It has been questioned whether allergens from pollen are broken down by hydrolytic enzymes in the extract during preparations. Loveless *et al.*[1] found appreciable losses of nitrogen and carbohydrates from ragweed extract during extensive dialysis through cellophane. Frankel *et al.*[16] examined the same pollen species and they believe that a number of weakly active peptide carbohydrate complexes in the dialysate have arisen by fragmentation of the undialysable residue, which represented the main activity.

Either inactive or still active components could be formed by an enzymatic cleavage. In the case of alder pollen (Table 2) no loss of activity was found after dialysis. Even if a limited hydrolysis of allergens could have taken place, it is of interest to purify and study an active fragment. The small scale extraction with sulphuric acid was made in order to study the activity yield under conditions where proteolytic cleavage is supposed to be prevented[34]. The activity in this extract, however, was not higher than in the phenol-sodium chloride extract used for the fractionations. The activity of the sulphuric acid extract was lowered only a little when it was kept at 4°C during 20 h.

The active material did not pass the dialysis membrane used in the initial step of the fractionation. This does not exclude the possibillity that a pene-

tration could take place in a later stage, when originally present weak complexes could have been split. Consequently no definite conclusions can be drawn from this experiment about the molecular size of the allergens.

The experiments reveal that fraction "Core" was remarkably stable to heating. The heat stability of pollen allergens is of considerable interest, because already differences in this property may give hints to differences in their chemical nature. It is therefore important to emphasize that in the case of alder pollen here investigated, no inactivation was observed even after one hour's heating at 100°C. It is interesting to compare this result with similar studies made by Augustin [23] on grass pollen. She found that only 10 % of the activity remained after 15 min at 100°C, and that already after one minute's heating all precipitating power for the rabbit antibody was lost and that precipitates were no longer formed in gel diffusion tests.

As seen from the experiments no loss of activity was found after treatment of fraction "Core" with trypsin or chymotrypsin. The same result was found

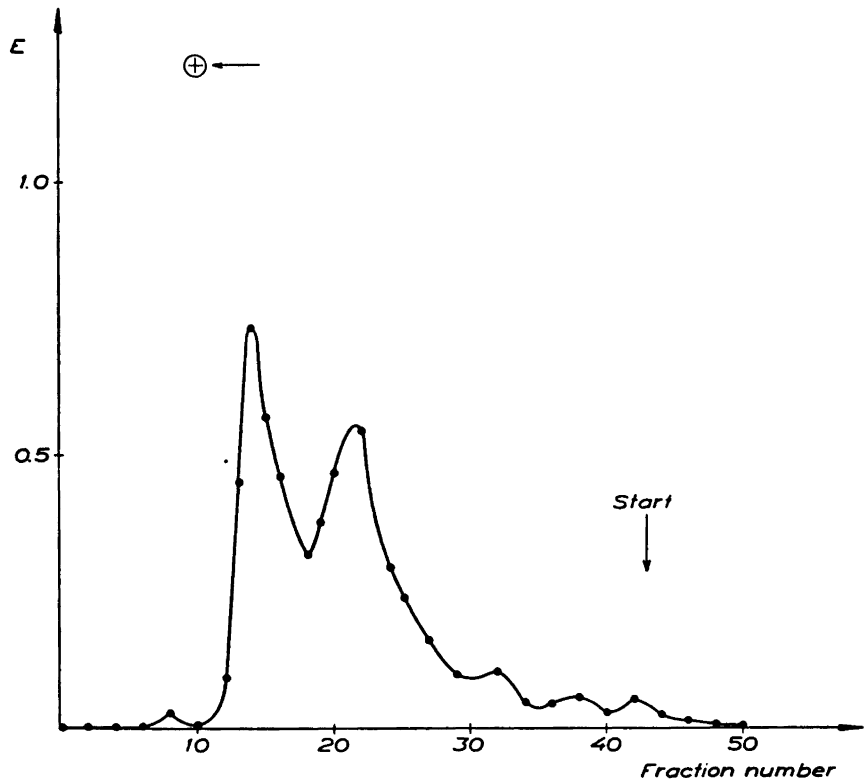

Fig. 3. Electropherogram of 69 mg of preparation TEAE—BP obtained after 15 h electrophoresis at 15 mA in a 90 × 1.6 cm column using 0.05 N triethylammonium carbonate buffer of pH 8.6. Fractions of 3 ml were collected.

—·—·— Ninhydrin curve obtained from 0.1 ml samples from every other tube.

with pepsin in the tests made on two of the patients. A third patient gave a negative response to the pepsin digest, but the initial activity value was in this case rather low, and therefore no definite conslusions can be drawn. There might be several allergens and some of these do not exhibit resistance towards pepsin. Augustin has preliminarly described similar studies on grass pollen extracts [23]. In those cases the treatment with pepsin and trypsin destroyed all activity within one hour, whether the digestion was carried out on the crude extract or on the purified protein solution.

Allergens from pollen are often referred to as pigmented carbohydrate-rich compounds. On the other hand, it is preliminarily reported that one of the allergens from grass pollen contains only 2 % of carbohydrates [23]. Referring to the experiments on alder pollen, it is seen from Fig. 1 that the orcinol curve does not indicate the presence of any carbohydrates in the active fractions displaced from the SE-cellulose. On the other hand, it cannot be excluded

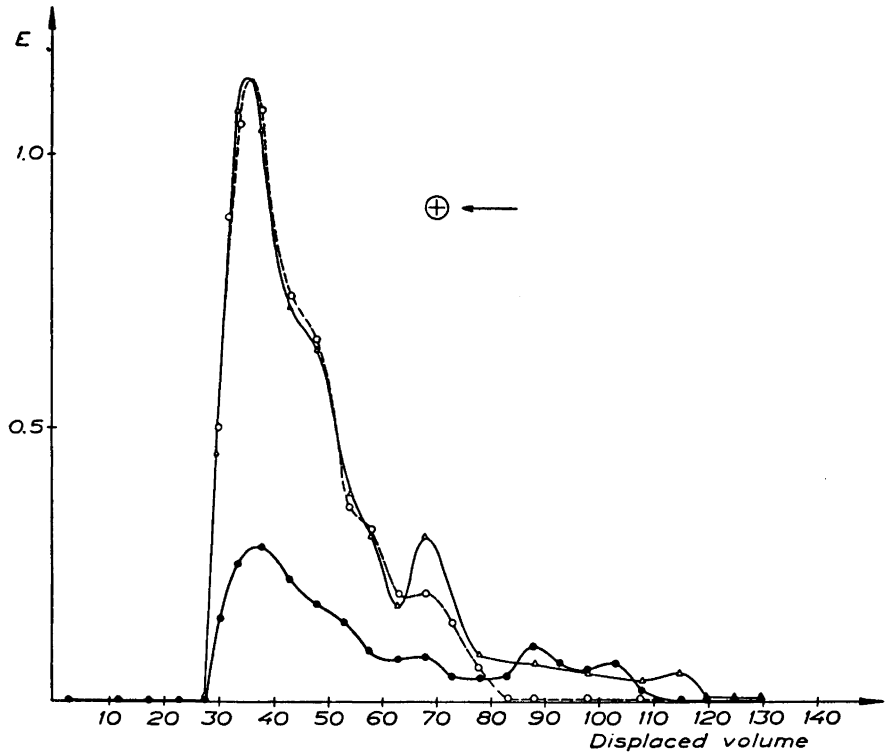

Fig. 4. Electropherogram of 30 mg of preparation E—2B obtained after 39 h electrophoresis at 25 mA in a 90 × 1.6 cm column using 0.05 N triethylammonium carbonate buffer of pH 9.0. Fractions of 2.5 ml were collected.

—•—•— Ninhydrin curve obtained from 0.1 ml samples from every other tube.

that there are components present containing small amounts of carbohydrates, which are not revealed by the reagent. It is possible that the cellulose ion-exchangers used in the purification may give off small amounts of cellulose, and this would interfere in an accurate carbohydrate determination. Consequently a final fractionation has to be made in order to get rid of ion-exchange material.

No experiments have been made in order to determine whether the activity in fraction SE-B (Table 8) is caused by an overloading of the column, or if the material in this fraction is different from that in fraction SE-D (Table 8). In the fully active fraction SE-D no proteins were found, and there were probably no free amino acids. A sample of this kind would presumably be suitable for fractionation with zone electrophoresis. The unfortunate reduction of activity during the electrophoresis (Fig. 2) can perhaps be explained by

the fact that too small amounts of material have been used. Under these conditions oxidation, bacterial growth and adsorption have a pronounced effect on the activity yield.

When the extract is stored and during evaporations of solutions the solubility of the components is often changed. Especially the pigments tend to crystallize. Consequently there are risks of coprecipitations. Precipitates are often difficult to get into solution without drastic treatments. It was possible to make use of this fact in order to obtain information about the allergens. As seen from the experiment (passage H) a highly pure fraction (sample TEAE-BP) was obtained. The electrophoretic patterns are shown in Figs. 3 and 4. The active peak contains bound amino acids together with a yellow pigment. No experiments have been made in order to reveal if the activity is caused by the bound amino acids or by the pigment or by a possible complex between them. Stevens *et al.*[35,23] have met with a similar problem in the course of studies of an amorphous glucoside precipitate that was formed in the extract of giant ragweed pollen. They found that biologic activity remained as long as nitrogen was associated with the glucoside (*iso*quercetin), while the pure glucoside was inactive.

The stability towards drastic treatments such as heating, evaporation and proteolysis suggests that the bulk of the activity in the dialysed extract is not due to proteins. The adsorption of the active material on the cellulose ion-exchangers strongly indicates the presence of acid and basic groups in the active molecule(s). The electrophoretic behavior (Fig. 2) of a fraction, with about 300 times as high specific activity as the initial extract, reveals that the allergen(s) is (are) negatively charged at pH 8.6. The bound amino acids found in the active peak are probably parts of the allergen(s).

The data that are presented point to the conclusion that the allergen(s) is (are) of peptide nature.

The Separation of Nucleotides by Ionophoresis and Chromatography on Paper

ROLF BERGKVIST

Institute of Biochemistry, University of Lund, Sweden

The separation of a complex mixture of 5′-ribonucleotides by a combination of ionophoresis and chromatography on paper is described.

The development of ionophoresis on paper has greatly facilitated separations of substances which would be impossible by paper chromatography and time consuming by ion exchange methods. The combination of paper ionophoresis with chromatography, either carried out simultaneously or separately, sometimes permits separations to be effected that can not be carried out by either technique alone. Numerous workers have used this method for the separation of different substances but most of the methods concerned with the separation of nucleotides have been found to give satisfactory separations of only a few nucleotides. In the course of studies of the nucleotide content of various plant materials, a method has been developed for the separation of all the main components to be found in these materials [1]. The nucleotides are fractionated into groups by paper chromatography and then completely separated by ionophoresis. The present paper describes a two-dimensional fractionation of these substances on a single sheet of filter paper.

The mixture of nucleotides to be separated was applied as a narrow band about 15 mm in length and 6 cm from the edge of a large sheet of Whatman No. 1 filter paper (Fig. 1). The resolution in the first direction was obtained by ionophoresis using the long-paper apparatus described earlier [1]. The paper was impregnated with an acetate buffer of pH 4.15 and of ionic strength 0.1 by dipping as previously described. Then the paper was folded along the line CD and placed on a glass frame. The frame and paper were then immersed in a carbon tetrachloride vessel so that the ends FG and HI dipped into the electrode vessels. The frame was constructed as a three piece unit in order to facilitate placing the paper on it as illustrated in Fig. 2. The ionophoresis was carried out at 1 000 V for 10 h, at which time the nucleotides were distributed over the interval BE. The paper was then dried at room temperature and, after cutting away the tabs BCGF and EDHI, the separation in the second

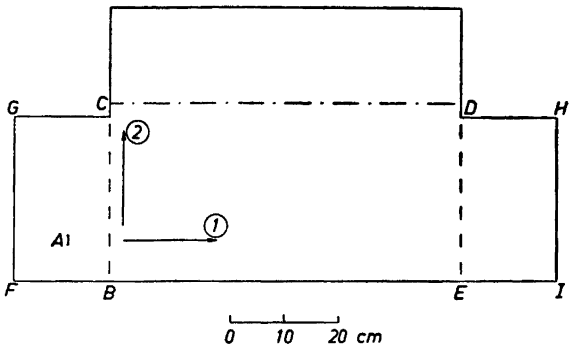

Fig. 1. The dimensions and shape of the filter paper sheet. The substances are applied at point A. The paper is folded along the line CD and the tabs FG and HI dip into the electrode vessels. The substances are fractionated by ionophoresis in direction 1 and then by paper chromatography in direction 2.

direction was achieved by chromatography. The previously described solvent system consisting of saturated ammonium sulphate solution — *iso*propanol — water (79:2:19) could be used for obtaining a complete separation of all the components, but better separation of the pyrimidine nucleotides was achieved using *n*-butanol instead of *iso*propanol. The paper sheet was impregnated with buffer salts from the ionophoretic development; but, when using the butanol mixture, these salts did not interfere with the separation of the various substances. The spots obtained by this method are as compact as those which result from other two-dimensional systems. All the 5′-mono-, di- and triphosphates of adenosine (AMP, ADP and ATP), guanosine (GMP, GDP and GTP), cytidine (CMP, CDP and CTP) und uridine (UMP, UDP and UTP) together with diphospho- and triphosphopyridine nucleotides (DPN and TPN) are separated as shown in Fig. 3. Uridine diphosphate glucose (UDPG) and

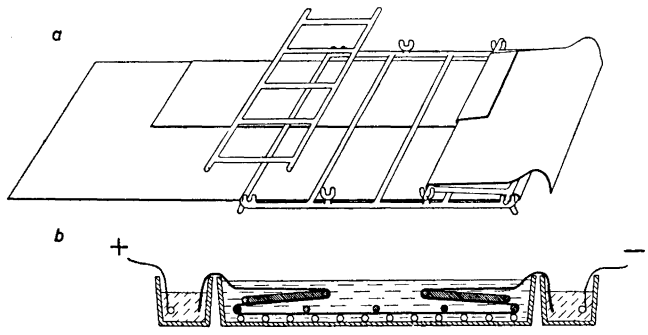

Fig. 2. a) The fitting of the paper to the glass frame. b) Cross section showing the paper and frame in place in the ionophoresis apparatus.

uridine diphosphate acetylglucosamine (UDPAG) are not completely separated from each other, but are clearly separated from the other nucleotides.

The method described gives a rapid separation of the nucleotides. It is usable for preliminary analyses of mixtures and especially when only small amounts of material are available. An approximate estimation of the amounts of the different substances can be obtained by eluting the ultraviolet absorbing spots with 0.1 N hydrochloric acid and estimating the ultraviolet absorption of these eluents.

EXPERIMENTAL

The ionophoretic fractionation was performed using the apparatus and technique previously described [1]. The two-dimensional separation was carried out on Whatman No. 1 paper purified by washing with 1 N hydrochloric acid and water. The mixture to be separated was applied as a line to the dry paper and then the paper was impregnated with sodium acetate buffer of pH 4.15 and of ionic strength 0.1. The nucleotides were distributed over a maximum usable interval after the paper had been exposed to a voltage of 1 000 V for 10 h. The paper was dried at room temperature and then the initial fractionation of the mixture was observed by photographic printing in ultraviolet light of 254 mμ.

The chromatographic separation in the second direction was made after cutting away the unnecessary parts of the paper sheet. The best separations were obtained by the descending technique with a solvent system of saturated ammonium sulphate solution — *n*-butanol — water (79:0.5:19). The chromatogram was run for 10 h at 20—22°C. The resulting separations of the nucleotides were established by making a contact print in ultraviolet light of the whole sheet.

Materials. The nucleotides used as standard substances were obtained from the Sigma Chemical Company.

Studies Related to Naturally Occurring Acetylene Compounds. XXII * Correctional Studies on the Constitution of the Polyacetylenes of some Annual *Coreopsis* Species

JÖRGINE STENE SÖRENSEN and NILS ANDREAS SÖRENSEN

Institutt for Organisk Kjemi, Norges Tekniske Högskole, Trondheim, Norway

One of the polyacetylenes previously isolated from some annual *Coreopsis*-species and supposed to be *1*-phenyl-undeca-1:3:5-triyne-7:9-diene (IV) is shown to be a mixture of trideca-1:3:11-triene-5:7:9-triyne (V, R = H), probably with *cis* configuration at the 3:4 double bond, and *trans*-1-phenyl-hepta-1:3-diyn-5-ene (I, R = H).

In the XVII[th] Communication of this series J. Stene Sörensen and N. A. Sörensen [1] described the isolation of 4 new acetylenic compounds from some annual garden varieties of the genus *Coreopsis, viz. C. tinctoria Nutt., C. Drummondii* Torr. & Gray and *C. cardaminifolia* (D.C.) Torr & Gray. The 4 new acetylenic compounds were given the following constitutional formulas I, R = $OCOCH_3$, II, III, R = H, and IV.

—C≡C—C≡C—CH=CH—CH_2—R I

RH_2C—CH=CH—C≡C—C≡C—CH=CH—CH=CH—CH=CH_2 II

RHC=CH—C≡C—C≡C—C≡C—C≡C—CH=CH_2 III

—C≡C—C≡C—C≡C—CH=CH—CH=CH—CH_3 IV

The correctness of I, R = $OCOCH_3$ was proved by Bruun, Skatteböl and Sörensen [2] by the total synthesis, revealing that the configuration of the double bond is *trans*.II was shortly afterwards synthesised by Bohlmann [3]; this synthesis confirmed the supposition of Sörensen and Sörensen [1] that the configuration was all-*trans*.

* XXI Communication, *cf.* Festschrift Arthur Stoll, Basel 1957.

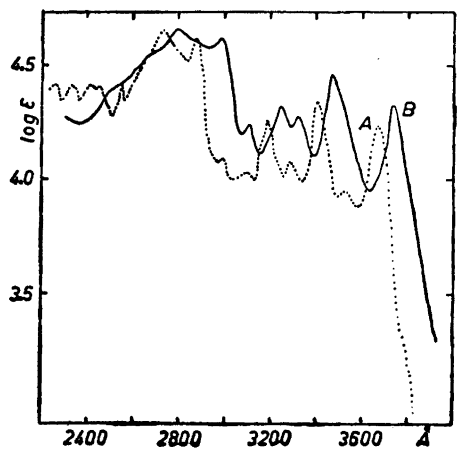

Fig. 1. Ultraviolet absorption of
A: "3650" Hydrocarbon supposed to be IV according to Sörensen *et al.*[1]
B: *trans* IV, redrawn from Bohlmann *et al.*[3]

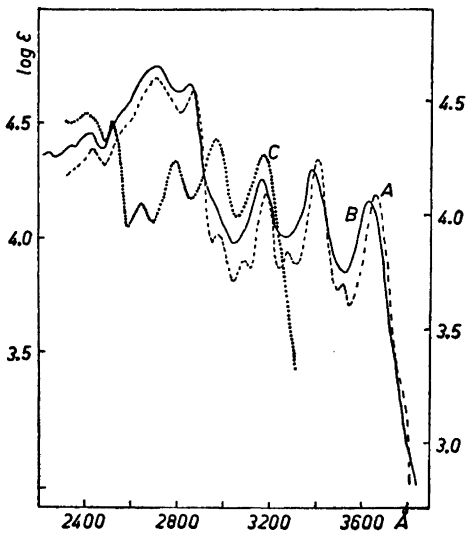

Fig. 2. Ultraviolet absorption in hexane of:
A. *cis* trideca-1:3:11-triene-5:7:9-triyne — — — — — —
B. *trans* trideca-1:3:11-triene-5:7:9-triyne ————
C. *trans* 1-phenyl-hepta-1:3-diyn-5-ene (scale right side) .....

The hydrocarbon III, R = H was synthesised by Jones, Thompson and Whiting [4] and turned out to be very similar but not identical with the so-called 3910-hydrocarbon from *Coreopsis* oils; Skatteböl [5] synthesised both the *trans* and the *cis* isomers of the homologue III, $R = CH_3$. The *trans* compound turned out to be identical with the 3910-hydrocarbon, m.p. 43°C, which has a rather wide occurrence inside some tribes of the family *Compositae*. This brilliant synthetic work further established that the *cis* compound III, $R = CH_3$, undoubtedly also occurred in some chromatographic fractions from *Coreopsis* species measured by Sörensen and Sörensen [1] in the infrared.

Bohlmann [6] described the synthesis of the *trans* isomer of IV. Although there was some similarity in the ultraviolet spectra, synthetic *trans* IV was undoubtedly different from the compound occurring in the flowering parts of the investigated annual *Coreopsis* species, *cf.* Fig. 1. Bohlmann put forward the hypothesis that the naturally occurring compound might be one of the possible *cis* isomers. This, however, was unlikely since the synthetic *trans* isomer has the ultraviolet absorption maxima about 65 Å at longer wave-lengths than the natural compound, whereas *cis* polyen-ynic isomers mostly absorb at longer wave-lengths than their corresponding *trans* isomers [7].

I—III were solids which could be purified by recrystallisation; IV, however, was a liquid the homogeneity of which was difficult to guarantee. Sörensen and Sörensen [1] recorded some difficulties in their experimental work; thus

the perhydrogenation product, which should be 1-phenyl-*n*-undecane could not be brought to correct melting point, — 5°C, although the melting point obtained, —8 to —6.5°C, came very close to that of the best synthetic preparation of 1-phenyl-*n*-undecane which Sörensen and Sörensen were able to synthesise and no clear-cut m.p. depression could be observed.

That in reality the constitution of the perhydrogenation product was completely misinterpreted became clear when Dr. A. J. P. Martin most kindly investigated a melting point sample of the perhydrogenation product in his vapour fractometer. According to a personal report from Dr. Martin the perhydrogenation product contained at least two products one of which might possibly be *n*-tridecane. Thus the constitution of the compound supposed to be IV had to be reinvestigated.

The characteristic double maxima in the longwaved band group of this compound, *cf.* Fig. 1, were taken by Sörensen and Sörensen as an indication of the occurrence of a mixture of compounds. However, all chromatographic fractions from the different garden varieties showed the same relative intensity of the main and subsidiary maxima, a very improbable happening with a mixture of compounds.

By the reinvestigations these double maxima in ultraviolet were again taken as the analytical mark, but every effort to obtain an alteration in the relative intensities by taking narrower cuts in the chromatographic fractions were again without success.

The picture remained unchanged when the chromatographic cuts were made still narrower; elution with 2—4 % benzene in petroleum ether taking 5—20 fractions at each concentration. When, however, these fractions with conform long-wave band group in the ultraviolet region simultaneously were investigated in the infrared region characteristic definite differences emerged. The characteristic phenyl-peaks at 1 494, 753 and 686 cm^{-1} changed in intensity relative to the acetylenic one at 2 200 cm^{-1} and a characteristic peak at 775 cm^{-1}.

Reinspection of the ultraviolet spectra then revealed that the fractions with the most intensive phenyl peaks in the infrared had some extra ultraviolet bands at 3 180 and 2 970 ÅU. With these experimental facts well established repeated chromatography on deactivated alumina finally led to a separation of this part of the flower oil into two components of constant properties. Both could be crystallised. Recrystallisation seemed rather unsuccessful however, as a method of separation, possibly because of mixed crystals. Both components were very readily soluble in most solvents which of course hampered purification of small amounts of substance by recrystallisation.

Fig. 2. gives the ultraviolet spectra of the 2 compounds. As will be seen the main component still has the characteristic double maxima in the long-wave band group. Fig. 3, which gives the infrared spectra, reveals that the most long-wave chromophore belongs to a compound containing no phenyl group, whereas the minor component with first maximum in ultraviolet at 3 180 Å obviously is a phenyl compound.

With the tedious separation of the two components achieved constitutional work could again be started.

Table 1. Ultraviolet absorption maxima of ene-triynes and phenyl-triynes (Å).

	3 335	3 125	2 935	2 767	—	2 545	2408*

* in ether

The hydrocarbon with the first maximum at 3 670 Å could be crystallised from petroleum ether and showed m.p. 50.5—56°C. By the catalytical hydrogenation 8.25 moles of hydrogen were taken up. The perhydrocompound crystallised readily in the refrigerator m.p. —7°. *n*-Tridecane has m.p. —6.5 to —6°, a 1:1 mixture showed no depression. The infrared spectrum was in every detail identical with that of *n*-tridecane. Although normal paraffins higher than *n*-decane show nearly identical infrared spectra the identity of the perhydrogenation product and *n*-tridecane should be well established.

Sörensen and Sörensen [1] obtained in very small yield an adduct with maleic anhydride from what they supposed to be 1-phenyl-undeca-1:3:5-triyne-7:9-diene IV. The yield was to small for elementary analysis, the m.p. was given as 146°C and the adduct was characterised by a U.V.spectrum which came very close to that of *1*-phenyl-octa-1:3:5-triyne.

It turned out that this adduct belongs to the aliphatic hydrocarbon with the characteristic double maxima. From the pure hydrocarbon the yield was appreciably higher, but still low.

The fact which was overlooked by Sörensen and Sörensen was that the spectra of phenyl-triynes and ene-triynes are very similar, especially in the long-wave band group. The main differense is a small displacement of the first sharp maximum of the short-wave band group. As will be seen from Table 1 where some characteristic examples are collected, the phenyl triynes have this maximum some 90 Å at longer wave-lengths.

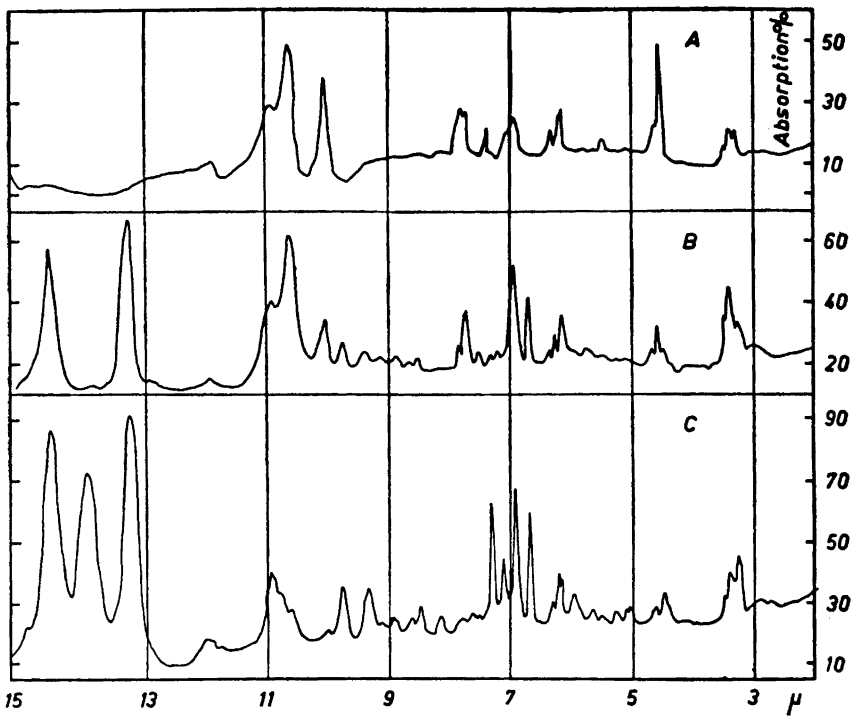

Fig. 3. Infrared absorption of:

A. trideca-1:3:11-triene-5:7:9-triyne in $CHCl_3$, c = 10.6 %, l = 0.05 mm.
B. *trans* 1-phenyl-hepta-1:3-diyne-5-ene liq.
C. *cis* 1-phenyl-hepta-1:3-diyne-5-ene liq.

The maleic anhydride adduct isolated by Sörensen and Sörensen from the "3 650"-hydrocarbon has the strongest band at 2 450 Å and so Bohlmann [6] was correct in his suggestion that the adduct had originated from an other poly-yne-diene present in the fraction. As Table 1 demonstrates the adduct belongs to the ene-triyne class.

The hydrogenation experiments and the properties of the dien-adducts reveal that the hydrocarbon is a *n*-trideca-triene-triyne. So it is the missing link between the *n*-trideca-tetrayne-diene (II, R = CH_3) isolated from the root part of the annual *Coreopsis* species and the *n*-trideca-diyne-tetraene II (R = H) isolated from their leaves.

The infrared spectrum, *cf.* Fig. 3, gives clear indication (1 840 cm^{-1}) of a vinyl group in the triene-triyne.

The ultraviolet spectrum of the maleic anhydride adduct further gives the information that the acetylenic bonds are conjugated; it remains then only 2 possible formulas for a *n*-trideca-triene-triyne, *viz* V, R = H, and VI.

$$R-H_2C-CH=CH-C\equiv C-C\equiv C-C\equiv C-CH=CH-CH=CH_2 \qquad V$$
$$H_3C-C\equiv C-C\equiv C-C\equiv C-CH=CH-CH=CH-CH=CH_2 \qquad VI$$

Of these possibilities V, R = H, should be the correct one for the following reasons. From *Carlina vulgaris* Sörensen and Sörensen [12] isolated an acetate for which they deduced formula V, R = $OCOCH_3$. Bohlmann [13] has synthesised the *trans* isomer of this 1-acetoxy-*n*-trideca-2:10:12-triene-4:6:8:triyne which differed from the *Carlina* acetate but gave the same anhydride adduct. Bohlmann concluded that the Carlina acetate differs in having *cis* configuration at C_{10-11}.

These *cis* and *trans* 1-acetoxy-trideca-triene-triynes (V, R = $OCOCH_3$) show ultraviolet spectra conform with our triene-triyne-hydrocarbon which definitely points to V, R = H, as the correct formula. V, R = H is just the 9:10-dihydro-compound of III, R = CH_3 and the 5:6-dehydro-compound of II, R = H. Finally the choice between V, R = H and VI has been supported by synthetic work, which, because of some interesting side-reactions, will be described in a separate communication.

As to the configuration of the *n*-deca-triene-triyne from *Coreopsis* species an accidental observation gave valuable hints. A chromatographic fraction of nearly pure triene-triyne was so small that both ultraviolet and infrared spectra had to be taken on the same sample. Accidentally the infrared spectrum was recorded first. Surprisingly the subsequent ultraviolet spectrum demonstrated remarkable changes. As Fig. 2 demonstrates, the long-wave group has lost the characteristic double maxima, at the same time the main maxima have moved about 40 Å towards shorter wave-lengths.

This spectral difference relative to the nearest fractions indicated that a *cis-trans* isomerisation had taken place during the infrared measurement. It was not further investigated if the transformation was due to heat alone or to traces of HCl in the solvent chloroform. Instead the *cis-trans* isomerisation was achieved in the usual way through action of light in the presence of traces of iodine in spectral hexane.

As mentioned above [7] it is usual in polyenynes that the *cis* isomers absorb at somewhat longer wave-lenghts than the *trans* isomers; in the known pair of spectra of *cis-trans* isomers the spectra have, however, been very nearly conform. Therefore the characteristic double maxima in the naturally occurring *cis* isomer of V, R = H, might be due to special constitutional details. We find it reasonable to suppose that the *cis-trans* isomerism occurs at least at the C_{3-4} double bond. Assuming that a conjugated molecule tends to exist in a planar conformation, if at all possible, inspection of models, *cf.* Fig. 4, revealed that the 3-*cis*-*n*-trideca-1:3:11-triene-5:7:9-triyne may exist in two planar conformations of rather different molecular shape. Synthetically it should be possible to provide spectra of model compounds which might elucidate whether the double maxima are due to a coexistence of these two rotational isomers.

The second, phenyl-containing component was difficult to purify because of low crystallising power and high solubility in all solvents. The purest fraction obtained had m.p. 25—27°.

The ultraviolet spectrum of this fraction showed great similarity with the 1-phenylhepta-1:3-diyn-5-en-7-ol acetate isolated from all parts of the investigated annual *Coreopsis* species. For this reason we guessed on the structure 1-phenylhepta-1:3-diyn-5-ene (I, R = H) and tested this hypothesis by

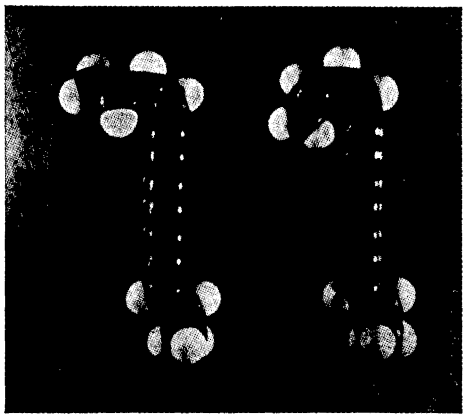

Fig. 4. The two planar conformations of 3-*cis* 1:3:11-triene-5:7:9-triyne (V, R = H).

the synthesis of the *cis* and *trans* isomers of this hydrocarbon by oxidative coupling of phenyl-acetylene with *cis* and *trans* pent-3-en-1-yne, respectively. The synthesis is described in the experimental part. Comparison with the synthetic isomer proved that the phenyl compound from *Coreopsis* leaves was 1-phenyl-1:3-diyn-5-*trans*-ene (I, R = H).

This correctional work revealed some interesting facts. First that the 5 acetylenic compounds so far isolated from annual *Coreopsis* species are all C_{13}-compounds.

The two new polyacetylenes described in this paper I, R = H, and V, R = H are isomeric $C_{13}H_{10}$-compounds differing only in the curling up of the dien-yne-tail of V, R = H, to the phenylresidue of I, R = H.

The same type of isomerism was demonstrated in our XIXth communication to exist between the *Carlina* acetate, V, R = $OCOCH_3$, and the 1-phenyl-hepta-1:3-diyn-5-en-7-ol acetate, I, R = $OCOCH_3$, from *Coreopsis*. Thus it seems possible that some *Compositae* are able to synthesise the phenyl residue in this direct way, not passing oxygenated 6-ring precursors.

EXPERIMENTAL

1. *Separation of the "3650"-hydrocarbon into components.* The starting material was a sample of 5 g of the essential oil of the flowering part of *Coreopsis cardaminifolis* harvested late in the autumn (Sept. 23rd). The main separational procedure was chromatography on the slightly deactivated alumina of Mancera *et al.*[14] Washings with petroleum ether eluted only saturated paraffins and nonchromophoric hydrocarbons. Then followed elution with increasing concentrations of benzene, *viz.* 1.5 %, 2 %, 4 %, 10 % *etc.*

The first polyacetylenic substance to be eluted was the diene-tetrayne (III, R = CH_3) mixed with the "3650"-hydrocarbon. When reaching 10 % benzene in petroleum ether there appeared mixtures exhibiting the "3650"-chromophore spectrum with the indistinct spectrum of the tetraene-diyne (II). II crystallised readily from these fractions in a pure state. All the fractions eluted between the polyenynes II and III showed ultraviolet spectra very similar to that originally given for the "3650"-hydrocarbon. When these fractions were inspected in infrared (mostly 12–20 fractions were taken between 2 % and 10 % benzene in petroleum ether) it turned out that the intensity of the peaks be-

longing to a monosubstituted phenyl-residue (1 493, 752 and 686 cm^{-1}) increased relative to the other infrared bands with increasing concentration of benzene. Chromatography alone only lead to a slight displacement of the concentrations. By fractional distillation at $10^{-3}-10^{-4}$ mm Hg the phenyl-containing component was slightly more volatile than the aliphatic component. Redistillation, therefore, on the one hand was suitable to get rid of solvents and decomposition products, on the other hand some enrichment of the phenyl-compound took place in the most volatile part.

All fractions solidified at -40 to $-70°$; also from petroleum ether crystals will mostly be deposited at $-70°$. The crystallisates were more or less greasy and mostly the solutions had the same composition as the whole fraction. However, when chromatography, distillation and rechromatography had brought the separation above a certain concentration, crystallisation at $-70°$ sometimes gave the components nearly spectroscopically pure.

2. n-*Trideca-1:3:11-triene-5:7:9-triyne, (V, R = H)*. The purest fraction obtained showed a rather unsharp m.p. at 51—56°, vacuum; the U.V.spectrum is given in Fig. 2, the infrared spectrum in Fig. 3.

Catalytical hydrogenation: 30.8 mg V, R = H, were hydrogenated in absolute alcohol with 20 mg palladium on barium sulphate as catalyst. At 764 mm, t = 20°C, 37.3 ml of hydrogen (8.25 ⌶) were taken up, calculated for 9 ⌶ 40.8 ml. The solution was worked up in the usual way. After distillation at 8 mm the distilled product melted at -7.5 to $-6.8°$. *n*-Tridecane [1] melted at -6.5 to $-5.5°$, mixed m. p. -7.3 to -6.3°C. The infrared spectrum agreed in every detail with that given for *n*-tridecane [1].

3. trans-*1-phenylhepta-1:3-diyn-5-ene from* Coreopsis. The purest fraction obtained melted at 22—24°. The U.V.-spectrum is given in Fig. 2, the infrared spectrum in Fig. 3.

Synthesis of cis *and* trans *hepta-1:3-diyn-5-ene*. The synthesis was achieved by oxidative coupling of phenylacetylene with *cis* and *trans*-pentenyne. The pentenyne isomers were prepared according to Eglinton and Whiting [15], the fractionation being controlled by infrared measurements. Both oxidative couplings were carried out under the same experimental conditions, as exemplified for the *cis* compound:

2 ml of *cis*-pentenyne and 4 ml of phenylacetylene were dissolved in 200 ml of a 1:1 mixture of methanol and acetone at -20°C; to this mixture was slowly added a solution of 15 g of cuprous chloride, 40 g of ammonium chloride, 2 g of iron(III) chloride and 1 ml of conc.hydrochloric acid in 125 ml of water with a vivid stream of oxygen bubbling through the solution. The flask containing the mixture was kept in a bath of acetone-carbon dioxide maintained at $-20°$ for 18 h. The reaction mixture was extracted with ether; the ether solution on evaporation left a crystalline mass. Some of the diphenyldiacetylene remained undissolved by washing with ether. This ether solution again was evaporated and the residue dissolved in petroleum ether and chromatographed on alumina with 2 % benzene in petroleum ether.

The first fractions were oily at room temperature, these fractions were distilled at 0.0001 mm. At room temperature deca-diene-2:8-diyne-4:6 went off, at 50° (bath temperature) 0.15 g of a colourless liquid distilled off. This fraction remained as a liquid at -20°C.

Ultraviolet absorption of *cis*-1-phenylhepta-1:3-diyn-5-ene in hexane:

ε_{max}	20 400	24 000	17 800	10 800	32 400	33 900	
λ_{max}	3 190	2 990	2 800	2 650	2 520	2 410	Å

The maxima differ neither in position nor in intensity from the naturally occurring and the synthetic *trans* isomer within the limits of experimental errors (*cf.* below). The synthetic *trans* isomer melted at 23—24°C.

Ultraviolet absorption of *trans*-1-phenylhepta-1:3-diyn-5-ene in hexane:

ε_{max}	19 300	22 650	18 200	11 750	26 900	29 200	
λ_{max}	3 180	2 975	2 795	2 645	2 525	2 410	Å

As will be seen from Fig. 3 the *cis* and *trans* isomers differ appreciably in the infrared and just in the positions expected. The infrared spectra confirm the conclusion from the melting point that the *Coreopsis* Compound is the *trans* isomer. At the same time small

additional peaks in the infrared spectrum of the phenylheptadiynene from *Coreopsis* species just agree with the strongest peaks in the *n*-decatrienetriyne, and clearly indicate that the separation was not completely successfull, although the contamination is so small that it does not disturb the identification.

Studies Related to Naturally Occurring Acetylene Compounds XXIII. 1-Phenylhepta-1:3:5-triyne from *Coreopsis grandiflora*, Hogg ex Sweet

JÖRGINE STENE SÖRENSEN and NILS ANDREAS SÖRENSEN

Institutt for Organisk Kjemi, Norges Tekniske Högskole, Trondheim, Norway

A preliminary investigation of some perennial species belonging to the genus *Coreopsis* revealed the occurrence of 1-phenylhepta-1:3:5-triyne (VII) in Nature. The constitution of this new polyacetylene has been confirmed by synthesis.

In the XVII[th] communication of this series Sörensen and Sörensen [1] described the isolation of 4 new polyacetylenic compounds from some annual garden varieties of the genus *Coreopsis* L., family *Compositae*. As shown in the preceding communication [2] one of these compounds turned out to be a mixture of two previously unknown polyacetylenes raising the number of acetylenic compounds with established structure in annual *Coreopsis* species to the 5 compounds (I)—(V).

(I) $CH_3-CH=CH-C\equiv C-C\equiv C-C\equiv C-C\equiv C-CH=CH_2$

(II) $CH_3-CH=CH-C\equiv C-C\equiv C-C\equiv C-CH=CH-CH=CH_2$

(III) $CH_3-CH=CH-C\equiv C-C\equiv C-CH=CH-CH=CH-CH=CH_2$

$-C\equiv C-C\equiv C-CH=CH-CH_2-R$, (IV) R=H, (V) R=OCOCH$_3$

(VI) $CH_3-C\equiv C-C\equiv C-C\equiv C-C\equiv C-C\equiv C-CH=CH_2$

(VII)

$-C\equiv C-C\equiv C-C\equiv C-CH_3$

In that preliminary work only one single perennial *Coreopsis* species was investigated, *viz. C. verticillata* L. The tetrayne (I) was present in the roots, but otherwise *C. verticillata* differed remarkably from the other *Coreopsis* species through a high content of 2:6-dimethyloctatetraene = Cosmene, first isolated

A.	1-Phenyl-hepta-triyne-1:3:5 (VII) ————	(scale left side)
B.	6(?)-chloro-1-phenyl-hepta-1:3-diyn-5-ene — — — — — — —	» » »
C.	1-Phenyl-hepta-1:3-diyn-5-en-ol-7-acetate (V) —.—.—.	» » »
D.	1-Phenyl-hepta-1:3-diyn-5-ene (IV)	» » »

from *Cosmos bipinnatus*, but so far only found in traces in one annual *Coreopsis*, *viz. C. Drummondii* [3].

The next perennial *Coreopsis* which incidentally was investigated was *C. grandiflora*, Hogg ex Sweet. Although the tetrayne (I) was readily recognisable in the long-wave part of the spectrum of the primary acetone exctracts from the root part, the U.V.-spectra of all parts of *C. grandiflora* were dominated by a fine structure spectrum, *cf.* Fig. 1, curve A, so far not found in the investigated annual members of the genus. By chromatography on alumina the new chromophore followed immediately after small fractions containing the characteristic absorption bands of the tetra-acetylene (I) and the penta-acetylene (VI). The occurrence of (VI) seems to be characteristic of tribus *Inuleae* but

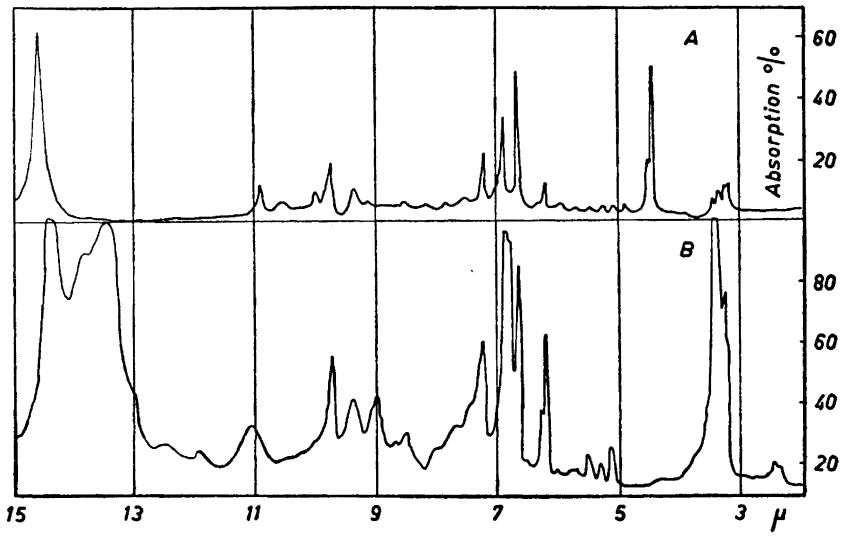

Fig. 2. Infra red absorption of
A. 1-Phenyl-hepta-1:3:5-triyne in $CHCl_3$, c = 11 %, l = 0.05 mm
B. 1-Phenyl-*n*-heptane, liq. l = 0.025 mm.

has not so far been found in the genus *Coreopsis* itself; it has already been found in other members of tribus *Heliantheae* including representatives of sub-tribus *Coreopsidinae*. A number of chromatographic fractions eluted with 10 % benzene in petroleum ether immediately delivered the new chromophore in crystalline condition. Recrystallisation from petroleum ether gave colourless prisms m.p. 55—56°C.

The ultraviolet spectrum was much sharper in fine structure than that of the 1-phenyloeta-1:3:5-triyne synthesised by Bruun, Skatteböl and Sörensen [4] but identical in position of the maxima within the limits of the experimental errors:

$C_6H_5-(C\equiv C)_3-CH_2-CH_3$	λ_{max} :	3 315	3 100	2 905	2 735	2 595	2 510	2 387 Å
C. grandiflora, m. p. 55—56°	λ_{max} :	3 309	3 097	2 908	2 735	2 590	2 504	2 380 Å

That the new compound did contain the phenyl group was obvious from strong peaks in the infrared at 1 495 and 686 cm^{-1}, *cf.* Fig. 2, curve A.

Catalytical hydrogenation gave a liquid hexahydrocompound with a consumption of 5.9 mole hydrogen (calc. as $C_{13}H_8$). The infrared spectrum of this hexahydrocompound agreed almost completely with that of 1-phenyl-*n*-octane. These few facts strongly indicated the structure 1-phenylhepta-1:3:5-triyne (VII). This compound was synthesised along the same route which was used for the homologue [4], *viz.* reaction of phenylpropargylaldehyde with the di-Grignard derivative of but-1-yn-3-ol to give 1-phenylhepta-1:4-diyne-3:6-diol. Through the dichloride this glycol was converted into 1-phenylheptatriyne.

The intermediate glycol could not be obtained crystalline and although the synthesis was successful and the synthetic 1-phenylheptatriyne was identical with the new hydrocarbon from *C. grandiflora* a number of side reactions were met with. Some of these are described in the experimental part.

1-Phenylheptatriyne is a rather stable compound. It is volatile with steam and so it may also be isolated from essential oils. Due to the characteristic U.V.-spectrum it is easily recognised also when present in small quantities. For this reason we do not think it is a general component of the essential oil of all members of the genus *Coreopsis*. Rather it seems more abundant in the perennial members than in the annual. Of *C. tripteris* L. only a few plants were available and (VI) was present only in traces.

In *C. lanceolata* L. and *C. saxicola* Alex., of which the first is botanically closely related to *C. grandiflora*, the oils were in part so enriched in (VII) that it crystallised out when stored in a refrigerator.

That (VII) is not restricted to some section of the genus *Coreopsis* was established by a preliminary investigation of some members of the genus *Bidens*, some of which turned out to be very rich in VII. These investigations will be described in later communications of this series.

The botanists long ago have placed the 3 genera: *Bidens*, *Coreopsis* and *Cosmos* close together and many of their species have synonymous names in all three genera. A close relation *Bidens-Coreopsis* has been confirmed by the investigations of their acetylenes; so far, however, the few members of *Cosmos* which have been investigated have not shown any of those extensive variations in polyacetylenes which make *Bidens* and *Coreopsis* a promising field of further studies.

EXPERIMENTAL

Coreopsis grandiflora, Hogg ex Sweet, flowers. The flowering heads collected medio June 1954 were extracted with acetone and the lipids transferred to petroleum ether. The crude extract (0.75 ‰ of the fresh flowers), which was still deep orange from flower pigments, was chromatographed on alumina from petroleum ether solution. Washing with petroleum ether removed rather large amounts of colourless hydrocarbons (28 %). No chromophore appeared until the content of benzene in the eluting mixture was raised to about 10 %. In the first fraction the U.V.-maxima of the tetra-yne (I) which were just traceable in the spectrum of the crude oil, came out very clearly, however, with faint extra maxima belonging to the penta-yne (VI). This penta-yne, with the characteristic first maximum at 4 100 has been found in a lot of tribes of the *Compositae*, but so far not in the genus *Coreopsis*. As the calculated amounts of (I) and (VI) were far below 1 mg no attempt was made to isolate them in the crystalline state.

The subsequent washings with 10 % benzene in petroleum ether contained the new hydrocarbon, which on evaporation crystallised immediately. Recrystallisation of the residues from petroleum ether gave long, colourless prisms, m. p. 55° – 56°, unchanged on further recrystallisation.

U.V.-Spectrum, Fig. 1, curve A, infrared Fig. 2, curve A. Catalytical hydrogenation: 222.9 mg were hydrogenated with $Pd/BaSO_4$ catalyst; consumed 232 ml calculated for $C_{13}H_8$, 6 = 237 ml (759 mm, 21.5°C). The hexahydro compound was isolated in the usual way and the oil distilled. U.V.-Spectrum typical toluene type, λ_{max} 2 683 Å, log ε_{max} = 2.315. Infrared, Fig. 2, curve B.

Another batch of flowers of *C. grandiflora* was distilled in steam, yield 0.75 ‰. The essential oil (1.5 g) was stored in a refrigerator at −18°; phenyl-triyne (VII) after some time crystallised directly from the crude oil. Further amounts could be obtained in pure condition by chromatography as above. Total amount 0.22 g or close to 15 % of the essential oil.

Synthesis of 1-phenylhepta-1:3:5-triyne. But-1-yn-3-ol was prepared according to Campbell *et al.*[5] Phenylpropargyl aldehyde was prepared from α-bromo-cinnamic aldehyde (*Org. Syntheses 25*, 92) via the ethylene glycol acetal [6]. The dehydrobromination of this acetal was effected by boiling 113 g of the acetal with a solution of 50 g of potassium hydroxide in 500 ml of ethanol for 75 min. The phenylpropargyl aldehyde ethylene acetal was extracted with chloroform, dried and distilled, yield 96 %. The hydrolysis was carried out as for the diethyl acetal.

1-Phenylhepta-1:4-diyne-3:6-diol. 23 g of ethyl bromide was grignardised with Mg in 40 ml of dry ether. 7 g of but-1-yn-3-ol was added slowly during 1 h with external cooling. Dry tetrahydrofurane, 3 × 50 ml, was added to keep the Grignard compound in solution. To this solution 13 g of phenyl-propargyl aldehyde were added slowly, the temperature not being allowed to raise above 5°C. The reaction mixture was left for 12 h at room temperature, then decomposed with ammonium chloride and extracted with ether. The product was a viscous oil which could not be brought to crystallisation. In preliminary experiments purification by chromatography and high vaccum distillation was attempted, but with no success.

The crude diol was dissolved in 200 ml of dry ether, 10 ml of dry pyridine was added, and the temperature was brought down to −35°. As addition of thionyl chloride still gave vigorous reaction and dark tars, the thionyl chloride was diluted with 5 parts of dry ether and the reaction continued at −50 to −70°. The solvent was evaporated at 0° by suction. The oily residue was slowly added to a solution of 8 g of potassium in 140 ml of absolute alcohol at −30° and the reaction mixture stirred for half an hour during which the temperature rose to −20°. Pure nitrogen was led through the solution which was allowed slowly to reach 12° (1.5 h). It was decomposed with water and extracted with ether in the usual way.

The U.V.-spectrum of the crude reaction product was disappointingly unsharp, the unusual sharp peaks of the *C. grandiflora* substance being just noticeable. Chromatography on alumina removed all discolouring impurities but the fraction eluted with 10 % benzene in petroleum ether still had a very complex spectrum. Rechromatography and redistillation at first furnished 2 crystalline substances. The final chromatographic washings with 10 % benzene afforded fractions with U.V.-spectra identical with the *C. grandiflora* substance. These fractions gave a crude crystallisate, m. range 38−45°, after one recrystallisation from petroleum ether m. p. 52−53°, recrystallisation m. p. 55−55.5°, mixed m. p. 1:1 mixture 55 to 55.8° sharp. Infrared and U.V.-spectra identical within the errors of observation.

Whereas the main chromatographic fractions still gave very complex spectra, the first fractions with 10 % benzene gave oils devoid of the phenyl-triyne-chromophor. These could be induced to crystallise from petroleum ether in the low temperature refrigerator. The crystals did not show a sharp m. p., range 45−49°, but could be recrystallised to a rather sharp m. p. 61−62°. (Found: C 79.8; H 5.05. Infrared gave no indication of hydroxylic or carbonyl oxygen. The Beilstein test revealed halogen. Calc. for $C_{13}H_8Cl$: C 77.8; H 4.52.) As evident from the U.V.-spectrum, *cf.* Fig. 1, curve B, the substance must contain a phenyldiyn-ene chromophore, $C_6H_5-C\equiv C-C\equiv C-\underset{|}{C}=\underset{|}{C}-R$. In Fig. 1, curve C, *trans* 1-phenylhept-5-ene-1:3-diyn-7-ol acetate [1] and *trans* 1-phenylhept-5-ene-1:3-diyne [2] are given for comparison, both previously isolated from annual *Coreopsis* species and the constitution proved by total synthesis. It thus seems very probable that the crystalline side product, m. p. 61°, is 6-chloro-1-phenylhept-5-ene-1:3-diyne.

The liquid fractions were measured in the infrared. A band at 1 960 cm^{-1} indicated the presence of allenes; the nearest possibility should be 1-phenylhepta-5:6-diene-1:3-diyne. However, this liquid fraction did not give further amounts of 1-phenyl-hepta-triyne by treatment with potassium hydroxide.

Coreopsis grandiflora; leaves. The leaves and stems were distilled in steam; the essential oil amounted to 1.2 ‰. The U.V.-spectrum of the essential oil was nearly conformed with that of phenylheptatriyne (VII), calculated content 6.3 %. Chromatography as above furnished 440 mg of pure (VII).

Coreopsis grandiflora, root. The roots were extracted with acetone and the lipids transferred to petroleum ether. Yield 1.3 %. The U.V.-spectrum of the crude extract was dominated by the characteristic bands of (VII), but those of both (I) and (VI) could be recognised. Chromatography as above afforded 215 mg = 2.5 % of pure (VII). The components of some of the minor fractions will be treated in a following communication.

Coreopsis saxicola, leaves. The plants were cultivated at N.T.H., Trondheim, on open ground and harvested on September 16th 1955. Only very few flowers had appeared, altogether weighing 16 g from which 12 mg of essential oil was prepared. The U.V.-absorption of this small amount of essential oil from the flowers came very close to that of the leaves and so no further investigation of the flower oil was carried out.

5.2 kg of fresh leaves gave 0.7 ‰ of essential oil. The crude essential oil gave a sharp U.V.-absorption spectrum dominated by phenylhepta-triyne, calc. concentration of (VII) = 25 %. Incidentally this oil was stored for a long time in a refrigerator (−15°C) and then had deposited a layer of crystals, which after one recrystallisation from petroleum ether, melted at 54°. Mixed m. p. with authentic phenyl-heptatriyne (VII) 53−54°; ultraviolet and infrared spectra identical.

The mother liquor was chromatographed on deactivated alumina. The eluates with 8−10 % benzene in petroleum ether gave U.V.-spectra of pure (VII), all crystallised, giving altogether 1 g of pure (VII).

Coreopsis lanceolata, leaves. The plants were cultivated at N.T.H., Trondheim, on open ground and harvested during September 1955. Yield of essential oil 0.25 ‰. The oil was chromatographed on deactivated alumina and eluted with mixtures of petroleum ether and benzene. The eluates with less than 8 % benzene were devoid of absorption in the ultraviolet. All fractions eluted with petroleum ether with 8 % benzene gave the U.V.-spectrum of pure (VII) and all of them crystallised directly on evaporation, giving altogether some 100 mg of pure (VII) m. p. 55°, undepressed by authentic phenylhepta-triyne.

Studies Related to Naturally Occurring Acetylene Compounds XXIV. 2-Phenyl-5(α-propynyl)-thiophene from the essential oils of *Coreopsis grandiflora*, Hogg ex Sweet

JÖRGINE STENE SÖRENSEN and NILS ANDREAS SÖRENSEN

Institutt for Organisk Kjemi, Norges Tekniske Högskole, Trondheim, Norway

A crystalline compound, m. p. 43°, isolated from the flowers and leaves of *Coreopsis grandiflora*, Hogg ex Sweet, has been shown to be 2-phenyl-5-(α-propynyl)-thiophene (III) by synthesis of the tetrahydro compound 2-phenyl-5-*n*-propyl-thiophene. The relation of (III) and other naturally occurring thiophenes to polyacetylenic compounds is discussed.

The preceding (XXIII[rd]) communication of this series described the isolation of 1-phenylheptatriyne (I) from some perennial members of the genus *Coreopsis*[1]. (I) was the dominating chromophore of all parts of these oils and in some cases (I) crystallised directly from the crude oils. The oils from all parts of the plants were, however, fractionated by chromatography on slightly deactivated alumina in the usual way. (I) then appeared with the eluates with 10 % benzene in petroleum ether. Since *Coreopsis* species mostly have been characterised by a mixture of polyenynic hydrocarbons, the eluates with 10 % benzene in petroleum were arbitrarily divided into a number of fractions. After evaporation of these solutions in vacuum pure (I) crystallised immediately.

(I) 
(II) 
(III) 
When this standard procedure was applied to the extract from *Coreopsis grandiflora*, Hogg ex Sweet, five nice looking crystallisates were obtained, to the naked eye apparently very similar. The three first fractions melted sharply

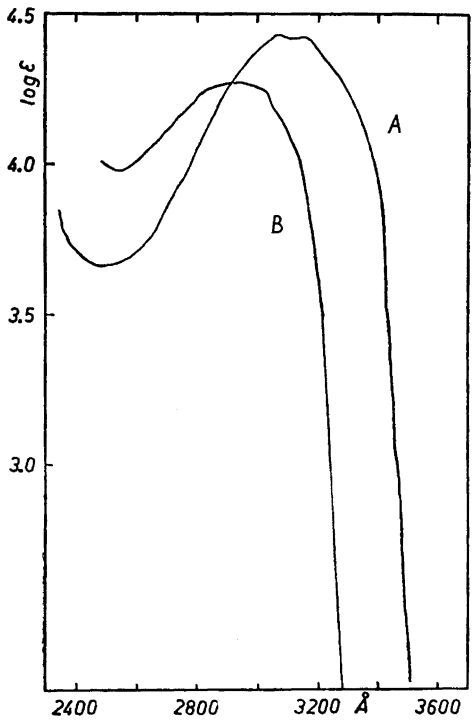

Fig. 1. Ultraviolet absorption in hexane of
A. 2-Phenyl-5-(α-propynyl)-thiophene.
B. 2-Phenyl-5-(*n*-propyl)-thiophene.

around 54°C, the two later also rather sharply, but around 40°C. Recrystallisation brought the m.p. of the later to 43°.

The U.V.-Spectrum, Fig. 1, curve A, with the broad single maximum at 3 100 Å did not indicate any relationship to phenylheptatriyne-1. The infrared spectrum, Fig. 2, curve A, with the sharp peak at 2 240 cm^{-1} revealed that the new compound was a disubstituted acetylene, further the characteristic peaks at 688 and 753 cm^{-1} indicated a monosubstituted phenyl residue.

Catalytical hydrogenation gave a liquid hydrocompound with a consumption of hydrogen so small that on a reasonable molecular weight obviously only the acetylenic bond had been hydrogenated. This was confirmed by the infrared spectrum of the tetrahydrocompound where the acetylenic band had disappeared, Fig. 2, curve B. The U.V.-spectrum of the tetrahydro compound, Fig. 1, curve B, demonstrated on one hand by the movement of the maximum about 200 Å towards shorter wavelengths relative to the starting material that the acetylenic bond was conjugated with the main chromophore, on the other hand that the tetrahydro compound must contain another chromophore resistant towards hydrogenation and conjugated with the phenyl group. Since carbonyl groups were absent, this result was somewhat surprising. Just at this stage of the investigations, however, appeared the communication of Birkinshaw and Chaplen [1] about one of the volatile components, "Junipal", of *Daedelia juniperina*, for which they proved the constitution 6-(α-propynyl)-

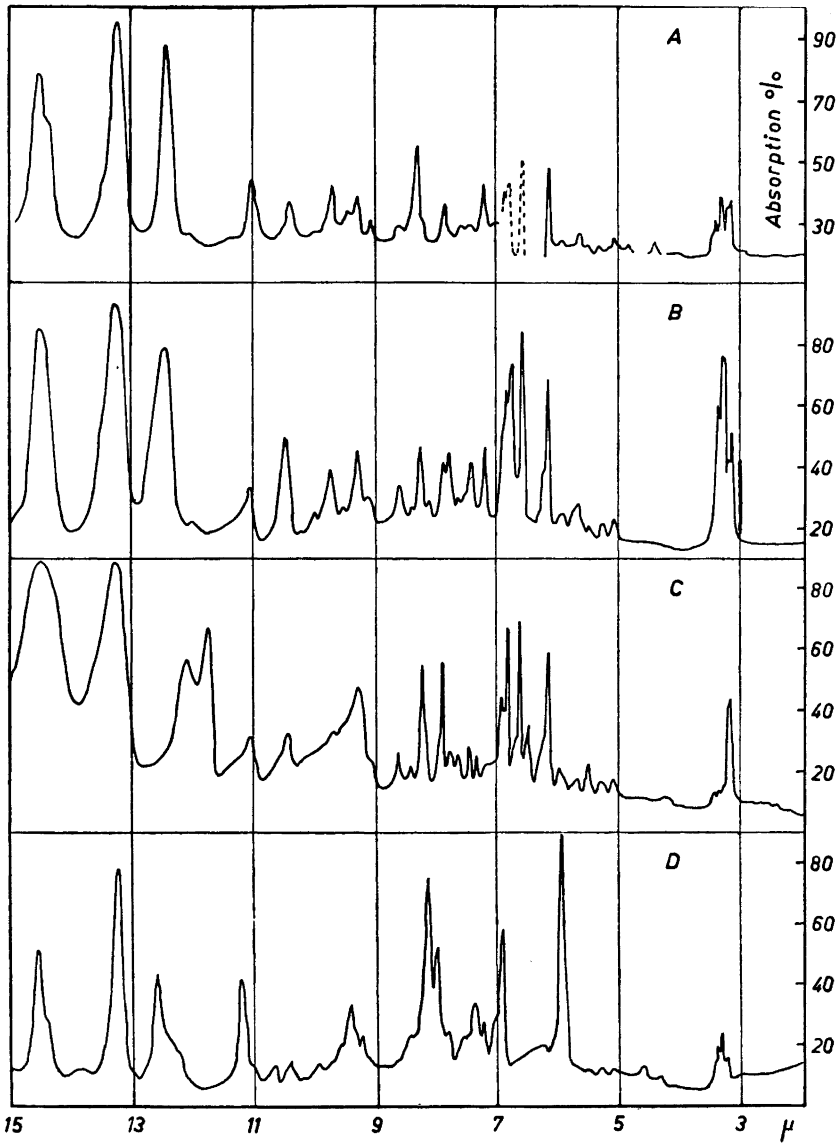

Fig. 2. Infrared absorption of

A. 2-phenyl-5-(α-propynyl)-thiophene (III) in CS_2; c = 24 %; l = 0.05 mm; dotted curve in CCl_4.
B. 2-phenyl-5-*n*-propyl thiophene liq.
C. 2-phenyl-thiophene liq. l = 0.0125 mm.
D. 2-phenyl-5-propionyl-thiophene in CS_2, c = 9.6 %; l = 0.05 mm.

2-formyl-thiophene (II). As there were some similarities in the infrared spectra the new compound, m.p 43°, was analysed on sulphur and gave 16.0 % S, calc. for $C_{13}H_{10}S$: S 16.3.

A compilation of the known infrared spectra of thiophenes, surveyed in the following communication [3], revealed that 2.5-disubstituted thiophenes are characterised by a single, strong peak at about 12.5 μ whereas all the other types of substituted thiophenes have two or more bands in other positions in the 11—15 μ area.

As will be seen from Fig. 2 the new compound fits well into the 2:5-disubstituted class and the observations cited then definitely pointed to the constitution as 2-phenyl-5-(α-propynyl)-thiophene (III).

The easiest way to prove this conclusion was by synthesis of the tetrahydro compound, 2-phenyl-5-*n*-propylthiophene, which followed the route 2-phenylthiophene → 2-phenyl-5-propionylthiophene → 2-phenyl-5-*n*-propylthiophene which, as expected, turned out to be identical in the U.V. and infrared with the tetrahydro compound.

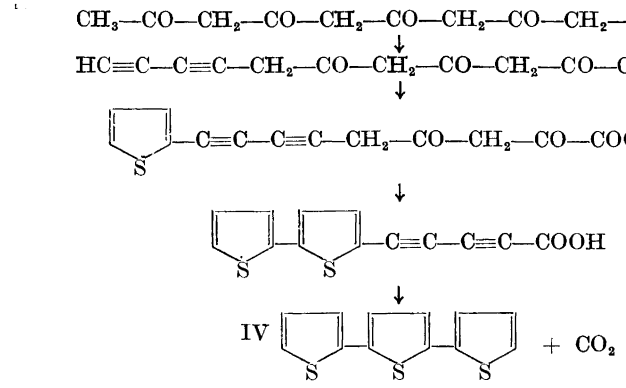
The new compound, m.p. 43, so definitely was proved to be 2-phenyl-5-(α-propynyl)-thiophene. Only 2 thiophene derivatives so far have been considered as naturally occurring thiophenes. The origin of the very numerous thiophene derivatives isolated from petroleum or shale oils is still quite uncertain. The first to be found was terthienyl (IV) isolated by Zechmeister and Sease [4] from the petals of the so-called "African" variety of *Tagetes erecta* L., belonging to the family of the *Compositae, Tribus Helenieae*. The second was the above metioned "Junipal" (II) from *Daedelia juniperina*, a bassidiomycete. Challenger and Holmes [5] suggested a connection between the occurrence of terthienyl and various polyacetylenes in the *Compositae*. Such a connection could be a very close one between 1-phenylheptatriyne (I) and 2-phenyl-5-(α-propynyl)-thiophene (III), as only an addition of hydrogen sulphide to a di-acetylenic group would transform (I) into (III) — chemically not at all an unlikely reaction. Terthienyl, which recently has been found in another *Compositae* plant, *Echinops sphaereocephalus*, would, however, by such a process demand the acetylenic precursor hexa-acetylene V

(V) $H-C\equiv C-C\equiv C-C\equiv C-C\equiv C-C\equiv C-C\equiv CH$

(VI) $HOOC-\underset{\underset{O}{\|}}{C}-CH_2-CH_2-\underset{\underset{O}{\|}}{C}-\underset{\underset{O}{\|}}{C}-CH_2-CH_2-\underset{\underset{O}{\|}}{C}-\underset{\underset{O}{\|}}{C}-CH_2-CH_2-\underset{\underset{O}{\|}}{C}-COOH$

As is well known the stability of unsubstituted acetylenes decreases very rapidly with chain-length. Diacetylene may be distilled, b.p. 9.5—10° [7], triacetylene decomposes already at −50° [8]; efforts to synthesise higher free polyacetylenes have only led to carbonaceous material [9]. Thus even in dilute solution in plant cells in the presence of possible stabilisers the occurrence of hexa-acetylene itself sounds very unlikely. We think it is more probable that some poly-keto precursors analogous to the poly-β-keto-precursors originally proposed by Collie [10] and revived in recent years by Robinson [11], Birch [12], Lipmann [13] and Woodward [14], may be the common precursors to both polyacetylenes and naturally occurring thiophenes. A direct formation of the

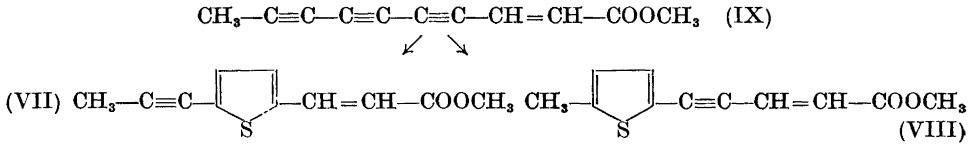
thiophene nucleus demands 1:4-diketo groupings, for example VI. It may be, however, that the ordinary β-keto-scheme is at work, that however, dehydration and thiophene formation follow stepwise:



We hope to bring further information on this interesting problem as preliminary investigations have revealed that about a dozen new compounds from members of the *Compositae* are really thiophene derivatives, in part acetylenic thiophenes.

The above mentioned *Echinops sphaereocephalus* is a very interesting case since it contains both terthienyl (IV) and some new polyacetylenes. The content of acetylenic compounds is low which makes progress rather difficult.

That the connection formally is in some cases as close as between phenylheptatriyne (I) and 2-phenyl-5-(α-propynyl) thiophene (III) has been demonstrated by a new compound isolated by E. Guddal from *Chrysanthemum vulgare* and for which he so far has been able to restrict the constitutional possibilities to (VII) and (VIII) which, however, formally are generated from the dehydromatricaria ester (IX) — found in closely related species — by addition of H_2S.



EXPERIMENTAL

The *Coreopsis grandiflora* oils used in this investigation are the same as in the preceding communication. III was not found in the extract from the root; the behaviour of the essential oils from the leaves and the flowers was so similar that only one of them is reported. *Ca.* 4 g of essential oil from the leaves (no accurate weight is given as the evaporation of the solvent (petroleum ether) intentionally was somewhat incomplete) was chromatographed on deactivated alumina. The material in the fractions containing 4—8 % benzene in petroleum ether crystallised immediately, all gave the correct m. p. 54—55° and had the characteristic ultraviolet spectrum of phenyl-heptatriyne (I). The succeeding eluates containing 8—15 % benzene in petroleum ether also crystallised very

well on evaporation to give prismatic needles resembling those of (I) very much, the m. p., however, was in the 40° range. Admixture with (I) gave a liquid at room temperature. Recrystallisation gave a sharp m. p. 42—43°. (Found (Zimmermann): S 15.4 and 16.0. Calc. for $C_{13}H_{10}S$: S 16.3). Ultraviolet spectrum in hexane, Fig. 1, curve A; log $\varepsilon_{max} = 4.43$; $\lambda_{max} = 3\,100$ Å; infrared spectrum, Fig. 2, curve A.

Catalytical hydrogenation. 27.7 mg (III) was hydrogenated with a Pd—$BaSO_4$ catalyst in alcohol. Consumed 6.9 ml hydrogen, $t = 18.5°C$, $p = 758$, calculated for $C_{13}H_{10}S$, 1 = 6.95 ml. The tetrahydro compound was isolated in the usual way and distilled, b. p. 45° (air bath) at 0.001 mm Hg. Ultraviolet spectrum of the tetrahydro compound in hexane, Fig. 1, curve B; log $\varepsilon_{max} = 4.30$: $\lambda_{max} = 2\,900$ Å. Infrared spectrum of the tetrahydro compound, Fig. 2, curve B.

*Synthesis of 2-phenyl-5-*n*-propylthiopene.* 2-Phenyl-thiophene was synthesised from β-benzoylpropionic acid according to Chrzasz-Czewska [15]. The m. p. of 2-phenylthiophene could not be raised above 32—33°C; reported [15] 42—43°. (Found: S 19.8 and 19.5. Calc. for $C_{10}H_8S$: S 20.0). Infrared spectrum Fig. 2, curve C.

650 mg of 2-phenylthiophene was condensed with 1 g of propionyl chloride according to Hartough and Kosak [16]. The reaction mixture was diluted with ether and then washed with water, potassium hydroxyde, water and the solvent was evaporated. The residue was distilled in high vacuum giving 360 mg of distillate which partly crystallised. Recrystallisation from petroleum ether gave slightly coloured plates, m. p. 87—88°. (Found: S 14.8. Calc. for $C_{13}H_{12}SO$: S 14.75). Infrared spectrum of 2-phenyl-5-propionylthiophene, Fig. 2, curve D. A Clemmensen reduction of 2-phenyl-5-propionylthiophene was first attempted in water at room temperature according to Fieser and Kenelly [17]. About one half of the unchanged ketone was recovered, the rest was lost. Then 100 mg of 2-phenyl-5-propionylthiophene was reduced with 2 g of amalgamated zink in alcoholic solution (6 ml of ethanol, 4 ml of hydrogen chloride (1:1)). The solution became turbid but turned clear with stirring and slight warming, reaction time 2 h.

The crude reaction product was devoid of carbonyl bands in the infrared. The oil was distilled, b.range 60—65°, air bath, 0.001 mm Hg. Ultraviolet and infrared spectra of the distillate were identical with those of the tetrahydro compound, which thus is 2-phenyl-5-*n*-propylthiophene.

Short Communications

The Crystal Structure of (—)-2-Methyl-2-Ethyleicosanoic Acid

ERIK von SYDOW

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

In connection with crystal structure investigations of normal and branched chain fatty acids [1-3], the molecular packing of (—) - 2 - methyl - 2 - ethyleicosanoic acid ($C_{23}H_{46}O_2$) has been determined. Only one X-ray investigation of a fatty acid substituted with a larger group than a methyl group is published: the unit cell dimensions of 14-DL-ethylhexadecanoic acid by Clark and Chu [4].

Ställberg-Stenhagen [5] points out that (—)-2-methyl-2-ethyleicosanoic acid crystallizes from light petroleum (b.p. 40—60°C) in a very beautiful way. The crystals are extremely long (5 cm) and lath-shaped, and they have a lustrous appearance. The racemic form of the acid does not crystallize so easily. No polymorphism is reported or observed.

The shape and the optical properties of the crystals indicated an orthorhombic space group, which was confirmed by the single crystal X-ray investigation, from which the following data was obtained:

$a = 8.150$, $b = 9.214$, $c = 31.50$ Å (± 0.2 %)
$d_{calc.} = 0.996$ gcm^{-3}, $d_{meas.} = 0.991$ gcm^{-3},
4 molecules per unit cell.

Absent reflexions: ($h00$) when h odd, ($0k0$) when k odd.
Space group: D_2^3—$P\,2_12_12$ (No. 18).

Sharpened Patterson projections along the three axes were calculated. From these and from the reciprocal lattice the subcell, *i. e.* the cell which describes the repetition in and of the hydrocarbon chains, was evaluated (Fig. 1). Its dimensions are $a_s = a = 8.150$, $b_s = b = 9.214$ and $c_s = 2.551$ Å (± 0.2 %), 8 CH_2-groups per subcell and space group D_2^3—$P\,2_12_12$ with $x_1 = 0.315$, $y_1 = 0.205$, $z_1 = 0$ and $x_2 = 0.315$, $y_2 = 0.295$, $z_2 = 0.500$. The chains are parallel and run parallel with c_s and c, and all the chain planes are also parallel with each other and with the $_sc_s$-plane (bc-plane). This subcell has never been found before.

Knowing the subcell structure and the main cell symmetry, the positional parameters of the atoms in the hydrocarbon chains could be directly determined. From spatial considerations the rest of the atoms were placed in the main cell and cycles of structure factor calculations and electron density projections along the shortest axes were performed. The molecular packing is shown schematically in Fig. 2. The structure will be refined in three dimensions.

There are two particularly interesting things in this structure: the new subcell and the hydrogen bond system. This subcell will be called O ∥ as compared with O ⊥ for the common orthorhombic chain pack-

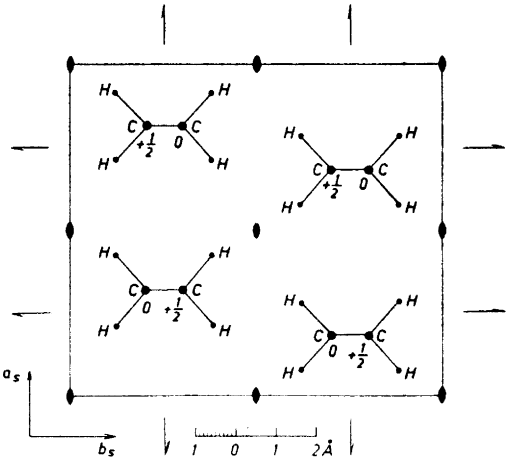

Fig. 1. The new orthorhombic subcell O ∥.

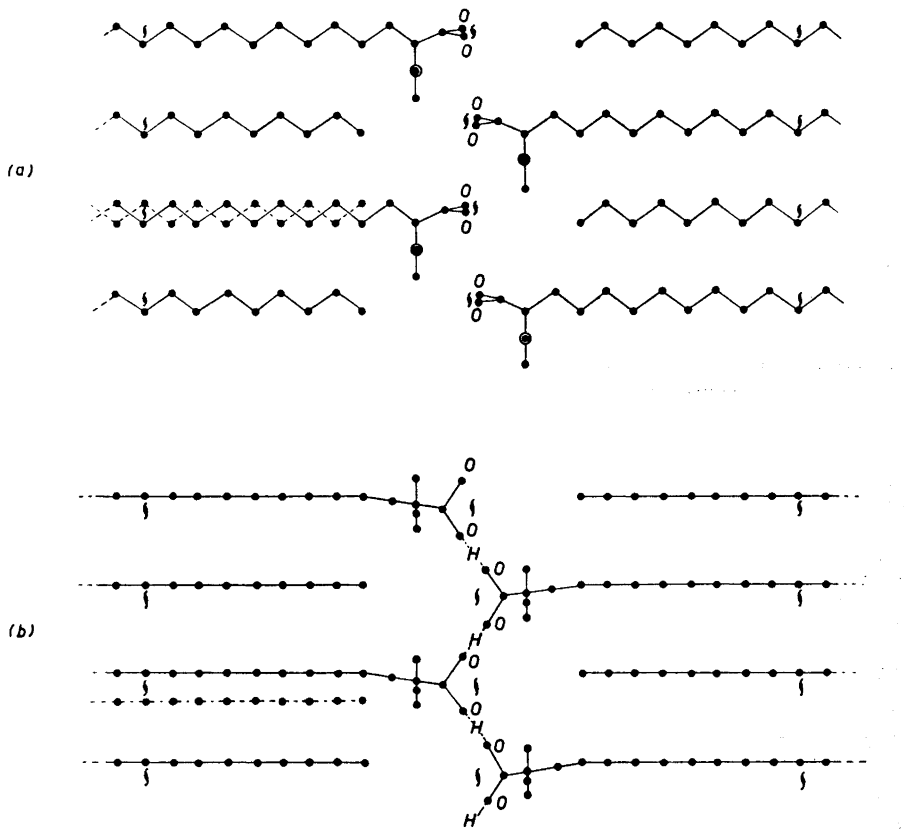

Fig. 2. (a) Schematic view along the *a*-axis and (b) along the *b*-axis of (—)-2-methyl-2-ethyleicosanoic acid.

ing [1], in which every second chain plane is approximately perpendicular to the others, and with T ∥ for the triclinic chain packing [1], in which all chain planes are parallel. Following a suggestion by Vand [6], the crystal structure of (—)-2-methyl-2-ethyleicosanoic acid should be classified as O ∥ (001), where (001) are the indices in the subcell of the *ab*-plane of the main cell.

A detailed comparison with the X-ray photographs given by Buerger [7] for *a*-sodium stearate hemihydrate reveals that that compound has the same hydrocarbon chain packing as (—)-2-methyl-2-ethyleicosanoic acid, *i. e.* O ∥.

The volume per CH_2-group in O ∥ is 23.95 Å^3, which is significantly larger than the corresponding volume in O | with comparable chain length [1] (23.3 Å^3). This means that the van der Waals interaction between chains of this length is larger in O ⊥ than in O ∥. In the case of (—)-2-methyl-2-ethyl-eicosanoic acid, however, this is compensated by the fact that, seen along the chains, the space occupied by two chains (Figs. 1 and 2) in O ∥ is the same as the space occupied by the branching groups and the carboxyl group of one molecule. The resulting hydrogen bond system (Fig. 2 b) is interesting in that one molecule is not bound to one other molecule (dimerization), as is usually the case with fatty acids [1-3], but to two other molecules, giving an one dimensional hydrogen bond helix parallel with the *a*-axis. Thus it is not surprising to find that

the *a*-direction is the same as the very much pronounced lath-direction of the crystals, mentioned above. The cleavage is also consistent with this arrangement. A somewhat similar hydrogen bond system has been found for formic acid [8], but never before for a long chain carboxylic acid.

Thanks are due to Professor S. Ställberg-Stenhagen for the crystals and to Professor E. Stenhagen for the measured density and his constant interest in this work. The expenses involved have been defrayed by grants from the *Swedish Natural Science Research Council.*

The Fractionation of Spruce Wood

J. A. McPHERSON

Institutt for Treforedlingskjemi, Norges tekniske högskole, Trondheim, Norway

During the investigations on milled spruce wood, Björkman [1] was able to isolate material containing both lignin and carbohydrates and which was designated lignin-carbohydrate complexes (LCC).

It is proposed to report the preliminary results of further investigations on the extraction of wood with dimethyl sulphoxide (DMSO), of which brief mention has already been made [2].

The fractionation of milled spruce wood has been carried out by the successive extraction with dioxane, dimethyl formamide (DMF), DMSO and water, following which the cellulosic residues were recovered in yields of 41—43 %. These residues contained small amounts of lignin and hemicelluloses.

The extracts were fractionated at first by precipitation with selective solvents, but in an effort to avoid coprecipitation, later work involved distribution on columns of alumina, sand, or metallic oxides. However, when these were found to degrade the lignin, Celite columns were used instead. But in each case it was possible to isolate a series of lignin-carbohydrate complexes, together with relatively pure lignin and hemicellulose fractions. Except in one case where a small amount of a fraction containing glucose and mannose only (1:1.24) together with small amounts of lignin, was isolated from an alumina column, the LCC even where the lignin content was very small, still contained carbohydrates in the same approximate ratio as in the original hemicelluloses.

In one series of fractionations of milled spruce wood, the total amount extracted (31 %) was recovered almost entirely in the dioxane (9 %), DMF (7 %), DMSO (11.2 %) and the aqueous extracts (2 %). The difference is to be found in the DMSO mother liquors which were not further investigated in this series. The dioxane extract yielded a series of lignin fractions (CH_3O, 13—15 %) containing small amounts of carbohydrates, while the DMF extract gave a series of LCC (CH_3O, 5—12 % and lignin 10—90 %). Both the DMSO and the aqueous extracts could be largely precipitated by ethanol, yielding LCC material with 4 % CH_3O and about 22 % lignin. Whether the DMSO extract was precipitated by dioxane, ethanol or benzene, the complexes obtained still had methoxyl contents of about 3.5—4 % and lignin of about 22 %. Refractionations of these LCC gave a number of widely different fractions, with respect to their lignin content. Such fractionations were usually carried out on Celite columns with a combination of various solvent systems, *e. g.* ethyl acetate-acetic acid-water, butanol-pyridine-water or DMF-dinitromethane-water *etc.*

Intermediate lignin fractions, soluble in benzene and sometimes ether, were obtained in the first fractions from the Celite columns.

Since the relative proportion of the lignin to hemicellulose in the LCC modifies the solubility of the complex it was not surprising that LCC were isolated from clear solutions of benzene, dioxane, ethanol, water etc. Perhaps better methods for their isolation may be based on electrophoretic techniques.

the *a*-direction is the same as the very much pronounced lath-direction of the crystals, mentioned above. The cleavage is also consistent with this arrangement. A somewhat similar hydrogen bond system has been found for formic acid [8], but never before for a long chain carboxylic acid.

Thanks are due to Professor S. Ställberg-Stenhagen for the crystals and to Professor E. Stenhagen for the measured density and his constant interest in this work. The expenses involved have been defrayed by grants from the *Swedish Natural Science Research Council.*

The Fractionation of Spruce Wood

J. A. McPHERSON

Institutt for Treforedlingskjemi, Norges tekniske högskole, Trondheim, Norway

During the investigations on milled spruce wood, Björkman [1] was able to isolate material containing both lignin and carbohydrates and which was designated lignin-carbohydrate complexes (LCC).

It is proposed to report the preliminary results of further investigations on the extraction of wood with dimethyl sulphoxide (DMSO), of which brief mention has already been made [2].

The fractionation of milled spruce wood has been carried out by the successive extraction with dioxane, dimethyl formamide (DMF), DMSO and water, following which the cellulosic residues were recovered in yields of 41—43 %. These residues contained small amounts of lignin and hemicelluloses.

The extracts were fractionated at first by precipitation with selective solvents, but in an effort to avoid coprecipitation, later work involved distribution on columns of alumina, sand, or metallic oxides. However, when these were found to degrade the lignin, Celite columns were used instead. But in each case it was possible to isolate a series of lignin-carbohydrate complexes, together with relatively pure lignin and hemicellulose fractions. Except in one case where a small amount of a fraction containing glucose and mannose only (1:1.24) together with small amounts of lignin, was isolated from an alumina column, the LCC even where the lignin content was very small, still contained carbohydrates in the same approximate ratio as in the original hemicelluloses.

In one series of fractionations of milled spruce wood, the total amount extracted (31 %) was recovered almost entirely in the dioxane (9 %), DMF (7 %), DMSO (11.2 %) and the aqueous extracts (2 %). The difference is to be found in the DMSO mother liquors which were not further investigated in this series. The dioxane extract yielded a series of lignin fractions (CH_3O, 13—15 %) containing small amounts of carbohydrates, while the DMF extract gave a series of LCC (CH_3O, 5—12 % and lignin 10—90 %). Both the DMSO and the aqueous extracts could be largely precipitated by ethanol, yielding LCC material with 4 % CH_3O and about 22 % lignin. Whether the DMSO extract was precipitated by dioxane, ethanol or benzene, the complexes obtained still had methoxyl contents of about 3.5—4 % and lignin of about 22 %. Refractionations of these LCC gave a number of widely different fractions, with respect to their lignin content. Such fractionations were usually carried out on Celite columns with a combination of various solvent systems, *e. g.* ethyl acetate-acetic acid-water, butanol-pyridine-water or DMF-dinitromethane-water *etc.*

Intermediate lignin fractions, soluble in benzene and sometimes ether, were obtained in the first fractions from the Celite columns.

Since the relative proportion of the lignin to hemicellulose in the LCC modifies the solubility of the complex it was not surprising that LCC were isolated from clear solutions of benzene, dioxane, ethanol, water etc. Perhaps better methods for their isolation may be based on electrophoretic techniques.

Spruce wood chlorite holocellulose was also milled under the same conditions as for the wood, where it was found that extraction with DMF yielded about 10 % of a brown film, containing both modified lignin and hemicelluloses, while extraction with water gave about 22 % of a very white powder, which contained only hemicelluloses. The cellulosic residue was obtained in a yield of 43 %.

Experiments with Methyl-fluoro-phosphorylcholine-inhibited Cholinesterase

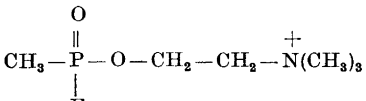
INGER ENANDER

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

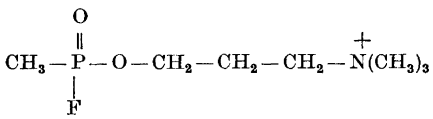
Organophosphorus cholinesterase inhibitors are considered to phosphorylate an esteratic site of the enzyme [1]. It has been demonstrated that phosphorylated cholinesterase can be reactivated through dephosphorylation by hydroxylamine derivatives [2].

Methyl-fluoro-phosphorylcholines have been shown to be potent cholinesterase inhibitors and cholinergic drugs [3,4]. It seemed thus to be of interest to investigate the possibilities of reactivating methyl-fluoro-phosphorylcholine-inhibited human erythrocyte acetylcholinesterase.

The inhibitors investigated were:



Methyl-fluoro-phosphorylcholine



Methyl-fluoro-phosphorylhomocholine

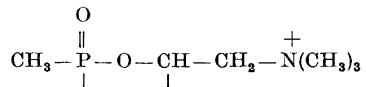
The reactivators investigated were: Pyridine-2-aldoxime methiodide (PAM)[5]; Nicotinhydroxamic acid methiodide (NAM)[6]; Di*iso*nitrosoacetone (DINA)[6]; Diacetylmonoxime (DAM, Hopkin and Williams Ltd. Chadwell Heath Essex, Engl.)

The reactivators were solved in Michel's veronal buffer (pH = 8) [7], the concentrations being 4×10^{-3} and 5×10^{-4} M. The experiments were carried out according to Davies and Green [6].

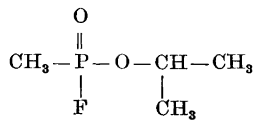
Washed erythrocytes, diluted to blood volume with saline, were treated with an aqueous inhibitor solution (10^{-6} M) for 10 min at 25°C. The inhibited cell-suspension was centrifuged, the erytrocytes washed and diluted to the same volume as before. Equal volumes of this cell-suspension and the reactivator-buffer solution were mixed and stored at 25°C. At intervals between 10 and 60 min after incubation, samples were taken for enzyme activity determinations, which were carried out by means of an electrometric method [7].

None of the reactivators reactivated the enzyme preparations, inhibited with any of the three methyl-fluoro-phosphorylcholines. However, as could be expected, Sarin-inhibited enzyme was reactivated by PAM[8] in parallel runs.

The prevented reactivation is interesting because it may throw some further light on the nature of the inhibitor-enzyme reaction. An ionic bond in the inhibited enzyme, analogous to that postulated in the substrate enzyme complex [9], and a shielding (Fig. 1) of the ionic site from the reactivator seem to explain the obstructed reactivation. The ionic bond increases the attraction of the organophosphoryl residue to the enzyme, which alone may be a sufficient explanation in case of DINA and DAM. In case of PAM and NAM



Methyl-fluoro-phosphoryl-β-methylcholine



Methyl-*iso*propoxy-phosphoryl fluoride, Sarin

Spruce wood chlorite holocellulose was also milled under the same conditions as for the wood, where it was found that extraction with DMF yielded about 10 % of a brown film, containing both modified lignin and hemicelluloses, while extraction with water gave about 22 % of a very white powder, which contained only hemicelluloses. The cellulosic residue was obtained in a yield of 43 %.

Experiments with Methyl-fluoro-phosphorylcholine-inhibited Cholinesterase

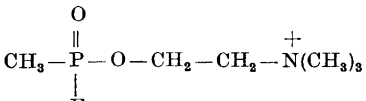
INGER ENANDER

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

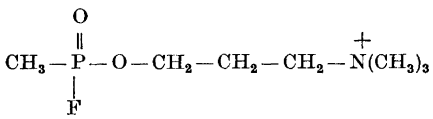
Organophosphorus cholinesterase inhibitors are considered to phosphorylate an esteratic site of the enzyme [1]. It has been demonstrated that phosphorylated cholinesterase can be reactivated through dephosphorylation by hydroxylamine derivatives [2].

Methyl-fluoro-phosphorylcholines have been shown to be potent cholinesterase inhibitors and cholinergic drugs [3,4]. It seemed thus to be of interest to investigate the possibilities of reactivating methyl-fluoro-phosphorylcholine-inhibited human erythrocyte acetylcholinesterase.

The inhibitors investigated were:



Methyl-fluoro-phosphorylcholine



Methyl-fluoro-phosphorylhomocholine

The reactivators investigated were: Pyridine-2-aldoxime methiodide (PAM)[5]; Nicotinhydroxamic acid methiodide (NAM)[6]; Di*iso*nitrosoacetone (DINA)[6]; Diacetylmonoxime (DAM, Hopkin and Williams Ltd. Chadwell Heath Essex, Engl.)

The reactivators were solved in Michel's veronal buffer (pH = 8) [7], the concentrations being 4×10^{-3} and 5×10^{-4} M. The experiments were carried out according to Davies and Green [6].

Washed erythrocytes, diluted to blood volume with saline, were treated with an aqueous inhibitor solution (10^{-6} M) for 10 min at 25°C. The inhibited cell-suspension was centrifuged, the erytrocytes washed and diluted to the same volume as before. Equal volumes of this cell-suspension and the reactivator-buffer solution were mixed and stored at 25°C. At intervals between 10 and 60 min after incubation, samples were taken for enzyme activity determinations, which were carried out by means of an electrometric method [7].

None of the reactivators reactivated the enzyme preparations, inhibited with any of the three methyl-fluoro-phosphorylcholines. However, as could be expected, Sarin-inhibited enzyme was reactivated by PAM[8] in parallel runs.

The prevented reactivation is interesting because it may throw some further light on the nature of the inhibitor-enzyme reaction. An ionic bond in the inhibited enzyme, analogous to that postulated in the substrate enzyme complex [9], and a shielding (Fig. 1) of the ionic site from the reactivator seem to explain the obstructed reactivation. The ionic bond increases the attraction of the organophosphoryl residue to the enzyme, which alone may be a sufficient explanation in case of DINA and DAM. In case of PAM and NAM

Antitryptic Effect of Some Seromucoids

HANS BENNICH and JOHN GOA

Department of Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden

It has since long been established that human plasma exerts an antitryptic effect, and many attempts have been made to isolate the active inhibitor from plasma. These experiments have been reviewed by Laskowski and Laskowski [1]. Thus Landsteiner [2] found the inhibitory activity within the albumin fraction, whereas Fujimoto [3] found inhibitory activity in both the albumin and globulin fractions. By means of paper electrophoresis Jacobsson [4] was able to confirm the suggestion that there are at least two different trypsin inhibitors in human serum, one moving with the α_1- and one with the α_2-globulin fraction.

It is also known that orosomucoid is resistent to tryptic digestion as shown by Yamashina [5] and by Popenoe and Drew [6]. In an earlier investigation [7] crude seromucoid was prepared by perchloric acid precipitation of human serum, and from the crude preparation seven subfractions were obtained by means of chromatography and preparative electrophoresis. The subfractions were called A-1, A-2, B-1, B-2, C-1, C-2 and C-3. Fraction B-1 was identical with the well known orosomucoid. With this fraction the earlier experiments showing its stability against tryptic hydrolysis were confirmed. Fraction B-1 or orosomucoid was also tested for antitryptic action. No inhibitory effect could be found when a pure preparation was used, whereas the crude seromucoid fraction inhibited tryptic hydrolysis of casein.

In the present investigation the inhibiting action against trypsin of all the subfractions of seromucoid have been studied. The experiments were performed at a constant pH with automatic registration of the amount of sodium hydroxide consumed as a function of time and with casein as substrate.

Experimental. The equipment used for the experiments consisted of a titrator, type TTT 1 a, Radiometer, Copenhagen. The amount of reagent consumed was registered by a mechanical recorder (constructed by Ole Dich, Copenhagen). The recorder also drives a microsyringe (0.5 ml) (Agla). The pH-stat is in detail described by Jacobsen *et al.*[8] The reaction vessel used was a three-necked beaker of pyrex glass so dimensioned that volumes down to 2 ml may be used without inconvenience. The electrodes and stirrer were affixed to a cover of perspex. The type of glass electrode used was a G 202 BT, Radiometer. Sodium hydroxide and nitrogen gas were instilled through the two smaller necks. The reaction vessel was kept at 25 ± 0.01°C in a water bath. Changes in room temperature during the experiments did not exceed more

Antitryptic Effect of Some Seromucoids

HANS BENNICH and JOHN GOA

Department of Medical Biochemistry, University of Gothenburg, Gothenburg, Sweden

It has since long been established that human plasma exerts an antitryptic effect, and many attempts have been made to isolate the active inhibitor from plasma. These experiments have been reviewed by Laskowski and Laskowski [1]. Thus Landsteiner [2] found the inhibitory activity within the albumin fraction, whereas Fujimoto [3] found inhibitory activity in both the albumin and globulin fractions. By means of paper electrophoresis Jacobsson [4] was able to confirm the suggestion that there are at least two different trypsin inhibitors in human serum, one moving with the α_1- and one with the α_2-globulin fraction.

It is also known that orosomucoid is resistent to tryptic digestion as shown by Yamashina [5] and by Popenoe and Drew [6]. In an earlier investigation [7] crude seromucoid was prepared by perchloric acid precipitation of human serum, and from the crude preparation seven subfractions were obtained by means of chromatography and preparative electrophoresis. The subfractions were called A-1, A-2, B-1, B-2, C-1, C-2 and C-3. Fraction B-1 was identical with the well known orosomucoid. With this fraction the earlier experiments showing its stability against tryptic hydrolysis were confirmed. Fraction B-1 or orosomucoid was also tested for antitryptic action. No inhibitory effect could be found when a pure preparation was used, whereas the crude seromucoid fraction inhibited tryptic hydrolysis of casein.

In the present investigation the inhibiting action against trypsin of all the subfractions of seromucoid have been studied. The experiments were performed at a constant pH with automatic registration of the amount of sodium hydroxide consumed as a function of time and with casein as substrate.

Experimental. The equipment used for the experiments consisted of a titrator, type TTT 1 a, Radiometer, Copenhagen. The amount of reagent consumed was registered by a mechanical recorder (constructed by Ole Dich, Copenhagen). The recorder also drives a microsyringe (0.5 ml) (Agla). The pH-stat is in detail described by Jacobsen *et al.*[8] The reaction vessel used was a three-necked beaker of pyrex glass so dimensioned that volumes down to 2 ml may be used without inconvenience. The electrodes and stirrer were affixed to a cover of perspex. The type of glass electrode used was a G 202 BT, Radiometer. Sodium hydroxide and nitrogen gas were instilled through the two smaller necks. The reaction vessel was kept at 25 ± 0.01°C in a water bath. Changes in room temperature during the experiments did not exceed more

than ± 1.0°C from the temperature of the water bath.

In all experiments a 2.7 % solution of casein was used as substrate. The substrate was prepared as follows: 5—6 g casein were mixed with 80 ml 0.1 M KCl and the pH adjusted to 6—7 by addition of 0.1 N NaOH (55 ml). The mixture was boiled until all casein was dissolved (about 15 min). After boiling, the solution was cooled to room temperature and filtered. The protein concentration of the filtrate was determined by the micro Kjeldahl method, whereupon the solution was diluted with 0.1 M KCl to a final concentration of 2.7 %. The enzymes used were crystalline preparations of trypsin (containing 50 % $MgSO_4$; Mann) and chymotrypsin (containing 50 % $(NH_4)_2SO_4$; Armour). In each experiment 4 ml of substrate was incubated for 10 min in a water bath (25°C) and pH was adjusted to 8.2 with 0.1 N NaOH in the pH-stat. The enzyme dissolved in distilled water was added to the casein solution to give a 0.001 % solution. Three groups of experiments were performed. In each group the same preparation of enzyme and substrate solutions was used. Before and after each group of experiments a reference experiment was performed — enzyme + substrate — in order to test the activity of the enzyme.

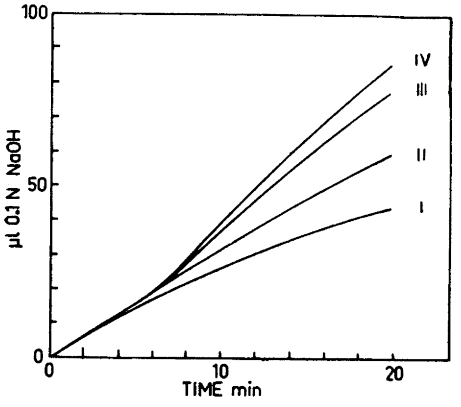

Fig. 1. Trypsin-inhibiting effect of crude seromucoid. In I, 4.3 mg of seromucoid was mixed with the substrate after which the enzyme was added. II is a reference experiment in which the standard amount of substrate was digested with the standard amount of enzyme. In III, a standard amount of enzyme digested a standard amount of substrate for 6 min, after which another standard amount of enzyme mixed with 0.3 mg seromucoid was added. In IV, a standard amount of substrate and enzyme reacted for 6 min and then an additional standard amount of trypsin was added.

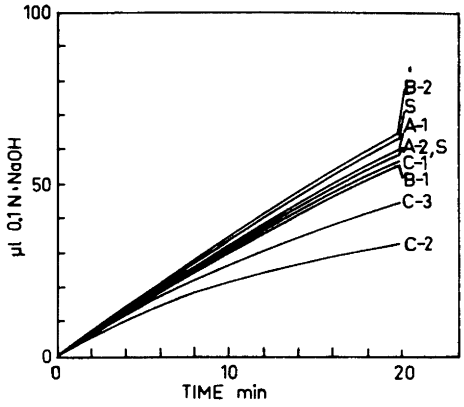

Fig. 2. Experiments with the subfractions of seromucoid. S means the reference experiments with standard amount of substrate and enzyme only. In each of the other experiments 5 mg of one of the different subfractions were incubated with substrate before addition of enzyme.

Results. Fig. 1 illustrates the experiments performed with crude seromucoid. The results indicate some trypsin-inhibiting effect of the crude fraction, this effect was obtained whether the seromucoid was incubated with the substrate or with enzyme as shown in the figure.

The next step was to test the effect on trypsin of each of the different subfractions prepared from the crude seromucoid as mentioned above. In each experiment 5 mg of each of the subfractions was dissolved in 4 ml substrate, incubated in a water bath and adjusted to pH 8.2 as described above.

From Fig. 2 it will be seen that mixing the substrate with either of the fractions C-2 or C-3 gave decreased hydrolysis as compared to that found in the reference experiments, thus indicating an inhibitory action of these fractions. This is in agreement with the observations of Jacobsson [4], as fraction C-2 electrophoretically is an α_1-globulin and fraction C-3 and α_2-globulin [7], as well as with the findings of Grob [8], that Cohn fractions IV-1 and IV-4 of human serum have protease-inhibitory

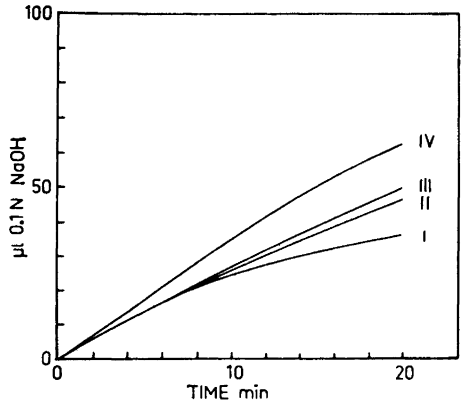

Fig. 3. In experiments I and IV, trypsin is used as enzyme. In I 5 mg of fraction C-2 is added, in IV no inhibitor. In experiments II and III chymotrypsin is used as enzyme, II with addition of 5 mg of fraction C-2, III without inhibitor.

activity. It will also be seen that fraction C-2 apparently has a stronger effect than fraction C-3. No inhibitory effect could be found when mixing the other subfractions of crude seromucoid with the substrate; the deviations from the reference experiments found were within the range of the experimental error (±5 %).

Finally the effect of fraction C-2 on hydrolysing casein with chymotrypsin was studied. Fig. 3 illustrates these experiments including a control experiment with trypsin. From the figure it will be seen that fraction C-2 showed no inhibitory effect on chymotrypsin.

The Alkaline Hydrolysis of Two Sarin Analogues and of Tabun

LENNART LARSSON

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

In an earlier report the alkaline hydrolysis of *iso*propoxy-methyl-phosphoryl fluoride (Sarin) has been studied, and the influence of substituents in the alkoxy and alkyl groups have been discussed [1]. In this paper the rate of the alkaline hydrolysis of two analogous compounds, dimethylamido-methyl-phosphoryl fluoride and ethylthio-methyl-phosphoryl fluoride, has been determined. Further it was of interest to study the alkaline hydrolysis of dimethyl-amido-ethoxy-phosphoryl cyanide (Tabun), the acid hydrolysis of which has earlier been examined [2].

The hydrolysis of the compounds was studied at various temperatures and pH-values in a 0.1 M solution of potassium chloride by means of an automatic recording titrator [3] by which the pH of the solution was maintained constant during the reaction. When the hydrolysis curves obtained from the recorder were treated according to the method given by Guggenheim, straight lines were obtained indicating first-order reactions.

In the hydrolysis of the two Sarin analogues two equivalents of acid were formed. In the hydrolysis of the dimethylamino derivative the P—N bond is assumed to be quite stable at the pH-values in question [4], and only the P—F bond can be considered to be broken. The hydrolysis products of the ethylthio derivative were analyzed by paper chromatography and only one spot indicating a phosphorus compound was obtained. When the paper was developed for sulphur one spot appeared which had the same R_F-value, 0.41, as the spot developed with the phosphorus reagent. These results indicate that only the P—F bond is split in the hydrolysis of the thio-compound also.

The first-order rate constants, k_1, for the hydrolysis of the two Sarin analogues are given in Table 1. The second-order rate constants, k_2, were calculated from

$$k_1 = k_2 \cdot c_{OH^-} = k_2 \cdot \frac{a_{OH^-}}{f_{OH^-}} = k_2 \cdot \frac{K_w}{f_{OH^-} \cdot a_{H+}}$$

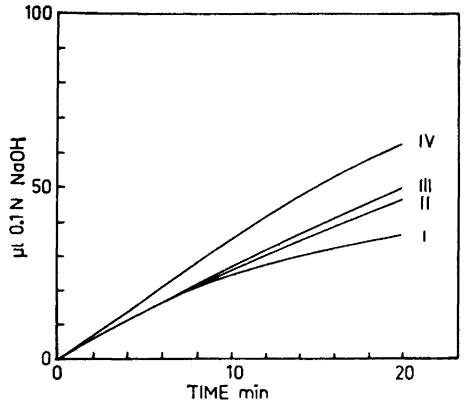

Fig. 3. In experiments I and IV, trypsin is used as enzyme. In I 5 mg of fraction C-2 is added, in IV no inhibitor. In experiments II and III chymotrypsin is used as enzyme, II with addition of 5 mg of fraction C-2, III without inhibitor.

activity. It will also be seen that fraction C-2 apparently has a stronger effect than fraction C-3. No inhibitory effect could be found when mixing the other subfractions of crude seromucoid with the substrate; the deviations from the reference experiments found were within the range of the experimental error (±5 %).

Finally the effect of fraction C-2 on hydrolysing casein with chymotrypsin was studied. Fig. 3 illustrates these experiments including a control experiment with trypsin. From the figure it will be seen that fraction C-2 showed no inhibitory effect on chymotrypsin.

The Alkaline Hydrolysis of Two Sarin Analogues and of Tabun

LENNART LARSSON

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

In an earlier report the alkaline hydrolysis of *iso*propoxy-methyl-phosphoryl fluoride (Sarin) has been studied, and the influence of substituents in the alkoxy and alkyl groups have been discussed [1]. In this paper the rate of the alkaline hydrolysis of two analogous compounds, dimethylamido-methyl-phosphoryl fluoride and ethylthio-methyl-phosphoryl fluoride, has been determined. Further it was of interest to study the alkaline hydrolysis of dimethyl-amido-ethoxy-phosphoryl cyanide (Tabun), the acid hydrolysis of which has earlier been examined [2].

The hydrolysis of the compounds was studied at various temperatures and pH-values in a 0.1 M solution of potassium chloride by means of an automatic recording titrator [3] by which the pH of the solution was maintained constant during the reaction. When the hydrolysis curves obtained from the recorder were treated according to the method given by Guggenheim, straight lines were obtained indicating first-order reactions.

In the hydrolysis of the two Sarin analogues two equivalents of acid were formed. In the hydrolysis of the dimethylamino derivative the P—N bond is assumed to be quite stable at the pH-values in question [4], and only the P—F bond can be considered to be broken. The hydrolysis products of the ethylthio derivative were analyzed by paper chromatography and only one spot indicating a phosphorus compound was obtained. When the paper was developed for sulphur one spot appeared which had the same R_F-value, 0.41, as the spot developed with the phosphorus reagent. These results indicate that only the P—F bond is split in the hydrolysis of the thio-compound also.

The first-order rate constants, k_1, for the hydrolysis of the two Sarin analogues are given in Table 1. The second-order rate constants, k_2, were calculated from

$$k_1 = k_2 \cdot c_{OH^-} = k_2 \cdot \frac{a_{OH^-}}{f_{OH^-}} = k_2 \cdot \frac{K_w}{f_{OH^-} \cdot a_{H+}}$$

Table 1. The first-order rate constants for the hydrolysis of dimethylamido-methyl-phosphoryl fluoride and ethylthio-methyl-phosphoryl fluoride at various temperatures and pH-values.

Dimethylamido-methyl-phosphoryl fluoride			Ethylthio-methyl-phosphoryl fluoride		
t°C	pH	$k_1 \times 10^4$ sec^{-1}	t°C	pH	$k_1 \times 10^3$ sec^{-1}
25.0	9.50	0.422	15.0	7.00	0.813
	9.50	0.428		7.00	0.770
	10.00	1.42		7.00	0.825
	10.00	1.42		7.50	2.49
	10.50	4.14		7.50	2.32
	10.50	4.29		7.50	2.53
35.0	9.42	1.42	25.0	7.00	2.60
	9.42	1.44		7.00	2.48
				7.00	2.56

The values of the activity coefficient, f_{OH^-}, and of the ionic product of water, K_w, were those reported in an earlier paper [1]. The values of k_2 and the energies and entropies of activation are given in Table 3.

The low rate of hydrolysis of the dimethylamino derivative can be attributed to the mesomeric effect of the nitrogen atom. Owing to the lower electronegativity of sulphur in comparison with that of oxygen it would be expected that the rate of hydrolysis of the ethylthio derivative should be lower than that of Sarin. However, the great hydrolytic instability of the thio-compound may probably be ascribed to the ready polarisability of sulphur [5] which also has been postulated by Heath for some related thio-compounds [6].

It has been shown that in the acid hydrolysis of Tabun the cyano group as well as the dimethylamino group are split off [2]. To check if the latter reaction occurred at pH 8.50 also, the reaction mixture was analyzed colorimetrically [7] for dimethylamine when the reaction had terminated (after about 20 h). It was found that about 4 % of dimethylamine had been formed. At higher pH-values the formation of dimethylamine was still less. This reaction could thus be neglected in the calculation of the rate constant for the split off of the cyano group. In the hydrolysis of Tabun less than two equivalents of alkali were consumed owing to the low dissociation constant of hydrocyanic acid. The observed rate constant, k_{obs}, was not found to be directly proportional to the hydroxyl ion concentration as appears from Table 2. Experiments with a 0.05 M solution of potassium chloride showed that the rate of hydrolysis was independent of the concentration of this salt. From these results one could conclude that a reaction between Tabun and water molecules also takes place and the following expression was found to be valid for the hydrolysis of Tabun:

$$k_{obs} = k_{H_2O} + k_2 \cdot c_{OH^-} = k_{H_2O} + k_2 \cdot \frac{K_w}{f_{OH^-} \cdot a_{H+}}$$

By plotting k_{obs} *versus* c_{OH^-} a straight line was obtained, and k_{H_2O} was found to be

Table 2. The observed rate constants for the hydrolysis of dimethylamido-ethoxy-phosphoryl cyanide (Tabun) at various temperatures and pH values.

$(0.40 \pm 0.02) \times 10^{-4}$ sec^{-1} at 25°C and $(0.44 \pm 0.11) \times 10^{-4}$ sec^{-1} at 35°C. The values of k_2 and the energies and entropies of activation for the alkaline hydrolysis of Tabun are given in Table 3.

Experimental. The syntheses of the two Sarin analogues have recently been published [8] and Tabun was synthesized according to Holmstedt [9]. In the kinetic experiments performed with the automatic titrator [3] the concentrations of the dimethylamino derivative and of Tabun were 0.40 mM and of the ethylthio derivative 0.20 mM. The first one was titrated with 0.1 M sodium hydroxide and the latter two with 0.05 mM sodium hydroxide. In other respects the procedure closely adhered to that described for the determination of the alkaline hydrolysis of Sarin [1]. In the paper chromatography ascending technique was used and 50 µl in portions of 5 µl of a 1 % aqueous solution of the ethylthio derivative were placed on a filter paper (Whatman No. 1). *Solvent: Tert.*-butanol: *iso*propanol: 2 M ammonium hydroxide (2:2:1). *Reagents:* Ammonium molybdate + hydrogen sulphide for the development of phosphorus [10] and N-ethyl-maleinimide for sulphur [11].

My sincere thanks are due to Professor G. Ljunggren, Director of this Institute, for the kind interest he has shown in this work.

$(0.40 \pm 0.02) \times 10^{-4}$ sec^{-1} at 25°C and $(0.44 \pm 0.11) \times 10^{-4}$ sec^{-1} at 35°C. The values of k_2 and the energies and entropies of activation for the alkaline hydrolysis of Tabun are given in Table 3.

Experimental. The syntheses of the two Sarin analogues have recently been published [8] and Tabun was synthesized according to Holmstedt [9]. In the kinetic experiments performed with the automatic titrator [3] the concentrations of the dimethylamino derivative and of Tabun were 0.40 mM and of the ethylthio derivative 0.20 mM. The first one was titrated with 0.1 M sodium hydroxide and the latter two with 0.05 mM sodium hydroxide. In other respects the procedure closely adhered to that described for the determination of the alkaline hydrolysis of Sarin [1]. In the paper chromatography ascending technique was used and 50 µl in portions of 5 µl of a 1 % aqueous solution of the ethylthio derivative were placed on a filter paper (Whatman No. 1). *Solvent: Tert.*-butanol: *iso*propanol: 2 M ammonium hydroxide (2:2:1). *Reagents:* Ammonium molybdate + hydrogen sulphide for the development of phosphorus [10] and N-ethyl-maleinimide for sulphur [11].

My sincere thanks are due to Professor G. Ljunggren, Director of this Institute, for the kind interest he has shown in this work.

The Influence of Anharmonicity upon the Vibrational Probability Densities and Mean Amplitudes in Molecules. The General Case of a Polyatomic Molecule with Non-Degenerate Normal Vibrations

ARNE REITAN

Institutt for teoretisk kjemi, NTH, Trondheim, Norway

The vibrational probability density for a general polyatomic molecule with non-degenerate normal vibrations and without accidental degeneracies has been calculated to terms of second order, making use of the Hamiltonian introduced by Darling and

Dennison [1], Herzberg [2], and Wilson, Decius and Cross [3]. The eigenvalues and eigenfunctions have been calculated by a standard second order perturbation calculation, and the summations over the different states have been performed by methods similar to those employed in the authors papers [4,5], the resulting probability density being

$$w(q_1,q_2,\ldots,q_f) = w^0\,(1 + a_0 + \sum_r a_r q_r + \sum_{r\leqslant s}\sum_s a_{rs}q_rq_s + \sum_{r\leqslant s}\sum_{s\leqslant t}\sum_t a_{rst}q_rq_sq_t + \sum_{r\leqslant s}\sum_{s\leqslant t}\sum_{t\leqslant u}\sum_u a_{rstu}q_rq_sq_tq_u + \sum_{r\leqslant s}\sum_{s\leqslant t}\sum_{t\leqslant u}\sum_{u\leqslant v}\sum_{v\leqslant x}\sum_x a_{rstuvx}q_rq_sq_tq_uq_vq_x)$$

where

$$w^0\,(q_1,q_2,\ldots,q_f) = \pi^{-f/2}\prod_{k=1}^{f}[\tanh(hc\omega_k/2kT)]^{1/2}\exp[-\tanh(hc\omega_k/2kT)\,q_k^2]$$

We have here introduced the convenient dimensionless coordinates

$$q_k = 2\pi(c\omega_k/h)^{1/2}\,Q_k$$

where ω_k is the wave-number corresponding to the normal coordinate Q_k, c is the velocity of light, and h is Planck's constant. The first order coefficients a_r and a_{rst}, as well as the second order coefficients a_0, a_{rs}, a_{rstu}, and a_{rstuvx} have been calculated in terms of the potential constants of the Hamiltonian, the wavenumbers ω_k, and the absolute temperature T, the obtained results being somewhat complex.

The results have been applied to the cases of non-linear and linear symmetrical XY_2 molecules (in the latter case the degeneracy of one of the normal vibrations has to be taken appropriately into account), and numerical calculations have been performed for the molecules H_2O and CO_2. The force constants have been obtained from Darling and Dennison [1] and Dennison [6]. The mean amplitudes

$$u_e^{AB} = [\overline{(R_{AB} - R_{AB}^{(e)})^2}]^{1/2}$$
$$u_a^{AB} = [\overline{(R_{AB} - \overline{R_{AB}})^2}]^{1/2}$$
$$u_m^{AB} = [\overline{(R_{AB} - R_{AB,m})^2}]^{1/2}$$

as well as the mean values $\overline{r_{AB}}$ and the most probable values $r_{AB,m}$ of the deviations $r_{AB} = R_{AB} - R_{AB}^{(e)}$, have been calculated. R_{AB} is here the distance between the nuclei A and B, $R_{AB}^{(e)}$, $\overline{R_{AB}}$, and $R_{AB,m}$ are the equilibrium value, the mean value, and the most probable value of R_{AB}, respectively. The results are listed in Tables 1 and 2.

Table 1. Mean amplitudes etc. for H_2O in Å units at $T = 300°K$.

O—H	Harmonic	Anharmonic	H—H	Harmonic	Anharmonic
$\overline{r_{OH}}$	0	0.0175	$\overline{r_{HH}}$	0	0.0277
$r_{OH,m}$	0	0.0121	$r_{HH,m}$	0	0.0274
u_e^{OH}	0.0655	0.0707	u_e^{HH}	0.1088	0.1166

A New γ-Glutamyltripeptide in *Juncus* Species

ARTTURI I. VIRTANEN and TERTTU ETTALA

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

Some years ago an acidic peptide was found in this laboratory in the ethanol extract of *Juncus conglomeratus* (Fig. 1). On a two-dimensional paper chromatogram the acid gave a violet spot on spraying with ninhydrin. After strong hydrolysis (6 N HCl, 20 h, 108°C), as well as after a mild one (0.5 N HCl, 10 h, 100° C), the spot was not detected on the chromatogram any longer, and hence it was apparently an easily decomposed peptide. The peptide was isolated in fairly pure form and was found to contain an easily split off glutamic acid molecule [1]. This peptide has now been isolated in completely pure form and its structure has been established.

For the isolation of the peptide 5 kg of *Juncus conglomeratus* was extracted in 70 % ethanol. The ethanol extract was run through an Amberlite IR-120 column. Amino acids were eluted by 1 N NH_4OH. When ammonia had been distilled off *in vacuo*, the residue was dissolved into 100 ml of water. The insoluble substance was filtered off and the filtrate was run through an Amberlite IR-45 column in acetate form. Neutral and basic amino acids were removed by water and the acidic ones by 0.5 N acetic acid. The unknown peptide (I) remained in the fraction with acidic amino acids, being accordingly acidic. After acetic acid had been distilled off there also was a substance (II) in the fraction of acidic amino acids which at first turned yellow on spraying with ninhydrin and then violet. This substance had apparently been formed through the partial decomposition of the original peptide. This peptide (I) was separated from the acidic amino acids on a cellulose powder column using butanol-acetic acid-water (630—100—270) as solvent. 160 fractions of 10 ml were taken and fractions 130—158 contained only the peptide without any free amino acids. These fractions were combined and the solvent was distilled off. The residue obtained was brown, however.

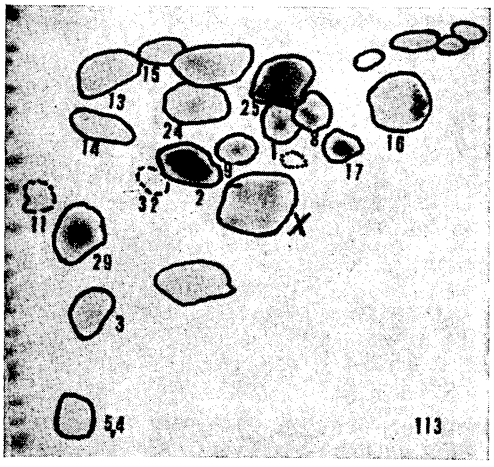

Fig. 1. Paper chromatogram of free amino acids (and some lowmolecular peptides) in *Juncus conglomeratus*. Solvents in text. × = unknown acidic peptide, 1 = gly, 2 = ala, 3 = val, 9 = threo, 16 = asp, 17 = glu, 29 = γ-amino-butyric acid.

As another method Dowex 1 resin (200—400 mesh, in acetate form) was used for the separation. About 100 mg of amino acids, eluted by 1 N NH_4OH from the Amberlite IR-120 column, were dissolved into 2 ml of 0.5 N acetic acid, and the solution was run through the Dowex 1 column (0.9 × 30 cm). The elution was performed by 0.5 N acetic acid and 1 ml fractions were taken. Also by this method the unknown peptide could be isolated, but the residue obtained after acetic acid had been distilled off was still brown.

After this both preparations were combined and once again run through the cellulose powder column, using water-saturated butanol as solvent. Now the brown impurity emerged from the column before the peptide, and the peptide-containing fractions were uncoloured. When the solvent was distilled off, the residue was white. The yield of peptide I was 160 mg.

When fractionating the original peptide from the cellulose powder column, the substance II was also collected. Since also this fraction was slightly coloured it was once again run through the cellulose powder column with water-saturated butanol. The yield obtained was 45 mg.

When hydrolysing the original peptide with 0.5 N HCl for 20 h at 100°C, glutamic acid was formed, as well as the substance

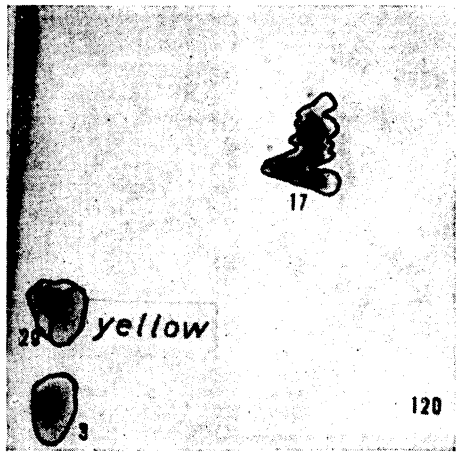

Fig. 2. Paper chromatogram of the unknown peptide after hydrolysis with 0.5 N HCl for 20 h at 100°C. 17 = glu, yellow = dipeptide formed on hydrolysis, 29 = added γ-amino-butyric acid, 3 = added val.

II which turned yellow on spraying with ninhydrin, and later on violet (Fig. 2). On hydrolysis of this substance in strong acid (6 N HCl, 20 h, 108°C) glutamic acid and valine were formed, and hence this substance also is a peptide. The same amino acids were also formed when hydrolysing the original peptide in strong acid.

The amounts of amino acids formed on hydrolysis were determined quantitatively using the copper salt method [2]. It was then found that on hydrolysis in dilute acid one molecule of glutamic acid was split off from the original peptide, and from the substance II one molecule glutamic acid and one molecule valine on hydrolysis in strong acid. The latter hydrolysis was not quite complete.

Tripeptide (I) (mild hydrolysis)	49	μg	glutamic	acid,	calc.	value*	50 μg
	45	»	»	»	»	»	50 »
Dipeptide (II) (strong hydrolysis)	25	»	»	»	»	»	39 »
	23	»	valine		»	»	31 »

The *molecular weight* of the original peptide, determined according to the method of Childs [3], was 341 (calc. value for a tripeptide containing two glutamic acid molecules and one valine molecule is 375). Glycyl-L-tyrosine, mol. wt. 238, was used as reference substance. The value obtained can be considered satisfactory when the low molecular weight of the known substance is taken into consideration.

The *nitrogen content* of the original peptide was determined by Kjeldahl according to Beet [4]; found 10.9 % N, calc. value for a tripeptide containing two glutamic acid molecules and one valine molecule ($C_{15}H_{25}O_8N_3$) 11.2 %.

The nitrogen content of the dipeptide formed on hydrolysis of the tripeptide in dilute acid was 10.81 %, calc. value for a dipeptide containing glutamic acid and valine ($C_{10}H_{18}O_5N_2$) 11.38 %.

R_F-values:	BuOH—AcOH—H_2O	Phenol
Tripeptide	0.31	0.49
Dipeptide	0.38	0.84

The position of glutamic acid and valine in the dipeptide was determined according to the method of Sanger [5]. It was found that the amino group in valine is free. Accordingly, the dipeptide is valyl-glutamic acid. Since the first glutamic acid molecule is split off from the tripeptide already on hydrolysis in dilute acid, it has to be linked to the dipeptide by its γ-carboxyl group, and the structure of the tripeptide is thus γ-glutamyl-valyl-glutamic acid HOOC · $CH(NH_2)$ · CH_2 · CH_2 · CO · NH · $CH(C_3H_7)$ · CO · NH · $CH(C_3H_5O_2)$ · COOH [6].

The tripeptide has been found by paper chromatography also in *Juncus effusus* and *Juncus filiformis*. There is about 100 mg/1 kg fresh plants of the tripeptide in *Juncus conglomeratus*.

Thanks are due to Miss Pirkko Kovakoski for her assistance in the isolation of the peptide and in the closer investigation of it in the first stage of the work in 1955.

* In the calculated values the original peptide has been supposed to be a tripeptide containing two glutamic acid molecules and one valine molecule.

Mass Spectrometric Evidence Regarding the Structural Relations between Dextropimaric, *Iso*dextropimaric, and Cryptopimaric Acids *

HENRIK H. BRUUN

Institute for Wood Chemistry, Åbo Akademi, Åbo, Finland,

RAGNAR RYHAGE

Laboratory for Mass Spectrometry, Kemiska Institutionen I, Karolinska Institutet, Stockholm, Sweden, and

EINAR STENHAGEN

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Sweden

A study of the mass spectra of the methyl esters of rosin acids, performed with a high-mass, high-resolution mass spectrometer with heated inlet system [1], has provided new evidence regarding the structural relations between dextropimaric acid, *iso*dextropimaric acid, and cryptopimaric acid [2].

The mass spectrum of the methyl ester of cryptopimaric acid (Fig. 1a) is strikingly similar to that of the methyl ester of dextropimaric acid (Fig. 1b). The base peak of the spectra is at *m/e* 121, and strong peaks occur at *m/e* 316 (molecular peak), 180, 181, 241, 257, and 301. The methyl ester of *iso*dextropimaric acid gives a quite different mass spectrum (Fig. 1c) that has the base peak at *m/e* 241 and strong peaks at *m/e* 316 (molecular peak), 256, 257, 287, and 301.

We interpret these results as showing that dextropimaric acid and cryptopimaric acid can be structurally different only with regard to the orientation of the methyl and vinyl groups attached to C7, and that dextropimaric acid and *iso*dextropimaric acid must be different with regard to the geometry of the ring system. The opinion of Wenkert [3] that the two last mentioned acids differ in the configuration at C13 is thus supported by the present evidence: As the proposed stereochemical difference at C7 [4] has recently been confirmed [5] it follows that the acids are stereochemically different both at C7 and C13.

The above conclusions seem to tally with monolayer [6] and infrared absorption [7-9] data.

Experimental. The cryptopimaric acid used had $[\alpha]_D^{12} - 21.7°$ and m.p. 160—162°.** Because of the small amount of material, the optical rotation was not checked by us. Keimatsu *et al.*[2] give m.p. 159—161° and $[\alpha]_D^{17.5} - 18.99°$ (in ethanol). The sample of dextropimaric acid had m.p. 207—208°, $[\alpha]_D^{25} + 70° \pm 3°$ ** (ethanol, micro tube), and the *iso*dextropimaric acid m.p. 160°, $[\alpha]_D^{25} \pm 0.00°$ ** in ethanol. The acids were converted into methyl esters by means of fresh diazomethane in ether solution. The mass spectra were run on 0.5 mg samples with the inlet system kept at a temperature of 200°.

Acknowledgements. We are indebted to Prof. H. Inamura, Government Forest Experiment Station, Meguro, Tokyo, for a sample of cryptopimaric acid, to Dr. R. V. Reactions between Quinones and Carbonyl Compounds Catalysed by Aluminium Oxide

RUNE MAGNUSSON

Institutionen för organisk kemi, Chalmers tekniska högskola, Göteborg, Sweden

In the course of studies on the oxidation of 2,6-dimethoxyphenol with sodium periodate [1], an attempt was made to separate, by chromatography on a column of aluminium oxide, a benzene solution of the previously unknown 3,8-dimethoxy-1,2-naphthoquinone (I) and 2,6-dimethoxy-*p*-benzoquinone (III). By irrigation with benzene, compound III was eluted while a red compound, assumed to be the naphthoquinone I, remained strongly adsorbed on the upper part of the column. This latter material was eluted with acetone and from the eluate two crystalline products were obtained. One of those was the expected naphthoquinone I; the other was a yellow substance. This indicated that an unexpected transformation of I had taken place either during the adsorption or during the elution step. To clarify this question, the following investigations were carried out.

When an acetone solution of the pure naphthoquinone I (m. p. 196°) was boiled for a few minutes in the presence of aluminium oxide the red solution became yellow, and from it yellow crystals (m. p. 142°) were obtained in a yield of 90 %. (In the absence of aluminium oxide a reaction did not occur and acetone was then a very suitable recrystallization solvent for I.) Analysis of the substance indicated that it might be an addition product formed from equimolar amounts of acetone and compound I. Ultra-violet and infrared absorption data, and the fact that on reduction the substance was converted into a compound having the properties of an α-naphthol with a free *p*-position, all suggested that the addition product might be the *o*-naphthoquinol of structure II.

2,6-Dimethoxy-*p*-benzoquinone (III) when heated in acetone solution in the presence of aluminium oxide also yielded an apparently similar type of addition product having m. p. 154°. Spectrographic examination of this compound, and its reduction to a phenol, to which the structure of 3,5-dimethoxy-4-acetonylphenol could be ascribed, indicated that the acetone addition compound of III was a *p*-quinol of structure IV.

Since the formation of the quinols II and IV involves a reaction of the aldol condensation type, it appeared possible that it might have been catalysed by traces of alkali present in the commercial aluminium oxide. This is improbable, however, as the catalytic effect of the aluminium oxide preparation was retained even after its thorough treatment with dilute hydrochloric acid (followed by washing with water). Thus, neutral aluminium oxide would appear to act as a catalyst of the reactions described.

Other ketones, for example methyl ethyl ketone, were also found to add to the quinones I and II in the presence of aluminium oxide.

Addition of acetone and of other ketones to tetrachloro-*o*-quinone has been reported by Schenck *et al.*[2] to be catalysed by dry

Reactions between Quinones and Carbonyl Compounds Catalysed by Aluminium Oxide

RUNE MAGNUSSON

Institutionen för organisk kemi, Chalmers tekniska högskola, Göteborg, Sweden

In the course of studies on the oxidation of 2,6-dimethoxyphenol with sodium periodate [1], an attempt was made to separate, by chromatography on a column of aluminium oxide, a benzene solution of the previously unknown 3,8-dimethoxy-1,2-naphthoquinone (I) and 2,6-dimethoxy-*p*-benzoquinone (III). By irrigation with benzene, compound III was eluted while a red compound, assumed to be the naphthoquinone I, remained strongly adsorbed on the upper part of the column. This latter material was eluted with acetone and from the eluate two crystalline products were obtained. One of those was the expected naphthoquinone I; the other was a yellow substance. This indicated that an unexpected transformation of I had taken place either during the adsorption or during the elution step. To clarify this question, the following investigations were carried out.

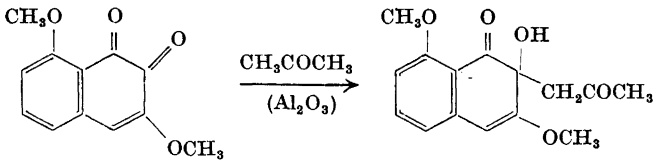
When an acetone solution of the pure naphthoquinone I (m. p. 196°) was boiled for a few minutes in the presence of aluminium oxide the red solution became yellow, and from it yellow crystals (m. p. 142°) were obtained in a yield of 90 %. (In the absence of aluminium oxide a reaction did not occur and acetone was then a very suitable recrystallization solvent for I.) Analysis of the substance indicated that it might be an addition product formed from equimolar amounts of acetone and compound I. Ultra-violet and infrared absorption data, and the fact that on reduction the substance was converted into a compound having the properties of an α-naphthol with a free *p*-position, all suggested that the addition product might be the *o*-naphthoquinol of structure II.

2,6-Dimethoxy-*p*-benzoquinone (III) when heated in acetone solution in the presence of aluminium oxide also yielded an apparently similar type of addition product having m. p. 154°. Spectrographic examination of this compound, and its reduction to a phenol, to which the structure of 3,5-dimethoxy-4-acetonylphenol could be ascribed, indicated that the acetone addition compound of III was a *p*-quinol of structure IV.

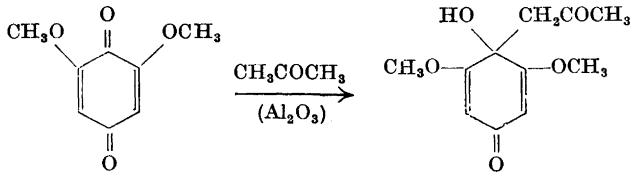
Since the formation of the quinols II and IV involves a reaction of the aldol condensation type, it appeared possible that it might have been catalysed by traces of alkali present in the commercial aluminium oxide. This is improbable, however, as the catalytic effect of the aluminium oxide preparation was retained even after its thorough treatment with dilute hydrochloric acid (followed by washing with water). Thus, neutral aluminium oxide would appear to act as a catalyst of the reactions described.

Other ketones, for example methyl ethyl ketone, were also found to add to the quinones I and II in the presence of aluminium oxide.

Addition of acetone and of other ketones to tetrachloro-*o*-quinone has been reported by Schenck *et al.*[2] to be catalysed by dry



I II



III IV

hydrogen chloride and probably resulted in the formation of the corresponding *o*-quinols. No other observations on the addition of ketones to quinones appear to have been published.

The quinols II and IV are stable in ethanol and in other neutral solvents. However, if an ethanolic solution of IV is heated in the presence of aluminium oxide, the quinone III is regenerated. It is possible, therefore, to reverse the reaction under those modified conditions.

This work is being continued and a detailed report will be published later.

Chlorination of *o*-Cresoxyacetic Acid

A Peculiar Side Reaction

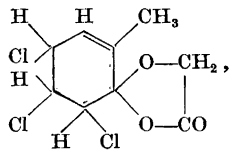
HAKON LUND

Chemical Institute, Aarhus University, Denmark

When *o*-cresoxyacetic acid is chlorinated in an organic solvent 4-chloro-2-methyl-phenoxyacetic acid is the main product, but a small amount of material which is insoluble in aqueous alkali is simultaneously formed. A compound, $C_9H_9O_3Cl_3$, has been isolated and is shown to be a cyclic ester-acetal of glycolic acid and 2-methyl-4,5,6-trichloro-*cyclo*hex-2-en-1-one.

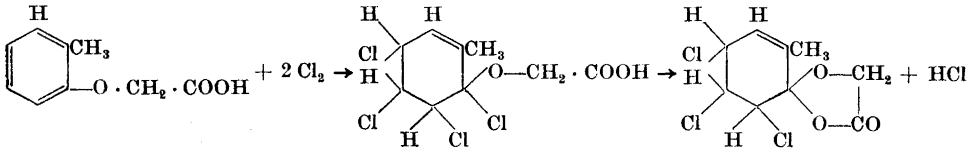
The "weed-killer" 2-methyl-4-chloro-phenoxyacetic acid is industrially prepared by chlorination of *o*-cresoxyacetic acid in an organic solvent [1]. The acid is extracted by means of aqueous alkali. In the organic solvent remains, however, a small quantity of material which is not directly soluble in aqueous alkali. After removal of the solvent *in vacuo* a rather viscous oil is obtained which, on cooling, partially crystallizes. Filtration is almost impossible; but when the hot oil is diluted with alcohol a well-defined compound A, m.p. 137°, is easily isolated. From the dark mother liquor a mixture of compounds can be obtained by distillation at 0.5—1 mm pressure. The percentage composition of this material is the same as that of compound A and corresponds to the formula $C_9H_9O_3Cl_3$. Apparently the material is a mixture of isomers of A.

Compound A can be isolated in an amount of about 30 % of the total product. The constitution of A seems to be



A thus being an ester-acetal of 2-methyl-4,5,6-trichloro*cyclo*hex-2-en-1-one and glycolic acid.

The formation of such a compound is rather surprising. Apparently 4 atoms of chlorine are *added* to the benzene ring and one molecule of hydrogen chloride split off with formation of the dioxolone ring:



Considering the very high rate of the *para* substitution reaction it is quite unexpected that an addition to the *unsubstituted* molecule takes place to a measurable extent. It is well-known [2] that aromatic amines and phenols can, on prolonged chlorination, *after* completed substitution add chlorine with the formation of highly chlorinated *cyclo*hexenones. If, however, *para* or *ortho* substitution had preceded addition of chlorine in the present case the non-aromatic molecule arising from *o*-cresoxyacetic acid by treatment with chlorine, and containing the dioxolone ring, should contain an even number of chlorine atoms, and if a dichloro cresoxy acetic acid had been formed before addition a $>CCl_2$-group should be present in the non-aromatic molecule. The infrared spectrum of the compound seems to exclude this possibility.

The constitution of A given above is based on the following evidence:

1. Quantitative analysis has established the formula $C_9H_9O_3Cl_3$.

2. The ultraviolet absorption spectrum exhibits no bands above 250 mμ, whereas phenol derivatives have high absorption around 275 mμ.

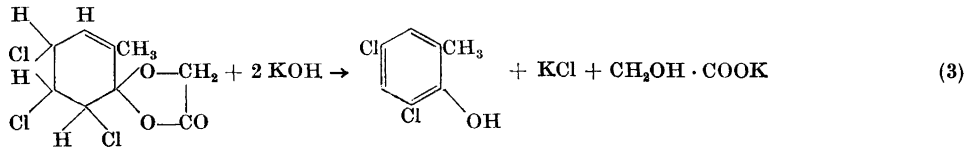
3. In alcoholic solution the compound reacts vigorously with potassium hydroxide with quantitative formation of 4,6-dichloro-2-methyl-phenol. 2 molecules of potassium hydroxide are consumed in the reaction.

4. Metallic zinc removes all chlorine from the compound in boiling alcoholic solution and *o*-cresoxyacetic acid is formed.

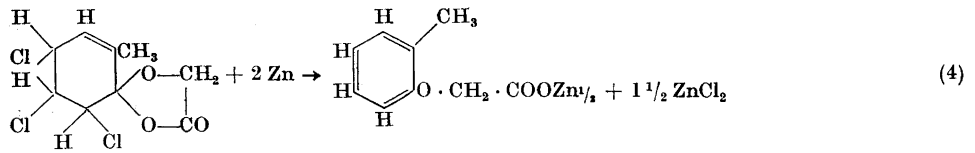
5. Anhydrous diethyl amine removes 1 molecule of hydrogen chloride with the formation of a dichloro cresoxyacetic acid, presumably the 5,6-derivative. The compound is different from both the 4,6- and 4,5-dichloro acid.

6. An aqueous-alcoholic solution of A liberates iodine from potassium iodide with formation of, *i.a.*, 6-chloro-2-methylphenoxyacetic acid. Besides, an oil is formed which is insoluble in aqueous potassium carbonate and thus probably consists of compounds in which the dioxolone ring is intact.

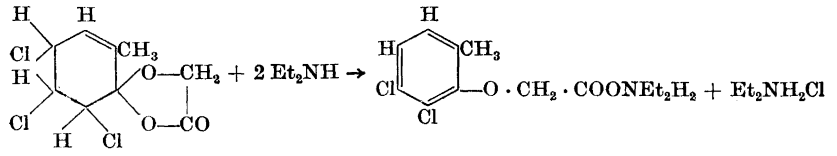
All these reactions are well explained by the constitution proposed above:



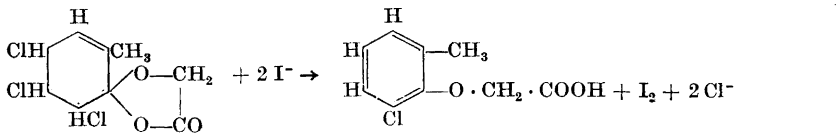
(3)



(4)



(5)



(6)

In the infrared spectrum * an unusually strong absorption band with two peaks at 5.49 and 5.58 μ indicates the presence of a somewhat anomalous carbonyl group. In order to test the absorption band of a carbonyl group in a dioxolone ring the compound  was synthesized from *p*-methyl*cyclo*hexanone and lactic acid. Its infrared spectrum contained a similarly intensive band with a peak at 5.59 μ. The similarity in intensity and position supports the dioxolone structure in compound A.

The formula contains 4 asymmetric carbon atoms in the homocyclic ring and explains the existence of a large number of isomers formed in the addition reaction.

On prolonged boiling in an alcoholic solution of hydrogen chloride compound A, as well as the mixture of isomers, is decomposed with formation of 4,6-dichloro-*o*-cresol.

EXPERIMENTAL

1. *Isolation of compound A.* The crude material is heated on a steam bath until completely liquid. 500 g is poured into 500 ml alcohol and cooled to 10°. The crystals are filtered off, yield about 170 g. They are dissolved in 1 200 ml of boiling alcohol and filtered hot from a small amount of inorganic material (sodium chloride) and on cooling to 0° about 150 g of pure material, mp. 137°, is obtained. Found: C 39.8; 39.6; H 3.35; 3.28; Cl 39.1; 39.0 %. $C_9H_9O_3Cl_3$ requires: C 39.76; H 3.34; Cl 39.2 %. Equiv.wt. by quantitative saponification with alcoholic potassium hydroxide, indicator methyl red (in order to avoid interference of the cresol): 135.0; 135.5; calc. 135.7).

2. *Reaction with potassium hydroxide.* To a hot solution of A (10 g) in alcohol (75 ml) was added slowly through the condenser 20 % aqueous potassium hydroxide (30 ml). The mixture boiled vigorously without external heating during the addition. Boiling was continued for 15 min. Water was added (50 ml) and the alcohol distilled off. On acidification and cooling 4,6-dichloro-*o*-cresol separated, yield 6.4 g (98 % of theory) and was identified by melting point (55°) and by preparation of the corresponding dichloro cresoxyacetic acid (mp. 184—85°).

3. *Reaction with metallic zinc.* To a solution of A (10 g) in boiling alcohol (75 ml) was added zinc wool (7 g). The reduction proceeded rapidly and from the resulting solution 5.0 g of *o*-cresoxyacetic acid was isolated, m. p. 155°, equiv.wt. by titration 165.5 (calc. 166).

4. *Reaction with diethyl amine.* To 10 g of A was added diethyl amine (20 ml) and the solution was boiled for 15 min. The excess of diethyl amine was distilled off and the

* Thanks are due to professor Børge Bak, Copenhagen, who has taken the infrared spectrograms.

residue dissolved in water and acidified. Yield of crystals 7.5 g, mp. 128°. (Found: C 45.7; 45.8; H 3.33; 3.36; Cl 30.3; 30.4 %; equiv.wt 234. Calc. for $C_9H_8O_3Cl_2$: C 45.9; H 3.43; Cl 30.2 %; equiv.wt. 235).

4,5-Dichloro-2-methyl-phenoxyacetic acid was prepared from 4,5-dichloro-2-methyl phenol [3] by condensation with monochloroacetic acid in alkaline solution, mp. 165—66°, thus evidently different from the acid obtained above, which, therefore, is assigned the 5,6-dichloro structure.

5. *Reaction with potassium iodide.* To a boiling solution of A (10 g) in alcohol (100 ml) was added an aqueous solution of potassium iodide (10 g). Iodine was slowly liberated and time after time reduced with sodium thiosulfate. After 3 hours' boiling no more iodine was formed. The alcohol was distilled off at diminished pressure and the remaining milky liquid was extracted with ether. The ethereal solution was extracted with aqueous sodium carbonate, from which 6-chloro-2-methyl-phenoxyacetic acid was obtained (mp. 110° after recrystallization from benzene, equiv.wt. by titration 199.5, calc. 200.5).

The ethereal solution on evaporation left an uncrystallizable oil which was not examined further.

6. *Catalytic hydrogenation of A was attempted (catalyst PtO_2).* The reaction proceeded rapidly at first, but stopped when 2—3 moles of hydrogen had been absorbed. The product, however, still contained chlorine and was obviously a complicated mixture of compounds distilling *in vacuo* over a very wide range of temperature; further examination was abandoned.

7. *Decomposition of A with alcoholic hydrogen chloride.* A solution of 15 g of A in 10 % alcoholic hydrogen chloride (60 ml) was boiled for 3 h. The alcohol was distilled off at diminished pressure. The oily residue was dissolved in ether and washed with aqueous sodium carbonate, dried, and the ether distilled off. The remaining oil solidified when cooled to 0°. The crystals were identified as 4,6-dichloro-*o*-cresol.

A similar process was carried out with an amount of the vacuum-distilled mother liquid from the crude product, giving similar results.

Studies on Monoalkyl Carbonates

XIV. The Monoalkyl Carbonates of Tetrahydrofurfuryl Alcohol and Furfuryl Alcohol

MARIANNE BOEG HANSEN and CARL FAURHOLT

The Royal Danish School of Pharmacy, Copenhagen, Denmark

The velocity constants of the reaction 'alcohol + OH^- + CO_2 = alkyl · CO_3^- + H_2O' and the equilibrium constants for the equilibrium 'alkyl · CO_3^- + H_2O = HCO_3^- + alcohol' have been determined for tetrahydrofurfuryl alcohol and furfuryl alcohol. The velocity of the decomposition of the monoalkyl carbonates in strongly basic medium is investigated and may be explained by assuming that the decomposition is a two-stage reaction, *viz.* 1) monoalkyl carbonate = alkoholate + CO_2; 2) CO_2 + OH^- = HCO_3^-.

1. The present investigation deals with the equilibrium conditions and the reaction mechanism for the formation and decomposition of the monoalkyl carbonates of tetrahydrofurfuryl alcohol and furfuryl alcohol in aqueous medium.

2. Tetrahydrofurfuryl alcohol was purified by distillation through a wiregauze column with 49 sets of platinum plates. The obtained tetrahydrofurfuryl alcohol boiled at 178.2—178.3°C/773 mm Hg (177.6—177.7°C/760 mm Hg), $n_D^{20.0°} = 1.4518$.

Furfuryl alcohol was purified first by simple distillation in vacuum and then by distillation through a wiregauze column with 49 sets of platinum plates at 100 mm Hg. The furfuryl alcohol thus obtained boiled at 171.5—172.3°C/764 mm Hg, $n_D^{20.0°} = 1.4872$.

As furfuryl alcohol is unstable under ordinary conditions and discolours, it is used immediately after the distillation.

3. No solid monoalkyl carbonate was prepared. Solutions were made by dissolving carbon dioxide in basic solutions of the alcohols.

4. As to the method of analysis we refer to previous investigations [1]. The data presented are corrected with regard to blank values unless otherwise stated. "Uncorr." values are not corrected at all and "corr." values are corrected not only with regard to blank values but also with regard to the decomposi-

tion mentioned in the next section. The blank values may amount to about 3 units of the percentage of monoalkyl carbonate in some of the experiments.

5. The experiments were carried out at 0°C. Velocity constants are expressed on the basis of the Briggs' logaritms and the minute.

On the formation of the monoalkyl carbonate from carbon dioxide and alcohol in basic solution and on the reaction

$$\text{alcoholate} + CO_2 = \text{monoalkyl carbonate}$$

The experiments were carried out in a 2 litre flask by vigorously shaking 1 100 ml of a basic solution of the alcohols with atmospheric air of which 550 ml were substituted by carbon dioxide. The strong basic solution of furfuryl alcohol was light yellow and became slight opalescent by standing at 0°C. The solutions were immediately analysed to determine the percentage of monoalkyl carbonate. Due to the rapid decomposition of the monoalkyl carbonates, we had to correct the results by means of the velocity constant which we also have determined, see later.

By introduction of the adjusted results in the expression:

$$k' = \frac{\%\ \text{monoalkyl carbonate} \cdot k_{CO_2OH^-}}{\%\ \text{carbonate} \cdot c_{\text{alcohol}}}$$

the k' values presented in Table 1 are calculated. k' is the velocity constant of the overall reaction:

$$CO_2 + \text{alcohol} + OH^- = \text{alkyl} \cdot CO_3^- + H_2O$$

For the value of $k_{\text{alkyl}\cdot CO_3^-}$ we get 0.0074 for tetrahydrofurfuryl alcohol and 0.054 for furfuryl alcohol when the values of K_{Eq} found in Table 2 are employed.

The equilibrium of the reactions

$$\text{alkyl} \cdot CO_3^- + H_2O = HCO_3^- + \text{alcohol}$$

The above equilibrium was established in aqueous solutions of alcohol, potassium bicarbonate and sodium carbonate.

5 » » 3 » 1.17, 1.13, 1.15

The contents of monoalkyl carbonate have been calculated as a percentage of HCO_3^- initially present; thus no attention was paid to carbonate.

In Table 2 are presented not only the '% monoalkyl carbonate' corrected for blank values and the decomposition taking place until the precipitate has been separated from the supernate, but the uncorrected as well. This has been done in order to illustrate the accuracy that may be attached to the values found. From the experimental results the equilibrium constant of the reaction

$$K_{Eq} = \frac{c_{alcohol} \cdot c_{HCO_3^-} \cdot f}{c_{alkyl \cdot CO_3^-} \cdot f}$$

may be calculated, the activity constants neutralizing each other.

On the velocity of the reactions

$$alkyl \cdot CO_3^- + H_2O = HCO_3^- + alcohol$$

Determinations have been made from the monoalkyl carbonate side only and in strongly basic medium, the alkyl carbonate thus being practically completely converted into carbonate.

The monoalkyl carbonate has been made by shaking the basic solutions with CO_2 as stated in the introduction. The solutions, therefore, contain ordinary carbonate, which, however, is of no importance in the present investigations.

In Table 3 are listed the experimental results of the decomposition of the alkyl carbonates. k_{mono} is the value of $\frac{1}{t} \log \frac{a}{a-x}$

The experiments are interpreted in a similar way to the one applied to the monoalkyl carbonates previously investigated. The decomposition takes place through the reactions:

1. $alkyl \cdot CO_3^- = alkylate^- + CO_2$
2. $CO_2 + OH^- = HCO_3^-$

k_{mono} may be calculated at $pa_H > 10$ by means of the following expression

$$k_{mono} = \frac{k' \cdot K_{Eq} \frac{K_{H_2O}}{K_{CO_2}}}{1 + k' \cdot \frac{c_{alcohol}}{k_{CO_2} \cdot OH^-}}$$

the values of K_{H_2O} and K_{CO_2} being $10^{-14.93}$ and $10^{-6.65}$, respectively.

Upon introduction of the constants the equation for tetrahydrofurfuryl alcohol is:

$$k_{mono} = \frac{0.0074}{1 + 1.3 \cdot c_{alcohol}}$$

and k_{mono} in 1 M and 0.5 M solutions of alcohol, $pa_H > 10$, will then be calculated to 0.0032 and 0.0045, respectively.

For furfuryl alcohol is:

$$k_{mono} = \frac{0.054}{1 + 4.9 \cdot c_{alcohol}}$$

and k_{mono} in 1 M and 0.5 M solution of alcohol, $pa_H > 10$, will be calculated to 0.0092 and 0.016, respectively.

The experimental and calculated values agree rather well.

Soladulcamarine, the Alkaloidal Glycoside of *Solanum dulcamara*

H. BAGGESGAARD RASMUSSEN and PER M. BOLL

Department of Organic Chemistry, The Royal Danish School of Pharmacy, Copenhagen, Denmark

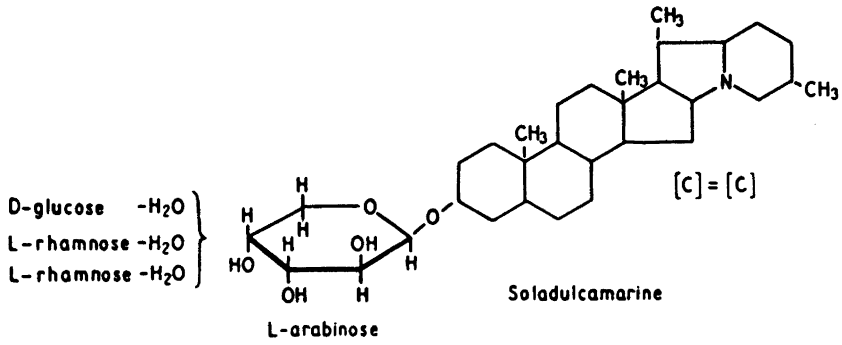
Extraction of the fresh leaves and stems of *Solanum dulcamara* led to the iolation of an alkaloidal glycoside m. p. 193—197°C (decomp.), which on hydrolysis yielded 1 mole of D-glucose, 1 mole of L-arabinose, 2 moles of L-rhamnose and an unsaturated alkaloidal aglycone m. p. 220—222°C. The names soladulcamarine and soladulcamaridine are suggested for the glycoside and its aglycone, respectively. Soladulcamaridine is tentatively assigned a solanidane structure.

Recently J. Tuzson [1], P. Tuzson and Kiss [2], and McKee [3] by paper chromatography have shown that the alkaloids in *Solanum dulcamara* and *Solanum turberosum* are not identical. P. Tuzson and Kiss[2] isolated from the latter plant, after acid hydrolysis, a steroidal saturated alkaloidal aglycone. They proposed the name soladulcidine for the aglycone, a name already in use to identify a bitter principle occurring in the same plant [4].

Schreiber [4] by paper chromatography found three alkaloidal glycosides and has shown all three glycosides to have soladulcidine as aglycone. Schreiber gives the empirical formula as $C_{27}H_{43}O_2N$ (m.p. 206.5° and $[\alpha]_D = -52.6°$ ($CHCl_3$)). Soladulcidine was found to be identical with 5α-solasodanol-(3β).

Our investigation has by paper chromatography indicated two alkaloidal glycosides to be present in *S. dulcamara*. The one of them is considered as the main alkaloid and has been isolated. It is neither solanine nor another known alkaloid, but a new alkaloidal glycoside for which we suggest the name *soladulcamarine*. The aglycone, also a new compound, has been designated *soladulcamaridine*.

The plant material used in this investigation consisted of naturally occurring plants. Only the tops were used. After crushing, the tops were extracted with 5 % acetic acid and the alkaloid together with inorganic salts were precipitated with ammonia-water. The yield was 0.3 g of crude alkaloid per kg of fresh material.

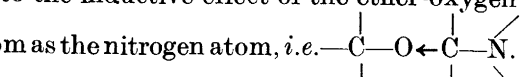


The alkaloid mixture was to some extent purified by column chromatography. Unfortunately, recrystallization of the alkaloid from various solvents was not possible as the alkaloid separated out as a gel in every attempt, but a chromatographically pure semi-crystalline alkaloidal glycoside was obtained through fractional crystallization.

By acid hydrolysis the glycoside was found to consist of an aglycone portion, soladulcamaridine, and a tetrasaccharide moiety composed of D-glucose, L-arabinose and two D-rhamnose units. The isolation from the plant genus *Solanum* of an alkaloidal glycoside containing L-arabinose has not been reported before. Soladulcamarine does not reduce Fehling's solution or react with phenylhydrazin. These results indicate that no free aldehyde groups are present and that the monosaccharides are united through their potential aldehyde groups. Oxidation of soladulcamarine with periodic acid revealed after hydrolysis and paper chromatography only L-arabinose. Since periodic acid oxidizes vicinal hydroxyl groups and the L-arabinose after oxidation still is attached to the alkaloidal aglycone, it can be concluded that the glycoside besides being an arabinoside has the hydroxyl groups of arabinose linked through glycosidic linkages to the monosaccharides in such a manner that arabinose has no vicinal hydroxyl groups. Soladulcamarine is not hydrolyzed when treated with 0.01 N hydrochloric acid for 10 h as shown by the lack of reducing power towards Fehling's solution. From this it is assumed that all the sugars are pyranose [5]. All *Solanum* alkaloids so far isolated have been shown to have the hydroxyl group of the aglycone connected to the sugar unit through a β-linkage. From biogenetic reasons it is assumed that an identical linkage also is present in soladulcamarine. The glycoside was found to have the empirical formula $C_{50}H_{81}O_{18}N$, 5 H_2O (M 1 074) and the equivalent weight was determined to 1 087 (titration in glacial acetic acid with perchloric acid) and 1 165 (acid/base titration). The aglycone has the empirical formula $C_{27}H_{43}ON$, 1 1/2 H_2O (M 425) and the equivalent weight was determined to 438.

The basicity of soladulcamarine and soladulcamaridine was determined in term of their pK_b-values and found to be 5.57 and 5.78, respectively. Bloom and Briggs [6] have determined the basicity of solanidine and solasodine and their derivatives. They found that the pK_b of solasodine and solasonine were

6.30 and 6.26, respectively, and of solanidine 5.38. They concluded that the weak basicity of solasodine was due to the inductive effect of the ether-oxygen atom attached to the same carbon atom as the nitrogen atom, *i.e.*



The pK_b values for soladulcamarine and soladulcamaridine seem to be closer to the values for solanidine.

All alkaloids isolated from the plant genus *Solanum* have either been solanidane or solasodane derivatives. The results discussed above indicate that soladulcamaridine probably is a solanidane derivative. The aglycone gave positive Alberti and Liebermann-Burchard [8] reactions for a steroid-double bond, but a negative reaction for conjugated double bonds or α,β-unsaturated alcohols [9]. The aglycone gave no precipitate with digitonin and can, therefore, not have a 3β-hydroxyl group. The colour reactions given by the aglycone were not similar to the colours given by solanidine, but closer to the colours given by solasodine.

It was not possible to prepare a picrate of the aglycone, which is in accordance with the difficulty often met in preparing picrates of tertiary amines.

Stipes dulcamara which is an old drug and consists of the stems of *Solanum dulcamara* was examined for alkaloids. The stems gave an extremely small yield of an alkaloidal glycoside. By paper chromatography it was found identical with soladulcamarine. The small yield is in conformity with the fact that the stems mostly consist of xylem and very little green bark.

EXPERIMENTAL

The melting points are corrected and have been determined with the hot stage microscope essentially according to Kofler.

Isolation of the glycoside. The plant material was collected at Lyngby Aamose near Copenhagen. 7 kg of the fresh tops were crushed in a mill and immediately extracted with 5 % acetic acid using the isolation procedure described by Kuhn and Löw [10]. The yield of crude alkaloidal glycoside was 2.2 g. Paper chromatography with following developing solvents: The upper phase of ethyl acetate — glacial acetic acid — water (3:1:3) to which is added 15 ml of 85 % ethanol per 160 ml of upper phase [10], and ethanol — N hydrochloric acid — water (50:2:48) [11] revealed two alkaloids when the spots were developed with Dragendorff reagent. The alkaloid with highest R_F-value was only present to a small extent.

The glycoside mixture formed a gel when attempted to dissolve it in water-saturated 1-butanol. Therefore, a solution in methanol was chromatographed on neutral aluminium oxide (Alcoa) and eluted with the same solvent. In this manner a certain degree of purification was obtained.

It was not possible to recrystallize the glycoside from various solvents due to formation of a gel. The solvents used both as pure solvents and in aqueous solution to attempt recrystallization were: 1-butanol, 1-propanol, ethanol, dioxan, acetone and ethyl ether.

Fractional recrystallization, on the other hand, was more successful. Addition of acetone to a concentrated methanol solution of the glycoside mixture produced an amorphous precipitate which adsorbed the green coloured impurities. In this manner 1.55 g of material was obtained. Addition of petroleum ether to the mother liquor gave 115 mg of faint yellow coloured material. This latter material was redissolved in a small volume of methanol and gave by repeated fractional recrystallization 20 mg of semi-crystalline glycoside. Repeated fractionation of crude glycoside gave some more semi-crystalline glycoside. M. p. 193—197°C (decomp.) (Found: C 55.80, 55.95; H 8.52, 8.79; H_2O 8.73. Calc. for $C_{50}H_{81}O_{18}N$, 5 H_2O: C 55.91; H 8.54; H_2O 8.40).

1 kg of commercially available *Stipes dulcamara* was extracted in the same manner as above. About 2 mg of crude glycoside mixture was obtained. By paper chromatography it was found to be identical with soladulcamarine.

The equivalent weight of the pure glycoside was determined by potentiometric titration of the glycoside dissolved in glacial acetic acid with 0.02 N perchloric acid (Found 1 101, 1 087. Calc. 1 074). The equivalent weight determined by dissolving the glycoside in a known excess of 0.01 N hydrochloric acid and back-titrating with 0.01 N sodium hydroxide was found to be 1 165 and 1 180. The glycoside gave a positive α-naphthol reaction for carbohydrates and a positive orcinol test (Bial reaction) for pentoses [7].

Isolation of the aglycone, soladulcamaridine. 0.5 g of soladulcamarine was refluxed with 25 ml N hydrochloric acid for 2 h. During the hydrolysis the hydrochloride of the aglycone began to precipitate. The hydrochloride was collected by filtration, dissolved in 80 % methanol and concentrated ammonia-water was added to precipitate the free alkaloid. 255 mg alkaloid was obtained. For further purification the alkaloid was dissolved in a small volume of benzene and chromatographed on a column of neutral aluminium oxide (13 × 1.6 cm). Benzene-methanol (9:1) was used as eluant and 30 ml fractions were collected. Fraction III contained the alkaloid and none of the other fractions gave any residue after evaporation of the solvent. The alkaloid was recrystallized from acetone and gave needle-shaped crystals melting at 220–222°C, $[\alpha]_D^{23}$ −78.4°, $[\alpha]_{Hg}^{23}$ −111° (methanol, c = 0.428). Before analysis the compound was dried at 105°C for 8 h. (Found: C 76.19, 76.24; H 10.34, 10.12. Calc. for $C_{27}H_{43}ON$, 1 1/2 H_2O: C 76.36; H 10.92.)

The equivalent weight was determined to 438 and 442 by dissolving the aglycone in a known excess of 0.01 N hydrochloric acid and backtitrating with 0.01 N sodium hydroxide. Soladulcamaridine dissolved in methanol does not give a precipitate with an ethanolic solution of digitonin. The compound gives positive Alberti [7] and Liebermann-Burchard reactions[9] for steroid double bonds, but no Rosenheim reaction [8] for conjugated double bonds or α,β-unsaturated alcohols.

Identification of the carbohydrates. The acidic mother-liquor remaining after precipitation of the aglycone from the hydrolysate as described above was treated with Amberlite IR-4B. Aliquots were chromatographed on Whatman No. 1 paper at 23°C. Aniline hydrogen phthalate was used as colour-developing reagent.

The solvent 1-butanol — ethanol — water (8:1:2) revealed spots with the following R_F-values: 0.43 L-rhamnose, 0.21 L-arabinose, 0.15 D-glucose.

The solvent 2,6-lutidine — water (65:35) revealed spots with R_F-values: 0.68 L-rhamnose, 0.54 L-arabinose, 0.51 D-glucose.

The results were controlled by chromatographing pure monosaccharides alone and in mixtures alongside the unknown monosaccharides.

Quantitative determination of the carbohydrates. Furthermore, the amounts of individual monosaccharides were determined quantitatively utilizing the ability of the sugars to reduce 2,3,5-triphenyltetrazolium chloride to red formazan. 2.4 mg of glycoside was refluxed in 0.5 ml N hydrochloric acid for 2 h (sealed tube).* Aliquots containing 98 μg hydrolysed glycoside were chromatographed and the amount of monosaccharide in each spot determined by the method of Fischer and Dörfel [12].

The results are given in Table 1.

Table 1. Quantitative determination of monosaccharides in 98 μg aliquots of hydrolysed soladulcamarine.

	μg	mole × 10^8	μg	mole × 10^8
L-Glucose	16	8.9	15.5	8.6
D-Rhamnose	28	17	30.5	19
L-Arabinose	12	8.0	9.0	6.0

* It was found unnecessary to neutralise the hydrolysate with Amberlite IR-4B before chromatographing. If the paper was well dried at room temparature after application of the solution to the paper no change in the R_F-values was observed.

The optical rotation of the carbohydrate mixture. 0.32 g of soladulcamarine was hydrolysed by refluxing with 20 ml N sulfuric acid for 2 h. The hydrolyzate was neutralized with barium carbonate and allowed to stand overnight. The precipitate was removed by filtration and carefully washed with water. The filtrate was concentrated to 10.0 ml *in vacuo*. The rotation found was $[\alpha]_D^{23}$ + 41.8° on the assumption that 1 074 g of glycoside gave 654 g of carbohydrate. For a mixture of 1 mole of D-glucose, 1 mole of L-arabinose and 2 moles of L-rhamnose the optical rotation can be calculated to $[\alpha]_{Hg}^{25}$ +43.4. The carbohydrate content of the hydrolysate was determined after the method of Rupp and Lehmann [13]. 585 g of carbohydrate was found, calculated as glucose per mole of glycoside. The theoretical value is 654 g of "glucose".

Periodate-oxidation of the glycoside (Kuhn and Löw [10]). 20 mg of soladulcamarine was allowed to stand for three days at room temperature with 4 ml 0.05 N acetic acid and 2 ml 0.25 N potassium periodate. After addition of 1 ml ethylene glycol the solution was heated shortly, made alkaline with solid sodium carbonate and then heated again to 50—60°C. The precipitate was collected by centrifugation, washed with water and then boiled with 2 ml N sulfuric acid. The sulfuric acid was neutralized with barium carbonate and the sugar solution separated from barium sulfate by filtration. After evaporation of the water the residue was chromatographed. Only L-arabinose was detected.

Colour reactions of soladulcamaridine [14]. 2—3 mg of soladulcamaridine and 2—3 mg of the following aldehydes were dissolved in about 1 ml of acetic acid to which 1 ml of conc. sulphuric acid was then carefully added. By mixing and heating following colour changes did develop:

p-*hydroxybenzaldehyde:* red/violet dichroic-purple-blue-violet/brown dichroic.
anisaldehyde: red/green dichroic — violet/green dichroic — blueviolet.
vanillin: green — blue — violet.
resorcinol: yellow — brown — olive — blue — violet — red/violet dichroic — fuchsin — cherry red — cherry red / chocolate fluorescent.

Elementary analysis are by Mr. P. Hansen, Universitetets kemiske laboratorium, Copenhagen. This work is part of investigations supported by *Statens almindelige Videnskabsfond (The Danish State Research Foundation)*.

The Photoinduced Oxidation of 2-Propanol by Acid Chromate

ULRIK KLÄNING

Laboratoriet for Fotokemi, Fotografi og Reproduktionsteknik, Polyteknisk Læreanstalt, Copenhagen, Denmark

The quantum yield of the photoinduced oxidation of 2-propanol by acid chromate depends on the concentration of 2-propanol, the acidity, the intensity and wave length of light and the concentration of acid chromate. At low intensity of light and high acidities the quantum yield approaches a value twice that obtained at high intensities of light and low acidities. The experimental results fit a mechanism in which chromium compounds in the oxidation states +6, +5, +4, +3 and +2 are involved. The photochemically active compound is shown to be an ester of acid chromate with 2-propanol. Furthermore the influence of the solvent on the quantum yield is discussed.

In slightly acid aqueous solutions the oxidation of aliphatic alcohols by chromic acid proceeds at negligible rate. When irradiated by ultraviolet light the oxidation takes place. Bowen *et al.*[1] have investigated these photoinduced oxidations. Their results may be summarized as follows. With the alcohols in excess the reactions are stoichiometrically pure. The quantum yields are small, not exceeding two in the pure alcohol. The oxidation therefore does not seem to be a chain process. Further Bowen and Chatwin [1] have shown, that of the two ions present in a dilute aqueous solution, $HCrO_4^-$ and $Cr_2O_7^{--}$, only $HCrO_4^-$ is photochemically active. Comparisons between the quantum yields obtained by oxidation of different alcohols, led to the conclusion, that only "alcoholated" forms of the acid chromate ions are photochemically active. From the relationship between quantum yield and acidity Bowen and Chatwin proposed the mechanism:

$$X \cdot HCrO_4^- + h\nu \rightarrow \text{aldehyde or ketone} + Cr^{IV}$$

$$Cr^{IV} + Cr^{IV} \rightarrow Cr^{V} + Cr^{III}$$

$$Cr^{IV} + Cr^{VI} \xrightarrow{H^+} 2Cr^{V}$$

$$Cr^{V} + \text{alcohol} \rightarrow \text{aldehyde or ketone} + Cr^{III}$$

where X stands for an alcohol and Cr^{VI}, Cr^{V}, Cr^{IV} and Cr^{III} represent chromium compounds in the oxidation states +6, +5, +4 and +3, respectively. Preliminary experiments made by the present author have shown that oxygen interferes with the photoinduced oxidation of 2-propanol by acid chromate. As Bowen and Chatwin have not taken the precaution to remove oxygen a reinvestigation has been undertaken.

Westheimer *et al.*[2,3] have investigated the kinetics of the oxidation of 2-propanol to acetone by acid chromate ions in aqueous solution, and have shown that the reaction proceeds by the way of the chromic acid ester, $(CH_3)_2CHOCrO_3H$.

The photochemical experiments reported here were made at low acidities ($<2 \times 10^{-2}$ M), at which the dark process proceeds at negligible rate. It may therefore be concluded that at low acidities the above mentioned ester is completely ionized to $(CH_3)_2CHOCrO_3^-$, the stability constant and spectrum of which have been determined by the present author [4,5] (in Ref.[4] no assumption concerning the nature of the complex of 2-propanol with acid chromate has been made and the formula has been written $CH_3CHOHCH_3 \cdot HCrO_4^-$). Our experiments show that the ester $(CH_3)_2CHOCrO_3^-$ is the only photochemically active ion as suggested by Bowen and Chatwin, but it has not proved possible to verify the mechanism proposed by these authors. The experimental data agreed with the following mechanism:

a) $CH_3CHOHCH_3 + HCrO_4^- = (CH_3)_2CHOCrO_3^- + H_2O$ equil.const.[5] $K = 8.3$

b) $(CH_3)_2CHOCrO_3^- + h\nu \rightarrow (CH_3)_2CHO\overset{*}{C}rO_3^-$ absorption

c) $(CH_3)_2CHO\overset{*}{C}rO_3^- + \text{solvent} \rightarrow (CH_3)_2CHOCrO_3^-$ deactivation

d) $(CH_3)_2CHO\overset{*}{C}rO_3^- \rightarrow Cr^{IV} + CH_3COCH_3$

1) $CH_3CHOHCH_3 + Cr^{IV} \rightarrow CH_3COCH_3 + Cr^{II}$ k_1

2) $Cr^{II} + Cr^{IV} \rightarrow 2Cr^{III}$ k_2

3) $HCrO_4^- + H^+ = H_2CrO_4$ equil.const. K_3

4) $Cr^{II} + H_2CrO_4 \rightarrow Cr^{V} + Cr^{III}$ k_4

5) $(CH_3)_2CHOCrO_3^- + H^+ = (CH_3)_2CHOCrO_3H$ equil.const. K_5

6) $\left.\begin{array}{l} Cr^{II} + (CH_3)_2CHOCrO_3H \rightarrow Cr^{V} + Cr^{III} + CH_3CHOHCH_3 \\ Cr^{II} + (CH_3)_2CHOCrO_3H \rightarrow 2Cr^{III} + CH_3COCH_3 \end{array}\right\} k_6$

7) $Cr^{V} + CH_3CHOHCH_3 \rightarrow Cr^{III} + CH_3COCH_3$.

In all experiments the total concentration of chromic acid was kept small enough to permit the neglection of the concentration of dichromate, and so small that stirring secured a uniform concentration of intermediates throughout the irradiated solutions. Denoting the quantum yield for formation of Cr^{IV} by Φ° we may therefore derive the following expression for the total quantum yield Φ, assuming a steady state concentration of the intermediates:

$$\Phi = \frac{1}{I_0}\left(-\frac{dc_1}{dt}\right) = \Phi^\circ - \left(\tfrac{1}{2}\Phi^\circ + c_a \cdot c_1 \cdot c_{H^+} \cdot \frac{1}{I_0} \cdot \frac{k_1 k^*}{2k_2}\right) \quad (8)$$

$$+\left(\tfrac{1}{2}\Phi^\circ + c_a \cdot c_1 \cdot c_{H^+} \cdot \frac{1}{I_0} \cdot \frac{k_1 k^*}{2k_2}\right)\left[1 + \frac{c_a \cdot \Phi^\circ \cdot c_1 \cdot c_{H^+} \cdot \frac{1}{I_0} \cdot \frac{k_1 k^*}{k_2}}{\left(\tfrac{1}{2}\Phi^\circ + \frac{k_1 k^*}{2k_2} \cdot c_a \cdot c_1 \cdot c_{H^+} \cdot \frac{1}{I_0}\right)^2}\right]^{\frac{1}{2}}$$

where c_a and c_1 are the alcohol concentration and the total concentration of acid chromate. I_0 is the intensity of the absorbed light. k^* is given by

$$k^* = K_3 k_4 + \frac{(K_5 k_6 - K_3 k_4) K \cdot c_a}{c_w + K \cdot c_a} \quad (9)$$

where c_w is the concentration of water.

The equation (8) gives that $\Phi^\circ < \Phi < 2\Phi^\circ$, and we note that Φ approaches $2\Phi^\circ$ at high values of $c_{H^+} \cdot c_a \cdot c_1/I_0$.

At 25°C Φ was measured at 366 mμ and at various light intensities, acidities, and alcohol concentrations. From (8), written in the form

$$\frac{k_1 k^*}{k_2} = \frac{\Phi^2 - \Phi \cdot \Phi^\circ}{(2\Phi^\circ - \Phi) \cdot c_1 \cdot c_{H^+} \cdot c_a \cdot \frac{1}{I_0}} \quad (10)$$

$k_1 k^*/k_2$ and Φ° were found by trial and error at each alcohol concentration. Tables 1, 2, and 3 show the measurements at $c_a = 1$ M, 2 M, and 3 M. The accuracy of the determination of $k_1 k^*/k_2$ is low as a change of 25 % in $c_{H^+} \cdot c_a \cdot c_1/I_0$ give a change of not more than 4—5 % in Φ, which is the experimental error in determining Φ. The reaction, therefore, was followed to a degree of advancement of 0.3, and the values of I_0, c_{H^+}, c_1, and c_a used in formula (10) to calculate Φ° and $k_1 k^*/k_2$ are the values at a degree of advancement of 0.15. From the three values of $k_1 k^*/k_2$ found at $c_a = 1$ M, 2 M, and 3 M $K_3 k_4 k_1/k_2$ and $K_5 k_6 k_1/k_2$ were found to be 13 litre^2/mole^2 · min and 55 litre^2/mole^2 · min, respectively (Fig. 1).

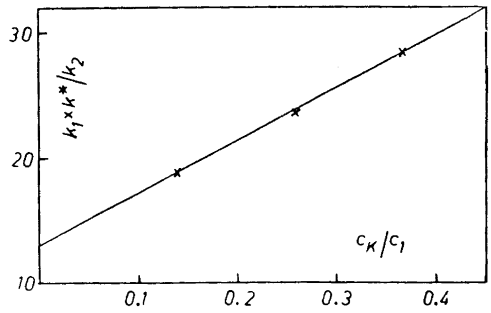

Fig. 1. $k_1 k^*/k_2 = K_3 k_4 k_1/k_2 + (K_5 k_6 k_1/k_2 - K_3 k_4 k_1/k_2) K \cdot c_a/c_w + K \cdot c_a$ (eqn. 9) plotted against the relative concentration of the complex: $c_K/c_1 = K \cdot c_a/c_w + K \cdot c_a$.

Table 1. Measured and calculated values of Φ_{366}.

$\left(\frac{k^*k_1}{k_2}\right)$ mean $= 18.8 \frac{\text{(litre)}^2}{\text{(mole)}^2 \text{ min.}}$, $c_a = 1.00$ M, $c_1 = 4.25 \times 10^{-5}$ M, $I_0 = 1.23 \times 10^{-5} \frac{\text{Einstein}}{\text{litre. min,}}$, $\Phi^\circ = 0.0385 \frac{\text{mole}}{\text{Einstein}}$

c_{H^+} mole/litre	$\frac{k^*k_1}{k_2}$ (litre)²/(mole)² min.	Φ found mole/Einstein.	Φ calc. mole/Einstein

Tables 1, 2, and 3 show that k_1k^*/k_2 at constant concentration of alcohol does not vary systematically with acidity and with light intensity, thus indicating the correctness of the proposed mechanism. The variation of k_1k^*/k_2 with the alcohol concentration is interpreted as being due to the reactions 5) and 6). Introduction of 5) and 6) in the reaction scheme is very natural, remembering that the concentration of the ester is rather high (at $c_a = 3$ M equal to 36 % of total concentration of acid chromate). The two equilibria 3) and 5) have been introduced as the oxidation agent in acid solution in the dark process seems to be the undissociated chromic acid [6]. The rates of 4) and 6) are proportional to c_{H^+} as both the acid chromate ion and the ester are very weak bases [4, 7].

