perfectly clear supernatant upon centrifugation at 100 000 *g* for 45 min. Together with the glycosidases about 80 % of the microsome protein remained in the supernatant. In spite of this, it could however be demonstrated in different ways that the glycosidases still were particulate:

1) The desoxycholate extract was dialyzed against phosphate buffer pH 7.5 to remove the desoxycholate. The effect of the dialysis was controlled by isotope-carbon-labelled desoxycholate, added to give 13 620 c.p.m. per ml. After dialysis for 72 h less than 0.5 % of the radioactivity remained. When now centrifuged at 100 000 *g*, the glycosidases slowly sedimented into a transparent, yellow pellet. If sodium desoxycholate was added to the sample before centrifugation, the glycosidases again remained in the supernatant.

2) When a desoxycholate extract was brought to pH 5.0 by the addition of acetate buffer, it became turbid, and the glycosidases sedimented readily in

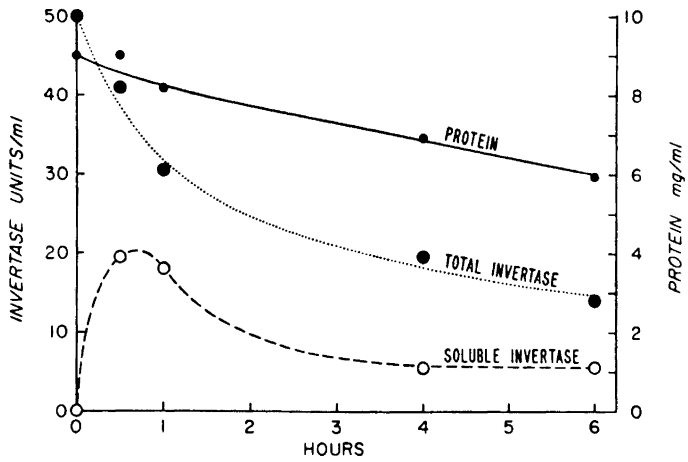

Fig. 1. Digestion of intestinal microsomes by trypsin in the absence of buffer. A suspension of microsomes in distilled water was added with 1 mg of trypsine per ml and incubated at 37°C. Soluble invertase was determined after ethyl alcohol precipitation (see the text) and (undigested) protein after precipitation with 5 % trichloroacetic acid.

an ordinary laboratory centrifuge (Wifug, 4 000 RPM for 10 min). This seems to be caused by agglutination of the particles at pH 5.0, a phenomenon which is well known [16].

3) When a desoxycholate extract was precipitated with ethyl alcohol in the cold, and the precipitate suspended in distilled water, all the invertase, maltase, and lactase activities were retained in the suspension (but the trehalase was partly inactivated by exposure to ethyl alcohol). When then centrifuged in Wifug at 4 000 RPM for 30 min, the glycosidases sedimented. The effect of ethyl alcohol precipitation seems to be the removal of desoxycholate, as the addition of desoxycholate after suspension of the precipitate retained the glycosidases in the supernatant.

When isolated microsomes were suspended in distilled water and incubated with trypsin, the glycosidases were inactivated parallel with the digestion of protein (Fig. 1). In the beginning of the reaction a solubilization of the glycosidases was, however, found to occur.

In the presence of phosphate buffer pH 7.5, the course of the reaction was found to be different (Fig. 2). In spite of the rapid digestion of protein, the invertase and maltase activities were unaffected even in a strong trypsin solution, and the enzymatic activity obtained in solution. The maltase activity indeed increased somewhat during the solubilization. The trehalase and lactase activities, on the other hand, decreased slightly during trypsin digestion. However, even in a solution containing 2 mg of trypsin per ml, incubated at 37°C for 4 h, less than 50 % of the lactase and trehalase activities were inactivated in the presence of phosphate.

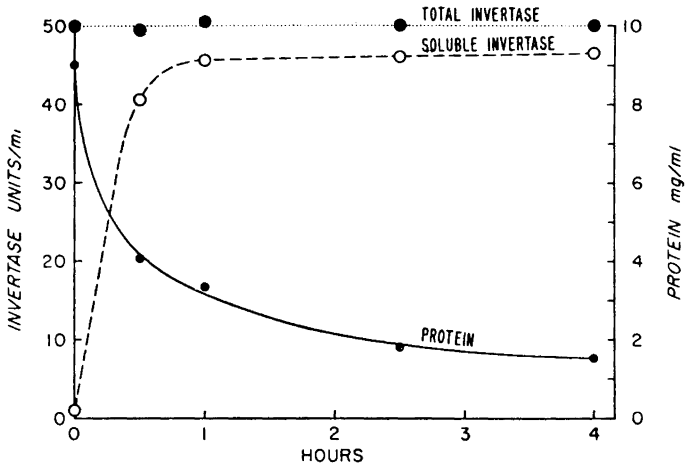

Fig. 2. Digestion of intestinal microsomes by trypsin in the presence of phosphate buffer. The same conditions as described in Fig. 1, but in the presence of 0.1 M phosphate buffer pH 7.5.

The influence of phosphate is not clearly understood. It was found that phosphate could be replaced by some other buffers as borate or tris-(hydroxymethyl) aminomethane but not by veronal buffer. Phosphate is not the only factor that is needed for protection of the glycosidases against trypsin digestion. When a solubilized glycosidase preparation, purified by ethyl alcohol precipitation, containing 5 mg of protein and 100 units of invertase per ml was incubated with 2 mg of trypsin per ml in 0.1 M phosphate buffer pH 7.5 at 37°C for 4 h, less than 10 % of the invertase and maltase activities remained. When, however, a boiled suspension of intestinal microsomes, with a protein content about equal to the purified glycosidase preparation, was added to the reaction mixture, 100 % of the maltase and 75 % of the invertase activities survived digestion under the same conditions.

The degree of solubilization of the glycosidases was measured after ethyl alcohol precipitation. A sample was precipitated in the cold with 5 parts of ethyl alcohol. After centrifugation, the sediment was suspended in distilled water to the original volume of the sample. The total glycosidases were determined on a sample of the suspension, and the rest was centrifuged in Wifug at 4 000 RPM for 20 min. The clear supernatant contained the soluble glycosidases, while the particle-bound glycosidases were found in the sediment.

Glycosidases from hog small intestinal contents. Intestinal contents from hog, obtained by gentle milking out by hand from an excised piece of intestine immediately after the slaughter, was found to contain rather much invertase (50—60 units per ml) and the same proportions of maltase, trehalase, and lactase as in the intestinal mucosa.

The glycosidases in intestinal contents seem to be in real solution. They are not sedimentable in the ultracentrifuge even after prolonged dialysis, they

Table 2. Comparison of the properties of invertase in the intestinal microsomes and the intestinal contents from swine.

	Intestinal microsomes	Intestinal contents
Optimum pH for sucrose hydrolysis	6.3–6.8	6.3–6.8
Optimum pH for melezitose hydrolysis	6.3–6.8	6.3–6.8
K_S for sucrose hydrolysis	2.5×10^{-2}	2.5×10^{-2}
K_S for melezitose hydrolysis	2.6×10^{-1}	2.8×10^{-1}
Action on melezitose *	0.002	0.002
Action on sucrose		
Action on raffinose	0	0

* Number of totally hydrolyzed melezitose molecules [22], divided with number of hydrolyzed sucrose molecules in 0.1460 M substrate concentration (5.0 % sucrose, 7.89 % melezitose . $2H_2O$) at pH 6.5 and temperature 37°C.

do not sediment in a centrifuge at pH 5.0, and they are readily soluble in distilled water after precipitation with ethyl alcohol.

To investigate if the glycosidases in the intestinal contents were identical with those obtained from the intestinal mucosa, some properties of the invertase from the two sources were compared (Table 2). The good agreement seems to show, that the enzyme preparations obtained from the two sources are identical.

When isolated microsomes were incubated with intestinal contents, a rapid solubilization of the glycosidases from the microsomes was found to occur.

Preparation of soluble intestinal glycosidases. The richest source for preparation of intestinal glycosidases was the material obtained by hard manual pressure or by pressing between two rolls pieces of the upper small intestine of hog. This material consists of the intestinal contents together with part of the intestinal mucosa and has an invertase activity of 100—150 units and a protein content of 50—60 mg/ml. If this material was frozen immediately, and thawed just before analysis, over 50 % of the invertase could be demonstrated to be in particular form, and in most cases it contained enough proteolytic enzymes to solubilize the glycosidases within 1—2 h at room temperature.

After storage for a few hours at room temperature, the material was chilled to 0°C and precipitated with 2 volumes of ethyl alcohol, previously chilled to —14°C. After centrifugation at 600 *g* for 10 min (International Refrigerated Centrifuge 2 000 RPM) the clear green supernatant was discarded, and the sediment suspended in its original volume of distilled water. By another centrifugation at 600 *g* a thick sediment, containing 2/3 of the protein, was obtained, while all glycosidase activity remained in the opalescent supernatant. The supernatant was then centrifuged in the Spinco ultracentrifuge at 35 000 *g* for 20 min (rotor 30, 20 000 RPM) to give a light yellow, clear supernatant. This supernatant was precipitated with 2 volumes of chilled ethyl alcohol and again centrifuged at 600 *g*. The sediment was yellow-stained, gelatinous, and

dissolved instantaneously in a small volume of distilled water to give a clear, yellow solution. The remaining ethyl alcohol was removed by dialysis against distilled water.

The solution thus obtained contained all the invertase, maltase, and lactase activities of the original material. The trehalase activity was found to be partly destroyed by exposure to ethyl alcohol at low temperature (Table 3), which clearly demonstrates that intestinal trehalase is an enzyme separate from maltase, invertase, and lactase. By keeping the solutions well chilled and avoiding unnecessarily long exposure to ethyl alcohol, about 50 % of the original trehalase activity could be obtained in the final solution.

The preparation obtained had a specific invertase activity of 55—60 units per mg of protein, which is about 50 times that in homogenates from intestinal mucosa.

Table 3. Action of ethyl alcohol on intestinal glycosidases. After ethanol treatment, the glycosidases are sedimented by centrifugation, and the sediment dissolved in water to the original volume. Invertase, maltase, and lactase activities are not affected by ethyl alcohol, but the trehalase activity is inactivated.

	Activity before treatment with ethyl alcohol units/ml	Activity after treatment with 60 vol. % ethyl days at +4°C units/ml	Per cent of activity remaining after ethyl alcohol treatment
Invertase	214	218	102
Maltase	325	324	99.5
Trehalase	78.5	5	6.5
Lactase	30	30	100

Separation of intestinal glycosidases on DEAE-cellulose. Columns of 0.5 g of DEAE-cellulose (dry weight) equilibrated with 0.01 M phosphate buffer pH 6.0 were used. A solution of solubilized glycosidases, containing 1 500 units of invertase, 3 000 units of maltase, 200 units of lactase, 400 units of trehalase, and 31 mg of protein, was dialyzed against 0.01 M phosphate buffer pH 6.0 and then applied to the column. The chromatogram was then developed with phosphate buffer pH 6.0 with a molarity continuously increasing from 0.01 to 0.16 M (Fig. 3). The rate of flow was 9 ml/h, and each fraction was collected over a 30 min interval.

1/4 of the total protein came out in the first three fractions, before any rise in molarity had occurred in the outcoming buffer. In this peak none of the glycosidases investigated could be detected. Already at 0.015 M phosphate the trehalase activity began to appear in the effluent. The lactase activity began to come out at 0.06 M phosphate and the invertase and maltase activities at 0.08 M phosphate. Thus trehalase, lactase, and invertase activities were clearly separated from each other. The maltase and invertase activities came out within the same interval, but the ratio of maltase activity to invertase activity increased from 1.0 at the beginning of the peak to 6.4 at its end (Table 4).

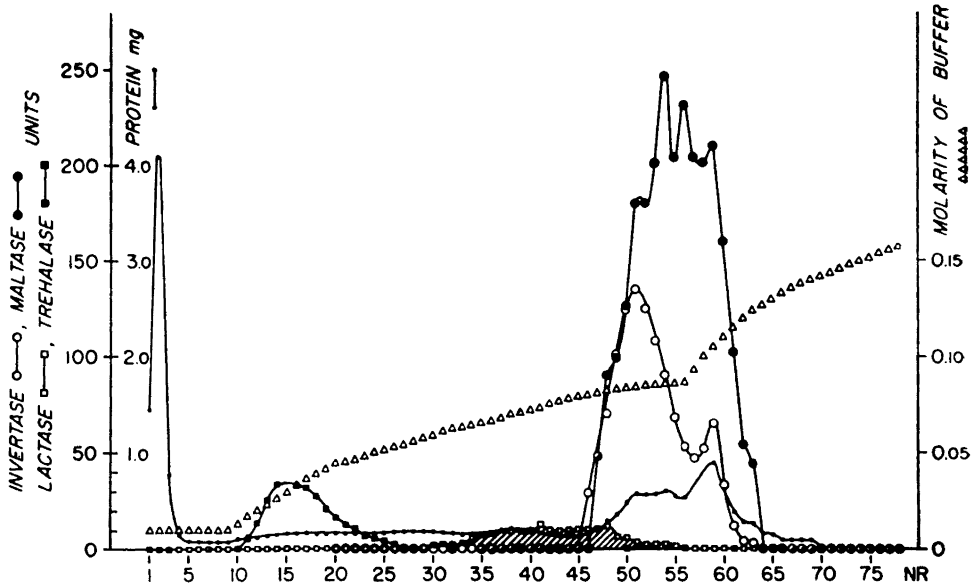

Fig. 3. Separation of intestinal glycosidases on DEAE-cellulose in phosphate buffer pH 6.0. The molarity of the effluent was determined by conductometry. The irregularity of the gradient around tube 52 is caused by a technical manipulation. For practical purposes all zero values for enzymatic activity are not shown in the figure.

It therefore seems probable that these activities are not caused by one single enzyme, as proposed by Weidenhagen [1] but that two different enzymes are involved in the hydrolysis of these sugars. It is, however, not possible at present, to say if there is one specific maltase and one specific invertase, or if

Table 4. Ratio maltase/invertase in fractions from the chromatography shown in Fig. 3.

Fraction No.	Invertase units/ml	Maltase units/ml	Ratio $\frac{\text{Maltase}}{\text{Invertase}}$
47	16.0	16.0	1.0
48	23.6	30.0	1.3
49	33.6	33.0	1.0
50	41.2	42.0	1.0
51	44.8	60.0	1.3
52	41.6	60.0	1.4
53	36.0	67.0	1.7
54	30.0	82.0	2.7
55	22.4	68.0	3.0
56	17.0	77.0	4.5
57	15.6	68.0	4.4
58	17.2	67.0	3.9
59	20.8	67.0	3.2
60	8.0	51.0	6.4

there are two enzymes with different relative activities against these two sugars. Chromatography of the enzymes on DEAE-cellulose at other pH values (from 5.0 to 8.5) did not give any better separation of the maltase and invertase activities. These enzymes were not absorbed to CM-cellulose.

In the most purified invertase fractions, the specific invertase activity was 250 units per mg of protein, which is 250 times that of intestinal mucosa, and 5 times that of the enzyme preparation applied on the column. The specific maltase activity reached 400 units per mg of protein, which is 200 times that of intestinal mucosa and 4 times that of the enzyme solution applied on the column.

MATERIALS AND METHODS

Intestinal mucosa. Pieces of hog intestine were chilled with crushed ice immediately after the slaughter. The pieces were cut from the upper part of the jejunum. The intestines were cut open, washed with tap water to remove the intestinal contents, and gently blotted with a piece of cloth. The mucosa was scraped off with a glass slide. The yield was 25—30 g of mucosa per meter of intestine.

Substrates. Sucrose and lactose were obtained from J. T. Baker Co., maltose from Merck A. G. (Germ.), *α,α*-trehalose and melezitose from Pfanstiehl Chemical Co. The trehalose was recrystallized from 80 % ethanol before use to remove traces of reducing substances. All the substrates used were chromatographically pure.

Assay of enzymatic activity. The reaction mixture was generally contained in 2.0 ml with 0.1388 M substrate concentration (4.75 % sucrose, 5.0 % maltose . H_2O, 5.0 % lactose . H_2O, and 5.25 % trehalose . $2H_2O$) in 0.05 M maleate buffer at optimum pH (6.5 for invertase and maltase, 6.0 for trehalase, and 5.6 for lactase). Toluene was used as preservative. The reaction mixture was incubated at 37°C for 60 min. With the non-reducing substrates (sucrose and trehalose) the degree of hydrolysis was determined with the 3,5-dinitrosalicylic acid method of Sumner [17] using a Beckman B spectrophotometer [18]. With the reducing substrates the method of Tauber and Kleiner [19] was used. Precipitation of proteins was made with the zinc-bariumreagent of Somogyi [20].

The hydrolysis followed a zero order reaction with a rate proportional to the amount of enzyme present up to over 10 % hydrolysis in 1 h. One unit of enzyme causes 1 % hydrolysis (= 1 mg of monohexoses produced) in 2.0 ml of reaction mixture at 37°C in 1 h.

Protein. Protein was determined with the method of Lowry *et al.*[21] A standard curve was made with human serum albumin (kindly supplied by A. B. Kabi).

Snake venom. Crotalus adamanteus venom was obtained from Ross Allen's Reptile Institute.

Sodium desoxycholate. Sodium desoxycholate (twice recrystallized) was kindly supplied by A. Norman.

Isotope-carbon labelled desoxycholic acid. 24-^{14}C-desoxycholic acid was a gift from S. Bergström. The activity was determined with a Tracerlab flow-counter.

Trypsin. Crystalline trypsin (Trypure Novo) was a gift from A.B. Ferrosan.

DEAE-cellulose. Diethylaminoethyl-cellulose was prepared from Whatman cellulose powder by the method of Peterson and Sober [9].

Conductivity measurements were with a Philips conductometer type PR 9500.

K_S *for the hydrolysis of sucrose and melezitose* were determined as described elsewhere [22].

Conjugate Additions of Grignard Reagents to alpha,beta-Unsaturated Esters

III. Additions of Methylmagnesium Bromide

JON MUNCH-PETERSEN

Organisk-kemisk Laboratorium, Polyteknisk Læreanstalt, Copenhagen, Denmark

The cuprous chloride catalyzed additions of methylmagnesium bromide to *sec*-butyl and ethyl esters of crotonic, tiglic and cinnamic acids and to *sec*-butyl β,β-dimethylacrylate are described. The crotonic esters give simple 1,4-addition products (*iso*valeric esters), whereas the other esters form saturated methyl ketones, resulting from both 1,4-addition and one 1,2-addition. The general features of additions of Grignard reagents to α,β-unsaturated esters are considered.

In principle, addition of a Grignard reagent to an α,β-unsaturated ester may lead to five different products, as the result of one 1,4- and one or two 1,2-additions. From crotonic ester and a methylmagnesium halide the following compounds could thus be formed:

$$CH_3CH=CH-COOR \xrightarrow{CH_3MgX} \begin{cases} CH_3CH=CH-CO-CH_3 & \text{I (1,2)} \\ CH_3CH=CH-C(OH)(CH_3)_2 & \text{II (1,2 + 1,2)} \\ (CH_3)_2CH-CH_2COOR & \text{III (1,4)} \\ (CH_3)_2CH-CH_2CO-CH_3 & \text{IV (1,4 + 1,2)} \\ (CH_3)_2CH-CH_2C(OH)(CH_3)_2 & \text{V (1,4 + 1,2 + 1,2)} \end{cases}$$

Methylmagnesium halides are, according to literature, usually added mainly to the carbonyl group of α,β-unsaturated carbonyl compounds, tertiary alcohols (type II) being produced [1–5], although the formation of small amounts of compounds resulting from 1,4-addition has also been reported, *e.g.* ethyl *iso*valerate (type III) (besides crotyldimethylcarbinol) from ethyl crotonate [4] and 3-methylpentanone-2 (type IV) (besides *iso*propenyldimethylcarbinol) from ethyl methacrylate [5].

In 1941, Kharasch and Tawney [6] demonstrated, that, in the case of the α,β-unsaturated cyclic ketone *iso*phorone, they were able to change the direction of addition of methylmagnesium bromide drastically from predominantly 1,2- to almost exclusively 1,4-addition by adding a catalytic amount of cup-

rous chloride. Such an effect of cuprous chloride has more recently been verified by other workers (for further references, see Ref.[3]).

As described in the first paper in this series [3], it was found that when cuprous chloride was present, *sec*-butyl *iso*valerate (III) was formed in 45 % yield by the conjugate addition of methylmagnesium bromide to *sec*-butyl crotonate, and with *sec*-butyl cinnamate this Grignard reagent gave a 40 % yield of 4-phenylpentanone-2 (VI) as a result of both 1,4- and 1,2-addition (*cf.* IV, above). In the second paper [7], however, in which the uncatalyzed 1,4-additions of higher Grignard reagents to *sec*-butyl crotonate and tiglate are described, it was stated that methylmagnesium bromide gives mixtures of compounds which are of little preparative value.

The present paper reports a number of addition reactions of methylmagnesium bromide with some α,β-unsaturated esters. It has been established that a catalyst, such as cuprous chloride must be present in order to secure any great degree of conjugate addition. When *sec*-butyl crotonate or cinnamate react with methylmagnesium bromide under conditions [7] which in the case of higher Grignard reagents lead to good yields of simple 1,4-addition compounds, well-defined substances can not be easily isolated by fractional distillation. The reaction products are mixtures, probably of several of the compounds corresponding to types I—V, as well as the below-mentioned high-boiling condensation-addition compounds and non-distillable polymerisation products from the unsaturated esters. When, however, the addition reactions are carried out in the presence of catalytic amounts of cuprous chloride under cooling in an ice-salt freezing mixture, there are obtained fair to good yields of products (Table 1), which in the case of crotonic ester is the simple 1,4-addition product (III, *iso*valeric ester), but in the case of cinnamic ester, is the above-mentioned saturated methyl ketone (VI), resulting from both 1,4- and 1,2-addition:

$$C_6H_5CH=CH-COO\text{-}sec\text{-}C_4H_9 \xrightarrow{CH_3MgBr} C_6H_5CH(CH_3)CH_2COCH_3 \qquad VI$$

Similarly, *sec*-butyl tiglate and *sec*-butyl β,β-dimethylacrylate give the saturated methyl ketones, 3,4-dimethylpentanone-2 (VII) and 4,4-dimethylpentanone-2 (methyl *neo*pentyl ketone, VIII), respectively.

It has further been found that, in this reaction, the ethyl esters give the same products in the same yields as do the *sec*-butyl esters (in the case of crotonic ester, of course, ethyl *iso*-valerate instead of the *sec*-butyl ester is formed).

As mentioned above, the reaction leading to products of type IV consists of one 1,4- and one 1,2-addition, and the question could be asked, as to which one of the two additions takes place first [5,2]. No answer, however, could be given on the basis of the experiments here described, since, in each case, only one of the possible products has been obtained. Probably this sequence differs from case to case, depending on the structure of the ester (and of the Grignard reagent), and the whole problem is thus intimately connected with the influence of the structure on the course of the addition. Investigations of this relationship are in progress.

Table 1. Additions of methylmagnesium bromide to α,β-unsaturated esters in the presence of cuprous chloride.

Ester	Product	Yield %	b. p., °C found	b. p., °C lit.	n_D^{25} found	n_D^{25} lit.
sec-butyl crotonate	*sec*-butyl *iso*valerate [a]	51	57/15 mm	100/98 mm [3]	1.4043	1.4075 [3]
ethyl crotonate	ethyl *iso*valerate	54	134	133.8 [8]	1.3967	1.3975 [8]
sec-butyl tiglate	3,4-dimethyl-pentanone-2, VII [b,g]	63	133—134	136—138 [9]	1.4088 n_D^{14}	1.4129 [9]
ethyl tiglate	3,4-dimethyl-pentanone-2, VII	64				
sec-butyl β,β-dimethyl acrylate	4,4-dimethyl-pentanone-2, VIII [c,g]	33 [d]	124	124—125 [10]	1.4037	1.4018 [10]
sec-butyl cinnamate [3]	4-phenyl-pentanone-2, VI	40 [e]	88.5/1.7 mm		1.5102	
ethyl cinnamate	4-phenyl-pentanone-2, VI [f,g]	77	69/0.8 mm		1.5071	

[a] III (R = *sec*-butyl); calc. for $C_9H_{18}O_2$ (158.23): sap.equiv. 158.2. Found: 158.1. [b] Calc. for $C_7H_{14}O$ (114.18): C 73.63; H 12.36. Found: C 73.75; H 12.48. [c] Calc. for $C_7H_{14}O$ (114.18): C 73.63; H 12.36. Found: C 73.40; H 12.32. [d] This yield could probably be increased by leaving the reaction mixture over-night in stead of for only 1—2 h, since a large amount (30 %) of unreacted ester was recovered in spite of a great excess of Grignard reagent. [e] This yield could probably be increased, since actually too little Grignard reagent (1.5 equiv.) was used, and a considerable amount (20 %) of unreacted ester was recovered (se Ref. [3]). [f] Calcd. for $C_{11}H_{14}O$ (162.22): C 81.44; H 8.70. Found: C 81.30; H 8.63. [g] Infra-red spectrum shows the presence of a ketone group, and the absence of hydroxyl groups and double bonds.

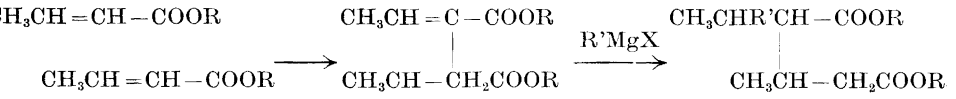
The experimental facts here described, together with the previously reported [3,7] results, seem to indicate the following general picture of the addition of Grignard reagents to α,β-unsaturated esters:

a. Adding ethyl esters to Grignard reagents without special precautions (as Grignard reactions are ordinarily carried out) results mainly in 1,2-additions (to the carbonyl group), tertiary alcohols (of type II) being formed *.

b. By the use of esters with large alcohol moieties, such as *sec*-butyl esters [3], instead of ethyl esters, 1,2-addition is largely prevented (except with certain Grignard reagents, e.g. methylmagnesium halides). Instead, 1,4-addition takes place, but if special conditions (*c*, below) are not fulfilled, the ester first, to a large extent, dimerizes by a Michael-type condensation to an α-alkylidene-

* One exception is the reaction between ethyl cinnamate and phenylmagnesium bromide, giving predominantly 1,4-addition (β,β-diphenylpropionic ester) [1].

glutaric ester. The Grignard reagent then adds to the α,β-carbon-carbon double bond of this latter ester, so that a high-boiling saturated, substituted glutaric ester is produced:



Only minor amounts of the simple conjugate addition product (type III) are formed.

c. The formation of the high-boiling condensation-addition product is suppressed by 1) cooling the Grignard solution during the addition of the ester, 2) diluting the ester solution (with ether) and 3) adding the ester solution slowly. Ordinary Grignard reagents, with the exception af methylmagnesium halides, may in this way give good yields of simple 1,4-addition products (saturated esters of type III) [7]. The reaction thus provides a practical route to 3-methyl-, 2,3-dimethyl- and 3-phenyl-substituted alkanoic acids.

d. The precautions mentioned under *c* do not prevent 1,2-addition in those cases where such addition takes place in spite of the use of *sec*-butyl esters, *e.g.* the Grignard reagent being a methylmagnesium halide.

e. Cuprous chloride has a definitely established effect in promoting 1,4-addition in favor of 1,2-addition.

f. Cuprous chloride has little, if any, effect in preventing the formation of the high-boiling condensation-addition compound [7].

The mode of action of cuprous chloride is still obscure, although it appears likely that some kind of Lewis-acid effect could operate, activating the carbon-carbon double bond [3].

The above-mentioned points *c* and *e* suggest that the combination of the conditions mentioned under *c* with the presence of cuprous chloride should make possible the use of ethyl esters in stead of *sec*-butyl esters in the simple 1,4-addition process. Preliminary experiments have shown, that *n*-butylmagnesium bromide with ethyl crotonate in the presence of cuprous chloride gives the 1,4-addition product ethyl 3-methylheptanoate in the same yield (about 70 %) as is obtained with *sec*-butyl crotonate without catalyst. With ethyl tiglate and cinnamate, however, much lower yields have been obtained. The results of this investigation will be published in a forthcoming paper.

EXPERIMENTAL

Microanalyses are by Mr. Preben Hansen, Microanalytical Division, The Chemical Laboratory, University of Copenhagen. Infra-red spectra were recorded in this laboratory by Mrs. Susanne Refn, M. Sc. Fractional distillations were through a simple 45 cm × 8 mm Podbielniak-type column with a tantalum wire spiral, heated jacket and partial reflux head.

sec-*Butyl esters* were prepared as previously described [3]. *Ethyl crotonate* and *tiglate* were prepared in 80 % yield by the conventional esterification procedure: boiling the acid with excess of ethanol in the presence of concentrated sulfuric acid. *Ethyl cinnamate* was obtained by the condensation of benzaldehyde with ethyl acetate.

Methyl bromide was either a commercial c. p. product (Fluka, purum) or a technical product (from a steel cylinder), which was purified by passing the gas through sodium hydroxide solution and concentrated sulfuric acid, followed by liquefaction. For weighing it was dissolved in ice-cold ether.

The cuprous chloride catalyzed additions of methylmagnesium bromide were carried out as previously described [3], except that a greater excess of Grignard reagent and a longer addition time for the ester were used. Effective stirring was applied throughout. The methylmagnesium bromide was usually prepared from 6.3 g (0.26 g-atom) of magnesium turnings and 28 to 32 g (about 0.3 mole) of methyl bromide in about 160 ml of ether. The clear solution, after being heated under reflux for 15 min, was cooled in ice-salt for 15 min; 0.25 g of cuprous chloride was added in one portion, and then 0.1 mole of the ester, dissolved in 100 ml of ether, was added dropwise from a graduated dropping funnel during about 1.5 h. During this period the temperature of cooling bath usually rose from about $-18°$ to about $-5°$. Stirring was continued for an additional 10—15 min at this temperature, then at room temperature for 1 to 2 h. (In the case of tiglic ester this period at room temperature was prolonged overnight, and this should probably also be done with β,β-dimethylacrylic ester in order to obtain maximum yield, *cf.* note[d], Table 1). The reaction mixture was finally poured onto ice and hydrochloric acid and worked up in the conventional way [3].

Characterization of Intestinal Invertase as a Glucosido-Invertase

I. Action on Different Substrates

ARNE DAHLQVIST

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The basis for classification of intestinal invertase as a glucosido-invertase is discussed.

The action of a preparation of intestinal glycosidases on some di- and trisaccharides, related to sucrose, has been studied.

No action upon raffinose [*O*-α-D-galactopyranosyl-(1→6)-*O*-α-D-glucopyranosyl-(1→2)-β-D-fructofuranoside] or gal-sucrose (α-D-galactopyranosyl-β-D-fructofuranoside) could be detected. Intestinal invertase can therefore not hydrolyze these sugars. This supports the view that intestinal invertase has a great specificity for the glucopyranoside part of the sucrose molecule.

Melezitose [*O*-α-D-glucopyranosyl-(1→3)-*O*-β-D-fructofuranosyl-(2→1)-α-D-glucopyranoside] was hydrolyzed, but at a very slow rate. The substitution in the fructofuranoside part of the sucrose molecule must therefore have a marked influence on the action of intestinal invertase. At present, however, we do not know, if sucrose and melezitose really are hydrolyzed by the same enzyme.

An attempt to demonstrate, if the sucrose linkage in melezitose can be hydrolyzed before the turanose linkage, had no success. This failure was explained by the slow rate of melezitose hydrolysis.

The results indicate that intestinal invertase has a very high degree of specificity for the glucopyranosyl part of sucrose, but that also alterations in the fructofuranosyl part of the molecule interfere strongly with the action of the enzyme. Further specificity studies require more purified enzyme preparations.

The division of invertases into glucosido- and fructosidoinvertase was first made by Kuhn, grounded on their inhibition by glucose or fructose, respectively [1–3]. Such inhibitions, however, show many irregularities [4–6], and are therefore no practical ground for the classification of invertases.

Later Kuhn *et al.* proposed the use of raffinose [*O*-α-D-galactopyranosyl-(1→6)-*O*-α-D-glucopyranosyl-(1→2)-β-D-fructofuranoside] and melezitose [*O*-α-D-glucopyranosyl-(1→3)-*O*-β-D-fructofuranosyl(2→1)-α-D-glucopyranoside] for the characterization of invertases [6]. These sugars are regarded as sucrose, where the glucosyl or the fructosyl parts, respectively, are substituted with a

third sugar. Glucosido-invertases should be able to hydrolyze melezitose and fructosido-invertases raffinose (into fructose and melibiose) in addition to sucrose.

That intestinal invertase cannot hydrolyze raffinose was observed by Bierry [7] already in 1912. Recent reports support this statement [8].

The behavior of intestinal invertase against melezitose has never been investigated, although the interest for such an investigation has been expressed [9].

Recently has been reported the synthesis of a new disaccharide, gal-sucrose (α-D-galactopyranosyl-β-D-fructofuranoside), which is a sucrose where the glucose has been replaced by galactose [10]. The only structural difference from an ordinary sucrose molecule is therefore that the hydrogen and the hydroxyl at the fourth carbon atom of the glucosyl part have shifted place. This substance seems very interesting for testing the specificity demands of invertases for the glucopyranosyl part of sucrose.

In the present paper are reported some experiments on the action of an intestinal glycosidase preparation upon raffinose, melezitose, and gal-sucrose. Turanose (3-*O*-α-D-glucopyranosyl-D-fructose) is also included, because it is a part of the melezitose molecule. For the substrates hydrolyzed, the optimum pH, relative rate of hydrolysis, K_s, and v_{max} have been determined.

As source of enzyme was selected swine intestinal mucosa. In this material invertase (together with maltase, lactase, and trehalase) has been found localized in the microsome fraction [11], obtained by differential centrifugation. The enzymes were extracted from the microsomes by sodium desoxycholate.

MATERIALS AND METHODS

Substrates. A sample of gal-sucrose was kindly supplied by D. Feingold, G. Avigad, and S. Hestrin, who recently reported the synthesis of this sugar [10]. The other substrates were commercial preparations of analytical grade purity, sucrose from J. T. Baker Co., raffinose and melezitose from Pfanstiehl Chemical Co., and turanose from Nutritional Biochemicals Corporation.