* $c_1 = 4.70 \times 10^{-5}$ M.

The fraction of the absorbed light I_0, which is absorbed by the ester is

$$\varphi = \frac{\varepsilon_k \cdot c_a \cdot K}{\varepsilon_k \cdot c_a \cdot K + \varepsilon_1 \cdot c_w} \tag{11}$$

where ε_k and ε_1 are the extinction coefficients of the ester and of the acid chromate ion, respectively. If the ester is the only photochemically active component we may expect that the following relation for the ratio between $\Phi^\circ(\lambda_1)$ and $\Phi^\circ(\lambda_2)$ at the two wave lengths λ_1 and λ_2 will be valid at constant alcohol concentration:

Table 4. Values of $\Phi^\circ(\lambda)$ and $\varphi(\lambda)$ at the wave lengths 313 mμ, 334 mμ, and 366 mμ.

λ mμ	c_a mole / litre	I_0 Einstein / litre.min	c_{H^+} mole / litre	Φ mole / Einstein	Φ° mole / Einstein	φ

$$\frac{\Phi^{\circ}(\lambda_1)}{\Phi^{\circ}(\lambda_2)} = \frac{\varphi(\lambda_1)}{\varphi(\lambda_2)} \tag{12}$$

$\varphi(\lambda)$ may be calculated as K and the absorption spectra of the ester and of the acid chromate ion are known [5]. Table 4 shows φ_{313}, φ_{334}, φ_{366}, Φ°_{313}, Φ°_{334}, and Φ°_{366} at the alcohol concentrations 2 M and 3 M. It may be noted that the agreement between $\frac{\varphi(\lambda_1)}{\varphi(\lambda_2)}$ and $\frac{\Phi^{\circ}(\lambda_1)}{\Phi^{\circ}(\lambda_2)}$ is rather good, proving that the ester is the only photochemically active ion in the solutions.

Table 5 shows Φ°_{366} at various concentrations. It may be noted that Φ°_{366} is not directly proportional to φ_{366}, but $\Phi^{\circ}_{366}/\varphi_{366}$ increases linear with the alcohol concentration indicating that the probability for the excited ester to decompose to Cr^{IV} and acetone increases if one of the nearest neighbours to the excited ester is an alcohol molecule (Fig. 2). To get a complete picture

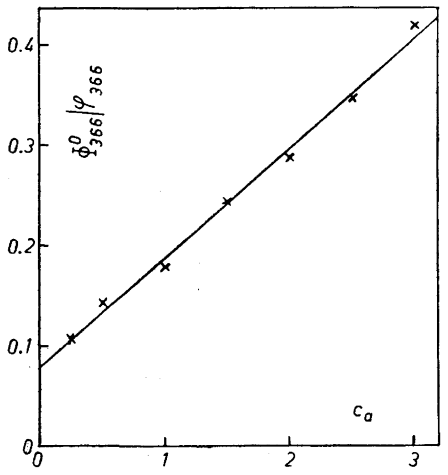

Fig. 2. $\Phi^{\circ}_{366}/\varphi_{366}$ plotted against c_a.

of the mechanism of deactivation the photoinduced oxidation of several alcohols would have to be investigated in a larger concentration interval.

EXPERIMENTAL

The light source was a mercury lamp (Osram HQA 1000, the outer bulb removed, operated on d—c with an adjustable ballast resistance). The light was made parallel with quartz lenses. The optical path of the quartz cell was 10 cm. The cell was furnished with a magnetic stirrer and was immersed in a 25°C thermostated water bath provided with windows of Uviol glass. The solutions to be irradiated were freed from oxygen by the bubbling through of nitrogen, deoxygenated over copper wire at 500°C. The light intensity was determined by means of the uranyl oxalate actinometer [8]. The actinometer solution was irradiated in the same cell as used in all experiments. The mercury lines 365—366 mμ, 334 mμ, and 312.6—313 mμ were isolated by means of filters described by Kasha [9]. The reaction was followed by measuring the change in optical density by means of a Baldwin Photometer M.N.D. The water was redistilled in Pyrex from alkaline permanganate, 2-propanol (Shell chemically pure) was distilled in a Glinsky still (b.p. 780 mm Hg 81.5—81.7°C (uncorr)) and controlled for acetone content by measuring the optical density at 280 mμ. Perchloric acid and potassium dichromate were Mercks pro analysi.

The author's thanks are due to professor Max Møller for information and help in the work.

Gas-Liquid Chromatographic Determination of the Fatty Acid Composition in Oil from Seeds of *Ulmus*

IB SØRENSEN and P. SØLTOFT

Laboratoriet for almen teknisk Kemi, Danmarks tekniske Højskole, Copenhagen, Denmark

By means of low-pressure chromatography methyl esters of the fatty acids in seeds from various species and varieties of the genus *Ulmus* have been determined. The statements in the literature according to which elm seed oil has a surprisingly high content of C_{10} fatty acids has been confirmed.

Gas-liquid chromatography was introduced in 1952 by James and Martin [1] and used for instance for the separation of volatile fatty acids with up to 11 carbon atoms on a column with Celite impregnated with silicon fluid in which 10 % stearic acid has been dissolved and using nitrogen as carrier gas. Later James and Martin [2] extended the applicability of the method to fatty acids with up to 18 carbon atoms, separating the methyl esters on a Celite column impregnated with Apiezon vacuum stopcock grease at 197°C. Cropper and Heywood [3] state that they are able to separate fatty acids with up to 22 carbon atoms as methyl esters at 230°C and a pressure of 20 mm Hg at the column outlet. Their column was packed with Celite impregnated with Dow Corning silicone grease and the carrier gas used was nitrogen. However, the pressure drop along a Celite column is great, and Cropper and Heywood [4] have therefore proposed the use of sodium chloride crystals to obtain a reduction of the pressure drop to one twentieth of that of the Celite column.

Since February 1955 work on gas-liquid chromatography has been in progress in »Laboratoriet for almen teknisk Kemi» with a view to the development of methods for quantitative analysis of mixtures of methyl esters of fatty acids. In the present article an account will be given of the experience gained with regard to suitable equipment, and the method is illustrated through an examination of oil from seeds of the genus *Ulmus*.

EQUIPMENT

Column. The chromatographic column (Fig. 1) is made up of four stainless steel tubes, each 1 meter long and secured by brazing to a top and a bottom flange. The bore of the tubes is 8 mm. The bottom flange is closed by means of a plate and a lead gasket by

means of which it is possible to connect all four tubes in series to form one column (4 m long) or to connect two tubes only to form a 2 m column. The detector is secured to the top flange by means of bolts and a lead gasket.

The detector. The detector used is a catharometer prepared from a brass block with four borings lined with stainless steel tubes of the same type as those used for the column. Two of the tubes (d) in the block are used for measurements of the thermal conductivity of the gas flow from the column, both directly and after removal by condensation of entrained material in a U-tube cooled in a mixture of solid carbon dioxide and acetone. In Fig. 1 this cooling-tube is shown attached to the column. The third tube (g) in the catharometer block is used for reheating the gas flow after the cooling process. The thermal conductivity is measured by means of two electrically heated platinum filaments which form a Wheatstone bridge together with two permanent resistances. The bridge is supplied with current from a storage battery which is charged continuously during the experiment. A 5 mV recording potentiometer is connected across the Wheatstone bridge. The platinum filaments are finely coiled and attached to platinum wires sealed into a glass support (Fig. 2). The sensitivity of the catharometer has been found by calculation to be 5/16 μg/ml N_2 at 20 mm Hg and 8 ml N_2/minute both for C_8 and C_{12} methyl esters.

Ampoule breaker. The fourth tube (a) in the catharometer block is used for the admission of nitrogen to the column. It also contains an ampoule breaker in which the small spherical glass ampoule with the weighed sample of methyl esters is placed at the beginning of the run. When the appropriate temperature and nitrogen flow conditions are attained the ampoule is broken admitting the sample to the column without interruption of the nitrogen stream.

The column with its detector is surrounded by an electrically heated furnace tube, in which the temperature is kept constant by means of a regulating transformer.

The pressure at the column outlet is kept constant by means of a manostat consisting of a 1 litre reference flask placed in a water bath and connected to one side of a regulating (electric contact) pressure gauge, the other side of which is connected to the system. The pressure gauge, which contains diethylene glycol, controls a magnetic air inlet valve through an electronic relay.

The rate of flow of nitrogen, which is used as carrier gas, is controlled by a needle valve at the column inlet.

Column packing. Acetate-washed silicone grease [4] was used as the static phase in all the experiments.

As inert carrier of the static phase either (1) sodium chloride crystals, or (2) Dixon rings of stainless steel gauze [5] were used. Preparation of the column packing took place according to either of the following methods:

(1) Stir 10 g acetate-washed silicone grease with 30 ml ethyl acetate and add 200 g sodium chloride, according to Dan. Pharm., which has passed through sieve No. 30, but which is retained on sieve No. 40. Mix thoroughly, but gently, so as not to crush the crystals. Stirring frequently heat in drying cabinet at 50°C until ethyl acetate has evaporated off.

(2) Wash 126 g Dixon rings, 1/16″ × 1/16″, Griffin & George Ltd., Cat. No. B 24—420, thoroughly with ethyl acetate. Add 18 g acetate-washed silicone grease to the gauze rings which must be thoroughly moistened with ethyl acetate, and distribute the grease uniformly by protracted, but gentle, stirring. Remove ethyl acetate by heating in drying cabinet at 100°C. After this procedure the grease will form a film filling the meshes of the gauze, but leaving the interior of the rings free.

COLUMN EFFICIENCY

The efficiency of a gas-liquid chromatograph may be expressed in terms of the number of theoretical plates, TP, calculated from the expression:

$$TP = 16(x/y)^2$$

where x is the distance from the starting point of the chromatogram to the centre of the elution peak, and where y is the distance between the points of intersection between the flex tangents of the elution peak and the base line.

Table 1 and 2 list the TP values obtained in a number of experiments made partly with the NaCl-column and partly with the Dixon ring-column at different temperatures and pressures. In all the experiments the rate of flow of nitrogen was 8.0 ml/min measured at atmospheric pressure and temperature.

Direct comparison between sodium chloride columns and Dixon ring columns shows the difference between the efficiencies of the two column

Table 1.

Length of column		2 m Dx	4 m Dx	4 m Dx	2 m NaCl
Temperature, °C		200	200	240	200
Outlet pressure, mm Hg		20	20	20	20
Pressure drop, mm Hg		4.5	8	10	52
Inlet pressure, mm Hg		24.5	28	30	72
TP	Methyl laurate	48	106	41	55
	Methyl myristate	89	183	112	102
	Methyl palmitate	137	374	121	200
	Methyl stearate	205	—	226	296

Table 2.

Length of column		2 m Dx	2 m Dx	2 m Dx
Temperature, °C		200	200	180
Outlet pressure, mm Hg		20	50	20
Pressure drop, mm Hg		4.5	4	4
Inlet pressure, mm Hg		24.5	54	24
TP	Methyl caprylate	16	30	21
	Methyl caprate	23	54	35
	Methyl laurate	36	90	64

types to be small. A comparison based on identical outlet pressures shows the Dixon rings to be only slightly inferior, while, in case it was possible to base the comparison on identical inlet pressures, the result of the comparison would change considerably in favour of the Dixon rings, since the pressure drop in this case is so low as to enable a considerable increase in the outlet pressure. It will be seen that the number of theoretical plates increases with increasing pressure and column length and with decreasing temperature.

CALIBRATION OF APPARATUS

The apparatus has been standardized against pure methyl esters of fatty acids. The methyl esters used were purified by repeated fractional distillations on a spinning band column, and the purity was ascertained by gas-liquid chromatographic analysis of large quantities of the compounds.

The following procedure was used: temperature, pressure, rate of flow of nitrogen and detector potential were adjusted at specified values. It is essential to perform this adjustment accurately to obtain reproducible values of the areas of elution peaks without using an "internal standard". The areas found are plotted against quantities according to a double-logarithmic scale, resulting in a family of rectilinear curves, one curve for each methyl ester. The equation

$$\log A = n \cdot \log M + \log k,$$

where A is the area, M the quantity of material, while n and k are constants, applies, and the conversion factors may be found from the curves. By means of these factors the quantity of material corresponding to the measured area in the analysis of an unknown mixture can readily be calculated.

In the calibration a temperature of 180°C, a pressure of 20 mm Hg, and a rate of flow of nitrogen of 8.0 ml/min were used for methyl esters of C_8, C_{10}, and C_{12} fatty acids. The following equations were found:

$$\begin{aligned} &\text{for } C_8 && \log A = 0.944 \log M + \log 9.0 \\ &\text{" } C_{10} && \log A = 1.045 \log M + \log 10.15 \\ &\text{" } C_{12} && \log A = 1.002 \log M + \log 12.35 \end{aligned}$$

For methyl esters of C_{14}, C_{16}, and C_{18} fatty acids a temperature of 200°C, a pressure of 20 mm Hg, and a rate of flow of nitrogen of 8.0 ml/min were used. The points determined are all on the same straight line, *viz*:

$$\log A = 1.041 \log M + \log 11.6$$

It was hoped that methyl esters of saturated and unsaturated fatty acids of the same chain length would prove to have identical calibration curves, since fatty acids of these types are not clearly separated under the usual experimental conditions, but occur in the same maxima. Unfortunately, experiments seem to indicate that this is not the case, since the equation for methyl oleate is

$$\log A = 1.115 \log M + \log 9.15$$

This circumstance complicates the conversion of areas into quantities by weight, since an accurate conversion cannot be made without knowledge of the ratio in which the quantities of stearic acid and unsaturated C_{18} acids are present in the methyl ester mixture to be analyzed. The problem may be circumvented by complete hydrogenation prior to the chromatography, a method which is necessary when very accurate analyses are required.

In the present work a calculation of the content of C_{18} acids in the elm seed oils based on the methyl oleate calibration has been considered to represent a sufficiently accurate compromise.

COMPOSITION OF ELM SEED OILS

The applicability of gas-liquid chromatography to fatty acid analysis has been demonstrated by the determinations of the fatty acid composition of oil from seeds of various types of elm trees. In an earlier examination [6] of a few types of elm seed oils C_{10} acids have been found to be present in quantities ranging from 50 to 60 %, which is very remarkable since no other plants outside the tropical zones are known to contain considerable quantities of lower fatty acids. It would therefore be interesting to find out whether oil from Danish elm types could be shown to have the same peculiar composition.

The investigation has included determinations of water and fat in the seeds. In addition refractive indices, iodine values and saponification values were determined (Table 3). The seeds were obtained from The Botanical Garden of the University of Copenhagen and from the gardens of The Royal Agricultural and Veterinary College *. The seeds were dried and the wings removed by gentle crushing and air separation.

The oil was obtained by extraction with petroleum ether. Fairly large quantities of seeds were used for the extraction because it served the double purpose of providing a determination of the fat content and material for subsequent experiments.

On the whole the examined seeds had a remarkably high oil content, considerably higher than the values given in the literature. Incidentally, the magnitude of the oil content does not, apparently, bear any relationship to the type or variety concerned, variations being presumably due to variations in growth condition.

* The authors wish to acknowledge their indebtedness to the staff of these two institutions for their kind assistance in supplying the seeds.

U. manshurica [7]		27	1.4552	251.4		22.5

Iodine value was determined according to AOCS, Cd 1—25, but using only 60 % of the stated quantities of material and reagents. A graphical representation of the relationship between iodine value and refractive index is given in Fig. 3. On the basis of this graph it is possible to arrive at an estimated iodine value in cases where no determination of this value has been made because the quantity of oil available was too small.

Saponification value was determined according to AOCS, Cd 3—25, likewise with reduced quantities of material and reagents.

To enable the gas-liquid chromatographic determination of the fatty acid composition, the fatty acids were converted into their methyl esters by the following method which takes into account the high solubility in water of the lower methyl esters:

About 1 g oil was dissolved in 20 ml hot methanol and a solution of 20 mg sodium methoxide in 2 ml methanol was added. The resulting solution was

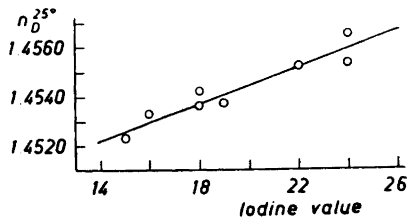

Fig. 3. The relation between iodine value and refractive index.

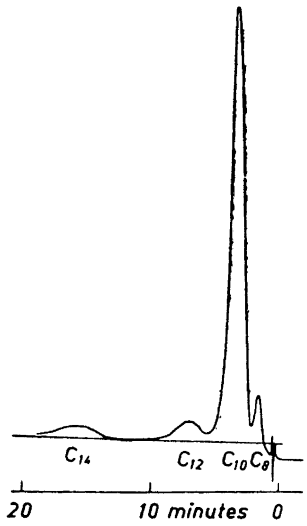

Fig. 4. Chromatogram of methyl esters from oil *U. glabra*, 180°C.

refluxed for a few hours and allowed to stand overnight. Now 20 ml ethyl ether was added and subsequently small portions of distilled water until the solution separated into two phases. The two phases were separated, and the aqueous phase was again extracted with ether. The ether extracts were combined and an equal volume of petroleum ether was added, resulting in the separation of a considerable quantity of water. The ether mixture was now dried with anhydrous sodium sulphate, and the solvents were removed by evaporation on a steam bath. Finally the methyl ester was kept at 60°C and 15 mm Hg for about one hour.

A column temperature of 180°C in the gas-liquid chromatograph was required to obtain good separation of C_8—C_{10}—C_{12} esters. Fig. 4 shows a characteristic chromatogram. The column efficiency is just sufficient to enable a fairly accurate determination. But the chromatogram further suggests that a determination of C_{14}—C_{16}—C_{18} esters will be difficult on account of their flattish maxima at this low column temperature. Fig. 5 shows a chromatogram run at 200°C and with a larger quantity of material. On the basis of this chromatogram a very accurate determination of C_{14}—C_{16}—C_{18} esters can be made, while C_8—C_{10}—C_{12} esters are only just separated.

It was thus necessary to run two chromatograms for each seed sample, *viz.* at 180 °C with about 1.8 mg for the determination of C_8—C_{10}—C_{12}, and at 200°C with 10—20 mg material for the determination of C_{14}—C_{16}—C_{18}. Altogether about 30 chromatograms have been run.

It is not possible by calculation to arrive at any numerical evaluation of the errors incident to the measurements made. Deviations of about 3 % have bee observed in most duplicate runs, although deviations right up to 10—20 % also occur. Presumably the error in connection with the determination of C_8 and C_{12} esters is 5—10 %, while with regard to determinations of C_{10}, C_{14} and C_{16} the error is 2—5 %. For the reason referred to in the section

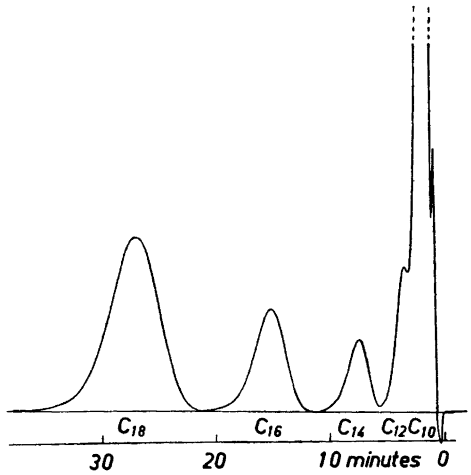

Fig. 5. Chromatogram of the same sample as in Fig. 4, 200°C.

on calibration the error in connection with the determination of C_{18} is considerably greater, perhaps 10—20 %. In the case of analytical samples with a more even distribution of saturated fatty acids the error may reasonably be assumed to be 1—2 %, which is greatly superior to the accuracy of other known analytical methods for similar determinations.

The gas-liquid chromatogram provides information as to the composition of the methyl ester mixture. The fatty acid composition may be obtained by calculation from the analytical results, since

$$S = \frac{E \cdot \frac{M}{14 + M}}{\Sigma E \cdot \frac{M}{14 + M}} \cdot 100$$

where S is the quantity of fatty acid and E the quantity of ester, both in per cent by weight, while M is the molecular weight of the fatty acid in question.

Table 4 lists the fatty acid composition for the species and varieties of elm examined. The table moreover includes a mean value which has been calculated for the purpose of enabling comparison with values given in the literature.

On the basis of the fatty acid composition found the saponification value of the corresponding elm seed oil has been calculated, the result has been included in Table 3. In the four cases where comparison has been possible, the agreement is satisfactory.

Table 4.

	Fatty acid composition, %					
	C_8	C_{10}	C_{12}	C_{14}	C_{16}	C_{18}
Ulmus glabra, Vet. College	6.2	72.4	5.3	3.3	5.0	7.8
U. glabra, var. *cornuta*	3.2	58.2	4.4	3.5	7.6	23.1

The Quenching of the Long-lived Fluorescence of Biacetyl in Solution

HANS L. J. BÄCKSTRÖM and KJELL SANDROS

Institutionen för fysikalisk kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

The quenching effect of different types of compounds on the long-lived fluorescence of biacetyl has been studied in solution at 20°C by measuring fluorescence decay rates. The results are in accord with the conclusion of Lewis and Kasha that the emitting state of biacetyl is a triplet or biradical state. Photochemical reactions of carbonyl compounds indicate that the structure of the biradical may be written as

$CH_3C(=O)-\dot{C}(-\dot{O})CH_3$ and that, due to the odd electron on oxygen, it has

the power of abstracting H-atoms from colliding molecules.

Two different classes of quenchers are distinguished. The first class comprises substances having a loosely bound hydrogen atom, such as primary and secondary amines, phenols, aldehydes, and alcohols. In this case the quenching mechanism is assumed to consist in a photochemical reaction of the kind indicated. The second class of quenchers comprises unsaturated and aromatic compounds, the strongest quenchers of this type being polynuclear hydrocarbons. Here the quenching mechanism is assumed to be an energy transfer, causing a triplet → singlet transition in the biacetyl molecule and the reverse transition in the quencher. This assumption is in accord with known values of triplet state energies, and is further supported by the results of preliminary photochemical experiments, showing that irradiation of a benzene solution of biacetyl and anthracene gives rise to a photosensitized formation of dianthracene. The quantum efficiency under the conditions employed is of the order of 1 %, increasing with increasing light intensity.

When solid solutions of unsaturated compounds are irradiated with ultraviolet light at liquid air temperatures, two kinds of photo-luminescence may be observed: normal fluorescence, and a more long-lived luminescence with an entirely different spectrum, displaced toward longer wavelengths. Under suitable experimental conditions the latter emission may be observed as phosphorescence. According to Lewis and Kasha [1], the phosphorescent state may be identified with the triplet or biradical state of the molecule. In accord-

ance with the selection rule prohibiting intercombinations between levels of different multiplicity, the radiative return from the triplet to the ground (singlet) level is a slow process.

In the case of most substances, warming the solution leads to a gradual disappearance of the long-lived emission as the fluidity of the solvent increases. A few exceptions are known, however, where it may be observed at ordinary temperatures [2]. In these cases the triplet state of the molecule must possess exceptional stability toward collisional deactivation. The most notable of these cases is that of biacetyl. The so-called "delayed fluorescense" of biacetyl has been studied extensively in the vapour state and to some extent also in water solution [3]. Its quenching by O_2 has been studied quantitatively in the vapour state [3]. The same phenomenon has been observed in water solution but no quantitative data have been reported.

The present study of the quenching effect of different types of compounds on the long-lived fluorescence of biacetyl in solution [4] was undertaken with the aim of obtaining information on the chemistry of the triplet state, about which very little is known [5].

The paper also gives some preliminary results of photochemical experiments on solutions of biacetyl and anthracene.

EXPERIMENTAL

In some preliminary experiments, quenching was studied by measuring the intensity of fluorescence under constant conditions of illumination. The final experiments, however, were made by studying the effect of quenchers on the rate of decay of fluorescence.

Apparatus

The experimental arrangement for measuring fluorescence decay rates is shown schematically in Fig. 1. Light from a single condenser discharge through the flash tube *a* passed through filter combination *c* before entering the solution through one of the end

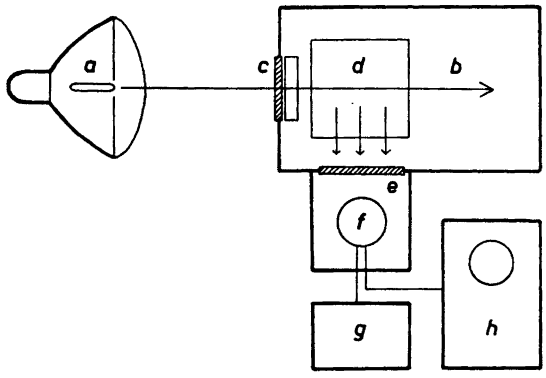

Fig. 1. Schematic diagram of apparatus for measuring fluorescence decay rates. (a) Flash tube. (b) Light-tight box. (c) Filter combination, consisting of 4 mm Chance glass OB1 + 1 cm 0.5 M sodium nitrite solution. (d) Cylindrical fluorescence cell. (e) Light filter (Chance OY3, 4 mm). (f) Photomultiplier tube. (g) Stabilized adjustable voltage supply. (h) Oscilloscope.

plates of the cylindrical fluorescence cell *d*. This filter combination confined the exciting light to the wavelength region 3 800—5 000 Å. The cell had a diameter of 4 cm and a length of 4 cm. Fluorescence radiation, perpendicular to the exciting light, passed through filter *e* to remove scattered incident light before inpinging on the photomultiplier tube *f*. Filter *e* removed all wavelengths below 5 000 Å. The long-wave fluorescence of biacetyl lies mainly in the region 5 000—6 000 Å. The voltage applied to the photomultiplier tube (RCA 931A) was varied between 600 and 900 V. About 700 V was generally found suitable. The output of the multiplier tube was fed into a resistance of 20 000 ohms and the voltage developed across the resistance applied to the vertical deflection terminals of a Tektronix Type 514D oscilloscope. The latter was equipped with a blue-fluorescing screen (Type P7) permitting photographic registration of the trace even at high sweep speeds. The multiplier tube was furnished with a cathode follower which reduced its response time to < 1 μsec. The sweep speeds of the oscillograph were checked using a Tektronix Time-Mark Generator, Type 180. Errors exceeding 1 % were not observed, and no corrections were applied. The oscilloscope was used with signal triggering, the photomultiplier signal automatically starting the sweep.

Our first measurements were made with flashes from a Philips stroboscope GM 5 500*. As only single flashes of moderate intensity were required, the stroboscope was later replaced by a simple electronic device built according to a description by de Bruin [6], using the same kind of argon-filled flash tube (Type 57 900 P/06) and the same relay valve (thyratron PL5) as in the Philips stroboscope. The condenser had a capacity of 4 μF and was charged to 700 V. Care was taken to use short and suitably designed leads to reduce the time of the flash. By direct observation of the flash by means of the multiplier-oscilloscope combination (using suitable light filters for preventing damage to the multiplier tube) it was found that the peak in light intensity occurred 4 μsec after flash initiation and that after 12 μsec the decrease in intensity followed an exponential curve with a half-time of 2.6 μsec. These data represent a marked improvement compared to the flash used previously and considerably extended the range of fluorescence decay rates that could be measured.

The procedure used in photographing a decay curve was as follows. With the fluorescence cell brought to the desired temperature and placed in position, the voltage of the photomultiplier tube, the sweep speed, and the intensity of the cathode ray were adjusted by the aid of trial flashes so as to give a satisfactory trace. The electron beam was displaced a sufficient distance for registration to begin at least 12 μsec after flash initiation. The camera was then placed in position, the shutter opened, and another flash produced. The photograph was enlarged by projection and analyzed. The decay curves were found to be strictly exponential. Usually four decay curves were registered for each solution. The mean life values calculated from these curves usually did not differ by more than 1 %, and there was no trend in the values, showing that the solutions were not changed by the exciting flashes **.

Because of the very strong quenching action of oxygen, all fluorescence measurements had to be made in the absence of air and on solutions that had been carefully freed from dissolved oxygen. The fluorescence cell with arrangements for degassing the solution is shown in Fig. 2. The cell itself (*a*) was a cylindrical flow-through absorptiometer cell from The Tintometer Ltd., Salisbury, made of glass with negligible fluorescence. For degassing a solution, the apparatus, in an inclined position and with the solution in bulb *b*, was connected to a vacuum system by means of ground-glass joint *f*. The volume of the bulb was about 110 ml, that of the cell 40 ml. The pump used for evacuation was a two-stage rotary oil pump, capable of giving a vacuum of 10^{-4} mm. Pressure readings were made on a McLeod gauge. After cooling the bulb with carbon dioxide ice and alcohol the stop-cock was opened and the air removed by pumping. With the stop-cock closed, the solution was then warmed to 20°C to liberate dissolved air. By repeating these operations four times, the air pressure in the vessel was reduced to < 0.01 mm. After bringing the solution to 20°C, it was transferred to the fluorescence cell by tilting the apparatus, and the fluorescence decay rate was measured as described.

* Kindly placed at our disposal by Professor S. Lundberg of the Department of Mechanical Engineering.

** Prolonged irradiation may lead to measurable changes in the composition of the solution. *Cf.* p. 830.

When studying the quenching action of oxygen, known small quantities of air were admitted into the apparatus above the frozen and degassed biacetyl solution. For this purpose a special gas burette was used, made of 2 mm manometer tubing, where volumes were measured under reduced pressure. As little as 10^{-6} mole of oxygen could be measured with an accuracy of 1 %. After adjusting the temperature to 20°C, the solution was shaken to attain equilibrium. Knowing the volume of the apparatus (188.5 ml), the volume of the solution (44.0 ml), and the solubility coefficient, the concentration of oxygen in the solution could be calculated.

Materials

The chemicals used were of the highest purity obtainable commercially and were further purified as indicated below.

Biacetyl was fractionally distilled in a nitrogen atmosphere under reduced pressure (100 mm), using a column corresponding to 15 theoretical plates. The same column was used for all other distillations. The purified biacetyl was stored in the dark. Its fluorescence properties remained unchanged for months.

Benzyl alcohol, *aniline*, and *nitrobenzene* were distilled at 9—12 mm, the following at NP: *benzene*, *carbon tetrachloride*, *perchloroethylene*, cyclo*hexene*, *methanol*, and iso*propanol*, the latter in a nitrogen atmosphere. *Stilbene* and *1,3,5-trinitrobenzene* were recrystallized from ethanol, p-*chlorobenzaldehyde* from a water-ethanol mixture, and *resorcinol* from benzene. *Triphenylamine* in benzene solution was repeatedly shaken with 5 M sulfuric acid to remove diphenylamine. It was then recrystallized from an ethanol-water mixture. *Naphthalene*, *phenanthrene*, *pyrene*, and *chrysene* were freed from anthracene by treatment with maleic anhydride in benzene or toluene solution [7,8]. The first three were then recrystallized from ethanol. Chrysene was refluxed with carbon tetrachloride containing benzoyl peroxide [7] and recrystallized once from acetone and twice from benzene.

Phenol, *hydroquinone*, *diphenylamine*, m-*dinitrobenzene*, *anthracene*, *benzpyrene*, and *1,2-benzanthracene* were used without further purification.

RESULTS AND DISCUSSION

The solvent found most suitable for our purpose was benzene. Dilute solutions of biacetyl in high quality benzene from different sources gave strongly varying values of fluorescence mean life (τ). However, by fractional distillation of the benzene we generally succeeded in raising the value of τ to about 0.98×10^{-3} sec at 20°C. The highest value observed was 1.03×10^{-3} sec. For biacetyl vapour at 25°C a value of 1.80×10^{-3} sec has been reported [9], as against 2.25×10^{-3} sec for a solid solution at 77°K[10].

Solutions of biacetyl showed the phenomenon of self-quenching, the value of τ decreasing with increasing biacetyl concentration. However, the effect was slight and variable, indicating that it was due to remaining traces of impurities in the biacetyl. It was found to obey the Stern-Volmer quenching formula [11], in that τ could be represented as a function of biacetyl concentration (C) by the equation:

$$\frac{1}{\tau_0} = \frac{1}{\tau} + kC \qquad (1)$$

The lowest value observed for k was 460 l mole^{-1} sec^{-1}. In studying quenching by foreign substances, the biacetyl concentration was kept so low that self-quenching was negligible.

Other liquids tried as solvents gave the following values of τ in μsec: carbon tetrachloride 784, chlorobenzene 447, anisole 307, methyl benzoate 278, water 229.

Stronger quenchers were studied in benzene solution. The results were found to obey the Stern-Volmer formula (1). In all cases the decay rate was measured at six different concentrations of the quencher such that τ varied between τ_0 and $\tau_0/10$. For anthracene a determination giving $\tau = \tau_0/40$ also gave good agreement with eqn. (1). The straight line relation between $1/\tau$ and C had a standard error in regression coefficients of 1—2 %. Table 1 gives the calculated values of k in l mole^{-1} sec^{-1}. The oxygen concentration in benzene solution was calculated using the solubility value given by Horiuti [12].

A closer study of the table leads to the conclusion, that substances with pronounced quenching action may be divided into two classes:

1. In the first class, comprising *i.a.* phenols, amines, and alcohols, quenching power is connected with the presence in the molecule of a loosely bound hydrogen atom. This is indicated by the almost complete loss of quenching power in going from phenol to anisol and from diphenylamine to triphenylamine. Also the general parallelism between quenching power and inhibitory action in autoxidation reactions, which is apparent, points in the same direction. It is interesting to note in this connection that the only aldehyde investigated, *p*-chlorobenzaldehyde, is a stronger quencher than the alcohols, that act as weak inhibitors (sometimes called retarders) of aldehyde oxidation. On the other hand, strong oxidation inhibitors like phenols and primary and secondary amines have quenching constants that exceed the value for the aldehyde by several powers of ten.

There can be little doubt that the quenching mechanism indicated by these results may be identified with a type of chemical reaction which is well-known

Table 1. Quenching constants (l mole^{-1} sec^{-1}) in benzene solution at 20°C.

Methanol	2.6×10^2
*Iso*propanol	2.7×10^3
Benzyl alcohol	6.9×10^3
p-Chlorobenzaldehyde	2.4×10^4
Phenol	8.9×10^7
Resorcinol	2.7×10^8
Hydroquinone	5.3×10^9
Aniline	1.8×10^9
Diphenylamine	6.8×10^9
Triphenylamine	3.9×10^4
Perchloroethylene	3.5×10^4
*Cyclo*hexene	1.0×10^5
Nitrobenzene	4.4×10^4
m-Dinitrobenzene	3.6×10^5
1,3,5-Trinitrobenzene	1.1×10^6
Stilbene	4.4×10^9
Naphthalene	3.8×10^3
Phenanthrene	2.3×10^3
Anthracene	8.1×10^9
Chrysene	2.4×10^8
Pyrene	7.5×10^9
Benzpyrene	8.2×10^9
1,2-Benzanthracene	3.8×10^9
Oxygen	5.1×10^9

from the photochemistry of carbonyl compounds. In the words of Plotnikow [13]: "Die Verbindungen, die die CO-Gruppe enthalten, besitzen die Eigenschaft, im Licht anderen organischen Körpern den Wasserstoff zu entziehen (sie zu dehydrieren) und ihn an diese CO-Gruppe anzulagern: $-C=O+H \rightarrow -C(OH)-$. Die Doppelbindung wird somit aufgehoben und eine Bindung frei gemacht. Dadurch wird der Verbindung die Möglichkeit gegeben, sich entweder zu kondensieren oder andere Moleküle anzugliedern." An example is the formation of benzopinacol, $(C_6H_5)_2C(OH)C(OH)(C_6H_5)_2$, and acetone when solutions of benzophenone in *iso*propanol are irradiated with ultraviolet light. It was suggested long ago [14,15] that an intermediate in this reaction is a biradical $(C_6H_5)_2\dot{C}-O\cdot$, formed from benzophenone as a result of light absorption, which due to its unpaired electron on the oxygen atom has the power of abstracting a loosely bound hydrogen atom from a neighbouring molecule. This biradical may be identified with the triplet state responsible for the phosphorescence of benzophenone in solid solution at low temperatures *.

Similarly biacetyl, when irradiated in ethanol solution [16], gives acetaldehyde and 3,4-dimethyl-hexanediol-(3,4)-dione-(2,5) (I).

I 
II 
* For a discussion of this point, see Bäckström, H. L. J., Steneryr, A. and Perlmann, P. *This Journal* **12** (1958) 8.

Thus the biradical of biacetyl reacts as if it had the structure II. Obviously, however, the true state of this biradical must be largely determined by the exceptional possibilities for resonance. Probably the resulting resonance stabilization is the cause of its remarkable stability.

2. The second class of quenchers consists of unsaturated and aromatic compounds. In view of the biradical nature of the triplet state it is of interest that these compounds are known to undergo addition reactions with free radicals. This is particularly the case with the polynuclear hydrocarbons, and a general parallelism between the quenching constants and the "relative methyl affinities" of Szwarc [17] seems to exist where comparison can be made. In the series of aromatic nitro compounds, increase in quenching constant parallels the tendency to undergo radical addition reactions.

Probably, however, we are here dealing with a quenching mechanism which is physical rather than chemical in nature. Terenin and Ermolaev [18] have shown that sensitized phosphorescence may take place in solid solutions at low temperatures. For instance, when a solution of naphthalene in ethanol at −195°C is excited by filtered radiation of wavelength 3 660 Å no luminescence is observed, since the onset of the absorption spectrum of naphthalene lies at 3 270 Å. However, when the solution contains, in addition, a suitable sensitizer like benzophenone, which absorbs at 3 660 Å, a bright phosphorescent emission of the triplet spectrum of naphthalene in the visible appears. By measuring intensities and decay times of the emission spectra as a function of the concentrations the authors were able to prove that the process taking place is a transfer of excitation energy, causing a triplet → singlet transition in the sensitizer and the reverse transition in the acceptor. The necessary condition is that the energy level of the triplet state of the sensitizer must lie above that of the acceptor.

The same process of energy transfer may be expected to take place in liquid solutions at ordinary temperatures. The approximate triplet state energy (E_T) of biacetyl as determined from its phosphorescence spectrum [1] is 56 kcal/mole, taking the energy of the ground state as zero. Table 2 gives the corresponding values for quenchers of class 2 where such data are available *. It will be seen that E_T-values below 56 kcal/mole correspond to high values of the quenching constant, those well above 56 kcal/mole to low values. Chrysene with $E_T = 57$ kcal/mole occupies an intermediate position.

In liquid solution at ordinary temperature, excitation of the acceptor to the triplet state will not normally result in sensitized phosphorescence. Molecules in this state will be deactivated by collisions before they have time to radiate. The only visible effect in the present case will therefore be the quenching of biacetyl fluorescence. The possibility exists, however, that the triplet excited quencher molecules may undergo some sufficiently rapid chemical reaction. This is how we interpret the sensitized formation of dianthracene described on p. 830.

Oxygen as a quencher represents a case by itself. It has long been known that oxygen reacts with biacetyl under the influence of light [20] but nothing

* According to Kasha and McGlynn[5], the value for stilbene given by Lewis and Kasha [1] is now known to be wrong.

Table 2. The relation between quenching constant and triplet state energy for some quenchers of class 2.

	log k	E_T kcal/mole	Ref.
Phenanthrene	3.4	62	19
Naphthalene	3.6	61	1
Nitrobenzene	4.6	60	1
Chrysene	8.4	57	19
Pyrene	9.9	48	19
1,2-Benzanthracene	9.6	47	19
Anthracene	9.9	42	1

is known about the reaction products. Since one of the carbon atoms of the biradical has an unpaired electron, the primary act is probably the addition of an oxygen molecule to this carbon atom.

In cases where the rate of a bimolecular reaction in solution is determined entirely by the rate of diffusion of the reactants towards each other, the value of the rate constant may be estimated by a formula given by Debye [21]. For benzene solutions at 20°C the calculated value is 1.0×10^{10} l mole^{-1} sec^{-1}. It will be seen that the values of k for the strongest quenchers closely approach this value, showing that in these cases the quenching process is so rapid as to be essentially diffusion controlled [22].

As regards the weaker quenchers in Table 1, special methods of purification were employed for removing as far as possible traces of chemically related substances with strong quenching action. As always, the purification process was followed by measuring the quenching constant. For instance, the k-value found for unpurified phenanthrene was 2.5×10^6. Two purifications by the method described above (p.826) reduced the value to 7×10^3, and four to the value given in the table (2.3×10^3). Presumably this is not far from the true value but provisionally it must be regarded as a maximum. The same applies to the k-values for other weak quenchers.

PRELIMINARY RESULTS OF PHOTOCHEMICAL EXPERIMENTS WITH ANTHRACENE

A degassed solution of 0.41 g of biacetyl and 0.42 g of anthracene in 50 ml of purified benzene, contained in an evacuated and sealed glass bulb, was exposed to daylight near a south window. In order to exclude wavelengths absorbed by anthracene, the bulb was immersed in a beaker with 1 M sodium nitrite solution. After about 2 weeks colourless crystals began to appear. After 9 months the bulb was opened and the crystals formed were washed with alcohol and dried. A microanalysis gave: C 93.97; H 5.71. Calc. for dianthracene: C 94.34; H 5.66.

The absorption spectrum in ethanol solution showed substantial agreement with that of dianthracene [23] but indicated that the product contained about 5 mole % of anthracene.

Confirmatory evidence for the photosensitized formation of dianthracene was obtained from similar experiments using light from a mercury arc, filtered to remove wavelengths absorbed by anthracene. The initial concentration of anthracene was lower (10^{-4} — 10^{-5} mole/l) and its rate of disappearance from the solution was followed by observation of biacetyl fluorescene and by measuring its decay rate when the anthracene concentration had decreased sufficiently for such measurements to the possible. The τ-values finally reached on prolonged irradiation were close to τ_0, showing that the reaction product had no noticeable quenching action. In order to prove that the disappearance of the anthracene was not, in spite of all precautions, caused by light absorbed by that substance, a degassed solution containing the same amount of anthracene but no biacetyl was irradiated twice the time used in the foregoing experiment. After opening the bulb, adding biacetyl, and degassing the solution, it was found that the fluorescence of biacetyl was completely quenched by the anthracene still present.

In the experiments described, the quantum efficiency of the photosensitized reaction of anthracene was determined using the potassium ferrioxalate actinometer of Parker [24]. The values obtained ranged from 0.1 to 1.9 %. They increased with increasing light intensity, but apparently also other factors such as the concentration of biacetyl are of importance.

The reaction product formed slowly decomposes again at room temperature. This is shown by the fact that when the solution is kept in the dark, τ again decreases. From the rate of decrease in τ, the rate of decomposition of dianthracene could be calculated. It corresponded to a half-life of about 1 400 days.

*iso*Thiocyanates XXX *. Glucohirsutin, a New Naturally Occurring Glucoside Furnishing (—)-8-Methylsulphinyloctyl *iso*Thiocyanate on Enzymic Hydrolysis

ANDERS KJÆR** and BO CHRISTENSEN

Chemical Laboratory of the University of Copenhagen, Denmark

A survey is presented of the straight-chain, *levo*rotatory ω-methylsulphinylalkyl *iso*thiocyanates (I) formerly recognized as enzymic hydrolysis products of glucosidic progenitors present in various plant species belonging to the family *Cruciferae*. Besides sulphoraphene (II), these mustard oils comprise the compounds I with n = 3, 4, 5, 9 and 10.

The present paper reports the identification of an additional glucoside, *glucohirsutin*, of this general type, present in seeds of *Arabis hirsuta* (L.) Scop. and affording *hirsutin*, the *levo*rotatory 8-methylsulphinyloctyl *iso*thiocyanate (I, n = 8), upon enzymic hydrolysis. The structure of the latter is proved by degradation.

On acid hydrolysis glucohirsutin furnishes hydroxylamine whereas its enzymic cleavage proceeds with liberation of glucose and sulphate in addition to hirsutin. These results establish (VII) as the correct expression for glucohirsutin.

In the course of a systematic search in this laboratory for mustard oil glucosides in seed material of various crucifers, several compounds have been encountered which possess in common the property of furnishing *levo*rotatory *iso*thiocyanates of the general structure (I) on enzymic hydrolysis.

n = 8: Hirsutin
n = 9: Arabin
n = 10: Camelinin

* Part XXIX of this series: *Acta Chem. Scand.* **11** (1957) 1423.

** Senior author. Present address: Organic Chemical Laboratory, Royal Veterinary and Agricultural College, Copenhagen V., Denmark.

*** Experimental work is in progress to establish the absolute configuration around the asymmetric sulphur atom. Comparable rotatory data for the homologous *iso*thiocyanates (I), as well as several series of the corresponding thiourea-derivatives, renders it almost certain that all of the parent glucosides, containing a sulphoxide-grouping in the side chain, belong to the same configurational series.

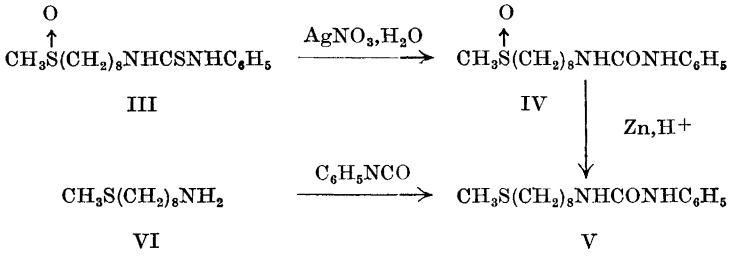
The first recorded compound of this type was sulphoraphene (II), isolated by Schmid and Karrer [1] subsequent to enzymic hydrolysis of a glucoside in seeds of radish (*Raphanus sativus* L. var. *alba*). A few years later, Schultz and Gmelin [2] isolated the crystalline glucoside glucoiberin from seeds of *Iberis amara* L. On enzymic hydrolysis it furnished a mustard oil (iberin) for which the structure (I, n = 3) was advanced, a formulation which has since been unequivocally established in this laboratory [3]. The homologous sulphoxide *iso*thiocyanate, (−)-sulphoraphane (I, n = 4), was synthesized by Schmid and Karrer [4] and has recently been recognized in this laboratory as an enzymic hydrolysis product of a glucoside of rather wide-spread natural occurrence [5]. A previous communication of this series [3] announced the discovery of a new glucoside, glucoalyssin, present in seeds of *Alyssum argenteum* Vitm. and several other *Alyssum* species (*cf.* also Ref.[6]). It was enzymically hydrolyzed to the mustardoil alyssin, identified as (−)-5-methylsulphinylpentyl *iso*thiocyanate (I, n = 5). Seed material of *Arabis alpina* L. served as the source of a formally similar glucoside (glucoarabin), the structure of which appeared from the fact that enzymic hydrolysis resulted in the formation of arabin, unambiguously identified as (−)-9-methylsulphinylnonyl *iso*thiocyanate (I, n = 9) [7,8]. Again, studies of seed extracts of *Camelina sativa* (L.) Crantz resulted in the discovery of glucocamelinin, undergoing enzymic fission to give camelinin which proved to be the next higher homologue, *viz.* (−)-10-methylsulphinyldecyl *iso*thiocyanate (I, n = 10) [9]. In the present paper we wish to extend this class of natural compounds by an additional glucoside, present in seed extracts of *Arabis hirsuta* (L.) Scop. and affording (−)-8-methylsulphinyloctyl *iso*thiocyanate (I, n = 8) upon enzymic hydrolysis.

Paperchromatographic analysis of a methanolic seed extract of *Arabis hirsuta* (L.) Scop. revealed its contents of two major glucosides, travelling in *n*-butanol: ethanol: water (4:1:4) as a single spot with an R_B-value [10] of 0.95 but distinguishable in the solvent system *n*-butanol: pyridine: water (6:4:3) as two spots possessing R_B-values of 0.90 and 0.75. The former glucoside is being further studied at the present, whereas the compound being strongly depressed in the basic solvent system has been identified as a glucoside different from all heretofore recorded species [11]. In accord with general usage in this field we propose the designation *glucohirsutin* for the new constituent which may be identical with an unidentified glucoside, paperchromatographically observed by Schultz and Wagner [10,12] in fresh parts of *Arabis hirsuta* and other *Arabis* species as a spot possessing R_B-values of 0.94 and 0.86 in *n*-butanol:acetic acid:water (4:1:3) and the above pyridine system, respectively.

When the residue from a seed extract of *A. hirsuta* (93 g of seeds) * was subjected to enzymic hydrolysis with a myrosinase preparation in a dilute phosphate buffer at pH 6.7, a chloroform-extractable, non-volatile mustard oil was liberated, derivable from glucohirsutin. The chloroform solution was washed with dilute alkali and water, dried and evaporated to yield the *levo*-rotatory mustard oil (hirsutin). Without further purification this was allowed

* An ample supply of seed material was procured by large-scale cultivation of the plant during the summer of 1957 in the *Botanical Garden of the University of Copenhagen*. We are greatly indebted for the generous assistance of the garden and wish to acknowledge also the good offices of Professor T. Böcher who supplied authentic seed material for sowing.

to react with aniline in chloroform solution to furnish the crystalline *phenylthiourea* (220 mg), $C_{16}H_{26}ON_2S_2$ (III). This *levo*rotatory derivative displayed a strong and characteristic sulphoxide band in the infra-red spectrum. Treatment of the phenylthiourea in aqueous ethanol with silver nitrate, a procedure successfully employed by us in similar cases [3,7,9], resulted in formation of the corresponding *levo*rotatory *phenylurea*, $C_{16}H_{26}O_2N_2S$ (IV), still possessing the sulphoxide-grouping as apparent from its infra-red spectrum. Reduction of the latter compound with zinc dust in acid solution was accompanied by disappearance of the optical rotation as well as the sulphoxide-band in the infra-red spectrum and resulted in production of the crystalline *phenylurea*, $C_{16}H_{26}ON_2S$ (V). This was identified as 1-(8-methylthiooctyl)-3-phenylurea upon critical comparison with an authentic, synthetic specimen produced by reaction of 8-methylthiooctylamine (VI), recently synthesized in this laboratory [8], with phenyl *iso*cyanate. Mixed melting point determination and coinciding infra-red spectra served to establish the identity of the two preparations.



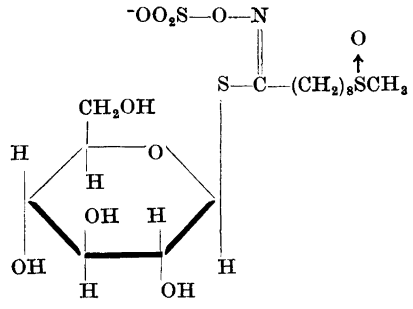
The above sequence of reactions establishes beyond doubt the structure of hirsutin as (−)-8-methylsulphinyloctyl *iso*thiocyanate (I, n = 8).

For further characterization, a separate hirsutin preparation was transformed into the corresponding, *levo*rotatory *8-methylsulphinyloctylthiourea* upon treatment with methanolic ammonia.

Thus far, no attempts have been made to isolate glucohirsutin in pure form, but the following evidence has been adduced to indicate that the glucoside is of the ordinary type. Acid hydrolysis of a paperchromatographically purified specimen of glucohirsutin, conducted according to the directions of Ettlinger and Lundeen [13], resulted in the production of hydroxylamine. The enzymic hydrolysis of a similarly purified glucoside preparation to give hirsutin proceeded with concomitant liberation of glucose and sulphate, a characteristic behaviour of the common mustard oil glucosides. Hence, there can be little doubt that the glucohirsutinate ion, the parent constituent of the employed seed material, possesses the structure (VII), depicted in accord with the recently established general formula for the mustard oil glucosides [13]. In addition to the absolute configuration of the sulphoxide-grouping the stereochemistry around the oxime double bond of (VII) still remains to be clarified.

EXPERIMENTAL

All melting points are uncorrected and determined in capillary tubes in a slowly heated bath. Rotations are measured in a 1 dm tube.



VII

Isolation of hirsutin phenylthiourea (III). A seed sample (93 g) of *Arabis hirsuta* (L.) Scop., produced by cultivation of plants derivable from seed material of wild plants collected near Beograd in Yugoslavia, was finely ground and extracted with one portion (300 ml) of 80 % methanol and two (each of 300 ml) of 70 % methanol. The combined extracts were taken to dryness *in vacuo* and the residue was dissolved in water (200 ml). To the filtered solution were added 1/15 M Na_2HPO_4-(20 ml) and 1/15 M KH_2PO_4-solution (20 ml), together with a cell-free myrosinase preparation (20 ml), and the mixture was set aside at room temperature for 18 h. Next day, it was extracted with three 100 ml-portions of chloroform and the organic layer was washed with 0.2 N NaOH (50 ml) and water. Centrifugation helped to overcome the troublesome emulsion formation at this stage. After being dried over anhydrous Na_2SO_4 the *levo*rotatory solution was concentrated *in vacuo* to a volume of 10 ml whereupon redistilled aniline (1 ml) was added. Next day, the solvent was removed and the residue triturated with ethyl acetate (10 ml) to give the crude, crystalline phenylthiourea derivative. This was dissolved in hot ethyl acetate (100 ml), treated with a little charcoal and the filtered solution concentrated to a volume of 25 ml. On cooling, colourless needles crystallized (117 mg, m. p. 137.5–138.5°). They were combined with additional material (103 mg) of the same m. p., separating from the mother liquor on standing. A specimen for analysis was prepared by two additional crystallizations from the same solvent, m. p. 139° (Found: C 58.90; H 8.18; N 8.65; S 19.81. Calc. for $C_{16}H_{26}ON_2S_2$: C 58.86; H 8.03; N 8.58; S 19.64), $[\alpha]_D^{24}$ −45.0° ± 1.5° ($CHCl_3$, c = 0.8). The infra-red spectrum (in KBr) displayed strong sulphoxide group absorption, apparent as a double band at 986 cm^{-1} and 1 003 cm^{-1}, the former peak being of highest extinction. This split peak character of the sulphoxide band has been frequently observed in this laboratory in spectra of similar compounds in the solid phase and may be attributable to strong hydrogen bonding or even chelation with the substituted thiourea-grouping. The split peak character of the S–O stretching mode around 1 000 cm^{-1} has been observed also by Susi *et al.*[14] in spectra of acids of the general type $RSO(CH_2)_{10}COOH$ in the solid state.

(−)-1-(8-Methylsulphinyloctyl)-3-phenylurea (IV). The above phenylthiourea (191 mg), dissolved in a mixture of ethanol (25 ml) and water (3.5 ml), was treated with a solution of $AgNO_3$ (199 mg) in ethanol, containing a slight amount of water, and the mixture was heated on the steam-bath for about 15 min. During this treatment a total of 1.17 ml of 1 N NaOH was gradually added to maintain neutral reaction. After cooling, precipitated Ag_2S (150 mg) (theoretical amount: 144 mg) was removed by filtration and the filtrate was evaporated to dryness. The residue crystallized in contact with a few ml of water and a pure specimen of the phenylurea was obtained as colourless, rhombic platelets after two recrystallizations from ethyl acetate, m. p. 121°, $[\alpha]_D^{23}$ − 59.7° ± 1.5° (96 % ethanol, c = 1.32) (Found: C 61.87; H 8.32; N 9.05. Calc. for $C_{16}H_{26}O_2N_2S$: C 61.91; H 8.44; N 9.03). The infra-red spectrum (in KBr) was indicative of the presence of a sulphoxide grouping exerting a strong absorption band at 1 005 cm^{-1} with an inflexion near 1 015 cm^{-1}.

Reduction of (IV) to (V). A solution of the sulphoxide-phenylurea (IV) (84 mg) in ethanol (10 ml), containing conc. HCl (0.4 ml), possessed the initial rotation −0.46°. Acid-activated zinc dust (54 mg) was added and the mixture was heated to reflux for 15 min, when the rotation had changed to zero. After filtration, the solution was taken to dryness *in vacuo;* the oily residue crystallized in contact with water to give the crude sulphide-phenylurea (V) (73 mg). Recrystallizations, first from 70 % ethanol and then from ethyl acetate:hexane afforded a pure specimen with m. p. 69°, alone or in admixture with the synthetic sample described below. The two specimens furnished infra-red spectra which were identical throughout the spectral region examined (650−4 000 cm^{-1} cm).

Authentic 1-(8-methylthiooctyl)-3-phenylurea (V). A solution of 8-methylthiooctylamine [8] (268 mg) and phenyl *iso*cyanate (182 mg) in anhydrous xylene (5 ml) was refluxed for 10 min and the solvent then removed *in vacuo*. The crude reaction product (340 mg) was recrystallized from 70 % ethanol and twice from ethyl acetate : hexane to give an analytically pure specimen (175 mg) of the phenylurea, m. p. 70° (Found: C 65.15; H 8.86; N 9.49. Calc. for $C_{16}H_{26}ON_2S$: C 65.29; H 8.90; N 9.52).

(−)-8-Methylsulphinyloctylthiourea. An alkali-washed mustard oil fraction, prepared from 65 g of *Arabis hirsuta* seeds as described above, was treated overnight at room temperature with methanol (25 ml), saturated at 0° with ammonia. Next day, the solution was treated with charcoal and the solvent removed to give an oily residue, which was repeatedly extracted with hot ethyl acetate from which the crystalline thiourea (145 mg) separated on cooling. Two additional recrystallizations from the same solvent afforded an analytically pure specimen of hirsutin-thiourea as colourless prisms, m. p. 88° (Found: C 47.95; H 8.87; N 11.17. Calc. for $C_{10}H_{22}ON_2S_2$: C 47.97; H 8.86; N 11.19), $[\alpha]_D^{23}$ −76° (96 % ethanol, c = 1.0). The IR-spectrum (in KBr) exhibited strong bands at 3 400, 3 280, 3 200, 3 120, 2 930, 2 845, 1 624, 1 575, 1 460, 1 422, 1 342, 1 302, 1 258, 1 230, 1 193, 1 162, 1 070, 1 000 (S−O), 942 and 730 cm^{-1}. On paper chromatography in water-saturated chloroform the thiourea migrated at a rate corresponding to an R_{Ph}-value [15] of 0.84.

Identification of hydrolysis products of glucohirsutin. A band chromatogram of the crude glucoside mixture from seeds of *Arabis hirsuta* was produced by using the upper layer of the solvent system: *n*-butanol:pyridine:water (6:4:3) as the mobile phase. The glucohirsutin-band (R_B-value 0.75), located by spraying two edge-cuts with $AgNO_3$, was eluted with water.

The dry residue was subjected to hydrolysis with conc. HCl for 18 h at room temperature and the concentrated solution chromatographed on paper for hydroxylamine by the method of Bremner [16] with methanol:6 N HCl (7:3) as the solvent system. Spraying with ethanolic picryl chloride revealed a spot of hydroxylamine indistinguishable from that given by an authentic sample of hydroxylamine hydrochloride on the same chromatogram.

Separate band eluates, prepared in the same manner, were subjected to enzymic hydrolysis in unbuffered solution with a sulphate-free myrosinase preparation. Sulphate liberation was revealed by precipitation of $BaSO_4$, and glucose established as a hydrolytic fragment by paper chromatography in *n*-butanol:ethanol:water (4:1:4) followed by spraying with aniline phthalate. Appropriate blanks were checked in all determinations.

The authors are indebted to Dr. R. Gmelin for valuable assistance in the preliminary phases of the present work. Microanalyses were performed in this laboratory by Mr. P. Hansen.

The work is part of investigations supported by *Statens Almindelige Videnskabsfond (The Danish State Research Foundation)* and *Carlsbergfondet (The Carlsberg Foundation)*. A special grant from *Kai Hansens Fond* is gratefully acknowledged.

Studies on Yeast Invertase

III. Inhibition by Ag^+. Model Experiments with Egg Albumin *

KARL MYRBÄCK

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Sweden

Yeast invertase is strongly inactivated by Ag+ and certain other metal ions. Several reasons, *i. a.* the fact that iodine-treated invertase is rather insensitive to Ag+, support the assumption that Ag+ is bound to HS-groups of the protein. Since the Ag-inhibition of the enzyme is strongly dependent on pH in the range 4—7 it is concluded that certain groups, probably imidazole groups, of the enzyme interfere with the HS-groups, rendering them unavailable to Ag+ in acid solution where the imidazole groups are protonated. For a comparison the Ag-binding capacity of egg albumin has been determined, directly as well as indirectly, using invertase for the Ag determination. The experiments support the view that Ag+ is bound to egg albumin principally if not exclusively to HS-groups. The binding of Ag+ by egg albumin is practically independent of pH in the pH-range mentioned, *i. e.* the HS-groups of egg albumin are, in contrast to those of invertase, freely available to Ag+ in this range. In agreement with earlier investigations the number of HS-groups in an egg albumin molecule (M = 44 000) is found to be 5.

In earlier investigations from this laboratory it was found [1,2] that, to explain the inhibition of yeast invertase by various mercury compounds, the assumption of a reaction of Hg with sulfhydryl groups of the enzyme appears to be consistent with all known facts. The enzyme is also strongly inhibited by Ag^+ (and several other heavy metal ions) and *a priori* one would be inclined to regard HS-groups as responsible also for these inhibitions. However, the inhibition by Ag^+ and certain other metal ions show a dependence on the acidity of the medium which seems to indicate a reaction of the metal ions with groups of the enzyme [3–9] having pK-values around 7. Several reasons, among others the fact that the complexing of Ag^+ by histidine [8] shows the same dependence on pH as the inhibition of the enzyme, suggest a participation of imidazole groups in the reaction of the enzyme with Ag^+. However, the affinity of histidine, not to speak of histamine [2] or imidazole [6], for Ag^+

* Part II, *cf.* Ref.[2]

is very weak compared to that of the enzyme, and if the assumption is correct that the Hg-inhibition of the enzyme is mediated by HS-groups it seems impossible to believe that Ag^+ with its very high affinity for sulfhydryl groups [6] should react preferentially with imidazole groups of invertase.

Investigations on iodine-treated invertase [2] appear to furnish an explanation of the somewhat conflicting experimental evidence. Treatment of yeast invertase with moderate amounts of iodine for a short time results in the formation of a modified enzyme "I-invertase", having an activity about 55 % of that of the native enzyme. Although iodine may conceivably act in several different ways on a protein, the simplest explanation is an oxidation of HS-groups. In the case of yeast invertase this assumption is strongly supported by the fact that I-invertase is much less sensitive to Ag-, Hg- and other inhibiting metal ions than the native enzyme [2]. In fact, the affinity of I-invertase for Ag^+ is so low that the Ag-inhibition of this modified enzyme may well be explained as a reaction of the metal ion with imidazole groups of the protein.

The experiments on the metal ion inhibition of invertase and I-invertase appear to show conclusively that HS-groups are in the first place responsible for the high affinity of the native enzyme for Hg, Ag and certain other metal ions. However, it remains to explain the pH-dependence of the Ag-inhibition of the enzyme. A tentative explanation has been given [2], involving the assumption of some sort of interaction, in the native enzyme, of the HS-groups with adjacent imidazole groups, possibly hydrogen bonding. Under all circumstances we have to conclude that in acid solution (pH $<$ *ca.* 5) the HS-groups of native invertase are unavailable ("masked") to the Ag ion. However, with pK $\sim$ 6.7 the native enzyme is converted reversibly to a structurally different form in which the HS-groups are available to Ag^+. If the groups with pK $\sim$ 6.7 are imidazole groups, which seems probable, it must be concluded that in the active enzyme these groups are protonated, but that loss of the proton is followed by a more or less radical change of protein structure, accompanied by reversible inactivation of the enzyme and by unmasking of the HS-groups. The reactivity of the HS-groups toward Ag and certain other metal ions will be determined by the presence or absence of the proton on the imidazole groups. Thus, in the interaction with Ag^+ (Cu^{++} etc.) the HS-groups of native invertase will have an apparent pK value of ca. 6.7. This is in accord with the assumption [3] that the Ag-binding groups of invertase are identical with the "acidic" group with pK $\sim$ 6.7, assumed by Michaelis [10] to explain the alkaline branch of the activity-pH-curve of invertase.

In order to compare the binding of Ag^+ by invertase and by a well-known, "ordinary" protein, experiments have been carried out with egg albumin which is known to contain more or less reactive HS-groups. Since this protein is easily available and can be obtained in a high degree of purity, it has been the object of a large number of investigations. The molecular weight has been determined by several authors; the values differ somewhat but a value of M = 44 000 should not be far from correct [11,12]. This value has been used in the following.

The number of HS-groups in an egg albumin molecule (or its cysteine content, respectively) has been determined by means of many different methods. Mirsky and Anson [13] and Anson [14] compared the action of several HS-

reagents; oxidation with ferricyanide under specified condition was considered to give reliable values. Native egg albumin was found to be inert to this reagent, but the denatured protein reduced ferricyanide: 10 mg protein corresponded to 0.001 mmole of the oxidant, *i.e.* one molecule of egg albumin was found to contain ca. 4.4 HS-groups. Iodine and iodoacetamide were found to react with the native protein, other HS-reagents generally only after denaturation. Egg albumin, treated with iodine, iodoacetamide or formaldehyde did not reduce ferricyanide. The authors conclude that native egg albumin has "free and accessible but relatively unreactive HS-groups which can react with iodine and acetamide despite the fact that they do not react with ferricyanide, porphyrindin or nitroprusside". Greenstein [15] and Brand and Kassell [16] likewise state that native egg albumin does not react with porphyrindin; in the denatured protein the HS-groups are oxidized. Values quoted by Greenstein and Jenrette [17] tend to show that at least 4, probably 5 HS-groups are present in an egg albumin molecule. Hellerman *et al.*[18], using iodosobenzoate, also give the number of HS-groups in egg albumin as 5. MacDonnell, Silva and Feeney [19] applied *p*-chloromercuribenzoate to egg albumin. They found, contrary to Anson's results, that 3 HS groups are reactive already in the *native* protein and 4 after denaturation. With a spectrometric method Boyer [20] found that 4.0 moles *p*-chloromercuribenzoate are bound at pH 4.6 by one egg albumin molecule, whereas Benesh, Lardy and Benesh [21] using an amperometric titration method with silver found 5 HS-groups per protein molecule.

Anson [14] found that iodine destroys the HS-groups of egg albumin. It seems to be generally assumed that the oxidation of protein HS-groups results in the formation of disulphide linkages. It should be noted, however, that according to Fraenkel-Conrat [22] the HS-groups of tobacco mosaic virus protein on treatment with iodine give stable sulphenyl iodide groups. "Overoxidation" of thiol groups to levels higher than the disulphide must also be considered. It should be emphasized that formation of disulphide linkages on treatment of proteins with iodine requires a sterically favourable position of the thiol groups, especially if intramolecular disulphide linkages are formed (*cf.* Ingram [23]).

EXPERIMENTAL

Materials

Invertase. The enzyme preparations used in the experiments were partly purified from autolysates of baker's yeast. The solutions were thoroughly dialyzed before use.

I-Invertase was prepared as described earlier [2]. The solutions were dialyzed with particular care to remove all iodide ions.

Buffer. Acetate-acetic acid buffers were used in all experiments. The buffer concentration was kept so low that complexing av Ag^+ by the acetate ion did not cause any serious decrease of the calculated Ag-ion concentration [5]. In the assay mixtures used for determination of enzymatic activity the concentration of the acetate ion was 0.01 N and in the solutions used for electrometric Ag-determination 0.05 N.

pH was determined by means of the glass electrode in all assay mixtures.

Egg albumin. Crystallized egg albumin was prepared according to the method of Sørensen and Høyrup [24] with minor modifications: *Albumin I* was recrystallized once, *Albumin II* three times. All albumin solutions were dialyzed thoroughly before use. The two albumin preparations behaved identically in all experiments; consequently the observed effects can be ascribed to egg albumin itself. *Albumin III* was a commercial pre-

paration; dialyzed solutions were used for a comparison in some experiments without further purification. Qualitatively it behaved as the crystalline preparations but its Ag-binding capacity was somewhat lower.

Methods

Invertase activity was determined polarimetrically as described earlier [4]. The relative activity (RA) refers to the activity of the same amount of enzyme without inhibitor at pH 4.5. The RA-values are means of 4—5 polarimetric determinations at different reaction times. All enzymatic determinations were carried out in 100 ml volume, containing 4.75 g saccharose. Temperature 30°C.

Electrometric determination of the Ag+ ion was carried out according to the simple method originally described by v. Euler and Svanberg [25]. These authors determined the Ag-binding capacity of various substances in order to find out the chemical nature of the Ag-binding groups of enzymes. They found, among other things, that egg albumin binds Ag+ very strongly. In the present investigation the electrometric determinations were carried out at several different pH-values; this is necessary since the Ag-binding capacity of invertase varies strongly with pH.

RESULTS

Binding of Ag^+ by egg albumin, determined electrometrically

The electrode vessels contained 5×10^{-5} M silver nitrate, acetate buffer (0.05 N Ac^-); to one of the vessels egg albumin solution was added. Total volume 20 ml, temperature 20°C. The constancy of the potential differences between the silver electrodes was checked by repeated measurements during at least 30 min. The Ag^+ concentrations were calculated in the conventional way (Table 1).

Table 1. Binding of Ag+ by crystalline egg albumin. $[Ag_{tot}] = 5 \times 10^{-5}$.

mg Albumin II in 20 ml	$[Ag^+] \times 10^5$		
	pH 4.5	pH 5.3	pH 5.95
0	5.00	5.00	5.00
2.82	3.55	3.25	2.74
5.64	1.94	1.33	1.12
8.46	0.44		

Fig. 1 shows the number of Ag^+ ions bound per molecule of egg albumin at different pH-values. For a comparison Fig. 2 shows corresponding results [8] for histidine. The Ag-binding capacity of histidine varies very strongly with pH in the range 4.5—6; the explanation is that H^+ competes with Ag^+ for the imidazole ($pK \sim 6.1$). In contrast, the Ag-binding of egg albumin is nearly independent of pH in the same range, showing that the groups essentially responsible for the binding of Ag^+ to the protein do not change their charge appreciably in the pH-range mentioned. This is obviously in accord with the assumption, that the binding of silver to egg albumin is mediated principally by HS-groups of the protein. The weak dependence of the silver-

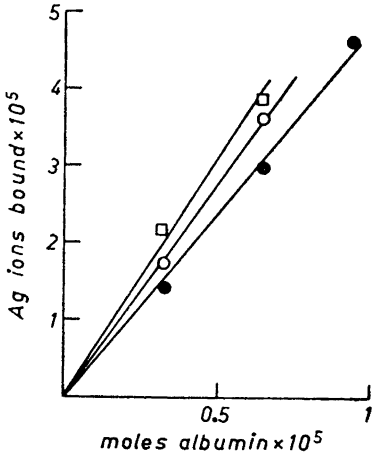

Fig. 1. Number of Ag ions (volume 1 000 ml) bound by egg albumin at pH 4.5 (●) pH 5.3 (○), and pH 5.95 (□).

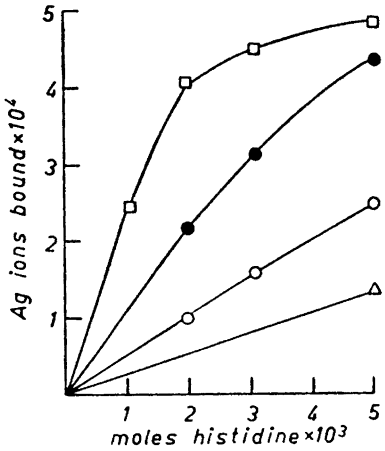

Fig. 2. Number of Ag ions (volume 1 000 ml) bound by histidine at pH 4.5 (△), pH 4.8 (○), pH 5.3 (●), and pH 5.95 (□).

binding of egg albumin upon pH may intimate that other groups than HS-groups are, to some small degree, responsible for the binding of silver ions, and that these groups have pK-values in the range 4—8.

In Fig. 1 the molar concentration of albumin has been calculated, assuming the molecular weight to be 44 000. The practically straight lines of the figure show that the affinity of egg albumin for Ag^+ is very high and the number of Ag^+ ions bound by one molecule of egg albumin can be calculated fairly accurately. One albumin molecule binds:

at pH 4.5	4.8 Ag^+ ions
at pH 5.3	5.5 » »
at pH 5.95	6.2 » »

Similar experiments were also carried out at the 10-fold Ag^+ concentration, 5×10^{-4} M. These experiments were less well reproducible; sometimes a precipitate was formed when protein and silver solutions were mixed. Nevertheless, as seen from Table 2, the results are in good agreement with those

Table 2. Binding of Ag+ by crystalline egg albumin. $[Ag_{tot}] = 5 \times 10^{-4}$.

mg Albumin II in 20 ml	$[Ag^+] \times 10^4$	
	pH 4.5	pH 5.3
0	5.00	5.00
14.1	—	3.68
28.2	2.89	2.58
42.3	1.72	1.64
56.4	0.84	0.65

Table 3. Binding of Ag+ by commercial egg albumin. $[Ag_{tot}] = 5 \times 10^{-5}$.

mg Albumin III in 20 ml	[Ag+] × 10^5			
	pH 4.5	pH 5.3	pH 5.7	pH 5.95
0	5.00	5.00	5.00	5.00
2.35	3.57	3.72	3.31	3.57
4.70	—	2.87	2.47	2.27
7.05	1.94	1.77	1.40	1.20
11.75	0.72	—	—	—
23.50	—	0.24	—	—

obtained in more diluted solutions: The metal ion is bound very strongly and the amounts bound at pH 5.3 are only slightly larger than those bound at pH 4.5. About 6 Ag ions are bound per molecule of albumin. This value is somewhat higher than that found in the experiments in more diluted solution. The explanation may be that at higher concentrations more Ag^+ ion is bound by non-HS-groups of the albumin.

Corresponding determinations were also carried out with the albumin preparation III. The lower Ag^+ concentration was used. Table 3 shows that the Ag-binding capacity of albumin III is slightly lower than that of albumins I and II; otherwise the results with all three preparations are very similar.

Binding of Ag^+ to egg albumin, determined by inhibition experiments with invertase

The Ag-binding capacity of egg albumin (or any other Ag-binding substance, not interfering with invertase) may be determined by studying the inhibition of invertase by Ag^+ in the presence of the substance in question. These deter-

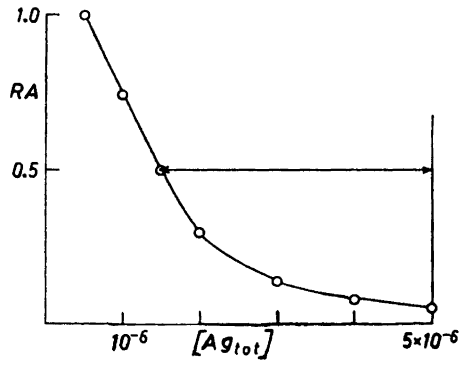

Fig. 3. Relative activity (RA) of invertase at various concentrations, $[Ag_{tot}]$, of silver ions; pH 5.3.

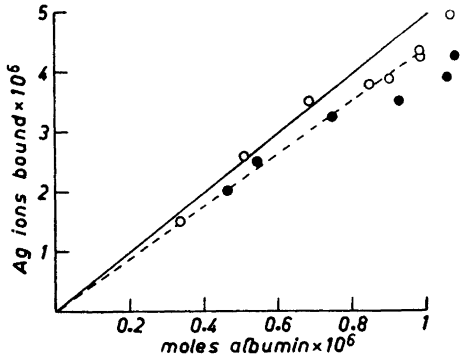

Fig. 4. Number of Ag ions in 1 000 ml bound by egg albumin at pH 5.3 as calculated from inhibition of invertase. Crystalline egg albumin (○), commercial preparation of albumin (●).

minations may be carried out at considerably lower Ag^+ concentrations than the electrometrical determination described above.

The invertase used for experiments of this kind need not be of any extremely high purity. The relative activity of a certain amount of enzyme is determined at constant pH and various Ag^+ concentrations. In one series of experiments the curve shown in Fig. 3 was obtained. A certain RA-value corresponds to a certain concentration of free Ag^+ ions, $[Ag_{free}]$, in equilibrium with $[Ag_{bound}]$, *i. e.* the concentration of Ag bound to invertase and, usually, to impurities in the invertase solution. For instance, RA = 0.06 corresponds to $[Ag_{tot}] = [Ag_{free}] + [Ag_{bound}] = 5 \times 10^{-6}$. If an experiment is carried out at this total Ag-concentration in the presence of, *e.g.* 3 mg of egg albumin, part of the silver will be bound to the albumin and a higher RA-value will be obtained, *e.g.* RA = 0.5. It is seen from Fig. 3 that this RA-value corresponds to a sum of free Ag-ion and Ag bound to substances in the enzyme solution $= 1.5 \times 10^{-6}$. Since the volume of the solution is 100 ml, we find that 3.5×10^{-7} g-ions Ag^+ have been bound by 3 mg egg albumine or 0.68×10^{-7} albumin molecules, *i.e.* one albumin molecule has bound 5 silver ions.

It should be added that experiments of this kind can give clearcut results only if *a*) the inhibition of the enzyme by Ag+ is independent or practically independent of the time of incubation of enzyme and inhibitor, and *b*) the binding of Ag^+ by the tested substance (egg albumin) is (practically) independent of any incubation time. If these requirements are not fulfilled the determination of the RA-values will be impossible or precarious. In the case of yeast invertase and Ag+ and of egg albumin and Ag+ the binding of the metal ion occurs with unmeasurably high velocity, and incubation of the proteins with Ag+ for reasonable times does not increase materially the uptake of the metal ion.

Using the method outlined above a series of experiments was carried out at pH 5.3 and $[Ag_{tot}] = 5 \times 10^{-6}$ in the presence of various amounts of recrystallized egg albumin (Table 4). The concentration of Ag bound by the albumin was estimated by means of the curve shown in Fig. 3. Fig. 4 shows the number of bound Ag-ions *vs* the number of albumin molecules. The curve is a practi-

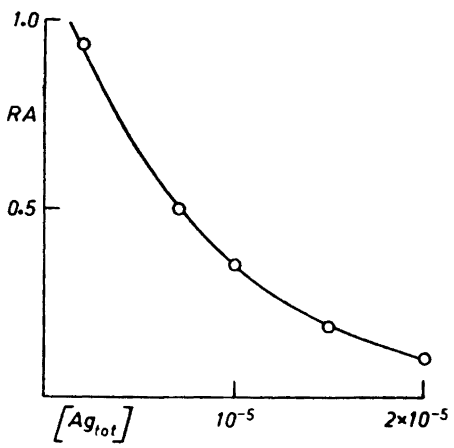

Fig. 5. Relative activity (RA) of invertase at various concentrations, [Ag_{tot}], of silver ions; pH 4.5.

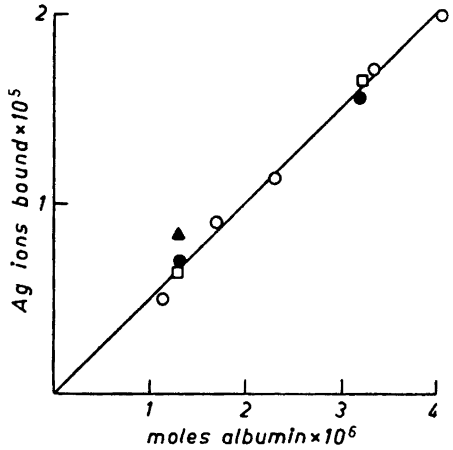

Fig. 6. Number of Ag ions in 1 000 ml bound by egg albumin at pH 4.5 as calculated from inhibition of invertase. Crystalline egg albumin I (○), crystalline egg albumin II (□), crystalline egg albumin II, treated with N NaOH (▲), crystalline egg albumin, treated with pepsin (●).

cally straight line, showing that Ag is bound very strongly by the albumin. One molecule of egg albumin binds 5.0 Ag ions; this number is in reasonably good agreement with that obtained (5.5) by electrometrical Ag-determination at the same pH.

In Fig. 4 have also been plotted corresponding values obtained with the commercial egg albumin preparation III. The results are qualitatively the same as with the crystalline albumin preparation but, as in the electrometric determinations, the values are somewhat lower with the commercial preparation.

Similar experiments with crystalline egg albumin were carried out at pH 4.5. The same invertase preparation was used and the RA-values in absence of egg albumin are plotted in Fig. 5 *vs.* [Ag_{tot}]; a comparison with the corresponding curve for pH 5.3 (Fig. 3) shows the much weaker inhibition by Ag^+ in the more acid solution: 50 % inhibition at pH 5.3 is caused by [Ag_{tot}] = 1.5×10^{-6} N Ag^+, at pH 4.5 by [Ag_{tot}] = 7×10^{-6} N.

The experiments in presence of egg albumin were carried out at [Ag_{tot}] = 2×10^{-5} and the amounts of Ag bound were calculated as above (Table 5). The native albumin preparations I and II were used as well as albumin II treated with alkali (N sodium hydroxide, 120 h, 20°). A peptic hydrolysate of egg albumin was also tested: Heat-coagulated albumin was treated with a small amount of pepsin at pH 1.6 (sulphuric acid). The coagulum was dissolved after *ca.* 5 h. The Ag-binding capacity of the hydrolysate was determined after 24 and 72 h, respectively. In Fig. 6 the number of bound Ag-ions have been plotted *vs.* the number of albumin molecules. The figure shows that all albumin preparations have the same Ag-binding capacity.

Table 5. Relative activity (RA) of invertase at pH 4.5 and $[Ag_{tot}]$ 2×10^{-5} in the presence of various albumin preparations.

Albumin preparation	mg Albumin in 100 ml	RA	$[Ag_{tot}] \times 10^5$ corresponding to RA	$[Ag] \times 10^5$ bound by albumin

	28.2	1.00	0	2.00
Albumin treated with papain	5.64	0.234	1.30	0.70
	14.1	0.700	0.44	1.56

The straight line of the figure demonstrates that at pH 4.5, just as in the experiments at pH 5.3, Ag^+ is bound by egg albumin very strongly. The number of Ag-ions bound per molecule of egg albumin is 5.0, *i.e.* the same number as was found at pH 5.3. Thus these experiments, in agreement with the electrometrical determinations, show that the Ag-binding capacity of egg albumin, in contrast to that of invertase, does not vary appreciably with pH in the range mentioned. The experiments are in accord with the view that Ag is bound to egg albumin by means of the HS-groups.

Ag-binding capacity of iodine-treated egg albumin

Iodine-treated invertase (I-invertase) is very much less sensitive toward Ag-ions than is the native enzyme [2]. This strongly supports the assumption that the high Ag-binding capacity of native invertase is due chiefly to HS-groups of the enzyme which, on treatment with iodine, are oxidized to yield groups (disulfides or possibly higher oxidation products) that have no or only a weak affinity for the Ag-ion.

If the binding of Ag by egg albumin, established in the experiments described in the foregoing, is mediated chiefly by HS-groups of the protein, then it should be expected that treatment of the egg albumin with iodine would markedly decrease its Ag-binding capacity. As mentioned, Anson [14] found that the HS-groups of native egg albumin are available to iodine; iodine-treated egg albumin does not reduce ferricyanide.

A diluted solution of crystalline egg albumin was treated with iodine approximately in the same manner as that used for the oxidation of invertase. The transformation of invertase to I-invertase occurs practically instan-

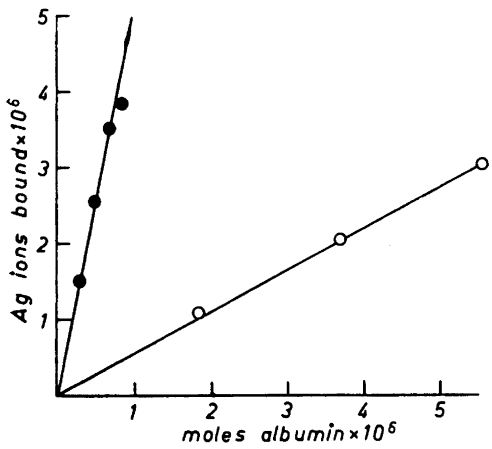

Fig. 7. Number of Ag ions in 1 000 ml bound at pH 5.3 by crystalline egg albumin (●), and by the same albumin oxidized with iodine (O).

taneously if a sufficient amount of iodine is added to the enzyme solution (pH about 5). To a certain volume of albumin solution was added a few drops of starch solution and then, dropwise, 0.01 N iodine solution until the blue colour persisted for about 30 sec. The same amount of iodine solution was then added to another albumin solution without starch. The oxidized albumin solution was freed from iodide ions by dialysis, the dry weight of the dialyzed solution was determined and suitable portions were used for the determination of the Ag-binding capacity at pH 5.3. The results are shown in Fig. 7 together with corresponding results for native egg albumin. It appears that the Ag-binding capacity of native egg albumin (5 Ag-ions per albumin molecule) has been strongly reduced by the treatment with iodine. The oxidized albumin binds less than 1 silver ion per molecule of M = 44 000. This supports the assumption that the combination of Ag with native egg albumin is mediated principally if not exclusively by the HS-groups.

DISCUSSION

A comparison of the binding of Ag^+ by yeast invertase and by egg albumin reveals several interesting facts. Both proteins bind Ag^+ very strongly, the egg albumin even more so than the enzyme; compare the straight lines of Figs. 1, 4 and 6 with the "dissociations curves" of Figs. 3 and 5. Whereas the invertase-Ag complex appears to have a dissociation constant[3,7] about 10^{-8}, the dissociation constant of the albumin-Ag compound seems to be considerably lower.

The number of Ag-ions bound by one molecule of egg albumin (M = 44 000), as determined by means of two independent methods, is 5.0—5.5. The slight deviation of the curves of Fig. 5 from the straight line may implicate that a small portion of the bound Ag is bound more loosely than the bulk which is bound very strongly. It seems probable that per molecule of egg albumin 5 Ag ions are bound by HS-groups and a further small number loosely bound by other groups, possibly imidazole groups. The weak dependence of the

silver-binding capacity of egg albumin on pH (Fig. 1) is also in accord with this view. The number of groups in egg albumin, strongly binding the silver ion, agrees with the number of HS-groups generally assumed to be present in the protein molecule. The fact that treatment of very diluted solutions of egg albumin with small amounts of iodine reduces the Ag-binding capacity to a very low value seems to show conclusively that Ag is bound to egg albumin chiefly by means of the HS-groups.

As mentioned before, previous investigations have shown the HS-groups of native egg albumin to be inaccessible to several HS-reagents, but accessible ("unmasked") after denaturation, *i.e.* an "unfolding" of the protein structure. It seems, however, that the HS-groups of the native protein react freely with silver ions, and practically no dependence of the silver-binding capacity on pH in the range investigated can be observed.

The reaction of invertase with iodine is probably accompanied by rather extensive changes in the superstructure of the protein. Such changes may explain why the activity of native invertase is not restored on treatment of I-invertase with cysteine or other reducing agents [2]. The binding of Ag^+ by invertase is not, or at least not immediately, followed by irreversible changes of the protein structure, since the inactivation of the enzyme by Ag^+ is freely reversible by H_2S, mercaptans etc., provided that the enzyme has not been incubated with the metal salt for a long time. From the behaviour of invertase in this respect no conclusion can of course be drawn regarding the behaviour of egg albumin; however, since the binding of Ag^+ by egg albumin is instantaneous and does not increase at incubation of protein and silver salt for a moderate time, it seems safe to assume that the reaction of Ag^+ with the HS-groups of egg albumin is not (rapidly) followed by destruction of the native protein structure. Thus it appears probable, that the HS-groups in native egg albumin are freely available to the silver ions without previous or simultaneous change of the protein structure.

The binding of Ag^+ by the HS-groups of egg albumin is not or only weakly dependent on pH in the range investigated. This means, that the phenomenon of a pH-dependent "masking" of the HS-groups, typical of yeast invertase, is not observed with egg albumin.

The experimental part of this investigation has been carried out by Mrs. Ebba Willstaedt whose assistance is gratefully acknowledged.

Distribution of D- and L-Amino Acids along the Chain of Poly-DL-Alanine

K. LINDERSTRØM-LANG

Carlsberg Laboratory, Copenhagen, Denmark

The question concerning the distribution of D- and L-forms along the peptide poly-DL-alanine has been investigated by digestion with carboxypeptidase and aminopolypeptidase which preferably attack bonds between two L-amino acids. The analysis of the digestion curves makes it likely that the distribution of D- and L-forms is very nearly random in the particular preparation under investigation.

In two previous papers [1,2] Arieh Berger and the author have explained the relatively high stability of the helix of poly-DL-alanine (PDLA) in aqueous solution by assuming that a certain number of pairs of D- and L-methyl groups form internal hydrophobic bonds from one turn of the helix to the next. Provided that the distribution of D- and L-forms is entirely random one fourth of all methyl groups would be able to form such bonds. Fig. 1 shows a model of the helix in question. It is built up by 30 alanine residues [1] and is right-handed. The pitch is 1.5 Å and there are 15 residues in four turns (see *e.g.* Refs.[3-5]). The D- and L-forms have been distributed by throwing a coin and it is therefore by chance that 7 out of 30 methyl groups are able to form hydrophobic bonds of the type assumed. Fig. 2 shows some of the characteristic distances in the model. The most important of these are:

1. Distance $C\beta\ L_5 \rightarrow C\beta\ D_8$, the closest approach of two methyl groups, one belonging to an L-alanine residue (8) and one to a D-alanine residue (5) (see Fig. 1). This distance is 3.74 Å.

2. Distance $C\beta\ D_8 \rightarrow O_8$ from a D-methyl group in a given residue to the carbonyl oxygen of the same residue. This distance is 2.70 Å.

The X-ray diffraction pattern of DL-alanine crystals [6,7] indicate that the corresponding minimum distances in the crystals are 3.64 and 2.52 Å, respectively. Hence from this comparison it may be concluded that there is no particular strain in our helical model.

However, other possible helical models have not been investigated and in view of reported strains in right-handed helical structures containing D-residues [8,9] an attempt was made to determine the distribution of D- and L-forms in the particular preparation of PDLA, the stability of which has

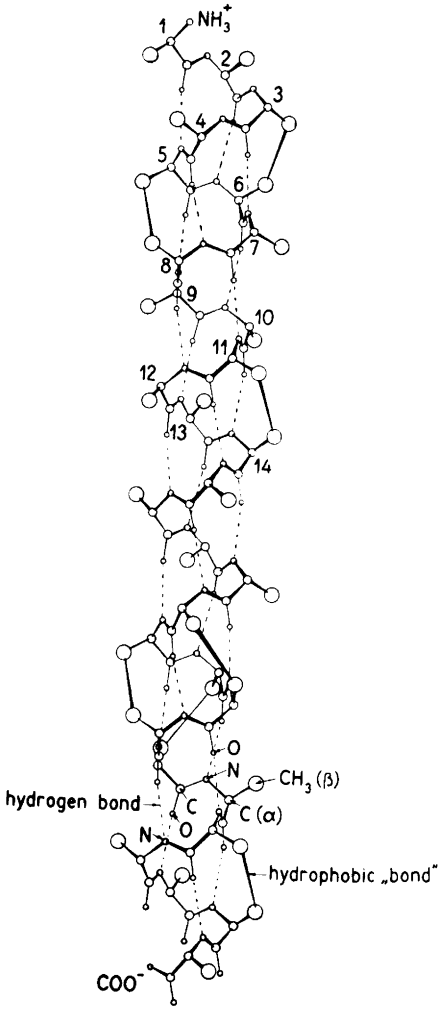

Fig. 1. Right-handed α-helix with 30 residues.

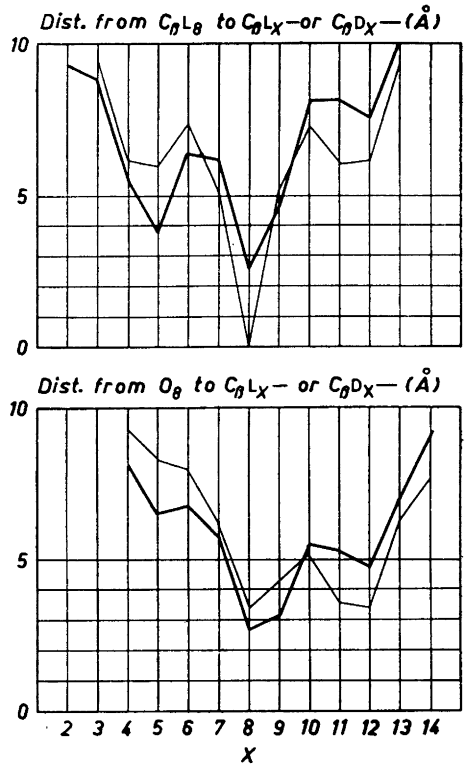

Fig. 2. Distances from atoms in residue 8 (see Fig. 1) to other atoms, numbered X. The distance $C\beta L_8 - C\beta D_8$ is between two β-carbon atoms (two methyl groups) on one α-carbon atom. Many of the other distances are calculated for arbitrary distributions of D- and L-forms and are not found in Fig. 1.

been studied [1,2]. In theory an optically inactive PDLA may consist of equal parts of right-handed helices with L-amino acid residues only and left-handed helices with D-amino acid residues only. Both these forms are generally acknowledged as being without strain. If now our preparation were constituted in this way, the above mentioned explanation of the stability as being due to internal hydrophobic bonds would fail, since the distance between the L-methyl groups in our right-handed model is too large to give effective hydrophobic bonds from one helical turn to another. The same is true for a left-handed helix with D-residues. In order to decide this important ques-

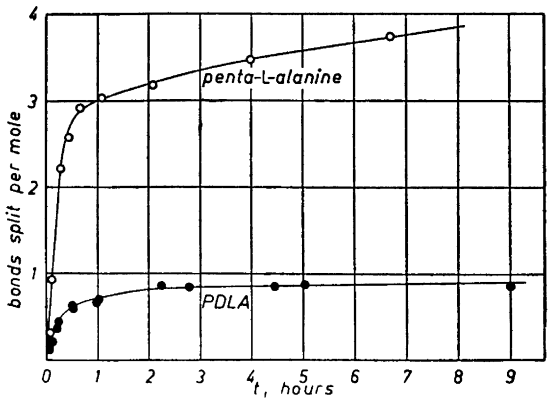

Fig. 3. Splitting of penta-L-alanine and PDLA by carboxypeptidase.

tion our PDLA preparation was digested with carboxypeptidase *, an enzyme which splits polypeptides from the carboxyl end provided the terminal amino acid residues have the L-configuration. Thus in penta-L-alanine ** 3 bonds were broken very fast while the last — in the remaining alanylalanine — was slowly split due to the proximity of the amino end group (Fig. 3). If now half of our PDLA preparation consisted of poly-L-alanine, we should expect a splitting of 14—15 bonds per mole of preparation, the remaining 14—15 bonds being situated in poly-D-alanine which is not attacked by the enzyme. As shown in Fig. 3 only 1/2—1 bond is actually split, indicating that D-amino acid residues are situated close to the carboxyl end in the majority of the molecules. It is easy to show that for random distribution of D- and L-residues the number of bonds, n, split per mole is given by

$$n = \frac{1 - (\frac{1}{2})^{q-1}}{2}$$

where q is the number of residues in the polypeptide, provided the action of carboxypeptidase is restricted to bonds between two L-amino acid residues, and

$$n = 1 - \tfrac{1}{2}^{q-1}$$

if bonds between L- and D-amino acid residues

$$\text{---}\ \text{---}\ \text{---}\ \text{D} \underset{\uparrow}{-} \text{L}$$

are attacked as well. For q equal to 30 it is therefore compatible with a random distribution of D- and L-residues that a fast reaction involving 1/2 bond per mole is observed. The further reaction leading to a splitting of another 1/2 bond may be due to a slow attack of the enzyme on the L—D-bonds, but it may also be the result of the action of a slight proteinase impurity in the

* The enzyme used was kindly placed at our disposal by Professor H. Neurath.
** This preparation was kindly given us by Professor Hans T. Clarke.

carboxypeptidase (see below). Such an impurity might open a bond in the middle of the chains thus exposing new C-terminal L—L-sequences to the carboxypeptidase. Finally the results might indicate a slight deviation from randomness of the distribution of D- and L-amino acid residues.

Similar experiments with aminopolypeptidase * gave essentially the same, though slightly lower results which might be explained by a low content of substituted terminal amino groups in PDLA [1]. We feel therefore justified in assuming random — or nearly random — distribution of D- and L-alanine residues along the chain of PDLA.

In the case of PDLA the carboxypeptidase experiments were carried out as follows: To 500 μl 1.57×10^{-2} M PDLA solution were added 500 μl 0.2 M veronal buffer pH 8.61 and 5 μl of a 1.8×10^{-4} M carboxypeptidase solution which was pre-treated with di*iso*propylfluorophosphate to knock out proteinase contaminations. The digestion mixture was prepared at 39.7°C and samples of 100 μl were taken out at intervals and mixed with 85 μl N/10 alcoholic HCl whereby the enzymatic reaction stopped. For determination of the splitting 2 ml acetone were added and the solution titrated with N/10 HCl in alcohol, using naphthylred as an indicator.

Substrate concentration	7.3×10^{-3} M
Enzyme »	8.6×10^{-7} M
Temperature	39.7°C

In the penta-alanine experiments the procedure was the same.

Substrate concentration	6.7×10^{-3} M
Enzyme »	8.6×10^{-7} M
Temperature	39.7°C

Investigations on the Osmotic Pressure of Aqueous Solutions of Dextran Glycerol Glycoside and of Potassium Hyaluronate

C. E. JENSEN and K. MARCKER

Københavns Universitets Fysisk-Kemiske Institut, Copenhagen, Denmark

A preparation of dextran giving a constant colloid osmotic pressure and having a molecular weight of 1.2×10^5 is prepared. It is shown that the ratio between the weight concentration (c) and the osmotic pressure (p) is fairly constant in the case of dilute solutions of the electrically neutral dextran; in case of dilute solutions of the electrically charged hyaluronate the value of this ratio decreases with increasing concentration. In respect to hyaluronate it is found that the relation between pressure and concentration can be given by the following expression: $c/p = A(1-Bc)$, where the constant B is independent of the molecular weight.

Although blood plasma substitutes, artificial "plasma expanders", were tried during the first world war, it was only during the second world war that their use developed. It seems to be a fact that dextrans surpass all plasma substitutes used so far, as they afford the most marked and most prolonged increase in circulating blood volume. Dextran which is a polymer of glucose joined chiefly through α-1,6-glycosidic linkages, is derived from the fermentation of sucrose by various strains of *Leuconostoc mesenterioides*. The native dextran has a molecular weight of several millions, and has a harmful effect when injected into the animal organism. When this so-called crude dextran is degraded, *e.g.* by acid hydrolysis, to a molecular size corresponding approximately to plasma proteins it becomes usable as "clinical dextran". If the partial depolymerization is carried out in glycerol solution (Hultin and Nordström [1]) the biologically active free aldehyde groups, often giving rise to allergic manifestations, are inactivated. By this process dextran glycerol glycoside is formed. Such a preparation is commercially available as "Infudex" or "Plasmodex *". The results of some osmotic investigations on such a preparation are reported in the present paper.

* This commercial preparation was kindly placed at our disposal by Roskilde Medical Company, Roskilde, Denmark.

EXPERIMENTS ON DEXTRAN

The colloid osmotic pressures were measured by means of the inverted microosmometer described by Christiansen and Jensen [2]. The solution of collodion used for the preparation of semipermeable membranes was made in the following way: 4 g of completely dry pyroxylin (Parlodion "Mallinckrodt") was dissolved in a mixture of 75 ml of absolute alcohol and 25 ml of anhydrous ether; to this mixture were added 5 ml of ethylene glycol freshly distilled *in vacuo*.

The first measurements were performed on an 1 % solution of "Plasmodex", the osmotic pressure of which was estimated at about 5.4 cm water pressure. It was observed, however, that the pressure was decreasing with time indicating that this preparation of dextran contained low molecular components capable of permeating the membrane employed. After 15 h the "equilibrium length" of the first mentioned solution had fallen to 4.5 cm; the result of this measurement is in Table 1.

In order to determine the proportion of low molecular components contained in this preparation of dextran the aqueous solution of the preparation was dialyzed for 24 h against running tap water in a tube of cellophane at room temperature. Then the dialyzed solution was distilled *in vacuo*, the temperature of the water being 40—45°C, and freeze-dried. The yield was 96 % of the starting material. Osmotic pressure measurements performed on this preparation showed, that a fraction of the dextran molecules was still permeating the collodion membrane and that the osmotic pressure was slightly lower than that of the nondialyzed preparation of dextran at the same concentration.

Then the dextran was dialyzed in a test-tube shaped membrane of collodion prepared in exactly the same way as the membranes used for the osmotic pressure measurements. The dialysis lasted for 6 days, the outer solution (distilled water) being replaced twice every 24 h, whereafter the solution was distilled *in vacuo* and freeze-dried. Yield: 40 % of the starting material. The osmotic pressure of a 0.6 % solution of this preparation was found to be about 2.6 cm water column. But even now some dextran molecules were permeating,

Table 1. Osmotic pressure of an 1 % solution of dextran. h = height of air column. V = rate of movement of the upper meniscus of the air column in micrometer divisions in 10 min. For details *cf.* Christiansen and Jensen [2].

h in cm	V in 10 min.
4.89	+0.18
3.80	−0.30
5.29	+0.38

4.10	−0.18
5.73	+0.55

Equilibrium length: 4.5 cm

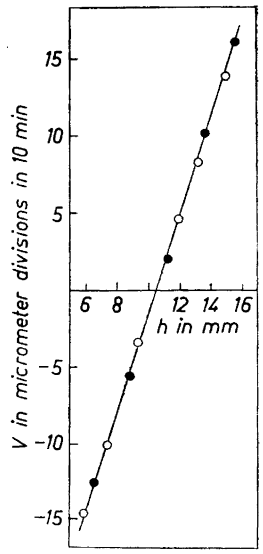

Fig. 1. Osmotic pressure of an aqueous solution of dextran. The graph shows the relation between height of the air column (abscissae), and the rate of movement of the upper meniscus of the air column (ordinates) in micrometer divisions in 10 min. Concentration of dextran: 5.20 mg in 1 ml of water. Equilibrium length: 10.5 mm water column. The measurements represented by the black spots are performed 24 h after the measurements represented by the circles.

although to a smaller degree than in the preceding experiment. Therefore another attempt was made to get rid of the low-molecular components by means of precipitation with acetone. 60 ml of acetone were added to 100 ml of a 10 % aqueous solution of dextran, which resulted in the appearance of a two-phase system. The lower layer was yellow and consisted predominantly of water and dextran, while the upper layer was white and consisted predominantly of acetone and little dextran. The upper layer was decanted, whereafter the lower layer was treated with acetone; by doing so the dextran was precipitated. The filtrate was washed several times with acetone and dried for 24 h in a vacuum desiccator containing phosphorus pentoxide. After dialysis in a collodion tube this preparation showed a constant osmotic pressure. The pressure of a 0.52 % aqueous solution was measured at 1.05 cm water column corresponding to a molecular weight of this preparation of 1.2×10^5. The result of these measurements are given in Fig. 1, the black spots corresponding to measurements performed 24 h after the measurements indicated by circles.

In order to investigate the validity of the well known limiting law of van't Hoff: $\lim_{c=0} (p/c) = RT$, where p is the difference in hydrostatic pressure between the inner and outer solutions at equilibrium, and c is the concentration of the solute in moles per liter of solution, we determined the osmotic pressure of dextran solutions at different concentrations of dextran. The results of these measurements are in Table 2. Evidently van't Hoff's law is valid at the lower concentrations, while at concentrations from about 2 g/100 ml a slight decrease of the ratio c/p is observed. Our results agree closely with those obtained by Mariani *et al.*[3] Further our results are in fair agreement with those obtained by Autio [4] who determined the osmotic pressure of solutions of dextran ("Macrodex") by means of the Holm-Jensen osmometer.

Table 2. The relation between concentration (c) and colloid osmotic pressure (p) of aqueous solutions of dextran.

EXPERIMENTS ON POTASSIUM HYALURONATE

Using osmotic meaurements, Christiansen and Jensen [2,5] estimated the molecular weight of potassium hyaluronate isolated from human umbilical cords and from vitreous bodies of cattle at 5×10^5 and 2.7×10^5, respectively. These determinations were performed on solutions which contained about 10 mg of hyaluronate per 1 ml of solution.

Molecular weight calculations from osmotic pressure data were made by means of the equation: $\frac{246.8 \times 10^5 \times c}{p}$ where c = concentration of dry substance in g per 1 ml of solution and p = osmotic pressure in cm water pressure. All measurements were performed at 20°C.

It has long been known, however, that this equation is not valid for electrically charged thread-shaped molecules at concentrations where experiments could be performed. The ratio p/c, the so-called reduced osmotic pressure, usually increases with the concentration so that its limiting value must be determined by some sort of extrapolation. To perform this extrapolation we plotted p/c against c, but this yielded a curve with a distinct bend upwards. When, however, we plotted c/p against c we got curves which were very nearly straight lines with a downward slope.

Four preparations of different molecular weight were used, three of them having relatively small and one a relatively high molecular weight. The measurements of the colloid osmotic pressure were determined at four or five different concentrations of hyaluronate. The molecular weights calculated from the pressures obtained from extrapolation to zero concentration (the so-called reduced molecular weight) appeared to be about one and a half as big as the uncorrected values obtained from measurements performed on solutions containing about 10 mg of hyaluronate in 1 ml of solution.

Attempts at finding an adequate relation between the colloid osmotic pressure of the solution (or the molecular weight) and the concentration of the solute resulted in the following empirical expression: $c/p = A(1-Bc)$. Here c is the weight concentration (mg/ml); p is the colloid osmotic pressure in cm water pressure; A is a quantity which is constant for a given preparation, but proportional to the molecular weight; B is a constant for all the employed preparations (independent of the molecular weight). The values of A and AB were obtained graphically by plotting c/p against c. The results of the

Table 3. The osmotic pressure of some preparations of potassium hyaluronate and some calculated quantities showing that the ratio between concentration and pressure is equal to A(1−Bc) where A and B are constants (For details see the text).

$B_{AV} = 0.0377$

measurements and the values of A, AB and B $\left(B = \frac{AB}{A}\right)$ are in Table 3. It is seen that the agreement between the measured values of c/p and $A(1 - B_{Av}c)$ is reasonably good. The most pronounced deviation is found in series IV at the highest concentration of hyaluronate, at which the measurements are difficult on account of the high viscosity of the solution. It is to be noted that the value used for B in the calculations is the average value of the individual B's of the four experiments. If we, in series IV, make use of the method of least squares giving equal weight to the individual experimental points we find the corrected values of A and AB to be 39.4 and 1.675, respectively. Using these values the differences between $(c/p)_{expt}$ and $(c/p)_{calc}$ are: − 0.24; 0.58; − 0.14; 0.34 and − 0.18, respectively.

From the results obtained from the experiments performed on dextran and on hyaluronate the difference in osmotic behaviour between solutions of electrically neutral and electrically charged substances is obvious from the fact that the values of c/p do not vary with the concentration of solute in the case of dextran, but do vary in the case of hyaluronate.

We are gratefully indebted to Professor J. A. Christiansen, head of the University Institute of Physical Chemistry, Copenhagen, for his inspiring guidance and valuable suggestions. One of us (C.E.J.) wishes to thank *Købmand i Odense Johann and Hanne Weimann, né Seedorf's Foundation*, and the *University of Copenhagen* for financial support.

The Accelerating Capacity of Organic Polythionates and Polysulphides

N. HOFMAN-BANG and H. LETH PEDERSEN

Chemistry Department A, Technical University of Denmark, and Chemical Research Laboratory, Northern Cable and Wire Works Ltd, Copenhagen, Denmark

In natural rubber bis-*p*-tolylsulphonyl sulphide, disulphide and trisulphide (the socalled organic polythionates), di-benzoyl trisulphide and tetrasulphide provoke a fair vulcanisation at 162°C preferably in combination with 2 PHR (parts per hundred rubber) sulphur. The coefficients of vulcanisation are determined by means of ^{35}S. The physical state of China Clay containing vulcanisates are intermediate and the ageing stability equals that of similar DPG-vulcanisates, the benzoyl tetrasulphide being the best.

The formal analogy of the sulphur bond in thiurams and polysulphides —S — S— suggests a possibility of vulcanisation with polythionates. X-Ray investigations by Dawson *et al.*[1] of bis-*p*-tolylsulphonyl sulphide and trisulphide indicated a zig zag sulphur chain. Orientating measurements comprising bis-*p*-tolylsulphonyl sulphide and disulphide (abbrev. tol-tri, tol-tetra) and di-benzoyl trisulphide and tetrasulphide (abbrev. benz-tri, benz-tetra) revealed practically no cure in absence of sulphur, the ability to vulcanising was, however, distinct upon addition of 1 PHR of sulphur. For instance the sulphurfree tol-tetra in a clay-whiting compound showed a tensile of 55 kg/cm^2 and a halving time for the tensile at 70°C in air of 17 days.

The following experiments were carried out with 2 PHR of sulphur in combination with 2 PHR of accelerator. Rates of vulcanisation were indicated as moduli at 110 % elongation, measured with a 32 oz strain gage (Statham Laboratories [2]), operated at a strain rate of 750 mm/min. Sensitivity is about 2 g in stress.

The sulphur reaction was determined after introduction [3] of ^{35}S on a micro mill (10—20 g rubber) and vulcanisation of discs, 65 mm diam., 0.75 mm thick.

From these samples discs of 25 mm (4.91 cm^2) were cut for measurement of activity using a Geiger-Müller-tube and a Frieseke-Höpfner scaler counting 10 000 counts. The sulphur had an activity of about 60 μC and 2 parts gave with the 4.91 cm^2 sample about 1 500 counts per min. Afterwards the samples were wrapped in gauze and acetone-extracted for 18 h either in the bottom of an ordinary Soxhlet filled with silica Raschig rings in order to reduce the volume or in a ASTM micro extractor [4]. The samples were then airdried and the activity measured. The ratio of activities of unextracted to extracted specimens duly corrected for decay is used as a very convenient measure of gross bound sulphur. Ten or more samples are measured in a few hours and the determination of the coefficients of vulcanisation completed in 24 h.

Ageing tests were performed at 70°C ($\pm$ 0.5°) in air with dumbbell specimen[5] tested with a Zwick Z.125 tensile machine at an elongation rate of 800 mm/min at 25°C.

RATE OF VULCANISATION

The basic composition of the mixes was

Smoked sheets	100	
Zinc oxide	10	
Stearic acid	1	
Whiting (Kragelund)	53	batch
China clay (Erbslöh P)	51	216.5 parts
Nonox CI	1.5	
Accelerator	2	
Sulphur	2	

The compounds were made from the batch using 108.25 g (= 50.0 g smoked sheets) and S and the accelerator was added on a micro mill (150 × 90 Φ mm rollers) thermostated by water circulation at 50°C. The radioactive sulphur compounds were made on the same mill using 21.65 g batch and 0.200 g ^{35}S. The micro mill was equipped with a hood and an absorber containing active carbon (Carboraffin). A vacuum cleaner performed the suction.

The state of vulcanisation was determined as modulus at 110 % elongation 15 sec after application of the load (rate 750 mm/sec) and is shown in Table 1.

The data are illustrated in Fig. 1.

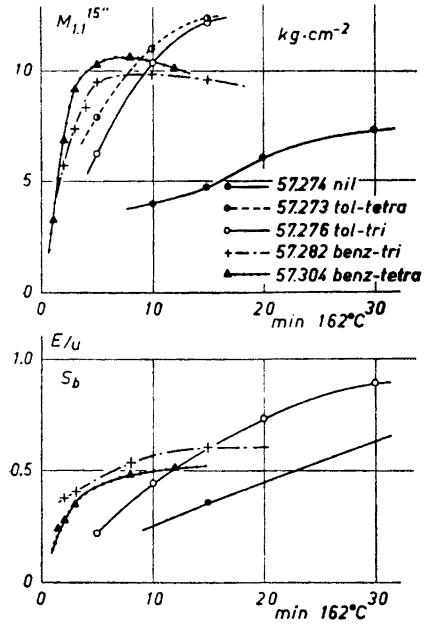

Fig. 1. Rate of vulcanisation: Modulus 110 % elongation and percent bound sulphur *vs.* time of vulcanisation at 162°C.

RATES OF OXIDATION

The rates of oxidation were measured at 1 mm thick slabs as described elsewhere [6].

In pure oxygen at 95°C the following rates were found, *cf.* Table 2. Initial rate was determined after 1 h oxidation at a starting pressure about 150 mm Hg below atmospheric pressure.

Table 2.

TB°, tensile at break before ageing.
$t_{\frac{1}{2}}$, days for half value of TB°.
σ, rate of decrease of tensile in kg/cm² per day.
μ, same for modulus at 300 % elongation.
ε, same for elongation at rupture in percent per day.
δ, marginal change of Shore A hardness.
r, straight line
exponents, period in days.

The ageing was only controlled until half value of the tensile was reached, at which point the samples in all cases were in fair condition. No tackiness or serious hardening was observed whereas generally a strong discoloration (brown) was noticed.

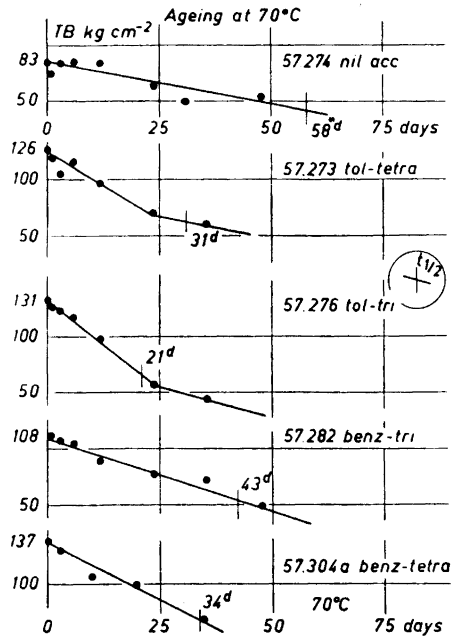

Fig. 3. Rate of ageing: Tensile strength at break *vs.* days at 70°C.

PREPARATIONS

Bis-*p*-tolylsulphonyl sulphide $(C_7H_7SO_2)_2S$, was prepared according to Otto and Troeger [7] by oxidation with iodine of equimolar mixture of potassium *p*-tolylthiosulphonate and *p*-tolylsulphinate. Crystallization from glacial acetic acid gave a product with m. p. 137°C corr. (Otto and Troeger [7] found 133—134°C, Dawson, Mathieson and Robertson [1] 138°C). (Found: S 28.5. Calc. for $C_{14}H_{14}O_4S_3$: S 28.1).

Bis-*p*-tolylsulphonyl disulphide $(C_7H_7SO_2)S_2$, was prepared according to Troeger and Hornung [8] by interaction of sodium *p*-tolylsulphinate with disulphur dichloride in carbon tetrachloride. We have slightly modified the preparation so as to get a higher yield (ca. 60 %). The raw product of bis-*p*-tolylsulphonyl disulphide is formed as a suspension in carbon tetrachloride, which according to Troeger and Hornung is distilled off on a water bath. However, the solubility of the said compound in cold carbon tetrachloride is rather small, so we just filtered off and discarded the filtrate. The raw product was then dried, washed with water, dried, washed with carbon disulphide, again dried, and then crystallized from glacial acetic acid. M. p. 113—114°C corr. (Christiansen [9] found 114°C). (Found: S 34.0. Calc. for $C_{14}H_{14}O_4S_4$: S 34.2).

Bis-*p*-tolylsulphonyl trisulphide $(C_7H_7SO_2)_2S_3$, was prepared according to Troeger and Hornung [8] by interaction of sodium *p*-tolylthiosulphonate and sulphur dichloride in carbon tetrachloride. Also in this case (*cf.* bis-*p*-tolylsulphonyl disulphide) we discarded the carbon tetrachloride solution. Crystallization from glacial acetic acid gave a product with m. p. 179.5—180°C corr. Christiansen [9] found 183°C just as Troeger and Hornung [8]; Dawson, Mathieson and Robertson [1] found 180°C). (Found: C 41.3; H 3.53; S 39.5. Calc. for $C_{14}H_{14}O_4S_5$: C 41.4; H 3.44 S 39.4).

Di-benzoyl trisulphide; $(C_6H_5CO)_2S_3$, and dibenzoyl tetrasulphide $(C_6H_5CO)_2S_4$, were prepared according to Bloch and Bergmann [10] by interaction of potassium thiobenzoate and sulphur dichloride in the former case and disulphur dichloride in the latter. M. p. of the trisulphide was 160°C corr., while Bloch and Bergmann [10] found 165—167°C. (Found: S 31.3. Calc. for $C_{14}H_{10}O_2S_3$: S 31.4 %). M. p. of the tetrasulphide was 68—69°C corr. while Bloch and Bergmann [10] found 83—84°C. (Found: S 39.3. Calc. for $C_{14}H_{10}O_2S_4$: S 37.8).

DISCUSSION

The accelerating power is moderate but definite. As shown the tensiles are about 120 as compared with about 180 obtainable with conventional accelerators. In their behaviour the accelerators show only slight analogy to thiurams. The ability to vulcanising in absence of sulphur is not very pronounced, and the oxidation and ageing characteristics are quite different. It is interesting to note that the S-addition curves show very varying amounts of bound S corresponding to optimum moduli, *e.g.* the benzoyl sulphides show rapid cure and a low percent of chemically bound sulphur, whereas the thionates vulcanise slowly but ending at about total binding of sulphur. Benz-tetra gives the fastest cure and maximum tensile. The sulphur determination and melting point of this compound showed a small content of free sulphur. This explains the high tensile and the reduced ageing stability of benzoyl tetrasulphide as compared with the trisulphide.

The oxidation curves show some interesting features, *e.g.* the thionates have about linear curves whereas the benzoyl sulphides have obvious autocatalytic curves resembling those of peroxide-vulcanisates. This might be explained as an analogy between S and O in the —X — X— group. The rates are in agreement with the $t_{\frac{1}{2}}$ values from the ageing tests. Thus the manometric method gives a fair screening here.

Finally the ageing resembles that of diphenylguanidine vulcanisates more than that of thiuram vulcanisates both in the decreasing moduli and the magnitude of $t_{\frac{1}{2}}$ *(70°C)*.

Some Solution Equilibria Involving Calcium Sulfite and Carbonate

I. Simple Solubility Equilibria of CO_2, SO_2, $CaCO_3$, and $CaSO_4$

GERHARD NILSSON, TORSTEN RENGEMO and LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Equilibrium constants for the reactions: 1) $CaSO_4(H_2O)_2(s) \rightleftharpoons Ca^{2+} + SO_4^{2-} + 2H_2O$ 2) $SO_2(g) + H_2O \rightleftharpoons H_2SO_3$ 3) $CaSO_3(H_2O)_{\frac{1}{2}}(s) + SO_2(g) + \frac{1}{2}H_2O \rightleftharpoons Ca^{2+} + 2\ HSO_3^-$ 4) $CO_2(g) + H_2O \rightleftharpoons H_2CO_3$ 5) $CaCO_3(s) + CO_2(g) + H_2O \rightleftharpoons Ca^{2+} + 2\ HCO_3^-$ were determined at 25, 35, and 75°C, using 1 m and 3.5 m $NaClO_4$ as ionic medium. The log K values (m scale) are given in Table 1.

The impetus to the work to be described below was a process once proposed for sulfur recovery in sulfite pulp mills. The principle is as follows:

(1) The sulfite waste liquor is burned and the SO_2 of the flue gases is absorbed in an ammonium sulfite solution; (2) or (2a) from this solution, calcium sulfite is precipitated by the addition of calcium carbonate.

$$SO_3^{2-} + SO_2(g) + H_2O \rightarrow 2\ HSO_3^- \quad (1)$$
$$2\ HSO_3^- + CaCO_3(s) \rightarrow CaSO_3(s) + CO_2(g) + H_2O + SO_3^{2-} \quad (2)$$
$$HSO_3^- + CaCO_3(s) \rightarrow CaSO_3(s) + HCO_3^- \quad (2a)$$

The calcium sulfite would then be separated and used for making fresh liquor; the remaining solution would be sent back to the absorber, to take up new SO_2, according to (1) or

$$HCO_3^- + SO_2(g) \rightarrow HSO_3^- + CO_2(g) \quad (1a)$$

The process might be advantageous in such mills where the excess steam available does not suffice for stripping the ammonium sulfite solution in the traditional way.

To study the feasibility of this process, a number of equilibria were studied involving solid $CaSO_3$ or $CaCO_3$ and a solution containing SO_3^{2-} ions. Since some oxidation to sulfate is unavoidable, the behavior of $CaSO_4$ and its hydrates in the solutions was also studied.

The main results of these equilibrium studies will now be published since the equilibrium constants may have an interest independent of the special process described. Even if the accuracy might have been better, it is thought that these data will give more precise information than was possible on the basis of previously published data, which were often conflicting.

Choice of experimental conditions

Three *temperatures* were studied, namely 25°C, 35°C, and 75°C. The first, 25°C, was chosen because it is a standard temperature for physicochemical measurements, and so makes our data directly comparable with a large amount of data compiled by other workers. It was kept constant by keeping the reaction vessel in a water thermostat of 25.0 ± better than 0.1°C. The experiments were moreover carried out in a thermostat room with 25.0 ± 0.5°C. The temperature 75°C was maintained by keeping the apparatus in an air thermostat of 75°C ± 1°; in the aqueous solutions the fluctuations were smoothed out so that the variations were considerably less.

As an intermediate temperature, one might have proposed 50°C; however, 35°C was chosen since it allows working with water thermostats without too much trouble from condensation of water vapor.

The *ionic medium* was kept constant, as far as possible, by making the solutions always contain either 1 m Na^+ or 3.5 m Na^+ (m = mole per 1 000 g of H_2O). The concentrations were given on a weight rather than a volume basis because the reactions would be considered at several temperatures. At 25°C, 3.5 m $NaClO_4$ is practically the same as 3.0 M $NaClO_4$. As anions the solutions contained sulfite, sulfate, and carbonate ions, depending upon which equilibria were to be studied; the balance was ClO_4^-.

As inert positive ion, Na^+ was chosen rather than NH_4^+, to avoid the necessity of making small corrections for the formation of NH_3, which would complicate the calculations unnecessarily without being essential for the process.

In the usual absorption process [1], combined with steam stripping, high concentration is an advantage, and the ionic concentrations are usually chosen above 10 m. However, in the precipitation processes to be studied, it would be preferable to work with a lower concentration, since this makes it easier to separate a pure precipitate. This was our reason for choosing 1 m and 3.5 m.

EXPERIMENTAL

Substances

Sulfur dioxide and *carbon dioxide* were taken from gas cylinders, and then washed first with water and then with a $NaClO_4$ solution of the desired concentration and temperature, to get the right water vapor pressure. Sodium carbonate, sodium sulfite, sodium sulfate, perchloric acid 70–72 %, calcium chloride, calcium sulfate dihydrate, and calcium carbonate were all of p. a. purity of Baker's, Kahlbaum's, or Merck's make.

Sodium perchlorate was prepared from sodium carbonate and perchloric acid. *Calcium sulfite* was precipitated from calcium chloride and sodium sulfite solutions, washed and sucked dry, all in a nitrogen atmosphere.

Ammonia was taken from a cylinder and purified only by being washed with distilled water.

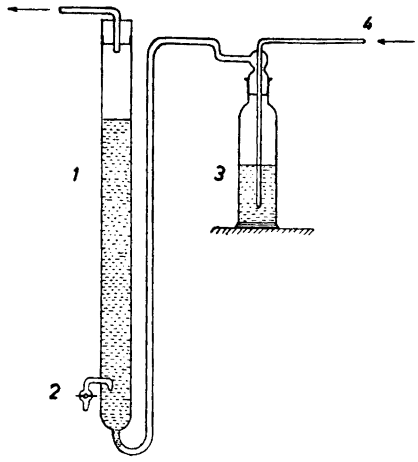

Fig. 1. Sketch of apparatus for equilibrating gas and solution (suspension). 1: glass tube, diameter 3 cm. 2: stop-cock for taking samples. 3: washing-bottle for preliminary equilibration with water vapor. 4: inlet for purified gas.

To avoid the oxidation of sulfite to sulfate by the oxygen of the air, all equilibrium experiments were carried out in an atmosphere of nitrogen from which oxygen had been removed by Meyer and Ronge's method [2], if a CO_2 or SO_2 atmosphere was not used. Moreover, the solutions contained 0.3 ml of benzyl alcohol per liter; this is an efficient chain inhibitor for the oxidation of SO_3^{2-} as found by Bäckström [3].

Apparatus

The central, thermostated, part of the apparatus is indicated in Fig. 1. The glass tube is about 60 cm long with an inner diameter of 3 cm. Like the washing bottle, it contains $NaClO_4$ solution, 1 m or 3.5 m. In some experiments, the tube also contained a solid in excess, $CaCO_3$(s) or $CaSO_3(H_2O)_{\frac{1}{2}}$(s).

The gas to be studied, CO_2 or SO_2, was first bubbled through the wash bottle, to become approximately saturated with water vapor, and then through the long tube. The solid phases were added only after the stream of gas had been started.

When no solid phase was present, samples were taken from the stop-cock at the lower part of the tube. Otherwise, samples were sucked very cautiously with an inverted bicycle pump (to avoid excessive under-pressure) through a pipette provided with a sintered-glass filter-stick.

In our 35°C thermostat, there was not enough room for this apparatus. Instead, a 500 ml bottle, provided with a stirrer, inlet and outlet tubes for the gas was used. Samples were taken by sucking, if necessary through a filter-stick.

The solubility of calcium sulfate, really $CaSO_4(H_2O)_2$, was determined simply by shaking 1 m or 3.5 m $NaClO_4$ solution with excess calcium sulfate dihydrate in bottles.

Analysis

Calcium was precipitated as oxalate, which was dissolved in sulfuric acid and titrated with $KMnO_4$.

To analyse for *sulfite*, excess of 0.05 M I_2 solution was added, the solution was acidified (if necessary), and excess iodine was titrated with thiosulfate.

Table 1. Summary of results (averages of two or more measurements).

	1 m $NaClO_4$			3.5 m $NaClO_4$		
	25°C	35°C	75°C	25°C	35°C	75°C
1. $CaSO_4$ (s) ⇌ Ca^{2+} + SO_4^{2-}

4. CO_2(g) + H_2O ⇌ H_2CO_3						
mmole/kg	26.5	21.7	9.25	19.2	16.0	7.75
mmole/kg H_2O	29.8	24.4	10.4	27.4	22.9	11.1
log K	− 1.51	− 1.59	− 1.78	− 1.55	− 1.62	− 1.78
5. $CaCO_3$(s) + CO_2(g) + H_2O ⇌ Ca^{2+} + 2 HCO_3^-						
mmole Ca/kg solution	12.8	10.9	6.72	6.42	5.05	2.64
mmole Ca/kg H_2O	14.4	12.3	7.55	9.18	7.22	3.77
log K	− 4.91	− 5.10	− 5.56	− 5.50	− 5.80	− 6.49

The *total carbonate* of the solution was precipitated by excess of barium hydroxide, the precipitate was washed in a centrifuge, and dissolved in excess of 0.1 M HCl. This solution was boiled and then the excess HCl was determined by titration with 0.1 M NaOH.

Sulfate was determined gravimetrically as $BaSO_4$.

RESULTS

The results of this part of our work are summarized in Table 1.

In the second reaction formula for brevity, H_2SO_3 means the uncharged molecular species present in the aqueous solution, whether it be H_2SO_3, SO_2, or $SO_2(H_2O)_n$. The same holds for H_2CO_3 in the fourth reaction. The formulas $CaCO_3$, $CaSO_3$, and $CaSO_4$ stand for the solid phase present at equilibrium, under our conditions they were $CaCO_3$ (calcite), $CaSO_3(H_2O)_{\frac{1}{2}}$ (see part II), and $CaSO_4(H_2O)_2$ (gypsum).

For each reaction, the first line gives the average of the data primarily obtained. Since the samples were weighed before analysis, the unit is mmole/kg solution. Each value is the average of two or more separate experiments; the difference was less than 1 % for the experiments involving SO_2, and less than 1.5 % for the others. The figures are the uncorrected analytical data: total solubility for the gases, and total Ca in the experiments with solid phases.

The second line of figures, for each equilibrium, gives the primary data corrected to the unit mmole/kg H_2O.

To obtain the figures in the third line, log K of the reaction, one must consider that the partial pressures of SO_2 and CO_2 were 1.00 atm minus the equilib-

rium pressure of water vapor, 0.031 atm at 25°C, 0.055 atm at 35°C, and 0.380 atm at 75°C, for pure water, which should be multiplied by the activity of water, which we calculated from Jones' osmotic coefficients [4] as 0.96_8 in 1 m $NaClO_4$ and 0.88_4 in 3.5 m $NaClO_4$.

Moreover, in the second equilibrium, the solubility of SO_2 in water, one should correct for the dissociation of H_2SO_3, which is a fairly strong acid. For 25°C, according to part III, log K_a is —1.37 in 1 m and —1.72 in 3.5 m $NaClO_4$. Assuming the same temperature dependence of log K as at zero ionic strength [6], we estimate —1.46 and —1.81 for 35°C, and —1.83 and —2.18 at 75°C. The corresponding correction can be neglected for H_2CO_3.

The spread of the experimental data corresponds to an uncertainty of about 0.01 in the first, third and fourth log K_a and $\pm$ 0.02 in the fifth. The systematic error in the constant for SO_2 solubility, because of the uncertainty of the K_a, may be of the same order of magnitude for 25°C, and larger for the other temperatures. The solubility of $CaSO_3$ is so large that the ionic medium is considerably changed, introducing an unknown error in the activity factors.

Comparison with literature data

There is an abundant literature on the solubility of gypsum in water and aqueous solutions [5]. Although there are no data that can be directly compared with ours, the general trend, with a solubility maximum around 40—50°C, agrees with our data. The value for the activity-solubility product at 25°C, according to Latimer *et al.*[8], is log $K_s = -4.625$ which, with our values, would give reasonable activity coefficients.

The solubilities of CO_2 and SO_2 agree well with previous determinations [6,7], with due regard to the salting-out effect.

The equilibrium $CaCO_3(s) + H_2O + CO_2(g) \rightleftharpoons Ca^{2+} + 2\ HCO_3^-$ has been studied carefully by Frear and Johnston [9]. Their value for log K at 25°C is —5.83, using activities.

The equilibrium $CaSO_3\ (H_2O)\frac{1}{2}(s) + \frac{1}{2}H_2O + SO_2(g) \rightleftharpoons Ca^{2+} + 2\ HSO_3^-$ has been studied by Conrad and Beuschlein [10] who, however, did not try to calculate the equilibrium constants. Their ionic strengths varied, and were too high for extrapolation to zero. Their lowest concentrations, 0.142 M $Ca(HSO_3)_2$ and $p_{SO_2} = 16.2$ torr at 25°C would give log $K = -0.27$ (M, atm units), which compares reasonably well with our value.

Some Solution Equilibria Involving Calcium Sulfite and Carbonate

II. The Equilibrium between Calcium Sulfate and Calcium Sulfite in Aqueous Solutions [1]

TORSTEN RENGEMO, URSULA BRUNE and LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The equilibrium constant for the reaction $CaSO_4(H_2O)_2(s) + SO_3^{2-} \rightleftharpoons CaSO_3(H_2O)_{\frac{1}{2}}(s) + SO_4^{2-} + 1.5\ H_2O$ has been determined at 25°C, 35°C, and 75°C, with Na+ concentrations 1 m and 3.5 m, and ClO_4^- as neutral anion. The average values for log K are, for both Na+ concentrations; at 25°C 1.88; at 35°C 1.96; and at 75°C 2.23; thus $K = [SO_4^{2-}]\,[SO_3^{2-}]^{-1} = 76$, 91, and 170 at the three temperatures.

The measurements suggest log $K_s = -6.5 \pm 0.2$ for the activity solubility product of $CaSO_3(H_2O)_{\frac{1}{2}}$ at 25°C.

The present paper will describe studies of the equilibrium

$$CaSO_4(s) + SO_3^{2-} = CaSO_3(s) + SO_4^{2-};\ K = [SO_4^{2-}] / [SO_3^{2-}] \qquad (1)$$

The available literature data that could be used for estimating K are in very bad agreement, giving values of K ranging from about 1 to several hundreds.

ESTIMATION OF K FROM LITERATURE DATA

The equilibrium constant K in (1) is the ratio of the concentrations of two binegative ions of practically the same size. The activity factors of these ions can be expected to be approximately equal although their values will, of course, vary very much with the ionic medium. If this is so, the apparent K in any aqueous solution will not be far from the real activity constant, and K will be fairly independent of ionic strength.

We made an attempt to estimate K from the relevant literature data, summarized in Table 1. The solubility of $CaSO_4(H_2O)_2$ in water at temperatures below 100°C has been very accurately measured by several workers, whose results agree well. The last column in Tab. 1 gives the concentration of the saturated aqueous solutions [2] in mM.

Table 1. Literature data on the solubilities of $CaSO_3(H_2O)_{\frac{1}{2}}$ in water and in saturated $CaSO_4(H_2O)_2$, expressed in mg $CaSO_3$ per 1 000 g solution.

R = Robart 1913.
L = van der Linden 1916 (The values in parentheses are the original data, expressed as mg of "$CaSO_3(H_2O)_2$" per 1 000 g solution).
W+S = Wurz and Swoboda 1948.

On the other hand, the data on $CaSO_3$ (really $CaSO_3(H_2O)_{\frac{1}{2}}$) are scarce and contradictory as seen from Table 1 where the data of Robart [3], van der Linden [4] and Wurz and Swoboda [5] are compared. The constant K could be estimated from them in two ways.

From the solubilities of $CaSO_3$ and $CaSO_4$ in pure water, we calculated the solubility products, making reasonable assumptions regarding the activity factors; K was then obtained as the ratio of the solubility products of $CaSO_4$ and $CaSO_3$. For both salts we used the activity factors for $ZnSO_4$ as given by Harned and Owen [6] on the basis of data of Cowperthwaite and LaMer [7] and Bray [8]; the activity factors for all metal(II) sulfates seem to vary with concentration in practically the same way [6].

In this way we obtained the following very approximate values for K:

from Robart's data	1.2(15°C) to	0.8(100°C)
from van der Linden's data	200(30°C) to	6 000(100°C)
from Wurz and Swoboda's data	70(20°C) to	140(80°C)

If, instead, one uses Kielland's activity factor tables [9], the constants in the two latter cases will be multiplied with a factor of about 1.5, and thus become 300 to 9 000, and 100 to 200; however, the $ZnSO_4$ values seem preferable.

We may also use the solubility of $CaSO_3$ in saturated calcium sulfate solutions. In these experiments one may expect $[SO_4^{2-}]$ to be practically the same

as in a saturated solution of $CaSO_4(H_2O)_2$ in pure water; since the two binegative ions are in the same solution no activity factor correction is needed, and the constant K is obtained as the ratio SO_4^{2-}/SO_3^{2-} in the solution. The values so obtained are approximately

from van der Linden's data	80(30°C) to 300(100°C)
from Wurz and Swoboda's data	65(20°C) to 40(80°C)

Not only do van der Linden's and Wurz-Swoboda's values disagree with each other; in each paper the two sets of data seem to lead to disagreeing results.

Robart's solubility values are so much higher than those given in the two other papers that one may suspect they are misquoted; since, however, Latimer and Hildebrand [10] had selected Robart's data we felt we should not discard them without making experiments of our own.

EXPERIMENTAL

The equilibrium (1) was studied in solutions with 1 m Na+ at 25°C, 35°C, and 75°C, and with 3.5 m Na+ at 25°C and 35°C (with one stray experiment at 75°C).

At the two lower temperatures, the solutions were shaken to equilibrium in 100 ml glass bottles in a water thermostat. At 75°C the solution was kept in an Erlenmeyer flask with a magnetic stirrer; the flask was kept in an air thermostat at 75°C.

The solutions were generally made up by adding to a sodium sulfite solution an excess of $CaSO_4(H_2O)_2$. In one case, the equilibrium was approached from the other direction, solid $CaSO_3(H_2O)$ being added to a sodium sulfate solution. As in part I [1] the solutions contained perchlorate ions as balance.

Especially at the lower temperatures, the time of contact was very long, 5—38 days, to assure that equilibrium was obtained. — At the end of an experiment, the stirring was stopped but the flask was still left in the thermostat. After a few hours, the solids had settled, and samples of the solution were sucked out through a glass filter-stick. The samples were weighed and analysed for sulfate and sulfite ions.

Sulfite was determined iodometrically (part I). Since the sulfite concentration in our solutions was low, the accuracy was only about 5 % at the lowest concentrations.

For determining *sulfate* the standard gravimetric method could not be used here because of the fear of the coprecipitation of sodium owing to the high Na+ concentration in the solutions. Instead, a volumetric method with the following principle [11] was used. The sulfite ions are first bound as a formalin complex and then sulfate precipitated with barium chloride at room temperature after adding acetic acid. The precipitate of $BaSO_4$ is washed, centrifuged, and then converted to $BaCO_3$ by means of a strong sodium carbonate solution. This reaction takes about 1 h at 100°C. The barium carbonate precipitate is washed till the reaction is neutral, and then the carbonate content determined by dissolving in a known excess of hydrochloric acid, and back-titrating with sodium hydroxide. The accuracy of the sulfate determination is better than 1 %, which is satisfactory considering the much larger uncertainty in the sulfite determination.

The solid phases. In order to make sure in what form calcium sulfite and sulfate were present, X-ray powder photographs were taken of the powder mixture in a number of the equilibrium solutions at 25°C and 75°C and compared with photographs of synthetic specimens. Calcium sulfate proved to be present in the form of the dihydrate $CaSO_4(H_2O)_2$, gypsum. Calcium sulfite was present in one and the same form at 25°C and 75°C; this phase was also prepared synthetically. The diffraction lines of this phase agreed very well with the data of Matthews and McIntosh [12]; these authors state that the composition of the phase is $CaSO_3(H_2O)_{\frac{1}{2}}$.

Table 2. Experiments on the equilibrium

$$CaSO_4(s) + SO_3^{2-} \rightleftharpoons CaSO_3(s) + SO_4^{2-}$$

75	3.5	0.1	743	4.31	172	2.24

RESULTS

Our results are given in Table 2. Since the equilibrium constant K of the reaction studied is a pure number, it is immaterial whether we express the concentrations in m, in M, or in mole/kg of solution. It is the latter unit we have chosen in the table, since it gives the easiest calculations, and thus the smallest chance of computation errors.

The columns of Table 2 are: temperature °C; concentration of Na^+, in mole/kg of water; time of equilibration, days; final concentration of SO_4^{2-}; final concentration of SO_3^{2-}; equilibrium constant K, and log K.

The single experiment where the equilibrium was approached starting with calcium sulfite is marked with an asterisk.

The correction for the hydrolysis of the sulfite ion according to

$$SO_3^{2-} + H_2O \rightleftharpoons HSO_3^- + OH^-$$

can be shown to be negligible in comparison with the other experimental errors; it is less than 1 %.

The equilibrium constant K is found to increase with temperature. There may be a slight increase with increasing ionic strength, though the accuracy of the data does not allow a certain conclusion. We prefer to give an average K for both ionic strengths:

$$\begin{array}{lll} 25°C & \log K = 1.88 & K = 76 \\ 35°C & \log K = 1.96 & K = 91 \\ 75°C & \log K = 2.23 & K = 170 \end{array}$$

If we compare these values with the literature data given above, our data are found to be in complete disagreement with Robart's. The best agreement

is with the K values from Wurz and Swoboda's solubilities in pure water, and with those from van der Linden's solubilities in calcium sulfate solutions.

The accuracy of our values for log K is, we hope, better than $\pm$ 0.10.

If we assume that the log K so obtained represents the true activity equilibrium constant, we can find the true activity solubility product for $CaSO_3$ by combination with the activity solubility product [13] $[Ca^{2+}]\,[SO_4^{2-}] = 10^{-4.63}$ at 25°C

$$[Ca^{2+}]\,[SO_3^{2-}] = K_s = 10^{-6.51}$$

The uncertainty in log K_s is estimated as $\pm$ 0.2.

From this value of K_s we may calculate the solubility of $CaSO_3(H_2O)_{\frac{1}{2}}$ at 25°C in pure water to be around 0.76 mM or 91 mg $CaSO_3$/l.

Some Solution Equilibria Involving Calcium Sulfite and Carbonate

III. The Acidity Constants of H_2CO_3 and H_2SO_3, and $CaCO_3$ + $CaSO_3$ Equilibria in $NaClO_4$ Medium at 25° C

MINA FRYDMAN, GERHARD NILSSON, TORSTEN RENGEMO and LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

A number of equilibrium constants have been determined, involving aqueous solutions, solid $CaSO_4(H_2O)_2$, $CaCO_3$ and $CaSO_3(H_2O)_{\frac{1}{2}}$ and gaseous CO_2 and SO_2. The equilibria have been studied at Na^+ concentrations 1 m and 3.5 m and at the temperatures 25, 35 and 75°C. The results are summarized in Table 1; applications to practical cases are given in the diagrams, Fig. 1 and Fig. 2.

In connection with the work in parts I and II, the acidity constants of H_2CO_3 and H_2SO_3 were determined for the ionic media studied, 1 m and 3.5 m Na^+, with ClO_4^- as neutral anion. Although some preliminary experiments were made at higher temperatures, only those at 25°C had an accuracy that made them worth publishing.

The experiments were carried out as potentiometric titrations, using a glass electrode for measuring $[H^+] = h$, and a silver-silver ion electrode as reference electrode:

— glass electrode/I m $NaClO_4$/0.01 m $AgClO_4$, (I—0.01) m $NaClO_4$/Ag +

$$E = E_o + E_j - 59.15 \log h$$

E_o and the liquid junction potential E_j were determined by comparison with solutions of the same ionic strength $I = 1$ or 3.5, but with some Na^+ replaced by H^+. These solutions either occurred naturally at one end of the titration, or were specially prepared and inserted in the cell before or after a titration. The procedure has been described in several papers from this laboratory, *e.g.* Refs.[1,2].

THE SECOND ACIDITY CONSTANT OF CARBONIC ACID

For convenience in the titrations, all concentrations were expressed in M units for the calculations (although, of course, the Na^+ concentration was always 1 m or 3.5 m).

The main experiments were made as titrations of 200 mM Na_2CO_3 or 100 mM Na_2CO_3 (balance $NaClO_4$) with $HClO_4$, with careful addition and mechanical stirring, to prevent loss of CO_2. For each point one could calculate, from the analytical data, $Z = [HCO_3^-]/([HCO_3^-] + [CO_3^{2-}])$, the number of protons bound per CO_3 group, and plot it as a function of log h. The experimental curve $Z(\log h)$ was fitted to a calculated normalized curve, $Z = v(1 + v)^{-1}$ *versus* $v(= \log h - \log K)$, and from the position of best agreement, log K was obtained [3].

For each of the two ionic media used, two titrations were carried out with 200 mM CO_3^{2-}, and one with 100 mM CO_3^{2-}. The curves $Z(\log h)$ coincided, as one might expect for a mononuclear process. The best values found were, at 25°C:

for $[Na^+] = 1\,000$ mm $\sim$ 950 mM: $K_{a2} = 10^{-9.59}$ M $= 10^{-9.57}$ m
for $[Na^+] = 3\,500$ mm $\sim 3\,000$ mM: $K_{a2} = 10^{-9.63}$ M $= 10^{-9.56}$ m

with an uncertainty of less than ± 0.02 in log K.

In a few preliminary experiments, we were thoughtless enough to start with an $NaHCO_3$ solution and stir with a stream of nitrogen. This led to losses of CO_2 with the gas stream, amounting to about 10 % of the whole carbonate content. When the curve-fitting [3] was applied, this error was immediately discovered because the apparent Z curve was shifted (*cf.* Fig. 2 d in Ref[3]); a correction could then easily be applied.

Titrations of $NaHCO_3$ with NaOH, applying mechanical stirring, gave somewhat smaller corrections, but we preferred the titrations of Na_2CO_3 with $HClO_4$, since they gave immediately Z curves of the right shape and, moreover, could be easily extended to an acid-base titration giving E_o and E_j.

FIRST ACIDITY CONSTANT OF CARBONIC ACID

In titrations of HCO_3^-—H_2CO_3 buffers, it is always hard to avoid the escape of some CO_2. It was decided to titrate instead $NaHCO_3$ with H^+, keeping $[H_2CO_3]$ constant by equilibrating with CO_2(g) at 1 atm. The constant obtained will be the following:

$$CO_2(g) + H_2O \rightleftharpoons HCO_3^- + H^+; \quad K_pK_{a1} = [H^+][HCO_3^-]p_{CO_2}^{-1}$$

In each point of the titration, one knows $[H^+] = h$ from the emf measurement, and $[HCO_3^-]$ from the original amount of HCO_3^- and from the amount of H^+ added.

The experiments were carried out in the same way as for K_{a2}, adding H^+ to a known amount of HCO_3^-, and bubbling CO_2 through the solution. The points after the equivalence point, when all the HCO_3^- had been consumed, could be used for determining E_o and E_j.

After correction to $p_{CO_2} = 1$ atm, the following results were obtained from two experiments with each ionic strength, starting with 200 mM HCO_3^-:

$[Na^+] = 1\,000$ mm $\sim$ 950 mM; $K_pK_{a1} = 10^{-7.59}$ M^2 atm^{-1} $= 10^{-7.55}$ m^2 atm^{-1}
$[Na^+] = 3\,500$ mm $\sim 3\,000$ mM; $K_pK_{a1} = 10^{-8.02}$ M^2 atm^{-1} $= 10^{-7.88}$ m^2 atm^{-1}

These values may be combined with the values for K_p found in part I, —1.51 for 1 m Na^+ and —1.55 for 3.5 m Na^+, to give

$$-\log K_{a1} = -6.04 \text{ for 1 m } Na^+, \; -6.33 \text{ for 3.5 m } Na^+$$

The accuracy is estimated to be ± 0.02. Literature values for 25°C and at infinite dilution are log K_{a1} = —6.366 (Shedlovsky and MacInnes [4]), —6.352 (Harned and Davis [6]), and —6.51 (Kauko and Carlberg [5]); log K_{a2} = —10.25 (MacInnes and Belcher [7]) and —10.24 (Kauko and Airola [8])

THE ACIDITY CONSTANTS OF H_2SO_3

After a number of preliminary experiments, we chose to start the titrations with initial [OH^-] from 20 to 100 mM, and to titrate with a solution of SO_2, from 0.16 to 1.2 M, and of the desired sodium concentration. By this procedure, losses of SO_2 were avoided.

The average values were:

for 1 m Na^+: $K_{a1} = 10^{-1.39}$ M $= 10^{-1.37}$ m: $K_{a2} = 10^{-6.36}$ M $= 10^{-6.34}$ m
for 3.5 m Na^+: $K_{a1} = 10^{-1.79}$ M $= 10^{-1.72}$ m: $K_{a2} = 10^{-6.43}$ M $= 10^{-6.36}$ m

The limits of error of these figures are somewhat higher, about ± 0.05 for log K_{a2} and ± 0.10 for log K_{a1}. Literature values for 25°C and infinite dilution are log K_{a1} = from —1.89 (Johnstone and Leppla[9]) to —1.76 (Tartar and Garretson [10]), and log K_{a2} = —7.20 (Tartar and Garretson [10])

CHECK OF CONSTANTS

Table 1 gives a summary of the log K values determined in the present work. At 25°C, it is possible to make a check on the constants, since the equilibrium constant of the reaction

$$SO_3^{2-} + H_2SO_3 \rightleftharpoons 2\ HSO_3^-$$

Table 1. Logarithms of measured and derived equilibrium constants.

No.	Reaction	1 m 25°C	1 m 35°C	1 m 75°C	3.5 m 25°C	3.5 m 35°C	3.5 m 75°C
1	$CaSO_4 \rightleftharpoons Ca^{2+} + SO_4^{2-}$	−2.92	−2.91	−2.94	−3.16	−3.09	−3.34
2	$SO_2 + H_2O \rightleftharpoons H_2SO_3$	0.03	−0.13	−0.53	0.06	−0.09	−0.50
3	$CaSO_3 + SO_2 + H_2O \rightleftharpoons Ca^{2+} + 2\ HSO_3^-$	0.09	−0.26	−1.30	−0.52	−0.91	−1.89
4	$CO_2 + H_2O \rightleftharpoons H_2CO_3$	−1.51	−1.59	−1.78	−1.55	−1.62	−1.78
5	$CaCO_3 + CO_2 + H_2O \rightleftharpoons Ca^{2+} + 2\ HCO_3^-$	−4.91	−5.10	−5.56	−5.50	−5.80	−6.49
6	$CaSO_4 + SO_3^{2-} \rightleftharpoons CaSO_3 + SO_4^{2-}$	1.88	1.96	2.23	1.88	1.96	2.23
7	$CO_2 + H_2O \rightleftharpoons H^+ + HCO_3^-$	−7.55			−7.88		
8	$HCO_3^- \rightleftharpoons H^+ + CO_3^{2-}$	−9.57			−9.56		
9	$H_2SO_3 \rightleftharpoons H^+ + HSO_3^-$	−1.37			−1.72		
10	$HSO_3^- \rightleftharpoons H^+ + SO_3^{2-}$	−6.34			−6.36		
1−6	$CaSO_3 \rightleftharpoons Ca^{2+} + SO_3^{2-}$	−4.80	−4.87	−5.17	−5.04	−5.05	−5.57
3−2	$CaSO_3 + H_2SO_3 \rightleftharpoons Ca^{2+} + 2HSO_3^-$	0.06	−0.13	−0.77	−0.58	−0.82	−1.39
(3−2)−(1−6)	$SO_3^{2-} + H_2SO_3 \rightleftharpoons 2\ HSO_3^-$	4.86	4.74	4.40	4.46	4.23	4.18
9−10	$SO_3^{2-} + H_2SO_3 \rightleftharpoons 2\ HSO_3^-$	4.97			4.64		
7−4	$H_2CO_3 \rightleftharpoons H^+ + HCO_3^-$	−6.04			−6.33		

Note: CO_2 and SO_2 are gaseous (pressure in atm), H_2CO_3 and H_2SO_3 are in aqueous solution. "$CaSO_4$" = $CaSO_4(H_2O)_2$, "$CaSO_3$" = $CaSO_3(H_2O)_{\frac{1}{2}}$, $CaCO_3$ = calcite.

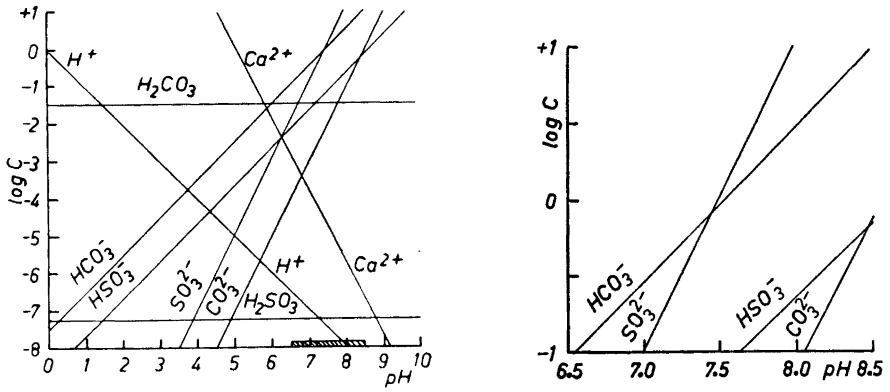

Fig. 1. Logarithmic diagram for aqueous solution (25°C, 1 m $NaClO_4$) in equilibrium with solid $CaCO_3$ and $CaSO_3$, and CO_2 of 1 atm. Horizontal axis: pH (= $-\log [H^+]$). Vertical axis: log of concentration of species in question. The approximate pH range of practical interest is marked out on the pH scale.

can be calculated in two independent ways, namely by combining the reactions 3 + 6 — 2 — 1 or 9 — 10 (Table 1). For 1 m Na^+ the results of the two calculations are 4.86 and 4.97; for 3.5 m Na^+ they are 4.46 and 4.64. The difference is 0.11 (0.18) in the logarithm, which is not too bad, considering the spread in the individual determinations, and the fact that for reactions 2 and 3 the ionic medium in the equilibrium solution differs substantially from the original one.

LOGARITHMIC EQUILIBRIUM DIAGRAMS

We shall now construct logarithmic diagrams, using the equilibrium constants we have found for 25°C and 1 m Na^+. First let us study the conditions imposed on the concentrations, if the solution is in equilibrium with CO_2 of 1 atm, solid $CaCO_3$, and solid $CaSO_3$. This is the state one may obtain by adding excess of calcium carbonate to a sulfite solution which has already absorbed some SO_2. We shall use the equilibrium constants for 4, 7, 8, 5, (1—6), 10 and 9. We use (1 minus 6), rather than (3 minus 2), which are slightly more uncertain. We find the following equilibrium conditions (Fig. 1):

1 atm CO_2: $\log [H_2CO_3] = -1.51$
$\log (HCO_3^-] = \text{pH} - 7.55$
$\log [CO_3^{2-}] = \log [HCO_3^-] + \text{pH} - 9.57 = 2\ \text{pH} - 17.12$
$CaCO_3$(s): $\log [Ca^{2+}] = -4.91 - 2 \log [HCO_3^-] = 10.19 - 2\ \text{pH}$
$CaSO_3$(s): $\log [SO_3^{2-}] = -4.80 - \log [Ca^{2+}] = 2\ \text{pH} - 14.99$
$\log [HSO_3^-] = \log [SO_3^{2-}] - \text{pH} + 6.34 = \text{pH} - 8.65$
$\log [H_2SO_3] = \log [HSO_3^-] - \text{pH} + 1.37 = -7.28$

From equilibrium 2 we see that $\log p_{SO_2}$ is less than — 7.
Provided that we have started with a pure sodium sulfite solution before

absorbing SO_2, we find the following condition on the concentrations (the charge, or electroneutrality condition):

$$2\,[Ca^{2+}] + [Na^+] + [H^+] = [HCO_3^-] + 2\,[CO_3^{2-}] + [HSO_3^-] + 2\,[SO_3^{2-}]\,(+\,[OH^-])$$

It will be immediately seen from the diagram that if $[Na^+]$ is 0.5 m or higher, $[Ca^{2+}]$ can certainly be neglected. The two predominant anionic species will be HCO_3^- and SO_3^{2-}; since the ratios $[HSO_3^-]/[HCO_3^-] = 10^{-1.10} = 0.079$ and $[CO_3^{2-}]/[SO_3^{2-}] = 10^{-2.13} = 0.0074$, the charge condition will be:

$$[Na^+] = 1.079\,[HCO_3^-] + 1.007\,[SO_3^{2-}] \approx [HCO_3^-] + [SO_3^{2-}]$$

We may thus expect the processes suggested in part I to be favored by equilibrium: if SO_2 is sorbed in a Na_2SO_3 solution, and excess $CaCO_3$ added, so much $CaSO_3$ will precipitate that the solution will finally contain a considerable amount of HCO_3^-.

Kinetic experiments on the reaction of $CaCO_3$ with $SO_3^{2-} + HSO_3^-$ solutions have confirmed that the reaction goes quickly to an equilibrium state corresponding to a mixture $HCO_3^- + SO_3^{2-}$. In the temperature interval studied, the times for establishment of equilibrium were of the order of minutes or tens of minutes.

CHECK ON $CaCO_3$ + $CaSO_3$ EQUILIBRIUM

Fist a series of experiments were made, where solid $CaCO_3$ and $CaSO_3$ were shaken with various $SO_3^{2-} + CO_3^{2-}$ solutions in order to study the equilibrium $CaCO_3(s) + SO_3^{2-} \rightleftharpoons CaSO_3(s) + CO_3^{2-}$. However, in these alkaline solutions, the reactions proved to be very slow, and even after several weeks had not reached equilibrium. The analytical ratios CO_3^{2-}/SO_3^{2-} kept changing and differed from each other and from any constant that could be calculated from the constants in Table 1. One reason may have been that the dissolution of $CaCO_3$ was inhibited, as may sometimes occur especially in the presence of traces of heavy metal ions (Erga and Terjesen [11]).

Attempts were made instead to study equilibria such as those described in Fig. 1, in the presence of $CaSO_3$, $CaCO_3$ and $CO_2(g)$ of 1 atm pressure. In

Table 2. Equilibrium with $CO_2(g)$, solid $CaCO_3$ + $CaSO_3(H_2O)_{\frac{1}{2}}$ at 25°C.

[Na+]	*a*	*b*	pH	log $[HCO_3^-]$	log $[HSO_3^-]$		log *K*	
					(a),	*(b)*,	*(a)*,	*(b)*
1.0	0.1064	0.0140	6.52	−1.08	−2.22	−2.24	1.14	1.16
1.0	0.1334	0.0168	6.61	−0.99	−2.17	−2.22	1.18	1.23
3.5	0.1326	0.0193	6.99	−1.04	−2.30	−2.38	1.26	1.34
3.5	0.1333	0.0262	6.95	−1.08	−2.18	−2.22	1.10	1.14
3.5	0.0928	0.0228	6.81	−1.22	−2.25	−2.17	1.03	0.97

Note: Concentrations on M scale, exept [Na+], which is 1.0 or 3.5 m.

$a = [HSO_3^-] + 2\,[SO_3^{2-}] + [HCO_3^-]$
$b = [HSO_3^-] + [SO_3^{2-}]$
$pH = -\log [H+]$

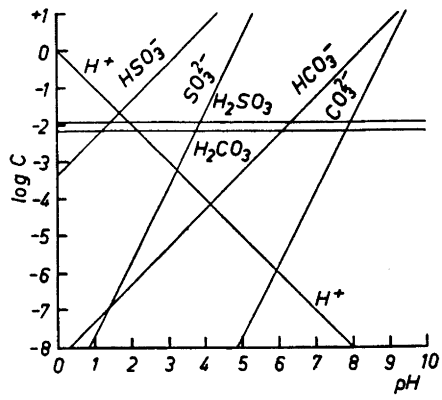

Fig. 2. Logarithmic diagram for aqueous solution in equilibrium with CO_2 of partial pressure 0.20 atm, and SO_2 of partial pressure 0.01 atm. Horizontal scale: pH, range of practical interest is between 2.5 and 4. Vertical axis: log of concentration of the various species.

this case, the equilibrium was established quite rapidly. From the original composition of the solution (a M $NaHSO_3$ or 2 a M Na_2SO_3) one knows

$$a = [HSO_3^-] + 2[SO_3^{2-}] + [HCO_3^-]$$

One may neglect $[CO_3^{2-}]$.

The solutions were analysed for Ca^{2+} (which was negligible) and total sulfite

$$b = [HSO_3^-] + [SO_3^{2-}]$$

as described in Part I. For the calculations it was necessary to know the "pH" (as above, —log h) which was measured for a sample of the equilibrium solution, still keeping it in 1 atm CO_2 atmosphere. Our experimental data are given in Table 2.

One could then calculate, using M units and the log K values 7.59 and 6.36 for 1 m Na^+ (for 3.5 m Na^+ 8.02 and 6.43):

$$[HCO_3^-] = p_{CO_2} \cdot 10^{pH-7.59}$$

$$[HSO_3^-] = \frac{a - [HCO_3^-]}{1 + 2.10^{pH-6.36}} \text{ or } [HSO_3^-] = \frac{b}{1 + 10^{pH-6.36}}$$

Table 2 gives the values of log K for

$$CaCO_3(s) + HSO_3^- \rightleftharpoons CaSO_3(s) + HCO_3^- \quad K = [HCO_3^-]/[HSO_3^-]$$

calculated with $[HSO_3^-]$ obtained in the two ways above, from a or from b. The average values are 1.18 ± 0.05 (1 m Na^+) and 1.15 ± 0.20 (3.5 m Na^+). We may also calculate this constant by means of two combinations:

(5—7) + (10 + 6 — 1) gives log K = 1.10 (1 m Na^+) and 1.06 (3.5 m Na^+)
(5—7 + (2 + 9 — 3) gives log K = 1.21 (1 m Na^+) and 1.24 (3.5 m Na^+)

The agreement with the direct equilibrium data is as good as might be expected.

SORPTION EQUILIBRIUM

We shall finally look at the equilibria in the sorption process. Let us suppose that the solution is brought to equilibrium with a flue gas with the partial pressures 0.01 atm for SO_2 and 0.20 atm for CO_2. By applying the equilibrium constants 2, 9, 10, 4, 7, and 8 for 25°C and 1 m Na^+ in Table 1 we find

$$\log [H_2SO_3] = -1.97$$
$$\log [HSO_3^-] = \log [H_2SO_3] + pH - 1.37 = pH - 3.34$$
$$\log [SO_3^{2-}] = \log [HSO_3^-] + pH - 6.34 = 2\ pH - 9.68$$
$$\log [H_2CO_3] = -1.51 - 0.70 = -2.21$$
$$\log [HCO_3^-] = -7.55 - 0.70 + pH = pH - 8.25$$
$$\log [CO_3^{2-}] = \log [HCO_3^-] + pH - 9.57 = 2\ pH - 17.82$$

The corresponding logarithmic diagram is given in Fig. 2. The charge condition will be:

$$[H^+] + [Na^+] + 2\ [Ca^{2+}] = [HSO_3^-] + 2\ [SO_3^{2-}] + [HCO_3^-] + 2\ [CO_3^{2-}]\ (+ [OH^-])$$

It is easily seen from Fig. 2 that under these conditions any ions of carbonic acid will be very thoroughly removed from the solution and replaced by HSO_3^- ions.

Acknowledgment. The work in these papers has been made possible by the generous support of Mo och Domsjö AB. We are especially indebted to Sixten Ulfsparre, Vice President in charge of production and development, and to Dr. Axel Scholander for valuable discussions and assistance in many ways. In the practical work, many members of the staff of the Department of Inorganic Chemistry have given valuable aid. Especially Mr. Erik Ekedahl and Dr. George Biedermann have been very helpful in discussing analytical problems, and Mr. Frans Ericson has given valuable practical aid. Some of the analyses were carried out by Mr. Bo Mueller and Mrs. Margareta Millén.

ACTA CHEMICA SCANDINAVICA 12 (1958) 885—890

On the Characterization of 2-Nitromorphine

H. BAGGESGAARD RASMUSSEN and PER M. BOLL

Department of Organic Chemistry, Royal Danish School of Pharmacy, Copenhagen, Denmark

2-Nitromorphine, which has been stated to be either a nitroso or a nitro derivative, is found to be, in fact, 2-nitromorphine. The elementary analyses and the titanometric titration were in agreement with a nitro derivative. Four moles of hydrogen were used for reduction. If the compound had been a nitroso derivative the uptake of 4 moles of hydrogen could only have been explained through a reductive splitting of the oxygen bridge in the molecule. That was not the case as it was possible to isolate dihydromorphine after diazotization of the reduced compound and replacement of the diazo group with hydrogen. Furthermore, the infrared spectrum supports the concept that a nitro group is present *ortho* to the phenolic hydroxyl group.

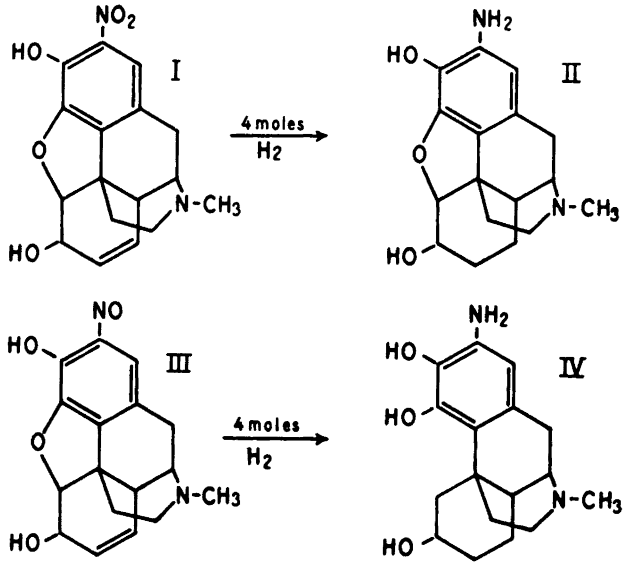
In 1918 Wieland and Kappelmeier [1] prepared a derivative of morphine, called 2-nitrosomorphine, by reacting an aqueous suspension of morphine hydrochloride with nitrous fumes at —2°C to —3°C. This compound has in alkaline solution a distinct red colour and has been used in colourimetric methods for determination of morphine in the presence of other alkaloids.

Baggesgaard Rasmussen *et al.*[2] have developed a method for determination of morphine based on the polarographic determination of 2-nitrosomorphine. The elementary analyses given in this paper for the latter compound were in agreement with a nitroso derivative.

However, two Japanese workers, Ochiai and Nakamura [3], have shown that the compound formed by the procedure of Wieland and Kappelmeier is not 2-nitrosomorphine but 2-nitromorphine. None of the numerous papers published on the determination of morphine by means of "2-nitrosomorphine" seem to have taken notice of the Japanese publication, as all papers mention the "2-nitrosomorphine method".

The purpose of this publication is to confirm the results obtained by Ochiai and Nakamura.

The 2-nitromorphine was prepared following the procedure given by Wieland and Kappelmeier. In the course of the investigation several batches of the compound were prepared and each time the experimental conditions mentioned by the latter authors were followed as closely as possible. The compound was extremely difficult to purify by recrystallization just as it



was difficult to reproduce the elementary analyses, especially the Dumas nitrogen determinations. This is apparently due to the fact that the compound is difficultly combustible. Column chromatography on alumina gave a pure compound and left a fairly large amount of side products adsorbed on the alumina. This is in agreement with the findings of Wieland and Kappelmeier that the reaction of nitrous acid with morphine affords different products and is highly dependent on temperature and time of reaction.

The resulting chromatographically pure 2-nitromorphine hydrochloride was titrated with titanium trichloride and gave an equivalent weight of 67. If the compound had been a nitroso derivative it would have required 4 equivalents of titanium trichloride for reduction and would have given a molecular weight of 268, whereas a nitro derivative requires 6 equivalents of titanium trichloride. The equivalent weight multiplied by 6 gives a molecular weight of 402, a value which is in agreement with the calculated value for 2-nitromorphine hydrochloride with 2 1/2 moles water of crystallization. The elementary analyses found and the analyses given by Ochiai and Nakamura are also in agreement with a hydrate of this composition.

By catalytic reduction of 2-nitromorphine the uptake of hydrogen was 4 moles. If the compound had been a nitroso derivative(III) this fact could only have been explained by an additional reductive splitting of the oxygen bridge. The reaction product would then be a monoaminotrihydroxy derivative(IV). This did not seem to be the case as it was possible to convert the reduced amino compound(II) to dihydromorphine by means of diazotization and a following replacement of the diazo group with hydrogen.

The absorption curves for 2-nitromorphine hydrochloride and the potassium salt 2-nitromorphine recorded for the ultraviolet part of the spectrum

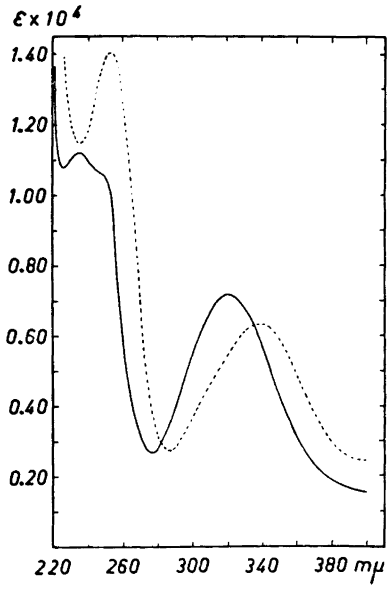


Fig. 1. The ultraviolet absorption spectra of 2-nitromorphine hydrochloride (full line) and the potassium salt of 2-nitromorphine (broken line).

are given in Fig. 1 and are similar to curves given earlier for "2-nitrosomorphine hydrochloride" and the potassium salt of "2-nitrosomorphine" [2].

Ochiai and Nakamura [3] observed that the compound did not give Liebermann's nitroso reaction or liberate iodine of an acidified potassium iodide solution. This was confirmed by this investigation just as the compound was found not to reduce Fehling's or Tollens' reagents. These negative results are, of course, in agreement with the concept that the compound is a nitro compound. On the other hand, we have tried the same reactions on 1-nitroso-2-naphtol and even in this case found them negative.

In the infrared part of the spectrum a nitroso compound (N↔O) is characterized by only one absorption band whereas a nitro compound due to both symmetrical stretching $\left(-\mathrm{N}\begin{smallmatrix}\swarrow\mathrm{O}\\ \rightarrow\\ \nwarrow\mathrm{O}\end{smallmatrix}\right)$ and unsymmetrical stretching $\left(-\mathrm{N}\begin{smallmatrix}\nearrow\mathrm{O}\\ \rightarrow\\ \nwarrow\mathrm{O}\end{smallmatrix}\right)$ is characterized by two absorption bands. All these bands have to be strong. The spectrum of the compound considered to be 2-nitromorphine hydrochloride has indeed such two bands at 1 525 and 1 350 cm^{-1}. These frequencies correspond closely to the frequencies expected for a nitro compound. A nitroso compound, on the other hand, should have given only one band at 1 525 cm^{-1}.

It has been shown by Amstuts *et al.*[4] that the fundamental band of hydroxyl absorption in the infrared part of the spectrum is lacking for 1-nitroso-2-naphtol, whereas 1-nitro-2-naphtol exhibits a definite, although weak band at approximately 3 250 cm^{-1}. This has been confirmed by one of us[5], who also

Table 1. Fundamental bands of hydroxyl and amine absorption in the infrared part of the spectrum.

Compound	Hydroxyl and amine band (cm^{-1})				Interpretation
	solid (KBr)		in $CHCl_3$		
2-Nitromorphine hydrochloride	3 450	(NH)	3 620	(NH)	intermolecular H-bond
	3 360	(OH)	3 540	(OH)	intermolecular H-bond
	3 220	(OH)	3 220	(OH)	intramolecular H-bond
Morphine hydrochloride	3 450	(NH)	3 620	(NH)	intermolecular H-bond
	3 360	(OH)	3 540	(OH)	intermolecular H-bond

showed that 4-nitrosoresorcinol did not give the fundamental band of hydroxyl absorption contrary to 4-nitroresorcinol *, which gave a distinct band.

2-Nitromorphine hydrochloride exhibits the same type of band as 1-nitro-2-naphtol and 4-nitroresorcinol at approximately 3 220 cm^{-1} and the bond is not shifted to a higher frequency by dissolving the compound indicating an intramolecular type of bonding. This observation that an intramolecular hydrogen bond is present, even in solution, appears to give further evidence for the compound being a nitro derivative. The presence of this intramolecular type of hydrogen bonding seems also to support the concept that the nitro group is *ortho* to the phenolic hydroxyl group.

EXPERIMENTAL

The melting points are corrected and have been determined with the hot stage microscope essentially according to Kofler.

Potassium salt of 2-nitromorphine. The compound was prepared according to Wieland and Kappelmeier [1] and purified by column chromatography in the following manner:

3.5 g of the crude potassium salt of 2-nitromorphine dissolved in 100 ml of methanol was poured onto a column of wet-packed alumina (Alcoa) and eluted with 90 % methanol. After collection of a 200 ml fraction, the eluant was changed to 70 % methanol and 120 ml had to be collected before the strongly red-coloured salt appeared in the eluate.On the alumina remained a very dark red-coloured band which only could be eluted with dilute hydrochloric acid.

Table 2. Fractionation of the potassium salt of 2-nitromorphine by column chromatography on alumina.

Fraction	Eluant	Volume (ml)	Colour	Weight of residue
I	effluent	100	colourless	0.004 g
II	90 % CH_3OH	200	weak yellow	0.012 g
III	70 % CH_3OH	120	weak yellow	0.037 g
IV	70 % CH_3OH	375	red	2.71 g

* It has to be mentioned that the hydroxyl group placed in the *para*-position to the nitro or nitroso group in 4-nitroresorcinol and 4-nitrosoresorcinol, respectively, showed intermolecular type of hydrogen bonding.

The salt which appeared as the residue after evaporation of fraction IV to dryness was recrystallized twice from 96 % ethanol. The needle-shaped, dark red crystals were dried in the air. When tested by paper chromatography the crystals gave only one spot. The crystals were chromatographed by descending chromatography at 25°C on Whatman No. 1 paper using water-saturated 1-butanol as developing reagent. The compound was visible as a red spot with an R_F-value = 0.42. In ultraviolet light no other spots could be detected. (Found: C 47.15; H 6.00; H_2O 13.40. Calc. for $C_{17}H_{18}O_3N(NO_2)K \cdot 3\ 1/2\ H_2O$ (mol.wt. 432.5): C 47.33; H 5.84; H_2O 14.61).

2-Nitromorphine hydrochloride. To a suspension of 2 g potassium salt in 10 ml of water was at one time and under stirring added 4 ml of 4 N hydrochloric acid. The salt dissolved and the yellow hydrochloride precipitated shortly after. After standing the hydrochloride was collected by filtration and washed with N hydrochloric acid. The yellow crystals were recrystallized from N hydrochloric acid and air-dried. (Found: C 49.40; H 5.77; H_2O 10.05. Calc. for $C_{17}H_{18}O_3N(NO_2) \cdot HCl \cdot 2\ ½\ H_2O$ (mol.wt. 411.8): C 49.59; H 5.87; H_2O 10.94.)

The uptake of hydrogen was determined quantitatively by means of the microhydrogenation apparatus described by Clauson-Kaas and Limborg [6]. Uptake: 4.03 moles of H_2 (Calc. for $C_{17}H_{18}O_3N(NO_2) \cdot HCl \cdot 2\ ½\ H_2O$: 4.00 moles of H_2).

After drying 2-nitromorphine hydrochloride *in vacuo* over phosphorus pentoxide the values were as follows: Found: C 53.25; H 5.57. Calc. for $C_{17}H_{18}O_3N(NO_2) \cdot HCl \cdot H_2O$: C 63.08; H 5.50.

Silver salt of 2-nitromorphine. The salt was prepared according to the procedure given by Wieland and Kappelmeier [1]. The salt precipitated as an insoluble voluminous red compound, which after drying changed to a nearly black powder. (Found: Ag 24.80. Calc. for $C_{17}H_{18}O_3N(NO_2)Ag$: Ag 24.61.)

2-Aminodihydromorphine hydrochloride. 3 g of the potassium salt of 2-nitromorphine was dissolved in 70 ml of water, 2 equivalents of hydrochloric acid were added and the compound was catalytically reduced using palladium carbon (5 %). After reduction the catalyst was removed by filtration and the filtrate evaporated under reduced pressure. The oily residue was dissolved in a little methanol and evaporated again. Addition of ethanol to the residue gave sandy crystals which after recrystallization from ethanol-methanol melted at 320—325°C (Lit.value[3] 325°C).

Transformation of 2-aminodihydromorphine to dihydromorphine. The aminomorphine was diazotized following the procedure of Wieland and Kappelmeier [1]. To 1.5 g of the hydrochloride suspended in 30 ml absolute ethanol was added under cooling 2.25 g of ethyl nitrite (prepared after Wallach and Otto [7]) and finally 3 ml of 19.5 % ethanolic hydrochloric acid.

The diazo compound was precipitated by addition of ethyl ether, removed by filtration, washed with more ethyl ether and immediately dissolved in 5 ml of absolute ethanol. Now 0.5 g of copper powder was added and the suspension was carefully heated to beginning nitrogen evolution. After cooling the suspension was filtered and the filtrate evaporated to dryness and then extracted with ethyl ether. The residue was now dissolved in a little water and sodium carbonate was added to precipitate the alkaloid. An amorphous and dark-coloured compound precipitated. Recrystallization from ethanol-water gave no purification. Therefore, it was purified on Amberlite IR-120. 100 mg of the crude product dissolved in 10 ml of methanol was chromatographed on the resin (H+ form, 9 cm × 1.6 cm), washed with 30 ml methanol and eluted with 0.5 N methanolic ammonia water. Only a few mg of product was obtained after evaporation of solvent. After recrystallization from methanol the crystals melted at 154—156°C (Lit. value [8] 155—157°C) and mixed with authentic dihydromorphine the melting point did not show any depression. Furthermore, the infrared spectrum of the isolated compound was identical with the spectrum of dihydromorphine.

Titanometric titration of the potassium salt and the hydrochloride. To a weighed sample (about 50 mg) in 10 ml glacial acetic acid was added 30 ml 2 N sodium acetate solution. During the titration carbon dioxide was led through the solution. After 5 min of carbon dioxide flow, a measured excess of titanium trichloride solution kept in a carbon dioxide atmosphere was added. After another 5 min, 20 ml of concentrated hydrochloric acid was added and the excess of titanium trichloride was titrated with 0.06 N ammonium thiocyanate using ferric ammonium sulphate as an indicator. The actual amount of titanium trichloride used for reduction was determined by titration of a blank (Table 3).

Table 3. Titanometric titration of two nitromorphine derivatives.

Compound	Equiv. wt. found	Mol. wt. of nitroso cpd.	Mol. wt. of nitro cpd.
Potassium salt of 2-nitromorphine	68 68.5	272 274	408 411
2-Nitromorphine hydrochloride	67 67	268 268	402 402

The infrared spectra of 2-nitromorphine hydrochloride, morphine hydrochloride and dihydromorphine were obtained on a Perkin-Elmer Spectrophotometer Model 21. Besides recording the spectra of the compounds in pressed potassium bromide discs, the spectra of the two first compounds were recorded as saturated solutions in chloroform.

Elementary analyses are by Mr. P. Hansen, Universitetets kemiske laboratorium, Copenhagen and the microhydrogenation determination by Mr. W. Egger, Novo Terapeutisk Laboratorium, Copenhagen. The authors are indebted to Professor Børge Bak, University of Copenhagen, for a discussion of the infrared spectrum of 2-nitromorphine hydrochloride.

On the Products Obtained from Ketones with Ammonium Polysulphide

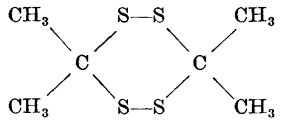
ARNE FREDGA

Chemical Institute, University of Uppsala, Uppsala, Sweden

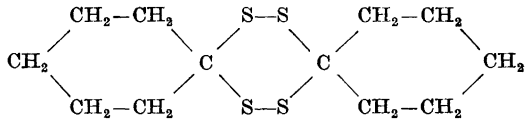
Two compounds obtained from *cyclo*hexanone and *cyclo*heptanone with ammonium polysulphide at room temperature are described (II, IV). The former contains a 1,2,4,5-tetrathiane ring in spirocyclic combination. The latter has a seven-membered ring with two carbon and five sulphur atoms (1,2,3,5,6-pentathiepane ring).

In 1887 Willgerodt published his first investigations on the reaction between ketones and ammonium polysulphide [1]. At higher temperatures, the ketone is transformed to an amide; this rather peculiar reaction has been studied by several authors and is now generally known as Willgerodt's reaction [2].

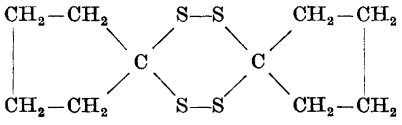
If a solution of polysulphide was left to stand with acetone at room temperature, however, Willgerodt obtained a crystalline compound answering to the formula $(CH_3)_2CS_2$. He assumed it to be dimeric and called it "duplodithioacetone". The structure was not discussed, but of course the formula I with a 1,2,4,5-tetrathiane ring is near at hand. In the "Ring Index" this structure is also postulated [3]. In connection with work in progress on the



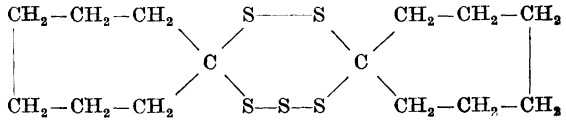
I



II



III



IV

disulphide group, an investigation on compounds of this type has been started in collaboration with Mr. B. Magnusson.

The acetone derivative is easily obtained according to Willgerodt's directions, but the preparation of higher homologues and derivatives from aromatic ketones met with difficulties, which have not been overcome as yet. Camphor did not react at all, even on standing for a long time. More promising results were obtained, however, with simple cyclic ketones. *Cyclo*hexanone yields a readily crystallising compound (m.p. 130.5—131.5°), which must be ascribed the spirocyclic structure II. *Cyclo*pentanone gives mostly dark-coloured, smeary products, but Mr. Magnusson could isolate the compound III (m.p. 151.5—153°) in low yield [4].

The results obtained with *cyclo*heptanone were rather unexpected. The compound isolated (m.p. 127—128°) has the formula $C_{14}H_{24}S_5$, thus containing five sulphur atoms instead of four. According to modern investigations [5,6], the occurrence of branched sulphur chains in organic compounds is very unlikely and the compound obtained from *cyclo*heptanone must thus be ascribed the formula IV. To the author's knowledge, a ring containing two carbon and five sulphur atoms (1,2,3,5,6-pentathiepane) has not been described previously.

An explanation of the different behaviours of *cyclo*hexanone and *cyclo*heptanone cannot be given at present. Preliminary experiments with the two ketones and preparations of ammonium polysulphide with various amounts of sulphur (from $(NH_4)_2S_2$ to $(NH_4)_2S_4$) gave only the compounds II and IV, respectively, in some cases contaminated with free sulphur. It is possible that the crude reaction mixture represents a dynamic equilibrium of substances with different sulphur-containing rings (perhaps also open chain polymers), and that the most readily crystallising compound ultimately separates.

The question of the conformation of the sulphur-containing rings is of a certain interest. For the six-membered ring, the rigid chair form (Fig. 1 A) is of course possible. The corresponding boat form is pliable and permits a series of arrangements; two extreme forms are represented by Figs. 1 B and C. Owing to the rather bulky groups attached to the carbon atoms, formula B must be excluded, but the boat form C seems quite reasonable and must be taken into consideration. The formulas A and B are symmetrical (the former has also a center of symmetry) and the sulphur atoms lie in one plane. Formula C has no plane or center of symmetry and the sulphur atoms are not situated in the same plane.

A crystallographic investigation has been started by Dr. I. Lindqvist in collaboration with Mr. R. Rosenstein, who have kindly submitted some preliminary results. As stated already by Willgerodt, the acetone derivative (I)

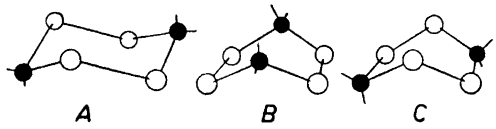


Fig. 1. Conformations of the tetrathiane ring.

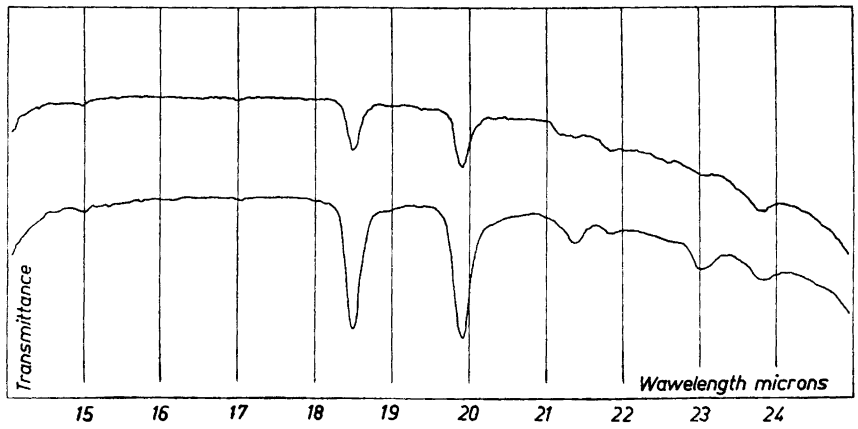

Fig. 2. IR absorption curve of the *cyclo*hexanone derivative.

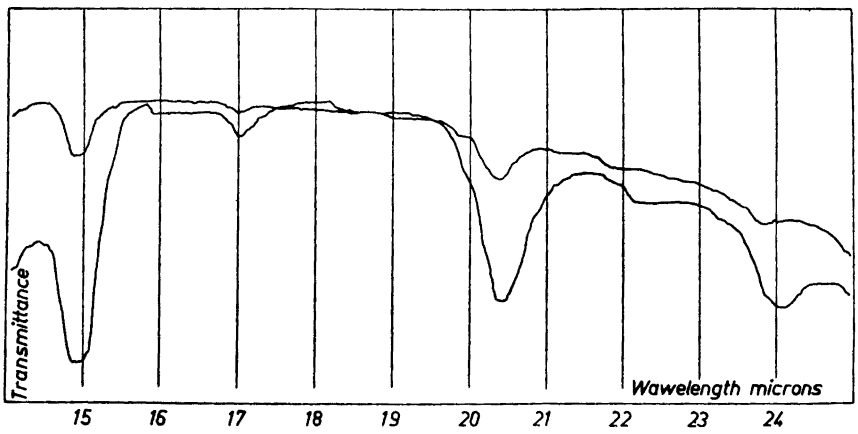

Fig. 3. IR absorption curve of the *cyclo*heptanone derivative.

is tetragonal and it seems that the molecules in the crystal have the conformation C (Fig. 1). The *cyclo*pentanone derivative (III) might possibly represent the conformation A. Both structures are comparatively simple.

The structure of the *cyclo*hexanone derivative (II) is more complicated and the results obtained as yet do not permit any conclusions as to the conformation.

For the seven-membered sulphur-containing ring in the *cyclo*heptanone derivative (IV) several conformations are possible. The preliminary data indicate that the structure is very complicated with a rather large unit cell.

Figs. 2 and 3 show the IR-spectra for the compounds II and IV in the region 14—25 μ, where the C—S and S—S bond frequencies should be located.

In the spectrum of the *cyclo*hexanone derivative (Fig. 2), the band at 19.9 μ might possibly be attributed to the S—S linkage; it should be said, however, that in our experience the S—S bands are in most cases broader and less distinct. Curiously enough there is no indication for a C—S band in the region 14—16 μ; the distinct band at 18.5 μ must have another origin and might be due to structural vibrations. The non-appearance of the C—S frequency might perhaps be due to special symmetry conditions in the molecule.

In the spectrum of the *cyclo*heptanone derivative, which is less symmetrical (Fig. 3), we find the C—S band at 14.9 μ and the S—S band at 20.4 μ. It is obvious that the sulphur-containing ring system is not the same in the two compounds. On the other side, there is no indication for the occurrence of a branched chain containing a coordinative or double sulphur-sulphur bond.

Preliminary IR-studies on the compounds I and III indicate that the acetone derivative (I) shows the normal C—S and S—S bonds, whereas they are missing in the spectrum of the *cyclo*pentanone derivative (III). This is in agreement with the crystallographic results, according to which only the latter compound should have a ring conformation with a center of symmetry.

A more detailed discussion of the spectra should be postponed until the conformation of the rings is established by crystallographic methods.

EXPERIMENTAL

Cyclo*hexanone derivative (Bis-3,3,6,6-pentamethylene-1,2,4,5-tetrathiane)*. *Cyclo*hexanone (0.1 mole) is left to stand with a concentrated solution of ammonium disulphide (0.25 mole) in a closed vessel with occasional shaking. Gradually the ketone layer sinks to the bottom and changes to a yellow mixture of smears and crystals. When no further change can be observed (after 4—5 days), the product is separated, washed with water and triturated with ethanol or methanol, which dissolves the smeary by-products leaving dry, pale yellow crystals. Repeated recrystallisations from ligroin and propanol, if necessary with charcoal, give a colourless product. Short-prismatic crystals with m. p. 130.5 —131.5°. The compound is easily soluble in benzene, chloroform and carbon disulphide. (Found: C 48.9; H 6.87; S 44.07; mol.weight 293, 299, 286. Calc. for $C_{12}H_{20}S_4$: C 49.25; H 6.89; S 43.83; mol.weight 292.5).

Cyclo*heptanone derivative (Bis-4,4,7,7-hexamethylene-1,2,3,5,6-pentathiepane)*. *Cyclo*heptanone (0.1 mole) was added to a solution of ammonium disulphide (0.25 mole) as described above. In this case the reaction proceeds more slowly and it is appropriate to shake the mixture on a machine for the first 10 h. After standing for about one week, the mixture is worked up as described above and the product recrystallised from propanol and ligroin. Colourless, thin needles with m. p. 127—128°, easily soluble in benzene, chloroform, and carbon disulphide. (Found: C 47.85; H 6.90; S 45.39; mol.weight 363, 340, 336. Calc. for $C_{14}H_{24}S_5$: C 47.68; H 6.86; S 45.46; mol.weight 352.6).

The *molecular weights* were determined by the boiling point method in benzene solution. Some experiments with the Rast method gave consistent results. The *IR-spectra* were recorded with a Perkin-Elmer model 21 double-beam spectrophotometer with a potassium bromide prism. The substances were studied in Nujol emulsions of two different concentrations.

The author is indebted to Dr. I. Lindqvist for preliminary reports on the crystallographic investigation and to Mr. B. Magnusson for private communications and part of the analyses. Thanks are also due to Dr. A. Rosenberg and Mr. S. Bergwall for expert advice and technical assistance in the IR-work.

On the Effect of Small Amounts of some Organic Compounds on the Ferric Ion Catalyzed Hydrogen Peroxide Decomposition

V. STEN ANDERSEN and H. NIEMANN

Department of Inorganic Chemistry, The Royal Danish School of Pharmacy, Copenhagen, Denmark

The authors have investigated the influence of benzene, phenol, phenacetin, and hydroquinone on the rate of the ferric-ion catalyzed hydrogen peroxide decomposition.

The experiments show that benzene, phenol, and phenacetin cause an induction period, the length of which depends on the amount of compound added; after the induction period the rate of reaction is greater than that of the pure ferric-catalyzed reaction. Hydroquinone does not retard the reaction but acts as a promotor from the very start of the reaction.

These findings seem to indicate that a reaction mechanism based on a chain reaction catalyzed by ferrous ions, similar to that proposed by Koefoed [1], is to prefer to the one put forward by Christiansen and Andersen [2], which is based on an open sequence reaction.

The experiments were carried out in a Brønsted shaking apparatus [3] modified in such a manner that the pressure of the oxygen evolved could be measured at constant volume, although the manometer was made of fairly wide glass tubing, in order to suppress the capillary forces.

In 1950 Christiansen and Andersen [2] proposed a reaction mechanism for the Fe(III)-catalyzed hydrogen peroxide decomposition which was based on an open sequence:

$$\begin{aligned} FeOOH^{++} &\rightleftharpoons Fe^{+++} + H\overset{*}{O}_2^- \\ H\overset{*}{O}_2^- + H_2O_2 &\rightarrow O_2 + OH^- + H_2O \end{aligned} \qquad \text{I}$$

($H\overset{*}{O}_2^-$ represents an activated hydrogen peroxide ion).

This scheme, although it fits very closely to the experimental results, has been met with some scepticism because it does not explain the fact that the

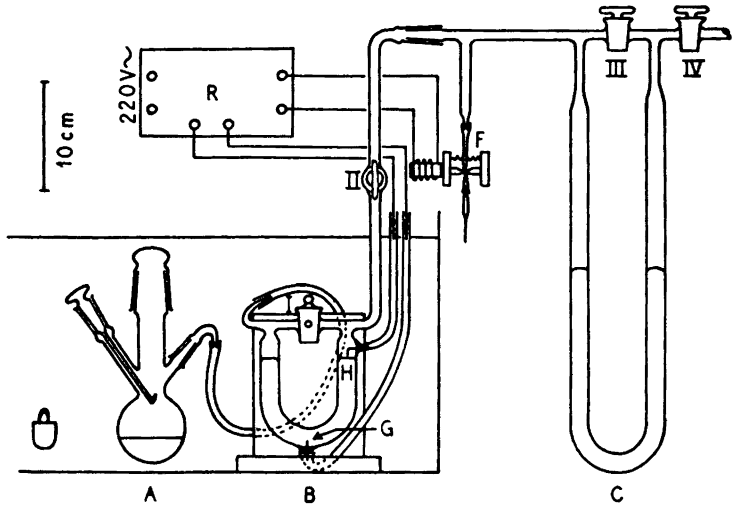

Fig. 1. A modified Brønsted shaking apparatus used for the experiments.

reaction is strongly retarded by small amounts of organic compounds (Bray and Peterson [4]) or the finding of Kuhn and Wassermann [5] who have demonstrated that ferrous ions can be detected in the reaction mixture. These features indicate a chain reaction and a valence shift of the iron ions. Koefoed [1] and Christiansen [6] have discussed such a reaction pattern, proposed by the former and based on a closed sequence.

In the present paper we have given an account of some new kinetic experiments on the influence of some benzene derivatives: benzene, phenol, phenacetin, and hydroquinone on the reaction in question and we have from a qualitative point of view discussed the experimental results in connection with the reaction schemes mentioned above.

EXPERIMENTAL

The kinetic experiments were carried out in a modified Brønsted shaking apparatus [3] by measuring the pressure of the oxygen evolved. The apparatus (Fig. 1) was constructed in such a manner that it was possible to measure the gas pressure at constant volume even though the manometer was made of glass tubing with an inner diameter of 14 mm. The reaction vessel A (volume about 165 ml) was mounted in an ordinary shaking apparatus. It was furnished with a side arm closed by a glass stopper onto which was sealed a glass rod; the end of this rod was formed as a small hook upon which a small plastic vessel (volume about 2 ml) could be hung.

The reaction vessel was connected to one side of a differential-tensiometer B by a piece of flexible plastic tubing. The tensiometer was again connected to a mercury manometer C, which was connected to a vacuum line on the other side. F is a piece of soft plastic tubing which served as a valve. This valve could be closed by means of two metal jaws pressed together by an ajustable spring. To prevent the walls sticking together they were lubricated with silicone oil ('formslip').

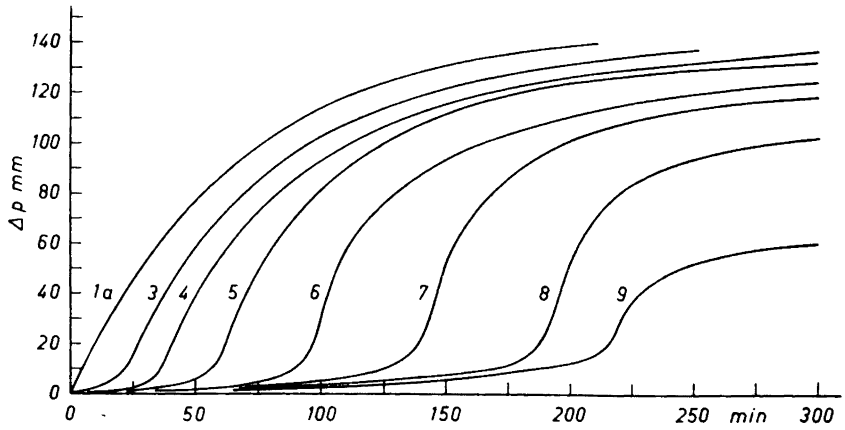

Fig. 2. Reaction curves from the experiments with phenacetin as an inhibitor. The pressure of the oxygen evolved is plotted against time. The reacting mixtures were all 0.003 M as to ferric perchlorate, 0.01 M as to perchloric acid and 0.046 M as to hydrogen peroxide. Temp. 25°C.

The molar concentrations of phenacetin were:

Concentration of phenacetin × 10^5:	0.0	3.03	6.06	12.1	24.2	45.5	91.0	227
Curve No:	1 a	3	4	5	6	7	8	9

The differential-tensiometer was furnished with two wolfram electrodes, G and H, and it was filled with enough mercury to enable the mercury level to touch the electrode H, when tap I was open. To avoid vibrations the tensiometer was mounted on a stand attached to a heavy lead base. The electrodes were used as a pick-up for a thyratron relay R, which was able to open the valve F by the electromagnet M when the mercury in the tensiometer touched the electrode H.

In this manner it is possible, on the wide manometer C, to measure at constant volume an increasing pressure which is smaller than the atmospheric pressure, in the reaction vessel A; of course the relay can easily be rearranged so that it works at decreasing pressure.

The modified Brønsted apparatus has the following advantages in preference to the original one:

1) It is possible to measure the pressure at constant volume.

2) The pressure can be measured with a greater accuracy in the wide manometer because the capillary effect is much smaller than in a narrow one *.

3) The resistance in the plastic tubing is much smaller than in the flexible glass tubing used by Brønsted because it is made much shorter and wider; in addition to this it is not breakable and therefore easier to handle.

The experiments were carried out as follows:

40.00 ml of an aqueous solution of ferric perchlorate acidified with perchloric acid was pipetted into the flask A; a known amount (about 1 ml) of a hydrogen peroxide stock-solution was placed in the plastic vessel which then was hung on the turnable hook. The flask was closed, the taps I, II, III and IV were opened, the relay switched off to close valve F and the whole system was evacuated for about 5 min. Subsequently the tap I was closed and the system (minus the reaction vessel) was evacuated to a pressure not

* See for instance: Ostwald-Luther, *Hand- und Hilfsbuch zur Ausführung physiko-chemischer Messungen.* Academische Verlagsges. Leipzig 1931, p. 197.

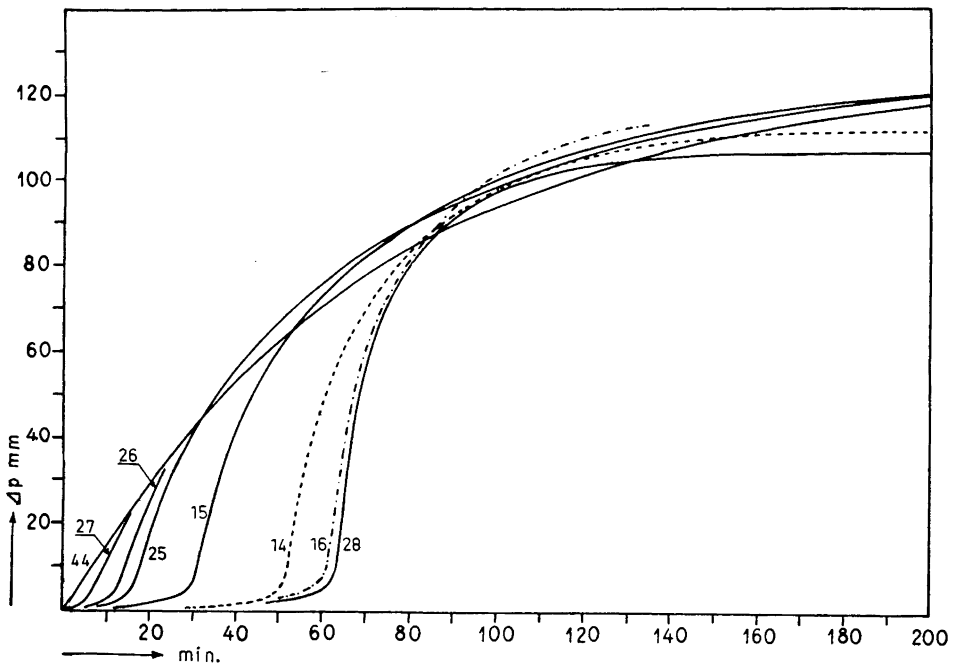

Fig. 3. Reaction curves from the experiments with phenol as inhibitor. The experimental conditions were all the same as those given in the subscript to Fig. 2.

The concentrations of phenol were:								
Concentration of phenol × 10^3:	0.0	0.010	0.030	0.052	0.102	0.260	0.517	1.03
Curve No:	44	27	26	25	15	14	16	28

exceeding 0.01 mm and the taps III and IV were closed. During this phase of the evacuation the water vapour in the reaction flask had moved the mercury in the tensiometer so much that the electrode H was submerged in the mercury. Therefore, when the relay then was switched on, it began to work and opened the valve F which let in air until the mercury no longer touched the electrode H; simultaneously the mercury in the manometer moved, so that when equilibrium was obtained, the pressure in the reaction vessel could be read on the manometer, by means of a reading microscope.

The reaction was started by dropping the plastic vessel with hydrogen peroxide into the solution in the reaction flask, and switching on the shaking apparatus; the rate of reaction was measured by reading the gas pressure as described above.

Four series of experiments were carried out: One with phenacetin, one with benzene, one with phenol, and finally one with hydroquinone.

The experimental results, together with the experimental conditions, are given in the Figs. 2, 3 and 4. We have not given the results from the experiments with benzene as inhibitor because they were not reproducible; due to the volatility of the benzene it was not possible to prevent its disappearance from the reaction mixture during evacuation of the apparatus.

It appears from Figs. 2 and 3 that phenacetin and phenol on the whole act in the same way; both interfere very strongly with the pure Fe(III)-catalyzed reaction: They cause an induction period during which no oxygen or only a small amount of oxygen is evolved.

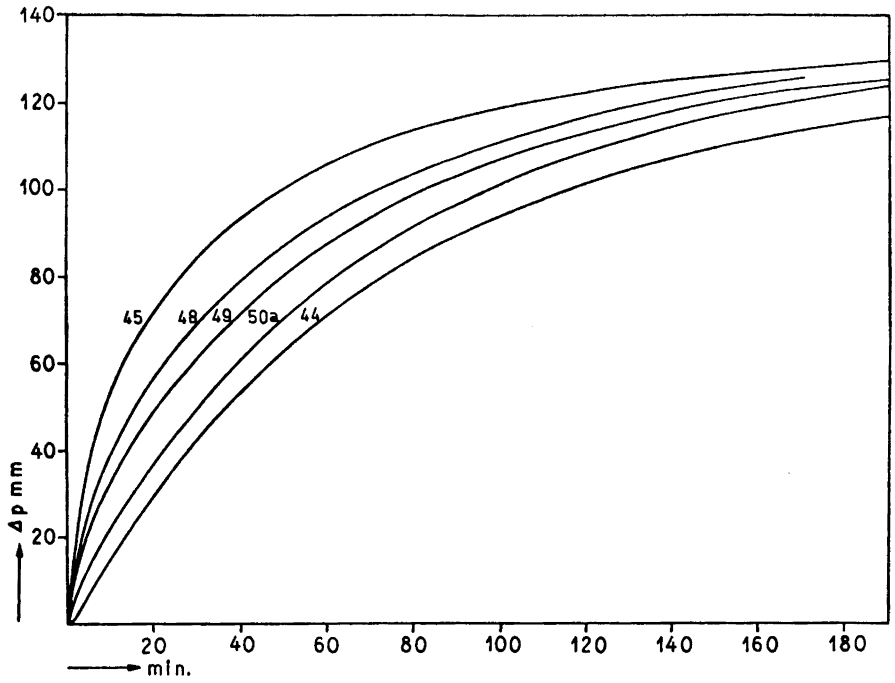

Fig. 4. Reaction curves for the experiments with hydroquinone. The experimental conditions were the same as those given in the subscript to Fig. 2.

The concentrations of hydroquinone were:

Concentration of hydroquinone × 10^4:	0.0	0.09	0.46	0.90	2.29
Curve No:	44	50 a	49	48	45

After this period, the hydrogen peroxide starts to decompose with a rate which is greater than that of the pure Fe(III)-catalyzed reaction. The experiments with greater amounts of inhibitor (see Fig. 2) show that a portion of the hydrogen peroxide is not decomposed into oxygen; obviously it is used for oxidizing the organic compound added. It should be mentioned that the experiments with benzene showed the same features as those just described. The reaction mixtures all turned more or less brown during the induction period.

The reaction curves in Fig. 4 show that hydroquinone, contrary to the compounds dealt with above, does not cause any induction period, but that it acts as a promotor from the very start of the reaction — or in other words it speeds up the Fe(III)-catalysis.

DISCUSSION

It seems difficult, if not impossible, to explain the experimental results by means of a reaction mechanism containing an open sequence similar to that proposed by Christiansen and Andersen [2] (scheme No. I on page 896). As pointed out by Bray and Peterson [4] and recently by Koefoed [1] the retarding

effect described above is much better explained by a reaction pattern containing a closed sequence. Koefoed has proposed the following chain reaction:

$$\begin{aligned} &Fe^{++} + FeO_2H^{++} \rightleftharpoons Fe \cdot FeO_2H^{++++} && 12 \\ &Fe \cdot FeO_2H^{++++} \rightleftharpoons OFeOH^{+} + Fe^{+++} && 23 \qquad \text{II} \\ &OFeOH^{+} + H_2O_2 \rightarrow Fe^{++} + O_2 + OH^{-} + H_2O && 31 \end{aligned}$$

(Concerning details of this scheme the reader is referred to Koefoed's paper).

If we, as Koefoed did, consider the $OFeOH^{+}$-ion as the most reactive intermediate the action of the inhibitor must be the removal of that intermediate (with benzene as an example):

$$OFeOH^{+} + C_6H_6 = Fe^{++} + C_6H_5OH + OH^{-} \qquad \overline{31}$$

that is to say that the inhibitor itself as illustrated in Fig. 5 is oxidized by a chain reaction.

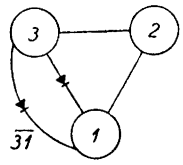

Fig. 5. Flow sheet of Koefoed's reaction cycle supplemented by reaction $\overline{31}$.

It does not seem unreasonable to assume that the phenol formed by reaction $\overline{31}$ again is oxidized to hydroquinone by a reaction similar to $\overline{31}$, because we know from the experiments that phenol also acts as an inhibitor.

In Koefoed's scheme the ferrous ion is presumed to act as a catalyst. Therefore, if we are able to increase the ferrous ion concentration in the reaction mixture, that should involve an increase of the rate of reaction. That is presumably what happens in the reacting mixtures containing benzene, phenol, or phenacetin when the rate of reaction suddenly increases, because, when hydroquinone is formed, it will react with ferric ions forming ferrous ions. At the same time the hydroquinone will be oxidized to quinhydrone in accordance with the brown colouring of the reaction mixture mentioned above.

From the above it follows that hydroquinone is to be expected to act, not as an inhibitor, but as a promotor for the reaction, which is in accordance with the experimental results given in Fig. 4.

CONCLUSION

Kinetic experiments on the influence of phenacetin, benzene, phenol, and hydroquinone under well defined conditions seem to indicate qualitatively that a reaction scheme for the Fe(III)-catalyzed hydrogen peroxide decomposition must be based on a closed sequence. Furthermore, they seem to confirm Koefoed's [1] assumption that ferrous ions act as a catalyst.

It appears from the experiments referred to in this paper and from earlier experiments [7] that benzene acting as an inhibitor successively is oxidized to phenol, hydroquinone, and finally to oxalic acid and carbon dioxide. Phenacetin, which is used as a stabilizer of medical hydrogen peroxide, obviously acts in the same way.

We wish to thank *Statens Almindelige Videnskabsfond* for financial support.

The Interelectronic Repulsion Integrals and the Purity of Molecular Orbital Configurations, as Derived from the Absorption Spectra of Transition Group Complexes

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The ligand field theory has made several steps of increasing generality regarding the partly filled shell in transition group complexes. The electrostatic model, where the radial function is not varied, is disproven by the nephelauxetic series (see eqn. 8), where the term distances are decreased, relative to the gaseous ions. It is here shown that the two possibilities: expanded radial functions of a *d*-shell, with appropriate angular dependence, or a molecular orbital theory with an integral number of γ_3 and γ_5 electrons, but without the assumption of $l = 2$, give nearly identical results of the interelectronic repulsion integrals, separating the levels of a given sub-shell configuration. Tanabe and Sugano's theory and the role of configuration intermixing in complexes and gaseous ions is discussed, and it is concluded that the number of electrons in the partly filled shell of a monomeric complex is very well defined.

Slater, Condon, and Shortley [1] demonstrated that it is a rather good approximation to the wavefunction of gaseous atoms and ions to assume well-defined electron configurations, *i.e.* an integral number between 0 and $4l + 2$ electrons in each *nl*-shell, by writing the wavefunction as the anti-symmetrized product of one-electron functions

$$\psi = \frac{1}{r} \cdot R_{nl}(r) \cdot A_l(\varphi,\vartheta) \qquad (1)$$

where the angular part A_l is a linear combination of the angular functions known from the theory of the hydrogen atom, while the radial part R_{nl} is not at all hydrogen-like, but must be determined, *e.g.* by Hartree's methods, for each atomic number Z and ionic charge $Z_0 - 1$. If the electron configuration contains at least one partly filled shell (with l at least 1), it corresponds to several energy levels, which in Russell-Saunders coupling can be assem-

bled in multiplet terms, characterized by definite values of the quantum numbers L and the total spin S. The fine structure of the multiplet terms, giving energy levels with different J, is caused by electrodynamic (*i.e.* magnetic) and relativistic effects and is proportional to the Landé factors ζ_{nl}. The energy differences between the LS-terms are caused by the electrostatic repulsion between the electrons in the partly filled shell. This repulsion depends even for identical R_{nl} and thus identical attraction by the nucleus on the angular distribution A. In the case of one partly filled l-shell, the relative energy differences are expressed [1] as linear combinations of the integrals F^2, F^4, . . . , F^{2l}, which are approximately [2] inversely proportional to the average distance from the nucleus. The much larger contribution $\frac{1}{2}q(q-1)F^\circ$ is identical for all terms of a given configuration and can be considered as the spherical symmetrical average of the electrostatic repulsion between the q electrons in the partly filled shell, just as the central field from the electrons in closed shells, which determines the radial function R_{nl}.

In systems with several nuclei, *i.e.* in molecules and complex ions, the nl-shells are substituted by molecular orbitals γ_n, and the LS-terms are substituted by energy levels, characterized by Γ_n and S. The quantum numbers γ_n and Γ_n are found by group theoretical methods and depend on the symmetry of the complex. Thus, in the symmetry O_h (that of cubes and regular octahedrons [3]) the wavefunctions must obey certain conditions when performing the transformations of the group (such as rotations of the system of coordinates around the axes of the complex *etc.*). In this way, the wavefunctions always fall in one of the ten classes γ_n (electrons) or Γ_n (whole systems), where $n =$ 1, 2, 3, 4, or 5, and the parity is odd or even. However, in molecules, the approximation of molecular orbital configurations is not as generally valid as in the gaseous ions placed in the high symmetry of empty space. The principal purpose of this paper is to study whether this approximation seems to be valid in octahedral complexes of the three transition groups, where the absorption spectra recently have been interpreted by ligand field theory [4–11].

Even though the intermixing of molecular orbital configurations presents much difficulty, *e.g.* in the aromatic hydrocarbons [12,13], its extent has not generally been recognized in chemical textbooks. For large internuclear distances in H_2 or O_2, the configurations are highly intermixed and do not correspond much to the equilibrium groundstate [14]. Since the covalent bonding in d^n-complexes does not depend alone on the behaviour of the partly filled shell, similar conditions might prevail there. Another feature of particular importance for d^n-complexes is the electrostatic repulsion between the d-electrons, producing the same correlation effects as those mentioned above in the gaseous ions. Actually, the relevant multiples of F^2 and F^4 have the same order or magnitude as the ligand field parameter Δ (also called (E_1-E_2) or 10 Dq) which is the energy difference between the γ_3- and the γ_5-subshell. Therefore, it is not always valid to assume the groundstate to have the maximum number of γ_5-electrons possible, even though γ_5 has lower orbital energy than γ_3. In the case of d^4, d^5, d^6, and d^7, this would produce states with lower values of S, *i.e.* magnetically anomalous complexes, than has the gaseous ion. How-

ever, this is only possible, when the spin-pairing energy [6,8,15], *i.e.* an appropriate linear combination of F^2 and F^4, is smaller than Δ.

Theoretically, the electrostatic repulsion energies can be found in molecular orbital theory as sums of four-electron integrals

$$(\mathrm{a\ b}\ g\ \mathrm{c\ d}) = \int\int \Psi_\mathrm{a}^*(\tau_1)\Psi_\mathrm{b}^*(\tau_2)\ \frac{e^2}{r_{12}}\ \Psi_\mathrm{c}(\tau_1)\Psi_\mathrm{d}(\tau_2)\ \mathrm{d}\tau_1\mathrm{d}\tau_2 \qquad (2)$$

which has the physical significance of the electrostatic interaction between two extended charge distributions $\Psi_\mathrm{a}^*\Psi_\mathrm{c}$ and $\Psi_\mathrm{b}^*\Psi_\mathrm{d}$. If the diagonal element of g for a given configuration is wanted, it is only necessary to use two types of two-electron integrals:

$$\mathrm{J(ab)} = (\mathrm{ab}\ g\ \mathrm{ab}) \text{ and } \mathrm{K(ab)} = (\mathrm{ab}\ g\ \mathrm{ba}) \qquad (3)$$

where a summation is performed over all pairs ab in the configurations, and with negative sign of the K-integrals, when they do not vanish. Since (2) vanishes *, if a and c do not have the same spin component m_s, or if b and d do not have the same m_s, the results will be for each pair

$$\begin{array}{llll} \mathrm{a^+b^+} : \mathrm{J(ab)} - \mathrm{K(ab)} & & \mathrm{a^+a^-} : \mathrm{J(aa)} & \\ \mathrm{a^+b^-} : \mathrm{J(ab)} & & \mathrm{b^+b^-} : \mathrm{J(bb)} & \\ \mathrm{a^-b^+} : \mathrm{J(ab)} & & & \\ \mathrm{a^-b^-} : \mathrm{J(ab)} - \mathrm{K(ab)} & & & \end{array} \qquad (4)$$

Since the wavefunctions usually do not need to be chosen as complex functions, the asterisks in (2) denoting complex conjugation will generally be superfluous, and in this case, the following relation will be valid:

$$(\mathrm{aa}\ g\ \mathrm{bb}) = (\mathrm{ab}\ g\ \mathrm{ba}) = \mathrm{K(ab)} \qquad (5)$$

representing the interaction of the charge distribution ab with itself, while J(ab) still is the classical interaction between the actual electron densities $\mathrm{a^2}$ and $\mathrm{b^2}$. It may be remembered that the integral of ab over the total space is zero and of $\mathrm{a^2}$ equal to one, being the orthogonalization and normalization conditions, respectively.

The electrostatic energies can now be found as the eigenvalues of determinants having as diagonal elements the molecular orbital configurations with given spin directions m_s (+ and − in eqn. 4) and identical values of M_s. The problem of an electronic configuration with two electrons with $l = 0$ and a higher value, as treated by Heisenberg in case of the excited

* Further, it is a group-theoretical requirement for (2) not to vanish that abcd contains the representation Γ_1, since g is a totally symmetric operator. This is equivalent to the condition that ac and bd have the same Γ_n in their products as applied p. 911.

states 1s *nl* of a helium atom *, and by Houston as a general problem with intermediate coupling in heavy atoms, corresponds to a determinant for $M_s = 0$ with two equal diagonal elements J(ab) of eqn. 4 and the non-diagonal element K(ab), having as eigenvalues the triplet energy J(ab)—K(ab) and the singlet energy J(ab) + K(ab). Below, the similar problem with three identical diagonal elements J and three non-diagonal elements $\pm$ K is of interest. If an odd number of the non-diagonal elements is + K, the eigenvalues will be J + 2K, J — K, and J — K, while if an even number has the positive sign of K, the eigenvalues will be J — 2K, J + K, and J + K. Generally, a determinant with q equal diagonal elements = J and all the $\frac{q}{2}(q-1)$ non-diagonal elements = K will have the eigen-value J + (q — 1)K and (q — 1)-fold the eigen-value J—K.

The determinant with a given value of M_s can be divided in subdeterminants, each being diagonal in a group-theoretical quantum number Γ_n appropriate to the symmetry, where all the orbitals a and b have different γ_n. Unfortunately, this is not possible in O_h, where the three degenerate γ_5-orbitals do not necessarily have the same electrostatic interaction with the two γ_3-orbitals. This difficulty can be removed by considering lower symmetries, such as tetragonal or rhombic, without altering the energies of the orbitals belonging to the same cubic γ_n. Mr. Schäffer has kindly informed me that there exist essentially different forms of rhombic symmetry, while the difference between the two tetragonal symmetries I and II (Ref.[16], p. 6) has no physical significance. The rhombic symmetry I is a case of C_{2v} with the two-fold axis and the two two-fold mirror axes in the direction of the ligands (being placed on the x,y,z-axes) while II is another C_{2v} with the z-axis still as the two-fold axis, but the two two-fold mirror axes along the lines x + y and x — y in the xy-plane. The behaviour of the five orbitals is then:

	tetragonal	rhombic I	rhombic II
cubic 3	1 + 3	1 + 1	1 + 3
cubic 5	4 + 5	2 + 3 + 4	1 + 2 + 4

* The following Table indicates the ratio T in per cent between the triplet-singlet distance, *viz.* 2K(ab) = 2 G_1 in Slater integrals[1] and the energy of the triplet-singlet midpoint, *viz.* the orbital *nl*-energy, for a set of series of He, Li^+, and Be. Further, T is shown to be approximately inversely proportional to the principal quantum number *n*:

	n =	2	3	4	5	6	7	8
He 1s *ns*	T =	18.22	11.42	8.35	6.59	5.44	4.63	4.04
	*n*T	36.44	34.25	33.39	32.93	32.64	32.42	32.32
He 1s *np*	T =	7.26	5.22	3.96	3.19	2.66	2.29	2.00
	*n*T	14.52	15.65	15.84	15.96	15.98	16.03	15.98
Li^+1s *ns*	T =	10.80	7.54	5.49	4.35	3.55	3.06	—
	*n*T =	21.59	22.61	21.96	21.74	21.30	21.39	—
Li^+1s *np*	T =	6.45	4.55	3.37	2.82	—	—	—
	*n*T =	12.89	13.63	13.49	14.08	—	—	—
Be $1s^2$2s *nd*	T =	—	19.94	12.26	9.02	7.23	5.85	5.25
	*n*T =	—	59.82	49.06	45.08	43.36	40.99	41.96

Since the orbital energies are inversely proportional to $(n+\delta)^2$, where δ is the Rydberg correction, the exchange integrals K(ab) are shown to vary nearly as n^{-3}, as mentioned by Van Vleck[30].

These group-theoretical results are very useful for the following arguments, when it is no longer supposed that the molecular orbital can be written as eqn. 1, *i.e.* that l is no longer well-defined. In most cases, it will be a linear combination of different radial and different angular functions, such that a separability into a product R·A will not be possible. In this case, the expansion of the electrostatic energy in a series of F^k-contributions (k = 0, 2, 4, ...) will no longer terminate, but contain members with very high k.

The ligand field theory has applied more or less refined approximations in the description of d^n-complexes, of which a fair selection would be:

1. First-order perturbation energy on A is considered, but only the diagonal elements of weak field (assuming well-defined L) or strong field (assuming well-defined sub-shell configuration $\gamma_5^a\gamma_3^b$) determinants are considered.

2. The same as 1, but the restriction of sharply defined L or $\gamma_5^a\gamma_3^b$ removed, such that the energy levels are eigenvalues of determinants of q'th degree, if q levels present the same combination of S and Γ_n. The theory has thus one parameter Δ, assuming fixed atomic term distances, and can be expressed as in the Orgel-diagram [6].

3. Besides the first-order perturbation energy on A, there subsist second-order perturbations on R, changing the central field and thus the radial function R. But there is still assumed hydrogen-like A, *i.e.* $l = 2$. The theory has two types of parameters, Δ and the relative decrease of F^k- integrals in complexes, relative to those of the gaseous ion and can be expressed in the Tanabe-Sugano-diagram [5], where the independent variable is $\Delta : B$. The ratio between $B = 1/49\ F^2 - 5/441\ F^4$ and $C = 5/63\ F^4$ is assumed to be constant $\sim 1/4$.

4. The molecular orbitals γ_3 and γ_5 are not assumed to have the same radial function, but still the set of A corresponding to $l = 2$. Thus, the parameters B and C change in each sub-shell configuration $\gamma_5^a\gamma_3^b$.

5. The molecular orbitals are even not assumed to have hydrogen-like angular dependence, but their configurations are assumed to be rather well-defined. In this case, the different J- and K-integrals are applied, as outlined above, in the place of B and C.

6. The complete molecular orbital theory is presumed with large intermixing of configurations.

Of these approximations, 1 is obsolete, as are also the discussions of whether a given complex could be said to have strong or weak ligand field (incidentally, the best agreement is obtained in nearly all complexes with the former type of diagonal elements). It was often overseen that also the strong field diagonal elements contain multiples of F^k besides the multiples of Δ, and some misleading remarks were made about the complete "quenching" of the interelectronic repulsion for $\Delta \to \infty$.

Approximation 2 concentrated the interest on Tsuchida's spectrochemical series, *i.e.* the variation of Δ as a function of the ligands for a given metal ion:

$$Br^- < Cl^- < F^- < \text{urea} < ox^{--} \lesssim H_2O < SCN^- < NH_3 < en \ll CN^- \qquad (6)$$

while the series as function of the central ion for the same ligand is:

$$Mn(II) < Ni(II) < V(II) < Fe(III) < Cr(III) < Co(III) < Mo(III) < Rh(III) < Ir(III) < Pt(IV) \qquad (7)$$

The most characteristic property of the "electrostatic model" of ligand fields is that the radial function is not made subject to a variation. However, the series (6) was nearly incredible as a result of a purely electrostatic effect of the ligands, and it was soon proposed [6,9] to re-investigate Van Vleck's old remark [17] that the intermixing of orbitals with the same γ_n and parity from the central ion and the ligands, *i.e.* partly covalent bonding in the L.C.A.O. description, might as well explain * the magnitude of Δ, which was a successful empirical parameter rather than an absolute result of the electrostatic model (where the hydrogen-like radial functions and point dipoles necessarily must imply wrong results [8]). Thus, the low values of Δ in halide complexes was now ascribed to π-bonding effects, which increase the energy of the anti-bonding γ_5-orbital, while σ-bonding and electrostatic effects tended to increase Δ.

The first reliable method of estimating the relative extent of the partly covalent bonding from the absorption spectra appeared, when it was realized that the approximation 3 very nearly describes the observed energy levels. It has, however, been a general error by most investigators (including the present author) of d^n-complexes, to draw the opposite conclusion that no other explanation could reasonably be valid, if a given model worked quite well. It is actually possible to arrange the complexes in a two-dimensional system, according to Δ and to $\beta = B_{\text{complex}} : B_{\text{gaseous ion}}$. Schäffer and the present author [18] have studied the nephelauxetic ** series, *i.e.* the tendency to decrease β below 1 as a function of the central ion (giving nearly the same series as (7) except that Mo(III) is placed before and Fe(III) after Cr(III)) and of the ligands:

$$F^- > H_2O > \text{urea} > NH_3 > \text{en} \gtrsim ox^{--} > SCN^- > Cl^- \gtrsim CN^- > Br^- \qquad (8)$$

which is quite different from (6). The nephelauxetic series corresponds to the general opinion about the relative tendency towards covalent bonding, and it corresponds nearly to the hyperchromic series [19,20] of increasing inten-

* The absolute magnitude of Δ can also be estimated from the intermixing of molecular orbitals (from the ligands and the central ion) with the same γ_n and parity, assuming known diagonal elements of energy, and non-diagonal elements proportional to known overlap integrals multiplied by the average of the two diagonal elements. There is no doubt that reasonable agreement can be obtained by this form of approximation No. 5 choosing among an infinite set of assumed diagonal energies and overlap integrals (which in most papers refer to the un-realistic hydrogen-like radial functions). However, the three interesting attempts [34-36] to explain the absorption spectra without making any allusion to the electrostatic model No. 2 have all neglected the interelectronic repulsion integrals, separating the levels of the same molecular orbital configuration. Especially, the recent treatment [36] of $Co(NH_3)_5Cl^{++}$ and $Co(NH_3)_4Cl_2^+$ have ascribed the distance, occurring in $Co(NH_3)_6^{+++}$ between $^1\Gamma_4$ and $^1\Gamma_5$, to the energy difference between the σ-anti-bonding orbitals γ_{t_3} and γ_{t_1}. An erroneous extension of this thought [36] has necessitated the identification of the two first bands of trans-$Co(NH_3)_4Cl_2^+$ as transitions to $^1\Gamma_{t_5}$ and $^1\Gamma_{t_4}$, *i.e.* implying $^1\Gamma_5$ in O_h, as originally supported by the electrostatic model of ligand fields[16]. The molecular orbital theory for D_{4h} explains the actual behaviour[23] assuming π-bonding from the halide ligands. There is no doubt that a very fine description could be obtained by taking also the interelectronic repulsion integrals into account, if the first-order perturbations on the diagonal elements could be reasonably estimated. *Cf.* the recent treatment of cobalt(III) complexes by Yamatera [37].

** The word »nephelauxetic» (= cloud-expanding) has been kindly proposed by Professor Kaj Barr, University of Copenhagen.

sities of the Laporte-forbidden d^n-transitions and to decreasing oxidation potential of the ligands, *i.e.* decreasing energy for the removal of an electron.* All these three properties are undoubtedly connected; the intensities are roughly inversely proportional to the square of the distance in wavenumbers between the ligand field bands and the "redox" electron transfer bands, and the covalent bonding is enhanced by the easy transfer of electrons from the ligands to the central ion. Schäffer [21] investigated a series of chromium(III) complexes with oxygen atoms in the first co-ordination sphere and found a wide distribution in the nephelauxetic series: sulfate has even higher β than water, while most anion complexes and the red ruby fall in middle of the series, and green Cr_2O_3 has even smaller β than $Cr(CN)_6^{-3}$. For all these complexes, Δ does not vary more than between 14 640 and 18 520 K (= cm^{-1}).

Since γ_3-electrons have more repulsive effects on the ligands than γ_5-electrons have, as can be implied from the differences in ionic radii and from the bandwidths, it is obvious to introduce the fourth approximation, p. 907. However, a new difficulty arises: the spin-forbidden bands deliver a linear combination of B and C, while the states with maximum value of S are separated by multiples of B only. Thus, it is not easily decided, whether β_3 is smaller in the γ_3 sub-shell. This problem is discussed in Refs.[22,23]. For the following discussion, it might be useful to classify the experimental evidence, which is used for the determination of Δ and B in the complexes:

Only the Jahn-Teller regular systems are considered, because the determination of β is so sensitive for small irregularities in the wavenumbers. Perhaps, d^2- and d^7-systems might also be studied, while the tetragonal distortions are too large in d^4 and d^8 ($S = 0$). Among the regular systems, Δ can be directly found as the wavenumber ** of the first spin allowed band (when corrected for possible intermixing with spin-forbidden bands) in d^3- and d^8 ($S = 1$) systems. In d^5 ($S = 5/2$) and d^6 ($S = 0$), it is necessary to correct the distances $^4\Gamma_4(G)-{}^4\Gamma_{1,3}(G)$ and $^1\Gamma_1-{}^1\Gamma_4$, respectively, for a contribution of F^k- type

* However, Bailey [38] has recently determined the electron affinity of gaseous fluorine atoms to be between that of chlorine and that of bromine atoms. Thus, the nephelauxetic series and the chemical intuition must be connected with polarizabilities rather than ionization potentials.

** This is only valid until approximation No. 3. As seen from eqns. 14 and 16, the energy difference between $^4\Gamma_5$ and $^4\Gamma_2$ of d^3 is $\Delta + 2\Theta$, where $\Theta = J(3.5) - K(3.5) - J(4.5) + K(4.5)$ (*cf.* eqn. 12). Similarly, the energy difference in d^2 between $\frac{3}{4}\,(^3\Gamma_5) + \frac{1}{4}\,(^3\Gamma_4\gamma_5\gamma_3) - (^3\Gamma_4\gamma_5^2)$ is $\Delta + \Theta$ (*cf.* eqns. 13 and 15). The quantity Θ is zero in the electrostatic model, but will probably tend to have a negative value in the molecular orbital theory. The most important contributions to Θ comes from the J-integrals (eqn. 10) which contain the Racah parameter A and thus F^0. It will probably be a rather good approximation to assume that the interaction between a γ_3- and a γ_5-electron is decreased ϑ and between two γ_3-electrons decreased $2\,\vartheta$, relative to the interaction between two γ_5-electrons, which are in average concentrated in a smaller volume. If the latter approximation is valid, the value of Δ will always be decreased $(n-1)\,\vartheta$ in a d^n-system. Thus, in this case the same apparent value of Δ will always be implied from one and two-electron transitions. Since F^0 is a large but unknown quantity$\sim$100 000 K, (=cm^{-1}) ϑ will have an important effect on Δ, even if it amounts only to some per cent of F^0. However, the physical significance of F^0 is of analogous nature to the whole self-consistent field influence, which determines the not very accessible orbital energies. Systems as d^8 can profitably be treated as d^{10}-systems, where two positively charged holes occur. The interaction between the ten electrons $\gamma_5^6\gamma_3^4$ is 6 J(1.3) + 2K(1.3) + 12J(1.4) − 6K(1.4) + 12J(3.4) − 6K(3.4) + 12J (4.5) + 3J(4.4) — 6K(4.5) which gives a mathematically complicated contribution to the energy of, *e.g.*, a zinc(II) complex.

(*viz.* C), and for effects of sub-shell configuration intermixing, for obtaining Δ. The value of β can be obtained with reasonable accuracy from six classes of energy differences:

$^4\Gamma_2 - ^2\Gamma_3$, $^2\Gamma_4$, $^2\Gamma_5$, all of γ_5^3 in d^3. They are the sharp "ruby" lines of Cr(III), Mo(III), and Re(IV) which are nearly independent of Δ. The suppression, due to interaction with other sub-shell configurations is largest for $^2\Gamma_5$, while it is smaller for $^2\Gamma_3$ and negligible for $^2\Gamma_4$. However, $^2\Gamma_3$ is distinctly the sharpest transition.

$^4\Gamma_5(F) - ^4\Gamma_4(F)$ (and $^4\Gamma_4(P)$) of d^3. The two first of the three broad bands yield a value of B directly from the second-degree determinant for $^4\Gamma_4$. Schäffer has demonstrated that the third band of Cr(III), when known, often deviates from the prediction contrary to the analogous d^8-case. This effect is perhaps caused by interactions with electron transfer states.

$^6\Gamma_1(S) - ^4\Gamma_1(G)$, $^4\Gamma_3(G)$ (and also $^4\Gamma_5(D)$, $^4\Gamma_5(D)$, and $^4\Gamma_2(F)$) of $\gamma_5^3\gamma_3^2$ in d^5. The two first quartet levels * are degenerate for $l = 2$ and produce the sharp band[39] of Mn(II) and Fe(III). They are independent of Δ to a high approximation* and indicate $10B + 5C$.

$^1\Gamma_4 - ^1\Gamma_5$ of $\gamma_5^5\gamma_3$ in d^6. This distance between the two first spin-allowed bands of diamagnetic Co(III), Rh(III), and Ir(III) complexes is $16B$ for $\Delta \rightarrow \infty$, but shall be corrected for the influence of other sub-shell configurations, which is larger for $^1\Gamma_5$ than for $^1\Gamma_4$ with resulting decrease of the distance in the Tanabe-Sugano diagram.

$^3\Gamma_2 - ^1\Gamma_3$ of $\gamma_5^6\gamma_3^2$ in d^8. The excited level of the first spin-forbidden band of Ni(II) is intermixed with the triplet levels by intermediate coupling[7,22]. The value of $8B + 2C$ is very little influenced by the other $^1\Gamma_3$ from $\gamma_5^4\gamma_3^4$.

$^3\Gamma_5(F) - ^3\Gamma_4(F)$ and $^3\Gamma_4(P)$ of d^8. Contrary to the case of Cr(III), all three excited quartet levels can be observed of most Ni(II) complexes, and 15 B thus found form the diagonal sum rule. Further, it has been demonstrated [7,22] that the individual positions of the two $^3\Gamma_4$ agree with the theory within some 200 K, (= cm^{-1}) if the deviations from cubic symmetry are not too large.

---

* When the determinants of d^5 are calculated by use of the rules Ref. [1], p. 173, it is found that most of the non-diagonal elements contain multiples of K-integrals only. The absolute number of J-integrals in each diagonal element is always $n(n-1)/2$ in a d^n-system (because it contains the F^0-integral in the electrostatic case). Thus, the groundstate $^6\Gamma_1$ has the energy J(1.3) − K(1.3) + 3J(1.4) − 3K(1.4) + 3J(3.4) − 3K(3.4) + 3J(4.5) − 3K(4.5), while the other states of $\gamma_5^3\gamma_3^2$ have excitation energies such as $^5/_2$ K(1.4) + $^5/_2$ K(3.4) for $^4\Gamma_1(G)$, while the energies of $^4\Gamma_3(G)$ and $^4\Gamma_3(D)$ are a complicated square-root expression in J- and K-integrals, analogous to configurations in gaseous ions, where several multiplet terms present the same *LS*. The two $^4\Gamma_3$ have different parent terms, $(^4\Gamma_2 . {}^1\Gamma_3)$ and $(^2\Gamma_3 . {}^3\Gamma_2)$, having as diagonal elements of excitation energy 2K(1.3) + $^3/_2$K(1.4) + $^3/_2$K(3.4) and K(1.4) + K(3.4) + 3K(4.5), respectively, but also a non-diagonal element $\sqrt{3}$ (K(1.4) — K(3.4))/2. The other quartet terms of $\gamma_5^3\gamma_3^2$ have excitation energies, relative to $^6\Gamma_1$, which are the sum of the excitation energies of the parent terms within γ_5^3 (eqn. 14) and γ_3^2 plus a contribution S'(K(1.4) + K(3.4)), where $S' = {}^3/_2$ for the quartet-singlet and $S' = 1$ for the doublet-triplet parent terms. It is thus possible to describe the excitation energy within a sub-shell configuration in terms of spin-pairing energy (which can either be a number of K-integrals, or, by the formation of doubly occupied orbitals, differences between J(aa) and J(ab)) and energy due to decreased seniority number v (v = 0 for $^1\Gamma_1$ of γ_5^2 and γ_3^2, v = 1 for $^2\Gamma_5$ of γ_5^3).

If the assumption No. 5 on p. 907 of well-defined molecular orbital configurations $\gamma_5^a\gamma_3^b$, but not necessarily with $l = 2$, is applied to this material, the initial treatment, given by Tanabe and Sugano [5], must be followed. For d-electrons in the octahedral symmetry, a particular theorem is valid:

$$J(aa) = J(ab) + 2\ K(ab) \tag{9}$$

for two different orbitals a and b, which both belong to one of the classes γ_3 or γ_5. Tanabe and Sugano [5] proved that (9) is valid for γ_3, even when it is no d-electron, while (9) is not generally valid for γ_5. Schäffer and the present author have demonstrated from the group-theoretical result, p. 906 that one sufficient condition for (9) is that $J(aa) = J(bb) = J(cc)$ for a, b, c being the irreducible representations in rhombicII. However, this cannot be expected to be valid for all possible γ_5-electrons. The physical significance is the following: if we write the angular function $A = x^a y^b z^c/rl$ (with $a + b + c = l$ and $x^2 + y^2 + z^2 = r^2$) as homogeneous polynomiae in the Cartesian coordinates, the three γ_5-orbitals with $l = 2$ have the three functions xy, xz, and yz. If these functions are rotated 45° in the xy-plane, new linea rcombinations $\sqrt{1/2}$ (xz + yz), and $\sqrt{1/2}$ (xz − yz) are formed with the same physical shape. Analogously, among the p-electrons with $A = x, y, z$, the linear combination $\sqrt{1/2}$ (x + y) is simply a new p-orbital, only rotated in space. However, for any new such combination $c = \sqrt{1/2}$ (a + b), where $J(aa) = J(bb)$ and ab having another Γ_n than Γ_1 of a^2 and b^2 (*cf.* the foot-note p. 905), it will be valid

$$J(cc) = \tfrac{1}{4}\{J(aa) + J(bb) + 2J(ab) + 4K(ab)\} \tag{10}$$

giving (9) if $J(cc) = J(aa)$. This will obviously be the case, if c has the same physical shape as a, only rotated in space. Therefore, Slater's rules mentioned below will be valid for γ_4(p-) and γ_5(d-) electrons, but not for any set of such three equivalent orbitals. Further, by rotation of the xy-orbital, belonging to γ_5, the $(x^2 - y^2)$ orbital of γ_3-symmetry can be obtained. Since $(z^2 - \frac{1}{2}x^2 - \frac{1}{2}y^2)$ can be shown to be equivalent with $(x^2 - y^2)$ also in this respect, the J-integrals between two electrons in the same of the five d-orbitals are always identical. In the cases, where (9) is valid, it follows that ${}^1\Gamma_3$ and ${}^1\Gamma_5$ of γ_5^2 have the same energy, and that ${}^2\Gamma_3$ and ${}^2\Gamma_4$ of γ_5^3 also are systematically degenerate.

It is not easy to compare the molecular orbital theory with experiments, since the interelectronic repulsion energies in the pure sub-shell configurations are described by nine rather than two parameters (the coefficients to the constant $A = F^0 - F^4$, and to B and C in approximation No. 3 are indicated below), *viz*:

$J\ (1.3) \sim A - 4B + C$	$K\ (1.3) \sim 4B + C$
$J\ (4.5) \sim A - 2B + C$	$K\ (4.5) \sim 3B + C$
$J\ (1.4) \sim A - 4B + C$	$K\ (1.4) \sim 4B + C$
$J\ (3.4) \sim A + 4B + C$	$K\ (3.4) \sim C$
$J\ (4.4) \sim A + 4B + 3C$	

(11)

since J (1.1) = J (3.3) can be found from eqn. 9, and J (4.4) = J (5, same 5). The numbers denote the tetragonal quantum numbers [3,16]. An interesting theorem is that

$$\begin{aligned}
\mathrm{J}\ (1.5) &= \frac{1}{4}\ \mathrm{J}\ (1.4) + \frac{3}{4}\ \mathrm{J}\ (3.4) \sim \mathrm{A} + 2\mathrm{B} + \mathrm{C} \\
\mathrm{J}\ (3.5) &= \frac{3}{4}\ \mathrm{J}\ (1.4) + \frac{1}{4}\ \mathrm{J}\ (3.4) \sim \mathrm{A} - 2\mathrm{B} + \mathrm{C} \\
\mathrm{K}\ (1.5) &= \frac{1}{4}\ \mathrm{K}\ (1.4) + \frac{3}{4}\ \mathrm{K}\ (3.4) \sim \mathrm{B} + \mathrm{C} \\
\mathrm{K}\ (3.5) &= \frac{3}{4}\ \mathrm{K}\ (1.4) + \frac{1}{4}\ \mathrm{K}\ (3.4) \sim 3\mathrm{B} + \mathrm{C}
\end{aligned} \tag{12}$$

where 5 denotes one of the two γ_{t5}-orbitals. Thus, the interaction of a filled γ_5^6-shell containing four t5 and two t4-electrons is identical with a t1- or a t3-orbital.

The eigenvalues in the sub-shell configuration γ_5^2

$$\begin{aligned}
&^3\Gamma_4: && \mathrm{J}\ (4.5) - \mathrm{K}\ (4.5) \\
&^1\Gamma_5: && \mathrm{J}\ (4.5) + \mathrm{K}\ (4.5) \\
&^1\Gamma_3: && \mathrm{J}\ (4.4) - \mathrm{K}\ (4.5) \\
&^1\Gamma_1: && \mathrm{J}\ (4.4) + 2\mathrm{K}\ (4.5)
\end{aligned} \tag{13}$$

can be found from the determinants with identical M_s and a given rhombic Γ_n, giving, *e.g.*, the result that $^1\Gamma_1$ the two states of $^1\Gamma_3$ are members of a Heisenberg-determinant (p. 905) with the eigen-values J (4.4) + 2 K (4.4) and J (4.4) − K (4.4) twice. With a similar application of one of the two sets of rhombic quantum numbers, the eigen-values in γ_5^3 are:

$$\begin{aligned}
&^4\Gamma_2: && 3\ \mathrm{J}\ (4.5) - 3\ \mathrm{K}\ (4.5) \\
&^2\Gamma_3: && 3\ \mathrm{J}\ (4.5) \\
&^2\Gamma_4: && 2\ \mathrm{J}\ (4.5) + \mathrm{J}\ (4.4) - 2\ \mathrm{K}\ (4.5) \\
&^2\Gamma_5: && 2\ \mathrm{J}\ (4.5) + \mathrm{J}\ (4.4)
\end{aligned} \tag{14}$$

proving the degeneracy of $^2\Gamma_3$ and $^2\Gamma_4$ and the ratio 3:5 between the wave-numbers of the first and the third ruby line for γ_5-orbitals satisfying eqn. 9. In the mixed configuration $\gamma_5\gamma_3$, the four energy levels are:

$$\begin{aligned}
&^3\Gamma_5: && \mathrm{J}\ (1.4) - \mathrm{K}\ (1.4) \\
&^3\Gamma_4: && \mathrm{J}\ (3.4) - \mathrm{K}\ (3.4) \\
&^1\Gamma_5: && \mathrm{J}\ (1.4) + \mathrm{K}\ (1.4) \\
&^1\Gamma_4: && \mathrm{J}\ (3.4) + \mathrm{K}\ (3.4)
\end{aligned} \tag{15}$$

while the quartet levels of $\gamma_5^2\gamma_3$ and $\gamma_5\gamma_3^2$ have the energies of interelectronic repulsion:

$^4\Gamma_5(\gamma_5^2\gamma_3)$: 3/2 J (1.4) − 3/2 K (1.4) + 1/2 J (3.4) − 1/2 K (3.4) + J (4.5) − K (4.5) (16)

$^4\Gamma_4(\gamma_5^2\gamma_3)$: 1/2 J (1.4) − 1/2 K (1.4) + 3/2 J (3.4) − 3/2 K (3.4) + J (4.5) − K (4.5)

$^4\Gamma_4(\gamma_5\gamma_3^2)$: J (1.3) − K (1.3) + J (1.4) − K (1.4) + J (3.4) − K (3.4)

Schäffer and the present author [23] shall discuss, why the structure of all the sub-shell configurations, containing a Γ_4 and a Γ_5 level with maximum value of S, is similar to that of (15) and (16). Thus, the distance between the two spin-allowed bands in d^2-, d^3-, d^7-, and d^8-systems with the symmetry O_h, which is 12 B under assumption of $l = 2$ and an arbitrary radial function, will be:

$$\text{J (3.4)} - \text{K (3.4)} - \text{J (1.4)} + \text{K (1.4)} \tag{17}$$

In the special case of diamagnetic d^6-complexes the energy difference (= 16 B for $l = 2$) between $^1\Gamma_4$ and $^1\Gamma_5$ of $\gamma_5^5\gamma_3$ is not given by (17) but by

$$\text{J (3.4)} - 2\ \text{K (3.4)} - \text{J (1.4)} + 2\ \text{K (1.4)} \tag{18}$$

and the energy difference between the analogous triplet terms $^3\Gamma_4$ and $^3\Gamma_4$ is only J (3.4) − J (1.4). This can be explained by the interaction with the γ_{t5}^4 core in the five pure tetragonal sub-shell configurations:

t5	t4	t3	t1			
4	2	0	0	$^1\Gamma_1$(t1)	12 J (4.5) + 3 J (4.4) − 6 K (4.5)	(19)
4	1	1	0	$^3\Gamma_4$(t2)	8 J (4.5) + 2 J (4.4) − 4 K (4.5) + 3 J (1.4) + 2 J (3.4) − 3/2 K (1.4) − 3/2 K (3.4)	
4	1	1	0	$^1\Gamma_4$(t2)	8 J (4.5) + 2 J (4.4) − 4 K (4.5) + 3 J (1.4) + 2 J (3.4) − 3/2 K (1.4) + 1/2 K (3.4)	
4	1	0	1	$^3\Gamma_5$(t4)	8 J (4.5) + 2 J (4.4) − 4 K (4.5) + 2 J (1.4) + 3 J (3.4) − 3/2 K (1.4) − 3/2 K (3.4)	
4	1	0	1	$^1\Gamma_5$(t4)	8 J (4.5) + 2 J (4.4) − 4 K (4.5) + 2 J (1.4) + 3 J (3.4) + 1/2 K (1.4) − 3/2 K (3.4)	

The two tetragonal sub-shell configurations (3 2 1 0) and (3 2 0 1) do not correspond to pure cubic quantum numbers, Γ_n but have energies, which are

$$\frac{1}{4}(\Gamma_4) + \frac{3}{4}(\Gamma_4) \text{ and } \frac{3}{4}(\Gamma_4) + \frac{1}{4}(\Gamma_5) \tag{20}$$

according to eqn. 11. This behaviour of the two levels Γ_{t5} is a general feature for all the sub-shell configurations discussed by Schäffer and the present author [23].

In nickel(II) complexes, the spin-forbidden transitions from $^3\Gamma_2$ to $^1\Gamma_3$ and $^1\Gamma_1$ of the ground configuration $\gamma_5^6\gamma_3^2$ should have the ratio 1:2 between the wavenumbers, because the excitation energies are those calculated [5] for γ_3^2, *viz.* 2 K (1.3) and 4 K (1.3). It is interesting that the promotion energy forming a planar, diamagnetic complex with the pure tetragonal configuration having an empty γ_{t_2}-orbital is 3 K (1.3) because in this case, the level $^1\Gamma_{t_1}$ is not intermixed with other tetragonal sub-shell configurations. Thus, the promotion energy [16] indicated as $\frac{4}{7}$ (^{1}D) + $\frac{3}{7}$ (^{1}G), *viz.* 8 B + 2 C or 2 K (1.3), is too low. In Ni^{++}, however, the state ^{1}S does not seem to have as high an energy as predicted by Slater's theory (22 B + 7 C above ^{3}F) with the result that $^1\Gamma_1$ has probably lower energy [22] and that the promotion energy for formation of planar complexes is smaller than 3/2 times the first spin-forbidden transition of the corresponding octahedral complex.

Of course, eqns. 12—19 allow a wider range of variability in the energy differences, where 12 B and 16 B now is explained as a sum of two positive and two negative quantities, and the wavenumbers of the spin-forbidden bands are multiples of K-integrals. It is not easily determined, whether the freedom of molecular orbitals without defined l actually is demanded by experimental evidence. The most surprising fact is that even this theory would predict the same type of ratios between the interelectronic repulsion energies as would the electrostatic model. This has two different aspects: on the one hand, it is very promising for the ligand field theory that nearly any assumption about the wavefunctions would lead to the same distribution of the energy levels of the partly filled shell (agreeing to a high accuracy with observations); on the other hand, unfortunately, it is not easy to draw any conclusions about the wavefunctions from the absorption spectra, except that the electrostatic model is disproven by the nephelauxetic series. One type of evidence about the question how good an approximation is $l = 2$, might be delivered by the temperature-independent paramagnetism, which is proportional to matrix elements of L without regard to the spatial extension of the wavefunctions. Ballhausen and Asmussen [24] have found so enormous residual diamagnetisms by application of Van Vleck's high-frequency formula (which rather was expected to yield too small paramagnetism, due to the neglect of other excited levels) that, disregarding the scattering of the calculated material, the agreement would be much better by taking only 40 % of Van Vleck's correction. This may be explained by a similar break-down of $l = 2$ as the change of the radial functions in approximation No. 3, expressed by the decrease of β. Griffith and Orgel [25] have treated the same problem, but though they applied different experimental values they concluded with the "possible quenching of L", suggesting a similar necessity of molecular orbitals, which are not d-electrons to a very large extent.

However, the success of the ligand field theory seems indirectly to prove that the last of the six approximations, p. 907, the strong intermixing of molecular orbital configurations, is at least not needed for explaining the energy levels. The calculations of this intermixing would be extremely complicated, but of course, it cannot be excluded that the final results would still resemble

the observed energy levels. The problem is here common to atomic spectroscopy of gaseous ions: it is not easily proven that the configurations are very pure. However, the magnitude of the correction $\alpha L(L+1)$ with $\alpha \sim 100$ K, which Trees [26] and Racah [27] introduced to the Slater theory [1] seems to indicate that the configurations usually are ~ 99 % pure in the squares of the wave-function. It is clearly proven, *e.g.* by Furlani's calculation [28] for Fe^{++}, that the correction due to configuration interaction is monotonically increasing with L. However, the present author has the impression that the terms of the lowest configurations rather are suppressed by a quantity, proportional to $1/(2L+1)$ or $1/(L+1)$, as also supported by the calculations of Ufford [29], where the non-diagonal elements between LS-terms of d^3 and d^2s are increasing in the series ^2G, ^2F, and ^2P. If such a proportionality with the constant $\sim 10\,000$ K can be applied, it would explain, why nearly all terms with $L = 0$ seem anomalously much depressed.

However, the agreement of atomic spectroscopy with Slater's theory [1] and of ligand field transitions with Tanabe and Sugano's theory [1] seems to indicate that the electron configurations in gaseous ions and the molecular orbital configurations in octahedral complexes have a purity of the same order of magnitude, *viz.* between 90 and 99 % in most cases.* This may be connected with the fact that the octahedral complexes (more so than, *e.g.*, the square-planar) are so near to having spherical symmetry that most of the electrostatic repulsion between the electrons in the partly filled shell is a common contribution of central field type to all the energy levels, which are not electron transfer states. The latter concept must now be defined as states, where the population of other orbitals than the partly filled γ_3 and γ_5 is changed, relative to the ground-state, since also the d^n-transitions from the old electrostatic model now must be assumed to involve change of the electron density in the ligands. It is a special case of the relatively high purity of molecular orbital configurations in complexes that the number a + b of electrons in the partly filled sub-shells $\gamma_5^a\gamma_3^b$ still is very good for classification of the complexes according to the oxidation state of the central ion, as implied from the primitive idea of a + b electrons in the d-shell. The classification after d^n may be expected to break down in strongly coloured polymeric complexes of the molybdenum(V,VI) blue or ferro-ferricyanide type, where the partly filled orbitals may be highly de-localized.

It is generally believed that the properties of atoms and molecules are functions of integers (especially the number of electrons) and that these functions are characterized by shell structure, *i.e.* the properties change suddenly by passing certain stabilized numbers. The periodical system of elements is

---

* We must here distinguish between the validity of pure configurations in the weak or in the strong sense. In the former, the observed energy differences can be brought in agreement with Slater's theory [1], assuming reasonable values of the parameters of interelectronic repulsion, while the parameters are directly calculated from the radial functions, assuming eqn. 1, in the latter case. Dr. Per Olov Löwdin and Dr. Klaus Appel, Kvantkemiska Gruppen, Uppsala University, have kindly informed me that the interelectronic repulsion invariably is calculated 10—40 % too large in gaseous d^n-ions, showing a rather large deviation from the "strong sense" theory. Thus, we must expect the configuration interaction, introduced by the electronic correlation, to have a similar extent in the transition group complexes [39].

strongly dominated by the stability of 2, 10, 18, 36, 54, 86, . . .electrons, while the nuclei with 2, 6, 8, 14, 20, 28, 40, 50, 82, 126, . . .neutrons or protons are especially stable, as explained by the action of Pauli's exclusion principle on another set of quantum numbers than those of the electrons. It must be realized that these shell structures are entirely dependent on the occurrence of quite pure configurations. In the nuclei, the central field seems strongly apt to deviations from spherical symmetry, and the configurations seem rather intermixed [31,32].

In complexes, it could not be assumed *a priori* that any electron configuration was a good approximation to the wavefunction. Since the time of Sidgwick, it has often been stated that since $S = 0$ of the groundstate of $Co(NH_3)_6^{+++}$, its configuration is to a certain approximation $[A]3d^{10}4s^24p^6$, *i.e.* [Kr], rather than [A] 3 d^6, which would give $S = 2$ and thus a paramagnetic complex. Pauling refined this idea in his hybridization theory, which is actually a molecular orbital theory with assumption of equal radial functions for the d-, s-, and p-part of d^2sp^3. Pauling [33] recognizes that the actual groundstate of most complexes is a resonance structure, *i.e.* an intermixing, of ionic and covalent formulae, and that the magnetic criterion cannot be used for an absolute distinction. However, just the assumption of identical radial functions makes a consistent refinement of this theory very difficult. It was not realized by many authors, that even though the configuration $[A]3d^{10}4s^24p^6$ might be a good description,* i.e. corresponding to the hydrogen-like angular functions for given l, the radial functions may vary from one complex to another, just as they do in the gaseous ions. When the excited states attracted more interest, it was necessary to abandon the valency-bond method for the more general molecular orbital theory. Here, other authors do not recognize that the bonding γ_3- and γ_5-orbitals always are filled, whatever the degree of partly covalent bonding may be, while the total number of electrons in the partly filled shell, represented by the anti-bonding γ_3- and γ_5-orbitals, is constant to a very high approximation. The evolution of partly covalent bonding, as expressed by the nephelauxetic series, corresponds to these anti-bonding orbitals smoothly varying from the d-shell of the gaseous ion to more expanded wavefunctions also present in the ligands. During this development, they may or may not retain $l = 2$ (approximation Nos. 3 and 4) with expanded radial functions, and they do not seem to reach the Pauling value with 50 % participation from the central ion and the ligands, since β still is above 0.3.

The conclusion of this paper is that the assumption (No. 5, p. 907) of negligible intermixing between the configurations $\gamma_5^a\gamma_3^b$ and other molecular orbital configurations seems to be consistent with all facts known about the energy levels and the corresponding wavefunctions. However, the electrostatic model has given a rather fine description, except of the absolute value of Δ (but it must now be rejected due to the nephelauxetic effect) so it cannot easily be concluded conversely that satisfactory agreement has proven the

* However, corresponding to spherical symmetry of the electron cloud. Only after having formed the covalent bonds, the hybridized configurations have any directional character, as not always recognized.

validity of the approximation of pure molecular orbital configurations of the partly filled shell, which is rather near to being a d-shell.

Acknowledgements. I am much indebted to my colleague, Mr. Claus E. Schäffer and to Professor Asger Nielsen, Physics Department of the Technical University of Denmark, for many interesting discussions about the subject of the present paper. Finally, I thank Dr. Robert Feltham, University of California, for several interesting comments, and Dr. John S. Griffith, Department of Theoretical Chemistry, University of Cambridge, for a very valuable remark about the independence of J(4.4) and J (4.5).

The Rate of Decarboxylation and the Dissociation Constants of Acetosuccinic Acid

KAI JULIUS PEDERSEN

Chemical Laboratory, Royal Veterinary and Agricultural College, Copenhagen, Denmark

Solutions of acetosuccinic acid were prepared from the diethyl ester which was first hydrolysed in alkaline solution. In order to find the time required for practically complete hydrolysis, a few experiments on the rate of hydrolysis were carried out, but, owing to the complicated nature of the reaction, a complete kinetic analysis of the data was not attempted.

As a contribution to the study of the spontaneous decarboxylation of β-keto carboxylic acids in aqueous solution, a kinetic investigation was made of the decomposition of acetosuccinic acid into levulinic acid and carbon dioxide at the temperatures 25.0 and 37.0°C in solutions containing an excess of barium hydroxide (by titration), and in solutions of hydrochloric acid and in acetate buffer solutions (manometrically). By analysis of the data, separate rate constants were evaluated for each of the three simultaneous reactions: decarboxylation of undissociated acetosuccinic acid, of its univalent and divalent ion. It was found that acetate ions catalyse the decomposition of the undissociated acid. It was shown that cupric ions have only a small catalytic effect in the decarboxylation of acetosuccinic acid. In this respect the acid differs from other dibasic β-keto carboxylic acids, such as oxaloacetic acid, dihydroxytartaric acid, and acetonedicarboxylic acid, where cupric ions have a powerful catalytic effect.

The two dissociation constants of acetosuccinic acid at 25.0°C were determined by glass-electrode measurements on acetosuccinate buffer solutions containing various concentrations of sodium chloride. From the rate of change of the e.m.f. with time it was possible to compute rate constants for the decarboxylation which are in reasonable agreement with those obtained by manometry and by titration.

ALKALINE HYDROLYSIS OF DIETHYL ACETOSUCCINATE

The solutions of acetosuccinic acid examined in this paper were prepared from diethyl acetosuccinate which was hydrolysed in alkaline solution at room temperature or at 25°C shortly before the experiment was started. The ester was prepared as described in *Organic Syntheses* [1] and was distilled twice under reduced pressure through a Widmer stillhead in an all-glass apparatus. The purified preparation distilled within a temperature interval of 0.3°C.

In order to get an idea of the time required for practically complete hydrolysis of the ester, a few rate-experiments were carried out at 25.0°C. The results are shown in Table 1 where the initial concentrations, x_0 M ester (Et_2X), u_0 M sodium hydroxide, are given at the top. At various times, t min after the ester was dissolved, samples were pipetted into a small excess of 0.05 M tartaric acid, and the mixture was quickly titrated back with sodium hydroxide. The concentrations of titratable base (u normal) found in the samples are given in the table. The reaction is kinetically rather complicated since it consists of two consecutive second- or first-order reactions, and, at large values of t, the slow decarboxylation of the acetosuccinate ion may affect the result. A complete kinetic analysis was therefore not attempted. Instead, $x = [Et_2X] + \frac{1}{2}[EtX^-]$ was computed by means of the equation $2x = u - (u_0 - 2x_0)$, and the equation for a first-order reaction, $k^*\ t = \log(x_0/x)$, was formally applied. Table 1 shows that k^*, within each of the three experiments, is roughly constant. In the first experiment k^* decreases a little, in the second it is almost constant until 90 %, in the third until 75 % of the ester is hydrolysed, after which it increases slowly. When the solutions examined in the following parts of this paper were prepared, the initial concentration of ester was in general about 0.04 M, and the concentration of base was about 0.12 N or more. It follows from Table 1 that the time of half life will here be less than 20 min at 25°C. In order to obtain practically complete hydrolysis, the solutions were therefore left for at least 4 h at 25°C or for at least 8 h at room temperature.

RATE OF DECARBOXYLATION IN BARIUM HYDROXIDE SOLUTIONS

When diethyl acetosuccinate is dissolved in an excess of strong base, the hydrolysis of the ester will be followed by a slow spontaneous decarboxylation of the divalent acetosuccinate ion

$$CH_3COCH(COO^-)CH_2COO^- + HO^- \rightarrow CH_3COCH_2CH_2COO^- + CO_3^{--}$$

When the strong base is barium hydroxide, the carbonate ion will be precipitated as barium carbonate, and the rate of decarboxylation may be followed by taking samples of the solution, adding phenolphthalein, and titrating them with hydrochloric acid. Data for two experiments, at 25.0 and 37.0°C, respectively, are shown in Table 2. The initial concentrations, x_0 M ester and u_0 N barium hydroxide, are given at the top of the table. The concentration of acetosuccinate ion (x M) at the time t hours after the ester was dissolved, was calculated from the concentration of titratable base (u N) by means of the equation $x = 3x_0 - u_0 + u$. The reaction was found to obey the first-order law with the values of the rate constant k given at the top of the table. When k is expressed in reciprocal hours, and x_0e^{-kt} is computed, the values given in the last column of the two halves of the table are obtained. Comparison with the observed values of x shows that the agreement with the first-order formula is good. Table 3 gives a summary of all the experiments on the decomposition in barium hydroxide solution. It is seen that k decreases a little when salt is

Table 3. Rate of decarboxylation of the divalent acetosuccinate ion by titration.

Temperature °C	Initial concentrations in mole / liter				$k \times 10^5$ sec^{-1}
	Ester	$Ba(OH)_2$	$BaCl_2$	KCl

25.0	0.04082	0.0549	0	0.400	0.182
37.0	0.03886	0.0546	0	0	0.876
37.0	0.03917	0.1096	0	0	0.960

added. The decrease is larger for barium chloride than for potassium chloride. On the other hand, k increases with increasing hydroxyl ion concentration. This increase may possibly be due to an error caused by a simultaneous reaction

$$CH_3COCH(COO^-)CH_2COO^- + HO^- \rightarrow CH_3COO^- + (CH_2COO^-)_2$$

It is however known that this type of reaction, the so called acid decomposition of β-keto carboxylate ions, is predominant only in concentrated alkali. As the most probable values of the rate constant k_2 for the spontaneous decarboxylation of the divalent acetosuccinate ion we therefore adopt

at 25.0°C: $k_2 = 0.191 \times 10^{-5}$ sec^{-1}

at 37.0°C: $k_2 = 0.876 \times 10^{-5}$ sec^{-1}

When the Arrhenius equation is applied, the following expression is obtained

$$k_2 = 2.39 \times 10^{11} \, e^{-23\,300/RT} \text{ sec}^{-1}$$

DECOMPOSITION IN SOLUTIONS OF HYDROGEN CHLORIDE

Rate experiments were carried out at 25.0 and 37.0°C on solutions of hydrogen chloride and sodium chloride, the total chloride ion concentration being 0.300 M. The reaction was followed by observing the pressure above the solution in an apparatus described in an earlier paper [2]. The difference P between the final pressure reading and the reading at the time t, is proportional to the total concentration (x M) of acetosuccinic acid at the time t: $P = \varphi x$, where φ is a constant. When α_0, α_1, and α_2 denote the fractions of the acid present in the form of undissociated acid (H_2X), univalent ion (HX^-), and divalent ion (X^{--}), respectively, the rate of decarboxylation may be written as follows

$$-\frac{dx}{dt} = (k_0\alpha_0 + k_1\alpha_1, + k_2\alpha_2)\, x \qquad (1)$$

where k_0, k_1, and k_2 are rate constants for the spontaneous decomposition of the molecules H_2X, HX^-, and X^{--}, respectively. The expression in parenthesis will vary more or less during the reaction. At the end it will approach the value

$$k = k_0\,\alpha_{0\,\infty} + k_1\,\alpha_{1\,\infty} + k_2\,\alpha_{2\,\infty} \qquad (2)$$

where the subscript ∞ denotes final values of the variables, corresponding to a hydrogen ion concentration equal to the concentration of hydrogen chloride (h M).

In order to interpret the experiments, it was necessary to know the dissociation constants of acetosuccinic acid and levulinic acid. Those for acetosuccinic acid were determined in a later section of this paper where $K_1 = 1.56 \times 10^{-3}$ and $K_2 = 3.64 \times 10^{-5}$ were found for 0.300 M sodium chloride at 25°C. Owing to the instability of the acid, it was not possible to measure the constants at 37°. The values found for 25° were therefore applied also at 37°. Accascina [3] has found the value 2.32×10^{-5} for the activity dissociation con-

stant of levulinic acid at 25°C. On the assumption that it increases with addition of sodium chloride in the same proportion as the dissociation constant of pyruvic acid [4], the value 4.57×10^{-5} is estimated for the solvent 0.300 M sodium chloride.

We shall now deduce a formula by means of which we shall compute k for the decomposition in solutions containing hydrogen chloride. We may here neglect the second dissociation of acetosuccinic acid and the dissociation of levulinic acid. We therefore obtain from eqns. 1 and 2 and the expression for the first dissociation constant of acetosuccinic acid

$$-\frac{dx}{dt} = k_0 x - (k_0 - k_1)\ \alpha_1 x \tag{3}$$

$$k = k_0 - (k_0 - k_1)\ \alpha_{1\infty} \tag{4}$$

$$\frac{\alpha_1\ (h + \alpha_1 x)}{1 - \alpha_1} = \frac{\alpha_{1\infty}\ h}{1 - \alpha_{1\infty}} \tag{5}$$

By means of eqn. 5, x may be written as a function of $\alpha_1 x$

$$x = \frac{1}{\alpha_{1\infty}}\ (\alpha_1 x) + \frac{1 - \alpha_{1\infty}}{\alpha_{1\infty}\ h}\ (\alpha_1 x)^2 \tag{6}$$

When first eqn. 6 and then eqn. 4 are introduced into eqn. 3, is obtained

$$-\frac{1}{\alpha_{1\infty}}\ \frac{d(\alpha_1 x)}{dt} - \frac{2\ (1-\alpha_{1\infty})}{\alpha_{1\infty}\ h}\ (\alpha_1 x)\ \frac{d(\alpha_1 x)}{dt} = \frac{k}{\alpha_{1\infty}}\ (\alpha_1 x) + \frac{k_0\ (1-\alpha_{1\infty})}{\alpha_{1\infty} h}\ (\alpha_1 x)^2$$

from which we get

$$-k\ dt = \frac{h\ d(\alpha_1 x) + 2\ (1 - \alpha_{1\infty})\ (\alpha_1 x)\ d(\alpha_1 x)}{h\ (\alpha_1 x) + \frac{k_0}{k}\ (1 - \alpha_{1\infty})\ (\alpha_1 x)^2}$$

which on integration gives

$$-kt + \text{const.} = \ln\ (\alpha_1 x) + \left(\frac{2k}{k_0} - 1\right) \ln\left[h + \frac{k_0}{k}\ (1-\alpha_{1\infty})\ (\alpha_1 x)\right] \tag{7}$$

When eqn. 6 is solved with respect to $\alpha_1 x$ and the abbreviation

$$\lambda = 4\ \alpha_{1\infty}\ (1 - \alpha_{1\infty})/h \tag{8}$$

is used, we obtain

$$\alpha_1 x = \frac{h}{2\ (1-\alpha_{1\infty})}\ (\sqrt{1 + \lambda x} - 1) = \frac{h\ \lambda\ x}{2\ (1 - \alpha_{1\infty})\ (1 + \sqrt{1 + \lambda x})} \tag{9}$$

If we further use the abbreviation

$$\varepsilon = 2\ (k_0 - k)/k_0 \tag{10}$$

and introduce eqn. 9 into eqn. 7, we get the formula

$$-kt + \text{const.} = \ln x - \ln (1 + \sqrt{1 + \lambda x}) + (1-\varepsilon) \ln (1-\varepsilon + \sqrt{1 + \lambda x}) \quad (11)$$

which may also be written in the form

$$-kt + \text{const.} = \ln x - \ln \left(1 + \frac{\sqrt{1 + \lambda x}-1}{2}\right) + (1-\varepsilon) \ln \left(1 + \frac{\sqrt{1 + \lambda x}-1}{2-\varepsilon}\right) \quad (12)$$

If we introduce $P = \varphi x$, write λ' instead of λ/φ, and transform to decadic logarithms, we get

$$-0.4343\ kt + \text{const.} = \log P - \log \left(1 + \frac{\sqrt{1 + \lambda' P}-1}{2}\right) + (1-\varepsilon) \log \left(1 + \frac{\sqrt{1 + \lambda' P}-1}{2-\varepsilon}\right) \quad (13)$$

When the hydrogen ion concentration is sufficiently large, λ will be so small that formula 13 may be simplified (using $\ln(1 + \delta) \simeq \delta$, and $\sqrt{1 + \delta} - 1 \simeq \delta/2$) to

$$-0.4343\ kt + \text{const.} = \log P - \frac{0.4343\ \varepsilon\lambda'}{4\ (2-\varepsilon)}\ P \quad (14)$$

If further $k_1\alpha_{1\,\infty} \ll k_0\ (1-\alpha_{1\,\infty})$ we find by means of eqns. 4 and 10 that $\varepsilon \simeq 2\alpha_{1\,\infty}$ which on introduction into eqn. 14 gives the following approximate formula in which k does not appear on the right side of the equation

$$-0.4343\ kt + \text{const.} = \log P - \frac{0.4343\ \alpha_{1\,\infty}^2}{\varphi\ h}\ P \quad (15)$$

The composition of the solutions examined and the results obtained are given in Table 4. The initial concentrations of acetosuccinic acid (x_0 M), given in the third column, have been calculated on the assumption that the ester has been completely hydrolysed while none of the acetosuccinic acid has been decarboxylated. Actually, up to 20 % of the acid had been decomposed when readings began, partly in alkaline solution and partly after the addition of hydrochloric acid, but this, of course, does not affect the kinetic result. The ethanol ($2x_0$ M) present in the solutions was produced by the hydrolysis. The degrees of dissociation $\alpha_{1\,\infty}$ and $\alpha_{2\,\infty}$ were calculated by means of the dissociation constants given before. In computing the rate constants k, it was for most of the solutions accurate enough to apply formula 15. For the other solutions, the approximate value of k found by means of this formula was used for the calculation of ε by means of eqn. 10 after which the exact formula 13 was applied. When the values of the expression on the right side of the equation were plotted against t, the points fell always very close to a straight line from the slope of which the final value of k was determined.

The reaction is, in the solutions examined here, predominantly a spontaneous decarboxylation of the undissociated acid. The data were therefore used for calculating k_0 by means of eqn. 2. It follows from the values of k_2

found in the preceding part of the paper that the last term of the equation may be neglected. When k_1 found in experiments on acetate buffers in the next part of the paper is applied, k_0 given in the last column of Table 4 is computed The average values at the two temperatures are

$$\text{at } 25.0°\text{C:} \qquad k_0 = 17.23 \times 10^{-5} \text{ sec}^{-1}$$

$$\text{at } 37.0°\text{C:} \qquad k_0 = 74.3 \times 10^{-5} \text{ sec}^{-1}$$

When the Arrhenius equation is applied, the following expression is obtained

$$k_0 = 4.38 \times 10^{12} \, e^{-22\,400/RT} \text{ sec}^{-1}$$

Two of the solutions in Table 4 contained cupric nitrate while the total ionic strength was the same as in the other solutions. The results show that cupric ions have no catalytic effect.

DECOMPOSITION IN ACETATE BUFFER SOLUTIONS

The rate of decarboxylation was studied by the manometric method at 25.0 and 37.0°C in solutions containing acetic acid, sodium acetate, and, in some cases, sodium chloride, the total ionic strength being always close to 0.300. The composition of the solutions examined is shown in Table 5.

In applying eqn. 1 to the experimental data, it must be taken into account that a_0, a_1, and a_2 change a little as the reaction progresses, from their initial values $a_{0\,0}$, a_{10}, and a_{20} (corresponding to the presence of x_0 M acetosuccinic

acid) to their final values $\alpha_{0\,\infty}$, $\alpha_{1\,\infty}$, and $\alpha_{2\,\infty}$ (when practically all acetosuccinic acid has been transformed into levulinic acid and carbon dioxide). In order to correct for this change, it was as an approximation assumed that α_0, α_1, and α_2 vary linearly with x. Eqn. 1 may then be written as

$$-\frac{dx}{dt} = (k + \beta x)x \tag{16}$$

where we have used the abbreviation

$$\beta = [k_0\ (\alpha_{0\,0} - \alpha_{0\,\infty}) + k_1\ (\alpha_{10} - \alpha_{1\,\infty}) + k_2\ (\alpha_{20} - \alpha_{2\,\infty})] / x_0 \tag{17}$$

By integration of eqn. 16, transformation to decadic logarithms, and insertion of $P = \varphi x$ and $\beta' = \beta/\varphi$, is obtained

$$-0.4343\ kt + \text{const.} = \log P - \log\ (1 + \beta' P) \tag{18}$$

The initial and final values of α_0, α_1, and α_2 were computed for all the solutions examined. In this computation were used the values of the dissociation constants of acetosuccinic acid and levulinic acid given in the preceding section of the paper. For the dissociation constant of acetic acid was, both at 25 and 37°C, used the value 3.20×10^{-5} estimated for the solvent 0.3 M sodium chloride on the basis of measurements by Harned and Hickey [5] and by Kilpatrick and Eanes [6]. The slight dissociation of carbonic acid was neglected. In Table 5 are, to save space, given only $\alpha_{0\,\infty}$ and $\alpha_{1\,\infty}$ together with the final acetate ion concentration $[Ac^-]_\infty$.

When k was computed from the observed data by means of eqn. 18, a method of successive approximations had to be used, since β' was unknown at the start. In the final step, when β' was calculated from eqn. 17 by means of the constants in the expressions for k given below (eqns. 19 and 20), the values of k shown in the next to the last column of Table 5 were obtained. When eqn. 2 was applied, it was found that k_0 could not have the value found previously for solutions of hydrogen chloride. Agreement could, however, be obtained when it was assumed that k_0 increases linearly with the acetate ion concentration, that is, acetate ions catalyse the decarboxylation of undissociated acetosuccinic acid. On this basis the following expressions for the rate constants were obtained

$$25.0°: \quad k \times 10^5 = (17.23 + 47.8\ [Ac^-])a_{0\infty} + 3.054\ a_{1\infty} + 0.191\ a_{2\infty} \qquad (19)$$

$$37.0°: \quad k \times 10^5 = (74.3 + 166\ [Ac^-])a_{0\infty} + 16.37\ a_{1\infty} + 0.876\ a_{2\infty} \qquad (20)$$

Each of the expressions contains two new constants, k_1 and the catalytic coefficient of the acetate ion (k_{Ac^-}), which have been computed so as to obtain the best agreement with the observed values of k. The last column of Table 5 shows k calculated by means of eqns. 19 and 20. When the Arrhenius equation is applied, the following expressions are obtained

$$k_1 = 2.10 \times 10^{14}\ e^{-25\,700/RT}\ sec^{-1}$$

and

$$k_{Ac^-} = 4.54 \times 10^{10}\ e^{-19\,100/RT}\ liter\ mole^{-1}\ sec^{-1}$$

Cupric ion catalysis. In Table 6 are given the results of rate measurements on acetate buffer solutions containing 0.00480 M cupric nitrate, the total ionic

Table 6. Decarboxylation of acetosuccinic acid (initially x_0 M) in the solvent: a M acetic acid, b M sodium acetate, 0.00480 M cupric nitrate, (0.286 − b) M sodium chloride, $2x_0$ M ethanol.

strength being 0.300. It was here necessary to take into account the complex formation between cupric and acetate ions while that between cupric and chloride ions was neglected. The initial and final values of the acetate, cupric, and hydrogen ion concentrations, and of α_0, α_1, and α_2, were computed by means of the dissociation constants of the acids given before and the following values of the complexity constants [7], corresponding to the ionic strength 0.300

$$[CuAc^+] / [Cu^{++}]\ [Ac^-] = 41.2$$

$$[CuAc_2] / [Cu^{++}]\ [Ac^-]^2 = 264$$

Only the final values of the acetate and cupric ion concentrations, and of α_0 and α_1, are given in Table 6. Rate constants k, computed from the observed data by the same procedure as for solutions without cupric nitrate, are given in the next to the last column. They are from 1 to 14 % higher than those shown in the last column which were computed by means of eqns. 19 and 20 on the assumption that cupric ions do not catalyse. The difference indicates that cupric ions have a small catalytic effect in the decarboxylation of acetosuccinic acid. The data are not accurate enough to establish a mechanism for the catalytic reaction, but they agree best with the assumption that the rate is proportional to the product $[CuAc^+]\alpha_2$.

It has been found earlier that certain metal ions, especially cupric ions, have a powerful catalytic effect in the decarboxylation of other dibasic β-keto carboxylic acids, such as oxaloacetic acid [8,9], dimethyloxaloacetic acid [10], acetonedicarboxylic acid [11], and dihydroxytartaric acid [12]. This catalysis was explained as being the result of a rapid decarboxylation of a complex of the chelate type between the metal ion and the divalent β-keto carboxylate ion. In this complex, the metal ion is bound to a keto and a carboxylate group. It is essential that a carboxylate group having a keto group in β-position is free, since a metal ion seems to stabilise the carboxylate group to which it is bound. Thus, the metal ion complexes of the nitroacetate ion do not split off carbon dioxide [13]. The chelates which decompose rapidly would therefore in oxaloacetic acid have the five-membered ring structure I, and in acetonedicarboxylic acid the six-membered ring structure II. In acetosuccinic acid two chelates are conceivable, the six-membered ring structure III and the seven-membered ring structure IV. The former would not be expected to split off carbon dioxide, and the latter may possibly be formed less readily since it has a seven-membered ring.

THE DISSOCIATION CONSTANTS OF ACETOSUCCINIC ACID

The first and second dissociation constant of acetosuccinic acid were determined by glass-electrode measurements at 25.0°C on acetosuccinate buffer solutions containing various concentrations of sodium chloride. The measurements were carried out, and the hydrogen ion concentrations computed, by the procedure followed by the author in earlier papers [4,14]. By the measurements was determined what is actually the e.m.f. (E volts) of cells of the composition

$$H_2;\ X;\ 3.5\ M\ KCl;\ 0.00999\ M\ HCl,\ 0.0900\ M\ NaCl;\ H_2$$

where X is the acetosuccinate buffer under investigation.

The buffer solutions were prepared in the following way. Diethyl acetosuccinate was weighed out and dissolved in a solution of sodium hydroxide and sodium chloride (concentrations shown in Table 10). The mixture was placed in a thermostat at 25.0°C. According to measurements in the first part of this paper, the ester was completely hydrolysed within 4 h. The buffer solutions to be measured were prepared by adding appropriate volumes of hydrochloric acid and water to samples taken from the alkaline solution after complete hydrolysis. If no decarboxylation had taken place, the solutions would have the composition shown in Tables 7 and 8 (x_0 M acetosuccinic acid, b M sodium hydroxide, s M sodium chloride, $2x_0$ M ethanol). Actually, more or less of the acetosuccinic acid had been transformed into levulinic acid and carbon dioxide when the measurement took place, partly by a slow reaction in alkaline solution, and partly by a more rapid reaction after acidification. In order to find the hydrogen ion concentration of solutions where no decarboxylation had taken place, two extrapolations were made, one to correct for decarboxylation in acid solution and another to correct for decarboxylation in the alkaline solution from which the buffer was made. In order to make the first extrapolation, E was measured with an interval of one minute in the time from 4 or 5 to 25 or 30 min after the acidification. When E was plotted against the time (t minutes after acidification of the solution), the points fell close to a straight line by means of which E corresponding to $t = 0$ was found. Three or four such series of measurements were carried out on buffer solutions of the same composition except that they were made up from the alkaline solution at different times (τ hours after its preparation). E corresponding to $t = 0$ for each series was plotted against τ, and E_0 was found by extrapolation to $\tau = 0$. In evaluating τ, a small correction was subtracted (estimated to be 0.4 h) in order to allow for the space of time in which the ester was not completely hydrolysed. Values of $-\log[H^+]_0$, pertaining to solutions where no decarboxylation had taken place, were calculated from E_0. They are given in Tables 7 and 8 together with, respectively, $-\log K_1$ and $-\log K_2$ computed from them in the usual way. In the tables are also shown the ionic strengths I of the solutions. When Debye-Hückel's limiting law is applied, it is found that the results may be expressed by the formulae

$$-\log K_1 = 3.048 - 1.013\ \sqrt{I}/(1 + 2.38\ \sqrt{I}) \qquad (21)$$

$$-\log K_2 = 4.952 - 2.026\ \sqrt{I}/(1 + 2.12\ \sqrt{I}) \qquad (22)$$

Table 7. First dissociation constant (K_1) of acetosuccinic acid at 25.0°C.

	$x_0 \times 10^3$	$b \times 10^3$	s	I	$-\log [H^+]_0$	$-\log K_1$	$-\log K_1$ calc.

When $-\log K_1$ and $-\log K_2$ are calculated by means of these expressions, the values given in the last column of Tables 7 and 8 are obtained. If it is permissible to extrapolate to $I = 0$ by means of eqns. 21 and 22, the two activity dissociation constants are $K_1 = 8.95 \times 10^{-4}$ and $K_2 = 1.12 \times 10^{-5}$.

For the buffer solutions examined in the first three lines of Table 7 (A 1—3) and the first three lines of Table 8 (B 1—3) are in Table 9 given the values of E and $-\log[H^+]$ found by extrapolation of the observed data to the time ($t = 0$) when the solution was acidified. In order to show how rapidly E changes, values of E and $-\log [H^+]$ corresponding to either $t = 10$ or $t = 20$ min are also given for most of the solutions. All the solutions of Table 9 were prepared from alkaline solutions of the same initial composition (given in the first line of Table 10).

Rate of decarboxylation from e.m.f. measurements. In order to estimate the rate of decarboxylation both in the alkaline solutions and in the buffer solutions, the concentrations of undecomposed acetosuccinic acid (x molar) were calculated from the hydrogen ion concentrations by means of the following formula (expressing the principle of electroneutrality)

$$(\alpha_1 + 2\alpha_2)\ x + (\alpha' + \alpha'')\ (x_0 - x) = b + [H^+] \qquad (23)$$

Table 10. Rate of decarboxylation in alkaline solution at 25.0°C from glass-electrode measurements.

Solutions	Ester mole/liter	NaOH mole/liter	NaCl mole/liter	$k_2 \times 10^5$ sec^{-1} (A)	$k_2 \times 10^5$ sec^{-1} (B)
A 1—3, B 1—3	0.0400	0.0995	1.100	0.173	0.160
A 4—6, B 4—6	0.0400	0.0995	0.700	0.177	0.166
A 7—9, B 7—9	0.0400	0.0995	0.300	0.188	0.174

While α_1 and α_2 have the same meaning as earlier in this paper, α' is the fraction of levulinic acid present as ion, and α'' is the fraction of carbon dioxide present as univalent ion (may be neglected for the solutions A 1—9). The values of α_0, α_1, and α_2 were computed from $[H^+]$ by means of the dissociation constants calculated from eqns. 21 and 22. In the computation of α' were used the following values of the dissociation constant of levulinic acid: 3.95×10^{-5}, 4.42×10^{-5}, and 4.57×10^{-5}, at the ionic strengths 0.1, 0.2, and 0.3, respectively (estimated from the measurements of Accascina [3] as explained earlier). The values of the dissociation constant of carbonic acid used in calculating α'', 7.8×10^{-7}, 9.0×10^{-7}, and 9.8×10^{-7}, at the ionic strengths 0.1, 0.2, and 0.3, respectively, were taken from a paper by Näsänen [15].

Values of x calculated by means of eqn. 23 are given in the sixth column of Table 9. In the next column are given the rate constants k_2 for the decarboxylation in alkaline solution computed by means of the formula for a first-order reaction from the values of x corresponding to $t = 0$ and x_0 given in Tables 7 and 8. The average value of k_2 for the series A 1—3 is 0.173×10^{-5} sec^{-1}, while for the series B 1—3 it is a little lower, 0.160×10^{-5} sec^{-1}. The results of similar calculations for the other solutions examined are summarised in Table 10. It is seen that the B-series always give a lower value than the A-series. A comparison with the values of k in Table 3 will show that there is a reasonable agreement between the values obtained by the titration method and those found by means of glass-electrode measurements.

The rate constants k for the decarboxylation in the buffer solutions given in the next to the last column of Table 9 were computed by means of the first-order formula from the two values of x shown in the table for each solution. Since the fractions α_0, α_1, and α_2 change a little in the interval examined, the reaction will not follow the first-order law strictly, but the values of k obtained should hold approximately for a solution in which α_0, α_1, and α_2 are constant and equal to the average of their values at the beginning and end of the interval. If k is calculated from the average values by means of formula 19 ($[Ac^-] = 0$), the values shown in the last column of Table 9 are obtained. They are in reasonable agreement with those found from the electrometric measurements.

A Study of the Pyrazoles formed by Reaction between *p*-Carboxyphenylhydrazine and some β-Diketones

STIG VEIBEL, BENT JUHL NIELSEN and SUSANNE REFN

Department of Organic Chemistry, University of Technology, Copenhagen, Denmark

It has been stated previously that pyrazole derivatives, crystallising with 1 mole of water, and not *p*-carboxyphenylhydrazones, are formed when reacting β-diketones with *p*-carboxyphenylhydrazine. This statement has been corroborated by investigating the UV- and the IR-absorption of the derivatives as well as their titration curves when titrated as acids and as bases.

Some 10 years ago it was proposed to use *p*-carboxyphenylhydrazine as a reagent for the identification of carbonyl compounds, the *p*-carboxyphenylhydrazones formed by the condensation reaction being titratable as acids and thus of value in determining the equivalent weight of the carbonyl compound investigated [1].

It is well known that β-diketones, when reacting with hydrazine derivatives, do not form mono- or bis-hydrazones but, by ring closure of the initial monohydrazones, pyrazole derivatives. This means that when calculating the molecular weight of the carbonyl compound from that of the *p*-carboxyphenylhydrazine-derivative one has to use the formula $E = E_{p\text{-Carb.}}—116.1$ instead of the formula $E = E_{p\text{-Carb.}}—134.1$ ordinarily used, as two molecules of water have been eliminated during the condensation reaction.

If was found, on the other hand, that when isolated and purified as usually (recrystallised from ethanol or aqueous ethanol) acetylacetone, benzoylacetone and dibenzoylmethane gave derivatives which titrated as the ordinary *p*-carboxyphenylhydrazones, not as the corresponding pyrazoles. When, however, these derivaties were dried *in vacuo* over phosphorus pentoxide at 56° or at atmospheric pressure at 130°, they titrated as pyrazoles. Recrystallised from ethanol they once more titrated as *p*-carboxyphenylhydrazones. It was, without further proof, stated that the pyrazoles crystallise with 1 mole of water of crystallisation which is removed by drying and taken up again by recrystallisation [1], thus ignoring the possibility that ring closure might take place when drying the substances, ring opening during their recrystallisation.

In order to settle this question finally we decided to compare the UV- and the IR-absorption of the dried and the recrystallised preparations with the UV- and the IR-absorption of a genuine *p*-carboxyphenylhydrazone of a monoketone with a CH_2-group instead of one of the carbonyl groups in the β-diketones.

Besides, we determined the titration curves of these substances when titrated as acids with sodium hydroxide and as bases with perchloric acid in glacial acetic acid, this last mentioned method making an estimation of the pK_B-values possible [2].

The result of this investigation is a corroboration of the previous statement. The absorption curves of the dried and of the dried and recrystallised preparations are within the limit of the experiment identical and different from the absorption curves of *p*-carboxyphenylhydrazones. The titration curves, too, indicate the identity of the dried and the dried and recrystallised preparations and their difference from a *p*-carboxyphenylhydrazone structure.

EXPERIMENTAL PART

All substances were prepared as described [1] and showed the m.p.'s indicated there.

Drying of the derivatives of acetylacetone (I), benzoylacetone (II) and dibenzoylmethane (III). Samples were dried at 56° *in vacuo* over phosphorus pentoxide. Loss of weight was: I, 8.37 %, II, 6.56 %, III, 6.54 %, calculated for 1 mole of water, I, 7.69 %, II, 6.08 %, III, 5.03 %.

Titration of the derivatives as acids. 1 mmole of the substances, once before drying, then after drying and finally after recrystallisation of the dried sample, was dissolved in 50 ml of ethanol and titrated with 0.1 N sodium hydroxide. At the same time the *p*-carboxyphenylhydrazones of methyl propyl ketone (IV) and of propiophenone (V) were titrated. Table 1 gives the equivalent weights found.

Table 1. Titration of the derivatives with NaOH.

	I			II		
	Undried	Dried	Recryst.	Undried	Dried	Recryst.
E found	235.9	214.7	234.3	295.6	278.6	297.4
E calc.	234.3	216.3	234.3	296.3	278.3	296.3
	III				IV	V
E found	362.6	342.9	362.4		218.1	265.5
E calc.	358.4	340.4	358.4		220.3	268.3

Ultraviolet absorption of I—V. Fig. 1 shows that the absorption curves of I, II and III are of the same type, especially in the region 2 700 Å—3 000 Å, and in this region quite different from the absorption of IV and V. No significant difference between the dried and the recrystallised preparations can be observed.

Infrared absorption of I—V. The absorption in the region from 3 700 cm^{-1} to 670 cm^{-1} was determined, using a Beckman IR 2 spectrophotometer and applying the potassium bromide disk technique.

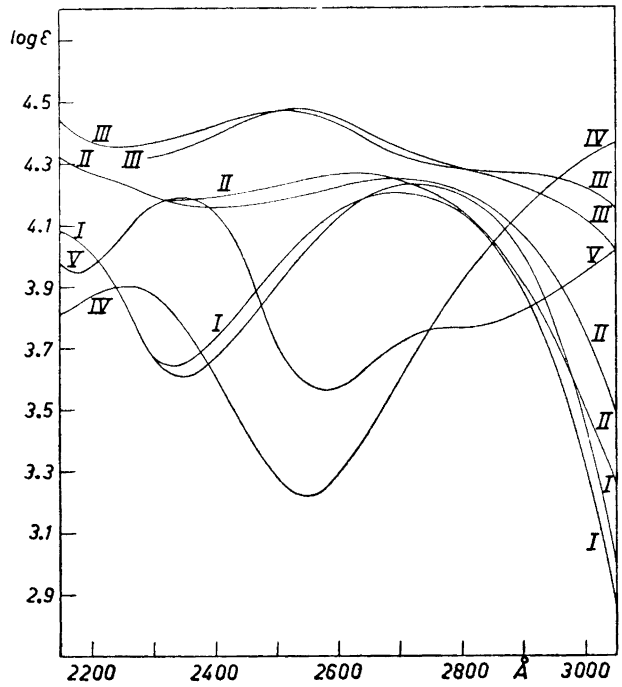

Fig. 1. UV-absorption curves of the substances investigated.
I. Acetylacetone-derivative. II. Benzoylacetone-derivative. III. Dibenzoylmethane-derivative. IV. Methyl propyl ketone-*p*-carboxyphenylhydrazone. V. Propiophenone-*p*-carboxyphenylhydrazone.

Neither the genuine *p*-carboxyphenylhydrazones (IV—V) nor the genuine pyrazoles (I—III dried *in vacuo*) possess absorption bands sufficiently characteristic to decide from such bands alone whether or not ring closure has taken place.

The spectra of the undried and of the dried and recrystallised specimens are identical for each of the substances I, II and III respectively. Of the dried specimens, II shows a spectrum identical with that of the other specimens of II, whereas in I insignificant changes in the relative intensities of adjacent bands at 870 cm^{-1}, 1 130 cm^{-1} and 1 260 cm^{1}, and in III similar insignificant changes at 765 cm^{-1}, 810 cm^{-1} and 1 430 cm^{-1} could be observed.

The spectra of the 3 specimens of I, II and III were, however, for each substance so closely identical that the identity of structure of the 3 specimens is unambiguous, the slight differences observed being possibly caused by the presence of water of crystallisation in the two specimens, whereas the third is anhydrous.

Titration of the derivatives as bases. 1 mmole of I, II, IV and V was dissolved in 50 ml of glacial acetic acid and titrated with 0.0985 N perchloric acid in glacial acetic acid, using a glass electrode and a calomel electrode as reference electrode. III is so sparingly soluble in glacial acetic acid that its titration under comparable conditions could not be carried through.

Table 2 shows that here, too, the dried and the recrystallised preparations are identical, the jump of potential being somewhat greater for the anhydrous preparations than for those with water of crystallisation, in accordance with the fact that water always will decrease the jump of potential in these titrations.

that there is no great difference in basic properties of the pyrazoles and the *p*-carboxyphenylhydrazones, the influence of the substituents being, however, somewhat greater in the latter than in the former group of derivatives.

The Magnetic Properties of the Thermochromic Compounds Cu_2HgI_4, Ag_2HgI_4 and Tl_2HgI_4

Studies in Magnetochemistry 23 *

R. W. ASMUSSEN and PALLE ANDERSEN

The Chemical Laboratory B, Technical University of Denmark, Copenhagen, Denmark

The magnetic susceptibilities of Cu_2HgI_4, Ag_2HgI_4 and Tl_2HgI_4 have been measured at varying temperatures: 90—403 °K, 88—335 °K and 84—403 °K, respectively. The compounds are diamagnetic at all temperatures in the intervals stated. The χ_g, T curves are nearly parallel to the T-axis. After correction for the diamagnetism of the electron systems of the ions it is shown that the corrected χ_M values represent a weak paramagnetism nearly independent of the temperature. No discontinuity is observed in any of the susceptibility curves at the colour transition temperatures. A colourimetric method for the determination of the colour transition temperatures has been worked out. The transition temperatures for Cu_2HgI_4, Ag_2HgI_4 and Tl_2HgI_4 are determined to be 69.5, 50.5 and 116.5 °C, respectively, for our preparations.

Silver(I)iodomercurate and copper(I)iodomercurate were prepared by Caventou and Willm [1], Mensel [2], Wegelius and Kilpi [3] and Popow [4]. Gallais [5] prepared the compounds mentioned and also the thallium(I)iodomercurate. The compounds are thermochromic having a low and a high temperature form of different colour. The two phases are usually designed β and α, respectively. Ketelaar [6,7] studied the crystal structures of the β and α forms of the silver and copper compound. The β forms are reported to be of pseudocubic tetragonal symmetry and the α phases cubic. Recently Hahn, Frank and Klingler [8] determined the structure of β-Cu_2HgI_4 and β-Ag_2HgI_4 with results differing from those of Ketelaar (compare also Suchow and Keck [9], Olsen and Harris [10] and Frevel and North [11]). Hoshino's [12] structure determination on α-Ag_2HgI_4 also differs from that of Ketelaar.

Furthermore, Ketelaar [13-15] measured the electric conductivity and the specific heat capacity of the different forms of the silver compound at varying

* No. 22 appeared in *Acta Chem. Scand.* 12 (1958) 578.

temperatures. Ag_2HgI_4 has ionic conductivity [13,15], which inreases rapidly just below the colour transition temperature. In the case of the copper compound an electronic conductivity is superimposed upon the ionic conductivity. Ketelaar has interpreted his experimental results in terms of an order-disorder mechanism. Suchow and Keck [9] investigated the system Cu_2HgI_4-Ag_2HgI_4 and report also Munsell colour specifications and reflectance measurements. Suchow and Pond [16] studied the temperature dependence of the electrical conductivity of the copper and the silver compound and their eutectoid.

Magnetic properties. Gallais [5] measured the magnetic susceptibilities of Cu_2HgI_4, Ag_2HgI_4 and Tl_2HgI_4 at room temperature. We considered it of value to study the magnetic properties of these compounds in a larger temperature interval covering the transition temperatures and the temperatures at which the electrical conductivities increase rapidly. The results of our measurements are given in the lower part of Fig. 1, where the diamagnetic gram susceptibilities measured are plotted against the absolute temperature. It is seen that the straight lines are nearly parallel to the temperature axis. If we correct the molar susceptibilities for the diamagnetism of the electron systems of Cu^+, Ag^+, Tl^+, Hg^{+2} and I^- (see experimental part) we obtain the small but paramagnetic susceptibilities, which are plotted against the absolute temperature in the upper part of Fig. 1. The vertical arrows indicate the position of the colour transition temperatures. The straight lines like those for χ_g are of course nearly parallel to the temperature axis.

The correction for diamagnetism has been performed under the assumption that the diamagnetic susceptibility of an ion is the same in the crystal as in the free state. The obvious and direct result of the calculation is that the total calculated molar diamagnetic susceptibility is numerically greater than the observed numerical value. The reason for the difference between the observed and the calculated diamagnetism may be that the ions are deformed in the crystal. The true diamagnetic susceptibility of the ions in the crystal may be numerically smaller than that in the free state because the mean square radii of the electrons in the ions are decreased. However, we must point out that the weak paramagnetism plotted in Fig. 1 may be a physical reality as a temperature independent paramagnetism, the general existence of which has been predicted by Van Vleck [17]. The presence of this paramagnetism has been verified experimentally in many deeply coloured substances (compare for instance Ballhausen and Asmussen [18]).

The magnetic measurements prove that no discontinuity in the magnetic properties occurs at the colour transition temperatures. This is so far in accordance with Ketelaar's order-disorder mechanism, since this does not involve a change in the electron configuration of the ions but a motion of metal ions to other positions during the continuous transformation process.

Colour transition temperatures. The colour transition temperatures were determined by means of reflectance measurements as described in the experimental part. In Fig. 2 the reflectances F are plotted against the temperature in °C. The black points represent measurements carried out during cooling of the preparation. Hysteresis phenomena were only observed when not quite pure preparations were used. The observations on Tl_2HgI_4 are of particular interest indicating that thermochromi is also a property of this substance.

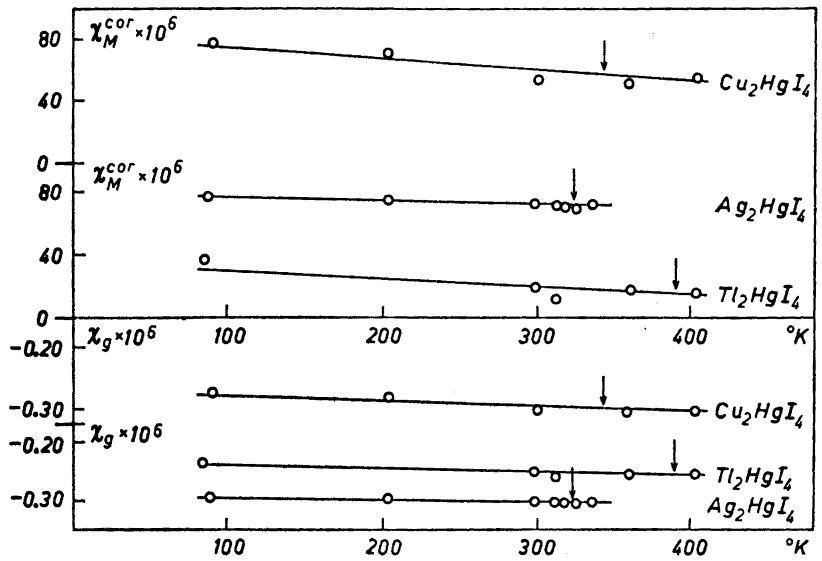

Fig. 1. Gram susceptibility and corrected molar susceptibility of Cu_2HgI_4, Ag_2HgI_4 and Tl_2HgI_4 plotted against the abs. temperature. The vertical arrows indicate the colour transition temperature.

The curves give the values 69.5, 50.5 and 116.5°C for the transition temperatures of Cu_2HgI_4, Ag_2HgI_4 and Tl_2HgI_4, respectively. In Table 1 is given a comparison between these observations and those of other authors.

Table 1. Colour transition temperatures.

Substance	Colour		Colour transition temperature, °C		
	β	α	Ketelaar [7]	Suchow and Pond [16]	Present paper
Cu_2HgI_4	ruby	darkbrown	70	66.6	69.5
Ag_2HgI_4	yellow	redorange	50.7	50.0	50.5
Tl_2HgI_4	orange	red			116.5

In Fig. 3 we report reflectance measurements on HgI_2. The red tetragonal crystal is transformed into a yellow rhombic form at 127 °C. The reflectance measurements show that the colour change occurs abruptly near 127 °C in contrast to the picture given in Fig. 2 of the colour change during the disordering process.

EXPERIMENTAL

Preparation and analysis of the compounds

Cu_2HgI_4 can be precipitated from a solution of K_2HgI_4 containing the equivalent amount of $CuSO_4$ (referred to the formula Cu_2HgI_4), by bubbling SO_2 through the solution.

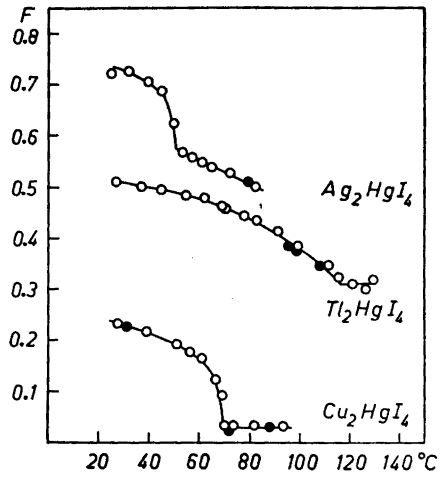

Fig. 2. Reflectance F of the compounds Cu_2HgI_4, Ag_2HgI_4 and Tl_2HgI_4 plotted against the Celsius temperature. The "black" points represent F-values measured at decreasing temperatures.

However, our experiences have shown that better developed and purer crystals can be obtained by a diffusion method. The preparations used for the magnetic and optical measurements were obtained as follows:

Two crystallizing dishes *A* and *B* of 7 cm diameter and 4.5 cm height were placed in a 21 × 11 × 11 cm glass vessel. The distance between *A* and *B* was 12 cm. *A* contained a 0.1 M aqueous solution of K_2HgI_4. *B* contained a saturated solution of CuCl in 20 % hydrochloric acid and a few pieces of copper turnings. *A* and *B* were completely filled with solutions. The junction liquid was 20 % hydrochloric acid saturated with SO_2. The glass vessel had an airtight glass lid. The first crystals were formed after 24 h. After 24 days the junction liquid was siphoned off and the crop of ruby crystals formed (mainly in *A*) was isolated, washed with water, and dried on filterpaper. A few larger crystal needles were also obtained. The yield was 50 %.

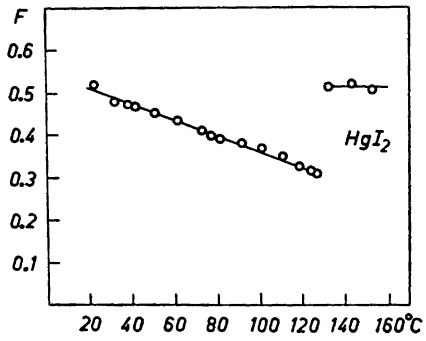

Fig. 3. Reflectance F of HgI_2 plotted against the Celsius temperature.

The amount of crystal needles could be increased by replacing *A* and *B* by two smaller dishes having a lesser diameter at the top part than at the bottom. The two dishes were covered with a piece of circular filterpaper. After 30 days a small crop of crystals was formed on the filterpaper upon *A*. The length of the needles was nearly 4 mm.

The quantitative analysis was carried out as follows: The sample was treated with conc. nitric acid in order to remove iodine and to convert Cu^{+1} to Cu^{+2}. The solution was evaporated (nearly to dryness). Nitrogen oxides were removed by boiling with dil. hydrochloric acid. Hg was determined by weighing as HgS, and Cu iodometrically. Iodine was determined by the iodate-method, the metals being eliminated by means of zinc.

Found: Cu 14.91 %; calc. 15.22 %
Found: Hg 23.95 %; calc. 24.01 %
Found: I 60.71 %; calc. 60.77 %

The copper determination gives values for per cent Cu, which are 2 % (relatively) lower than the theoretical value, when the analysis is carried out as described.

Ag_2HgI_4. Experiments were carried out in order to prepare this compound according to the diffusion method described above. The dish *B* contained a silver sulphate solution and the junction liquid was dil. sulphuric acid. We have, however, not succeeded in obtaining crystals of a purity sufficient for our purpose. The samples used for the physical measurements were prepared by precipitation as described by Henderson and Fernelius [19].

The quantitative analysis was confined to a determination of iodine by the iodate method after conversion of the metal ions to the metallic state (zinc-reductor).

Found: I 54.63 %; calc. 54.94 %

Tl_2HgI_4. The diffusion method gives crystal mixtures containing yellow, red, and black crystals. No well defined preparation could be obtained. The samples used for the measurements were prepared according to Gallais [5]. X-Ray powder-photos prove that the substance is a well defined compound. The crystals are of orange colour. The compound is decomposed above 130°C.

Magnetic measurements

The magnetic susceptibilities were measured by means of the Gouy method similar to that of Asmussen and Soling [20]. The observed diamagnetic gram susceptibilities are plotted against the temperature in °K in the lower part of Fig. 1. In the upper part of Fig. 1 the corrected molar susceptibilities are plotted against T°K. It should be noticed that the ordinates for each curve are measured from a zero-point, the position of which is fixed for each curve. The corrections applied for the diamagnetism of the electron systems of the ions Hg^{+2}, Cu^{+}, Ag^{+}, Tl^{+}, and I^{-} are, respectively: 47.6×10^{-6}, -19.3×10^{-6}, -42.1×10^{-6}, -17.0×10^{-6}, and -55.3×10^{-6}.

Gallais [5] has measured the magnetic susceptibilities of Cu_2HgI_4, Ag_2HgI_4, and Tl_2HgI_4 at room temperature only and gives the following diamagnetic gram susceptibilities: -0.26×10^{-6}, -0.19×10^{-6}, and -0.24×10^{-6}, respectively. Gallais' value for Ag_2HgI_4 is 37 % lesser than our room temperature susceptibility.

Determination of the colour transition temperatures

The colour transition temperature is usually measured by immersing small glass tubes containing the substance in a water-bath. The temperature of the water-bath is slowly increased and the colour change is observed visually.

We considered it of value to carry out objective measurements of the colour change for the $\beta \rightarrow \alpha$ transitions by means of the photoelectric tricolourimeter constructed by Buchmann-Olsen [21]. We have determined one coefficient only applying the filter OY 12, the transmission curves of which are given in the paper of Buchmann-Olsen [21] (page 82). This filter allows a recording of the reflections in a wavelength interval corresponding to that of visible light. In order to measure the reflectance at different temperatures a heating block of nickel plated brass (60 mm diameter and 85 mm height) was used. In the lower end of the block was a chamber, in which an incandescent lamp was mounted.

Regulation of the electric current through the filament allows to fix the temperature of the block. In the upper end of the block was a small chamber for the specimen powder (35 mm diameter and 0.5 mm deep). The block was thermally isolated from the surroundings by a brass tube covered with asbestos. A copper-constantan thermocouple was mounted in the specimen chamber through a drill sloping upwards so that the bead of the thermocouple was situated in the center of the bottom of the chamber. The temperature measured may be considered as a mean temperature of the surface of the specimen powder; the bead of the thermocouple being just covered with powder.

The photo-cell used in the tricolourimeter was a selenium photo-cell from Ewans Electro-selenium Ltd. The photo-current was measured with a Cambridge light spot galvanometer. The reflectance was measured as the ratio F of the readings on the galvanometer when light is reflected from the specimen powder and from a white standard. Each of the F values plotted in Figs. 2 and 3 are mean values of 3 measurements of F. The time necessary for these measurements was about 8 min. In this time interval the observed temperature did not vary more than 0.25 degrees. The F values were found to be reproducible within 1 %.

The Electrical Contact Potential and the Individual Activity of Single Ions

NIELS BJERRUM

Chemical Laboratory, The Royal Veterinary and Agricultural College, Copenhagen, Denmark

The difficulties met with in determinations of the site and the value of the electrical contact potential between different phases are described. They have as yet made it impossible to determine these contact potentials.

The relationship between these contact potentials and the activities and the partition coefficients of single ions is mentioned. As it has been impossible to determine contact potentials, it has also been impossible to determine the activities and the partition coefficients for single ions. This impossibility creates difficulties for an exact definition of Sørensen's pH-values and of Brönsted's concept of acidity, and these difficulties are discussed.

It is shown that by transfers of particles with electric charges from one phase to another not only the total work of transfer, but also the *electrical* part of it must depend on the nature of the particle considered. The electrical contact potential between two different phases therefore is not a single valued function of the nature of the two phases, but it also depends on the nature of the electric particle (ion or electron) to be transferred.

This fact explains the elusive character of the concept of a definite electrical contact potential between two different phases.

Since the discovery of the electrical contact potentials between different substances it has been difficult to ascribe definite values to these potentials. Volta constructed the first galvanic cell, consisting of plates of two different metals, separated by a moist plate. He assumed in the beginning that the electricity was created at the surfaces, where the metals were in contact with the moist plate, but experiments with a condenser made him think that the production of electricity took place mainly at the surface between the two metals [1].

The condenser experiment of Volta as modified by William Thomson (Lord Kelvin) [2] uses a condenser with plates of the two metals whose contact potential is to be measured. One of the plates is connected to a sensitive electrometer, and in the connection between the two plates is introduced a variable electromotive force. The value of that electromotive force which makes

possible the separation of the two condenser plates (after removal of the connection between them) without change in the electrometer is considered as the measure of the contact potential.

Millikan [3] later used a thermionic valve for determining the contact potential. In the valve two pieces of different metals could alternately be used as the anode, and Millikan assumed that the contact potential between them is equal to the displacement of the current-voltage curve along the voltage axis, observed when the one anode was replaced by the other.

These two methods have been found to give similar values for the contact potential. The accuracy obtained is not great, but the potential values found are similar in size to the electromotive force of the corresponding galvanic cell. This seems to support the conclusion of Volta that the site of the electromotive force is at the surface between the two metals, but this is erroneous. The quantity determined by the two methods is not the desired contact potential. It is determined by the force field in the air (or vacuum) between the two plates, and thus it is not the potential between two points within the two connected pieces of metal, but the potential between two points just outside the surfaces of the metals. Consequently the potential is in reality equal to the sum of three contact potentials: one between the two metals and two others between the metals and the surrounding air (or vacuum).

The first idea of Volta, that the site of the electromotive force in his galvanic cell was at the surface, where the metals are in contact with the moist plate, later got many adherents. De la Rive, Lodge, W. Ostwald, and most of the physical chemists of Ostwald's and van't Hoff's school, were of this opinion. The source of the electrical energy, given off by the element, must be the chemical processes at these surfaces, and it was also soon found that the electromotive force of a galvanic cell depended on the nature of the solution between the two metal, and that impurities on the surfaces of the two metals and the nature of the gas between the metal plates in the condenser experiments strongly influenced the value obtained for the contact potential.

Much work was done on the determination of the contact potentials at these surfaces, especially by the study of capillary phenomena at the surface of a mercury electrode. This method is based on the hypothesis that the surface tension should have its maximum value, when the contact potential is zero, because then there would not be an electrical double layer at the surface. But after much work had been done, it was found that this hypothesis did not lead to reliable results.

Attempts to determine the contact potential using the Peltier effect (the heat effect at the surface of contact of two metals, when an electric current is passed across it) also failed.

A theoretical calculation of the contact potential between two aqueous solutions of electrolytes was given by Nernst in 1888. The work of Nernst seemed to make it possible, for the first time, to calculate the value of a contact potential between two different phases. Nernst once told me about the enthusiasm of the old v. Helmholtz, when he told him about this result. For nearly a hundred years research on the contact potentials had been going on and now, at last Helmholtz saw the possibility of gaining an understanding of these mysterious and important phenomena.

Later developments, however, have shown that Nernst's solution of the problem is exact only in the limit, when the two aqueous solutions are very dilute, *i. e.* when in reality we have to do with a potential difference between points in the same phase.

In the nineteen-twenties a new interest in the contact potential, especially that between electrolytic solutions, arose. From several sides it was pointed out that the determination of activity or partition coefficients of *individual* ions was connected with the determination of contact potentials between electrolytic solutions (Bjerrum [4], Taylor [5], Guggenheim [6], Brönsted [7], Schottky [8]). An especially clear and exact description of the problem is found in Guggenheim's papers.

If we cannot determine the electrical potential difference between two electrolytic solutions in connection with each other, we cannot determine the activities of the individual ion species, and conversely, if we do not know the ratio of the activities in the two solutions of at least one individual ion species, we cannot determine the contact potential between them. It is possible, however, to determine the product of the activities of a group of ionic species with a total electric charge of zero (*e.g.* of $K^+ + Cl^-$ or of $K^+ - Na^+$) as the transfer of such a group of ions from one phase to another will result in no net transfer of electricity at all.

As both Guggenheim and Brönsted have pointed out, however, all equilibria and isothermal changes towards equilibria of the individual ions are describable in terms of a new thermodynamic function which they call the electrochemical potential of an ion. This function can be considered as the sum of the chemical potential of the ion, and the electrical potential at the position of the ion. But when an ionic species is present in two different media, this resolution of its electrochemical potential into a chemical term and an electrical term is quite arbitrary and without physical significance, unless the contact potential between the two media is known.

The reason for the failure of the classical definition of the electrical potential difference, when we have to do with points in different media, is that, as we now know, the electricity has an atomistic structure. We cannot determine nor speak of the work necessary for transferring an infinitely small amount of electricity from one medium to another, since we can only transfer the electricity in the form of electrons or ions.

As early as 1899 Gibbs [9] wrote in a letter: "Again, the consideration of the electrical potential in the electrolyte, and especially the consideration of the difference of potential in electrolyte and electrode, involves the consideration of quantities of which we have no apparent means of physical measurement, while the difference of potential in pieces of metal of the same kind attached to the electrodes is exactly one of the things which we can and do measure".

And in 1929 Guggenheim wrote: "It has previously been realized that only these" (*i.e.* the electrochemical potentials of individual ions) "and not the u_i" (*i.e.* the chemical potentials of the individual ions) "have any *thermodynamic* importance, but we maintain that only they have any *physical* significance, for only they are definable in terms of physical realities".

This result has consequences for many concepts used by chemists, *e.g.* Sørensen's pH-value and Brönsted's definition of acidity.

The pH-value of Sørensen was defined by him as the negative logarithm of the molar concentration of the hydrogen ion, but on account of later views on electrolytes it was necessary to change from the concentration of the hydrogen ions to the activity of these ions, defined in such a way that in aqueous solutions at the limit of infinite dilution the activity was equal to the molar concentration.

According to our present view on the impossibility of determining the activity of individual ions the pH-values defined in this way cannot be determined by electrometric measurements. The pA_H-values determined by Bjerrum and Unmack in a paper in 1929 [4] by use of a 3.5 molar KCl solution to diminish the contact potential between two electrolytic solutions and calculating the remaining potential by means of Henderson's formula are, as indicated by the authors, not exactly equal to the negative logarithms of the hydrogen ion activities. Their pA_H-values must also depend to a certain degree on the activities of the other ions present, since the transfer of hydrogen ions from one solution to another must be accompanied by the transfer of other ions (in this case, especially K^+ and Cl^-) whose charge can compensate the charge transferred on the hydrogen ions. In spite of this, by using their pA_H values in calculations of thermodynamically definable quantities, one always arrives at the right values, and the pA_H values will generally lead to individual ions activity coefficients which, at increasing dilution, converge to a well defined limit.

Brönsted wished to extend his conception of the acidity of acids to non-aqueous solutions. In order to obtain in non-aqueous solutions a numerical measure of this acidity, as defined by the activity of the hydrogen ions, it was necessary to have a definition of the electrical potential difference between solutions in which the solvents were different. As a conventional definition he made the proposal that the electrical potential in an isolated, homogeneous phase be considered as zero when the phase is electrically neutral, *i.e.* when it contains equal amounts of positive and negative electricity. Guggenheim [6] admits that Brönsted's definition leads to an electrical potential between different phases which is a potential in the mathematical sense. But he finds that it does not lead to a potential in the strict dynamic sense, *i.e.* it does not meaure the work done in any real process.

Brönsted writes [7] (p. 310—311): "Unsere Betrachtungen haben uns somit dazu geführt, dass auch für Ionen thermodynamische Funktionen definiert werden können, die durch die chemische Beschaffenheit der Lösungen, die die Ionen enthalten, und unabhängig von elektrischen Ladungspotentialen gegeben sind. Es sind derartige Funktionen, die zur Darstellung der chemischen Eigenschaften von Ionenlösungen geeignet sind, und von welchen wir z. B. für unsere Aciditätsdefinition hier Gebrauch machen wollen".

Brönsted further writes that his ion functions defined above cannot be determined by the common electrometric methods, but finally concludes: "Dass die Ionenfunktionen für ungleiche Medien durch die direkten thermodynamischen Methoden nicht messbar sind, besagt, dass sie auch thermodynamisch nur von untergeordneter Bedeutung sein können. Man darf daraus

jedoch nicht schliessen, dass sie überhaupt bedeutungslos sind. Speziell für den Begriff der Acidität, wie er oben definiert worden ist, müssen wir z. B. annehmen, dass er eine grosse kinetische Bedeutung besitzt, wenn es auch mit Schwierigkeiten verbunden wäre, den Aciditätseinfluss von der allgemeinen Wirkung des Mediums zu trennen". This idea of Brönsted that the acidity, determined according to his instructions, has a great kinetic significance does not seem to have been shown by him to be probable much less to have been proved, and it does not agree with the statement of Guggenheim according to which the chemical potentials of individual ions do not have any physical significance.

Brönsted has not given a laboratory method by the use of which we can determine the acidity by means of his definitions. So far I can see, Brönsted's proposal leads to an electrical potential difference between two phases which is determined by the electric field outside the two phases and thus to an electrical potential difference between them, equal to the work done by transferring an unit of electricity from a point just outside the surface of one phase to a point just outside the surface of the other phase. This is the electrical potential difference between two points outside the two phases, and not between two points inside the two phases.

Brönsted's definition can perhaps be used in the following way for the experimental determination of the difference in acidity of two phases. In each of the two phases is placed a hydrogen electrode and in the connection between the two hydrogen electrodes is introduced a variable electromotive force. The two phases are also used as plates in a condenser and these parts of the phases are each in direct connection with the part of the same phase, containing a hydrogen electrode. Finally one of the phases is connected with a sensitive electrometer. The value of the variable electromotive force, by which the condenser plates can be separated without change in the electrometer, will then be a measure of the sought for acidity difference. A practical difficulty arises when the two phases are both liquids. If the two plates in the condenser are placed horizontally the bottom plate can of course be a liquid, but the top plate can not. In that case it will therefore be necessary to use two condensers with the two liquid phases as bottom plates and as top plates two plates of same metal. The sought for acidity difference will then be measured by the value of the variable electromotive force by which it is possible to separate the plates in both condensers without change in the sensitive electrometer connected with the condensers.

Such a determination will certainly be very difficult to perform and will scarcely lead to an experimentally well defined value of the acidity difference, and as the result will be only the determination of a conventionally defined acidity difference of no great interest, I think that it will not pay to try it.

The concept of an electrical contact potential between two different phases is as elusive in character as the concept of absolute velocity in space. Not only is this potential difficult to determine experimentally, and apparently without physical interest, but also, from an atomistic point of view, it is not a single-valued potential which can be used in calculations of the electric work of transfer of all the different species of electrically charged particles from one phase to another. This can be seen in the following way. If we knew

exactly the positions of all the electrons and nuclei in two insulated and homogeneous pieces of two different phases in contact with each other, we could calculate in principle by means of Coulomb's law, the electric force in all points in and around the two pieces (except in the interior of the electrons and the nuclei), and we could therefore also calculate the classical electrical potential at all these points. But in order to obtain a phenomenological value for the electrical potential difference between the two different phases we would further have to determine the mean value in time and space of the electrical potential in the interior of the two phases. The space, however, over which we have to take the mean value is not given in a definite way. *E.g.*, how near should we go to the electrons and to the nuclei? It depends on the particle considered. And what weight should we assign to the potentials at the different points inside the two phases in the determination of the mean value? It is not sufficient to assume that an amount of electricity transferred to a phase is infinitely divisible and spread over the available space according to Boltzmann's distribution law. If we wish to use the mean value in calculations of the work of transfer of an electron or of a particular ion the mean value must be determined corresponding to the properties of this particular electrically charged particle. We thus arrive at the conclusion that a general and single-valued mean for the electrical contact potential which can be used in calculations of the electrical work of transfer of all species of particles with electric charge, does not exist.

There is also the other difficulty that according to the rules of quantum mechanics (Heisenberg's uncertainty relations) we cannot know exactly the positions and the velocities of the particles at a definite time. This uncertainty, however, does not seem to preclude the existence of a well defined and single-valued electric contact potential.

If we wish to use the concept of a definite electrical contact potential, we have to introduce a conventional definition for it, and when using such a conventionally defined potential we must always remember that it is not a physical reality, but only a mathematical device. It can be used in intermediate calculations, but must not appear in final expressions.

The Kinetics of Crystal Growth in Barium Sulfate Precipitation

ARNE E. NIELSEN

Universitetets fysisk-kemiske institut, Copenhagen, Denmark

The kinetics of barium sulfate precipitation is followed turbidimetrically and conductometrically. It is found that when the concentration of Ba^{++} and SO_4^{--} are larger than about 0.4 mM the kinetics may be expressed by

$$k_D t = \int_0^\alpha \alpha^{-1/3} (1 - \alpha)^{-1} \, d\alpha$$

where t is the time and α the degree of reaction (precipitation). When the said concentrations are smaller than 0.4 mM, approximately, the kinetics observed agrees with

$$k_R t = \int_0^\alpha \alpha^{-2/3} (1 - \alpha)^{-4} \, d\alpha$$

These findings agree with the assumption that below 0.4 mM the rate determining step in the crystal growth process is a fourth order reaction at the crystal-solution interface and, above 0.4 mM, the diffusional transport of matter from the bulk of the liquid to the surface of the growing crystals.

In a previous work on the kinetics of electrolyte precipitation [1] it was concluded that the rate of growth of barium sulfate crystals is controlled by some sort of chemical reaction with the rate determining step

$$2\ Ba^{++}\ (soln.) + 2\ SO_4^{--}\ (soln.) \rightarrow 2\ BaSO_4(crystal)$$

or, perhaps

$$2\ BaSO_4\ (soln.) \rightarrow 2\ BaSO_4(crystal)$$

taking place in the surface of the growing particles. This was found to be in agreement with experiments where the concentration of barium sulfate was less than 0.2 mM. In this work the experimental range is extended to much higher concentrations and it is observed that the above mentioned mechanism ceases to be rate determining at higher concentrations. According to the fourth order low the rate of crystal growth increases with the fourth power of concentration. Above 0.4 mM the rate becomes too high for the matter to diffuse

sufficiently fast to the surface of the crystals and therefore diffusion becomes the bottle-neck of the growth process. Nernst [2] and Brunner [3] found the dissolution process for several salts to be diffusion controlled, but the kinetics of the reverse process turned out [4] to be more difficult to explain.

It has been shown [1] that when the growth of a constant number of small particles of the same size is diffusion controlled, the degree of reaction α depends on time according to

$$k_D t = \int_0^\alpha \alpha^{-1/3}(1 - \alpha)^{-1} d\alpha = I_D$$

and when the rate is controlled by a fourth order reaction in the surface

$$k_R t = \int_0^\alpha \alpha^{-2/3}(1 - \alpha)^{-4} d\alpha = I_4$$

From this follows that if I_D is plotted against time a straight-line plot is obtained if the rate is determined by diffusion. In the following we shall prefer to plot log I_D against log t. This should give parallel straight lines 45° to the axis.

EXPERIMENTAL

The reacting systems were supersaturated solutions of $BaSO_4$ prepared by mixing equal volumes of solutions of the same molarity ($2c_0$) of $BaCl_2$ and Na_2SO_4. In three experiments NaCl was added in order to get the required ionic strength.

The advancement of the reaction was measured in two different ways: in the fastest experiments ($c_0 \geqq 1$ mM) the electric conductivity was measured with Radiometer's direct reading AC(70 – 3 000 c/s) conductivity meter. The degree of reaction α was found from the conductivity by means of a chart based on measurements of the conductivities of mixtures of solutions of $BaCl_2$, Na_2SO_4 and NaCl. The slower experiments were followed photometrically by means of an apparatus especially designed by Dr. J. Koefoed (of this institute) for measuring small optical densities. The voltages from the measuring selenium photocell and a similar reference cell both illuminated from the same lamp were compensated one against the other, giving the light intensity ratio I_0/I as the ratio of the resistors of the compensating bridge. From I_0/I α was found by taking $(\log(I_0/I))^{3/2}$ proportional to α. In order to find the proportionality factor the electric conductivity was measured at the end of each experiment. The advantage of not following the whole experiment conductometrically consists in that it is not necessary, then, to remove the layer of barium sulfate formed on the walls of the conductivity cell.

It is well known [5] that under these conditions the barium sulfate precipitation is a rather irreproducible process. The reason for this is probably that the number of particles formed per unit of volume comes out very differently even if one tries to make several identical experiments consecutively [6]. But during a precipitation experiment the number is constant and from microscopy it seems that the shape of the particles does not change much during growth. Therefore it is reasonable to put the volume proportional to the three halves power of the surface of the precipitate and this, again, proportional to the logarithm of the light intensity ratio I_0/I. Table 1 shows how the calculations were made.

In experiments with added salt (for ionic strenght) it would be a rather inexact method to find α from electric conductivity. Instead of this α was found by putting it equal to $1/7 = 0.143$ (as is required by the formula for I_4) at the point of inflexion on the curve of $(\log(I_0/I))^{3/2}$ against t. Since the point of inflexion in case of I_D is at $\alpha = 1/4 = 0.25$ this method can only be applied when it is known that the experiments follow I_4. This assumption is confirmed through the rectilinear arrangement of the points (squares and triangles) on Fig. 3.

The temperature was always between 22 and 23°C. All conductivities were corrected to 22.0°C by means of the empirically determined temperature coefficient $d\varkappa/dt = 0.022\,\varkappa$.

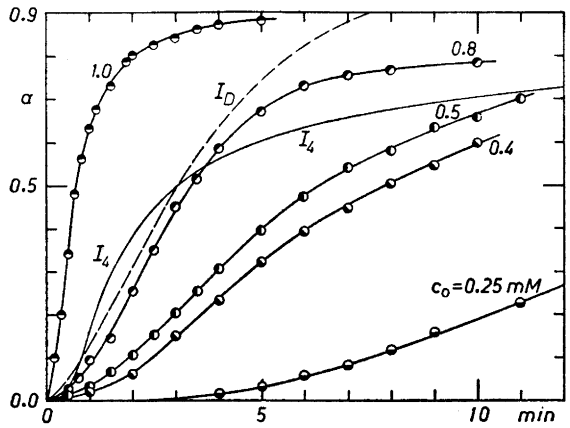

Fig. 1. The fraction α of the $BaSO_4$ present having deposited on the crystals at time t. I_D and I_4 are theoretical curves (in arbitrary time units) corresponding to diffusional and fourth-order-surface-reaction rate control, respectively. The experimental curves resemble I_D at small t (high concentration) and I_4 at large t (low concentration) as required by theory.

RESULTS

In Fig. 1 are some of the experimental values of α plotted against the time. For comparison I_D and I_4 — from numerical integration — are also shown, in arbitrary time units. It is seen that the experimental curves, except those of the lowest c_0, have the shape of I_D at small times (high concentrations) and become more like I_4 in the later parts of the experiments.

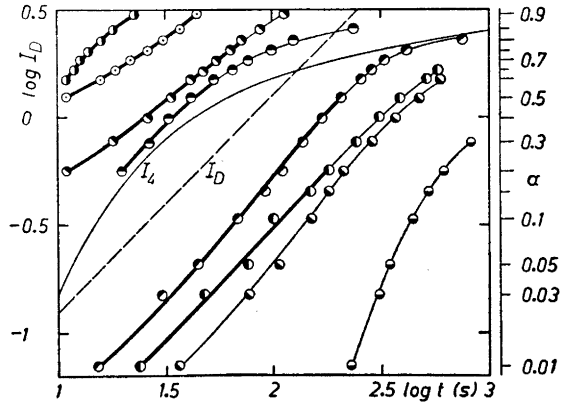

Fig. 2. A transformation of Fig. 1. which yields straight lines in case of diffusional rate control. The heavy (parts of the) lines correspond to $(BaSO_4) > 0.4$ mM.

Table 1. 50 ml 1.6 mM $BaCl_2$ + 50 ml 1.6 mM Na_2SO_4; c_0 = 0.8 mM.

t min	I_0/I	a	l μ	Δl μ	$\Delta l/\Delta t$ μ/min	mμ/s	c mM
0.5	1.013	0.025	1.67				
1.0	1.032	0.094	2.60	1.33	1.33	21.2	0.725
1.5	1.045	0.144	3.00				
2.0	1.063	0.253	3.60	1.02	1.02	17.0	0.598
2.5	1.079	0.350	4.02				
3.0	1.094	0.450	4.38	0.56	0.56	9.3	0.440
3.5	1.103	0.514	4.58				
4.0	1.112	0.582	4.76	0.62	0.31	5.2	0.334
5.0	1.124	0.670	5.00	0.38	0.19	3.15	0.264
6.0	1.132	0.730	5.14	0.20	0.10	1.67	0.216
7.0	1.135	0.755	5.20	0.09	0.045	0.75	0.196
8.0	1.137	0.768	5.23				
10.0	(1.139)	(0.785)	5.26				

Comments on Table 1. Immediately after the measurements at t = 10 min the solution was stirred and a drop transferred to a blood cell counting chamber of volume 0.9 mm³, and 202 particles were counted; N = 202/0.9 = 224 mm^{-3}. From this number and c_0 = 800 μM l_∞ was found by means of

$$l\infty = \sqrt[3]{800 \times 52/224} = 5.71 \ \mu$$

The value of I_0/I at t = 10 min (1.139) is extrapolated, since at this moment the electric conductivity was measured: $\varkappa = 224 \times 10^{-6}$ ohm^{-1} cm^{-1} (uncorrected) at 22.3°C. This corresponds to $\varkappa = 222.5 \times 10^{-6}$ ohm^{-1} cm^{-1} at 22.0°C. Applying a chart based on empirical values of $\varkappa$, a was found to be 0.785 at t = 10 min. The other values of a were calculated by means of

$$a = 0.785 \ [\log(I_0/I)/\log \ 1.139]^{3/2}$$

and l was obtained from

$$l = l_\infty a^{1/3}$$

In this and similar experiments $\Delta l/\Delta t$ was found directly from the measured values using intervals symmetric about the experimental t-values. This gives a reasonable degree of smoothing and reduces the calculating work. (In the fastest experiments all a-values were found conductometrically and had to be smoothed graphically before the differentiation).

Finally c was found as $(1-a)c_0$.

In Fig. 2 log I_D is shown as a function of log t. The part of the curves where ($BaSO_4$) < 0.4 mM is drawn in a heavier line than the rest of the curves. The high-concentration-parts of the curves are more straight than the low-concentration-parts.

Fig. 3 displays the dependence of the linear growth rate dl/dt on time; l is the length of the edge in a cube of the same volume as the single crystals. The growth rate was obtained from the measurements in the following way. The value of l at "infinite time" l_∞ was calculated from the molar volume of barium sulfate, 52 cm³/mole, the concentration c_0 of barium sulfate at t = 0 in the unit μM and the number N of particles per mm³, by means of

$$l_\infty = (52c_0/N)^{1/3} \qquad \text{(microns)}$$

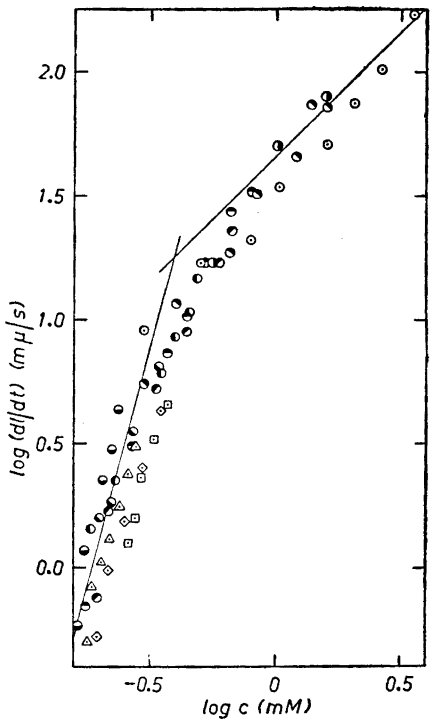

Fig. 3. The linear rate of crystal growth as function of ($BaSO_4$) in a logarithmic diagram. Below 0.4 mM (log $c = -0.4$) the rate increases proportional to the fourth power of concentration, above 0.4 mM the rate is directly proportional to the concentration of the supersaturated barium sulfate solution. The asymptotes are drawn without regard to the triangular and square "points".

l was found by multiplying l_∞ with $\alpha^{1/3}$. Then $\mathrm{d}l/\mathrm{d}t$ could be obtained through numerical differentiation. In a few cases (of very high c_0) the α-values had to be smoothed by means of a graph like Fig. 1.

The straight lines drawn in Fig. 3 are the apparent asymptotes to the curve determined by the points. Their inclinations are 4 and 1 respectively, and from the figure their equations are seen to be, respectively

$$\log(\mathrm{d}l/\mathrm{d}t) = 4 \log c + 2.80 \qquad (c < 0.3 \text{ mM})$$
$$\log(\mathrm{d}l/\mathrm{d}t) = \log c + 1.65 \qquad (c > 0.6 \text{ mM})$$

which is equivalent to

$$\mathrm{d}l/\mathrm{d}t = 630\ c^4 \qquad (c < 0.3 \text{ mM})$$
$$\mathrm{d}l/\mathrm{d}t = 45\ c \qquad (c > 0.6 \text{ mM})$$

when $\mathrm{d}l/\mathrm{d}t$ is measured in mμ/s and c in mM.
Similar points, even in different figures, refer to the same run of a kinetic experiment.

Salt effect

A reaction between two Ba^{++}- and two SO_4^{--}-ions must be subject to a large negative kinetic salt effect, decreasing the growth rate at higher ionic strengths, although it would probably be misleading to try to calculate it

from the Debye-Hückel limiting law or similar generalized expressions for the activity coefficients. Since this salt effect will reduce the rate most at high concentrations just as diffusion, it is important to know its magnitude. At the highest concentrations investigated ($c_0 = 5$ mM, circular "points" with a dot in the centre) the ionic strength was 0.030 M. In the experiments shown by square and triangular "points" with a dot in the centre the ionic strength was therefore adjusted to 0.030 M by means of NaCl. In this way all points with a dot in the centre correspond to experiments with approximately the same ionic strength. As expected there is a negative salt effect, since the "dotted" points mostly lie about 0.3 decadic units below the other points, showing that the addition of salt has halved the rate of crystal growth. This effect is, however, by far too small to explain the deviation from the fourth-power-law.

The rate of diffusion

On the other hand we may calculate from the diffusion coefficient of barium sulfate the greatest possible rate of transport of matter from the bulk of the solution to the surface of the growing particles. The geometry of the diffusional area looks rather different in case of a large and a small particle. For large particles Nernst [2] pointed out that the phenomenon may be described by means of a diffusion layer of thickness 10—100 μ, depending, among other things, on the stirring rate. But for particles of radius r comparable with or smaller than the thickness of such a diffusion layer Smoluchowski [7] showed by means of Fick's diffusion laws, that after a very short time (a fraction of a second) the concentration around such a "spherical sink" follows

$$(\mathrm{d}c/\mathrm{d}x)_{x=r} = (c - c_r)/r$$

where x is the distance from the center of the sink. In the present case we may neglect c_r in $c - c_r$. In the experiments on barium sulfate reported here c_r is about $c/100$. We then have, by Fick's first law, for the amount of matter deposited in unit time

$$\mathrm{d}n/\mathrm{d}t = 4\pi r^2 D(\mathrm{d}c/\mathrm{d}x) = 4\pi r c D$$

If this is multiplied by the molar volume of $BaSO_4$ one gets the rate by which the volume increases

$$v \times 4\pi r c D = v\mathrm{d}n/\mathrm{d}t = \mathrm{d}(\tfrac{4}{3}\pi r^3)/\mathrm{d}t = 4\pi r^2 \mathrm{d}r/\mathrm{d}t$$

or

$$\mathrm{d}r/\mathrm{d}t = vDc/r$$

Now we may use this in an estimate even though the actual particles are not spherical. In the following it will be convenient to express the volume of the crystals by means of the length l of the edge in a cube of the same volume, and we may substitute

$$l^3 = \tfrac{4}{3}\pi r^3 = 4.19r^3;\ l = 1.61r;\ l^2 = 2.60r^2$$

so that $dl/dt = 2.60vDc/l$. The diffusion coefficient of $BaSO_4$ may be calculated from the electric mobilities according to Nernst [8]

$$D = 2D_+D_-/(D_+ + D_-)$$

where

$$D_+ = kTl_+/q_+$$

$$D_- = kTl_-/q_-$$

Here l_+ and l_- are the electric mobilities of the Ba^{++} and SO_4^{--} ions, respectively, and $q_+ = q_- = q$ the electric charges of the ions, that is twice the proton charge. When we insert [9] $l_+ = 6.59 \times 10^{-4}$, $l_- = 8.27 \times 10^{-4}$ cm²/s·V and $2kT/q = 0.02569$V we find the diffusion coefficient of barium sulfate

$$D = (2kT/q)l_+l_-/(l_+ + l_-) = 9.42 \times 10^{-6} \text{ cm}^2/\text{s (at 25°C)}$$

Since the molar volume is $M/d = 233.4/4.499 = 51.9$ cm³/mole (at 15°C) we have

$$dl/dt = 2.60vDc/l = 1.27 \times 10^{-3}c/l$$

where dl/dt is measured in cm/s, c in mole/cm³ and l in cm; if we change to mμ/s, mM and μ, respectively, we get

$$dl/dt = 127c/l$$

From Fig. 3 we have from the upper asymptote

$$dl/dt = 45c$$

Now these two formulae cannot be compared directly since l is a parameter in only one of them. But we may substitute for l the mean value of all the experimental points, (half-black—half-white) closest to the upper line in Fig. 3. We have from the experiments the following values of l: 2.67, 3.39, 3.93, 4.34, 3.00, 4.96, 1.62 and 1.93 μ. The arithmetic mean value is 3.23 μ. This gives

$$dl/dt = 127c/3.23 = 39c$$

The experimental value of the coefficient (45) and the value calculated from the diffusion theory (39) agree within the accuracy of the measurements.

In Fig. 3 the two asymptotes intercept at $\log c = -0.4$, that is $c = 0.4$ mM. We may therefore say that the rate determining mechanism of crystal growth of barium sulfate changes from a fourth order surface reaction into diffusion around $c = 0.4$ mM. Further evidence of this is obtained by microscopy. The precipitate formed when $c_0 < 0.5$ mM consist of small prisms, which in the microscope look like rectangles with the longer side approximately twice as long as the shorter one. With initial concentrations between 0.5 and 1.5 mM the particles are more or less distorted prisms, the corners having grown more than the middle of the faces. And at $c_0 > 1.5$ mM the corners have grown far more than the other parts of the crystals, giving them the appearance of "stars"; see Figs. 2 and 3 in the previous work [6]. This appearance is to be expected in case of diffusional control of the growth rate, since the concentration then is greatest at the corners. The rectangular (orthorhombic)

shape is obtained when the concentration is approximately the same all over the surface, and it cannot be so when the consumption of matter is fast compared with the diffusion.

Remarks on the Reactivities of the Penta- and Hexathionate Ions

OLAV FOSS

Chemical Institute, University of Bergen, Bergen, Norway

The reactions of higher polythionates with nucleophilic reagents are discussed on the basis of existing possibilities of heterolytic cleavage of the sulphur-sulphur bonds. In addition to the principal reaction type involving a release of thiosulphate from the penta- and hexathionate ions, other modes of cleavage may lead to the release of sulphite, and of thiosulphate and sulphur.

The presence of unbranched and non-planar sulphur chains in the tetra- and pentathionate ions has recently been demonstrated through crystal structure determinations of barium tetrathionate dihydrate [1], orthorhombic and triclinic barium pentathionate dihydrate [2,3], and a solvate of barium pentathionate with acetone [4]. The structure analyses, which were made by two-dimensional Fourier methods by use of the heavy atom technique, were based on X-ray data alone, without recourse to assumptions of chemical nature.

The tetra- and pentathionate chains contain two and three divalent sulphur atoms, respectively, and terminal sulphur atoms to each of which are attached three oxygen atoms. The sulphonate groups, together with the adjacent divalent sulphur atoms, constitute thiosulphate groups, which have the shape of distorted tetrahedrons. The tetrathionate ion is thus built of two thiosulphate groups, linked together through their divalent sulphur atoms, and the pentathionate ion consists of a divalent sulphur atom to which are attached, through sulphur-sulphur, bonds, two thiosulphate groups. The structures, assigned to the ions on chemical grounds [5,6], are confirmed through the X-ray studies.

No structure determination of a salt of hexathionic acid has so far been reported. However, in view of chemical evidence, which speaks in favour of unbranched chains [5,6], and the fact that branching of sulphur chains has never been demonstrated to occur, it appears reasonably safe to conclude that the sulphur chain of hexathionate is unbranched, like that of pentathionate and tetrathionate.

The following brief review of some features of polythionate chemistry may be pertinent to the succeeding discussion of reaction schemes.

The polythionates are chemically characterized by the ease with which they undergo heterolytic cleavage in reactions with nucleophilic reagents. This behaviour is, presumably, due to a pronounced electrophilic character of the divalent sulphur atoms of the chains. Nucleophilic attacks have been found to take place at either one of the two equivalent, divalent sulphur atoms of the tetrathionate ion, at the middle sulphur atom of the pentathionate ion, and at the middle disulphur group of the hexathionate ion. The principal reactions of the polythionates with nucleophilic reagents may be summarized as follows [5-11].

Pentathionate and hexathionate behave as sulphur thiosulphates, $S(S_2O_3)_2^{--}$ and $S_2(S_2O_3)_2^{--}$. In some reactions with nucleophilic reagents, both thiosulphate groups are displaced by the reagent; in other reactions, only one.

Tetrathionate behaves as a sulphur sulphite-thiosulphate, with displacement of the sulphite and the thiosulphate group by a nucleophilic reagent, or of only one of the groups. A thiosulphate group is displaced more readily than a sulphite group.

Trithionate acts as a sulphur disulphite, $S(SO_3)_2^{--}$, with displacement of both sulphite groups, or of only one. Trithionate may also act as a thiosulphato-sulphonate, the nucleophilic attack in this case occurring at one of the sulphonate sulphur atoms.

The reactions, as far as their kinetics have been established, are bimolecular, and thus of the S_N2 type. This applies to the following reactions involving nucleophilic displacements on divalent sulphur: Those of tetra- and pentathionate with sulphite [12], hydrogensulphite [13] and cyanide [14-16] ions, of tetrathionate with azide ion [17,18] and of pentathionate with hydroxyl ion [19], of tri- and tetrathionate with thiosulphate ion [20,21] and of trithionate with sulphite ion [22]. Likewise, nucleophilic displacements on the divalent sulphur of sulphenyl sulphites [23] (thiosulphate esters) and disulphides [24] are of the S_N2 type, as is also the reaction of triphenylphosphine with elemental sulphur [25].

The electrophilic species in S_N2 reactions have no independent existence, and electropositive ions of divalent sulphur, even short-lived ones, do therefore not occur in the reactions.

The recognition of polythionates as derivatives of divalent electropositive sulphur, and their reactions as nucleophilic displacements, removes older arguments, on chemical basis, against the unbranched chain structures [6].

The occurrence of various displacement reactions, predicted on the basis of the reactivity principles outlined above, have been confirmed through experiments with sulphite and thiosulphate labelled with radioactive sulphur. Thus, the reactions of hexa-, penta- and tetrathionate with sulphite ion, to give the next lower polythionate, and thiosulphate, were formulated [5] as nucleophilic displacements of thiosulphate by sulphite:

$$^-O_3S-S-S-S-S-SO_3^- + S^*O_3^{--} = {}^-OS_3-S-S-S-S^*O_3^{--} + S_2O_3^{--} \quad (1)$$

$$^-O_3S-S-S-S-SO_3^- + S^*O_3^{--} = {}^-O_3S-S-S-S^*O_3^- + S_2O_3^{--} \quad (2)$$

$$^-O_3S-S-S-SO_3^- + S^*O_3^{--} = {}^-O_3S-S-S^*O_3^- + S_2O_3^{--} \quad (3)$$

The validity of this view, at any rate as far as tetra- and pentathionate are concerned, has been demonstrated by Christiansen and Drost-Hansen [26,27]. The reverse reactions, of tri- and tetrathionate with thiosulphate to give sulphite and the next higher polythionate, are also nucleophilic displacements [10,20,21].

In a study of exchange reactions of polythionates with thiosulphate, Fava [28] has shown that the displacement equilibria [5,10,29]:

$$^-O_3S_2-S-S-S_2O_3^- + S_2^*O_3^{--} = {}^-O_3S_2-S-S-S_2^*O_3^- + S_2O_3^{--} \quad (4)$$

$$^-O_3S_2-S-S_2O_3^- + S_2^*O_3^{--} = {}^-O_3S_2-S-S_2^*O_3^- + S_2O_3^{--} \quad (5)$$

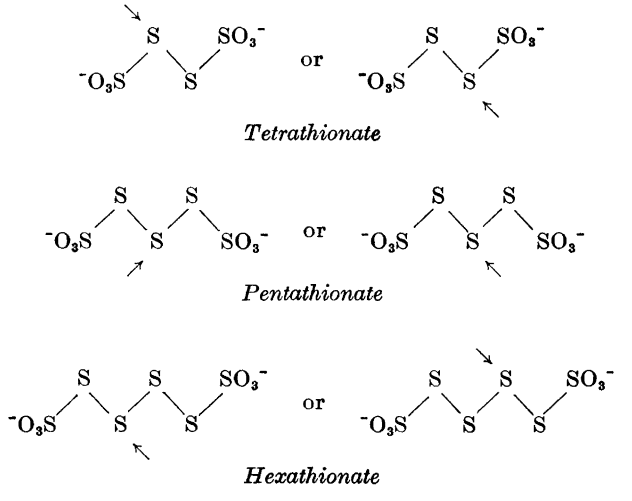
$$^-O_3S_2-S_2O_3^- + S_2^*O_3^{--} = {}^-O_3S_2-S_2^*O_3^- + S_2O_3^{--} \quad (6)$$

are established very rapidly at ordinary temperatures. The mechanism of the thiosulphate-catalyzed rearrangement of tetrathionate into tri- and pentathionate, formulated [10] as subsequent displacements of sulphite by thiosulphate and of thiosulphate by sulphite, has been confirmed by Fava and Bresadola [21]. Likewise, Fava and Pajaro [22] have found that trithionate exchanges with sulphite ion, although rather slowly.

Thus, recent studies on polythionates have established the unbranched chain structure, and the characteristic sensitivity towards basic reagents as due to nucleophilic attacks on the divalent sulphur chains. The reactivity principles recognize the electrophilic character of the middle sulphur atom of pentathionate and of the two equivalent, middle sulphur atoms of hexathionate. Nucleophilic attacks on these atoms, in directions so as to displace thiosulphate, are responsible for the principal reactions of the ions. There are, however, indications that nucleophilic attacks may occur also at other of the divalent sulphur atoms of the penta- and hexathionate ions, and in different directions.

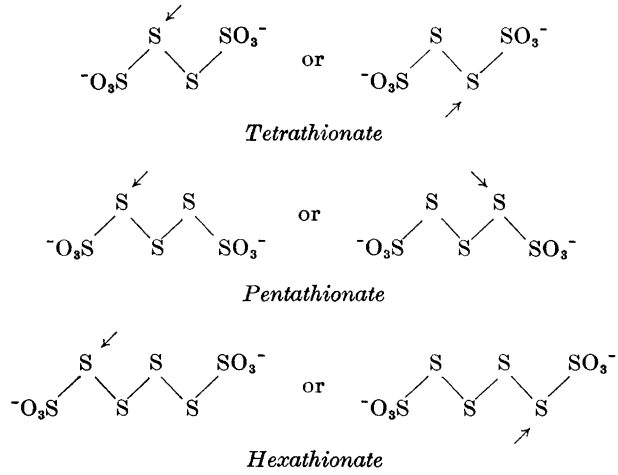
SCHEMES FOR THE REACTIONS OF HIGHER POLYTHIONATES WITH NUCLEOPHILIC REAGENTS

The various possibilities of nucleophilic attack on the divalent sulphur atoms of the tetra-, penta- and hexathionate ions are depicted through arrows in schemes 1 to 4 below. In each case there are two equivalent possibilities, corresponding to the two halves of the ions. The arrows are drawn so as to indicate a linear transition state, as in displacements on carbon; there is, however, as yet no definite information available concerning the configuration of the transition state.



Scheme 1. Principal directions of nucleophilic attack on the tetra-, penta- and hexathionate ions: Displacement of thiosulphate.

Schemes 1 and 2 lead to the displacement of thiosulphate and sulphite, respectively. The tetra-, penta- and hexathionate ions, on the action of the appropriate nucleophilic agent, eliminate thiosulphate more readily than sulphite; displacement of thiosulphate does, indeed, occur in the majority of the reactions of the ions, *e.g.*, in the reactions (1)—(6) above. Other examples include the reactions with piperidine, hydroxide, thiocarbonyl ions, and cyanide and sulphide ions.



Scheme 2. Alternative (less predominant) directions of nucleophilic attack on the tetra-, penta- and hexathionate ions: Displacement of sulphite.

Displacement of sulphite according to scheme 2 was first found to occur in the case of tetrathionate. In the reactions of tetrathionate with piperidine [5,8] and hydroxide [5,30,31], displacements of thiosulphate *and* sulphite take place, to like extents but probably in two steps of which a primary displacement of thiosulphate is more predominant than a primary displacement of sulphite. With thiosulphate as the nucleophilic reagent [10,21], the process is the reverse of the reaction of pentathionate with sulphite (Eqn. (2)) and takes place markedly slower than the displacement of a thiosulphate group of tetrathionate by the same reagent, as represented by Eqn. (6). Displacement of sulphite by sulphide also occurs [32,33], though to a small extent compared with the simultaneous predominant reaction, which is the displacement of thiosulphate.

For penta- and hexathionate, the probability, or ease, of reacting according to scheme 2 should be about the same as for tetrathionate. The attacks are on the divalent sulphur atoms situated next to the sulphite groups, so as to displace these, and the length of the sulphur chain on the other side of the electrophilic centre (one, two or three divalent sulphur atoms) should have relatively little influence. With thiosulphate as the nucleophilic reagent, the relevant reactions are, again, the reverse of the reactions of the next higher polythionates with sulphite.

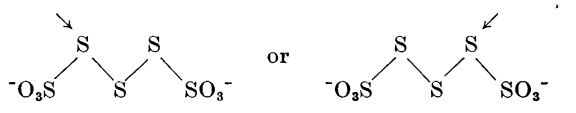
The reversal of the reactions of tetra- and pentathionate with sulphite takes place in acid solutions [34,35], since under such conditions sulphite is partly removed from the equilibria, as hydrogensulphite. Corresponding reactions of the still higher polythionates were held possible by Kurtenacker and Czernotzky [36], but Stamm, Seipold and Goehring [34,35] found no evidence for the formation of hexathionate and hydrogensulphite from pentathionate and thiosulphate in acid solutions. Nevertheless, it has been repeatedly maintained [21,29,37] that the reaction of hexathionate with sulphite is reversible, like those of pentathionate and tetrathionate. Preliminary experiments by the author indicate that pentathionate does react with thiosulphate, to give hexathionate and sulphite, if formaldehyde is used as a sulphite acceptor.

Like thiosulphate, other reagents with comparable or greater nucleophilicity towards divalent sulphur, *e.g.*, sulphide, cyanide or thiocarbonyl ions, should be able to displace sulphite from penta- and hexathionate, though in such cases the simultaneous, always predominant displacement of thiosulphate leads to the rapid formation of different species which do not eliminate sulphite. Thiosulphate is unique as a reagent for demonstrations of the less predominant schemes, because its participation in the preferential scheme 1 displacements leaves the polythionate unaltered, except in tracer experiments.

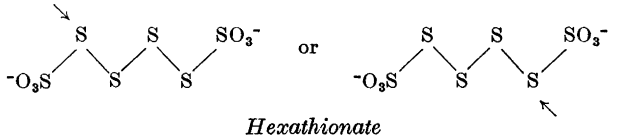
ADDITIONAL SCHEMES

In the case of tetrathionate, schemes 1 and 2 involve attacks at the same electrophilic centre, although in different directions. This is because the two divalent sulphur atoms of tetrathionate are equivalent. In penta- and hexathionate, the two types of attack occur at different centres, corresponding to the presence of two non-equivalent divalent sulphur atoms in these ions. However, attacks on any divalent sulphur atom of the polythionate chains, also of penta- and hexathionate, may in principle occur in two directions, to displace either one of the two groups bonded to the divalent atom.

Accordingly, scheme 3 for penta- and hexathionate involves nucleophilic attacks on the same sulphur atoms as in scheme 2, but in different directions, so as to lead, not to a displacement of sulphite, but of the species $(S{-}S_2O_3)^{--}$ and $(S{-}S{-}S_2O_3)^{--}$, which are unstable and will decompose into thiosulphate and sulphur.



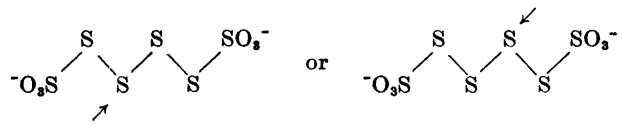
Pentathionate



Hexathionate

Scheme 3. Possible directions of nucleophilic attack on the penta- and hexathionate ions, leading to the release of thiosulphate and one or two sulphur atoms, respectively.

Similarly, scheme 4, which applies to hexathionate only, involves attacks on the same sulphur atoms as in the displacement of thiosulphate according to scheme 1, but in the other one of the two possible directions.



Hexathionate

Scheme 4. Possible directions of nucleophilic attack on the hexathionate ion, leading to the release of thiosulphate and one sulphur atom.