Glycosidase preparation. Pieces of swine intestine were taken from the slaughterhouse immediately after the slaughter, and chilled with ice during the transport to the laboratory. The pieces were cut from the proximal jejunum, because this part seems to be richest in invertase [12]. The mucosa was scraped off, homogenized in 0.25 M sucrose (previously chilled to 0° to prevent hydrolysis), and the microsomes were isolated by differential centrifugation [11]. The glycosidases were eluted from the microsomes with 0.5 % sodium desoxycholate (kindly supplied by A. Norman). The desoxycholate and the remaining sucrose were removed by dialysis against phosphate buffer pH 7.5, and then the buffer was removed by dialysis against distilled water. The suspension thus obtained contained 80—90 % of the invertase present in the original homogenate, and corresponding amounts of maltase, lactase, and trehalase [11].

Determination of enzymatic activity. Samples of enzyme solution were mixed at 37°C with buffered substrate solutions, to give a concentration of 0.1 M buffer (acetate or phosphate) and, when not otherwise noted, 0.1460 M substrate (5 % sucrose or turanose, 7.89 % melezitose . $2H_2O$, or 8.65 % raffinose . $5H_2O$). Toluene was used as preservative. The degree of hydrolysis was not allowed to exceed 5 % per hour. During these conditions, the reaction was found to be of zero order up to at least 10 % hydrolysis, and the (initial) reaction velocity was found to be proportional to the amount of enzyme present.

Gal-sucrose, of which only a total amount of 2 mg was available, was used in lower concentration as described later.

The degree of hydrolysis was determined by different methods, depending of the properties of the substrates.

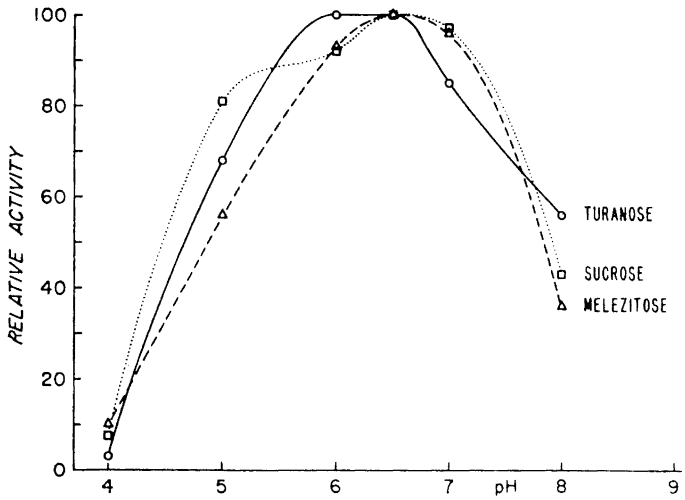

Fig. 1. Influence of pH on the hydrolysis of sucrose, melezitose and turanose. Buffers: 0.1 M acetate pH 4.0—5.0, 0.1 M phosphate pH 6.0—8.0. Temperature 37°C. Substrate concentration 0.1460 M.

1) Sucrose, raffinose, and melezitose are nonreducing. For determination of the monosaccharides produced from these sugars was used a modification of the 3,5-dinitrosalicylic acid method of Sumner [13,14], with spectrophotometric reading of the obtained colour [15]. No protein precipitation is necessary with this reagent.

2) Gal-sucrose is also nonreducing, but because this sugar was used in a very dilute solution, the highly sensitive method of Somogyi and Nelson [16,17] was used, after previous precipitation of proteins with Zn-Ba reagent [18].

3) Turanose is a reducing disaccharide. The liberated glucose was determined by the specific enzymatic method of Keilin and Hartree [19].

Samples of 0.4 ml of the reaction mixture were added 1.6 ml of 0.1 M acetate buffer pH 5.0, and the glycosidase action was interrupted by boiling in water-bath for 2 min. (The addition of acid buffer before boiling was found to be essential since turanose is a very alkali-labile sugar, and if it is boiled at a pH higher than 6.0, part of the turanose will be decomposed, leaving free glucose. This buffer will not interfere with the following enzymatic determination of glucose.) 1.0 ml of this solution was transferred to a Warburg flask (without central cylinder). 2.0 ml of a 0.1 M acetate buffer pH 5.6, containing 0.1 ml of catalase solution (Catalase, sterile solution, Worthington) and 0.02 ml of 99.5 % ethanol per 2 ml, were added. In the side arm of the flask was placed 0.5 ml of a 10 % glucose oxidase solution (Glucose oxidase, crude, Sigma). This contains no enzyme acting upon turanose (but it contains maltase) and might therefore in this case be used without further purification. After equilibration at 25°C, the tap was closed and the flask tipped. When no more oxygen was absorbed (after 30—45 min) the readings of the manometers were recorded. 124.4 mm^3 of oxygen absorbed corresponds to 1.0 mg of glucose oxidized.

Paper chromatography of sugars was performed by the ascending technique on 30 cm long pieces of paper (Whatman No. 1). A roll of equal breadth, containing about 120 cm of filter paper was placed on the top to absorb the solvent. The chromatograms were developed for 24 h with ethyl acetate:acetic acid:water 9:2:2 v/v. The sugar spots were detected with aniline hydrogen phthalate [20].

RESULTS

Sucrose was rapidly hydrolyzed by the enzyme solution, with an optimum pH between 6.3 and 6.8 (Fig. 1). The amount of invert sugar produced per

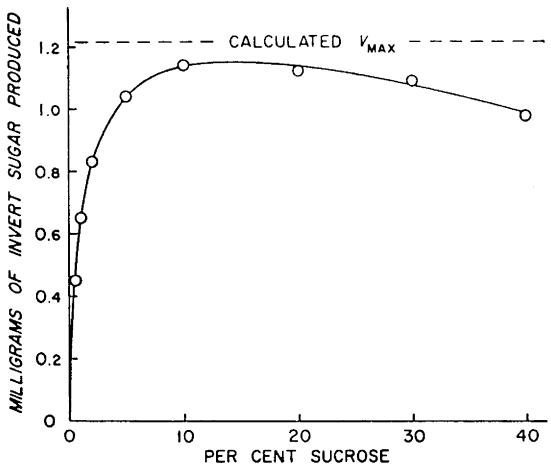

Fig. 2. Influence of substrate concentration upon the hydrolysis of sucrose. Reaction volume 2.0 ml in 0.1 M phosphate buffer pH 6.5. Incubated for 1 h at 37°C. Mg of produced invert sugar determined by the 3,5-dinitrosalicylic acid method. For calculation of v_{max} see Fig. 3.

time unit increased with increasing substrate concentration up to 10 % (0.2920 M) sucrose, but at higher substrate concentration the amount of invert sugar produced (as measured with the 3,5-dinitrosalicylic acid method) decreased somewhat (Fig. 2). This decrease may be caused by transglycosidation, which is marked at concentrations higher than 10 % sucrose, but hardly detectable at 5 % [21]. From the values obtained at substrate concentrations below 10 % the theoretical v_{max} for infinite substrate concentration and the K_s (*i. e.* the substrate concentration at which the initial rate of hydrolysis is half of the v_{max}) were calculated by the graphical method of Lineweaver and Burk [22] as modified by Dixon [23] (Fig. 3). The v_{max} was found to be 1.2 times the rate of reaction in 0.1460 M sucrose, and the K_s was calculated to 2.5×10^{-2} M sucrose.

No action upon raffinose could be detected. A solution of raffinose was mixed with enzyme solution to give a concentration of 0.1460 M raffinose in 0.1 M phosphate buffer pH 6.5. No reducing sugars could be detected after 72 h at 37°C, and only raffinose was found on a paper chromatogram. During the conditions used, a hydrolysis at a rate only 1/1000 of that of sucrose hydrolysis would have been easily detected.

Gal-sucrose (α-D-galactopyranosyl-β-D-fructofuranoside) was available only in a minute quantity (2 mg), and was therefore used in a considerably more diluted solution than the other substrates. For comparison of the results, it was therefore necessary to study the rate of hydrolysis in an equally diluted sucrose solution (Table 1). It is seen, that even in a 0.05 % solution of sucrose, this sugar is rapidly hydrolyzed. Corresponding experiments were then performed with weighed amounts of gal-sucrose (Table 2). As blanks were used

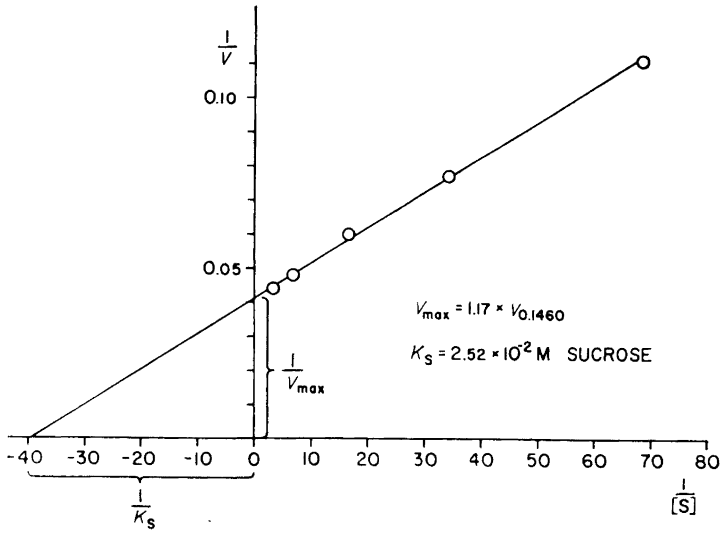

Fig. 3. Graphical determination of v_{max} and K_S for invertase. Temperature 37°C. 0.1 M phosphate buffer pH 6.5.

mixtures of enzyme and buffer, without sugar, incubated in the thermostat for the same time. It was also found necessary to correct the values obtained with gal-sucrose for a small amount of reducing sugar present as a contamination in this sugar (Table 2). No hydrolysis of gal-sucrose could be detected. During the conditions used a hydrolysis at a rate of only 1/500 of that of sucrose would have been easily demonstrated.

Table 1. Hydrolysis of a dilute sucrose solution by intestinal invertase. Sucrose solution, 1 mg/ml in 0.2 M phosphate buffer pH 6.5, is mixed with an equal volume of enzyme solution. After incubation at 37°C, the protein is precipitated with Zn-Ba-reagent, and reducing sugars are determined by the method of Somogyi and Nelson. The sucrose is rapidly hydrolyzed.

Turanose was hydrolyzed with optimum pH between 6.0 and 6.5 (Fig. 1). The initial rate of hydrolysis in 0.1460 M turanose at pH 6.5 and a temperature of 37°C was 0.15 times the rate of sucrose hydrolysis during the same conditions. The K_s was calculated to 2.8×10^{-2} M turanose, and the v_{max} to 1.2 times the rate at 0.1460 M substrate concentration. By paper chromatography turanose was shown to be completely hydrolyzed into glucose and fructose.

Melezitose was also hydrolyzed by the enzyme solution, with an optimum pH equal to that for sucrose hydrolysis (Fig. 1). The rate of melezitose hydrolysis was, however, very low. At 0.1460 M melezitose concentration, pH 6.5, and a temperature of 37°C, the amount of hexoses produced was only 0.003 times the amount produced from sucrose under the same conditions. Calculated as the number of glucosidic linkages split per time unit, the rate of melezitose hydrolysis is 0.004 times the rate of sucrose hydrolysis. The hydrolysis of melezitose proceeds to completion.

In order to find out which of the two glycosidic linkages in melezitose that is hydrolyzed first, the reaction was followed on repeated paper chromatograms, but none of the two possible intermediate disaccharides (sucrose or turanose) could be demonstrated at any stage of the reaction. This is apparently caused by the fact, that these disaccharides are hydrolyzed at a rate so great, compared with melezitose, that whichever of the linkages in the trisaccharide that is hydrolyzed first, the liberated disaccharide is almost instantaneously split. In calculating the rate of melezitose hydrolysis, it must therefore be more correct to compare the number of *completely* hydrolyzed

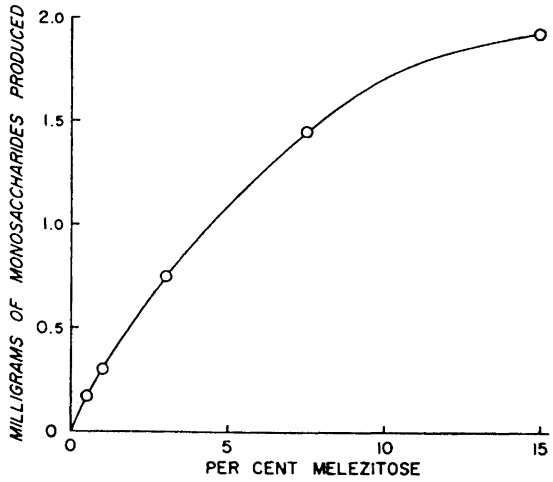

Fig. 4. Influence of the substrate concentration of the hydrolysis of melezitose. Reaction volume 2.0 ml in 0.1 M phosphate buffer pH 6.5. Incubated for 24 h at 37°C. Mg of produced monosaccharides determined by the 3,5-dinitrosalicylic acid method.

melezitose molecules with the number of hydrolyzed sucrose molecules. Calculated in this way, the rate of melezitose hydrolysis is only 0.002 times the rate of sucrose hydrolysis during the conditions used.

The rate of melezitose hydrolysis is rather much increased by increasing the substrate concentration, indicating that the enzyme has a low affinity for melezitose (Fig. 4). The K_s was calculated to 2.6×10^{-1} M melezitose and the v_{max} to 2.8 times the rate at 0.1460 M melezitose concentration.

It is not proven, if sucrose and melezitose really are hydrolyzed by the same enzyme. Both activities are inhibited by tris(hydroxymethyl)-aminomethane (buffer grade, Sigma) at alkaline pH (Fig. 5). This inhibition is caused by competition with the substrate for the enzyme. However, this inhibition seems to be common for several glycosidases, since Larner *et al.*[24] have found that both oligo-1,6-glucosidase and maltase (which they have separated from each other) are inhibited by tris(hydroxymethyl)aminomethane.

DISCUSSION

The findings of Bierry [7], that intestinal invertase has no action upon raffinose, was confirmed. Furthermore, it was found that the new disaccharide gal-sucrose was not hydrolyzed. These facts demonstrate, that intestinal invertase has a very high degree of specificity for the α-D-glucopyranosyl part of sucrose.

Melezitose, on the other hand, was hydrolyzed by the enzyme preparation used, but at a very slow rate as compared with sucrose. At 0.1460 M substrate concentration the hydrolysis of melezitose proceeded with a rate that was only

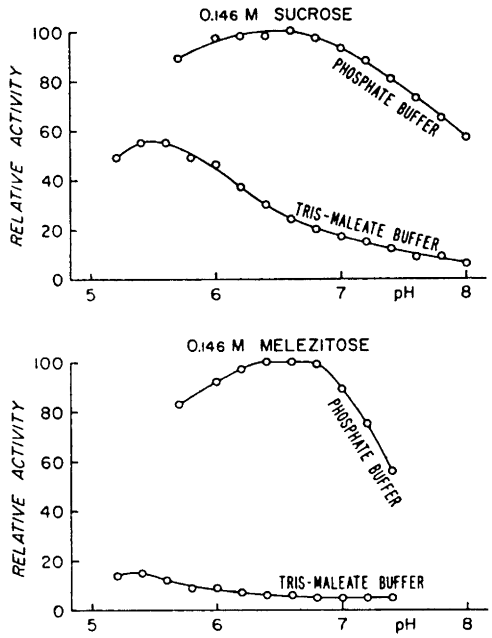

Fig. 5. Inhibition of the hydrolysis of sucrose and melezitose by tris(hydroxymethyl)-aminomethane at alkaline pH. Buffers: 0.05 M phosphate or maleate, respectively, with 0.05 M tris(hydroxymethyl)aminomethane. Maleate buffer without tris(hydroxymethyl)-aminomethane gave the same values as phosphate buffer.

0.002 times the rate for sucrose hydrolysis during the same conditions. The K_s for melezitose hydrolysis is about ten times greater than the K_s for sucrose hydrolysis, which indicates that the slow hydrolysis of melezitose is partly caused by a low affinity for this substrate. By comparing the v_{max} for the two substrates, however, one can see that the most important factor is a slow formation of the hydrolysis products from the enzyme-melezitose complex.

These calculations are valid only for the first hydrolyzed link in melezitose. Because melezitose is hydrolyzed so slowly, compared with sucrose or turanose, it was not possible to determine which of the linkages in the trisaccharide that was hydrolyzed first.

The calculations also presume that melezitose and sucrose are hydrolyzed by the same enzyme. At present no proof for this has been obtained. Conclusions must therefore be drawn with care. The action of purified preparations of intestinal invertase upon melezitose and turanose is under investigation.

It can, however, be stated, that, even if the substitution in the fructofuranosyl part of sucrose does not totally prevent the action of invertase, it interferes strongly with the reaction. It seems therefore probable that intestinal invertase has a marked specificity also for the fructofuranosyl part of the sucrose molecule.

This is in accordance with the recently observed multiple nature of intestinal glycosidases, which contests the view of Weidenhagen, who thought that mammalian intestine contains one single α-D-glucopyranosidase, hydrolyzing maltose, sucrose, and other α-D-glucopyranosides [25,26]. It has been shown that intestinal glycosidase preparations are without action upon α-methylglucoside [27–29]. The activities against *iso*maltose (6-*O*-α-D-glucopyranosyl-D-glucose) and nigerose (3-*O*-α-D-glucopyranosyl-D-glucose) have been partially separated from maltase activity [30–32]. The trehalase activity of intestinal mucosa has been totally separated from invertase and maltase activities, and the invertase and maltase activities partially separated from each other [11]. For a further study of the specificity demands of intestinal invertase, it is therefore necessary to separate the enzyme from the other glycosidases.

Preparation and Infrared Spectra of 1 D-, 2 D-, 1,2 D_2-, and 1,2,2′ D_3- Ethyl Fluorides and Bromides

BØRGE BAK, DANIEL H. CHRISTENSEN, JØRGEN MØLLER and SNEGULKA DETONI*

Chemical Laboratory of the University of Copenhagen, Copenhagen, Denmark

1 D-, 2 D-, 1,2 D_2-, and 1,2,2′ D_3-ethyl fluorides and bromides were prepared. Infrared absorption curves were recorded. In the spectra of the bromides the existence of rotational isomers is demonstrated.

In connection with a microwave determination of the structure of ethyl fluoride, the five isotopic species CH_3CH_2F (I), CH_2DCH_2F (II), CH_2CHDF (III), CH_2DCHDF (IV) and CHD_2CHDF (V) (b. p. —32°C), were prepared. A brief record of their preparation is given here together with the infrared absorption curves of the five intermediates, CH_3CH_2Br (I′), CH_2DCH_2Br (II′), CH_3CHDBr (III′), $CH_2DCHDBr$ (IV′) and CHD_2CHDBr (V′) (b. p. +38°C), referring to the substances in the liquid and the gas phase, and the infrared absorption curves of I—V, referring to the substances in the gas phase.

EXPERIMENTAL

A. Preparations. Henne [1] prepared ethyl fluoride from ethyl bromide and HgF_2. Later, he suggested [2] the use of the more easily available HgF which can be applied at the cost of yield. All five fluorides were prepared by us by the latter procedure, modified, for sake of simplicity, by using sealed-off glass ampullae instead of metal vessels. After twenty experiments in which the temperature, the reaction period, and the C_2H_5Br/HgF ratio were systematically varied it was found most advantageous to work at 110°C for 20 h with a 1:2 ratio between ethyl bromide and mercurous fluoride. Usually, ½—1 ml ethyl bromide was treated in a 50 ml pyrex glass ampulla. Occasional shaking proved to be very important for the magnitude of the yield which was 25—30 % of theory based on ethyl bromide. This amount of purified material was obtained after a crude distillation *in vacuo* from solid reaction products and subsequent gaschromatographical separation on a dry silica-gel column (length 150 mm, diameter 10 mm, temperature 82°C). The infrared spectrum of (I) (gas-phase) was identical with the spectrum published by Nielsen *et al.*[3] Its boiling point was correct (—32°C).

* On leave of absence from the University of Ljubljana, Yugoslavia.

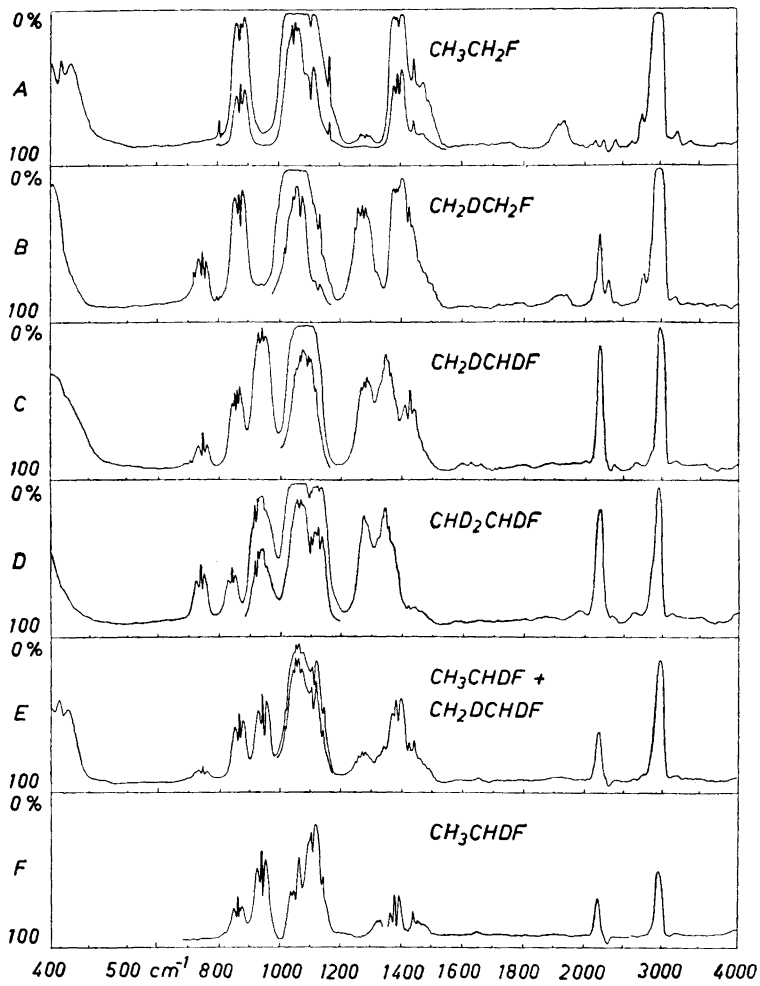

Fig. 1. Infrared spectra of gaseous ethyl flouride (A) and deuterated species (B)–(F) at room temperature. Pressure 150 mm unless otherwise stated. The spectrum (F) is the spectrum of the mixture $CH_3CHDF + CH_2DCH_2F$ (p = 75 mm), run against CH_2DCH_2F (p = 37 mm) in a reference cell (length 10 cm).
Ordinate: percent transmission at 10 cm path length.
Abscissa: wave numbers in cm^{-1}.

(II′)–(V′) were prepared by the reactions:

$$H_2C=CH_2 + DBr \rightarrow CH_2DCH_2Br \qquad (\alpha)$$

$$\left.\begin{array}{l} HC\equiv CH + 2DBr \rightarrow CHDBrCHDBr \ ^{4,5} \\ CHDBrCHDBr \rightarrow CHD = CHD \ ^{4,5} \\ CHD=CHD + HBr \rightarrow CH_2DCHDBr \end{array}\right\} \qquad (\beta)$$

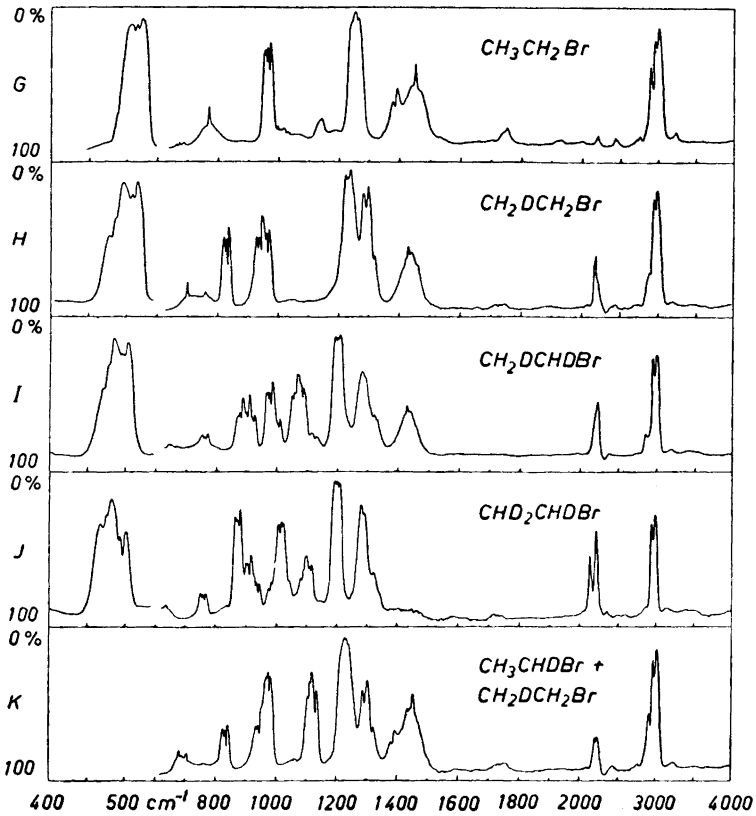

Fig. 2. Infrared spectra of gaseous ethyl bromide (G) and deuterated species (H)—(K) at room temperature. Pressure 70 mm Hg unless otherwise stated. The spectrum (K) is the spectrum of the mixture $CH_3CHDBr + CH_2DCH_2Br$. Because of a mishap, (K) was not run in the 400—600 cm^{-1} region.
Ordinate and abscissa as in Fig. 1.

(III′) was only obtained as a 50 % mixture with (II′):

$$\left.\begin{array}{l} CH_2{=}CHBr + DBr \rightarrow CH_2BrCHDBr \\ CH_2BrCHDBr \rightarrow CH_2 = CHD \ ^{4,5} \\ 2\ CH_2 = CHD + 2\ HBr \rightarrow (II') + CH_3CHDBr \end{array}\right\} \quad (\gamma)$$

$$\left.\begin{array}{l} HC{\equiv}CH + 2\ DBr \rightarrow CHDBrCHDBr \ ^{4,5} \\ CHDBrCHDBr \rightarrow CHD = CHD \ ^{4,5} \\ CHD = CHD + DBr \rightarrow CHD_2CHDBr \end{array}\right\} \quad (\delta)$$

The yield at the processes (α)—(δ) was 90 %. As shown by the infrared absorption spectra no undesired exchange took place. In all cases (including ethylene) the addition of HBr (DBr) took place under ultraviolet irradiation.

B. Infrared spectra. Infrared spectra of (I), (II), (III), (IV) and (V) in the gas phase were recorded on a Perkin-Elmer 21 double beam instrument at room temperature.

Table 1. Raman data [6] and infrared spectra of ethyl bromide and four deuterated species (liquids). Temperature 25°C. Infrared spectra were recorded in the 400—1 500 cm^{-1} region. Cell thickness 0.03 mm. In parenthesis, optical density at peak. The accuracy of the infrared measurements is ± 2 cm^{-1}.

* Not comparable with the numbers 14, 26 and 13 since no Raman data are available.

A cell thickness of 10 cm was applied throughout. Due to the usual band-spread in the spectra of gases a reliable normal vibration analysis on this basis is not possible. Since the spectra of (I)—(V) in the liquid phase were not obtained we shall refrain from extending Nielsen's work [3] on ethyl fluoride, but the spectra are nevertheless given because of their documentary value (Fig. 1).

Infrared spectra of the bromides (I′), (II′), (II′ + III′), (IV′) and (V′) in the liquid phase at room temperature were also taken. The absorption line frequencies are given in Table 1. We have attempted to subtract the lines originating from (II′) in the spectrum of (II′ + III′). For sake of comparison we have included the Raman observations made

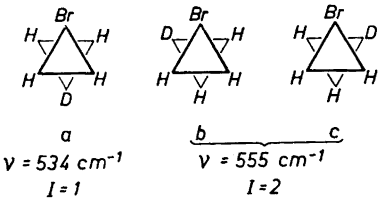

Fig. 3. Rotational isomers (*a*), (*b*) and (*c*) of CH_2DCH_2Br. Since (*b*) and (*c*) are mirror images they are spectroscopically indistinguishable. ν = frequency, I = relative intensity of observed bands.

by Langseth and Bak [6]. These are, *e. g.*, of special value in the identification of the (III′)-lines since Langseth and Bak prepared (III′) by the different process

$$CH_3CHN_2 + DBr \rightarrow CH_3CHDBr,$$

giving a sample not contaminated with CH_2DCH_2Br.

DISCUSSION

The default that no Raman data have been published for (IV′) and (V′) may tentatively be removed by the argument supported by columns 1—6 of Table 1, that the *total* number of different lines observed, either in the infrared or in the Raman spectrum, is approximately equal to the number of observed lines + 4n when n is the number of rotational isomers. Estimated in this way, the number of different bands from (IV′) or (V′) would be, respectively, 20 + 12 = 32 and 22 + 12 = 34. This is probably an upper limit so that for both (IV′) and (V′) we are so far from the number of theoretically observable lines, 39, that it is hard to avoid the conclusion that two of the rotational isomers have many coinciding bands. In fact we believe that these isomers can be pointed out.

In the spectrum of (II′) (Table 1. Two rotational isomers in a 1:2 ratio) it is seen that the rotational isomers absorb near 540 cm^{-1} (C—Br stretching frequencies). Fig. 3 illustrates the situation.

Now, the three spectroscopically distinguishable isomers (IV′) are, in fact, deuterium derivatives of the species in Fig. 3.

According to the Rayleigh rule, which it is legitimate to apply here because of the relatively isolated position of the C—Br band in question (*cf.* Table 1),

$$\nu \text{ (}e \text{ and } f\text{)} \leq 534 \text{ cm}^{-1}$$
$$\nu \text{ (}g \text{ and } h\text{)} \leq 555 \text{ cm}^{-1}$$
$$\nu \text{ (}i \text{ and } j\text{)} \leq 555 \text{ cm}^{-1}.$$

Now, two lines were observed at 526 and 543 cm^{-1}, their intensity ratio being about 1:2. The only solution is that

$$\nu \text{ (}e \text{ and } f\text{)} = 526 \text{ cm}^{-1}$$

$$\nu \text{ (}g \text{ and } h\text{)} \sim \nu \text{ (}i \text{ and } j\text{)} = 543 \text{ cm}^{-1}.$$

Therefore, the C—Br stretching frequencies coincide for the isomers (*g*, *h*) and (*i*, *j*).

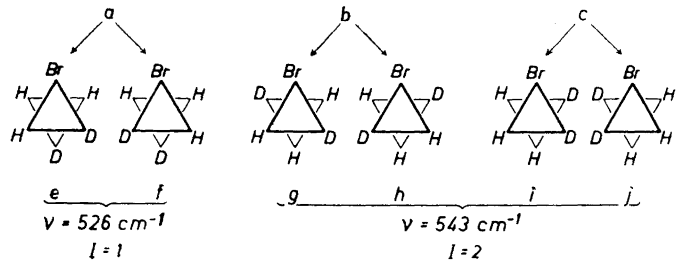

Fig. 4. Rotational isomers of $CH_2DCHDBr$. Since (*e*) and (*f*), (*g*) and (*h*), (*i*) and (*j*) are mirror images there are only three spectroscopically distinguishable isomers.

We can argue in a similar way considering (V′) as a deuterium derivative of (IV′). Selecting (*e*), (*g*), and (*i*) as suitable representatives we get the isomers (*k*), (*l*), (*m*), (*n*), (*o*) and (*p*) (Fig. 5).

According to the Rayleigh rule:

$\nu\ (k) \leq 526\ \text{cm}^{-1}$, $\nu\ (o) \leq 543\ \text{cm}^{-1}$. Since $(k) \equiv (o)$, $\nu\ (o) \leq 526\ \text{cm}^{-1}$
$\nu\ (l) \leq 526\ \text{cm}^{-1}$, $\nu\ (n) \leq 543\ \text{cm}^{-1}$. Since $(l) \equiv (n)$, $\nu\ (n) \leq 526\ \text{cm}^{-1}$.

Also

$$\nu\ (m) \leq 543\ \text{cm}^{-1},\ \nu\ (p) \leq 543\ \text{cm}^{-1}.$$

Again, two lines were observed at 542 and 523 cm^{-1} with an intensity ratio of 1:2. The only solution is that

$$\nu\ (k) \sim \nu\ (l) = 523\ \text{cm}^{-1}$$
$$\nu\ (m) = 542\ \text{cm}^{-1}.$$

It follows from the low number of observed lines in the spectra of (IV′) and (V′) that some coincidence of spectral lines must take place. Since the C—Br stretching frequencies coincide in the spectra of the rotational isomers (*g*) and (*i*), respectively (*k*) and (*l*), the remaining parts of these spectra may also be very similar.

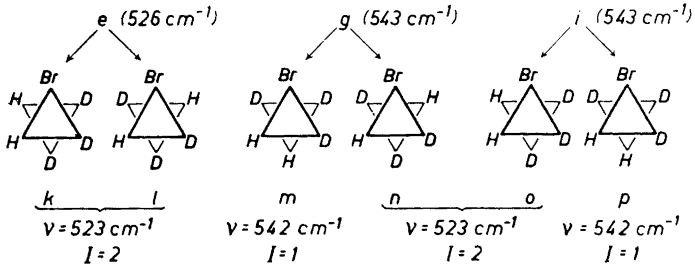

Fig. 5. Rotational isomers of CHD_2CHDBr. Here $(k) \equiv (o)$, $(m) \equiv (p)$, and $(l) \equiv (n)$.

Table 2. Comparison between infrared absorption frequencies of the C—Br stretching vibration of $CH_2DCHDBr$ (IV′) and CHD_2CHDBr (V′) in the liquid and gaseous states. Frequencies in cm^{-1}. In parenthesis, relative intensity.

	$CH_2DCHDBr$			CHD_2CHDBr		
Liquid	526(1)	543(2)		523(2)	542(1)	
Vapour	538.8(1)	556.6(1)	559.2(1)	536.0(1)	536.0(1)	554.7(1)

This postulated closer similarity is in harmony with the fact that (*k*) and (*l*) are identical molecules with respect to the grouping about one carbon atom and mirror images with respect to the grouping about the second carbon atom whereas no such simple relationship exists between (*k*) and (*m*).

In order to see whether the C—Br stretching frequencies of the rotational isomers (*g*) and (*i*), respectively (*k*) and (*l*), are at all separated, spectra of (IV′) and (V′) in the gas phase were run, using a Beckman IR3 spectrograph with a somewhat higher resolution than the Perkin-Elmer instrument. The path length was 10 cm and the pressure 150 mm Hg. In Table 2 the results are summarized and compared with the data for the liquid state.