Concerning these last possibilities, the following points may be made. Scheme 3 requires a heterolysis of the same sulphur-sulphur bond as in scheme 1. The latter represents a predominant type of reaction of the penta- and hexathionate ions, and has been interpreted [4,5] as due to a certain amount of ionic character, or polarity of the σ bond, in the direction of heterolysis. In scheme 3 the heterolysis is required to take place in the opposite direction of that in scheme 1 and thus in the opposite direction of the presumed polarity. Likewise, the electrophilic characters of the bond partners, *i.e.*, of the centres of nucleophilic attack in the two schemes, are probably different, so as, once more, to favour scheme 1. In view of the known tendency of sulphur-sulphur bonds to undergo heterolysis, it does not appear warranted, however, to exclude the possibility that penta- and hexathionate may react according to scheme 3, if acted upon by an appropriate nucleophilic agent. The displacements, even if occurring to a slight extent only, with small equilibrium concentrations of the primary products, $(S{-}S_2O_3)^{--}$ and $(S{-}S{-}S_2O_3)^{--}$, will lead to continuous changes because of the instability and subsequent decomposition of these species, into thiosulphate and sulphur. Thus, with thiosulphate as the nucleophilic reagent, the reactions:

$$^-O_3S_2{-}S{-}S_2O_3^- + S_2^*O_3^{--} = {}^-O_3S_2{-}S_2^*O_3^- + (S{-}S_2O_3)^{--} \quad (7)$$

$$^-O_3S_2{-}S{-}S{-}S_2O_3^{--} + S_2^*O_3^{--} = {}^-O_3S_2{-}S_2^*O_3^- + (S{-}S{-}S_2O_3)^{--} \quad (8)$$

with release of sulphur from the displaced groups, will proceed continuously to the right, and cause a break-down of the penta- and hexathionate ions into tetrathionate.

For hexathionate, the possibility of reacting according to scheme 4 should be greater than for penta- and hexathionate according to scheme 3. The nucleophilic attacks are at the same electrophilic centres as in scheme 1, and the sulphur-sulphur bond required to undergo heterolysis is the middle one, and is thus non-polar, *i.e.*, there is no opposing polarity as probable in scheme 3. In presence of thiosulphate, the process:

$$^-O_3S_2{-}S{-}S{-}S_2O_3^- + S_2^*O_3^{--} = O_3S_2{-}S{-}S_2^*O_3 + (S{-}S_2O_3)^{--} \quad (9)$$

should therefore occur more readily than the corresponding reaction (8) of hexathionate and (7) of pentathionate, although slower than the scheme 1 displacement of thiosulphate.

Scheme 4 bears resemblance to scheme 1 for tetrathionate, which also involves heterolysis of the middle sulphur-sulphur bond, and to the heterolytic cleavage of organic disulphides.

It is known that hexathionate, under the catalytic influence of thiosulphate ions, decomposes into pentathionate and sulphur [29,35,38]. Pentathionate, more slowly, decomposes into tetrathionate and sulphur. Whether hexathionate to some extent can decompose directly into tetrathionate, is not clear, since the analytical methods give the average sulphur content only, of hexa-, penta- and tetrathionate mixtures. It appears that the thiosulphate-catalyzed decompositions may be due to primary displacements according to schemes 3 and 4; in particular, the displacements represented by Eqns. (7) and (9). The greater lability of hexathionate as compared with pentathionate would be in accordance with the additional availability of the more probable scheme 4 for hexathionate.

The possibility of scheme 3 displacements as the cause of the catalytic decompositions was pointed out by the author [29] in 1949, but rejected in favour of a mechanism connected with displacements of thiosulphate according to scheme 1. Such displacements "proceed through a transition state, the energy of which is higher than that of the molecules in the initial state. The molecules are labile even in the initial state, and the increase in energy associated with the passing of the transition state serves to decrease the thermodynamic stability and accelerate the decompositions" [29]. The transition state complex, ordinarily unstable along one reaction coordinate only, was in this case thought to be unstable in two directions, *viz.*, in the one leading to displacements, as represented by Eqns. (4) and (5) of the present paper, and in the one leading to the release of sulphur.

Fava [28] in 1953 described the thiosulphate-catalyzed decompositions as due to nucleophilic attacks corresponding to schemes 3 and 4. There appears to be no way in which to decide experimentally between the possibilities. In the related case of iodide and acetate ion catalysis on the decomposition of telluropentathionate, an attack on tellurium, there substituted for the middle sulphur atom of pentathionate, is indicated [29]. However, the different catalysts do not necessarily act by the same mechanism, and in lack of definite information, the fact that thiosulphate does exert a catalytic influence on the decompositions serves as an indication that displacements according to schemes 3 and 4 may be possible.

In concluding, it appears that, as far as the available evidence goes, the more rapid displacement of thiosulphate according to scheme 1 will take place simultaneously with any other displacement, and in most cases dominate the reaction picture. A fuller understanding of the relative importance of the various schemes must await a knowledge of, *e.g.*, the nature of the transition state in nucleophilic displacements on divalent sulphur.

Conjugate Additions of Grignard Reagents to alpha, beta-Unsaturated Esters

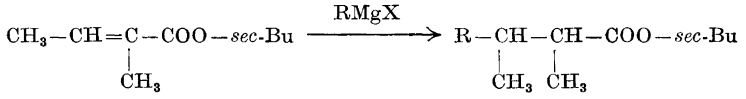
II. The Preparation of 3-Methyl- and 2,3-Dimethylalkanoic Acids

JON MUNCH-PETERSEN

Organisk-kemisk Laboratorium, Polyteknisk Læreanstalt, Copenhagen, Denmark

A previously published method for the preparation of 3-methyl-alkanoic acids from *sec*-butyl crotonate and Grignard reagents has been revised, improved and simplified. It has further been extended to *sec*-butyl tiglate, from which fair yields of 2,3-dimethylalkanoic acids are obtained.

In a recent publication [1] the addition of Grignard reagents to the double bond of *sec*-butyl crotonate as a way of preparing in high yields 3-methyl-substituted fatty acids was described. Certain other α,β-unsaturated esters were investigated, but only with cinnamic ester were reasonable yields obtained, whereas the reaction with tiglic and methacrylic esters failed. Of these, the reaction with tiglic esters would be of particular interest, on one hand since this ester is rather easily accessible, and on the other hand because of the difficulties reported [2] in obtaining 2,3-dimethyl-substituted fatty acids by other routes:



Since the publication of the first paper there have been difficulties in obtaining the high yield stated for the preparation of *sec*-butyl 3-methylheptanoate from *sec*-butyl crotonate and *n*-butylmagnesium bromide. This has prompted a reinvestigation of the reaction and of most of the work reported in the first paper. Although no explanation for the discrepancy has been found so far, a new procedure has been worked out, which gives almost as good a yield, and which is considerably simpler. Furthermore, by this procedure tiglic ester gives good to fair yields of *sec*-butyl esters of 2,3-dimethylalkanoic acids (Table 1).

In the first paper it was reported that the presence of cuprous chloride was essential to the success of the addition reaction, since it had been found that, under the conditions there described, the absence of this catalyst resulted in the formation of a high-boiling condensation-addition product. It has not been possible to verify this remarkable catalytic effect of cuprous chloride in promoting the simple 1,4-addition to the conjugated carbon-carbon double bound in competition with the condensation-addition process. On the contrary, carrying out the addition as described resulted in varying, but rather low yields (30—50 %), and with the formation of larger amounts of the high-boiling condensation compound. In numerous experiments with *sec*-butyl

crotonate and *n*-butylmagnesium bromide the conditions have been varied systematically (including the testing of different qualities of cuprous chloride and magnesium, and changes in the addition temperature, the addition time and the dilution of the ester), apparently without effect on the yield.

Eventually the use of a greater excess of Grignard reagent (at least 0.5 mole with 0.2 mole of ester) was found to result in an increase in the yield, and at the same time the use of cuprous chloride appeared to be of little effect. The procedure now worked out and described below gives about a 75 % yield for the reaction of crotonic ester with *n*-butylmagnesium bromide.

Using the new procedure, those other additions, which had previously been found to give low or no yields of simple 1,4-addition product, were repeated. These results, as well as those of some new addition reactions, are given in Table 1, which for comparison also includes the results previously reported using the cuprous chloride procedure.

The yields for crotonic ester with ethyl- and *iso*propylmagnesium bromides have increased, but methylmagnesium bromide — in contrast to the earlier findings with cuprous chloride — now gives an unseparable mixture of compounds. Similar results of reactions of methylmagnesium halides with α,β-unsaturated systems have been reported previously [3,1]. The yields with tiglic ester from *n*-butyl- and *iso*propylmagnesium bromides are quite good, whereas those from *n*-amyl-, *n*-octyl-, and phenylmagnesium bromides are somewhat lower. Methacrylic and acrylic esters give mostly polymerisation products, β,β-dimethylacrylic ester gives a mixture of unreacted ester and some unidentified low-boiling compound as well as some polymerisation product.

The high-boiling compounds obtained as by-products from the reactions with crotonic and tiglic esters were identified previously [1] and were not further investigated during the course of this work. They are considered to be di-*sec*-butyl α-(2-alkyl)-β-methylglutarates and di-*sec*-butyl α-(2-alkyl)-α, β, γ-trimethylglutarates, respectively, (2-alkyl = $R-\underset{\displaystyle CH_3}{\underset{|}{CH}}-CH_3$), produced by addition of the Grignard reagents to the α,β-unsaturated dimerisation products, which are again formed by a Michael-type self-condensation of the original esters.

Further investigations of the reaction are in progress.

EXPERIMENTAL

Analyses are by Mr. Preben Hansen, Microanalytical Division, The Chemical Laboratory, The University of Copenhagen. Fractional distillations were through a simple 45 cm × 8 mm Podbielniak-type column with a tantalum wire spiral, heated jacket and a partial reflux head.

sec-Butyl esters were obtained by esterification of the corresponding acids in 75—85 % yield, according to the general procedure previously described [1] for crotonic, tiglic, methacrylic, and cinnamic esters. The yield for *sec*-butyl tiglate, b. p. 75°/16 mm, n_D^{25} 1.4339, has been raised to 75 % (Ref.[1] b. p. 86—87°/30 mm, n_D^{25} 1.4335, yield 60 %). New esters are: *sec*-butyl acrylate, b. p. 29°/18 mm, n_D^{20} 1.4268, and *sec*-butyl β,β-dimethylacrylate, b. p. 68—70°/13 mm, n_D^{20} 1.4379.

The corresponding acids were commercial products (Fluka AG., Buchs/SG, Switzerland), except for methacrylic [4] and tiglic [5] acids, which were prepared through the corresponding ketone cyanohydrins as described in the literature. It should be pointed out that it has been found essential for the success of the tiglic acid synthesis [5] that the temperature-controlled hydrolysis and elimination process between methyl ethyl ketone cyanohydrin and 100 % sulfuric acid be carried out under extremely vigorous stirring, since otherwise foaming and tar-formation takes place, resulting in low yields.

Additions of Grignard reagents to α,β-unsaturated esters. The solution of Grignard reagent was prepared (without use of iodine or other catalyst) in an 1 liter three-necked flask, provided with effective stirrer, from 12.5 g (0.52 g-atom) of magnesium turnings and 0.65 mole of halide dissolved in 150—200 ml of ether. The reaction is completed by boiling for 10—15 min, after which the Grignard solution is cooled for 15—20 min in an ice-water bath. Under effective stirring in the ice-bath, 0.20 mole of ester, dissolved in 200 ml of ether is now added dropwise from a graduated dropping funnel during a period of at least 1.5 h. When the addition is completed, stirring is continued in the ice-bath for additional 15 min, and for 1 h at room temperature. The reaction mixture is then worked up in the conventional way, as previously described [1].

The higher halides (octyl *etc.*) are dissolved in a somewhat greater quantity of ether in order to prevent crystallisation of the Grignard reagent during the cooling. Working up after reactions with phenylmagnesium bromide should include a washing of the ether extract with sodium hydroxide solution in order to remove phenol, which will otherwise make distillation troublesome and contaminate the product.

Saponification of sec-butyl esters may be carried out with ethanolic potassium hydroxide as previously described [1]. In this way (on a 0.05 mole scale) *2,3-dimethylheptanoic acid*, b. p. 89°/1 mm, n_D^{20} 1.4356, was obtained in 80 % yield; neutr.equiv. calcd. for $C_9H_{18}O_2$ 158.2, found 157. *2,3-Dimethylhendecanoic acid*, b. p. 131°/1 mm, n_D^{20} 1.4461, yield 73 % (*cf.* Table 1); calcd. for $C_{13}H_{26}O_2$ (214.34): C 72.84; H 12.23. Found C 72.85; H 12.20; neutr. equiv. 213.

A Study of the Vanadium Tellurides

FREDRIK GRØNVOLD, OLAF HAGBERG and HAAKON HARALDSEN

Kjemisk institutt A, Universitetet i Oslo, Blindern, Norway

The existence of two intermediate phases, β and γ, has been established in the system vanadium tellurium. None of these phases have a simple stoichiometric composition, corresponding to the mono- or ditelluride.

The β-phase has a composition close to V_5Te_4 and no appreciable homogeneity range. The structure is monoclinic with the lattice constants:

$$a = 13.48 \text{ Å}, b = 3.91_3 \text{ Å}, c = 13.82 \text{ Å}, \beta = 93.5_8°$$

when quenched from 1 000°C.

The *γ-phase* has a homogeneity range between about 53 and 62 atomic per cent tellurium in samples quenched from 1 000°C, and between 55.6 and 64.9 atomic per cent tellurium in samples quenched from 750°C. For slowly cooled samples the vanadium rich limit of the γ-phase is at about 56.5 atomic per cent tellurium. Within the γ-phase region four structurally related phases are recognized:

1. The γ_1-phase with a hexagonal NiAs-like structure and composition around 53 atomic per cent tellurium in samples quenched from 1 000°C only. The lattice constants of the hexagonal structure as determined from the two-phase preparation with 52.38 atomic per cent tellurium are:

$$a = 3.942 \text{ Å}, \quad c = 6.126 \text{ Å}, \quad c/a = 1.55_3$$

2. The γ_2-phase with a related monoclinic structure and composition between 55.5 and 63.0 atomic per cent tellurium in samples quenched from 750°C. In this range the lattice constants vary continuously between the limits:

$$a = 6.763 \text{ Å}, \quad b = 3.807 \text{ Å}, \quad c = 2\times 6.225 \text{ Å}, \quad \beta = 91.52°$$

at 55.56 atomic per cent tellurium, and

$$a = 6.460 \text{ Å}, \quad b = 3.685 \text{ Å}, \quad c = 2\times 6.335 \text{ Å}, \quad \beta = 90.3°$$

at 62.96 atomic per cent tellurium.

For samples quenched from 1 000°C the tellurium-rich limit of the γ_2-phase is close to 62 atomic per cent tellurium.

3. The γ_3-phase with a hexagonal NiAs-$Cd(OH)_2$-like structure and a narrow composition range in samples quenched from 750°C. The lattice constants for this structure at the composition 63.96 atomic per cent tellurium are:

$$a = 3.689 \text{ Å}, \quad c = 6.405 \text{ Å}, \quad c/a = 1.736$$

This phase was neither observed in samples quenched from 1 000°C nor in slowly cooled.

4. The γ_4-phase with an orthorhombic $Cd(OH)_2$-like structure and composition between 64.3 and 64.9 atomic per cent tellurium. For a sample with 64.91 atomic per cent tellurium, quenched from 750°C, the lattice constants are:

$$a = 6.333 \text{ Å}, \quad b = 3.618 \text{ Å}, \quad c = 2 \times 6.427 \text{ Å}$$

Density measurements show that the solid solution within the γ-phase takes place by subtraction of vanadium atoms as the tellurium content increases.

Only a few references to vanadium tellurides are present in the literature and the earliest work seems to be by Hoschek and Klemm [1]. The tellurides prepared by these authors by the reaction between vanadium (III) oxide or chloride with hydrogen telluride generally had a composition close to the ratio V:Te = 1. Hoschek and Klemm were not able to establish the composition or structure of any of the tellurides formed in their experiments and the tellurium was reported to be relatively weakly bonded. Montignie [2] was not successful in preparing vanadium tellurides by heating vanadium (V) oxide and tellurium under hydrogen.

The first description of a well defined vanadium telluride is due to Ehrlich [3], who obtained the monotelluride by heating the elements in evacuated, sealed silica tubes at 800 to 1 000°C. The compound was found to have a structure of the NiAs-type with unit cell dimensions * $a = 3.81_3$ Å, $c = 6.13_2$ Å and $c/a = 1.60_8$. The X-ray powder photograph of the compound contained, however, some weak reflections which could not be explained on basis of a simple NiAs-like structure. Whether these additional reflections were due to a superstructure or to other phases could not be decided by Ehrlich.

Gal'perin and Perekalina [4] found that the structure of vanadium monotelluride was not of the NiAs-type, but were unable to interpret it.

Ehrlich [5] has indicated the existence of a compound with structure of the $Cd(OH_2)$-type in the system vanadium tellurium, without giving any experimental evidence for the existence of such a phase.

EXPERIMENTAL

The alloys used in this study were synthesized by heating the elements in the desired ratio in evacuated and sealed silica tubes. In a few cases preparations were made also by adding tellurium to previously prepared alloys containing less tellurium.

The metallic *vanadium* was supplied by the Vanadium Corporation of America and reported to contain 99.6—99.8 % vanadium. The impurities were specified as follows: iron 0.05 %, silicon 0.05 %, aluminium less than 0.05 %, nitrogen less than 0.001 %, and oxygen balance.

The *tellurium* was from the British Drug Houses Ltd. and purified further by distillation *in vacuo*. A spectrographic analysis, which was kindly carried out by siv.ing. S. Rutlin at the Central Institute for Industrial Research, Norway, showed that the puri-

* The lattice constant values given by Ehrlich, presumably expressed in kX units, have been changed into Å by multiplication by the factor 1.00202.

fied tellurium contained less than 0.01 % iron and only traces of aluminium, magnesium and lead.

During the first preparations of the alloys it was observed that samples with more than 45.5 atomic per cent vanadium heavily attacked the silica tubes by reducing the silicon dioxide and forming trivanadium monosilicide, V_3Si. In order to avoid this detrimental reaction, alloys with more than 45.5 atomic per cent vanadium were prepared in small crucibles of pure alumina ("Degussit" from Degussa) placed inside the silica tubes. Alloys with less than 45.5 atomic per cent vanadium could be prepared without this precaution.

A number of alloys with compositions varying from 24.81 to 71.43 atomic per cent tellurium were synthesized. The mixture of vanadium and tellurium was first heated for 2 days at 1 000°C. By this heating a sintered reaction product was obtained which could easily be changed into a powder by shaking the silica tube. The heating was continued at 1 000°C for 2 more days in the same tube. It was then quenched in ice water and small portions of each sample taken out for X-ray investigation. The rest of the sample was heated further for 20 days at 750°C and quenched from that temperature.

In this way it was only possible to obtain alloys with less than 62 atomic per cent tellurium. In alloys with higher tellurium content some tellurium was left unreacted after quenching from 1 000°C. In order to make the reaction complete above 62 atomic per cent tellurium it was necessary to cool the samples slowly down from 1 000 to 750°C. In this way alloys with up to 71.43 atomic per cent tellurium could be prepared. They were also annealed for 20 days at 750°C and quenched.

In addition to these two series of samples, one quenched from 1 000°C and the other from 750°C, small parts of some of the samples were heated further for 30 days at 550°C and cooled slowly to room temperature during 5 days. In one case a sample was also cooled slowly from 750°C. The purpose of these heat treatments was to check if the lower annealing temperature and the slower cooling rate might cause any changes of the phases and structures observed in the quenched samples. The samples slowly cooled from 550°C contained 52.38, 54.55, 64.29 and 66.67 atomic per cent tellurium and that from 750°C 63.64 atomic per cent tellurium.

The samples were all easily crushed in an agate mortar into dark gray powders. They were then subjected to an X-ray examination by the powder method.

The X-ray photographs were taken in 11.48 cm diameter cameras with asymmetric film mounting. Vanadium filtered chromium radiation was used in most cases. In a few cases nickel filtered copper radiation was also used. The lattice constants are expressed in Ångström units on the basis of $\lambda CrK\alpha_1 = 2.2896$ Å and $\lambda CuK\alpha_1 = 1.5405$ Å. The mean error in the lattice constants in judged to be less than 0.1 %.

PHASE ANALYSIS

1. Samples quenched from 1 000 °C

The most vanadium-rich sample that was prepared contained 24.81 atomic per cent tellurium, corresponding to the composition $VTe_{0.33}$. By X-ray examination this sample was found to consist of two phases: metallic vanadium — the *α-phase* — and an intermediate phase — the *β-phase*. Samples with 41.18 and 44.44 atomic per cent tellurium ($VTe_{0.70}$ and $VTe_{0.80}$, respectively) gave only reflections from the β-phase, whereas another phase — the *γ_1-phase* — was observed together with the β-phase at 47.37 atomic per cent tellurium ($VTe_{0.90}$). Accordingly, it is concluded that the β-phase contains about 44 atomic per cent tellurium ($VTe_{0.8}$) and thus has a composition which is markedly different from that of a monotelluride. As no displacement of the X-ray reflections on photographs of samples containing the β-phase is observed, the phase probably has a rather narrow homogeneity range.

The β-phase is observed together with the γ_1-phase in preparations with 50.00 and 52.38 atomic per cent tellurium ($VTe_{1.00}$ and $VTe_{1.10}$, respectively).

At the latter composition the reflections from the β-phase are few and weak. The remaining reflections can all be explained in terms of the hexagonal, NiAs-like structure which Ehrlich [3] attributed to vanadium monotelluride. However, all the samples with 50 atomic per cent tellurium studied here turned out to be two-phase preparations, containing both the β-phase and the γ_1-phase. Thus, a vanadium monotelluride with the exact stoichiometric composition VTe does apparently not exist. The additional reflections which Ehrlich observed on the photograph of the sample with composition corresponding to the monotelluride, were probably due to the β-phase.

The X-ray photographs of samples with compositions in the concentration range 52.38 to 62.26 atomic per cent tellurium ($VTe_{1.10}$ to $VTe_{1.65}$, respectively) are all very similar. Some characteristic features should, however, be emphasized. First of all, no reflections from the β-phase are present for samples with 54.55 atomic per cent tellurium ($VTe_{1.20}$). Furthermore, a splitting of many of the hexagonal reflections is observed at the same composition. Finally, a marked shift in the positions of the reflections is observed as the tellurium content of the samples increases in the whole concentration range up to 60.00 atomic per cent tellurium.

These observations show that the γ_1-phase with a hexagonal, NiAs-like structure has only a narrow existence range between 52.38 and 54.55 atomic per cent tellurium ($VTe_{1.10}$ and $VTe_{1.20}$, respectively). With increasing tellurium concentration the hexagonal structure changes into one with a lower, probably monoclinic, symmetry as has earlier been found for many of the chalcogen systems of the 3*d* transition elements (see for instance Haraldsen [6]). The corresponding phase — the *γ_2-phase* — has a homogeneity range between about 54.55 and 62.26 atomic per cent tellurium, the latter composition being the highest one in tellurium which could be attained for samples quenched from 1 000°C without the tellurium phase being present.

The designations γ_1 and γ_2 are chosen to indicate that the phase γ_1 with hexagonal structure and γ_2 with monoclinic structure might constitute only one phase — the *γ-phase* — in analogy with what has been found for many related systems[6]. This further means that the hexagonal structure, present at the vanadium-rich limit of the homogeneity range, continuously changes into the monoclinic structure as the tellurium content increases.

2. Samples quenched from 750°C

In the series quenched from 750°C, a phase with a hexagonal structure, corresponding to that of the γ_1-phase in the series quenched from 1 000°C, could not at all be observed. Instead, large amounts of the β-phase were present in the sample with 52.38 atomic per cent tellurium, and also the γ_2-phase with its splitted reflections. A considerable change in the positions of these reflections was observed in the range from 55.56 to 62.96 atomic per cent tellurium ($VTe_{1.25}$ to $VTe_{1.70}$.).

The X-ray powder photographs of the preparation with 63.64 atomic per cent tellurium ($VTe_{1.75}$) could, however, be indexed hexagonal. Consequently, the system vanadium tellurium shows the same characteristic features as has

been found in many other chalcogen systems of the 3*d* transition elements [6]. Depending upon the temperature to which the statement refers, there exists in the range between 50 and 66.7 atomic per cent chalcogen one or more phases which at concentrations low in chalcogen possess a hexagonal NiAs-like structure, at intermediate concentrations a monoclinic structure and at concentrations high in chalcogen again a hexagonal $Cd(OH)_2$-like structure, derived from the NiAs-like structure by subtraction of metal atoms. In the present case it could not be decided whether the hexagonal structures and the monoclinic structure constitute a single phase or three different phases, γ_1, γ_2 and γ_3, separated-by two-phase regions.

The hexagonal $Cd(OH)_2$-like structure was found to exist also at the composition 63.96 atomic per cent tellurium ($VTe_{1.775}$), but not at 64.29 atomic per cent tellurium ($VTe_{1.80}$), where a splitting of the X-ray reflections was again noted. The hexagonal γ_3-phase has thus only a narrow existence range, just as the hexagonal γ_1-phase which was observed in the series quenched from 1 000°C.

In samples with 64.29 to 64.91 atomic per cent tellurium probably another phase — the *γ_4-phase* — exists. The corresponding X-ray powder photograph was tentatively indexed as orthorhombic (see Table 5). The photographs of the samples with 65.52, 66.67 and 71.43 atomic per cent tellurium ($VTe_{1.90}$, $VTe_{2.00}$, and $VTe_{2.50}$ respectively) contained also a few weak reflections which might be caused by elemental tellurium, in addition to the reflections from the γ_4-phase. No shift in the positions of the reflections from the γ_4-phase is observed on the photographs of the samples with 64.91 to 71.43 atomic per cent tellurium, and the γ_4-phase should therefore not contain more than 64.91 atomic per cent tellurium ($VTe_{1.85}$). The change from hexagonal to orthorhombic structure takes place within a narrow composition range, 63.96 to 64.29 atomic per cent tellurium, and it is very slight. It seems reasonable to suppose that the transition from the monoclinic γ_2-phase, *via* the hexagonal γ_3-phase, into the orthorhombic γ_4-phase is continuous at high temperatures and that the γ-phase has a homogeneity range between about 55.56 and 64.91 atomic per cent tellurium ($VTe_{1.25}$ and $VTe_{1.85}$) at 750°C, as far as it can be judged from the quenched samples.

3. Slowly cooled samples

The most striking feature of the slowly cooled preparations is the absence of the hexagonal structure both at low and at high tellurium concentrations. Consequently, neither the γ_1-phase, nor the γ_3-phase exists at low temperatures.

The preparation with 52.38 atomic per cent tellurium ($VTe_{1.10}$) consists also in this case of two phases, β and γ_2, whereas at 54.55 atomic per cent tellurium ($VTe_{1.30}$) only the γ_2-phase remains. With regard to the position of the X-ray reflections the photographs of these two samples are practically identical with that of $VTe_{1.30}$ quenched from 750°C, which indicates that the γ_2-phase does not contain less than 56.52 atomic per cent tellurium at room temperature. Similarly, the photograph of the slowly cooled sample with 63.64 atomic per cent tellurium indicates that the tellurium-rich limit of the γ_2-phase is close to 61.54 atomic per cent, as it is very similar to that of $VTe_{1.60}$ quenched from 750°C. The γ_4-phase was found free from other phases at 64.29 atomic

per cent tellurium ($VTe_{1.80}$) and mixed with free tellurium at 66.67 atomic per cent tellurium ($VTe_{2.00}$).

It follows from the results obtained here that a vanadium ditelluride with the exact stoichiometric composition VTe_2 does not exist, no more than a stoichiometric monotelluride VTe, at least not under the described experimental conditions. The most tellurium-rich phase obtained, the γ_4-phase, has a composition which differs markedly from the formula VTe_2, and changes in the heat-treatment apparently makes no difference as to the non-existence of the stoichiometric mono- and ditelluride.

LATTICE CONSTANT VALUES

1. The β-phase

Single crystals of the β-phase were found in the preparation with 44.44 per cent tellurium, quenched from 1 000°C. Weissenberg photographs showed that the crystals were monoclinic, and also gave approximate values for the unit cell dimensions. The powder photographs of the β-phase could then be

indexed as shown in Table 1. The lattice constants, as determined for samples of the three series, are listed in Table 2 and they are practically the same.

Missing reflections on the photographs are of the type:

$$hkl \text{ when } h + k = 2n + 1,\ k + l = 2n + 1,\ (l + h = 2n + 1)$$

$$h0l \text{ when } l = 2n + 1,\ (h = 2n + 1)$$

$$0k0 \text{ when } (k = 2n + 1)$$

Table 2. Lattice constants of the β-phase.

Annealing temperature °C	a in Å	b in Å	c in Å	β	Volume of the unit cell in Å^3
1 000	13.48	3.91_3	13.82	93.5_8°	727.1
750	13.47	3.92_7	13.86	93.66°	731.6
550	13.47	3.92_0	13.85	93.6°	729.9

They are characteristic of the space groups C_s^4 and C_{2h}^6. The observed density, 6.73_7 g cm^{-3}, corresponds to 19.3 vanadium and 15.4 tellurium atoms in the unit cell. The true content is probably 20 vanadium and 16 tellurium atoms, which corresponds to the formula V_5Te_4 or $VTe_{0.80}$. The determination of the structure is under way.

2. The γ-phase

The lattice constants of the γ-phase determined for the three series of samples at different compositions are given in Table 3. Weak additional lines on the photographs of the monoclinic samples, both when quenched from 750°C and when slowly cooled, require for their explanation a doubling of the c-axis, and this is indicated in the table.

The values determined for the hexagonal γ_1-phase at the composition 52.38 atomic per cent tellurium and 1 000°C agree fairly well with the values found by Ehrlich [3] as far as the c-axis is concerned ($a = 3.81_3$ Å, $c = 6.13_2$ Å). The a-axis is, however, considerably larger.

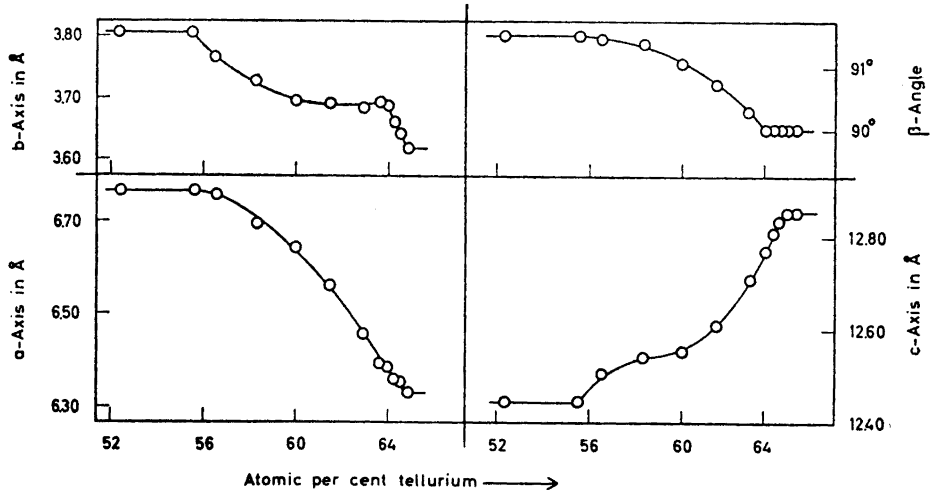

Fig. 1. Lattice constants of the γ-phase after quenching from 750°C.

Table 3. Lattice constants of the γ-phase.

* slowly cooled.

The variations in lattice constants with composition are seen from Fig. 1, where the lattice constants of the γ-phase for the 750°C series are plotted against the composition. The a-axis decreases smoothly with increasing tellurium content in the whole concentration range, while the b-axis shows an abrupt decrease at about 64 atomic per cent tellurium as the structure changes

from hexagonal to orthorhombic. Even though the c-axis increases, the volume of the unit cell decreases as well, see Table 3.

It is furthermore apparent from Fig. 1 that the vanadium rich limit of the homogeneity range of the γ-phase for the 750°C series is at about 55.5 atomic per cent tellurium. This is somewhat higher than found on basis of the 1 000°C series, where the limit lies between 52.38 and 54.55 atomic per cent tellurium if the hexagonal range is included.

The lattice constant values for the hexagonal structures fall nicely on the curves drawn through the values for the monoclinic structure. This is also the case with the hexagonal lattice constants of the 1 000°C series (not shown in the figure). This might indicate that the transition from one structure into the other is continuous under the experimental conditions used here. The observations are, however, too few for deciding this question with certainty.

As already stated, the X-ray powder photograph of the γ_4-phase was indexed orthorhombic. This gave a satisfactory agreement between observed and calculated $\sin^2\Theta$-values for most of the reflections, as can be seen from Table 4 where the values are listed. There remain, however, a few, very weak reflections which cannot be accounted for in this way. They might be due to a superstructure, indicating that the true unit cell is larger.*

The lattice constants calculated for the orthorhombic unit cell are:

$$a = 6.333 \text{ Å}, \; b = 3.618 \text{ Å}, \; c = 2 \times 6.427 \text{ Å}$$

at 64.91 atomic per cent tellurium.

* Note added in proof: Weissenberg photographs of a crystal of $VTe_{1.85}$ has confirmed the correctness of the orthorhombic interpretation and shown that she b-axis must be tripled.

Table 5. Interatomic distances in the hexagonal γ_1 and γ_3 structures.

Atomic per cent tellurium	V—Te	V—V	Te—Te within the layers	Te—Te between the layers
52.38	2.74 Å	3.06 Å	3.94 Å	3.82 Å
63.64	2.67 Å	3.20 Å	3.69 Å	3.85 Å

The structure bears a close relationship to that of the hexagonal γ_3-phase, but it has so far no parallel among the other sulfides, selenides and tellurides of the 3*d* transition elements. It is especially worth mentioning that the structure is not of the marcasite type as one might have thought on basis of its orthorhombic structure and its composition.

In the hexagonal γ-phase, each vanadium atom is surrounded by six tellurium atoms at the corners of a deformed octahedron (trigonal antiprism) and two vanadium atoms at the distance $c/2$. The tellurium atoms form an approximately hexagonal closepacking. The distances vanadium-tellurium, vanadium-vanadium and tellurium-tellurium found in the two preparations with 52.38 and 63.96 atomic per cent tellurium are listed in Table 5.

The distances vanadium-tellurium are distinctly shorter than the sum of the ionic radii: 0.74 Å + 2.11 Å = 2.85 Å. They agree, however, very well with the sum of the metallic radii as given by Pauling [7]. With an average coordination number of 7.6 for vanadium and 5.5 for tellurium in the vanadium rich preparation and 6.4 for vanadium and 3.5 for tellurium in the tellurium rich preparation, the sum of the metallic radii is:
1.27 Å + 1.50 Å = 2.77 Å and 1.26 Å + 1.44 Å = 2.70 Å, respectively, *i.e.* only 0.03 Å higher than the experimental values.

The distance tellurium-tellurium between the layers remains almost unchanged from 52.38 to 63.96 atomic per cent tellurium, whereas the distance within

Table 6. The distance metal-tellurium in tellurides with NiAs-like, respectively $Cd(OH)_2$-like structure.

Composition $MeTe_n$	Distance Me-Te in Å	Sum of ionic radii r(Me) + r(Te) in Å	Sum of metallic radii r(Me) + r(Te) in Å
TiTe	2.736		1.41 + 1.51 = 2.92
$TiTe_2$	2.717	0.64 + 2.11 = 2.75	1.38 + 1.42 = 2.80
$VTe_{1.1}$	2.74	0.74 + 2.11 = 2.85	1.27 + 1.50 = 2.77
$VTe_{1.7}$	2.67		1.26 + 1.44 = 2.70
$CrTe_{1.5}$	2.726	0.65 + 2.11 = 2.76	1.28 + 1.46 = 2.74
MnTe	2.923	0.91 + 2.11 = 3.02	1.21 + 1.51 = 2.72
$FeTe_{1.5}$	2.62	0.67 + 2.11 = 2.78	1.18 + 1.46 = 2.64
$CoTe_{1.2}$	2.62	0.82 + 2.11 = 2.93	1.19 + 1.49 = 2.68
$CoTe_{1.8}$	2.58		1.17 + 1.43 = 2.60
$NiTe_{1.1}$	2.654	0.78 + 2.11 = 2.89	1.18 + 1.50 = 2.68
$NiTe_2$	2.584		1.15 + 1.42 = 2.57

Table 7. Pycnometric densities of vanadium-tellurium preparations.

Atomic per cent tellurium	Density in g cm^{-3}	Atomic per cent tellurium	Density in g cm^{-3}
41.18	6.682	60.00	6.876
44.44	6.737	61.54	6.855
47.37	6.775	62.96	6.844
50.00	6.770	63.64	6.840
54.54	6.830	64.29	6.850
55.56	6.850	65.52	6.854
56.52	6.860	66.67	6.841
58.33	6.869		

the layers changes from 3.94 Å to 3.69 Å. This great change brings about that the distance within the layers, which is the larger one at 52.38 atomic per cent tellurium, is the smaller one at the tellurium rich composition.

The system vanadium-tellurium was the only tellurium system of the 3*d* transition elements from titanium to nickel for which data about the distance metal-tellurium still lacked. A compilation of the values found for this distance in the phases with NiAs-like, respectively $Cd(OH)_2$-like structure, is presented in Table 6 and compared with distances calculated on the basis of the ionic radii of Goldschmidt, and the metallic radii of Pauling. The metallic radi have been corrected for the coordination number valid for the compositions given in the table.

It can be seen from Table 6 that the observed distance metal-tellurium for the titanium tellurides TiTe and $TiTe_2$ and for manganese monotelluride MnTe is best in accordance with the sum of the ionic radii, whereas the metallic radii lead to the most satisfactory agreement for the vanadium, iron, cobalt and nickel tellurides. The chromium telluride $CrTe_{1.5}$ represents an intermediate case in so far as the distance chromium-tellurium agrees equally well with the sum of the ionic radii as that of the metallic radii.

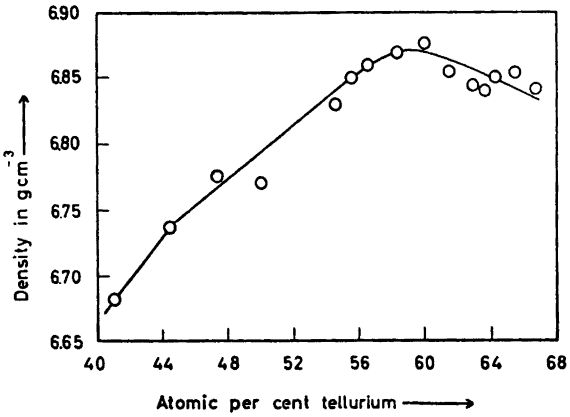

Fig. 2. Densities of the vanadium tellurides.

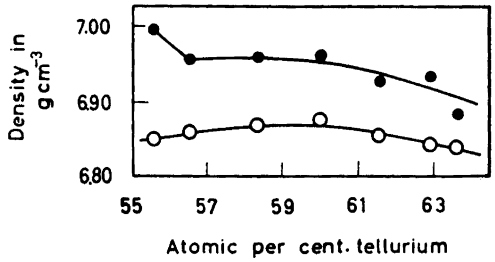

Fig. 3. Observed density o and calculated density ● of the γ-phase.

DENSITY MEASUREMENTS

Density measurements of the 750°C series were carried out at 25°C by the vacuum pycnometric method and with kerosene as displacement liquid. The results are listed in Table 7, and plotted against the composition of the samples in Fig. 2. There is a break in the curve at about 44.4 atomic per cent tellurium, coinciding with the composition of the β-phase, and a maximum at about 60 atomic per cent tellurium, *i.e.* within the homogeneity range of the γ-phase.

The densities which are found within the homogeneity range of the γ-phase confirm, furthermore, that the solid solubility in this concentration range is due to a subtraction of vanadium atoms. This appears from Fig. 3 where the densities, calculated on the basis of this hypothesis, are compared with the observed values. The agreement between the calculated and observed values in the concentration range 56.5 to about 64 atomic per cent tellurium leaves no doubt that a subtraction of vanadium atoms occurs in this region. An addition of tellurium atoms to the lattice or substitution of vanadium atoms by tellurium atoms would lead to an increase in the values of the calculated densities, and is not at all consistent with the observations. The subtraction of the vanadium atoms does, however, not go so far that a complete transition into a structure of the $Cd(OH)_2$-type is reached. The subtraction comes to an end at the tellurium rich limit of the γ_4-phase, *i.e.* at about 64 atomic per cent tellurium.

Certain changes which are observed in the relative intensities of the X-ray reflections, are also in favour of the hypothesis that the solid solution is of the subtractive type. The reflection (001) for example, which is forbidden in a structure of the NiAs-type, is distinctly seen on the photograph of the preparation with 62.96 atomic per cent tellurium.

Determination of Specific Gravity with Divers and Hydrometers with Loose Stem

SØREN BERG and J. J. V. LUNDBERG

The Laboratory of Porcelænsfabriken "Danmark" Ltd., Lyngby-Copenhagen, Denmark

A new method has been developed for determining the specific gravity of liquids, with divers or floats which may be loaded with metal weights to attain the floating equilibrium. The diver may also be provided with a loose stem of metal wire so that the instrument may function as a hydrometer.

Generally, only two divers are required for the measurements, *viz.* one of density 0.75 and another of density 0.95. Both divers are so dimensioned that their weights and volumes approximately satisfy an equation indicated in the article. Under these conditions, the specific gravity of the liquid may be calculated with sufficient accuracy from the results of the measurements by the diver method as well as from the results of measurements by the hydrometer method, using only a slide rule.

The random error of the diver method is about 0.9×10^{-5}. The random error of the hydrometer method is greater, and further a systematic error is introduced, *e. g.* because of adhesion between the fluid and the stem. The order of magnitude of this systematic error may be determined by comparative measurements according to the diver method and the hydrometer method.

Many investigators have tried to measure the specific gravity of fluids by applying bodies of known specific gravity, so-called divers, which during the measurements are completely submerged. The floating equilibrium of the diver is attained by addition of platinum weights to the diver, by alteration of the temperature of the fluid, by diluting the fluid, *etc.*

Divers have particularly been used for determining the specific gravity of sea water [1-4] and heavy water *etc.*[5-11] and in the fineness analysis [12-17] to determine the specific gravity in sedimenting suspensions, where the application of divers is advantageous for two reasons. First, in a heterodisperse, sedimenting suspension the specific gravity increases from the surface downwards, and there will therefore always be a level at which a diver with lower specific gravity than the homogeneous suspension, but with higher specific gravity than the suspending medium, may attain the floating equlibrium. Such special arrangements to attain the floating equilibrium may therefore be omitted, when a series of divers of different specific gravities are available.

Second, a consideration of the sedimentation process shows that a diver, which is in equilibrium in a sedimenting suspension, will move downwards with the same velocity as the largest particles present at the level of its geometric centre of gravity. *I.e.* it moves downwards faster than the sedimenting velocity of every particle present above this level. As a hydrometer, therefore, it will not be overtaken by sedimenting particles and systematic errors caused by deposition of particles onto the diver will be very small.

Finally, it may be mentioned that Nansen [3] has proposed to provide the diver with a loose stem, which, when the diver is in equilibrium, protrudes through the surface of the fluid so that the instrument is altered to a hydrometer (with loose stem).

With the exception of the examination of the specific gravity in sedimenting suspensions by the fineness analysis, it seems as if the method is not widely used for the determination of the specific gravity of fluids in spite of its very great precision and the quickness of the measurements. This is probably due to the fact that hitherto it has been necessary to calculate the specific gravity from a non-logarithmic expression by the application of logarithms with at least five figures.

It may, however, be shown that by applying two divers, the weights and volumes of which both satisfy a later indicated equation, one may calculate the specific gravity of the fluid with sufficient accuracy without other calculating facilities than a slide rule. By this method the specific gravity is determined with a random error of $\pm 0.9 \times 10^{-5}$ and the method is therefore more precise than the hydrometer method and Westphal's balance. It is further possible to make the method still more accurate, but this will require a very precise thermostat and the application of more than two divers, if the calculations are still to be simply made.

By providing the diver with a loose stem of platinum wire, for instance, one can, with moderate decrease in preciseness, make the measurements according to the hydrometer method. To obtain a satisfactory preciseness in this case, it is necessary to carry out comparative measurements according to the diver method and the hydrometer method for each new fluid which may be examined in order to determine the systematic error of the hydrometer method and to be able to correct for it. These errors are particularly due to adhesion between the fluid and the stem, to changes in the condition of the surface of the stem, and to fluid attached to the protruding part of the stem.

In the following:

a	indicates the weight of the diver (*in vacuo*),
x	" " " " " load (" "),
$\varrho_{20,20}$	the specific gravity of the unloaded diver at 20°C
$\varrho_{20,4}$	compared to water at 20° and 4°C, respectively,
$\alpha_{20,20}$	the increase in specific gravity of the diver at 20°C
$\alpha_{20,4}$	compared to water at 20°C and 4°C, due to the load,
$p_{20,20}$	the specific gravity of the load at 20°C compared
$p_{20,4}$	to water at 20°C and 4°C, respectively,
$z_{20,20}$	an arbitrary specific gravity at 20°C compared
$z_{20,4}$	to water at 20°C and 4°C, respectively.

When a diver is in floating equilibrium in a medium with the load x one has:

$$\frac{a+x}{\frac{a}{\varrho_{20,4}}+\frac{x}{p_{20,4}}} = \varrho_{20,4} + \alpha_{20,4} \tag{1}$$

and since

$$z_{20,4} = z_{20,20} \times 0.99823$$

one gets

$$\frac{a+x}{\frac{a}{\varrho_{20,20}}+\frac{x}{p_{20,20}}} = \varrho_{20,20} + \alpha_{20,20}$$

from which may be deduced

$$\frac{a+x}{\frac{a\,p_{20,20}}{\varrho_{20,20}}+x} = \frac{\varrho_{20,20}+\alpha_{20,20}}{p_{20,20}}$$

and

$$\frac{a+x}{a\left(\frac{p_{20,20}}{\varrho_{20,20}}-1\right)} = \frac{\varrho_{20,20}+\alpha_{20,20}}{p_{20,20}-\varrho_{20,20}-\alpha_{20,20}} = \frac{1+\frac{\alpha_{20,20}}{\varrho_{20,20}}}{\frac{p_{20,20}}{\varrho_{20,20}}-\frac{\alpha_{20,20}}{\varrho_{20,20}}-1}$$

Multiplying by $\left(\frac{p_{20,20}}{\varrho_{20,20}}-1\right)$ one gets

$$\frac{a+x}{a} = \frac{\frac{p_{20,20}}{\varrho_{20,20}}+\frac{p_{20,20}\cdot\alpha_{20,20}}{\varrho_{20,20}^2}-\frac{\alpha_{20,20}}{\varrho_{20,20}}-1}{\frac{p_{20,20}}{\varrho_{20,20}}-\frac{\alpha_{20,20}}{\varrho_{20,20}}-1}$$

and

$$1+\frac{x}{a} = 1+\frac{\frac{p_{20,20}\cdot\alpha_{20,20}}{\varrho_{20,20}^2}}{\frac{p_{20,20}}{\varrho_{20,20}}-\frac{\alpha_{20,20}}{\varrho_{20,20}}-1}$$

from which may be derived

$$x = \frac{a\cdot\alpha_{20,20}}{\frac{\varrho_{20,20}^2}{p_{20,20}}\left(\frac{p_{20,20}}{\varrho_{20,20}}-\frac{\alpha_{20,20}}{\varrho_{20,20}}-1\right)}$$

and we have

$$x = \frac{a\cdot\alpha_{20,20}}{\varrho_{20,20}\left(1-\frac{\varrho_{20,20}-\alpha_{20,20}}{p_{20,20}}\right)} \tag{2}$$

from which may be derived

$$a_{20,20} = \frac{x \cdot \varrho_{20,20}\left(1 - \frac{\varrho_{20,20}}{p_{20,20}}\right)}{a\left(1 + \frac{\varrho_{20,20} \cdot x}{a \cdot p_{20,20}}\right)} \tag{3}$$

(3) is the non-logarithmic expression by which the difference between the specific gravity of the loaded and the unloaded diver may be calculated.

x being the load which corresponds to the floating equilibrium in water at 20°C, we have

$$\varrho_{20,20} + a_{20,20} = 1 \tag{4}$$

By substituting (4) into (2) it may be shown that

$$a_{20,20} = \frac{1}{1 + \frac{a \cdot p_{20,20}}{x\,(p_{20,20}-1)}} \tag{5}$$

Using (4) and (5), the specific gravity of the unloaded diver may be determined by floating experiments in water since only divers with lower specific gravity than water are used.

Eqn. (3) may be written

$$a_{20,20} = \frac{x \cdot \varrho_{20,20}\,(p_{20,20} - \varrho_{20,20})}{a \cdot p_{20,20}\left(1 + \frac{\varrho_{20,20} \cdot (p_{20,20} - \varrho_{20,20}) \cdot x}{a \cdot p_{20,20}\,(p_{20,20} - \varrho_{20,20})}\right)}$$

Simplifying, we introduce

$$\frac{a \cdot p_{20,20}}{\varrho_{20,20}\,(p_{20,20} - \varrho_{20,20})} = C \tag{6}$$

which gives

$$a_{20,20} = \frac{x}{C} \frac{1}{1 + \frac{x}{C(p_{20,20} - \varrho_{20,20})}} \tag{7}$$

As

$$\frac{1}{1+\beta} = 1 - \frac{\beta}{1+\beta}$$

where β is an arbitrary number, eqn. (7) may be written:

$$a_{20,20} = \frac{x}{C}\left(1 - \frac{\frac{x}{C(p_{20,20} - \varrho_{20,20})}}{1 + \frac{x}{C(p_{20,20} - \varrho_{20,20})}}\right)$$

and

$$a_{20,20} = \frac{x}{C}\left(1 - \frac{1}{1 + \frac{C}{x}\,(p_{20,20} - \varrho_{20,20})}\right)$$

and we further have:

$$\alpha_{20,20} = \frac{x}{C} - \frac{\left(\frac{x}{C}\right)^2}{\frac{x}{C} + p_{20,20} - \varrho_{20,20}} \tag{8}$$

When the weight and specific gravity of the diver are so chosen that C is a whole number, for instance 10, 20 or 50, x/C may conveniently be calculated by mental calculation and as the second term is smaller than 0.00350 except in special cases, it may be calculated with sufficient preciseness by a slide rule.

It may further be shown that when $\frac{x}{C} < 0.1$ and $p_{20,20} - \varrho_{20,20} > 20$ or $\frac{x}{C} < 0.08$ and $p_{20,20} - \varrho_{20,20} > 15$ the following approximate equation may be used

$$\alpha_{20,20} = \frac{x}{C} - \frac{\left(\frac{x}{C}\right)^2}{p_{20,20} - \varrho_{20,20}} \tag{9}$$

When C is not exactly a whole number

$$C = N\ (1 + \varepsilon)$$

where ε is a small number and N is a whole number.

When $\varepsilon < 0.001$ x/C may be computed by mental calculation by the following approximate equation

$$\frac{x}{C} = \frac{x(1 - \varepsilon)}{N} \tag{10}$$

The diver is made preferably from thermometer glass (Jena 16 III) to minimize the thermal after-effect, or from quartz, and the upper tip of the diver is drawn out into a short glass stem. The instrument is shown on Fig. 1 without and with the metal stem. Q is a ballast of mercury. M is a horizontal plate of soft iron, supported by a rod S fixed by shellac to the inside of the diver's lower tip. The diver may therefore be manipulated from the outside with a magnet when it is in floating equilibrium.

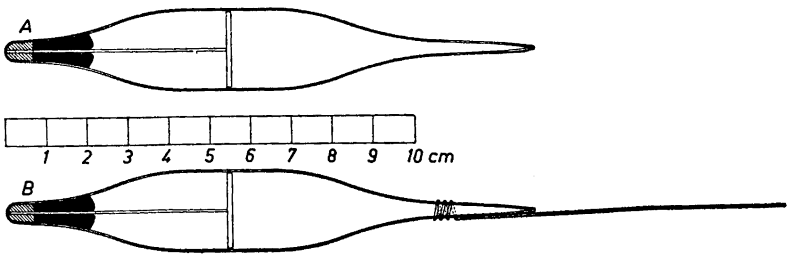

Fig. 1. A: Diver. B: Hydrometer with loose stem.

To secure that C and $\varrho_{20,20}$ do not differ more than 1 ‰ from N and the desired specific gravities, 0.75 and 0.95, respectively, the following course of procedure may be applied: From (6) we have

$$\frac{a}{\varrho_{20,20}} = C\,\frac{p_{20,20} - \varrho_{20,20}}{p_{20,20}} = Y \tag{11}$$

where Y is the weight of the water displaced by the diver at 20°C.
As

$$\varrho_{20,20} = \frac{\varrho_{20,4}}{0.99823}$$

where 0.99823 is the density of water at 20°C, we further have

$$\frac{a}{0.99823\,\varrho_{20,20}} = \frac{a}{\varrho_{20,4}} = \frac{C(p_{20,20} - \varrho_{20,20})}{0.99823\,p_{20,20}} = V \tag{12}$$

where V is the volume of the diver. From (11) and (12) it is seen, that Y and V are determined when C and $\varrho_{20,20}$ are chosen.

Before the stem of the diver is cut off to the desired length, the diver is put down in a graduated glass filled to a mark with mercury and the approximate volume of the diver is read from the rising of the mercury. The stem is then cut off to such a length that the volume of the diver is somewhat greater than the volume calculated by (11). Enough mercury is now introduced into the diver so that the latter may float submerged in water at 20°C with the stem closed by a small rubber hood. The stem is then sealed with a flame and by loading the diver with weights of platinum it is brought to floating equilibrium in water at 20°C.

From the load and the weight of the diver its specific gravity and volume may be calculated by (3), (4) and (12). By etching with hydrofluoric acid and by new floating experiments, the volume of the diver may now be decreased to approximately the calculated volume.

The tip of the stem is then cut off and sufficient mercury is removed from the diver to bring its specific gravity approximately to the desired one. The stem is now once more sealed in a flame. By new floating experiments and repeated etching, it is now possible to adjust both the C-value and the specific gravity of the diver to the desired values within a tolerance of less than 1 ‰. This is sufficient, but it is of course necessary afterwards to determine both values with a tolerance of less than about 0.5×10^{-5} by loading experiments in water by 20°C. These determinations may conveniently be repeated up to 10 times in order to give a good average.

For the measurements, one diver with a specific gravity of about 0.75 and another with a specific gravity of about 0.95 are applied and $\alpha_{20,20}$ is computed by (8) or (9) and (10).

For the most part, ringshaped weights of platinum are used which may be conveniently placed around the glass stem of the diver. Weights smaller than 10 mg should be made from stainless steel or titanium, preferably, (densities 7.85 and 4.5, respectively) provided that these materials are not corroded by the liquid to be investigated. The reason is that such small platinum weights (density 21.5), 5 mg and less, are rather difficult to handle.

As stainless steel and titanium have almost the same appearance as platinum, it is also advantageous to make 10, 20, and 50 mg weights of gold (density 19.3).

The weights of stainless steel, titanium and gold are made sufficiently more heavy than the corresponding weights of platinum so that the buoyancy of the weights in water is the same. All these weights being small, their relative accuracy may be rather limited, and thus in many cases it is not necessary to correct for the difference in buoyancy when the medium has a specific gravity different from 1.

For weights of stainless steel of specific gravity 7.85 and weight R the correction ΔR is calculated from the following formula, when the specific gravity of the medium is $\sigma_{20,20}$:

$$\Delta R = 0.1\ (1 - \sigma_{20,20})R \tag{13}$$

For weights of gold of specific gravity 19.3 and weight G the corresponding formula is

$$\Delta G = 0.005\ (1 - \sigma_{20,20})G \tag{14}$$

Big weights may be made of tantalum (density 16.6) instead of platinum as tantalum is very wear-resistant and almost as resistant against corrosion as gold and platinum.

To estimate loads smaller than the smallest weights applied, one may interpolate from the ascending and sinking velocities of the diver near the floating equilibrium. The velocity varies approximately directly with the load.

The medium which is to be examined is filled into a glass container which is placed in a water thermostat regulated at 20°C. Before the determinations, the diver with load must be freed from air bubbles by brushing it with a brush with soft hairs. To avoid a greater random error than $\pm 0.5 \times 10^{-5}$ the thermostat must regulate with a tolerance of $\pm$ 0.02°C.

In the examination of mixtures it is necessary to take precautions against alteration of the composition by evaporation of one of the components.

To save time it is advantageous to provide the diver with a loose stem, ordinarily of platinum wire, with a winding at one of its ends, so that it may be fixed around the glass stem of the diver. In computing the load which the stem represents, it must be taken into consideration that the buoyancy is acting only on that part of the stem which is situated under the surface of the fluid. Since the volume of that part of the stem which is above the surface of the fluid is ordinarily small, it is very often possible to estimate the weight of the corresponding volume of fluid with sufficient accuracy without knowing the accurate density of the fluid. When this weight is added to the weight of the stem, we get the weight of loads submerged in the fluid which corresponds to the actual weight of the stem, provided the stem and the loads are of the same material. The calculation of $\sigma_{20,20}$ may then be carried out as by the diver method.

Before the stem is placed on the diver, the latter must be loaded with such a weight that it will come into floating equilibrium when part of the stem is above the surface of the fluid. With some practice this may be estimated by observing how large a part of the glass stem is protruding from the surface of the fluid before the platinum stem is placed on the diver.

The surface tension of water being about 70 dyn/cm, the influence of the surface tension of a fluid of the same surface tension as water on a stem of diameter 0.5 mm may under certain conditions amount to

$$0.05\ \pi \cdot 70 = 11 \text{ dyn } (ca.\ 11 \text{ mg})$$

It is therefore necessary to determine the systematic error of the hydrometer method for every new fluid by comparative measurements with the apparatus according to the diver method and the hydrometer method.

EXPERIMENTAL

The diver method. To determine the specific gravity of the divers used and the random error of the diver method, the load was determined by floating equilibrium in water at 20 ± 0.02°C, ten times with a diver of density about 0.75 and ten times with a diver of density about 0.95.

From the average loads of the two divers their specific gravities are calculated from (4) and (5) and their C-values from (6).

To determine the random error of the diver method the specific gravity of the water examined has been calculated from (8) and (4) as well as the deviations λ of the single measurements from the average (1.000000). These deviations are numerically the same as the deviations from the average one would find when calculating from (8) and (4) as well as the specific gravity of the diver $\varrho_{20,20}$, the increase in specific gravity of the diver $a_{20,20}$ corresponding to the single measurement. From the λ-values it is therefore possible to calculate the random error $\mu_{d,m}$ of the specific gravity of the diver (taken as an average of ten measurements)

$$\mu_{d,m} = \sqrt{\frac{\sum_1^n \lambda^2}{n(n-1)}} \tag{15}$$

in which n is 10.

Further it is possible to calculate the random error μ of a single determination of the specific gravity of the water from the formula

$$\mu = \sqrt{\frac{\sum_1^n \lambda^2}{n\,(n-1)} + \frac{\sum_1^n \lambda^2}{n-1}} = \sqrt{\frac{(n+1)\sum_1^n \lambda^2}{n(n-1)}} \tag{16}$$

in which n = 10

The results of the experiments are given in Tables 1 and 2.

The hydrometer method. To determine the systematic as well as the random error of the hydrometer method the specific gravity of distilled water at 20 ± 0.02°C has been determined according to the hydrometer method with the two divers, the specific gravity of which were determined by ten floating experiments according to the diver method.

Three platinum stems with the diameters 0.5, 0.3 and 0.2 mm were used and ten experiments were carried out with each stem in combination with each diver. The total load on the diver was calculated as the weight in g of the load + the weight in g of the stem + the volume of the protruding stem in cm³. From the total load, the specific gravity of the water is calculated from (8) and (4) disregarding the systematic error of the hydrometer method.

The quantity K defined by the equation

$$K = 1 - \varrho_{20,20} - a_{20,20} \tag{17}$$

0.99937	0.950155	1.000001	+ 1
0.99931	0.950158	0.999998	− 2
0.99948	0.950150	1.000006	+ 6
0.999354	0.950156	1.000000	

$a_{20,20} = 0.049844$; $\varrho_{20,20} = 0.950156$
$C = 20.0010$
$\mu_{d,m} = 1.3 \times 10^{-6}$
$\mu = 4.3 \times 10^{-6}$

is then tabulated and the average K_m of the K-values is calculated.

A corrected value $\varrho_{f,20,20}$ of the specific gravity of the water is determined from the equation

$$\varrho_{f,20,20} = \varrho_{m,20,20} + K_m + a_{20,20} \quad (18)$$

Here $\varrho_{m,20,20}$ is the specific gravity of the diver determined by the diver method as an average of 10 determinations.

The differences λ between the corrected specific gravities of the water and 1.000000 are tabulated.

These differences are numerically the same as the differences one would get by subtracting K_m from the individual K-values and by subtracting the average of the $a_{20,20}$-values from the individual $a_{20,20}$-values.

The random error μ_{K_m} of the quantity K_m, which is approximately the systematic error of the hydrometer method, may therefore be calculated from the formula

Table 3. Hydrometer method, diver No. 8, diameter of stem 0.5 mm, $\varrho_{20,20} = 0.749534$, $C = 19.9994$; weight of stem 0.500 g.

$\mu_{K,\mathrm{m}} = 8.1 \times 10^{-6}$		0.99721	0.999894	11		
$\mu_{\varrho_{f,20,20}} = 27 \times 10^{-6}$						

$$\mu_{K_m} = \sqrt{\mu_{dm}^2 + \frac{\sum_1^n \lambda^2}{n(n-1)}} \tag{19}$$

where n = 10 (and μ_{dm} is the random error of the determination of the specific gravity of the diver by 10 experiments).

Further the random error of a single determination $\mu_{f,20,20}$ of the specific gravity $\varrho_{f,20,20}$ of water determined by the hydrometer method may be expressed by the equation

$$\mu_{\varrho f,20,20} = \sqrt{\mu_{dm}^2 + \mu_{Km}^2 + \frac{\sum_1^n \lambda^2}{n-1}} = \sqrt{2\mu_{dm}^2 + \frac{(n+1)\sum_1^n \lambda^2}{n(n-1)}} \tag{20}$$

where n = 10.

The results of the experiments are given in Tables 3 – 8.

Syntheses of Pyridine-2-^{13}C and Pyridine-3-^{13}C

BØRGE BAK

Københavns Universitets kemiske Laboratorium, Copenhagen, Denmark and

NIELS CLAUSON-KAAS

Centrallaboratoriet, Sadolin & Holmblad A/S, Copenhagen, Denmark

For the exact determination of interatomic distances in pyridine pyridine-2-^{13}C and pyridine-3-^{13}C have been prepared.

For the exact determination of interatomic distances in pyridine mixtures of isotopic pyridines containing pyridine-2-^{13}C and pyridine-3-^{13}C have been prepared by the series of reactions shown in Fig. 1. Potassium cyanide containing about 20 % of potassium cyanide-^{13}C was used as starting material. It is evident from the syntheses that the mixture containing pyridine and pyridine-2-^{13}C also must contain a minor amount af pyridine-2,6-$^{13}C_2$.

The constitution and the purity of the two pyridines follows from the syntheses, the infrared and microwave spectra and measurements of their vapor pressure. A report on the infrared spectra of all ^{13}C-compounds prepared here and on the microwave spectra of the pyridines will be published later.

EXPERIMENTAL

Diethyl malonate-1-^{13}C. Potassium cyanide [35.0 g (0.538 mole) of a product containing 21.6 % of potassium cyanide-^{13}C] and chloroacetic acid (44.0 g, 0.465 mole) were transformed into 52.5 g (0.328 mole, 61 %) of diethyl malonate after the directions of Vogel [1].

1,3-Dibromopropane-1-^{13}C, cf. Ref.[2] Diethyl malonate-1-^{13}C (52.5 g, 0.328 mole) in ether (500 ml) was added to a stirred mixture of lithium aluminium hydride (21.8 g, 0.575 mole) and ether (700 ml) during 20 min. The reaction mixture was heated under reflux (1 h). Acetic anhydride (700 ml) was added and about 1 100 ml of solvent distilled. Acetic anhydride (150 ml) and acetic acid (50 ml) were added to the residue and the mixture kept in an oil-bath of 125° (4 h). After cooling, ether (1 250 ml) was added and the precipitate of salts removed by filtration (G 3) and washed with ether (200 ml). The

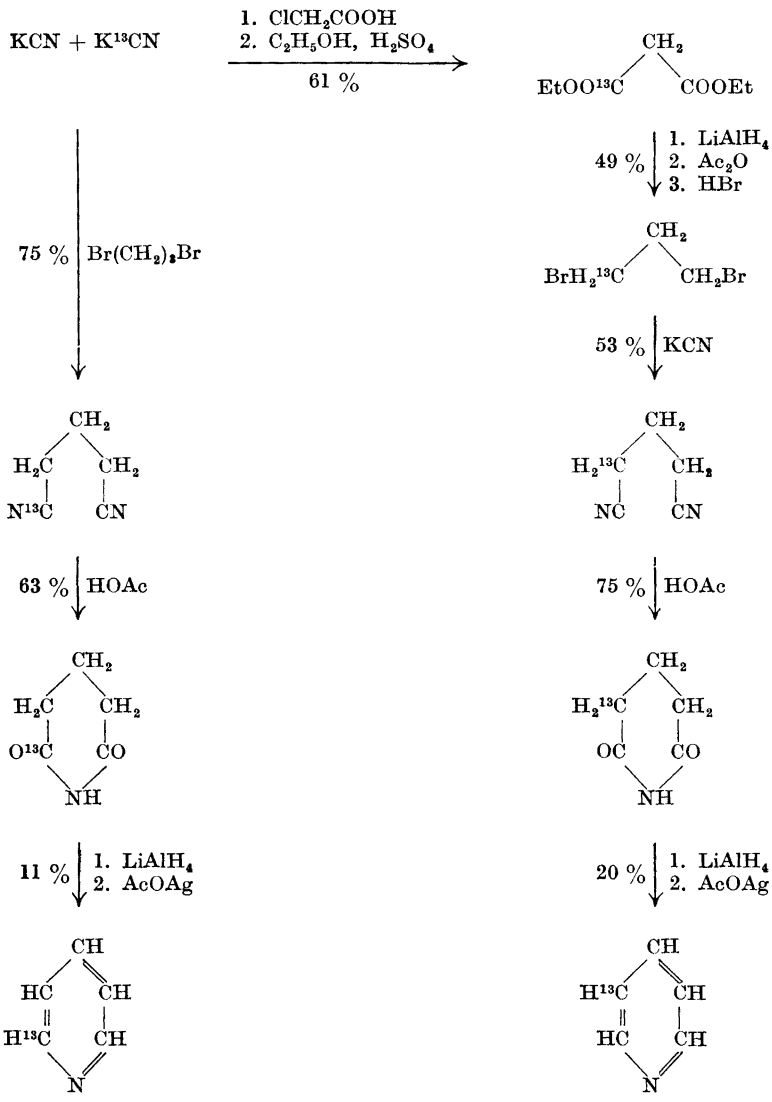

Fig. 1. Routes to pyridine-2-^{13}C and pyridine-3-^{13}C.

solvent was distilled through a small packed column. Ether (100 ml) was added to the semisolid residue and another crop of salts removed by filtration and washed with ether (50 ml). The solution was distilled through the above column, first under atmospheric pressure, then under 15 mm. The fraction boiling at 86—108° (35.0 g) and consisting mainly of 1,3-propanediol diacetate was collected and heated under reflux (7 h) with hydrobromic acid (48 %, 300 ml). About 100 ml of liquid containing dibromopropane was distilled. The dibromopropane layer was separated and washed with the same volume of

water, concentrated hydrochloric acid, water, potassium hydrogen carbonate (20 %) and water. Ether was added and the etheral solution dried with magnesium sulfate and distilled. The yield was 32.3 g (0.160 mole, 49 %) of dibromopropane (b.p.$_{760}$ 164—170°).

Glutaronitrile-2-^{13}C. 1,3-Dibromopropane-1-^{13}C (32.3 g, 0.160 mole) and potassium cyanide (25.0 g, 0.384 mole) were transformed into 8.00 g (0.0849 mole, 53 %) of glutaronitrile following the directions of Vogel [3]. The reaction mixture was heated under reflux for 48 h instead of the recommended 35 h and chloroform was used instead of ethyl acetate for extraction of the inorganic salts. An infrared spectrum of the final product showed it to contain certain impurities, but not less than 95 % of glutaronitrile.

Glutarimide-3-^{13}C cf. Ref.[4] Glutaronitrile-2-^{13}C (8.00 g, 0.0849 mole) was dissolved in glacial acetic acid (65 ml) and the solution heated in a sealed tube (210°, 15 h). The solvent was distilled under 15 mm from a water-bath (85°) and the semisolid residue crystallized from ethanol (30 ml). The crystals were washed with ethanol (10 ml) and dried. The yield was 7.19 g (0.0636 mole, 75 %) of glutarimide.

Pyridine-3-^{13}C. Glutarimide-2-^{13}C (7.19 g, 0.0635 mole) was suspended in dry ether (300 ml). Lithium aluminium hydride (8.4 g, 0.22 mole) was added in one portion and the mixture heated with stirring under reflux (8 h). Water (25 ml), followed by a solution of sodium hydroxide (50 g) in water (275 ml), was added dropwise with stirring. The mixture was distilled, first from a water-bath and then by heating with a free flame until the residue solidified. Water (100 ml) was added to the residue and distilled. Acetic acid (30 ml) was added to the combined distillates consisting of ether, water and piperidine. The mixture was distilled from a water-bath (80°), finally under 15 mm. 6.5 g of an oil consisting mainly of piperidine acetate remained.

The oil was dissolved in water (130 ml) and the solution stirred to a paste with silver acetate (130 g), *cf.* Ref.[5] The paste was heated in a glass-lined autoclave under 100 atmospheres of nitrogen (210°, 18 h). The reaction mixture was washed into a 250 ml flask with water (15 ml). A solution of sodium hydroxide (66 g) in water (60 ml) was added together with a large portion of boiling chips, and the mixture distilled by heating with a free flame. After 100 ml of distillate had been collected, water (40 ml) was added to the distillate and another 40 ml distilled. Concentrated hydrochloric acid (14 ml) was added to the combined distillates and the solution evaporated under 20 mm to dryness from a water-bath (70°). The residue was kept in the bath for 3 min under 0.5 mm. The remaining crystals containing pyridine hydrochloride were dissolved in water (20 ml) and a warm solution of mercury chloride (20 g) in water (100 ml) added, *cf.* Ref.[6] The mixture was left standing (1 h) at 0° and the crystals removed by filtration and dried under 0.1 mm. The dry crystals were cooled in liquid air and sodium hydroxide powder (12 g) added rapidly. The solids were mixed thoroughly by shaking with cooling. The mixture was heated slowly under 0.1 mm in an oil-bath to 220°. At 180—200° pyridine and water was evolved rather suddenly and condensed in a receiver containing pulverized sodium hydroxide (2.0 g). The reaction was complete after 20—30 min. The distillate of aqueous pyridine was dried by successive distillations from sodium hydroxide as described previously [7]. The yield was 1.02 g (0.0129 mole, 20 %). The infrared and microwave spectra and the vapor pressure showed the product to be a mixture of pyridine and pyridine-3-^{13}C.

Glutaronitrile-1-^{13}C. 1,3-Dibromopropane (15.5 g, 0.0772 mole) and potassium cyanide [10.0 g (0.154 mole) of a product containing 21.6 % of potassium cyanide-^{13}C] were transformed into 5.45 g (0.0579 mole, 75 %) of glutaronitrile as described above.

Glutarimide-2-^{13}C. Glutaronitrile-1-^{13}C (5.41 g, 0.0574 mole) was transformed into 3.88 g (0.0343 mole, 63 %) of glutarimide as described above.

Pyridine-2-^{13}C. Glutarimide-2-^{13}C (3.88 g, 0.0343 mole) was transformed into 0.30 g (0.038 mole, 11 %) of pyridine as described above. The infrared and microwave spectra and the vapor pressure showed the product to be a pyridine-mixture containing pyridine and pyridine-2-^{13}C. Pyridine-2,6-$^{13}C_2$, which also must be present in the mixture, was not identified.

A Note on Oscillating Reactions

THOR A. BAK

Universitetets Fysisk-Kemiske Institut, Copenhagen, Denmark

The equations originally set up by Volterra to describe the interaction between two biological species are interpreted as a set of chemical reactions and discussed from a thermodynamic point of view. The equations are solved by the methods of Kryloff and Bogoliuboff, and it is shown that the frequency is lower the farther the system is from the stationary state, decreasing proportional to the square of the average distance from the stationary state.

1. In recent years the possible existence of oscillating chemical reactions and their use in explaining certain biological phenomena have attracted considerable attention [1–5]. Burton [1] discussed it from a biological point of view in connection with "overshoot phenomena", and Christiansen [2] has recently suggested it as an explanation of "spike potentials". Moore [3] has studied a specific model closely related to the one we shall discuss here, where the periodicity is caused by autocatalytic steps. Hearon [4] has considered the possibility of oscillations for several simple reaction mechanisms and concludes that, under certain general conditions, periodicities are not possible for them. Finally Bierman [5] has discussed more complicated mechanisms and shown how autocatalytic steps or reactions at the wall (where the absorption is assumed to be governed by a Langmuir isotherm) can lead to oscillatory behaviour. This paper also contains a discussion of the biological implications of these mechanisms. It must be remarked that in no cases have the differential equations set up by Bierman actually been solved.

By far the simplest example of an oscillating system, however, is that proposed by Volterra [6,7] as a model of interacting biological species. A similar model was discussed by Lotka [8] who gave an interpretation in terms of chemical reactions. Prigogine and Balescu [9] have used the Volterra equations, similarly interpreted, as an example in a discussion of the thermodynamics of irreversible processes.

Although these interpretations in principle are correct, it is exceedingly doubtful whether the Volterra equations represent a set of chemical reactions which actually occur in nature. Even as a model for the study of population dynamics [10] it probably is too simplified. On the other hand it is as realistic

as any other model proposed so far, and therefore, because of its simplicity, the one that should be studied first. The interpretation in terms of chemical reactions is convenient, because it easily leads to an expression for the entropy-production.

It is the purpose of this note to show how the Volterra equations can be solved using the methods of Kryloff and Bogoliuboff. We start by giving the equations and deriving expressions for the relevant thermodynamic quantities.

2. It was assumed by Volterra that the interaction between two biological species, 1 and 2, of which 2 feeds on 1, can be described by the equations

$$\dot{A}_1 = w_1 A_1 - w_2 A_1 A_2$$

$$\dot{A}_2 = w_3 A_1 A_2 - w_4 A_2$$

n which A_1 and A_2 are concentrations and w_i (i = 1, 2, 3, 4) are constants. Below we give and interpretation of these equations in four partial reactions. J_i (i = 1, 2, 3, 4) are the corresponding flows and X_i (i = 1, 2, 3, 4) are the thermodynamic forces defined so that $\sigma = \Sigma X_i J_i$ is the entropy production in units of the gas-constant R per second.

Reaction	Flow	Force
$A_1 \rightarrow 2A_1$	$J_1 = k_1 A_1$	$X_1 = \ln \frac{k_1}{k_{-1} A_1}$
$A_1 + A_2 \rightarrow A_2$	$J_2 = k_2 A_1 A_2$	$X_2 = \ln \frac{k_2 A_1}{k_{-2}}$
$A_1 + A_2 \rightarrow 2A_2$	$J_3 = k_3 A_1 A_2$	$X_3 = \ln \frac{k_3 A_1}{k_{-3} A_2}$
$A_2 \rightarrow M$	$J_4 = k_4 A_2$	$X_4 = \ln \frac{k_4 A_2}{k_{-4}}$

(M is an inert substance)

The four reactions correspond biologically to growth of species 1, species 2 feeding on 1, species 2 propagating the faster the more food there is, species 2 dying.

If the four reactions are considered as chemical reactions it is evident that they do not conserve matter, *i.e.*, other substances, whose concentrations are kept constant, must be involved.

We see that with $k_1 = w_1$, $k_2 + k_3 = w_2$, $k_3 = w_3$, and $k_4 = w_4$ we have $\dot{A}_1 = J_1 - J_2 - J_3$ and $\dot{A}_2 = J_3 - J_4$. We must now eliminate k_{-1}, k_{-2}, k_{-3}, k_{-4} from the expressions for the forces. To do so we observe that the original equations have a stable stationary point $(A_1^s, A_2^s) = (w_4/w_3, w_1/w_2)$. It is known form the investigations of Volterra [6] that the representative point in the A_1, A_2-plane moves in closed curves counter-clockwise around this stationary point. This suggests introducing relative forces $\Delta X_i = X_i - X_i^s$ in which X_i^s is the force at the stationary point.

We find:

$$\Delta X_1 + \Delta X_3 + \Delta X_4 = 0 = \Delta X_1 + \Delta X_2$$

so that

$$\sigma - \sigma^s = \Sigma \Delta X_i J_i = (J_1 - J_2 - J_3)\ \Delta X_1 + (J_3 - J_4)\ (\Delta X_1 + \Delta X_3) = \Sigma j_i x_i$$

with

$$x_1 = \Delta X_1 = \ln \frac{w_4}{w_4 + w_3 a_1} \sim - \frac{w_3}{w_4} a_1$$

$$x_2 = \Delta X_1 + \Delta X_3 = \ln \frac{w_1}{w_1 + w_2 a_2} \sim - \frac{w_2}{w_1} a_2$$

In these equations j_i is the time derivative of A_i (or a_i) and $a_i = A_i - A_i^s$. The approximate values given are valid for $a_i \sim 0$. In terms of the a_i's the original equations read

$$\dot{a}_1 = - \frac{w_2 w_4}{w_3} a_2 - w_2 a_1 a_2$$

$$\dot{a}_2 = \frac{w_1 w_3}{w_2} a_1 + w_3 a_1 a_2$$

and we see that when $a_1 a_2$ can be neglected compared with a_1 or a_2, *i.e.*, when we linearize the equations, the representative point describes an ellipse around the stationary point (0,0) in the a_1, a_2-plane.

We see that near the stationary point $\dot{a}$ and a as well as x and j are connected by matrices with constant coefficients and no diagonal elements. They are, however, not simply antisymmetric matrices as in the simpler case discussed by Prigogine and Balescu [9]. To ensure oscillations the 2×2 matrix must have purely imaginary eigenvalues. The conditions for this is that the determinant is positive and the trace vanishes. These conditions are satisfied.

The system so far described has no tendency to approach the stationary state, and this state is therefore, thermodynamically speaking, not a stable state. If $w_1 A_1$ is replaced by a constant as suggested by Lotka [8] or if terms containing A_1^2 and A_2^2 are included in the equations [6], the representative point in the A_1, A_2-plane will spiral in towards the stationary state. This is seen by linearizing the equations. Arbitrarily close to the stationary state there will, however, exist states with $\sigma - \sigma^s < 0$ and therefore the approach to the statinary state does not minimize σ. Nor does it seems possible to construct a physically meaningful function which is minimized. We have, therefore, here a thermodynamically stable state which seemingly is not governed by a minimum principle related to the principle of minimum entropy production.

Finally we should mention the differential form

$$\Sigma j_i dx_i = w_2 a_2 \mathrm{d}a_1 - w_3 a_1 \mathrm{d}a_2$$

which has been shown by Glansdorff and Prigogine [12] to be always negative. Since the rotation is counter-clockwise this is immediately verified, and the theorem of Glansdorff and Prigogine can be said to fix the sense of rotation as pointed out by Prigogine and Balescu [9]. This differential form will not in general possess an integrating multiplier [13] although in this case, with only two independent variables, it does (*i.e.*, $(\alpha_1\alpha_2)^{-1}$).

3. If one tries to solve the non-linear equations of Volterra by usual iteration-methods starting from the solution of the linearized equation one immediately gets terms which diverge strongly as $t \to \infty$. We must therefore use an iterative procedure where, at each step, the occurrence of such terms is prevented. Such a method has been devised by Kryloff and Bogoliuboff [11], and we refer to their book for details.

It is convenient to introduce new variables y_1 and y_2 by $\alpha_1 = w_2\sqrt{w_4}y_1$ and $\alpha_2 = w_3a\sqrt{w_1}y_2$. We then have

$$\dot{y}_1 = -\nu y_2 - a y_1 y_2$$

$$\dot{y}_1 = \nu y_1 + b y_1 y_2$$

with $\nu = \sqrt{w_1 w_4}$; $a = w_2 w_3 \sqrt{w_1}$; $b = w_2 w_3 \sqrt{w_4}$ or:

$$\ddot{y}_1 + \nu^2 y_1 = b y_1 \dot{y}_1 - a\nu y_1^2 + \frac{a\dot{y}_1^2}{\nu + a y_1}$$

and an analogous equation for y_2.

In the first approximation the representative point in y_1y_2 space now moves on a circle around (0,0). We see that the right-hand side of the last equation contains terms which, when expanded in power series near (0,0), are smaller than the terms on the left-hand side by increasing orders of magnitude. Expanding the fraction on the right-hand side we rewrite the equation as:

$$\ddot{y}_1 + \nu^2 y_1 = \varepsilon(b y_1 \dot{y}_1 - a\nu y_1^2 + \frac{a}{\nu}\dot{y}_1^2) - \varepsilon^2(\frac{a}{\nu})^2 \dot{y}_1^2 y_1 + \ldots$$

$$= -\varepsilon f_1(y_1, \dot{y}_1) - \varepsilon^2 f_2(y_1, \dot{y}_1) - \ldots$$

where the factor ε indicates the smallness of the perturbation. This separation of the right-hand side into terms of increasing order of smallness appears to be necessary for the successful application of the Kryloff-Bogoliuboff method. In the final solution we shall of course put $\varepsilon = 1$.

We want to find a solution of the form $y_1 = z(\tau)$, with $\tau = \omega t + \varphi$, where $z(\tau)$ is a function with period 2π. Substitutiong we get

$$\omega^2 z'' + \nu^2 z = -\varepsilon f_1(z, \omega z') - \varepsilon^2 f_2(z, \omega z') - \ldots$$

and we now assume

$$z = z_0(\tau) + \varepsilon z_1(\tau) + \varepsilon^2 z_2(\tau) + \ldots$$

$$\omega = \omega_0 + \varepsilon\omega_1 + \varepsilon^2\omega_2 + \ldots$$

Using the above assumption and collecting powers of a we have the recursive system:

1. $\omega_0^2 z_0'' + \nu^2 z_0 = 0$

2. $\omega_0^2 z_1'' + \nu^2 z_1 = -f_1(z_0,\ \omega_0 z_0') - 2\omega_0\omega_1 z_0''$

3. $\omega_0^2 z_2'' + \nu^2 z_2 = -f_1'(z_0,\ \omega_0 z_0') - f_2(z_0,\ \omega_0 z_0') - (\omega_1^2 + 2\omega_0\omega_2) z_0'' - 2\omega_0\omega_1 z_1$

etc.

These linear differential equations are solved, and at each step in the iterative procedure we adjust ω so that secular terms do not develop, *i.e.*, we adjust ω so that the Fourier-expansion of the right-hand side does not contain terms with sin ωt or cos ωt. We obtain:

1. $y_1 = r\ \cos(\nu t + \varphi) \quad \nu = \sqrt{w_1 w_4}$
   $y_2 = r\ \sin(\nu t + \varphi)$

2. $y_1 = r\ \cos(\nu t + \varphi) + \frac{a}{3\nu} r^2 \cos 2(\nu t + \varphi) + \frac{b}{6\nu} r^2 \sin 2(\nu t + \varphi)$

   $y_2 = r \sin(\nu t + \varphi) - \frac{b}{3\nu} r^2 \cos 2(\nu t + \varphi) + \frac{a}{6\nu} r^2 \sin 2(\nu t + \varphi)$

   $\omega_1 = 0$, *i. e.*, the frequency is as in the first approximation

3. $\omega_2 = -\frac{r^2}{12}(a^2 + b^2)$, *i. e.*, the frequency is

   $\nu - \frac{r^2}{12}(a^2 + b^2) = \sqrt{w_1 w_4} - \frac{w_2^2 w_3^2 r^2}{12}(w_1 + w_4)$

It is hardly worth while to go on to higher approximations for y_1 and y_2, since the most important result certainly is the expression for the frequency. Experimentally the frequency will be easily accessible even for very fast reactions, and if the chemical reactions leading to the Volterra equations could be realized, it would be easy to check this expression, since at least one rate-constant can be changed at will simply by adding the substance which must serve as "food" for A_1 to conserve matter. It is of course intuitively clear that the frequency will decrease when r increases, since the path length increases towards infinity and at the same time the path approaches the other stationary point (which is unstable). Although the frequency goes down, the actual velocity of the system in its path in a_1, a_2 space increases — in the first approximation proportional to r.

The method we have applied here can be used on most second order non-linear differential equations leading to oscillations and should therefore make it possible to discuss more closely the models for oscillatory behaviour which are found in the literature.

The author is indebted to professor J. A. Christiansen for having drawn his attention to this problem as well as for numerous discussions.

Determination of Magnetic Susceptibilities between 81 and 295°K by Means of a Modified Sucksmith Balance

Studies in Magnetochemistry 24 *

H. SOLING

The Chemical Laboratory B, Technical University of Denmark, Copenhagen, Denmark

A detailed description is given of the construction and use of a Sucksmith ring balance, which is operated according to a compensation principle: The current exiting the electromagnet is regulated until the magnetic force exerted upon the sample exactly compensates the removal of a known weight from the elastic phosphor bronze ring, which constitutes the sensitive part of the balance. By introduction of the compensation principle errors due to changes in the elasticity of the ring have been eliminated. An electromagnetically operated weight manipulator, which may be charged with three ring-formed weights at a time, allows 13 different loads to be applied to the phosphor bronze ring. A set of six interchangeable ring weights cover the scale from less than 1 mg to about 80 mg. A cryostat arrangement is also described. The sample is surrounded by a double walled glass tube, which is immersed in liquid air. When the space between the walls of the glass tube has been suitably evacuated, the sample may be given any temperature between 81 and 295°K by heating the inner wall of the tube electrically. Examples of the reliability of the apparatus during actual measurements both at room temperature and at lower temperatures are given.

Several methods of measuring the magnetic gram susceptibility, χ_g, rest upon the relation

$$K = \chi_g \, m \, H \frac{\delta H}{\delta z} \tag{1}$$

where K is the force exerted upon a sample of mass m, which is suspended in an inhomogeneous magnetic field H with the gradient $\delta H/\delta z$ perpendicular to the magnetic lines of force. Accurate determinations of $\delta H/\delta z$ are rather difficult, measurements of the gram susceptibility are therefore often relative. That is, the magnetic force exerted upon the sample under investigation is

* No. 23 appeared in *Acta Chem. Scand.* **12** (1958) 939.

compared with that exerted upon some standard substance placed in the same position in the magnetic field. The measuring problem is thus essentially reduced to that of measuring the force K.

A very convenient apparatus for measurements of magnetic susceptibilities over a wide range of temperatures is the ring balance originally designed by Sucksmith [1,2] and later modified by Jackson [3], v. Oort [4], and others [5,6]. The essential features of the ring balance are as follows (*cf.* Fig. 1): An elastic ring made of phosphor bronze is clamped at the top, while a quarts capillary carrying the sample is attached to the diametrically opposite point. Two small mirrors facing each other are fixed to the ring. The light from a distant lamp passing a lens is reflected from the mirrors and focused on a vertical scale. When the magnetic field is switched on, the force acting on the sample deforms the ring and so causes a displacement of the light spot upon the scale, which may be calibrated in terms of the force acting on the sample.

When the balance is used in this manner, it needs rather frequent recalibration, probably due to small changes in the elasticity of the ring. This difficulty is circumvented if the ring balance, as mentioned by Cooke and Duffus [5], is used as a pure zero instrument. The current exiting the electromagnet is regulated until the effect of removing a known load from the ring is exactly compensated. By this means all the facilities connected with a compensation method are introduced. In order to obtain the necessary flexibility in the choice of loads to be compensated, a weight manipulator has been constructed. In the following sections the constructional details of the balance and its accessories together with a description of the operating procedure and the calibration are given.

THE APPARATUS

In Fig. 1 the main features of the apparatus are shown. The ring A, which is made from a strip of phosphor bronze 0.1 mm thick and 3 mm wide, is clamped at the top in vertical position. The diameter of the ring is 60 mm.

The perfectly straight quarts capillary B, which carries the sample C is attached to the lowest point of the ring by means of an aluminium clamp D. The external diameter of the capillary is 1 mm.

Two flat spiral springs pasted to the quarts capillary with a drop of shellac at E_1 and E_2 effectively prevent lateral movements of the sample. In a special experiment it was demonstrated that the spirals reduce the lateral movements of a strongly paramagnetic sample to less than 0.1 mm under the influence of the strongest field obtainable with the magnet. In the absence of the spirals the sample suddenly adhered to the pole pieces even when moderate fields were applied. The spirals are cut from a sheet of phosphor bronze of 0.05 mm's thickness.* They only diminish the sensitivity of the balance 1—2 %.

The quadratic mirrors F_1 and F_2 ** of 10 mm edge and 1 mm thickness are made from optically plane glass and coated on the front side with a reflecting layer of aluminium. They are pasted with shellac to small pieces of phosphor

* The author is thanks due to Mr. O. Gram Jeppesen for the design of the spirals.

** The mirrors were obtained from Messrs. I. G. Müller GmbH Wedel, Holsten, who guarantee a planarity of at least 600 m.

bronze and bolted to the ring at the points, where the angular deflection is calculated to be a maximum [1,7].

A mated glass plate illuminated from behind serves as a source of light. A transparent glass plate with an engraved fine cross is pressed against the

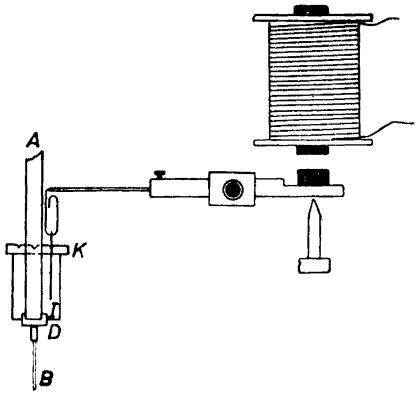

Fig. 2. Side view of a single unit of the weight manipulator.

mated plate. When the light has passed the lens G and has been reflected from the mirrors, the sharp shadow of the cross is easily observed by a low power microscope. The microscope is provided with a cross hair in the ocular. For a given load on the ring the exact position of the reflected light beam is indicated by setting the microscope so that the centers of the shadow cross and the ocular cross coincide. This zero-position is very stable and reproducible. The ring may be loaded and unloaded several times before slight readjustment is necessary.

The elastic ring is extremely sensitive to vibrations, which completely blur out the shadow cross and render the setting of the zero-position impossible. The balance is therefore placed on a large cement block in the basement of the laboratory building, and supported adequately by thickwalled rubber tubes. However, occasional heavy traffic in the building still causes severe blurring. An aluminium damping vane H immersed in Apiezon oil reduces these disturbances to a tolerable level.

The balance is loaded by placing ring formed weights J on the beam K (*cf.* also Fig. 2). Six carefully calibrated ring weights ranging from 4 to 40 mg have been prepared from platinum wires.

The loading an unloading of the balance is performed by means of a weight manipulator, which can be operated electromagnetically from the observers table. For the sake of simplicity the weight manipulator, which can be charged with three ring loads at a time, is not shown on Fig. 1. A single of the three identical units of the manipulator is shown, slightly schematically on Fig. 2. The capital letters on the latter figure have the same meaning as those on the former.

From the six platinum weights available 20 sets of three weights can be selected. Each set may be combined to 13 different loads, *viz.* 7 sums and 6 differences. The differences may be utilized in the following way: A given load is placed on the rider beam and the zero-position is adjusted. The load is then exchanged with another ligther one. The magnetic force necessary to reestablish the zero-position is equal to the difference between the two loads. The 260 possible combinations give 116 different loads, which cover a scale from less than 1 mg to about 80 mg.

The balance is enclosed in a cubic box of plexiglas provided with plane glass windows L. During the measurements the sample is surrounded by a glass tube (not shown) connected to the balance compartment by a spherically ground joint M. The temperature is measured by a calibrated copper-constantan thermocouple placed immediately below the sample. When measurements at lower temperatures are performed, the glass tube is replaced by the cryostat tube described below. The balance compartment may be evacuated through N and refilled with a suitable gas.

The electromagnet is mounted on a turning table provided with three levelling screws by means of which the magnet can be moved vertically. Plane cylindrical pole pieces O of 10 cm diameter ensure a sufficiently large volume, where $H\delta H/\delta z$ may be considered constant. The width of the pole gap is always kept at exactly the same value, 27 mm, by a brass block P inserted between the pole pieces. With an exiting current of about 10 A, a maximum value of $H\delta H/\delta z$ of about 1.2×10^7 Gauss^2/cm is obtained. The electric current is taken from the 220 volts main lines and regulated by a system of rheostats. The current is read on a Siemens & Halske precision ammeter.

OPERATING PROCEDURE

Only finely powdered substances are measured. The powder is packed in the spherical part of the pyrex phial shown in Fig. 3 a. After thoroughly cleansing of the capillary the phial is evacuated and the bulb is sealed off and pasted to a quarts capillary by a minimum of wax (Fig. 3 b and c.). The quarts capillary is then in turn cemented rigidly to the balance system at R (Fig. 1.). The bulbs usually contain 100—200 mg of powder.

It is very essential that all samples are placed accurately in the rather narrow region of the magnetic field where $H\delta H/\delta z$ has a rather flat maximum. That is, where the current necessary to compensate the removal of a given load is a minimum. This position must be found by trial for each particular sample under investigation. During this procedure the vertical position of the sample is controlled by the brass rod Q, which defines the vertical axis of the magnetic field. A brass cylinder (not shown) with a drill, which fits to Q controls the horizontal position of the sample by means of a horizontally

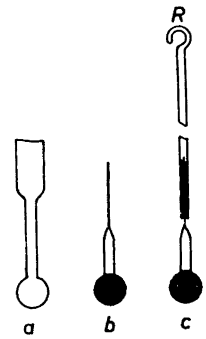

Fig. 3. Preparation of the sample.

b) The filled, evacuated and sealed-off bulb.
c) The bulb pasted to the quarts capillary.

moving fine screw. The presence of this device in the pole gap has no detectable influence upon the field characteristics. Five independent settings of the same sample gave the following compensation currents in amperes: 8.36, 8.37, 8.36, 8.38, 8.37. It has been verified that the position of the maximum of $H\delta H/\delta z$ is independent of the field strength.

The final measurements are carried out in the following manner. A suitable weight is placed on the rider beam, and the zero-position is adjusted. After removal of the weight the magnetic field is switched on and three readings of the compensation current are taken. The zero-position is checked at once. Changes are rarely observed. The mean value of the three readings is taken as the result of a single measurement. This procedure is repeated twice and the mean value of the three mean values constitutes the final result of the measurements at that particular field strength. The spread of the ammeter readings is illustrated by two typical examples from the measuring book.

$Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$	No. VI

$$\chi g \times 10^6 = \frac{23.20}{10.54 \times 0.2093} = 10.52$$

Temperature 19.0°C

METHOD OF CALIBRATION

By a series of measurements on samples of $Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$, Mohr's salt, the relation between the compensation current and $H\delta H/\delta z$ was established. Three different samples from a preparation of Mohr's salt, which has served as a magnetic standard in this laboratory for several years, were measured at as many values of $H\delta H/\delta z$ as were permitted by the possible load combinations. The gram susceptibility of the standard was put equal to $9\,500 \times 10^{-6}/(T+1)$, ($T$ = abs. temperature) [8,9]. $H\delta H/\delta z$ was then calculated from eqn. (1) and plotted against the observed compensation currents. The plot comprehended 80 points, through which a smooth curve could be drawn. The calibration has been checked several times through more than a year, but no change has been observed. These latter measurements then reflect the reproducibility of independent measurements on the same substance. The standard deviation from the calculated value was 0.3 %.

Since the measurements are made on powdered substances, appropriate corrections must be applied for the force exerted upon the glass container. For this purpose eqn. (1) is rewritten

$$K = H\frac{\delta H}{\delta z}(\mathrm{m}\,\chi_g + m^{\mathrm{glass}}\chi_g^{\mathrm{glass}}) \qquad (2)$$

The gram susceptibility of the glass sort used for the bulbs has been determined separately with a Gouy balance to -0.285×10^{-6}. The mass of the bulb is about 0.03 g. The correction for the diamagnetism of the container is thus small. In the two examples mentioned above the corrected values for the gram susceptibilities are 32.45×10^{-6} and 10.56×10^{-6}, respectively.

With the purpose of tracing possible systematic errors either in the calibration of the apparatus or in the measuring method, the susceptibilities of some simple substances were measured. The substances selected for this test represent a rather wide scale of susceptibilities. The results of the measurements are collected in Table 1 together with some relevant results taken from the literature. The value of a comparison of results obtained in different laboratories is severely limited by the difficulty of obtaining materials of high magnetic purity. Nevertheless the general accordance between the susceptibilities found and those qouted from the literature can scarcely be accidental, so it is concluded that systematic errors are scarcely present.

Table 1. Magnetic gram susceptibilities of various substances at 22.0°C.

Substance	$\chi_g \times 10^6$ found	$\chi_g \times 10^6$ literature	
$FeSO_4 \cdot 7H_2O$	41.80	40.70[8]	42.04[10]
$Mn(NH_4)_2(SO_4)_2 \cdot 6H_2O$	37.05	37.11[11]	
$Fe(NH_4)_2(SO_4)_2 \cdot 6H_2O$	32.14	32.09[8]	
$NiSO_4$	26.12	26.27[8]	
$NiSO_4 \cdot 7H_2O$ I	15.35	15.24[12]	
$NiSO_4 \cdot 7H_2O$ II	15.56	15.85[8]	15.53[8]
$Ni(NH_4)_2(SO_4)_2 \cdot 6H_2O$	10.45	10.38[8]	
$CuSO_4 \cdot 5H_2O$	5.89	5.76[13]	5.85[14]

The susceptibilities have been adjusted to 22.0°C by means of the temperature dependence given in the literature.

Concerning the materials used for the test is stated: $NiSO_4$ was prepared by quantitative conversion of a very pure Ni-bis-acetylacetonate into the sulphate. The hydrated sulphates were the finest c.p. chemicals available, which were recrystallized to constant susceptibility. The double sulphates were prepared from the above mentioned recrystallized simple sulphates and $(NH_4)_2SO_4$ c.p. The preparate of Mohr's salt used for the test was thus independent of that used for the calibration.

Each susceptibility listed in Table 1 is the mean value of measurements at several different values of $H\delta H/\delta z$. Field strength dependence of the susceptibility was not traced in any case. In Table 2 are shown two arbitrarily selected examples of the values of χ_g found at different $H\delta H/\delta z$ values. The standard deviation only measures the precision of the physical method.

Table 2. Magnetic gram susceptibilities at different values of $H\delta H/\delta z$.

MEASUREMENTS AT LOW TEMPERATURES

The value of a magnetochemical investigation is considerably enhanced if it is extended over a range of temperatures. In the following section a fairly simple device, which allows measurements at any temperature in the range 81 to 295°K, is described.

The cryostat arrangement shown on Fig. 4 consists of a silvered Dewar vessel A and a cryostat tube B. The latter is connected to the balance com-

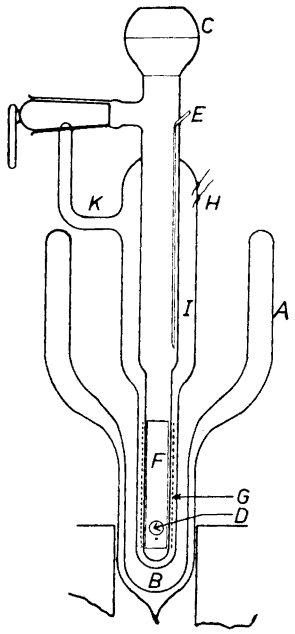

Fig. 4. General view of the cryostat arrangement.

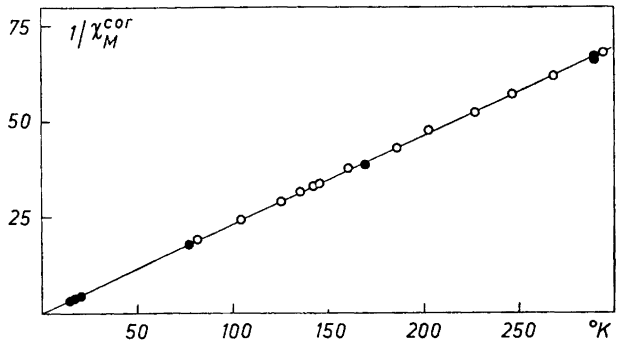

Fig. 5. Reciprocal, corrected molar susceptibility of $Mn(NH_4)_2(SO_4)_2 . 6H_2O$. O Present author. ● Jackson and Kamerlingh Onnes [11]

partment by the spherically ground joint C. The position of the sample inside the inner tube is indicated by a circle D. The point immediately below the circle indicates the position of the measuring junction of the copper-constantan thermocouple. The thermocouple is introduced through the narrow tube E and kept in a fixed position by a sheet of phosphor bronze F. The tube E is sealed with Apiezon wax. A coil G of 0.1 mm Ø constantan wire is wound around the inner tube and connected to a variable transformer by means of the sealed-in wires H. When the space I is evacuated and liquid air is poured into the Dewar vessel, any temperature between 81 and 295°K may be established by application of a suitable heating current in the coil. Only slight regulation of the heating current is necessary to keep the temperature constant within half a degree.

In actual laboratory work two cryostat tubes are used. One, which has been evacuated to a few mm and sealed off at K, covers the temperature scale from 81 to 145°K by application of a maximum heating effect of 1.1 W in the coil. The temperatures from 140 to 295°K are established by means of a second cryostat tube, which must be evacuated to less than 10^{-4} mm the day before use. A permanently evacuated tube like the first one would indeed have been more convenient. The insulated wire of the heating coil, however, cannot be effectively outgassed, so that the necessary high vacuum cannot be maintained for more than a couple of days at a time. The maximum heating effect used in this cryostat tube is 0.8 W.

The thermocouples have been compared *in situ* with a thermocouple, which in turn has been compared with a standard resistance thermometer at 80.5, 195.5 and 293.0°K. The EMF's of the thermocouples are determined by compensation. The detailed EMF/temperature relation for the cryostat thermocouples has been established magnetically by means of the relation

$$(T - \Theta)\ \chi_g = C. \qquad (3)$$

Mohr's salt again served as a reference substance ($\Theta = -1$). The temperatures determined magnetically nicely supplement the above mentioned fix point values to a temperature scale which is considered reliable within at least one degree.

The effectivity of the entire apparatus was finally checked by a series of measurements on $Mn(NH_4)_2(SO_4)_2 \cdot 6H_2O$, which has been investigated magnetically by Jackson and Kamerlingh Onnes [11]. The result of these measurements is shown in Fig. 5, where the reciprocal corrected molar susceptibilities are plotted against the absolute temperature (open circles). For comparison the measurements of Jackson and Kamerlingh Onnes are also shown, appropriately corrected for the diamagnetism (full circles). The accordance is considered very satisfactory.

In conclusion just a few remarks concerning the details of the operating procedure should be given. During all measurements at low temperatures the apparatus is filled with hydrogen. Measurements are taken at both falling and raising temperatures during the same investigation, and the results are carefully inspected for signs of temperature hysteresis. Measurements at a single temperature usually take one hour. In the course of 10 min the temperature in question is etablished. 20 min later the first series of measurements is taken. After another 20 min interval the measurements are repeated. In a special experiment it was found that the sample came to thermal equilibrium with the surroundings within less than 10 min. All later experiences during actual measurements confirm this.

It should be mentioned that even 295°K may be established by means of the cryostats set-up, that is with liquid air in the Dewar vessel and a suitable heating of the coil. Results obtained under these conditions are in wholly accordance with those obtained in a more straightforward manner.

Acknowledgment. The author is very much indebted to the head of the laboratory professor R. W. Asmussen for having suggested this work and for valuable criticism.

The Solubility of Nitrogen, Argon and Ethane in Alcohols and Water

J. CHR. GJALDBÆK and H. NIEMANN

Department of Inorganic Chemistry, The Royal Danish School of Pharmacy, Copenhagen, Denmark

The solubility of nitrogen expressed as the Bunsen absorption coefficient is determined at 25°C in the following solvents: *n*-propanol 0.121, *n*-pentanol 0.102, *c*-hexanol 0.0562 and ethylene glycol 0.0140. For argon the following solubilities were determined at 25°C: *n*-propanol 0.231, *n*-butanol 0.220, *n*-pentanol 0.205 and ethylene glycol 0.0317. For ethane at 25°C: methanol 2.14, ethanol 2.52, *n*-propanol 2.60, *n*-butanol 2.61, *n*-pentanol 2.53, *c*-hexanol 1.75, and ethylene glycol 0.215.

Several of the experiments were also carried out at 35°C. A semi-empirical explanation of the magnitude of the gas solubilities in the solvents is given using solubility parameters and dielectric constants for the solvents and solubility parameters and polarizabilities for the gases. Solubilities of helium, hydrogen, carbon monoxide, and nitrous oxide have been included in the investigation.

The solubilities of non-polar gases in non-polar liquids can be calculated from the equation

$$-\log x_2 = -\log x_2^i + 0.4343\frac{\overline{V}_2}{RT}(\delta_1-\delta_2)^2 + \log\frac{\overline{V}_2}{V_1} + 0.4343\left(1-\frac{\overline{V}_2}{V_1}\right) \qquad (1)$$

In this equation, x_2 denotes the solubility in mole fraction, x_2^i the "ideal" solubility, $\overline{V}_2$ the partial molal volume of the dissolved gas, V_1 the molal volume of the solvent, δ_1 and δ_2 solubility parameters of solvent and gas, respectively, R the gas constant and T absolute temperature. With regard to the derivation of eqn. (1) reference should be made to Hildebrand and Scott [1].

In a recent paper [2] it was shown that eqn. (1) predicts too small solubilities of gases in polar non-associated solvents. It was, moreover, shown that for oxygen, carbon monoxide, nitrogen, and carbon dioxide the ratios between experimental values and values calculated from eqn. (1) are approximately proportional to the dipole moments of the solvents.

The purpose of the present paper is to examine the solubilities in the associated solvents: water and alcohols. In these solvents, all of which have nearly the same dipole moment (μ about 1.8 Debye), the solubilities vary

considerably. The solubilities of nitrogen, argon, and ethane increase in the following order of the solvents: water, ethylene glycol, methanol, ethanol, *n*-propanol, *n*-butanol, *n*-pentanol, see Table 5. The solubility of ethane is about 360 times higher in *n*-pentanol than in water. It will be shown how it is possible to account fairly accurately for the solubilities in methanol, ethanol, *n*-propanol, *n*-butanol, *n*-pentanol, and *c*-hexanol and even obtain a rough estimate for the solubilities in ethylene glycol and water.

MATERIALS AND PROCEDURE

The solubility determinations were carried out by a procedure described in an earlier paper [3].

Nitrogen from "Dansk Ilt- og Brintfabrik" was shown to contain less than 0.13 % oxygen by absorption analysis in an apparatus as described by Christiansen and Wulff [4]. *Argon* and *ethane* were of the same purity as described in a previous paper [5].

Methanol, ethanol, and n-*propanol* were dried by means of magnesium using iodine as a catalyst according to Lund and Bjerrum [6]; these three alcohols were fractionated in a wire gauze column which had about 35 theoretical plates. The fractions used showed the following constants: methanol b. p. 64.60 – 64.63°C and n_D (20°) 1.3285; ethanol b.p. 78.49°C and n_D (20°) 1.3614; *n*-propanol b.p. 97.1 – 97.4°C and n_D (20°) 1.3856. n-*Butanol* was fractionated in the same column and showed a b.p. of 117.75 – 117.83°C and n_D (20°) 1.3995. n-*Pentanol* was fractionated twice in the column at about 115 mm pressure and showed a b.p. of 137.83 – 137.90°C (760 mm) and n_D (20°) 1.412.

c-*Hexanol* was dried by boiling with quicklime and then fractionated in the column at about 115 mm pressure. The bottles containing those fractions which were solid at room temperature were placed upside down in a thermostat; the temperature of the thermostat was slowly increased from 20° to 24°C; slight amounts of liquid impure c-*hexanol*, which were collected in the neck of the bottles, were rejected. By this procedure we obtained samples which were completely solid at 24°C. The melting point reported in the literature [7] is 25.15°C, corresponding to a content of 0.05 % water in our fractions.

Ethylene glycol was fractionated in the column at about 53 mm pressure; the fractions used showed a b.p. of 197.30 – 197.42°C (760 mm) and n_D (20°) 1.4320.

All the boiling points mentioned were determined by distillation of 30 ml liquid in a boiling point apparatus as described by Baggesgaard Rasmussen and Reimers [8]. At least 90 % of each of the samples distilled in the temperature intervals stated. All the temperatures were recalculated to a pressure of 760 mm, but no thermometer corrections were used. The temperature intervals mentioned are a criterion for the purity of the liquids.

EXPERIMENTAL RESULTS

The results of the solubility determinations are given in Tables 1, 2, and 3. The experiments were carried out at 25°C, and in addition some were carried out at 35°C.

It appears from Table 4 that our values for the solubility of ethane in methanol and ethanol are slightly higher than values given by McDaniel [10]. Our value for the solubility of ethane in *c*-hexanol is about three times as high as the value given by Cauquil[11]. Cauquil found that one liter of *c*-hexanol dissolved 711.5 ml ethane at 26°C and 755 mm corresponding to the Bunsen absorption coefficient $\alpha = 0.64$ at 26°C. If we use the same temperature coefficient for the solubility of ethane in *n*-propanol and in *c*-hexanol our value

at 26°C is $\alpha = 1.72$. To prove that our ethane was pure it was analyzed by means of gaschromatography, and the absorption spectrum in infrared was determined, see a previous paper [5]. As a further criterion for the purity of ethane we determined the solubility in water. The result was $\alpha = 0.0416$ at 25°C. Winkler [12] found $\alpha = 0.0410$ and Morrison and Billett [13] $\alpha = 0.0391$. It can be mentioned that Cauquil's value for the solubility of argon in c-hexanol ($\alpha = 0.157$ at 26°C) is somewhat higher than the value given by Lannung [14] ($\alpha = 0.112$ at 25°C).

A survey of the solubilities expressed as mole fractions ($x_2 \times 10^4$) at 25°C is given in Table 5 together with some values from the literature.

CORRELATION WITH THEORY

It will be shown in the following how it is possible to account for the solubilities using solubility parameters, molal volumes, and dielectric constants for the solvents together with solubility parameters and polarizabilities for the gases. The solubility parameters of the solvents are calculated from heats of vaporization, which will now be discussed.

The heat of vaporization (ΔH) for *methanol* equal to 9 034 ± 30 cal/mole at 25°C was calculated from vapour pressure measurements by Young [15]; a 1.8 % deviation from ideality of the methanol vapours was used. The value $\Delta H = 9\,000 \pm 140$ at 25°C was estimated by graphical interpolation using calorimetric measurements between 20° and 110°C by Fioch et al.[16] and Bartoszewiczowna [17]. From values given in *Int. Crit. Tables* (V, p. 138) we interpolated $\Delta H = 8\,930$ at 25°C. The value $\Delta H = 9\,000$ cal/mole will be used in the present paper.

ΔH for *ethanol* equal to 10 170 at 25°C was calculated from vapour pressure measurements given by Merriman [18]. A 0.3 % deviation from ideality of the ethanol vapours was used. From calorimetric measurements by Fioch et al.[16] and Bartoszewiczowna [17] we interpolated $\Delta H = 10\,200$ at 25°C; an identical value was found by interpolation of values given in *Int. Crit. Tables* (V, p. 138). We will use the value 10 170 cal/mole, which presumably is valid within an accuracy of about 2 %.

ΔH for n-*propanol* equal to 11 330 at 25°C was calculated from vapour pressure measurements by Young [15]. Bartoszewiczowna [17] gives the calorimetric value 180 cal/g at 20°C corresponding to about 10 740 cal/mole at 25°C. The vapour pressures of propanol and of the alcohols mentioned below are so small, that the vapours can be regarded as ideal for our purpose. The value 11 300 cal/mole will be used in the following.

ΔH for n-*butanol* equal to 13 050 at 25°C was calculated from vapour pressure measurements by Kahlbaum [19]. Heats of vaporization were also calculated from vapour pressure measurements by Dreisbach and Schrader [20]; extrapolation to 25°C resulted in the value 12 100. Bartoszewiczowna [17] gives the calorimetric value 149.5 cal/g at 20°C corresponding to about 11 000 cal/mole at 25°C. We will use the value 12 100 cal/mole, which is estimated to be reliable within 8 %.

For ΔH for n-*pentanol* we use the estimated value 13 500 cal/mole at 25°C. This estimate is based on the approximate linear dependence between heats of vaporization of methanol, ethanol, *n*-propanol, and *n*-butanol and the molecular weights of these alcohols. From vapour pressure measurements given in *Int. Crit. Tables* (III, p. 220) we calculated the value 12 200; this result is considered to be rather erroneous due to the low and inaccurate vapour pressure data.

McKinley-McKee and Moelwyn-Hughes [21] have given the formula

$$\Delta H \text{ (cal/mole)} = 24\,357 - 12.48 \cdot RT$$

which is a result of vapour pressure measurements for *ethylene glycol* between 86° and 198°C. If we use this formula at 25°C we get about 17 000 cal/mole.

From vapour pressure data of cyclo*hexanol* given by Nitta [22] we have calculated $\Delta H = 14\,900$ between 28° and 37°C and $\Delta H = 14\,400$ between 40° and 60°C; from these values we get $\Delta H = 15\,000$ cal/mole at 25°C. The vapour pressures vary from only 0.906 mm at 27.9°C to 9.202 mm at 60.0°C, and therefore the calculated value of the heat of vaporization is regarded as being rather inaccurate.

ΔH for *water* equal to 2 436 joule/g at 25°C (*Int. Crit. Tables* V, p. 138) corresponds to $\Delta H = 10\,490$ cal/mole.

The solubility parameters of the solvents are calculated from

$$\delta_1 = \sqrt{\frac{\Delta H - RT}{V_1}} \tag{2}$$

where ΔH is the heat of vaporization. The results of the calculations at 25°C are given in Table 5 together with values for the molal volumes (V_1) and the dielectric constants (ε) of the solvents.

Table 6. Values of ideal solubilities, solubility parameters, molal volumes and polarizabilities for nitrogen, argon, and ethane at 25°C.

	N_2	A	C_2H_6
$x_2^i \times 10^4$	16.0	21.6	242
δ_2	5.2	5.43	7.55
$\overline{V}_2$	53	46	88
$\alpha \times 10^{25}$	17.6	16.4	44.7

If we calculate the solubilities of the gases in the alcohols, using eqns. (1) and (2) together with the constants x_2^i, δ_2 and $\overline{V}_2$ from Table 6, we get values which are too low. If we use

$$-\log x_2 = -\log x_2^i + 0.4343 \frac{\overline{V}_2}{RT}(\delta_1^* - \delta_2)^2 + \log \frac{\overline{V}_2}{V_1} + 0.4343\left(1 - \frac{\overline{V}_2}{V_1}\right) \quad (3)$$

where

$$\delta_1^* = \delta_1 - (\varepsilon - 1)\,(0.165 - 0.00143\,\alpha \times 10^{25}) \quad (4)$$

we can account for the experiments with an accuracy which appears from Table 8. The values of

$$\Delta = (-\log x_2)_{\text{calc.}} - (-\log x_2)_{\text{exp.}} = \log \frac{x_{2(\text{exp.})}}{x_{2(\text{calc.})}}$$

are given in Table 8. The antilogarithm of Δ shows how many times the experimental value of the mole fraction is greater than the calculated value.

We have evaluated eqn. (4) in the following manner. By means of eqn. (1) and the experimental values for the solubilities of argon we calculated values δ'_1 for each alcohol and for water. It is shown in Fig. 1 that there is an approximate linear dependence between the difference $\delta_1 - \delta'_1$ and the

Ethanol	0.07	0.00	−0.07
n-Propanol	−0.02	−0.04	−0.09
n-Butanol	−0.08	−0.08	−0.11
n-Pentanol	−0.07	−0.06	−0.07
c-Hexanol	−0.07	−0.11	0.00
Ethylene glycol	0.14	−0.01	0.52
Water	−0.35	−0.51	0.35

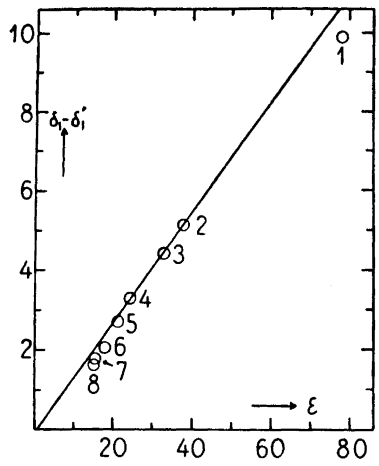

Fig. 1. ($\delta_1-\delta_1'$)-values for *argon* in water (1), ethylene glycol (2), methanol (3), ethanol (4), *n*-propanol (5), *n*-butanol (6), *n*-pentanol (7), and *cyclo*hexanol (8). ε is the dielectric constant of the solvent.

dielectric constant ε. The straight line is drawn through the abscissa value ε—1. The same linear dependence was found for nitrogen, ethane, helium, hydrogen, carbon monoxide, and nitrous oxide. The slopes of the lines are given in Table 7 together with polarizabilities of the gases ($\alpha \times 10^{25}$). The approximate linear dependence between the slopes (S) of these lines and the polarizabilities of the gases is shown in Fig. 2. By means of the slope of the straight line in Fig. 2 (0.00143) and the intersection on the ordinate axis (0.165) we get eqn. (4).

It appears from Table 8, that the calculations of the solubilities of the three gases in water and of ethane in ethylene glycol are very inaccurate. The largest deviation is found for the solubility of argon in water for which the calculated and experimental values are $x_2 = 0.82 \times 10^{-4}$ and 0.25×10^{-4}, respectively. It should be emphasized that the differences Δ in Table 8 are very sensitive to small variations in the δ_1 values. If we use $\delta_1 = 10.64$ for *n*-butanol instead of $\delta_1 = 10.2$ we get $\Delta = 0.04$, $\Delta = 0.03$ and $\Delta = 0.01$

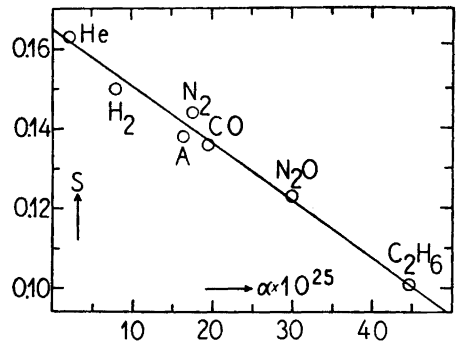

Fig. 2. S (see the text) for different gases. $\alpha \times 10^{25}$ is the polarizability of the gas.

for nitrogen, argon, and ethane, respectively. $\delta_1 = 10.64$ corresponds to the heat of vaporization 13 050 cal/mole (see p. 1020).

Acknowledgements. We wish to express our gratitude to Professor Carl Faurholt, director of the laboratory, for his kind interest in the investigations. Our thanks are also due to lecturer Georg Kilde for many valuable discussions. The financial support from *Statens almindelige Videnskabsfond* is gratefully acknowledged.

Capillary Height in Inclined Tubes

H. HØJGAARD JENSEN

Physics department, Technical University, Copenhagen, Denmark

The surface form and the length of the liquid column in a cylindrical capillary tube inclined against the vertical direction are studied by a method of successive approximations. The results are obtained as expansions in powers of $\lambda = \varrho G a^2/2C$, where a is the radius of the tube, G the acceleration of gravity, ϱ the density and C the surface tension of the liquid. The length of the liquid column is given to third order in λ.

Expressions for the form and height of the surface of a liquid in a vertical, cylindrical capillary tube are known from the literature [1]. They are, *e.g.*, used in precision measurements of surface tension by the method of capillary rise.

Recently Koefoed and Villadsen [2] have improved this method by using capillary tubes which are not vertical. For this reason we have found it worthwhile to derive expressions analogous to those in Ref.[1], but valid also for tubes inclined against the vertical direction.

We have only treated the case in which the angle of contact between the liquid and the tube is 180°, this being the most important from the metrological point of view.

This note describes the principles and results of the calculations. The detailed and somewhat lengthy derivations are largely omitted, since they do not present any novel features.

NOMENCLATURE AND METHOD

We consider a free surface in a capillary tube, the radius of which is a. We want to treat both cases shown in Fig. 1 in one calculation. We therefore introduce a cylindrical system of coordinates (r, φ, z) according to the following rules (*cf.* Fig. 1):

The origin is at the level of the undisturbed surface of the liquid outside the tube. The z-axis is the axis of the tube, oriented *from liquid to gas*. The angle from the z-axis to the upward vertical is denoted by α.

The height and form of the surface will adjust itself in such a way that the free energy F of the system is a minimum. The variable part of F has

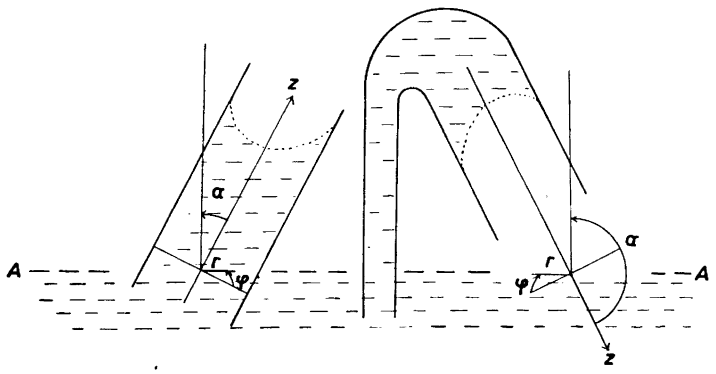

Fig. 1. Cylindrical coordinate systems used for surfaces turned upward and downward, respectively. A—A is the level of the undisturbed surface.

three components, the gravitational energy F_G, the energy of the free surface in the tube F_S, and the energy due to the interface between the liquid and the wall of the tube, F_T. Let $z = z(r, \varphi)$ be the equation of the surface. The three contributions to F can then be written in the following forms valid for all values of α. (The arbitrary additive constants are chosen so as to give simple expressions):

$$F_G = \varrho G \int_0^{2\pi} d\varphi \int_0^a r dr (\tfrac{1}{2} z^2 \cos \alpha - zr \cos \varphi \sin \alpha) \tag{1}$$

$$F_S = C \cdot S = C \int_0^{2\pi} d\varphi \int_0^a r dr \sqrt{1 + (z'_r)^2 + (z'_\varphi)^2/r^2} \tag{2}$$

$$F_T = -C \int_0^{2\pi} d\varphi \cdot a z(a, \varphi) \tag{3}$$

Here G is the acceleration of gravity, C the surface tension and ϱ the density of the liquid. (Strictly speaking ϱ should be the difference between the densities of the liquid and the medium outside the surface.) S is the area of the free surface in the tube. z'_r and z'_φ mean $\partial z/\partial n$ and $\partial z/\partial \varphi$, respectively. The integral in (3) is the area of the interface between liquid and tube.

The function $z(r,\varphi)$ is now a solution of the variational equation

$$\delta F \overset{def}{=} \delta(F_G + F_S + F_T) = 0 \tag{4}$$

where $z(r,\varphi)$ is to be varied subject to the boundary condition that the angle of contact shall be constant and equal to 180°, *i.e.* z'_r must go to plus infinity when r goes to a. Furthermore we assume that $z(r,\varphi)$ is at least twice differentiable.

By varying the height, but not the form, of the surface, *i.e.* by letting $\delta z = \text{const.}$, we are able to derive one exact equation from eqn. (4). In this case only F_G and F_T contribute to δF, and we get

$$\frac{1}{\pi a^2}\int_0^{2\pi} d\varphi \int_0^a r\, dr \cdot z \overset{def}{=\!=} \bar{z} = \frac{h}{\cos\, \alpha} \tag{5}$$

where $\bar{z}$ is written for the mean value of z over the surface, and where

$$h \overset{def}{=\!=} \frac{2C}{\varrho G a} \tag{6}$$

is the expression valid for the capillary height in a very narrow, vertical tube. Eqn. (5) may also be derived from an elementary consideration of the equilibrium between the forces from the walls of the tube and those due to gravity.

It is not possible to give the solution to eqn. (4) in closed form by means of tabulated functions. We therefore try to solve it by successive approximations, $z(r, \varphi)$ being written as an expansion in a suitable dimensionless perturbation parameter. As such we shall choose

$$\lambda \overset{def}{=\!=} \frac{a}{h} = \frac{\varrho G a^2}{2C} \tag{7}$$

When λ is very small the surface will be a hemisphere of radius a. It has the parametric representation (with Θ as a parameter defined by eqn. (8)):

$$r = a\, \sin\Theta \tag{8}$$

$$z = A - a\, \cos\Theta \tag{9}$$

The single adjustable constant A is most easily found by inserting eqns. (8) and (9) in eqn. (5). The result is

$$A = h/\cos\, \alpha + \tfrac{2}{3}\, a \tag{10}$$

This, then, has led to the terms in z/h proportional to λ^0 and λ^1, respectively, *i.e.* to the wellknown first and second order approximations.

In order to improve the result two ways are possible. First, one may choose for $z(r, \varphi)$ a suitable trial function with a number of adjustable constants to be determined from eqn. (4). The simplest trial function, which takes into account both the departure from spherical form and from axial symmetry, is an inclined ellipsoid: $z = k_1 - k_2 \cos\varphi + k_3 \cos\varphi \sin\Theta$, where Θ is still defined by eqn. (8). The use of this function leads to a result which is sufficiently accurate for many purposes. The other method is a consistent perturbation calculation. We put

$$\frac{z}{h} = \frac{1}{\cos\alpha} + \lambda(\tfrac{2}{3} - \cos\Theta) + \lambda^2 f_1(\Theta,\varphi) + \lambda^3 f_2(\Theta,\varphi) + \cdots \tag{11}$$

and by means of eqn. (4), where F is also expanded in powers of λ, we derive differential equations for the unknown functions f_1, f_2. The first few of these equations turn out to be exactly soluble. We therefore prefer this way of attack and shall not give the results of the first method mentioned.

THE THIRD AND FOURTH ORDER APPROXIMATIONS

Eqns. (11), (1), (2) and (3) lead to an expansion of F in powers of λ. The first term, which depends on the unknown functions in eqn. (11), is the following:

$$F_4 = \frac{2C^2\lambda^3}{\varrho G} \cdot \int_0^{2\pi} \mathrm{d}\varphi \int_0^{\pi/2} L_1 \, \mathrm{d}\Theta \tag{12}$$

where $L_1 = \sin\Theta \cos\Theta \, [(^4/_3 \cdot \cos\alpha - 2\cos\alpha \cos\Theta - 2\sin\alpha \cos\varphi \sin\Theta) \cdot f_1$

$$+ \tfrac{1}{2} \cos\Theta (f'_{1,\Theta})^2 + \tfrac{1}{2} \frac{\cos\Theta}{\sin^2\Theta} (f'_{1,\varphi})^2] \tag{13}$$

The first step in the perturbation calculus now consists in determining f_1 so that F_4 is a minimum. On varying f_1 (and later f_2) we keep the boundary values $f_1\left(\frac{\pi}{2}, \varphi\right)$ (and $f_2\left(\frac{\pi}{2}, \varphi\right)$)fixed, but on the other hand we require, in agreement with eqn. (5), that $\overline{f_1} = 0$ (and $\overline{f_2} = 0$). This fixes an otherwise arbitrary constant in f_1 (and f_2). The variational problem is of standard form and leads to the Euler-Lagrange differential equation

$$\frac{\partial}{\partial\Theta} \frac{\partial L_1}{\partial f'_{1,\Theta}} + \frac{\partial}{\partial\varphi} \frac{\partial L_1}{\partial f'_{1,\varphi}} = \frac{\partial L_1}{\partial f_1} \tag{14}$$

From the differential equation or directly from the variational problem and the way in which φ appears in L_1, it follows that f_1 must be of the form

$$f_1 (\Theta,\varphi) = g_1 (\Theta) + g_2 (\Theta) \cos \varphi \tag{15}$$

Eqn. (14) thus separates into two equations, one for g_1 and one for g_2.

The differential equation determining g_1 becomes

$$\frac{\mathrm{d}}{\mathrm{d}\Theta}\left(\sin\Theta \cos^2\Theta \frac{\mathrm{d}g_1}{\mathrm{d}\Theta}\right) = \tfrac{4}{3} \cos\alpha \sin\Theta \cos\Theta - 2\cos\alpha \cos^2\Theta \sin\Theta \tag{16}$$

The integration is elementary. The first constant of integration follows from the requirement that $\mathrm{d}g_1/\mathrm{d}\Theta$ must be finite for $\Theta = 0$. The second is determined from the condition $\overline{f_2} = 0$. The result is

$$g_1 = \tfrac{1}{3} \cos \alpha \, (2 \ln (1 + \cos\Theta) - 1) \tag{17}$$

The equation determining g_2 is

$$\frac{\mathrm{d}}{\mathrm{d}\Theta}\left(\sin\Theta \cos^2\Theta \frac{\mathrm{d}g_2}{\mathrm{d}\Theta}\right) = \frac{\cos^2\Theta}{\sin\Theta} g_2 - 2\sin\alpha \sin^2\Theta \cos\Theta \tag{18}$$

The condition that g_2 must be finite at both ends of the interval $0 \leq \Theta \leq \frac{\pi}{2}$ determines both constants in the complete integral to this equation.

We find

$$g_2 = \tfrac{2}{3} \sin\alpha \sin\Theta \left(\frac{\ln (1 + \cos\Theta)}{\cos\Theta} + \frac{1}{1 + \cos\Theta}\right) \tag{19}$$

For $r \to a$, the partial derivative $f'_{1,r}$ must not go so rapidly to negative infinity that the boundary condition for the complete function $z(r, \varphi)$ can not be fulfilled. This puts a limit on the magnitude of λ, but it is found from eqns. (15), (17) and (19) that the condition ($\lambda \lessapprox 1$, dependent on α) is fulfilled for all values of λ which lead to a useful perturbation expansion.

We are now able to carry the perturbation calculus one step further. The known function f_1 is introduced into the free energy and the first term in the expansion which depends on f_2 is minimized. This leads to an equation like (14), from which it is seen that f_2 is of the form

$$f_2(\Theta,\varphi) = G_1(\Theta) + G_2(\Theta)\cos\varphi + G_3(\Theta)\cos 2\varphi \qquad (20)$$

We have only determined $G_1(\Theta)$. The reason is that G_2 and G_3 vanish (like Θ and Θ^2, respectively) for $\Theta \to 0$; their contributions to the height of the meniscus will therefore be of higher order in λ than the contribution form G_1.

G_1 is found in the same way as g_1. We omit the details in the calculations. The result is

$$G_1(\Theta) = \tfrac{2}{3}\cos^2\alpha\left[\frac{\ln(1+u)}{u} - 2\ln(1+u) + u\right]$$
$$+ \tfrac{1}{9}\sin^2\alpha\left[(\ln(1+u))^2\left(\frac{1}{u}+\frac{1}{u^3}\right) + 2\ln(1+u)\left(\frac{5}{u}-\frac{1}{u^2}\right) + \frac{4}{1+u} + \frac{1}{u} - 3u\right]$$
$$- \tfrac{8}{3}\ln 2 + \tfrac{14}{9} - \tfrac{2}{3}\sin^2\alpha, \qquad (21)$$

where, for brevity, $\cos\Theta$ has been denoted by u.

THE CAPILLARY HEIGHT

From eqn. (11) we now find the parameters of that point of the surface where the tangential plane is perpendicular to the axis of the tube ($z'_\Theta = 0$). The value of z/h for this point is denoted by z_m/h and is found on inserting the said parameters in eqn. (11). z_m/h is written as an expansion in λ:

$$\frac{z_m}{h} = \frac{1}{\cos\alpha} - \tfrac{1}{3}\lambda + \tfrac{1}{3}\cos\alpha\,[2\ln 2 - 1]\cdot\lambda^2 - [\cos^2\alpha(\tfrac{10}{3}\ln 2 - \tfrac{20}{9}) + \sin^2\alpha(2\ln 2 - \tfrac{5}{6})]\cdot\lambda^3 + \cdots$$
$$= \frac{1}{\cos\alpha} - \tfrac{1}{3}\lambda + 0.129\cos\alpha\cdot\lambda^2 - [0.088\cos^2\alpha + 0.553\sin^2\alpha]\cdot\lambda^{3'}_{,} + \ldots \qquad (22)$$

For $\alpha = 0$ the first three terms in this expansion have been found by Poisson and Volkmann [1]. On considering the way in which the acceleration of gravity enters into h and λ, one sees that the first three terms in (22) are obtained from Poissons expression on replacing G by $G\cos\alpha$, *i.e.* by the component of the acceleration of gravity along the negative z-axis. However, it is also seen that the term in (22) proportional to λ^3 is affected by the asymmetry of the surface and consequently it depends also on the component of G perpendicular to the axis of the tube.

The results obtained are valid for both positive and negative values of $\cos\alpha$. However, it must be remembered that the z-axis is oriented downwards

for cosα negative (hanging surface). In the method of Koefoed and Villadsen [2], the distance is measured between two surfaces in tubes of different radii (a_1 and a_2) and with different values of α ($\alpha_1 = \alpha$; $\alpha_2 = \pi + \alpha$). This distance l will be

$$l = z_1 - |z_2| = z_1 + z_2$$
$$= \frac{h_1 - h_2}{\cos\alpha} - \tfrac{1}{3}(a_1 + a_2) + 0.129 \cos\alpha \left(\frac{a_1^2}{h_1} - \frac{a_2^2}{h_2}\right) -$$
$$- (0.088 \cos^2\alpha + 0.553 \sin^2\alpha)\left(\frac{a_1^3}{h_1^2} + \frac{a_2^3}{h_2^2}\right) + \ldots \qquad (23)$$

where $h_1 = 2C/\varrho G a_1$, and $h_2 = 2C/\varrho G a_2$.

For the purpose of measuring surface tension, the formula (23) is most easily utilized when inverted so as to give $2C/\varrho G$ as an expansion in powers of, *e.g.*, a_2/l.

We conclude with a few words about the practical convergence of the expansion found. The last term in eqn. (22) becomes equal to 0.1 % of the first term at a value of λ approximately equal to 1/5, but somewhat dependent on α. For water this corresponds to a tube diameter of $2a \approx 3.5$ mm. When $\sin^2\alpha$ is small, an accuracy of about 0.1 % may be expected even for values of λ as large as 1/3 ($2a \approx 4.5$ mm for water). However, for larger values of $\sin^2\alpha$ this is presumably not the case, because the fourth term in eqn. (22) becomes larger than the third term, a fact that points to a slow convergence of the expansion.

Determination of the Solidus Curve by a Tracer Technique. The System $CaCl_2$—NaCl

A. SELTVEIT and H. FLOOD

Royal Norwegian Council for Scientific and Industrial Research, Institute of Silicate Science, Norwegian Institute of Technology, Trondheim, Norway

Based on a modification of the high-temperature filtration previously described [1], a new technique for the determination of the solidus curve of a phase diagram is described. A small amount is added of a third, radioactive component which is soluble in the liquid, but insoluble in the solid phase in question.

The method is applied to the system calcium chloride — sodium chloride. The data of the composition of the solid phase are in favour of the existence of an incongruently melting compound Na_4CaCl_6. The solubility of calcium chloride in solid sodium chloride reaches a maximum of 15 mole percent. A discussion of the data indicates the occurrence of $CaCl_4^{--}$ ions in the liquid phase.

METHOD

In phase diagrams involving solid solutions, the extent of this solid solution, described by the solidus line, is often difficult to establish. This is particularly true for high-temperature systems. Thermal analysis will in general give only very approximate results for the solidus curve. Quenching techniques, with microscopic and/or X-ray examination of the quenched sample, have given a considerable amount of information, particularly in silicate systems where the phase transformations appear sufficiently slowly for the quenching to be effective. High-temperature X-ray techniques have also been used, but this method is rather elaborate and, notably at higher temperatures, difficult.

A knowledge of the solidus curve, however, is of decisive importance for a discussion of the thermodynamic and structural properties of the liquid (as well as the solid) solution, based on the phase diagram. Such discussion has yielded information of considerable interest for a number of systems, but so far the work has been limited to the consideration of systems without solid solution, since the solidus curves for other systems are in general not known with sufficient accuracy. Hence it became desirable to devise a method

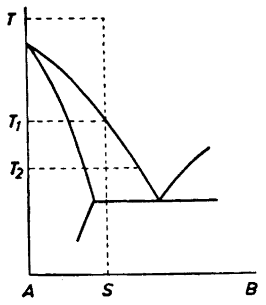

Fig. 1. Binary phase diagram where component A forms solid solutions with component B (schematic).

for reliable determination of the solidus curve in high-temperature systems. Such a method, employing the addition of a radiactive tracer, will be described.

The procedure is in principle as follows. To the components of the system (mixed in known amounts) is added a small amount of a third, radioactive component, which is so chosen that it cannot enter into the solid phase in question. The procedure may be illustrated by considering the binary system A—B (Fig. 1). The components A and B are mixed to give the chosen composition *s*, a small amount of radioactive tracer (order of magnitude 0.05 %) is added, and the mixture is brought to the temperature T where only liquid is present. A sample is withdrawn from this liquid and its radioactivity per gram is determined. (Eventually the composition of the melt may also be checked by chemical analysis of the same sample.) Next, the system is cooled. The system is then brought to equilibrium at the temperature T_2 (which for practical reasons must be so chosen that the ratio of liquid to solid phases is roughly within the limits 1.5 and 0.5). At this temperature, another sample is withdrawn from the liquid phase, and its radioactivity is determined. The radioactivity per gram of this second sample must necessarily be higher than that of the first, since the total amounts of liquid phase in the system has diminished while all of the radioactive tracer is present in that phase only. The ratio between these two specific activities gives directly the fraction of the total system present in the liquid state at temperature T_2.

The composition of the second sample, *i.e.* the liquid phase, is determined by chemical analysis. This analysis may be checked against the liquidus curve obtained from thermal analysis, or otherwise, one might rely upon the thermal analysis and omit the chemical analyses altogether.

Now, the gross composition is known from the outset, the relative amounts of liquid and solid has been determined from measurements of the radioactivity, and the composition of the liquid is known. By combination of this information, the composition of the solid phase may easily be calculated.

ON THE SYSTEM SODIUM CHLORIDE — CALCIUM CHLORIDE

As the first system to be investigated by the method outlined above was chosen the system sodium chloride — calcium chloride. At least five earlier investigations of this system are to be found in the literature. Lamplough [2] concluded from his work in 1911 that probably neither solid solution nor any compound between the components exist in this system. Menge [3] on the other hand, found in the same year a compound to which he attributes the formula $4\,NaCl \cdot CaCl_2$, and he also found that solid solutions are formed on the sodium chloride side. He indicates a maximum solid solubility of about 10 weight-%. His conclusions are based on thermal analysis in combination with microscopy.

In 1920, Scholich [4] re-investigated the system, and concluded that neither solid solution nor any compound is present. According to this author, Menge's results may probably be explained by assuming the presence of hydrated calcium chloride in his samples.

The presence of solid solutions is again maintained by Sato and Amano in 1935 [5] who find a maximum solid solubility of 4 to 5 % calcium chloride in sodium chloride, but no compound formation. These results are again supported by Miyake and Suzuki in 1954 [6] on basis of their X-ray investigations which were, however, carried out on slowly cooled samples.

EXPERIMENTAL

In the tracer method, the first question concerns the choice of a suitable tracer. In the case at hand, some radioactive ion which cannot enter into the solid sodium chloride lattice had to be used. As such, cobalt (^{60}Co) was used, and later on cesium (^{134}Cs), both in the form of the chlorides. Cobalt ion has about 18 % lower ionic radius than sodium ion, in addition to its double charge, and there are also reasons to believe that Co will be present in the NaCl-melt as $CoCl_4^{-2}$ complexes. Cesium ion has an ionic radius about 65 % higher than that of sodium ion. The fact that points obtained with the two different tracers agree may be taken as an indication that neither of them have entered the solid phase to any measurable extent.

Sodium chloride and calcium chloride (both *fusum pro analysi* from E. Merck A.G., Darmstadt) were weighed into a platinum crucible to a total of about 40 g for each run, with about 20 mg of radioactive cobalt chloride or cesium chloride added.

The furnace is shown in Fig. 2. It consists essentially of a Pythagoras tube wound with Kanthal resistance wire, the windings being closer spaced towards the ends to compensate for the extra heat loss at the ends. The furnace shell was water-cooled to do away with the influence of changes in ambient temperature. The temperature was controlled by a Kent Multelec potentiometric controller in connection with a platinum-platinumrhodium thermocouple located closely outside the heater windings. The temperature in the melt was followed with another thermocouple with the bare wires of the hot junction dipping directly into the melt. This thermocouple was connected to a Tinsley thermoelectric-free potentiometer in combination with a recording galvanometer (Multiflex galvanometer with Nachlaufschreiber from Dr. B. Lange, Berlin). This equipment will record, *e. g.*, a coolingcurve with an accuracy of about 0.07° per mm. The thermocouple was checked against the melting points of pure sodium chloride (800.6°) and sodium sulphate (885.0°). The furnace was equipped with a rotating stirrer which was lowered into the crucible after the salts had melted, to insure thorough mixing as well as even temperature. The stirrer shaft and thermocouple were running through packing glands in the top lid. A third packing gland was provided for the sample takers, an open scoop for sampling the homogeneous liquid and a platinum filter for sampling the heterogeneous system.

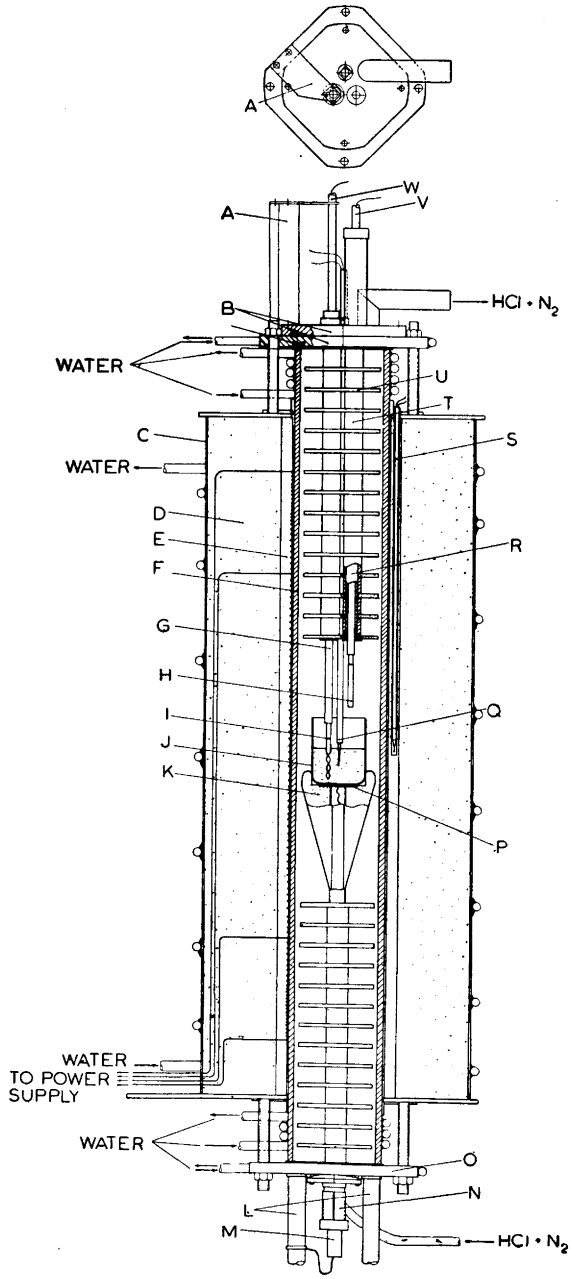

Fig. 2. High-temperature filtration furnace.

H = filtration tube
I = Pt stirrer on ceramic shaft
J = crucible with the equilibrium mixture
K = supporter
Q = thermocouple
U = radiation shields

The cobalt and calcium chlorides were protected from hydrolysis and oxidation by using an atmosphere of nitrogen plus hydrogen chloride in the furnace. In order to withstand this atmosphere, the top and bottom lids were made of pure nickel, with rubber gaskets.

A typical run was as follows. The platinum crucible with contents was placed in the furnace, which was then closed and a slow stream of the protective gas mixture was conducted through the furnace while it was heated. When a temperature was reached at which all of the charge would be molten, the stirrer and thermocouple was lowered into the melt. After 10—15 min of stirring, a sample (varying from about 0.2 to 0.5 g) was taken from the homogeneous melt, and the sample taker removed from the furnace and replaced by the platinum filter tube (see below). The furnace was then allowed to cool at a rate of about 1° per min, while the temperature of the melt was followed by the recording galvanometer described above.

After the break had been recorded (corresponding to temperature T_1 of Fig. 1) the cooling was continued to the chosen temperature (T_2), and the melt was held constant at this temperature sufficiently long for the equilibrium to be established. Experiments showed that 2 h was sufficient, but for practical reasons the constant temperature was usually held overnight. (Some particular run in which equilibrium was difficult to establish will be discussed under "Results".)

After equilibrium was supposedly established, the platinum filter assembly was lowered into the crucible. This consisted essentially of a platinum tube about 40 mm long, closed at the lower end by a platinum bottom with fine needle holes. The platinum tube was joined moderately gas-tight to a fused-quartz tube running through the packing gland at the top of the furnace. An electrical lead to the crucible and another to the filter, in combination with a low-voltage source and a pilot light, showed when the filter was in contact with the melt. The filter was then lowered some 5 mm more, and a sample sucked into the filter by application of a syringe at the top of the quartz tube. The filter assembly was then removed and replaced by a sample taker.

The temperature was then raised again until all of the charge had melted, stirred for a while, and another sample taken from this homogeneous liquid. This last sample served to check the total radioactivity present, *i. e.*, that nothing had disappeared from the crucible except for the samples.

Analysis for composition and radioactivity.

Each of the samples was dissolved in water and diluted to a known volume. In one part of the solution, the calcium content was determined by titration with ethylenediamine-tetraacetic acid, disodium salt ("Titriplex III", E. Merck A. G., Darmstadt) with "Eriochrome black T" as indicator. The sodium chloride content was determined as difference.

In another part of the solution, the radioactivity was measured with a scintillation counter for liquids (Scintillation Counter for Ultrasensitive Measurements, Type N 550, in connection with a Decatron Scaler N 530 A, both from E. K. Cole, Ltd., London). Only the ratios between the radioactivities (per gram) of the three different samples from the same run were of interest.

RESULTS

A part of the experimental data are given in Table 1, and the phase diagram is shown in Fig. 3. The eutectic lies at 500 $\pm$ 2°C and 48 mole percent NaCl. At 600°C the solubility of $CaCl_2$ in solid NaCl is about 15 mole percent (24 weight percent), hence is appreciably higher than estimated by earlier investigators. In the solid $CaCl_2$, on the other hand, no solubility of NaCl was detected.

The observations regarding the composition of the solid phase on the NaCl side of the diagram are not entirely unambiguous, and two different interpretations seem possible:

Table 1. Data of thermal analysis and high temperature filtrations of the system $NaCl-CaCl_2$.

» 4 and 5: Calculated composition of liquid and solid solutions.
» 6: Tracer.

1. As assumed by Menge, there exists a compound of the composition $CaCl_2 \cdot 4$ NaCl, which melts incongruently at 594°C (*cf.* the full lines in the diagram, Fig. 3).

2. No compound exists, but the content of $CaCl_2$ in the solid NaCl increases with decreasing temperature, reaching the maximum value of 20 mole percent at the eutectic temperature (*cf.* the broken line in Fig. 3). In favour of this latter alternative is that we have not yet succeeded in obtaining any X-ray evidence for the existence of a compound. Melts with about 58 mole percent NaCl were slowly cooled, or quenched, in both cases powder patterns showed strong lines of NaCl.

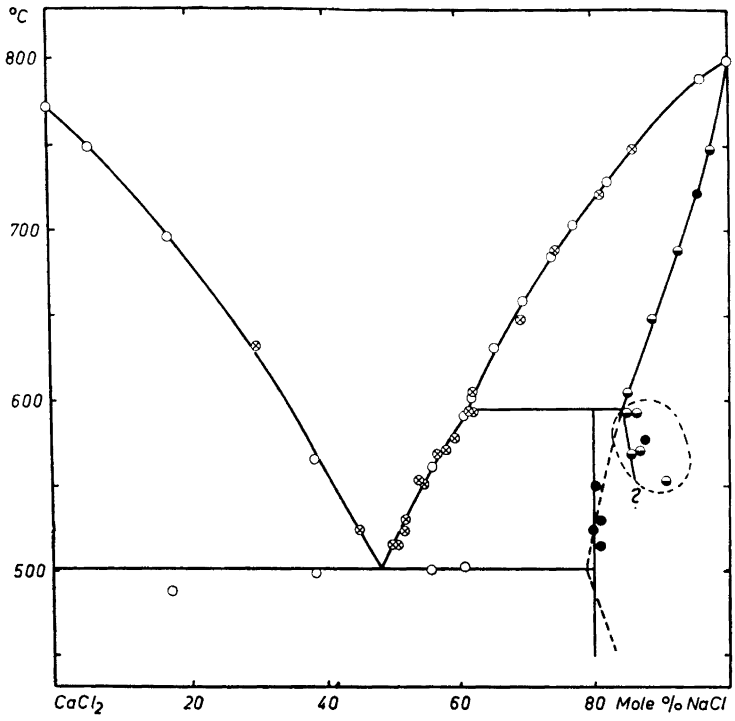

Fig. 3. The system NaCl—$CaCl_2$.

Filled circles: » » » » ^{134}Cs-tracer.

The data in the composition of the solid phase in the temperature range 500 to 550°C are not incompatible with this interpretation, but they fit better with the assumption of a compound $CaCl_2 \cdot 4\ NaCl$. Two other arguments also favour the existence of this compound. First, the liquidus curve has a weak but definite discontinuity at 594°C (as also observed by Menge). The second argument is the group of obviously erratic points for the solid phase composition in the temperature range 550 to 600°C (inside the circled area in the diagram Fig. 3). These points have been obtained using both CsCl and $CoCl_2$ tracers, and they seem to indicate that in this area it is difficult to attain true equilibrium between solid and liquid. This would be difficult to explain if a continuous range of solid solutions exists down to the eutectic temperature. If on the other hand the compound exists below 594°C, the following explanation seems reasonable. Our filtration technique demands that the system is cooled at least some 50° below the temperature of the first crystallization in order to get an appropriate ratio between the amounts of liquid and solid

compositions. In the range 550 to 600°C it is therefore necessary to start with melts containing more than 62 mole % NaCl, resulting in primary cyrstallization above 594°C. When next the melt is cooled below this temperature, a certain amount or $NaCl-CaCl_2$ solid solution will have to react with the liquid to form the compound before equilibrium is established. This reaction may very well be a slow process. Difficulties of this kind should be absent when the compound is the primary product of crystallization, and this is just what is observed. Starting with mixtures with less than 62 mole percent NaCl, the results for the solid phase composition show very little scattering.

If the existence of the compound is accepted, one will have to explain why it does not appear in the X-ray powder patterns. One reason might be that it is unstable at room temperature. It is evident that the solid solubility decreases strongly with decreasing temperature, (compare Sato and Amano [5]), furthermore the weakness of the break in the liquidus line at the peritectic temperature may indicate that the stability of the compound does not greatly exceed that of the undercooled solid solution. The final answer in this case should be given by high-temperature X-ray examination.

Another possibility is that the compound is stable down to room temperature, but has a crystal lattice very similar to that of NaCl. The solid solution in all probability has a NaCl lattice in which part of the Na^+ ions are replaced by Ca^{++} ions and cation vacancies (eventually forming pairs), distributed at random over the cation sites. The compound might have a similar structure, but with 1/5 of the Na^+ ions replaced by 1/10 Ca^{++} ions and 1/10 cation vacancies in an *ordered* distribution over the cation sites. In this case, X-ray examination at elevated temperatures would not be expected to furnish further evidence.

The question cannot be considered to be finally settled. When we have discussed it in some detail here, one reason is that if the compound formation is real (as we believe) the observations indicate a difficulty in the present method of determining the solidus line which may be expected to occur also in other systems.

STRUCTURAL INTERPRETATIONS

Considerable evidence favours the view that molten salt mixtures can in many cases be considered as ideal or regular mixtures of simple ionic components over certain ranges of composition. The study of phase diagrams may give valuable information about the validity of any chosen model for the structure of the melt, compare the alkali chloride — magnesium chloride systems, where the formation of $MgCl_4^{--}$ complex ions in the molten mixtures is strongly indicated [7]. In the following the system $NaCl-CaCl_2$ is examined from similar points of view.

In a system of coexisting solid and liquid phases, the equilibrium condition for the major component can be expressed by the well-known equation

$$\ln a_{(l)} - \ln a_{(s)} = \frac{\Delta H_m}{R}\left(\frac{1}{T} - \frac{1}{T_m}\right)$$

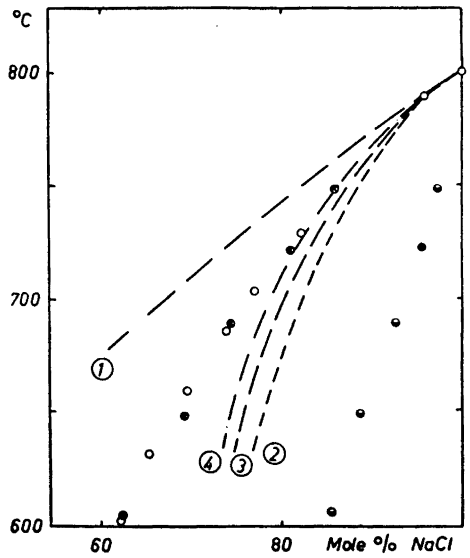

Fig. 4. The NaCl side of the diagram. Experimental data compared with calculated curves.

Here $a_{(l)}$ and $a_{(s)}$ are the activities of the component in the two phases, referring to its pure liquid and its pure solid respectively as standard states, and ΔH_m is the molar heat of melting of the component, considered to be independent of the temperature over the range studied.

a) *The NaCl side.* The molar heat of melting of NaCl is determined calorimetrically by Lyashenko [8] to 6.8 kcal, and by Roth and Berthrand [9] to 7.4 kcal. Careful investigations of the systems NaCl—Na_2SO_4 (Flood, Förland and Leirnes [10]) and NaCl—NaF (Grjotheim [11]), however, are in agreement with 7.1 kcal; this value will be adopted in the following.

We will first examine the possibility that the melt behaves as an ideal Temkin mixture of Na^+, Ca^{++} and C^- lions. This would give

$$a_{NaCl} = N_{Na+} \cdot N_{Cl} = \frac{n_{Na}}{n_{Na} + n_{Ca}} \cdot 1 = \frac{n_{NaCl}}{n_{NaCl} + n_{NaCl_2}} \qquad (1)$$

If, as a first approximation, the correction for the solid solubility is neglected, a calculation according to this model gives curve 1 in Fig. 4. It is evident that the real melt shows strong negative deviations from ideality according to this model, or in other words, the components seem to be more strongly bonded in the melt than corresponding to the ideal Temkin mixture of simple ions.

The second model to be tried is the same as proved valuable in the corresponding magnesium system [6], *viz.*, that tetrachloro complexes are formed in the melt according to the reaction

$$2\ Cl^- + CaCl_2 = CaCl_4^{--}$$

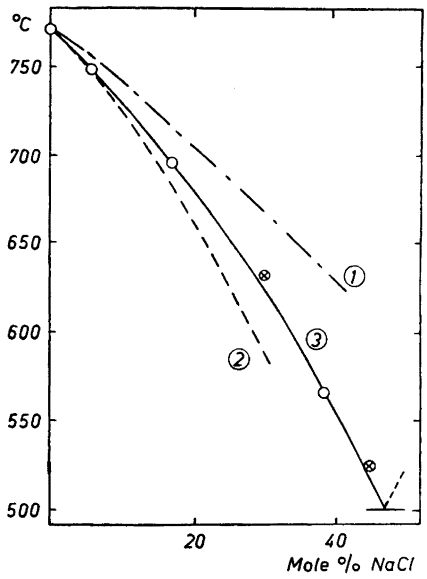

Fig. 5. The $CaCl_2$ side of the diagram. Experimental data compared with calculated curves.

Again assuming ideal Temkin ionic mixture:

$$a_{NaCl} = N_{Na^+} \cdot N_{Cl^-} = \frac{n_{Cl^-}}{n_{Cl^-} + n_{CaCl_4^{--}}} = \frac{n_{NaCl} - 2\, n_{NaCl_2}}{n_{CaCl_2} - n_{CaCl_2}}$$

Neglecting the solid solubility correction, the curve 2 in Fig. 4 is calculated. This curve shows a better agreement with the experimental data, remembering that the correction for the solid solubility will tend to lift the curve and thus bring it closer to the experimental points.

The calculation of the solid solubility correction depends upon the chosen model for the solid solution. Assuming a Temkin ideal solution for the solid (and no complex ions), the calculation gives curve 3 of Fig. 4. The second (more probable) model for the solid is the "equivalent fraction" model, which gives

$$a_{NaCl} = \frac{n_{NaCl}}{n_{NaCl} + 2\, n_{CaCl_2}}$$

The calculation based on this model for the solid and tetrachloro complexes for the liquid is shown as curve 4 in Fig. 4. This curve shows excellent agreement with the observations up to about 20 mole percent $CaCl_2$. The introduction of the "equivalent fraction" is in accordance with present ideas regarding solid solutions, when $CaCl_2$ is introduced in a NaCl lattice it is assumed that two Na^+ ions are exchanged with one Ca^{++} ion and one cation vacancy.

The deviations that occur between calculation and experiment at higher $CaCl_2$ concentrations may be explained either as a negative deviation from ideality in the solid solution or positive deviation in the liquid solution. Since the solid solubility is limited, negative deviations in the solid is improbable. Positive deviations in the liquid, on the other hand, could be explained simply as due to incomplete complex formation at the higher $CaCl_2$ concentrations.

b) *The $CaCl_2$ side.* The curve 1 in Fig. 5 has been calculated on the assumption of a simple Temkin mixture, and shows that this model disagrees with experiment also on the $CaCl_2$ side of the diagram. A formation of tetrachloro complexes could take place according to the following scheme

$$CaCl_2 + 2\ NaCl = CaCl_4^{2-} + 2\ Na^+$$

The corresponding expression for the (ideal) activity of $CaCl_2$ is:

$$a_{CaCl_2} = \left[\frac{n_{Na}}{n_{Ca} + n_{Na}}\right]\left[\frac{n_{Cl}}{n_{Cl} + n_{CaCl_4}}\right]^2 =$$

$$\left[\frac{n_{CaCl_2} - 1/2\, n_{CaCl}}{n_{CaCl_4} + 1/2\, n_{CaCl}}\right]\left[\frac{2\, n_{CaCl_2} - n_{NaCl}}{2\, n_{CaCl_2} - 1/2\, n_{NaCl}}\right]$$

and the result of the calculation is given as curve 2 in Fig. 5. Although this curve is in somewhat better agreement with the experiments than curve 1, the deviations are still considerable at NaCl concentrations above 5 mole percent. It should be noted that this latter model results in a mixture composed of two different anions (Cl^- and $CaCl_4^{2-}$). Theoretical considerations [12] have shown that such mixtures with both mixed cations and mixed anions in general would be expected to show considerably larger deviations from ideality than mixtures with one common ion.

According to the theory, the expression for the activity of $CaCl_2$ should be corrected by an activity coefficient

$$\gamma_{CaCl_2} = \exp\ (N'_{Na} N'_{CaCl_4}\ \Delta G/RT)$$

where the N's are equivalent fractions and ΔG is the free enthalpy change for the reaction

$$CaCl_2 + Na_2(CaCl_4) \rightleftharpoons Ca(CaCl_4) + 2\ NaCl$$

But a calculation along these lines would need support from other evidence before it could be considered to be of more than formal interest. The possibility of a treatment based on an entirely different type of model should be kept in mind, and will be considered in connection with a more extensive study now in progress regarding systems of this type.

It should finally be mentioned that surprisingly good agreement between calculation ad experiment can be obtained over the whole range by assuming the formation of $CaCl_6^{4-}$ complex ions in the melt, see curve 3 of Fig. 5. But it seems difficult to believe in the existence of discrete $CaCl_6^{4-}$ units in such a melt.

Our investigations have been carried out with aid of grants from *Statsminister Gunnar Knudsen og hustru Sophie f. Cappelen Familjelegat (Borgestad Legat IV)*, for which we wish to express our sincere gratitude.

The authors also wish to thank Mrs. G. Hägh for assisting at the experimental work and instituttingeniör K. Motzfeldt for valuable discussions and also help in preparing the English manuscript.

Ein Vergleich zwischen Pyridin, Äthylalkohol und Azeton als Löslichkeitsvermittler

GUSTAF HOLST

Försvarsväsendets kemiska anstalt, Sundbyberg 4, Schweden

In Zusammenhang mit Untersuchungen über die Hydrolyse von $\beta\beta'$-Dichlordiäthylsulfid sind die Homogenitätsgebiete einiger Lösungsmittelgemische bestimmt worden.

Bei der Durchführung chemischer Reaktionen zwischen wasserunlöslichen organischen Flüssigkeiten und wässrigen Lösungen anorganischer Verbindungen ist es für eine möglichst schnelle und vollständige Umsetzung vielfach wünschenswert, dass die reagierenden Stoffe in einer einzigen Phase vorhanden sind. In solchen Fällen bietet der Zusatz eines mit Wasser einerseits und mit der organischen Flüssigkeit andererseits in allen Verhältnissen mischbaren (chemisch indifferenten) Lösungsmittels die fast einzige Möglichkeit, ein homogenes System zu erreichen.

Die vorliegende Arbeit entstand in Zusammenhang mit einer kinetischen Untersuchung über die oxydative Zerstörung von $\beta\beta'$-Dichlordiäthylsulfid durch wässrige Hypochloritlösungen, worüber an anderer Stelle kurz berichtet wurde [1]. Sie enthält einige vergleichende Messungen über die Mischungsverhältnisse in einigen flüssigen Dreistoffsystemen mit Wasser als eine Komponente.

Die folgenden vier organischen Flüssigkeiten ziemlich weit verschiedener Konstitution wurden dabei jeweils als die "wasserunlösliche" Komponente gewählt: Benzol, Tetrachlorkohlenstoff, Schwefelkohlenstoff und $\beta\beta'$-Dichlordiäthylsulfid. Die Löslichkeit dieser Verbindungen in Wasser ist sehr klein. Sie beträgt z.B. in 100 Vol. H_2O bei 22° für CS_2, 0,17 Vol. und für C_6H_6 0,08 Vol. Ebenso löst sich [2] in 100 Vol. CS_2 bzw. C_6H_6 nur 0,96 bzw. 0,22 Vol. H_2O.

Als Vertreter der dritten Komponente (Löslichkeitsvermittler) kamen Pyridin, Äthylalkohol und Azeton zur Verwendung, so dass insgesamt zwölf verschiedene Kombinationen untersucht wurden.

Der Einfluss einer *dritten* Komponente auf die gegenseitige Löslichkeit zweier Flüssigkeiten ist vielfach ausserordentlich gross, was sich in einer erheblichen *Verschiebung der kritischen Entmischungstemperatur* des binären Systems wiederspiegelt. Grundlegende Untersuchungen auf diesem Gebiete verdanken wir u.a. Timmermans [3].

Als Beispiel der Löslichkeitsverhältnisse sei ferner erwähnt, dass sich Dichlordiäthylsulfid in jedem Verhältnis in absolutem Äthylalkohol oberhalb 15,6° löst, dagegen erst oberhalb 38,6° in 92,5 %-igem Äthylalkohol [4].

VERSUCHE

Die verwendete Versuchsmethodik war sehr einfach. In ein kleines Reagenzglas wurde mit einer Mikropipette je 0,50 ml der organischen Flüssigkeit (F) und des Löslichkeitsvermittlers (L) eingeführt, wobei ein homogenes Gemisch erhalten wurde. Danach wurde aus einer in 0,01 ml geteilten Mikrobürette mit feiner Spitze Wasser (W) tropfenweise zugesetzt, bis eine momentane Trübung beobachtet wurde, wobei zwei Phasen entstanden, die beim Schütteln bestehen blieben. Das zugesetzte Wasservolumen wurde abgelesen. Dann wurde noch 0,50 ml (L) und aus der Bürette (W) zugeführt, bis eine Entmischung wieder beobachtet werden konnte usw. Die aus den zugesetzten Volumen (ml) berechneten Molprozente (N) gehen aus den folgenden Dreieck-Diagrammen hervor (Fig. 1—4). Alle Bestimmungen wurden bei Zimmertemperatur (etwa 20°) ausgeführt.

Es sei hier nebenbei bemerkt, dass diese einfache sog. "Trübungstitration" für das Studium der Lösung hochmolekularer Polymerisationsverbindungen eine wichtige Verwendung gefunden hat.

In dem folgenden Ausdruck bedeutet n die Anzahl Millimole der jeweils vorhandenen Komponenten (W, F und L). Die Grösse N bedeutet der Molprozent, z.B.

$$N_F = 100 \cdot \frac{n_F}{n_F + n_W + n_L}$$

und 0,50 ml Flüssigkeit (F) entspricht den folgenden Werten von n_F

F	C_6H_6	CCl_4	CS_2	$S(CH_2 \cdot CH_2Cl)_2$
n_F	5,65	5,19	8,32	4,08

In den Dreieckdiagrammen (Fig. 1—4) bedeuten:
Kurve I C_5H_5N — Mischungen
Kurve II C_2H_5OH — "
Kurve III $(CH_3)_2CO$ — "

Wenn wir die gegenseitige Lage der drei Entmischungskurven in den vier Dreiecken mit einander vergleichen, so erkennen wir zunächst, dass von

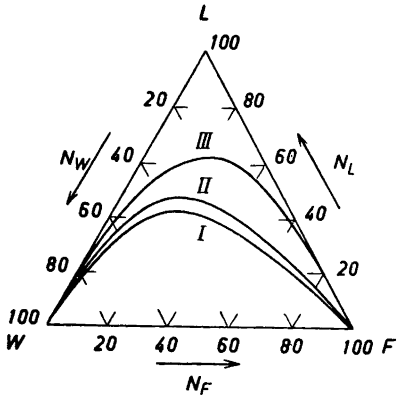

Fig. 1.

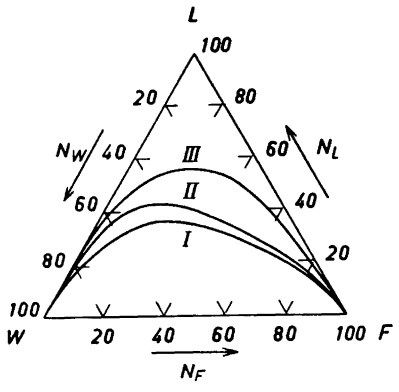

Fig. 2.

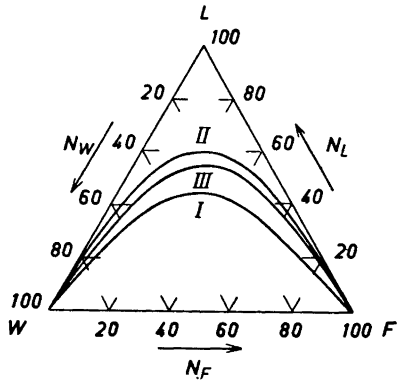

Fig. 3.

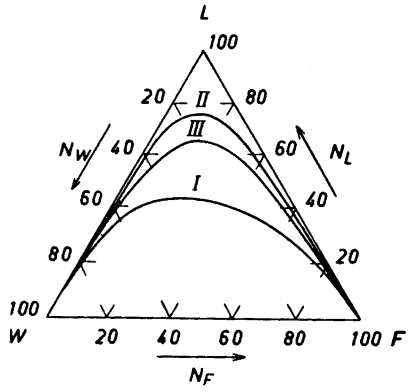

Fig. 4.

Pyridin (Kurve I) in sämtlichen Fällen ein kleinerer Molprozent (N) erforderlich ist um eine vollständige Mischung zu erreichen und dass diese Kurve sehr flach ist. Dabei ist allerdings zu bedenken, dass Pyridin ein höheres Molgewicht (79) besitzt als die anderen wasserlöslichen Verbindungen, Alkohol (46) und Azeton (58).

Zwischen den letzten Flüssigkeiten bestehen charakteristische Unterschiede. Wenn wir z.B. die zwei Substanzpaare: C_6H_6—CS_2 in Fig. 1 und 3, bzw. CCl_4—$S(CH_2{\cdot}CH_2Cl)_2$ in Fig. 2 und 4 mit einander vergleichen, wobei die Molgewichte von C_6H_6 (78) und CS_2 (76), bzw. CCl_4 (154) und $S(CH_2.CH_2Cl)$ (159) je etwa dieselben Grössen besitzen, so erkennen wir, dass für die *Schwefelverbindungen* die Alkohol-Kurve höher liegt als die Azeton-Kurve, während für die *anderen Verbindungen* die Verhältnisse umgekehrt liegen.

Aus den Diagrammen 1 und 2 geht mit aller Deutlichkeit hervor, dass Äthylalkohol für C_6H_6 und CCl_4 ein wesentlich besserer Löslichkeitsvermittler ist als Azeton. Ebenso zeigen die Kurven II der Diagramme 2 und 4, dass ein erheblich kleinerer Zusatz von Alkohol nötig ist, um für das binäre System CCl_4-Wasser eine vollständige Mischung zu erreichen, als für das System $S(CH_2CH_2Cl)_2$-Wasser. Dasselbe gilt, obwohl etwas weinger scharf ausgeprägt, für die binäre Mischung C_6H_6—H_2O im Vergleich mit CS_2—H_2O (Kurven II, Fig. 1 und 3).

ANHANG

Hydrolyseversuch mit ββ'-Dichlordiäthylsulfid in alkalischer Äthylalkohol-Wasserlösung

Die Hydrolyse dieser Verbindung wurde in *homogenem System* untersucht, worüber hier kurz berichtet wird. Die wässrige Hydrolyse und deren Abhängigkeit von dem Verteilungszustand des Sulfids war schon früher von Wilson und Mitarbeitern [5] untersucht worden. Nach den Ergebnissen Wilsons ist die Hydrolyse der Dihalogenverbindung ausschliesslich an den in der wässrigen Phase gelöst vorhandenen Molekeln geknüpft, und die Grösse der Phasengrenzfläche bestimmt nur die Lösungsgeschwindigkeit des Sulfids in Wasser. Es wurde ferner eine merkliche Beschleunigung in Anwesenheit sulfonierter pflanzlicher und tierischer Öle festgestellt. Diese Stoffe, z.B. "Türkischrotöl" besitzen nämlich die Eigenschaft, den Dispersionsgrad des Sulfids zu erhöhen. Die *Auflösung* des Sulfids ist also der langsamste Vorgang und für die Gesamtreaktion *in heterogenem System massgebend.*

Die von mir gewählten Versuchsbedingungen gehen aus dem folgenden Beispiel hervor.

Eine benzolische Lösung von 1,000 g Dichlordiäthylsulfid in 50 ml Volumen wurde bereitet und im Thermostaten bei 50° aufbewahrt. 5 ml von dieser Lösung wurde zu einer ebenfalls bei 50° temperierten Mischung von 75 ml Äthylalkohol und 25 ml 0,1 N NaOH-Wasserlösung gesetzt und diese Reaktionslösung wurde während der ganzen Versuchszeit bei 50° gehalten. 10 ml Proben der Lösung wurden zu bestimmten Zeiten auspipettiert, und die Reaktion durch Titration mit 0,05 N HCl gegen Methylrot verfolgt. Ausgangskonzentrationen: NaOH = 0,024 N; Sulfid = 0,006 M

Zeit, Min.	5	10	15	20	30	45	60	100
Hydrolyse, %	17,3	32,1	43,0	56,8	71,6	85,3	92,4	99,3

Die Umsetzung ist also schon nach 20 Minuten zu mehr als 50 % fortgeschritten und nach 2 Stunden praktisch beendet.

Diese Untersuchung wurde im Jahre 1941 in der Forschungsabteilung von *Försvarsväsendets Kemiska Anstalt*, Ulriksdal bei Stockholm, durchgeführt, jedoch zufolge verschiedenen Umständen bisher nicht veröffentlicht.

Der Verfasser dankt seinem damaligen Chef, Herrn Prof. Dr. G. Ljunggren, für sein Interesse, sowie Herrn Dr. L. Melander für seine Mithilfe in der experimentellen Arbeit.

Kinetics of Complex Formation

IV. Rates of Decomposition and Transformation Mechanisms of Chromium(III) Ammines in Aqueous Solution

ERIK JØRGENSEN and JANNIK BJERRUM

Chemistry Department A, Technical University of Denmark and The Royal Danish School of Pharmacy, Copenhagen, Denmark

The aquation of the hexammine, pentammine and tetrammine chromium(III) ions in acidic as well as in basic solution was studied by chromatographic analysis of the reaction mixtures. Further, the aquation of tetraquodiammine ion was followed by a pH-titration method, and the existence of a relatively stable monammine ion was proved. The monammine which completes the series of chromium(III) ammines from hexammine to hexaquo ion was isolated as a cesium alum.

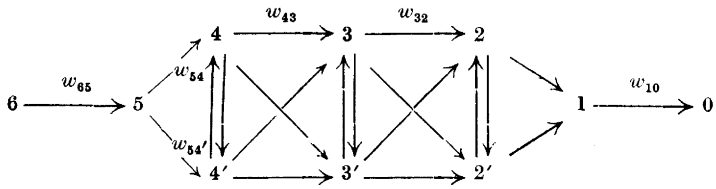
In a previous paper [1] of this series one of the authors has found that the aquation of the hexammine chromium(III) ion in nitric acid solution is independent of the hydrogen ion concentration, and the following expression was found for the pseudo-unimolecular velocity constant (in sec^{-1})

$$k_{-6} = 10^{12.3} \exp \frac{-26\,000}{RT} .$$

This study has now been extended to the pentammine, tetrammine and diammine chromium complexes both in acidic and alkaline solution (*cf.* Ref.[2]).

The aquation is most simple in acidic solution because the equilibria between aquo- and hydroxo complexes can be stoichiometrically neglected and are also without importance to the reaction rates which are independent of the hydrogen ion concentration contrary to what is found for most acido complexes, *e.g.* for the aquation of the chloro chromium complexes [3]. This is in agreement with the fact that the reaction rates, at least for the higher ammines, are of the same order of magnitude in a basic solution as in an acidic solution. Hydroxo-pentammine decomposes even more slowly than aquopentammine. It is also an advantage that an acid reaction mixture remains homogeneous and that the formation of polynuclear compounds is suppressed.

The aquation of the luteo ion in acidic solution may then be supposed to consist of 20 consecutive and simultaneous exchanges of ammonia with water and *cis-trans* isomerizations:



The figures give n in $Cr(NH_3)_n(H_2O)_{6-n}^{+++}$: 2,3,4 stand for the *cis*, and 2',3',4' for the *trans* complexes. w_{65} is the probability per unit time [4] of the hexammine reacting to form the pentammine. The other w's are analogously defined.

In basic solution a similar scheme can be established for the hydroxylation of hexammine down to trihydroxotriammine — more or less complicated by the formation of polynuclear compounds (*cf.* Figs. 1 and 2).

The complete solution for every intermediate is rather complex but may be readily calculated by matrix algebra as indicated in the appendix by one of the authors (E.J.).

Such calculations show that the relative amounts, a_j, of reaction product j can be expressed as the following function of t:

$$a_j = \sum_i Q_{ji} \exp(-\lambda_i t)$$

with 10 possible values of λ, which can be identified with the conventional gross velocity constants k_{-6}, k_{-5}, k_{-4}, $k_{-4'}$, . . . , k_{-1} plus a zero for the components present at equilibria, in this case hexaquo chromium ions only. Q_{ji} is a constant, usually a fraction containing the reaction probabilities, see appendix.

For k_{-6}, k_{-5} and k_{-1} we have the simple expressions:

$$k_{-6} = \frac{-\mathrm{d}\ \ln[Cr(NH_3)_6]}{\mathrm{d}t} = w_{65},\quad k_{-5} = w_{54} + w_{-54'},\quad k_{-1} = w_{10},$$

while the other gross constants are complicated functions of the w's. Of course, k_{-4} and $k_{-4'}$ and similarly k_{-3}, $k_{-3'}$ and k_{-2}, $k_{-2'}$ will only have their intuitive meaning when the *cis-trans* isomerization is very slow compared to the liberation of ammonia. Otherwise it is impossible to attach a definite one of the k's to a definite one of the tetrammines. Their bearing on the reaction probabilities are such that k_{-4} and $k_{-4'}$, are roots of

$$R^2 - (w_{44'} + w_{43} + w_{43'} + w_{4'4} + w_{4'3} + w_{4'3'}) \cdot R + (w_{44'} + w_{43} + w_{43'}) \cdot (w_{4'4} + w_{4'3} + w_{4'2'}) - w_{44'} \cdot w_{4'4} = 0,$$

and similar expressions exist for k_{-3}, $k_{-3'}$, and k_{-2}, $k_{-2'}$.

The rate experiments were all carried out in darkness at 40°C.

The concentration of the complexes most rich in ammonia in the reaction mixtures were determined by chromatography on alumina as developed by

Bjerrum, Jensen and Woldbye [5]. A separation of some lower ammines by chromatographic analysis on alumina was also attempted, but without success due to their low robustness in alkaline solution.

A representative selection of experiments in nitric acid solution ($c_{HNO_3} + c_{KNO_3} = 0.4$ M) is given in Tables 1—4, and similarly in alkaline solution ($c_{NaOH} + c_{KNO_3} = 0.4$ M) in Tables 5—7.

When the ammine complexes split off ammonia, an equivalent amount of acid is neutralized, and in a number of experiments also the amount of free acid has been determined in order to calculate the average number of ammonia bound per chromium atom in the reaction products. It was done by a pH titration and the equivalence point was estimated from the appearance of the titration curve. This procedure was used in the experiments with hexammine, pentammine and tetrammine chromium(III) salts. Some more accurate titrations of this kind were carried out in order to follow the aquation of the tetraquodiammine chromium(III) ion since in this case we were unable to analyze the mixture of ammines by chromatography. Most of these results are given in Table 8.

EXPERIMENTAL

Preparation of salts. The complex salts used were the following: $Cr(NH_3)_6(NO_3)_3$. *Anal.* Calc.: Cr 15.29; NH_3 30.02. Found: Cr 15.23; NH_3 29.76. $Cr(NH_3)_5(H_2O)(NO_3)_3$. *Anal.* Calc.: Cr 15.24. Found: Cr 15.10.

trans(?)-$[Cr(NH_3)_2(H_2O)_2(OH)_2]Cl,H_2O$ *Anal.* Calc.: Cr 24.81; NH_3 16.25; OH 16.23; Cl 16.91. Found: Cr 24.69; NH_3 16.30; OH 16.22; Cl 17.15.

cis-$[Cr(NH_3)_4(H_2O)OH]SO_4$ and *cis*-$[Cr(NH_3)_4(H_2O)OH]S_2O_6$.

With minor modifications the complex salts were prepared according to methods described in the literature. The *cis*-hydroxoaquotetrammine chromium(III) sulphate was kindly supplied by C. E. Schäffer, who also suggested making the dichlorodiaquodiammine chromium(III) chloride which was used in preparing the dihydroxodiaquodiammine chloride by oxidizing the Reinecke salt with hydrogen peroxide: The hydrogen peroxide (30 %) was added dropwise to the solid Reinecke salt moistened with concentrated hydrochloric acid. The vigorous reaction was slowed down by cooling in ice. The dark red solution was frequently decanted off and the joined fractions were saturated with hydrogen chloride in the cold. The solution was placed at room temperature till the next day. The precipitate formed was used for the next preparation after a single reprecipitation with hydrochloric acid.

Reinecke salt has been shown to be the *trans*-diammine compound [6], and we have assumed that the tetraquodiammine ion also has *trans*-configuration.

Chromatography. 2—5 ml were brought to the approximate composition of the eluating liquid by adding the necessary electrolytes [5]. The dimension of the column was usually 11 × 200 mm. For the separation of hexammine and pentammine solutions were used of the following composition: 0.1 M KOH, 0.2 M KCl, 0.8 M $(C_2H_5)_4NBr$ followed by 0.1 M KOH, 1.0 M KCl. Pentammine passes first. Hexammine is recovered practically quantitatively by addition of the latter solution. A shorter column was used for the separation of pentammine and tetrammine. Pentammine is displaced quickly with a solution of the composition 1.0 M NH_3, 0.1 M NH_4Cl, 1.0 M $NaNO_3$ with a loss of about 10 %, after which the tetrammine is displaced with 0.1 M NaOH, 1.0 M LiCl. Separation of tetrammine from the lower ammines was performed with solutions of the composition 0.1 M NaOH, 1.0 M $NaNO_3$, giving a loss of approximately 30 % due to the relatively low robustness of the tetrammine. The lower ammines were completely decomposed by this treatment.

The concentration in the eluate was in a few cases determined from the optical density, but in the majority of cases the acidified solutions were boiled until there was complete transformation to hexaquo ions. The chromium(III) ions were oxidized by

persulphate, using silver ions as catalyst. The chromate formed was then titrated with ferrous ions [7].

pH-titrations. A pH Meter 22 (Radiometer) was used. In order to increase its sensibility in the more accurate titrations (Table 8) it was supplied with an external meter covering the pH range 6—8. Between the calomel electrode and the input was inserted a pH-standard (PHN 2a, Radiometer). It was then possible to change the input voltage in jumps which correspond to one half unit in pH.

The procedure for the experiments given in Table 8 was the following: A sample of 10 ml of the reaction mixture was taken out and cooled. The extinction at 570, 540, 520, 480 and 385 mμ was measured in a Beckman DU spectrophotometer. Then it was transferred into the titration vessel together with 15 ml 0.5 M $NaNO_3$, and the titration curve was determined at ca. 20°C. with 0.5018 M NaOH as titrant.

The equivalence point is not a sharp point of inflection, and the various complexes have different values for the first acid dissociation exponent, pK_{a1}. It was, therefore, necessary to determine both equivalence point and a mean value of pK_{a1} for every titration. The interdependence of these quantities is, under the conditions of the experiments in Table 8 (0.473 mmole chromium complex contained in 25 ml liquid), expressed by

$$pH_{titr} = 0.5\left\{ pK_{a1} - \log\left(\frac{10^{-pH_0+1.372}}{x(25+x)} - 10^{-pH_{titr}}\right)\right\}$$

where

x: ml 0.5018 M NaOH used until the equivalence point

pH_{titr}: pH at the equivalence point

pH_0: pH of the initial solution before the titration

pK_{a1}: calculated from the data when the first aquo group in the complex is 50 % neutralized.

The true values for x, pH_{titr} and pK_{a1} are then found by iteration.

RESULTS AND DISCUSSION

The rate constants which head the third column of Tables 1—7 are evaluated graphically from the slope of the straight line obtained by plotting the logarithm of the experimental complex concentrations (given in the second column) against the time measured in hours. The concentrations in the third column are calculated from the rate constant and the initial complex concentration. When the figures of these two columns are compared, it is easily seen that the agreement is satisfactory only when due regard is paid to the loss of chromium on the column during the chromatographic analysis. This is certainly the case with the tetrammine chromium ions and particularly with the figures of Table 7. The value of k_{-4} is in this case given only as a size of order guess. As a whole, however, the numerical values of the rate constants are considered reliable. The value of k_{-6} given in the previous publication [1] from an altogether different way of analysis is 1.34×10^{-6} sec^{-1} = 0.0048 h^{-1}.

In Tables 1 and 5 are also given the concentrations of aquopentammine and hydroxopentammine found during the aquation and hydroxylation, respectively, of the hexammine, and they are seen to agree with the concentrations which can be calculated from the expression for the intermediate in two consecutive unimolecular reactions, see for example the second example in the appendix. Similarly, in Table 3 the concentration of tetrammine accumulated during the aquation of pentammine is given but does not at all correspond to the rate constant found for *cis*-diaquotetrammine (Table 4). It must then be concluded that the aquopentammine aquates mainly through the *trans*-diaquotetrammine. A column in Table 3 shows the concentrations of tetrammine to be expected if the pentammine was aquated through the *trans*-diaquotetrammine exclusively and if this complex disappeared at a rate ten times faster. It will be seen that this assumption gives a rather good agreement. It should be mentioned that *cis-trans* isomerization has been completely neglected.

The last column in Tables 1, 2 and 4 indicates the average number of ammonia per chromium atom in the aquated reaction products exclusive of the initial complex. The figures give immediately the impression that di- and monammine are just as robust as hexammine and that triammine roughly is as robust as pentammine.

The interpretation of the experimental results concerning the aquation of tetraquodiammine given in Table 8 requires a somewhat different practice. Already a look at the experimental values of pK_{a1} in Table 8b shows qualitatively that there must exist an intermediate of comparatively high stability with a higher value of pK_{a1} than that of the diammine and hexaquo ion. To the quantitative treatment we have the following relationships: The decrease in the hydrogen ion concentration $-\Delta[H^+]$ according to the appendix can be described by

$$\frac{-\Delta[H^+]}{C_{Cr}} = 2 - a_1\exp(-k_{-2'}t) - a_2\exp(-k_{-2}t) - a_3\exp(-k_{-1}t)$$

or

$$\bar{n} = a_1\exp(-k_{-2'}t) + a_2\exp(-k_{-2}t) + a_3\exp(-k_{-1}t)$$

where C_{Cr} is the total chromium concentration, and $\bar{n}$ is the average number of ammonia molecules bound per chromium atom in the reaction mixture.

The experimental values for $\bar{n}$ which are given in the third column of Table 8b are now fitted to these expressions by trial and error. A particularly systematic "least square method" has not been used because of the overwhelming number of numerical calculations necessary. Due regard is paid to the fact that the 6 parameters are not independent. From the appendix it will be seen that a_1, a_2, a_3 can be expressed by 4 independent parameters: k_{-1}, k_{-2}, $k_{-2'}$ and $w_{2'1}$. In addition there are 3 different possibilities for choosing k_{-1}, but for the remaining two the indices are exchangeable. For the eighteen esperimental results, most of them given in Table 8, the following parameters were chosen:

a_1: 0.60	a_2: 0.36	a_3: 1.04
$k_{-2'}$: 0.041	k_{-2}: 0.0025	k_{-1}: 0.0093

The seventh column contains $\bar{n}$ calculated from these parameters.

w_{10} is identical with $k_{-1} = 0.0093$ and $w_{2'1}$ can be directly calculated as the sum $a_1k_{-2'}$, $+ a_2k_{-2} + a_3k_{-1} = 0.035$.

It is now possible to calculate the relative amounts of *cis* and *trans* diammine ($a_2 + a_{2'}$), monammine a_1 and hexaquo chromium ion a_0 as a function of time, since the previously mentioned Q_{j_i}'s contain $k_{-2'}$, k_{-2}, k_{-1} and $w_{2'1}$ only. They are listed in Table 8b and show quantitatively that the monammine is the predominant complex for the period of 30—80 h after the start of the reaction.

If we denote the measured properties of the reacting solution (pK_{a1} and the molar extinction coefficients at various wavelenths) by U, the corresponding property of the monammine is obtained as the slope of the straight line in a plot of $\frac{U - a_0u_0}{a_{2'} + a_2}$ *versus* $\frac{a_1}{a_{2'} + a_2}$. This relationship should only be a straight line when the properties of *cis* and *trans* diammine are only slightly different, and this seems to be the case with a possible exception for ε_{480}, in which case the plot indicates a higher extinction for the *cis* than for the *trans* isomer.

The estimated properties for the monammine are given in Table 9 compared with the corresponding properties for the diammine and the hexaquo chromium ion. The molar extinctions of the monammine are also represented as crosses in Fig. 3.

Table 9. Estimated properties for the pentaquomonammine chromium(III) ion at ~20°C.

	pK_{a1}	ε_{570}	ε_{540}	ε_{520}	ε_{480}	ε_{385}
$Cr(NH_3)_2(H_2O)_4^{+++}$	4.11	12.1	19.2	21.0	12.1	24.2
$Cr(NH_3)(H_2O)_5^{+++}$	4.4	18	20	17	5.5	16
$Cr(H_2O)_6^{+++}$	4.26	13.6	10.1	6.9	3.44	11.9

The remaining reaction probabilities are related by

$$k_{-2}k_{-2'} = w_{2'2}w_{21} + w_{22'}w_{2'1} + w_{2'1}w_{21}$$
$$k_{-2} + k_{-2'} = w_{2'2} + w_{2'1} + w_{22'} + w_{21}$$

giving

$$w_{2'2} \cong 0.0056 \qquad w_{21} + w_{22'} \cong 0.0027$$

The distribution of the diammine chromium ion between the *cis* and *trans* isomer throughout the reaction can also be approximated, and it is seen from the last column of Table 8b that the maximum amount of the *cis* isomer is more than 11 %. However, it is necessary to make serious reservations regarding this figure as well as regarding the estimates of $w_{2'2}$ and $w_{21} + w_{22'}$, because the rate equation is not critically influenced by these quantities.

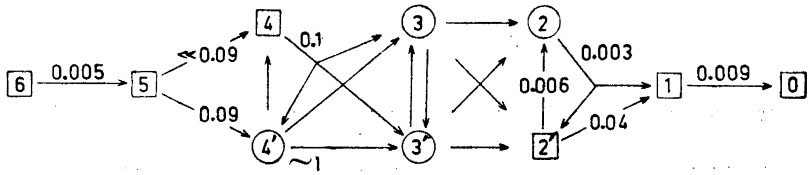

Fig. 1. Velocity constants (hour^{-1}) in > 0.1 M HNO_3 at 40°C.

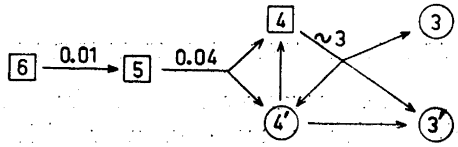

Fig. 2. Velocity constants (hour^{-1}) in ~ 0.1 M NaOH at 40°C.

The reaction probabilities found in acidic and basic solution are summarized in Figs. 1 and 2. As a whole, the hydroxo-ammine complexes are less robust than the corresponding aquo complexes. It is therefore remarkable that hydroxopentammine is seen to decompose more slowly than the aquopentammine chromium ion. Triaquotriammine chromium(III) salts have been prepared by Werner [8] but have not been utilized in this study. The squares in Figs. 1 and 2 indicate the components which have been used in our experiments. The spectra of these complexes in acidic solution are recorded in Fig. 3, which also gives the spectrum of the monammine. This compound was obtained in crystalline form in a preliminary attempt to prepare it from the reaction mixture. The data which were calculated from the mixed spectra are seen to be represented by the curve fairly well.

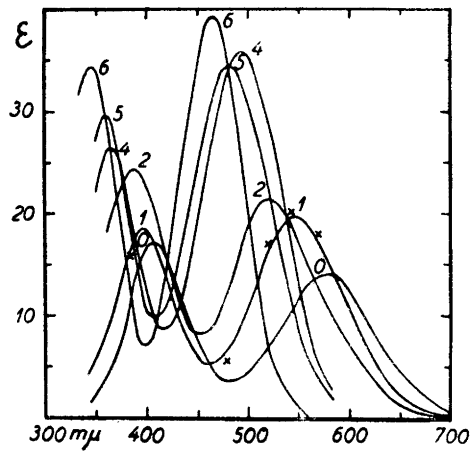

Fig. 3. Some absorption spectra of aquoammine chromium(III) ions in 0.5 M nitric acid at room temperature.

Curve 6: hexammine, 5: aquopentammine, 4: *cis*-diaquotetrammine, 2: *trans*(?)-tetraquodiammine, 1: pentaquomonammine (0.1 M HNO_3) and 0: hexaquo ions (1 M HNO_3). ×-points for the monammine are calculated from the data given for the mixed spectra in the reaction mixtures of Table 8.

PREPARATION OF THE MONAMMINE AS CONSTITUENT OF A CESIUM ALUM

The monammine, which completes, apart from isomers, the series $Cr(NH_3)_6^{+++}$ . . . $Cr(H_2O)_6^{+++}$, was prepared in the following way. 0.440 g $[Cr(NH_3)_2(H_2O)_2(OH)_2]Cl$ was dissolved in 40 ml 0.55 M HNO_3 and placed at 40°C for 48 h. After this time the reaction mixture contained the maximum amount of monammine, *cf.* Table 8. It was now intended to precipitate the hexaquo ions as the cesium alum, which according to N. Bjerrum and Faurholt [9] is shown to be a very complete precipitation under the following conditions: To the cold solution 1 ml 2 M H_2SO_4 and 2 g cesium sulphate were added, followed by 20 ml 96 % alcohol after 1 h. It was remarkable that the precipitate did not have the greyish violet colour of the hexaquo ion but had a distinct purple colour probably due to the presence of monammine. The supernatant was placed for some hours at 0°C and a slight precipitate was formed which consisted of cyclamen coloured octaeders. An examination under the polarization microscope showed them to be isotropic. The crystals were not isolated but dissolved in 4—5 ml 0.1 M HNO_3 after rinsing with alcohol. After the spectrum had been taken, the concentrations of chromium and ammonia were found to be 0.0252 M and 0.0259 M, respectively. It is thus shown to be a monammine, and the octaederform of the crystals suggests it to be an alum, $CsCr(SO_4)_2,NH_3,11\ H_2O$.

In order to confirm the presence of monammine in the main precipitate it was dissolved in 40 ml of water and 1/4 ml H_2SO_4, and 2 g cesium sulphate

was added. The precipitate was still somewhat more reddish than the hexaquo chromium ion. The concentrations of chromium and ammonia in the supernatant were 0.00815 M and 0.00842 M, respectively.

THE ACID-BASE CONSTANTS OF THE TETRAQUODIAMMINE CHROMIUM(III) ION

From the data for the titration of the tetraquodiammine solution the second and third dissociation exponents, pK_{a2} and pK_{a3}, were estimated in addition to pK_{a1}. The following values (also mentioned in Table 8b) were determined in $\sim$ 0.5 M nitrate solution at $\sim$ 20°C:

$$pK_{a1} = 4.11, \quad pK_{a2} = 6.59, \quad pK_{a3} = 9.17.$$

A slow drift towards larger values of pH took place when more than 2 mole NaOH per chromium atom was added, showing that $[Cr(NH_3)_2(OH)_3H_2O]$ splits off its ammonia rather quickly at room temperature. This drift was accounted for by the estimate of pK_{a3}. A drift in the opposite direction was observed in the 22 hours' reaction mixture after an addition of 1.33 base equivalents, and after the lapse of a longer time even after addition of little more than one base equivalent per chromium atom due to the formation of polynuclears from the increasing amount of $Cr(H_2O)_4(OH)_2^+$.

Our thanks are due to Mr. C. E. Schäffer for valuable help in the preparing of salts.

APPENDIX

(by *Erik Jørgensen*)

The reactions dealt with in this paper belong to a rather common class. The partial reactions can be expressed by

$$X_i + (A) \rightarrow X_j + (X_k)$$

X_i is the i'th of the time dependent components and A is a component in great excess (or a component the concentration of which for some other reason can be kept constant during the reaction), it may be the solvent molecules. A and X_k are bracketed as they need not necessarily enter the scheme.

The calculations necessary to obtain the integrated rate expression can be systematized and simplified by introducing matrix methods. In the following it will be aimed at bringing this class of reactions within the framework of matrix algebra as, for example, it is formulated by Margenau and Murphy [10] whose widespread book is referred to concerning definitions and symbolism.

Let the initial component be X_1 and the reaction products $X_2, X_3, X_4, \ldots, X_n$ in a convenient numerical order, X_n being one of the components present at equilibrium.

Setting c_{Xi} equal to x_i, we will define the *concentration vector* $\boldsymbol{x}$ as the column vector $\{x_1, x_2, x_3, \ldots, x_n\}$. The mass action law determines a matrix $\boldsymbol{A}$ which transfers $\boldsymbol{x}$ to $-\mathrm{d}\boldsymbol{x}/\mathrm{d}t$.

$$-\mathrm{d}\boldsymbol{x}/\mathrm{d}t = \boldsymbol{A}\boldsymbol{x} \qquad (1)$$

A contains only constants at the conditions given. These constants are the "microscopic velocity constants" in question, which we according to Christiansen [4] may call "reaction probabilities per unit time" and represent by $w_{i,j(k)}$ for the above-mentioned partial reaction.

The characteristic matrix of A is $K = (\lambda E - A)$. The eigenvalues will be called λ_i — one of them, let it be λ_n, always being zero. If all the eigenvalues are different, which is practically no qualification, A can be reduced to true diagonal form.

Two orthogonal matrices, P and Q, may be constructed for this purpose in the following way:

$$P_{ij} = \frac{K^{jn}(\lambda_i)}{K^{1n}(\lambda_i)} \qquad Q_{ij} = \frac{P^{ji}}{|P|} \tag{2}$$

Now
$$PAQ = \{\lambda_i \delta_{ij}\} \tag{3}$$

Forming another *concentration vector*

$$y = Px \tag{4}$$

i.e. $x = Qy$, we get from (1)

$$-Q\mathrm{d}y/\mathrm{d}t = AQy$$

which multiplied by P gives

$$\mathrm{d}y/\mathrm{d}t = -\{\lambda_i \delta_{ij}\}y$$

with the solution

$$y = \{c_1 \cdot \exp(-\lambda_1 \cdot t), c_2 \cdot \exp(-\lambda_2 \cdot t), \ldots, c_n \cdot \exp(-\lambda_n \cdot t)\}$$

Setting the initial concentration of x_1 equal to x_1^0, we have at $t = 0$ from (4)

$$y = x_1^0\{P_{11}, P_{21}, P_{31}, \ldots, P_{n1}\}$$

From (2) it is seen that $P_{i1} = 1$, meaning that the c's are all equal to x_1^0. Then the complete solution including the boundary condition is

$$y = x_1^0\{\exp(-\lambda_1 \cdot t), \exp(-\lambda_2 \cdot t), \ldots, \exp(-\lambda_n \cdot t)\}$$

or

$$x = x_1^0 Q\{\exp(-\lambda_1 \cdot t), \exp(-\lambda_2 \cdot t), \ldots, \exp(-\lambda_n \cdot t)\} \tag{5}$$

P and Q may also be valuable tools for additive molar properties of the n components — conductivity, optical density, etc. If $u = \{u_1, u_2, \ldots, u_n\}$ is the vector containing these properties, the total property, $U = \tilde{u}x$, can be described as a function of time by $\tilde{u}_\lambda\{\exp(-\lambda_1 \cdot t), \exp(-\lambda_2 \cdot t), \ldots, \exp(-\lambda_n \cdot t)\}$.

Now the following relations hold between the *property vector* u and the *coefficient vector* u_λ:

$$u_\lambda = x_1^0 \tilde{Q} u \tag{6}$$

$$u = (x_1^0)^{-1} \tilde{P} u_\lambda \tag{7}$$

Differentiation of U with respect to t and setting t equal to zero leads to another useful formula:

$$\tilde{u}\{A_{11}, A_{21}, \ldots, A_{n1}\}\, x_1^0 = \tilde{u}_\lambda\{\lambda_1, \lambda_2, \ldots, \lambda_n\} \tag{8}$$

How the matrix algebra is to be applied should be evident from the following rather simple examples.

The first example is that of isomerism between 2 components. In this case

$$X_1 \rightleftharpoons X_2$$

$$A = \begin{bmatrix} w_{12} & -w_{21} \\ -w_{12} & w_{21} \end{bmatrix} \qquad K = \begin{bmatrix} \lambda - w_{12} & w_{21} \\ w_{12} & \lambda - w_{21} \end{bmatrix}$$

$$\lambda_1 = w_{12} + w_{21} \qquad \lambda_2 = 0$$

$$K^{12} = -w_{12} \qquad K^{22} = \lambda - w_{12}$$

$$P = \begin{bmatrix} 1 & -\dfrac{w_{21}}{w_{12}} \\ 1 & 1 \end{bmatrix} \qquad Q = \begin{bmatrix} \dfrac{w_{12}}{w_{12}+w_{21}} & \dfrac{w_{21}}{w_{12}+w_{21}} \\ -\dfrac{w_{12}}{w_{12}+w_{21}} & \dfrac{w_{12}}{w_{12}+w_{21}} \end{bmatrix}$$

The second example is the wellknown one of two consecutive reactions:

$$X_1 \rightarrow X_2$$
$$X_2 \rightarrow X_3$$

$$A = \begin{bmatrix} w_{12} & 0 & 0 \\ -w_{12} & w_{23} & 0 \\ 0 & -w_{23} & 0 \end{bmatrix} \qquad K = \begin{bmatrix} \lambda - w_{12} & 0 & 0 \\ w_{12} & \lambda - w_{23} & 0 \\ 0 & w_{23} & \lambda \end{bmatrix}$$

$$\lambda_1 = w_{12} \quad \lambda_2 = w_{23} \quad \lambda_3 = 0$$

$$K^{13} = w_{12}w_{23} \quad K^{23} = -w_{23}(\lambda - w_{12}) \quad K^{33} = (\lambda - w_{12})(\lambda - w_{23})$$

$$P = \begin{bmatrix} 1 & 0 & 0 \\ 1 & \dfrac{w_{12} - w_{23}}{w_{12}} & 0 \\ 1 & 1 & 1 \end{bmatrix} \qquad Q = \begin{bmatrix} 1 & 0 & 0 \\ -\dfrac{w_{12}}{w_{12} - w_{23}} & \dfrac{w_{12}}{w_{12} - w_{23}} & 0 \\ \dfrac{w_{23}}{w_{12} - w_{23}} & \dfrac{-w_{12}}{w_{12} - w_{23}} & 1 \end{bmatrix}$$

The third example is the reaction scheme which has been necessary to describe the aquation of the *trans*-tetraquodiammine chromium(III) ion in the present paper. Therefore, the indices have been changed to conform with those of the main text (2′∼1, 2∼2, 1∼3, 0∼4).

$$\begin{array}{lcl} X_{2'} & \rightleftharpoons & X_2 \\ X_{2'} & \rightarrow & X_1 \\ X_2 & \rightarrow & X_1 \\ X_1 & \rightarrow & X_0 \end{array}$$

$$A = \begin{bmatrix} w_{2'2} + w_{2'1} & - w_{2'2} & 0 & 0 \\ - w_{2'2} & w_{22'} + w_{21} & 0 & 0 \\ - w_{2'1} & - w_{21} & w_{10} & 0 \\ 0 & 0 & - w_{10} & 0 \end{bmatrix}$$

$$\lambda_1 \cdot \lambda_2 = k_{-2'} \cdot k_{-2} = w_{2'2}w_{21} + w_{22'}w_{2'1} + w_{2'1}w_{21}$$

$$\lambda_1 + \lambda_2 = k_{-2'} + k_{-2} = w_{2'2} + w_{2'1} + w_{22'} + w_{21}$$

$$\lambda_3 = k_{-1} = w_{10} \qquad \lambda_4 = 0$$

$$K^{14} = - k_{-1}(k_{-2'}k_{-2} - w_{2'1}\lambda) \qquad K^{24} = - k_{-1}(k_{-2'}k_{-2} - w_{21}\lambda)$$

$$K^{34} = - k_{-1}(\lambda - k_{-2})(\lambda - k_{-2'}) \qquad K^{44} = (\lambda - k_{-1})(\lambda - k_{-2})(\lambda - k_{-2'})$$

$$P = \begin{bmatrix} 1 & \dfrac{k_{-2}-w_{21}}{k_{-2}-w_{2'1}} & 0 & 0 \\ 1 & \dfrac{k_{-2'}-w_{21}}{k_{-2'}-w_{2'1}} & 0 & 0 \\ 1 & \dfrac{k_{-2'}k_{-2}-w_{21}k_{-1}}{k_{-2'}k_{-2}-w_{2'1}k_{-1}} & \dfrac{(k_{-1}-k_{-2})(k_{-1}-k_{-2'})}{k_{-2'}k_{-2}-w_{2'1}k_{-1}} & 0 \\ 1 & 1 & 1 & 1 \end{bmatrix}$$

$$Q = \begin{bmatrix} \dfrac{(k_{-2}-w_{2'1})(k_{-2'}-w_{21})}{(k_{-2'}-k_{-2})(w_{21}-w_{2'1})} & - \dfrac{(k_{-2}-w_{21})(k_{-2'}-w_{2'1})}{(k_{-2'}-k_{-2})(w_{21}-w_{2'1})} & 0 & 0 \\ - \dfrac{(k_{-2}-w_{2'1})(k_{-2'}-w_{2'1})}{(k_{-2'}-k_{-2})(w_{21}-w_{2'1})} & \dfrac{(k_{-2}-w_{2'1})(k_{-2'}-w_{2'1})}{(k_{-2'}-k_{-2})(w_{21}-w_{2'1})} & 0 & 0 \\ - \dfrac{k_{-2'}(k_{-2}-w_{2'1})}{(k_{-2'}-k_{-2})(k_{-1}-k_{-2'})} & \dfrac{k_{-2}(k_{-2'}-w_{2'1})}{(k_{-2'}-k_{-2})(k_{-1}-k_{-2})} & \dfrac{k_{-2'}k_{-2}-w_{2'1}k_{-1}}{(k_{-1}-k_{-2'})(k_{-1}-k_{-2})} & 0 \\ \dfrac{k_{-1}(k_{-2}-w_{2'1})}{(k_{-2'}-k_{-2})(k_{-1}-k_{-2'})} & - \dfrac{k_{-1}(k_{-2'}-w_{2'1})}{(k_{-2'}-k_{-2})(k_{-1}-k_{-2})} & - \dfrac{k_{-2'}k_{-2}-w_{2'1}k_{-1}}{(k_{-1}-k_{-2'})(k_{-1}-k_{-2})} & 1 \end{bmatrix}$$

The property measured was the decrease of the hydrogen ion concentration during the reaction. Accordingly, the *property vector* and *coefficient vector* are the following:

$$\boldsymbol{u} = \begin{bmatrix} 0 \\ 0 \\ 1 \\ 2 \end{bmatrix} \quad \boldsymbol{u}_\lambda = x_1^0 \widetilde{\boldsymbol{Q}} \boldsymbol{u} = x_1^0 \begin{bmatrix} \dfrac{(2k_{-1}-k_{-2'})(k_{-2}-w_{2'1})}{(k_{-2'}-k_{-2})(k_{-1}-k_{-2'})} \\ -\dfrac{(2k_{-1}-k_{-2})(k_{-2'}-w_{2'1})}{(k_{-2'}-k_{-2})(k_{-1}-k_{-2})} \\ -\dfrac{k_{-2'}-k_{-2}-w_{2'1}k_{-1}}{(k_{-1}-k_{-2'})(k_{-1}-k_{-2})} \\ 2 \end{bmatrix} = x_1^0 \begin{bmatrix} -a_1 \\ -a_2 \\ -a_3 \\ 2 \end{bmatrix}$$

Eqn. (8) gives

$$w_{2'1} = -(x_1^0)^{-1} \widetilde{\boldsymbol{u}}_\lambda \{\lambda_1, \lambda_2, \lambda_3, \lambda_4\} = a_1 k_{-2'} + a_2 k_{-2} + a_3 k_{-1}$$

which of course can also be seen by direct calculation.

The experimental results in one way or other written as a sum of exponential functions are seen directly to give w_{10} and $w_{2'1}$. $k_{-2'}$ and k_{-2} contain the remaining three reaction probabilities, and at least one further independent determination is necessary to calculate all of them.

On the Isomerism of Hydroxyurea

X. Kinetics of the Isomerization

HELMER KOFOD

Royal Danish School of Pharmacy, Dept. of Organic Chemistry, Copenhagen, Denmark

The kinetics of the conversion of the lower melting isomeride in alkaline buffers, pH 9.2—12.3, have been examined, using a polarographic method of analysis.

At 25°C and pH 12 the reaction conformed to the empirical expression $Bt = \log(c_0/c) + A(c^{-1} - c_0^{-1})$. The constant A did not vary significantly with concentration in the range 1 to 8 mM but appeared to decrease with increasing pH, the overall reaction thus approximating to first-order kinetics in strongly alkaline solution.

At elevated temperatures and pH 12 the isomerization appears to be complicated by partial decomposition of the reactant into hydroxylamine and cyanate, in close analogy to the established chemical reversibility of the classical Wöhler synthesis of urea.

In the course of a general investigation on the polarographic behaviour of the lower melting isomeride (OU_{72}) it was previously observed (Ref. [1], Fig. 1) that on remeasurement of alkaline aqueous solutions, stored at 25°C, the characteristic cathodic wave rapidly vanished. In slightly alkaline and neutral buffers the process was found to be much slower, and in acidic buffers no diminution of the wave was noticed within a period of 72 h, (Ref [1], Table 1).

It is fortunate that the pH-region, ca. 9—13, in which the isomerization proceeds at a convenient velocity also happens to be the most favourable one for polarographic analysis (Ref.[1], Fig 2). It was feasible, therefore, if desired to follow the advancement of the isomerization in the polarographic cell itself. The OU_{72}-wave is well developed in this pH-region, and the isomerization product, OU_{140}, does not produce any interfering wave. Previously published paper-chromatographic work of a qualitative nature [2] suggested that in alkaline solution the conversion process might be sufficiently simple to justify a closer kinetic examination.

THE pH-DEPENDENCY OF THE ISOMERIZATION $OU_{72} \rightarrow OU_{140}$ AT 25°C

In the first series two experiments were carried out with 0.1 M potassium borate buffers at pH 10.5 and 12.3, respectively. The composition of the buffers and general technique are described p. 1077. The initial concentration of OU_{72} was 5.0 mM in both experiments.

5 ml of potassium borate buffer at pH 10.5 containing 0.1 % methylcellulose as a maximum suppressor was deaerated in the polarographic cell and the absence of dissolved oxygen was secured polarographically at high sensitivity. 1.90 mg of OU_{72} was weighed out and quickly dissolved in the cell contents (zero time). Polarographic recordings were run at time intervals. The results are listed in Table 1; t is the time in minutes from the dissolution of the solid until the maximum wave-height was attained during the recording of the polarogram. This point on the wave was reached 3 min after the recording had been started, the scanning speed being 1/3 V per min.

In the next column i represents the diffusion current in μA, calculated from from the wave-height. The data are plotted in Fig 1, upper curve. The experimental points fit a straight line; although this suggests a zero-order reaction, it should be remembered that the degree of advancement in this experiment amounts to about 30 % only.

The reaction was accelerated in the next experiment by raising the pH to 12.3, other conditions remaining as above. The data are listed in Table 2, columns 1—2, and graphically represented in Fig 1, lower curve. The degree of advancement in this experiment is 98 %. The remaining data in Table 2 will be discussed under the heading "Order of reaction", p. 1073.

In another series of experiments, Tables 3—6, the initial concentration was fixed at $c_o = 2.0$ mM, and measurements were carried out in phosphate buffers at pH 12.3 and 11.5, a carbonate buffer at 10.7 and a borate buffer at 9.2. A 20.0 mM stock-solution of OU_{72} in redistilled water was freshly prepared, and 5.4 ml of the appropriate buffer solution was measured into the thermostated polarographic cell and deaerated; 0.6 ml of the stock solution was added (zero time). Immediate mixing was secured by passing the nitrogen stream through the cell for another minute, and polarograms were recorded at suitable time-intervals. The experiment at pH 12.3 (Table 3) was carried out separately, whereas the solutions at pH 11.5, 10.7 and 9.2 (Tables 4—6) were measured intermittantly in one and the same experiment. The cells were stored, well stoppered, in the thermostat at 25.0°C and removed for polarographic recording, according to a minute rota. The experimental data

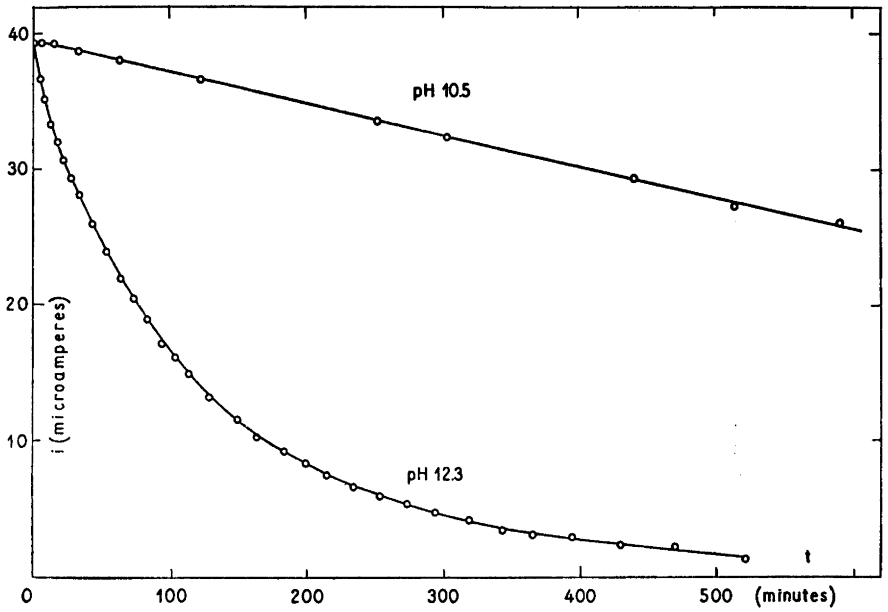

Fig. 1. Isomerization of OU_{72} at 25°C. Polarographic wave-height against time. Initial concentration c_0 = 5.0 mM. Data in Tables 1 and 2.

in Tables 3—6 are graphically represented in Fig 2. As above t represents the time in minutes from the mixing of the stock solution with the appropriate buffer until the maximum wave-height was attained during the recording of the individual polarogram.

CONCENTRATION DEPENDENCY OF THE ISOMERIZATION AT pH 12.0 AND 25°C

On the basis of the preceding experiments the potassium phosphate buffer at pH ≈ 12 was selected for the investigation of concentration influences upon the rate of isomerization.

In planning the experiment in detail the following had to be taken into account: (1) In order to keep the autoisomerization of the unbuffered stock solution at a negligible level the experiment should be carried out within a single day; (2) Recording of the requisite part of the polarogram from −0.8 to 1.8 V *vs.* SCE required 3 min. Rinsing and wiping off the electrodes and changing from one cell to another took a further 2 min; (3) The concentrated solutions should be measured every 5 min at the outset and every 10 and 20 min at later stages. The dilute solutions should be measured every 20 min from the outset; (4) The zero time for the respective solutions should be arranged so as to avoid too frequent alterations in the set sensitivity of the polarographic instrument.

These requirements were met by the rota indicated in Tables 7a and 7b.

An aqueous stock solution containing 10.0 mmoles/l of OU_{72} was freshly prepared, deaerated and stored in a well-stoppered flask. Solution No. 1 was prepared by mixing stock solution and buffer in appropriate proportions to give an initial concentration of 8.0 mM. The zero time was 10 o'clock (Table 7a) and polarographic recordings were run according to Table 7b. When this reaction had slowed down solution No. 2 was started *etc.* The

* calculated by means of the relation $i = 8.3\,c$.

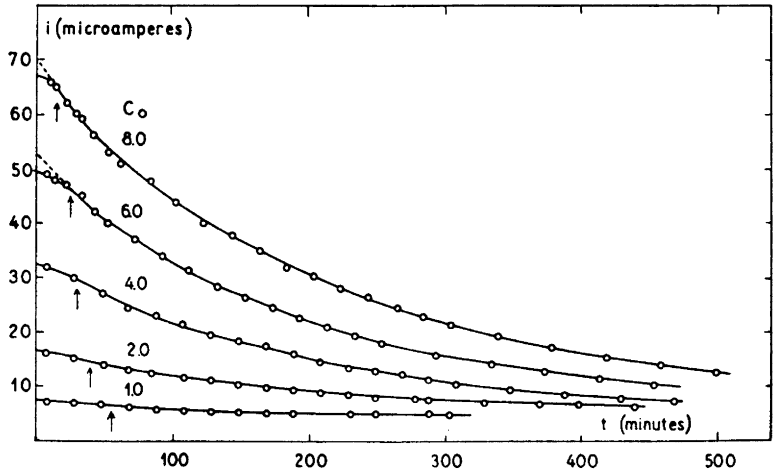

Fig. 3. Isomerization of OU_{72} at 25°C and pH 12.0. Influence of initial concentration c_o. Polarographic wave-height against time. Data in Tables 8—12.

The results are graphically represented in Fig. 3. The polarographic wave height i in μA has been plotted against time and the experimental points were visually fitted with the best curve. The initial values of i ($t = 0$) were calculated from the stoichiometric concentration c_o of OU_{72} by means of the relation $i = 8.3\ c$ (Table 13)

On the graphs, Fig. 3, there appears to be a time-lag at the outset of the reaction. Although the irregularities are close to the experimental error, there is a definite trend in all the graphs, and furthermore the time-lag has to be assumed in order to get a reasonable accordance, *cf.* Table 13, between the stoichiometric value for the initial wave-height i_o and the extrapolated one. Extrapolation from the main part of the graph ($t > 50$ min) is seen to give too high initial values.

The pH of the solutions were checked at the end of the experiment. They all had pH 12.0 ± 0.1.

ISOMERIZATION AT 35°C AND pH 12

In a provisional experiment the isomerization was studied in a phosphate buffer at pH 12 and at 35°C, the initial concentration was 6 mmoles/l. The reaction was quenched by reducing the pH to approximately 7; this was done by diluting withdrawn samples in the proportion 1:10 with the appropriate buffer; polarographic recordings of the dilutions were run immediately. The reaction was, however, found to be inconveniently rapid under these conditions and in a subsequent experiment it was slowed down by reducing the pH to 9.2, the temperature being maintained at 35°C.

CONVERSION PROCESSES AT 35°C AND pH 9.2

The initial concentration was 5.0 mmoles/l and the reaction was quenched in withdrawn samples simply by rapidly reducing the temperature to 25°C. Immediately upon temperature equilibration in the polarographic cell, recordings were run directly on the undiluted samples at pH 9.2. The current-voltage curves are reproduced in Fig. 4 Nos. 2—10. They display a characteristic

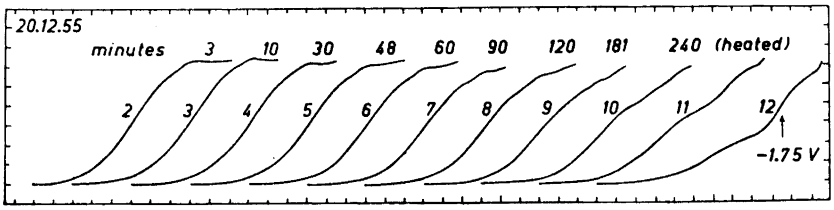

Fig. 4. Conversion of OU_{72} at 35°C and pH 9.2. Cathodic polarographic waves recorded at 25°C. Initial concentration $c_o = 5.0$ mM. All waves begin at -0.8 V *versus* the saturated calomel electrode (SCE). One unit on the abscissa represents 0.1 V. One unit on the ordinate represents 6.66 μA. Drop-time of mercury electrode 3.6 sec; rate of mercury outflow 2.46 mg sec^{-1}.

feature, which was not noticed at 25°C, namely the appearance of a new wave with a half-wave potential of approximately −1.75 V. In order to corroborate this observation a withdrawn sample from the reaction vessel was briefly heated to 80°C, cooled to 25° and polarographed (No. 11). The cell contents were heated once more to 80°C for 2 min and now produced curve No. 12, in which the new wave is clearly distinguishable.

A blank test with the supporting buffer alone proved that the new wave did not originate from the buffer or the vessel upon heating. Neither was it due to the isomerization product OU_{140}, since this has been shown to be polarographically inactive in the voltage region covered by these experiments.

A solution of 5 mg of OU_{140} in 5 ml borate buffer pH 9.2 was heated to 80°C for a short time and subsequently polarographed at 25°C. The current-voltage curve was identical with that of the buffer itself, even at a sensitivity increased by a factor 10. The isomeric hydroxyurea OU_{140} does not, therefore, appear to produce the wave at −1.75 V, observed in the experiment with OU_{72} under similar conditions.

It appears reasonable to regard the wave as being due to hydroxylamine. The estimated half-wave potential −1.75 *vs.* S.C.E. is in accordance with the value previously determined for hydroxylamine (Ref.[1] p. 463, Fig. 6), and the formation of hydroxylamine in alkaline solution at elevated temperatures by reversion of the formation process

$$HONH_3^+ + {}^-OCN \rightleftharpoons OU_{72} \qquad (1)$$

has a close analogy in the well-established reversibility — in the chemical sense — of the urea formation from ammonium cyanate

$$NH_4^+ + {}^-OCH \rightleftharpoons U \qquad (2)$$

Walker and Hambley [3] in 1895 first called attention to the reversibility of Wöhler's classical synthesis, and since then several authors have studied the kinetics of the reaction [4]. Although they all agree that ammonium cyanate is an intermediate in the decomposition, the numerical values of the rate constants differ and so do the proposed mechanisms. Lately the decomposition of urea in aqueous solution has been subjected to a careful investigation by Shaw and Bordeaux [4]. The reaction was studied at urea concentrations ranging from 6 to 1 200 mmoles/l at six different temperatures in the presence and absence of acid. The reaction is reported to be first-order with respect to urea and — contrary to the findings of other authors — uncatalyzed by acid. Within the experimental uncertainties the rate constants were the same in water and in acid, though with a slight trend towards higher rate constants in acid. This was explained by assuming that in water alone recombination of the ions to form urea occurs to a small degree. In acid this reaction is prohibited, because the cyanate ion formed by the decomposition (the reverse of reaction 2) is rapidly and quantitatively converted into ammonium ion[4,5].

$$HOCN + H_3O^+ \rightarrow CO_2 + NH_4^+ \qquad (3)$$

or

$$^-OCN + 2H^+ + 2H_2O \rightarrow NH_4^+ + H_2CO_3 \qquad (4)$$

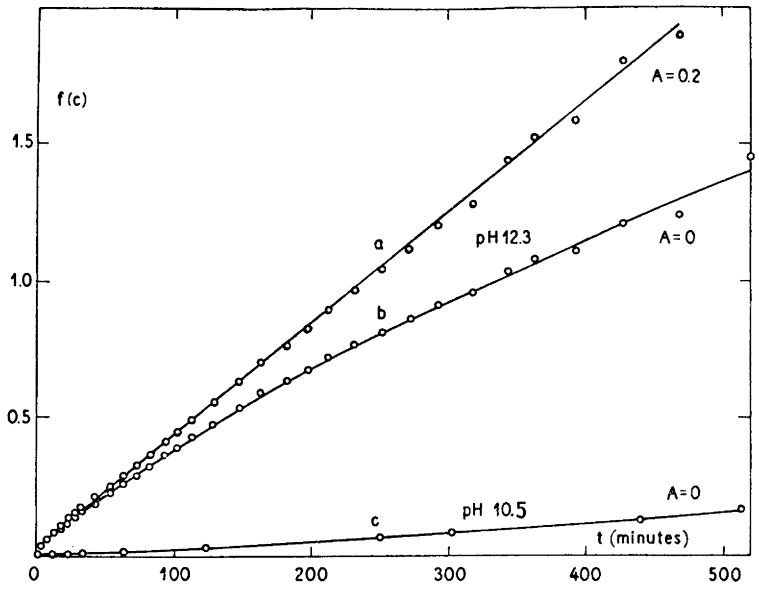

Fig. 5. Plot of the empirical function $f(c) = \log_{10}(c_0/c) + A(c^{-1} - c_0^{-1})$ against time; $c_0 = 5.0$ mM. Data in Tables 1 and 2.

Certain anomalies at high acid concentrations were explained as a result of the equilibrium $U + H^+ \rightleftharpoons UH^+$ (U standing for urea) assuming that the uronium ion UH^+ cannot be directly decomposed into ammonium cyanate. This has previously been postulated by several authors. The stability of OU_{72} in acid solution at room temperature [6] (Ref.[1], Table 1), may be understood on similar grounds; this substance has even more pronounced basic properties than urea (Ref. [6], p. 498). OU_{140} on the other hand is a weak acid. The existence of a stabilized anion in alkaline solution may account for the fact that this substance does not decompose readily into hydroxylamine as shown above by polarographic tests.

ORDER OF REACTION

Since the isomerization at higher temperatures was found to be complicated by competing decomposition reactions, the discussion of the order of reaction will be based entirely on the data obtained at 25°C. The data on Table 2 obtained at pH 12.3 will first be considered on the basic assumption that they correspond to a simple isomerization mechanism, either a single reaction or a set of consecutive reactions.

The data were tested in the integrated first-order equation

$$k_1 t = 2.303 \log_{10}(c_0/c) \qquad (5)$$

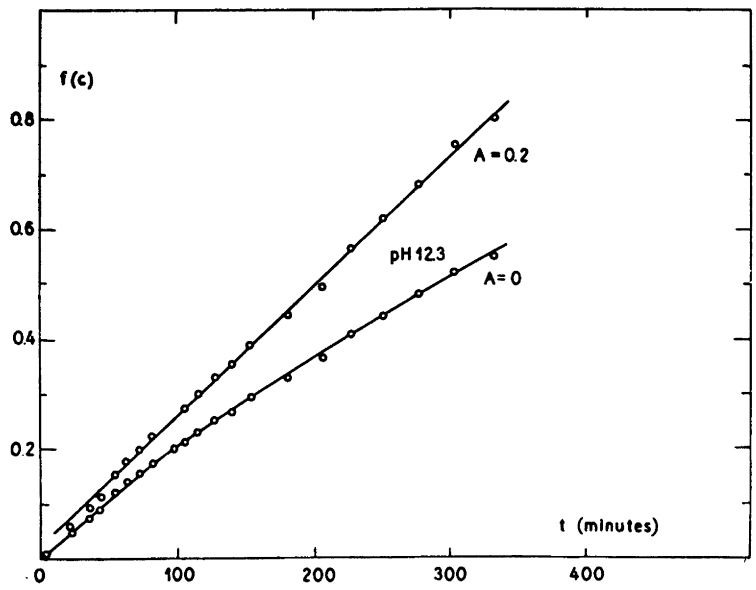

Fig. 6. Plot of the empirical function $f(c) = \log_{10} (c_o/c) + A(c^{-1} - c_o^{-1})$ against time $c_o = 2.0$ mM. Data in Table 3.

c_o being the initial concentration of OU_{72} and c the concentration at any time t. Since a linear relationship between concentration and polarographic wave-height i has been experimentally demonstrated, c_o/c may be replaced by i_o/i

$$k_1 t = 2.303 \log_{10} (i_o/i) \tag{6}$$

Calculated representative values for the first-order rate "constant" k_1 are given in Table 2, col. 4. The systematic drift of the "constant" indicates the invalidity of the assumption of first-order or pseudo-first-order kinetics. The same is obvious from the decided curvature of the graph Fig. 5 b, which in fact is a plot of log (c_o/c) *versus* t and hence should be linear. Salt effects have been neglected, but they are not apt to alter the order of reaction under the present conditions. Though the same reaction mixture was polarographed repeatedly, the consumption of OU_{72} due to the electrode process cannot be made responsible for the deviation. On the first hand it is of a negligible magnitude, and on the other hand it would give rise to an error in the opposite direction.

The data were then tested in the second-order equation

$$k_2 t = c^{-1} - c_o^{-1}$$

or

$$k'_2 t = i^{-1} - i_o^{-1} \tag{7}$$

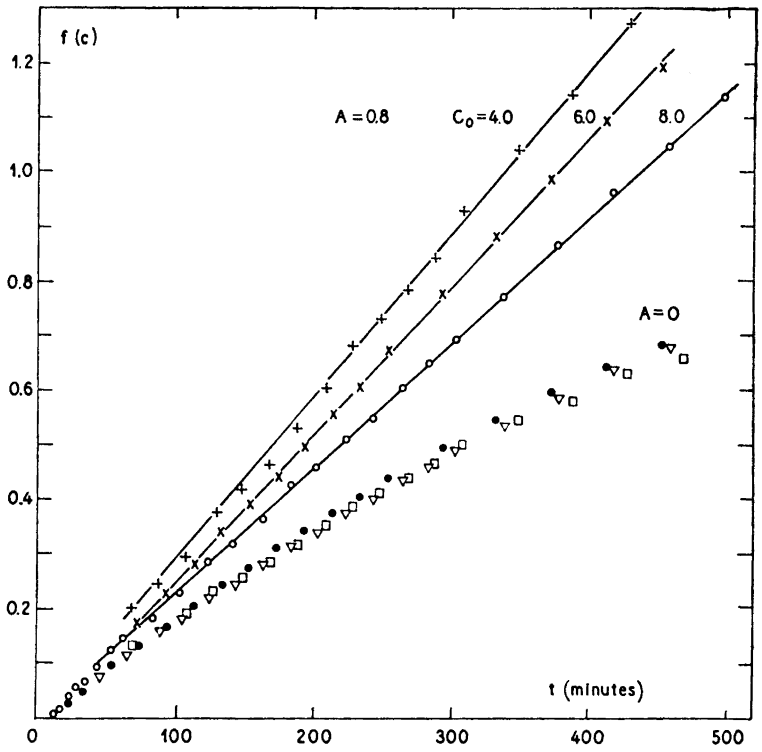

Fig. 7. Plot of the empirical function $f(c) = \log_{10}(c_o/c) + A(c^{-1} - c_o^{-1})$ against time. Data in Tables 8—10.

Non-linearity of the plot of i^{-1} *versus* t indicated that the reaction does not conform to second-order kinetics with respect to OU_{72}.

When general chemical observations are scarce, or present a complicated picture, it is customary to attempt by the method of trial and error to construct a combined function fitting the experimental data with reasonable accuracy. The procedure of Christiansen [7] for a linear sequence of reactions was adopted.

In the equation

$$t = B_1 \cdot I_1 + B_2 \cdot I_2 + \ldots . \qquad (8)$$

t stands for time in minutes, B_1, B_2 . . . are constants and I_1, I_2 . . . are the common integrated kinetic expressions c, $\log(c_o/c)$, $(c^{-1} - c_o^{-1})$, $(c^{-2} - c_o^{-2})$ *etc.* As above c_o is the initial concentration and c the concentration remaining at any time t.

By selecting first- and second-order expressions, respectively, for I_1 and I_2 the modified function (9) was obtained.

$$Bt = \underbrace{\log_{10}(c_o/c)}_{f(c)} + A(c^{-1} - c_o^{-1}) \qquad (9)$$

By the method of hit and miss a value of the constant A was found, which upon insertion of the experimental sets of data c,t (Table 2) rendered the right-hand side of (9) a linear function of t (Fig. 5a). The value $A = 0.2$ is seen to give a statisfactory linearity, except for a short interval at the outset of the reaction (*cf.* p. 1073). The slope of the line is $B = 0.004$. Towards the end of the reaction the scattering is somewhat large, owing to experimental errors, but there is no systematic deviation from linearity up to 95 % advancement. The line does not pass exactly through the origin, but there is a small positive intercept on the ordinate axis. It is uncertain whether this is kinetically significant, but the empirical expression fitting the data in Table 2 is

$$0.004\ t + 0.004 = \log_{10}(c_o/c) + 0.20(c^{-1} - c_o^{-1}) \qquad (10)$$

For the sake of control values of t have been calculated from eqn. 10 They are included in Table 2, col. 6, and show a fair agreement with the experi mental values.

The data in Table 3 were similarly tested in the empirical eqn. 9. In this experiment the pH was unaltered and equal to 12.3 within the accuracy of measurement, ± 0.1, but the initial concentration of OU_{72} was $c_o = 0.2$ mmoles/l. Fig. 6 ($A = 0$) shows the plot of log c_o/c *versus* t. It is decidedly curved, again indicating the invalidity of first-order kinetics. The upper graph represents the mixed function f(c). The selected value of A, which rendered the plot linear, is the same (0.2) as previously found, but it should be pointed out that a reasonable linearity may be achieved for values of A between the limits 0.15 and 0.25 so that the accordance may be incidental rather than significant.

The crucial test of the validity of the empirical expression (9) is the independency of the constants A and B of concentration. The data in Tables 8—12 (*cf.* Fig. 3) were intended for this test. This series of experiments is not directly comparable with the previous ones, since the pH was somewhat lower (12.0). It appears from Fig. 7 that for the three highest concentrations a linear plot of f(c) *versus* t is obtained when 0.8 is selected for the constant A. For the lower concentrations the experimental error gives rise to a considerable scattering of the calculated values of f(c) and it is not possible to select a reasonably well-defined value of A to give linearity. There is no direct indication, however, that A varies with concentration, but this actually needs confirmation by experiments carried out at still higher concentrations. For such measurements, however, the polarographic method is unsuitable.

Table 14. Values of constants A and B (eqn. 9) at 25°C.

pH	12.3 b	12.3 p	12.0 p	12.0 p	12.0 p
c_o	5.0	2.0	8.0	6.0	4.0
A	0.2 ± 0.1	0.20 ± 0.05	0.80 ± 0.05	0.8 ± 0.1	0.8 ± 0.2
$10^3\ B$	4.0 ± 0.5	2.3 ± 0.2	2.3 ± 0.1	2.7 ± 0.2	2.9 ± 0.5
Table	2	3	8	9	10
Fig.	5	6	7	7	7

* b borate buffer p phosphate buffer

The selected values of A and the graphically determined slopes B are summarized in Table 14, with the estimated errors.

The value of A seems to decrease rapidly with increasing pH. The overall process, therefore, seems to approximate to simple first-order kinetics in strongly alkaline solution, probably because a rapid, base-catalyzed, pseudo-first-order isomerization is predominating. In weakly alkaline or neutral solution the overall process seems to proceed by a more complicated sequence of reactions or alternatively by a mechanism of concurrent reactions. The possibility of decomposition into hydroxylamine and cyanate obviously should be taken into account, *cf.* p. 1072.

A discussion of reaction mechanisms in terms of the actual molecular structures will be presented elsewhere in a larger context.

MATERIALS AND GENERAL TECHNIQUE

The preparation and characterisation of the isomeric oxyureas have been reported in a previous publication [8]. Freshly prepared samples were used.

All chemicals used for preparing the supporting buffer-solutions were analytical grade products. The solvent was water, carefully redistilled in Pyrex apparatus.

The compositions of the buffer stock solutions are indicated in Table 15.

Table 15. Composition of buffer stock solutions.

A. 1 M boric acid, 1 M potassium dihydrogen borate
B. 1 M potassium monohydrogen phosphate
C. 1 M potassium hydrogen carbonate
D. 1 M potassium hydroxide

The set of stock solutions used in the various experiments are given in Table 16. Unless otherwise stated appropriate volumes were mixed and diluted to the tenfold volume with water containing 0.02 % methylcellulose as a maximum suppressor.

The instrument for measurement of the pH as well as the polarographic equipment and technique have been described in a previous paper (Ref[1]., p. 468–469).

Table 16.

Experiment Table	Fig.	pH	Stock solutions (c_o. Table 15)		Buffer type
1	1	10.5	A	D	borate
2	1	12.3	A	D	borate
3	2	12.3	B	D	phosphate
4	2	11.5	B	D	phosphate
5	2	10.7	C	D	carbonate
6	2	9.2	A		borate
8–12	3	12.0	B	D	phosphate

Two different capillaries were used for the dropping mercury electrode in the present experiments. The characteristic data for No. 1, employed in the experiments, Tables 1 and 2, were as follows; height of mercury column 45 cm, drop time 3.3 sec, rate of mercury outflow into water 2.7 mg sec^{-1}. The experimental relationship between wave-height i

(diffusion current in μA) and concentration c of OU_{72} was $i/c = 8.0$; (*cf.* Ref.[1], Fig. 4.) Capillary No. 2, employed for the rest of the experiments (Tables 3—6 and 8—12) had the following characteristics; heights of mercury column 23 cm, drop time 3.0 sec, rate of mercury outflow into water 3.0 mg sec^{-1}. The relation between wave-height and concentration for this capillary was $i/c = 8.3$. The conversion factor cannot be determined directly at pH 12 and 25°C with any great accuracy, owing to the rapid isomerization of the substance. It has been established for the employed capillary by measurements of a series of concentrations at pH 9.2, and it is assumed that the same conversion constant is valid at pH 12.2. The assumption is justified by previous experiments (Ref.[1], Fig. 2) showing that the wave-height for a given concentration does not vary significantly with pH in the region 6.3—12.3.

Acid-base, *cis-trans* and Complex Equilibria in the Chromium(III) Ethylenediamine System

FLEMMING WOLDBYE

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

The three *cis-trans* equilibrium constants and the four acid dissociation constants related to the ions $Cren_2(H_2O)_2^{+++}$, $Cren_2(OH)(H_2O)^{++}$ and $Cren_2(OH)_2^{+}$ have been determined by spectrophotometric and glass electrode measurements, respectively. The absorption spectra of these six ions and of the $Cren_3^{+++}$ ion have been recorded. In an attempt to determine the stability constant of this last ion its hydrolysis in ethylenediamine buffers at pH $\geq$ 9.5 has been followed spectrophotometrically. The product of this hydrolysis which proceeds until almost completion except in very concentrated buffers is the *cis-trans* equilibrium mixture of dihydroxobisethylenediaminechromium(III) ions. Only an estimate of the upper limit of the stability constant could be given.

An error in the calculation of the stability constant for the $Coen_3^{+++}$ ion in Ref.[1] has been corrected (p. 1093).

In the present investigation the acid-base and *cis-trans* equilibria of the following system:

$$\begin{array}{ccccccc} cis\text{-}Cren_2(H_2O)_2^{+++} & \rightleftharpoons & cis\text{-}Cren_2(H_2O)(OH)^{++} + H^+ & \rightleftharpoons & cis\text{-}Cren_2(OH)_2^{+} + 2H^+ \\ \updownarrow & & \updownarrow & & \updownarrow \\ tr.\text{-}Cren_2(H_2O)_2^{+++} & \rightleftharpoons & tr.\text{-}Cren_2(H_2O)(OH)^{++} + H^+ & \rightleftharpoons & tr.\text{-}Cren_2(OH)_2^{+} + 2H^+ \end{array}$$

have been determined and the hydrolysis of $Cren_3^{+++}$ in acid and alkaline solution has been studied with the intention to determine the complexity constants

$$k_3 = \frac{[Cren_3^{+++}]}{[Cren_2(H_2O)_2^{+++}]\,[en]}$$

for the *cis-* and *trans* ions, respectively.

Further, the spectra between 650 and 325 mμ of all the species mentioned have been recorded.

The measurements have been carried out at 25.0±0.1°C, and in order to eliminate salt effects a comparatively strong constant salt medium of 1 M

$NaNO_3$ has been used. This also renders the quantities calculated directly comparable with those obtained by Bjerrum and Rasmussen [1] for the corresponding Co(III) system.

Following the notation in Ref.[1] * the constants pertaining to the acid-base equilibria are defined as follows:

$$*k_{s,1}(cis) = \frac{[H^+]\ [cis\text{-}Cren_2(H_2O)(OH)^{++}]}{[cis\text{-}Cren_2(H_2O)_2{}^{+++}]}$$

$$*k_{s,2}(cis) = \frac{[H^+][cis\text{-}Cren_2(OH)_2{}^+]}{[cis\text{-}Cren_2(H_2O)(OH)^{++}]}$$

(and the analogous $k_{s,1}(tr.)$ and $k_{s,2}(tr.)$ for the *trans* system), and the *cis-trans* equilibrium constants are defined as follows:

$$q_0 = \frac{[cis\text{-}Cren_2(H_2O)_2{}^{+++}]}{[tr.\text{-}Cren_2(H_2O)_2{}^{+++}]} \qquad q_1 = \frac{[cis\text{-}Cren_2(H_2O)(OH)^{++}]}{[tr.\text{-}Cren_2(H_2O)(OH)^{++}]} \qquad q_2 = \frac{[cis\text{-}Cren_2(OH)_2{}^+]}{[tr.\text{-}Cren_2(OH)_2{}^+]}$$

Between these seven constants there are two independent relations, so when five of them are determined experimentally, the remaining two can be calculated.

Preliminary spectrophotometric experiments showed that in acid solution ($1 < pH < 2$) the tris-ethylenediamine ion will hydrolyze to form the *cis*-diaquo ion **, which will in turn hydrolyze forming blue, violet and finally green solutions, while the *trans*-diaquo ion apparently partly will isomerize to form the *cis*-diaquo ion at a rate somewhat higher than that of the hydrolysis.

In alkaline solution, however, it has been possible to establish the *cis-trans* equilibrium and so to determine q_2.

The values of the constants obtained at 25°C and in 1 M $NaNO_3$ are:

$*k_{s,1}(cis) = 10^{-4.80}$ mole/l (Co $10^{-6.06}$) $*k_{s,2}(cis) = 10^{-7.17}$ mole/l (Co $10^{-8.19}$)

$*k_{s,1}(tr.) = 10^{-4.08}$ mole/l (Co $10^{-4.45}$) $*k_{s,4}(tr.) = 10^{-7.49}$ mole/l (Co $10^{-7.94}$)

$q_0 = 12.8$ (Co 58) $q_1 = 2.44$ (Co 1.42) $*q_2 = 5.1$ (Co 0.80)

the quantities marked by an asterisk being calculated directly from measurements upon solutions in which the corresponding equilibria were established.

On comparison with the cobalt system (values from Ref.[1] given in parenthesis) it is seen that the chromium compounds are stronger acids than the corresponding cobalt compounds.

As might be expected empirically [1,3], the *trans*-diaquo ion is a stronger acid than the *cis*-diaquo ion with respect to the dissociation of the first proton, but this difference is smaller than that between the corresponding cobaltic ions. The ratio of the first and second acid dissociation constants is

for the *cis*-diaquo ions $10^{2.37}$ (Co $10^{2.13}$)

" " *trans* " " $10^{3.41}$ (Co $10^{3.39}$)

* C_A and [A] designate initial and actual concentration of A in mole/liter.

** This is in accordance with the findings of Schläfer and Kling[2], who have made a kinetic investigation of this reaction.

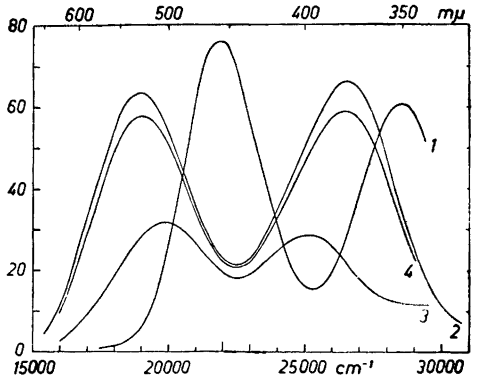

Fig. 1. Spectra in 1 M $NaNO_3$ at 25°C of the ions $Cren_3^{+++}$ (1), *cis*-$Cren_2(OH)_2^+$(2) *trans*-$Cren_2(OH)_2^+$(3) and of the *cis-trans* equilibrium mixture of the $Cren_2(OH)_2^+$ ions(4). The equilibrium spectrum has been calculated from the spectra of the pure isomers using the *cis-trans* equilibrium constant $q_2 = 5.1$ (see Table 5).
Abscissa: Wave numbers in cm^{-1} and wavelength in mμ.
Ordinate: The molar decadic extinction coefficient.

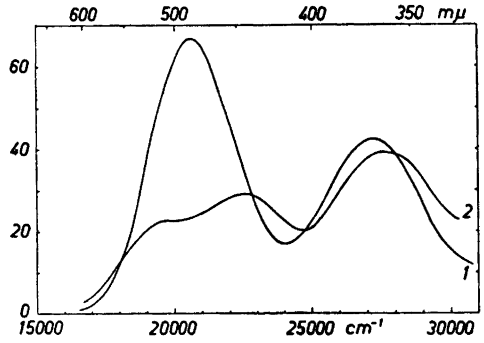

Fig. 2. Spectra in 1 M $NaNO_3$ at 25°C of the ions *cis*-$Cren_2(H_2O)_2^{+++}$ (1) and *trans*-$Cren_2(H_2O)_2^{+++}$(2).
Abscissa: Wave numbers in cm^{-1} and wavelength in mμ.
Ordinate: The molar decadic extinction coefficient.

Figs. 1, 2 and 3 show the spectra of the species concerned in this investigation recorded in 1 M $NaNO_3$ solution in the region of 650 mμ—325 mμ, and in Table 1 are given the data of the maxima in the spectra.

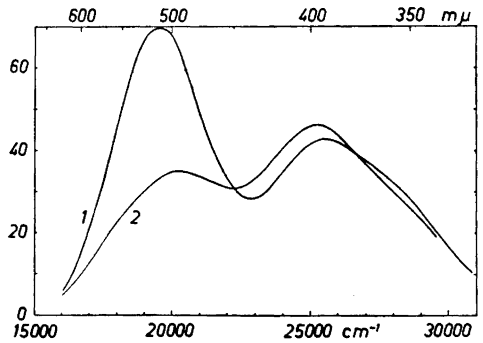

Fig. 3. Spectra in 1 M $NaNO_3$ at 25°C of the ions *cis*-$Cren_2(OH)(H_2O)^{++}$(1) and *trans*-$Cren_2(OH)(H_2O)^{++}$(2). These spectra are the averages of those calculated from the solutions in Table 2 which differed 2—3 % with respect to the extinction coefficients.
Abscissa: Wave numbers in cm^{-1} and wavelength in mμ.
Ordinate: The molar decadic extinction coefficient.

Table 1. Data of maxima in the spectra shown in Figs. 1, 2 and 3; 25°C, 1 M $NaNO_3$.

tr.-$Cren_2(H_2O)_2^{+++}$	19 700	22.5	22 600	29.3	27 700	39.2
cis-$Cren_2(OH)(H_2O)^{++}$	19 550	69.3	25 550	43.0		
tr.-$Cren_2(OH)(H_2O)^{++}$	20 200	35.0	25 250	46.0		
cis-$Cren_2(OH)_2^{+}$	19 000	63.6	26 550	66.0		
tr.-$Cren_2(OH)_2^{+}$	19 900	31.8	25 250	28.9		

The absorption curves have been measured at 25° ± 1°C by means of a Cary Recording Spectrophotometer.

The $Cren_3^{+++}$ ion is sufficiently robust for a direct recording of its spectrum in acid, neutral and alkaline solutions. As expected the spectra thus obtained are identical and in fair agreement with spectra published earlier [2,4].

The *cis*- and *trans*-$Cren_2(H_2O)_2^{+++}$ and $Cren_2(OH)_2^{+}$ ions, however, are so labile that small changes in the absorption of their solutions can be registered within a few minutes after preparation of the solutions. Therefore the following procedure was used in recording their spectra: The solvent was prepared at 25°C, the solute added and dissolved at time 0 and the solution made up to the mark and the first absorption curve recorded at time 3 min. During the next 15 min another 3 absorption curves were recorded on the same sheet, and the absorption curve of the pure substance was then obtained by extrapolation to time 0. In all cases the differences between the curve obtained after 3 min and the extrapolated curve were very small, namely from 1 to 3 times the experimental uncertainty. In each case the pH of the solution was measured immediately after preparation.

The spectra of the *cis*- and *trans*-aquohydroxo ions have been calculated from the absorption curves of solutions, the pH of which has been adjusted so that they would contain a relatively large concentration of the ion in question, a smaller concentration of either the corresponding diaquo or dihydroxo ion and a negligible amount of the remaining of these three ions. The data of these solutions are given in Table 2.

A calculation of the spectrum of the *cis*-$Cren_2(OH)(H_2O)^{++}$ from the two first solutions by subtracting the absorption of the $Cren_2(H_2O)_2^{+++}$ and the $Cren_2(OH)_2^{+}$, respectively, from the total absorption of the solutions yielded

Table 2. Composition of the solutions from which the spectra of the *cis*- and *trans*-$Cren_2(OH)(H_2O)^{++}$ have been calculated. C_{Cr} indicates total complex concentration. Concentrations are in mole/l. 25°C, 1 M $NaNO_3$.

C_{Cr}	pH	$[Cren_2(OH)(H_2O)^{++}]$	$[Cren_2(OH)_2^{+}]$	$[Cren_2(H_2O)_2^{+++}]$
0.02875 *cis*	5.033	0.0181	0.0002	0.0105
0.02879 *cis*	6.517	0.0235	0.0052	0.0001
0.01268 *tr.*	5.876	0.0122	0.0003	0.0002
0.00973 *tr.*	4.159	0.00532	negligible	0.00441

two curves which were in complete agreement with respect to the wavelengths of their maxima and differed less than 2 % with respect to the extinction coefficients. Similar results were obtained for the *trans*-$Cren_2(OH)(H_2O)^{++}$ except that the difference between the extinction coefficients at some wavelengths amounted to as much as 3 %. This agreement furnishes a good cross-check of the values of the acid dissociation constants.

An interesting feature of these two spectra is the "shoulder" near 29 000 cm^{-1} which at least in the *cis*-spectrum seems far beyond the experimental uncertainty.

EXPERIMENTAL

Preparations. *$Cren_3Cl_3,3\frac{1}{2}H_2O$* was prepared from $CrCl_3$ and anhydrous ethylenediamine according to the method of Linhard and Weigel [5] except that the precipitation was effected by means of ethanol instead of NH_4Cl. (It was found by analysis that precipitates produced by NH_4Cl contained NH_4Cl which was difficult to remove by recrystallization.) The salt was reprecipitated and the spectrum was shown not to be influenced by further reprecipitations or recrystallizations.

cis- and trans-$Cren_2(H_2O)_2Br_3$ were prepared according to the following scheme:

$$Cren_3(ClO_4)_3 \xrightarrow[70°]{HCl} \left[\begin{array}{l} cis\text{-}Cren_2Cl_2ClO_4 \rightarrow cis\text{-}Cren_2(OH)(H_2O)S_2O_6 \rightarrow cis\text{-}Cren_2(H_2O)_2Br_3,2H_2O \\ \qquad\qquad \downarrow \; HgBr_2 \;\Big|\; HBr \\ tr.\text{-}(Cren_2Br_2)Br,HgBr_2 \rightarrow tr.\text{-}Cren_2(OH)(H_2O)Br_2 \rightarrow tr\text{-}Cren_2(H_2O)_2Br_3,2H_2O \end{array}\right.$$

cis-$Cren_2Cl_2ClO_4$ was prepared according to Ref.[5], p. 119. To prepare *cis*-$Cren_2(H_2O)_2Br_3$, 6 g *cis*-$Cren_2Cl_2ClO_4$ was dissolved in *ca.* 50 ml warm water and the solution heated until colour change from violet to orange. 10 ml pyridine and excess of $Na_2S_2O_6$ were added and the solution cooled in ice for 1 h whereby the *cis*-aquohydroxo dithionate was precipitated. Treament of this with HBr yielded *ca.* 3 g *cis*-$Cren_2(H_2O)_2Br_3$, $2H_2O$.

To prepare the corresponding *trans*-compound 8.5 g *cis*-$Cren_2Cl_2ClO_4$ was dissolved in 30 ml water at 50°C and 16 g $HgBr_2$ and 16 ml const. boil. HBr were added. The solution was evaporated to dryness on the steam bath and the residue washed with water containing HBr until colourless filtrate, leaving bright green, slightly soluble crystals of *trans*-$(Cren_2Br_2)Br,HgBr_2$ in a yield of 13.5 g. A suspension of 19 g of this salt in 20 ml water was saturated with H_2S and the HgS removed by centrifuging. Spectra of the solution recorded at regular intervals indicated that a maximum of *trans*-$Cren_2(H_2O)_2^{+++}$ was present after 24—36 h at *ca.* 22°C. The solution was then saturated with KBr and 20 ml pyridine was added. The pink precipitate formed after cooling in ice for 1 h was washed several times with 50 % ethanol to remove most of a considerable content of KBr, leaving 2.5 g *trans*-$Cren_2(H_2O)(OH)Br_2$. Treatment of this salt with the equivalent amount of const. boil. HBr yielded 2.2 g *trans*-$Cren_2(H_2O)_2Br_3,H_2O$.

The diaquobisethylenediamine salts were originally prepared by Pfeiffer [6] along the path outlined here

$$CrCl_2(H_2O)_4Cl,2H_2O \xrightarrow{py} Crpy_2(OH)_2(H_2O)_2Cl \xrightarrow{en} (Cren_2(H_2O)Br)Br_2$$

$$(Cren_2(H_2O)Br)Br_2 \rightarrow cis\text{-}Cren_2(OH)(H_2O)Br_2 \rightarrow cis\text{-}Cren_2(H_2O)_2Br_3,2H_2O$$

$$\downarrow \; HgBr_2 \;\Big|\; HBr$$

$$tr.\text{-}(Cren_2Br_2)Br,HgBr_2 \rightarrow tr.\text{-}Cren_2(OH)(H_2O)Br_2 \rightarrow tr.\text{-}Cren_2(H_2O)_2Br_3,H_2O$$

Considering that $Cren_3Cl_3$ is now so easily accessible, the procedure outlined above seems more convenient.

Analysis. The salts prepared have been analyzed as follows. *Chromium* has been determined on a semimicro scale either by decomposition with sulfuric acid, heating in

hydrogen atmosphere and weighing as Cr_2O_3, or by a complexometric method, boiling the salt with a known amount of ethylenediaminetetraacetic acid in a buffer solution at pH about 4.6 and back titrating the excess of ENTA with zinc sulfate, using eriochromschwartz as an indicator [2].

Halogen has been determined by weighing as silver halide and *nitrogen* by the Kjeldahl method.

The diaquo salts have been titrated potentiometrically as dibasic acids.

The results of these analyses are given in Table 3.

ACID DISSOCIATION CONSTANTS OF THE DIAQUO- AND THE AQUOHYDROXO-IONS

The acid dissociation constants of the *cis*- and *trans*-diaquobisethylenediamine ions at 25°C were calculated from glass electrode measurements of hydrogen ion concentrations in solutions of the complex salts partly neutralized with sodium hydroxide.

The measurements were made with a selected glass-electrode the performance of which had been tested [7] and a PHM 3 pH-meter from "Radiometer", Copenhagen.

Readings of the EMF of the cell glass-electrode calomel electrode are designated E.

As a standard was used dilute nitric acid in which $C_{HNO_3} = 0.005005$; $C_{NaNO_3} = 1.000$. Readings in this solution are designated E_{st}.

As a consequence of the isomerization of the *cis*- and *trans*-ions and the difference in acid strength of the corresponding *cis*- and *trans*-acids, the hydrogen ion concentration in a (freshly prepared) solution of a pure *cis*- or *trans*-salt will vary with time.

By a rapid preparation of the solutions it was possible to make the first measurement 30 sec after the solid had dissolved * (when finely powdered, the salts dissolve very rapidly). The measurements were then continued for

* The glass-electrode requires some time for its adjustment, so meaningful measurements can hardly be made faster.

some time and E was recorded as a function of time. The E data of Table 4 are the results of an extrapolation of these functions to time zero. The rate of change of E was in no case higher than 1.5 mV/min. E_{st} was recorded before and after each set of measurements, and the results never varied more than 0.3 mV.

The acid dissociation constants have been calculated by means of formulae of the type derived by J. Bjerrum [1,8].

The average number of protons produced by the diaquo ion may be calculated from the experimental quantities as

$$\bar{\nu} = \frac{C_{NaOH} + [H^+] - [OH^-]}{C_{Cr}}$$

and expressed in terms of $k_{s,1}$ and $k_{s,2}$ as

$$\bar{\nu} = \frac{k_{s,1}[H^+] + 2k_{s,2}\cdot k_{s,2}}{[H^+]^2 + k_{s,1}[H^+] + k_{s,1}\cdot k_{s,2}}$$

Combining these expressions and rearranging, one obtains for $\nu < 1$

$$-\log k_{s,1} = -\log[H^+] + \log\frac{1-\bar{\nu}}{\bar{\nu}} + \log\left(1 + \frac{(2-\bar{\nu})k_{s,2}}{(1-\bar{\nu})\ [H^+]}\right)$$

for $\bar{\nu} > 1$

$$-\log k_{s,2} = -\log\ [H^+] + \log\frac{2-\bar{\nu}}{1-\bar{\nu}} - \log\left(1 + \frac{\bar{\nu}[H^+]}{(\bar{\nu}-1)k_{s,1}}\right)$$

In the experiments recorded in Table 4 $\bar{\nu}$ has been kept close to 0.5 and 1.5, respectively, in order to ensure the smallest possible uncertainty in the calculated constants (*i.e.* in the terms $\frac{1-\bar{\nu}}{\bar{\nu}}$ and $\frac{2-\bar{\nu}}{\bar{\nu}-1}$, respectively).

THE *cis-trans* EQUILIBRIUM CONSTANTS

Spectrophotometric experiments have shown that in acid solution the *trans*-$Cren_2(H_2O)_2^{+++}$ isomerizes to form the corresponding *cis*-ion (roughly estimated the conversion is almost completed within 24 h at 25°C in 1 M $NaNO_3$, $[H^+] \sim 0.02$). But the rate of hydrolysis of the *cis*- and the *trans*-ions can not be neglected in comparison to the rate of isomerization. Thus the spectrum of a 24 h old solution of the *cis*-salt cannot be very accurately represented by a linear combination of the spectra of the *cis*- and *trans*-ions. Because of this hydrolysis and because of the fact that the equilibrium mixture of the two ions according to a rough calculation would contain less than 10 % of the *trans*-ion, no attempt has been made to determine the *cis-trans* equilibrium constant in acid solution.

In an ethylenediamine buffer solution at about pH = 10 the *cis*- and *trans*-$Cren_2(OH)_2^+$ are sufficiently stable to allow the *cis-trans* equilibrium to be established. Such equilibrium mixtures have been analyzed spectrophotometrically and chromatographically.

For the spectrophotometric determination of the *cis-trans* constant a weighed amount of *cis-* (or *trans-*) $Cren_2(H_2O)_2Br_3,2H_2O$ was dissolved in a suitable ethylene diamine buffer solution prepared from standard ethylene diamine solution, standard nitric acid and 5 M $NaNO_3$ in such a way that in the final solution pH would be close to 10 and $[NO_3^-] = 1$.

The solution was prepared and kept at 25°C in a dark bottle, and the spectrum of the solution was recorded immediately after preparation and at intervals until no further change could be observed. The *cis-* as well as the *trans*-solutions finally exhibited the equilibrium spectrum shown in Fig. 1 corresponding to 83.6 % *cis-* and 16.4 % *trans*-$Cren_2(OH)_2^+$.

Table 5 shows the data from four experiments of this type from which q_2 may be calculated. ε_{cis} and $\varepsilon_{tr.}$ designate the extinction coefficients of *cis-* and *trans*-$Cren_2(OH)_2^+$, respectively. The quantities $\varepsilon_{cis} - \varepsilon_t$ and $\varepsilon_t - \varepsilon_{tr.}$ have been calculated from the spectra using the formula $\dfrac{|D^\circ - D^t|}{l \times C_{Cr}}$ where

$|D^0—D^t|$ is the difference in the optical density of the solution at time 0 and at time t read directly from the curves recorded by the Cary, and l is the cell length. The degree of reaction, α, α has been calculated from $\alpha = \frac{\varepsilon_{cis} - \varepsilon_t}{\varepsilon_{cis} - \varepsilon_{tr.}}$ and $\alpha = \frac{\varepsilon_t - \varepsilon_{tr.}}{\varepsilon_{cis} - \varepsilon_{tr.}}$ and q_2 from $q_2 = \frac{1-\alpha}{\alpha}$, and $q_2 = \frac{\alpha}{1-\alpha}$, respectively.

In order to check these values further, an aliquot of each of the equilibrium solutions was acidified by means of nitric acid, the volume was doubled after addition of sufficient $NaNO_3$ to keep $[NO_3^-] = 1$, and the spectrum was recorded immediately after. When working fast, one may assume that the ratio of the *cis*- and *trans*-ions will remain almost unchanged during this procedure, so q_2 may likewise be calculated from these spectra. The results of these experiments are also given in Table 5. Here ε_{cis} and $\varepsilon_{tr.}$ designate the extinction coefficients of *cis*- and *trans*- $Cren_2(H_2O)_2^{+++}$, respectively.

For the chromatographic determination of the *cis-trans* constant was used a two years old solution prepared by dissolving $Cren_3Cl_3$ in an ethylenediamine buffer of a composition similar to that mentioned above *. As will be seen from the following, the $Cren_3^{+++}$ in such a solution will be converted into an equilibrium mixture of *cis*- and *trans*-$Cren_2(OH)_2^+$ whereupon a very slow process of unknown character takes place. Due to practical difficulties the solution could not be kept at 25 + 0.1°C for two years but prior to the following experiment it was kept at 25°C for some days in order to establish the equilibrium between possible contents of *cis*- and *trans*-$Cren_2(OH)_2^+$ corresponding to this temperature.

By a technique similar to that described in Ref.[9] an aliquot of the solution was then chromatographed on a column of Al_2O_3. The eluate obtained using 0.1 M KOH, 1 M KCl as an eluent, contained two red fractions which were collected separately in nitric acid at 0° and examined spectrophotometrically. The shape of the spectra (*i.e.* number and position of bands and the relative heights of these bands) was identical with the shape of the spectra of *trans*- and *cis*-$Cren_2(H_2O)_2^{+++}$, respectively, the first of the fractions exhibiting the *trans* spectrum.

Experiments showed that when a freshly prepared solution of *cis*- and *trans*-$Cren_2(OH)_2^+$ is run through the column, the two ions get separated and may be collected at a loss of only a few per cent of each. In accordance with a rule that seems rather general the *trans* ion shows the weaker adsorption on the column.

This strongly indicates that the two red fractions from the equilibrium solution actually represent its content of *trans*- and *cis*-$Cren_2(OH)_2^+$.

Since the eluate from the column was too dilute to permit an accurate spectrophotometric determination of the content of *cis*- and *trans*-$Cren_2(H_2O)_2^{+++}$, the chromium content in the two fractions was instead determined titrimetrically. (Decomposition by evaporating to dryness, heating the residue with H_2SO_4, dissolving and oxidizing chromium(III) to chromium(VI) by means of $K_2S_2O_8$ in the presence of Ag^+, and finally titrating with Fe^{++} using barium diphenylaminesulfonate as an indicator [10].)

The eluate from a chromatogram of 20 ml equilibrium solution was found to contain: in the *trans* fraction 0.029 mmole and in the *cis* fraction 0.133 mmole chromium. (This corresponds to about 60 % of the original chromium content of the solution. The rest of the chromium was so strongly adsorbed on the column that it could not be displaced.) Thus $q_2 = 4.6$ with an estimated uncertainty of $\pm$ 10 %.

However, the spectrophotometric determinations of q_2 given in Table 5 must be considered the more accurate, and the average of these $q_2 = 5.1$ combined with $k_{s,1}(cis)$, $k_{s,2}(cis)$, $k_{s,1}(tr.)$ and $k_{s,2}(tr.)$ yields $q_1 = 2.44$ and $q_0 = 12.8$.

THE HYDROLYSIS OF THE TRISETHYLENEDIAMINECHROMIUM(III) ION IN ALKALINE SOLUTION

In order to determine the complexity constants

$$k_3 = \frac{[\mathrm{Cren_3}]}{[\mathrm{Cren_2(H_2O)_2}^{+++}][\mathrm{en}]}$$

(for the *cis*- and *trans*-ions, respectively) it was attempted to establish the equilibrium

$$\mathrm{Cren_3}^{+++} + 2\ \mathrm{OH}^- \rightleftharpoons \mathrm{Cren_2(OH)_2}^{+} + \mathrm{en}$$

at 25°C in a 1 M salt medium. Preliminary spectrophotometric experiments have shown that in a strongly alkaline (as well as in acid) solution the hydrolysis will proceed further than this first step. On the other hand, test tube experiments have shown that a solution of $\mathrm{Cren_3Cl_3}$ in the following medium: 2 g en,2HCl + 2 g 75 % en + 3 ml $\mathrm{H_2O}$ ($\mathrm{enH}^+/\mathrm{en} \sim 3$) will stay yellow at room temperature as well as at 100°C. And a solution of $\mathrm{Cren_2(H_2O)_2Br_3}$ in this medium slowly turns yellow. Therefore it was hoped that the above equilibrium could be established in an ethylenediamine buffer at about pH = 10 ($\mathrm{p}k_{\mathrm{enH}^+} = 10.2$, Ref. [11]).

In such solutions it would be possible to follow the hydrolysis and to calculate $[\mathrm{Cren_3}^{+++}]$ and $[\mathrm{Cren_2(OH)_2}^{+}]$ in an eventual equilibrium solution spectrophotometrically, and [en] could be determined by means of glass-electrode measurements. Provided that the above hydrolysis is the only reaction taking place, the degree of conversion of $\mathrm{Cren_3}^{+++}$ into $\mathrm{Cren_2(OH)_2}^{+}$, α, in a solution in which the initial concentration of $\mathrm{Cren_3}^{+++}$ is C_{Cr}, may be calculated from

$$\alpha = \frac{D_0 - D_\alpha}{l \times C_{\mathrm{Cr}}(\varepsilon_{\mathrm{Cren_3}^{+++}} - \varepsilon_{\mathrm{Cren_2(OH)_2}^{+}})} \qquad (1)$$

where D_0 and D_α are the optical densities at the wavelength λ of the solution before and after the conversion has taken place, while ε is the extinction coefficient at the wavelength λ of the species in the subscript, and l is the cell length.

Table 6. Data of isosbestic points. The uncertainties refer to the reproducibility of the isosbestic points.

	44.5	43.0	44.0 ± 0.5	42.8 ± 0.5

Calculating α in an equilibrium solution, one should obviously insert for $\varepsilon_{Cren_2(OH)_2^+}$ the extinction coefficient of the *cis-trans* equilibrium mixture of the dihydroxo ions *. When calculating α in a solution not yet in equilibrium, one is presented with the question of which value to insert for $\varepsilon_{Cren_2(OH)_2^+}$. It seems reasonable to assume that the first hydrolysis product would be the *cis*-dihydroxo ion which would then isomerize to form the *cis-trans* equilibrium mixture:

$$Cren_3^{+++} \rightarrow \textit{cis}\text{-}Cren_2(OH)_2^+ \rightleftharpoons \textit{tr.}\text{-}Cren_2(OH)_2^+$$

Qualitatively it may be seen that if the isomerization were fast compared to the hydrolysis, it would be permissible to consider the ratio

$$\frac{[\textit{tr.}\text{-}Cren_2(OH)_2^+]}{[\textit{cis}\text{-}Cren_2(OH)_2^+]}$$

as a constant (and equal to the equilibrium ratio) during the reaction; otherwise this ratio would be a function of time increasing from zero to the equilibrium ratio.

This problem might be circumvented by choosing values of λ within a range where there is very little difference between the extinction of the *cis* ions and the extinction of the *cis-trans* equilibrium mixture (*vide* Fig. 1).

But fortunately the question may be settled spectrophotometrically by consideration of the isosbestic points which are likewise useful in deciding whether $Cren_3^{+++}$ and *cis*- and *trans*-$Cren_2(OH)_2^+$ are the only species present in the solutions.

* provided concentrations of *cis*- and *trans*-$Cren_2(OH)(H_2O)^{++}$ may be neglected. For the purpose of the following discussion this approximation is certainly sufficient for pH > 9.5. Due to the similarity between the spectra of the ions in question the correction that would have to be made for the content of $Cren_2(OH)(H_2O)^{++}$ does not exceed the experimental uncertainty until this content exceeds 5 % of $[Cren_2(OH)_2^+]$.

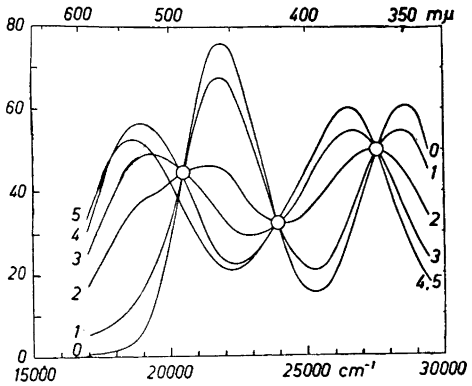

Fig. 4. Spectra in 1 M $NaNO_3$ at 25°C of solution No. 1 in Table 7 at time 0 (0), 69 h (1), 334 h (2), 624 h (3), 1 800 h (4) and 5 900 h (5).
Abscissa: Wave numbers in cm^{-1} and wavelength in mμ.
Ordinate: The molar decadic extinction coefficient.

A number of solutions of $Cren_3Cl_3$ in ethylenediamine buffers at pH $\geqq$ 9 containing the buffer system in various concentrations has been prepared and followed spectrophotometrically and by glass electrode measurements. In no cases, however, it was possible to establish an equilibrium containing analyzable amounts of $Cren_3^{+++}$.

To illustrate the results of these experiments the data of two representative solutions are given in Table 7 and the spectra of No. 1 of these are recorded in Fig. 4. It is seen that all of the consecutive spectra (except that at $t=5$ 900 h) have three common points of intersection. In Table 6 the wavelengths at which these points occur are compared to those which may be predicted from the spectra in Fig. 1 assuming that the components of the mixture are either $Cren_3^{+++}$ and *cis*-$Cren_2(OH)_2^+$ or $Cren_3^{+++}$ and the *cis-trans* equilibrium mixture of the dihydroxo ions. Further the isosbestic extinction coefficients observed ($\varepsilon = D/C_{Cr} \times$ cell length) are compared to those calculated under the two assumptions. A fairly good agreement is found with the assumption that the *cis-* and *trans*-dihydroxo ions are present in their equilibrium ratio. But the points of intersection in the spectra of the reaction mixtures can of course not be determined very accurately until the shape of the spectrum is considerably different from the initial shape. The validity of the above arguments is therefore limited to solutions in which $\alpha >$ *ca.* 40 %, although there is no experimental evidence against their validity at lower values of α*.

* This agreement is, therefore, not at variance with the assumption that the *cis*-dihydroxo ion is the first hydrolysis product. If one solves the differential equations pertaining to the mechanism

$$A \xrightarrow{k_1} B \underset{k_3}{\overset{k_2}{\rightleftharpoons}} C$$

and calculates the ratio [B]/[C] as a function of time in a system which at time zero contains only A inserting $k_3 = 5k_2 = 10k_1$ (which is not very far from correct for the solutions considered here, vide Tables 5 and 7), one finds that when 50 % of A has disappeared [B]/[C] is only 12 % greater than the equilibrium value.

The results of calculating α from (1) at suitable wavelengths inserting the *cis-trans* equilibrium values of $\varepsilon_{Cren_2(OH)_2}{}^{+}$ are given in Table 7. Here, the quantity $\frac{D_o-D_\alpha}{l \times C_{Cr}}$ has been designated $\varepsilon_o-\varepsilon_t$. From the data concerning solution No. 1 it may be concluded that the primary reaction is an almost complete conversion of $Cren_3{}^{+++}$ into $Cren_2(OH)_2{}^{+}$. But the solution thus formed is not a true equilibrium solution, as its spectrum continues to change very slowly so that the absorption in the ultraviolet increases while the band at 19 000 cm^{-1} moves towards longer wavelengths and decreases slightly. This behaviour is typical of most of the solutions investigated.

In solution No. 2 the buffer concentration has been increased. Also in this medium $Cren_3{}^{+++}$ is almost completely converted into $Cren_2(OH)_2{}^{+}$, but the following changes in the spectrum are extremely slow (the spectrum was practically unchanged for a year except for a slight increase in the ultraviolet). It may therefore be assumed that the desired equilibrium has very nearly been established in this solution. The accuracy of the spectrophotometric measurements, however, does not permit a determination of $[Cren_3{}^{+++}]$.

An attempt was therefore made to determine this concentration chromatographically. It was shown that when a mixture of the trisethylenediamine and the *trans*- and *cis*-dihydroxo ions was chromatographed on a column of Al_2O_3 using 0.1 M KOH, 1 M KCl as an eluent, the three ions were clearly separated and eluated in the said order. 20 ml of solution No. 2 were chromatographed this way and all of the apparently colourless effluent (*ca.* 30 ml) leaving the column in front of the *trans* band was collected. The optical density of this effluent in an absorption cell with a 10 cm light path was recorded by the Cary whereby it should be possible to ascertain the presence of $Cren_3^{+++}$ in concentrations down to about 7×10^{-5} mole/l which would give rise to the optical density 0.05 at the maximum of the highest absorption band. However, the optical density observed was smaller than this, and it would hardly be safe to draw any other conslusion from the experiment than that $[Cren_3^{+++}]$ in the effluent was below 5×10^{-5} mole/l and in solution No. 2 therefore below 7.5×10^{-5} mole/l corresponding to $\alpha \sim 99.5$ %.

Although it is impossible to determine the stability constant k_3 from the present experiments, it is still of some interest to estimate its maximum value. Using the data of solution No. 2 in Table 7 at $t = 5\,220$ h: $-\log[H^+] = 9.85$, $[en] = 0.16$ (calculated under the assumption that one molecule en has been split off by the $Cren_3^{+++}$), $[OH^-] = 1.07 \times 10^{-4}$ (calculated using for the ionic concentration product of water, $k_{H_2O} = 10^{-13.82}$, the value given by Bjerrum and Unmack [12] for 1 M KCl at 25°C) and $\alpha \geqq 99.5$ %, this may be done as follows. Let us define a hydrolysis constant for $Cren_3^{+++}$

$$k_{h,1} = \frac{[Cren_2(OH)_2^+]\,[en]}{[Cren_3^{+++}]\,[OH^-]^2} = \frac{\alpha\,[en]}{(1-\alpha)\,[OH^-]^2}$$

Inserting the above values, we obtain $k_{h,1} \geqq 3 \times 10^5$ (Co 1.76). The corresponding constants $k_{h,1}(cis)$ and $k_{h,1}(tr.)$ are connected through

$$k_{h,1}(cis) + k_{h,1}(tr.) = k_{h,1} \text{ and } \frac{k_{h,1}(cis)}{k_{h,1}(tr.)} = q_2$$

Thus $k_{h,1}\ (cis) \geqq 2.5 \times 10^5$ (Co 0.78) and $k_{h,1}\ (tr.) \geqq 5 \times 10^4$ (Co 0.98). k_3 is related to these quantities through

$$k_3 = \frac{k_{s,1} \cdot k_{s,2}}{k_{h,1} \cdot k_{H_2O}^2}$$

In Ref.[1] k_3 for the cobalt(III) ethylenediamine system has erroneously been calculated from

$$k_3 = \frac{k_{h,1} \cdot k_{s,1} \cdot k_{s,2}}{k_{H_2O}^2}$$

Due to the fact that in the cobalt system $k_{h,1}$ is not very far from unity (when measured in liter/mole) the errors thus introduced are fortunately relatively small. The corrected values are given in parenthesis below.*

* As a consequence of these corrections the quantities calculated for the cobalt (III) ethylenediamine system at ionic strength, $\mu = 1$ and 30°C (Table 1 of Ref. 1) should be changed as follows:

$\log k_1 = 19.2$ $\log k_2 = 16.2$ $\log k_3 = 13.31$ $\beta_1 = 1986$ $\beta_2 = 137$

Inserting the appropriate constants, we arrive at

$$k_3(cis) \leqq 10^{10.2}\ (\mathrm{Co}\ 10^{13.50})\ k_3(tr.) \leqq 10^{11.3}\ (\mathrm{Co}\ 10^{15.26})$$

and defining $k_3(gr.)$ as k_3 for a system in *cis-trans* equilibrium so that

$$\frac{1}{k_3(cis)} + \frac{1}{k_3(tr.)} = \frac{1}{k_3(gr.)}$$

we obtain

$$k_3(gr.) \leqq 10^{10.2}\ \text{liter/mole}\ (\mathrm{Co}\ 10^{13.49}).$$

Acknowledgement. I wish to thank the head of this laboratory, Professor Jannik Bjerrum for having suggested this investigation, for valuable advice and encouragement and for his never failing interest in this work. My thanks are further due to Civilingeniør C. W. Kallenbach Pedersen, for his valuable experimental assistance.

Remarks on Evaluating Kinetic Data for Technical Purposes

OTTO STELLING and OTTO von KRUSENSTIERNA

Division of Applied Inorganic Chemistry, Royal Institute of Technology, Stockholm, Sweden

The chemical engineer studying the kinetics of catalyzed reactions is often unaware of the limitations of his experimental method and uses hidden parameters which diminish the value of his data. The Langmuir-Hinshelwood method, the Hougen-Watson method and the exponential equations of Temkin are critically discussed. The conclusion is that, independant of the choice of adsorption isotherm, the same rate equation can be derived. The backward rate expression cannot be derived exactly from the forward rate expression but some restrictions on the form of the backward rate expression can be obtained with the help of Horiuti's "stoichiometric numbers". Some often occurring weak points in kinetic investigations are summarized and a standard procedure for kinetic investigations is outlined and illustrated with an experimental investigation of the watergas-shift reaction.

The processing techniques of the chemical industry show now a very marked tendency to change from the classical discontinuous processes as those of the dye industry to modern continuous processes exemplified by the petrochemical industry. These modern processes are often based on heterogeneous catalysis and the desired product is obtained by the use of the highest possible accuracy in the process control. This change in the industry has been made possible by a better general knowledge of the processes and especially by a more detailed understanding of all the kinetic problems involved. These problems have to be solved before a calculation of the engineering equipment of a process can start. If kinetics is defined as including both the chemical processes and the physical processes of mass- and heat-transfer one is bound to state that the branch of kinetics has a dominating position in modern chemical engineering research.

The chemical engineer and the research-chemist approach the problems of heterogeneous kinetics from two different sides. The chemical engineer is usually satisfied if he can find a rate equation reliable enough to permit reactor calculations and process control in the practical working range of pressures and temperatures. The research-chemist on the other hand wants to find the reaction mechanism itself with the help of experimental kinetic data and

tries to determine the simple primary reaction steps from which the complicated total reaction is built up. The distance between these two outlooks has been lessening during the last decades in as much as the interest of the chemical engineer is changing into a more exact knowledge of the mechanism of a reaction and its bearings on process possibilities and catalyst characteristics. The exact determination of the reaction mechanism in detail to its primary steps is, however, still very difficult and even such simple classical reactions as the oxidation of hydrogen and of carbon monoxide are still debated.

The main difficulty in mechanism determinations is often the experimental accuracy which is too limited to determine the often very small differences between different reaction mechanisms. This means that it usually pays back to invest work in increasing the experimental accuracy and to use an experimental approach that gives crucial data rather than general ones which are used for calculations based on more or less plausible mechanisms. On the other hand, as Christiansen [1] recently has pointed out, an *underestimation* of the accuracy can lead to serious consequences when data are used to fit a chosen mechanism.

Many different experimental methods and methods of data evaluation have been used in the study of kinetics and it is easy to understand that sometimes kineticists have been unaware of the limitations in their experimental method. Very often hidden parameters make the general treatment of valuable experimental data impossible. An often occurring case is the laboratory chemist who neglects the importance of diffusion processes and produces data which have only a limited value outside the laboratory. The chemical engineer on the other side often makes too far reaching conclusions about the nature of the plausible reaction mechanism which fits his data.

With these views in mind we have thought it to be of some value to discuss critically some of the methods which usually have been used for the kinetic investigations of heterogeneous processes of technical interest. In connection with this discussion we propose a standard procedure to be followed in investigations of this kind and which perhaps could help to diminish the confusion which one encounters in the current literature. As an example of this procedure we finally give some data from a kinetic investigation of the watergas-shift reaction.

THE LANGMUIR-HINSHELWOOD METHOD

The classical Langmuir-Hinshelwood method has in many cases given a good qualitative and sometimes also a quantitative explanation of experimental data by an assumed reaction mechanism. A reaction of the type

$$A + B = R + S$$

is studied by measuring the conversion at different partial pressures p_A while the other partial pressures are kept constant. If a low conversion is chosen the consumed and produced amounts of A, B, R and S are so small that the initial pressures p_A, p_B, p_R and p_S need to be only very slightly corrected. When reversible reactions are studied it is usually convenient to chose pressure conditions so that the backward reaction can be neglected.

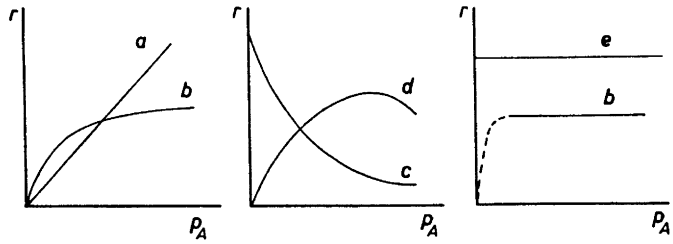

Fig. 1. The rate of reaction, r, as a function of the partial pressure p_A when p_B, p_R and p_S are constant. Each curve a—e corresponds to a Langmuir-Hinshelwood mechanism (Eqns. 1a—1e).

If for instance the rate of the forward reaction r_f and its variation with p_A is investigated, the experimental data often can be correlated with one of the following equations graphically represented in Fig. 1 (curves a—e).

$$r_f = kp_A \quad (1a); \qquad r_f = kp_A/(b + K_A p_A) \quad (1b); \qquad r_f = k/(c + K_A p_A) \quad (1c);$$
$$r_f = kp_A/(d + K_A p_A)^2 \quad (1d); \qquad r_f = k \quad (1e);$$

The following mechanisms can be derived from these different cases with the Langmuir-Hinshelwood method: Eqn. (1a) shows that the rate is proportional to the number of collisions of A with the active catalyst surface. Eqn. (1b) shows that the rate is proportional to that part of the active surface which is covered with adsorbed A. Eqn. (1c) shows that the rate is dependant on the part of the surface that is not covered with A and that A acts as an inhibitor. Eqn. (1d) shows that the rate is proportional to the product of two adsorbed substances one of which is A. Finally eqn. (1e) shows that the rate is independant of A. This can be interpreted as an mechanism in which A is not involved or that A is so strongly adsorbed — eqn. (1b) — that $K_A p_A \gg b$.

The same measurements are performed with the other gascomponents and finally the rate can be expressed as a function of all the involved reactants and products, *i.e.*

$$r_f = f[(p_A), (p_B), (p_R), (p_S)]$$

This function can then, after closer inspection of the involved constant pressures, be written in the form of a rate equation.

Assume for instance that the experimental data have resulted in $r_f = f[(p_A), (p_B/(b+K_B p_B)), (1/(c+K_R p_R), (p_S)^\circ]$
and that closer examination of the constants b and c has revealed the connections $q = 1 + K_R p_R$ and $c = 1 + K_B p_B$. The rate equation can then be formulated

$$r_f = k\, p_A p_B/(1 + K_B p_B + K_R p_R)$$

This equation should describe the reaction rate for the experimental conditions as well as the rate of the forward reaction when the reactants are converted simultaneously in the technical process. The equivalent mechanism is the collision of A, from the gas phase, with adsorbed B as the slowest and rate determining step and with the product R partly covering the active surface and therefore diminishing the rate.

Technical investigations often only determine the rate of the forward reaction but for some reversible reactions as the NH_3-synthesis, the SO_2-

oxidation etc., the total rate must be determined. The backward rate r_b is then evaluated in the same manner as r_f and the total (net) rate becomes

$$r = r_f - r_b$$

The experimental apparatus used in connection with the Langmuir-Hinshelwood method have been both of the static and of the flow-system type. In modern investigations, however, the flow system is preferred as it gives defined diffusion conditions and very often a higher accuracy of analysis.

An excellent example of the Langmuir-Hinshelwood method applied to a technical process is the investigation of Gadsby, Hinshelwood and Sykes [2] and the following investigations [3-5] of the complicated system steam-carbon with four different simultaneous reactions.

THE HOUGEN-WATSON METHOD

An extension of the Langmuir-Hinshelwood approach has been developed by Hougen and Watson [6] and Hougen and Yang [7] and this method has often been used during the last decade mostly in the U.S.A. for the kinetic investigation of technical processes.

The Hougen-Watson method uses an elegant formal way of expressing the chemisorption of a gas on the active catalyst surface and together with other simplifications is it possible to derive the rate equation for every possible reaction mechanism with a minimum of calculations.

The Hougen-Watson method can, for instance, be used to derive the rate equation for the mechanism of the before mentioned example. The first reaction step is assumed to be the collision of A from the gas-phase with B adsorbed on the surface. The products formed are adsorbed R and S in the gas-phase. If the adsorptions of B and R are fast in comparison with the first step, they can be treated as adsorption equilibria and the first step becomes rate determining. The rate of the reversed reaction is then the collision of S with adsorbed R.

The concentrations of the adsorbed particles are represented by c_B and c_R, the concentration of free active centers by c_l and the total concentration of active centers by L. The chemisorption can then be written as a chemical reaction between a gas particle and an active center l. In this case

$$B + l = Bl \qquad R + l = Rl \qquad A + Bl = Rl + S$$

where the last expression constitutes the rate determining step. The rate, the adsorption equilibria and the surface-concentrations can now be written

$$r = k_1 p_A c_B - k_2 p_S c_R$$

$$K_R = c_R/p_R c_l \qquad K_B = c_B/p_B c_l$$

$$L = c_l + c_B + c_R$$

The elimination of the unknown surface-concentrations gives the rate equation expressed in the measurable partial pressures

$$r = \frac{k_1 K_B (p_A p_B - (1/K) p_R p_S)}{1 + K_B p_B + K_R p_R}$$

where K is the equilibrium constant for the reaction. For the forward reaction this

expression is identical with the one in the foregoing example. However, this rate equation could have been written directly with the help of formula tables which have been constructed by Hougen and Yang [7] *.

The formal ease with which the different rate equations can be derived has often influenced the experimental approach when the Hougen-Watson method is used.

The reaction rates are measured with an isothermal flow-reactor for which the general equation holds

$$F\ \mathrm{d}x = r\ \mathrm{d}W$$

where F = feed (mole) / (min), $\mathrm{d}x$ = conversion (mole) / (mole F), $\mathrm{d}W$ = mass catalyst (g) and r = rate (mole) / (g catalyst) (min). Other units, dimensionally consistent, could of course be used. If diffusion is not a limiting factor a differential reactor (small catalyst bed, low conversion) or an integral reactor (large catalyst bed, high conversion) can be used and the rates would be, respectively

$$r_{\mathrm{diff}} = (\Delta x/\Delta W)\ F \qquad\qquad r_{\mathrm{int}} = \mathrm{d}x/(\mathrm{d}W/F)$$

For the integral-reactor the rate is the tangent to the experimentally determined function $x = \mathrm{f}(W/F)$ and can be calculated by graphical derivation. By variation of the partial pressures, usually in a restricted range, as compared to the Langmuir-Hinshelwood-method, a number of r-values are produced.

The next step is to derive all the theoretical possible rate mechanisms and their equivalent rate equations. In this way as much as 75—100 equations can be set up [8] but this number can often be reduced to 10—20 by an inspection of initial-rate data. Hougen and Yang [7] have demonstrated useful relations between the initial rate, the pressure and the mole fractions for different rate equations which are similar to the curves in Fig. 1.

After this test the constants of the remaining equations are determined graphically or by the method of least-squares. Equations with negative constants are eliminated as being physically unsound and the last 3—4 equations usually show a good fit to the experimental data. The last decision is often difficult but a comparison of the integrated equation with data from an integral-reactor can usually be helpful. An unnormal variation of the constants with temperature can also be used for the elimination of equations.

Apart from the mentioned original articles [6,7] the Hougen-Watson method has been presented in some textbooks [9,10] and the calculations involved have been discussed in detail by Corrigan [11].

THE VALIDITY OF THE LANGMUIR-HINSHELWOOD AND THE HOUGEN-WATSON METHODS

Recently the LH- and the HW-methods have been critically discussed by Weller [12] and Boudart [13] and the use of the HW-method in technical investigations has been questioned. Weller points out that the Langmuir adsorption isotherm, which is the base of both methods, has been derived with the assumption of a constant heat of adsorption independant of the surface coverage. However, experiments always show a decreasing heat of adsorption with increasing coverage. This interaction of adsorbed molecules or atoms has also been observed when several gases are adsorbed simultaneously. The

* For the example treated here a misprint in the original work, Table 4, has led to a misleading discussion of initial-rate effects for this case, p. 154 and Table 5.

adsorption of one gas can sometimes increase the adsorption of another gas. If the adsorption of A increases when B also is adsorbed the amount of adsorbed A, c_A, can according to Weller be expressed in the following form:

$$c_A = kp_A/(1 + K_Ap_A - K_Bp_B)$$

This expression has a negative adsorption-constant which in the Hougen-Watson-method was a characteristic mark of physically unsound rate equations which therefore were ruled out.

According to Weller the Langmuir-Hinshelwood method should be used with care and only for qualitative considerations. The Hougen-Watson method should be used as a purely empirical method for data-fitting and as a method by which a mechanism can be determined "which the unwary investigator is often led to believe that he has uniquely deduced".

Instead the use is recommended of exponential expressions of the form $r = k\,(p_A)^m(p_B)^n(p_R)^q \ldots\ldots$ where the exponents have integral or half-integral values or zero. Weller demonstrates on several investigations described in the literature how a simple exponential expression with only one constant gives the same data fitting as complicated Hougen-Watson expressions with up to 4 constants. Rate equations of the simple exponential form can therefore with advantage be used for technical calculations.

The real difference between Wellers exponential expressions and the Langmuir-Hinshelwood and Hougen-Watson expressions is, however, not so large. It is a matter of choice of the adsorption isotherm. Weller uses indirectly the Freundlich isotherm and the other expressions are based on Langmuir.

Boudart [13] shows in a following article that the use of Langmuir's isotherm for non-ideal surfaces, "the paradox of surface catalysis", can be explained by the broad energy distribution of the active centers and also by the possible mathematical approximation

$$\Theta_F = k\ p^n \approx \Theta_L = bp/(1 + bp)$$

This means that the pure empirical Freundlich isotherm, Θ_F with an exponential distribution of the heat of adsorption always can be approximated by an expression Θ_L of the same mathematical form as the Langmuir isotherm. This is of course the reason why Weller can fit his simple one-constant expressions with about the same deviations as those found with the Hougen-Watson method.

Some rate equations which are believed to be uniquely expressed in the exponential form must with the same argument be derivable from the Langmuir isotherm and Boudart shows how this can be done for the well-known Temkin-Pyzhev rate equation for the ammonia synthesis.

To sum up it can be said that the Langmuir isotherm, exactly valid only for ideal surfaces, can be used with advantage for the derivation of rate equations. It must be observed, however, that the involved constants are not real adsorption constants but rather a kind of average constants for the different "surfaces" of which a heterogeneous surface is made up. This is independant

of the real nature of the variation in the heat of adsorption, it may be due to surface heterogeneity, interaction between adsorbed particles or to some form of electron effects of the bulk of the catalyst.

Deviations from the normal adsorption mechanisms occur. As shown above Weller pointed out that mixed chemisorption sometimes can give effects which can be interpreted by negative adsorption constants. These cases of mixed chemisorption, so important for the understanding of heterogeneous catalytic processes, are still not very much investigated [14–16]. Most likely the observed effects are due to a kind of surface compounds ("adducts") and by this assumption it will be shown here how adsorption isotherms can be derived without the use of negative adsorption coefficients. Assume that the adsorption of CO is increased with increasing pressures of H_2 and that the surface compound CO-H_2-1 is produced. With the formal writing of the Hougen-Watson method:

$$\begin{aligned} H_2 + 1 &= H_2\text{-}1 & K_1 &= c_{H_2}/(p_{H_2}c_1) \\ CO + 1 &= CO\text{-}1 & K_2 &= c_{CO}/(p_{CO}c_1) \\ H_2\text{—}1 + CO &= CO\text{—}H_2\text{—}1 & K_3 &= c_{CO\text{-}H_2}/(p_{CO}p_{H_2}) \end{aligned}$$

$$L = c_1 + c_{H_2} + c_{CO} + c_{CO\text{-}H_2}$$

If the total amount of adsorbed CO is $C_{CO} = c_{CO} + c_{CO\text{-}H_2}$

then

$$C_{CO} = \frac{L\,K_2 p_{CO}}{\left(\dfrac{1 + K_1 p_{H_2}}{1 + \dfrac{K_3}{K_2} K_1 p_{H_2}}\right) + K_2 p_{CO}} \approx k \left(\frac{1 + \dfrac{K_3}{K_2} K_1 pH_2}{1 + K_1\, pH_2}\right)^m \left(K_2 p_{CO}\right)^m$$

If $K_3 > K_2$ the adsorbed amount of CO is increasing with increasing pressure p_{H_2} as observed and if $(K_3K_1/K_2)p_{H_2} \gg 1$ the isotherm can be written $C_{CO} = k(p_{CO})^m(p_{H_2})^{am}$; $(0 < a,\ m < 1)$.
With the mechanism $H_2 + CO\text{—}1 = H_2\text{—}CO\text{—}1$, a similar simpler expression can be derived, $C_{CO} = k(p_{CO})^n(1 + K_2 p_{H_2})^n$; $(0 < n < 1)$.

Other forms that deviate from the normal Langmuir isotherm are derived from switch-mechanisms like

$$AB + 1 = B\text{—}1 + A \qquad \text{or} \qquad A + B\text{—}1 = A\text{—}1 + B$$

For instance the amount of adsorbed N_2 in Temkins mechanism for the ammonia synthesis, C_{N_2}, is obtained from the step:

$$2\ NH_3 + 2\ 1 = 2\ N\text{-}1 + 3\ H_2$$

$$C_{N_2} = k\ p_{NH_3} / \left(p_{H_2}^{1.5} + K^{0.5}\ p_{NH_3}\right)^2$$

The large number of possible mechanisms makes an *a priori* derivation of every plausible mechanism impossible. In spite of this, technical investigations show a tendency to overestimate the calculating possibilities. It is not unusual

that some simple experimental series solve the problems faster and more reliable than tideous and unsure calculations of data fitting. A "most plausible" mechanism is often overvalued. As an example the work of Barkley, Corrigan, Wainwright and Sands [17] on the catalytic reversed shift reaction will be discussed.

They investigated the rate of the reaction $CO_2 + H_2 = H_2O + CO$ and found on the basis of a least-square treatment of plausible equations

$$r = k\frac{(p_{CO_2}p_{H_2} - p_{CO}p_{H_2O}/K)}{1 + K_A p_{CO_2} + K_R p_{CO}}$$

As the products CO and H_2O are produced in equivalent amounts and only CO_2 and H_2 are shown to have been experimentally varied in the feed, the experimental data could as well have been expressed by a rate equation with a denominator of the form $(1 + K_A p_{CO_2} + K_S p_{H_2O})$. This equation is founded on a mechanism which was not selected as plausible but seems to be more in accordance with other investigations [18,19].

THE TEMKIN METHOD

In their derivation in 1940 of the well-known rate equation for the ammonia synthesis, Temkin and Pyzhev [20] started with a non-ideal adsorption isotherm with a linear decrease of the heat of adsorption with coverage. The assumed mechanism was

$$N_2 \rightleftharpoons N_2\text{-ads} \qquad \text{(a)}$$

$$3\ H_2 + N_2\text{-ads} = 2\ NH_3 \qquad \text{(b)}$$

The adsorption of nitrogen (a) is rate determining and reaction (b) is assumed to be in equilibrium. The rate of the slow reaction is now the difference between the rates of adsorption and desorption or

$$r = k_a p_{N_2} e^{-g\Theta} - k_d e^{h\Theta}$$

The adsorption isotherm has the form

$$\Theta = \frac{1}{g + h} \ln a_0 p_{N_2}$$

The equilibrium (b) gives

$$P^*_{N_2} = (N_2\text{-ads}) = K_N \frac{(p_{NH_3})^2}{(p_{H_2})^3}$$

where $P^*_{N_2}$ is the fictitious pressure that gives the equivalent N_2-adsorption. If this "pressure" or fugacity is put into the adsorption isotherm and then Θ is eliminated from the rate equation the final equation becomes

$$r = k_1 p_{N_2}\left[\frac{(p_{H_2})^3}{(p_{NH_3})^2}\right]^{\alpha} - k_2\left[\frac{(p_{NH_3})^2}{(p_{H_2})^3}\right]^{1-\alpha}$$

Later Temkin [21] showed that the same expression could be derived with the Freundlich isotherm which has an exponential decrease of the heat of adsorption with coverage and Boudart has demonstrated, as mentioned, that the Temkin equation could be derived with a pure Langmuir-Hinshelwood reasoning.

With the formal Hougen-Watson writing this derivation is simply done and if the slow step is assumed to be $N_2 + 2l = 2$ N-l the rate equations becomes

$$r = \frac{k_1 L^2 [p_{N_2}(p_{H_2})^3 - (p_{NH_3})^2/K]}{((p_{H_2})^{1.5} + K_N{}^{0.5} p_{NH_3})^2}$$

With the approximation $kx/(1 + kx) \approx ax^{1-a}$ and with $x = K_N{}^{0.5}(p_{NH_3})/(p_{H_2})^{1.5}$ the equation above is transformed into the Temkin equation.

The different ways of deriving the Temkin rate equation have shown that rate equations seem to be quite insensible to the choice of adsorption isotherm. The exponential form of the rate equations may be easier to fit to the experimental data but the Langmuir form has the advantage of covering the whole pressure range. The Langmuir expression above shows for instance the limiting rates for high p_{H_2} and low p_{NH_3} and the reverse, to be $r = k\ p_{N_2}$ and $-r = k$, which has been experimentally observed.

In Table 1 some experimentally determined rate equations have been grouped together with their equivalent Langmuir or Temkin expressions. A star marks out the form in which the equation was presented in the literature. The equations in the table all show, when properly rewritten, how the factor $1/(P_1^a + K_1 P_2^b)$ in the Langmuir expressions is equivalent to $1/[(P_1^a)^n (P_2^b)^{1-n}]$. This last expression is similar in form to the "inhomogeneity factor" $F = [\Theta^n (1\text{-}\Theta)^{1-n}]$ which de Bruijn [20,24] derived from the Temkin ammonia-equation, assuming an arbitrary distribution of active centers. In fact, $1/F$ is exactly the factor which transforms, without mathematical approximations, a Langmuir expression ("ideal surface") to an exponent expression of the Temkin type ("inhomogeneous surface").

THE RELATION BETWEEN THE FORWARD AND BACKWARD REACTION RATES

The rate of a reaction can be written as the difference between the forward rate r_f and the backward rate r_b

$$r = r_f - r_b = k_f F_f - k_b F_b$$

where k_f and k_b are rate constants and F_f and F_b are algebraic expressions of the reactants and products A,B, . . . and R,S, . . . At equilibrium $r = 0$ and

$$\frac{F_b}{F_f} = \frac{k_f}{k_b} = f(T)$$

where k_f/k_b is a constant only determined by temperature. Usually this constant is put equal to the equilibrium constant of the reaction

Table 1. Comparison of rate equations.

r_T = exponential Temkin-form r_L = Langmuir-form

1. Reaction: $3\ H_2 + N_2 = 2\ NH_3$

* $$r_T = k_1 P_{N_2}\left(\frac{P_{H_2}^3}{P_{NH_3}^2}\right)^n - k_2\left(\frac{P_{NH_3}^2}{P_{H_2}^3}\right)^{1-n} \qquad n = \tfrac{1}{2} \qquad (20)$$

$$r_T = \left[\frac{1}{(P_{H2}^3)^{1-n}\,(P_{NH_3}^2)^n}\right] k\ (P_{N_2}\ P_{H2}^3 - P_{NH_3}^2/K)$$

$$r_L = \left[\frac{1}{P_{H2}^3 + K_N\ P_{NH_3}^2}\right] k\ (P_{N_2}\ P_{H2}^3 - P_{NH_3}^2/K);\ N_2 \text{ not dissociated}$$

$$r_L = \left[\frac{1}{(P_{H_2}^{1.5} + K_N^{0.5} P_{NH_3})^2}\right] k\ (P_{N_2}\ P_{H2}^3 - P_{NH_3}^2/K);\ N_2 \text{ dissociated}$$

2. Reaction: $2\ SO_2 + O_2 = 2\ SO_3$

* $$r_T = k_1\ P_{O2}\left(\frac{P_{SO2}}{P_{SO3}}\right)^{2n} - k_2\left(\frac{P_{SO3}}{P_{SO2}}\right)^{2(1-n)} \qquad \begin{matrix} V_2O_5\text{–cat: } n = \tfrac{1}{4} \\ Fe_2O_3\text{–cat: } n = \tfrac{3}{4} \end{matrix} \qquad \begin{matrix} (22) \\ (23) \end{matrix}$$

$$r_T = \left[\frac{1}{(P_{SO_2}^2)^{1-n}\ (P_{SO_3}^2)^n}\right] k\ (P_{O2}\ P_{SO_2}^2 - P_{SO_3}^2/K)$$

$$r_L = \left[\frac{1}{P_{SO_2}^2 + K_O\ P_{SO_3}^2}\right] k\ (P_{O2}\ P_{SO_2}^2 - P_{SO_3}^2/K);\ O_2 \text{ not dissociated}$$

$$r_L = \left[\frac{1}{(P_{SO_2} + K_O^{0.5}\ P_{SO_3})^2}\right] k\ (P_{O2}\ P_{SO_2}^2 - P_{SO_3}^2/K);\ O_2 \text{ dissociated}$$

* $$r_T = k_1\ P_{SO_2}\left(\frac{P_{O_2}^{0.5}}{P_{SO_2}}\right)^n - k_2\left(\frac{P_{SO3}}{P_{O_2}^{0.5}}\right)^{1-n} \qquad \text{Pt–cat: } n = 1/2 \qquad (23)$$

$$r_T = \left[\frac{1}{(P_{O_2}^{0.5})^{1-n}\ (P_{SO_2})^n}\right] k\ (P_{SO_2}\ P_{O_2}^{0.5} - P_{SO_3}/K)$$

$$r_L = \left[\frac{1}{P_{O_2}^{0.5} + K_S\ P_{SO_3}}\right] k\ (P_{SO_2}\ P_{O_2}^{0.5} - P_{SO_3}/K)$$

3. Reaction: $CO + H_2O = CO_2 + H_2$

* $$r_T = k_1 P_{CO}\left(\frac{P_{H2O}}{P_{H_2}}\right)^n - k_2\ P_{CO_2}\left(\frac{P_{H_2}}{P_{H2O}}\right)^{1-n} \qquad (18)$$

$$r_T = \left[\frac{1}{(P_{H_2})^n\ (P_{H2O})^{1-n}}\right] k\ (P_{CO}\ P_{H2O} - P_{CO_2}\ P_{H_2}/K)$$

$$r_L = \left[\frac{1}{P_{H_2} + K_O\ P_{H2O}}\right] k\ (P_{CO}\ P_{H2O} - P_{CO_2}\ P_{H_2}/K)$$

* $$r_L = \left[\frac{1}{P_{CO_2} + K_{CO}\ P_{H2O}}\right] k\ (P_{CO}\ P_{H2O} - P_{CO_2}\ P_{H_2}/K) \qquad (19)$$

$$r_T = \left[\frac{1}{(P_{CO_2})^n\ (P_{H2O})^{1-n}}\right] k\ (P_{CO}\ P_{H2O} - P_{CO_2}\ P_{H_2}/K)$$

$K_c = (R)^r(S)^s/(A)^a(B)^b$. Manes, Hofer and Weller [25] and Denbigh and Prince [26] have shown that this is not a necessary condition but that all thermodynamic conditions are fulfilled if only

$$\frac{k_f}{k_b} = f(T) = (K_c)^z \quad \text{and} \quad z > 0$$

Very often $z = 1$, which gives the classical relation $k_f/k_b = K_c$. Horiuti developed in 1939 the "stoichiometric number" which is defined as the coefficient with which the stoichiometric formula of every reaction step has to be multiplied to give the wanted coefficients in the stoichiometric formula of the total reaction. The stoichiometric number ν_r of the slowest, rate determining step has been shown by Horiuti [27,28] to be identical with $1/z$, and therefore

$$\frac{k_f}{k_b} = (K_c)^{1/\nu_r}$$

The relation between the algebraic expressions for the forward and the backward reaction rate can now be written

$$\frac{F_b}{F_f} = \frac{k_f}{k_b} = (K_c)^{1/\nu_r} = \left[\frac{(R)^r(S)^s}{(A)^a(B)^b}\right]^{1/\nu_r}$$

or

$$F_b = F_f\left[\frac{(R)^r(S)^s}{(A)^a(B)^b}\right]^{1/\nu_r}$$

The value of ν_r, the stoichiometric number of the rate determining step, is however not known. A reaction step must be assumed to be a reaction between whole particles — molecules or atoms — and therefore ν_r or $1/\nu_r$ must be an integral number. If different values of ν_r are inserted in the last equation above, different expressions for the backward rate will be obtained. Denbigh and Prince [26] found for instance in an experimental investigation $z = 1/\nu_r = 1/4$ in contrast to the expected classical $z = 1/\nu_r = 1$. The value of z is restricted as total reactions with high stoichiometric coefficients are seldom which is due to the fact that primary reactions between more than three particles are highly inprobable. The stoichiometric number is therefore assumed to vary between 1/4 and 4.

It may be that some more restrictions on the stoichiometric number ν_r can be deduced in each investigated case and that reasoning in line with Christiansens [1] theory of sequences could be applied. The final determination must however, be made experimentally. If both F_f and F_b are determined it should be possible to calculate ν_r and from that obtain information useful for the determination of the rate determining step. Finally it can be mentioned that a relation exists, near equilibrium, between the free energy of the total reaction, the forward rate, the total rate and the stoichiometric number

$$\nu_r = (r_f/r)\ \Delta G/RT$$

which in special cases can be used for the determination of ν_r.

THE EXPERIMENTAL DESIGN OF KINETIC INVESTIGATIONS

It was pointed out in the introduction that even relatively modern kinetic investigations have a tendency of using hidden parameters and it is astonishing how limited the value often is of even large experimental series described in the literature on kinetics of reactions based on heterogeneous catalysis.

Some of the most often occurring factors which diminish the value of experimental data are

1. Too many variables such as contact-time, partial pressure and temperature have been varied at the same time so that only a few data points are unambigously showing the influence of one single variable.
2. The partial pressures have been varied only in narrow ranges of technical interest. A recalculation of the used pressures to mole-fractions will show this very clearly.
3. The contact-time has not been defined clearly.
4. The experiment has been designed so that too many temperatures have been investigated with too few data points for every temperature.
5. The absolute accuracy of analysis has been low.
6. Diffusion effects have been neglected or measured at low temperatures where the reaction rate has not its maximum value. Sometimes diffusion calculations are based on unsafe assumptions.
7. Different catalysts and different particle dimensions have been used without measuring the pore-diffusion effects.
8. The temperature distribution in the catalyst bed has not been measured during the reaction.
9. The catalyst has not been described in detail, has been undefined and chemical changes, ageing, and weight losses have been neglected.
10. The possibility of exchanging experimental data with calculated data has been overvalued.

The pronounced technical character of many investigations is naturally an explanation of the occurrence of some of these factors. A more careful experimental design would, however, without any marked increase in the amount of work, give experimental data of a much more general value. If a kind of standard procedure could be accepted for technical investigations some of the confusion in the literature would be eliminated and comparison of the literature data would be simpler.

With these views in mind a standard experimental design will be roughly outlined.

Apparatus

On the assumption that the analysis is accurate enough to permit the detection of small conversions a differential reactor should be used. For preliminary measurements integral-reactor measurements should also be possible. The constancy of the temperature must be better than $\pm$ 5°C at 500°C and it must be possible to measure the temperature all along the catalyst bed. The flow-meters — one for each gascomponent and one for the inert dilution gas — should have an absolute accuracy of better than 1 %. This can practically be obtained with the general calibration method for capillary flow-meters described by Ergun [29]; *cf.* also Benton [30]. If the total pressure of the system is held constant by means of a valve in the exhaust line, the flow measurements are further simplified.

Nomenclature

The reaction rate r should always be expressed as mass of converted material per unit mass of catalyst and unit time, *e.g.* (mole)/(g catalyst)(min). The mass of catalyst W should be expressed in (g). The area of the catalyst is often expressed in square-meters per g by the B.E.T. standard method. The gas feed F is expressed in mass per unit time, *e.g.* (mole)/(min). The contact-time W/F is then independant of the temperature of the reactor and is exactly defined as for instance (g catalyst)(min)/(mole F). The conversion x is expressed as converted mass of initial feed F_o, *e.g.* (mole converted F_O)/(mole F_O). When integral-reactor data are represented by the function $x = f(W/F)$, the conversion x must always be calculated on the same feed F with which the contact-time is calculated. If for instance F is the total feed of gas then x must be calculated on the total feed F, etc.

Program for experimental runs

1. Diffusion effects. The effect of the external diffusion is determined at the highest temperature used in the investigation (highest rate) by the relation between the conversion x and the feed F at constant W/F. Above a certain limiting gas velocity F_D the conversion x is constant. A simple approximation formula is given by Wheeler [31].

The internal diffusion (pore-diffusion) is determined by measuring x at constant W/F and varying the diameter of the catalyst particles d. Under a certain diameter d_D the conversion x is constant. Calculating formulas are given by Wheeler [31] and recently a general formula by Weisz [32].

2. Preliminary data. Integral-reactor data with $F \geq F_D$ and $d \leq d_D$ are taken for different contact-times W/F and the function $x = f(W/F)$ is obtained. This function can be considered as a graphical form of the rate equation and can be used for preliminary calculations. The initial feed-gas-mixture should be varied widely for instance in the proportions 1:4, 1:1 and 4:1.

3. Initial-rate data with variation of one partial pressure. Initial-rate data are produced in the following way: The total pressure and all partial pressures except one (and the inert gas) are kept constant. One partial pressure is varied from very low to very high values while the whole gas-mixture always is kept far away from equilibrium values to avoid the influence of the reverse reaction. As the conversion x is kept low the reaction rate is $r = x(F/W)$ where $x \leqq 5$ % of the equilibrium conversion. All reactants and products are studied in this way and the experimental data are graphically represented. Inspection of the curves with the help of the Langmuir-Hinshelwood reasoning gives hints to possible mechanisms and these can be further investigated by experiments with pressures chosen in a crucial way. For instance the mole-fraction method of Hougen and Yang [7].

4. Tests with the established rate equation. A final rate equation with its mechanism — for derivations the Hougen-Watson formalism can be used with advantage — is established and the expressions for the formal and backward reaction are examined from a thermodynamic point of view by means of Horiuti's theorem for stoichiometric numbers. A fit to the integral-reactor curves is made and constants are evaluated by graphical methods.

5. Influence of temperature. After the establishment of the rate equation measurements at two relatively different temperatures are started. Only a limited number of runs are necessary as the rate equation is known. Activation energies are calculated from the temperature variation of the constants. Bends in the Arrhenius lines have been discussed by Christiansen[1]. A bend concave upward or downward shows that two parallell or two series reactions are involved.

6. Investigations of other catalysts. If the purpose of the investigation was not only the establishment of the rate equation but also information about the catalyst, the change in mechanism when promotors are added etc., the investigation can with advantage be carried on with the initial-rate method. Determination of the activation energy can give informations concerning the influence of additives and of different methods of treatment. A detailed program on catalyst-testing has recently been given by Dowden and Bridger [33].

Finally experiments in static systems can sometimes complement the outlined course of the investigations, as for instance adsorption measurements of the different gas-components. Reference is again made to the work of Gadsby, Hinshelwood and Sykes [2] and subsequent works [3–5].

The watergas-shift reaction

As an example of how the proposed experimental procedure can be applied some results will be presented here of an investigation of the watergas-shift reaction [34].

The rate of the reaction

$$CO + H_2O = CO_2 + H_2$$

was studied in the presence of an iron-oxide catalyst. The diffusion- and pore-diffusion effects were measured and the allowed minimum gas velocity and maximum particle size was determined. With an integral reactor preliminary data were produced but partly due to the ageing of the catalyst a Hougen-Watson treatment to determine the rate equation was not successful.

Then the initial-rate method was applied and the difficulties of ageing gave no trouble as now the general form of the curves, rather than their exact slope, is the important factor for the evaluation. The experimental rate expressions for the different varied partial pressures were then united in one rate equation. A comparison with the integral-reactor data was made and constants were determined. Some of the measurements are presented in Fig. 2 which shows the variation of the forward rate when different gas-components are varied in pressure. From Fig. 2 c it can be seen that even very small amounts of CO_2 have a strong inhibiting effect. If the experimental curve I in Fig. 2 a is corrected for the small CO_2-amount produced at the low conversion used, the corrected curve II shows that the rate is directly proportional to p_{CO}.

The other curves indicate that H_2O and CO_2 are strongly adsorbed and that H_2 does not take part in the reaction. The experimental rates can be grouped together to the form

$$r_f = f\left[(p_{CO}), \left(\frac{p_{H_2O}}{b + K_1 p_{H_2O}}\right), \left(\frac{1}{c + K_2 p_{CO_2}}\right), (p_{H_2})^0 \right]$$

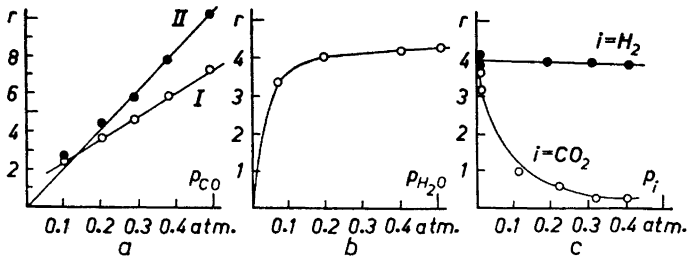

Fig. 2. The variation of the forward rate of the watergas-shift reaction when partial pressures of only one reactant or product are varied. Iron-oxide catalyst. Temperature 390°C. Pressures in atm. Rates in (10^{-4} mole) / (g catalyst) (min). In Fig. 2 a the curve II represents the values of curve I, corrected for CO_2-inhibition.

By closer inspection of the data this is transformed into the rate equation for the forward reaction

$$r_f = k \frac{p_{CO} p_{H_2O}}{p_{CO_2} + K_B p_{H_2O}} \approx k\, p_{CO} \left[\frac{p_{H_2O}}{p_{CO_2}}\right]^n$$

In this rate equation the influence of each gas-component has been unambigously determined and the experimental approach has eliminated such parameters as diffusion, particle size and temperature variations. Variables as partial pressures and contact-times have been used directly for the rate determination and are not parameters.

A Frequency Rule for Non-Isotopic Molecules

SVEND BRODERSEN and A. LANGSETH

Chemical Laboratory of the University of Copenhagen, Denmark

Recently the present authors have pointed out that there exists a simple relation between the vibrational frequencies of certain isotopic molecules. A complete isotopic rule was formulated which allows the calculation of all vibrational frequencies of one isotopic molecule from those of two others.

In the present paper it is shown that this rule may even be applied to chemically different (non-isotopic) molecules with reasonable success. For a few molecules, taken as examples, all the vibrational frequencies are calculated, in each case from the known frequencies of two related molecules. In spite of the apparently rough approximations, introduced when the isotopic rule is applied to non-isotopic molecules, the results obtained are sufficiently accurate to be a valuable help in the interpretation of complex vibrational spectra.

One of the objectives of molecular spectroscopy is — through measurement and interpretation of the spectra — to determine the potential function of the molecule under investigation. As the potential function may be regarded as a quantitative representation of the valence forces within the molecule, it is of evident chemical interest and of fundamental importance for the further development of the quantum-mechanical valence theory.

The interpretation of the observed bands in a spectrum in terms of fundamentals, combination frequencies, and overtones is often a rather difficult task. Except for di-atomic and certain high-symmetrical tri-atomic molecules it will always be necessary to include an investigation of certain istopic molecules as well, in order to make an unambiguous interpretation of the spectrum possible, and — at the same time — to get sufficient experimental data for the evaluation of the potential constants.

As the potential function is unaltered by isotopic substitution there exist certain relations between the fundamental frequencies of isotopic molecules. Such relations (so-called "isotopic rules") represent one or more single relations between the vibrational frequencies and the geometrical parameters of the isotopic molecules, but the potential constants ("force constants") do not occur. Therefore, the fulfilment of the requirements of these isotopic rules is a very useful check on the correctness of a given interpretation.

Recently the present authors have reported on a new isotopic rule [1]. This rule we have called "the complete isotopic rule" because it allows the calculation of all the vibrational frequencies of certain molecules from the frequencies of other definite isotopic molecules.

The proof of this rule is based on the assumption of a harmonic (quadratic) potential function. The agreement between observed and calculated frequencies achieved by use of the complete isotopic rule is, however, much better than that obtained by the ordinary calculation of vibrational frequencies based on a definite harmonic potential function. This is due to the fact that the application of the complete rule actually amounts to a sort of interpolation between the frequencies of two "extreme" molecules to give the frequencies of the "intermediate" molecule in question. This means that we need not assume one definite harmonic potential function — which would be an approximation, the real potential function always being more or less anharmonic — but implicitely uses three slightly different harmonic functions for the three isotopic molecules involved in the calculation. If these functions are "linearly" related a significantly better approximation to the real anharmonic potential function of the "intermediate" molecule is to be expected. This has been verified in an extensive study and calculation of the fundamental frequencies of all the different deuterated species of benzene [2].

This situation suggests that the complete isotopic rule may even be applied to chemically different molecules with tolerable success. Derivatives of a definite compound formed by substitution of one or more atoms for equivalent atoms of other elements will have materially different potential functions

even if the geometry of these derivatives is approximately the same. It may, however, be expected that the potential function of an "intermediate" derivative with a fair approximation can be obtained by "linear" interpolation between the potential functions of two "extreme" molecules, as for instance that of O=C=S from those of O=C=O and S=C=S. If this is the case the complete frequency rule may be applied with reasonable success.

As discussed in detail in our previous paper [1] the complete isotopic rule is strictly valid for all fundamental frequencies of linear molecules and for the out-of-plane fundamentals of plane molecules (as for instance ethylene and aromatic hydrocarbons). As examples for the application of the complete frequency rule to non-isotopic molecules we have therefore chosen O=C=S and some fluoro and chloro derivatives of ethylene: CF_2=CFCl, CF_2=CCl_2, *trans*-CFCl=CFCl, and CFCl=CCl_2. The fundamentals of O=C=S are cal-

culated from those of CO_2 and CS_2, and all the out-of-plane fundamentals of the ethylene derivatives from those of $CF_2=CF_2$ and $CCl_2=CCl_2$. The procedure used in the calculations is exactly the same as that described for isotopic molecules [1]. The results are given in Tables 1 and 2 together with the observed frequencies. The agreement obtained is quite satisfactory in consideration of the material differences between the potential functions of the various molecules. An accuracy like that obtained in these examples will in most cases be sufficient for assignment purposes.

Recently Mann *et al.*[3] have calculated the vibrational frequencies of the fluoro and chloro derivatives of ethylene using a method of calculation which in principle has much in common with the one proposed here. According to these authors the frequencies are calculated from a definite potential function for each molecule. Every separate one of these functions has been derived from those of $CF_2=CF_2$ and $CCl_2=CCl_2$ by interpolation for each potential constant separately. The results obtained by Mann *et al.* are for the sake of comparison included in Table 2. It is seen that they are slightly better than ours.

As we have shown in our previous papers [1,2] the field of application of the complete isotopic rule may be extended considerably for hydrocarbons by introducing a splitting of the rule into separate rules comprising either the low frequencies or the high hydrogen (or deuterium) stretching frequencies. Because of the great difference in frequency the interaction between these groups of fundamentals is small enough to make the separation permissible. This approximation extends the applicability of the complete isotopic rule also to the planar vibrational frequencies of a great number of plane molecules.

For the halogen derivatives, which we are considering here, a corresponding separation should from a theoretical point of wiew not be permissible because the C—F and the C—Cl stretching frequencies are much lower, being actually of the same order of magnitude as several of the other fundamental frequencies. On the basis of this consideration one should therefore not expect the frequency rule to hold to a sufficient aproximation when applied to the planar frequencies of the substituted ethylenes. If we, nevertheless, use the frequency rule as if the separation were permissible we get the results shown in Table 3. It is seen that the results are almost as good as those obtained from the "valid" rule given in Tables 1 and 2. The results of Mann *et al.*, included in Table 3, are again slightly, but not essentially, better than ours. However, considering the enormous simplification of the calculations achieved by use of the frequency rule rather than the extremely elaborate procedure used by Mann *et al.*, the small gain in quality of the results seems insignificant.

The unexpected success of applying the complete isotopic rule to these cases seems to indicate that the potential functions to a fairly good approximation allow the separation of stretching frequencies from other vibrational frequencies even if they all are of the same order of magnitude. A definite establishment of this interesting feature will, however, require a much larger material than that presented here. If it actually can be shown that the separation is generally permissible the frequency rule will be a most valuable instrument for the interpretation of a great many vibrational spectra. We hope to be able to give a more detailed discussion of this problem in a later paper.

Simple Proof of the Ergodic Theorem

HARALD WERGELAND

Fysisk Institutt, Norges Tekniske Högskole, Trondheim, Norway

An attempt is made to prove the equivalence of time and space averages in statistical mechanics, without invoking the theory of sets. Apology is therefore due because of the lack in rigor, but there appear to be possibilities to show how the argument could be sharpened to mathematical precision*.

Ergodic theory is now a province of pure mathematices, but its origin is in the mechanical theory of heat. Specifically it is the assumptions made by Boltzmann and Maxwell to justify the substitution of the time average of mechanical quantities by an average over the phase space. By ergodic theorem we shall presently just mean the statement (when true), that *time average equals phase average*, and not the original hypotheses upon which this conclusion has been based. It is well known, that the latter — though sufficient to prove the theorem — did not stand the test of mathematical critique.

The first encounter with this situation will usually arouse the curiosity of the student of statistical mechanics. Now, the immediate answer to him is of course that the ergodic theorem in the sense defined above, was indeed proved by Birkhoff, Neumann and others [1] in 1932. But I think that those who look up the original papers may be a little overwhelmed by their abstractness and mathematical subtlety.

It is therefore desirable to have a proof in plainer language even if not rigorous. This is the aim of the present paper. In this spirit we shall employ only the ordinary calculus and in particular no more general concept of measure than the Riemann integral. Thus point sets of Lebesgue measure zero, which play a great role in the more mathematical formulations, will be bypassed in silence.

1. STATEMENT OF THE PROBLEM

The mechanical state of a system is determined by a point,

$$\mathbf{P} = \{q_1 q_2 \ldots q_f p_1 \ldots p_f\} \tag{1}$$

or eventually delimited by the cartesian volume element,

$$\mathrm{d}\Omega = \mathrm{d}q_1 \mathrm{d}q_2, \ldots \mathrm{d}p_f \tag{2}$$

* Private communication from Professor Kac.

in the $2f$-dimensional phase space. The system will be restricted by external conditions to a finite part Ω of the phase space, for example the energy shell,

$$E \leq H(\mathbf{P}) \leq E + \mathrm{d}E \tag{3}$$

A thermodynamical variable must primarily be identified with the time average

$$f^* = \lim_{t \to \infty} \frac{1}{t} \int_0^t f(\mathbf{P}(t))\ \mathrm{d}t \tag{4}$$

of some phase function $f(\mathbf{P})$. Now, for mathematical reasons we are only able to compute phase averages

$$\overline{f} = \frac{1}{\Omega} \int_{\Omega} f(\mathbf{P})\ \mathrm{d}\Omega \tag{5}$$

But the ergodic theorem asserts that these two kinds of average are equivalent:

$$\boxed{f^* = \overline{f}} \tag{6}$$

which is the proposition to be proved.

2. TRANSITIVITY

The decisive progress in the ergodic problem was Birkhoffs idea of transitivity. In order to explain this concept it will be convenient to survey briefly also some other notions of general dynamics:

a) A region Ω of phase space is said to be *invariant* if for any point $\mathbf{P}$ in Ω also the total orbit through $\mathbf{P}$ belongs to Ω.
b) Such a region is said to be *indecomposable* if it cannot be divided into parts $\Omega' + \Omega''$ which are separately invariant.
c) If the orbit from any point $\mathbf{P}$ in Ω will come arbitrarily close to any other point $\mathbf{P}'$ in Ω, then the motion is said to be *transitive*. Indecomposability and transitivity are equivalent. It is evidently a property of the Hamiltonian.

In the ergodic problem we consider closed systems, and hence the energy as constant. Certainly one might instead conceive a thermodynamical system as an open one with a stochastically time dependent Hamiltonian. Such an interpretation has actually been worked out by Delbrück and Molière [2]. There are, however, two drawbacks in this point of view: Firstly it deprives us of the justification of statistical mechanics for a closed system. Secondly, although ergodicity could no doubt be ensured that way, it would be — as Rosenfeld has once put it — so to speak *a fortiori*. Therefore we shall assume the Hamiltonian to be independent of time and consider the energy shell as the region to be inspected for transitivity.

A little further insight into the meaning of transitivity can be obtained from a general classification of the integrals of the motion. By the elementary theory of linear partial differential equations [3] the $2f-1$ time independent integrals of the Hamiltonian system can be taken to be of the form:

$$g_i(\mathbf{P}) = c_i \quad (i = 1,2 \ldots 2f-1) \tag{7}$$

Here a characteristic alternative shows up: S u c h a n i n t e g r a l m a y o r m a y n o t d e f i n e a s u r f a c e i n Ω. In the former case eqn. (7), considered as an equation for any one single variable p_k or q_k, has only isolated solutions. The alternative is infinitely many roots in a finite interval. The integrals defining surfaces are denoted as *univalued.*

The existence of a univalued integral will lower the dimensionality of Ω by one. In the extreme case that there are $2f-1$ of them, Ω will be reduced to the one-dimensional continuum of the orbit, which now appears as a section between surfaces c_i, $c_1 \ldots c_{2f-1}$. Probably this means a closed orbit, or in other words, exact periodicity.

When the number of univalued integrals is less than $2f-1$, a phase space Ω of more than one dimension remains, and fixing the non unique integrals will not further reduce the dimensionality. It is of course still true that specification of all the constants of integration, c_i, $(i = 1 \ldots 2f-1)$, will determine the orbit completely, but it is only the constants fixing univalued integrals which affect the long time averages. Whatever values we choose for the others, — because of the infinite multivaluedness of any variable — the orbit must interweave the remaining phase Ω space densely. We could also say the univalued integrals decompose the phase space into invariant parts $g_1(\mathbf{P}) = c_1, \ldots g_m(\mathbf{P}) = c_m$. The intersection of these, which is of dimension $2f-1-m\ldots$, is indecomposable.

A simple illustration is afforded by any completely separable many body problem *e.g.* the Conditionally Periodic Systems of the old quantum theory. For these, the action variables constitute a complete set of f univalued integrals. If the frequencies are incommensurable, a remaining f-dimensional space of the coordinates is indecomposable. A two dimensional projection of the orbit will then have the character of a Lissajou figure. It should be remembered, however, that separable systems are not ergodic in the sense of statistical thermodynamics; since they have no transfer of energy between the different degrees of freedom and therefore cannot approach thermodynamical equilibrium.

The question is how many univalued integrals are in general to be expected. At any rate the energy $E(\mathbf{P}) = E$ will always be one. It is perhaps a reasonable guess that in large systems there are essentially * no others. This would leave the widest possible region, namely the energy shell indecomposable.

Apart from the hypothesis of transitivity — which is possibly a strong one — only well established theorems of dynamics are needed in the proof, *viz.* Liouvilles theorem: that the motion of the elements of phase space is an incompressible flow, and Poincaré's theorem: that any state, $\mathbf{P}$ in $\Delta\Omega$, will recur. These three premises will be used repeatedly in the following.

* Strictly speaking, also the total linear momentum and the total angular momentum are always univalued integrals, but they can be disregarded for special reasons.

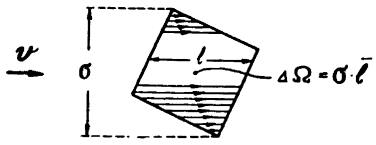

Fig. 1.

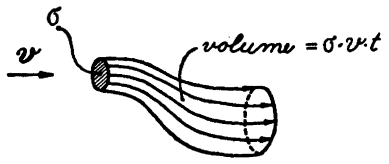

Fig. 2.

3. TWO LEMMAS

In order to avoid digression in the main proof, it will be useful to derive two auxiliary formulae beforehand.

3.1 The life time of a state: {P in $\Delta\Omega_i$}

When the representative point **P** traverses a particular cell $\Delta\Omega_i$ in phase space the duration of the passage depends strongly upon how it hits the cell, whether centrally or grazingly, see Fig. 1.
The mean duration or "life time" τ_i must be equal to the mean segment $\bar{l}$ of the orbit inside $\Delta\Omega_i$ — divided by the velocity v:

$$\tau_i = \frac{\bar{l}}{v(\mathbf{P}_i)} \tag{8}$$

where

$$v = [\dot{q}_1^2 + \dot{q}_2^2 + \ldots . \dot{p}_f^2]^{1/2}$$

In the course of long times the orbit will intersect $\Delta\Omega$ with a dense array of parallel chords. Introducing now by an obvious geometrical analogy the "projection" σ of $\Delta\Omega$ along v (see Fig. 1) we have for the mean chord

$$\bar{l} = \frac{\Delta\Omega}{\sigma} \tag{9}$$

and consequently:

$$\tau = \frac{\Delta\Omega}{\sigma v} \tag{10}$$

3.2. The recurrence time T of **P** in $\Delta\Omega$.

Consider now an area σ orthogonal to the velocity field v in phase space. In a time t a phase volume $\sigma \cdot v \cdot t$ will have passed the cross section σ. At latest after a time $\Omega/\sigma v$, recurrences must have taken place.
Some points may be delayed, but others will be advanced and it is a natural guess that the mean recurrence time is just

$$T = \frac{\Omega}{\sigma \cdot v} \tag{11}$$

We shall substantiate this a little: Denote the number of phase points which have passed σ once by n_0, twice by n_1 and so forth. The total number of recurrences in a time t will then be:

$$N(t) = 1 \cdot n_1 + 2 \cdot n_2 + \ldots . \tag{12}$$

while the total flow points is

$$\sigma \varrho v t = n_0 + 1 \cdot n_1 + 2 \cdot n_2 + \ldots . \tag{13}$$

where ϱ is a constant density to be fixed later. Hence the mean interval between two recurrences is

$$\frac{t}{N} = \frac{t}{\sigma \varrho v t - n_0} \tag{14}$$

Now again by Poincaré's theorem the class of points n_0 cannot increase *i.e.* all orbits crossing σ once must sooner or later cross it again. Therefore in the course of long time

$$\frac{t}{N} = \frac{\lambda}{\sigma \varrho v} \tag{15}$$

We must now speak more definitely about the density ϱ. It may be looked upon as representing an ensemble of $\mathcal{N} = \varrho \cdot \Omega$ systems, uniformly distributed in phase. We might therefore also write

$$\frac{t}{N} = \frac{\Omega}{\sigma v} \cdot \frac{1}{\mathcal{N}} \tag{16}$$

Now since the number of recurrences as well as the number of points crossing σ in unit time is proportional to $\mathcal{N}$, the conclusion seems certain that $\mathcal{N} = 1$ or a density $\varrho = 1/\Omega$ gives the appropriate average count of recurrences in one single system. This leads then to the formula (21).

4. THE PROOF

In the integral (4) we shall understand the representation point **P** to move according to a definite Hamiltonian, transitive in Ω, so that we have incompressibility, recurrence and indecomposability. The first step is to replace the time integral by its Riemann sum:

$$\int_0^t f(t)\ \mathrm{d}t = \lim \sum_n f(t_n)\ \Delta t_n \tag{17}$$

Here the subdivision of the time interval is arbitrary as long as

$$t = \Sigma \Delta t_n = \text{constant} \tag{18}$$

We may in particular choose the time differences Δt in (18) equal to the transit times of **P** through the cells $\Delta\Omega_i$ of a fixed subdivision of Ω. Now by Poincaré's theorem every cell will be traversed many times. Let Δt_{ir} be the time spent by the representation point inside $\Delta\Omega_i$ during the r'th passage. And let $N_i(t)$ be the number of recurrences in the time interval $(0, t)$. We have then

$$\sum_n f(t_n)\,\Delta t_n = \sum_{i=0}^{\Omega/\Delta\Omega} \sum_{r=0}^{N_i} f(\mathbf{P}_i)\cdot \Delta t_{ir} \tag{19}$$

In the second sum we may write

$$\sum_{r=0}^{N_i} f(\mathbf{P}_i)\Delta t_{ir} = f(\mathbf{P}_i)\cdot N_i\,\overline{\Delta t_i} \tag{20}$$

where $\overline{\Delta t_i}$ is the average transit time over N_i recurrences.

After these preparations we can rewrite the time average of a phase function $f(\mathbf{P})$:

$$\frac{1}{t}\int_0^t f(\mathbf{P}(t))\,\mathrm{d}t = \lim_{\Delta\Omega\to 0} \sum_{i=0}^{\Omega/\Delta\Omega} f(\mathbf{P}_i)\cdot\frac{\overline{\Delta t_i}}{t/N_i} \tag{21}$$

According to the proposition (6) we have still to consider the limit $t\to\infty$ and this must be carried out before making the cells $\Delta\Omega$ infinitesimal.

Now $\overline{\Delta t_i}$ and t/N_i must obviously approach definite limits for $t\to\infty$:

$\lim \overline{\Delta t_i} = \tau_i =$ mean life time of the state: {**P** in $\Delta\Omega_i$}
$\lim t/N_i = T_i =$ » recurrence time » » » » » »

Thus we have for the time average of f over an infinite period:

$$f^* = \lim_{\Delta\Omega\to 0} \sum f(\mathbf{P}_i)\,\frac{\tau_i}{T_i} \tag{22}$$

But according to the formulae (10) and (11), the ratio of the life time to the recurrence time of the state: **P** in $\Delta\Omega_i$ is

$$\frac{\tau_i}{T_i} = \frac{\Delta\Omega_i}{\Omega} \tag{23}$$

Therefore we have

$$\sum_i f(\mathbf{P}_i)\,\frac{\tau_i}{T_i} = \sum_i f(\mathbf{P}_i)\,\frac{\Delta\Omega_i}{\Omega}$$

and passing to the limit in eqn. (22)

$$\lim_{i\to\infty}\frac{1}{t}\int_0^i f(\mathbf{P}(t))\,\mathrm{d}t = \frac{1}{\Omega}\int_\Omega f(\mathbf{P})\,\mathrm{d}\Omega$$

as was to be proved.

Surface Tension of Liquid Mixtures

A Micro-Method Applied to the Systems: Chloroform-Carbon-tetrachloride, Benzene-Diphenylmethane and Heptane-Hexadecane

JØRGEN KOEFOED and JOHN V. VILLADSEN

Universitetets Fysisk-Kemiske Institut, Copenhagen, Denmark

An apparatus is described which measures surface tension of small samples (10—30 μl) with an accuracy better than one in thousand. A glass capillary of 2 mm diameter in the lower end and 0.25 mm in the upper end was inclined to bring the liquid in equilibrium each time at the same position in the capillary.

Experimental results are reported for 10 pure liquids and for three sets of mixtures of varying mole fraction. The applicability of recent theories of the surface tension of regular mixtures is discussed and a new treatment is proposed.

THE APPARATUS

The apparatus was designed for measuring surface tension of some biological fluids which were available in very small quantities only. These measurements will be described elsewhere. For the measurements described in this paper the extreme economy in volume was not particularly advantageous, but did no harm either, even in the work with mixtures because evaporation could be kept correspondingly low.

For adaptation to micro-scale, the capillary rise method is obviously the most suitable. Surfaces of intermediate dimensions ($50 > d > 2$ mm) have a complicated shape and involve awkward correction terms. Usually the reference surface is kept above this interval and treated as a plane surface, but another possibility is to keep both surfaces so small that they can be treated as perfectly spherical. An unfortunate circumstance in this arrangement is that only one of the surfaces can approach the equilibrium position in receding motion. It has, however, been possible to make very accurate measurements.

The laborious search for a capillary of sufficiently constant diameter was saved by measuring to the same narrow region of an ordinary first class capillary. To be able to have both surfaces at prescribed positions in the capillary, gravitational force on the liquid was varied by inclination of the capillary.

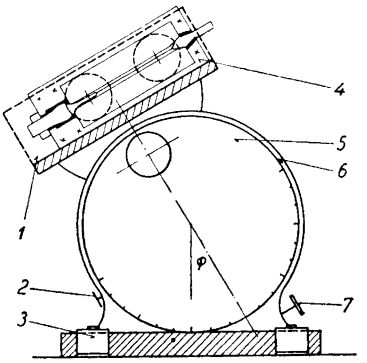

Fig. 1. Sketch of the apparatus. The optical measuring table is solidly clamped to the desk. On the movable table is fixed a U steel, 1, carrying the two microscopes and the Perspex chamber, 4. The fine adjustment screw 7 is engaged or disengaged by turning 2.

The measuring capillary (made to order by F. C. Jacob, Copenhagen) is shown on Fig. 1 together with the Perspex chamber,4, in which it is inserted. Two pieces of Portex tubing (soft PVC) on the two bulbs provide the packing material, the lower one being expanded when the screw is tightened on a thin brass runner. Water is circulated through the chamber from a thermostat. The chamber is fixed to the one side of a length of U-shaped steel,1, (37 × 50 mm) and two microscopes (Hensoldt Metami, 20 ×) are fitted into holes in the other side, focussing on the capillary around its two etched markings which are 50 mm apart. The plane bottom of the U-steel rests against the plane table of an "Optischer Winkel-Mess-Tisch" (Miller, Innsbruck) commercially available from precision-tool dealers. The scale has divisions for every 5′ permitting easy interpolation to 1′.

The horizontal position, read as 0°, is carefully adjusted as the position in which a small mercury drop does not move in the narrow capillary (± 2′).

Although mounting and dismounting of the capillary is very easy, the rinsing and filling is usually made *in situ*. For the filling, the table is moved to bring the tube in an upside down position (—70°), the narrow end is closed with a finger and the liquid is applied as a drop in the wide end of the capillary from a 25 μl capillary pipette. The finger is released until the drop is caught by the narrow part of the capillary and the table is tilted back to a small positive angle (+ 10 — + 15°). The upper surface will now be in the conical part of the tube above the narrow capillary and can be "vacuum-cleaned" for surface impurities through a thin polythene tube.

The capillary is brought to vertical position (+ 90°) and tilted backwards and forwards until the upper surface is at the desired place. The position of both surfaces l_1 and l_2 are read on the ocular scales of the microscopes (0.05 mm divisions). The angle φ is read and the surface tension can be worked out from the following expression, the meniscus to meniscus distance in mm being $50 + l_1 - l_2$:

$$\begin{aligned} \gamma &= Kd(1 + (l_1 - l_2)/50) \sin\varphi \\ K &= g(50 + (r_1 + r_2)/3) / (2/r_1 - 2/r_2) \\ d &= d_{\text{liq}} - d_{\text{air}} \end{aligned} \qquad (1)$$

Actually, the constant K was determined by standardization on pure benzene and checked on several other substances. The questions of the correction term $(r_1 + r_2)/3$ and of the neglected terms of higher order in r_1 and r_2 have been treated by Højgaard Jensen.[1]

SURFACE TENSION OF SOME PURE LIQUIDS

Ten readings were taken for each liquid. The largest discrepancy was usually within 2 parts in thousand and the accuracy of the mean value should therefore be about 7/10 000. The results are given in Table 1 together with the best values, found in the literature.

The agreement between our measurements and others is very satisfactory. Only diphenylmethane appears not to have been measured before. The measurements on *n*-paraffins by JKG are made in vacuum and seem very accurate, but it is surprising that they report surface tensions of higher paraffins far below the melting point of any reasonably pure sample. Their method gives no proper check on systematic errors in their apparatus and the impressive consistency in their results may depend on their use of the same apparatus throughout. The paraffins used by Vogel appear to have been of moderate purity.

In measuring ethyl ether a small correction (0.23 %) was made for the weight of the air stem in the tube on both sides of the liquid, because the saturation with ether made the air heavier. For the other liquids a similar correction would be smaller than 0.05 % and was neglected.

Table 1. Surface tensions of pure compounds.

MATERIALS

Benzene and *carbon tetrachloride.* Merck p.a., dried with silica gel and distilled.

Chloroform. Merck p.a., 1 % alcohol added. Alcohol removed by washing twice with water. Separated. Dried with silica gel and distilled. All samples containing chloroform were stored in dark bottles and measured within a few days from their preparation.

n-*Heptane.* Phillips Petroleum Comp. "more than 99 % pure" (presented by the makers to the late prof. J. N. Brønsted in 1947).

n-*Dodecane* and n-*hexadecane.* Synthetic samples of high purity, as used for the measurements by Brønsted and Koefoed [2].

Diphenylmethane. Fluka, highest purity. 6 times recrystallized, each time discarding about 1/5 as liquid phase, m. p. 26.8°C.

Methanol. Merck p. a.

Ethanol. Alcohol absolutus 99.9 %. Ph. Dan., De Danske Spritfabrikker.

Ethyl ether. Struers, Copenhagen. Best commercial quality, distilled from sodium metal.

SURFACE TENSION OF SOME MIXTURES

Chloroform-Carbontetrachloride. The surface tensions of these mixtures have been measured many years ago by Whatmough [3] and our results agree qualitatively with his. Densities and vapour pressures are known from the work of McGlashan and Prue [4] who showed that the mixtures are regular with the parameter $W = 930$ joule/mole.

Our determinations of densities agree well with those of McGlashan and Prue[4] which are certainly more accurate than ours whereas the values tabulated in *International Critical Tables* appear incorrect. We must have had some losses of chloroform in the making up of the mixtures and we obtained the most consistent results if we based our x-values on the density measurements and not on the weighings.

The experimental results are tabulated in Table 2 and plotted in Fig. 2. In the same figure are plotted values calculated from Guggenheim's equation [5] (2) and from Hoar and Melfords equation [6] (3) for regular solutions:

$$\begin{aligned}\gamma &= \gamma_1 + \frac{RT}{\sigma_1}\ln\frac{x_1'}{x_1} + \frac{W}{\sigma_1}\left(\frac{x_2'^2}{2} - \frac{3x_2^2}{4}\right)\\ &= \gamma_2 + \frac{RT}{\sigma_2}\ln\frac{x_2'}{x_2} + \frac{W}{\sigma_2}\left(\frac{x_1'^2}{2} - \frac{3x_1^2}{4}\right)\end{aligned} \qquad (2)$$

$$\begin{aligned}\gamma &= \gamma_1 + \frac{RT}{\sigma_1}\ln\frac{x_1'}{x_1} + \frac{W}{\sigma_1}\left(\frac{x_2'^2}{2} - x_2^2\right)\\ &= \gamma_2 + \frac{RT}{\sigma_2}\ln\frac{x_2'}{x_2} + \frac{W}{\sigma_2}\left(\frac{x_1'^2}{2} - x_1^2\right)\end{aligned} \qquad (3)$$

Eqn. (2) corresponds to Guggenheims derivation but σ_1 and σ_2 are not put equal to one another.

The calculations were carried through in the following way: For $x_1 \leqq 0.5$ was inserted: $x_1'/x_1 = 1 + \delta$; $\ln x_1'/x_1 = \delta$; $\ln x'_2/x_2 = -x_1\delta/(1-x_1)$; $(x_1'/x_1)^2 = 1 + 2\delta$ and $(x_2'/x_2)^2 = 1 - 2x_1\delta/(1-x_1)$. An explicit expression for δ was developed from each of eqns. (2) and (3). For each of them δ was calculated and inserted in both equations for γ. If the two values of γ agreed, this was taken as evidence for a satisfactory approximation. If not, small corrections were made by iteration until agreement was obtained. After-

wards the other halves of the curves, $x_1 > 0.5$, were found by similar sets of equations with x_1 and x_2 interchanged so that $x_2'/x_2 = 1 + \delta'$ *etc.* The reason for using two different expressions is that the terms $x/(1—x)$ get large as x approaches 1 and threaten the successfulness of the approximations.

It is evident from Fig. 2 that Guggenheim's expression gives a much better agreement with the experimental values than Hoar and Melfords. A discussion of the two models is found in the last part of this paper.

Benzene-Diphenylmethane. No measurements of density or surface tension of these mixtures have been published. Everett [7] has mentioned the existence of unpublished density measurements by Duff. From the work of Everett [8] we know the vapour pressures, which follow the rules of "athermal" mixtures.

Our measurements are tabulated in Table 3 and the surface tensions are plotted against mole fraction in Fig. 3. The curve is on the positive side of the right line and plotted against volume fraction it comes out on the negative side. The density measurements show that mixing is accompanied by an appreciable contraction (2.9 % at $x = 0.5$).

In measuring the surface tensions we had to take precautions to prevent evaporation from the surface. The two ends of the tube were connected to a T-tube and the air in the tubes was kept at about the right benzene pressure by evaporation from moistened bits of cotton wool. The solutions rich in diphenylmethane were very viscous and by standing unprotected over night the surface tension approached that of pure diphenylmethane, but a subsequent mixing of the 20 μl lot showed that it was only the surface which had lost an appreciable amount of benzene.

pressure of n-paraffins have been studied extensively in this laboratory [2] and elsewhere and heats of mixing are known from the work of van der Waals [9]. His results are in moderate agreement with unpublished measurements by Brønsted and Halvard in this laboratory.

The surface tensions were measured at two temperatures and the results are tabulated in Table 4. In Fig. 4 the values at 20°C are plotted against mole fraction. The results at 30°C give exactly the same appearance. The curves are positive and exactly as in the system benzene-diphenylmethane we find on plotting against volume fraction a negative deviation from linear behaviour. For vapour pressures, inversely, the curves are negative when plotted against mole fraction and positive when plotted against volume fraction.

Both of the last two systems are known to deviate rather little from ideality. But starting from Guggenheim's equation for an ideal surface we find that very large deviations from ideal surface behaviour have to be introduced to account for the fact that the curve is much nearer to the straight line than a Guggenheim-ideal surface tension would be. We take this as evidence for the soundness of accepting the straight line relationship as representing ideal behaviour as discussed below.

THE THERMODYNAMICS OF SURFACES

"In the thermodynamics of surfaces there is no theorem more important than that known as Gibbs' adsorption theorem, which determines how the surface tension of a solution varies when the composition is varied at constant temperature. Its derivation by Gibbs has all the logical conviction and elegance characteristic of Gibbs" (Guggenheim[10]).

The situation with regard to this theorem is unsatisfactory in two respects. The existing proofs of the theorem are not irreproachable and the theories of surface tension of binary mixtures lead to disagreement with the theorem as soon as such terms are included in the partition function which take account of the interaction with the bulk phase. Guggenheim's equation, (2), thus is not consistent with Gibbs' theorem. We first thought that the answer to these questions was that Gibbs' theorem was not correct. However elegant Gibbs' proof may be, it involves the use of chemical potentials of molecules in the surface layer with no proper analysis of whatever this may mean. The proof given by Guggenheim [10] involves a hypothetical experiment which is treated as if it were reversible although it most obviously cannot be reversed. It was pointed out to us, however, by H. Højgaard Jensen that it is possible to give a proof which involves nothing more than the second law and the conservation of mass.

A careful analysis of the energetic conditions of molecules in the surface and what could be meant by the chemical potentials of these brought out, then, that it was possible to give a treatment which is inherently consistent with Gibbs' theorem and which leads to a different concept of ideal behaviour with regard to surface tension.

How this result was originally derived from Brønsted's energetic theory and how it relates to other "transport complex" treatments will be discussed elsewhere. We will give here only a short account of its derivation along the lines of Guggenheims *Thermodynamics* [11].

The actual difficulty is in the definition of a chemical potential when other energetic variables are involved than the classical: S, V, N, T, P, μ. The same problem is involved in electrochemistry and in a gravitational field. In surface problems it is the field of the cohesive forces which interferes as a *partly* external force.

If we decide to specify the potential energy of the i'th component with respect to cohesive forces in a gas and in a liquid we can introduce a parameter χ_i. We can split up our ordinary chemical potential accordingly:

$$\mu_i = \mu_i^l + \chi_i^l = \mu_i^g + \chi_i^g \tag{7}$$

and in analogy with the nomenclature for electrochemical and gravitational systems we would refer to μ_i^l and μ_i^g as the "purely chemical potentials" and to our ordinary μ_i as the "cohesion-chemical potential". It will be the latter which determines the equilibrium between two phases in the same way as the electro-chemical and the gravitation-chemical potentials within their fields.

In the bulk phases χ_i is constant but in a surface layer the molecules will move in a field from the cohesive forces. Within a very short distance the potential energy of the van der Waals attraction rises from a large negative value, χ_i^l, in the bulk liquid phase to a value $\chi_i^g \simeq 0$ in the gas. In the same way as in a gravitational field, therefore, the equilibrium conditions are *not* homogeneity in P and the μ_i's but P,μ_i and χ_i are all functions of the position in the surface layer described through a parameter, t, measured along an axis normal to the surface, here supposed to be plane. The condition for equilibrium of a single component, i, is the same as in a mixture in a gravitational field (Guggenheim [11], eqn. 11.07.2):

$$\mathrm{D}\mu_i^t + V_i^t \mathrm{d}P^t + \mathrm{d}\chi_i^t = 0 \tag{8}$$

where $\mathrm{D}\mu_i = \Sigma_s(\partial\mu_i/\partial x_s)\mathrm{d}x_s$ accounts for the variations with composition of the bulk phase (*cf.* Guggenheim [11]). This condition shall be fulfilled for any value of t and therefore also in the bulk phases, whence we have at changing compositions of the bulk phases and hydrostatic pressure P:

$$\mathrm{D}\mu_i^t + V_i^t \mathrm{d}P^t + \mathrm{d}\chi_i^t = \mathrm{D}\mu_i^l + V_i \mathrm{d}P + \mathrm{d}\chi_i^l \tag{9}$$

We have no possibility neither in practise nor in principle to define the functions $\mu_i(t)$, $V_i(t)$, $P(t)$ or $x_i(t)$ in a thermodynamic way. The splitting up of the electrochemical potential in an electric part and a chemical part implies non-thermodynamic and to a certain degree arbitrary assumptions, and the same applies here.

The only entity which is physically measurable is the surface tension:

$$\gamma = \int_l^g (P - P^t)\mathrm{d}t \tag{10}$$

The integral extending from a point $t = l$ which is with certainty in the potential-homogeneous interior of the liquid to a point $t = g$ which is similarly situated in the gas. At both ends therefore $P^t = P$, making the exact positions of l and g immaterial.

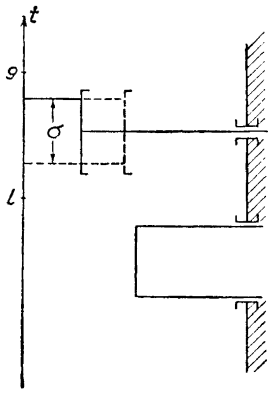

Fig. 5. "Surface piston."

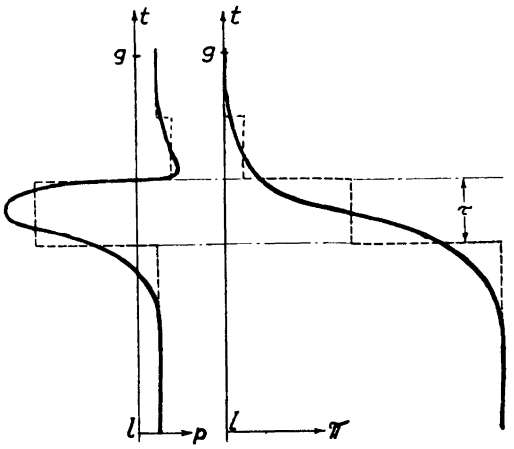

Fig. 6. Hypothetical shape of curves showing changes in pressure, p, and internal pressure, π, in passing from a point in the liquid, l, through the surface to a point in the gas, g.

γ can be measured by a surface piston arrangement (Fig. 5), but any attempt to measure P^t by sliding in pistons with an edge in the zone of potential-inhomogeneity, σ, will imply the creation of new boundary layers and yield no useful information on P^t.

To be able to give our functions definite values we must therefore assume some potential function, χ_i^t, and some equation of state $\Phi_i = \Phi_i(V_i, P, \chi_i) = 0$, and we can imagine that we could get a pressure curve like that of Fig. 6 with a narrow zone of expanded liquid under a large negative pressure and a zone of adsorbed, slightly compressed gas, but such assumptions are obviously outside the domain of thermodynamics, and a further treatment along such a line would fall under the theory of the liquid state and would remind of the classical works of van der Waals and Bakker [12].