As seen from Table 2, three distinct Q-branches were observed only in the case of the rotational isomers (*e*), (*g*) and (*i*) with the common formula $CH_2DCHDBr$.

Acknowledgement. We are grateful to Dr. F. A. Andersen for taking the spectra on the Beckman instrument. One of us (S.D.) wants to express her thanks for a Danish Government scholarship.

The Use of Half Width and Position of the Lines in the X-Ray Diffractograms of Native Cellulose to Characterize the Structural Properties of the Samples

JON GJØNNES and NICOLAI NORMAN

Central Institute for Industrial Research, Oslo, Norway

Measurements of the position and half width of the (002)-reflexion for different samples of cellulose I (native) have been carried out. The values of the half widths have been compared with the degree of amorphity determined from a separation of the observed intensity into an amorphous and a crystalline part, and it is shown that this factor increases monotonically with the half width. The structural interpretation of the half width parameter is ambiguous, but its value should be related to the diameter and state of order of the microfibrils.

In a previous paper [1] it has been demonstrated that the X-ray diffractograms of cellulose I (native) to a fair degree of approximation can be interpreted as a superposition of broad crystalline reflexions, each reflexion having the shape of a Cauchy distribution. The normalized intensity distribution can thus be written

$$I(s) = \sum K_j \frac{\alpha_j}{\alpha_j^2 + (s - s_{oj})^2} \qquad (1)$$

where

$s = \frac{4\pi}{\lambda} \sin \Theta$

s_{oj} = peak position
$2\alpha_j$ = half width of the j'th reflexion
K_j = constant depending on the structure factor of the j'th reflexion

Each sample of cellulose I is in this way characterized by the parameters in equation (1). Of these the α_j and s_{oj} can be measured from the diffractograms.

The intensity distribution below $s = 2$ is dominated by the four reflexions (101), (10$\bar{1}$), (02$\bar{1}$) and (002). (101), (10$\bar{1}$) and (002) are of special interest as

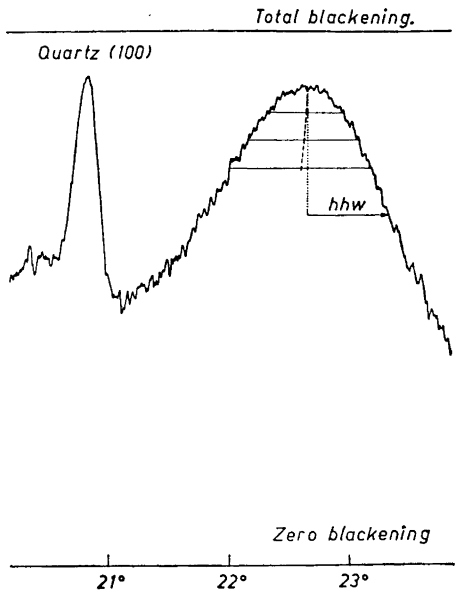

Fig. 1. Part of microphotometer curve. Residue of H_2SO_4 treated surgical cotton.

they give informations about dimensions and lattice distortions in directions normal to the fibre axis. As an accurate determination of the position and half width of (101) and (10$\bar{1}$) is impeded by the superposition of the two peaks, the investigations were restricted to the measurement of the peak position and half width of the (002)-reflexion.

EXPERIMENTAL PROCEDURE

Powder patterns of the investigated samples were prepared in a Guinier vacuum camera using Cu $K\alpha$-radiation. For accurate determination of the (002) peak position the samples were mixed with quartz (15 % by weight) and pressed into thin sheets in a briquetting machine. From the diffractograms film density curves were obtained by means of a recording microphotometer, the angular scale of the diffractograms being determined from the zero mark and the position of the quartz reflexions.

Fig. 1 shows a typical microphotometer curve. The peak abscissa was determined by bisecting horizontal cords and extrapolating to the peak level, as indicated in the figure. The half half-width was measured from the peak abscissa towards the high-angle side of the peak, as the low-angle side is strongly influenced by the (021)-reflexion, especially for samples with low order. The ordinates were read from zero film blackening, *i. e.* no coherent or incoherent background was subtracted.

RESULTS

11 different qualities of cellulose I were investigated. Half widths and peak positions were measured for five samples of each quality, and the mean values are listed in Table 1.

Table 1. (002)-peak position and half width for samples of cellulose I. Degree of amorphity determined by the method of Ellefsen *et al.*[2]

* by definition

Based on the 40 diffractograms for samples 1—8, the standard deviation in peak position and half width for the average values in Table 1 were found to be 0.015° and 0.03°, respectively. For the ground samples the errors are appreciably higher.

DISCUSSION

Owing to the overlap of the reflexions, the correct values of the parameters α and s_0 can only be obtained when the line profile is corrected for neighbouring peaks and the structure independent scattering. In order to carry out such corrections the intensity distribution would have to be normalized, and more thorough considerations be made about line shapes. As the corrections will involve a considerable amount of work and in no case alter the sequence in which the samples can be placed on the basis of half width or peak position, such corrections were omitted. The error in the measured width was estimated from eqn. (1) using the parameters from the previous article [1]. The widths in Table 1 were found to be 5 % and 8 % too high for the cotton and acetate pulp samples, respectively.

The results in Table 1 seem to be in consistency with the technological knowledge of the cotton and pulps involved. A narrow width corresponds to a well crystalline material, a broad peak to a sample of less order, herein included small particle size.

In order to compare the results with other measurements, the Degree of amorphity determined by the method of Ellefsen, Wang Lund, Tønnesen and Øien [2] was calculated for 7 of the samples. The numbers are given in the last column in Table 1. In Fig. 2 the Degree of amorphity is plotted *versus* measured half width, and it can be seen that it increases monotonically with the half width. This result is by no means surprising since the calculated Degree of amorphity is proportional to the normalized intensity at $s = 1.32$ ($2\Theta = 18.6°$) where the adjusted intensity curve for the amorphous material touches

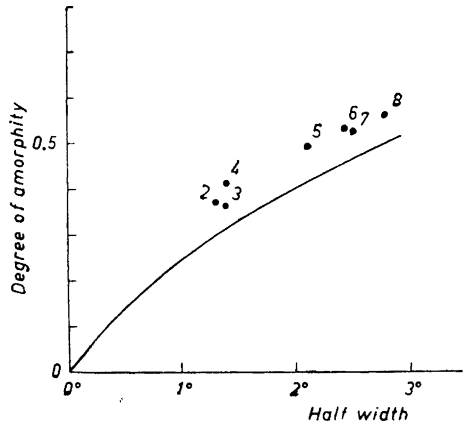

Fig. 2. Degree of amorphity *versus* half width for samples of cellulose I. The numbers correspond to the sample numbers in Table 1. The full drawn curve is based on the calculated intensity from eqn. (1) at $s = 1.32$.

the total intensity curve. Assuming eqn. (1) to be valid and the widths of the four significant (101), (10$\bar{1}$), (021) and (002) peaks to be interdependent in accordance with earlier results [1], an estimate of the total intensity at $s = 1.32$ can be made. The calculations led to the values of the Degree of amorphity represented by the full-line curve in Fig. 2, and it is seen that the plotted values in the same figure follow the trend of this curve.

The data in Table 1 seem to indicate a connection between half width and peak position, an observation which is illustrated in the graphical plot in Fig. 3. The reason for the almost linear decrease in the position of the (002)

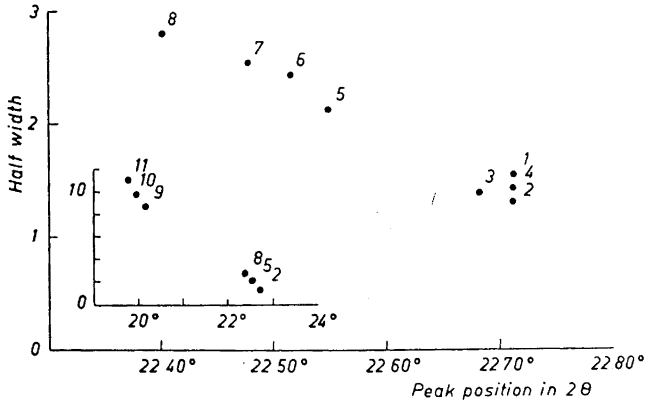

Fig. 3. Half width and position of the (002)-peak for samples of cellulose I. The numbers correspond to the sample numbers in Table 1.

peak with increasing half width may be found in an increase in the average interplanar spacing, though such a conclusion is highly uncertain since shifts in the position of the peak of the observed magnitude may be due to the influence of the other crystalline reflexions.

It is a question whether the measured half width can be associated more directly with structural parameters like the dimensions and intrinsic order of the microfibrils. Also here it is necessary to be cautious as the interpretation of line widths to a certain extent is arbitrary when only one order of the reflexions from a set of lattice planes can be measured. If the broadening of the line is attributed to small particle size only, calculations give a mean particle diameter of 60 Å for cotton and 30 Å for sulfite pulp. These dimensions should be taken as lower limits.

Finally the influence of the experimental technique should be considered. In pressing the samples the fibres are preferentially oriented with their axes in the plane of the sheet. This will for instance lead to a much higher intensity of the (021) peak compared with the (101), (10$\bar{1}$) and (002) peaks in a diffractogram of a sample in a symmetrical transmission set up than in a symmetrical reflexion set up. The position and half width of the (002)-reflexion from some pressed samples were therefore also measured in the Bragg-Brentano focusing set up with a proportional counter. The determination of half widths was further carried out on unoriented samples in the Guinier camera. For the counter measurements it was found a systematic shift of magnitude 0.05° towards higher angles in the peak position, and the half widths decreased 5 to 10 %. The half width determined from the film diffractograms of the unoriented samples led to values between the counter readings and the data in Table 1. When different samples are compared, the same technique should therefore be used in order to obtain the best result.

CONCLUSION

The present X-ray method gives an expedient and accurate prodecure to describe differences in the structural properties of samples of cellulose I. For measuring half widths it is not necessary to add a standard substance, and the line width can be read directly from a microphotometer trace or a counter diffractogram. The interpretation of the half width is somewhat arbitrary, but its value depends on the dimensions and lateral order of the microfibrils.

When the specimen also contains cellulose II, the influence of the new reflexions has to be considered. Further work on cellulose II and of mixtures of cellulose I and II is in progress.

The authors are indebted to cand.real. Ø. Ellefsen for supplying the samples, and they also want to thank Mrs. L. Bryn and Miss T. L. Arstal for their help in preparing the diffractograms. This investigation is part of a research program on the structure of cellulose carried out at the Central Institute for Industrial Research and The Norwegian Pulp and Paper Research Institute. Financial support from the *Royal Norwegian Council for Industrial Research* is gratefully acknowledged. One of the authors (J.G.) is indebted to the *Norwegian Research Council for Science and the Humanities* for financial support.

Immunologic Studies of the Old Yellow Enzyme. A Comparison between the Enzyme and Its Apoprotein

STEN KISTNER

Biochemical Department, Nobel Medical Institute, Stockholm, Sweden

To achieve immunization rabbits were injected with preparations of Warburg's Old Yellow Enzyme (OYE) and its apoprotein. This resulted in the appearance of precipitating antibodies. The antigen-antibody reaction was studied by means of quantitative precipitin reactions and agar gel diffusion experiments. Crude enzyme preparations were found to contain several antigenic components, one of which was identical with the crystalline enzyme. The precipitin reaction between crystalline OYE and antiserum showed a regular behaviour in excess antibody and equivalence zones, and after diffusion in agar gel one single precipitin line was formed. A comparison between OYE and its apoprotein showed an immunologic identity of the two proteins. The coenzyme, flavin mono-nucleotide, did not have hapten activity. The biologic significance of these findings is discussed.

Enzymes, being proteins, may act as antigens. The resulting antibodies, in their reaction with the specific antigen, are often inhibitors of the catalytic activity. The inhibition of enzyme activity by antibodies is a mechanism of considerable biological interest, and has been the subject of a great number of investigations. Recent reviews have been published by Sevag [1,2], Marrack [3] and Cinader [4]. The importance of the catalytic sites on the enzyme molecule in these antigen-antibody reactions has been emphasized. If these sites are identical with the sites of antigenic activity, the binding of antibody takes place here. Another possibility of inhibition arises when the antibodies couple to other parts of the enzyme molecule, causing steric blocking of the catalytic sites. In some instances precipitating antibodies with little effect on the enzyme activity *in vitro* have been obtained [5]. However, such antibodies may afford protection against the catalytic activity *in vivo*, probably because the antigen-antibody complexes are rapidly removed from the circulation [3,5,6].

In many enzymes the catalytic activity is centered in a prosthetic or coenzyme group. These groups are often identical in widely different species. Antibodies formed to fit such groups might then cross-react with enzyme sys-

tems in the immunized organism, causing a non-desirable condition of auto-immunization. It does not appear, however, that antibodies are produced against such structures, but rather against the species specific protein part of the molecule [7,8]. One would therefore not expect these coenzyme groups to act as haptens [1].

Although much work has been done in this field, the role of the catalytic sites in different enzyme — antienzyme* systems has not yet been finally settled. Many difficulties prevent the study of the eventual participation of coenzyme groups as antigenic determinants. In most cases the interaction between coenzyme and the corresponding apoprotein is unknown, in other cases the reversibility of this reaction makes the immunologic studies erratic. The present work is a study of Warburg's »Old Yellow Enzyme» (OYE) using immunologic methods. This enzyme offers certain advantages for such an investigation. It can be prepared in a crystalline form [9], and it has a molecular weight [10] of about 104 000, suggesting good antigenic properties. The coenzyme group is flavin-mononucleotide (FMN), an *iso*alloxazin derivate, which may have the properties of a hapten. OYE contains 2 FMN molecules per mole [9], which can easily be split off [11], and thus the apoprotein is formed. The reaction

$$\text{coenzyme} + \text{apoprotein} \rightleftharpoons \text{enzyme}$$

has been extensively studied by Theorell and Nygaard by fluorescence measurements [12–14]. The equilibrium is shifted far to the right, and thus the enzyme is rather stable, as well as the apoprotein in the absence of FMN.

MATERIALS AND METHODS

1. Preparation of OYE and apoprotein

OYE was prepared from brewer's bottom yeast **, using the method described by Theorell and Åkeson [9]. The light absorption spectrum of crystalline OYE was in good agreement with that found by these authors. The enzyme was stored at 4°C under 80 % saturated ammonium sulphate solution until used. To determine the amount of enzyme and the degree of purity in the different fractions, the light absorption at 464 mμ was measured in a Beckman DU spectrophotometer. Using the value β_{464} for FMN = 2.43×10^7 cm²/mole and FMN-content in OYE = 0.877 %, the amount OYE corresponding to this absorption could easily be calculated. Dry weight determinations were done on the same sample. The degree of purity was expressed as the ratio

$$\frac{\text{amount enzyme found by light absorption}}{\text{amount enzyme found by dry weight determination.}}$$

For the crystalline OYE this "purity index" was 1.00 ± 0.05.

Apoprotein was obtained after dissociation of the enzyme by the procedure of Warburg and Christian [11]. The solutions of apoprotein showed no light absorption corresponding to the 383 mμ or 464 mμ peaks of OYE or the 445 mμ peak of FMN. The activity could be controlled and the concentration determined in a recording fluorescence meter by measuring the ability of the apoprotein to quench the fluorescence of FMN, as described

* In this paper the word »anti-enzyme» is used in the meaning: antibody against enzyme.
** Kindly supplied by Hamburgerbryggeriet, Stockholm.

by Theorell and Nygaard [12]. In all experiments where OYE and apoprotein were compared, the apoprotein was first prepared by cleaving the enzyme. The concentration was determined on a small aliquot of the solution. The rest was divided into two equal parts. FMN, slightly exceeding the equivalence, was added to one part, and a buffer blank to the other. Excess FMN was removed by dialysis. OYE thus obtained by dissociation and reassociation with FMN, showed the characteristic light absorption of the enzyme. The other solution contained an equivalent amount of apoprotein. All experiments were carried out in 0.15 M sodium phosphate buffer, pH 7.4. The "titration" of apoprotein with FMN was done at room temperature.

FMN-solutions were made up from a commercial preparation (Sigma Chemical Company). A fresh solution was prepared the same day as the experiments were carried out and kept in the dark and the cold until used. The concentration was determined by measuring the light absorption [9], using the value β_{445} for FMN = 2.81×10^7 cm²/mole *.

2. Immunization

Four male albino rabbits, 6 months old, weighing 2.5—3 kg, were used for immunization. Rabbit No. 1 received 3 weekly i. m. injections of an enzyme preparation with purity index 0.20. Each injection contained 60 mg substance, as determined by dry weight, corresponding to 12 mg of pure enzyme. For the other rabbits a Freund's adjuvant [15,16] as described by Cohn [17] was used. About 2/3 of the antigen were given in the first injection. Three weeks later the rest was injected i. m. without adjuvant as a booster dose. Rabbit No. 2 received 32 mg of a preparation with purity index 0.70 (corresponding to 22 mg of pure enzyme). For the last two rabbits an enzyme preparation with purity index 0.56 was used. The enzyme was dissociated, and one part of it reassociated with FMN. Each part contained 54 mg (corresponding to 30 mg of pure enzyme or the equivalent amount of apoprotein, respectively). Rabbit No. 3 received the OYE, and No. 4 the apoprotein.