To develop thermodynamic equations which are useful for the kind of problems we are dealing with here, we will choose another approach: the monolayer model. We neglect the adsorbed gas-layer and assume that what is different from the bulk phases can be thought of as concentrated in one homogeneous liquid layer of thickness τ. This represents a way of averaging the deviations from bulk phase behaviour by substituting continuous curves as those in Fig. 6 with "square wave" functions. Average values in the monolayer we designate by index s and obtain:

$$\gamma = (P - P^s)\ \tau \qquad\qquad \sigma_i = V_i^s/\tau$$

The equilibrium condition (9) takes the form

$$D\mu_i^s + V_i^s dP^s + d\chi_i^s = D\mu_i^l + V_i dP + d\chi_i^l \qquad (11)$$

Neglecting compressibility we can put $V_i^s = V_i$ and imagine a transfer from l to s in a continuous way which allows the integration:

$$\mu_i^s + V_i P^s + \chi_i^s = \mu_i^l + V_i P + \chi_i^l \quad (12)$$

or after insertion of γ and σ_i:

$$\mu_i^s + \chi_i^s - \gamma\sigma_i = \mu_i^l + \chi_i^l \quad (13)$$

Reverting to usual chemical potentials, or cohesion-chemical potentials, we put:

$$\mu_i^s + \chi_i^s = \mu_i' \qquad \text{and} \qquad \mu_i^l + \chi_i^l = \mu_i$$

and derive:

$$\mu_i' - \gamma\sigma_i = \mu_i \quad (14)$$

Our μ_i' is a cohesion-chemical potential and if we want a chemical potential which is the same both in surface and in bulk phases in equilibrium we must interpret the last equation as *defining* a special surface-cohesion-chemical potential, the surface part of which is zero in the bulk phases. Whichever view we take of this equation we can derive the same relations if we work in a consistent way. Equation (14) corresponds to similar relations derived by Defay and Prigogine[14], and the difference from their treatment appears only in the application, when we take into account that μ_i' itself depends on γ, because $\partial\mu_i'/\partial\gamma = -\sigma_i$ corresponding to the usual relation $\partial\mu_i/\partial P = V_i$ as in the surface layer $V_i = \tau\sigma_i$ and $\tau \mathrm{d}P^s = -\mathrm{d}\gamma$.

The thermodynamic difference between μ_i and μ_i' is:

$$\mu_i' = (\partial F'/\partial n_i')_{T,\gamma,\mathrm{nj}'} \neq \mu_i = (\partial F'/\partial n_i')_{T,A,\mathrm{nj}'}$$

Before we turn to the application of (14) to special cases, we should make its scope and its limitations clear. The introduction of a σ_i- or of a n_i'-parameter will always involve some arbitrary choice which relates closely to the arbitrariness involved for instance in the splitting up of the electro-chemical potential in a chemical and an electrical term. The derivation above indicates clearly that the possibility of introducing a characteristic partial molar surface area σ_i for a component rests on the neglection of the gaseous part of the surface layer. This neglection can be justified only at moderate pressures and far from critical point conditions. To investigate the influence of gas pressure on surface tension or the behaviour of surface tension near the critical point we would have to choose some other approach.

It will be of interest to see what order of magnitude the negative pressure in the surface layer will get. Taking CCl_4 at 25°C, 1 atm. as an example, we derive for close-packed lattice dimensions: $V = 97.07$ ml/mole; $\sigma = 19.5 \times 10^8$ cm²/mole; $\tau = 5.0$ Å; $P^s = 1 - \gamma/\tau = -500$ atm.

We can also compare the internal pressures $\pi = (\partial E/\partial V)_T$ in liquid and in monolayer, relating the latter to the surface energy $E' = (\partial E/\partial A)_T$. We have the two thermodynamic equations of state:

$$P + \pi = T(\partial P/\partial T)_V \quad (15)$$

$$-\gamma + E' = -T(\partial\gamma/\partial T)_A \quad (16)$$

The latter we can interpret as:

$$(P - P^s)\tau + (\pi - \pi^s)\tau = T\ (\partial(P - P^s)/\partial T)_V \tau \quad (17)$$

In CCl_4: $\pi = 3\,310$ atm (Hildebrand and Carter[16]) and $E' = 65.6$ dyn/cm giving $\pi - \pi^s = 1\,300$ atm and $\pi^s = 2\,010$ atm.

[MONO-LAYER SURFACES OF IDEAL AND REGULAR MIXTURES

Having derived the condition $\mu_i' - \gamma\sigma_i = \mu_i$ we can directly write down the expressions for μ' and μ corresponding to the model of regular solutions or we can construct partition functions and derive the μ's from these. We will differ from previous treatments in two respects: by letting the potential of the forces from the bulk phase, χ_i^b, contain not only a quadratic term but also a linear term in the mole fraction of the bulk phase and by appreciating that μ'_i depend on the surface tension. With a constant term $2\gamma_1\sigma_1$ in χ_1^b adjusted to fit in the limit $x_2 = 0$ we get for component 1:

$$\mu_1 - \mu_1^\circ = RT\ln x_1 + Wx_2^2 \tag{18}$$

$$\mu_1' - \mu_1^\circ = RT\ln x_1' + W'x_2'^2 + \chi_1^b - \sigma_1\gamma \tag{19}$$

$$\chi_1^b = 2\sigma_1\gamma_1 + \alpha_1 x_2 + W''x_2^2 \tag{20}$$

These expressions and the analogous for component 2 are in agreement with Gibbs' theorem which incidentally is identical with the Gibbs-Duhem condition applied to the mono-layer phase:

$$\begin{aligned} 0 &= x_1'\mathrm{d}\mu_1' + x_2'\mathrm{d}\mu_2' \\ &= x_1'\mathrm{d}\mu_1 + x_2'\mathrm{d}\mu_2 + (x_1'\sigma_1 + x_2'\sigma_2)\mathrm{d}\gamma \\ &= \left\{RT\left(\frac{x'_1}{x_1} - \frac{x'_2}{x_2}\right) - 2W(x_1' - x_1)\right\}\mathrm{d}x_1 + (x_1'\sigma_1 - x_2'\sigma_2)\mathrm{d}\gamma \\ &= 0\mathrm{d}x_1' + \{\alpha_2 x_2' - \alpha_1 x_1' - 2W''(x_1' - x_1)\}\,\mathrm{d}x_1 - (x_1'\sigma_1 + x_2'\sigma_2)\mathrm{d}\gamma \end{aligned} \tag{21}$$

The general relation between the surface tension of the mixture, γ, and those of the pure components, γ_1 and γ_2 is then:

$$\begin{aligned} \gamma &= \gamma_1 + \frac{1}{2\sigma_1}\left\{\alpha_1 x_2 + RT\ln\frac{x_1'}{x_1} + W'x'^2_2 - (W - W'')x_2^2\right\} \\ &= \gamma_2 + \frac{1}{2\sigma_2}\left\{\alpha_2 x_1 + RT\ln\frac{x_2'}{x_2} + W'x'^2_1 - (W - W'')x_1^2\right\} \end{aligned} \tag{22}$$

To derive Guggenheim's equation for regular mixtures we put $\alpha_1 = \alpha_2 = 0$, $\sigma_1 = \sigma_2 = A/2$ and $W = 2W' = 4W''$. Guggenheim's ideality requires further $W = 0$. Similarly Hoar and Melford's eqn. (18) appears if $\alpha_1 = \alpha_2 = 0$, $W = 2W'$ and $W'' = 0$. It is only in a formal way that (22) is brought to agree with these other expressions by doubling the surface area.

Since μ' contains a χ-term, there is no reason why α_1 and α_2 should be zero. Hence a more natural choice of what to define as an ideal or perfect surface will be:

$$\alpha_1/\sigma_1 = -\alpha_2/\sigma_2 = \gamma_2 - \gamma_1 \tag{23}$$

$$W = W' = W'' = 0 \tag{24}$$

which implies the relations:

$$x_1'/x_1 = \exp(\sigma_1(\gamma - \gamma_1)/RT) \tag{25}$$

$$\gamma_{id} = x_1\gamma_1 + x_2\gamma_2 \tag{26}$$

which give exactly the same distribution between bulk phase and monolayer as previous treatments. The difference is the rectilinear dependence of surface tension on mole fraction.

The same concept of ideal surface behaviour has been advanced before. Defay and Prigogine [13,14] use it, but only as an approximation which may be reasonable when γ_1 and γ_2 are not too different from each other.

Passing to regular solutions it is reasonable to maintain the α-values (23) and introduce values for W,W' and W'' corresponding to Guggenheim's model. This leads to the same distribution of the components as Guggenheim's own expressions, eqn. (2) above. The surface tension, however, comes out as the mean between the ideal value, γ_{id}, from eqn. (26) and the γ as calculated from Guggenheim's equation (2). This improves the agreement with our experiments in the region of low chloroform concentrations, but makes it worse in the other end.

The reason why our results for chloroform-carbontetrachloride mixtures corresponded quite well to Guggenheim's regularity is probably that the two components not only form regular mixtures but also have about the same surface tensions.

More experimental data are needed, particularly on regular mixtures of components with widely different surface tension.

The thermodynamic derivations in this paper draw heavily on ten years old discussions with Dr. Th. Rosenberg, now at the Danish Atomic Energy Research Station, Risø, and on recent discussions with professor H. Højgaard Jensen. The experimental work was carried out in collaboration with Dr. T. A. Bak and K. Andersen, who measured the viscosities of the same mixtures (to be published later).

On the Mathematical Iteration Principle and its Application to Chemical Equilibrium Calculations

A. E. LANSNER

Universitetets Fysisk-Kemiske Institut, Copenhagen, Denmark

The practical application of the method of iteration for the numerical calculation of roots in equations which cannot be solved is discussed.

It is shown that the theoretical condition of iteration convergence is to be substituted with a practical condition which makes the method appropriate for actual calculation. The method is demonstrated on chemical equilibrium calculations.

The importance of a particular "sensitive" variable is stressed.

In his work with chemical equilibrium expressions the chemist very often has to determine a root in an equation which cannot be solved or which can be solved only with difficulty. In the following the method of successive approximation (iteration) will briefly be mentioned. This method seems to be very useful for determination of approximate root values.

Suppose the given equation is $F(x) = 0$, and that r is the unknown root of interest. If it is possible to rewrite the equation $F(x) = 0$ in the form:

$$x = f(x)$$

where $f(x)$ is differentiable and $|f'(x)| \leq c < 1$ in the interval to be considered containing the root r, then the series

$$x_0,\ x_1 = f(x_0),\ x_2 = f(x_1), \ldots,\ x_n = f(x_{n-1}), \ldots$$

where x_0 is an estimated value for the root r, will be convergent with the limit

$$r = f(r)$$

This follows by repeated application of the meanvalue theorem:

$$\begin{aligned} |x_n - r| &= |f(x_{n-1}) - f(r)| \\ &= |f'(u)|\ |x_{n-1} - r| \\ &\leq c\ |x_{n-1} - r| = c\ |f(x_{n-2}) - f(r)| \\ &= c\ |f'(v)|\ |x_{n-2} - r| \\ &\leq c^2\ |x_{n-2} - r| = \ldots \\ &\leq c^n\ |x_0 - r| \rightarrow 0 \end{aligned}$$

when $n \rightarrow \infty$, *q.e.d.*

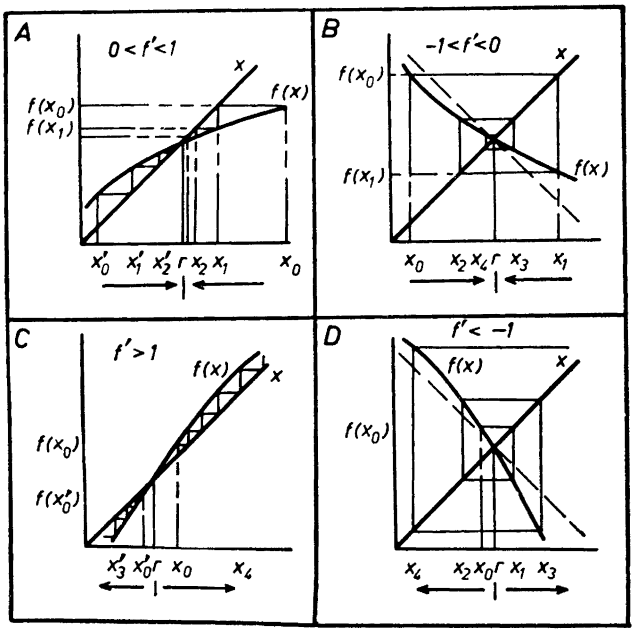

Fig. 1. A and B: condition of iteration is fulfilled, *i. e.* convergence.
C and D: condition of iteration is not fulfilled, *i. e.* divergence.
A and C: $f' > 0$, *i. e.* steady motion.
B and D: $f' < 0$, *i. e.* oscillating motion.

Further and analogous considerations in the case: $|f'(x)| \geq c \geq 1$ make clear, that the *condition of iteration convergence*

$$|f'(x)| < 1$$

in the neighbourhood of r, in theoretical respect is necessary and sufficient for the series convergence, but it must be emphazised that this condition is *not* sufficient for practical purposes, as will be seen in the following example: If $1 \simeq |f'(x)| < 1$, then n must be large if $x_n \simeq r$. This is tantamount to the necessity of calculation of many $f(x)$-values, which follows from: $|x_n - r| \leq c^n |x_0 - r|$ where $1 \simeq c < 1$. It is also evident from A, B-type diagrams (see Fig. 1).
Consequently the *practical condition of iteration convergence* must be:

$$|f'(x)| < c,$$

where c is essentially less than 1. Or otherwise expressed: The nearer $f(x)$ is by constancy in the interval containing the root, the faster the iteration process will progress (consider A,B-type diagrams for $f'(x) \simeq$ or $= 0$).

In many cases it is possible and appropriate first to rewrite the $F(x)$ given, so that the $F(x)$ function is mainly (and preferably strongly) depending on a

certain, single $x = x_s$ (the most "*sensitive*" x) in the $F(x)$ expression. Then this x_s is to be isolated in the equation given, *i.e.* $F(x) = 0$ is rewritten as $x_s = f(x)$. This $f(x)$ will fulfill the practical condition of iteration.

The principle of this successive approximation method is shown graphically in four characteristic cases where the condition of iteration: $|f'(x)| < 1$ partly is and partly is not fulfilled (diagrams A and B, and C and D, respectively).

Mathematical example

Suppose that calculations on a mass action expression has given the equation:

$$F(x) = x^4 + 10^{-2}x^3 - 10^{-4} = 0$$

where x is the degree of reaction. Consequently $0 < r < 1$. It is evident that the equation $F(x) = 0$ can be rewritten in many other forms. On account of the practical condition of iteration, it is appropriate to select an $f(x)$ function which depends only slightly on x ($f'(x)$ near 0).
Hence $F(x) = 0$ is rewritten in the form:

$$(x + 10^{-2})x^3 = 10^{-4} = 0$$

The greater x-exponent difference in this equation causes one of the two $f(x)$ functions, $(f_B(x))$, which is the most natural to select here, to be only slightly dependent on x, while the other, $(f_D(x))$, contrary to the condition of iteration, varies strongly with x. Obviously the most "sensitive" $x(= x_s)$ is contained in the factor x^3. Consequently

$$x_s = f_B(x) = \left(\frac{10^{-4}}{x + 10^{-2}}\right)^{1/3}$$

$$(x = f_D(x) = \frac{10^{-4}}{x_s^3} - 10^{-2}),$$

where $f'_B(x)$ and $f'_D(x)$ is < 0, and subscripts B and D refer to diagrams B and D. Notice that it is neither convenient nor necessary in general to calculate $f'(x)$. As $f(x)$, $f_B(x)$ is chosen because it is only a slightly varying function.

Now it only remains to choose a suitable x_0 (preferably in the neighbourhood of the root r). The general method for selection of x_0 is that the equation given is first solved qualitatively, with more or less good approximation. In most cases one can be helped through chemical considerations (pH-diagrams etc; see also "chemical example"). But in this and other cases one must try to estimate the root directly from the equation given. Thus it is often convenient to try the insertion of probable powers of ten for x_0. From $F(x) = 0$ rewritten in the form:

$$g(x) = (x + 10^{-2})x^3 = 10^{-4}$$

is estimated, that $r = 10^{-1}$, which gives:

$$g(10^{-1}) = 1.1 \times 10^{-4} \simeq 10^{-4}$$

i.e., 10^{-1} is an applicable value for x_0.

Consequently the convergence series is:

			error (%)
$x_0 = 10^{-1} =$		0.10000	2.4
$x_1 = f_a(x_0) = \left(\frac{10^{-4}}{10^{-1} + 10^{-2}}\right)^{1/3} =$		0.09688	0.7
$x_2 = f_a(x_1) =$		0.09781	0.2
$x_3 = f_a(x_2) =$		0.09752	0.07
$x_4 = f_a(x_3) =$		0.09761	0.02
$x_5 = f_a(x_4) =$		0.09759	0.01
$x_6 = f_a(x_5) =$		0.09759	0.01
—			
—			

Notice that even $x_1 = f(x_0)$ is a good approximation to $r = 0.09759\ldots$ Hence continuation of the iteration process for $n > 2$ generally will be superfluous in cases like the present.

Chemical example 1

Given is a gaseous mixture having the following composition

SO_2	7.8 vol %
O_2	10.8 vol %
N_2	81.4 vol %
	100.0 vol %

This gaseous mixture is passed into a converter where in the presence of a catalyst the SO_2 is oxidized to SO_3. The temperature in the converter is maintained at 500°C and the pressure at 1 atm, which is corresponding to $K_c = 177\ 800$ l/st* for the equilibrium:

$$2SO_2 + O_2 = 2SO_3$$

Calculate the composition of the gases leaving the converter, assuming that equilibrium conditions are reached. It may be assumed that the fugacity coefficients are equal to unity.

Qualitative solution. Notice that $K_c \gg 1$ and the amount of O_2 equivalent to the 7.8 vol % SO_2 (in the gas mixture given) is $1/2 \times 7.8 = 3.9 < 10.8$ vol % (= vol % O_2 in the mixture). Consequently the composition of the equilibrium mixture must approximately be:

SO_2	0 vol %	SO_3	8 vol %
O_2	7 "	N_2	85 "

Quantitative solution

$$2SO_2 + O_2 = 2SO_3$$

$n_{total} = n_{SO_2} + n_{O_2} + n_{SO_3} + n_{N_2}$	moles of equilibrium mixture
$n_{total} = (a - 2x) + (b - x) + (0 + 2x) + c$	" " "
$n_{total} = a + b + c - x$	" " "

* st is by definition the number of moles equal to the stoichiometrical coefficients in the given scheme of reaction.

where a, b, 0 and c is the initial number of moles of SO_2, O_2. SO_3 and N_2, and x is the equilibrium conversion of SO_2.
Suppose $a + b + c = 100$ moles; then we get $n_{total} = 10 - x$ moles.
If by definition

$$K_n = \Pi n_i^{\nu_i} = \frac{(n_{SO_3})^2}{(n_{SO_2})^2\,(n_{O_2})}$$

where ν_i is the stoichiometrical coefficient of the i-th component, then:

$$K_c = K_n v^{-\Sigma\nu_i} = K_n v \text{ (for } -\Sigma\nu_i = -(2-2-1) = 1.$$

If the ideal gas laws are valid

$$v = n_{total} RT/p = (100-x)RT/p$$

i.e.,

$$K_c = \frac{(2x)^2(100-x)\;RT}{(a-2x)^2(b-x)\;p}, \text{ or}$$

$$\frac{x^2(100-x)}{(a/2-x)^2\,(b-x)} = \frac{pK_c}{RT}$$

Now

a	$= 7.8$ mole	p	$= 1$ atm
b	$= 10.8$ "	R	$= 0.08205$ l.atm/K.mole
K_c	$= 177\,800$ l.atm/K.mole	T	$= 773.2$ K

Hence the equation $F(x) = 0$ is

$$\frac{x^2\,(100-x)}{(3.9-x)^2\;(10.8-x)} - 2802.6 = 0$$

From the qualitative solution we have:
$n_{SO_3} = a - 2x \simeq 0$ (almost complete reaction), *i.e.*

$$x \simeq \frac{a}{2} = 3.9.$$

Consequently 3.9 must be suitable as the initial value x_0. The qualitative result, $x \simeq 3.9$, also makes clear that it is the x $(= x_s)$ in the group $3.9-x$ which is the most "sensitive". Hence we rewrite $F(x) = 0$ in the form

$$x_s = 3.9 - \frac{x}{53}\sqrt{\frac{100-x}{10.8-x}}$$

We now use the iteration principle

$$x_{n+1} = 3.9 - \frac{x_n}{53}\sqrt{\frac{100-x_n}{10.8-x_n}}$$

and get the following convergence series

x_0	$=$	3.900
x_1	$= 2.9 - \frac{3.9}{53}\sqrt{\frac{100-3.9}{10.8-3.9}} =$	3.63
x_2	$=$	3.649
x_3	$=$	3.647
—		
—		

i.e.

$$x = r \simeq 3.647 \simeq 3.65.$$

Consequently

n_{SO_3}	$= 2x$	$= 2 \times 3.65$	$=$	7.30	mole or	7.58	vol %
n_{O_2}	$= b\text{-}x$	$= 10.8 - 3.65$	$=$	7.15	" "	7.42	"
n_{SO_2}	$= a\text{-}2x$	$= 7.8 - 7.30$	$=$	0.50	" "	0.52	"
n_{N_2}	$=$			81.40	" "	84.47	"
				96.35	mole or	100.00	vol %

which is in agreement with the qualitative solution.

Simultaneous equations

In the general case, with simultaneous equations in several unknowns, the method of iteration is given by the following two-equation example:

Suppose the given equations are

$$F(x,y) = 0 \text{ and } G(x,y) = 0.$$

In general the two independent variables are asymmetrical in the equations, and this is to be utilized for a fast working iteration process.

Assume that a certain $x = x_s$ in $F(x,y)$ is the relatively most "sensitive" of all the x's *and* y's in the two (eventually rewritten) functions given, and that y_s is the most "sensitive" of the y's only in the other function $G(x,y)$. Then isolate x_s in $F(x,y) = 0$ and y_s in $G(x,y) = 0$:

$$x_s = f(x,y) \text{ and } y_s = g(xy).$$

Now the two iteration principles are

$$x_{n+1} = f(x_n,y_n)$$

and

$$y_{n+1} = g(x_{n+1}, y_n)$$

i.e.

$$y_{n+1} = u(x_n, y_n) = g(f(x_n, y_n), y_n).$$

The initial values x_0 and y_0 are also in this case to be selected by qualitative solution of the problem considered.

Chemical example 2

Calculate c_{H+} and c_{H_2Ox} in a 0.1 M solution of potassium hydrogen oxalate in water. Assume that the activity coefficients are equal to unity, and that

$$K_1 = 10^{-1.19} \text{ and } K_2 = 10^{-4.21}$$

The schemes of significant reactions are

		degree of reaction
HOx^-	$= H^+ + Ox^{--}$	x
$2HOx^-$	$= H_2Ox + Ox^{--}$	y

Qualitative solution

$pH = 1/2(pK_1 + pK_2) = 2.7$, *i.e.* $C_{H+} = x = 0.002$ and $y = 0.003$

Quantitative solution

$$\begin{array}{llll} H^+ & = x & Ox^{--} & = x + y \\ H_2Ox & = y & HOx^- & = 0.1 - x - 2y \end{array}$$

Hence

$$K_1 = 10^{-1.19} = \frac{x}{y}(0.1 - x - 2y)$$

$$K_2 = 10^{-4.21} = \frac{x(x+y)}{0.1 - x - 2y}$$

rewritten as

$$F(x,y) = x^2\left(1 + \frac{10^{-1.19}}{0.1 - x - 2y}\right) = 10^{-5.40} = 0$$

$$G(x,y) = x\frac{0.1 - x - 2y}{y} - 10^{-1.19} = 0$$

It is to be seen that "x_s" is contained in the group x^2 in the F function. Hence

$$x_{n+1} = f(x_n, y_n) = \left(\frac{10^{-5.40}}{1 + \dfrac{10^{-1.19}}{0.1 - x_n - 2y_n}}\right)^{1/2}$$

and analogously

$$y_{n+1} = g(x_{n+1}, y_n) = x_{n+1}\frac{0.1 - x_{n+1} - 2y_n}{10^{-1.19}}$$

From the qualitative solution we choose $x_0 = y_0 = 0$. Consequently the two convergence series are derived as follows:

$$\begin{array}{llll} x_0 & = 0 & y_0 & = 0 \\ x_1 & = f(x_0,y_0) & y_1 & = g(x_1, y_0) \\ & = 1.556.10^{-3} & & = 2.371.10^{-3} \\ x_2 & = f(x_1, y_1) & y_2 & = g(x_2, y_1) \\ & = 1.535.10^{-3} & & = 2.229.10^{-3} \\ x_3 & = f(x_2, y_2) & y_3 & = g(x_3, y_2) \\ & = 1.536.10^{-3} & & = 2.237.10^{-3} \\ - & & y_4 & = g(x_3, y_3) \\ - & & & = 2.236.10^{-3} \end{array}$$

i.e.

$$x = 1.54.10^{-3} \text{ and } y = 2.24.10^{-3} \text{ (mole/l)}$$

It is a matter of course that the practical condition of iteration convergence is also well applicable to the approximative solution of transcendental equations as, for instance, $F(x) = 2\,\mathrm{tg}x - x = 0$.

Finally it is noticed that the iteration process can easily be accelerated, if by the calculation of say x^{n+1}, it is possible, from the foregoing series values to estimate a better value x'_n than the x_n, and then insert this x'_n instead of x_n.

Short Communications

Mass Transfer by Laminar Free Convection at Vertical Electrodes

GÖSTA WRANGLÉN

Division of Applied Electrochemistry, Royal Institute of Technology, Stockholm 70, Sweden

The following notion is used:

x = distance along electrode surface from lower edge of cathode or upper edge of anode
y = distance from electrode surface
h = electrode height
$\delta_{d\,0.99}$ = thickness of diffusion boundary layer or electrode film, defined so that $|c-c_e| = 0.99\,\Delta c$
δ_h = thickness of hydrodynamic boundary layer
δ_N = thickness of the Nernst diffusion layer or effective film thickness
$\delta_=$ = distance from electrode at which diffusion = convection
u = vertical flow velocity in boundary layer
c, c_b, c_e and c_s = concentrations in diffusion layer, of bulk electrolyte, on electrode surface and at saturation, respectively
$\Delta c = |c_e - c_b|$
ϱ = density in diffusion layer
$a = \frac{\delta \ln \varrho}{\delta c}$ = specific densification coefficient
ν = kinematic viscosity
D = diffusion coefficient
g = acceleration of gravity
i = current density
$j = \frac{i(1-t)}{zF}$ = diffusion current density
t = transference number of reacting ion
z = valency of electrode reaction
F = Faraday's constant
i_{lim} = local limiting current density
Nu_x = $jx/D\Delta c$ and Nu_{av} local and average Nusselt numbers, respectively
$Sc = \frac{\nu}{D}$ = Schmidt number
Gr_x = local Grashof number

In earlier work on mass transfer under free convection conditions, in which the analogy with heat transfer was used, δ_d and δ_h have usually been assumed identical [1,2]. While this is often justified in heat transfer, available numerical solutions of the boundary layer equations [3,4] show that with high Schmidt numbers ($Sc \simeq 1\,000$), as in mass transfer in liquids, δ_h is 10—15 times larger than δ_d. Generally [5], $\delta_h/\delta_d \simeq Sc^{1/3}$. Furthermore, u_{max} is reached at a distance of about 2/3 δ_d from the electrode.

As to boundary conditions, two important cases have to be distinguished, *viz.* I) constant concentration or potential on the electrode surface, and II) constant concentration gradient or current density on the electrode surface. Case I is probably realized only under limiting current conditions [6].

Considering the numerical solutions referred to [3,4], the following approximations are applied for the concentration profile in the boundary layer

$$|c - c_b| = \Delta c \left(1 - \frac{y}{\delta_d}\right)^2 \qquad \text{(case I)}$$

$$|c - c_b| = \frac{j\delta_d}{2D}\left(1 - \frac{y}{\delta_d}\right)^2 \qquad \text{(case II)}$$

and for the velocity profile in both cases

$$u = 3.375\, u_{max} \frac{y}{\delta_d}\left(1 - \frac{y}{2\delta_d}\right)^2 \text{ for } 0 \leq y \leq \frac{2}{3}\delta_d$$

and

$$u = 0.07\, u_{max}\, Sc^{1/3}\left(1.5\, Sc^{1/3} - \frac{y}{\delta_d}\right) \text{for } \frac{2}{3}\,\delta_d \leq y \leq 1.5\, Sc^{1/3}\delta_d$$

With these expressions, the boundary layer equations can be integrated according to von Kármán to give approximate analytical solutions. The numerical coefficients are then obtained by comparison with the numerical solutions of the analogous heat transfer problems, corresponding to case I (3) and case II (4). The following results are obtained. They refer to cathodic deposition and anodic dissolution of metals. Details of the calculations will be published elsewhere.

Case I (limiting current density)

$$i_{\lim} = 0.499 \frac{zF}{1-t} D \Delta c \left(\frac{g a \Delta c}{D \nu x}\right)^{1/4}$$

$$\delta_{d\,0.99} = 3.54 \left(\frac{D \nu x}{g a \Delta c}\right)^{1/4}$$

$$\delta_N = 0.57\ \delta_{d\,0.99}, \quad \delta_{\infty} = 0.55\ \delta_{d\,0.99}$$

$$u_{\max} = 1.0 \left(\frac{D g a \Delta c x}{\nu}\right)^{\frac{1}{2}}$$

$$Nu_x = 0.499\ (ScGr_x)^{1/4}$$

$$Nu_{\mathrm{av}} = \frac{4}{3} Nu_h = 0.665\ (ScGr_h)^{1/4}$$

At the cathode $c_e = 0$, at the anode $c_e = c_s$ under limiting current condition. $i_{\lim}$ is then the passivating c.d. at the anode.

Case II (normal electrolysis)

$$\Delta c = 1.59\ j \left(\frac{\nu x}{D^2 g a j}\right)^{1/5}$$

$$\delta_{d\,0.99} = 3.09 \left(\frac{D^2 \nu x}{g a j}\right)^{1/5}$$

$$\delta_N = 0.51\ \delta_{d\,0.99}$$

$$u_{\max} = 1.1 \left(\frac{g a j}{\nu}\right)^{2/5} D^{1/5} x^{3/5}$$

$$Nu_x = 0.558\ (ScGr_x)^{1/4}$$

$$Nu_{\mathrm{av}} = \frac{6}{5} Nu_h = 0.670\ (ScGr_h)^{1/4}$$

In the presence of a conducting inert electrolyte, a correction term appears in a. The correction derived by Wilke and coworkers [2] for case I is applicable also in case II.

Detection of Small Amounts of Δ^3-Carene in α-Pinene

ERKKI PULKKINEN, EERO SILTANEN and VEIKKO PIRILÄ

Institute of Chemistry, University of Helsinki and Institute of Occupational Health, Helsinki, Finland

In connection with investigations on the sensitization of the skin to oil of turpentine [1-3] it was necessary to detect small amounts of Δ^3-carene in α-pinene. Widmark [4] has investigated the purity of various terpenes with the microsorption method according to Blohm [5]. With this method he was able to show the index inhomogeneity of α-pinene into which 0.2 % or more Δ^3-carene had been added [6]. When investigating the purity of various terpenes we have used the infrared spectrophotometry which has the advantage of being specific. As a criterion for purity we have used the spectra of the series of American Petroleum Institute Research Project 44 *.

In order to purify different terpenes, fractional distillation with Podbielniak-column and displacement chromatography were used. The latter method was more practicable giving equal or better results in shorter time. The displacement was performed on a macro scale by jointing together some columns with different diameters [7,8], in order to gain sharp fronts. The fractions were analyzed with infrared spectrophotometry [8,9]. For detection of Δ^3-carene in α-pinene the absorption peak of wave number 714 cm^{-1} appeared to be most suitable and made it possible to show 0.39 % Δ^3-carene (Fig. 1) with a liquid

* Serial No. 566 for α-pinene, 567 for β-pinene, 1 469 for Δ^3-carene and 462 for *d*-limonene.

With these expressions, the boundary layer equations can be integrated according to von Kármán to give approximate analytical solutions. The numerical coefficients are then obtained by comparison with the numerical solutions of the analogous heat transfer problems, corresponding to case I (3) and case II (4). The following results are obtained. They refer to cathodic deposition and anodic dissolution of metals. Details of the calculations will be published elsewhere.

Case I (limiting current density)

$$i_{\lim} = 0.499 \frac{zF}{1-t} D \Delta c \left(\frac{g a \Delta c}{D \nu x}\right)^{1/4}$$

$$\delta_{d\,0.99} = 3.54 \left(\frac{D \nu x}{g a \Delta c}\right)^{1/4}$$

$$\delta_N = 0.57\ \delta_{d\,0.99}, \quad \delta_{\infty} = 0.55\ \delta_{d\,0.99}$$

$$u_{\max} = 1.0 \left(\frac{D g a \Delta c x}{\nu}\right)^{\frac{1}{2}}$$

$$Nu_x = 0.499\ (ScGr_x)^{1/4}$$

$$Nu_{\mathrm{av}} = \frac{4}{3} Nu_h = 0.665\ (ScGr_h)^{1/4}$$

At the cathode $c_e = 0$, at the anode $c_e = c_s$ under limiting current condition. $i_{\lim}$ is then the passivating c.d. at the anode.

Case II (normal electrolysis)

$$\Delta c = 1.59\ j \left(\frac{\nu x}{D^2 g a j}\right)^{1/5}$$

$$\delta_{d\,0.99} = 3.09 \left(\frac{D^2 \nu x}{g a j}\right)^{1/5}$$

$$\delta_N = 0.51\ \delta_{d\,0.99}$$

$$u_{\max} = 1.1 \left(\frac{g a j}{\nu}\right)^{2/5} D^{1/5} x^{3/5}$$

$$Nu_x = 0.558\ (ScGr_x)^{1/4}$$

$$Nu_{\mathrm{av}} = \frac{6}{5} Nu_h = 0.670\ (ScGr_h)^{1/4}$$

In the presence of a conducting inert electrolyte, a correction term appears in a. The correction derived by Wilke and coworkers [2] for case I is applicable also in case II.

Detection of Small Amounts of Δ^3-Carene in α-Pinene

ERKKI PULKKINEN, EERO SILTANEN and VEIKKO PIRILÄ

Institute of Chemistry, University of Helsinki and Institute of Occupational Health, Helsinki, Finland

In connection with investigations on the sensitization of the skin to oil of turpentine [1-3] it was necessary to detect small amounts of Δ^3-carene in α-pinene. Widmark [4] has investigated the purity of various terpenes with the microsorption method according to Blohm [5]. With this method he was able to show the index inhomogeneity of α-pinene into which 0.2 % or more Δ^3-carene had been added [6]. When investigating the purity of various terpenes we have used the infrared spectrophotometry which has the advantage of being specific. As a criterion for purity we have used the spectra of the series of American Petroleum Institute Research Project 44 *.

In order to purify different terpenes, fractional distillation with Podbielniak-column and displacement chromatography were used. The latter method was more practicable giving equal or better results in shorter time. The displacement was performed on a macro scale by jointing together some columns with different diameters [7,8], in order to gain sharp fronts. The fractions were analyzed with infrared spectrophotometry [8,9]. For detection of Δ^3-carene in α-pinene the absorption peak of wave number 714 cm^{-1} appeared to be most suitable and made it possible to show 0.39 % Δ^3-carene (Fig. 1) with a liquid

* Serial No. 566 for α-pinene, 567 for β-pinene, 1 469 for Δ^3-carene and 462 for *d*-limonene.

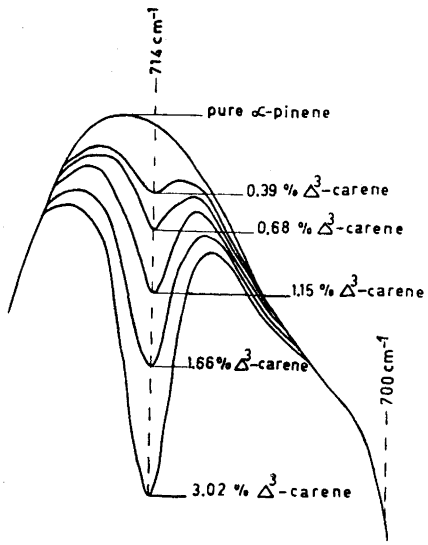

Fig. 1. A part of the infrared spectrum of Δ^3-carene in α-pinene with the peak at 714 cm^{-1} (1.0 mm cell).

layer of 1.0 mm thickness. After enrichment by displacement chromatography 0.1 % of Δ^3-carene could be detected in some experiments. Silica gel and aluminium oxide were used as adsorbents. With both these adsorbents *d*-α-pinene and Δ^3-carene could be separated sharply from their mixtures. According to our observations, however, when using silica gel it must be taken into consideration, that the adsorbent, if too activated, tends to cause rearrangement of α-pinene.

Experimental part. Purification of α-pinene by chromatography.

20 ml of *d*-α-pinene (Variochem VVB Schimmel, Miltitz, Bz Leipzig, $[\alpha]_D$ +38.42°, distilled over sodium, infrared spectrophotometrically impure) was displaced by ethyl alcohol with alumina (E. Merck, Darmstadt, standardised according to Brockmann) as adsorbent using a series of three columns (41 300π + 11 000π + 4 500π mm^3). Judging from the infrared spectra of the collected fractions, about 70 % of the input was free of impurities.

Purification of Δ^3-carene by chromatography. The raw product of Δ^3-carene (from Enso-Gutzeit Oy, Finland) was rectified with Podbielniak-Skärblom-Linder-column [10] and a fraction, boiling range 170—171°C, was purified by displacement with ethyl alcohol using silica gel (Davison, 1 # Grade 922 Mesh Size T. 200, Davison Code No. 922—08-4X-1926) as adsorbent. Filters: 2 200π + 1 000π mm^3. The infrared spectra of the collected fractions showed that about 50 % of the input had at least 95 % purity, comparing with the spectrum of Δ^3-carene of the American Petroleum Institute.

Detection of small amounts of Δ^3-carene in α-pinene. 20 ml of the mixture, which contained 0.1 % Δ^3-carene in *d*-α-pinene was submitted to displacement using, as above, ethyl alcohol as the displacing agent and silica gel (Davison, 922-08-4X-1926) as the adsorbent. Filters: 41 000π+11 500π + 4 250π mm^3. After 18.2 ml of the effluent had been collected, the next 0.4 ml (fraction 18.2—18.6 ml) gave the peak of Δ^3-carene at 714 cm^{-1} in the infrared spectrum. It could be calculated that about 18 % of the amount of Δ^3-carene added to α-pinene was found in this fraction. Similar results were obtained using alumina as the adsorbent.

All infrared spectra were measured with a Perkin-Elmer Spectrometer Model 12-C equipped with a rock salt prism.

Structure of the Crystalline Compound Benzene-Bromine (1 : 1)

O. HASSEL and KNUT O. STRØMME

Universitetets kjemiske institutt, Blindern-Oslo, Norway

Several models have been suggested for the complexes between benzene and halogen molecules known to exist in solutions, one of which, the "axial" model, has the halogen atoms situated on the six-fold axis of the benzene molecule, the symmetry being C_{6v}.

In order to gain some direct experience regarding the structure of complexes containing aromatic hydrocarbons and halogens we have tried to prepare solid compounds and to investigate the crystals by X-rays. In the case of benzene we obtained single crystals of a 1:1 compound with bromine (m.p. −14°C) which were studied at temperatures between −40° and −50°C. Crystals having one of their chief crystallographic axes approximately parallel to the capillary tube in which they were grown were chosen for exposure in a Weissenberg camera. The (monoclinic) axes are $a = 7.75$; $b = 8.83$; $c = 5.94$; $\beta = 99.3°$. From observed extinctions all space groups but $C2/m$, $C2$ and Cm could be excluded. Assuming a reasonable value of the density it follows that *two* molecules of either kind are contained in the unit cell. Suggesting the most symmetrical group $C2/m$ to be the correct one, the parameters of the bromine atoms were worked out from Patterson projections and trial and error computations.

A very satisfactory agreement between observed and calculated intensities was thus obtained. From the coordinates of the bromine atoms alone Fourier maps giving projections of the structure along the a and c axes were computed. Although all structure factor signs were computed neglecting the lighter atoms, the resultant charts turned out to contain, besides the heavy peaks corresponding to the bromine atoms, lower peaks allowing the localisation of the carbon atoms also with some degree of accuracy. The final maps are reproduced in Fig. 1 (*a*) and (*c*). No spurios peaks are observed and termination of series effects are small due to strong thermal vibrations resulting in an unusually marked fall in intensities for larger ϑ values.

The bromine-bromine distance found is 2.28 Å and appears therefore to be very nearly the same as observed in the free molecule. The line joining the two bromine atoms is parallel to [101] and passes through the symmetry centre of the benzene ring. The angle between this direction and the benzene plane is at least very nearly 90°. The distance from each bromine atom to the adjacent benzene plane is 3.36 Å. It is interesting to note that the π electrons of all six C−C bonds must be equally involved in formation of the electron transfer bond. This is not necessarily so, of course, in the case of the 1:1 complex present in solutions. Here a somewhat stronger binding may possibly result if the axis of the bromine molecule is parallel to the benzene plane. The symmetrical chains of alternating benzene and bromine molecules and the fact that both atoms of a bromine molecule take part in bond formation provide an interesting analogy to the structure of the dioxan-bromine compound.

The very marked drop in X-ray intensities for increasing reflexion angles, in fact more marked than in any addition compound so far examined, indicates the weakness of the binding forces between the two components. The amplitudes of vibration appear to be particularly large in directions perpendicular to the direction of the molecule chains — [101]. This may indicate either that the potential energy of the bromine atom has only one very flat minimum for a position on the chief axis of the benzene ring or perhaps six minima outside this axis.

The computed "reliability factor" R (taking into account the anisotropic vibrations) is found equal to 0.12 for both projections reproduced in Fig. 1 (*a*) and (*c*). We think that the structure derived from our present material is certainly essentially correct, but hope to be able to supplement the investigation with material obtained at lower temperatures. Such investigations might contribute towards clearing up the question (mentioned above) regarding the potential energy curve of the bromine atom.

Preparation of Deuterated Vinyl Fluorides

BØRGE BAK and DANIEL H. CHRISTENSEN

Chemical Laboratory of the University of Copenhagen, Denmark

Recent attempts to analyze the infrared spectrum of *vinyl fluoride* [1] and to determine the structure of the molecule by microwave measurements [2] necessitated the preparation of all the deuterated derivatives. Since the combination of processes used and the yields obtained may be of value for future work on vinyl fluoride in the above-mentioned or quite different directions (such as reaction kinetics) it seemed justified to give a brief account of our results. Vinyl fluoride (I) and its seven deuterated derivatives have been prepared, three as pure compounds, CH_2CDF (II), CD_2CHF (V), and CD_3CDF (VI), and four as *cis-trans* mixtures, *cis-trans* CHDCHF (III), and *cis-trans* CHDCDF (IV).

Experimental. All the preparations described here are combinations of 4 or 6 of the following 7 processes (A—G), for sake of brevity illustrated below with 'light' ethylene bromide, vinyl bromide *etc.*

A: $\begin{matrix}CH_2Br\\|\\CH_2Br\end{matrix} \xrightarrow[KOH]{} \begin{matrix}CH_2\\\|\\CHBr\end{matrix}$ Ref.[3]

B: $\begin{matrix}CH_2\\\|\\CHBr\end{matrix} \xrightarrow[Br_2]{} \begin{matrix}CH_2Br\\|\\CHBr_2\end{matrix}$ Ref.[3]

C: $\begin{matrix}CH_2Br\\|\\CHBr_2\end{matrix} \xrightarrow[SbF_3]{} \begin{matrix}CH_2Br\\|\\CHBrF\end{matrix} + \begin{matrix}CH_2Br\\|\\CHF_2\end{matrix}$ =mixture M Ref.[3,4]

D: M $\xrightarrow[Zn]{}$ $\begin{matrix}CH_2\\\|\\CHF\end{matrix}$ Ref.[3]

E: $\begin{matrix}CH_2Br\\|\\CHBr_2\end{matrix} \xrightarrow[EtONa]{} \begin{matrix}CH_2\\\|\\CBr_2\end{matrix}$ Ref.[5]

F: $\begin{matrix}CH_2\\\|\\CBr_2\end{matrix} \xrightarrow[HBr]{} \begin{matrix}CH_2Br\\|\\CHBr_2\end{matrix}$ Ref.[6,7]

G: $\begin{matrix}CH_2\\\|\\CBr_2\end{matrix} \xrightarrow[DBr]{} \begin{matrix}CH_2Br\\|\\CDBr_2\end{matrix}$ Ref.[6,7]

The directions given in the literature [3-6] were modified with respect to the fact that much smaller quantities than usual were prepared. For example, procedure *C* was carried out in a sealed-off glass tube (24 h at 100°C) instead of in the platinum apparatus prescribed by Swarts, without serious decrease in the yield. In the *E* process, 2.5 ml $CH_2BrCHBr_2$ (or $CD_2BrCDBr_2$ a.s.o.) were converted to CH_2CBr_2 in a nitrogen atmosphere. Vinylidene bromide was removed from the small reaction container by a syringe and rapidly transferred to a nitrogen-filled test tube, from which it was distilled *in vacuo* at 20°C ($p \sim 60$ mm) after drying over $CaCl_2$ for a couple of hours. — SbF_3 and DBr were prepared according to prescriptions in Ref.[8] resp. Ref.[7]

The purity of all intermediates was controlled by infrared spectra. In all cases except one, the intermediates were 95—100 % pure. The reaction product from *C* is a mixture ('M') which was not separated into its components, since both yield the product desired. The addition of HBr, resp. DBr to the double bond (processes *F* and *G*) occurred very smoothly at room temperature under irradiation by mercury light in containers of ordinary Pyrex glass. Addition of a trace of pure oxygen had a pronounced catalytical effect. No exchange reactions took place.

The isotopic vinyl fluorides were liberated as gases (b.p. —51°C) from the mixture of 'M', Zn-dust, and ethyl alcohol. They were condensed in a trap cooled by liquid air and afterwards distilled, the trap being immersed in a —80°C bath. Only fractions of approximately correct pressure were taken. The final purification occurred on dry silica-gel in a gas chromatograph at 43°C (inside diameter of tube $\sim$ 10 mm, length of column 11 cm). In this way, the last non-isotopic impurities were removed as demonstrated by the infrared spectra taken. Also, since a complete collection of deuterated species was prepared, a useful check on the *isotopic* purity of the samples was obtained from the spectra.

Prior to the present investigation we thought that the *stability* of vinyl fluoride, kept in glass containers at room temperature and in daylight would be a problem. Infrared spectra of samples kept for months under the conditions mentioned showed the samples to be stable.

Our results are given in condensed form in Tables 1 and 2.

Table 1. Procedures applied (A—G), per cent yields obtained, and amount of final product (in ml at t°C = 25, p = 760 mm) at the preparation of vinyl fluoride (I), CH_2CDF (II), CD_2CHF (V), CD_2CDF (VI), the *cis-trans* mixture CHDCHF (III), and *cis-trans* mixture CHDCDF (IV). The general formula of the starting material is taken as CXYBrCXYBr, Z grams of this material being applied.

Determination of Barbituric Acid Derivatives as Mercury Complexes

C. O. BJÖRLING, A. BERGGREN and B. WILLMAN-JOHNSON

Research Laboratories, Pharmacia Ltd., Uppsala

A. GRÖNVALL and B. ZAAR

Department of Clinical Chemistry, University Hospital, Uppsala, Sweden

Barbituric acid derivatives give precipitates with mercuric ions and this characteristic has since long been used for their detection and determination [1-3]. The precipitates are, however, soluble in certain organic solvents and this fact has been the base for the present method, the principles of which are as follows.

To a solution of 50—250 μg of a barbituric acid in 10 ml of water add 1 ml of 0.3 % mercuric nitrate solution and buffer solution to pH 8.0. Extract with 3 or 4 × 10 ml of a suitable organic solvent. Filter the organic phase through glass-wool moistened with the solvent, carefully avoiding any entrainment. To the combined extracts add an exactly measured volume of a 0.0015 % dithizone solution in chloroform and dilute to 100 ml with chloroform. Make a blank by mixing an equal amount of the dithizone solution with the same volume of the extraction solvent as above and making up to 100 ml with chloroform. Measure the extinction difference at 605 mμ. Calculate the amount of the barbituric acid from a standard curve prepared by applying the method to known quantities of barbiturate. It is, however, more convenient to use mercuric chloride when constructing a standard curve which can be used for all barbituric acids. 1 mole of mercury corresponds to 2 moles of the N-substituted barbiturates and to 1 mole of all the others.

Smaller amounts of barbituric acid can easily be determined by reducing the volumes. Thus, 2 μg of amylobarbitone (amytal) in a final volume of 5 ml gives an extinction difference of 0.130 in 1 cm cuvette, which corresponds to a sensitivity 5 times greater than that obtained by the ultraviolet methods now in use [4].

CHDBrCHDBr was prepared from acetylene and DBr [7].

Determination of Barbituric Acid Derivatives as Mercury Complexes

C. O. BJÖRLING, A. BERGGREN and B. WILLMAN-JOHNSON

Research Laboratories, Pharmacia Ltd., Uppsala

A. GRÖNVALL and B. ZAAR

Department of Clinical Chemistry, University Hospital, Uppsala, Sweden

Barbituric acid derivatives give precipitates with mercuric ions and this characteristic has since long been used for their detection and determination [1-3]. The precipitates are, however, soluble in certain organic solvents and this fact has been the base for the present method, the principles of which are as follows.

To a solution of 50—250 μg of a barbituric acid in 10 ml of water add 1 ml of 0.3 % mercuric nitrate solution and buffer solution to pH 8.0. Extract with 3 or 4 × 10 ml of a suitable organic solvent. Filter the organic phase through glass-wool moistened with the solvent, carefully avoiding any entrainment. To the combined extracts add an exactly measured volume of a 0.0015 % dithizone solution in chloroform and dilute to 100 ml with chloroform. Make a blank by mixing an equal amount of the dithizone solution with the same volume of the extraction solvent as above and making up to 100 ml with chloroform. Measure the extinction difference at 605 mμ. Calculate the amount of the barbituric acid from a standard curve prepared by applying the method to known quantities of barbiturate. It is, however, more convenient to use mercuric chloride when constructing a standard curve which can be used for all barbituric acids. 1 mole of mercury corresponds to 2 moles of the N-substituted barbiturates and to 1 mole of all the others.

Smaller amounts of barbituric acid can easily be determined by reducing the volumes. Thus, 2 μg of amylobarbitone (amytal) in a final volume of 5 ml gives an extinction difference of 0.130 in 1 cm cuvette, which corresponds to a sensitivity 5 times greater than that obtained by the ultraviolet methods now in use [4].

The optimum pH range of the extraction varies for different barbiturates, but a pH of 8.0 is suitable for most of the compounds.

Chloroform can be used for the extraction of the N-substituted compounds and of 5-*iso*amyl-5-ethyl- and 5-allyl-5-phenyl-barbituric acids. Chloroform with 20 % dioxane is suitable for 5-ethyl-5-phenyl-barbituric acid. Chloroform with 20 % of benzyl alcohol extracts 5,5-diallyl-, 5,5-diethyl-, 5-allyl-5-*iso*propyl-, and 5-ethyl-5-*cyclo*hexenyl-barbituric acids.

The infrared spectra of some barbituric acids and their compounds with sodium, barium, and mercuric ions indicate that the mercury forms complexes rather than salts with the barbituric acids.

Of compounds containing nitrogen and having a structure similar to barbituric acid certain hydantoins and cyclic imides of dicarboxylic acids will be extracted and interfere.

The method has been applied to the determination of barbituric acids in blood. A full report will be published elsewhere.

A New Type of Cholinesterase in Sow's Milk

KLAS-BERTIL AUGUSTINSSON

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

Choline esters are generally not hydrolysed by milk. In two instances, however, milk was shown to exhibit high or moderate cholinesterase activity (acetylcholine used as substrate), *i.e.*, the colostrum of dog [1] and the colostrum and milk of swine [2]. These two sources of cholinesterases are interesting species differences in biochemical behaviour for which no biological explanation is known so far.

Table 1. Enzymic hydrolysis of various choline esters and phenyl esters by the milk of sow and cow. Substrate concentration, 0.01 M. Activity expressed in b_{30} per 0.1 ml of milk.

Acyl radical	Choline esters		Phenyl esters	
	Sow	Cow	Sow	Cow
Acetyl	290	0	465	1
Propionyl	280	1	255	1.5
Butyryl	500	1	205	0
Benzoyl	65	1	—	—
Succinyl	55	0	—	—

The properties of cholinesterase present in sow's colostrum and milk were investigated in connection with studies on the variation of esterase activities of milk and plasma of swine during the course of lactation and suckling [3]. The most characteristic feature of this esterase (Table 1) is the rapid hydrolysis of choline esters and phenyl esters; in the first group of esters butyrylcholine is hydrolysed at the highest rate, in the second group the acetate is hydrolysed more rapidly than both the propionate and butyrate. The specificity pattern with choline esters as substrates differs from those of all other cholinesterases known, except that of swine plasma cholinesterase which contains the same enzyme in 20—25 times lower concentration; the exceptional substrate specificity of the plasma enzyme as far as choline esters are concerned was reported previously [4,5]. Both acetylcholine and propionylcholine are hydrolysed more slowly than butyrylcholine, and acetylcholine more rapidly than propionylcholine. Benzoylcholine and succinylcholine are also split by the milk esterase; the hydrolysis of the latter ester is exceptional since no other animal tissue so far studied hydrolyses this ester at such a relatively high rate.

It was demonstrated in summation experiments, as well as in inhibition experiments with selective esterase inhibitors, that a single enzyme in sow's milk is responsible for the hydrolysis of both the choline and aromatic esters tested. It is characteristic of this esterase that butyrylcholine and phenyl acetate are hydrolysed at about the same high rate when tested at the same substrate concentration ($[S] > 5 \times 10^{-3}$ M); in this concentration range K_S is the same for the two reactions (2.8×10^{-3}). Triglycerides are also

The optimum pH range of the extraction varies for different barbiturates, but a pH of 8.0 is suitable for most of the compounds.

Chloroform can be used for the extraction of the N-substituted compounds and of 5-*iso*amyl-5-ethyl- and 5-allyl-5-phenyl-barbituric acids. The properties of cholinesterase present in sow's colostrum and milk were investigated in connection with studies on the variation of esterase activities of milk and plasma of swine during the course of lactation and suckling [3]. The most characteristic feature of this esterase (Table 1) is the rapid hydrolysis of choline esters and phenyl esters; in the first group of esters butyrylcholine is hydrolysed at the highest rate, in the second group the acetate is hydrolysed more rapidly than both the propionate and butyrate. The specificity pattern with choline esters as substrates differs from those of all other cholinesterases known, except that of swine plasma cholinesterase which contains the same enzyme in 20—25 times lower concentration; the exceptional substrate specificity of the plasma enzyme as far as choline esters are concerned was reported previously [4,5]. Both acetylcholine and propionylcholine are hydrolysed more slowly than butyrylcholine, and acetylcholine more rapidly than propionylcholine. Benzoylcholine and succinylcholine are also split by the milk esterase; the hydrolysis of the latter ester is exceptional since no other animal tissue so far studied hydrolyses this ester at such a relatively high rate.

It was demonstrated in summation experiments, as well as in inhibition experiments with selective esterase inhibitors, that a single enzyme in sow's milk is responsible for the hydrolysis of both the choline and aromatic esters tested. It is characteristic of this esterase that butyrylcholine and phenyl acetate are hydrolysed at about the same high rate when tested at the same substrate concentration ($[S] > 5 \times 10^{-3}$ M); in this concentration range K_S is the same for the two reactions (2.8×10^{-3}). Triglycerides are also

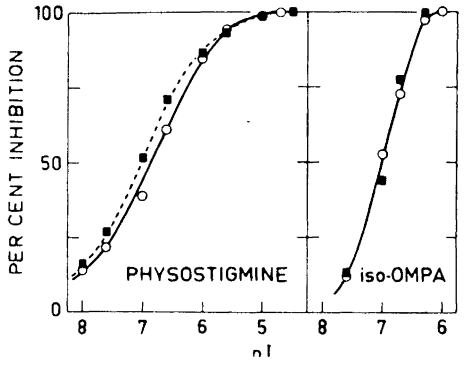

Fig. 1. Inhibition of sow's milk esterase by physostigmine salicylate and tetra-*iso*propyl-pyrophosphoramide (iso-OMPA). Substrates (0.01 M): butyrylcholine iodide (■) and phenyl acetate (○). pI = — log molar inhibitor concentration in the reaction mixture. Enzyme incubated 50 min with the inhibitor prior to addition of substrate.

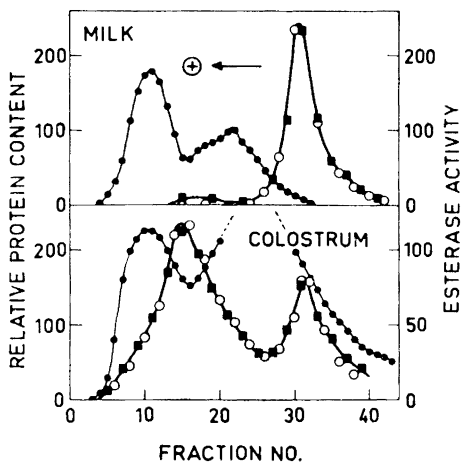

Fig. 2. Electropherograms of sow's milk and colostrum obtained with 3.0 ml material in cellulose columns (1.5 cm. × 40 cm.; veronal buffer, pH 8.4, $I = 0.1$). Displacement from the column in 1.5 ml fractions. Thin line (●): relative protein contents (optical density of the Folin colour). Heavy line: esterase activity (b_{30}/0.4 ml fractions); ■, butyrylcholine; ○, phenyl acetate.

hydrolysed by this enzyme, but the hydrolysis rate is only 1—3 % of those obtained with butyrylcholine and phenyl acetate.

The esterase is a cholinesterase, because it is sensitive to both physostigmine and organophosphorus compounds ($pI_{50} > 5$). Phenothiazine derivatives (*e.g.*, 10-[-diethylamine-propionyl] phenothiazine hydrochloride) are comparatively strong inhibitors, indicating that the enzyme is classified as a Group II cholinesterase [6], to which the butyrylcholinesterases of other sources belong. The sensitivity to 62C47 (1,5-bis[4-trimethyl-ammoniumphenyl] pentane-3-one diiodide) is in favour of this suggestion. Fig. 1 shows the inhibition curves obtained with butyrylcholine and phenyl acetate as substrates and physostigmine and iso-OMPA (tetra-*iso*propylpyrophosphoramide) as inhibitors; these results are indicative evidence that the same enzyme hydrolyses the two substrates. The inihibition by physostigmine differs from that of other cholinesterases by not being of the true competitive type.

Additional proof for the existence of one esterase in sow's milk was performed by electrophoresis analysis in cellulose columns [7]. Typical electrophoresis patterns of sow's milk and colostrum are illustrated in Fig. 2. The milk electropherogram is characteristic by a sharp esterase peak, being due to the highly active butyrylcholinesterase, which moves slower than all major milk protein components. In contrast to mature milk, colostrum gives an electropherogram in which a second, faster-moving peak is much more prominent, and the slow-moving peak correspondingly reduced. The two esterase fractions of colostrum have identical properties, as far as enzyme specificity and sensitivity to inhibitors are concerned. The mobility of the faster-moving cholinesterase fraction of colostrum is identical with the cholinesterase fraction of swine plasma, and the substrate specificity and other properties are also the same for the two fractions. It is therefore suggested that the faster-moving esterase component of sow's colostrum and swine plasma cholinesterase are identical, and that the electrophoretic mobility of the esterase present in colostrum is previously lowered during the course of lactation.

Evidence has been presented recently that esterases are localized mainly in the microsomes of animal tissues. Milk con-

tains microsomes [8] which are derived from mammary tissue and might serve as a vehicle for its butyrylcholinesterase. It may therefore well be that the slow-moving component represents microsomal esterase and the fast-moving one, free enzyme.

A full account of this work including studies on the esterases present in swine plasma will be published in *Biochem. J.*

This investigation was supported by a grant from the *Swedish Natural Science Research Council*. I am grateful to Dr. Bertil Olsson (Royal Veterinary College, Stockholm) for the milk samples.

On Vitamins in Sewage Sludge

VII. Production of Vitamin B_{12} by an Enrichment Culture of *Methanobacterium omelianskii*

HALINA Y. NEUJAHR and DANLEY A. CALLIERI

Royal Institute of Technology, Division of Food Chemistry, Stockholm 70, Sweden

An enrichment culture of *Methanobacterium omelianskii* was grown in the synthetic medium of Barker with and without the addition of various compounds. The ability of the culture to produce vitamin B_{12} factors was investigated.

The culture was shown to produce one single vitamin B_{12} factor when grown in the simple Barker medium. This factor has an R_c-value = 0.7 (R_F-value relative to that of cyanocobalamin) and could not be identified with any other factor. It is called factor Met. In the presence of Co^{2+}, factors B and Z were produced simultaneously with factor Met. It is suggested that both these latter factors are precursors of factor Met and cyanocobalamin. When supplied with 5,6-dimethyl benziminazole and Co^{2+}, the culture produced only cyanocobalamin, the yield of which was 80 mμg/ml. The addition of Bacto Peptone stimulated the formation of vitamin B_{12} activity, mainly due to the formation of factor Met. Cyanocobalamin was formed only when 5,6-dimethyl benziminazole was supplied and its yield was not increased by Bacto Peptone. It is suggested that the enrichment culture has a limited synthetic ability with respect to 5,6-dimethyl benziminazole but can produce all the other parts of the vitamin B_{12} molecule and join them together. Unlike 5,6-dimethyl benziminazole, adenine could not be used by the culture to produce $\psi-B_{12}$. The ability of sterilized sewage and sewage sludge to maintain the growth and vitamin B_{12} production of the enrichment culture was also investigated.

The culture did not produce any vitamins of the folic and folinic acid groups. Cu++ was found to have an inhibiting effect upon the growth and vitamin B_{12} production of the culture.

The anaerobic bacterium *Methanobacterium omelianskii* was isolated in pure culture by Barker in 1939[1]. This organism appears to be one of the most abundant bacteria active in the anaerobic digestion of sewage sludge[2]. It has been shown in previous reports from this laboratory[3] that the anaerobic digestion of sewage sludge is accompanied by a considerable production of vitamin B_{12} factors. It was therefore interesting to investigate the ability

of *Methanobacterium omelianskii* to produce vitamin B_{12} factors. A pure strain of *Methanobacterium omelianskii* was received through the courtesy of Professor Barker. However, this strain proved to be very difficult to handle and, in fact, we were not able to obtain an active, quickly fermenting culture from it.

Barker's method was used to isolate a strain of *Methanobacterium omelianskii* from digesting sewage sludge but required, of course, a considerable amount of time. The ability of this strain to produce vitamin B_{12} will be investigated in the near future. In the present work, the authors used enrichment cultures of *Methanobacterium omelianskii* prepared from digesting sludge by successive reinoculations into the medium of Barker [1]. Microscopic examinations of such cultures revealed that they consisted mostly of *Methanobacterium omelianskii*. They proved to be very convenient for large experimental series since, with the chosen, carefully standardized conditions, the gas production started relatively soon after the inoculation and it was found that the agreement between the parallel series was very good. The determination of the gas production is of special importance when culturing methane bacteria since these bacteria tend to form bulky precipitates and occur mostly in the sediment thus making accurate turbidity measurements impossible. The quantity of gas evolved is a good measure of the amount of growth.

Using such an enrichment culture of *Methanobacterium omelianskii*, the authors investigated its ability to produce vitamin B_{12} factors, partly in the simple medium elaborated by Barker [1], which contains ethanol as the only organic compound, and partly in the Barker medium with various additions, *e.g.* organic nutrient extracts, Co^{2+}, Cu^{2+}, 5,6-dimethyl benziminazole, adenine. The ability of the culture to ferment sterilized sewage and sewage sludge was also investigated.

EXPERIMENTAL

The enrichment culture of *Methanobacterium omelianskii* was prepared by successively reinoculating a raw culture obtained from digesting sludge using the medium given by Barker [1]: K_2HPO_4 0.6 %; KH_2PO_4 0.9 %; $(NH_4)_2SO_4$ 0.03 %; $MgSO_4 \cdot 7\ H_2O$ 0.01 %; $FeSO_4 \cdot 7\ H_2O$ 0.001 %; saturated $CaSO_4$ solution 1 %; C_2H_5OH 2 % and tap water. An additional component (2 ml of 1 % $Na_2S \cdot 9\ H_2O$ solution +8 ml of 5 % $Na_2CO_3 \cdot 10\ H_2O$ solution) was sterilized separately and added to every 100 ml of the medium.

A few milliliters of digesting sludge were put into 300 ml substrate in a conical flask and incubated at 37°C. When the gas evolution became considerable, a reinoculation was done in the same way, followed by a second reinoculation and so on. After 10—15 reinoculations the culture was almost totally free from the initial sludge solids.

The inocula for the experimental series were prepared from the enrichment culture by reinoculating into the same medium in conical flasks of 100—300 ml capacity and incubating until a considerable gas evolution was established (usually 2—10 days). During the earlier part of the work, longer periods, 7—10 days, were usually required to obtain an active inoculum whereas, in the later series, an active inoculum could be obtained even after 2—3 days.

The experimental series were performed in test tubes of 15 ml capacity. Each series consisted of several identical tubes which were removed one by one during the course of the experiment, their contents being analyzed for vitamin B_{12} activity. Each tube contained a small gas tube and was filled with 5 ml of the medium. After sterilization, 0.5 ml of the separately sterilized component was put into each tube and thereafter, at an appropriate temperature, 5 drops of the inoculum were released from a pipet.

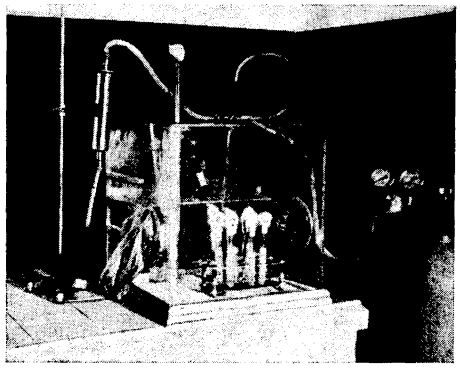

Fig. 1. Carbon dioxide chamber for inoculating methane bacteria. For description see text.

To *ensure anaerobic conditions* all manipulations, *e. g.* necessary additions to the medium, inoculations and reinoculations, were performed in a specially constructed chamber (Fig. 1). The chamber consisted of a box (40 × 40 × 40 cm) five sides of which consisted of plexiglas plates firmly attached to each other whereas the sixth consisted of a wooden base plate provided with tightening arrangements along its edges. The upper (plexiglas) part could be easily removed from the bottom plate so that the various vessels could be put inside. The two parts of the box fitted tightly together. The chamber was provided with gas inlets and outlets, a few openings for the insertion of pipets and two openings with plastic sleeves for the hands. Compressed carbon dioxide or nitrogen could be passed into the chamber at its bottom and removed at the top. Both gases passed a microbiological filter before entering the chamber. The substrate-containing vessels were put into the chamber while still hot after the sterilization in the autoclave, nitrogen being blown through the chamber at 0.5 kg/cm². The extra component was then added to the substrate. When the temperature of the substrate had reached 40 – 30°C, carbon dioxide instead of nitrogen was blown * through (0.5 kg/cm²) and the reinoculations were performed.

All the cultures were incubated at 37°C.

To *maintain the anaerobic conditions after the inoculation* the liquid surfaces in the tubes as well as in the conical flasks were covered with a 0.5 – 1 cm thick layer of sterilized paraffin oil. During the first of these investigations, the test tubes and flasks were also plugged with cotton wool impregnated with an alkaline pyrogallol solution (containing equal parts of 20 % pyrogallol solution and 20 % K_2CO_3 solution). This additional security was found superfluous in later work and the tubes were plugged with ordinary cotton wool.

Sampling was achieved by removing a tube from each series at appropriate time intervals. The samples were autoclaved with cyanide (100 μg KCN/ml sample) and kept at −20°C. Their activity for *E. coli* 113 – 3 and, in a few cases, also for *S. faecalis* and *Leuconostoc citrovorum*, was determined in the cup plate assay. The presence of different vitamin B_{12} factors [4] was revealed by bioautography on *E. coli* plates using chromatography in two solvent systems as described elsewhere [5] and by ionophoresis according to Holdsworth [6]. The R_F-values of the chromatographic spots are always given relative to that of cyanocobalamin and are called R_c. Two groups of experiments were performed. In the first group (expts 1 – 4) an inoculum was used which had been obtained by ten successive reinoculations of the raw culture into the medium of Barker [1]. The second group of experiments was performed several months later and the inoculum was obtained

* Carbon dioxide was not introduced from beginning in order to avoid pH-changes in the substrate.

by twenty five successive reinoculations. The details of the different experiments were as follows:

Experiment 1. Influence of different nutrients. Preliminary investigation. The following additions to Barker's medium were made: Co^{2+} 2 500 mμg/ml; Bacto Vitamin-free Casamino Acids (Difco) 0.25 %; Bacto Yeast Extract Dehydrated (Difco) 0.25 %; Bacto Peptone (Difco) 0.25 %; biotin 0.002 ppm. Samples were taken 3, 10, 17 and 30 days after the beginning of gas evolution. The results are given in Table 1.

Experiment 2. Influence of 5,6-dimethyl benziminazole and adenine. The two bases were added to the medium at the following levels: 100; 1 000 and 10 000 mμg/ml. The simple Barker medium was used both without any addition (a) and also with the addition of 0.25 % Bacto Peptone (b). Samples were taken 3, 10, 17 and 30 days after the beginning of gas evolution. The results can be seen in Table 2 and Fig. 2.

Experiment 3. Influence of Co^{2+}. The following additions of Co^{2+} were used: 0; 1 000; 2 000; 5 000; 10 000 and 25 000 mμg/ml*. The Co^{2+} was added to the medium as $CoCl_2 \cdot 6H_2O$. Barker's medium without (a) and with 0.25 % Bacto Peptone (b) was used. Samples were taken after 3, 10, 17 and 30 days. The results are given in Table 3.

Experiment 4. Influence of Cu^{2+}. The following additions of Cu^{2+} were used: 0; 1 000; 2 000; 5 000; 10 000 mμg/ml. The Cu^{2+} was added to the medium as $CuSO_4 \cdot 5 H_2O$. Barker's medium without (a) and with 0.25 % Bacto Peptone (b) was used. Samples were taken after 3, 10, 17 and 30 days. The results can be seen in Table 4.

Experiment 5. Influence of Co^{2+} and of 5,6-dimethyl benziminazole in the simple medium. Three parallel series were performed with (I) the medium of Barker (a), (II) (a) with added 3 000 mμg Co^{2+}/ml, (III) (a) with added 3 000 mμg Co^{2+}/ml and 1 000 mμg 5,6-dimethyl benziminazole/ml. Samples were taken every day. The results are given in Figs. 2a, 2b and 2c.

Experiment 6. Influence of Co^{2+} and 5,6-dimethyl benziminazole in the presence of Bacto Peptone. This experiment was performed in exactly the same way as expt. 5, except that the Barker medium was supplemented with 0.25 % Bacto Peptone. The results can be seen in Figs. 3a, 3b and 3c.

Experiment 7. In this experiment the ability of five "natural" substrates to maintain the growth of the enrichment culture was investigated. The substrates were taken from a sewage plant where the sewage is sedimented and where the sedimented solids (fresh sludge) undergo digestion in digestion tanks. Liquid separated during the digestion process is withdrawn and is called "digested sludge water". The effluent from the sedimentation tanks is not further treated.

The following five substrates were used in the experiment: incoming sewage, I; effluent, E; digested sludge water, W; fresh sludge, F; digested sludge diluted 100 times, D. The substrates were sterilized by tyndallization. F was diluted 10 times and D 10 times (called Dl). A part of D was alkali treated (called D2). I, E, and W were not diluted. The substrates were buffered with phosphate (total concentration 1.5 %) to pH 7.7.

The final substrates thus obtained had the following dry solid contents and *E. coli* activities:

Substrate	Dry solids mg/ml	*E. coli* activity calc. as cyanocobalamin mμg/ml
I	0.7	0.5
E	0.6	0.5
W	1.9	1.5
F	3.0	0.5
D	0.9	2.5
Dl	0.09	2.0
D2	0.9	—

Conical flasks of 100 ml capacity were filled with the different media, sterilized and inoculated with the enrichment culture. The results are given in Table 5.

* Due to the presence of S^{2-} the actual concentration of Co^{2+} in the fermentation liquor was probably lower than indicated by the additions.

RESULTS AND DISCUSSION

Experiment 1. Yeast extract, peptone and casamino acids stimulated considerably the growth of the culture as deemed by the gas evolution. Yeast extract was most effective in this respect — the gas started to evolve after only 60 h of incubation as compared with about 100 h for the cultures containing the other two organic nutrients. The addition of Co^{2+} (2.5 μg/ml) in the absence of organic nutrients seemed to retard the growth of the culture — the gas evolution starting after ~ 200 h of incubation. This phenomenon, however, could not be observed in later experiments in which a more purified enrichment culture was used. Biotin was without effect upon the growth.

The effect of the nutrient additions upon the formation of vitamin B_{12} factors can be seen in Table 1. The total *E. coli* activity is markedly stimulated by the different additions, except biotin. The stimulating effect depends

* Calculated as cyanocobalamin, cup plate assay.

probably upon the better growth of the culture obtained with the active nutrients. It can be seen in Table 1 that, at the beginning of the fermentation, the culture produced, in most cases, smaller amounts of several factors together with a greater amount of one single factor whereas after 10 days of fermentation only this latter factor was produced. It is a striking fact that cyanocobalamin was not produced at all. The very small amounts of cyanocobalamin produced in the beginning of the fermentation could not be found in later investigations with a more purified enrichment culture. The addition of Co^{2+} alone, or together with biotin, markedly stimulated the formation of factor B. It is easily seen in Table 1 that biotin does not contribute to this effect. Since factor B has been shown to be the fundamental part of all B_{12} vitamins [7] so far characterized, the phenomenon observed suggests that the enrichment culture has a limited synthetic ability with respect to the other parts of the vitamin B_{12} molecule. From Table 1, it seems evident that the enrichment culture of *Methanobacterium omelianskii*, grown in the simple Barker medium, produces specifically one single vitamin B_{12} factor, albeit in limited amounts. This has also been proved by all later experiments. So far we have not succeeded in identifying this factor with any other vitamin B_{12} factor hitherto described (*cf.* p. 1165). It is provisionally called factor Met. The culture produces greater amounts of this factor when supplied with some organic nutrient (see Table 3). It cannot, however, be concluded whether these additions stimulate the formation of factor Met *per se* or if the effect depends merely upon the enhanced growth of the culture.

* Calculated as cyanocobalamin.

Since Bacto Peptone evidently had the greatest stimulating effect upon the formation of factor Met, we chose this nutrient as a standard addition to the medium in several further experiments.

Experiment 2. This experiment was performed in order to elucidate whether the formation of factor Met by the enrichment culture is to be considered as an individual biochemical feature of the culture or whether it was merely caused by absence of precursors for other vitamin B_{12} factors when the culture was grown in the simple Barker medium [1] or in this medium modified as in expt. 1.

It can be seen in Table 2 that the culture produces cyanocobalamin when supplied with the specific base of this factor — 5,6-dimethyl benziminazole. Adenine, however, which is the specific base of ψ-B_{12}, cannot be utilized by the culture to produce the corresponding factor. Instead of ψ-B_{12}, factor Met is produced as in the case without the addition of adenine. These results suggest that the organism is unable to synthesize 5,6-dimethyl benziminazole but can synthesize all the other parts of the cyanocobalamin molecule and couple them together. Such a suggestion cannot of course be conclusive since only an enrichment culture, and not a pure strain, was used in this experiment. It would be interesting to see if some compounds of adenine, *e.g.* the appropriate nucleoside and nucleotide, can be utilized in a better way by the culture. Such compounds, however, were not available in this preliminary study.

For subsequent experiments, 1 000 mμg/ml of 5,6-dimethyl benziminazole was chosen as a standard addition.

Experiment 3. The highest total *E. coli* activity was obtained with 2 000 —5 000 mμg Co^{2+}/ml of medium a (*cf.* Table 3). The activity values reached,

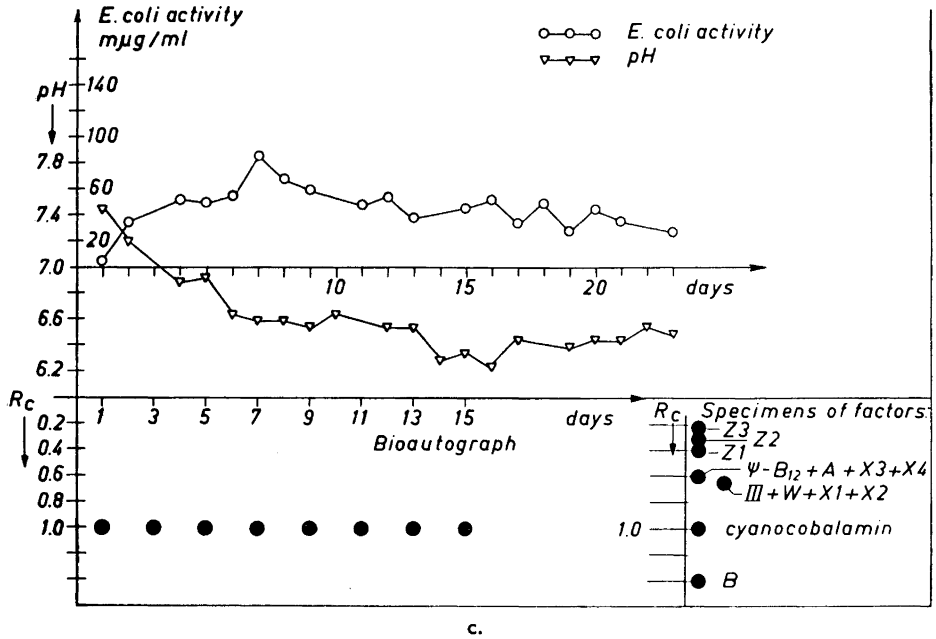

Fig. 3. Fermentation and vitamin B_{12} production by an enrichment culture of *Methanobacterium omelianskii* grown in the medium of Barker modified by the addition of 0.25 % Bacto Peptone:

a. not supplemented;
b. supplemented with Co^{2+} (3 000 mμg/ml);
c. supplemented with Co^{2+} (3 000 mμg/ml) and 5,6-dimethyl benziminazole (1 000 mμg/ml).

also formed. For subsequent experiments, 3 000 mμg/ml of Co^{2+} was chosen as standard addition.

Experiment 4. 1 000—2 000 mμg Cu^{2+}/ml had a retarding effect upon the growth and vitamin B_{12} production of the enrichment culture. 5 000—10 000 mμg Cu^{2+}/ml markedly inhibited both growth and vitamin B_{12} production (*cf.* Table 4).

Experiment 5. The results of this experiment which has been performed more thoroughly and with a more purified enrichment culture than expts. 1—4 confirm the preliminary findings of these early experiments. An examination of Fig. 2a, 2b and 2c leads to the following conclusions:

1) When grown in the simple Barker medium, the enrichment culture of *Methanobacterium omelianskii* produces one single factor Met (with $R_c = 0.7$) as shown by chromatography and ionophoresis (*cf.* p. 1165). The yield of factor Met is rather low and corresponds to at most 10 mμg/ml calculated as cyanocobalamin (*cf.* Fig. 2a).

2) When supplied with Co^{2+} (3 000 mμg/ml), the culture produces factors B and Z together with factor Met suggesting that both the two former factors

are precursors of factor Met and cyanocobalamin. The total *E. coli* activity is at most 140 mμg/ml calculated as cyanocobalamin (*cf.* Fig. 2b).

3) With Co^{2+} (3 000 mμg/ml) and 5,6-dimethyl benziminazole (1 000 mμg/ml), the culture produces only cyanocobalamin, the yield of which is at most 80 mμg/ml (*cf.* Fig. 2c).

Experiment 6. It can be seen from Fig. 4a that the addition of Bacto Peptone to the simple Barker [1] medium stimulates the formation of *E. coli* activity (*cf.* Fig. 3a) but does not influence the kind of factors formed since, as before, factor Met is exclusively produced. With Co^{2+} (3 000 mμg/ml) in the modified medium, only factor Met is again formed (see Fig. 3b) except in the beginning of the fermentation when small amounts of cyanocobalamin and of one of the factors Z are formed. The fermentation in the presence of Bacto Peptone differs in this respect markedly from that without this nutrient (*cf.* Fig. 2b). The total *E. coli* activity in the presence of Bacto Peptone is much higher than in experiment 5 and reaches at most 240 mμg/ml. With additions of Co^{2+} and 5,6-dimethyl benziminazole (see Fig. 3c), cyanocobalamin is formed exclusively as in the corresponding experiment without Bacto Peptone (*cf.* Fig. 2c). The yield of cyanocobalamin is likewise of the same order of magnitude, *viz.* 85 mμg/ml.

Experiment 7. It can be seen in Table 5 that the sterilized and buffered effluent E and digested sludge, diluted 100 times, D, and 1 000 times, D1, could not be fermented by the enrichment culture. However, sterilized and buffered incoming sewage, I, digested sludge water, W, alkali treated diluted digested sludge, D2, and fresh sludge, F, could maintain the growth of the culture. The total *E. coli* activity/ml substrate was largest with fresh sludge (70 mμg/ml) and lowest with incoming sewage and alkali treated digested sludge (~15 mμg/ml. However, calculated on the basis of initial dry solid content, the yields obtained with fresh sludge and incoming sewage were

Table 5. The ability of sterilized sewage to maintain the growth and vitamin B_{12} production of an enrichment culture of *Methanobacterium omelianskii.*

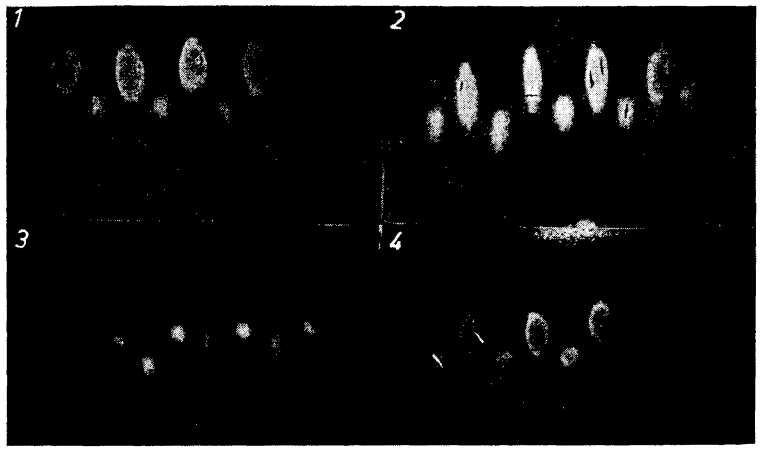

Fig. 4. Experiments to identify factor Met by paper chromatography. Bioautographs on *E. coli* 113—3 plates.
1. Factor A (upper spots) and factor Met (lower spots). 2. Factor X4 (upper spots) and factor Met (lower spots). 3. Factor W (upper spots) and factor Met (lower spots). 4. Factor III (upper spots) and factor Met (lower spots).

comparable ($\sim$ 20 000 mμg/g) and comparable with that of spontaneously digested sewage sludge. These yields are considerably higher than the yield obtained with the other substrates. Paper chromatography revealed two spots, one due to cyanocobalamin, the other due to some factor or factors with R_c in the range 0.6—0.7. As reported above, the factor produced by *Methanobacterium omelianskii* in synthetic substrates, factor Met, has a R_c-value = 0.7 and it might be that this factor is also produced when the enrichment culture is grown in sterilized sewage. This, however, has not yet been more closely investigated.

Experiments to identify factor Met. When chromatographed in solvent system I [5], factor Met moved distinctly quicker than all the other factors with R_c-values in the range 0.6—0.7. Some of the experiments are shown in Fig. 4, which contains bioautographs of some of the factors together with factor Met. Spots of factor Met were put on each chromatogram alternately with spots of the respective factors. The uncertainty due to uneven wandering of the solvent front was thus eliminated.

However, upon ionophoresis in 2 M HAc in the presence of KCN, the mobility of factor Met was found to be almost identical with that of factor W, factor III, cyanocobalamin and of the slower fraction of factor X4.

The latter factor, though found a homogeneous three years ago, has now been found to separate into two electrophoretic fractions, one with a mobility about that of factor B (or A?) (quick-moving) and the other with a mobility about that of factor Met (*cf.* Fig. 2). The solution of factor X4 was kept at —20°C but had been thawed on several occasions.

As has been noticed many times before, the identification of vitamin B_{12} factors on the basis of their chromatographic and ionophoretic mobilities very often seems to give misleading results.

Vitamins of the folic and folinic acid groups. Fermentations, performed with the enrichment culture of *Methanobacterium omelianskii* in the simple Barker medium with and without the addition of various compounds, were tested for *S. faecalis* and *Leuconostoc citrovorum* activity. No such activity could, however, be detected.

Acknowledgements. The authors are grateful to Professor H. Lundin, Head of the Division, for his encouraging interest in and valuable advice on the execution of this work.

On Vitamins in Sewage Sludge

VIII. Utilization of Some Vitamin B_{12} Factors by an Enrichment Culture of *Methanobacterium omelianskii*

HALINA Y. NEUJAHR and DANLEY A. CALLIERI

Royal Institute of Technology, Division of Food Chemistry, Stockholm 70, Sweden

An enrichment culture of *Methanobacterium omelianskii* was grown in the synthetic medium of Barker [3], with and without the addition of 1 000 mμg/ml of 5,6-dimethyl benziminazole and some vitamin B_{12} factors previously isolated from sewage sludge.

In the absence of 5,6-dimethyl benziminazole, most factors were converted to factor Met [1].

In the presence of 5,6-dimethyl benzimianzole, the incomplete factors B, Z1, Z2, Z3 and a greater part of the factor X4 preparation could easily be converted to cyanocobalamin by the culture.

The complete, nucleotide-containing factor W may also to a certain extent be converted to cyanocobalamin.

In a preceding paper [1], a series of experiments performed in order to investigate the ability of an enrichment culture of *Methanobacterium omelianskii* to produce vitamin B_{12} factors was reported. Using the same enrichment culture and an identical experimental technique, the authors have now investigated the ability of the culture to utilize some vitamin B_{12} factors previously isolated from sewage sludge [2]. The culture was grown in the synthetic medium of Barker [3] containing 2 % ethanol as the only organic compound. The different factors were added to the medium at levels of approximately 1 000 mμg/ml. Two series of experiments were made. Series I was a preliminary investigation and was carried out with a less purified enrichment culture. The inoculum had been prepared by ten successive reinoculations of the raw culture into Barker's medium. In series II, an inoculum was used which had been obtained by 25 successive reinoculations of the raw culture.

RESULTS AND DISCUSSION

Series I

From the results of the preliminary investigation which are shown in Table 1, it seems as though the different factors are converted by the enrichment culture into factor Met. The effectivity of the conversion seems be higher in the simple medium than in the presence of Bacto Peptone. However, when Bacto Peptone was present, cyanocobalamin was formed together with factor Met and this fact may account for the lower activity values obtained in the presence of Bacto Peptone. In plate assay with *E. coli*, several vitamin B_{12} factors are known to cause greater growth zones than cyanocobalamin and this may also apply to factor Met.

When adenine was added together with factor B or factor X4, small amounts of factor B were detected in the fermentation liquor together with factor Met but no ψ-B_{12} was found. Thus, adenine in the presence of factor B is not utilized for the production of ψ-B_{12}. This is in agreement with an earlier observation [1] that the enrichment culture of *Methanobacterium omelianskii* cannot use adenine to produce ψ-B_{12}. It is interesting to observe that the microbiologically inactive factor Z1 was converted in medium a to the microbiologically active factor Met. That a conversion really took place can be

Table 1. seen from *E. coli* activity values: 20 mμg/ml when the fermentation was carried out without factor Z1 and 130 mμg/ml in the presence of it. The corresponding values for medium b cannot be so readily explained.

The conversion of factor B as well as factor X4 to factor Met (in medium a) seems to be more effective than the conversion of the other factors investigated.

The question of whether the enrichment culture of *Methanobacterium omelianskii* can utilize the different factors as precursors for the cyanocobalamin molecule has been more thoroughly investigated in Series II.

Series II

The fermentations of this series were carried out in the simple medium of Barker[3] supplemented with 1 000 mμg/ml of 5,6-dimethyl benziminazole. The different factors were added at levels of approximately 1 000 mμg/ml. A series of 24 tubes was prepared for every factor. Twenty of these were inoculated, the reamaining four serving as non-inoculated controls. A control

series to which dimethyl benziminazole but no vitamin B_{12} factor had been added was fermented simultaneously with the other series. Samples were taken almost every day by removing a tube from each series. Samples from the non-inoculated controls were taken at 5 day intervals. The results of these experiments are given in Table 2—8.

Factor B. An examination of Tables 2 and 8 leads to the conclusion that factor B in the presence of dimethyl benzimidazole can be converted into cyanocobalamin by the enrichment culture. Taking into consideration the decrease of *E. coli* activity in the non-inoculated controls, a conversion of at least 20 % can be estimated as follows. After fermentation for 7—12 days, the *E. coli* activity had decreased from about 1 000 to about 100 mμg/ml. This would suggest a conversion of factor B to cyanocobalamin of about 10 %. In the non-inoculated controls there was a decrease to about half of the original *E. coli* activity. This means that the conversion of factor B to cyanocobalamin in the fermented series was at least 20 %.

Table 4. Utilization of factor Z2 by an enrichment culture of *Methanobacterium omelianskii*, grown in Barker's medium supplemented with 5,6-dimethyl benziminazole (1 000 mμg/ml); Cy = cyanocobalamin; Z = factor(s) Z.

* Calculated as cyanocobalamin in plate assay.
** Identified by paper chromatography in solvent system I[4].

In reality the yield might be much higher since factor B is known to give much greater growth zones than cyanocobalamin when assayed with *E. coli* in the plate assay. The considerable stability of factor B and of cyanocobalamin upon incubation at 37°C for several days is rather surprising. The reducing character of Barker's medium might be favourable for this stability. The maximum yield of cyanocobalamin was about 100 mμg/ml.

Factor Z1. It can be seen in Table 3 (*cf.* also Table 8) that the microbiologically almost inactive factor Z1 is converted by the enrichment culture into cyanocobalamin. In this fermentation, cyanocobalamin seems to be less stable than in the fermentation with factor B. The maximum yield of cyanocobalamin was 50—70 mμg/ml. Factor Z1 seems to be unstable upon incubation at 37°C and is spontaneously converted into factor B in the reducing medium of Barker (*cf.* values for non-inoculated controls). A partial spontaneous conversion of the factors Z into factor B was observed during their isolation [2].

The conversion of factor Z1 to cyanocobalamin seems to take place more rapidly than that of factor B (*cf.* Table 2).

Table 5. Utilization of factor Z3 by an enrichment culture of *Methanobacterium omelianskii*, grown in Barker's medium supplemented with 5,6-dimethyl benziminazole (1 000 mμg/ml). Brackets mean that the factor in question is present only in small amounts; Cy = cyanocobalamin; Z = factor(s) Z.

Factor Z2. Unlike factor Z1, factor Z2 is fairly stable on incubation at 37°C (see Table 4 and *cf.* Table 8). This factor is also converted into cyanocobalamin by the enrichment culture. The maximum yield of cyanocobalamin was about 80 mμg/ml. The rate and possibly also the extent of conversion of factor Z2 was comparable with that of factor B (Table 2).

Factor Z3. This factor seems to be less stable than factor Z2, but more stable than factor Z1. Upon incubation at 37°C, a small part of it is spontaneously converted into factor B (see Table 5, *cf.* also Tables 4 and 8). The enrichment culture converts it to cyanocobalamin, the maximum yield reaching 90 mμg/ml.

Factor X4 (see Table 6 and *cf.* Table 8). This factor seems to be surprisingly stable during incubation at 37°C. The enrichment culture converts a part of it (~half of the amount) into cyanocobalamin, but the other part remains unconverted or is converted to a factor which is indistinguishable from factor X4 by paper chromatography in solvent system I. The conversion or other-

wise of this latter part was not further investigated. That conversion of a part of factor X4 really took place (*i.e.*, that the cyanocobalamin produced was not due merely to an independent synthesis in the presence of 5,6-dimethyl benziminazole) was indicated by the decrease in *E. coli* activity values in the fermentation liquor as compared with the practically unchanged values in the non-inoculated controls.

The yield of cyanocobalamin obtained from this factor cannot be estimated since factor X4 is also present in the fermentation liquor and contributes to the *E. coli* activity.

Factor W (see Table 7 and *cf.* Table 8). This factor was not very stable on incubation at 37°C. After only 3—4 days, the *E. coli* activity had decreased to almost one third. In the medium fermented for 3—4 days by the enrichment culture, the activity of the factor was almost unchanged. A pronounced decrease took place only after 6—7 days. However, with a longer fermentation time (> 7 days), the *E. coli* activity values for the fermented medium were always lower than those for the non-inoculated controls, which may suggest some conversion at least.

Table 7. Utilization of factor W by an enrichment culture of *Methanobacterium omelianskii*, grown in Barker's medium supplemented with 5,6-dimethyl benziminazole (1 000 mμg/ml); Cy = cyanocobalamin.

CONCLUSIONS

As already reported [4], factor W behaves as a complete, nucleotide-containing factor whereas the other factors used here behave like incomplete nucleotide-lacking factors. In agreement with this, factors B, Z1, Z2, Z3 can easily be converted into cyanocobalamin by the enrichment culture if 5,6-dimethyl benziminazole is present in the medium. Factor X4, which has also been characterized as an incomplete factor, is converted only partially to cyanocobalamin. This may be explained by the fact that the preparation has now, after 3 years, been shown to separate into two electrophoretic fractions [1]. This investigation suggests that even factor W — being a complete nucleotide-containing factor — may to a certain extent be converted to cyanocobalamin when 5,6-dimethyl benziminazole is present in the medium.

An X-Ray Investigation of the Binary System Stearic Acid—Palmitic Acid

GUNNAR DEGERMAN and ERIK von SYDOW

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The molecular arrangement for the 1:1 compound between stearic (S) and palmitic (P) acid has been determined. The structure is built up of S—P pairs. Its unit cell is very like those of the components, but the symmetry is lower: $P\ 2_1$ instead of $P\ 2_1/a$. To get disordered 1:1 phases, which are of technical importance, the number of solid $\rightleftharpoons$ liquid transitions should be limited, the lowest possible temperatures should be used and solidification accomplished as rapidly as possible.

Long chain alifatic materials of biological and technical importance are generally complicated mixtures of several related compounds, *e.g.* homologous members of series such as fatty acids, glycerides and sodium soaps. Although the number of components is very often larger than two, binary systems are the only ones which have been fairly well investigated.

PHASE DIAGRAMS

Smith [1] summarizes the phase diagrams of binary systems of homologues of long chain alifatic compounds, classifying them into three different types: continuous series of solid solutions (with no maximum or minimum or with minimum), eutectic mixtures, and compound formation (with congruently or incongruently melting compounds). To the last category belong the binary systems of homologues of normal chain acids, methylesters, iodides, amides, anilides [1] and triglycerides [2]. The pure components of these systems all form double molecular sheets in the solid state. Compound formation has also been observed under certain conditions between normal fatty acids and *anteiso*- and *iso*-acids[3,4] and between normal amides and *anteiso*-amides [3]. Varying the polar groups or the position of the polar group often seems to give simple eutectic mixtures [1], *e.g.* 11-bromohendecanoic acid and 10-bromohendecanoic acid [5]. This is not unexpected, of course, considering steric variations as well as the variation in chemical bonding between the different polar groups.

Of the binary systems between homologues showing compound formation, the stearic acid — palmitic acid system (here called the S—P system) has been the most extensively investigated. In 1898 de Visser [6] published the first phase diagram of the S—P system using very pure components (setting point 69.32°C and 62.62°C, respectively). It indicates an incongruently melting compound at 50 % (s.p. 56.4°C) with an eutectic point at 54.8°C and 27.5 % S. This phase diagram has later been confirmed by Francis *et al.*[7], Schuette and Vogel [8] and Rawitsch and Volnova [2]. The last two investigators succeeded also in getting an eutectic point (55.9°C, 59 % S) on the S side of the compound by extremely slow cooling of the melts, thus having better equilibrium conditions. Similar phase diagrams for systems of other even-numbered fatty acids have also been found [8–13]. There seems to be no ambiguities or uncertainties about the phase diagram and its interpretation for the S—P system, and we have accepted it as correct.

The fact that there is a 1:1 compound formed in the solid state between stearic and palmitic acid has been said by some authors to imply necessarily the existence of S—P pairs instead of S—S pairs and P—P pairs in the compound structure. This is, however, not theoretically necessary, as the lattice in principle can be equally well built up with, *e.g.*, one S—S pair and one P—P pair in each unit cell instead of two S—P pairs.

Sarkadi and de Boer [14] find from infrared absorption measurements that the association degree for fatty acids in the liquid state, *e.g.* 0.953 at 123°C for stearic acid, is almost independent of chain length. If this is assumed to be exactly true, there will be equally many S—P pairs in the 1:1 melt as there are S—S and P—P pairs together, so whatever pairs the crystal structure contains, considerable time is required at the solidification point for the completion of the reaction 2 S—P $\rightleftharpoons$ S—S + P—P. As has been pointed out already, the best phase diagrams are obtained by extremely slow cooling [2,9].

LONG SPACING INVESTIGATIONS

The long spacing, which is frequently given for long chain compounds, is the perpendicular distance between planes containing the end groups of the molecules. Such measurements with X-rays on the S—P system have been performed by Slagle and Ott [15], Francis *et al.*[7] and by the authors. The result for specimens crystallized from melt is summarized in Fig. 1, where our own values are included. The pure acids give only one long spacing value (the C-form) when crystallized form melt. On rapid cooling of specimens of intermediate compositions, only one long spacing value is found as well [7,15] (Fig. 1), but on slower cooling two spacings may appear at compositions separated from 0, 50, and 100 %. The values group themselves around three spacings: 39.9 Å (the C-form of S), 36 Å (35.5 Å for the C-form of P) and 38.6 Å suggested by Francis *et al.*[7] to be the long spacing of the 1:1 compound.

Francis *et al.*[7] have also investigated S—P specimens crystallized from solvent, but the result of that investigation falls outside the scope of this paper.

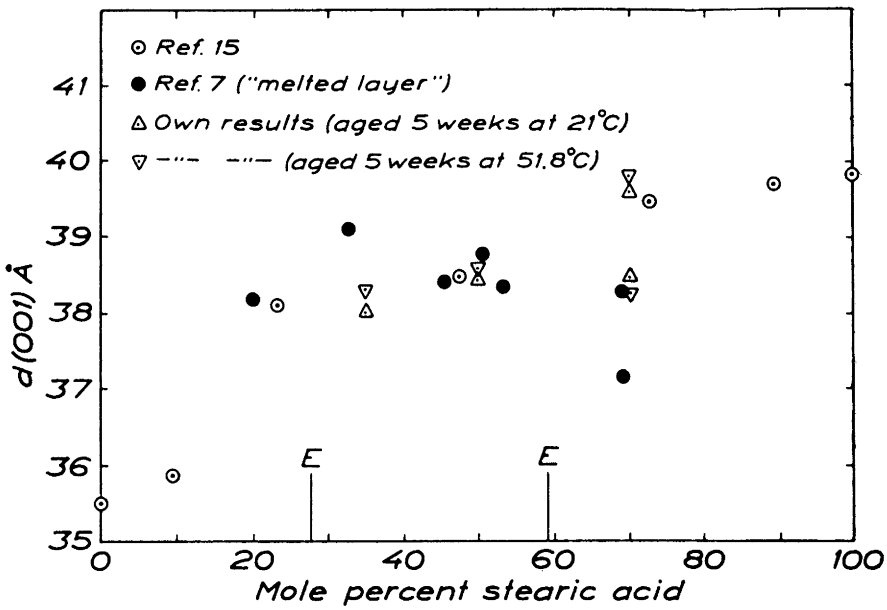

Fig. 1. Long-spacing as a function of composition for S—P specimens crystallized from melt. E = Eutectic composition.

In this work we are mostly dealing with the 1:1 compound, which has been investigated with X-ray powder and single crystal methods. The result is correlated with the structural behaviour of the components, which has been described by von Sydow [16] and Abrahamsson and von Sydow [17] and with the known crystal structures of homologues of the components: lauric acid determined by Vand *et al.*[18] and *n*-hendecanoic acid determined by von Sydow [19]. These structures have the orthorhombic chainpacking with every second chain plane perpendicular to the others [16]. The structures can be classified as O⊥ (021), if *a* is the shortest axis, following a suggestion by Vand [20] complemented by von Sydow [21].

MATERIAL USED

The very pure acids used were kindly put at our disposal by Prof. E. Stenhagen. The stearic acid has m. p. 69.4—69.7°C, and the palmitic acid has m. p. 62.6—62.9°C, as compared with 69.6 and 62.9°C, respectively, given by Francis and Piper [22]. Mixtures of the acids with 35.1, 50.1 and 70.1 mole % stearic acid, respectively, were melted together in an oil bath and kept at 100°C for 15 min, in order to attain equilibrium. The temperature was then lowered below the solidification point at 0.75°C/min. Parts of the specimens were annealed at 51.8°C for 5 weeks.

X-Ray powder photographs were taken at 20°C in a Guinier camera using Cu $K\alpha$ radiation. KCl was mixed into the samples as a calibrating substance (a = 6.292 Å).

Single crystals from the 1:1 specimen of a fairly large size were investigated optically and in a Weissenberg camera. Two out of ten gave good diffraction pictures; they were mounted along the *a*- and *b*-axes, respectively. Rotation and Weissenberg photographs were taken, using very long exposure times.

THE 1:1 COMPOUND

The X-ray powder photographs of the 1:1 specimens compared with those of the pure components (C-form) immediately revealed a striking resemblance between the structure of the compound and components. The powder photograph of the compound was indexed with use of the single crystal data obtained and the cell dimensions were accurately determined. They are given in Table 1 together with the cell dimensions for the components *, taken from the work by Abrahamsson and von Sydow [17]. A suggestion by Kofler [23] that the 1:1 specimen is a "stabilisierte Zwischenphase" is thus not adequate. The short spacings given by Fieldes and Hartman [24] for two reflexions, which can be identified as (110) and (200), are roughly in agreement with our cell dimensions.

Table 1. Cell dimensions and calculated densities at +20°C and space groups for stearic acid (C-form), palmitic acid (C-form) and the 1:1 compound between the two.

	a Å	b Å	c Å	β	Long spacing $d(001)$ Å	Calculated density gcm^{-3}	Space group
Stearic acid C-form	9.357 ±0.020	4.956 ±0.004	50.76 ±0.08	128° 14′ ±6′	39.87 ±0.04	1.022 ±0.002	$P\ 2_1/a$
1:1 Compound of stearic and palmitic acid	9.46 ±0.04	4.96 ±0.01	49.13 ±0.20	128° 14′ ±8′	38.59 ±0.08	0.992 ±0.005	$P\ 2_1$
Palmitic acid C-form	9.42 ±0.02	4.96 ±0.01	45.73 ±0.08	128° 40′ ±6′	35.72 ±0.04	1.020 ±0.002	$P\ 2_1/a$

The fact that the unit cell of the 1:1 compound is approximately an "average" between the cells of the components, leads to a rather limited number of possible molecular arrangements. They are shown in Fig. 2 as deduced from the works by Vand *et al.*[18] and von Sydow [19]. The first one ($P\ 2_1/a$), which is also representative of either of the components, represents a completely disordered phase with 1:1 composition containing S—P pairs or S—S and P—P pairs or all three. This is, however, not a very probable solution for a phase diagram showing compound formation, but rather for a system with a continuous series of solid solutions, *e.g.* for hydrocarbons or ethyl esters [1].

The following arrangements in Fig. 2 are ordered phases. The two middle ones are built up with S—P pairs and have the space groups $P\ 2_1$ and Pa, which also are monoclinic but with a lower symmetry than $P\ 2_1/a$. The last one is built up with S—S and P—P pairs and has the triclinic symmetry $P\ \bar{1}$ with a *pseudo*-monoclinic unit cell. As can be seen from Fig. 2 it is a rather

* There seems to be a slight increase in the differences for the c-dimension and the long spacing with increasing chain length. Thus the error limits given for the coefficients P and p in the linear equations for c and d (001) should be doubled.

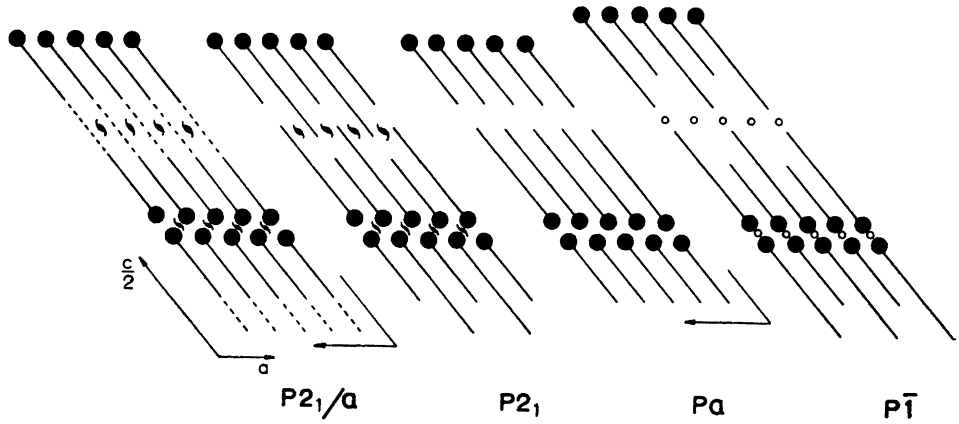

Fig. 2. Hypothetical molecular arrangements for the 1:1 compound between stearic and palmitic acid. $P\ 2_1$ is the correct one.

bulky structure with large holes in it and thus very improbable. A more close-packed arrangement of S—S and P—P pairs than the one to the right in Fig. 2 ($P\ \bar{1}$) will lead to a higher long spacing value (approximately twice the ones for the structures shown to the left in Fig. 2), which in one case (alternating S—S and P—P sheets through the crystal) should be easily measurable. In four cases (A- or B-centering of the $P\ \bar{1}$-type in Fig. 2) there will be systematic absences among the $00l$-reflexions for l odd, so the large real long spacing value will be halved. These four cases, which will be found inconsistent with the result from the single crystal measurements (see below), can, however, be ruled out at once from structural reasons, in that they will lead to the result that the chain planes of either two hydrogen bonded molecules or two molecules with close-packed end groups (CH_3-) are perpendicular. This has never been found to be the case for any crystal form of the normal fatty acids [16].

Each of the space groups of the four possibilities in Fig. 2 has different conditions for systematic absences, which are given in Table 2. Any possible deviation from $P\ 2_1/a$ will, however, be very weak, as all cases are *pseudo*-$P\ 2_1/a$, and the contribution will be from only two extra methylene groups on every second molecule. In order to secure the correct choice, very long

Table 2. Space group and absent reflexions for the four hypothetical molecular arrangements of the 1:1 compound (Fig. 2).

Space group	Conditions for systematic absences
$P\ 2_1/a$	$h0l$, when h odd and $0k0$ when k odd
$P\ 2_1$	$0k0$, when k odd
$P\ a$	$h0l$, when h odd
$P\ \bar{1}$	no

exposure times were used for the Weissenberg photographs. There was absolutely no trace of any $0k0$-reflextions with k odd, but $h0l$-reflexions with h odd appeared (Table 3). This definitely confirms the space group $P2_1$ and the molecular arrangement (marked $P\ 2_1$ in Fig. 2) for the 1:1 compound between stearic and palmitic acid. (The space group $P\ 2_1/m$, which has the same extinction conditions as $P\ 2_1$ has a mirror plane (m), which is inconsistent with the chain-packing [16].)

A comparison between the structure of the compound and the components (Table 1 and Fig. 2) reveals that the acid molecules are packed side by side in a slightly different way. This is caused by the puckered end group planes (Fig. 2), which when they are packed together, arrange themselves so they fit into the chain packing of the opposite sheet. This makes the c-dimension and long spacing higher than the arithmetic mean between those of the components. This is probably somewhat compensated by increased possibilities in van der Waals interaction over the methyl group gap [16] (Fig. 2). The result is, however, a less effective molecular packing for the compound than for the pure components, as revealed by the density 0.992 gcm^{-3} for the compound compared with 1.022 and 1.020 gcm^{-3}, respectively, for the components (Table 1). This is also consistent with the melting temperatures for the compound and the components given above.

It is now easy to understand the conditions for the formation of ordered and disordered phases of the 1:1 compound. If the melt contains few S—P-pairs, *i.e.* many S—S and P—P pairs, (by rapid melting together of the pure components at lowest possible temperature) and one wants an ordered phase, an extremely low rate of cooling must be used in the solidification, so that the reaction S—S + P—P → 2 S—P will take place completely. A repeated procedure of melting and solidification of the compound within a very small temperature interval should give the best ordered compound phase.

In technical processes of this kind there is generally a desire for obtaining disordered phases, however, as they are smoother and less grainy. To get such phases one should therefore limit the number of solid ⇌ liquid transitions, work at lowest possible temperatures and solidify as rapidly as possible.

Table 3. Observed reflexions $h0l$, which definitely establish the correct space group $P\ 2_1$ and the molecular arrangement for the 1:1 compound (Fig. 2). Visibility limit = 0.

TWO-PHASE MIXTURES

Several specimens from melt with compositions differing from 0, 50 and 100 mole % S were investigated with X-rays by Slagle and Ott [15] and Francis *et al.*[7] (Fig. 1). Their long-spacing values found are in excellent agreement with the phase diagram (except 37.1 Å for a composition of 69 % S[7]) considering the rapid cooling used.

These values have been complemented by investigating unannealed and annealed specimens with 35.1 % and 70.1 % S prepared under slow cooling. The first ones, which are between the P-eutectic point and the compound, show one diffuse long-spacing (Fig. 1) slightly lower than that for the 1:1 compound. The last ones, which are between the S-eutectic point and pure stearic acid, show two spacings (Fig. 1) corresponding to those of pure stearic acid and compound. This is in line with an observation by Francis *et al.*[7], that the palmitic rich phases have a more variable long-spacing than the ones rich in stearic acid. This is reasonable, as it must be easier to replace S-molecules with P-molecules in pure stearic acid than to replace P-molecules with S-molecules in pure palmitic acid. This is, of course, also the reason for the unsymmetrical phase diagram for the S—P system and for the difficulties in obtaining the S-eutectic point in comparison with the P-eutectic point, as it must be easier to make the compound richer in P than in S (Fig. 2).

We are indebted to Professors G. Hägg and E. Stenhagen for their interest in this work and for the facilities put at our disposal. The expenses involved have been defrayed by a grant from the *Swedish Natural Science Research Council.*

Structure of a Glyceritol Glycoside from *Polysiphonia fastigiata* and *Corallina officinalis*

BÖRJE WICKBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The O-α-D-galactopyranosyl-(1→6)-O-β-D-galactopyranosyl-(1→1)-glyceritol previously isolated from wheat flour lipids, has been found in the red algae *Polysiphonia fastigiata* and *Corallina officinalis*. The glyceritol residue has been shown to have the D-configuration.

Investigation of the red alga *Polysiphonia fastigiata*[1] gave a glycoside (A), m. p. 196—198°, $[\alpha]_D^{23}$ +88°, which after acid hydrolysis gave spots indistinguishable from those given by D-galactose and glyceritol on paper chromatograms. The same glycoside has now been obtained in small quantities from another red alga, *Corallina officinalis, Florideae*, order *Cryptonemiales*, which was previously found to contain floridoside [2]. The structure of glycoside A has now been investigated in greater detail.

A quantitative determination of the products of hydrolysis, which were assumed to be galactose and glyceritol, analysis for carbon and hydrogen and the results of periodate oxidation, including periodate consumption and formic acid and formaldehyde liberated, indicated that A could be assigned the general structure O-galactopyranosyl-(1 → 6)-O-galactopyranosyl-(1 → 1)-glyceritol. Provided the galactose belongs to the D-series the moderately high optical rotation of A is consistent with the presence of one α- and one β-linkage in the molecule.

Glycoside A was strikingly similar to a glycoside (B), O-α-D-galactopyranosyl-(1 → 6)-O-β-D-galactopyranosyl-(1 → 1)-glyceritol, m. p. 182—184°, $[\alpha]_D$ + 86.4°, which had recently been isolated from wheat flour lipids by Carter *et al.* [3] A second glycoside (C), O-β-D-galactopyranosyl-(1 → 1)-glyceritol, m. p. 139—140°, $[\alpha]_D$ + 3.77° was also isolated from the same source. The anomeric configurations of B and C were evident from enzymatic degradations; B, though unaffected by β-galactosidase from *E. coli*, was split by α-galactosidase in a yeast hexokinase preparation to yield D-galactose and glycoside C. The latter compound was hydrolysed by β-galactosidase to give D-galactose and glyceritol.

As glycosides A and B might have differed in the position of the α- and β-linkages, A was incubated with α- and β-galactosidase preparations from sweet almonds, and the reaction was followed qualitatively on paper chromatograms. It was found that A was attacked very slowly by a β-galactosidase with low α-activity, which rapidly hydrolysed a synthetic specimen of O-β-D-galactopyranosyl-(1 → 1)-D, L-glyceritol. An enzyme preparation with about equal α- and β-galactosidase activity liberated galactose and later also glyceritol. The identity of A with B indicated by these experiments, was later confirmed by direct comparison with a sample of glycoside B *. The corrected melting point of B determined with the same apparatus used for A was 195—197°, the mixed melting point showed no depression and the infrared spectra of the two samples were identical.

The question of the configuration of the glyceritol residue, which is optically active due to substitution in the 1-position, has been solved by synthesis of O-β-D-galactopyranosyl-(1 → 1)-D- and -L-glyceritol [4]. The D-glyceritol galactoside was found to be identical with a sample of glycoside C* and therefore the glyceritol residue in A also has D-configuration.

EXPERIMENTAL **

The isolation of glycoside A from *Polysiphonia fastigiata* was described in a previous paper [1]. It was purified by chromatography on Whatman 3 MM thick filter paper and recrystallised from aqueous ethanol, m. p. 196—198°, $[\alpha]_D^{23}$ + 88° (water, c = 1.8). (Found: C 43.5; H 6.68. Calc. for $C_{18}H_{28}O_{18}$: C 43.3; H 6.78).

A sample of *Corallina officinalis* (575 g) was extracted with ether and methanol and the methanol extract was worked up as described earlier [1] yielding a syrup (6.1 g). This was separated on a carbon — Celite column in the usual way [1]. Paper chromatograms of the eluate indicated the presence of floridoside and a number of other carbohydrates. One fraction gave a spot with about the same R_F value as glycoside A. This fraction was concentrated, the residue (100 mg) was dissolved in aqueous ethanol and the solution was seeded with a trace of glycoside A. The crystals separating (41 mg), after recrystallisation had m. p. 194—196.5° and $[\alpha]_D^{20}$ +90° (water, c = 1.8). The melting point was undepressed on admixture with glycoside A or B, and the infrared spectra of the three preparations were identical.

Molar ratio of D-*galactose and glyceritol in glycoside A.* The glycoside (*ca.* 5 mg) was hydrolysed in 0.2 N hydrochloric acid (0.15 ml) at 105° for 17 h. The hydrolysate was passed through a small column of Amberlite IR 4B and was then put on a strip of Whatman 3 MM filter paper which had been prewashed with water and then dried. The chromatogram was developed with ethyl acetate — acetic acid — water (3:1:1) and the appropriate areas were then cut out and extracted with water; adjoining empty areas of the paper were treated in the same way and these extracts were used as blanks. Suitable amounts of the extracts were oxidised with sodium metaperiodate overnight and the excess of periodate was determined essentially as described in a previous paper [5]. The glyceritol and galactose content of the hydrolysate was calculated empirically by comparison with synthetic mixtures of glyceritol and D-galactose which were separated and oxidised in the same way. The amounts of glyceritol and galactose thus obtained were 98 and 97 %, respectively, of the theoretical calculated for a glyceritol digalactoside.

Periodate oxidations. a) The consumption of periodate, determined as described earlier [5], was *ca.* 4.9 moles/mole of glycoside A after 3 h and 5.0 moles/mole after 21 h.

* A sample was kindly supplied by Dr. Carter.
** All melting points are corrected.

b) The formaldehyde was determined as its dimedone compound, essentially by the method of Reeves [6]. Aqueous sodium metaperiodate (0.2 M, 0.5 ml) was added to a solution of glycoside A (7.08 mg) in water (4 ml) and after 4.5 h the oxidant was reduced by the addition of 0.8 M aqueous disodium arsenite (0.5 ml), 0.8 N hydrochloric acid (0.5 ml) and 1 N aqueous sodium acetate (0.5 ml). After the addition of a 5 % ethanolic solution of dimedone (0.5 ml) the mixture was heated at 100° for 10 min and left in a cool place for 1 h. The sticky precipitate (10 mg) was collected on a filter stick, washed with water and after drying sublimed at *ca.* 0.01 mm pressure. Yield 3.75 mg corresponding to 0.75 mole of formaldehyde/mole of glycoside A; m. p. 186—193°. Recrystallisation from aqueous ethanol gave a product with m. p. 191—194°, alone or mixed with an authentic sample.

c) A sample of glycoside A (6.95 mg) was oxidised in 0.2 M sodium metaperiodate solution (1 ml) overnight, ethylene glycol (2 drops) was added and the formic acid produced was titrated with 0.01 N sodium hydroxide solution using phenol red as an indicator. Found: 1.93 moles of formic acid/mole of glycoside A.

Enzymatic degradation. a) Enzyme activity. The activity of the enzyme preparations was determined approximately by incubation with 5 % solutions of melibiose or lactose in 0.1 M sodium acetate buffer (pH 4.6) at 25°: the hydrolysis was followed polarimetrically over periods of 15—170 h. The activities were calculated as mg of disaccharide hydrolysed in 1 h by 1 ml of enzyme solution. Alternatively a mixture of enzyme solution (13.3 μl) and a 2 % solution (1 ml) of *o*-cresyl α- or β-D-galactopyranoside [7,8] in 0.1 M acetate buffer of pH 4.6 was kept at 25° for 5 min (β-galactoside) or 1 h (α-galactoside). The hydrolysis was stopped by the addition of 0.5 M sodium carbonate buffer of pH 10.6 (2 ml), 0.05 N iodine solution (1.00 ml) was added and after 20 min the mixture was acidified with acetic acid (2 ml) and the excess of iodine was titrated with 0.01 N sodium thiosulphate solution. A blank was run in a similar way but the carbonate buffer was added before the enzyme solution and oxidation with iodine was done immediately. The activities were calculated as mg of cresyl galactoside hydrolysed by 1 ml of enzyme solution in 1 h.

b) α-Galactosidase. Emulsin was extracted from de-fatted sweet almond meal essentially according to the procedure described by Sumner and Somers [9]. The meal (10 g), which had been stored in a refrigerator for about a year, was stirred with 1/2-saturated aqueous ammonium sulphate (100 ml) for 5 min. After filtration the filter cake was extracted with 1/4-saturated aqueous ammonium sulphate (100 ml), ammonium sulphate (2 g/10 ml of filtrate) was added to the extract which was centrifuged and the precipitate was dialysed against distilled water. The dialysed solution was centrifuged and the supernatant solution concentrated to a small volume (0.75 ml). Acetone (0.25 ml) was added in the cold, the solution was clarified by centrifuging, a further quantity of acetone (0.5 ml) added and after 1 h the precipitated emulsin was isolated by centrifuging. It was dissolved in water (1 ml). α-Galactosidase activity: 2.1 mg of melibiose/ml/h; 11 $\pm$ 2 mg of *o*-cresyl α-D-galactopyranoside/ml/h. β-Galactosidase activity: 2.2 mg of lactose/ml/h; 90 $\pm$ 20 mg of *o*-cresyl β-D-galactopyranoside/ml/h.

c) β-Galactosidase was prepared by the method of Edman and Jorpes [10], omitting the final steps of purification. Sweet almonds (1 000 g), with the cuticle, were ground and de-fatted, the meal was extracted with dilute aqueous ammonia, impurities were precipitated from the extract by adding dilute acetic acid, the emulsin fraction was precipitated by adding ammonium sulphate and the precipitate after centrifuging dialysed against distilled water and clarified. The final solution (100 ml) contained 52 mg of dry material/ml. α-Galactosidase activity: 0.1 mg of melibiose/ml/h; 2 $\pm$ 2 mg of *o*-cresyl α-D-galactopyranoside/ml/h. β-Galactosidase activity: 18 mg of lactose/ml/h; 940 $\pm$ 20 mg of *o*-cresyl β-D-galactopyranoside/ml/h.

d) Enzymatic hydrolysis. A mixture of the substrate (2 mg) in 0.1 M sodium acetate buffer (pH 4.6, 0.1 ml) and enzyme solution (13.3 μl) was kept at 25°. At intervals samples were withdrawn and run on paper chromatograms in ethyl acetate — acetic acid — water (3:1:1). The spots were detected by spraying with periodate — benzidine [11], silver nitrate — sodium hydroxide [12] or anisidine hydrochloride reagents. The β-galactosidase preparation gave almost complete hydrolysis of O-β-D-galactopyranosyl-(1 → 6)-D-galactose in 24 h, and after 16 h synthetic O-β-D-galactopyranosyl-(1 → 1)-D,L-glyceritol gave strong spots for D-galactose and glyceritol. However, after 21 h a sample of glycoside A, which had been incubated with the β-galactosidase, gave only a faint spot for D-galactose with the silver nitrate and anisidine reagents, and even after 36 h no hydrolysis products were

detected with the periodate spray. With the α-galactosidase preparation glycoside A gave spots for D-galactose with all spray reagents after 4.5 h, and after 12 h the periodate spray revealed a faint spot from glyceritol. With the same spray the galactose spot acquired a yellowish tinge which has been observed with 1-glyceritol galactopyranosides in general. These compounds would not separate from D-galactose on the chromatograms. The experiments strongly indicate that glycoside A is first attacked by α-galactosidase to yield D-galactose and a glyceritol β-D-galactopyranoside, which is later split by the β-galactosidase present to give D-galactose and glyceritol.

Identification of glycoside C with O-β-D-galactopyranosyl-(1 → 1)-D-glyceritol. The synthesis of O-β-D-galactopyranosyl-(1 → 1)-D-glyceritol, m. p. 140.5—141.5°, $[\alpha]_D^{20}$ −7° (water, c = 2.0), and the corresponding L-glyceritol derivative, m. p. 104—107°, $[\alpha]_D^{20}$ +2° (water, c = 2.1) is described in a later paper [4]. The compounds are isomorphous and both of them can be induced to crystallise from an ethanolic solution upon seeding with glycoside C. Though the specific rotation reported [3] for glycoside C agrees best with that of the L-glyceritol derivative, the corrected m. p. of C, 139.5—142°, and the infrared spectra [4] prove its identity with the D-glyceritol derivative.

Infrared spectra were recorded with a *Perkin-Elmer* double-beam spectrometer Model 21 with a rock-salt prism, using the potassium bromide disc technique.

Synthesis of 1-Glyceritol D-Galactopyranosides

BÖRJE WICKBERG

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

The so called *iso*floridoside, which has been isolated from *Porphyra umbilicalis* and shown to be an O-α-D-galactopyranosyl-(1 → 1)-glyceritol, has now been reinvestigated. It has been found to be an isomorphous mixture of the diastereoisomeric D- and L-glyceritol derivatives of the structure given above. These compounds and the corresponding β-D-galactopyranosides have been synthesised from glyceritol derivatives of known configuration; the α-glycosides were also isomorphous. The reaction between 2,3-O-*iso*propylidene-D-glyceritol and tetra-O-acetyl-α-D-galactopyranosyl bromide in the presence of silver oxide unexpectedly gave a mixture of D- and L-glyceritol derivatives. In one case a Koenigs-Knorr synthesis using silver oxide gave an unusually high yield of the α-anomer. The infrared spectra of the 1-glyceritol D-galactopyranosides are recorded.

A glyceritol glycoside (glycoside A) found in the red algae *Polysiphonia fastigiata*[1] and *Corallina officinalis*[2] was shown in a preceding paper[2] to be an O-α-D-galactopyranosyl-(1 → 6)-O-β-D-galactopyranosyl-(1 → 1)-glyceritol. This compound was first found in wheat flour lipids by Carter *et al.*[3] who showed it to have the above structure. The occurrence of this glycoside in plant materials of such widely different origin gives greater interest to the possible biochemical role of the glyceritol glycosides in red algae. Those previously found are: O-α-D-galactopyranosyl-(1 → 2)-glyceritol (floridoside)[4–7] O-α-D-mannopyranosyl-(1 → 3)-O-α-D-galactopyranosyl-(1 → 2)-glyceritol [8] and O-α-D-galactopyranosyl-(1 → 1)-glyceritol (*iso*floridoside) [9]. In *iso*floridoside and glycoside A the glyceritol is asymmetrically substituted, and as a possible relationship between the two compounds might have been revealed by the configuration of the glyceritol residues, the synthesis of the four possible 1-glyceritol D-galactopyranosides * was undertaken to provide material for comparison with the natural compounds. As a result of this work the glyceritol residue of glycoside A has been shown to have the D-configuration [2]; the investigation of *iso*floridoside and the synthetic work will be described below.

In an attempt to prepare 1-D-glyceritol β-galactoside, 2,3-O-*iso*propylidene-D-glyceritol (I), which is easily available from 1,2:5,6-di-O-*iso*propylidene-

* For convenience, O-α-D-galactopyranosyl-(1 → 1)-D-glyceritol will be referred to in the following as 1-D-glyceritol α-galactoside *etc.*

D-mannitol[10–12], was allowed to react with tetra-O-acetyl-α-D-galactopyranosyl bromide following Reynolds' and Evans' modification [13] of the Koenigs-Knorr method, but neither the intermediate products nor the expected 1-D-glyceritol β-galactoside crystallised spontaneously. It was thought that the α-anomer of this glycoside might be identical with *iso*floridoside; the hexaacetate of the presumed 1-D-glyceritol β-galactoside was therefore treated with titanium tetrachloride in chloroform [14] to effect anomerisation. Residual β-galactoside in the product after deacetylation was hydrolysed with a β-galactosidase preparation and the carbohydrate mixture obtained was separated on a carbon column. One fraction was chromatographically similar to *iso*floridoside * and crystallised upon seeding with it, but the melting point **, 121—127°, raised to 125—127° after repeated recrystallisations, was much lower than that previously reported for *iso*floridoside [9] (134—135° uncorr.) and the mixed melting point showed a wide range but no depression. However, the melting point of analytically pure *iso*floridoside, as redetermined on a Kofler hot stage, was 132—141°, and a reasonable explanation compatible with the experimental data was thus that both samples were isomorphous mixtures of 1-D- and 1-L-glyceritol α-galactosides. This assumption was confirmed by resolving the mixtures on a carbon column which had previously been found to give very sharp separations. Both *iso*floridoside and the synthetic sample gave the same two components, m. p. *ca* 131—133° and 149—151.5° (*cf.* Table 1); no melting point depression was observed with mechanically mixed samples of these compounds but the mixed fusion technique gave a melting point minimum of 120°.

Table 1. 1-Glyceritol galactopyranosides.

	M. p.	$[\alpha]_D^{20}$	Analysis			
			Per-iodate[a]	Formic acid[b]	C	H
Calculated for $C_9H_{18}O_8$:			3.00	1.00	42.5	7.14
Compound:						
O-α-D-Galactopyranosyl-(1→1)-D-glyceritol	150 —152°	+155°	2.91	0.93	42.8	7.37
O-α-D-Galactopyranosyl-(1→1)-L-glyceritol	131.5—133°	+159°	2.90	0.95	42.9	7.45
O-β-D-Galactopyranosyl-(1→1)-D-glyceritol	140.5—141.5°	−7°	2.89	0.97		
O-β-D-Galactopyranosyl-(1→1)-L-glyceritol[c]	104—107°	+2°	2.89	0.97	42.4	7.45

[a] Moles of sodium metaperiodate consumed overnight by 1 mole of glycoside [27].
[b] Moles of formic acid formed from 1 mole of glycoside on periodate oxidation overnight.
[c] The central parts of crystals in a solidified sample melted at 108—110°.

* Kindly supplied by Dr. B. Lindberg.
** Melting points are corrected unless stated otherwise.

The 1-glyceritol β-galactoside preparation obtained above crystallised when seeded with 1-D-glyceritol β-galactoside * from wheat flour lipids [2,3], m. p. 139.5—142°, but the product had m. p. 124—128°, and this value was not appreciably raised by recrystallisation. The low specific rotation, $[\alpha]_D^{20}$ -3°, excludes the presence of α-D-galactopyranosides, and as no melting point depression was observed on admixture with the high-melting glycoside used for seeding, the synthetic preparation was assumed to be an isomorphous mixture of 1-D- and 1-L-glyceritol β-galactosides.

The results show, either that the 2,3-O-*iso*propylidene-D-glyceritol used as starting material in the Koenigs-Knorr reaction was extensively racemised before the reaction or that racemisation took place during the reaction. The first alternative seems very improbable as two different preparations of 2,3-O-*iso*propylidene-D-glyceritol had $[\alpha]_D^{23}$ +14.0° and 14.1°. On the other hand the racemisation could be due to traces of acid liberated in the Koenigs-Knorr reaction and the experiment was therefore repeated using a large excess of silver oxide. However, after alkaline and mild acid hydrolysis and subsequent fractionation of the product on a small carbon column, crystalline preparations were obtained which melted over the ranges 97—116° and 124—129°, indicating that extensive racemisation still took place. This phenomenon remains to be explained.

The synthesis of the 1-D-glyceritol α- and β-galactosides was finally accomplished in the following way. 2,2'-O-Methylene-bis-(3-O-benzoyl-D-glycerose)[15], obtained by oxidising II with lead tetraacetate, was reduced catalytically to the crystalline glyceritol derivative (IV) and this was allowed to react with tetra-O-acetyl-α-D-galactopyranosyl bromide under Reynolds' and Evans'

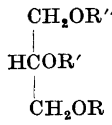
conditions, giving V. After acetolysis and alkaline alcoholysis the product was separated on a carbon column and then gave 17 % of the α- and 36 % of the β-galactoside. As this yield of α-anomer is unexpectedly high the experiment was repeated adding the halide much more rapidly to see whether this would influence the yields. These were now *ca.* 3 % and 28 % for the α- and β-anomer, respectively. The yield of α-galactoside was thus still fairly high.

Mixed fusion confirmed the identity of 1-D-glyceritol α-galactoside and the high-melting component of *iso*floridoside.

The anomalous course of the above reaction is probably not due to simple steric hindrance in the aglycone, as a much more hindered molecule, 2,2'-O-methylene-bis-(3-O-trityl-L-glyceritol) (VI), under similar conditions gave 21 % of the theoretical yield of 1-L-glyceritol β-galactoside only; no α-anomer was isolated. VI was prepared from IV by tritylation and debenzoylation.

1-L-Glyceritol β-galactoside was more readily prepared starting from 2,3-O-*iso*propylidene-D-glyceritol (I). Benzylation of I and acid hydrolysis of the benzyl ether gave VIII [16,17] witch was tritylated and the trityl ether (IX) was benzylated to give crystalline 1-O-trityl-2,3-di-O-benzyl-L-glyceritol (X). This was detritylated by heating with aqueous acetic acid and the crude amorphous 2,3-di-O-benzyl-L-glyceritol (XI) obtained was used directly in the Koenigs-Knorr reaction without distillation. The product from this reaction (XII) was deacetylated, the benzyl groups were removed by catalytic hydrogenolysis and the glycoside mixture was separated by recrystallisation and fractionation on a carbon column, giving 1 % and 59 %, respectively,



VIII R,R′ = H; R″ = $C_6H_5CH_2$

of 1-L-glyceritol α- and β-galactosides. The α-anomer had a lower melting point (127—129°) than the low-melting component of *iso*floridoside (m. p. 131.5—133°), but the two samples were shown to be identical by mixed fusion. If the synthetic sample had contained considerable amounts of the isomorphous 1-D-glyceritol α-galactoside a melting point minimum would have been observed, but the presence of a small quantity of this diastereoisomer could not be excluded. This would imply that the 1-L-glyceritol β-galactoside was contaminated with some of the corresponding D-glyceritol derivative, and the rather broad range of the melting point (*ca.* 101—107°) lent some support to this idea. However, chromatography on an efficient carbon column showed that this was most probably not the case. The material was slightly hygroscopic, and a pure sample after intensive drying had m. p. 104—107°. On mixed fusion with 1-D-glyceritol β-galactoside (m. p. 140.5—141.5°) it gave a melting point minimum of 98—99°.

Another possible route to the 1-L-glyceritol galactosides was also considered. 2,5-O-methylene-3,4-O-benzylidene-D-mannitol (XIII), prepared from its easily available dibenzoate (XIV)[15], was allowed to react with tetra-O-acetyl-α-D-galactopyranosyl bromide. This would be expected to give the digalacto-

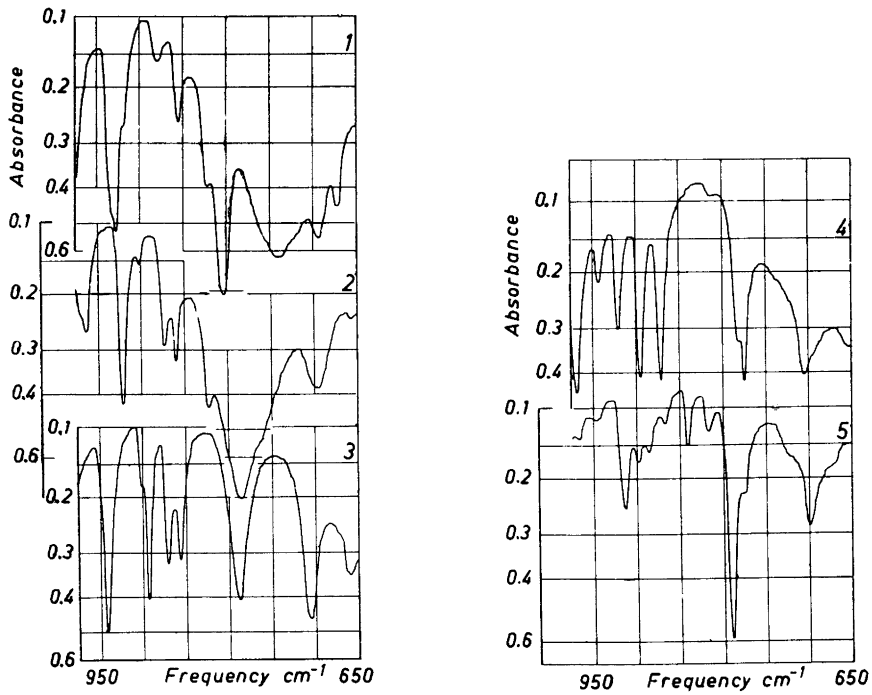

Fig. 1. Infrared absorption curves of 1) O-α-D-Galactopyranosyl-(1 → 1)-D-glyceritol; 2) O-α-D-Galactopyranosyl-(1→1)-L-glyceritol; 3) O-β-D-Galactopyranosyl-(1→1)-D-glyceritol; 4) O-β-D-Galactopyranosyl-(1→1)-L-glyceritol; 5) O-α-D-Galactopyranosyl-(1→6)-O-β-D-galactopyranosyl-(1→1)-D-glyceritol.

side octaacetates (XV) which by catalytic hydrogenolysis to III, lead tetraacetate oxidation and catalytic hydrogenation to VII and subsequent hydrolysis would ultimately give the desired 1-L-glyceritol galactosides. However, while XIII rapidly consumed the theoretical volume of hydrogen in the presence of palladium on charcoal, the product that should have contained XV was not susceptible to hydrogenolysis under similar conditions. Raney nickel catalyst gave some reaction as was evident from the change in optical rotation, but the product finally obtained by following the scheme above was a rather complex mixture. Chromatography on a carbon column gave fractions with the chromatographic properties of a glyceritol galactoside but could not be induced to crystallise. It is possible that some ketal migration analogous to that observed with the 2,3-O-*iso*propylidene-D-glyceritol above takes place in this Koenigs-Knorr reaction.

Infrared spectra of glycoside A and of the 1-glyceritol galactosides were recorded with a Perkin-Elmer double beam spectrometer Model 21 with a sodium chloride prism, using the potassium bromide disc technique. Previous studies of the infrared spectra of carbohydrates have been confined to the frequency range 730—960 cm^{-1} (Ref.[18]); the corresponding sections of the spectra recorded here are shown in Fig. 1. The frequencies of the absorption bands in this region are given in Table 2. Barker *et al.*[19] made the following assignments for some of the characteristic infrared bands of D-galactopyranose derivatives (Nujol mull): Type 2 a, 825 ± 11 cm^{-1}, deformation mode of equatorial hydrogen at the anomeric carbon atom of α-anomers; type 2 b, 895 ± 9 cm^{-1}, deformation mode of axial hydrogen at the anomeric carbon atom of β-anomers; type 2 c, 871 ± 7 cm, deformation mode of equatorial hydrogen at carbon atom 4. The spectra now recorded agree with these interpretations. It is known that with compounds which take up water of crystallisation, the spectra may gradually change as the potassium bromide discs are stored [20]. However, no hydrates of the 1-glyceritol glycosides have been found, and no spectral changes were observed.

Table 2. Infrared bands of 1-glyceritol glycosides in the region 730—960 cm^{-1}. Frequencies * in cm^{-1}.

Frequencies assigned[18]:			Type 2a 825 ± 11		Type 2c 871 ± 7		Type 2b 895 ± 9

* Points of inflexion are given in brackets.

EXPERIMENTAL

*2,3-O-*Iso*propylidene-*D*-glyceritol (I).* 2,3-O-*Iso*propylidene-D-glycerose, b. p.$_{20}$ 55°, was prepared from D-mannitol by the method of Baer and Fischer [10,11]. The aldehyde (23 g), which had polymerised to some extent, was dissolved in ethanol and this solution was added with shaking to potassium borohydride (7 g) in 0.2 M disodium phosphate solution (150 ml). After standing overnight the mixture was acidified to pH *ca.* 6 by adding acetic acid and when the evolution of hydrogen had stopped the solution was made alkaline with sodium hydroxide and extracted repeatedly with chloroform. The extract was dried over potassium carbonate and concentrated. The residual oil was distilled through a short Vigreux column. Yield 18.9 g (81 %), b. p.$_{14}$ 82—83°, $[\alpha]_D^{23}$ +14.1° (pure oil), Baer and Kates report [12] $[\alpha]_D^{20}$ +14.0°.

Attempted preparation of 1-D-*glyceritol β-galactoside from I.* 2,3-O-*Iso*propylidene-D-glyceritol (I) (9.1 g), Drierite (100 g), freshly prepared silver oxide (25 g) and dry chloroform (100 ml) were stirred together in the dark for 1 h. A solution of acetobromogalactose (31 g) and iodine (4 g) in chloroform (120 ml) was gradually added with stirring during the next 2 h, and the mixture was then kept with stirring overnight. After filtration the chloroform solution was washed with water, dried over magnesium sulphate and concentrated under reduced pressure to a syrup (*ca.* 36 g). Paper chromatograms run in ethyl ether—dimethyl sulphoxide [21] showed one spot with R_F *ca.* 0.8 which appeared slowly with the silver nitrate—sodium hydroxide reagent and two spots with R_F *ca.* 0.2 and 0.4 which appeared quickly with this reagent. By countercurrent extraction between ethyl ether and dimethyl sulphoxide containing 10 % of water using 5 separating funnels [21], the fastest component was obtained in a chromatographically pure state (14.2 g from 27 g of the crude product). It did not crystallise and was obviously a mixture of diastereoisomers, consisting of 2,3-O-*iso*propylidene-D-glyceritol β-galactoside tetraacetate and the corresponding L-glyceritol derivative. Later a sample was deacetylated with sodium ethoxide in ethanol and hydrolysed (0.02 N sulphuric acid, 20°, 17 h) to give a syrup which crystallised from methanol—ethanol only when seeded with 1-D-glyceritol β-galactoside; m. p. 124—128°, undepressed on admixture with the material used for seeding, $[\alpha]_D^{20}$ −3° (water, c = 2.0). *Cf.* Table 1.

Part of the crude acetate (9 g) from the Koenigs-Knorr reaction was deacetylated with sodium ethoxide in ethanol, a small quantity of water was added and the solution was saturated with carbon dioxide, filtered and concentrated. On paper chromatograms run in ethyl acetate—acetic acid—water (3:1:1) * and then sprayed with periodate—benzidine [22], the deacetylated material gave a rather strong and somewhat trailing spot with R_F *ca.* 0.7. Some much slower spots were also observed. The deacetylated material was dissolved in water and added to a carbon—Celite mixture (100 g + 100 g) contained in a Büchner funnel. On batch-wise elution with aqueous ethanol (1, 2, 4, 6, 8, 10, 15, 25, 35 and 50 %, 500 ml of each) a fraction (2.8 g of dry material) was obtained which on paper chromatograms gave one main spot with R_F 0.7. It did not crystallise, but was assumed to be a mixture of *2,3-O-*iso*propylidene-*D*-glyceritol β-galactoside* and the corresponding L-glyceritol derivative, as mild hydrolysis (0.02 N sulphuric acid at 20° overnight) gave a homogeneous product (paper chromatographically) which when seeded with 1-D-glyceritol β-galactoside (from wheat flour lipids) gave crystals from methanol—ethanol having m. p. 120—124° and $[\alpha]_D^{18}$ −3° (water, c = 2.3). *Cf.* values for pure 1-D- and 1-L-glyceritol-galactosides, Table 1. On paper chromatograms run in ethyl acetate—acetic acid—water the 1-glyceritol β-galactosides travel with the same rate and slightly faster than galactose.

In a second run a mixture of I (0.72 g), silver oxide (4 g), Drierite (10 g) and chloroform (10 ml) was stirred for 1 h and then a solution of acetobromogalactose (2.5 g) and iodine (0.3 g) in chloroform (12 ml) was added with stirring over a period of 3 h. After stirring overnight the chloroform solution was washed with water, dried over magnesium sulphate and concentrated. The residue was deacetylated with sodium ethoxide in ethanol, and then hydrolysed for 30 min at 50° in 0.1 N hydrochloric acid. After treatment with Amberlite resin IR 4B and concentrating, the aqueous solution was added to a

* This solvent system was used throughout unless stated otherwise.

carbon—Celite column (1:1, 24 × 3 cm). On gradient elution with aqueous ethanol (2 000 ml), the concentration of which was raised linearly from 1 to 30 %, material with low optical rotation and with the paper chromatographic properties of a 1-glyceritol β-galactoside was obtained as an apparently homogeneous fraction. The first and last halves of this were collected and worked up separately. The first gave material (0.5 g) which crystallised from methanol—ethanol when seeded with 1-D-glyceritol β-galactoside. Yield 0.39 g; m. p. 124—129°, $[\alpha]_D^{18}$ −4° (water, c = 2.4). The second half (0.4 g) similarly gave 0.20 g, m. p. 110—116°, $[\alpha]_D^{18}$ −3° (water, c = 2.1). It is thus evident that some separation of the 1-D- and 1-L-glyceritol β-galactosides was achieved.

Anomerisation of D,L-glyceritol β-galactoside [14]. Purified 2,3-O-*iso*propylidene-D,L-glyceritol β-galactoside tetraacetate (4.0 g) from the preparation described above was refluxed for 20 min with 2 N sulphuric acid (2 ml) in 60 % aqueous ethanol (100 ml) to remove the *iso*propylidene group. The solution was treated with Amberlite resin IR 4B and concentrated to dryness under reduced pressure. The residue so obtained was acetylated with acetic anhydride and pyridine to give 1-D,L-glyceritol β-galactoside hexaacetate (3.9 g). This was dissolved in dry chloroform (100 ml), titanium tetrachloride (1.2 ml) was slowly added and the mixture was refluxed for 20 h with the exclusion of moisture. Pyridine (4 ml) and an excess of water were then added, the mixture was filtered with Celite and the chloroform phase was washed with sodium carbonate and water, dried over magnesium sulphate and concentrated under reduced pressure. To deacetylate the residual syrup (3.8 g) it was dissolved in absolute ethanol (100 ml) to which sodium (0.2 g) had previously been added and was then left at room temperature overnight. The solution obtained on dilution with water (100 ml), was filtered through Amberlite resins IR 120 H and IR 4B, concentrated under reduced pressure to a small volume, treated with decolorising carbon, filtered and concentrated to give the mixed α- and β-galactosides as a syrup (1.75 g).

To hydrolyse the remaining β-galactoside the syrup was incubated at 30° with a β-galactosidase solution [2,23] (5 ml) in 0.1 N sodium acetate buffer (pH 4.6, 100 ml). When the optical rotation of the solution had reached a constant value (after 60 h) acetone (120 ml) was added and after centrifugation the solution was further purified by precipitation with aqueous lead acetate, filtration with Celite, saturation with hydrogen sulphide and filtration. The solution obtained was concentrated under reduced pressure to a small volume (30 ml) and was then added to a carbon—Celite column (1:1, 24 × 3 cm). Gradient elution with aqueous ethanol (1—30 %, 2 000 ml) gave three separate fractions which were shown by paper chromatography to contain glyceritol, galactose and 1-glyceritol galactosides, respectively. The glycoside fraction crystallised from a methanol—ethanol mixture on seeding with *iso*floridoside (m. p. 132—141°, $[\alpha]_D^{21}$ +157°). Yield 0.51 g; m. p. 121—127°, $[\alpha]_D^{21}$ +157° (water, c = 2.0). After three further recrystallisations the product (*ca.* 0.2 g) had m. p. 125—137°, undepressed on admixture with *iso*floridoside.

The synthetic glycoside mixture and its concentrated mother liquors were combined (0.6 g in total), dissolved in water (10 ml) and the solution was added to the top of an efficient carbon—Celite column (1:1, 43 × 3.5 cm). Aqueous ethanol (4 000 ml), the concentration of which was raised linearly from 3 % to 6 %, was used as eluant. The optical rotation of the eluate showed two strong peaks which were only partly separated. The optically active part of the eluate was cut into 3 fractions. Fraction 1, corresponding to the first peak and fraction 2, corresponding to the second peak, were separated at the point of minimum rotation; the "tail" of the slowest component was collected separately to give fraction 3. As some overlapping could be expected, fraction 2 was run through the column again in the same way. However, there were no indications of the presence of any material from fraction 1 in the eluate.

Fraction 1 was concentrated to dryness and the residue (0.24 g) was recrystallised from methanol—ethanol. Yield 0.21 g; m. p. 131.5—133°, $[\alpha]_D^{20}$ +159° (water, c = 1.9). The properties did not change on further recrystallisation (analysis: see Table 1).

Fraction 2 similarly gave crystalline material (0.15 g), m. p. 149—151.5°, $[\alpha]_D^{20}$ +152° (water, c = 2.0).

Fraction 3 (35 mg) gave a small crop of crystals with m. p. 143—149°.

Fractionation of iso*floridoside on carbon.* A sample of *iso*floridoside [9] (0.25 g), m. p. 132—141°, $[\alpha]_D$ +157° from which the low-melting component had been partially removed by extensive recrystallisation, was fractionated in the same way as the synthetic α-galactosides and then gave fraction 1′ (0.06 g), m. p. 130.5—132°, $[\alpha]_D^{18}$ +155° (water, c = 1.9) and fraction 2′ (0.12 g), m. p. 149.5—151.5°, $[\alpha]_D^{18}$ +156° (water, c = 1.7).

As the melting point of mechanically mixed samples of the high- and low-melting glycoside showed no depression, but a very wide range (*ca.* 130—150°), further comparisons were made by the mixed fusion technique [24] using a Kofler hot stage. The samples to be compared were placed on each side of and close to a *ca.* 1 mm wide splinter of a cover glass which was placed on the glass slide of the hot stage. Heating was applied gradually until the molten material spreading from each side under the cover glass had met, if possible so that a few crystals of the most high-melting component were left. If necessary a seed crystal was added. The temperature was then adjusted so that the crystals grew at a maximum rate and the process was followed by polarised light. When all had solidified the new melting points were determined.

On mixed fusion of fraction 1′ and 2′ the crystallisation of the latter was found to be fairly fast up to the boundary between the samples. The zone of mixing was passed only very slowly, but then the rate of the crystal growth increased again and when all had solidified the crystals appeared perfectly homogeneous. On renewed heating a narrow channel indicating the zone of mixing formed at *ca.* 120°; fraction 1′ melted at 129—132° and fraction 2′ at 149—151°. When compared in the same way, 1-L-glyceritol α-galactoside (m. p. 127—129°; from 2,3-di-O-benzyl-L-glyceritol, XI) and fraction 1 and 1′ behaved as one compound, though the melting points of the solidified samples were slightly different, 126—129°, 131—134° and 129—132°, respectively. 1-D-Glyceritol α-galactoside (m. p. 150—152°; from 2,2′-O-methylene-bis-(3-O-benzoyl-D-glyceritol), (IV) was in the same way found to be identical with fraction 2 and 2′; the melting points of the solidified samples were 150—152°, 149—151° and 149—151°, respectively.

*2,2′-O-Methylene-bis-(3-O-benzoyl-*D*-glyceritol) (IV).* 1,6-Di-O-benzoyl-2,5-O-methylene-D-mannitol (II) was prepared from D-mannitol by the procedure of Ness *et al.*[15] As the synthesis was carried out on about 25 times the scale used by these authors, special care was taken to avoid overheating; the overall yield of a crude product, m. p. 117—121°, was 69 %. A sample was recrystallised from methanol, m. p. 119.5—121°, $[\alpha]_D^{22}$ −66° (chloroform, c = 2.0).

Finely powdered lead tetraacetate (44 g) was added slowly with stirring to a solution of II (40 g) in dry ethyl acetate (300 ml) and after standing for an hour the precipitated lead salts were filtered off. The filtrate was washed successively with water, aqueous sodium bicarbonate and water, and was then dried for a short time over sodium sulphate, filtered and concentrated to a smaller volume (*ca.* 100 ml). Carefully washed Raney nickel W-2 catalyst [25] (*ca.* 10 ml) was added and the mixture was hydrogenated at 70° and 130 atm pressure for 3 h. When the cooled hydrogenation vessel was opened the product had partly crystallised. It was brought into solution by gentle heating, the solution was filtered and an equal volume of light petroleum (b. p. 45—65°) was added to the combined filtrate and washings. After the mixture had been kept cold for a while the crystals (28 g, m. p. 104.5—106°) were filtered off, the mother liquors were concentrated under reduced pressure and the residue was recrystallised from carbon tetrachloride, giving a second crop (4 g, m. p. 101—105°). The combined material was recrystallised from chloroform—carbon tetrachloride. Yield 30 g (75 %), m. p. 105—106.5° $[\alpha]_D^{20}$ −58° (chloroform, c = 2.0). After recrystallisation from aqueous ethanol a sample had m. p. 106.5—108° and $[\alpha]_D^{18}$ −60° (chloroform, c = 2.3). (Found: C 61.9; H 6.00. Calc. for $C_{21}H_{24}O_8$: C 62.4; H 5.98.)

In order to test the stability of IV to silver oxide, a sample (m. p. 105—107°; 80 mg) was shaken with freshly prepared silver oxide (200 mg) in chloroform (4 ml) for 120 h at room temperature. The specific rotation of the samples remained unchanged and afterwards the filtered chloroform solution, when concentrated, gave a crystalline residue with m. p. 103—106° without further purification. Thus no significant racemisation took place.

*1-*D*-Glyceritol α- and β-galactosides.* A mixture of 2,2′-O-methylene-bis-(3-O-benzoyl-D-glyceritol) (IV) (10 g), freshly prepared silver oxide (17 g), Drierite (75 g) and dry chloro-

form (150 ml) was stirred for 1 h and then a solution of acetobromogalactose (22.5 g) and iodine (3 g) in chloroform (100 ml) was added dropwise with stirring during 2 h. Care was taken to protect the reaction mixture from light. After 2 days in a dark place, inorganic material was removed by filtration, the filtrate was washed with water, dried over magnesium sulphate and concentrated under reduced pressure. To split the methylenedioxy-bridge of V, the residual syrup was dissolved in a mixture of acetic anhydride (70 ml), acetic acid (30 ml) and sulphuric acid (1 ml). After 1 h at room temperature anhydrous sodium acetate (4 g) and water (100 ml) were added and when the anhydride had decomposed, the mixture was diluted with more water and extracted with chloroform. The chloroform solution was washed with aqueous sodium carbonate and water, dried over magnesium sulphate and concentrated. The residue was treated with a solution of sodium (4 g) in absolute ethanol (600 ml) at room temperature overnight. Water (600 ml) was then added, the solution was filtered through Amberlite resins IR 120 H and IR 4B and the filtrate was concentrated under reduced pressure. When dissolved in methanol (10 ml), the residue crystallised spontaneously but the product (7.3 g) had m. p. 121—136° and $[\alpha]_D^{21}$ +38° (water, c = 2.0) and was probably a mixture of the α- and β-galactosides. Recrystallisation from methanol gave 1-D-glyceritol β-galactoside (2.1 g) m. p. 138—140°, $[\alpha]_D^{21}$ ±0 (water, c = 2.0), and 1-D-glyceritol-α-galactoside (0.2 g), m. p. 150—152°, $[\alpha]_D^{18}$ +155° (water, c = 1.8), (analysis: See Table 1.)

The combined mother liquors were concentrated, the residue was dissolved in water and the solution was added to the top of a carbon—Celite column (1:1, 50 × 5 cm). Gradient elution with aqueous ethanol (2—8 %) gave two fractions containing material with the R_F value of a 1-glyceritol galactoside. The fractions were not completely separated, as judged by spot tests, but the first of them was easily distinguished by its high positive optical rotation. On concentration and recrystallisation of the residue from methanol—ethanol this fraction gave 1-D-glyceritol α-galactoside (1.9 g), m. p. 150—151.5°. The next fraction similarly gave 1-D-glyceritol β-galactoside (2.4 g), m. p. 138.5—140.5°. A sample was recrystallised from methanol and then had m. p. 140.5—141.5°, $[\alpha]_D^{20}$ −7° (water, c = 2.0), (analysis: See Table 1.)

The total yield of the α- and β-anomer was thus 2.1 g and 4.5 g or 17 % and 36 % calculated on IV, respectively.

The synthesis was repeated on half the scale described above; one quarter of the acetobromogalactose solution was added at once and the rest during *ca.* 40 min. The yield of α-anomer (m. p. 150—152°) and β-anomer (m. p. 137—140°) was now only 3 % and 28 % of the theoretical, respectively.

2,2'-O-Methylene-bis-(3-O-trityl-L-glyceritol) (VI). A solution of 2,2'-O-methylene-bis-(3-O-benzoyl-D-glyceritol) (IV) (8.1 g) and trityl chloride (13 g) in dry pyridine (60 ml) was kept at 100° for 4 h and was then poured into ice-water. The mixture was extracted with ether and the ether phase was washed successively with water, sodium bicarbonate and water and was then dried over sodium sulphate. After filtration the ether solution was concentrated and the remaining amorphous *2,2'-O-methylene-bis-(1-O-trityl-3-O-benzoyl-D-glyceritol)* was dissolved in ethanol (50 ml) containing potassium hydroxide (6 g). After heating on a water bath for 1 h the mixture was diluted with water and extracted with chloroform. The chloroform extract was washed with water, dried over sodium sulphate and concentrated under reduced pressure and the residue was recrystallised from carbon tetrachloride. Yield 11.3 g (83 %); m. p. 142—146°. A pure sample obtained by recrystallisation from an ethanol—ethyl acetate mixture had m. p. 146—147.5° and $[\alpha]_D^{18}$ +58° (chloroform, c = 2.0). (Found: C 79.0; H 6.39. Calc. for $C_{45}H_{44}O_6$: C 79.4; H 6.51.)

1-L-Glyceritol β-galactoside from VI. A mixture of 2,2'-O-methylene-bis-(3-O-trityl-L-glyceritol) (VI) m. p. 142—146°; 5.0 g), freshly prepared silver oxide (7.4 g), Drierite (29 g) and dry chloroform (40 ml) was stirred for 1 h and then a solution of acetobromogalactose (6.7 g) and iodine (0.9 g) in chloroform (30 ml) was added with stirring during 3 hours. The mixture was kept with stirring in a dark place until a sample of the chloroform solution no longer gave a positive bromide test with silver nitrate in ethanol (12 days).

The reaction product was isolated and subjected to acetolysis and deacetylation, essentially as described above for V in the preparation of the 1-D-glyceritol galactosides. Most of the tritanol which was liberated in the acetolysis, could be filtered off after the excess of acetic anhydride had been destroyed by the addition of water.

The deacetylated material gave strong spots for galactose and glyceritol on paper chromatograms. It was separated on a carbon—Celite column (1:1, 50 × 5 cm) by the gradient elution technique. Aqueous ethanol (1—8 %, 8 000 ml) was used as eluant and the eluate was investigated polarimetrically and by paper chromatography. One fraction (1.0 g) had the chromatographic properties of a 1-glyceritol galactoside and crystallised from a methanol—ethanol mixture when seeded with 1-D-glyceritol β-galactoside. Yield 0.78 g, (21 % calc. on VI), m. p. 97—100°. After recrystallisation from the same solvent it still had m. p. 97—100° and $[\alpha]_D^{18}$ +1° (water, c = 2.5). These values are somewhat lower than those observed with the same compound prepared from 2,3-di-O-benzyl-L-glyceritol (see Table I).

1-L-Glyceritol α-galactoside travels a little faster than the corresponding β-galactoside on carbon columns, but when the part of the eluate which would contain the α-galactoside was concentrated, the residue (0.16 g) had a low specific rotation ($[\alpha]_D$ +16°) and could not be induced to crystallise.

3-O-Benzyl-L-glyceritol (VIII) has previously been prepared by treating the sodium salt of 2,3-O-*iso*propylidene-D-glyceritol (I) with benzyl bromide and then removing the *iso*propylidene group by mild hydrolysis [16,17]. The benzylation procedure of Zemplén *et al.*[26] was used in the present investigation and seems to give a higher yield.

A mixture of 2,3-O-*iso*propylidene-D-glyceritol (18.9 g), finely powdered potassium hydroxide (115 g) and dioxane (250 ml) was placed in a three-necked flask equipped with a mechanical stirrer, a reflux condenser and a dropping funnel. The flask was immersed in an oil bath which was kept at 80° and freshly distilled benzyl chloride (100 ml) was added through the funnel over a period of 45 min with vigorous stirring. The reaction mixture was kept at 80—90° with stirring overnight. After cooling it was filtered, the filter cake was dissolved in water and the solution was extracted with benzene. The dioxane solution and the benzene extract were combined, dried over magnesium sulphate, filtered and concentrated under reduced pressure (to *ca.* 100 ml). This residue was distilled *in vacuo*, giving a fore-run (54 g) of unreacted benzyl chloride, b. $p._{13}$ 65—66° and then a fraction (43 g), b. $p._{0.3}$ 90—96° and α_D^{21} +13.7° (1 dm, pure oil), containing *1-O-benzyl-2,3-O-*iso*propylidene-D-glyceritol.* In a pure state this compound has b. $p._{0.3}$ 95—97° and α_D +17.8° (1 dm, pure oil) [16]; the theoretical yield should be only 31.8 g. The crude product was probably contaminated with dibenzyl ether, but it was used in the next step without further purification.

The crude benzyl ether obtained above (43 g) was dissolved in methanol (300 ml). Water (100 ml) and 2 N sulphuric acid (20 ml) were added and the mixture was heated to the boiling point and then left at room temperature overnight. The methanolic solution was extracted with five 50 ml portions of light petroleum (b. p. 45—65°) to remove any dibenzyl ether; the light petroleum extracts were washed successively with two 50 ml portions of 80 % aqueous methanol to retain any VIII carried away. The combined methanolic solutions were concentrated under reduced pressure to remove most of the methanol and the residual aqueous solution (*ca.* 150 ml) was extracted with chloroform. The chloroform extract was washed with aqueous sodium carbonate and water, dried over sodium sulphate, filtered and concentrated under reduced pressure and the residual syrup (25.4 g) was distilled *in vacuo* through a Vigreux column. A small fore-run (1.7 g) b. $p._{0.15}$ 123°, n_D^{21} 1.5450, was discarded; VIII then distilled at 128—133° and ca 0.05 mm pressure. Yield 23.1 g (88 % calc. on I; n_D^{21} 1.5322, α_D^{21} +6.6° (1 dm, pure oil). Sowden and Fischer [16] give b. $p._{0.3}$ 138—139°, n_D^{16} 1.5342, α_D +6.1° (1 dm, pure oil).

1-O-Trityl-2,3-di-O-benzyl-L-glyceritol (X). A solution of 3-O-benzyl-L-glyceritol (VIII) (23.1 g), and trityl chloride (35.4 g) in dry pyridine (150 ml) was kept at room temperature for 2 days and then heated at 60° for 4 h. It was then stirred into ice-water and the aqueous mixture was extracted with ether. The ether phase was washed several times with water, then as quickly as possible with cold 0.5 N sulphuric acid and finally with aqueous sodium carbonate and water. After drying over sodium sulphate the ether-

eal solution was filtered and concentrated under reduced pressure to give crude *1-O-trityl-3-O-benzyl-*L*-glyceritol* (IX) as a syrup which, however, did not crystallise.

Freshly distilled benzyl chloride (60 ml) was added gradually with vigorous stirring to a mixture of the crude trityl compound and finely powdered potassium hydroxide (50 g) in dioxane (150 ml), while the temperature was kept at 80°. Stirring was continued overnight at this temperature. The insoluble material was then filtered off, the filter cake was dissolved in water and the aqueous suspension obtained was extracted with benzene and the benzene extract was added to the residue remaining after the dioxane filtrate had been concentrated under reduced pressure. The benzene solution was washed with sodium bicarbonate and water, dried over sodium sulphate, filtered, concentrated and finally taken to dryness at *ca.* 0.3 mm pressure and 150° (bath temperature). The residue crystallised when stirred with light petroleum. The crude product was ground to a paste with light petroleum—*iso*propyl ether (1:1, 50 ml), filtered and then recrystallised from benzene—ethanol. After recovering a few grams from the mother liquors, the yield of pure X was 52 g (80 % calc. on VIII); m. p. 84.5—86°, $[\alpha]_D^{18}$ −9° (chloroform, c = 2.5). (Found: C 83.6; H 6.69. Calc. for $C_{36}H_{34}O_3$: C 84.0; H 6.66.)

*2,3-Di-O-benzyl-*L*-glyceritol (XI).* A solution of 1-O-trityl-2,3-di-O-benzyl-L-glyceritol (X) (48,8 g) in acetic acid (340 ml) was heated under reflux and water (240 ml) was added at a moderate rate so that no oil separated. The mixture was refluxed for a further hour and then kept in a refrigerator overnight. Tritanol (23.5 g or 95 %) was filtered off and the mother liquors were concentrated under reduced pressure to give crude XI as a colourless oil (26.7 g). After drying azeotropically with benzene, it was used in the next step without further purification. A sample was distilled *in vacuo*. It had b.p.$_{0.05}$ *ca.* 150°, n_D^{25} 1.5490, d_4^{23} 1.106 and $[\alpha]_D^{23}$ +3.8° (pure oil).

*1-*L*-Glyceritol α- and β-galactosides from XI.* A mixture of crude, dry 2,3-di-O-benzyl-L-glyceritol XI (11 g), freshly prepared silver oxide (19 g), Drierite (50 g) and dry chloroform (100 ml) was stirred for 1 h and then a solution of acetobromogalactose (18 g) and iodine (2.4 g) in dry chloroform (100 ml) was added during 3 h. The reaction mixture was shielded from light. After stirring for a further 20 h a sample of the chloroform solution gave no reaction with ethanolic silver nitrate solution. Insoluble material was then filtered off, the filtrate was washed with water, dried over sodium sulphate and concentrated under reduced pressure. The residue was treated overnight with absolute ethanol (500 ml) to which sodium (0.75 g) had been added, the alkali was neutralised by adding 2 N sulphuric acid (16 ml) and after filtration the ethanolic solution was concentrated to a small volume. 2 N sodium carbonate solution (5 ml) was added to the residue and the di-O-benzylglyceritol galactosides were extracted with three 200 ml portions of ethyl acetate. The extracts were filtered successively through a cellulose column (10 × 3.5 cm), pre-equilibrated with water-saturated ethyl acetate, and then concentrated under reduced pressure. The amorphous residue (16 g) was free from reducing sugars. It was dissolved in methanol (200 ml) and hydrogenolysed in the presence of palladium on charcoal catalyst (2 g) containing 10 % of Pd. The uptake of hydrogen was 2 000 ml in 4 h; theory requires 1 940 ml. After filtration the methanolic solution was concentrated under reduced pressure and the residue was dissolved in a small quantity of water. Some crystalline material (0.2 g, m. p. 80—94°), probably triphenylmethane, was filtered off and the filtrate was concentrated under reduced pressure. The residual syrup was dissolved in methanol—ethanol and seeded with 1-D-glyceritol β-galactoside, giving crystalline 1-L-glyceritol β-galactoside (5.0 g), m. p. 101—103°, $[\alpha]_D^{20}$ +2° (water, c = 3.0).

The residue (3.0 g) obtained on concentration of the mother liquors was separated on a carbon—Celite column (50 × 5 cm) as described previously, using aqueous ethanol (2—8 %, 8 000 ml) as the eluant. Glyceritol was present in the first part of the eluate as indicated on paper chromatograms. After a large empty fraction there followed a fraction with a low positive optical activity and immediately after this another which gave a spot for a 1-glyceritol galactoside on paper chromatograms but was optically inactive.

The optically active fraction was concentrated under reduced pressure giving a residue (0.12 g) which crystallised from methanol—ethanol. Recrystallisation from the same solvent gave 1-L-glyceritol α-galactoside (70 mg), m. p. 127—129°, $[\alpha]_D^{18}$ +156° (water, c = 1.8). As described above, this compound was shown by mixed fusion to be identical with the low-melting component of *iso*floridoside.

The residue (1.5 g) from the next fraction gave 1-L-glyceritol β-galactoside (1.0 g), m. p. 102—107°, $[\alpha]_D^{20}$ +2° (water, c = 2.0). The total yield of this compound was thus 6.0 g (59 %). The melting points of various preparations were somewhat irregular and a sample (400 mg) was therefore added to an efficient carbon—Celite column (1:1, 43 × 3.5 cm) and then eluted with aqueous ethanol (3.5—6.5 %, 4 000 ml). 0.5 ml aliquots of the eluate were oxidised with sodium metaperiodate and the excess of oxidant was determined iodometrically [27] after 4 h. The periodate consumption showed only one peak; the two successive halves of the corresponding part of the eluate were worked up separately giving two crystalline preparations which both had m. p. 102.5—105°. They were combined and recrystallised but the melting point was unchanged except that a few crystals remained up to 107°. However, when a sample was dried intensively and then immediately transferred to the hot stage so that contact with atmospheric moisture was avoided, the m. p. was raised to 104—107°; $[\alpha]_D^{18}$ +2° (water, c = 2.0), (analysis: See Table 1.) Mixed fusion with 1-D-glyceritol β-galactoside gave a melting point minimum of 98—99°, the solidified D- and L-glyceritol derivatives melted at 140—141.5° and 105—110°, respectively. About two days were required for the melt to crystallise at 85°; the crystals appeared homogeneous.

1,6-Di-O-benzoyl-2,5-O-methylene-3,4-O-benzylidene-D-mannitol (XIV). Ness *et al.*[15] prepared XIV in 83 % yield by treating 1,6-di-O-benzoyl-2,5-O-methylene-D-mannitol (II) with 5 parts of benzaldehyde in the presence of 1 part of fused zinc chloride at room temperature. This procedure was somewhat modified to facilitate the preparation of XIV on a larger scale.

Powdered anhydrous zinc chloride (110 g) was added with stirring to freshly distilled benzaldehyde (1 100 ml). When all had dissolved the solution was cooled to room temperature and diluted with dry *iso*propyl ether (1 100 ml). 1,6-Di-O-benzoyl-2,5-O-methylene-D-mannitol (225 g) was added with stirring and when completely dissolved the mixture was allowed to stand at room temperature overnight. The benzylidene compound soon started to crystallise. After keeping in a refrigerator for a day the mixture was filtered and the filter cake was carefully washed with water, aqueous sodium bicarbonate and water and was then dried. Yield 180 g; m. p. 153—156°. A further quantity (60 g), m. p. 153—156° was obtained from the mother liquors by washing with water and aqueous sodium bicarbonate, drying over sodium sulphate, concentrating under reduced pressure and recrystallising the residue from ethyl acetate—methanol (1:3). The total yield of XIV was thus 88 %; $[\alpha]_D^{20}$ +59° (chloroform, c = 2.0). Ness *et al.*[15] record m. p. 151—152° and $[\alpha]_D^{20}$ +61.2°.

2,5-O-Methylene-3,4-O-benzylidene-D-mannitol (XIII) was prepared by refluxing its dibenzoate (XIV) (240 g) with a solution of sodium hydroxide (45 g) in ethanol (1 200 ml) and water (500 ml) for 90 min. Most of the ethanol was distilled off under reduced pressure, water (500 ml) was added and after cooling the crystals were filtered off and recrystallised from water. Yield 108 g (82 %); m. p. 129.5—132°. After concentration under reduced pressure the mother liquors gave a second crop of crystals. A sample was recrystallised from ethyl acetate, m. p. 130—132°, $[\alpha]_D^{18}$ +28° (chloroform, c = 2.3). (Found: C 59.7; H 6.49. Calc. for $C_{14}H_{18}O_6$: C 59.6; 6.43.) On treatment of XIII with benzoyl chloride in pyridine the expected dibenzoate (XIV) was regenerated.

Attempted preparation of 1-L-glyceritol β-galactoside from XIII. A mixture of 2,5-O-methylene-3,4-O-benzylidene-D-mannitol (XIII) (1.0 g), freshly prepared silver oxide (2.7 g), Drierite (10 g) and dry chloroform (10 ml) was stirred for 1 h and then a solution of acetobromogalactose (3.4 g) and iodine (0.4 g) in dry chloroform (15 ml) was added during the next 2 h. After the mixture had been stirred overnight the chloroform solution was free from reactive bromide. Insoluble material was filtered off and the filtrate was washed, dried and concentrated in the usual way giving a syrup (3.7 g), presumed to be XV, which was only moderately soluble in ethanol. A very small quantity of crystals, m. p. 235—237°, which separated from an ethanolic solution, gave a positive formaldehyde test with chromotropic acid.

Part of the syrup (1.8 g) was dissolved in ethanol (40 ml) and hydrogenated at room temperature for 87 h in the presence of palladium on charcoal catalyst (0.5 g) containing 10 % of Pd. However, the hydrogen uptake was of the order 2 ml/h and could be attri-

buted to losses by diffusion. The theoretical volume of hydrogen required for removal of a benzylidene group from XV is *ca.* 80 ml. The hydrogenolysis of a comparable amount (0.54 g, 2 mmoles) of XIII using the same catalyst (0.5 g) was complete in 1 h, giving 2,5-O-methylene-D-mannitol [15], m. p. 176—177.5°, $[\alpha]_D^{20}$ −50° (water, c = 2.0). The presence of catalyst poisons seems to be excluded by the fact that subsequent addition of XIII to the hydrogenation mixture containing the product from the Koenigs-Knorr reaction, resulted in a rapid hydrogen uptake. Either the hydrogenolysis of XV is sterically hindered or XIII rearranges before the Koenigs-Knorr reaction takes place, to give a less reactive molecule.

As an experiment showed that XIII could be hydrogenolysed using Raney nickel as the catalyst, the product (3.4 g, from 3.4 mmoles of XIII) from a Koenigs-Knorr reaction, carried out as described above, was dissolved in ethyl acetate (20 ml) and then Raney nickel catalyst W-2[26] (3 ml) was added. Treating the mixture with hydrogen at 95° and 150 atm, the optical rotation of the solution read in a 1 dm tube was +0.76° at the start and then reached a constant value of −0.78° in 24 h. The catalyst was filtered off and lead tetraacetate was gradually added to the filtrate. *Ca.* 1.0 g of oxidant was rapidly consumed; calculated on the amount of XIII used as starting material the theoretical consumption should be 1.5 g. The excess oxidant was destroyed by adding ethylene glycol, the mixture was filtered and the filtrate was washed with water and aqueous sodium bicarbonate, dried over magnesium sulphate and concentrated under reduced pressure. The residue was hydrogenated for 15 h at 75° and 140 atm in the presence of Raney nickel catalyst (1 ml) in ethyl acetate (15 ml). The hydrogenated product (*cf.* VII) was acetylated and deacetylated as described for V in the preparation of 1-D-glyceritol galactosides. The final product (0.66 g) on paper chromatograms gave an elongated spot with about the R_F value of galactose as well as two slow fairly strong spots and traces of faster spots (periodate—benzidine spray [22]). The mixture was separated on a small carbon column in the usual way giving two adjoining fractions (75 mg and 180 mg) which had the chromatographic properties of 1-glyceritol galactosides but could not be induced to crystallise.

Acetylation of pure samples of the 1-glyceritol galactosides described above, using acetic anhydride in pyridine, gave amorphous products. The paper chromatography of the acetates in dimethyl sulphoxide solvent systems has been described in a previous paper [21].

On the Separation of Cobalt(III) and Chromium(III) Ammines by Column Chromatography

ARNE JENSEN*, JANNIK BJERRUM and FLEMMING WOLDBYE

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

A method is developed for the separation of cobalt(III) and other robust coordination complexes on columns of activated alumina with the aid of aqueous salt solutions of proper composition as eluents. The scope and applicability of the method are illustrated by a variety of separations which have been achieved. Some of the factors influencing and producing the separations are considered.

A problem of increasing importance in modern coordination chemistry is the separation and analysis of reaction mixtures of robust complexes, for example of Co(III) and Cr(III), a task which can be accomplished by classical and spectrophotometric methods only in special cases. It seems therefore desirable to attack problems of this kind from different angles, for example by adsorption methods. Ion exchange technique may be used for separations of this kind with good results, as shown *e.g.* by Gustavson[1] and King and coworkers [2]. Lederer [3] has made some experiments on the separation of cobalt(III) nitroammines in non-aqueous solutions by means of paper chromatography, and Maki [4] has separated robust complexes, *e.g.* the chloroaquochromium(III) complexes in aqueous buffer solutions by means of electrochromatography on filter paper. In preliminary communications [5] we have described how robust complexes can be separated on columns of activated alumina using aqueous salt solutions as eluents. Sacconi [6] has obtained some qualitative results with pure aqueous solutions of cobalt(III) ammines, and Hein [7] has used columns of alumina for separating aqueous mixtures of phenylchromium compounds in a way which in principle is similar to the method used by us.

Chromatography on activated alumina is a very complex phenomenon as especially shown by Umland [8]. However, under specific conditions (proper composition and controlled pH of the solutions) we have developed this

* Guest from: Dept. of Inorganic Chemistry, The Royal Danish School of Pharmacy, Copenhagen.

technique to a useful method for analyzing aqueous mixtures of robust complexes. Cation complexes are separated in basic solution, the anions on the other hand in weakly acidic buffers. As displacing agents were used relatively concentrated solutions of various colourless electrolytes with which the columns were also treated in advance. The separations are highly dependent on the salt applied, being in some cases limited to special kinds of electrolytes. Thus $Co(NH_3)_6^{+++}$ could be separated quantitatively from $Cr(NH_3)_6^{+++}$ with 0.01 M KOH, 1 M KCl as a displacing agent, with much better results than with basic solutions of NaCl or $N(C_2H_5)_4Cl$. On the other hand, alkaline $N(C_2H_5)_4Cl$ was necessary for separating mixtures of Co en_3^{+++} and Cr en_3^{+++} (see Table 2).