Blood samples were collected by puncturing the central artery of the ear. Before immunization 10—12 ml of blood were taken from each animal to obtain serum for control experiments. 7—10 days after the last injection the rabbits were anaesthetized and a cannula inserted into the left carotid artery. In this way 50—100 ml of blood were collected from each rabbit. The blood was allowed to clot at room temperature, and the clot retraction accomplished by incubation at 37°C for 30 min. Serum was sucked off and stored at —15°C in small aliquots. When used for experiments it was 1—3 months old.

3. Precipitin reactions

The appearance of precipitating antibodies in the immune-sera was checked by ring tests [18]. Quantitative precipitin reaction [19] was performed, using ultraviolet absorption spectroscopy to measure the precipitate [20,21]. Antigen solution in 0.15 M sodium phosphate buffer pH 7.4 was mixed with 1 ml serum. The volume was kept constant at 2.5 ml. The incubation time was 60 min at 37°C, followed by 48 h at 4°C. The precipitates were washed twice in saline in the cold and dissolved in 0.25 M acetic acid [21] to a volume of 3.0 ml. The absorption was read in a Beckman DU spectrophotometer at 277 mμ, where antigen as well as precipitate in acetic acid solution had a maximum. The extinction coefficient of the antigen had previously been determined. In excess antibody and equivalence zones the optical density of the antibody could be obtained by subtracting the optical density of antigen from that of the precipitate [21].

Control experiments were run, using serum from the immunized animals, but collected before immunization.

---

* FMN Sigma contains some impuriries [12]. The apoprotein reacts, however, preferentially with the component identical with FMN from OYE [12-14]. With FMN in excess, the OYE obtained in these association reactions could therefore be expected to be identical with the product obtained, when FMN from OYE is used.

4. Electrophoresis

Paper electrophoresis was performed, using Durrum's technique [22], in barbiturate buffer pH 8.6, ionic strength 0.075, for 16 h at 100 V, on 30 cm long Whatman No. 1 paper strips. Staining of proteins was done for 16 h in 0.01 % bromophenol blue, the fractions were cut out, eluted in 0.01 N NaOH, and the absorption read at 590 mμ[22]. To correct for different uptake of stain by albumins and globulins, the values obtained for globulins were multiplied by 1.3.

5. Antigen-antibody reactions in agar gel

The technique described by Ouchterlony was used [23]. The gel contained 1.5 % agar, 0.15 M sodium phosphate buffer pH 7.4, and merthiolat 1:10 000. The reactions were performed in sealed Petri dishes. A 50 × 50 mm glass plate was placed in the bottom of each dish under the agar [24]. Antigen and antibody were added in concentrations close to their equivalence ratio. Incubation was done at 4°C, room temperature, or 37°C for different periods of time. In some experiments the basins were refilled 2 or 3 times, each filling consisting of 0.15—0.20 ml. After the reactions were completed, the gel was washed in saline, distilled water, and finally dehydrated with ethyl alcohol [24]. The gel was cut along the sides of the glass plate and allowed to dry at room temperature [25]. In this way a thin film containing the precipitin lines was obtained on the glass plate. These preparations were stained for 20—30 min in a solution of azocarmine B containing 10 % acetic acid and 50 % methyl alcohol. Excess stain was removed by washing the film in the solvent. After this procedure the precipitin lines showed a strong red colour, whereas the rest of the film was practically without colour.

Buffer solutions of OYE and apoprotein were used as antigens. They were tested against sera from the immunized animals, collected before and after immunization. 1/10 volume EDTA-solution (1 g sequestrene-Na_2 and 0.7 g NaCl per 100 ml solution) was added to all sera. In absorption experiments different amounts of OYE or apoprotein were added in the basins containing serum. Absorbed sera were tested against OYE and apoprotein solutions. All experiments were run in duplicate.

RESULTS

Precipitating antibodies were found in the serum of all animals on the 4th week of immunization. In rabbits receiving adjuvant, antibodies appeared even before the booster-dose was given. Paper electrophoresis of the sera showed a relative decrease of the albumin fraction and increase of globulin fractions, especially β and γ, following immunization in all animals. These changes were essentially the same, regardless of the technique of immunization, and whether OYE or apoprotein was used as antigen.

Quantitative studies of the precipitin reaction showed a regular behavior of the OYE-anti-OYE system in excess antibody and equivalence zones. Plotting the amount of antigen added against the amount of precipitate formed gave a parabolic curve. When, according to the equation of Heidelberger and Kendall [19], the amount of antigen added was plotted against the ratio

$$\frac{\text{antibody precipatated}}{\text{antigen precipitated}} \quad (R)$$

a straight line was obtained. Curve A of Fig. 1 shows the results, when a crystalline preparation of OYE was tested against an anti-OYE serum. In excess antigen zone there is a rather slow decline of the curve. Even in large

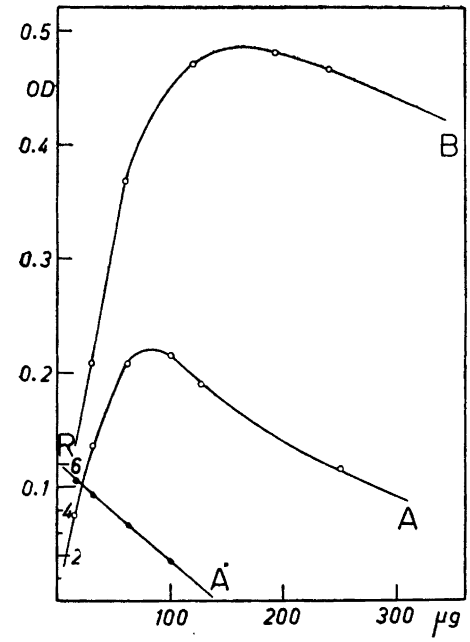

Fig. 1. Quantitative precipitin reaction. Anti-OYE serum from a rabbit, immunized with a total of 54 mg of an enzyme preparation with purity index 0.56 (No. 3). Curve A shows the reaction with crystalline OYE, purity index 0.97, as antigen. A′ is the corresponding line, obtained by plotting the amount of antigen added against $R\left(\frac{\text{antibody precipitated}}{\text{antigen precipitated}}\right)$. In B the antigen is an enzyme preparation with purity index 0.52. See text.

excess antigen, *i.e.* 5 times as much as the amount needed to reach the equivalence zone, there was a small precipitate formed. This behaviour of the system will be further commented on in the discussion. The reaction did not show the same regularity when an impure enzyme preparation was tested against the same serum. Also, the equivalence point was moved towards higher concentrations of antigen, (Curve B, Fig. 1). The antigen in this case contained about 50 % OYE, and about twice as much as of crystalline OYE was needed to reach the equivalence point. This did not, however, indicate that OYE was the only reacting antigen, since the precipitate formed was much larger [26]. In this latter case the decline of the curve in the antigen excess area was even less pronounced than in the reaction, where crystalline enzyme was used as antigen.

Hapten reactions [18] were performed in the equivalence zone, using crystalline OYE as antigen. The antiserum was incubated with FMN before adding the enzyme. The concentration of FMN was determined on the basis of the amount of OYE taking part in the reaction. Thus, in different experiments incubation with 1 to 20 moles of FMN per mole of OYE was tried. In no case did the presence of FMN reduce the formed precipitate significantly nor was a precipitate formed when FMN alone was incubated with antiserum.

When crystalline OYE reacted with anti-OYE serum after diffusion in agar gel, only one precipitine line was formed, whereas impure preparations caused the appearance of several lines. The two antigen solutions were tested simultaneously against the same serum, using agar plates with 3 basins, as

Fig. 2. Antigen-antibody reaction in agar gel. The gel contained 3 basins, arranged as described in Ref.[23]. Antigens and antiserum were the same as in the experiments illustrated in Fig. 1. The upper left basin contained the crystalline OYE, 0.1 mg/ml, the upper right contained the impure enzyme, 0.2 mg/ml, and the lower basin contained the anti-OYE serum. The basins were filled 4 times. Incubation at 37°C. Lines appeared after 24–36 h. Note the fusion of the single line on the left side, representing the reaction between the crystalline OYE and antiserum, into one of the 4 lines on the right side (crossing the first and completely fusing into the second line from the left).

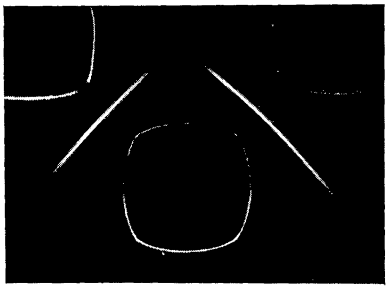

Fig. 3. Antigen-antibody reaction in agar gel. Anti-OYE serum in the lower basin tested against an OYE-preparation (purity index 0.60, 0.15 mg/ml) in the upper left basin and the equivalent apoprotein solution in the upper right. The basins were filled three times. Incubation at 37°C. Three lines appeared on each side of the serum basin after 24–36 h, forming a symmetric pattern, with the lines on one side fusing into those on the other side.

described in Ref [23]. Crystalline OYE was added in one basin, a crude enzyme preparation in another, and antiserum in the middle. The line formed between the crystalline enzyme and antiserum fused into one of the lines formed between the crude enzyme and serum. Fig. 2 is a photograph of such an experiment, where antigens and antiserum tested were the same as those in the quantitative precipitin reactions illustrated in Fig. 1. Similar results were obtained with all anti-OYE sera. Incubation at lower temperatures did not alter the results, although a longer time was necessary for the lines to develop. Leaving the plates at 4°C for several weeks did not result in the appearance of more precipitin lines. Negative results were consistently obtained in these experiments when sera from the immunizied animals, collected before immunization, were tested.

Different preparations of OYE were compared with corresponding apoprotein solutions (see Material and Methods, 1) in similar experiments. The pattern of lines between OYE and anti-OYE serum was identical with that between apoprotein and the same serum, and the lines on one side fused into those on the other side (Fig. 3). When crystalline OYE and apoprotein, obtained after cleaving the crystalline enzyme, were tested, one line was formed on each side of the serum basin (Fig. 4). When the same experiments were repeated using anti-apoprotein serum, the results were identical with those obtained with anti-OYE serum.

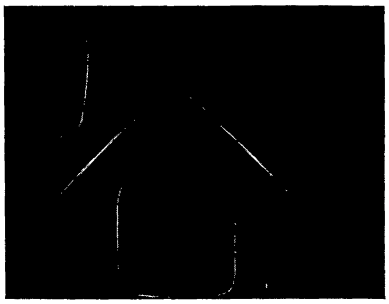

Fig. 4. Antigen-antibody reaction in agar gel. Anti-OYE serum in the lower basin tested against a solution of crystalline OYE, 0.1 mg/ml, in the upper left basin, and an equivalent solution of apoprotein in the upper right. The basins were filled 4 times. Incubation at 37°C. The lines appeared after 24 h. An identical result was obtained when the same antigens were tested against an anti-apoprotein serum.

A rough estimation of the sensitivity of the agar gel diffusion technique was done when 10 μg of crystalline OYE were tested against the equivalent amount of serum, as found by quantitative precipitin reaction. A clearly visible line was obtained.

Anti-OYE and anti-apoprotein serum from rabbits Nos 3 and 4 were tested after absorption with antigen. Only crystalline OYE and apoprotein from crystalline OYE, respectively, were used in these experiments. The equivalence point of each serum with the homologous antigen was determined. Serum and the equivalent amount of antigen were mixed in one basin in an agar plate and tested against OYE and apoprotein. Antigens, used for absorption, were then reversed, *i.e.* anti-OYE serum was absorbed with apoprotein and vice versa. In no experiment did the absorbed serum retain the ability to react with either OYE or apoprotein. The two antigens seemed able to replace each other, and to absorb homologous as well as heterologous serum.

DISCUSSION

Attempts to immunize rabbits with preparations of OYE have previously been made by Várterész and Kesztyüs [27]. The antigen used was a crude enzyme preparation. These workers found no precipitating or complement fixating antibodies, nor was the activity of the enzyme inhibited by the antiserum. Their conclusion was that OYE lacks antigenic properties, possibly due to identical structure in different species. This opinion clearly differs from the common concept of protein specificity, and has also been criticized [1,28]. Considering later investigations it appeared even more probable that antibodies against OYE could be obtained, since immunization with crystalline yeast enzymes had been successful [29,30]. Results of the present work show that crude preparations of OYE contain several antigenic components. One of these is evidently identical with the crystalline OYE.

When crystalline OYE reacted with anti-OYE serum, a precipitate was formed. Quantitative studies showed a regularity of this reaction in excess antibody and equivalence zones, suggesting a single antigen-antibody system [26]. There was still a precipitate formed in rather large excess antigen. This may be an indication of impurities in the antigen, or of cross-reactions with several antibodies. Certain antigens, however, although of somewhat different type,

have been described to cause this type of reaction (see Ref [26]). Also, in this particular case the method employed influenced the curve. At the wave length where the precipitates were measured, the extinction coefficent of crystalline OYE is higher than that found for different rabbit antibodies [21]. Precipitates formed in excess antigen thus caused a relatively high absorption. — A careful analysis of the quantitative precipitin reaction was not done because of the shortage of material. It was mainly employed to determine optimum reaction conditions for other experiments.

The reaction between crystalline OYE and anti-OYE serum in agar gel diffusion experiments resulted in a single precipitin line. This is an indication of antigenic homogeneity of the material. Also it appeared that the precipitate was the result of the reaction between enzyme and specific antibody. A cross reaction with some other yeast protein antibodies was not likely, since the precipitin line fused into an identical line on the site of reaction between antiserum and crude enzyme, which contained the same concentration of pure OYE as did the crystalline preparation (Fig. 2). The existence of an eventual homologous antigen in this area would have prevented a cross reaction to occur here [31,32], and the line between the crystalline enzyme and serum on the left side would probably have shown partial coalescence [33] into the line representing the reaction between the homologous antigen and serum on the right side. The complete fusion of the two lines into an arc that now occurred is evidence of identical antigen on both sides [23,33]. The same antigen diffused from the basins containing crystalline and crude enzyme.

OYE and apoprotein showed same reactivity with anti-OYE as well as anti-apoprotein serum. Both sera were equally absorbed with any one of these antigens. Also, FMN did not have the effect of a hapten. The enzyme and its apoprotein were identical from the immunologic point of view. The coenzyme group was apparently not engaged in the antigenic active part of the enzyme molecule or in the binding to antibody.

It may be asked whether injection of OYE and apoprotein into the animals actually ment the introduction of two different antigens. Injected OYE could hardly have dissociated to any great extent because of the firm association between FMN and apoprotein*. On the other hand, it may be postulated that injected apoprotein associates with free FMN *in vivo* to form flavoprotein. If this is true, apoprotein, for all practical purposes, is immunologically identical with OYE. Such an association could not be assumed to take place in the *in vitro* experiments. The assumption that the coenzyme group does not take part in the immunologic active part of the enzyme molecule therefore appears to be valid. The biologic importance of this finding has already been discussed in the introduction. Production of antibodies reacting with structures common to the immunized organism, does not seem beneficial. Antibodies against the

* The equilibrium constant in the dissociation reaction of OYE has been determined by Theorell and Nygaard. It was found to be around 0.7×10^{-8} in a buffer of pH 5.75, containing 0.25 M Na-phosphate and 0.4 M NaCl [12]. At pH around 7 and lower Cl^- the constant is considerably decreased [13]. It is therefore very unlikely that injected OYE dissociated to any notable extent. At least this could not be true in rabbit No. 1, which was immunized with injections of enzyme without adjuvant, and results with immune serum from this rabbit were in good agreement with those obtained with serum from the other animals.

enzyme may still inhibit the activity. This problem is presently under investigation. It is possible, however, that replacement of the coenzyme group with some structually related compound, as perhaps happens in chemotherapy [34], may alter the antigenic behaviour of the enzyme.

Studies on Histidyl Peptides

II. The Synthesis of L-Histidyl-L-Leucine and its Optical Homogeneity

DIMITRIOS THEODOROPOULOS*

Department of Medical Biochemistry, University of Gothenburg, Sweden

The potentialities of the new procedure [1] for the incorporation of an histidine residue into synthetic peptides have been demonstrated during the synthesis of several histidine and histidyl peptides [2]. The latter were obtained through condensation of carbobenzoxy-*im*.benzyl-L-histidine (I) with amino acid esters for which purpose the carbodiimide method [3] for the peptide bond formation was employed. Owing to the slight solubility of (I) in various organic solvents and especially in cold, its condensation was accomplished in dimethylformamide solution although at a higher temperature than that customarily used. This alteration naturally raises speculations regarding the optical homogeneity of peptides thus produced. It has also been reported recently from two different laboratories [4,5] that, as a condensing agent, carbodiimide yields partly racemized peptides in certain cases. Among the factors which influence racemization, it has been found that temperature and solvents predominate.

Consequently, it was considered desirable to reveal whether racemization takes place while (I) is being coupled with amino acid esters under the experimental conditions previously described [2], and if possible, to eliminate such a risk by carrying out the reaction at a lower temperature.

When (I) was coupled with L-leucine benzyl ester in the same way as previously reported [2], the product, carbobenzoxy-*im*. benzyl-L-histidyl-L-leucine benzyl ester (IIa) showed an $[\alpha]^{22}D$ value of $-13.4°$ (*c* 3.6 in glacial acetic acid).

Alternatively, the same product was synthesized by mixing (I) with the equivalent amount of triethylamine in dimethylformamide or methylene chloride, thus causing the carbobenzoxy derivative to dissolve, followed by addition of the equivalent amount of L-leucine benzyl ester *p*-toluenesulfonate [6] and carbodiimide. The above modification not only facilitates the condensation of (I) at room temperature but more-over, produces better yields. Carbobenzoxy-*im*.benzyl-L-histidyl-L-leucine benzyl ester (IIb) was thus obtained at a rate of 65 % as against 50 % yield produced by the previously described procedure [2].

It is signifficant that compounds (IIa) and (IIb) showed identical optical rotations and melting points.

This evidence, however, does by no means exclude the possibility that compounds (IIa) and (IIb) have suffered racemization to the same extent during their syntheses. Carbobenzoxy-*im*.benzyl-L-histidyl-L-leucine benzyl ester, prepared by either of the two above mentioned processes, was therefore converted into free peptide L-histidyl-L-leucine, and the optical value of the latter was compared to that reported by Holley and Sondheimer [7]. These authors synthesized L-histidyl-L-leucine by he azide procedure which, up to the present, has been believed to cause no racemization.

Carbobenzoxy-*im*.benzyl-L-histidyl-L-leucine benzyl ester was hydrogenated in the presence of palladium black or reduced by sodium in liquid amonnia [8], to produce L-histidyl-L-leucine.

* Research Fellow at the University of Gothenburg under funds defrayed by A. B. Marabou.

The obtained peptide, L-histidyl-L-leucine, showed and $[\alpha]^{22}D$ value of 45.2° as a 1 % solution in 0.10 N sodium hydroxide, practically identical with the reported $[\alpha]^{22}D$ value of 43.5° as a 1 % solution in 0.10 N sodium hydroxide. This finding emphasizes the capability of the new procedure [1] in producing optically active histidyl peptides.

EXPERIMENTAL

Carbobenzoxy-im.*benzyl*-L-*histidyl*-L-*leucine benzyl ester. A. Modified procedure.* To a suspension of 1.89 (0.005 mole) of carbobenzoxy-*im*.benzyl-L-histidine in 30 ml of dimethylformamide, 0.5 g (0.005 mole) of triethylamine was added. This caused the carbobenzoxy derivative to dissolve almost completely. A solution of 1.89 g (0.005 mole) of L-leucine benzyl ester *p*-toluenesulfonate in 10 ml dimethylformamide was then added, followed by the addition of 1.1 g of carbodiimide. The mixture was stirred overnight at room temperature, and di*cyclo*hexylurea was subsequently removed by filtration. The solution was treated in the manner described below and the peptide derivative thus obtained at 65 % yield, melted at 112—114° and showed an optical rotation of $[\alpha]^{22}D$ —13.8° (*c*, 3.5 in glacial acetic acid). (Found: C 70.2; H 6.80; N 9.80. Calc. for $C_{34}H_{38}O_5N_4$: C 70.08; H 6.57; N 9.61.) B. Carbobenzoxy-*im*.benzyl-L-histidine (0.005 mole) was treated with L-leucine benzyl ester (0.005 mole) and 1.1 g of carbodiimide as previously described [2]. Di*cyclo*hexylurea was filtered and the solution diluted with 500 ml of water. The precipitating product was recrystallized by dissolving in ethylacetate followed by addition of petroleum ether. Yield 1.4 g (50 %), needles, m. p. 112—114°, $[\alpha]^{22}D$ —13.4° (*c*, 3.6 in glacial acetic acid).

Carbobenzoxy - im.*benzyl* - L - *histidyl* - im.*benzyl* - L - *histidine benzyl ester.* Carbobenzoxy-*im*.benzyl-L-histidine (1.89 g) was dissolved in 30 ml of methylene chloride by addition of 1.01 g of triethylamine. To this solution 3.4 g of *im*.benzyl-L-histidine benzyl ester di-*p*-toluenesulfonate dissolved in 5 ml of methylene chloride and 1.1 g of di*cyclo*hexylcarbodiimide were then added. After 12 h the di*cyclo*hexylurea was filtered and the solution washed with water. It was then dried over Na_2SO_4 and the solvent evaporated *in vacuo*. The residue was crystallized by addition of ether. It was recrystallized from ethylacetate-petroleum ether. Yield 2.2 g (65 %), small needles, m. p. 137°, (reported [2] 137°), $[\alpha]^{22}D$ —23.3° (*c*, 4.5 in glacial acetic acid), reported $[\alpha]^{22}D$ —22.3° (*c*, 5.3 in glacial acetic acid).

L-*Histidyl*-L-*leucine. By catalytic hydrogenation.* A solution of 1.48 g of carbobenzoxy-*im*.benzyl-L-histidyl-L-leucine benzyl ester in 25 ml of dimethylformamide-water (1:1) was hydrogenated in the presence of 200 mg of palladium black. Half an h later a thick mass was formed and then an equal portion of 50 % ethanol followed by 500 mg of palladium on charcoal were added. Since no more CO_2 was evolved, the hydrogenation continued in a closed apparatus for 24 h. At that time all the precipitate was redissolved. The catalyst was filtered, washed with 50 % ethanol and the combined filtrates evaporated *in vacuo*. The product was recrystallized in accordance with the directions of Holley and Sondheimer [7]. Yield 300 mg (70 %), m. p. 220—222° (reported [7] 214—217°), $[\alpha]^{22}D$ —45.2° (*c*, 1 in 0.10 N NaOH), reported [7] $[\alpha]^{22}D$ —43.5° (*c*, 1 in 0.10 N NaOH).

im.*Benzyl* - L - *histidine benzyl ester di-p-toluenesulfonate.* This compound was prepared in the same way as described for the corresponding dibenzenesulfonate derivative [2]. The product was obtained in 80 % yield when recrystallized by dissolving in *iso*propyl alcohol and precipitating by addition of ether, m. p. 176—177°. (Found: N 6.05. Calc. for $C_{34}H_{39}O_8N_3S_2$: N 6.16.)

A Simple Apparatus for Making Holes in Agar Plates

DANLEY A. CALLIERI

Royal Institute of Technology, Division of Food Chemistry, Stockholm, Sweden

The cup-plate method for vitamin and antibiotic assays is nowadays widely used because of its simple technique and the satisfactory results obtained. Nevertheless, when the number of samples is very large considerable time is taken to make the numerous holes in the agar plates by means of the cork-borer technique. Some mechanical apparatuses combined with suction have been tested, but without satisfactory results as the holes produced are not sufficiently sharp-edged and clean-cut. Moreover, the agar surrounding the holes is often lifted from the bottom of the plate due to the suction.

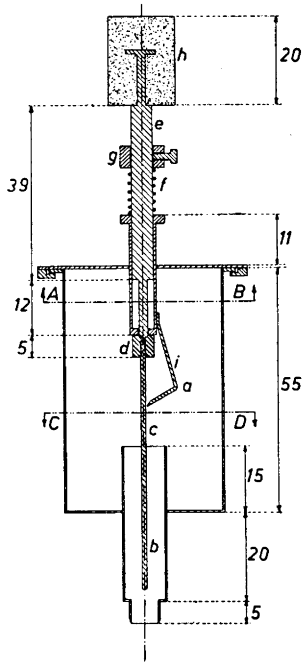

Fig. 1.

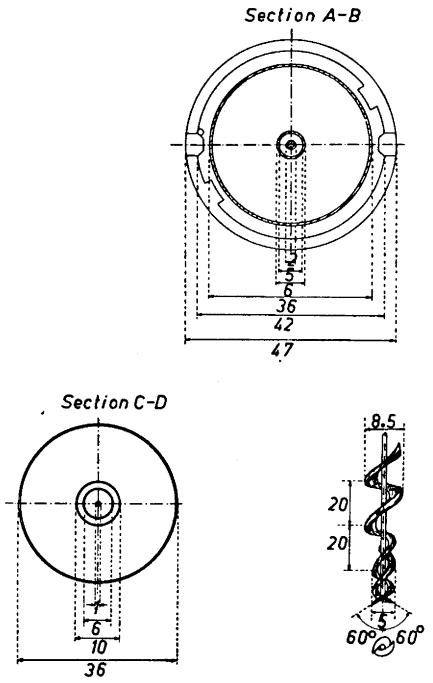

Fig. 2.

The apparatus described below does not require any suction, has a simple design, makes sharpedged and clean holes. It is easy to keep clean and does not need the help of any other device, which provides a high degree of independence in its use. The best material for the construction of this apparatus is stainless steel.

Description. The apparatus consists of two separable parts, part I and part II.

Part I. The shape and the dimensions (in mm) can be seen in Fig. 1. This part consists of the cylinder (a) in which the pieces of agar are collected as they are taken up from the plate, and the cylinder (b) which cuts the agar and brings the pieces of agar into the cylinder (a) by means of a helical conveyer. For the sake of simplicity the helical conveyer does not appear in Fig. 1 but is seen in detail in Fig. 2.

Part II consists of the lid and the following parts attached to it:

(c) Shaft of the helical conveyer.
(d) Device to join the shaft in such a way that the shaft or helical conveyer

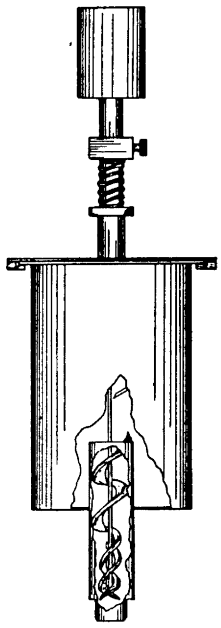

Fig. 3.

can be changed if it breaks or becomes defected during use. Part (d) acts also as a stop for the piston on its way up.

(e) Piston.

(f) Spring which brings the piston up automatically, once the hole has been made. This movement allows a more perfect function of the apparatus because it cleans the terminal and narrowest part of the cylinder (b).

(g) Movable part (attached to the piston by a screw) which acts as a stop for the piston on its way down. It permits adjustment of the effective length of the piston thereby bringing the ends of the helical conveyer into the most favourable working position.

(h) Knob.

(i) Wiper to remove the pieces of agar attached to the shaft by making them fall into cylinder (a).

Procedure. The apparatus is placed on the agar plate and pushed down vertically to cut the agar. The piston is pushed down and turned simply by rotating the knob between the thumb and the forefinger. In this way the pice of agar is taken up by the helical conveyer. On releasing the downward pressure on the screw-cap the piston readily slides up into its initial position.

Capacity. 100–120 holes/min.

Conjugate Additions of Grignard Reagents to alpha, beta-Unsaturated Esters IV. Cuprous Chloride Catalysed Additions to Ethyl Esters

JON MUNCH-PETERSEN

Organisk-Kemisk Laboratorium, Polyteknisk Læreanstalt, Copenhagen, Denmark

Additions of Grignard reagents to *sec*-butyl esters of α,β-unsaturated acids, such as crotonic, tiglic and cinnamic acids, have been found to usually take place at the double bond (1,4-addition) [1] whereas, in general, additions to the corresponding ethyl esters take place predominantly at the carbonyl group (1,2-addition). However, in certain cases 1,4-addition to *sec*-butyl esters does not occur to any appreciable extent. This is for instance the case in some recently described [2] additions of methylmagnesium bromide, but it was found [2,3] that the presence of cuprous chloride during the addition of the esters to the Grignard reagent would secure fair to good yields of 1,4-addition products. It was further found that these yields were obtained not only with *sec*-butyl esters but also with ethyl esters. Crotonic esters thus gave the corresponding *iso*valeric esters, whereas tiglic and cinnamic esters gave saturated ketones as results of both 1,4- and 1,2-addition.

The present investigation was carried out as a consequence of the above-mentioned findings in order to establish if 1,4-addition products would also with higher Grignard reagents be the major products from ethyl esters in the presence of cuprous chloride, thus avoiding the use of *sec*-butyl esters. As model reactions the additions

Conjugate Additions of Grignard Reagents to alpha, beta-Unsaturated Esters IV. Cuprous Chloride Catalysed Additions to Ethyl Esters

JON MUNCH-PETERSEN

Organisk-Kemisk Laboratorium, Polyteknisk Læreanstalt, Copenhagen, Denmark

Additions of Grignard reagents to *sec*-butyl esters of α,β-unsaturated acids, such as crotonic, tiglic and cinnamic acids, have been found to usually take place at the double bond (1,4-addition) [1] whereas, in general, additions to the corresponding ethyl esters take place predominantly at the carbonyl group (1,2-addition). However, in certain cases 1,4-addition to *sec*-butyl esters does not occur to any appreciable extent. This is for instance the case in some recently described [2] additions of methylmagnesium bromide, but it was found [2,3] that the presence of cuprous chloride during the addition of the esters to the Grignard reagent would secure fair to good yields of 1,4-addition products. It was further found that these yields were obtained not only with *sec*-butyl esters but also with ethyl esters. Crotonic esters thus gave the corresponding *iso*valeric esters, whereas tiglic and cinnamic esters gave saturated ketones as results of both 1,4- and 1,2-addition.

The present investigation was carried out as a consequence of the above-mentioned findings in order to establish if 1,4-addition products would also with higher Grignard reagents be the major products from ethyl esters in the presence of cuprous chloride, thus avoiding the use of *sec*-butyl esters. As model reactions the additions

of *n*-butylmagnesium bromide to ethyl crotonate, tiglate and cinnamate have been tried. The results are given in Table 1.

In the case of crotonic esters a good yield of simple 1,4-addition product was indeed obtained, and it appears as if in this case the two alternative procedures to prepare β-methylsubstituted fatty acids are equally good. In fact, when the conditions of the procedure previously described [1,2] were otherwise observed, it was found that no particular precautions with respect to the quality of cuprous chloride and the cooling of the reaction mixture were necessary: cooling in ice-water and the use of commercial cuprous chloride (Merck, p.a., without any previous reduction or drying) were sufficient to secure the same yield as was obtained in the non-catalyzed reaction with *sec*-butyl crotonate.

Methyl crotonate, with *n*-butylmagnesium bromide in the presence of cuprous chloride, has previously [3] been found to give 1,4-addition, although, in this case, the primarily produced ester self-condensed to give an acetoacetic ester.

When no cuprous chloride is used, ethyl crotonate has been found to give a mixture of different compounds, including large amounts of high-boiling material.

In the case of the cuprous chloride catalyzed reaction with ethyl tiglate, the simple 1,4-addition product (α,β-dimethyl-substituted ester) was not formed, but the saturated ketone (resulting from both 1,4- and 1,2-addition) was produced, as was the case when methylmagnesium bromide [2] was used. Only a 45 % yield was obtained.

With ethyl cinnamate and *n*-butylmagnesium bromide a 15 % yield of the simple 1,4-addition product, 3-phenylbutyric ester, was obtained.

It may be concluded that, as a practical procedure for preparing substituted fatty acids from α,β-unsaturated acids (by the conjugate addition of Grignard reagents), the cuprous chloride catalyzed reaction with ethyl esters is not as generally applicable as the use of *sec*-butyl esters; although 3-methyl-substituted acids (from crotonic esters) do arise in equally good yields by the two methods.

Table 1. Additions of *n*-butylmagnesium bromide to ethyl esters of α,β-unsaturated acids.

Ethyl ester	Product	Yield %	b. p. °C	Refractive index
Crotonic	ethyl 3-methylheptanoate [a]	70—74	89— 90/20 mm 81/15 »	n_D^{20} 1.4186
Tiglic	6,7-dimethylundecanone-5 [b]	45	118—119/15 »	n_D^{25} 1.4370
Cinnamic	ethyl 3-phenylheptanoate [c]	15	113°/1 mm	n_D^{25} 1.4879

Chromatographic Separations of Cytosine Containing Compounds

PETER REICHARD

Department of Chemistry I, Karolinska Institutet, Stockholm, Sweden

During work on the biological formation of deoxyribosidic compounds it became important to separate deoxyribosides and deoxyribotides from the corresponding ribosides and ribotides. The present note describes the separation of different cytosine containing compounds by a simple procedure involving chromatography on Dowex 50 (H+-form, 200–400 mesh). Fig. 1 shows a complete separation of cytidine-5′-phosphate, deoxycytidine-5′-phosphate, cytidine, deoxycytidine and cytosine on such a column. Cytidine-2′ (and -3′)-phosphate moved as the deoxyribotide. The recovery of all substances was 95–100 %. The compounds may be recovered quantitatively by simple evaporation *in vacuo* of the solvent.

The compounds could also be separated by paper chromatography with a borate containing solvent (20 ml of 5 M ammonium acetate, pH 9.5, 80 ml of saturated sodium tetraborate, 220 ml ethanol and 0.5 ml of 0.5 M versene). This solvent is a modification of the one originally described by Plesner [1]. The following R_F values were obtained: Cytidine-5′-phosphate = 0.06; deoxycytidine-5′-phosphate = 0.12; cytidine = 0.27; cytosine = 0.68; and deoxycytidine = 0.76. The R_F values changed considerably in different experiments but the relative positions of the substances remained the same. The same solvent could also be used for a similar separation of uracil or thymine containing compounds.

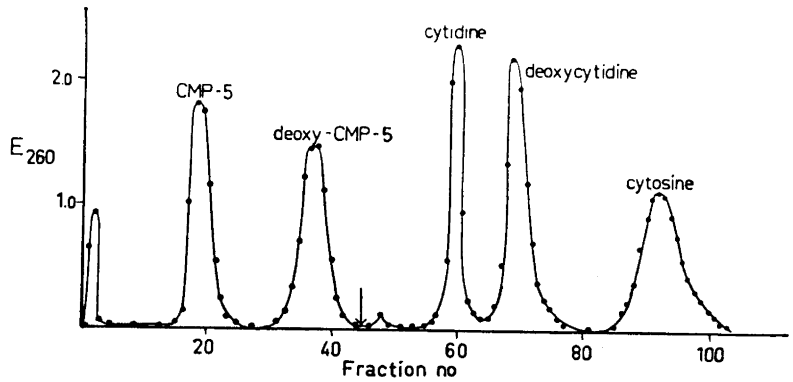

Fig. 1. Separation of 4—5 μmoles each of cytidine-5′-phosphate, deoxycytidine-5′-phosphate, cytidine, deoxycytidine, and cytosine on Dowex 50 (H+-form, length 10 cm, diam. 0.9 cm). Fraction size: 4—5 ml per 30 min. The chromatogram was first developed with 0.2 N acetic acid; at the arrow elution was started with N HCl. The first peak represents uracil containing compounds present as impurities in the commercial cytosine derivatives.