According to Tiselius [9] one can distinguish between displacement analysis and elution analysis. In the separations considered here the displacing electrolyte penetrates and separates the coloured zones of the complexes. The case seems, therefore, to correspond closely to what Tiselius and coworkers [10] denote as non-ideal displacement. Accordingly, our guiding principle was to look for salts whose cations or anions, respectively, were supposed to have an adsorption tendency comparable with that of the complex cations and anions. Added in a sufficiently high concentration the proper salts were found to separate completely very similar complexes such as the luteo ions mentioned. The displacing power of the various cations decreases with increasing ionic radius, *i.e.* in the sequence Li^+, Na^+, K^+, $N(C_2H_5)_4^+$ and $C_{16}H_{33}N(CH_3)_3^+$. It was found that Tl^+ enters this series before Na^+. On the other hand, very little difference was found between the displacing power of anions, such as Cl^-, Br^- and NO_3^-.

EXPERIMENTAL

The columns were prepared from Merck's alumina standardized according to Brockmann. The apparatus was constructed to permit continuous addition of solutions and eluating agents.

Technique. The adsorption tubes were made of Pyrex glass. Their normal dimensions were 11 by 250 mm, but larger columns with an internal diameter of 15 mm and a length of up to 500 mm were also used in special cases. The tubes were provided with a ground-glass joint which contained a removable sintered glass disc. The tubes and the ground-glass joints were held together with wire spirals.

The columns were made by quickly pouring a thick aqueous slurry of the alumina [11] into the tubes. Especially with the normal size tubes columns made in this way lead to a uniform development of the zones. The tubes were usually filled to about three fourth of the volume, leaving the upper part of the volume for the addition of solutions. In order to save time the solutions were pressed through the columns by means of the pressure produced and regulated with the aid of two movable mercury reservoirs. The columns were equipped with a construction according to Sannie [12] which permits the introduction of eluating agents without releasing the pressure.

Procedure. Before an analysis the column was treated with the eluating solution to be used. Then 2–5 ml of the mixture of complexes were added to the column. The complex salts were sometimes but not necessarily dissolved in the eluating solvent. The eluating solution was added just at the moment when the complex mixture had passed into the column, but so quickly that the top of the column was not sucked dry. When an extra pressure of 0.5–1 atm. was applied, an experiment could usually be finished within 15–30 min. If no air bubbles happened to be evolved when the pressure was released, the same column could be used for other experiments.

The coloured effluents were collected in individual flasks, and in most cases the complexes could be separated and eluated completely. This could be done either with a

single eluent, or occasionally by the successive use of two eluents of increasing displacing power so that — in the ideal case — each component of the mixture was eluated by a specific eluent leaving the others for the following eluent.

For quantitative studies the collected samples of a given component were diluted to a known volume in a measuring flask, and the absorption curve of the solution measured with a recording Cary spectrophotometer. The absorption curve of the initial solution of the pure component diluted to the same extent was measured with the same instrument, and in this way information about the quality of the separations was obtained.

Various reagents were used to test the intermediate fractions. Sodium sulphide was an especially good reagent for testing traces of Co(III) complexes in mixtures of Co(III) and Cr(III) complexes.

Materials. The complex salts used were prepared according to prescriptions in the literature, or were from the laboratory collection of complex salts prepared by S. M. Jörgensen.

Basic alkali metal and quaternary ammonium salt solutions were used as eluating agents. Tetraethylammonium bromide and cetyltrimethylammonium bromide (technical pure) from Milton Industrial Chemicals (London) Ltd. gave colourless solutions and were sufficiently pure for the experiments. The bromides were converted to the corresponding hydroxides by means of an anion exchanger (Amberlite Resin IRA-400); in other cases we have applied mixed solutions of the quaternary ammonium salts and potassium hydroxide. The cetylammonium salt separated out on standing, but was easily dissolved before use by gentle heating.

In a few cases, *e. g.* for the separation of anion complexes, acidic solutions were used as eluents. To escape turbidity (due to colloidal dissolution of the alumina) acid-treated alumina was used. The alumina (Brockmann) was treated with 0.5 M HCl for a few minutes, washed with water and dried at 120°C.

RESULTS AND DISCUSSION

We have experimented with a single complex on the column in order to decide to what extent it can be recovered by displacement. Some examples are given in Table 1. 2 ml of a luteo salt solution were added to the columns and eluated with the basic salt solution mentioned in the table. The forerun was usually 10—15 ml, and the fraction containing the luteo salt had about the same volume. It was diluted to 25 ml in a measuring flask and the absorption curve compared with that of the initial solution diluted to the same extent. The losses (given in per cent) were somewhat variable especially in the case of $Co(NH_3)_6Cl_3$, which is bound so strongly to the alumina that the colour of the absorbed complex is distinctly more reddish than that of the solid salt. Here as for the chromium(III) ammines the loss is probably to some extent caused by decomposition of some of the luteo salt (not necessarily caused

Table 1. Experiments on the recovery of luteo salts. Loss in per cent.

Displacing sol. / Luteo salt sol.	0.1 M NaOH 1 M LiCl	0.1 M NaOH 5 M LiCl	0.1 M NaOH 1 M NaCl	0.01 M NaOH 1 M LiCl	1 M NH_3 1M NH_4Cl
0.03 M $[Co(NH_3)_6]Cl_3$	av. 4.1				2.4
0.03 M $[Co\ en_3]Cl_3$	av. 3.6	3.5		0.5	
0.1 M $[Co\ en_3]Cl_3$	0.5				
0.03 M $[Cr(NH_3)_6]Cl_3$	2.7				
0.03 M $[Cr\ en_3]Cl_3$		3.0	3.0		

by the column). Thus a column which had been used for 10—15 determinations gave a cobalt reaction only near the top when developed with Na_2S.

To decrease decomposition the hydroxyl ion concentration of the eluents should be as low as possible. Furthermore, it seems to be of some importance not to have too low a concentration of the salts to be displaced (*cf.* the experiments with Co en_3Cl_3).

Separation of luteo complexes

In Table 2 the results of some experiments on the separation of mixtures of luteo complexes are compared. About 0.03 M solutions of the luteo salts dissolved in the displacing solvent were mixed in equivalent amounts, and 2 (or 3) ml of the solution were analyzed. The coloured fractions of the two (or three) components diluted to 25 ml, were measured in 5 cm cells, and the absorption curve compared with that of the pure luteo salt solution at the same dilution.

Table 2. Separation of luteo complexes. Conc. (mole/l) in solution to be analyzed.

Salts separated	According to prep.	Chromatogr. found	Displacing solutions
Cr en_3Cl_3	0.0162	0.0155	0.1 M KOH, 1 M $(C_2H_5)_4NBr$
Co en_3Cl_3	0.0142	0.0139	
Co en_3Cl_3	0.0136	0.0136	0.1 M KOH, 1 M $(C_2H_5)_4NBr$
$Cr(NH_3)_6Cl_3$	0.0135	0.0135	0.1 M KOH, 1 M KCl
$Co(NH_3)_6Cl_3$	0.0138	0.0130	
Co en_3Cl_3	0.0158	0.0139	0.1 M KOH, 1 M $(C_2H_5)_4NBr$
$Cr(NH_3)_6Cl_3$	0.0160	0.0152	0.01 M KOH, 1 M KCl
Cr en_3Cl_3	0.0150	0.0147	0.01 M KOH, 1 M KCl
$Co(NH_3)_6Cl_3$	0.0150	0.0146	
$Cr(NH_3)_6Cl_3$	0.0160	0.0140	0.01 M KOH, 1 M KCl
$Co(NH_3)_6Cl_3$	0.0144	0.0132	

It will be seen that the tendency to adsorption increases in the series: Cr en_3^{+++}<Co en_3^{+++}<$Cr(NH_3)_6^{+++}$<$Co(NH_3)_6^{+++}$. Quaternary ammonium salts were necessary in order to accomplish the separation of the two ethylenediamine complexes. The use of 0.1 M KOH, 1 M $(C_2H_5)_4NBr$ as a displacing agent gave a clear separation into two yellow fractions the first of which gave only a very weak reaction for cobalt with Na_2S. But already substitution of the quaternary ammonium salt with KCl gave no separation. Separation could also be performed with alkaline cetyltrimethylammonium salt solutions, but the eluates became more diluted, and the quasicrystalline character of the solvent also gave other difficulties in this case. In the table is given an example of the separation of a mixed solution of three of the luteo salts. Co en_3^{+++} was first displaced with 0.1 M KOH, 1 M $(C_2H_5)_4NBr$ after which

$Cr(NH_3)_6^{+++}$ and $Co(NH_3)_6^{+++}$ were separated and displaced with 0.1 M KOH, 1 M KCl. The three luteo fractions alternated with colourless runs, and the intermediate Cr(III)-fraction gave no reaction for cobalt.

Hexammine, pentammine and tetrammine complexes

We have also used the method in the analysis of other kinds of mixtures of cobalt(III) and chromium(III) ammines. J. Bjerrum [13] has shown that if hexammine cobalt(III) nitrate is shaken with activated carbon in an ammoniacal ammonium salt solution, an equilibrium mixture of hexammine, hydroxopentammine and dihydroxotetrammine is formed. Of the three complexes, dihydroxotetrammine is fixed very strongly to the column, while on the other hand hexammine is bound more strongly than hydroxopentammine. A mixture of pentammine and hexammine can be separated practically quantitatively using 0.01 M KOH, 1 M KCl as displacing agent (see Fig. 1). We have found that the separation is poor when K^+ is replaced by Na^+, but that a good separation is still obtained when Cl^- is replaced by F^-. Hexammine as well as hydroxopentammine can be displaced, but not separated with a less basic solution of the composition: 0.1 M NH_4Cl, 1 M NH_3, 1 M KCl. Dihydroxotetrammine has a much shorter lifetime than the two other complexes in alkaline solution, but is stable as a diaquo ion in acidic solution. These considerations lead to the procedure described in Table 2. The mixture of all three ions is introduced into column I, which preferably should be a short column, and the pentammine and hexammine are displaced from

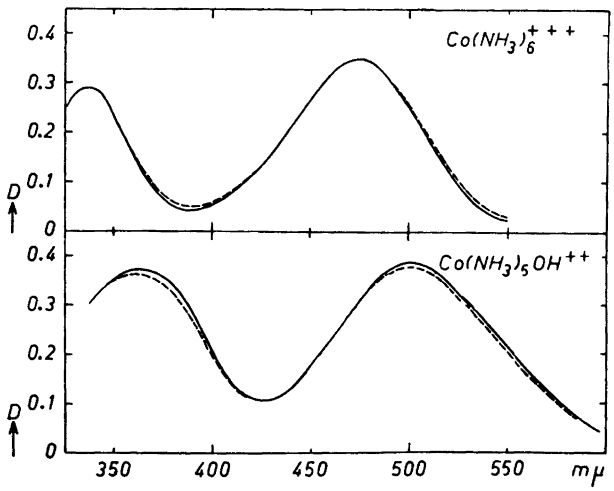

Fig. 1. Analysis of a mixture of $Co(NH_3)_6^{+++}$ and $Co(NH_3)_5OH^{++}$. 1 ml 0.030 M hexammine chloride and 1 ml 0.029 M pentammine nitrate were mixed, separated and displaced with 0.01 M KOH, 1 M KCl, and the fractions containing each component diluted to 25 ml. The optical density D was measured in 5 cm cells. Original mixture after dilution (0.0012 M $Co(NH_3)_6^{+++}$ and 0.00115 M $Co(NH_3)_5OH^{++}$): fulldrawn curves. Fractions after separation: dotted curves.

Table 3. Analysis of mixtures of: $Co(NH_3)_6^{+++}$, $Co(NH_3)_5OH^{++}$, $Co(NH_3)_4(OH)_2^{+}$. Equilibrium established with activated carbon as a catalyst.

$$Co(NH_3)_6^{+++} + H_2O \rightleftharpoons Co(NH_3)_5OH^{++} + NH_4^{+} \quad (1)$$
$$Co(NH_3)_5OH^{++} + H_2O \rightleftharpoons Co(NH_3)_4(OH)_2^{+} + NH_4^{+} \quad (2)$$

	Column I Separation	Column I Displacement	Column II Separation
Pentammine Luteo Tetrammine	0.1 M NH_4Cl, 1 M NH_3 + 1 M KCl	1 M HNO_3	0.01 M KOH + 1 M KCl

Sol. 1. Initial: 0.040 M $[Co(NH_3)_6](NO_3)_3$, 1.00 M NH_3

	$C_{Lut.}$	$C_{Pent.}$	$C_{Tetr.}$	$[NH_4^+]$	K(1)	K(2)
Chromatogr.	0.0081	0.0264	0.0018	0.036	0.117	0.0025
Classical methods	0.0097	0.0258	0.0023	0.034	0.091	0.0031

Sol. 2. Initial: 0.040 M $[Co(NH_3)_4(H_2O)_2](NO_3)_3$, 1.00 M NH_3, 0.1 NaOH

	$C_{Lut.}$	$C_{Pent.}$	$C_{Tetr.}$	$[NH_4^+]$	K(1)	K(2)
Chromatogr.	0.0028	0.0234	0.0062	0.0096	0.080	0.0025

the column with 0.1 M NH_4Cl, 1 M NH_3, 1 M KCl. Then the tetrammine is displaced as quickly as possible with 1 M HNO_3. The pentammine and hexammine are then separated on column II (of normal length, about 25 cm) by means of 0.01 M KOH, 1 M KCl.

The tetrammine could also be displaced with 0.1 M NaOH, 5 M LiCl and collected in dilute nitric acid, but due to fast decomposition in alkaline solution there is a considerably lower yield than when displaced with nitric acid. The use of nitric acid requires preliminary treatment of the alumina with acid as already described in the experimental section.

In Table 3 is given the result of an analysis of two equilibrium solutions of different composition. The ammonium ion concentration in the equilibrium solutions was determined by glass electrode measurements against a standard solution with known concentrations of ammonia and ammonium ion. It will be seen that the estimated hydrolysis constants corresponding to eqns. (1) and (2) agree satisfactorily for the two solutions, and that there is also a fair agreement with the data previously obtained by J. Bjerrum [13] for one of the solutions. In the case of solution 1 J. Bjerrum determined the hexammine gravimetrically as luteo oxalate, the pentammine as chloropentammine, and the tetrammine indirectly by titration of the amount of cobalt which was reduced to Co(II) when boiled with 20 % HCl. Mixtures of only hexammine and pentammine were analyzed spectrophotometrically [13], but the contents of these ions can also be estimated polarographically in 0.1 M H_2SO_4 as found by R. A. Vasadeva Murthy *. As a rule, however, polarography is not a good method for analyzing mixtures of related complexes with the same central ion.

* Visitor from The Indian Institute of Science, Bangalore, India.

In a study on the decomposition of chromium(III) ammines Jørgensen and Bjerrum [14] have used a procedure for separating hexammine, hydroxopentammine and dihydroxotetrammine, which in principle is similar to that described here for the corresponding cobalt(III) complexes. Hexammine and pentammine are first displaced leaving the tetrammine on the column, and then separated on another column.

Separation of *cis* and *trans* complexes

The chromatographic method is also suitable for the separation of *cis* and *trans* complexes. Thus we have analyzed an alkaline equilibrium mixture of the *cis* and *trans* dihydroxobis(ethylenediamine)cobalt(III) ion prepared from a solution of the composition: 0.02 M *cis*-[Co $en_2(H_2O)_2](NO_3)_3$,0.1 M NaOH, 1 M $NaNO_3$. At room temperature equilibrium is reached in about a week [15]. We used a column of the larger type. The *trans*-compound was first displaced by means of 0.1 M NaOH, 1 M NaCl, and the *cis*-compound afterwards by means of the stronger displacing agent 0.1 M NaOH, 1 M LiCl. In this way it was found that $C_{cis}/C_{trans} = 0.57$. When calculating this ratio from the absorption spectrum of the mixture we found $C_{cis}/C_{trans} = 0.65$ in fairly good agreement. It should be mentioned that Woldbye[16] similarly has determined the *cis-trans* equilibrium constant for the dihydroxobis(ethylenediamine)chromium(III) ions, using 0.1 M KOH, 1 M KCl as eluating agent.

The hydroxyl group is a strongly polar group, and there is much evidence that the complex with the two strongest polar groups in *cis* position is more strongly bound than the corresponding *trans* compound. This rule was also confirmed in case of the dinitrotetrammines.

Separation of nitroammines

Systematically we have examined the wellknown series of nitroammines of the type $Co(NH_3)_{6-x}(NO_2)_x^{3-x}$ for x = 0, 1, 2, 3 and 4, and we have established conditions under which they can be separated in the case that two or three of the complexes are present simultaneously. *Tr.*-$Co(NH_3)_4(NO_2)_2^+$ and $Co(NH_3)_2(NO_2)_4^-$ form a slightly soluble salt, but otherwise all combinations are possible. The results are summarized in Table 4. Some of the complexes, especially Erdmann's salt $Co(NH_3)_3(NO_3)_3$ are considerably decomposed in alkaline solution, and for this reason the recovery of the complexes was not complete. It will be seen that the adsorption tendency in basic solution decreases in the series: $Co(NH_3)_6^{+++} > Co(NH_3)_5NO_2^{++} >$ *cis*-$Co(NH_3)_4(NO_2)_2^+ > Co(NH_3)_3(NO_2)_3 >$ *tr.*-$Co(NH_3)_4(NO_2)_2^+$, and inversely in acidic solution the anion complex $Co(NH_3)_2(NO_2)_4^-$ is more strongly adsorbed than $Co(NH_3)_3(NO_2)_3$ and the cation complexes. In the example given *cis*-$Co(NH_3)_4(NO_2)_2^+$ and $Co(NH_3)_3(NO_2)_3$ are displaced from $Co(NH_3)_2(NO_2)_4^-$ with a weak acetic acid buffer while a 1 M LiCl-acetic acid buffer is necessary to eluate the anion complex from the column. The *cis* and *trans* complexes $Co(NH_3)_4(NO_2)_2^+$ have previously been separated by King and Walters [2] by the ion exchange method. Table 4 shows that the separation of these two isomers can be accomplished just as well, and more conveniently, by the chromatographic method. On the other

Table 4. Separation of mixtures of $Co(NH_3)_{6-x}(NO_2)_x^{3-x}$ for x = 0, 1, 2, 3, 4. Conc. (mole/l) in solution to be analyzed.

Salts separated	According to prep.	Chromatogr. found	Displacing solutions (R = $C_{16}H_{33}(CH_3)_3N$)

$[Co(NH_3)_5(NO_2)](NO_3)_2$	0.0065	0.0062	0.1 M KOH, 1 M KCl
$[Co(NH_3)_6](NO_3)_3$	0.0067	0.0064	0.1 M NaOH, 1 M LiCl
tr-$[Co(NH_3)_4(NO_2)_2]NO_3$	0.0075	0.0067	0.01 M ROH, 0.02 M RBr
cis-$[Co(NH_3)_4(NO_2)_2]NO_3$	0.0105	0.0105	0.01 M KOH, 1 M KCl
tr-$[Co(NH_3)_4(NO_2)_2]NO_3$	0.0050	0.0048	0.01 M ROH, 0.02 M RBr
$[Co(NH_3)_3(NO_2)_3]$	0.0056	0.0031	
$[Co(NH_3)_3(NO_2)_3]$	0.0071	0.0062	0.01 M ROH, 0.02 M RBr
cis-$[Co(NH_3)_4(NO_2)_2]NO_3$	0.0051	0.0051	0.01 M ROH, 0.02 M RBr, 0.8 M KCl
$[Co(NH_3)_3(NO_2)_3]$	0.0046	0.0023	0.01 M HAc, 0.001 M NaAc }
cis-$[Co(NH_3)_4(NO_2)_2]NO_3$	0.0054	0.0043	further sep., see above }
$Rb[Co(NH_3)_2(NO_2)_4]$	0.0049	0.0049	0.09 M HAc, 0.01 M NaAc, 1 M LiCl

hand, the corresponding ethylenediamine complexes are more difficult to separate chromatographically, and we have obtained only partial separation of *cis* and *trans* $[Co\ en_2(NO_2)_2]NO_3$ using our longest column (55 cm) and 0.01 M $C_{16}H_{33}N(CH_3)_3OH$, 0.02 M $C_{16}H_{33}N(CH_3)_3Br$ as displacing solvent. Experiments with mixed solvents of water, dioxan or *tert.*-butanol gave no better results. The complexes were fixed more strongly to the column and were more difficult to displace, but the separations were not improved.

In general cations are easily eluated and poorly separated in acidic solution. Inversely anions are easily eluated and poorly separated in basic solution. However, we have established the following adsorption tendency in solutions buffered with $NaHCO_3$: $Co(CO_3)_3^{---} > Co\ enta^- > Fe(CN)_6^{----} > Fe(CN)_6^{---}$. In acidic solution the highest charged anions are relatively much more strongly adsorbed. Thus in acetic acid buffers $Fe(CN)_6^{---}$ is more strongly adsorbed than the ethylenediaminetetraacetatocobalt(III) ion, and $Co(NH_3)_2NO_2)_4^-$ much more weakly than $Co(NO_2)_6^{---}$. This last ion can be removed from the column with 0.09 M HAc, 0.01 M HAc, 1 M LiCl, but more easily when 1 M LiCl is replaced by 1 M Na_2SO_4.

In conclusion it may be said that the chromatographic method developed here for separation of robust complexes seems to have a considerable range of application and offers several advantages over the ion exchange method. Thus, contrary to what is the case for ion exchange resins, even trivalent complexes can easily be removed from the column, and the coloured zones of the complexes are much more easily seen on the white alumina than on the resins.

Our thanks are due to Mr. Erik Jørgensen, who has performed some of the measurements.

Incorporation of Labelled Acetate in Emodin in *Penicillium islandicum*

STEN GATENBECK

Department of Biochemistry, University of Lund, Sweden

The distribution of the isotopic content in emodin obtained from *Penicillium islandicum* when grown on $CH_3-{}^{14}COOH$ has been studied. The results clearly indicate that the biosynthesis of emodin involves a head to tail condensation of acetate.

The field of aromatic biosynthesis has been extended in recent years with the demonstration by Birch of a head to tail condensation of acetate as the source of the aromatic rings in various phenolic products [1,2]. Birch and others have employed the acetate theory as a working hypothesis for the determination of the then unknown structures of complex ring systems [3]. Since there are many natural polyhydroxyanthraquinones which fit such a theory of origin, it was decided to attempt to confirm the direct incorporation of acetate into emodin.

If the biosynthesis of emodin involves head to tail condensations of acetic acid units it is reasonable to suppose that the methyl group of emodin is an unchanged methyl group from acetic acid. Starting with that methyl group, the acetic acid residues must be orientated as indicated in Fig. 1. The methyl groups from acetic acid will then be found in the positions m, 1, 3, 6, 8, 9, 11 and 14 as indicated in Fig. 2.

Emodin is produced in very small amounts in organisms suitable for growth experiments with labelled compounds. Skyrin [4], a dimer of emodin,

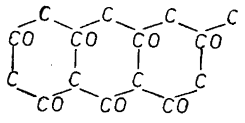

Fig. 1.

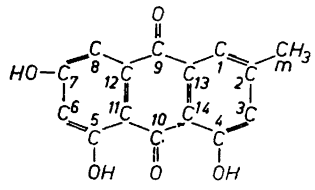

Fig. 2.

occurs in large amounts in the mycelium of *Penicillium islandicum* when supplied with glucose as a carbon source. Skyrin is easily transformed into emodin by reductive cleavage with sodium dithionite. As it is highly probable that skyrin is formed by a condensation of emodin, or a common precursor, skyrin has been used as a source of emodin. Free emodin is produced by *P. islandicum* in amounts that are scarcely detectable by paper chromatographic techniques.

P. islandicum Sopp N.R.R.L. 1175 was supplied with $CH_3{}^{14}COONa$ and the emodin was isolated from the skyrin fraction of the mycelium. The radioactive emodin was diluted with inactive emodin obtained from chrysarobin [5]. The emodin was totally oxidized to carbon dioxide collected as barium carbonate, and the radioactivity was measured. Acetic acid was obtained from the carbons m and 2 after a Kuhn-Roth oxidation. The degradation of the acetic acid, according to Phares [6], gave the radioactivity of each of these carbon atoms. Nitration of emodin to 1,3,6,8-tetranitroemodin and hypobromite cleavage of the nitrocompound gave the carbons 1, 3, 6 and 8 as bromopicrin which was converted to carbon dioxide and the radioactivity measured as above.

EXPERIMENTAL

Culture conditions. Penicillium islandicum Sopp, N.R.R.L. 1175 was grown under the conditions described by Howard and Raistrick. 4 flasks, each containing 500 ml of medium, were grown for 12 days, at this time a solution containing about 0.3 mC of carboxyl labelled sodium acetate was added to each flask. Growth was continued for another 10 days.

Isolation of emodin. The mycelium, from each flask, was removed by filtration, washed with distilled water, and air dried. The dried mycelium was extracted with petroleum ether (b.p. 40—60°) for 1.5 h in a Soxhlet apparatus. The extraction was continued with acetone until nearly all of the pigment had been extracted. The acetone solution was then evaporated to dryness on a steam bath. The dry weight of the acetone extract was 3.32 g. It was dissolved in 750 ml of 1 N Na_2CO_3. The solution was heated on a steam bath and 700 ml of water containing 100 g of $Na_2S_2O_4$ was added during a 10—15 min period with stirring. The solution was stirred continuously for another 20 min and then cooled to room temperature under running water, and neutralized with concentrated HCl. The neutralized solution was then extracted several times with ether. The ether phase was next washed with 1 N Na_2CO_3. The sodium carbonate phase was separated, acidified with concentrated HCl, and again extracted with ether. The ether solution was dried over anhydrous Na_2SO_4 and then evaporated to dryness. The residue was run through a silica column with a mixture of chloroform-acetone (4—1) as solvent. The fraction with a yellow-green fluorescence in UV-light was collected, evaporated to dryness and washed with petroleum ether. The weight of the dried residue was 72.4 mg with m. p. 254—255°. This substance gave all the color reactions of emodin and the melting point was not depressed on admixture of authentic emodin.

The radioactive emodin was diluted about 5-fold with inactive emodin and recrystallized from chloroform yielding 282 mg, m. p. 256—257°.

Radioactive assay. Radioactivity measurements were made with a Tracerlab Autoscaler Type SC-51 in conjunction with a Tracerlab TGC-2 Geiger tube. All the determinations of radioactivity were made after converting the material to barium carbonate. Only self-absorption corrections were made, since all other variables were kept constant.

Combustion. Emodin and bromopicrin were oxidized by the van Slyke-Folch method [7]. The evolved carbon dioxide was trapped in a carbonate free barium hydroxide solution.

Kuhn-Roth oxidation of emodin: The Kuhn-Roth oxidation of emodin (75 mg) gave acetic acid that was isolated by steam distillation. The carbon dioxide formed during the reaction was trapped in barium hydroxide solution. The Kuhn-Roth reaction was quantitative, both for the acetic acid and the carbon dioxide. The acetic acid was degra

ded by a Schmidt reaction and the carboxyl group isolated as barium carbonate. The methylamine produced by the Schmidt reaction was oxidized with alkaline permanganate to carbon dioxide, which, after acidification, was trapped as barium carbonate.

1,3,6,8-Tetranitroemodin. Emodin (90.3 mg) was dissolved in sulfuric acid (2.0 ml, *d* 1.84) and nitric acid (0.33 ml, *d* 1.52) was added dropwise. The mixture was heated on a steam bath for 45 min and then cooled with ice and diluted with ice-water. The yellow crystalline product was filtered and washed with distilled water. The air dried substance was recrystallized from glacial acetic acid, yielding tetranitroemodin (61.4 mg) m. p. 301—302° (decomp.). Tetranitroemodin was prepared in the same way about ten times from non-labelled material. The nitrogen content in these experiments varied between 11.4 and 12.5 %, the theoretical value being 12.4 %.

Hypobromite degradation of 1,3,6,8-tetranitroemodin. Tetranitroemodin (60.0 mg) was suspended in 5 ml aqueous, carbonate-free, saturated barium hydroxide. 40 ml of cold (0°), carbonate-free, aqueous barium hypobromite was added to the nitroemodin suspension. The barium hypobromite solution was prepared from barium hydroxide (2.5 g) and bromine (0.3 ml) in 40 ml of water. The reaction mixture was kept at 0° for 24 h with occasionally shaking. The bromopicrin formed by this process, was isolated by steam distillation. The distillate was trapped in a conical centrifuge tube cooled with ice-water. The bromopicrin was washed with distilled water by centrifugation, and oxidized to carbon dioxide according to van Slyke-Folch. The barium carbonate that was formed during the hypobromite reaction was filtered off and washed with distilled water. The carbon dioxide was regenerated by acidification with perchloric acid and again trapped in aqueous barium hydroxide. Tests with unlabelled nitroemodin showed that the yield of the bromopicrin and carbon dioxide was about 80 %, indicating that all the nitrogen atoms in tetranitroemodin were represented in the bromopicrin and that the central ring in the anthraquinone molecule was oxidized to carbon dioxide.

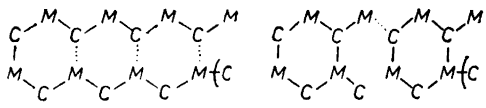

Fig. 3.

RESULTS AND DISCUSSION

The data of the various radioactivity measurements are given in Table 1 in counts/min/mg $BaCO_3$. All radioactive measurements were counted for a sufficient time to give a probable error of less than 1 %. The data in columns 4 and 5 are obtained from two different experiments. In column 3 are found the numbers of carboxyl and methyl groups from acetic acid which the emodin molecule will contain if the acetate theory is valid. Since the radioactivity of the carboxyl group and the methyl group of the acetate obtained in the Kuhn-Roth oxidation are measured directly, these values have been taken as a basis of calculating the theoretical activities of the samples measured which are listed in column 7. These theoretical values show a very good agreement to the experimentally determined. The results support entirely the acetate theory of the biosynthesis of emodin, but do not distinguish between various possible intermediary compounds between acetic acid and emodin. The work by Birch on 2-hydroxy-6-methylbenzoic acid indicates that the formation of emodin by intermolecular condensation of a polyketoacid or a condensation of two phenol carboxylic acids will give the same labelling of emodin from acetic acid, Fig. 3.

The author thanks Professor G. Ehrensvärd for advice and encouragement.

Electron Diffraction Studies of Hexaphenylbenzene Vapour

A. ALMENNINGEN, O. BASTIANSEN and P. N. SKANCKE

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway;
Institutt for teoretisk kjemi, Norges Tekniske Høgskole, Trondheim, Norway

Electron diffraction studies of hexaphenylbenzene in vapour have been carried out. The peripherical rings are found to be nearly orthogonal to the central ring. The model is, however, not found to be rigid and it is concluded that the outer rings of the molecule oscillate with no appreciable restriction in a rather limited angle interval of approcimately $\pm 10°$ from the orthogonal form.

The arrangement of aromatic ring systems connected with single bonds have been studied in a series of papers [1–5]. In this connection we found it of interest to include hexaphenylbenzene.

A sample of the compound was kindly placed at our disposal by Professor E. R. H. Jones, Oxford. The diagrams were taken at a temperature of approximately 340°C using a modified s^3-sector. The intensity data were read off from the photometer curves and the various corrections were carried out [6]. In Fig. 1 is presented the final intensity curve after subtraction of the background. The theoretical background gave as a whole a fairly good agreement with the experimental curve, but corrections had to be carried out particularly for the innermost and the outermost part of the intensity curve.

Radial distribution curves were calculated using the damping factor $\exp(-ks^2)$.

The results for $k = 0.0009$ and 0.0036 are reproduced in Fig. 2. An analysis of the position of the maxima of these curves gives the following bond distances: C—C in the rings 1.40 Å, C—C bridge distance 1.52 Å and C—H 1.08 Å. The error of the first C—C distance and of the C—H distance is less than 0.005 Å. The situation is less favourable for the bridge C—C distance as this is determined indirectly by larger internuclear distances between two different rings. Error estimates suggest that the error is probably less than 0.01 Å.

By applying the observed bond distances and the assumption of 120° valence angles all through the molecule, the internuclear distances of the whole molecule have been calculated. There is a large group of distances which depend upon the angle of twist around the C—C bridges, but there are also altogether 23 CC distances which are independent of the angle of twist. In

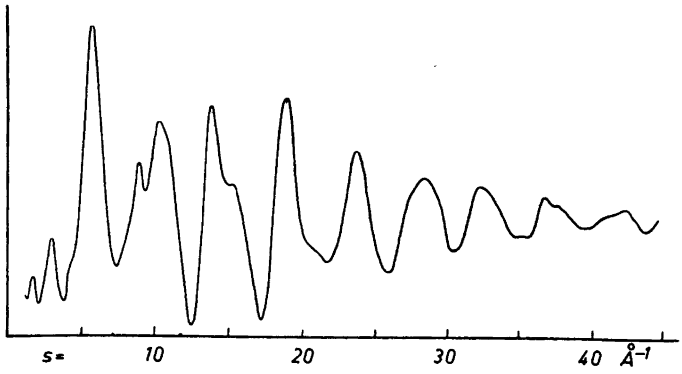

Fig. 1. Intensity curve of hexaphenylbenzene.

addition there is a whole series of CH distances. In Fig. 2 all the invariable CC distances for the calculated radial distribution curve are represented by vertical lines. The length of each line is proportional to the weight of the corresponding distance. The CH distances are omitted with the exception of the two shorter ones. The line diagram of the invariable distances explains essential features of the radial distribution curve. For r values less than 7 Å there are, however, three easily detectable irregularities. The first one is a well resolved peak at 3.39 Å, the second one is a maximum at 4.63 Å, and the third is an extra contribution to the peak at approximately 6 Å. The position of this latter peak is at higher r-values than expected from the invari-

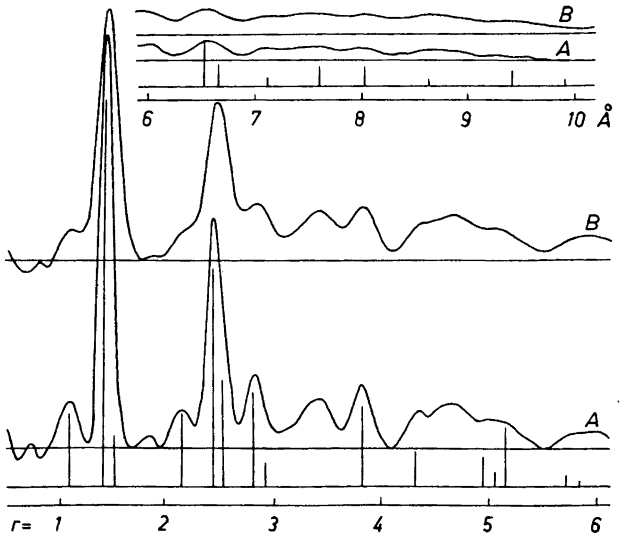

Fig. 2. Radial distribution curves of hexaphenylbenzene. A, $k = 0.0009$; B, $k = 0.0036$.

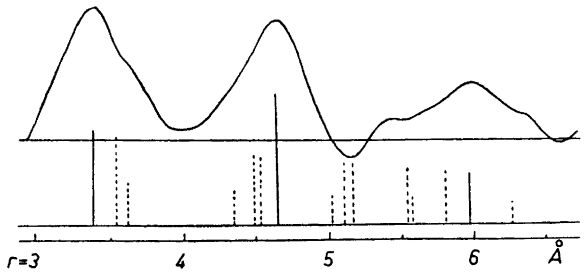

Fig. 3. Difference radial distribution curve when the contribution of invariable distances have been subtracted.

able distances only. The subtraction of the contribution of the invariable distances gives at these three points peaks with maxima 3.39 Å, 4.63 Å and 5.97 Å, respectively. The result of such a subtraction of the invariable distances is demonstrated in Fig. 3 ($k = 0.0036$). The variable distances which would first of all be expected to contribute to this radial distrubution curve are the following: C_2C_8, C_2C_{12}, C_2C_9, C_2C_{11}, C_3C_9, and C_3C_{11}. (For the numbering of the atoms see Fig. 4). In the case of an angle of 90° the six indicated distances will be reduced to three, as pairs like C_2C_8 and C_2C_{12} will be equal. The three main peaks of the curve in Fig. 3 correspond to an angle of 90° between the central ring and the outer rings, as the theoretical distances in an orthogonal

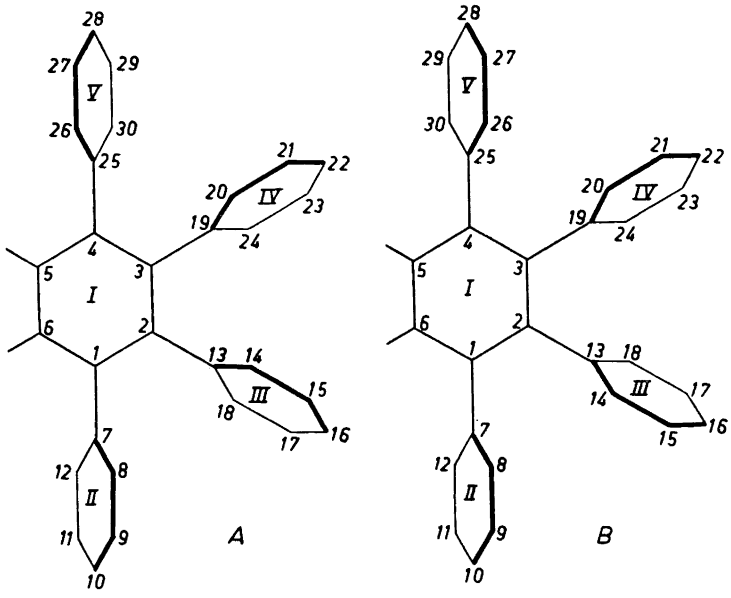

Fig. 4. Structure models of hexaphenylbenzene. A "propeller" and B "antipropeller" model.

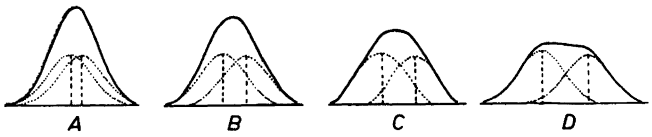

Fig. 5. Radial distribution peak for the C_2C_8 and C_2C_{12} distances corresponding to various angle deviations from orthogonality. A, 5°; B, 10°; C, 15°; and D, 20°.

case are 3.39 Å, 4.65 Å, and 5.97 Å, respectively. The positions and the weights of the three distances in question are given as solid vertical lines under the peaks of Fig. 3. The conclusion one would be tempted to draw from this is that all the peripherical rings are orthogonal to the central ring. On the other hand, it can easily be shown that a limited deviation from orthogonality will not appreciably change the maximum position of the three peaks under consideration. In case of a rotation from the orthogonal position each of the three distances will split up in two distances, one of which is smaller and one larger, leaving the average very nearly the same. As a demonstration of this the theoretical form of the 3.39 Å peak is given in Fig. 5 for four various angles of twist from the orthogonal position. The half width of the Gaussian-normal curve used for this construction is obtained from the corresponding resolved peak in the radial distribution curve of biphenyl [5]. A comparison of the peaks in Fig. 5 with the corresponding experimental one in Fig. 3 shows that the split, if any, cannot be larger than 15°. On the other hand, the comparison also indicates that a rigid model is less probable. An angle of 10° seems to be the right order of magnitude. It is of course impossible from the study of the three peaks in Fig. 3 to decide between a rigid model with a deviation of say 10° from orthogonality and a model with some oscillation around an orthogonal conformation. In fact the latter assumption would from usual structural experience be the more probable one.

For further information on this point a study of the internuclear distances between the peripherical rings would obviously be necessary. The line diagram of broken lines under the difference radial distrubution curve of Fig. 3 gives the positions and weights of all variable internuclear CC distances in the presented interval between peripherical rings, in a rigid and orthogonal model. A study of this diagram leads to the rejection of the entirely rigid orthogonal model. To obtain information about the possibility of other rigid models than the orthogonal one a whole series of various models was considered. None of them lead to a decisive conclusion. As an example both the experimental and two theoretical radial distrubution curves are presented in Fig. 6 for the interval 3 to 6.5 Å. The two calculated models are a "propeller" and an "antipropeller" model described in Fig. 4 with an angle of twist from orthogonality of 10°. The correspondence between experimental and calculated curves in Fig. 6 is not satisfactory and do not give possibilities for a choice, though the "antipropeller" model seems to be somewhat more favourable. Further considerations along this line lead to abandoning rigid models. A natural conclusion should then be that the outer rings of the molecule oscillate with

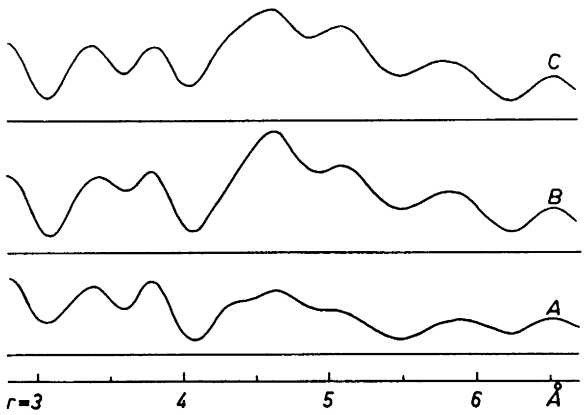

Fig. 6. Radial distribution curves. A, experimental curve; B, "propeller" model; C, "antipropeller" model. (10° deviation from orthogonality.)

no appreciable restriction in a rather limited angle interval of approximately $\pm 10°$ from the orthogonal form.

So far the discussion is based upon the radial distribution curve interval up to approximately 7 Å. The outer part of the curve is also of considerable interest in this connection. Studying the theoretical contribution to this part of the curve it is easily seen that the total weight of the variable distances should be considerably larger than the total weight of the invariable distances. On the other hand, a comparison of the line diagram of the invariable distances with the radial distribution curve shows that the curve can to a great extent be explained by the invariable distances alone (Fig. 2). The contribution of all the variable distances seems to have been evened out. The fact that practically all peaks in the interval 7—10 Å are interpretable is a strong argument for the correctness of the curve. The variable distances in this interval are of the type going between ring II and IV and between II and V. The fact that these distances are smoothed is in agreement with the general idea presented above and serves as a demonstration of the nonrigidity of the hexaphenylbenzene molecule. The variable distances, of course, contribute to the diffraction patterns, but they do not lead to detectable peaks and are therefore to a great extent lost when drawing the envelope [6].

It is no doubt of interest to study if our general sturucture picture can be brought into accordance with steric considerations. The effect of p orbital is no doubt insignificant for the bridge C—C bond so far away from the planar form. If two neighbouring peripherical rings are rotated towards each other the hydrogen atoms of the type H_8 and H_{14} will be the first pair of atoms to be brought into contact. If a packing distance of 2.4 Å is applied corresponding to the Pauling van der Waals radius for hydrogen [7] of 1.2 Å, contact will be reached at an angle of 10.5° from orthogonality. If a "propeller" model is assumed, steric conflicts will not lead to serious difficulties until a rotation

of approximately 40° is performed. In order to realize such a form it is necessary to rotate all the peripherical rings in the same direction. If only one ring is out of order the rest would have to assume an arrangement near the orthogonal conformation. The probability of the symmetrical 40° "propeller" should, therefore, be rather small for pure statistical reasons. On the other hand, this symmetrical form might well be present in the crystalline state. X-Ray crystallographic studies are in progress in the Institute of Theoretical Chemistry, Trondheim.

Acknowledgement. The authors wish to thank Professor E. R. H. Jones, Oxford, for having placed a sample of hexaphenylbenzene at their disposal.

An Electron Diffraction Reinvestigation of the Molecular Structure of 1,3-Butadiene

A. ALMENNINGEN, O. BASTIANSEN and M. TRÆTTEBERG

Universitetets Kjemiske Institutt, Blindern — Oslo;
Institutt for teoretisk kjemi, Norges Tekniske Høgskole, Trondheim, Norway

The electron diffraction sector method was used for a reinvestigation of the structure of 1,3-butadiene vapour. It was shown that the planar *trans* form is predominating, and no signs of other conformations were observed. The observed molecular parameters are the following: C—H: 1.082 Å, C—C: 1.483 Å, C=C: 1.337 Å, ∠ C = C—C: 122.4°, and ∠ C = C—H: 119.8°. The probable error of C = C is less than 0.005 Å. For the C—H and C—C distances the error is somewhat larger, about 0.01 Å.

The present work is a part of our endeavour to collect more precise informations of C-C bond lengths, particularly in conjugated systems. 1,3-butadiene was already studied in 1939 by Schomaker and Pauling [1], using the visual electron diffraction method. Their parameter determinations were in good agreement with the present knowledge of this type of distance.

The justification of the present work is the narrower error limits that can be obtained by the modern electron diffraction technique rather than any doubt of the values obtained earlier. The fact that the earlier work was not able to determine unambiguously the general shape of the molecule also made a reinvestigation desireable.

Electron diffraction diagrams were taken at various distances between the diffraction point and the photographic plate, using a somewhat modified s^3-sector. Photometer records of the plates were read off at intervals of $\Delta s = 1/4$ Å^{-1}. The necessary corrections were made to transfer the photometer curves into intensity values. At this stage a theoretical background was fitted in. The overall correspondence between intensity curve and background was good except for the inner s range ($s < 5$). The background was fitted in by a least square procedure asking for the position of the intensity zero line and the intensity scale [2]. After the sector correction had been carried out, minor refinements of the background were made and the corrected background subtracted from the intensity curve. The first radial distribution curves were calculated using a damping factor exp $(-0.0009\, s^2)$. The best molecular

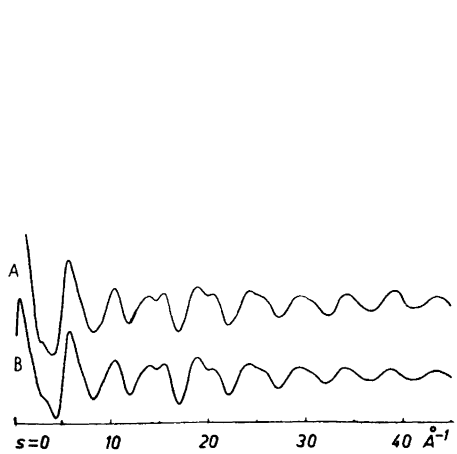

Fig. 1. Experimental (A) and theoretical (B) intensity curves for 1,3-butadiene.

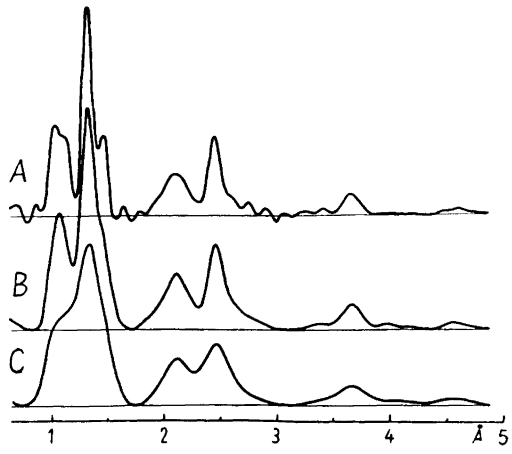

Fig. 2. Radial distribution curves of 1,3-butadiene. (A: $k = 0$, B: $k = 0.0009$, and C: $k = 0.0036$).

model obtained from these curves was used as a basis for theoretical intensity-curve calculations. The correspondence between experimental and theoretical intensity curves is very good (Fig. 1), except for some disagreement at the inner s-range indicating the necessity of a further background correction for $s < 5$. In fact a correction of this type has been necessary in a series of investigations, indicating a measurable deviation between calculated and observed backgrounds for small s values. After subtraction of the final background a series of radial distribution curves was calculated using three different k-values (0, 0.0009, and 0.0036) and Δs values of 1/4 and 1/2. As a matter of

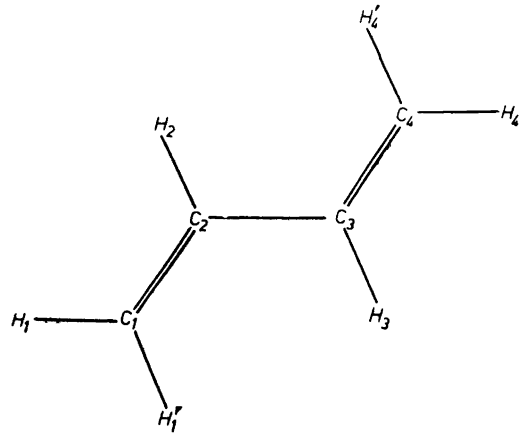

Fig. 3. Numbering of the atoms in the 1,3-butadiene molecule.

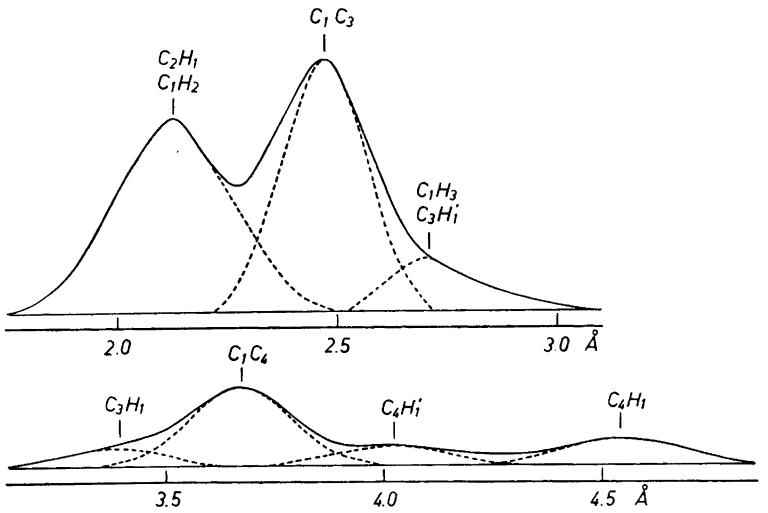

Fig. 4. An example of the resolution of parts of a radial distribution curve in Gaussian-like peaks ($k = 0.0036$).

fact two complete sets of diagrams were taken and each set treated independently by two persons. As a whole the correspondence between the results of the two investigations was very good, and the preliminary results as to structure data were almost identical. Therefore, in the final refinements it was preferred to use curves obtained as an average of the two sets.

In Fig. 2 three radial distribution curves are given with damping constants $k = 0$, 0.0009, and 0.0036, respectively.

From an analysis of the radial distribution curves a set of internuclear distances was obtained. These distances are listed in Table 1, second column. The numbering of the atoms in the first column of Table 1 is demonstrated in Fig. 3. For the shorter distances (bond distances) the values obtained from the radial distribution curve of $k = 0$ gave the best consistency. For the longer distances the radial distribution curves of higher k values were preferred. As a matter of fact the longest C—H distances are hardly recognizable on a radial distribution curve from an undamped intensity curve. On the other hand the radial distribution curves of $k = 0.0036$ have easily separable peaks corresponding to the larger C—H distances. The internuclear distances mentioned were obtained by resolving the radial distribution curves into Gaussian peaks including the use of the least square method. In Fig. 4, as an example, there is shown the outer parts of a radial distribution curve ($k = 0.0036$) resolved in Gaussian shaped peaks corresponding to the various distances.

The observed distance values settle beyond doubt the overall structure of the molecule. The molecular structure is a planar *trans* form without observable contribution from other conformations.

Table 1. Internuclear distances in the 1,3-butadiene molecule.

Distances and angles	Observed values	2nd order approximation values
C—H	1.083 Å	1.082 Å
C=C	1.341 Å	1.337 Å*
C—C	1.484 Å	1.483 Å
∠C=C—C		122.40°
∠C=C—H		119.78°
C_2H_1 } C_1H_2 }	2.125 Å	2.124 Å
C_1C_3	2.477 Å	2.472 Å
C_1H_3 } C_3H_1' }	2.721 Å	2.699 Å
C_3H_1	3.402 Å	3.453 Å
C_1C_4	3.680 Å	3.688 Å
C_4H_1'	4.031 Å	4.019 Å
C_4H_1	4.568 Å	4.567 Å

As is seen from Table 1 there are altogether 10 observed internuclear distances. If a planar *trans* molecule is assumed, the carbon structure is described by three parameters. If the hydrogen atoms are included, two additional parameters have to be considered, even with the assumption of the same C—H bond distances and the same C=C—H angles throughout the molecule. There should then be 10 equations for the determination of 5 parameters. The parameters were now determined by a least square procedure, using proper weight factors on the various observed distances. Except for minor changes in the fourth decimal place, the parameters and the deduced internuclear distances of the 1st approximation were preserved in the 2nd approximation. The results are given in third column of Table 1.

Because of the unavoidable overlap of the C=C and C—C bond peaks, the accuracy of these bond distances is somewhat lower than in the cases of well-resolved peaks. The C=C double bond distance is determined with an error less than 0.005 Å, but for the C—C single bond distance the situation is less favourable. The rather large C—C distance of 1.483 Å is obtained even if the zero order approximation value in the least square procedure is as low as 1.473 Å. Though the analysis of the inner part of the radial distribution curve of $k = 0$ strongly indicates this large distance, it has to be admitted that a least square analysis of the carbon-carbon bond complex in a radial distribution curve with $k = 0.0009$ leads to a value of 1.473 Å for the single bond. If the observed value of 1.484 Å is substituted by 1.473 Å in the list of second column of Table 1, the final C—C bond distance from the least square calculations is as large as 1.478 Å, while the other parameters are practically uninfluenced. This demonstrates that the longer internuclear distances are

* *Added in proof:* After this article was submitted for publication a study of the infrared spectra of ethylene has been published (Allen, H. C. and Plyler, E. K., *J. Am. Chem. Soc.* **80** (1958) 2763). The C=C distance is found to be **1.337** Å in good agreement with the result of this work and with the electron diffraction study of ethylene (Bartell, L. S. and Bonham, R. A., *J. Chem. Phys.* **27** (1957) 1414).

Table 2. Theoretical and experimental values for areas under the peaks in the radial distribution curves.

Distances	Theoretical	Experimental
C—H	41.7	38
C=C	53.5	55
C—C	24.7	22
C_1H_2; C_2H_1; C_3H_2	28.2	23
C_1C_3	29.0	24
C_1H_3; $C_3H'_1$	10.8	9
C_3H_1	4.3	3
C_1C_4	9.8	12
$C_4H'_1$	3.7	4
C_4H_1	3.3	4

in better accordance with the large C—C bond distance. It is very difficult to give a definite statement concerning the error limits of the single bond, but it is unlikely that the error is more than 0.01 Å. However, the analysis indicates an unsymmetrical error distribution, making an error of + 0.01 Å less probable than an error of — 0.01 Å.

In order to look for a possible contribution of a *cis* form, the areas under the resolved peaks of the radial distribution curves have been studied. Again the less damped curves were used for the inner peaks and the more damped curves for the outer peaks. These areas were compared with the theoretical calculated values obtained by the formula $n \cdot Z_i Z_j / r_{ij}$, where n is the number of times the distance in question occurs in the molecule and r_{ij} is the distance itself. Z is 6 for carbon and 1.25 for hydrogen. The theoretical and measured areas are listed in Table 2, normalized on the same arbitrary scale. The correspondence is satisfactory and gives no indication of any misinterpretation of the peaks. In fact the experimental area for the C_1C_4 peak is somewhat larger than anticipated from theory. If any other conformations than the *trans* form were present, this peak should have a smaller area than that calculated for a rigid *trans* molecule. The deviation in the area of the C_1C_4 distance is probably merely due to errors caused by difficulties in determining the exact form of the envelope.[3]

The Catalytic Effect of CrO_4^{2-}, MoO_4^{2-} and WO_4^{2-} on the Hydrolysis of *iso*Propoxy-methyl-phosphoryl Fluoride (Sarin)

LENNART LARSSON

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The catalytic effect of eighteen anions on the hydrolysis of Sarin has been examined. Based on these results a detailed study of the effect of chromate, molybdate and tungstate ions has been performed. The catalytic constants of these ions, as well as their energies and entropies of activation, have been given. The catalytic effect of the ions has been ascribed mainly to complex formation of the ions with the Sarin molecule.

In the study of the pH-dependence of the hydrolysis of *iso*propoxy-methyl-phosphoryl fluoride (Sarin) in different buffer solutions it was evident that, in addition to the catalytic effect of the hydroxyl ions, the ions included in the buffer solutions also influenced the rate of hydrolysis. For that reason the hydroxyl ion catalyzed hydrolysis of Sarin was studied by means of an automatic titrator which maintained the pH constant at a preselected value in the absence of disturbing ions [1]. The influence of some ions on the hydrolysis of di*iso*propoxy-phosphoryl fluoride (DFP) has earlier been reported by Kilpatrick [2]. Wagner-Jauregg *et al.* have shown that the hydrolysis of DFP is accelerated by some metal salts and complexes, in particular copper(II) chelates of dipyridyl and histidine [3]. It was also shown that sodium molybdate markedly catalyzed the hydrolysis.

It was thus of interest to study the catalytic effect of a lot of common anions on the rate of hydrolysis of Sarin. The effect of chromate, molybdate and tungstate ions was of special interest and was the object of a more detailed study.

A similar study of the effect of different anions on spontaneous and enzymatically catalyzed hydrolysis of dimethylamido-ethoxy-phosphoryl cyanide (Tabun) has been performed by Augustinsson [4].

EXPERIMENTAL

Materials. Sarin was synthesized in this institute and a stock solution of Sarin in dioxane (E. Merck c.p. purified from peroxides and redistilled over sodium) was prepared[1].

The salts used were of anal. reagent grade except sodium persulphate which was chemically pure, and sodium hypochlorite which was supplied as a solution, the exact concentration of which was determined iodometrically.

Kinetic measurements. Procedure I. Introductory experiments were performed by a Warburg manometric method, and the technique closely adheres to that described by Augustinsson [5]. The reaction took place at 25°C in a sodium bicarbonate buffer at pH 7.6. The amount of CO_2 evolved during the reaction was read at intervals during 60 min and from these data the rate of the reaction was determined. The initial concentration of Sarin was 5.0 mM, and that of the catalyst was 1.0 mM.

Procedure II. The detailed study of the catalytic effect of chromate, molybdate and tungstate ions was performed by means of an automatic recording titrator [6] at 15°C, 25°C and 35°C at pH 8.50, and at 25°C also at pH 9.00. A solution containing 38.00 ml of 0.10 M potassium chloride and 1.00 ml of appropriately diluted solution of the catalyst was adjusted by the titrator to the desired pH-value, after which 1.00 ml of the stock solution of Sarin was added. In other respects the procedure adheres to that described in an earlier paper [1]. The initial concentrations of Sarin and the catalysts in the different runs appear in Table 1.

RESULTS

Introductory experiments

From the introductory experiments performed by the manometric Warburg method the following results were obtained:

1) Potassium sulphate, ammonium chloride and sodium chlorate, perchlorate, sulphite, azide, hypophosphite, formate and salicylate showed no, or slight, catalytic effect.

2) Potassium persulphate and sodium nitrite and phosphate showed a small catalytic effect.

3) Sodium molybdate (Na_2MoO_4) and ammonium molybdate ($[NH_4]_6Mo_7O_{24}$) showed a marked, catalytic effect.

4) A considerable acceleration of the hydrolysis was obtained with sodium hypochlorite and perborate (the effect of the latter can probably be attributed to the formation of perhydroxyl ions).

The hydrolysis of Sarin catalyzed by hypochlorite ions has been described by Epstein *et al.*[7], and the reaction of perhydroxyl ions with Sarin has recently been published [8,9].

Catalytic effect of chromate, molybdate and tungstate ions

When the recorded curves from the automatic titrator were treated according to Guggenheim, straight lines were obtained indicating that the catalyzed hydrolyses proceed as first-order reactions. This fact shows that the chromate, molybdate and tungstate ions are not consumed in the reactions but function as true catalysts. From the slopes of the straight lines the observed rate constants, k_{obs}, were determined, and the catalytic constants, k_c, were calculated from the expression:

$$k_c = \frac{k_{obs} - k_s}{c_c}$$

Table 1. Rate constants for the hydrolysis of Sarin catalyzed by chromate, molybdate and tungstate ions at various concentrations, pH-values and temperatures.

t°C	pH	c_s mM	c_c mM	$k_{obs} \times 10^4$ sec^{-1}			$k_s \times 10^4$ sec^{-1}	$k_c \times 10^2$ 1 mole^{-1} sec^{-1}

35.0	8.18	0.300	2.50	6.42	8.50	8.92	1.76	18.6	27.0	28.6
		0.300	2.50	6.73	8.59	8.66		19.9	27.3	27.6

where k_s is the rate constant of the spontaneous hydrolysis [1] and c_c is the concentration of the catalyst.

The constants are given in Table 1, where it is shown that the catalytic constants are independent of pH above 8.50. The catalytic ions are probably present in the monomeric form, *i.e.* CrO_4^{2-}, MoO_4^{2-} and WO_4^{2-}. In the preliminary experiments at pH 7.6 $(NH_4)_6Mo_7O_{24}$ was found to be 6—7 times more effective a catalyst than Na_2MoO_4, which supports this hypothesis. The mean values of the catalytic constants given in Table 2 are calculated from the values obtained only at pH 8.50, because the difference between k_{obs} and k_s at pH 9.00 is so small that it markedly influences upon the accuracy of k_c.

By plotting $1/T$ against k_c straight lines were obtained. From the slopes of the lines, calculated by the method of least squares, the energies of activation were obtained. The entropies of activation were calculated from the equation of absolute reaction rates. The values of the entropies and energies of activation are given in Table 2.

Table 2. Catalytic constants, and energies and entropies of activation for the hydrolysis of Sarin catalyzed by chromate, molybdate and tungstate ions.

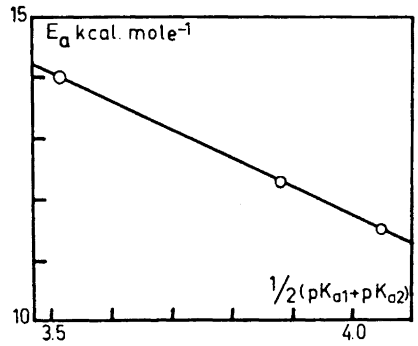

Fig. 1. Relationship between 1/2 (pK_{a1} + pK_{a2}) and E_a in the hydrolysis of Sarin catalyzed by chromate, molybdate and tungstate ions.

DISCUSSION

For reactions involving nucleophilic displacements in general Edwards [10] has pointed out that the character of a nucleophilic reagent is related to its electrode potential as well as to its basicity. It has, however, been reported that the thiosulphate ion which has a high electrode potential but low basicity, has no effect upon the hydrolysis of either Tabun [4] or Sarin [7]. On the other hand it has been shown from a study of the reaction of Sarin with catechols that the rate of the reactions is related to the basicity of the catechols [11]. This favours the theory that the basicity of the reagent is the decisive factor in nucleophilic attacks on the phosphorus atom.

As appears from Fig. 1, the activation energies of the hydrolysis of Sarin catalyzed by chromate, molybdate and tungstate ions are found to be inversely proportional to the negative logarithms of the mean dissociation constants of the acids given by Schwarzenbach [12], indicating the relationship between the catalytic effect and the basicity of the catalysts. The slight catalytic effects obtained in the preliminary experiments with other ions of about the same basicity as chromate, molybdate and tungstate ions indicate, however, that the catalytic effects of the latter ions cannot be attributed only to the basicity of the ions. Moreover, a lower energy of activation of the alkaline hydrolysis of Sarin [1] would be expected if such a relationship were valid. In the main the catalytic effect of the ions can probably be ascribed to complex formation of the ions with the Sarin molecule which facilitates the cleavage of the P—F bond. The decreasing entropy of activation, when going from chromate to tungstate ions, is consistent with an increasing stability of the activated complex. The tendency of chromate, molybdate and tungstate ions to form complex with phosphorus compounds is also wellknown from their insoluble complex with phosphate ions.

My sincere thanks are due to the Director of the Research Institute of National Defence, Dept. 1, Professor G. Ljunggren, for the kind interest he has shown in this work.

Synthesis of Adrenochrome Alkyl Ethers *

JAAKKO HUKKI and NIILO SEPPÄLÄINEN

Lääketehdas Orion Oy, Helsinki, Finland

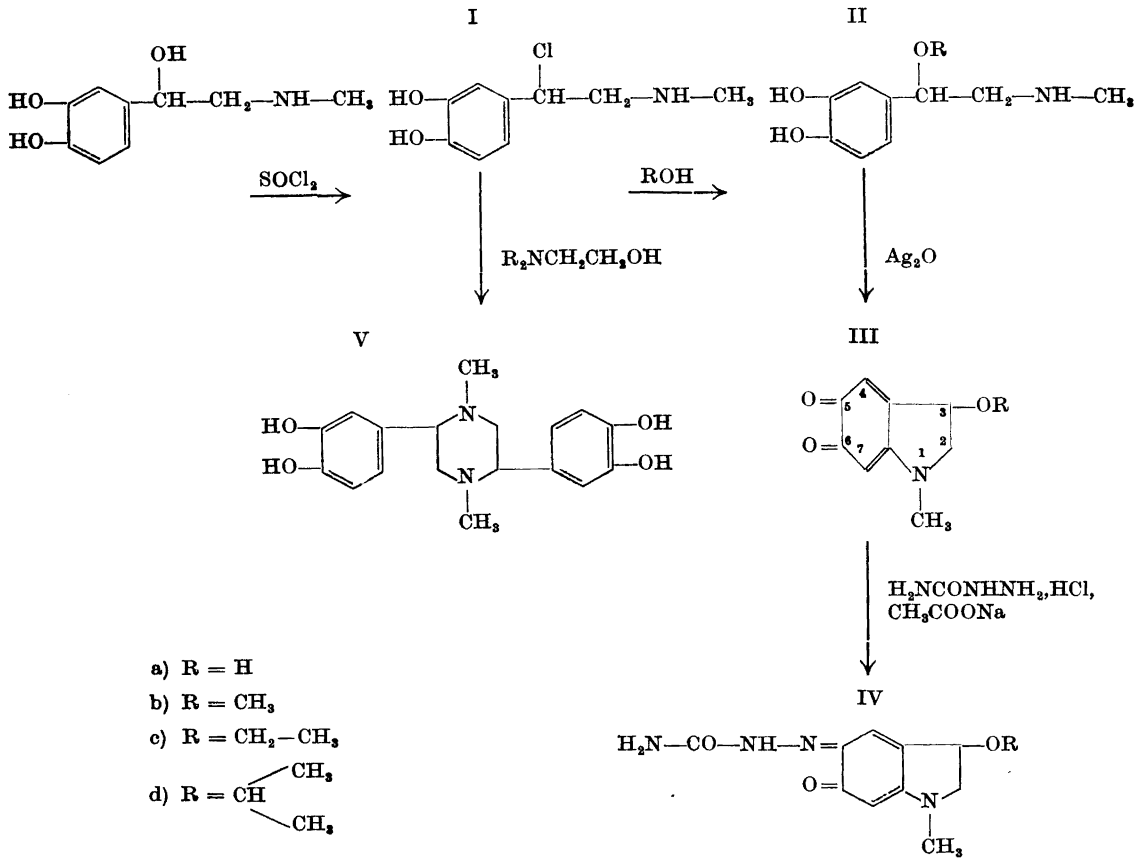
From adrenaline, its alkyl ethers (methyl, ethyl and *iso*propyl) were prepared through a common intermediate, methylaminomethyl-3,4-dihydroxyphenylchloromethane. On oxidation with silver oxide, these ethers were converted into those of adrenochrome and isolated as their monosemicarbazones.

Adrenochrome (III a), the quinoid oxidation product of adrenaline, is a well-known hemostatic agent. But, being an *ortho*-quinone, it readily deteriorates in aqueous solution. Several stable derivatives have been prepared from it, one of which, the monosemicarbazone (IV a), is commercially available under the name of adrenoxyl. Some homologs of adrenochrome, noradrenochrome [1], N-*iso*propylnoradrenochrome [2] and 2-ethylnoradrenochrome [2] have been reported. Two halogen substitution products, 2-iodo- [3] and 2-bromoadrenochrome [3], are described in the literature. Recently N-[β-hydroxyethyl]-noradrenochrome [4] has been synthesized. Most of the above compounds have been prepared as their monosemicarbazones.

The present paper is concerned with the synthesis of adrenochrome ethers. Owing to the instability of the adrenochrome molecule, direct etherification was not attempted. Instead, a circuitous route, starting from the corresponding adrenaline ethers, was chosen.

A methyl and an ethyl ether of adrenaline (II b and II c) have previously been prepared by Funk and Freedman [5] by passing dry hydrogen chloride into a boiling solution of adrenaline in the appropriate alcohol. The present method made use of an intermediate, methylaminomethyl-3,4-dihydroxyphenylchloromethane hydrochloride (I), which is readily formed from adrenaline with excess of thionyl chloride. It proved to be a crystalline compound, only stable if kept in the refrigerator and protected from light and moisture. It could not be recrystallized for analysis. The correctness of the above formula is shown by the formation of the following reaction products. It readily formed adrenaline hydrochloride with water. Heating with methanol or ethanol at 60° led to the formation of ethers identical with the corresponding ones pre-

* From the thesis for the M. A. degree of Niilo Seppäläinen, University of Helsinki, 1955.



pared by the method of Funk and Freedman [5]. The former etherification method was used throughout in this work. An *iso*propyl ether of adrenaline was also synthesized. Some data on the adrenaline ethers, which were all obtained as hydrochlorides, are presented in Table 1.

When the synthesis of amino alkyl ethers of adrenaline was attempted by the above method, complications arose. A high-melting compound was formed in all cases, irrespective of the amino alcohol used. By analysis and melting point determination it was shown to be identical with the dimolecular ring condensation product obtained by Bretschneider [6] from methylaminomethyl-3,4-diacetoxyphenylchloromethane hydrochloride with diethylamine. Obviously the ring condensation reaction predominates under the strongly alkaline conditions produced by the amino alcohols. A structural formula of 2,5-bis(3,4-dihydroxyphenyl)-1,4-dimethylpiperazine (V) was suggested for this compound by Bretschneider.

The oxidation methods used for converting the adrenaline ethers into the corresponding adrenochrome ethers were essentially analogous with the famil-

iar ones employed in the synthesis of adrenochrome from adrenaline. Oxidation with silver oxide in methanol acidified with formic acid proved the best. The resultant adrenochrome ethers were isolated as the monosemicarbazones. All these were dark red, glistening, crystalline compounds. They were crystallized from aqueous pyridine, from which they were obtained without water of crystallization. The data for the ethers are presented in Table 2. For further characterization of these new compounds ultraviolet absorption spectra were made both of these and of the unetherified adrenochrome monosemicarbazone (adrenoxyl). The curves obtained are presented in Fig. 1. As can be seen, the general shape of the curves of the three ethers and the position of their maxima and inflection points are fully coincident with those of the curve of adrenoxyl.

As would be expected, the solubility of the monosemicarbazones of adrenochrome ethers in water is even poorer than that of adrenoxyl. In order to improve the solubility of adrenoxyl, its ability to form salts was studied. A bright yellow crystalline hydrochloride of adrenoxyl could readily be ob-

tained with a nearly quantitative yield. This was shown by analysis to be a monohydrochloride containing one molecule of water of crystallization. The salt is distinctly more soluble in water than adrenoxyl, but unfortunately it readily decomposes in solution, especially in the light. That the compound really was a salt of adrenoxyl was proved by liberating the base with pyridine. The base was shown to be identical with the starting adrenoxyl by melting point determination and ultraviolet absorptium spectrum. Whether the salt-forming ability of adrenoxyl is to be ascribed to the tertiary ring-nitrogen atom or to the semicarbazone side chain, was not investigated. The former possibility was taken into account by Ramirez and Ostwalden[7] when they studied the structure of adrenoxyl in the light of ultraviolet absorption spectra.

EXPERIMENTAL

All melting points are uncorrected. Microanalyses were performed by the Microanalytisches Laboratorium im Max-Planck-Institut für Kohlenforschung, Mülheim, Germany. Ultraviolet data, from the Analytical Laboratory of Lääketehdas Orion Oy, are for solutions in absolute methanol (concentration 0.01 g per liter).

Starting materials. The adrenaline used was an Uclaf product, m. p. 207—208.5°. The adrenoxyl was from Labaz, for parenteral use, m. p. 206—207°.

Methylaminomethyl-3,4-dihydroxyphenylchloromethane hydrochloride (I). To 70 g of thionyl chloride in an Erlenmeyer flask of 500 ml capacity was added 10 g of adrenaline after removal of the air with nitrogen. In about one minute a vigorous reaction set in, resulting in the formation of a clear solution. The gaseous reaction products were swept

off by passing in a continual stream of nitrogen. After about half an hour crystals began to separate from the liquid. When crystallization was complete, the product was filtered off and washed, first with benzene, then with ether. The yield of the colorless material was 13 g (99 %), m. p. 90—100° (decomp.). It could not be recrystallized, owing either to its insolubility in or to its reactivity with the usual solvents. It darkened rapidly in daylight but could be kept for some days in the refrigerator when protected from light and moisture.

Adrenaline ethers (II). A mixture of 2 g of methylaminomethyl-3,4-dihydroxyphenylchloromethane hydrochloride in 20 ml of the appropriate alcohol was refluxed for 1 h, the temperature of the boiling reaction mixture being kept at 60° by means of ether added through the condenser. The resulting solution was evaporated *in vacuo* almost to dryness. After addition of 25 ml of acetone the mixture was allowed to stand in the refrigerator overnight. The crystals deposited were filtered off, washed with acetone and dried in a desiccator. The ethers so obtained were sufficiently pure for oxidation to adrenochromes. For purification of an ether it was dissolved in hot absolute ethanol and as much acetone was added as possible without causing turbidity. The mixture was allowed to stand in the refrigerator overnight to ensure complete crystallization. No analysis of the ethers was made. Their constitution was confirmed by analyzing the corresponding adrenochrome ether monosemicarbazones prepared from them.

2,5-Bis(3,4-dihydroxyphenyl)-1,4-dimethylpiperazine hydrochloride (V). When dimethylaminoethanol was used as the alcohol component in the above etherification reaction, a high-melting (m. p. 303°) compound was the only product that could be isolated. The same compound was also obtained by allowing methylaminomethyl-3,4-dihydroxyphenylchloromethane hydrochloride to react with conc. aqueous ammonia. (Found: C 53.39; H 6.16; N 6.78. Calc. for $C_{18}H_{22}N_2O_4$, 2HCl: C 53.59; H 6.00; N 6.94.)

Adrenochrome ether monosemicarbazones (IV). The appropriate adrenaline ether hydrochloride (0.027 mole) was dissolved in a mixture of 2 ml of formic acid (99—100 %) and 100 ml of dry methanol. Freshly precipitated dry silver oxide (0.108 mole) was added. The mixture was shaken vigorously for 2—4 min at about 40° and filtered by suction into a solution previously prepared by dissolving semicarbazide hydrochloride (0.027 mole) and sodium acetate (0.073 mole) in 40 ml of distilled water. After washing with 10 ml of dry methanol the combined dark red filtrates were allowed to stand for 10 min at room temperature and then overnight at 0°. The dark red, glistening crystals were filtered, washed with water and dried in a desiccator.

Adrenoxyl hydrochloride. 3 g of adrenoxyl was placed in an Erlenmeyer flask, from which the air had been displaced with nitrogen and 120 ml of 2 % hydrochloric acid was added. The stoppered flask was shaken at room temperature until all the adrenoxyl had dissolved. Almost immediately a bright yellow crystalline compound began to separate. After separation had been completed in the refrigerator, the crystals were filtered off, washed with acetone and dried in a desiccator (without vacuum). The yield of the hydrochloride was almost quantitative. Upon crystallization from 2 % hydrochloric acid it melted at about 150° (decomp.). (Found: C 41.41; H 5.40; N 19.04; Cl 12.09. Calc. for $C_{10}H_{12}N_4O_3$, HCl, H_2O: C 41.31; H 5.20; N 19.27; Cl 12.20.)

Rearrangement of 4-Phenylazo-5-hydroxy-1,2,3-triazoles to Amides of 2-Phenyl-5-carboxytetrazole

CHRISTIAN PEDERSEN

Department of Organic Chemistry, University of Technology, Copenhagen, Denmark

4-Phenylazo-5-hydroxy-1,2,3-triazoles (II), unsubstituted or substituted with methyl-, phenyl-, and benzyl- in position 1, have been prepared. It has been shown that II, when heated in glacial acetic acid, rearrange to amides of 2-phenyl-5-carboxytetrazole (IV). The rearrangement is believed to take place through an intermediate, aliphatic diazocompound (III).

Dimroth [1] and Curtius [2] have shown that 5-hydroxy-1,2,3-triazoles (I) couple with diazonium salts in alkaline solution with formation of 4-arylazo-5-hydroxy-1,2,3-triazoles (II).

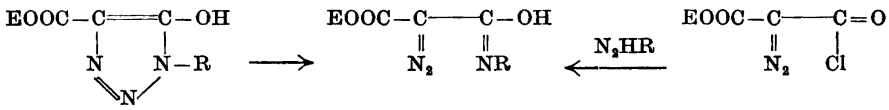
III IV VII

It was reported by Dimroth [1] that the orange-coloured 1-phenyl-4-phenylazo-5-hydroxy-1,2,3-triazole (IIa), on recrystallization from glacial acetic acid, rearranged to an isomeric, colourless compound which, as opposed to IIa,

had no acidic properties *. In the same way Curtius and Thomson [2] obtained a colourless isomer of IIe. No attempt has been made to find the structures of the two colourless compounds.

A number of esters of 4-carboxy-5-hydroxy-1,2,3-triazoles (V) were prepared by Dimroth and he showed that these compounds can isomerize to amides of diazomalonic ester (VI) when heated, alone or dissolved in water or organic solvents [3a-d]. When 1-*p*-nitrophenyl-4-ethoxycarbonyl-5-hydroxy-1,2,3-triazole was recrystallized from glacial acetic acid it gave the corresponding diazocompound (VI, R = *p*-nitrophenyl-) in quantitative yield [3c]. The mechanism of this reaction has been reinvestigated in more recent papers [4,5].



V VI VIII

In view of this it would be reasonable to assume that compounds of type II can also isomerize to aliphatic diazocompounds with the structure III. Compounds of type III will probably undergo a spontaneous ring closure with formation of amides of 2-aryl-5-carboxytetrazole (IV), in analogy with the preparation of 2,5-disubstituted tetrazoles by reaction of amidrazones with nitrous acid where intermediates with structure similar to III are likely to be formed [6,7]. This means that Dimroth's colourless isomer, formed by rearrangement of IIa, should be 2-phenyltetrazole 5-carboxanilide (IVa).

To prove this IVa was prepared by an unambiguous method, starting with the known 2-phenyl-5-carboxytetrazole (VII), which was made according to Bladin [6]. The acid (VII), *via* the chloride, gave the anilide (IVa) which had the same melting point and infrared spectrum as the rearrangement product from II and thus proving the structure of the latter.

To test the generality of this rearrangement it was tried in three other cases, starting with 5-hydroxy-1,2,3-triazoles, unsubstituted or substituted with methyl- and benzyl- in position 1. The coupling with phenyldiazonium chloride was done in 2 N sodium hydroxide and gave the 4-phenylazo-5-hydroxy-1,2,3-triazoles (Table 1). The latter, when boiled in glacial acetic acid solution for a few minutes, gave the corresponding tetrazoles (IV) in good yields (Table 2). The authentic tetrazoles, prepared from 2-phenyl--carboxytetrazole, all had melting points and infrared spectra completely identical with the tetrazoles prepared by rearrangement.

The 4-hydroxy-1,2,3-triazole (Ib) was prepared from ethyl diazomalonate monochloride (VIII) which with ammonia gives the monoamide (VI, R = H) [8]. VI was rearranged to 4-ethoxycarbonyl-5-hydroxy-1,2,3-triazole (V, R = H) with ethanolic potassium hydroxide. Saponification and decarboxylation of V

* Dimroth[1] thought that he obtained the coloured isomer (IIa)by coupling in 20 % sodium carbonate and the colourless isomer in weak basic solution, but according to our experience the coloured isomer is formed in both cases and the rearrangement takes place on recrystallization from acetic acid.

yielded 4-hydroxy-1,2,3-triazole [3c]. The 1-methyl-5-hydroxy-1,2,3-triazole was prepared in the same way.

The colourless isomer which Curtius and Thomsen [2] obtained from 1-carboxamidomethyl-4-*p*-tolylazo-5-hydroxy-1,2,3-triazole (IIe) on recrystallization from glacial acetic acid has not been included in the present investigation, but there can hardly be any doubt that it is also a tetrazole derivative and has the structure IVe.

Dimroth [1,3] showed that the rearrangement of V to VI takes place in a number of different solvents. Whether the rearrangement of II to IV can be effected in solvents other than glacial acetic acid has not been tried extensively, but prolonged heating of compounds of type II in ethanolic solution gave oily decomposition products with a strong smell of *iso*cyanides. Boiling in acetonitrile or dimethyl formamide also caused decomposition.

Solvents used for recrystallization: a) ethanol, b) light petrol (b.p. 100/140°), c) glacial acetic acid. Yields given in brackets refer to preparation of authentic tetrazoles.

EXPERIMENTAL

Melting points are uncorrected.

5(4)-Hydroxy-1,2,3-triazoles

4-Hydroxy-1,2,3-triazole. Ethyl diazomalonate monochloride [8] (8.5 g) was added during 5 min to 30 ml of ice-cold, stirred, 25 % ammonia. Stirring and cooling was continued for 30 min. The cream-coloured ethyl diazomalonate monoamide was filtered off and washed with water. Yield 6.2 g (81 %), m. p. 142—143° (reported [3c,8] m. p. 142° and 143°.)

The monoamide (4.15 g) was dissolved in 40 ml of hot absolute ethanol and the solution added to 4.45 g (3 moles) of KOH in 50 ml of hot ethanol. The potassium salt of 4-ethoxycarbonyl-5-hydroxy-1,2,3-triazole precipitated immediately, causing the mixture to solidify. After 10 min the ethanol was removed *in vacuo*, 25 ml of water was added and the resulting solution refluxed for 1 h. The solution was then acidified with conc. HCl (pH should be 3—4; excess of acid decomposes the 4-hydroxytriazole and a product results which is very difficult to purify) and boiled for 1—2 min to complete the decarboxylation. The mixture was evaporated to dryness *in vacuo* and the residue extracted with boiling absolute ethanol (3 × 15 ml). The ethanolic solution was evaporated to dryness and the residue extracted 7—8 times with 25 ml portions of boiling ether; the ether solution was concentrated to ca 50 ml and the 4-hydroxytriazole precipitated with light petrol. Yield 1.60 g (70 %), m. p. 126—128°. A sample was recrystallized twice from ethyl acetate and finally sublimed *in vacuo* (0.1 mm) at 110°. M. p. 130—132° (reported [3c,2] m. p. 130° and 135°). (Found: C 28.15; H 3.63; N 49.29. Calc. for $C_2H_3N_3O$: C 28.20; H 3.55; N 49.40.)

1-Methyl-5-hydroxy-1,2,3-triazole. Ethyl diazomalonate monochloride in ether was treated with dry methylamine; the methylamine hydrochloride was filtered off and the ether removed *in vacuo* leaving ethyl diazomalonate monomethylamide as a yellow oil, which could not be induced to crystallize. The crude oil was treated in the same way as above and gave 1-methyl-5-hydroxy-1,2,3-triazole in 65 % yield. The product was recrystallized from ethanol, m. p. 168—170°. (Found: C 36.45; H 5.00; N 42.48; Calc. for $C_3H_5N_3O$: C 36.30; H 5.08; N 42.40.)

1-Phenyl-5-hydroxy-1,2,3-triazole was prepared according to Dimroth [1].

1-Benzyl-5-hydroxy-1,2,3-triazole. 1-Benzyl-4-ethoxycarbonyl-5-hydroxy-1,2,3-triazole [9] was saponified and decarboxylated in the same way which Gompper [10] used for the methylester. Yield 85 %, m. p. 157—158°.

4-Phenylazo-5-hydroxy-1,2,3-triazoles

4-Phenylazo-5-hydroxy-1,2,3-triazole. A phenyldiazonium chloride solution, prepared from 0.54 ml of aniline in 15 ml N HCl and 0.41 g (1 mole) of sodium nitrite, was added during ca 5 min with stirring and ice cooling, to a solution of 4-hydroxy-1,2,3-triazole (0.5 g, 1 mole) in 15 ml 2N NaOH. The orange solution was kept for 1 h at 0°. Acidification with conc. HCl gave 4-phenylazo-5-hydroxy-1,2,3-triazole as a yellow precipitate which was filtered off and washed with water. Yield 1.03 g (93 %), m. p. 151—153°. After two recrystallizations from ethanol the substance was pure, forming yellow needles.

The same product was obtained when 4-carboxamido-5-hydroxy-1,2,3-triazole was used, the carboxamido group being split off during the reaction. With the same conditions as above the yield of azocompound was 96 %.

1-Methyl- and *1-benzyl-4-phenylazo-5-hydroxy-1,2,3-triazole* were prepared in the same way from 1-methyl- and 1-benzyl-5-hydroxy-1,2,3-triazole, respectively. They were both recrystallized from ethanol. Properties are given in Table 1.

1-Phenyl-4-phenylazo-5-hydroxy-1,2,3-triazole was prepared according to Dimroth [1] by coupling in 20 % Na_2CO_3. When 2N NaOH was used the product was very impure. The product was recrystallized from methanol; prolonged heating should be avoided during the recrystallization to avoid decomposition.

Rearrangement of 4-phenylazo-5-hydroxy-1,2,3-triazoles

2-Phenyltetrazole-5-carboxanilide. 1-Phenyl-4-phenylazo-5-hydroxy-1,2,3-triazole (1.2 g) was dissolved in 10 ml of boiling glacial acetic acid and the solution was boiled for 5 min. The orange colour of the azocompound disappeared almost immediately. On cooling the tetrazole crystallized; it was filtered off and washed with ether. Yield 0.75 g, m. p. 159–161°.

In the other three cases the rearrangement was done in the same way. If the product did not crystallize on cooling of the acetic acid solution it was precipitated with ether or light petrol. Their properties are given in Table 2.

Preparation of authentic tetrazoles

2-Phenyltetrazole-5-carboxanilide. Dried 2-phenyl-5-carboxytetrazole [6] (0.5 g) and phosphorus pentachloride (0.6 g, 1.1 mole) were mixed and heated for a few minutes until the vigorous reaction had ceased. Phosphorus oxychloride and excess of phosphorus pentachloride were then removed *in vacuo* at 100°. The crude chloride, which formed a solid, was cooled in ice and treated with excess aniline dissolved in ether. The mixture was stirred and the lumps were broken with a glass rod to complete the reaction. The solid was then collected by filtration and washed with diluted HCl and water.

The three other tetrazoles were prepared in the same way, IVb and IVc with 25 % aqueous ammonia and methylamine, respectively, and IVd with benzylamine in ether. Yields are given in brackets in Table 2. They were all analysed but the values are not given here; the analyses in Table 2 are those of the rearrangement products.

The infrared spectra were taken on a Beckman I.R.2 in strument using the KBr-disk technique.

The author is indebted to Civilingeniør S. Refn for the infrared spectra. Microanalyses were made by Mr. P. Hansen.

On the Reaction between Polyacrylonitrile and Hydrazine

SVEN SÖNNERSKOG

A-B Svenskt Konstsilke, Borås, Sweden

Polyacrylonitrile reacts with hydrazine or hydrazine hydrate. The new polymer is insoluble in all known solvents for polyacrylonitrile even at low extents of reaction. Insolubilization is caused by intermolecular reactions. The interlinking unit is 4-*N*-amino-1,2,4-triazole.

Solutions of polyacrylonitrile in dimethylformamide slowly react with hydrazine or hydrazine hydrate at room temperature. A gel gradually separates, insoluble in all known solvents for unmodified polymer. Ammonia and dimethyl amine are simultaneously formed and easily identified in the vapor phase of a closed system. At elevated temperature — 80°C — gelation is complete within 50—65 min. The reaction seems to be specific for hydrazine in the meaning that ammonia, amines and even aliphatic diamines only cause a discoloration of polymer solutions but no observable change of solubility characteristics. What is said above refers to 2 % solutions of polyacrylonitrile (red.ox.grade, aver.-visc.mol.wt. about 8×10^4), dissolved in a mixture of three parts (by wt) of dimethylformamide and one part of hydrazine (technical grade, content of hydrazine 95—97 %). The polymer dissolves in this mixture above 40°C and is stable at room temperature for several hours until the action of hydrazine is noticeable. Even at 80°C the system remains fluid until incipient gelation takes place within the last few minutes, when the gel expands to a viscous foam. The escaping gas contains ammonia, dimethyl amine and hydrazine vapor, which are partly separable in a series of cooling traps.

Identical effects have been observed for other stoichiometric ratios between reacting species and it is well established that the gel formation is not limited to the special working conditions mentioned above. Insolubilization takes place in other solvents, such as dimethylsulfoxide. The action of hydrazine hydrate is equivalent to that of hydrazine. Even solid polymer, suspended in aqueous solutions of hydrazine, is gradually converted into a reddish-orange modification, definitely insoluble in customary solvents for linear polymer. Of course this does not mean that the *extent* of reaction is the same in all these cases, yet high enough to cause insolubility even of the primary polymer particle.

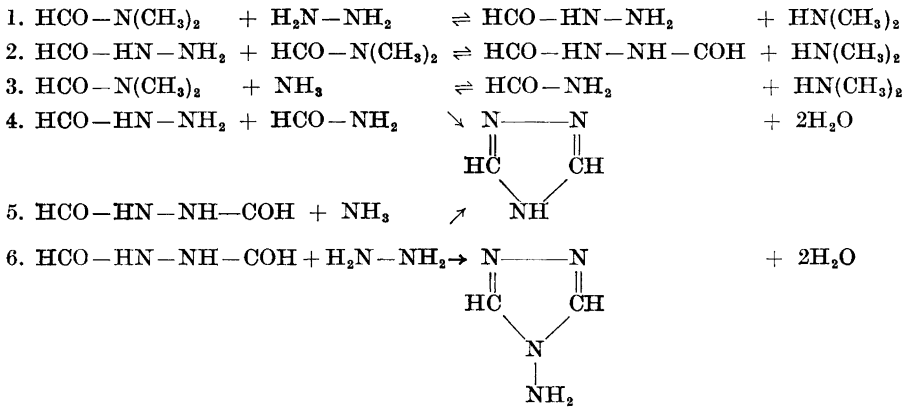
The primary gel is rubbery in character. During purification by repeated soaking in hot water and methanol (absence of air) it is gradually converted into a brittle, distinctly yellow powder. The color turns into orange on drying in air at room temperature. Contrary to standard homopolymer this final modification is resistent to alkaline hydrolysis. It evolves only a minor amount of ammonia on boiling in 10—20 % sodium hydroxide solution. The degree of swelling is low compared with the primary gel volume. Such a drastic change of physical properties might be caused by

1) a reduction of the number of solvogenic groups,

2) a decrease of the number of independent kinetic units,

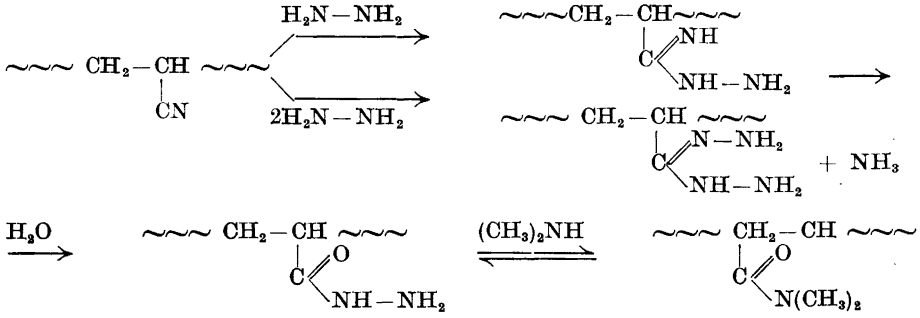
or by both cases in combination. In other words both inter- and intramolecular type reactions between polyacrylonitrile and hydrazine must be considered. However, it is equally important to pay attention to competing side reactions between solvent and hydrazine, including the contribution from water and ammonia always present in technical grades of said chemicals. The following list is given as a summary:

A. Interchange reactions between dimethylformamide and hydrazine:

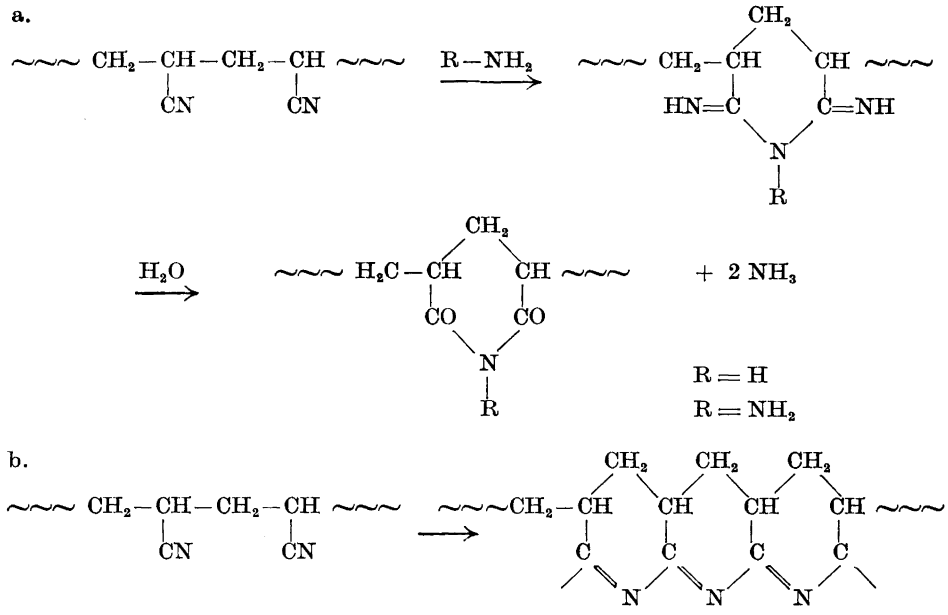


B. Reactions between polymer, hydrazine, coreactants:

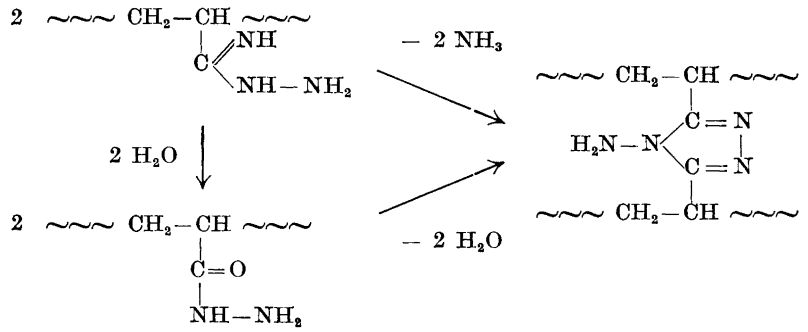
1. Hydrazidine formation, accompanied by hydrolysis and amide interchange:



2. Intramolecular cyclization at isotactic sequences [1,2]:



3. Intermolecular reaction at random between hydrazide or hydrazidine groupings (compare case A: 4,6). The interlinking unit formed in this way is 4-*N*-amino-1,2,4- triazole:



As is seen from this survey of type reactions the formation of water is initiated by ammonia as well as of hydrazine. Water is consumed by hydrolysis of imino groups in the reacting polymer but regenerated when hydrazide groups are converted into heterocyclic units by intermolecular condensation.

The ammonia, liberated according to B:1 -3, is recycled in secondary reactions and represents a potential source of new water molecules. This explains why the rate of gelation is fairly constant even at a large change of water

content in the initial reaction mixture (*e.g.* when hydrazine hydrate is used instead of hydrazine).

The final structure of the polymer can evidently be realized in so many ways that it is hardly permitted to speak of a single, reproducible composition. This does not imply that the gelation effect is caused by all reactions between polymer and active reagents. The extent of *intra*molecular cyclization cannot be made responsible for insolubilization, as this would contradict all previous [1,2] experience on color formation in polyacrylonitrile, caused by the action of ammonia and aliphatic amines. These chemicals do not decrease solubility of the polymer in dimethylformamide. It is much more probable that the gel effect is caused by intermolecular reactions. Insolubilization would then take place, regardless of the intramolecular balance between nitrile, hydrazidine, hydrazide and naphtyridine groupings, when the amount of interlinking units has reached, on an average, the critical value of incipient gelation. As the reaction also has been observed in the system hydrazine—solid polymer it seems permitted to anticipate its existense also in the gel phase. This only emphasizes the difficulty of obtaining a good reproducibility, as the termination of the reaction is depending on the following schedule of purification.

A crosslinked polymer, formed in this way, would act as an anion exchanger due to the presence of primary amino groups in the interlinking units. This has been confirmed by saturation with hydrochloric acid, followed by regeneration with sodium hydroxide solution and titration of liberated chloride ions. The exchange capacity amounts to 0.2—0.3 mequiv./g dry polymer in a series of six specimens. This property remains after heating the polymer at 80—100°C in strong sodium hydroxide solution. The degree of swelling increases at this saponification step, as stated above, but no dissolution of polymer has been detected.

The triazole nucleus is known to be very stable to the hydrolytic action of mineral acids. The present polymer is not dissolved by hot concentrated hydrochloric acid or by 70 % sulphuric acid. The latter is known to be a good solvent for the parent polymer. Strong nitric acid also shows good solvent properties for polyacrylonitrile and polyacrylic acid, but is incapable of dissolving the actual polymer at moderate temperatures. However, dissolution takes place rapidly in strong (60—80 %) acid at 110—115°C, apparently connected with an oxidative degradation of the sample. On dilution with water after cooling a voluminous precipitate is obtained, easily soluble in dimethylformamide. Viscosity measurements indicate a very low molecular weight. Similar effects have been obtained on samples previously reacted with nitrous acid.

Infra-red spectra of the polymers, prepared in homogeneous or heterogeneous system, show essentially the same features. Fig. 1 is a juxtaposition of relevant regions of infrared absorption for I:primary polymer, II:reacted polymer, obtained by the action of 10 % hydrazine hydrate solution in a suspension of primary polymer, III: "gel polymer", obtained from reaction in homogeneous system, followed by immediate washing and drying after insolubilization. A most striking difference is the low extent of reaction in case II and the very high one in case III, as indicated by the band at 2 260 cm^{-1}, measuring the amount of unreacted nitrile groups. The lower level,

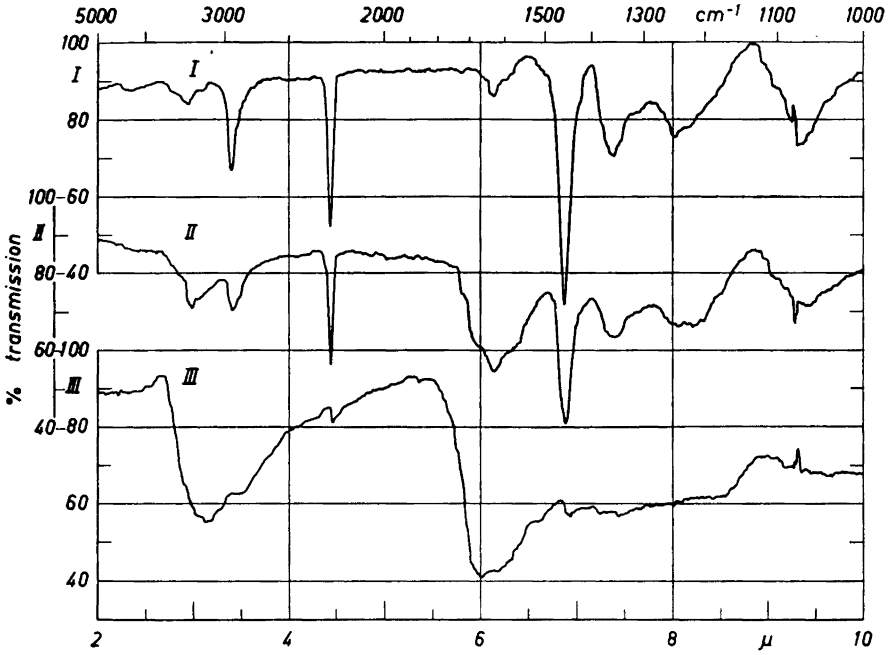


Fig. 1. Infra-red spectra of I: pure polyacrylonitrile II: polymer powder heated in 10 % hydrazine hydrate solution, III: polymer dissolved in dimethyl formamide-hydrazine, soaked after reaction in water and methanol, dried at room temperature in air.

however, is sufficient for complete insolubilization. New, broad bands arise in two regions with absorption maxima approximately at 3 and 6 μ. Their intensities are apparently related to the extent of reaction (disappearence of nitrile groups) likewise the exact location of the absorption maxima. In the case of completely reacted polymer (III) the latter band covers a variety of conceivable groupings (amides, amines, hydrazides) usually found at 1 600—1 700 cm^{-1}. The absorption maximum at 1 625 cm^{-1} is earlier [1] offered as evidence for the formation of C = N linkages in similar systems. The other (3 350 cm^{-1}) band, fairly distinct at a low extent of reaction (II), is located in the region where amino and imino groups show their stretching frequences. The list above of type reactions would thus fit at least qualitatively into the picture obtained from the infra-red spectra. A more detailed analysis requires a variety of model substances for exact frequency determinations.

Analytical. The presence of oxygen in the final polymer (III) was confirmed by elementary analysis (Unterzaucher-Zimmermann *). The oxygen content is 13.7 %. Nitrogen determination, according to Kjeldahl, was carried out on six specimens, showing a considerable scattering (12.3—13.4 %). The limiting nitrogen content after saponi-

* Carried out by Dr. A. Bernhardt, Mülheim, Ruhr.

fication at 100°C in 30 % sodium hydroxide solution is 5.1—5.5 %. Work is continued on model substances, obtained by reaction between polyacrylonitrile and hydrazine in an inert solvent (dimethylsulfoxide). This facilitates separation of the different reaction steps, ending in insolubilization, as the influence of water can be excluded. The single volatile byproduct is ammonia.

Acknowledgement. The author is greatly indebted to professor Erich Adler for good advice and valuable criticism, and to his coworker Mr. Bo Gustafsson for recording of the infra-red spectra shown in Fig. 1.

Acid Compounds of Hemins and Hemoproteins (B–Compounds) *

A. C. MAEHLY

E. R. Johnson Foundation for Medical Physics, University of Pennsylvania, Philadelphia, and Nobel Medical Institute, Biochemical Department, Stockholm, Sweden **

Acid compounds of several hemoproteins and free hemins are studied and described, notably in respect to their spectra, equilibrium constants and their reaction with halogen ions. Fluorescent measurements are used to study the possible dissociation of the central iron atom from the porphyrin molecule in acid solutions.

The possible reactions involved are briefly discussed. A detailed discussion will be found in the second communication of these series.

The properties of hemins and hemoproteins in strongly acid aqueous solutions have been relatively little studied. Many hemoproteins, like hemoglobin, myoglobin, and to some extent catalase, are denatured below pH 4. So far only horseradish peroxidase [1,2] and cytochrome c [3–5] have been investigated in strongly acid solutions which did not denature the protein irreversibly.

Iron-porphyrins in their free state have very low solubilities in aqueous systems in the acid range, and it is therefore difficult to study them. In 1929, Hicks and Holden [6] measured the absorption of hemoglobin and of protohemin in the Soret region (*ca.* 350—450 mμ) at low pH, and in 1947 Erdman and Corwin [7] published a very interesting paper on the acid spectra of mesohemin-dimethylester in pyridine and dioxane.

The present investigation was begun in order to study the nature of compounds observed by Theorell and Paul [8], by B. Chance [9] and by this author [1] on acidifying solutions of horseradish peroxidase (HRP) with acid. At least two such compounds were identified and this author proposed to call them compounds A and B, respectively. Acidification of HRP by H_2SO_4, HNO_3, or $HClO_4$ yields the acid compound B, where the protein moiety is denatured. With HCl, a hydrochloride, HRP-HCl or compound A is formed, which on further acidification reversibly splits into hemin and undenatured protein.

* Part of the results published here have been reported at a meeting of the Swedish Biochemical Society in Uppsala in December 1953.

** Present address: Statens rättskemiska laboratorium, Stockholm, Sweden.

Compound B is only present in small concentrations. HBr, HF, and HCN have effects similar to HCl. B-Compounds can be defined as compounds formed from hemin-containing substances at low pH in the absence of halogen or cyanide ions and are characterized by a high sharp absorption band, somewhere between 380 and 398 mμ [1].

METHODS AND MATERIALS

The hemins were prepared by known methods as described in an earlier paper [10] and were crystallized once from acetic acid saturated with sodium chloride. A sample of crystalline horseradish peroxidase (HRP) mentioned in previous work [2] was used. Its ratio of optical densities at 403 mμ and 275 mμ (RZ,*) was 2.68. Hemoglobin (Hb) was prepared from washed human erythrocytes and the dialyzed solution was used without further treatment. Sheep myoglobin (ShMb) was kindly donated by Dr. M. Beznák and had the properties described in her paper [11]. A sample of human serum albumin was kindly given us by Dr. M. Surgenor (Boston) in the form of fraction V.

Two types of recording spectrophotometers were used in addition to a standard Beckman DU instrument: an apparatus designed by B. Chance [12] recording changes of transmission with respect to time, and a spectrophotometer built by Yang and Legallais [13] recording absorption spectra (optical density *versus* wavelength). Cuvettes with 1 cm lightpath were used and the temperature was adjusted by circulating thermostated water through »thermospacers». As a rule, measurements of pH were made inside the optical cuvettes using micro-electrodes (Beckman »baby stomach» electrodes) and pH meters of the same firm. The reproducibility of this setup was better than ± 0.1 pH units, wich was sufficient for this type of work. The accuracy was considerably higher for the duration of a given experiment.

RESULTS

Spectral data on the acid compounds of HRP. Virtually complete transformation of HRP into HRP—B was accomplished by the addition of sulfuric acid to an aqueous solution of the peroxidase to give a pH of 0.6. The spectrum of the relatively unstable compound B was measured at +5° with the recorder of Yang and Legallais and checked at critical wavelengths with Chance's double-beam spectrophotometer. The formation of B from HRP is most easily observed in the Soret region [1]. In 1944, Theorell and Paul [8] found that the addition of HCl to HRP leads to spectral changes, notably a pronounced increase in optical density at 615 mμ and a smaller decrease at 655 mμ. They attributed these to pH changes and found, by titrating HRP with HCl, two pK values: 4.0 (measured at 655 mμ) and 5.0 (measured at 615 mμ).

Chance [9] showed that the negative logarithm of the dissociation constant of the HCl compound of HRP is $pK_{FeH^+Cl^-} = 5.5$, but in terms of H^+ ion concentration the pK appears [9] to lie at 3.4. Sulfuric acid, in contrast to hydrochloric acid, does not influence the spectrum of HRP above pH 3.5 and the pK of compound B by spectrophotometric titration with H_2SO_4 at 397 mμ was found [1] to be 2.30. Chance and Maehly working at 615 mμ (*cf.* Ref.[9]) confirmed this value.

* For a definition of this unit see Maehly, A. C. in *Methods in Enzymology*, Vol. II, S. P. Colowick and N. O. Kaplan, eds., Academic Press, New York 1955, p. 801.

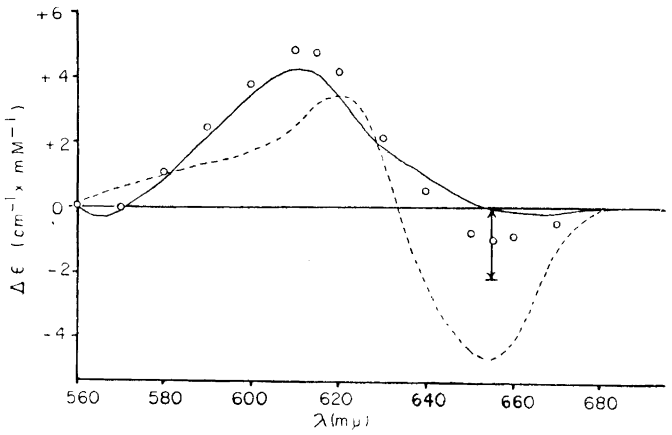

Fig. 1. The spectra of the difference "HRP-B minus HRP" as well as "Theorell and Paul's data" [8] and "compound A minus HRP".

- - - - - - - - HRP-B at pH 0.6 minus neutral HRP (concentration 7.5×10^{-6} M).

O O O O Theorell and Paul's measurements of acidified HRP (extrapolated to pH 2.7) minus neutral HRP (concentration 4.7×10^{-4} M).

———— Theorell and Paul's data, corrected for the calculated contribution of HRP-B at pH 2.7. A continuous curve is drawn to fit the calculated points and the resulting spectrum is assumed to represent the difference spectrum of HRP compound A (cf (1)) minus neutral HRP.

The arrow indicates the maximal decrease of the extinction coefficient obtained by Theorell and Paul by addition of HCl to HRP in a separate experiment (pH5.4).

Addition of HCl to HRP has two separate effects, namely (i) the formation of compound A (HRP · HCl) with absorption bands at 407 and 615 mμ, and (ii) the partial formation of compound B (acid compound) with bands at 397, 500, and 635 mμ. Fig. 1 shows the difference spectrum obtained by subtracting the spectrum of neutral HRP from that of compound B (obtained by addition of H_2SO_4). It also shows some data of Theorell and Paul[8]. These values were arrived at by subtracting the extinction values of neutral HRP from those measured after the addition of HCl. If the "dip" of these data at 655 mμ is attributed to partial B formation, then the values can be corrected for the contribution of compound B and the difference spectrum of compound A minus neutral HRP obtained (solid line). It shows a peak at 611 mμ. Some implications of these findings have been discussed by Chance [9].

Acid compounds of other hemoproteins. The formation of acid compounds (B compounds) from HRP and from horseblood catalase (HBC) by sulfuric, perchloric, or nitric acids have been described previously [1]. It has since been found that Hb and ShMb also give B compounds under these conditions. Fig. 2 shows the original recordings of their spectra obtained with the recorder of

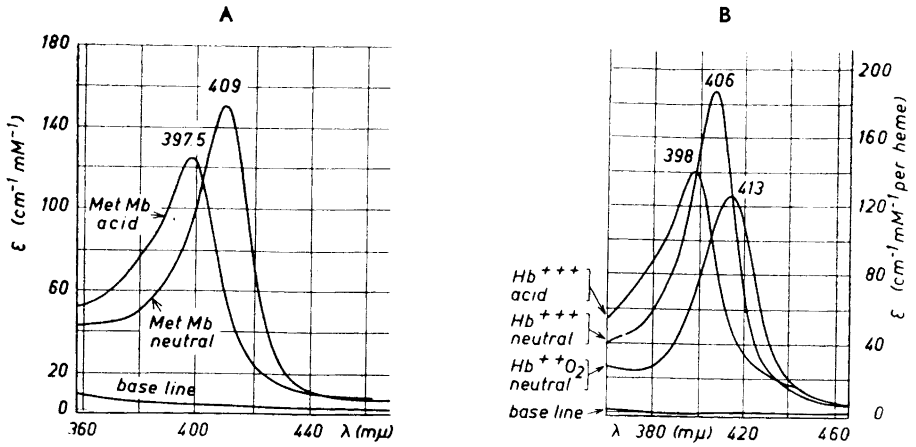

Fig. 2. Original recordings on the apparatus of Yang and Legallais [13]. A: The spectra of sheep metmyoglobin at pH 7.0 (phosphate buffer) and of ShMb-B (H_2SO_4, pH ~ 1). The concentration of ShMb was 3.8 μM. B: The spectra of HbO_2, MetHb (both at pH 7, 0.01 M phosphate buffer) and of Hb-B, formed by the addition of H_2SO_4 to give pH 1. The concentration of hemoglobin was 3.8 μM.

Yang and Legallais. The peak of the Soret band of B lies at 397 mμ. A typical titration curve for Hb-B is presented in Fig. 3.

Human serum albumin is known to bind hemins, but the resulting "hemalbumins" have not been shown to exhibit any biological activity. Protohemalbumin, studied in some detail by Rosenfeld and Surgenor [14] and others, shows a spectrum that is very similar to that of HRP. When H_2SO_4

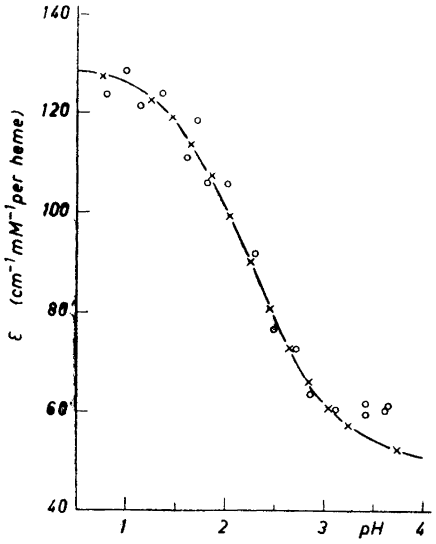

Fig. 3. The titration of hemoglobin with H_2SO_4. — Each point represents the results of a separate experiment: addition of H_2SO_4 to neutral 2.4 μM HbO_2 solution and determination of the maximal optical density at 397 mμ reached during the reaction, as well as of the pH.

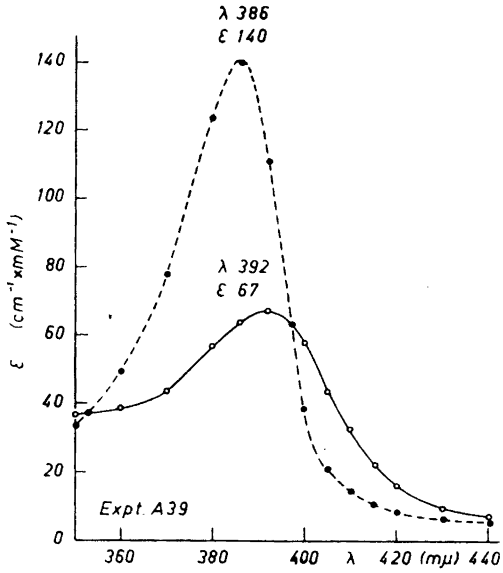

Fig. 4. The Soret spectra of deuterohemalbumin and its B compound.

O—O—O deuterohemalbumin, obtained by adding 2.9 μM deuterohemin to 5.8 μM human serum albumin in 0.02 M phosphate buffer, pH 6.8.

is added, the B compound is formed with a peak at 397 mμ and $\varepsilon = 130$ $cm^{-1}mM^{-1}$, quite comparable to the compounds of HRP, HBC, ShMb, and Hb. If deuterohemin is added to albumin solutions at pH 6.8 (0.02 M phosphate), deuterohemalbumin is formed. This compound has not been previously reported and its Soret spectrum is therefore rendered in Fig. 4*. When the pH is lowered to about 1 by adding H_2SO_4, the corresponding B compound is readily formed with a peak at 387 mμ and $\varepsilon = 140$ $cm^{-1}mM^{-1}$.

Acid compounds of some free hemins. Protohemin is soluble in water only at alkaline pH. Sodium carbonate, or better 0.1 N NaOH, is required to dissolve the compound completely. However, considerable polymerization takes place. This polymerization increases when the pH is lowered, as Shack and Clark [15] have found by experiments involving diffusion, dialysis, and ultracentrifugation. Further acidification leads to a change in spectrum, and the addition of more acid precipitates the hemin from all but the most dilute solutions. At very low pH a further change takes place: compound B is formed, as indicated by the spectrum in the Soret region (Fig. 5). This acid compound

* Compounds formed by a combination of mesohemin with human serum albumin and other proteins have been described by Rosenberg, L. L. and Clark, W. M. *J. Biol. Chem. 205* (1953) 617.

is also only slightly water-soluble and undergoes further, irreversible changes on standing.

Deutero- and mesohemin lack the two vinyl groups of protohemin and are therefore chemically simpler model compounds. Mesohemin gives a B compound with a Soret band at 380 mμ, deuterohemin forms a similar compound with a peak at 388 mμ. Titration data show that deuterohemin (having no sidechains in 2- and 4-positions) is most readily transformed into its B-form (p*K* 3.0—3.1). Mesohemin (2 ethyl groups as sidechains) requires more acid

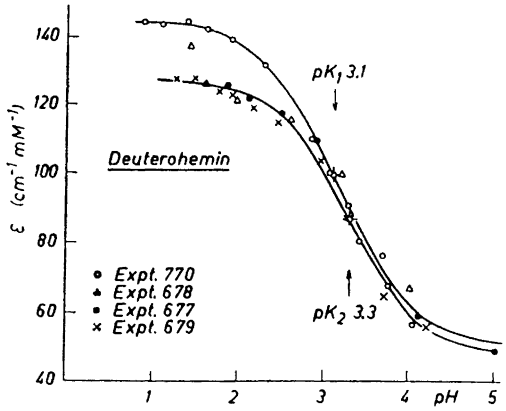

Fig. 6. The reversibility of the formation of the B compound obtained from deuterohemin. A solution of deuterohemin was acidified with H_2SO_4, acid potassium tartrate was added, and the pH as well as the optical density at 388 mμ were measured after addition of increasing amounts of NaOH to the sample (Expts. 677—679). The "normal" titration curve from Fig. 8A is represented forcomparison (Exp. 779). The concentration of deuterohemin was 5.8 μM when going from high to low pH, and 2.1—2.4 μM when the pH was raised.

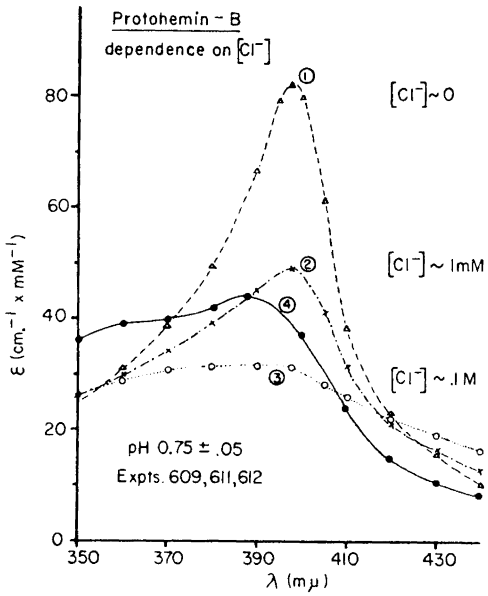

Fig. 7. The influence of the Cl′ ion concentration on the Soret band of protohemin-B (PHB). Protohemin was acidified with H_2SO_4 (pH .75) and its spectrum recorded. The recording was repeated with identical solutions, except for the presence of increasing concentrations of KCl.

(1) △-------△ PHB, no KCl

(2) x·····x PHB, ~ 1 mM KCl

The protohemin concentration varied between 7 and 11 μM.

(pK 2.25), and protohemin (2 vinyl groups) still more (pK 1.5). Deuterohemin-B appears to be best suited for further studies on the nature of B compounds since it can be obtained under relatively mild conditions. The instability of protohemin in aqueous solutions and its tendency to polymerize make it the least suitable of these hemins for such studies.

The relatively high stability of deuterohemin-B allowed a measurement of the reversibility of B formation. The technique for obtaining titration data for hemoproteins as well as hemins consisted of adding a definite and increasing amount of acid to each of as many aliquots of the solution of a neutral sample of the compound as there were values needed (*cf.* Ref.[1]). The instability of B made a simple reversal of this technique impractical. Some tartrate and increasing amounts of NaOH were added to only one sample of acidified deuterohemin (compound B), and the pH as well as the optical density were rapidly

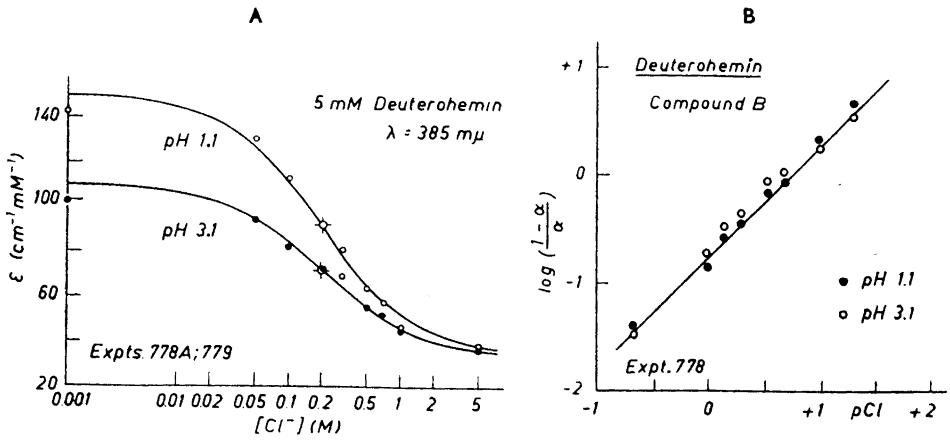

Fig. 8A. The "titration" of deuterohemin-B (DHB) with chloride. Aliquots of a neutral deuterohemin solution were added to solutions of increasing concentrations of KCl, all of them acidified with H_2SO_4 to give either pH 1.1 or 3.1. The optical density of each sample was measured near the peak of the Soret band (385 mμ). The final DHB concentration was 4.4—5.2 μM.

Fig. 8B. A straight line plot of the data represented in Fig. 8A. A logarithmic expression of the law of mass action is used:

$$K = \frac{[DHB]\,[Cl']^n}{[DHB\,(Cl')_n]} \quad (1); \qquad a = \frac{[DHB]}{[\text{Total deuterohemin}]} \quad (2)$$

$$\frac{1}{K} = \left(\frac{1-a}{a}\right)\frac{1}{[Cl']^n} \quad (3) \qquad \log\left(\frac{1-a}{a}\right) = n \log [Cl'] - \log K \quad (4)$$

Abscissa: the negative logarithm of the Cl′ ion concentration

Ordinate: $\log\left(\frac{1-a}{a}\right)$

The data lie on a line with the slope n = 1 and a pK_{Cl} = 0.7.

measured after each addition. The data are plotted in Fig. 6 and show that the titration is essentially reversible. The diminished extinction values are believed to be due to the slow decomposition of B, the shift of the pK from 3.1 to 3.3 may be caused by the presence of high concentrations of tartrate.

The reaction of B compounds with chloride ions was investigated next. In the case of HRP, the addition of chloride at neutral pH has no observable influence. When the solution is acidified, the HCl compound of HRP is formed. If the pH is lowered even more, splitting of the enzyme is brought about and the rate of splitting is accelerated by the presence of chloride [1]. In the case of free hemins, increasing concentrations of Cl^- depress the height of the Soret band at 397 mμ upon acidification of the solutions, indicating the formation of a compound of hemin with either Cl^- or with both Cl^- and H^+. Fig. 7 shows the Soret spectra of protohemin B at concentrations of $<10^{-5}$, 10^{-3}, and 10^{-1} M Cl^-. A complete "titration" of deuterohemin-B with chloride at two different pH values is shown in Fig. 8. At pH 3.1 only half of the

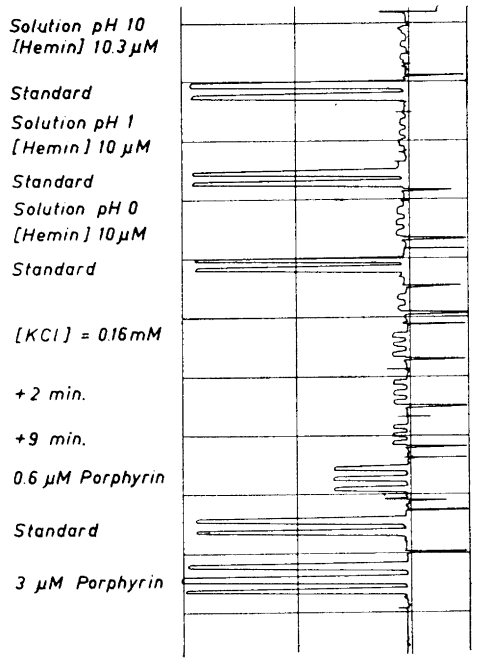

Fig. 9. Original recording of fluorescence measurements on protohemin-B. The apparatus described by Theorell and Nygaard [17] was used to investigate the possible fluorescence of protohemin-B. The experimental procedure is described in the text.

Ordinate: amount of fluorescence.

Abscissa: time sequence. The recorder was started for short time intervals after each addition of reactants. The record should be read from top to bottom.

Standard: A piece of fluorescent plastic was inserted into the apparatus as a reference standard.

hemin is present as B compound, so that the extinction coefficient at 385 mμ reaches only a value of about 108 $cm^{-1}mM^{-1}$ at infinitely low Cl^- concentration. At pH 1.1, compound B is almost fully formed at low [Cl^-]. The inflection point, however, lies at 0.2 M Cl^- in both cases ($pK_{Cl'} = 0.7$).

Fluorescence measurements. It is well known that hemins lose their iron under strongly acid conditions, notably if the iron is kept in the reduced state. The resulting porphyrins have well-defined spectra and show sharp bands in the Soret region not far from 400 mμ. Lemberg and Legge [16] cite from the literature the following Soret bands of porphyrins in strong HCl: Protoporphyrin: 408 mμ; deuteroporphyrin: 404 mμ; mesoporphyrin: 401 mμ. Since these wavelengths are close to the peaks of the B compounds, it was important to check whether a complete or partial removal of iron could take place on B formation. Professor H. Theorell kindly allowed the author to use his recording fluorescence meter [17].

Free porphyrins fluoresce strongly, whereas hemins do not. The apparatus was therefore used for detecting the possible formation of porphyrin from protohemin by strong acid at room temperature. A 10 μM solution of protohemin was prepared and its fluorescence measured, as shown in Fig. 9. The pH was lowered to 0 by the addition of sulfuric acid and the fluorescence remeasured. Addition of 1.6×10^{-4}M KCl did not change the result, even after 9 min waiting: the fluorescence remained insignificant, indicating the virtual absence of protoporphyrin. As a check, first 0.6 μM, then 3.0 μM protoporphyrindimethylester were now added and gave the expected large deflections.

DISCUSSION

The formation in aqueous solutions of well defined acid compounds is common to hemoproteins and to free hemins as far as they were investigated. These compounds, called B compounds, all show characteristic sharply defined Soret bands with peaks between 380 and 398 mμ and ε between 81 and 163 $cm^{-1}mM^{-1}$. Their visible spectra are far less conspicuous, showing relatively flat and low bands. HRP—B has such bands at around 500 mμ (ε = 6.4 $cm^{-1}mM^{-1}$) and at about 632 mμ (ε = 2.3 $cm^{-1}mM^{-1}$). The titration of hemin solutions with sulfuric acid yields sigmoid titration curves with n = 1 and pK values of between 1.5 and 3.1. Table 1 gives a summary of the spectrophotometric and titrimetric data on B compounds. It is seen that the height and position of the 397 mμ band is the same for all five protohemin-containing proteins investigated ($\varepsilon = 131 \pm 1$ $cm^{-1}mM^{-1}$ per hemin). Free protohemin-B, while showing the same position of the peak, has a much lower extinction coefficient. The low extinction coefficient of protein-free protohemin-B might well be due to polymerization, which is known to occur in aqueous solutions of this hemin. The addition of protein to protohemin-B increases the Soret band. Alcohols seem to act in a similar way as will be further discussed in the following paper [18]. Deuterohemin-B and mesohemin-B do not show abnormally low bands in the Soret region and apparently undergo less polymerization than protohemin *. If this assumption is correct one should not expect any marked intensification of the Soret band of these hemins by the presence of protein, which was indeed observed with the B compound of deuterohemalbumin.

A comparison of the data of Table 1 with the scant values from the literature shows some similarities, even though the experimental conditions were different. Erdman and Corwin's spectrum of acid mesohemindimethylester in dioxane [7] has a Soret peak at 390 mμ (ε = 175 $cm^{-1}mM^{-1}$), compared to 380 mμ and ε = 163 for mesohemin-B in water at pH 1 reported here. Hicks and Holden [6] acidified protohemin with HCl and obtained a peak between 374 and 386 mμ (emission lines of the iron spark source of their spectrograph) and a minimal extinction coefficient of 45.6 $cm^{-1}mM^{-1}$. Comparison with Fig. 7 indicates that the pH must have been about 2, corresponding to a Cl^- concentration of 0.01 M.

* Shack and Clark [15] observed that mesohemin has a much smaller particle weight than protohemin in aqueous solution.

Table 1. Soret bands and pK values of some B compounds.

Starting material / Magnitudes measured		"pK" [a]	$cm^{-1}mM^{-1}$ per hemin [b]	max [c] mμ
Peroxidase	HRP	2.30	132	397

a) accuracy ± 0.05 pH units. For the meaning of »pK» *cf.* text.
b) accuracy ± 1 %
c) accuracy ± 1 mμ

The "pK" values of Table 1 do not all simply refer to true dissociation constants of the reaction

$$\text{Hemin} + H^+ \rightleftharpoons \text{compound B}$$

In the case of deuterohemin, the reversibility of B formation with a dissociation constant of about 10^{-3} has been demonstrated. The "pK" values of hemoproteins, on the other hand, represent merely the pH at which half of the B compound has been formed, since the breaking of bonds between protein and hemin is also reflected in the data and is thought to be responsible for the variations in "pK" between 2.00 and 2.30 for several protohemin-containing hemoproteins. The abnormally low "pK" of free protohemin suggests that an additional chemical reaction may be required for forming the B compound. This may very well be a partial depolymerization of the hemin.

The results of the fluorescence experiments show that at the most 1 % of the hemin could possibly have been converted to protoporphyrin under the conditions of B formation and also when chloride was added to the solution.

The data presented here make it seem probable that the formation of B compounds involves the configuration around the iron atom of the hemin molecule: The vinyl groups can be excluded as participants, since deutero- and mesohemin also give B compounds. At pH 1.5 (the "pK" of protohemin B) one should expect the propionyl groups to be present in their undissociated and uncharged form, even though their pK has never been determined directly. A further discussion of the possible structure and the reactions of the B compounds is included in the following paper [18].

Acknowledgments. The author wishes to thank Prof. B. Chance for his interest and encouragement, and Prof. H. Theorell for the permission to use the fluorescence recorder and his hospitality at the Nobel Medical Institute in Stockholm.

Stabilization of Aqueous Hemin Solutions *

A. C. MAEHLY** and Å. ÅKESON

E. R. Johnson Foundation for Medical Physics, University of Pennsylvania, Philadelphia, Pa., U.S.A. and Nobel Medical Institute, Biochemical Department, Stockholm, Sweden

The deterioration of aqueous hemin solutions upon standing in light and air is studied and ways of stabilizing such solutions are described. Alcohols are found to be efficient stabilizing agents, apparently due to the formation of hemin-alcohol compounds. The paper describes spectra, titration data and magnetic properties of these hemin compounds. Their possible structures are included in the discussion which also covers data of the preceding publication.

The properties of aqueous solutions of protohemin change quite rapidly on standing. This is apparently due to several processes closely related to each other. Polymerization is one of these processes and has been studied by Zeile, Haurowitz, Gralén, and especially by Shack and Clark [1] in 1947 who also cite earlier literature. The particle size depends on the pH, the kind of buffer and time, and the apparent molecular weight varies between about 3 000 and 100 000 [1].

The spectral changes of hemin solutions as a function of time have also been measured by Shack and Clark [1] from 400 mμ to 700 mμ. They find that, under their experimental conditions, the spectrum of a freshly prepared solution undergoes a change for several days when a new spectrum is formed which then remains stable for more than 60 days. Similar results were obtained more recently by Blyumenfeldt [2] who studied the spectrum in the Soret region.

At least one method for preventing or slowing down the reactions responsible for the instability of protohemin in water will be described here.

EXPERIMENTAL

The hemins and hemoproteins used in these studies are described in the preceding paper [3]. The horse myoglobin (HMb) mentioned here was prepared as described by Theorell and Åkeson [4]. The spectra and the pH were measured with the same apparatus mentioned in *Ref.*[3]. The magnetic measurements were performed by A. Ehrenberg (Nobel Medical Institute, Stockholm) using a highly sensitive apparatus designed by Theorell and Ehrenberg [5].

* A preliminary report of some of the data presented here was made by one of us (A. C. M.) at the 128th Meeting of the Am. Chem. Soc. in Minneapolis (1955), p. 68 C.

** Present address: Statens rättskemiska laboratorium, Stockholm, Sweden.

RESULTS

Spontaneous changes of aqueous hemin solutions

Blyumenfeldt's results with protohemin [2] were, on the whole, confirmed. It was found that the Soret band changes its appearance and that this change follows the kinetics of a first order reaction which is half complete after one to twenty hours after preparing a fresh solution, the half-time depending on the conditions of the experiment. The initial and final spectra from 230 to 490 mμ, the latter extrapolated to infinite time and from a series of experiments, are plotted in Fig. 1.

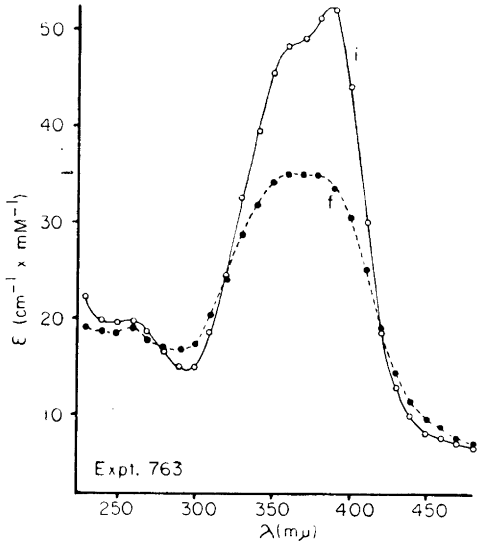

Fig. 1. The spectra of a fresh and an aged solution of protohemin at pH 10.4. Protohemin was dissolved in 0.1 N NaOH and diluted to 1.46×10^{-5} μM with 0.01 M phosphate buffer. The resulting pH was 10.4. The spectrum of the solution was measured within a few minutes and the measurements repeated at appropriate intervals for several hours. Extrapolation of the values to infinite time gave the spectrum of the final product. The reaction is of first order, as shown in Fig. 3.

i—O—O— initial spectrum of a fresh solution (2—20 min after dissolving the protohemin).
f- -●- -●- - final spectrum of the aged solution at infinite time.

Shack and Clark [1] had reported that the changes of the visible spectrum were the same, whether the hemin solution was kept under hydrogen or in the air. Joan Keilin [6], on the other hand, found that hemin solutions in Na_2CO_3 would change several of their properties (formation of a caffeine-CO compound, solubility in ether-acetic acid, crystallizability from acetic acid and NaCl) when standing in air, but not under strictly anaerobic conditions.

We found that the hemin spectrum remained unchanged for more than a week if the solutions were kept and measured in an anaerobic cuvette [7], which

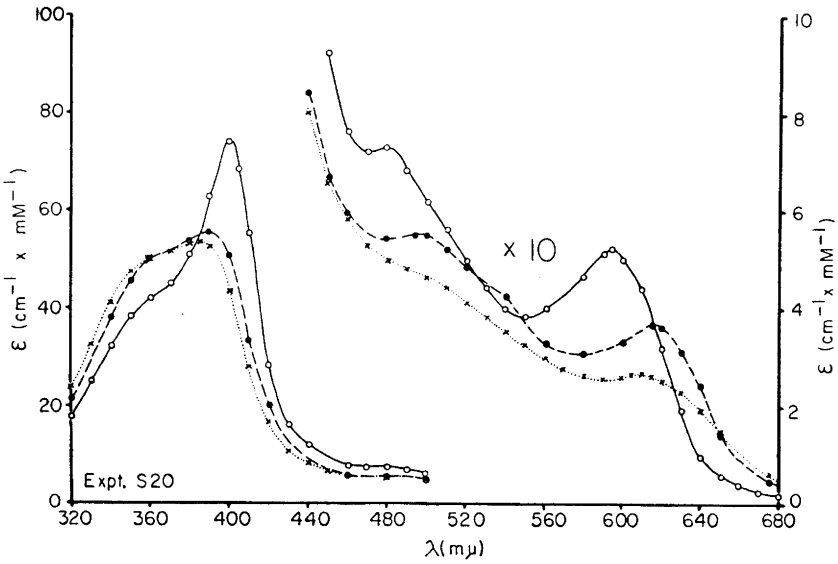

Fig. 2. The spectra of protohemin in water, 50 % ethanol and 30 % sucrose. Phosphate buffer of pH 7.0 was added to give a final concentration of 0.01 M.

X·····X solvent: water
O———O solvent: 50 % ethanol
●-----● solvent: 30 % sucrose or 30 % glycerol
The final concentration of protohemin was of the order of 10^{-5} M in each case.

was evacuated after some wet $Na_2S_2O_4$ had been placed in one of its sidearms, a procedure recommended by Keilin [6]. The reaction was also slowed down considerably, even in air, if light was excluded. It was further found that the Soret spectrum of aqueous mesohemin and deuterohemin solutions exposed to light and air did not change within three days.

Alcohol has been used by several workers for solubilizing hemin solutions[8–10]. Davies [11] suspected the formation of an alcohol compound of hemin from spectroscopic observations. Around 1930, Hamsik [12] crystallized "active hematin" or α-hematin from aqueous acetone or alcohol. He reported spectroscopic differences between hemin dissolved in these solvents and dissolved in water. He found further that the ability of protohemin to couple with free globin from hemoglobin is lost on standing for some time ("nach einiger Zeit") if the hemin is dissolved in aqueous buffer, but is maintained longer if aqueous acetone or alcohol are used as solvents.

Ethanol, glycerol, and sucrose were tried as stabilizing agents in the present studies. Fig. 2 shows the spectra of freshly prepared hemin solutions in phosphate buffer at pH 7 without addition and in the presence of these solvents. It is readily seen that only ethanol has a strong influence on the spectrum, both in the visible and in the Soret regions. The bands at 385, (495) and 610 mμ of aqueous hemin are sharpened and shifted to 400, 482, and 597 mμ, respectively.

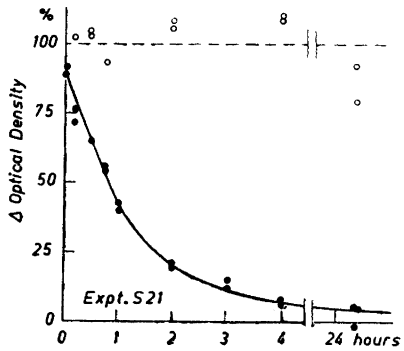

Fig. 3. The change in the Soret spectrum of aqueous and of alcoholic protohemin solutions. The optical density of the Soret band at 385 mμ of aqueous protohemin (0.01 M phosphate buffer of pH 7.0) was determined as a measure of the spontaneous reaction of protohemin described in the text. The optical density of 50 % alcoholic protohemin (in the presence of the same phosphate buffer as above) at 400 mμ was also determined. The measurements were repeated as often as practical and the data plotted in percent of the corresponding values at zerotime at the ordinate, and time in hours at the abscissa, including one final value after 24 h.

O— — —O optical density at 400 mμ of 50 % alcoholic protohemin
O———O optical density at 385 mμ of aqueous protohemin. The curve is a theoretical first order reaction curve.

The stability of the hemin solutions was tested in two different ways. One was the change of the Soret spectrum, the other the velocity of the coupling reaction of hemin with apomyoglobin (the protein part of myoglobin after removing the hemin by HCl in acetone) to yield active myoglobin. The completely reversible splitting of myoglobin was first described by Theorell and Åkeson [4] and some detailed aspects of the coupling reaction will be published later. In Fig. 3, the decrease in the height of the Soret band is plotted *versus* time. Other experiments show that an addition of ethanol preserved these properties of the hemin best whereas glycerol is less satisfactory and sucrose is practically useless for this purpose. The velocity of the coupling reaction with apomyoglobin of aqueous protohemin solutions decreases markedly after some hours whereas 50 % alcoholic solutions of protohemin retain their coupling speed for at least 24 h.

Alcohol compounds of protohemin

The spectral changes of freshly prepared aqueous hemin solutions of pH 7 (0.01 M phosphate buffer) upon the addition of ethanol were measured quantitatively at 400 mμ and yielded a titration curve with a slope n = 2 and pK = −0.75 (the concentration of ethanol bringing about one half of the change is 5.6 M). The extinction coefficient of the ethanol compound was computed to be 81 cm^{-1} mM^{-1} (using the fact that 100 % EtOH is 17.2 M) as compared to ε_{385} = 53 cm^{-1} mM^{-1} for aqueous hemin. The results of such experiments are

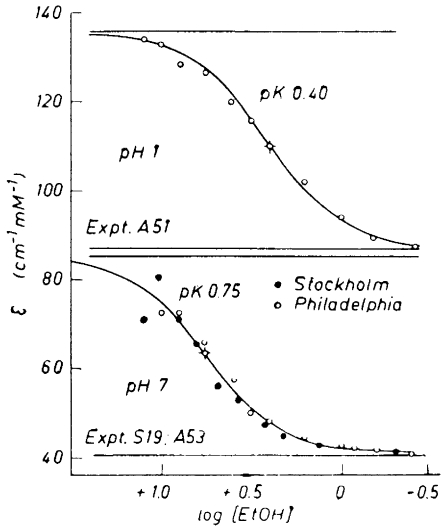

Fig. 4. Spectrophotometric titration of protohemin with ethanol at pH 1 and pH 7. Solutions of 0.1 N H_2SO_4 and 0.02 M phosphate buffer respectively, containing increasing amounts of ethanol were made up. An equal small amount of a concentrated solution of protohemin was added to each sample and the optical density at the maximum of the Soret band (398 mμ at pH 1, and 400 mμ at pH 7) was measured. The hemin concentration was 8—11 μM. The millimolar extinction coefficient is plotted versus the logarithm of the ethanol concentration.

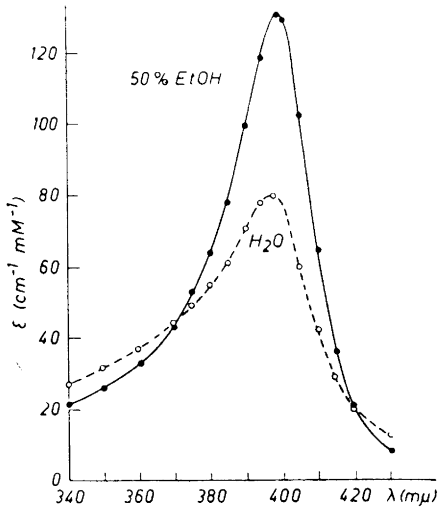

Fig. 5. The Soret spectra of protohemin in water and alcohol at low pH. Protohemin was dissolved in 0.01 N NaOH and added to 0.1 N H_2SO_4 in water and in 50 % ethanol respectively. Final concentration, 5—8 μM hemin.

O- - - - - - -O aqueous protohemin solution
●————● alcoholic protohemin solution

presented in Fig. 4. The very high dissociation constants obtained from these plots suggested the possibility that an impurity in the alcohol might be the true reactant. In order to exclude this possibility, three experiments were made. First, especially purified double distilled ethyl alcohol was used. The results obtained with the "ordinary" alcohol were duplicated within the experimental error. Second, Swedish ethanol, and ethanol obtained in Philadelphia gave identical results. Finally, aqueous protohemin solutions were titrated with methanol (absolute, redistilled). This alcohol also forms a hemin compound with a Soret band at 396 mμ (= 81 cm^{-1} mM^{-1} by extrapolation to 100 % or 24.7 M MeOH). The slope of the titration curve was also found to be n = 2 (at pH 7, 0.01 M phosphate buffer) and the dissociation constant 10.7 M (pK −1.03), higher than in the case of ethanol.

These results indicate the formation of true alcohol compounds of hemin, with a high tendency to dissociate. Dilution of such alcohol-hemin solutions with aqueous buffer yields the spectrum normally observed with hemin solutions in water, proving the reversibility of the reaction. The readings of optical density at 400 mμ in the above mentioned titration experiment with ethanol were repeated after 24 h to test the stability of the alcoholic solutions. At alcohol concentrations above 5 M, no spectral change was noted. Since this corresponds to 23 % (w/v) or 29 % (v/v) ethanol, a 0.01 M phosphate buffer containing 30 % (v/v) ethanol is sufficient to insure the stability of protohemin solutions for at least one day. At this alcohol concentration, each hemin binds on the average, about 1 molecule of ethanol.

At low pH, a different alcohol compound of protohemin is formed. The spectra of protohemin B (*cf.* Ref.[3]) and of this acid ethanol compound at 50 % or 8.6 M EtOH are represented in Fig. 5. The Soret peak lies in this case at 398 mμ. Spectrophotometric titration gave the values represented in Fig. 4. The data lie on a theoretical dissociation curve with a pK of −0.40, somewhat different from that at pH 7.0. The slope of the curve, here also, is n = 2. Extrapolation to 100 % ethanol gives $\varepsilon = 134$ cm^{-1} mM^{-1} *.

There is an intermediate pH range where the titration values lie on curves with very high n values. At pH 4, n was found to be >4. This is the pH region where the alcoholic hemin precipitates even at low concentrations.

Reduction of the alcohol compound at pH 6.8 by sodium dithionite did not change the Soret spectrum but gave a very featureless spectrum in the visible region. The characteristic double bands of hemochromogens were completely absent.

Protohemin in 50 % EtOH showed only the two spectra reproduced above: an acid type (Fig. 5) and an alkaline type (Fig. 2). The pH of conversion lies between 4 and 6 (pH of the buffers before adding the alcohol) but attempts to measure the pK more accurately failed: spectrophotometric titration gave data which were scattered about a straight line instead of the expected sigmoid curve, and potentiometric titration was made impossible by the low solubility of protohemin between pH 4 and 6 (though the solubility seems to be higher than in the absence of alcohol).

* Sulfuric acid was exclusively used in order to avoid effects of halogen ions wich are so dramatically reflected in the Soret spectrum of aqueous acid hemin solutions (*cf.* Ref. [3]).

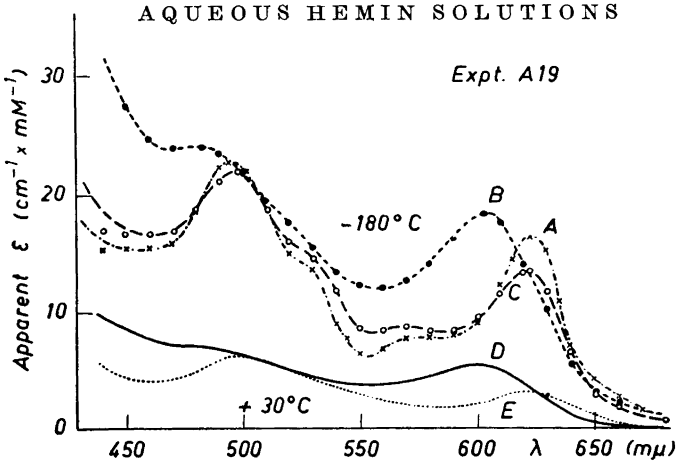

Fig. 6. The effect of temperature upon the absorption spectrum of protohemin. Three solutions were prepared, each containing 50 % ethanol. Solution A had 50 % 0.1 N H_2SO_4, solution B 0.1 N NaOH, and solution C 0.02 M phosphate buffer of pH 6.8. Small identical amounts of protohemin in 50 % alcoholic 0.05 N NaOH were added and the spectrum was measured using lucite cuvettes of 1 mm lightpath. D is the spectrum of alkaline protohemin-ethanol, and E that of acid protohemin-alcohol at room temperature. The "neutral" compound (in phosphate buffer) also showed spectrum D. The cuvettes were now chilled in liquid air, warmed up to about −55° and chilled again, as described by Estabrook and Mackler [13]. The resulting hemin spectra in solutions A, B, and C are plotted and marked in this order.

The influence of low temperatures on the spectra of protohemin-alcohol compounds was studied in co-operation with Dr. R. W. Estabrook of the Johnson Foundation *. Lucite cuvettes were filled with the hemin-ethanol solutions (50 % EtOH) and the spectrum recorded on the Yang and Legallais apparatus [3]. The cuvettes were then cooled in liquid air and the spectra recorded again, at about −180°. The details of this procedure are described elsewhere [13]. Low temperature treatment had two separate effects. One was a 3-fold intensification of the visible bands, without any significant shifts of the peaks as shown in Fig. 6. The other effect was a conversion of the alkaline type of spectrum to the acid type within a certain pH range. At pH 6.8 (0.01 M phosphate) and room temperature, the spectrum of the alkaline protohemin-EtOH compound was found. At the temperature of liquid air, the same solution showed an almost complete spectral conversion into the acid form (curve C in Fig. 6). An investigation of these phenomena (changes of K_w, hydratation etc. with temperature) lies outside the scope of these experiments.

Interaction of ethanol, hydroxyl ions, and cyanide ions with protohemin

In alkaline aqueous solutions, one hydroxyl group per iron atom is bound to protohemin, and the resulting compound is known as hematin. Hogness

* Measurements of spectra of biological material at low temperatures have been undertaken by Sinsheimer, Scott, and Loofbourow[14] and, for hemin compouns, by Keilin and Hartree[15] who used visual spectroscopy.

and coworkers [16] showed in 1937 that hematin in aqueous solutions forms dimers * and that cyanide ions are able to dissociate them according to eqn. (1):

$$Fe_2(OH')_2 + 4CN' \rightleftharpoons 2Fe\ (CN')_2 + 2OH' \qquad (1)$$

If ethanol is bound to the central iron atom, the former would be expected to interact with both CN′ and OH′ ions. Experiments were designed to study such interactions.

The spectrum of an aqueous solution of hemindicyanide in 25 mM borate buffer (pH 9.2) containing 2.5 μM of protohemin and 20 mM of KCN was measured in the presence and in the absence of ethanol. The effect of 50 % ethanol on the spectrum was very small, resulting in a shift of the Soret band from 425 to 427 mμ, whereas the position of the bands at 355 and 542 mμ ** remained unchanged. The bands increased in intensity, but this increase was at the most 13 %.

A protohemin solution in 50 % ethanol and 25 mM borate (pH 9.2) was titrated with KCN and the values obtained were found to lie on a theoretical dissociation curve with a dissociation constant of 1.6×10^{-3} and n = 2, when calculated for the reacting species, namely CN′. When the dissociation constant for hemin cyanide in aqueous solution is computed from the data of Hogness *et al.*[16] for this particular pH, a value of $K = 0.21 \times 10^{-3}$ is found. The dissociation constant is therefore about 8 times greater for alcoholic hemin cyanide than for hemin cyanide in water.

The extinction coefficient of alcoholic hemin solutions (50 % EtOH) was found to be independent of the protohemin concentration from 0.5 to 5.0 μM hemin at pH 1.0, and from 0.32 to 6.40 μM hemin at pH 7.0: Beer's law is valid within these limits. At pH 13 (0.1 M NaOH) it was found, on the other hand, that the extinction coefficient decreases with the concentration of protohemin, all other experimental conditions being held constant. The possibility was therefore considered that ethanol may depolymerize the hemin dimer molecules in a similar manner as cyanide does. The equilibrium of this reaction is then (*cf.* eqn. (1) and Ref.[16]):

$$K = \frac{[Fe_2(OH)_2]\ [EtOH]^4}{[Fe(EtOH)_2]^2[OH']^2} \qquad (2)$$

If the pH and the ethanol concentration are kept constant, we obtain:

$$K^* = \frac{[Fe_2(OH)_2]}{[Fe(EtOH)_2]^2}\ ;\ \text{equivalent to}$$

$$\log\ [Fe(EtOH)_2] = \log\ [Fe_2(OH)_2]^{\frac{1}{2}} - \tfrac{1}{2}\ \log\ K^* \qquad (3)$$

A plot of log $[Fe(EtOH)_2]$ *versus* log $[Fe_2(OH)_2]^{\frac{1}{2}}$ should thus give a straight line with a slope of 1 and an intercept of $-\frac{1}{2}$ log K.* Fig. 7 shows that the experimental data do lie on such a line.

---

* The assumption of dimeric hemin molecules is, however, not generally accepted, as will be discussed below.

** Hogness *et al.*[16] report the bands of aqueous hemin cyanide to lie at 365, 422.5, and 545 mμ, respectively.

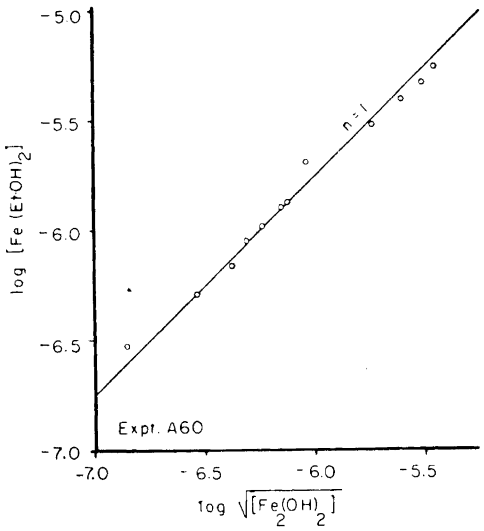

Fig. 7. A plot of the relationship of eqn. (3). While keeping the concentrations of ethanol and hydroxyl ions constant at 5.0 M EtOH and pH 13, the total hemin concentration was varied from 0.338 μM up to 2.35 μM and the resulting optical density measured at 402 mμ using cuvettes of 5.0 cm optical pathlength. The hemin concentration was further increased from 2.35 μM up to 17.25 μM and D_{402} measured in 1.0 cm cuvettes. From these data, a plot according to eqn. (3) was made. A straight line with the slope of 1.0 was located to give the best fit for the experimental data. The meaning of the formulas is explained in the text.

Magnetic susceptibility

The magnetic susceptibility of free hemins and hematins has been measured by several groups of workers. Hartree [17] has written an excellent review on the subject in 1946 and included magnetic data on hemoproteins. The magnetic measurements reported here were made in cooperation with A. Ehrenberg of the Nobel Medical Institute, using the highly sensitive Gouy balance of Theorell and Ehrenberg [5]. A stock solution of protohemin was prepared by dissolving 6.49 mg of the hemin in 0.60 ml of 0.03 N NaOH and adding 1.40 ml of ethanol to give 1.96 ml total solution of 5.08 mM protohemin. Of this stock solution 0.35 ml was added to 0.80 ml of 0.13 N H_2SO_4 in 67 % EtOH (v/v), and 0.35 ml to 0.80 ml of aqueous 67 % EtOH (v/v). The final concentration of hemin was thus 1.55 mM in each case. The molar magnetic susceptibility in the acid solution was found to be 12 400 ($\pm$250) $\times$ 10^{-6} c.g.s. e.m.u. at 20.5°. The alkaline solution gave 13 450 ($\pm$300) $\times$ 10^{-6} c.g.s. e.m.u. at 20.5°. These values correspond to 5.41 and 5.64 Bohr magnetons respectively and indicate an essentially ionic bond type with 5 unpaired electrons. The theoretical value for 5 unpaired electrons is 5.92 Bohr magnetons.

Alcohol compounds of deuterohemin

Deuterohemin IX, which differs from protohemin IX by the absence of the two vinyl groups in positions 2 and 4 of the porphyrin ring, gives compounds with ethanol very similar to those of protohemin. Spectrophotometric studies on deuterohemin are facilitated by the stability of its alkaline solutions. The study of alcohol binding was performed at two selected pH regions, pH 1 (0.1 N H_2SO_4) and pH 12 (0.01 N NaOH). The acid and alkaline alcohol compounds formed show distinct spectra, reproduced in Fig. 8. The alcohol compounds at intermediate pH values show either one or the other of these spectra as is the case with protohemin. The pH region at which the acid ethanol compound of deuterohemin changes into the alkaline one has not yet been ascertained because of complications brought about by the pronounced changes of the spectrum of deuterohemin in aqueous solution in the neutral pH region.

The titration data of deuterohemin at pH 1 and pH 12 show that in both cases 2 moles of EtOH are entering the hemin molecule, and that the dissociation constant is nearly the same, namely 0.46 M at pH 12 and 0.57 M at pH 1.

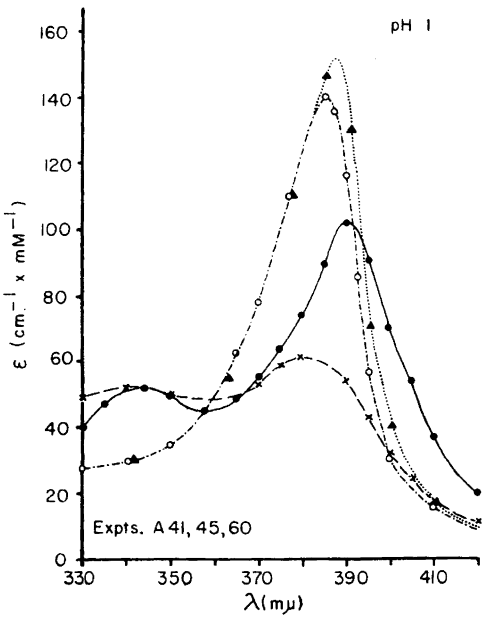

Fig. 8. The Soret spectra of deuterohemin and its alcohol compounds at pH 1 and pH 12. Small amounts of deuterohemin dissolved in 0.01 N NaOH and added to the solutions listed below gave the following spectra plotted in the figure:

O--O--O in 0.1 N H_2SO_4 of pH 1
▲···▲···▲ in 0.1 N H_2SO_4 containing 50 % EtOH
X---X---X in 0.01 N NaOH of pH 12
●—●—● in 0.01 N NaOH containing 50 % EtOH

The deuterohemin concentrations used were of the order of 10^{-5} M.

Table 1. Spectra and equilibrium constants of hemins in alcohol.

Hemin[a]	Alcohol[b]	pH[c]	λ(mμ)	ε[d]	λ(mμ)	ε[d]	λ(mμ)	ε[d]	pK[e]
Proto-	EtOH	1.0	398	131	504	6.0	627	2.5	−0.40
Proto-	EtOH	7.0	400	74	482	7.4	597	5.4	−0.75
Deutero-	EtOH	1.0	386	171	—	—	—	—	−0.59
Deutero-	EtOH	12.0	390	96	478	11.7	582	7.8	−0.46
Proto-	MeOH	7.0	396	73	—	—	—	—	−1.03

a) All hemins were of type 9.
b) EtOH stands for ethanol; MeOH för methanol.
c) The pH of the aqueous solution before adding alcohol.
d) All extinction coefficients were calculated from 50 % alcoholic solutions and have the dimension $cm^{-1}mM^{-1}$
e) The negative logarithm of the alcohol concentration (in Moles x $liter^{-1}$) at which half of the spectral change was observed.

Since the reproducibility of these constants was not better than 0.05 M, this difference can not be regarded as significant.

Table 1 gives a summary of the data on the alcohol compounds of protohemin and deuterohemin presented in this paper.

DISCUSSION *

Evidence for hemin alcohol compounds

The evidence for the formation of true alcohol compounds of hemin can be analyzed as follows: (i) The absorption spectrum of protohemin undergoes a pronounced change on the addition of 50 % ethanol. This suggests the formation of alcohol compounds of the hemin, though a change in the state of aggregation due to the change in solvent can not be excluded. (ii) At all pH values except in a critical neutral range, 2 moles of alcohol are needed to bring about the spectral change. Within the neutral pH range more than 2 alcohol molecules are needed per mole of hemin to convert them into alcohol compounds. Apparently the alcohol compounds can be formed only after some large aggregates of hemin molecules have been dissociated by the alcohol. (iii) The strict adherence to the deviations of Beer's law to a proposed mechanism of dimer splitting suggests that a stoichiometric reaction is involved. (iv) The possibility that an impurity in the alcohol might be the reacting species is excluded by the observation that methanol gives similar, but not identical compounds as ethanol, and that the use of ethanol from different sources gives identical results. (v) The fact that ethanol does not change the spectrum of aqueous hemin-dicyanide appreciably seems to indicate that the CN ions compete for the binding sites of the ethanol molecules. The magnetic data show clearly that the bond type of hematin in ethanol (5.64 B.M.) is different from that measured by Rawlinson [18] (3.62 B.M.) and by Hartree [17] (3.23 B.M.)

* The results of the preceding paper[3] are included in the discussion.

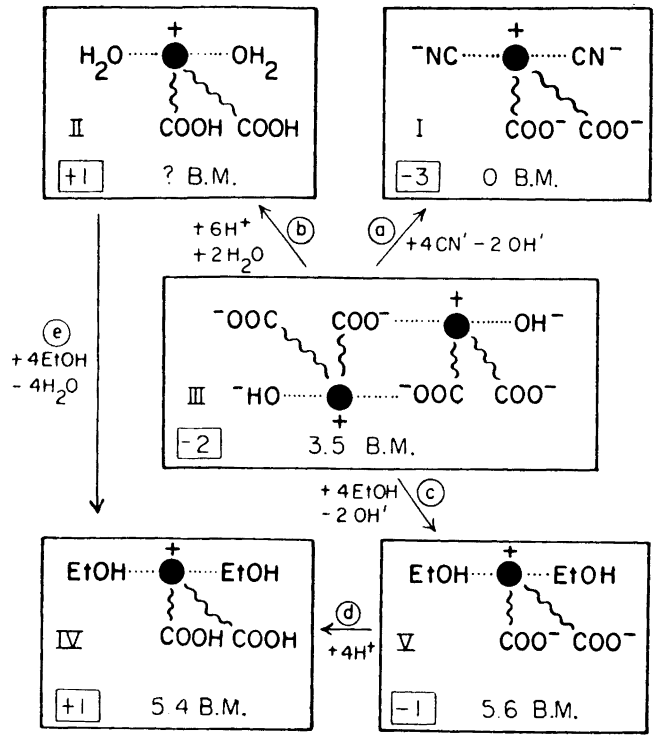

Fig. 9. The proposed reaction mechanism of protohemin with ethanol, cyanide and hydroxyl ions. The compounds are labeled thus (EtOH stands for ethanol):

I protohemin-dicyanide *
II protohemin compound B (acid hemin, *cf.* (3)) *
III protohematin (dimer)
IV acid protohemin-ethanol *
V alkaline protohemin-ethanol *

The hemin molecule is not shown as such. Only the central iron atom, marked by a solid circle, 2 of the total of 6 co-ordination places (4 are taken up by the 4 pyrrol nitrogens), and the 2 carboxyl groups of the propionyl sidechains appear in the formulae. The postulated overall charge is shown inside a small box. The paramagnetic susceptibility where known, is given in Bohr Magnetons (B.M.). The individual reactions are marked with small letters inside a circle. The iron remains in the trivalent state throughout.

of protohemin in aqueous NaOH. (vii) The fact that glycerol or sucrose do not change the spectrum of aqueous hemin solutions shows that the alcohol is not merely influencing the hydratation of the hemin molecule.

The dimer theory

The alcohol binding data lend further support to the theory that hematin forms a dimer in aqueous solution, since the deviation from Beer's law can be

* Two moles (to fit the stoichiometric relationships).

quantitatively explained on the basis of this assumption. The splitting of the dimer by alcohol is quite akin to the action of cyanide observed by Hogness *et al*[16]. The spectrophotometric observations of Davies [11] also fit the dimer theory.

The structure of the dimer as drawn in Fig. 9 (Compound III) was proposed by Lemberg and Legge [19]. It is assumed that the iron atom of each hemin molecule interacts with one of the propionyl groups of the other hemin molecule, thus leaving one of the six coordination places of each iron free for the binding of a hydroxyl ion. We constructed models of two hemin molecules, using the correct bond angles and degrees of freedom of the $-CH_2-CH_2-CO-O$-chain and found that a strainfree structure linking two molecules in the fashion discussed above could be obtained, with the porphyrin "disks" oriented in parallel planes. An additional bond between the iron atom of one hemin and the second propionyl group of the other hemin is sterically impossible.

The scheme outlined in Fig. 9 is suggested for the reactions of ferric protoporphyrin with ethanol, cyanide ion, and hydroxyl ion, although one must keep in mind that absolute proof for dimerization is still lacking.

The structure of hemin alcohol compounds

The suggested structure of alkaline hemin-ethanol (V of Fig. 9) is subject to some doubt due to the electrophoretic experiments of Haurowitz [9] which suggest a negative overall charge for the unesterified form of V. In order to account for it one can consider heptacoordination as suggested by Coryell and Stitt [20].

The transition from the alkaline to the acid form of hemin-ethanol seems to take place at around pH 5, though accurate measurements could so far not be achieved. The carboxyl ions of the propionyl side chains are the only obvious sites for the reception of hydrogen ions, unless heptacoordination is adhered to. This would also explain why only one spectral change could be observed within the pH range from 1 to 13.

Acid hemin compounds

Fig. 9 shows the formation of an acid hemin compound in aqueous solution (reaction b) where 3 protons and 1 H_2O are taken up by the hemin molecule. This overall reaction is composed of at least 2, but probably 3 or 4, steps. Starting from the alkaline range, the first change of spectrum and redox potential occurs between pH 7 and 8 (Mori [21] and Shack and Clark [1]).

The large spectral change taking place at around pH 1.5 has been described in the preceding paper [3], where it was also shown that this reaction does not involve the vinyl groups and that no removal of iron takes place. The compound B formed at very low pH by sulfuric, perchloric, or nitric acid reacts with halogen ions [3]. It incorporates one Cl′, the equilibrium being independent of the H^+ concentration, at least between pH 1—3 [3]. This reaction differs from that of acid cytochrome c, where Boeri *et al.*[22] had found that 2 Cl′ are taken up simultaneously and that the dissociation constant increases with

decreasing pH. The authors postulated that the Cl′ ions form a "bridge" between the positively charged Fe atom of the hemin and the —NH-groups of the imidazole rings that are believed to participate in the binding of the hemin to the apoprotein of cytochrome c. A similar effect in free hemin would only be possible if polymerization of the hemin molecules with the help of Cl′ bridges is assumed. The observed collapse of the high Soret band of acid hemins in the presence of increasing Cl′ concentrations makes this assumption not improbable.

The data so far obtained strengthen the hypothesis of Erdman and Corwin [23] that compound B represents the free ionized form of acid hemin, in contrast to "neutral" hemin, where negative ions of small radius (especially F′, Cl′, Br′, I′) are thought to move into one of the co-ordination places of the iron and are not dissociated appreciably in aqueous solutions. Erdman and Corwin could show that the spectra of hemin-chloride, -bromide, and -iodide in dioxane are not identical and that these compounds are essentially undissociated *.

There remains one phenomenon that is unexplained. It is not readily evident how the complexing of protohemin with ethanol is able to prevent the spontaneous changes that have been shown to occur in aqueous solutions. The experimental data show that the vinyl groups must be involved in the reaction, since the spectrum of deuterohemin in aqueous solution remains unaltered. It was also demonstrated that the process requires oxygen. It can be postulated that hemin catalyses its own oxydation and that it is the solvent action of alcohol that prevents this process.

Substituted Diphenyl-(2-pyridyl)-methanes

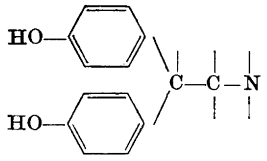
KURT RUBINSTEIN and JYTTE CHRISTIANSEN

Aktieselskabet Pharmacia, Research Division, Copenhagen — Vanløse, Denmark

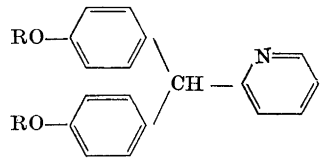
In order to gain further insight into the relationship between chemical structure and laxative activity three substituted diphenyl-(2-pyridyl)-methanes were prepared by condensing *p*-methoxyphenyl-2-pyridyl carbinol with phenol, *m*-cresol and *m*-chlorophenol, respectively.

In another approach to the synthesis of diphenyl-(2-pyridyl)-methanes from *bis*-(*p*-methoxyphenyl)-2-pyridyl carbinol the reactions took an unexpected course with the production of a new red-brown compound, the structure of which is discussed.

In the course of investigations on the relationship between chemical structure and laxative activity, Schmidt and Seeger [1] found the grouping I to be of particular importance for the attainment of laxative effect (*cf.* Ref.[2]). Recently, the substituted diphenyl-(2-pyridyl)-methanes, II—IV, were synthesized [3–6]; pharmacological evaluation demonstrated II and III to be very potent laxatives [1,2]. Again, laxative activity was reported for IV[3], yet without presentation of pharmacological data.



I



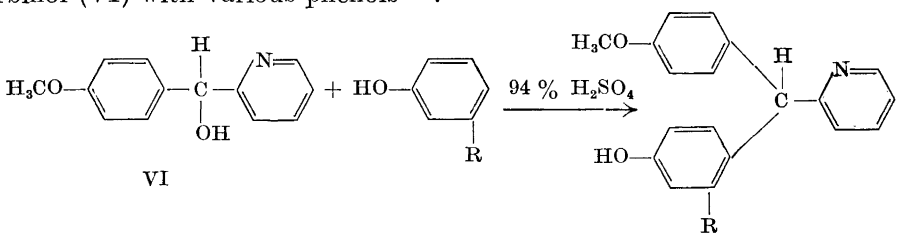
II, R = H
III, R = $COCH_3$
IV, R = CH_3

The dimethoxy compound IV has been reported as an oil [3,6]. In our hands, however, a sample of IV crystallized after having been stored in a closed vessel for some time. After recrystallization from petroleum ether the pure substance melted at 62—63°. Pharmacological evaluation showed IV to possess a laxative effect comparable to that of III.

Schultz and Geller [6,7] lately reported the surprising observation that IV on standing in an open flask at room temperature suffers hydrolytic cleavage to pyridine and *p,p'*-dimethoxybenzhydrol (V) (no m.p. or analytical data were presented), the latter claimed to possess high laxative activity. We have

not been able to detect any laxative activity of authentic V (m.p. 70—71°). The similarity in melting points of IV and V, however, leaves the identity of Schultz and Geller's active product open to discussion *.

In order to gain further insight into the relationship between chemical structure and laxative activity, a series of *p*-hydroxy-*p*'-methoxy-diphenyl-(2-pyridyl)-methanes were synthesized and pharmacologically evaluated. Previously reported methods for preparing substituted diphenyl-(2-pyridyl)-methanes [3–6] are limited to yielding compounds with identical substituents in the benzene rings. The present paper, however, reports a synthetic route to diphenyl-(2-pyridyl)-methanes, VII—IX, dissimilarly substituted in the two aromatic rings, *viz.* the condensation of *p*-methoxyphenyl-2-pyridyl carbinol (VI) with various phenols **.



VI

VII, R = H
VIII, R = Cl
IX, R = CH_3

When R = H it was found, as expected, that condensation took place at the *p*-position to the aromatic hydroxy group. This course of reaction was proved by transforming VII into the known *bis*-(*p*-hydroxyphenyl)-(2-pyridyl)-methane (II), which was, in turn, acetylated to its known diacetyl derivative *bis*-(*p*-acetoxyphenyl)-(2-pyridyl)-methane (III). In those cases where R = Cl and R = CH_3 it is believed that condensation proceeds analogously at the position located *para* to the hydroxy grouping.

The synthesis of VI from anisaldehyde and 2-bromopyridine by the Grignard reaction has been previously described [8]. It was found advantageous, however, to employ 2-pyridinealdehyde and *p*-bromoanisole as reactants in the Grignard synthesis, which under these conditions proceeded to give VI in a yield of 82 %.

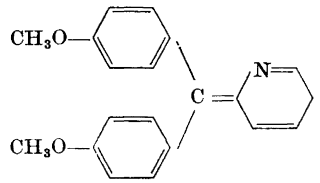
In another approach to the synthesis of diphenyl-(2-pyridyl)-methanes *bis*-(*p*-methoxyphenyl)-2-pyridyl carbinol (X), formerly synthesized from 2-pyridyl lithium and *p,p*'-dimethoxybenzophenone [9], was prepared from ethyl picolinate and *p*-bromoanisole by Grignard reaction. Attempted reduction of X with formic acid to give IV (*cf.* the synthesis of triphenyl methane by formic acid reduction of triphenyl carbinol [10]) resulted in the production of a red-brown compound (XI), m.p. 146°. Similarly, XI was obtained on attempted dealkylation of X with anhydrous aluminium chloride in carbon disulphide.

* *Note added in proof:* Schultz, O. E. and Schnekenburger, J. (*Arch. Pharm.* **291/63** (1958) 356) now report that the cleavage of IV to pyridine and V could not be reproduced. The product obtained was crystalline IV (m.p. 63—63.5°).

** Patent pending.

The observed diamagnetic properties of XI excluded its free radical character.

The alternative possibility of XI representing the 'double' molecule, 1,1,2,2-*tetrakis*-(*p*-methoxyphenyl)-1,2-*bis*-(2-pyridyl)-ethane, is ruled out by its colour as well as by a comparison of its infrared spectrum with that of IV. The absorption patterns indicate that the methoxysubstituted aromatic rings are retained in the coloured product whereas the pyridine moiety seems to be involved in the formation of a quinoid system. On basis of the available evidence a structure such as XII appears to be a likely proposal, compatible also with the cryscopically determined molecular weight. No further attempts have been made to substantiate the structure XII.