These methods have been used for the preparation of deoxycytidine and deoxycytidine-5′-phosphate from *in vitro* experiments [2].

The Solubility Curve for the System Adipic acid—*p*-Dioxane

GUNNAR B. LINDSTRÖM

Division of Physical Chemistry, Royal Institute of Technology, Stockholm, Sweden

A figure for the solubility of adipic acid in *p*-dioxane was required for the preparation of tritium labelled dioctyl-adipate. The determination was performed in a 100 ml test tube with a thermometer (graduated to 1/10°C) and a stirrer inserted through the cork. 50 ml *p*-dioxane (m. p. 11.3°C, b. p. 100—101.5°C) was pipetted into the tube and the adipic acid (m. p. 151—153°C) subsequently added in small portions. The tube was heated in a water bath until the acid had completely dissolved. It was then cooled and the temperature, at which the first inhomogeneities were observed, was recorded. The cooling was performed in a water-filled Dewar vessel kept at a temperature about 5°C below the expected temperature for the phase separation. Three readings were taken for each concentration.

Table 1. Phase separation temperature for adipic acid — *p*-dioxane mixtures.

Amount of adipic acid per 50 ml (= 50.18 g) *p*-dioxane		Temperature for phase separation (mean of three determinations)
g	mole %	°C
0.00	0.00	11.3
1.00	1.18	10.7
2.21	2.48	9.9
3.39	3.91	11.5
4.63	5.27	25.3
6.13	6.85	34.7
10.30	11.01	53.5
12.47	13.03	61.0
14.53	14.86	67.4
20.62	19.92	77.6
26.69	24.27	88.5
33.42	28.65	96.5

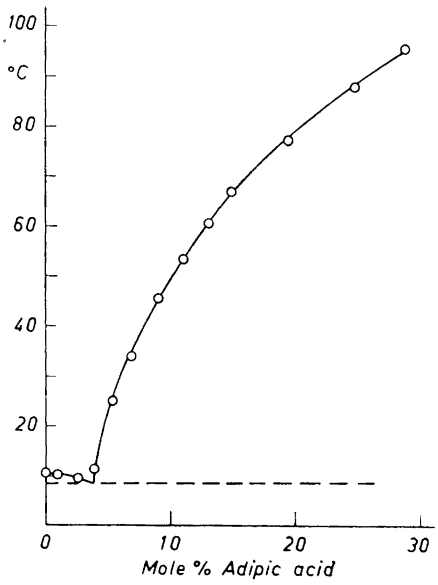

Fig. 1. Solubility curve for the system adipic acid — *p*-dioxane.

The results show that the system behaves like an ordinary binary mixture. At 2.9 mole % adipic acid, the curve has a eutectic point, the extrapolated temperature of which is 9.5°C. The readings at high temperatures do not agree exactly with those at low temperatures. This was probably due to the fact that some dioxane evaporated at the high temperatures, causing the actual concentrations of adipic acid to be higher than the calculated ones.

On the Biological Methylation of Histamine. 3

KERSTIN M. LINDAHL

Institute of Zoophysiology, University of Uppsala, Uppsala, Sweden

It is well known that many biological transmethylation reactions require methionine [1]. However, in the case of guanidinoacetate and nicotinamide it has been shown by Cantoni and co-workers [2] that the active methylating agent is S-adenosylmethionine.

In an earlier study [3] it was demonstrated that radioactive methylhistamine was formed, when methionine labelled with ^{14}C in the methyl group was incubated with histamine, enzyme extract from mouse liver, and appropriate cofactors. It was thus concluded that the methyl group of methionine can be utilized for the methylation of histamine.

In this communication it is demonstrated that the histamine methylating enzyme in mouse liver utilizes with great efficiency S-adenosyl-methionine as methyl donor.

Methods. Enzyme extract. Fresh mouse liver was ground in a blendor with 3 volumes of cold 0.1 M sodium acetate buffer pH 5.6. The homogenate was centrifuged for 30 min at 25 000 *g* in the cold. The supernatant liquid was heated to 47°C for 10 min, centrifuged, and dialyzed for 2 h against 0.05 M sodium acetate buffer pH 6.0 [3,4].

Determination of histamine according to Schayer and co-workers [5,6]. Histamine dihydrochloride was added to the sample as carrier. After removal of the proteins, the pipsyl derivative was prepared, and recrystallized until the radioactivity count was unchanged for at least three successive crystallizations. The average value of the constant samples was used.

Determination of methylhistamine. Carrier methylhistamine * was added to the sample, extracted with chloroform [7] after protein precipitation, and converted into the picrate which was recrystallized until constant radioactivity was attained. The activity was considered constant, if three successive values coincided within experimental errors.

S-adenosylmethionine was isolated from yeast according to Schlenk and De Palma [8]. A chromatographically pure product was obtained by extraction with $HClO_4$, chromatography on Dowex 50, and precipitation with phosphotungstic acid.

Results. Histamine-2-^{14}C-dihydrochloride was incubated with the enzyme extract obtained from mouse liver for 1 h at 37°C. The incubation mixture was analyzed for histamine and its N-methylated metabolite, 1-methyl-4-(β-aminoethyl) imidazole (methylhistamine), according to the isotope dilution method, developed by Schayer and co-workers [5-7] (see under Methods).

It was found that nearly all histamine remained intact after 1 h incubation, and that very little methylhistamine was formed. However, when S-adenosylmethionine was added to the incubation mixture, virtually all histamine had disappeared after 1 h, and the radioactivity was recovered as methylhistamine.

The essential figures from an experiment are given in Table 1. From these results, in comparison with earlier studies [3,4] it is obvious that the soluble fraction of mouse liver contains a histamine methylating enzyme which utilizes S-adenosylmethionine as methyl donor with great

Table 1. The complete system contained 0.5 ml of the enzyme preparation, 15.5 μg ^{14}C histamine dihydrochloride, 1.5 μmole S-adenosylmethionine, and Tris 0.5 M, pH 7.4, to make 1 ml. The calculated maximal radioactivity count is denoted as 100 % *.

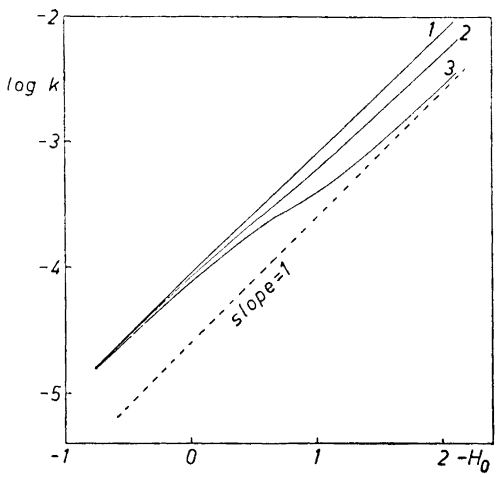

Fig. 1. A plot of log k against $-H_0$ for competing uni- and bimolecular reactions. Aqueous hydrochloric acid solutions, 25°C. In dilute acid the bimolecular reaction assumes 25 % (*curve 1*), 50 % (*curve 2*), and 75 % (*curve 3*) of the overall reaction.

On the Applicability of the H_0 Acidity Function to the Case of Two Competing Mechanisms

PENTTI SALOMAA and RAILI LINNANTIE

Department of Chemistry, University of Turku, Turku, Finland

The H_0 acidity function has become the subject of a great number of studies on the mechanisms of acid catalysis [1,2], although cases have been also reported in which this function is of a limited applicability [2]. Apart from the fundamental restrictions involved in assuming certain activity coefficient terms to remain constant in different media, there is the following particular case, in which the use of the acidity function may lead, at least partly, to fallacious conclusions.

Let us consider an acid-catalysed hydrolysis reaction in which the unimolecular and bimolecular mechanisms are in competition. The overall rate coefficient k, which can be measured experimentally, is then made up of the two individual rate coefficients, k_1 and k_2, which refer to the different mechanisms. If the Zucker-Hammett hypothesis is valid, k_2 should be proportional to the acid concentration, whereas $\log k_1$ should vary similarly as the value of $-H_0$ of the solution. Fig. 1 shows some examples calculated for the dependence of $\log k$ on $-H_0$ in such cases. The H_0 values of aqueous hydrochloric acid solutions used in the calculations are those revised by Paul and Long [3].

The most striking feature is that the contribution of the bimolecular mechanism becomes largely masked by the unimolecular mechanism, when higher acidities are approached. Thus the curves are experimentally indistinguishable from a straight line of a slope of nearly unity, which would correspond to a purely unimolecular reaction, except that case where the bimolecular mechanism is the prominent in dilute acid; here the curve shows a clearly notable point of inflexion. Such a behaviour is thus highly characteristic of competing mechanisms which depend on the acidity of the solution in a different way.

An example of the masking of a mixed unimolecular and bimolecular reaction by

efficiency. The metabolization of histamine corresponds to at least 110 μg/h/g fresh liver.

The H_0 values of aqueous hydrochloric acid solutions used in the calculations are those revised by Paul and Long [3].

The most striking feature is that the contribution of the bimolecular mechanism becomes largely masked by the unimolecular mechanism, when higher acidities are approached. Thus the curves are experimentally indistinguishable from a straight line of a slope of nearly unity, which would correspond to a purely unimolecular reaction, except that case where the bimolecular mechanism is the prominent in dilute acid; here the curve shows a clearly notable point of inflexion. Such a behaviour is thus highly characteristic of competing mechanisms which depend on the acidity of the solution in a different way.

An example of the masking of a mixed unimolecular and bimolecular reaction by

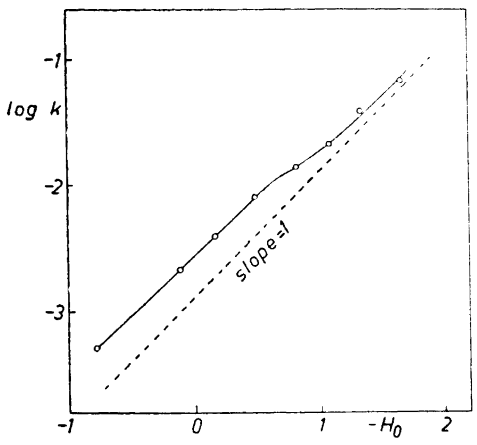

Fig. 2. A plot of log k against $-H_0$ for the hydrolysis of β-chloroethoxymethyl formate in aqueous hydrochloric acid solutions at 25°C.

the prominent unimolecular reaction is furnished by the hydrolysis of methoxymethyl formate, reported earlier [4]. On the other hand, a curve showing a point of inflexion was observed in the hydrolysis of β-chloroethoxymethyl formate (Fig. 2).

In cases like that of Fig. 2, an accurate determination of the rates of the individual reactions should require the use of more specialised kinetic methods. If, however, such methods are not available, the relative contributions may be roughly estimated, as described below. The most essential limitation in these calculations is that the value of k_2 is usually not strictly proportional to the acid concentration, and that the slope of the plot of log k_1 against $-H_0$ may slightly differ from unity, and therefore the results should be regarded as very approximate.

It may be found that the position of the point of inflexion depends on the relative rates of the competing reactions. If R denotes the ratio of the rate of the unimolecular reaction to that of the bimolecular reaction in dilute hydrochloric acid, it can be calculated that the following numerical relation holds for the H_0 value of the point of inflexion:

$$R = 10^{H_0}\left(\frac{1-2.35\ H_0 + 1.17\ H_0^2}{-0.93-1.27\ H_0 + 4.60\ H_0^2}\right)$$

This equation was derived by representing the concentration of hydrochloric acid in 0.1—6.0 M solutions as a polynomial of H_0 of the second power, the coefficients of which were calculated by the method of least squares using weighed values of c_{HCl} (the weights were chosen as inversely proportional to the values of the acid concentration). The H_0 data given by Paul and Long [3] were used.

The method of iteration may be also applied, taking into account that it is the unimolecular reaction that predominates at high acidities, and thus the value of k in these media gives the value of k_1 as a first approximation, from which the values of k_1 for dilute acids may be calculated with the use of the respective H_0 values. These give first approximations for the values of k_2 in dilute acid solutions ($k_2 = k - k_1$), from which, in turn, the values of k_2 for the higher acid concentrations may be calculated.

In the example shown in Fig. 2, the point of inflexion lies at a H_0 value of -0.67 ± 0.10, from which it is estimated that in dilute acid the unimolecular reaction assumes 27 ± 9 % of the overall reaction. Calculations by the iteration method gave a corresponding estimate of 39 ± 7 %. These percentages correspond to a value of 0.0022 ± 0.0005 l mole^{-1} s^{-1} for the rate coefficient of the bimolecular reaction at 25°C, which is a very reasonable value, as the rate coefficients reported for the bimolecular $A_{AC}2$ hydrolysis of alkyl formates are of the same magnitude under similar conditions [5,6].

A full account of the experimental details and examples of other similar reactions will be published shortly.

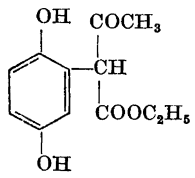
The Reaction between *p*-Benzoquinone and Ethyl Acetoacetate

ERLING BERNATEK and TORE LEDAAL

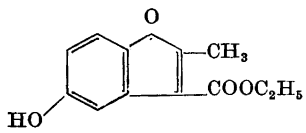
Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

This reaction has since its discovery by v. Pechmann [1] and Ikuta [2] evoked only sporadic interest. Graebe and Levy [3] extended the synthesis to include toluquinone and one of the present authors has in several articles [4-8] treated this and analogous reactions. Recently Grinev and collaborators [9,10] have published some results which are the occasion for this article.

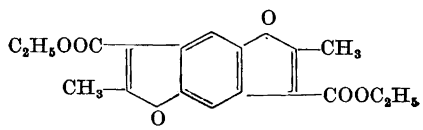
The first step in the reaction is believed to be the formation of a quinol (I).



I



II



III

Quinols of the type I have not been isolated, but indirect evidence for their existence has been furnished [4]. This primary quinol can react in two ways: It can be cyclised to a benzofuran (II) or be oxidised to its corresponding quinone by unreacted benzoquinone. Further this newformed quinone can add a second molecule of ethyl acetoacetate forming a disubstituted quinol which in turn will be cyclised to a benzodifuran (III). Normally there is formed a mixture of II and III, the ratio of the amounts being determined by the competition between oxidation and cyclisation of I.

In synthetic practice it has for several reasons been an object to obtain a good yield of II and suppress the formation of III. Grinev reports a yield of 98 % of II in a procedure where a mixture of anhydrous ethanol and ether is used as solvent and the reaction performed in an extraction apparatus with benzoquinone in the thimble. This technique was adopted in order to ensure a slow addition of benzoquinone, the reaction requiring 27 h. We have repeated Grinev's experiments but in no case obtained the yields claimed by him. The amounts of II fell far short of 98 % and appreciable amounts of III were formed. Further it is our experience that alcohols are not ideal as solvents in this reaction as dark substances are formed which contaminate the product.

It is well known that the potentials of reduction-oxidation systems of quinols and quinones are very sensitive to changes in the proton activity. A possible mode of displacing the benzofuran-benzodifuran ratio could therefore be to change the acidity of the reaction mixture. Two reduction-oxidation systems are present: [Quinol-benzoquinone] and [the quinol I — the corresponding quinone]. *A priori* it is impossible to say how changes in the proton activity will alter the potentials of the two systems relative to each other in the very special solvent employed (acetone-ethyl acetoacetate-zinc chloride). Actually it was found that the addition of small amounts of strong bases and acids was very detrimental to the overall yield and in some cases benzodifuran was formed almost exclusively. Acetic acid, however, proved to be a suitable additive, a fair amount of very pure II being obtained while only traces of III were observed. (The effect of acetic acid may also include a kinetic contribution, *e. g.* catalysis of the ring-closure of I.) On this basis a reliable procedure has been worked out in which acetone has been adopted as solvent as originally proposed by Graebe and Levy. The main advantage of our procedure is that it furnishes II free from III rather than a high overall yield as it is difficult to separate the two compounds without heavy losses.

Experimental. Ethyl 2-methyl-5-hydroxybenzofuran-3-carboxylate. *p*-Benzoquinone (27 g) was dissolved in a mixture of ethyl acetoacetate (100 ml) and acetone (100 ml) at

room temperature. This mixture was added during 10 h to a solution of anhydrous zinc chloride (35 g) in acetone (50 ml) and acetic acid (2.5 ml). The reaction mixture was kept at 75° and stirred mechanically. Afterwards it was kept overnight in an open beaker, cooled well in ice and filtered by suction. The light brownish product was washed with small amounts of ice-cold methanol thus becoming white. M. p. 138°. The substance gave a clean purple colour with hot concentrated sulphuric acid. (The benzodifuran III gives a blue colour with this reagent and even a small contamination of II with III changes the colour to violet.) Yield 33 g (60 %, calculated on the basis of benzoquinone).