XII

EXPERIMENTAL *

bis-(p-*Methoxyphenyl*)-(*2-pyridyl*)-*methane (IV)*. IV was prepared according to Schultz and Geller [6]. After having been stored in a closed vessel for some time, IV crystallized. After recrystallization from petroleum ether the m. p. of IV was 62—63°. (Found: C 78.8; H 6.2; N 4.7. Calc. for $C_{20}H_{19}NO_2$ (305.4): C 78.7; H 6.3; N 4.6.)

p,p'-*Dimethoxybenzhydrol (V)*. V was prepared according to Bergmann and Hervey[11]. The m. p. of V was 70—71° (previously reported [11] 70—72°). (Found: C 74.0; H 6.6; OCH_3 25.4. Calc. for $C_{15}H_{16}O_3$ (244.3): C 73.8; H 6.6; OCH_3 24.9.)

p-*Methoxyphenyl-2-pyridyl carbinol (VI)*. Magnesium turnings (97.2 g, 4.0 moles) were placed in a 10 l three-necked flask fitted with a stirrer, dropping funnel and a reflux condenser protected by a calcium chloride tube. *p*-Bromoanisole (936 g, 5.0 moles), dissolved in anhydrous ether (2.4 l), was added in small portions until the reaction started and then, at such a rate (1.5 h) that gentle reflux was maintained. The reaction mixture was further heated under reflux for 2 h and cooled in an ice-salt mixture whereupon 2-pyridinealdehyde (214 g, 2.0 moles), dissolved in anhydrous ether (400 ml), was gradually added in the course of 1 h. Stirring was continued for another hour at room temperature. 4 N Hydrochloric acid (2.4 l), followed by conc. hydrochloric acid (800 ml), were added during 1 h to the cooled solution. The reaction mixture was left standing overnight, and the ether layer removed. The aqueous layer was further extracted with ether (2 × 800 ml) and then made alkaline by adding 15 % aqueous ammonia under cooling. The precipitate formed was removed by filtration and dried. The yield was 401 g (93 %) of crude VI, m. p. 128—131°. Crystallization from ethanol (3 l) gave 353 g (82 %) of VI as colourless crystals, m. p. 132—134° (previously reported [8] 133—134°).

p-*Hydroxy*-p'-*methoxy-diphenyl-(2-pyridyl)-methane (VII)*. VI (300 g, 1.4 moles) and phenol (329 g, 3.5 moles) were placed in a three-necked flask provided with stirrer and reflux condenser protected by a calcium chloride tube. Under cooling in an ice bath, 94 % sulphuric acid (210 g) was added with stirring. The reaction mixture was kept in

* All melting points are uncorrected. Microanalyses have been performed by Mr. P. Hansen, The Chemical Laboratory of the University of Copenhagen, and by Mr. W. H. Kirsten, University of Uppsala, Sweden.

the ice bath for 30 min, then at room temperature for 1.5 h and finally at 100° for 30 min. After cooling, 30 % sodium hydroxide (1.5 l) was added followed by water to at total volume of 8 l, whereby a clear solution was obtained. After extraction with ether (3 × 700 ml), the aqueous layer was neutralized with 50 % acetic acid. The precipitate formed was removed by filtration, washed with water, dried, and crystallized first from *iso*propyl alcohol (1 750 ml) and then from ethyl acetate (1 500 ml). The yield was 217 g (64 %) of VII (colourless crystals, m. p. 149—150°). (Found: C 78.2; H 5.8; N 4.8. Calc. for $C_{19}H_{17}NO_2$ (291.3): C 78.3; H 5.9; N 4.8.)

bis-(p-*Acetoxyphenyl*)-*(2-pyridyl)-methane (III)*. VII (1.94 g) was dissolved in a 35 % solution (15 ml) of hydrogen bromide in 90 % acetic acid and the reaction mixture heated under reflux for 3 h. After cooling, water was added and the reaction mixture neutralized under cooling with 2 N sodium hydroxide. An oil was formed, which soon crystallized. Filtration, washing and drying gave 1.82 g (98 %) of crude *bis*-(*p*-hydroxyphenyl)-(2-pyridyl)-methane (II) which, without further purification, was dissolved in a mixture of acetic anhydride (9.1 ml) and pyridine (3.6 ml). The reaction mixture was heated under reflux for 15 min, cooled and poured into water (90 ml). An oil was formed which soon crystallized. After filtration, the product was stirred with ice-cold 3 % sodium hydroxide, removed by filtration, washed with water and dried. The yield was 2.22 g (94 %) of crude III (m. p. 132—133°). Crystallization from ethanol (10 ml) gave 2.00 g (84 %) of III (almost colourless crystals, m. p. 133—134°, previously reported [6] 135—136°). The mixed m. p. of III and a specimen of *bis*-(*p*-acetoxyphenyl)-(2-pyridyl)-methane, prepared according to Schultz and Geller [6] (m. p. 131—132°), was 131—133°.

p-*Hydroxy*-o-*chloro*-p'-*methoxy-diphenyl-(2-pyridyl)-methane (VIII)*. VI (5.0) and *m*-chlorophenol (7.5 g) were condensed in 94 % sulphuric acid (3.5 g) for 2 h as described above for the preparation of VII. The crude product was crystallized twice from aqueous dimethyl formamide. The yield was 4.8 g (38 %) of VIII (colourless crystals, m. p. 220—222°). (Found: C 70.0; H 5.1; N 4.5; Cl 10.8. Calc. for $C_{19}H_{16}ClNO_2$ (325.8): C 70.1; H 4.9; N 4.3; Cl 10.8.)

p-*Hydroxy*-o-*methyl*-p'-*methoxy-diphenyl-(2-pyridyl)-methane (IX)*. VI (5.0 g) and *m*-cresol (6.3 g) were condensed in 94 % sulphuric acid (3.5 g) for 30 min as described above for the preparation of VII. The crude reaction product was boiled with ethanol (200 ml). After filtration, the filtrate was evaporated and the residue recrystallized from aqueous dimethyl formamide. Another crystallization from methanol gave 2.5 g (35 %) of IX as colourless crystals with m. p. 205—207°. (Found: C 78.0; H 6.5; N 4.5. Calc. for $C_{20}N_{19}NO_2$ (305.4): C 78.7; H 6.3; N 4.6.)

bis-(p-*Methoxyphenyl*)-*2-pyridyl carbinol (X)*. Magnesium turnings (19.3 g, 0.80 moles) were placed in a three-necked flask fitted with a stirrer, a dropping funnel and a reflux condenser with a calcium chloride tube, and a stream of dry, oxygen-free nitrogen was passed through the apparatus. *p*-Bromoanisole (148 g, 0.80 moles), dissolved in anhydrous ether (310 ml), was added during 1 h and the reaction mixture was then heated under reflux for 1 h. After cooling in an ice bath, ethyl picolinate (20.0 g, 0.13 moles) dissolved in anhydrous ether (60 ml) was added during 1.25 h, and the reaction mixture was allowed to stand at room temperature for 1 h. After cooling in an ice bath, 4 N hydrochloric acid (650 ml) was slowly added, the mixture was filtered, and the aqueous layer separated, washed with ether (2 × 100 ml) and made alkaline by adding 10 % aqueous ammonia. An oil separated which was extracted with a chloroform-ether mixture, the extract was dried with magnesium sulphate and evaporated in a vacuum. The oily residue (41.6 g) was dissolved in hot methanol (50 ml). Cooling and addition of a little water gave 27.7 g of crude X. After crystallization from methanol (50 ml) the yield was 20.9 g (49 %) of colourless crystals with m. p. 90—92° (previously reported [9] 90—91°).

XI. A mixture of X (1.00 g) and 99 % formic acid (15 g) was heated under reflux for 3 h. After cooling, water (15 ml) was added and the reaction mixture made alkaline by 2 N sodium hydroxide. A black oil formed which was extracted with benzene. After washing with water and drying with magnesium sulphate the benzene was distilled off in a vacuum and the residue (0.93 g) recrystallized from aqueous *iso*propyl alcohol. The yield was 0.75 g (79 %) of XI (red-brown crystals, m. p. 145—147°). Two further crystallizations from aqueous *iso*propyl alcohol furnished red-brown crystals, m. p. 146—147°. (Found: C 78.7; H 5.7; N 4.5; OCH_3 19.8. Calc. for $C_{20}H_{19}NO_2$ (305.4): C 78.7; H 6.3; N 4.6; OCH_3 20.4.)

XI was also obtained in the following experiment. A mixture of X (0.70 g), anhydrous carbon disulphide (20 ml) and anhydrous aluminium chloride (0.61 g) was heated under reflux for 7 h. After cooling, the reaction mixture was shaken with water and the organic layer dried with magnesium sulphate and evaporated in a vacuum. The residue (0.48 g) was recrystallized from aqueous *iso*propyl alcohol to yield 0.26 g (39 %) of XI as red-brown crystals, m. p. 145–147°. Two further crystallizations from the same solvent gave red-brown crystals, m. p. 146–148°. (Found: C 79.0; H 5.8; N 4.6; OCH_3 20.1.)

Magnetic measurements. On basis of determination of the magnetic susceptibility of XI at four different field intensities it was concluded that the compound was diamagnetic, a result excluding its character as a free radical.

Infrared spectra. The infrared spectra of XI and IV were determined in the solid state (KBr pellets) on a Perkin-Elmer double-beam spectrophotometer (Model 21 B).

The C–H stretching modes of the aromatic rings (3 040 cm^{-1}) and the CH_3O-groupings (2 840 and 2 950 cm^{-1}) were detectable in both compounds. Again, bands attributable to the aromatic ether C–O vibration (1 250 cm^{-1}) and the corresponding aliphatic stretching mode (1 025 cm^{-1}) were conspicuously present in XI and IV, yet possibly masked by pyridine bands in the latter compound. A strong C=C absorption band in IV at 1 608 cm^{-1} was substituted with a band at 1 620 cm^{-1} in XI, possibly assignable to a C=N stretching vibration such as would be expected from the structure XII. In the C–H-deformation vibration region the band complex at 750 cm^{-1}, expected from a 2-substituted pyridine moiety, was present in IV but lacking in XI. Both compounds displayed strong absorption around 800 cm^{-1} attributable to *para*-substituted aromatic rings.

Molecular weight determination. The molecular weight of XI was determined in camphor by the usual Rast method. (Found: 228. Calc.: 305.4.)

*Pharmacology.** III, IV, V, VII, VIII, IX and XI were evaluated orally in rats for laxative activity following a technique similar to that used by Schmidt [2]. In doses of 11 mg/kg/day, III, IV and VII displayed strong laxative effect. IX was less active, and even in doses of 76 mg/kg/day the effect was not maximal. VIII was without appreciable effect in doses of 76 mg/kg/day. V was found devoid of laxative activity in a dose of 126 mg/kg/day. XI was found without laxative effect in a dose of 45 mg/kg/day. On a dose of approximately 70 mg/kg/day the rats fed with XI died in 4–5 days.

Acknowledgment. We are grateful to prof. B. Bak and prof. A. Kjær, both of the Chemical Laboratory of the University of Copenhagen, for the recording and interpretation of the infrared spectra, and to Dr. B. Nygaard, of the same laboratory, for the magnetic measurements.

ACTA CHEMICA SCANDINAVICA 12 (1958) 1279—1285

The Equilibrium Constant of the System Ethanol, Aldehyde, DPN^+, DPNH and H^+

KARL-INGEMAR BÄCKLIN

Nobel Medical Institute, Biochemical Department, Stockholm, Sweden

The equilibrium constant for the ethylalcohol + DPN^+ ⇌ acetaldehyde + DPNH + H^+ reaction has been determined at different pH's, temperatures and ionic strengths, using yeast ADH as catalyst. At 20°C and ionic strength 0.1, K is found to be $0.801 \pm 0.014 \times 10^{-11}$ M in the pH range 7—10. The free-energy change for the reduction of DPN has been calculated by combining the experimental values with reliable free-energy data for alcohol and acetaldehyde. At 25°C and zero ionic strength, $\Delta F^\circ = 5.47$ kcal mole^{-1}. Calculation of the oxidation-reduction potential for the DPN—DPNH system gives $E'_o = -0.326$ V at pH 7, 25°C and zero ionic strength, which is in good agreement with recent data in the literature.

Some values have been reported previously for the equilibrium constant of the enzyme catalysed reaction

$$CH_3CH_2OH + DPN^+ \underset{ADH}{\rightleftharpoons} CH_3CHO + DPNH + H^+$$

By using a crude enzyme preparation from Lebedew juice, von Euler *et al.*[1] found the inverse equilibrium constant,

$$k = \frac{[DPN]\,[CH_3CH_2OH]}{[DPNH]\,[CH_3CHO]}$$

to have the value 0.73×10^4 at pH 7.6. As could be expected from the reaction formula, this constant was found to be strongly dependent on pH. Negelein and Wulff[2] using a crystalline preparation of yeast ADH, found the same constant to have the value 1.35×10^3 at pH 7.9 and 20°C. For the overall equilibrium constant

$$K = [DPNH]\,[CH_3CHO]\,[H^+]/[DPN^+]\,[CH_3CH_2OH]$$

Racker[3] found $K = 1.15 \times 10^{-11}$ at 25°C, the value being independent of pH throughout the range investigated. Theorell and Bonnichsen[4] determined K at low concentrations of liver ADH and found, on an average, $K = 0.86 \times 10^{-11}$ at 20°C over the pH range 7 to 10.

Because of the discrepancies between the values, which could be due to the influence of temperature and ionic strength, the value of K for the yeast ADH catalysed reaction has been determined at 20°C for the pH range 7—10 with $\mu = 0.1$; at different ionic strengths at pH 7 and 20°C and at different temperatures in the pH range 7 to 9 with $\mu = 0.1$. The effect of sodium chloride on K has also been determined.

MATERIALS AND METHODS

Yeast ADH was prepared according to the method of Racker [3] and recrystallized several times. Before use the enzyme was dialysed against the buffer. At pH 10, some loss of activity could not be avoided.

A commercial sample of DPN from the Sigma Chemical Company which was found to be 84 % pure was used.

All buffers ($\mu = 0.1$) were stabilized with Versene (0.001 M), phosphate being used at pH 7 and 8 and glycine-NaOH at pH 9 and 10.

The experiments were carried out in 1 cm Beckman cuvettes (3 ml), the temperature being controlled by water circulated from a thermostat through coils on both sides of the cell compartment of a Beckman DU spectrophotometer.

To a cuvette containing 2.8 ml of buffer, 0.1 ml of a dilute alcohol solution and 0.1 ml of a DPN solution, 5—10 μl of the enzyme solution were added with rapid stirring. The concentration of DPNH at equilibrium was determined by measuring the light absorption at 340 mμ. The molecular extinction coefficient [5] for reduced DPN was taken as 6.22×10^6 cm^2/mole.

The temperature dependence of K was determined by measuring the light absorption at 340 mμ and hence K first at 15°C, and then for each 5°C rise in temperature. It was thus possible to determine K in one and the same reaction mixture at all the temperatures. In order to prevent evaporation of the acetaldehyde, the cuvettes had to be covered with lids.

Corrections were made for the pH dependence on temperature of the different buffers [6]. These were checked in separate experiments.

The method unaccountably failed at pH 10, but gave good results from pH 7 to 9.

EXPERIMENTAL RESULTS

Varying pH. Temperature and ionic strength constant. Some of the experimental results for the pH range 7 to 10 (20°C, $\mu = 0.1$) are collected in Tables

1—4. As stated previously, K is seen to be independent of pH. An average value of $K_{20°, \mu=0.1} = 0.801 \pm 0.014 \times 10^{-11}$ M has been calculated from a larger number of experiments.

Varying ionic strength. pH and temperature constant. The results of these experiments, carried out in phosphate buffer (pH 7, 20°C) are summarized

Table 5. Equilibria at 20°C. Phosphate buffers of different ionic strengths at pH 7.0 and added sodium chloride.

[ADH] $\times 10^{-4}$	[EtOH] $\times 10^{-4}$	$[DPN]_{tot} \times 10^{-4}$	% Red	[NaCl]	μ	$K \times 10^{11}$
0.0062	1 062	0.398	35.2	—	0.096	0.801
0.0062	5 393	0.398	63.8	—	0.096	0.813
0.0062	5 393	0.398	59.8	—	0.050	0.736

0.0062	5 393	0.398	52.3	0.667	0.749	1.184

in Table 5. Fig. 1, where for a temperature of 20°C log K has been plotted against $\sqrt{\mu}$, shows that an increase of ionic strength causes an increase of K. Addition of sodium chloride also increases K in the same manner. Perhaps the increase of K is due to the effect of ionic strength on the activity coefficients of the reactants. Similar results have been reported by Burton and Wilson [7] for the malic dehydrogenase system.

Statistical analysis gave a regression line with a slope of 0.315 and an intercept of log $K + 12 = 0.8085$ at $\sqrt{\mu} = 0$, which corresponds to a value of $K_{20°, \mu=0} = 0.646 \times 10^{-11}$ M.

Varying temperature and pH. Ionic strength constant. The experimental results for the temperature dependence of K at different pH's when $\mu = 0.1$ are shown in Fig. 2, where $K_{\mu=0.1}$ has been plotted against $1/T$. The equation for the regression line is log $K = (1554/T) - 5.80$.

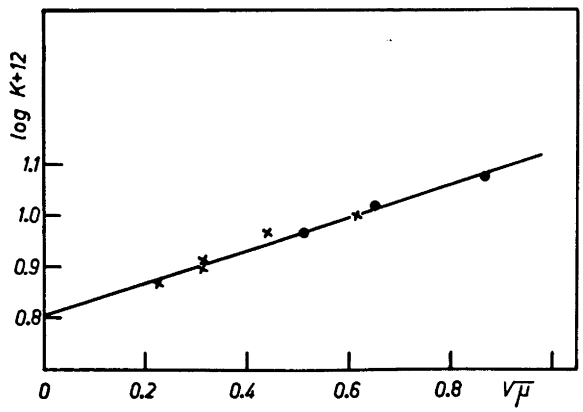

Fig. 1. Equilibrium constant, K, at varied ionic strength. Temp. 20°C; log $K + 12$ plotted *versus* $\sqrt{\mu}$; × phosphate buffers pH 7; ● added NaCl.

Table 6. $K \times 10^{11}$ at different temperatures, ($\mu = 0.1$), and the related thermodynamic constants

pH	Slope of the line	15°C	20°C	25°C	30°C	35°C	$\Delta H°$ kcal/mole	$\Delta S°$ cal/mole · degr.
7.0	−1.55	0.646	0.800	0.977	1.202	1.445	7.09	−26.6
8.0	−1.52	0.642	0.795	0.966	1.175	1.413	6.96	−27.1
9.0	−1.60	0.635	0.794	0.972	1.200	1.454	7.32	−25.8
Mean:	−1.55	0.641 ±0.005	0.796 ±0.004	0.972 ±0.006	1.192 ±0.020	1.437 ±0.020	7.13 ±0.20	−26.5 ± 0.7
$\Delta F°$ kcal/mole		14.76	14.89	15.02	15.16	15.29		

Table 6 gives the mean value of $K_{\mu=0.1}$ for different temperatures and pH's and the corresponding thermodynamic constants, obtained by applying the general formulas

$$\frac{d(\log K)}{d(1/T)} = -\frac{\Delta H°}{R \ln 10}; \quad \Delta F° + RT \ln K = 0; \quad \Delta H° = \Delta F° + T \Delta S°$$

from which

$\Delta H° = 7.13 \pm 0.20$ kcal mole^{-1} at $\mu = 0.1$
$\Delta S° = -26.5$ cal mole^{-1} degree^{-1} at $\mu = 0.1$
$\Delta F° = 14.89$ kcal mole^{-1} at 20°C (15.02 kcal mole^{-1} at 25°C) and $\mu = 0.1$

Extrapolation to zero ionic strength gives $\Delta F° = 15.01$ kcal mole^{-1} at 20°C (15.15 kcal mole^{-1} at 25°C).

Burton [8] has calculated that for the reaction

$$CH_3CHO\ (aq) + H_2\ (g) \rightleftharpoons CH_3CH_2OH\ (aq)$$

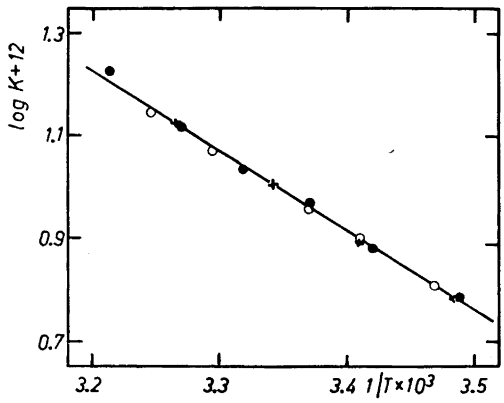

Fig. 2. Equilibrium constant, K, at different temperatures and pH's; $\mu = 0.1$. $\log K + 12$ plotted *versus* $1/T \times 10^3$; ● pH = 7; ○ pH = 8; × pH = 9.

$\Delta F^\circ = -9.68 \pm 0.4$ kcal mole^{-1} at 25°C. Combining this value of ΔF° with the above value of $\Delta F^\circ = 15.15$ kcal mole^{-1} gives for the reaction

$$DPN^+ + H_2 \rightleftharpoons DPNH + H^+$$

$\Delta F^\circ = 5.47$ kcal mole^{-1} ($\pm$ 0.4 kcal mole^{-1} according to Burton [8]) at 25°C and $\mu = 0$. This in turn gives $E'_0 = -0.326$ V ($\pm$ 0.008 V) as the value of the oxidation-reduction potential for the DPN — DPNH system at pH 7, 25°C and $\mu = 0$, calculated by using the formula

$$E'_0 = -\frac{\Delta F^\circ}{2F} - \frac{RT \ln 10 \text{ pH}}{2F}$$

DISCUSSION

Recalculating the value of the equilibrium constant reported by Negelein and Wulff [2] and correcting for the erronous molecular weight of DPN (N. and W. used 700 instead of 663) and molecular extinction coefficient of DPNH ($\varepsilon = 7.7 \times 10^6$ instead of 6.22×10^6 cm^2/mole), gives for a 50 % reduction of DPN, $K = 0.896 \times 10^{-11}$ M at pH 7.9 and 20°C. This value agrees with ours if they worked at an ionic strength of $\mu = 0.20$.

When recalculating the value reported by von Euler *et al.*[1], K is found to be $= 0.342 \times 10^{-11}$ M at pH 7.6. No temperature data are reported, but this value is certainly too low and would be still lower if recalculated [5] with $\varepsilon = 6.22 \times 10^6$ cm^2/mole instead of the value 4.05×10^6 cm^2/mole used by von Euler *et al.* The low value could be due to the crude enzyme preparation used.

Under the conditions of ionic strength (0.04) and temperature (25°C) used by Racker [3], K as calculated from our values should be $= 0.92 \times 10^{-11}$ M, the assumption being made that the influence of ionic strength on K is constant in the temperature interval 20—25°C. The value of $K = 1.15 \times 10^{-11}$ M reported by Racker [3] therefore seems to be too high, particularly as he used the higher value for the molecular extinction coefficient of reduced DPN ($\varepsilon = 6.28 \times 10^6$ cm^2/mole) reported by Ohlmeyer [9].

The value of $K = 0.86 \times 10^{-11}$ M at 20°C and $\mu = 0.1$ reported by Theorell and Bonnichsen [4] should be corrected for the protein concentration. If 50 % reduction of the 40 μM DPN used at a protein concentration of 0.004×10^{-4} M ($= 0.8$ μN) is assumed, $K = 0.83 \times 10^{-11}$ M which is close to the value found in this investigation.

The value reported here for the oxidation-reduction potential of the DPN—DPNH system is in good agreement with the value $E'_0 = -0.320$ V at pH 7 and 25°C recently reported by Burton [8] from investigations of the *iso*propanol-DPN-acetone system. Rodkey [10] has found, by potentiometric titration, the value $E'_0 = -0.318 \pm 0.001$ V at pH 7 and 30°C. The formerly accepted value for the DPN-DPNH potential (—0.282 V at pH 7 and 30°C) reported by Borsook [11] thus again seems to be too high.

Grateful acknowledgement is made to Professor Hugo Theorell for suggesting the present investigation and for his kind advice and criticism in connection with the work. The author is indebted to *Institutet för Maltdrycksforskning* for financial support.

Enzymatic Hydrolysis of Organophosphorus Compounds

VIII. Effect of Anions

KLAS-BERTIL AUGUSTINSSON

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

Molybdate and tungstate are markedly active in increasing the spontaneous hydrolysis of tabun. Among the 25 anions tested, chromate, metavanadate, perborate and selenite are also active in this respect, but less so than molybdate and tungstate. None of the anions influence the enzymatic hydrolysis of tabun by phosphorylphosphatase (prepared from human serum), except fluoride which is an inhibitor. The degradation products formed after treatment of tabun with molybdate do not inactivate cholinesterase. This enzyme is protected from inactivation by tabun when mixed with molybdate prior to addition of tabun.

The effect of metallic ions on phosphorylphosphatases was reported in a recent paper of this series [1]. The present report deals with the results obtained in studies of the effect of a variety of anions on both the enzymatic and spontaneous hydrolysis of dimethylamido-ethoxy-phosphoryl cyanide (tabun).

METHODS AND MATERIAL

The determination of hydrolysis rates, spontaneous as well as enzymatic, was carried out in a 0.04 M $NaHCO_3-CO_2$ buffer by the Warburg manometric technique at 25°C and pH 7.6 [2]. Hydrolysis rates were expressed in μl CO_2 evolved (b_{30}) or μmoles of substrate hydrolysed in 30 min. Tabun was used as substrate, and its concentration in the reaction mixture (total volume, 2.00 ml) was 5.3×10^{-3} M (*i. e.* 10.6 μmoles of tabun present).

The phosphorylphosphatase preparation was prepared from human serum, dissolved in the bicarbonate buffer, and dialysed free from other ions. The cholinesterase preparation was purified from human serum and was free from phosphorylphosphatase activity. Cholinesterase activity was determined in a Ringer bicarbonate buffer by the Warburg technique with acetylcholine iodide (3.3×10^{-3} M) as substrate.

In testing the effects of various anions, sodium and ammonium salts were used in most cases; the salt concentration in the reaction mixture during hydrolysis rate determinations was 1.0×10^{-3} M. The phosphorylphosphatase was incubated 50 min with the ions before the substrate (tabun) was added. The same incubation time was employed in iactivation experiments with cholinesterase, except as otherwise stated.

RESULTS

Effect of anions on the spontaneous hydrolysis of tabun. The effects of a number of anions on the rate of spontaneous hydrolysis of tabun are illustrated in Table 1. Most anions did not influence the hydrolysis rate in the concentration range tested. Perborate, selenite and thiocyanate increased the rate of hydrolysis, and still more active were chromate and metavanadate. Especially active in increasing the rate of spontaneous hydrolysis were tungstate and molybdate. The effect of molybdate ($Na_2MoO_4.2H_2O$) was such that the time required for 50 % hydrolysis of 10.6 μmoles of tabun under the experimental conditions used was decreased from 3h 40 min to 15 min by 20 μmoles of molybdate, and to 2 min by 100 μmoles.

Fig. 1 illustrates the effect of molybdate on tabun hydrolysis as a function of molybdate concentration, and Fig. 2 the graphical evaluation of first order reaction constants for the reactions in the absence and presence respectively of molybdate.

Table 1. Effect of anions (1.0 mM) on the spontaneous (non-enzymatic) and enzymatic hydrolysis of tabun. Enzyme: purified phosphorylphosphatase of human serum. Sodium salts used, unless otherwise stated.

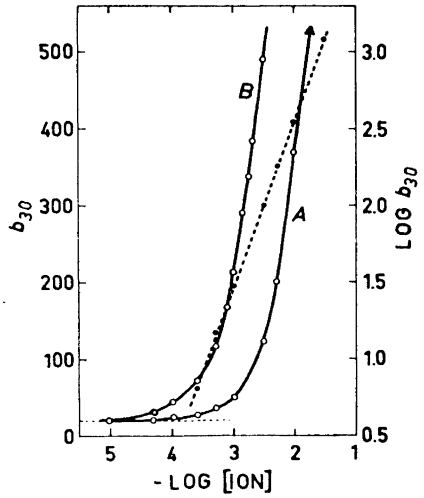

Fig. 1. Effect of molybdate on the spontaneous initial hydrolysis rate of tabun. Molar concentrations of anion are those in the reaction mixture (2.00 ml) during rate determination. A: $Na_2MoO_4 \cdot 2H_2O$; B: $(NH_4)_6[Mo(MoO_4)_6] \cdot 4H_2O$. The log curve (dotted line) refers to the effect of Na_2MoO_4 (log μl CO_2/30 min), corrections made for blank (no molybdate present).

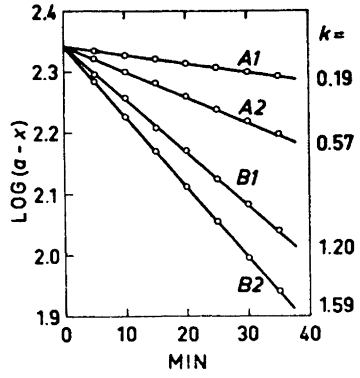

Fig. 2. Graphical evaluation of first order reaction constants for the spontaneous (A) and enzymatic (B) hydrolysis of tabun, in the absence (1) and presence (2) of 1.0 mM Na_2MoO_4. Note that the differences between the rate constants for the reactions taken part in the absence and presence of molybdate are the same (0.38 and 0.39 h^{-1} respectively).

It was found in previous reports that copper(II) salts accelerate the spontaneous hydrolysis of tabun [1] and di*iso*propoxy-phosphoryl fluoride [4]. Under the experimental conditions of the present investigation, 4 μmoles of $CuCl_2$ increased the initial rate of tabun hydrolysis by a factor of 2, in both the absence and presence of molybdate (Table 2). The effects revealed by Cu^{2+} and molybdate are therefore assumed to be purely additive, and a copper complex which might be particularly active, was not formed. Mixtures of $CuCl_2$ and molybdate with other ratios than that used in Table 2 gave similar results.

The spontaneous hydrolysis of tabun was inhibited by fluoride (Table 1). It was of interest to find out whether this effect was reflected in the cholinesterase inactivating effect of a tabun solution "stabilized" with fluoride. The

Table 2. Hydrolysis of tabun in the presence of mo ybdate and copper(II) chloride. Initial reaction rate expressed as μmoles of tabun/10 min.

10.6 μmoles tabun	0.3
+ 15 μmoles Na_2MoO_4	2.6
+ 4 μmoles $CuCl_2$	0.7
+ 15 μmoles Na_2MoO_4 + 4 μmoles $CuCl_2$	5.2
+ 2 μmoles ammonium molybdate	2.7
+ 2 μmoles ammonium molybdate + 4 μmoles $CuCl_2$	5.0

Table 3. Effect of fluoride on the cholinesterase inactivating effect of tabun. Tabun was incubated for 24 h in bicarbonate solutions with and without NaF (1 mM) at room temperature. The inactivating effect of these solutions was then measured and expressed in pI_{50} values [8]. A freshly prepared tabun solution was used as control ("No incubation"). Other experimental conditions, as in Table 4.

Incubation medium	No incubation	HCO_3^-	$HCO_3^- + F^-$
pI_{50}	7.80	6.35	6.95

experimental results of Table 3 show that this is the case. A solution of tabun in a bicarbonate buffer containing NaF was more powerful in inactivating cholinesterase than a bicarbonate solution without fluoride. The stabilization, however, was far from complete in this experiment, but the effect of fluoride in this respect was obvious.

Effect of anions on the enzymatic hydrolysis of tabun. Most of the anions studied did not influence the enzymatic hydrolysis of tabun by a purified phosphorylphosphatase preparation of human serum (Table 1). The results obtained with molybdate are illustrated in Fig. 2. Fluoride was an inhibitor, and weak inhibiting effects were obtained with hydrosulphide and thiocyanate. There was no marked acceleration of the enzymatic reaction in any case when the anions (2 μmoles) were added to the reaction mixture. The weak increase in the rate of enzymatic hydrolysis observed with borate, formate, persulphate, etc. may be due to complex formation with some enzyme inhibitor present in the preparation used.

The study was broadened with phosphorylphosphatases of other sources (swine kidney and liver). Anions did not have any significant effect on these enzymes either, except for calcium perchlorate which was a strong inhibitor of the kidney enzyme (93 % inhibition by 10^{-4} M $Ca(ClO_4)_2$).

Effect of molybdate on the cholinesterase inactivation by tabun. With the observation of strong increase in the spontaneous hydrolysis rate of tabun by molybdate, the effect of this and some other anions on the cholinesterase inactivation by tabun was studied. The results obtained are summarized in Table 4. Molybdate, in the concentrations used, did not influence the cholinesterase activity (Column 4). When cholinesterase was inactivated 85—95 % by tabun and molybdate was then added, no reactivation of enzyme activity was observed (Column 3). A tabun solution which had been treated for 30 min with molybdate prior to adding to the enzyme solution, did not inhibit cholinesterase (Column 6). It was also observed that the enzyme could be "protected" from inactivation by tabun when the enzyme was mixed with molybdate prior to addition of tabun (Column 5); compared with controls, complete protection was not achieved in the experimental series of Table 4. Complete protection, however, was obtained by using higher molybdate concentration. Similar results were obtained with ammonium molybdate. Sodium perborate which showed an accelerating effect on tabun hydrolysis (Table 1),

Table 4. Effect of molybdate and perborate on the cholinesterase (ChE) inactivation by tabun. Inactivator (tabun), 1.0×10^{-8} M (during incubation of ChE). Concentration values refer to the reaction mixture during enzyme activity determination, unless otherwise stated. Incubation time 30 min for reagents in brackets, followed by another 50 min incubation with salt or/and inactivator before addition of substrate. Activity expressed in b_{30} values.

		1	2	3	4	5	6
Salt	M	Control	(ChE + Tabun)	(ChE + Tabun) + Salt	(ChE + Salt)	(ChE + Salt) + Tabun	(ChE + (Tabun + Salt)
$Na_2MoO_4 \cdot 2H_2O$	1.0×10^{-3}	134	11.5	10.5	136.5	66	135
	5.0×10^{-3}	156	20.5	27.5	151.5	132.5	156.5
$(NH_4)_6[Mo(MoO_4)_6] \cdot 4H_2O$	7.5×10^{-4}	150.5	26	23	146.5	81	150
$NaBO_2$	1.0×10^{-4}	150	2.5	3	146	—	67

but less so than molybdate, also gave similar results vis-à-vis cholinesterase inactivation.

Effect of anions on the hydrolysis of sarin. Similar studies of spontaneous hydrolysis as those described for tabun were performed by Larsson [5] with sarin (methyl-*iso*propoxy-phosphoryl fluoride). Among the salts tested as catalysts with the gasometric technique, sodium perborate, sodium molybdate and calcium hypochlorite markedly accelerated the hydrolysis of sarin. Calcium hypochlorite was also active on some sarin analogoues and on parathion. The effect of calcium hypochlorite on the tabun hydrolysis was much lower. Generally, various organophosphorus compounds show differences as to the catalytic effect of various inorganic agents, cations as well as anions, on spontaneous hydrolysis.

DISCUSSION

An interpretation of the catalysing effect of a salt on the spontaneous hydrolysis of tabun (and other organophosphorus compounds as well) may be the formation of a labile complex with the organophosphorus compound. This likely is the explanation of the activation of hydrolysis rates caused by molybdate and tungstate, the complex formed being of unknown nature. The formation of such complexes with molybdate and other organophosphorus compounds [7] has been discussed.

The hydrolysis products of tabun do not inhibit cholinesterase [6,8] when present in concentrations lower than 10^{-3} M. The products formed in the molybdate catalysed reaction are also inactive as cholinesterase inhibitors, as demonstrated above. The fact that cholinesterase mixed with molybdate is protected from inactivation by tabun, the capacity of protection being dependent on the molybdate concentration, makes it likely that molybdate reacts directly with the phosphorus atom which is the site of the inhibiting compound that reacts with the active group of the enzyme molecule. The more this

atom is in the cationic state, dependent on the electrophilic strenght of the acid constituent of the molecule (CN in the case of tabun), the higher affinity does it have for the enzyme and also for molybdate. It is reasonable to regard the formation of an organophosphorusmolybdate complex as a sort of "model" reaction for that of the substrate-enzyme complex (*cf.* Ref.[4]).

In contrast to certain metallic ions [1], anions do not influence the enzymatic hydrolysis of tabun by phosphorylphosphatase. The enzyme activity is probably not dependent on the presence of SH-groups, for those agents which react with these groups do not inhibit the activity. The inhibiting effect observed with fluoride is probably due to a shift in equilibrium of the reactions in which cyanide is set free, the base-catalysed spontaneous reaction as well as the enzymatic hydrolysis reaction.

The kind interest shown this investigation by Professor Gustaf Ljunggren, Chief of the Research Institute of National Defence, Department 1, is gratefully acknowledged.

A Group Separation Method for Gamma Spectrometry of Complex Radionuclide Mixtures — with Special Application to Stainless Steel and its Corrosion Products

K. SAMSAHL

Nuclear Chemistry Laboratory, AB Atomenergi, Stockholm, Sweden

Short anion exchange columns coupled in series and saturated with chloride, citrate and hydroxide ions have been used for simple and very rapid separations of common elements in water solutions as a pretreatment for subsequent analysis with gamma spectrometry. A method was developed for the analysis of stainless steel, its corrosion products, and other elements, present as impurities in a water cooled nuclear reactor. Practical examples are described in detail.

With this method it seems possible to measure continuously water corrosion rates of individual or small groups of stainless steel elements.

Since the use of scintillation counters for gamma radiation was originally described by Bell and Cassidy [1], it has been shown that gamma spectrometry makes possible the identification and quantitative determination of gamma emitters in mixtures of radionuclides [2,3].

As most elements form radioactive gamma emitting isotopes on irradiation with thermal neutrons in an atomic reactor, gamma spectrometry has become a modern analytical tool of increasing importance.

Gamma spectrometric analysis of simple radionuclide mixtures can in many cases be carried out successfully without prior chemical separation of individual constituents. However, a coarse separation of the present elements in groups is often necessary or preferable. The presence in a sample of only minute amounts of common elements with extremely high activation cross section and hard gamma radiation, like sodium and manganese, giving rise to $^{24}_{11}$Na and $^{56}_{25}$Mn, can by Compton distribution partly or completely mask the activity of other elements. In many analyses the alkalies and alkaline earths constitute only interferring impurities without interest. A rapid and accurate anion exchange method for separating them from, as it seems, all other elements has been worked out. The method simultaneously allows the latter elements to be gathered in groups suitable for gamma spectrometry.

Samuelson and Schram [4] used an anion exchange column (as citrate) for separating alkali salts from various cations in a water solution. The use of anion exchange resins as solid precipitants and filters was suggested by Glueckauf and Roberts [5]. The present method makes use of these principles. The behaviour of different cations has been studied by flowing neutral water solutions through short anion exchange columns in the citrate- and the hydroxide form. An anion exchanger in the chloride form was also studied, in as much as metals like tungsten and molybdenum can be easily separated from many other elements as negatively charged ions by the chloride form after an initial HCl-H_2O_2 standard treatment of irradiated samples.

EXPERIMENTAL

The experiments were performed with irradiated metallic chromium, molybdenum and tungsten, and furthermore salts of the cations, Na^+, Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^+, Zn^{2+} and Sr^{2+}. The samples were individually brought into solution with hot 1:1 HCl containing a few drops of H_2O_2 and taken to dryness on a water bath. Subsequently they were dissolved in water and diluted to a suitable strength of gamma activity. Carriers were added in amounts of about 5 mg of the appropriate cation per 100 ml of solution. No carriers were added to the solutions of tungsten and molybdenum. Then 20 ml portions of a single gamma emitter solution were added to four ion exchange columns consisting of Dowex 2, 200—400 mesh in the citrate, chloride- and hydroxide form, and Dowex 50, 200—400 mesh in the hydrogen form. Each column consisted of 10 ml in water sedimented resin contained in a 2.5 cm diameter glass filter crucible. The active solutions were sucked through at a rate of about 4 ml/min and the columns washed with two five ml portions of water and drained by suction. Finally the crucibles were placed directly at definite geometry on the top of a gamma scintillation detector, and the activity assayed with a single channel pulse analyzer.

The activity of the Dowex 50 resin was measured and used as a standard for the estimation of the per cent absorbtion on the others. The eluate was controlled for possible gamma activity.

RESULTS AND DISCUSSION

The behaviour of the different ions on the ion exchange columns is summarized in Table 1.

The first column of the table illustrates the oxidation states of the elements after the initial HCl-H_2O_2 treatment.

The behaviour of hydrogen peroxide in acid medium can be advantageously utilized for the analysis of stainless steel elements, which is shown by a practical example further on. Besides its powerful solving and oxidizing action on many elements it will for example reduce possible higher valences of manganese to the divalent state and does not effect oxidation of trivalent chromium in hydrochloric acid. As a result chromium, if not initially present as chromate, and manganese can easily be quantitatively separated from other elements.

The molybdates and tungstates obtained by solution of the metals consist of many complicated compounds which do not seem to be very well known. Their partly retention on the Dowex 50 resin is probably due to the precipatation of the corresponding acids, as additional experiments showed that they were not or only to a very small extent adsorbed on a cation exchanger in Na^+ form.

Table 1.

Cation	% adsorbtion		Error < 5 %	
	Dowex 2 chloride	Dowex 2 citrate	Dowex 2 hydroxide	Dowex 50 hydrogen
Na^+	0	0	0	100
Mn^{2+}	0	0	100	100
Fe^{3+}	0	100	100	100
Co^{2+}	0	100	100	100
Ni^{2+}	0	100	100	100
Cu^{2+}	0	100	100	100
Zn^{2+}	0	50—70	100	100
Sr^{2+}	0	0	0	100
Cr^{3+}	0	0	100	100
Molybdates	100	100	100	30—70
Tungstates	100	100	100	30—70

The retention of Zn^{2+} on the citrate form was found to be 90 % if the final washing procedure with two 5 ml portions of water was omitted. Washing with about 100 ml of water caused a quantitative break through of the zinc activity.

PRACTICAL EXAMPLES

1. Stainless steel analysis

According to Table 1 a separation into three groups of common steel components is achieved by passing a water solution of the irradiated sample through three Dowex 2 columns subsequently in chloride-, citrate- and hydroxide form. Molybdenum and tungsten are quantitatively retained on the chloride form. Other elements pass through to the citrate resin, where iron, cobalt and nickel are adsorbed as complexed ions. Manganese and chromium, however, still pass through and are finally precipitated on the hydroxide form.

The practical arrangement is shown in Fig. 1. It consists of three identical glass filter crucibles attached to each other and to a suction flask by means of rubber rings.

Carriers of Ni^{2+}, Co^{2+}, Mn^{2+} and Cr^{3+} are added to the sample solution. An even flow rate of the active solution is obtained if the crucibles are filled with water before being attached to each other.

After drainage of the active solution the upper crucible is washed with water and removed for counting. The next one is then drained and treated in the same way, and so on.

Separation speed. The various resin forms are kept on stock under distilled water, and the whole separation procedure is finished about one hour after removal of the sample from the pile. The gamma spectrometric measurements of the first resin column in the series can start about 20 min earlier. However, a few experiments with stainless steel has been carried out by converting the sample to water soluble sulphates with a H_2SO_4-H_2O_2 treatment before irradia-

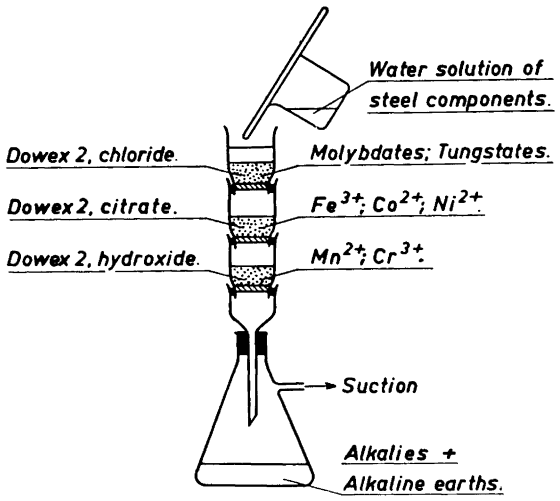

Fig. 1.

tion. The active material was directly dissolved in water and passed through the resin columns. The activity measurements could then start about 10 min after the end of irradiation. In this way it may be possible to analyze elements with short lived isotopes, like vanadium in steel and magnesium in aluminium alloys. However, the possible interferring influence on the separation of Szilard-Chalmers reactions has not been studied in detail.

Gamma spectrometric measurements. The single channel pulse analyzer used for the analysis has previously been standardized against known amounts of the various elements. The measurements are carried out in the usual way by writing spectra and following decays.

The separation procedure as now described is, however, not ideal for the gamma spectrometry of cobalt-containing steel. Because of the similar gamma radiation emitted from $^{60}_{27}$Co and $^{59}_{26}$Fe, which both are retained on the citrate form of the resin, their individual determination is difficult. The problem can, however, be easily solved by eluting the resin, extracting the iron with ether and again adsorbing the cobalt activity on an ion exchanger for comparative measurements.

The determination of small amounts of molybdenum in the presence of tungsten is best done after some days decay of the 24 hours $^{187}_{74}$W. Chromium in the presence of manganese is easily determined about one day after the end of irradiation.

2. Corrosion measurements

Some measurements of corrosion products in the heavy water of the Swedish R1 reactor has been carried out. 20 ml portions of D_2O were passed without pretreatment and addition of carriers through the same arrangement of resin

forms as used for the steel analysis, except that an additional Dowex 50 column in the hydrogen form was coupled after the resin in the hydroxide form for the control of the adsorbtion efficiency of the others.

About 20 ml of each resin form were used and the D_2O samples passed through at a rate of about 3 ml/min, owing to the extremely small salt concentration in the heavy water, which is continuously demineralized in the external reactor system.

The measurements started 30 min after the end of irradiation. $^{187}_{74}W$ was found only on the chloride form and $^{56}_{25}Mn$ on the hydroxide form, just as in steel analysis. $^{64}_{29}Cu$ had been quantitatively retained on the citrate form. The cation exchanger, ending the series, showed only a clean $^{24}_{11}Na$ spectrum. The eluate was inactive. Although in all cases the separation of various elements seemed to be quantitative, this is difficult to state definitely, due to the very small amounts of activities present in a sample. However, there is reason to believe that the separation method described may be of some value for the continuous control of individual- or groups of water corrosion products in a nuclear reactor, and for material testing experiments.

CONCLUSIONS

From the practical examples given, in addition to a lot of other cases, it appears that the present group separation method used in connection with gamma spectrometry, is very helpful for the identification and quantitative determination of many elements. Because of the simplicity of the method, and also its rapidity it has been adopted as a routine procedure in this laboratory. However, it may also exist many possibilities to prepare the anion exchange resin in other forms, *e.g.* sulphide, sulphate, carbonate, fluoride *etc.* to allow more advantageous separations in many practical cases.

The Structure of Hexagonal Mercury(II)oxide

KARIN AURIVILLIUS and INGA-BRITT CARLSSON

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden; Joint Establishment for Nuclear Energy Research, Kjeller, Norway

The crystal structure of hexagonal mercury(II)oxide has been determined by means of X-ray and neutron diffraction methods. The symmetry is $P3_121$ (No. 152) or the enantiomorphous symmetry $P3_221$ (No. 154). The structure is built up of infinite spiral chains $(-O-Hg-)_n$ running parallel to the c axis of the hexagonal unit cell. Within the chains, the Hg-O distance is 2.03 ± 0.02 Å and the angles O—Hg—O and Hg—O—Hg are 176° ± 3° and 108° ± 2°, respectively. The structure is analogous to that of hexagonal mercury (II) sulphide (cinnabar).

In addition to the well-known orthorhombic modification of mercury(II) oxide, the structure of which was reported in a previous article [1], another form of hexagonal symmetry was recently described by Laruelle [2]. The crystal structure of the latter has now been determined by means of X-ray and neutron diffraction methods.

PREPARATION AND ANALYSIS

The hexagonal modification of mercury(II)oxide was synthesized according to Laruelle[2] by adding sodium hydroxide to a solution of K_2HgI_4, containing an excess of KI. The experimental conditions, such as concentrations and temperature, were varied within wide limits. The best method for preparing a pure sample of hexagonal mercury(II) oxide was to mix one part of 0.1 M K_2HgI_4, containing an excess of 0.025 M KI, with two parts of 5.5 M NaOH or KOH at about 50°C and to keep the solution at this temperature for about 100 h. The purity of the sample was checked by means of X-ray powder photographs. Identical preparations were also obtained by substituting rubidium or caesium for the potassium or sodium ions. It was, however, not possible to prepare hexagonal HgO from a solution of Li_2HgI_4, LiI and LiOH, probably because of the relatively low solubility of LiOH. The hexagonal modification mostly crystallized in spherical conglomerates of extremely small red crystals but sometimes it sedimented as a yellow powder. The preparations were not always pure but were sometimes mixed with orthorhombic mercury(II)oxide or with other phases probably containing alkali. Occasionally, red transparent plates appeared. They were always found to be built up of both hexagonal and orthorhombic mercury(II)oxide.

The pure sample described above was analysed for Hg, Na, K, I and H_2O and was found to contain neither alkali, iodine nor water. The result of the mercury analysis performed using electrolysis was 92.1 % in fair agreement with the value of 92.6 % calculated for HgO.

CELL DIMENSIONS AND SYMMETRY

The powder photographs were taken in a Guinier focussing camera of 80 mm diameter using monochromatic Cu$K\alpha_1$ radiation and potassium chloride (a = 6.2930 Å) [3] as an internal standard. The powder pattern is given in Table 1. Amply exposed photographs (3 h) did not show any lines that were

not visible in normally exposed ones (1 h). The powder pattern could be interpreted by means of a hexagonal unit cell with the cell dimensions:

$$a = 3.577 \text{ Å} \qquad c = 8.681 \text{ Å} \qquad V = 96.2 \text{ Å}^3$$

The observed density 11.0 indicates a cell content of 3 formula units of HgO (calculated density 11.2).

The only crystals that were large enough for single crystal studies with the equipment available were obtained from samples containing both forms of the oxide. Several crystals were investigated and found to be composed of individuals of both modifications. However, a Weissenberg photograph was finally taken, registering both the reflexions $h0l$ of hexagonal HgO and $hk0$ of orthorhombic HgO.

The only systematic extinction found in the powder and Weissenberg diagrams of hexagonal HgO was $00l$ absent for $l \neq 3n$, which is characteristic of the space groups $P3_112$ (No. 151), $P3_121$ (No. 152), $P3_212$ (No. 153) and $P3_221$ (No. 154). Because the unit cell contains 3 formula units of HgO, both the mercury and oxygen atoms must occupy threefold point positions 3(a) and/or 3(b). Since the (a) and (b) point positions only differ with respect

Table 2. Observed X-ray intensities *hkl* from the powder sample of HgO examined with a Geiger-Mueller diffractometer. The intensities are calculated: I) for the mercury atoms only, neglecting the influence of the oxygen atoms; II) for both the mercury and oxygen atoms. In each case, I_{calc} was normalized so as to give the best agreement with I_{obs}. A correction factor for each reflexion was taken from a curve where log I_{obs}/I_{calc} was plotted against $\sin^2\Theta$.

to the choice of origin, 3(*a*) was arbitrarily chosen as the site of the mercury atoms. For these point positions, the two groups with enantiomorphous symmetry ($P3_121$ and $P3_221$) and ($P3_112$ and $P3_212$) differ with respect to the structure amplitudes of the reflexions *h*0*l* and *h*0$\bar{l}$, which are different for the former but assume identical values for the latter space-groups. Actually the intensities I_{h0l} differed from $I_{h0\bar{l}}$, as judged from the Weissenberg diagram, which suggested the symmetry to be $P3_121$ (or $P3_221$) in accordance with the data given by Laruelle [2]. Due to the composite character of the crystal, which was likely to give rise to serious absorption effects, this observation could not be considered conclusive. By means of neutron diffraction data (*v. infra*), however, it was possible to confirm the symmetry.

THE POSITIONS OF THE MERCURY ATOMS

Accurate values for the intensities of the X-ray powder reflexions were obtained by means of a Hilger Y 115 G.M. diffractometer, using Cu$K\alpha$ radiation. The sample was carefully ground and mounted in a cavity in an aluminium holder and the specimen was adjusted to the reflexion position. The intensities of the diffraction peaks were measured at counter intervals of 1°/60 scattering angle. The observed intensities obtained by measuring the areas under the peaks are given in Table 2. For overlapping reflexions, the sum of the intensities is given.

In the following the structure will be discussed in terms of the symmetry $P3_121$. The parameter value x for the mercury atoms in 3(a) was derived by trial and error, the best accordance between calculated and observed intensities being obtained for $x = 0.745$ (*cf.* Table 2).

THE POSITIONS OF THE OXYGEN ATOMS

The difference between mercury and oxygen in their scattering power for X-rays is considerable and this made it impossible to locate the latter from the observed intensity data. The relative scattering powers of the two elements for neutrons are much more favourable.

	Scattering amplitude[4] *(10^{-12} cm)*	
	Neutron	X-ray ($\Theta = 0°$)
Hg	1.31	22.5
O	0.58	2.25

The amplitude values for neutrons are independent of the scattering angle, while those for X-rays decrease with Θ and relatively more so for oxygen than for mercury.

The neutron diffraction work was carried out on a powder sample in a flat aluminium container. The reactor was run at a level of 450 kW. The diffracted intensity was measured at intervals of 0.2° scattering angle, counts being taken during the time necessary for accumulating 200 000 neutron counts from the monitor in the incident monochromator neutron beam. The appearance of the curve obtained by plotting the counts against the angles is given in Fig. 1. The observed intensities, obtained by measuring the areas under the peaks with a planimeter and corrected for the small contribution of the intensities of the aluminium reflexions 111 and 200 from the container, are given in Table 3. Due to serious overlapping, the intensities of reflexions at higher Θ angles could not be evaluated.

From space considerations, it was found that both mercury and oxygen atoms cannot occupy the same point position (3(a)) since this would give mercury-oxygen distances shorter than $a/2 \sim 1.8$ Å. The only point position left for the oxygen atoms is thus 3(b). Systematic variation of the parameter for the oxygen atom position gave the best agreement between observed and calculated intensities when x_o was equal to 0.46 (Table 3). The neutron intensities of the reflexions were calculated according to Bacon[4], the temperature factor, however, being neglected. (The R index for the data given in Table 3 was found to be 0.7 %. This means, of course, that the agreement is good

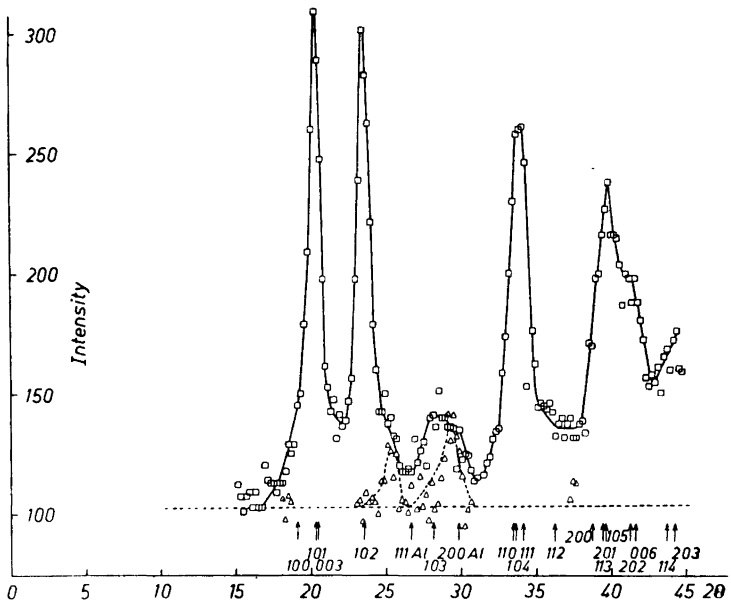

Fig. 1. Neutron diffraction powder diagram of a sample of hexagonal mercury(II) oxide in an aluminium container.

Table 3. Observed neutron intensities from a powdered sample of HgO in a flat aluminium container. The reflexions 102 and 103 are corrected for the small contributions of the aluminium reflexions 111 and 200. The calculations are made according to Bacon [4]. No correction was made for thermal vibrations. The value μt was found by measurement to be 1.23. The intensities are calculated: I) for the mercury atoms only, neglecting the influence of the oxygen atoms; II) for both the mercury and oxygen atoms. In each case I_{calc} was normalized so as to give the best agreement with I_{obs}.

but the small number of reflexions implies that the R index is lacking in statistical significance.)

The X-ray intensities of the reflexions *hkl* were now recalculated, the influence of the oxygen atoms being also taken into account (*cf.* Table 2 and Fig. 2). In this way the agreement between calculated and observed intensities was improved. (The R index for the data given in Table 2 was thus found to decrease from 16.3 % to 13.0 %.)

DESCRIPTION OF THE STRUCTURE

The following structure for the hexagonal modification of mercury(II) oxide has been arrived at:

Cell content: 3 HgO.
Symmetry: $P3_121$, No. 152 or $P3_221$, No. 154.
Space-group $P3_121$; 3 Hg in 3(*a*): $x0\frac{1}{3}$; $0x\frac{2}{3}$; $\bar{x}\bar{x}0$ $\quad x = 0.745$
3 O in 3(*b*): $x0\frac{5}{6}$; $0x\frac{1}{6}$; $\bar{x}\bar{x}\frac{1}{2}$ $\quad x = 0.46$

The structure is built up of infinite spiral chains, $(—O—Hg—)_n$, running parallel to the c axis of the hexagonal unit cell (*cf.* Figs. 3 and 4).

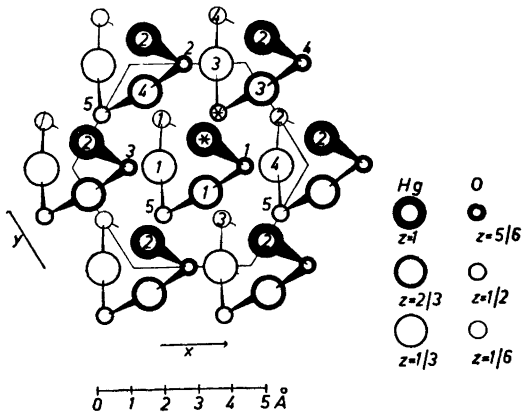

Fig. 3. Projection parallel to [00*l*] of the structure of hexagonal mercury(II) oxide. The diagram shows the coordination of the atoms. The large circles indicate mercury atoms and the smaller ones oxygen atoms.

Every mercury atom (*e.g.* Hg *, $(\bar{x}\bar{x}0)$ in Fig. 3) is surrounded by:

2	O	(1)	at 2.03 ± 0.02 Å
2	O	(2)	2.79 ± 0.02 Å
2	O	(3)	2.90 ± 0.03 Å
2	Hg	(1)	3.30 ± 0.02 Å
6	Hg	(2)	3.58 Å = a
4	Hg	(3,4)	3.72 ± 0.02 Å

The oxygen atoms around each mercury form a greatly distorted octahedron.
Every oxygen atom (*e.g.* O *, $(\bar{x}\bar{x}\frac{1}{2})$ in Fig. 3) is surrounded by:

2	Hg	(3)	at 2.03 ± 0.02 Å
2	Hg	(4)	2.79 ± 0.02 Å
2	Hg	(1)	2.90 ± 0.02 Å
2	O	(4)	4.06 ± 0.04 Å
6	O	(5)	3.58 Å = a
4	O	(1,2)	3.41 ± 0.02 Å

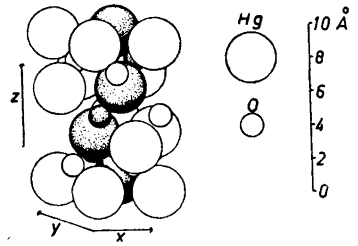

Fig. 4. Diagram showing the spiral chain $(-Hg-O-)_n$ which extends parallel to the *c* axis of hexagonal mercury(II)oxide.

The angles within the chains are:

Hg — O — Hg	108° ± 2°
O — Hg — O	176° ± 3°

The Hg—O distance found within the chain and the bond angles are nearly the same as those found in the planar zig-zag chain of orthorhombic mercury(II) oxide [1]. Thus, for the hexagonal modification, it can also be suggested that the bond between the Hg and O atoms within the chain is mainly homopolar. The forces between the chains are far weaker since the interatomic distances are considerably larger than those within the chains. It is probable that the chains support each other by means of these Hg—O contacts.

A comparison between the structures of hexagonal mercury(II)oxide and hexagonal mercury(II)sulphide (cinnabar [5]) indicates that these compounds are isostructural.

These studies form part of a research program on metal oxides and fluorides financially supported by the *Swedish Natural Science Research Council.*

The authors wish to thank Professor A. Ölander for his kind interest in this work. The authors are also much indebted to Dr. A. Magnéli for very valuable discussions. Thanks are also due to Dr. J. A. Goedkoop, head of the Neutron Physics Department of the *Joint Establishment for Nuclear Energy Research*, Kjeller, Norway, for his kind hospitality and for very valuable help in the neutron diffraction work. The Hilger Y 115 G.M. diffractometer was kindly placed at our disposal by Messrs. Bergman and Beving AB, Stockholm.

The Ionization Constant, Solubility Product and Solubility of Lauric and Myristic Acid

VERA NYRÉN and ERNST BACK

Paper Technology Department, Swedish Forest Products Research Laboratory, Stockholm, Sweden

The ionization constant (K_S), solubility product (K_L) and solubility of lauric and myristic acid at 20°C have been determined simultaneously from potentiometric titrations of their aqueous sodium salt solutions according to the method of Back and Steenberg. Measurements were carried out at soap anion concentrations ranging from below the concentration of limited ion association to above the critical concentration for micelle formation. The data obtained support the conception of Ekwall that limited soap anion association starts at a well defined concentration.

Below this concentration of limited ion association the following electrolytic constants were obtained. For lauric acid: $pK_S = 5.3$; $pK_L = 10.0$, and L, the solubility of unionized acid, $= 2.3 \times 10^{-5}$ moles/litre. For myristic acid: $pK_S \leq 6.3$; $pK_L = 11.5$, and $L \leq 0.6 \times 10^{-5}$ moles/litre.

Data published on the ionization constant and the solubility in water of higher fatty acids are scarce and of insufficient mutual agreement. This is due to experimental difficulties arising in consequence of both the low solubility of these acids and the low concentration at which their anions start to associate.

Ionization constants of fatty acids have been obtained by extrapolation from lower, more soluble homologues [1,2], by recalculation of pH measurements in water-ethanole mixtures [3,4] and by pH measurements in dilute solutions of neutral sodium salts [5]. In a recent review Ekwall [6], referring to unpublished measurements, has indicated the apparent change in the ionization constant of lauric acid with soap concentration due to ion association and thereupon following micelle formation. Reported solubilities of fatty acids have been determined using conductivity measurements [7] or conductometric titration [8,9] of fatty acids in saturated water solutions.

Here the method of Back and Steenberg [10] for simultaneous determination of both the ionization constant, the solubility product and the solubility of the unionized protolyte by single potentiometric titrations has been used. Measurements were carried out with sodium laurate and sodium myristate

solutions at concentrations ranging from above the critical concentration for micelle formation (CMC) to below the concentration of limited ion association (LAC).

EXPERIMENTAL

Purissimum Lauric acid (of St. Just) with a melting point of 42.4°C and myristic acid (of Eastman Kodak) with a melting point of 52.5°C have been used. Sodium salt solutions were prepared by dissolving the acid under nitrogene atmosphere in 0.1 N sodium hydroxide, added in an excess of about 3–5 %. Distilled water and sodium hydroxide solutions had been freed from carbon dioxide by passing a weak anion exchange resin column. After dilution the soap solutions were titrated with 0.02 and 0.002 N hydrochloric acid under nitrogene atmosphere using a magnetic stirrer and a low alkaline error glass electrode, a saturated calomel electrode and a vacuum tube voltmeter. The pH meter was calibrated at pH values 4.00, 6.88 and 9.22 using freshly prepared standard buffers of respectively, potassium hydrogene phtalate [11], an equimolar mixture of monopotassium phosphate- and disodium phosphate [12] and sodium tetraborate [13]. All titrations were carried forward beyond the second equivalence point. To prevent interference of carbon dioxide, the soap solutions prepared had to be transferred rapidly into the titration vessel. Thus, it was decided to determine the total amount of sodium soap titrated from the two equivalence points of the titration curve. These equivalence points were determined using the method of Gran [14]. At checking points during the titration, at which a fresh liquid junction was desirable at the saturated potassium chloride and the soap solution interface, the calomel electrode was removed before releasing some potassium chloride. Measurements were performed at 20° ± 1°C.

Activity coefficients of soap anions were estimated according to the simplified Debye-Hückel equation, and were used in the calculation of ionization constants and solubility products. For calculation of the ionization constant only titration points down to a pH value corresponding to the solubility limit of unionized acid were employed. A few titration points close to the equivalence point also were disregarded because of the very low buffering capacity at these points. Yet within a single titration there appeared a slight downward trend in the ionization constants calculated, when carrying forward the titration with hydrochloric acid. Thus in Figs. 1 and 2 most titrations are represented by a line connecting the lowest and highest value of the ionization constant calculated.

At very low soap concentrations the accuracy of the titration method naturally falls off. Thus only soap solutions exceeding 0.0004 M were employed. At concentrations considerably exceeding the critical concentration for micelle formation, the equilibrium pH was reached extremely slowly, thus lowering the accuracy of the results.

RESULTS

The ionization constant, K_s, the solubility product, K_L, and the solubility of unionized acid, L, all are calculated according to the method of Back and Steenberg [10] assuming the simple equilibrium conditions

$$K_s = \frac{a_{H_3O^+} \cdot a_{A^-}}{a_{HA}} \tag{1}$$

and

$$K_L = a_{H_3O^+} \cdot a_{A^-} \tag{2}$$

to be valid. The fatty acid anion activity $a_{A^-} = f_{A^-}\, c_{A^-}$ is calculated from the total concentration, c_a, of titrand HA and A^- and from the concentration of titrator added in excess of the neutralization point, c_s, according to

$$c_{A^-} = c_a + c_{H_3O^+} - c_s - c_{OH^-} \tag{3}$$

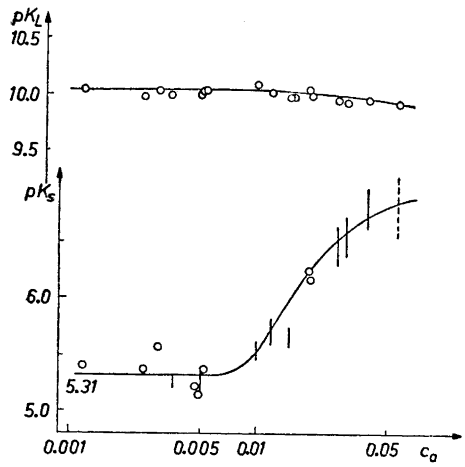

Fig. 1. pK_s and pK_L of lauric acid at 20°C *versus* the total titrand (soap) concentration c_a in moles/litre at the neutralization point.

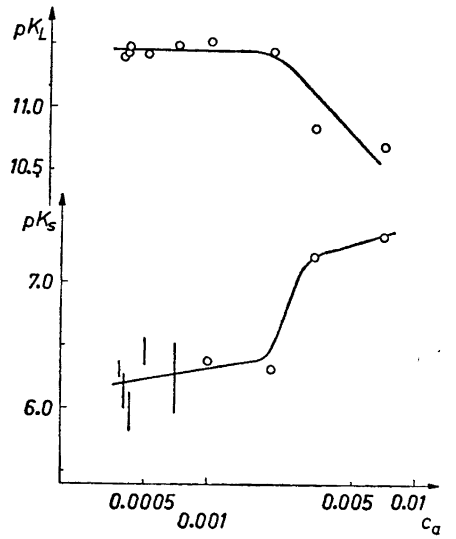

Fig. 2. pK_s and pK_L of myristic acid at 20°C *versus* the total titrand (soap) concentration c_a in moles/litre at the neutralization point.

Correspondingly c_{HA} is obtained as

$$c_{HA} = c_s + c_{OH^-} - c_{H_3O^+} \quad (4)$$

If due to formation of micelles or associated ions eqns. (3) and (4) or eqn. (2) are not valid, the constants calculated naturally represent pseudoconstants only.

Ionization constants. The lower part of Figs. 1 and 2 presents the pK_s values *versus* the total titrand concentration c_a at the neutralization point, using a logarithmic scale.

A general agreement exists between these results for fatty acids and those of Ekwall, Rosendal and Löfman for bile acids [15] as well as the preliminary data of Ekwall for lauric acid [6]. As obvious from the data in Fig. 1 for lauric acid, the pK_s values are independent of the total titrand concentration at the neutralization point as long as this concentration is low enough. The slight upward trend in pK_s within a single titration, which might indicate complex formation between fatty acid anion, and unionized fatty acid here also appears negligible. It seems justifiable to consider the corresponding pK_s value of 5.3 as given in Table 1 with its 90 % confidence range, as the true ionization constant for lauric acid. For myristic acid it was not possible to perform reliable potentiometric titrations at concentrations low enough to finally secure this true ionization constant. Only a lower limit for the ionization constant, *i.e.* $pK_s \leq 6.3$, appears from the measurements.

At an intermediate concentration range, within which Ekwall and coworkers by the use of several other methods have demonstrated a limited association

Table 1. Ionization constants of some fatty acids in water.

Fatty Acid	Temp. °C	pK_s with 90 % confidence range	Method
Lauric	20°	5.31 ± 0.08	pH measurements, titration in
Myristic	20°	≤ 6.3	water, (this work)
Lauric	20°	4.9—5.0	(3) pH measurements
Myristic	20°	4.9—5.0	(3) in
Palmitic	25°	5.06	(4) water-ethanol
Oleic	25°	5.02	(4) mixture
Lauric	25°	4.8	(5) pH measurements in sodium
Myristic	25°	5.7	soap water solutions
Lauric	20°	5.5	(6) measurements in water *
Lauric	25°	4.82	(2) extrapolated from lower homologues

* extrapolated from data presented.

of laurate ions [16,17,18], the pKs values calculated increase with total titrand concentration, again levelling off to constant values at the critical concentration for micelle formation. This change in the apparent ionization constants is to be interpreted as a decrease in activity a_{HA} of unionized acid due to complex formation and provides another indication of beginning ion association.

At higher concentrations the corresponding pseudoconstant again shows up as mainly concentration independant, indicating the size of the micelles to be essentially constant.

Table 1 gives a comparison between the true pK_s values obtained here and those obtained by other methods. Obviously the direct method as used in this work gives higher pK_s values, *i.e.* lower ionization constants, than an extrapolation from lower fatty acid homologues or a recalculation from titrations in water-ethanol mixtures.

Solubility products. When the potentiometric titration of the soap solution is carried forward at low titrand concentrations, the free fatty acid is precipitated and coagulated near the neutralization point, as expected. If ion association would not occur this precipitation point should move towards the neutralization point at higher titrand concentrations. But obviously this is not the case. Fig. 3 shows a titration starting with a total titrand concentration at the neutralization point of 0.019 moles/litre. When adding hydrochloric acid after this point, the solution slowly turns slightly turbid. Yet precipitation does not occur until late in the titration curve, in connection with a pronounced discontinuity in this curve. The upper part of Fig. 3 presents the solubility product calculated assuming eqns. (2) and (3) to be valid all over the titration curve. Obviously only after the precipitation point has been reached, a constant pK_L-value occurs, indicating a solubility product to be valid within the later part of the titration curve. This means that a solid phase of unionized acid here seems to exist, while in the earlier part of the titration curve unionized

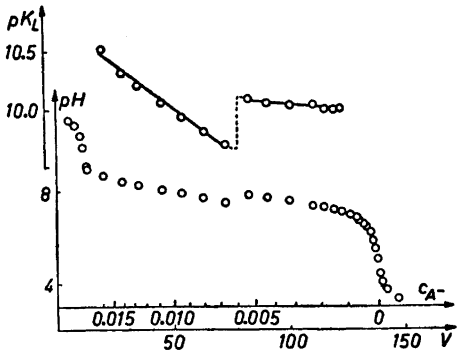

Fig. 3. Titration curve for a 0.019 M sodium laurate solution and the corresponding pK_L values calculated. Abscissa expressed in V ml 0.0216 N HCl added in excess of the neutralization point as well as in overall concentration of untitrated laurate anions, c_{A^-}, in moles/litre.

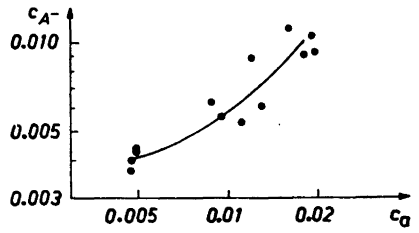

Fig. 4. Overall concentration c_{A^-} of laurate anion at the titration curve discontinuity point, *versus* the corresponding total titrand concentration, c_a, both in moles/litre.

fatty acid is associated to fatty acid anions and thus held in solution. When checking these results by a retitration from the acid to the alkaline side, the discontinuity in the titration curve was less obvious but the change in pK_L as shown in Fig. 3 still was apparent.

The upper part of Figs. 1 and 2 presents the solubility product obtained *versus* the total titrand concentration at the neutralization point. It is obvious from these data that a true solubility product exists at low total titrand concentrations, and that this solubility product is valid also above the concentration of limited ion association (LAC) as soon as a solid phase of free acid has formed. The solubility products with their 90 % confidence range thus obtained are:

for lauric acid 9.98 ± 0.03; for myristic acid 11.45 ± 0.01

Ekwall and coworkers have pointed out that within the concentration range of limited ion association unionized fatty acid molecules are associated with fatty acid anions. This is evident also from the data in Fig. 3 typical for this concentration range, showing the precipitation of free fatty acid to be delayed. Further proof is given in Fig. 4 showing that the residual concentration of untitrated fatty acid anions at the point of precipitation is approximately equal to this concentration of limited ion association. The slight upward trend of residual anion concentration with increasing total titrand concentration at the neutralization point indicates that after the precipitation point and the formation of a solid fatty acid phase, residual fatty acid anions still occur to some extent in associated form.

Solubility of unionized fatty acid and total solubility. According to the method af Back and Steenberg [10] the solubility of unionized fatty acid, L, is obtained as the quotient of the solubility product and the corresponding ionization

Table 2. Solubility of some fatty acids in water.

Fatty acid	Temp. °C	Solubility of unionized acid		Total solubility		Reference
		in moles/litre × 10^5	in mg/litre	in moles/litre × 10^5	in mg/litre	
Lauric	20°	2.3	4.6	3.4	6.8	
(90 % confidence range)		1.8 −3.0	3.6 −5.9	2.6 −4.4	5.2−8.8	This Work
Myristic	20°	≤ 0.6	≤ 1.4	≤ 0.8	≤ 1.8	
Lauric	25°	1.19	2.4	2.4	4.8	John and Mc Bain [7]
	50°	3.5	7.0	5.5	11.0	
	40°	—	—	3.9	7.8	Eggenberger *et al.*[8]
	50°	—	—	4.6	9.2	
Myristic	25°	0.09−0.11	0.21−0.25	0.42−0.51	1.0−1.2	John and Mc Bain [7]
	50°	0.34	0.78	0.97	2.2	
	50°	—	—	1.84	4.2	Eggenberger *et al.*[8]

constant. Table 2 gives the data thus obtained together with their 90 % confidence limits. Also given are the total solubilities of these fatty acids in a saturated water solution, *i.e.* the total solubilities at the acid equivalence point, at which $a_{H_3O^+} = a_{A^-}$. For comparison other published data also are given. The total solubilities established in this work are lower than those of Eggenberger *et al.* [8] obtained by conductometric titration of with fatty acid saturated water solutions when rechecking earlier data of their own.

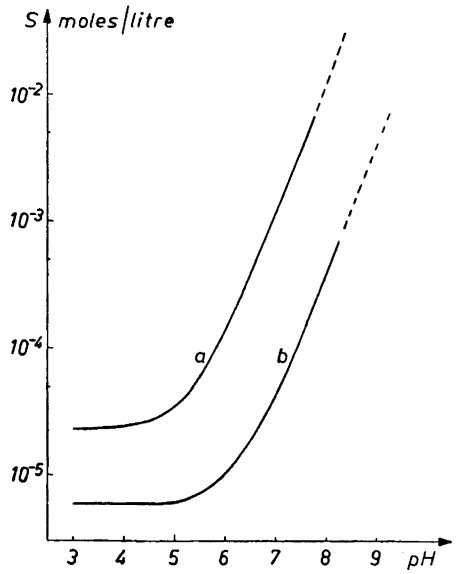

Fig. 5. Total solubility, *S*, in moles/litre as a function of pH, for a) lauric acid, b) myristic acid.

On the other hand our data are in reasonable agreement with those of John and Mc Bain [7], obtained from conductivity measurements using earlier data on the equivalence conductance of soap ions and selecting as the ionization constant for these fatty acids, the one of acetic acid.

To give a complete picture of the solubility of these fatty acids, Fig. 5 shows our values for the total solubility as a function of the pH, (adding the solubility of unionized acid to that of the fatty acid anion determined by the solubility product). Naturally, this solubility product is valid only as long as the fatty acid anion concentration does not exceed the LAC. After the LAC is reached the total solubility increases more rapidly due to solubilization of fatty acid by fatty acid anions. The dotted lines in Fig. 5 within this later region thus present a minimum total solubility only. Naturally, in mixtures of fatty acid the total solubility as calculated for each fatty acid separately, will be exceeded when mixed associate soap anions or mixed micelles begin to form.

Die Isolierung von Meerrettichperoxydase

K. G. PAUL

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Schweden

Eine vereinfachte Methode zur Isolierung von Meerrettichperoxydase wird beschrieben. Die Ausbeute an Aktivität, mit der Mesidinmethode gemessen, ist höher als 40 % des Rohauszuges. Durch Chromatographie auf Karboxymethylzellulose kann das Enzym in vier Komponenten aufgetrennt werden.

Meerrettichperoxydase (MRP) interessiert als Häminproteid und ist auch ein praktisch verwendbares Mittel für gewisse Oxydationen. Sie wird ebenfalls als zuverlässige Vergleichsubstanz benutzt, wenn man vor der Frage steht, ob ein beobachteter Stoffwechselvorgang möglicherweise durch Peroxydase katalysiert werden kann. In diesen Fällen und für die Aufklärung des Peroxydasemechanismus ist es notwendig, reinste Enzympräparate zu verwenden. So fanden z.B. Paul und Avi-Dor [1] in Versuchen über Harnsäureoxydation, dass Allantoin nicht nachzuweisen war, wenn MRP, die etwa 1 % Hämin enthielt, verwendet wurde. Der Nachweis gelang nur mit der kristallisierten Peroxydase mit 1.26 % Hämin.

MRP wurde zum erstenmal von Theorell [2] kristallisiert. Diese Methode ist jedoch etwas mühsam, und verschiedene Autoren [3-5] haben andere Darstellungsverfahren angegeben, die vom Verfasser nachgeprüft wurden. Die Ergebnisse gehen aus dem folgenden hervor.

METHODEN UND MATERIALIEN

Die Aktivitätsbestimmungen wurden nach der Mesidinmethode [6] ausgeführt. Die unten in Molen angegebenen Peroxydasemengen sind also auf ältere Aktivitätsbestimmungen mit "reinen" Präparaten bezogen. Die Guajacolmethode [7] wurde ebenfalls versucht, erwies sich aber in den ersten Stufen der Reinigung ebensowenig zuverlässig wie die Purpurogallinmethode — Ausbeuten über 100 % kamen vor. Mit steigender Reinheit der Peroxydase normalisierten sich die Ausbeuten. Man sieht bei den Aktivitätsbestimmungen an Rohauszügen, dass die zunächst auftretende Farbe bald verschwindet; dies kann nicht die Folge einer Peroxydasehemmung sein, offenbar findet auch eine Entfärbung des Oxydationsproduktes durch die Verunreinigungen in den Rohauszugen statt.

Bei den Häminbestimmungen [8] wurde der Wert $\beta = 8{,}0 \times 10^7$ cm^2 × Mole^{-1} für den molaren Absorptionskoeffizienten des α-Bandes des Pyridinhämochromogens benutzt *.

* $\beta = \frac{1}{c} \times \frac{1}{d} \times \ln \frac{I_0}{I}$ wo c = Konzentration in Molen pro cm^3, d = Schichtdicke der Küvette in cm.

Stickstoff wurde nach Kjeldahl bestimmt. Zur Bestimmung des Trockengewichts wurde 6 Std auf 105° und zur Aschenbestimmung 1 Std auf 500°C erhitzt.

Das Verhältnis Q zwischen den Extinktionen bei 403 mμ (Maximum der Häminbande) und etwa 280 mμ (Maximum der Eiweissbande) wurde ebenfalls bestimmt. Die zu untersuchende Lösung wurde, wenn nötig, mit 0,1 M Phosphatpuffer von pH 7 verdünnt.

ARBEITSGANG

1. Extraktion und erste Ammoniumsulfatfällung

Fein zerteilter Meerrettich (26,2 kg) wurde zweimal mit 39,3 und einmal mit 19,7 l destilliertem Wasser, jedesmal wenigstens vier Stunden unter gelegentlichem Umrühren oder über Nacht, bei Zimmertemperature extrahiert. Die Extrakte wurden vom Rückstand mittels Gaze getrennt und ohne weitere Behandlung bis auf etwa das halbe Volumen in Vacuum eingeengt. Der scharfe Meerrettichgeruch verschwand dabei. Der Extrakt wurde in Glaszylindern im Kältezimmer einige Stunden oder über Nacht stehengelassen. Die Flüssigkeit, die noch trübe, aber von grossen Partikeln frei war, wurde abgehebert, der Bodensatz mit etwas Wasser ausgewaschen und zentrifugiert. Die vereinigten Lösungen wurden mit Ammoniumsulfat auf 40 %-ige Sättigung gebracht (230 g Ammoniumsulfat pro Liter Flüssigkeit, +4°C). Der Niederschlag, der nur wenig Aktivität enthielt, wurde abzentrifugiert und ohne erneute Extraktion verworfen. Das Gesamtvolumen des nicht ganz klaren Extraktes war dann 39,6 l. Nach der Aktivitätsbestimmung enthielt es 30,0 μMole MRP.

Die Beobachtung [3,9], dass die Menge einer mit Wasser extrahierbaren Substanz, wahrscheinlich von Kohlenhydratnatur, mit der Jahreszeit schwankt, wurde bestätigt; die Schwierigkeiten, die mit der Aufarbeitung von herbstgeernteten Wurzeln verknüpft sind, wurden jedoch durch die zweistufige Ammoniumsulfatbehandlung (2. Stufe, siehe unten) beseitigt. Bei unmittelbarer Sättigung des Rohextraktes mit Ammoniumsulfat fällt zwar MRP aus, die Trennung des Niederschlags und der Mutterlauge ist aber schwierig, was auch bei den früheren Methoden anscheinend der Fall war.

Die Behandlung des Rohextraktes mit Alkohol-Chloroform [4] wurde zweimal versucht. Es wurden keine Verluste beobachtet (Ausbeute 98 und 104 %, Mesidinmethode), der Reinigungseffekt war aber mässig (1,22 und 1,18). Diese Behandlung wurde daher nicht weiter ausgeführt.

Ein aus praktischen Gründen wichtiger Befund war, dass die Dauer der Extraktion kritisch ist. Bei der kürzeren Extraktionszeit von z.B. dreimal dreissig Minuten ist zwar die Ausbeute an Peroxydaseaktivität fast unverändert, aber der Niederschlag nach dem zweiten Alkoholzusatz (siehe unten) kann nur mit Schwierigkeit in Lösung gebracht werden. Die darauf folgende Ammoniumsulfatfällung gibt einen sehr klebrigen Niederschlag, was auch von Keilin und Hartree [3] gefunden wurde. Die Behandlung mit Dowex-2 bewirkt nur eine unbedeutende Reinigung.

Während der Extraktion färbt sich allmählich der Meerrettichbrei graubraun. Extrakte aus solchen verfärbten Breien sind meistens leicht zu reinigen. Auch wenn ein Kausalitätszusammenhang zwischen der Verfärbung und der Leichtigkeit, mit der der Brei aufzuarbeiten ist, vielleicht nicht besteht, ist doch die "Reife" des Breies Voraussetzung für eine einfache Reindarstellung der Peroxydase.

Es ist zweckmässig, die Wurzeln während 2—4 Tagen in fliessendem Leitungswasser liegen zu lassen. Dadurch wird die Ausbeute erhöht und das Zerkleinern erleichtert. Physiologische Kochsalzlösung [5] als Extraktionsmittel für solche mit Wasser behandelte Wurzeln hat gegenüber dem Wasser keine besonderen Vorteile.

2. Ausfällung mit Ammoniumsulfat

Die 39,6 l MRP-Lösung, die schon an Ammoniumsulfat zu 40 % gesättigt war, wurden mit weiteren 12,0 kg Salz versetzt, wodurch 85 % Sättigung erreicht wurde. Der Niederschlag war leicht abzuzentrifugieren. Die völlig inaktive Mutterlauge wurde verworfen. Der Niederschlag wurde in etwas 0,01 M Phosphatpuffer von pH 7 aufgelöst und im Kältezimmer bis zur Sulfatfreiheit gegen Wasser dialysiert und weiter über Nacht gegen 0,04 M Acetatpuffer (K-Salz) von pH 5. Die MRP-Lösung wurde in der Kälte zentrifugiert und der graue Bodensatz einmal mit Acetatpuffer gewaschen. Die vereinigten Lösungen ergaben 1 210 ml, die 22 μMole MRP enthielten. $Q = 0{,}21$. Trockengewicht 13,3 und Asche 0,3 mg/ml.

Die Dialyse wurde die ganze Zeit über in ziemlich kleinen Glasgefässen mit oft erneuertem Wasser durchgeführt, da rohe Peroxydasepräparate Zellophan angreifen, wodurch die Schläuche zerbrechlich werden. Zur Sicherheit wurde auch bei *jeder* Präparation nach einigen Stunden die Innenflüssigkeit in frische Schläuche übergeführt.

3. Alkoholfällung

Anderthalb Volumen (1,8 l) von 96 %-igem Aethylalkohol von —13°C wurden langsam unter mechanischem Umrühren der eiskalten MRP-Lösung zugesetzt. Der graue Niederschlag wurde in der Kälte abzentrifugiert, in etwas Wasser aufgelöst, mit Alkohol umgefällt und der Niederschlag verworfen. Die vereinigten Lösungen wurden mit 2,5 Volumen kaltem Alkohol (3,2 l) versetzt. Der braune MRP-Niederschlag wurde auf der Zentrifuge gesammelt, in einer minimalen Menge Wasser aufgelöst und gegen Wasser dialysiert. Nach zwei Tagen wurde die Lösung scharf zentrifugiert, der graue Niederschlag mit etwas Wasser gewaschen und verworfen. Das Volumen der MRP-Lösung war dann 147 ml mit einem Trockengewicht von 11.30, Asche 0,50 und Hämin 0,090 mg pro ml. Die Gesamtmenge MRP betrug nach der Aktivitätsmessung 21,0 nach dem Hämingehalt 20,4 μMole. $Q = 1{,}72$. Die Lösung wurde durch Gefriertrockung auf etwa 50 ml konzentriert.

Nach der Alkoholbehandlung wurden Schwankungen im Reinheitsgrad von $Q = 0{,}9-1{,}7$ und im Hämingehalt von 0,53—0,80 % in verschiedenen Präparationen gefunden. Es ist gelegentlich notwendig, einige Tropfen gesättigter KCl-Lösung zuzusetzen, um die Koagulation des Kolloids nach dem zweiten Alkoholzusatz zu beschleunigen.

Die Abtrennung des Niederschlags nach dem zweiten Alkoholzusatz kann bei grossen Mengen von Meerrettich zeitraubend werden. Das folgende Verfahren kann dabei benutzt werden. Die MRP-Lösung, die mit 0,04 M Acetatpuffer von pH 5 im Gleichgewicht steht, wird wie oben beschrieben mit 1,5 Volumen Alkohol versetzt und der Niederschlag abzentrifugiert. MRP in der Mutterlauge wird dann auf Karboxymethylzellulose (siehe unten) adsorbiert, entweder durch Rühren oder in einer Säule. MRP wird mit 0,1 M Acetatpuffer von pH 5 in Abwesenheit von Alkohol eluiert. Die Wahl zwischen dem erstgenannten Verfahren mit vier Volumen Alkohol und der Zellulosemethode wird von den zugänglichen Zentrifugen bestimmt. Der erste Weg wird vom Verfasser empfohlen.

4. Behandlung mit Anionenaustauscher

Vorbehandlung des Ionenaustauschers. Käufliches "Dowex-2, 8—10 % cross linking, 200—400 mesh", wurde mit dem zehnfachen Volumen von etwa molarer Salzsäure bis zum Aufhören der Gasentwicklung (etwa 24 Std) gerührt,

Tabelle 1. Reinigung der Meerrettichperoxydase mit Dowex 2. Für Einzelheiten siehe Text.

			100

mehrmals mit Wasser gewaschen, abgenutscht und endlich in 0,05 M Tris HCl-Puffer von pH 8,6 aufgerührt. Das Chromatographierohr wird mit Puffer beschickt, die Austauschersuspension eingegossen und die Säule bis zum pH-Gleichgewicht mit dem Puffer gewaschen.

Dieselbe Säule kann mehrmals benutzt werden, wenn sie mit dem Puffer jedesmal nach der Verwendung bis zur Lichtabsorptionsfreiheit bei 280 mμ gewaschen wird. Es ist jedoch vorzuziehen vor dem Waschen das oberste Zehntel der Säule zu entfernen und die entsprechende Menge frischer Dowex einzufüllen.

Die MRP-Lösung wurde mit dem Tris-Puffer ohne Dialyse auf 147 ml verdünnt und in drei Portionen (I 50, II 50, III 47 ml) durch eine Säule (60 × 2,7 cm) von Dowex-2 mit einer Geschwindigkeit von 22—26 ml pro Stunde filtriert. Fraktionen wurden manuell gesammelt, wenn sich das Eluat braun zu färben begann (Tabelle 1). Die Fraktionen I 1—2, II 1—2 und III 1—3 wurden vereinigt. Das Gesamtvolumen war nach dem Waschen 201 ml mit Q 2,56. Nach der Aktivitätsbestimmung enthielt die Lösung 17,2 μMole MRP.

Die Bedingungen für die Reinigung der Peroxydase mittels Dowex-2 sind nicht kritisch. Der Puffer kann innerhalb der Grenzen 0,02—0,10 M Tris und pH 7,6—8,6 variieren. Die Präparatmenge kann ohne Verschlechterung des Q-Werts hoch gehalten werden (<2 mg pro cm^3 der Säule), ebenso die Durchlaufgeschwindigkeit (<5 ml pro cm^2/Stunde). Bei grösseren Ansätzen oder schnellerem Filtrieren werden zwar die Begleitpigmente zurückgehalten, eine farblose Verunreinigung wird aber nicht entfernt.

5. Ammoniumsulfatfällung

182 ml der obengenannten Lösung wurden mit festem Ammoniumsulfat versetzt (41,8 g, 40 % Sättigung). Ein kleiner, jedoch inaktiver Niederschlag wurde auf der Zentrifuge abgeschieden, und die Mutterlauge mit 69,2 g Ammonium-

sulfat versetzt (88 % Sättigung). Nach einigen Stunden im Kühlschrank wurde scharf zentrifugiert, die Peroxydase in 0,01 M Phosphatpuffer von pH 7 aufgelöst und gegen Wasser einige Tage lang dialysiert.

Analyse: Volumen 18,5 ml, Q 3,03. Trockengewicht 33,80 mg, Asche 0,05 mg, Hämin 0,404 mg und Eisen 33,4 μg, alles pro ml. Der Stickstoffgehalt war 13,3 %. Die Aktivitätsbestimmung gab die Gesamtmenge von 10,5 μMolen MRP *.

Bei vorsichtigem Zusatz von Ammoniumsulfat kristallisiert MRP zum Teil. Es ist aber zu empfehlen, die Peroxydase mittels Ammoniumsulfat quantitativ auszufällen und in diesem Zustand in geschlossenen Gefässen im Eisschrank aufzubewahren. Die Aktivität bleibt dabei jahrelang nahezu unverändert, und die Peroxydase kann bei Bedarf weitergereinigt werden.

6. Chromatographie auf Karboxymethylzellulose (CMC)

Vorbehandlung des Ionenaustauschers. Zellulose ("Whatman cellulose powder, standard grade"), die nach Peterson und Sober [10] karboxyliert ist, wird mit Puffer (30 ml 1 M Essigsäure + 15 ml 1 M NaOH + Wasser auf 1 l) im Kältezimmer bis zum Gleichgewicht gerührt. Das Rohr wird mit Puffer gefüllt, die Karboxymethylzellulose eingegeben, und man lässt sie ohne Druck bis zu konstantem Volumen sedimentieren. Danach wird die Säule einige Stunden lang mit kaltem Wasser gewaschen.

Grössere Ansätze als 8 mg Substanz pro cm³ Säule wurden nicht untersucht, wählt man jedoch Mengen bis zu dieser Konzentration, so werden die Chromatogramme identisch. Fig. 1 zeigt ein Beispiel für das Verfahren. Die gegen Wasser dialysierte MRP-Lösung wird verwendet, und man beginnt die

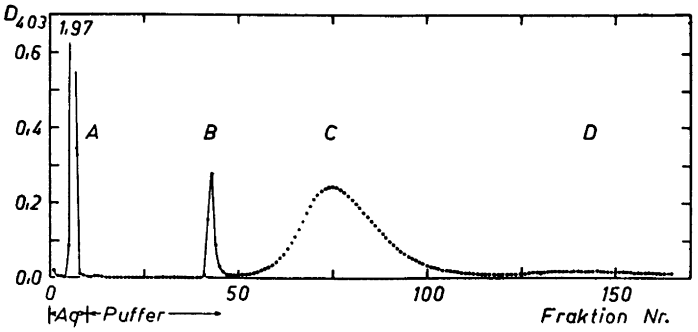

Fig. 1. Chromatographie von Meerrettichperoxydase auf Karboxymethylzellulose. Ausgangsmaterial: 0,50 ml einer gegen Wasser dialysierten Lösung mit log (I_0/I) = 29,5 bei 403 mμ, Q = 2,44. Ansatz etwa 8 mg. Säule 210 × 9 mm. Durchlaufgeschwindigkeit 5,9 ml pro cm² pro Stunde. 20 Min. pro Fraktion. Sämtliche Fraktionen ohne Verdünnung in Beckman DU-Spektrophotometer gemessen.

* Wegen Unfall ging hier in dieser Preparation etwa ein Drittel verloren. Diese Stufe ist sonst praktisch ohne Verluste.

Tabelle 2. Analysen der vier Meerrettichperoxydasen.

	A	B	C	D
Hämin [1]	1,04	1,28	1,44	1,36
Asche [2]	7,1	2,9	1,8	2,4
Stickstoff [1]	11,07	13,41	13,24	13,06
Q	3,53	2,92	3,31	3,13
Aktivität nach				
der Guaiacolprobe [3]	0,019	0,080	0,075	0,077
der Mesidinprobe [4]	0,48	1,28	1,25	1,25

Elution mit Wasser. Etwa ein Viertel des Enzyms wird nicht zurückgehalten, wandert aber schnell abwärts. Diese Fraktion, als MRP A bezeichnet, wird gegen Wasser dialysiert und im gefrorenen Zustand getrocknet. Das Eluat bleibt dann farblos, und die MRP-Bande im obersten Teil der Säule bewegt sich nicht.

Das Chromatogramm wird dann mit dem oben beschriebenen Acetatpuffer weitereleuiert, wobei drei Fraktionen MRP B, C und D erhalten werden. Sie werden gegen Wasser über Nacht dialysiert und danach, zwecks Konzentrierung, auf drei Säulen adsorbiert (wie oben CMC in Puffer, mit Wasser ausgewaschen). Diese Säulen können klein sein, z.B. für 500 mg MRP C in 1 200 ml 50 × 9 mm. Nach Adsorption und Waschen mit Wasser wird mit Acetatpuffer (30 ml 1 M Essigsäure + 20 ml 1 M NaOH + Wasser auf 1 l) eluiert, die Peroxydasen gegen Wasser dialysiert und endlich analysiert

Die Aschenwerte sind auffallend hoch. MRP A und C wurden elektrophoretisch untersucht und zeigten dabei eine Verunreinigung, die noch bei pH 4.6 anodisch wanderte. Sie machte in A einen Drittel, in C weniger als zehn Prozent aus. Versuche, die saure Fraktion, die von Kohlenhydratnatur sein dürfte, chromatographisch, auch auf Dowex 2-Borat, abzutrennen, sind bisher nicht erfolgreich geworden. Es ist von Interesse, dass Paraperoxydase aus MRP A bei pH über 9, besonders in Boratbuffer, leicht gebildet wird, aus den anderen Peroxydasen aber nicht. Peroxydase und Paraperoxydase waren auf Dowex-2 bei pH 7, Phosphatpuffer, leicht zu trennen. Paraperoxydase bewegte sich dabei etwas langsamer.

Der Befund von Jermyn und Thomas [11] über die Uneinheitlichkeit der Meerrettichperoxydase ist somit bestätigt worden. Die vier Peroxydasen A, B, C und D werden am besten innerhalb der pH-Grenzen 4,2—4,9 getrennt. Bei niedrigerem pH bewegen sich C und D kaum, bei höherem pH wandern B, C und D als eine Fraktion. Wenn die Säule nicht mit Wasser gewaschen wird, bleibt A unverändert, B kommt aber als eine zwar gut begrenzte und fast symmetrische aber weit ausgedehnte Bande heraus.

Drei MRP-Präparationen aus herbstgeernteten Wurzeln gaben nahezu konstante Mengenverhältnisse zwischen den vier Peroxydasen und zwar verhielt sich A:B:C:D wie 2:1:4:1. Die relativen Q-Werte der vier Peroxydasen sind auch ziemlich konstant. A hat

[1] In % des aschefreien Trockengewichtes.

[2] In % des Gesamttrockengewichtes.

[3] In $1/t$ min^{-1}, wo t = Zeit fur die Steigerung des D_{470} mit 0.050. 6.9×10^{-6} μMole von MRP-Hämin in der Kuvette.

[4] In $1/t$ min^{-1}, wo t = die Zeit, in der $D_{490} = 0.450$ erreicht wird. 10^{-4} μMole von MRP-Hämin in der Kuvette.

immer den höchsten und B den niedrigsten Q-Wert. Das Spektrum von A variiert stark mit dem pH und Q-Werte über 4,5 sind für Lösungen in Acetatpuffer beobachtet worden. Wenn die Zellulosesäule mit grossen Mengen beladen war, konnte zweimal eine kleine und sehr ausgedehnte, aber deutlich begrenzte Fraktion E beobachtet werden. Es wurde kein Versuch gemacht, sie zu isolieren.

Diese Arbeit wurde von *Statens naturvetenskapliga forskningsråd* unterstützt. Fräulein A. Hartkoorn sei sehr wertvolle Assistanz gedankt.

The Constituents of Conifer Needles

I. Low Molecular Weight Carbohydrates in the Needles of *Pinus silvestris*

ANDERS ASSARSSON and OLOF THEANDER

Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

An investigation has been made of the low-molecular weight carbohydrates in needles collected from *Pinus silvestris*. Glucose, fructose, sucrose, melibiose, raffinose, *myo*-inositol and pinitol, the principal carbohydrates, were isolated together with smaller amounts of cellobiose, laminaribiose, a glucopyranosyl-fructose and a glucopyranosyl-mannose. Oligosaccharides were found which contained residues of glucose, galactose and fructose. Paper chromatography indicated the presence also of small amounts of galactose, arabinose and xylose.

In the present investigation a study has been made of the low-molecular weight carbohydrates present in the needles of *Pinus silvestris*, which had been collected in October. Glucose, fructose, sucrose, raffinose and pinitol were previously found [1,2] in conifer needles and the present investigation was made to get information on their amounts and on other components, some of which might be of interest in connection with the biosynthesis of polysaccharides.

By treating the needles successively with ethanol and methanol, a mixture of neutral carbohydrates was obtained. It was fractionated on carbon columns and sub-fractionated by chromatography and by electrophoresis on thick filter paper. The values for the monosaccharides were determined quantitatively following paper chromatographic separation while the other values are for these substances which were isolated in a pure state (See Table 1).

Myo-inositol, pinitol, melibiose, sucrose and raffinose crystallised. From a mixture containing glucose, fructose and some of the pinitol, the two monosaccharides were isolated as their *iso*propylidene derivatives. Smaller amounts were isolated of four disaccharides and of two higher oligosaccharides; the latter two gave glucose, galactose and fructose on hydrolysis. Galactose, arabinose and xylose were detected on paper chromatograms and also smaller amounts of compounds having higher R_F-values.

The four minor disaccharides were investigated by paper chromatography and electrophoresis and by studying the products obtained, both when they were hydrolysed and when they were reduced with borohydride prior to hyd-

Myo-inositol	0.3
Pinitol	2.0

rolysis. By these methods two of the disaccharides were shown to be indistinguishable from laminaribiose and cellobiose. The other two were found to be reducing, and it was concluded that they were a glucopyranosyl-mannose and a glucopyranosyl-fructose.

It was possible that a portion of the sugars might have been formed from higher oligosaccharides by hydrolysis during either the extraction or the purification. To determine whether or not this was the case, a sample of the purified extract, which had not been passed through a carbon column, was examined on chromatograms. There it was compared with samples of non-purified extracts obtained by treating needles immediately after their removal from the same tree. In one case, cold ethanol was used to minimise the possibility of acid hydrolysis and, in the other, boiling ethanol was used to inactivate the enzyme systems as rapidly as possible. Those two extracts were similar; glucose, fructose, sucrose, melibiose and raffinose were present as the principal sugars. Glucopyranosyl-fructose was also shown to be present in those extracts as, when they were concentrated on the chromatograms the disaccharide gave an intense red spot on treatment with resorcinol in acid. There were slight indications of reactions with *p*-anisidine hydrochloride at those positions on the chromatogram where the other, and minor, disaccharides might be. On the other hand the examination showed that, under the mild conditions used for extraction and purification, some of the sucrose and raffinose had been hydrolysed.

The investigation will be repeated on a larger scale to obtain further informations on certain of the substances present.

EXPERIMENTAL

All melting points were corrected. Solvents were removed either by distillation, carried out under reduced pressure (bath temperature under 40°), or by lyophilisation. Whatman No. 1 filter paper was normally used for paper chromatography and electrophoresis, but large scale separations were carried out on Whatman No. 3 MM paper, which had previously been thoroughly washed with water. Reagents used for the detection of substances on chromatograms and electrophoretograms were silver nitrate-ethanolic sodium hydroxide, *p*-anisidine hydrochloride and resorcinol-hydrochloric acid.

The chromatographic solvents and the buffer used in the electrophoresis were:

A — Ethyl acetate — acetic acid — water, 3:1:3 (the upper phase).
B — Butanol — ethanol — water, 10:3:5.
C — Butanol — pyridine — water, 6:2:3.
D — Borate buffer [3] pH 10.0, 0.1 M.

5-Hydroxymethylfurfural was used to enable correction to be made for electroendosmotic movement. This compound is readily detected with all the sprays used in this investigation.

The needles were collected at the end of October from all parts of the branches. The age of the tree was about 20 years. The fresh needles (540 g, corresponding to a dry weight of 230 g) within a few hours of their having been collected were cut into pieces (*ca.* 1 cm) and were boiled with ethanol (5 l) for 30 min. The mixture, when cold, was filtered and the residue washed with ethanol. The residual material was air-dried, disintegrated in a Wiley-mill and then treated with methanol (3 × 24 h) in a Soxhlet extractor. The final extract, which was almost colourless, yielded only 1.9 g of material on removal of the solvent. The ethanolic extracts, the wash liquids and the three methanolic extracts were examined chromatographically and found to be similar. They were combined and concentrated to *ca.* 400 ml. Water (200 ml) was added and the solution was shaken with successive volumes (400 ml) of chloroform. After removal of the solvent from an aliquot of the aqueous layer, the total soluble non-volatile material was found to be 44 g. The aqueous layer was deionised by passing it through columns containing Amberlite IR 120 and IR 4B. The eluate was evaporated to about 500 ml and to the solution there was added ethanol to give a final concentration of 50 % with respect to the ethanol. This solution was shaken for 16 h with a mixture of charcoal and Celite (1:1; 150 g). After filtration and washing of the residues, the filtrate and washings were concentrated and yielded a colourless product (32.1 g). Part of this product was separated on paper chromatograms (Solvents A and C) and the monosaccharides were quantitatively determined by the method of Saeman *et al.*[4] *Glucose* and *fructose* were the principal sugars and there were smaller amounts of *galactose*, *arabinose* and *xylose* (see Table 1). The products were examined on paper chromatograms and there compared with the components in two other extracts from the needles of the same tree. One of those extracts was obtained by treating the needles with cold ethanol for a day at room temperature, the other, by boiling the needles with ethanol for 30 min. The extracts were not purified. Appropriate volumes of the two solutions were concentrated directly on the starting-line of the chromatogram by a stream of cold air.

The main part of the purified product (31.8 g) was fractionated on a carbon-Celite column (50 × 6 cm), using the gradient-elution technique (ethanol: 0—20 %, 15 l, and 50 %, 10 l). The fractions, after examination on paper chromatograms, were then grouped and combined to give two main fractions. Fraction I contained most of the monosaccharides and inositols (17.8 g) while fraction II contained mainly oligosaccharides (9.8 g). Fraction II was refractionated on the same column (water, 4 l; ethanol 0.30 %, 14 l; and ethanol 50 %, 6 l). The first sub-fractions (1.33 g) from it contained monosaccharides and inositols and they were combined with fraction I. The later sub-fractions from fraction II on chromatographic and electrophoretic examination were found to contain compounds indistinguishable from melibiose, sucrose and raffinose (stated in the order in which they emerged from the column). A portion of each of these sugars was crystallised from aqueous ethanol; each sugar was crystallised from that fraction in which it was present in its highest concentration. In order to estimate the total amounts of the individual sugars the mother liquors and fractions containing smaller sugar concentration, or aliquots of them, were evaporated to dryness, and the material redissolved and separated on thick filter papers using solvent A. The various sugars were eluted from the papers, the eluate evaporated to dryness, and the residue weighed. Two disaccharides (I and II), which had been eluted from the carbon column together with melibiose, and two (III and IV), which had been eluted together with sucrose, were separated by pairs on the paper chromatograms. Smaller amounts of two other oligosaccharides (*ca.* 25 mg of each), probably a tetra- and pentasaccharide, were also separated on the chromatograms. They gave galactose, glucose and fructose on hydrolysis with N sulphuric acid (100°, 2 h).

Pure fractions of the four disaccharides (about 10—30 mg of each) were obtained by electrophoresis of the individual pairs of disaccharides on thick filter papers. The sugars were eluted from the papers with N acetic acid and, after having deionised the eluate, it was evaporated to dryness. Each of the disaccharides would appear to have a glycosidically-linked pyranose residue as they were all but little affected by those hydrolysis conditions which led to complete hydrolysis of sucrose, that is, by treatment with 0.1 N hydrochloric acid at 100° for 5 min.

The disaccharides I and III, on hydrolysis with N sulphuric acid (100°, 2 h) yielded

glucose only. They were indistinguishable from *laminaribiose* and *cellobiose*, respectively, on both paper chromatograms and electrophoretograms, but were distinguishable from nigerose, maltose, *iso*maltose and gentiobiose.

Disaccharide II ($M_{G^3} = 0.52$) on hydrolysis yielded approximatively equimolar amounts of glucose and mannose. Reduction with borohydride, and hydrolysis of the reduction product yielded glucose as the only reducing sugar. The results obtained indicated that it was a *glucopyranosyl-mannose*.

Disaccharide IV ($M_{G^3} = 0.62$) on hydrolysis yielded approximately equimolar amounts of glucose and fructose. It was reduced and hydrolysed as above and then gave glucose as the only reducing sugar. The results obtained indicated that disaccharide IV was a *glucopyranosyl-fructose*. It was distinguishable both chromatographically and electrophoretically from turanose.

The disaccharide II had the following $R_{Glucose}$ -values: 0.48 (A), 0.49 (B) and 0.57 (C) and the disaccharide IV: 0.30 (A), 0.29 (B) and 0.34 (C).

Melibiose (0.40 g) crystallised as the dihydrate (m. p. 75—76°) and was characterised as melibiitol, obtained by borohydride reduction. It had $[\alpha]_D^{22}$ +111 (*c*, 2 in water) and m. p. 173—175°, not depressed on admixture with an authentic sample.

Sucrose (2.82 g) was recrystallised from aqueous ethanol. It had $[\alpha]_D^{22}$ +66 (*c*, 2 in water) and m. p. 183—185°.

Raffinose (1.38 g) was recrystallised from aqueous ethanol. It had $[\alpha]_D^{21}$ +106 (*c*, 2 in water; literature: raffinose pentahydrate $[\alpha]_D^{20}$ +105), m. p. 135—139°, as had both an authentic sample of raffinose pentahydrate and a mixture of the two samples. Examination in polarised light revealed that the material lost its crystalline properties at 76—80° due to dehydration. The shape of the material, however, remained unaltered until the solid collapsed at 135—138°. Hydrolysis with 0.1 N hydrochloric acid (100°, 5 min) gave melibiose and fructose.

From the combined fractions containing the monosaccharides and inositols (19.33 g), a sample (4.00 g) was taken and fractionated on a smaller carbon-Celite column (32 × 4 cm) using the gradient-elution technique (water, 3 l; ethanol 0.5 %, 4 l, and 50 %, 3 l).

Myo-inositol (0.16 g) was obtained from the first fractions. It was chromatographically and electrophoretically indistinguishable from an authentic sample and after recrystallisation from aqueous ethanol it had m. p. and mixed m. p. 228—231°.

By paper chromatography and electrophoresis certain of the fractions were shown to contain glucose, fructose and pinitol, as principal components, and smaller amounts of *myo*-inositol, galactose, arabinose and xylose. Those combined fractions were taken to dryness and the residues dissolved in aqueous ethanol. Part of the *pinitol* (0.72 g) crystallised and after recrystallisation from the same solvent it had m. p. and mixed m. p. 189—190° and $[\alpha]_D^{22}$ +64 (*c*, 2, water). The material in the mother liquors was treated with acetone and sulphuric acid to convert the sugars to their di-*iso*propylidene derivatives while leaving the remaining pinitol unaffected. A further crop of crystalline pinitol was obtained (0.21 g) and by following the partial hydrolysis technique of Bell [5], crystalline *iso*propylidene derivatives of glucose and fructose were also isolated. *1,2*-O-iso*propylidene-glucofuranoside*, on recrystallisation from ethyl acetate, had m. p. 160—161° (lit. 161—162.5) and *2,3-4,5-di (*O-iso*propylidene)-fructo-pyranoside*, on recrystallisation from petrol ether, had m. p. 95—96° (lit. 95—96).

The authors are indebted to Dr. S. A. Barker (Birmingham University) and Dr. W. J. Whelan (Lister Institute, London) for a gift of reference specimens.

A Cryoscopic Study of Ionic Association in Bivalent Metal Sulphates using Saturated Aqueous Solutions

JOUKO KENTTÄMAA

Institute of Chemistry, University of Helsinki, Helsinki, Finland

The classical dissociation constants of a number of bivalent metal sulphates have been determined at three ionic strengths by the method previously used by the author. The dependence of pk values on ionic strength has been expressed with the aid of the Debye-Hückel formula and the thermodynamic dissociation constants have been extrapolated.

A considerable amount of work has been done in the field of incomplete dissociation of higher charge type electrolytes in water. Spectrophotometric methods have frequently been used but in most cases the evaluation of the degree of association has been based on deviations from the Debye-Hückel theory or other theories based on similar models. This type of procedure always includes some arbitrary assumptions, *e.g.* about the activities or conductivities of the ions or associated molecules. These theories give reliable approximations for the changes in the activity or conductivity of ions only in very dilute solutions in which the degree of association often is very slight. Very accurate measurements are needed but still leave some doubt about the interpretation of the results. However, most investigations support the existence of association in higher charge type electrolytes and give association constants of the same order of magnitude. Nevertheless, this ionic association has not been generally accepted and papers have frequently been published, in which complete dissociation has been assumed in conditions where it is certainly not valid. Further work is required in this field to draw attention to these phenomena and to provide additional information. In particular, there is a need for the development of methods that do not involve arbitrary assumptions about ion activities and allied properties.

METHOD

The approach employed in this paper is based on the behaviour of a mixture of ice and water saturated with an electrolyte like a one component solvent [1–6] in cryoscopic measurements. The author [6] has previously introduced the use of such "solvent" in the study of the incomplete dissociation of

some bivalent metal sulphates at one ionic strength. This paper describes the extension of this study to three ionic strengths. These "solvents" themselves contain a certain concentration of ions, dependent on the saturating electrolyte, and the activity factors of the ions in them will therefore change only slightly or will remain almost constant when considerable amounts of some other electrolyte are added, provided that the saturating electrolyte is soluble to raise the ionic strength, about up to 0.05 or more. The depression of the freezing point of this kind of "solvent"-ice mixture is therefore almost directly proportional to the sum of the concentrations of ions, and associated ions, other than those arising from the saturating electrolyte. Hence the method provides a means of estimating the sum of the concentrations of these. When these and the corresponding stoichiometric concentrations of an electrolyte are known, it is possible to find the dissociation constant for this electrolyte by extrapolation. Data obtained from solutions containing relatively high concentrations of the electrolyte being studied and showing a relatively large effect due to the ionic association can be used for the extrapolation. This method has been applied here to the study of 2—2 type electrolytes but, it can be used to study the association of any type of electrolyte.

For a water-ice mixture saturated with an electrolyte, the dependence of the freezing point depression ΔT, on Σm_i, the sum of the concentrations of the ions and molecules that are not common with those arising from the saturating electrolyte is given by

$$\Sigma(dm_i + m_i d\ln f_i) = d(\Delta T)/K^\circ_f \quad (1)$$

When the changes in activity coefficients are small the expression

$$\Sigma m_i \simeq \Sigma \bar{m}_i \equiv \Delta T/K^\circ_f \quad (2)$$

gives a good approximation, $\Sigma\bar{m}_i$, for Σm_i. However, from eqn. (1) it is essential, that

$$\lim_{m_s \to 0} \Sigma\bar{m}_i = \Sigma m_i \quad (3)$$

where m_s is the stoichiometric concentration of added electrolyte.

The molar depression of the freezing point of a saturated solution, K°_f, is best derived from the freezing point depressions of 1—1 electrolytes for which the association is negligible. Extrapolation of the values given by

$$K_f \equiv \Delta T/2m_s \quad (4)$$

to infinite dilution for the added 1—1 electrolyte gives the value of K°_f.

In solutions of a bivalent metal sulphate MSO_4, there may be MSO_4 molecules and $M(SO_4)_2^{2-}$ ions present due to ion-pair formation in addition to M^{2+} and SO_4^{2-} ions. If the dissociation constants are

$$k_1 = [M^{2+}]\,[SO_4^{2-}] \,/\, [MSO_4] \quad (5)$$

and

$$k_2 = [MSO_4]\,[SO_4^{2-}] \,/\, [M(SO_4)_4^{2-}] \quad (6)$$

it can be shown that[6]

$$\varphi = 2m_s - \Sigma m_i/(\Sigma m_i - m_s)^2 = 1/k_1 + \Sigma m_i/k_1 k_2 \quad (7)$$

Replacement of Σm_i by $\Sigma \bar{m}_i$ obtained from measurements according to eqn. (2) gives an approximate value $\bar{\varphi}$ for φ. The value of $\bar{\varphi}$ equals the value of φ when extrapolated to infinite dilution of the added electrolyte, as can be seen from eqns. (3) and (7). For the electrolytes studied in this investigation the variation of $\bar{\varphi}$ with $\Sigma \bar{m}_i$ in all cases is linear within the limits of the experimental error. The intercept of these lines on the y-axis gives the value $\bar{\varphi} = 1/k_1$. The slope of these lines gives at most only a rough approximation for $1/k_1k_2$ due to the changes in activity coefficient. In addition the ions of the saturating electrolyte may also participate in ion-pair formation. The effect of this on $\bar{\varphi}$ can be assumed to be slight. It may be pointed out that the same method could be applied using pure water as a solvent but the variation of $\bar{\varphi}$ with $\Sigma \bar{m}_i$ would not be linear, and here again some arbitrary assumptions about the ion activities would be necessary for the extrapolation of $1/k_1$. The method will, of course, give classical dissociation constants at the ionic strengt of the saturating electrolyte.

RESULTS

The author has previously studied [6] the ion association of cupric sulphate, zinc sulphate, nickel sulphate and magnesium sulphate in saturated potassium perchlorate solutions. The same dissociation constants have now been determined in saturated potassium chlorate and potassium nitrate solutions. The freezing point depressions were measured using the method of Richards [7]. The apparatus used, consisting of two Dewar vessels, propeller driven water circulator and ten-junction thermocouples, and the method have been described previously [5,6]. The accuracy in temperature measurements was about 0.0003°C. The concentrations of copper, zinc, nickel and magnesium were determined by complexometric methods. All reagens were of A.R. grade.

The molar depressions of the eutectic points of these solutions in equlibrium with ice were determined using nitric acid in the case of potassium chlorate and hydrochloric acid in the case of potassium nitrate. As before [6], an empirical equation

$$K_f \equiv \Delta T/2m_s = K^\circ_f + a \cdot m_s \qquad (8)$$

was found suitable for the extrapolation of K°_f values. The following equations were derived using the method of least squares:

$$K_f = 1.803 - 0.106\ m_{HNO_3} \qquad (9)$$

for potassium chlorate solutions and

$$K_f = 1.693 - 0.141\ m_{HCl} \qquad (10)$$

for potassium nitrate solutions. All concentrations are expressed in moles per kg of water. The eutectic point for saturated potassium chlorate solution in equilibrium with ice was found to be —0.800°C and the saturation concentration at this temperature was 0.258 molal, for saturated potassium nitrate solution these values were —2.831°C and 1.150 moles per kg of water, respecti-

Tables 1 and 2. Eutectic point depressions for saturated potassium chlorate (1) and potassium nitrate (2) solutions produced by various sulphates and dissociation constants calculated from these data.

for saturated potassium nitrate solutions. For saturated potassium perchlorate solutions the author earlier [6] obtained the equations:

$$\begin{aligned} \bar{\varphi}_{CuSO_4} &= 49.3 + 359\Sigma\bar{m}_i \\ \bar{\varphi}_{ZnSO_4} &= 51.1 + 238\Sigma\bar{m}_i \\ \bar{\varphi}_{NiSO_4} &= 50.5 + 161\Sigma\bar{m}_i \\ \bar{\varphi}_{MgSO_4} &= 36.3 + 157\Sigma\bar{m}_i \end{aligned} \qquad (13)$$

In all cases the variation of φ with $\Sigma\bar{m}_i$ is linear within the limits of experimental error. This is an empirical assumption, and much more accurate measurements are required to show whether it is really valid. In any case the relationship between $\bar{\varphi}$ and $\Sigma\bar{m}_i$ is so nearly linear that even where it is more complicated the linear extrapolation will not lead to any large error in k_1. There can hardly be any unexpected variations in $\bar{\varphi}$ between the points of intersection and the first points measured at such relatively high ionic strengths. The variations in the values of k_1 obtained from eqns. (11), (12)

and (13) with ionic strength have been expressed by means of the Debye-Hückel equation

$$pk_1 = pk^\circ_1 - 3.9\sqrt{I}/(1 + a\sqrt{I}) + BI \qquad (14)$$

The values obtained for pk°_1, a and B and the values of pk_1 at different ionic strengths are shown in Table 3. The values of k_1 for each ionic strength were measured at several temperatures for solutions of different saturating electrolytes and, strictly speaking, eqn. (14) is not applicable as such to the experiments. The effect of the temperature on k_1 can be estimated according to the Bjerrum theory of ion-pair formation[8]. For instance, for the pk_1 value 2.300 at 0°C this gives a theoretical value of 2.293 at —3°C. The effects of temperature differences are, therefore probably within the limits of the experimental error and have been ignored. The characteristic salt effects of the different saturating electrolytes on the pk_1 values can similarly be assumed to be negligible. The dissociation constants for these sulphates have been reported frequently before [9–14]. Although the values obtained depend on various assumptions on activity factors of ions, they agree, being mostly of a magnitude of 0.003—0.008, remarkably well with each other and the values in Table 3. Näsänen [15] has obtained spectrophotometrically for cupric sulphate

$$pk_1 = 2.099 - 4.05\ \sqrt{I}/(1 + 1.618\ \sqrt{I}) + 0.0521I \qquad (15)$$

Table 3. Values of pk_1, pk°_1, a, and B for some bivalent metal sulphates.

	t°C	$\sqrt{I}$	$CuSO_4$	$ZnSO_4$	$NiSO_4$	$MgSO_4$
pk_1, KNO_3 sol.	−2.831	1.073	0.724	0.663	0.690	0.380
pk_1, $KClO_3$ sol.	−0.800	0.508	1.290	1.312	1.267	1.061
pk_1, $KClO_4$ sol.	−0.163	0.220	1.692	1.708	1.703	1.561
pk°_1, water	0.000	0.000	2.259	2.256	2.294	2.186
a	—	—	2.55	2.90	2.22	1.87
B	—	—	−0.36	−0.50	−0.32	−0.36

According to this the variation of pk_1 values with ionic strength is similar to that obtained by the author at low values of ionic strength. At higher ionic strengths some differences appear due to the abnormally large B-values obtained in this work. The fact that the optical method of Näsänen gives values for k°_1 about one and a half times as large as those given by e.m.f., conductance and cryoscopic methods [16] raises again the question whether all such ion-pairs formed by electrostatic forces, which can be detected by the latter methods, undergo any changes in optical properties. For cupric sulphate Fronæus [17,18] obtained spectrophotometrically $k_1 = 0.2$ and potentiometrically $k_1 = 0.1$ at I = 1. The former value is in excellent agreement with the corresponding value, $k_1 = 0.200$, obtained in this paper.

Short Communications

Factor 3 and 6-Selenoctic Acid

KLAUS SCHWARZ and CALVIN M FOLTZ

National Institute of Arthritis and Metabolic Diseases, National Institutes of Health, Bethesda 14, Maryland, U.S.A.
and
GÖRAN BERGSON

Chemical Institute, University of Uppsala, Sweden

Factor 3 was recognized as a nutritional agent *per se* in 1951 by Schwarz [1]. It protects against dietary liver necrosis in the rat and the pig [2], multiple necrotic degeneration (heart, liver, kidney, and muscle necrosis) in the mouse [3], as well as against exudative diathesis in the chick [4,5] and the turkey. Factor 3 has been shown to be an organic compound of high biological potency which contains the element selenium as an essential constituent [6]. Recently G. Bergson described the synthesis of 6-selenoctic acid, the selenium analogue of 6-thioctic acid; the author stated that "the hypothesis may be advanced that Factor 3 is identical with or related to 6-selenotic acid" [7]. This assumption can be eliminated for the following reasons:

(a) The possible involvement of thioctic acid or of compounds with similar physicochemical properties was excluded in 1951, in the course of extensive unpublished fractionation studies on Factor 3 carried out at Bethesda. Various procedures which separated thioctic acid from Factor 3 were applied to prepurified Factor 3 fractions from enzymatic casein digests and other sources. For instance, continuous extractions at a low pH with solvents such as benzene removed thioctic acid readily, but failed to remove the Factor 3-activity from the aqueous phase *.

(b) Following the discovery of selenium as an integral part of the Factor 3 molecule, a large variety of organic selenium compounds has been tested for Factor 3 activity, using the quantitative assay against dietary necrotic liver degeneration in the rat. An appreciable degree of chemical specificity was detected [8,9]. Several types of selenium compounds are inactive, while others prevent liver necrosis. The majority of the compounds tested, including selenate, selenite, and also the selenium analogues of cystine, cystathionine and methionine, was found to afford 50 % protection at dose levels which supply 2—3 μg of selenium per 100 g of diet (ED_{50} = 2—3 μg % Se). A purified preparation of α-Factor 3 from pork kidney powder was more potent than any other compound investigated. The fraction was accurately analyzed for selenium by radio activation analysis; its ED_{50} was established to be 0.7 μg % Se.

Animal assays for Factor 3 potency, at Bethesda, with 6-selenoctic acid from Uppsala have resulted in a value of 3.8 μg % Se for 50 % protection (Table 1) * §. Comparison of this ED_{50} value to that for α-Factor 3 clearly indicates that the latter is different from 6-selenoctic acid. The potency of the thioctic acid analogue is only 1/5 of that of the α-Factor 3 preparation, and somewhat less than that of selenite, selenocystine, etc. At present, the structure of the organic part of the Factor 3 molecule remains to be established.

Experimental. Synthesis and properties of 6-selenoctic acid have been described in this journal [7]. For the animal tests, the substance was dissolved in ethanol and added to the basal diet. Details of the standardized procedure

* Schwarz, K. *Unpublished results.*

* The authors wish to express their appreciation to Dr. B. Sjögren, Astra Research Laboratories, Södertälje, for advice.

§ A test with 6-selenoctic acid in chicks on an exudative diathesis producing diet (30 % *Torula* yeast, 28 % purified soy protein, 4% vitamin E free lard), carried out by J. G. Bieri, showed that 15 μg % of selenium in form of this compound protected all animals against the disease, while 7 out of 8 controls succumbed to the deficiency.

19	10	10	0	100	

* The experiments were terminated on the 30th day.

of the Factor 3 assay using a vitamin E and Factor 3-free 30 % *Torula* yeast ration [10], and weanling, inbred Fischer 344 rats [11] have been specified elsewhere. For evaluation of the results, the average velocity of death from liver necrosis (V_{st}) was calculated from individual survival times [12]. The effects were expressed in "% protection", *i.e.*, in per cent reduction of the velocity as compared to that of the control groups (% protection = 100 — 100 × V_{st} exp./V_{st} contr.). Weighted averages were used, and the ED_{50} was computed from those results which fell on the ascending part of the dose response curve (between 15 and 85 % protection). The assay method, set up twice weekly with 10—15 groups of 10 rats each, yields very consistent ED_{50}'s for selenite, Factor 3 and other compounds tested.

Preparation of Monoperphthalic Acid

S. LINHOLTER and P. SØRENSEN

Department of Organic Chemistry, University of Technology, Copenhagen, Denmark

The method for preparing monoperphthalic acid by oxidising phthalic anhydride with an alkaline solution of hydrogen peroxide, first suggested by Böhme [1], gives according to *Organic Syntheses* [2] normally 65—70 % yield. We found, however, this reaction to be somewhat capricious, sometimes giving only 40—50 % yield. By slightly modifying the procedure we succeeded in eliminating the capriciousness, and at the same time the yield was raised to 90—95 %.

The essential problem is to keep the solution sufficiently cool during the reaction. Operating the same charge as indicated in *Organic Syntheses* we cooled the solution in a carbon dioxide-acetone mixture and maintained a temperature below —5° during the whole reaction. At this temperature a crystal-layer will cover the walls of the reaction vessel, thus preventing the transmission of the heat of reaction to the cooling mixture. It is, therefore, necessary constantly to scrape down the crystals from the walls, which may easily be effected when using a beaker as reaction vessel instead of a flask. Using this procedure no foaming is observed and practically no phthalic acid was formed.

After the addition of sulphuric acid the temperature is allowed to rise to 0° and enough water is added to dissolve the inorganic material. The solution is extracted 5 times with ether, the ether-solution washed 3 times with ammoniumsulphate solution and dried over magnesiumsulphate.

The yield, ranging from 90 to 95 %, was estimated iodometrically as indicated in *Organic Syntheses*.

Zur Bestimmung von γ-Aminobuttersäure und Glutaminsäure in biologischem Material mit Hilfe von Hochspannungselektrophorese

ARNE HANSON und WILFRIED v. STUDNITZ

Chemisches Zentrallaboratorium d. Allg. Krankenhauses, Malmö, Schweden

Bei Untersuchungen im hiesigen Laboratorium über die Glutaminsäure-dekarboxylase im Gehirn ist die Bestimmung von γ-Aminobuttersäure (γ-ABS) und Glutaminsäure (GLTS) aktuell geworden. Die bisher vorliegenden Methoden beruhen entweder auf der Säulenchromatographie oder der Papierchromatographie. Beide Methoden sind relativ zeitraubend und bei einer quantitativen Bestimmung gibt letztere keine zufriedenstellenden Resultate. So waren wir interessiert eine Methode zu finden, die es ermöglicht γ-ABS und GLTS *gleichzeitig* und mit relativer Genauigkeit in kurzer Zeit zu bestimmen. Wichtig war es auch für uns mit relativ kleinen Mengen Ausgangsmaterial auszukommen, da wir als solches Gehirnextrakt verwandten. — So arbeiteten wir eine Methode aus, die mit Hilfe der Hochspannungselektrophorese die von uns gewünschten Kriterien erfüllte.

Methode. Hochspannungselektrophorese nach Wieland und Pfleiderer [1]. Als Träger diente Papier von Macherey & Nagel Nr. 214. Pufferlösung: konz. Ameisenäure: Eisessig : Wasser (15:10:75) v/v. Elektrophoresedauer 75 Min bei einem Spannungsgefälle von 2 100 Volt zwischen den Elektroden (55 Volt/cm). Auftragsstelle 8 cm von der Anode. Wir trugen 0.005—0.03 ml Gewebeextrakt auf (alkoholischer Extrakt eines sauren Gewebeinkubates). Ein Entsalzen fällt bei den hier verwandten Spannungen weg. Nach einer Elektrophoresezeit von 75 Min ist die GLTS 10.5 cm und die γ-ABS 15.8 cm kathodenwärts gewandert. (Siehe Bild 1.) Nach Trennung wird das Papier bei 75° im Trockenschrank eine halbe Stunde getrocknet, wobei sich die Pufferlösung verflüchtigt. Anschliessend wird das Pherogramm mit einer 0.5 % Ninhydrinlösung in *n*-Butanol, der mit einer Mischung von Pyridin:Eisessig:Wasser (10:1:95) pH 6, gesättigt ist, besprüht. Dann wird das Papier für 20 Min vor einem Ventilator bei ca. 40° getrocknet und der Farbentwicklung im Trockenschrank bei 65° für 20 Min überlassen. Nun wird die gebildete Ninhydrinfarbe nach Kawerau und Wieland [2] in einen Kupferkomplex überführt. Es wurde das Kupferreagens in der Modifikation nach Fischer und Dörfel [3] verwandt. Die gebildeten roten Farbflecke werden nach Trocknem im kalten Luftstrom mit einer bestimmten Menge (in unseren Versuchen 4 ml) Methanol eluiert und nach 20 Min im Beckman-Spektrophotometer B bei 504 mμ in 1 cm-Küvetten gemessen. — Zur Errechnung des Leerwertes wird ein entsprechend grosses Papierstück, das auf die gleiche Art behandelt wurde, eluiert und der erhaltene Extinktionswert von den anderen abgezogen. — Eine bekannte Standardlösung von γ-ABS und GLTS wird — am besten in 3 verschiedenen Konzentrationen — mit pherographiert und entsprechend behandelt. Mit Hilfe der von den Standardlö-

sungen erhaltenen Extinktionen (nach Korrektion mit dem Leerwert) werden Eichkurven angefertigt und so die Konzentration an γ-ABS und GLTS in der zu untersuchenden Lösung rechnerisch ermittelt. Beispiel siehe Bild 2. — Sollten in dem zu untersuchenden Material (z.B. Serumextrakt) grössere Mengen Glycin auftreten, so kann es vorkommen, dass in Folge eines "Overloading"-Effektes die γ-ABS nicht klar vom Glycin zu trennen ist. Letzteres hat eine etwas grössere Mobilität als γ-ABS. (Siehe Bild 3 A.) Hier kann man sich weiter helfen in dem man in einem Puffermilieu von pH 3,5 arbeitet. (Puffer: Eisessig:Pyridin:Wasser, 15:1:89, v/v.) Bei gleichen Versuchsbedingungen wie oben erhält man ein Trennungsbild wie im Bild 3 B; Auftragsstelle 12 cm von der Anode. γABS wandert 15 und Glycin nur 5 cm zur Kathode. Auch GLTS ist in diesem Milieu gut zu bestimmen und wird bei ihrer kurzen Wanderungsstrecke (1 cm) nicht von anderen Aminosäuren überlagert.

Die Untersuchungen wurden vom *Schwedischen Medizinischen Forschungsrat* unterstützt.

On Light-Induced Phosphorylation in *Rhodospirillum rubrum*

HERRICK BALTSCHEFFSKY and MARGARETA BALTSCHEFFSKY

Wenner-Gren Institute, University of Stockholm, Sweden

Light-induced phosphorylation (LIP) was described in 1954 by Arnon, Allen and Whatley [1] for plant and by Frenkel [2] for bacterial systems. Among the concepts about its mechanism are: (1) the phosphorylation reactions are coupled to an electron carrier chain, which recombines the photochemical oxidant (OH) and the

On Light-Induced Phosphorylation in *Rhodospirillum rubrum*

HERRICK BALTSCHEFFSKY and MARGARETA BALTSCHEFFSKY

Wenner-Gren Institute, University of Stockholm, Sweden

Light-induced phosphorylation (LIP) was described in 1954 by Arnon, Allen and Whatley [1] for plant and by Frenkel [2] for bacterial systems. Among the concepts about its mechanism are: (1) the phosphorylation reactions are coupled to an electron carrier chain, which recombines the photochemical oxidant (OH) and the

photochemical reductant (H) from the Hill reaction, or its equivalent in bacteria, to H_2O, and (2) P + ADP = ATP * is the net chemical reaction in LIP. Molecular oxygen is not involved in the process. Arnon, Whatley and Allen [3] have suggested that FMN, vitamin K and ascorbate are three of the components in the postulated carrier chain in isolated spinach chloroplasts. Recently, however, they have included TPN and excluded ascorbate and postulated that vitamin K and FMN participate in "alternative pathways for cyclic photophosphorylation" [4], in agreement with the hypothesis of Wessels. [5] Smith and Baltscheffsky [6] have shown that a substance with an absorption spectrum peak at 434 mμ appears to be involved in LIP in extracts of *Rhodospirillum rubrum*. It very probably is identical with the hemoprotein isolated by Vernon and Kamen [7] and recently described by Bartsch and Kamen [8]. Phenazine methosulfate stimulates the phosphorylation in *R. rubrum* [9] and in isolated chloroplasts [10]. The mechanism of the phosphorylation reactions is unknown.

This preliminary communication about LIP in cell-free extracts of *R. rubrum* deals with inhibitor effects, the action of phenazine methosulfate, ATP-ase and ^{32}P-ATP-exchange reactions. The bacteria were grown anaerobically at 30°C in light from incandescent lamps, in essentially the medium of Gest, Kamen and Bregoff [11]. After one washing of the harvested bacteria with distilled water and one with 0.02 M glycylglycine, pH 7.4, the extracts were prepared by grinding with alumina [6] and securing the supernatant from a 10 min centrifugation at 10 000 × *g*. The phosphorylation experiments were performed at saturating light intensities and 30°C. Phosphate was measured according to Lindberg and Ernster [12].

Table 1 shows the effect of some inhibitors on our system. In agreement with earlier data by Smith and Baltscheffsky [13] the inhibitors of mitochondrial respiration, KCN and NaN_3 did not influence LIP, whereas the uncoupler of oxidative phosphorylation dicoumarol had a strong effect. The observations of Smith and Baltscheffsky [6] that HOQNO and of Geller and Gregory [9] that antimycin A inhibit LIP are confirmed. Both inhibit electron transport between cytochrome b and cytochrome c_1 in mitochondria [14], thus it would seem logical to assume that the point of action is the same in LIP as in mitochondria. The absence of an effect of KCN and NaN_3 on LIP is in line with the fact that the hemoprotein, which Bartsch and Kamen [8] described and which very probably is the compound suggested by Smith and Baltscheffsky [6] to take part in LIP, does not form addition compounds with KCN and NaN_3. We consider the possibility that this hemoprotein, assumed by Chance and Smith [15] and by Bartsch and Kamen [8] to be a terminal oxidase for *R. rubrum*, reacts in LIP with oxidizing equivalent produced by the bacterial equivalent of the Hill reaction.

Table 1. Effect of different inhibitors on LIP. Medium: 2 ml 0.2 M glycylglycine pH 7.4, 20 μmoles K_2HPO_4, 10 μmoles ADP, 35 μmoles $MgCl_2$, 30 μmoles NaF, diluted to a final volume of 3.0 ml.

Inhibitor	Final concentration of inhibitor M	% Inhibition
KCN	10^{-3}	0
NaN_3	10^{-3}	0
Dicoumarol	10^{-4}	> 90
HOQNO	2×10^{-6}	> 95
Antimycin A	3×10^{-6}	> 95
Atebrin	7×10^{-3}	about 25

Table 2 shows a typical stimulation of the LIP obtained by 0.02 % phenazine

Table 2. Effect of HOQNO and phenazine methosulfate on LIP. Medium: as in Table 1. Where added: 2×10^{-6} M HOQNO and 0.01 % phenazine methosulfate, final concentrations.

Addition	μmoles P/hour/"OD_{800}" *
—	22
HOQNO	0
Phenazine methosulfate	180
HOQNO + phenazine methosulfate	130

* Abbreviations: P, orthophosphate; ADP, adenosine diphosphate; ATP, adenosine triphosphate; ATP-ase, adenosine triphosphatase; TPN, triphosphopyridine nucleotide; FMN, flavin mononucleotide; HOQNO, 2-*n*-heptyl-4-hydroxyquinoline-N-oxide; M, moles per liter.

* "OD_{800}" stands for the optical density of the absorption spectrum peak near 800 mμ of the bound chlorophyll (compare with Frenkel [17]).

methosulfate and the effect of HOQNO in the absence and the presence of phenazine methosulfate. Similar effects as with HOQNO are obtained with antimycin A and dicoumarol. Geller [16] assumes that phenazine methosulfate serves as a fast "by-pass" around the site which is rate limiting in the system. Our data indicate that a site which is inhibited by antimycin A and HOQNO is "by-passed" by phenazine methosulfate. The point at which dicoumarol acts, which is also "by-passed" may or may not be the same as is acted upon by antimycin A and HOQNO.

Frenkel [17] has reported that an active ATP-ase is present in his "crude" preparation of *R. rubrum*. In our system both a Mg++-stimulated ATP-ase and a ^{32}P-ATP-exchange reaction are present. The ATP-ase activity was inhibited to more than 90 % and the ^{32}P-ATP-exchange activity to about 80 % by 7 mM atebrin, which Löw [18] has shown to inhibit respiration, ATP-ase and ^{32}P-ATP-exchange reactions in liver mitochondria. The possible relation between these reactions and LIP is under investigation.

Chromatography of Tropolones on Paper Impregnated with Ethylenediaminetetraacetic Acid and Dimethyl Sulphoxide

CARL AXEL WACHTMEISTER and BÖRJE WICKBERG

Institutionen för organisk kemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

Tropolones have recently been found in a number of conifer heartwoods and their identification by paper chromatography is therefore a matter of considerable interest. Conventional methods for the identification of phenols have been tried but give bad results due to tailing of the spots. This disadvantage was successfully eliminated by Zavarin and Anderson [1] by using paper impregnated with phosphoric acid and toluene — *iso*octane as mobile phase. In a search for a chemically less agressive stationary phase, which would also be suitable for preparative work, the use of dimethyl sulphoxide was investigated. Although highly polar, this is a good solvent for most lipophilic compounds and has been used with advantage in paper chromatography of sugar acetates and related compounds [2].

Preliminary experiments using dimethyl sulphoxide impregnated paper with light petroleum as mobile phase indicated favourable R_F-values although the spots were still very elongated, extending from the starting line. The length of the spots was dependent on the amount of substance applied but the distance travelled by the lower edge of the spot reached a limit when the amount of tropolone was increased. These results point to an irreversible adsorption of the tropolones.

Tropolones are known to form stable chelates with a number of multivalent cations and an obvious explanation of their

methosulfate and the effect of HOQNO in the absence and the presence of phenazine methosulfate. Similar effects as with HOQNO are obtained with antimycin A and dicoumarol. Geller [16] assumes that phenazine methosulfate serves as a fast "by-pass" around the site which is rate limiting in the system. Our data indicate that a site which is inhibited by antimycin A and HOQNO is "by-passed" by phenazine methosulfate. The point at which dicoumarol acts, which is also "by-passed" may or may not be the same as is acted upon by antimycin A and HOQNO.

Frenkel [17] has reported that an active ATP-ase is present in his "crude" preparation of *R. rubrum*. In our system both a Mg++-stimulated ATP-ase and a ^{32}P-ATP-exchange reaction are present. The ATP-ase activity was inhibited to more than 90 % and the ^{32}P-ATP-exchange activity to about 80 % by 7 mM atebrin, which Löw [18] has shown to inhibit respiration, ATP-ase and ^{32}P-ATP-exchange reactions in liver mitochondria. Chromatography of Tropolones on Paper Impregnated with Ethylenediaminetetraacetic Acid and Dimethyl Sulphoxide

CARL AXEL WACHTMEISTER and BÖRJE WICKBERG

Institutionen för organisk kemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

Tropolones have recently been found in a number of conifer heartwoods and their identification by paper chromatography is therefore a matter of considerable interest. Conventional methods for the identification of phenols have been tried but give bad results due to tailing of the spots. This disadvantage was successfully eliminated by Zavarin and Anderson [1] by using paper impregnated with phosphoric acid and toluene — *iso*octane as mobile phase. In a search for a chemically less agressive stationary phase, which would also be suitable for preparative work, the use of dimethyl sulphoxide was investigated. Although highly polar, this is a good solvent for most lipophilic compounds and has been used with advantage in paper chromatography of sugar acetates and related compounds [2].

Preliminary experiments using dimethyl sulphoxide impregnated paper with light petroleum as mobile phase indicated favourable R_F-values although the spots were still very elongated, extending from the starting line. The length of the spots was dependent on the amount of substance applied but the distance travelled by the lower edge of the spot reached a limit when the amount of tropolone was increased. These results point to an irreversible adsorption of the tropolones.

Tropolones are known to form stable chelates with a number of multivalent cations and an obvious explanation of their

tailing would be complex formation between the tropolone molecules and cations adsorbed on the cellulose surface. The ion exchange properties of cellulose due to its content of carboxyl groups is well known [3] and the influence of adsorbed metal ions on the tailing of ionisable compounds in paper chromatography has been discussed [3,4].

In view of these considerations it appeared possible to eliminate the tailing of the tropolone spots simply by adding an excess of a competing chelating agent. This was successfully achieved by chromatography on paper impregnated with partly neutralised solutions of ethylenediaminetetraacetic acid (EDTA) before impregnation with dimethyl sulphoxide. Under slightly acidic conditions which gave the best results, the tropolones investigated gave well-defined, almost circular spots. Light petroleum, *cyclo*-hexane and di-*iso*propylether were used as mobile phases, and the chromatograms were run in an atmosphere of low moisture content. The first two solvents gave a satisfactory separation of β- and γ-thujaplicins which have very similar properties. The R_F-values observed are given in Table 1. Within the range 5—200 μg these values were largely independent of the amount of substance applied. The R_F-values were fairly reproducible if care was taken to carry out the impregnation under identical conditions.

It is obvious that the use of paper impregnated with EDTA may be of a general value in eliminating tailing caused by adsorbed inorganic ions. The use of other chelating agents would also be possible; the phosphoric acid used by Zavarin and Anderson [2] is probably also an example of this.

Table 1. R_F-values of tropolones on paper impregnated with EDTA and dimethyl sulphoxide.

Mobile phase	Light petroleum B.p. 60—71°	*Cyclo*-hexane	Di-*iso*propyl ether
Tropolone	0.08	0.10	0.30
7-Hydroxy-4-*iso*propyl-tropolone	0.15	0.18	0.40
γ-Thujaplicin	0.32	0.38	0.55
β-Thujaplicin	0.40	0.45	0.60
α-Thujaplicin	0.62	0.65	0.75
Nootkatin	0.72	0.75	0.82

Experimental. The strips of paper (46 × 12 cm, Whatman No. 1) were soaked in an aqueous solution containing 0.015 moles of the disodium salt of EDTA and 0.005 moles of EDTA per litre. After drying in air, the strips were impregnated twice with a 25 % v/v solution of dimethyl sulphoxide in toluene as described previously [2]. The solvents were of reagent grade and were used without drying. The moisture content of the air in the tanks containing hydrocarbon solvents was kept low with anhydrous silica gel.

The tropolones (5—200 μg) were applied as 1—5 % solution in chloroform and the strips were protected from contact with air by covering with glass slides [2]. The chromatograms were developed by the descending technique, the solvent front reaching 30 cm from the starting line in 1—3 h. After short drying in air, the strips were sprayed with a 1 % solution of iron (III) chloride to give spots of red or, in case of 7-hydroxy-4-*iso*propyltropolone, violet colours. The tropolones could also be located under the ultra-violet lamp as dark spots which after spraying with alkali showed a greenish or yellowish fluorescence. They gave red or yellow spots on treatment of the chromatograms with a solution of *bis*-diazotised benzidine [5] followed by spraying with a sodium carbonate solution.

Acknowledgement. The authors are indebted to Dr. H. Fernholz and Dr. J. A. F. Gardner for generous gifts of tropolone and 7-hydroxy-4-*iso*propyltropolone, respectively, to *Statens Naturvetenskapliga Forskningsråd* for financial support and to Dr. B. Thomas for checking the English.

Crystal Data on Salts of Hexathionic Acid

OLAV FOSS and KARSTEN H. PALMORK

Chemical Institute, University of Bergen, Bergen, Norway

The existence of hexathionic acid, $H_2S_6O_6$, was first established by Weitz and Achterberg [1] in 1928, through the isolation of the potassium salt from the reaction of potassium thiosulphate and potassium nitrite with hydrochloric acid. Although the polythionate series extends far higher, up to and including the hydrophilic Odén's sulphur sols which appear to be sodium polythionates $Na_2S_xO_6$ with $50 < x < 100$, hexathionates are the highest polythionates which have been isolated in a pure state and not as mixtures with higher and lower homologues [2-5].

The present authors have made a preparative and X-ray crystallographic study of salts of hexathionic acid, for subsequent attempts at structure analyses, and the results are given below. Unit cell and space group data have been obtained for two salts the crystals of which are, in view of the rather unstable nature and poor crystallization power of hexationates, surprisingly well developed and stable. The salts are, *trans*-dichloribis(ethylenediamine)cobalt(III) hexathionate, first prepared by Weitz and Achterberg [1], and a potassium barium double salt found in the present work. As starting material for their preparation served the potassium salt, prepared by Weitz and Achterberg's procedure [1] as slightly modified by Stamm, Seipold and Goehring [6].

The X-ray data were derived from oscillation and Weissenberg photographs of single-crystal specimens, using CuK radiation, $\lambda(\alpha) = 1.542$ Å, and for the cobalts salts FeK radiation, $\lambda(\alpha) = 1.937$ Å. The axial lengths were calibrated against potassium chloride powder lines superimposed on zero-layer Weissenberg photographs, and are believed to be accurate to within 0.5 %. Density determinations were made by flotation in bromoform-carbon tetrachloride mixtures.

Potassium hexathionate, $K_2S_6O_6$. The salt crystallizes in small, very thin plates [1,2], and only in one sample was a crystal found large enough for some photographs to be taken. The crystals are triclinic, with $a = 7.37$ Å, $b = 7.43$ Å (from layer-line separations on oscillation photographs), $d_{100} = 7.07$ Å, $d_{010} = 7.15$ Å, $d_{001} = 10.42$ Å, $\alpha^* = 74\frac{1}{2}°$, $\beta^* = 73\frac{1}{2}°$ (from zero-layer Weissenberg photographs about the a and b axes). The a and b axes lie in the plane of the plate and make an angle of about 90° with each other. This gives a cell volume of about 570 Å^3 and a density of about 2.13 g/cm^3 for two formula units per unit cell; found, 2.15 g/cm^3.

trans-*Dichlorobis(ethylenediamine)cobalt(III)hexathionate*, $[Coen_2Cl_2]_2S_6O_6 \cdot H_2O$. Green, long, orthorhomic prisms {110}, with $a = 12.12$ Å, $b = 19.13$ Å, $c = 6.43$ Å, and two formula units per unit cell; density, calc. 1.80, found 1.80 g/cm^3. Systematic absences, $0kl$ when k is odd, $h0l$ when h is odd. Of the two space groups compatible with these absences, C_{2v}^8 —*Pba*2 is probably the correct one; it requires that the hexathionate ion lies on a twofold axis of symmetry. The other possible place group, D_{2h}^9—*Pbam*, would require the symmetry 2/m for the ion, which is quite improbable. The space group *Pba*2 appears to be rare, no example being listed by Donnay and Nowacki [7] (1954).

Although no mentioning of water of crystallization was made by Weitz and co-workers [1,2], the density and the analytical data point to the presence of one mole of crystal water in the salt. The water molecule would lie on the second set of twofold positions (twofold axes) of the space group. In a vacuum over phosphorus pentoxide the finely powdered salt lost 1.3 % weight in the course of three weeks; calc. for monohydrate, 2.2 %.

The salt was prepared from equal volumes of about 0.2 M aqueous *trans*-dichlorobis(ethylenediamine)cobalt(III) chloride and about 0.13 M potassium hexathionate in 0.5 N hydrochloric acid, by mixing at about 50°C, and cooling. For analysis, 0.6055 g was dissolved in water, and the solution run through a 'Zeo-Karb' 225 ion exchange column (acid form) and then made up to 250 ml in a volumetric flask. Four 25 ml samples were pipetted out and analyzed for hexathionate by means of the sulphite method [8]: 22.98±0.02 ml of 0.00982 N iodine; calc. for monohydrate, 22.94 ml. Cobalt and total sulphur were determined gravimetrically in separate samples, sulphur as barium sulphate, and cobalt as sulphate after ignition of the substance and treatment of the residue with sulphuric acid, in both cases as described by Weitz and Spohn [2]. (Found:

S 23.81, Co 14.62. Calc. for monohydrate, S 23.86, Co 14.62.)

Potassium barium hexathionate, $K_2Ba(S_6O_6)_2$. Monoclinic prismatic, $a = 11.58$ Å, $b = 10.81$ Å, $c = 9.14$ Å, $\beta = 112°$. There are two formula units per unit cell; density, calc. 2.48, found 2.49 g/cm³. The space group is C_{2h}^4-$P2/c$, which requires that the barium ions lie in special, twofold positions.

The salt crystallized, very slowly, as well developed prisms extended along the c axis, bounded by {100} (dominant) and {110} and terminated by {$\bar{1}$11}. It has a faint yellowish colour, discernible only in the larger crystals.

The crystal structure has been solved [9], through Fourier projections along the b and c axes by use of the heavy atom technique in the first stages. All the cations lie in special, twofold positions, the barium ion and one of the potassium ions on a twofold axis at $0,y,\frac{1}{4}$ with $y = 0$ and $y = 0.45$, respectively, and the other potassium ion in a symmetry centre at $\frac{1}{2},0,0$. The hexathionate ions occupy general, fourfold positions. The sulphur chain of the hexathionate ion is unbranched and nonplanar, and the configuration of the chain is *cis-cis*, *i. e.*, as in the S_8 ring of orthorhombic sulphur.

Crystals of the salt, admixed with crystals of barium chloride, were first observed in an attempt to prepare barium hexathionate from crude potassium hexathionate, containing potassium chloride, through metathesis with barium perchlorate. A subsequent experiment using pure, recrystallized potassium hexathionate (5 g) and half the equimolar amount (2.66 g) of barium perchlorate trihydrate, in which, after addition of methanol, and standing, 1.4 g of potassium hexathionate first crystallized and then 0.35 g of the double salt, led to the following procedure: 3.6 g of potassium hexathionate was dissolved in 6 ml of 0.5 N hydrochloric acid at about 50°C, and the solution added to 2.66 g of barium perchlorate trihydrate in 1 ml of water. The mixture was cooled and the potassium perchlorate filtered off, and 5 ml of methanol was added to the filtrate. Yield, after two days in a refrigerator, 0.9 g of the double salt.

Barium was determined gravimetrically as sulphate, and potassium as tetraphenylborate. 0.1242 g substance gave 0.0372 g $BaSO_4$ and 0.1110 g $KB(C_6H_5)_4$ (Found: Ba 17.6, K 9.75. Calc. for $K_2Ba(S_6O_6)_2$: Ba 17.3, K 9.87.) Polythionate analysis was made by the sulphite method: One fifth of 0.1307 g substance gave 19.85 ml of 0.01 N iodine; calc. 19.79 ml.

In the course of the work, unit cell and space group data were obtained also for three pentathionates.

Sodium pentathionate dihydrate, $Na_2S_5O_6 \cdot 2H_2O$. Orthorhombic prisms extended along the c axis, with $a = 8.94$ Å, $b = 22.86$ Å, $c = 5.53$ Å. There are four formula units per unit cell; density, calc. 1.99, found 2.05 g/cm³. Systematic absences, $0kl$ when $k+l$ is odd, $h0l$ when l is odd. In view of the shortness of the c axis and the known configuration and dimensions of the pentathionate ion, the existence of a mirror plane normal to the c axis appears unlikely, so that the space group is probably $C_{2v}^6 - Pnc2$.

The salt was prepared from potassium pentathionate through metathesis with sodium perchlorate. It was described as a dihydrate by Kurtenacker and Laszlo [10], and as a trihydrate by Deines and Christoph [11]. Iodometric analysis of the X-ray sample by the sulphite method indicated two moles of water, and in a vacuum over phosphorus pentoxide the sample lost 9.5 % weight; calc. for dihydrate, 10,6 %.

Ammonium pentathionate hemitrihydrate, $(NH_4)_2S_5O_6 \cdot 1\frac{1}{2}H_2O$. Orthorhombic bipyramidal, $a = 20.59$ Å, $b = 9.33$ Å, $c = 12.61$ Å. The space group, from systematic absences, is $D_{2h}^{14} - Pbcn$. These X-ray data indicate that the salt is isomorphous with a series of pentathionate, selenopentathionate and telluropentathionate hemitrihydrates described earlier [12]. They contain eight formula units per unit cell. Iodometric analysis by the sulphite method gave a formula weight agreeing with that of a hemitrihydrate.

The salt was obtained as long prisms by recrystallization from 2 N hydrochloric acid of a sample of ammonium hexathionate (containing about 35 mole % of pentathionate) prepared from benzidinium hexathionate as described by Weitz and Spohn [2]. It appears that the '*überraschend gut ausgebildete, bis zu 1 cm lange Stäbchen*' of alleged ammonium hexathionate obtained in the same way by Weitz and Spohn [2] may have been the pentathionate.

trans-*Dichlorobis(ethylenediamine)cobalt(III) pentathionate*, $[Co\ en_2Cl_2]_2S_5O_6$. Green, monoclinic prisms extended along the c axis, with $a = 23.30$ Å, $b = 18.46$ Å, $c = 6.53$ Å, $\beta = 97°$, and four formula units per unit cell; density, calc. 1.80,

found 1.80 g/cm³. The systematic absences, $0k0$ when k is odd, indicate that the space group is $C_2^2-P2_1$ or $C_{2h}^2-P2_1/m$. No molecular symmetry is required in either case.

The crystals are thus different from those of the corresponding hexathionate, described above. From hexathionate upwards to about nonathionate, mixed crystals of *trans*-dichlorobis(ethylenediamine)cobalt(III) polythionates, indicating isomorphism, appear to exist [2].

Structure of the Hexathionate Ion in a Potassium Barium Salt

OLAV FOSS, ASBJØRN HORDVIK and KARSTEN H. PALMORK

Chemical Institute, University of Bergen, Bergen, Norway

The tetra- and pentathionate ions are built up of unbranched and non-planar sulphur chains, with three oxygen atoms bonded to each of the terminal sulphur atoms, according to crystal structure determinations of barium tetrathionate dihydrate [1], orthorhombic and triclinic barium pentathionate dihydrate [2,3], barium pentathionate hydrate acetonate [4], and sodium tetrathionate dihydrate [5,6]. The present note reports the preliminary results of a structure analysis of a salt of hexathionic acid.

In a preceding note [7], crystal data were given for a potassium barium hexathionate, $K_2Ba(S_6O_6)_2$. The crystals are monoclinic, with $a = 11.58$ Å, $b = 10.81$ Å, $c = 9.14$ Å, $\beta = 112°$, and two formula units per unit cell. The systematic absences, $h0l$ when l is odd, together with the monoclinic-prismatic morphology of the crystals, indicated that the space group is C_{2h}^4-P2/c. This space group has, beside the fourfold general positions, six set of special, twofold positions, two on twofold axes and four on symmetry centres; the latter are in the glide plane c at $y = 0$ and $\frac{1}{2}$, and atoms in these positions do not contribute to hkl reflections with l odd. It was observed on oscillation photographs about the c axis that reflections on odd layer lines were, particularly for large scattering angles, weak relative to those on even layer lines, and it was therefore proceeded on the assumption that the barium ions lie in symmetry centres of the space group C_{2h}^4-P2/c.

The intensities of the $h0l$ and $hk0$ reflections were estimated visually from zero-layer Weissenberg photographs taken with CuK radiation, and were converted to relative structure amplitudes in the usual way. The signs of the larger terms (74 out of 114 observed $h0l$ reflections and 70 out of 141 observed $hk0$ reflections) were then put positive and Fourier syntheses made. The resulting maps gave the positions of the sulphur atoms, and also showed that the potassium ions lie in two sets of twofold positions, and that the barium ion lies, not in a symmetry centre but on a twofold axis with y equal to or very close to zero. Structure factor calculations including the potassium and sulphur contributions and next also the oxygen contributions led to more refined electron density maps, one of which is shown in Fig. 1. Of the 141 $hk0$ reflections included in the synthesis of this map, only 7 very weak ones have negative signs.

The cations are in the following twofold positions of the space group C_{2h}^4-P2/c: The barium ion and one of the potassium ions on a twofold axis at $0,y,\frac{1}{4}$ with $y = 0$

found 1.80 g/cm³. The systematic absences, $0k0$ when k is odd, indicate that the space group is $C_2^2-P2_1$ or $C_{2h}^2-P2_1/m$. No molecular symmetry is required in either case.

Structure of the Hexathionate Ion in a Potassium Barium Salt

OLAV FOSS, ASBJØRN HORDVIK and KARSTEN H. PALMORK

Chemical Institute, University of Bergen, Bergen, Norway

The tetra- and pentathionate ions are built up of unbranched and non-planar sulphur chains, with three oxygen atoms bonded to each of the terminal sulphur atoms, according to crystal structure determinations of barium tetrathionate dihydrate [1], orthorhombic and triclinic barium pentathionate dihydrate [2,3], barium pentathionate hydrate acetonate [4], and sodium tetrathionate dihydrate [5,6]. The present note reports the preliminary results of a structure analysis of a salt of hexathionic acid.

In a preceding note [7], crystal data were given for a potassium barium hexathionate, $K_2Ba(S_6O_6)_2$. The crystals are monoclinic, with $a = 11.58$ Å, $b = 10.81$ Å, $c = 9.14$ Å, $\beta = 112°$, and two formula units per unit cell. The systematic absences, $h0l$ when l is odd, together with the monoclinic-prismatic morphology of the crystals, indicated that the space group is C_{2h}^4-P2/c. This space group has, beside the fourfold general positions, six set of special, twofold positions, two on twofold axes and four on symmetry centres; the latter are in the glide plane c at $y = 0$ and $\frac{1}{2}$, and atoms in these positions do not contribute to hkl reflections with l odd. It was observed on oscillation photographs about the c axis that reflections on odd layer lines were, particularly for large scattering angles, weak relative to those on even layer lines, and it was therefore proceeded on the assumption that the barium ions lie in symmetry centres of the space group C_{2h}^4-P2/c.

The intensities of the $h0l$ and $hk0$ reflections were estimated visually from zero-layer Weissenberg photographs taken with CuK radiation, and were converted to relative structure amplitudes in the usual way. The signs of the larger terms (74 out of 114 observed $h0l$ reflections and 70 out of 141 observed $hk0$ reflections) were then put positive and Fourier syntheses made. The resulting maps gave the positions of the sulphur atoms, and also showed that the potassium ions lie in two sets of twofold positions, and that the barium ion lies, not in a symmetry centre but on a twofold axis with y equal to or very close to zero. Structure factor calculations including the potassium and sulphur contributions and next also the oxygen contributions led to more refined electron density maps, one of which is shown in Fig. 1. Of the 141 $hk0$ reflections included in the synthesis of this map, only 7 very weak ones have negative signs.

The cations are in the following twofold positions of the space group C_{2h}^4-P2/c: The barium ion and one of the potassium ions on a twofold axis at $0,y,\frac{1}{4}$ with $y = 0$

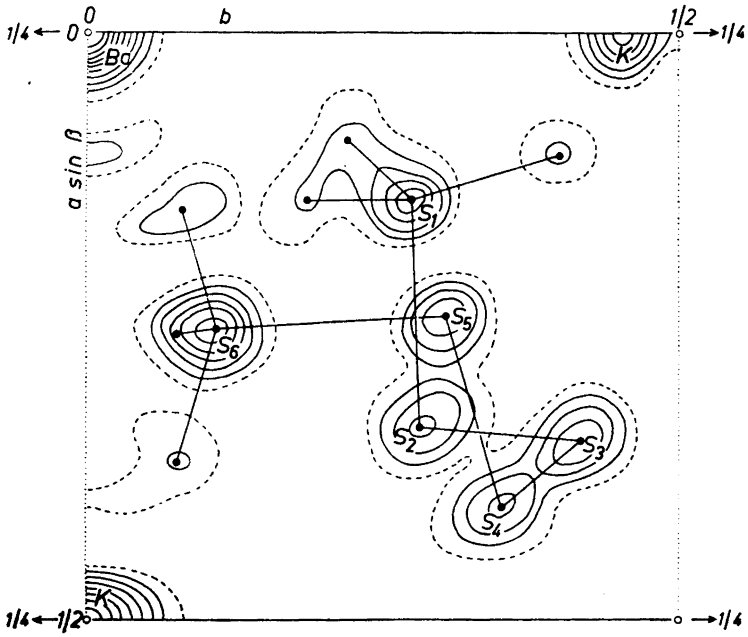

Fig. 1. Electron density projection of potassium barium hexathionate, $K_2Ba(S_6O_6)_2$, along the c axis. The 7-electron line is dashed, and contours are at intervals of 20 e · Å^{-2} for the barium peak and 5 e · Å^{-2} for the other atoms.

and $y = 0.45$, respectively, and the other potassium ion in a symmetry centre at ½,0,0. The sulphur coordinates are at present as listed in Table 1. The reliability index *R*, with approximate oxygen contributions and temperature corrections included in the calculated structure factors, is 14 % for the *hk*0 reflections. Refinement of the structure is in progress.

In elemental sulphur and in sulphur chain compounds, a dihedral angle of about 90° occurs between successive planes through three and three sulphur atoms. Given a chain of four, a fifth sulphur atom may occupy a *cis* or a *trans* position relative to the first. This leads to two possible rotational-isomeric forms of the pentathionate ion [8], one *cis* form in which the first and fifth sulphur atoms are on the same side of the plane through the three middle ones, and a *trans* form in which they are on opposite sides. In the three barium pentathionates referred to above [2-4], the *cis* form occurs. For the hexathionate ion, with a sulphur chain of six, three forms should be possible, one *cis-cis* in which the fifth and sixth atoms are in *cis* positions relative to the first and second, respectively, one *cis-trans* or *trans-cis*, and one *trans-trans*. All three forms may be right- or left-handed; a *cis-trans* form is the mirror-image of a *trans-cis*. The *cis-cis* form represents a segment of the S_8 ring of orthorhombic sulphur, and the *trans-trans* form corresponds to the helical chains of fibrous sulphur and hexagonal selenium and tellurium; these two forms of the six-membered chain possess a twofold axis of symmetry provided that

bond lengths and angles are equal in the two halves.

In the crystals of potassium barium hexathionate the configuration of the sulphur chain is *cis-cis*. Thus, in the pentathionates and the one hexathionate for which structural data so far are available, the sulphur chain has the same configuration as in orthorhombic sulphur. Whether or not this is the preferred form of the ions, or due in some measure to the presence of oxygen-coordinating barium ions in the crystals, must await a study of other salts. A *trans* five-membered sulphur chain occurs in sulphur dimethanethiosulphonate [9], and a *trans-trans* six-membered one in cesium hexasulphide [10].

Preliminary Note on the Solubility of Oxygen in α-Zirconium

BO HOLMBERG and ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

In the course of studies on the crystal chemistry of titanium and vanadium oxides at elevated temperatures which are being carried out at this Institute with the sponsorship of the Office, Chief of Research and Development, U.S. Department of Army, through its European Office, ordered phases have been found to occur in the solid solubility range of oxygen in α-titanium [1]. In connection with these studies an investigation has also been started of the corresponding region of the zirconium-oxygen system.

The solubility limit for samples heat-treated at 800°C has been found to be close to the composition $ZrO_{0.40}$ in agreement with data reported by previous authors [2]. The length of the a axis reaches a maximum at the approximate composition $ZrO_{0.25}$ (a(Zr) = 3.232 Å[3]), $a(ZrO_{0.25})$ = 3.256 Å, $a(ZrO_{0.40})$ = 3.245 Å), while the length of the c axis increases with increasing oxygen content over the whole solubility range (c(Zr) = 5.148 Å[3]), $c(ZrO_{0.25})$ = 5.188 Å, $c(ZrO_{0.40})$ = 5.207 Å). The behaviour is similar to that observed for the titanium-oxygen system [4].

When annealed at 800°C the sample $ZrO_{0.30}$ gives X-ray powder photographs which show the oxygen atoms to be distributed at random in the interstices of the zirconium lattice. The preparation $ZrO_{0.35}$, similarly heat-treated, gives a powder pattern essentially corresponding to a structure of *anti*-$Cd(OH)_2$ type. The oxygen atoms should thus occur only in every second layer of octahedral holes extending normally to the c axis. About 30 % of these holes must thus be vacant. The metal atoms are slightly forced apart by the interstitial atoms. The z parameter of the zirconium atoms thus acquires the value of 0.26 as compared to 0.25 for the ideal structure. There are, however, also indications of the vacancies in the oxygen positions being ordered. Research on this matter will be continued.

Syntheses of Some Hydroquinone Derivatives

ULF ULFVARSON

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Work has been in progress in this laboratory for some time on the synthesis of a number of substituted phenyl- and benzoylalkanes. A Friedel-Crafts reaction on adipoyl chloride and hydroquinone dimethylether gave 1,4-bis(2,5-dimethoxybenzoyl)butane and δ-(2,5-dimethoxybenzoyl)valeric acid. The ratio of the two reaction products depended on the proportion of adipoyl chloride to hydroquinone dimethylether.

Reduction and demethylation of 1,4-bis(2,5-dimethoxybenzoyl)butane gave 1,6-bis(2,5-dihydroxyphenyl)hexane. Oxidation of this hydroquinone gave the corresponding quinone.

Until recently the only attempt that had been made to prepare these types of substances was that of Bruce *et al.* [1] who obtained δ-(2,5-dihydroxybenzoyl)valeric acid in poor yield from hydroquinone and adipic acid using an $AlCl_3$-NaCl melt. No other products were isolated. Okuma and Tamura [2] have now prepared some of these substances by other methods for use as antioxidants.

Experimental. (Melting points were determined with a Koefler apparatus.)

δ-(2,5-Dimethoxybenzoyl)valeric acid and 1,4-bis(2,5-dimethoxybenzoyl) butane. Hydroquinone dimethylether (70 g, 0.5 mole) and adipoyl chloride (183 g, 1.0 mole) were dissolved in dry carbondisulfide (300 g) and finely ground $AlCl_3$ (266 g, 2.0 mole) was added with stirring. The temperature was not allowed to exceed 10°C. After the addition of $AlCl_3$ was complete the solvent was decanted from the orange-red syrup, and this was decomposed with ice. The reaction products were shaken out with chloroform and the acid fraction was separated by shaking with $NaHCO_3$-solution. δ-(2,5-Dimethoxybenzoyl)valeric acid was precipitated with hydrochloric acid, dried and recrystallised from benzene-light petroleum, white prisms, m.p. 80.5—82°C (65 g). (Found: C 63.55; H 6.69; OCH_3 22.7. $C_{14}H_{18}O_5$ requires C 63.14; H 6.81; OCH_3 23.3.)

The neutral chloroform solution was dried and evaporated and the 1,4-bis (2,5-dimethoxybenzoyl) butane was recrystallised from 95 % ethanol, white needles, m.p. 112—113°C (10 g) (Found: C 68.50; H 6.63; $C_{22}H_{26}O_6$ requires C 68.37; H 6.78.)

δ-(2,5-Dihydroxybenzoyl)valeric acid. δ-(2,5-Dimethoxybenzoyl) valeric acid (5 g) was demethylated by refluxing for 1 h in a mixture of hydrobromic acid (48 %, 40 ml) and acetic acid (100 ml). The acetic acid was evaporated and the δ-(2,5-dihydroxybenzoyl) valeric acid was precipitated by cooling and recrystallised from water, yellow leaves m.p. 130—131.5°C (Bruce *et al.*[1]: 130°C) (3 g).

The crystalline acid chloride of δ-(2,5-dimethoxybenzoyl)valeric acid was prepared in good yield with oxalyl chloride in dry benzene at room temperature by the method of Adams[3]. It gave 1,4-bis (2,5-dimethoxybenzoyl) butane by reaction with hydroquinone dimethylether and aluminium chloride as above.

1,6-Bis (2,5-dimethoxyphenyl) hexane. 1,4-Bis(2,5-dimethoxybenzoyl)butane (10 g) suspended in absolute ethanol (300 ml) was hydrogenated over a 5 % Pd on charcoal catalyst (2 g) (Theilacker [4]). 2 400 ml of hydrogen (760 torr) was adsorbed in 120 min. The reduced product was soluble in ethanol; the catalyst was filtered off and the solvent evaporated giving 1,6-bis (2,5-dimethoxyphenyl) hexane (7.5 g) which was recrystallised from light petroleum, white needles, m.p. 55—56°C. (Found: C 73.38; H 8.33. $C_{22}H_{30}O_4$ requires C 73.71; H 8.44.)

1,6-Bis (2,5-dihydroxyphenyl) hexane. 1,6-Bis (2,5-dimethoxyphenyl)hexane (5 g) was mixed with pyridine hydrochloride (20 g) and heated to 200°C in oil bath for 2 h by the method of Prey [5]. After cooling, 150 ml of water was added to the reaction mixture. The oil which separated crystallised on standing and was recrystallised from acetonitrile, white needles, m.p. 160.5—162°C (3 g). (Found: C 70.61; H 7.18; $C_{18}H_{22}O_4$ requires C 71.50; H 7.34.)

1,6-Bis(p-benzoquinoyl)hexane. 1,6-Bis (2,5-dihydroxyphenyl) hexane (400 mg) dissolved in acetic acid (50 ml) was heated to about 50°C, and a 10 % solution of CrO_3 in water (2 ml) was added. The quinone which separated was filtered after cooling and recrystallised from acetonitrile, yellow leaves m.p. 153.5—155.5°C. (Found: C 72.15; H 6.10. $C_{18}H_{18}O_4$ requires C 72.47; H 6.08.)

ε-(2,5-Dimethoxyphenyl)hexanoic acid. δ-(2,5-Dimethoxybenzoyl)valeric acid was reduced in the same way as the 1,4-bis (2,5-dimethoxybenzoyl)butane; white crystals, m.p. approx. 40°C. It was difficult to purify and was characterised by its *p*-toluidide: ε-(2,5-

Dimethoxyphenyl) hexanoyl chloride (1 g), prepared with oxalyl chloride in the same way as δ-(2,5-dimethoxybenzoyl)valeroyl chloride, was refluxed with *p*-toluidine (2 g) in dry benzene (50 ml) for 15 min. After cooling the solution was washed with water, dilute hydrochloric acid and bicarbonate solution. The solution was dried and evaporated and the residue was recrystallised from benzene--light petroleum and gave white needles m.p. 103.5—105°C. (Found: C 73.26; H 7.98; N N 3.79. $C_{21}H_{27}O_3N$ requires C 73.86; H 7.97; N 4.10.)

1,4-Bis(2-hydroxy-5-methoxybenzoyl) butane. 1,4-Bis(2,5-dimethoxybenzoyl)butane (3 g) was dissolved in a cooled solution of $AlCl_3$ (12 g) in nitrobenzene (150 ml). After 45 h at room temperature the mixture was decomposed with ice and the nitrobenzene was removed by steam distillation. The solid product was dissolved in chloroform and shaken with sodium hydroxide solution (1 N). The alkaline solution was acidified with hydrochloric acid and the crystals which separated were dissolved in chloroform. After drying the chloroform solution was run through a silica gel column and evaporated. A small amount of pure 1,4-bis(2-hydroxy-5-methoxybenzoyl)butane was obtained. It was recrystallised from ethanol-benzene, yellow prisms, m.p. 157—158°C. It gave a violet colour with $FeCl_3$ in methanol. (Found: C 66.49; H 6.22; OCH_3 15.9. $C_{20}H_{22}O_6$ requires C 67.03; H 6.19; OCH_3 16.1.)

An attempt to prepare this substance from adipoyl chloride, hydroquinone monomethylether and aluminium chloride using the same conditions as in the preparation of 1,4-bis (2,5-dimethoxybenzoyl)butane gave the bis-*p*-methoxyphenylester of adipic acid, white needles from ethanol, m.p. 126—127°C. (Found: C 67.13; H 6.04. $C_{20}H_{22}O_6$ requires C 67.02, H 6.19.)

Infrared spectrum of 1,4-bis(2-hydroxy-5-methoxybenzoyl)butane indicated that the demethylation took place in the *ortho* positions to the carbonylgroups. There was no absorption attributable to a hydroxyl group in the 3 500—2 500 cm^{-1} region. The same is true for *o*-hydroxyacetophenone which is attributed to intramolecular hydrogen bonding by Hergert [6].

The carbonyl frequency of 1,4-bis(2,5-dimethoxybenzoyl) butane was measured to 1 665 cm^{-1} and that of 1,4-bis(2-hydroxy-5-methoxybenzoyl) butane to 1 650 cm^{-1}. The difference is 15 cm^{-1}. The difference between the carbonyl frequencies of *o*-methoxyacetophenone and *o*-hydroxyacetophenone [6] is 14 cm^{-1}, from 1 649 cm^{-1} to 1 635 cm^{-1}.

The low carbonyl frequency of 1,4-bis(2-hydroxy-5-methoxybenzoyl)butane may be explained if a conjugated chelate system as in *o*-hydroxyacetophenone [6] is assumed.

Metal-Metal Bonding in a Mixed Chromium Molybdenum Oxide Phase of Rutile Structure

ANITA SUNDHOLM, STEN ANDERSSON, ARNE MAGNÉLI, and BENGT-OLOV MARINDER

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

Mixed chromium molybdenum oxide $(Cr,Mo)O_2$ of rutile type has been prepared by heating mixtures of chromium(III)-oxide, molybdenum(IV)oxide and molybdenum (VI)oxide ($Cr_2O_3 + aMoO_2 + MoO_3$) in sealed, evacuated silica tubes and keeping the temperature at about 1 000°C for several days. For values of a of 3 – 7.5 the X-ray powder patterns showed that the products only contained the rutile type phase. The width of the homogeneity range was not determined. No indications were observed of the metal atoms being ordered. The following unit cell dimensions were obtained:

	a	c	V
$Cr_{0.33}Mo_{0.67}O_2$	4.696 Å	2.886 Å	63.64 Å^3
$Cr_{0.22}Mo_{0.78}O_2$	4.749	2.858	64.44
$Cr_{0.19}Mo_{0.81}O_2$	4.760	2.848	64.53

The increase of the unit cell volume with the molybdenum content is in accordance

Dimethoxyphenyl) hexanoyl chloride (1 g), prepared with oxalyl chloride in the same way as δ-(2,5-dimethoxybenzoyl)valeroyl chloride, was refluxed with *p*-toluidine (2 g) in dry benzene (50 ml) for 15 min. After cooling the solution was washed with water, dilute hydrochloric acid and bicarbonate solution. The solution was dried and evaporated and the residue was recrystallised from benzene--light petroleum and gave white needles m.p. 103.5—105°C. (Found: C 73.26; H 7.98; N N 3.79. $C_{21}H_{27}O_3N$ requires C 73.86; H 7.97; N 4.10.)

1,4-Bis(2-hydroxy-5-methoxybenzoyl) butane. 1,4-Bis(2,5-dimethoxybenzoyl)butane (3 g) was dissolved in a cooled solution of $AlCl_3$ (12 g) in nitrobenzene (150 ml). After 45 h at room temperature the mixture was decomposed with ice and the nitrobenzene was removed by steam distillation. The solid product was dissolved in chloroform and shaken with sodium hydroxide solution (1 N). The alkaline solution was acidified with hydrochloric acid and the crystals which separated were dissolved in chloroform. After drying the chloroform solution was run through a silica gel column and evaporated. A small amount of pure 1,4-bis(2-hydroxy-5-methoxybenzoyl)butane was obtained. It was recrystallised from ethanol-benzene, yellow prisms, m.p. 157—158°C. It gave a violet colour with $FeCl_3$ in methanol. (Found: C 66.49; H 6.22; OCH_3 15.9. $C_{20}H_{22}O_6$ requires C 67.03; H 6.19; OCH_3 16.1.)

Metal-Metal Bonding in a Mixed Chromium Molybdenum Oxide Phase of Rutile Structure

ANITA SUNDHOLM, STEN ANDERSSON, ARNE MAGNÉLI, and BENGT-OLOV MARINDER

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

Mixed chromium molybdenum oxide $(Cr,Mo)O_2$ of rutile type has been prepared by heating mixtures of chromium(III)-oxide, molybdenum(IV)oxide and molybdenum (VI)oxide ($Cr_2O_3 + aMoO_2 + MoO_3$) in sealed, evacuated silica tubes and keeping the temperature at about 1 000°C for several days. For values of a of 3 – 7.5 the X-ray powder patterns showed that the products only contained the rutile type phase. The width of the homogeneity range was not determined. No indications were observed of the metal atoms being ordered. The following unit cell dimensions were obtained:

	a	c	V
$Cr_{0.33}Mo_{0.67}O_2$	4.696 Å	2.886 Å	63.64 Å^3
$Cr_{0.22}Mo_{0.78}O_2$	4.749	2.858	64.44
$Cr_{0.19}Mo_{0.81}O_2$	4.760	2.848	64.53

The increase of the unit cell volume with the molybdenum content is in accordance

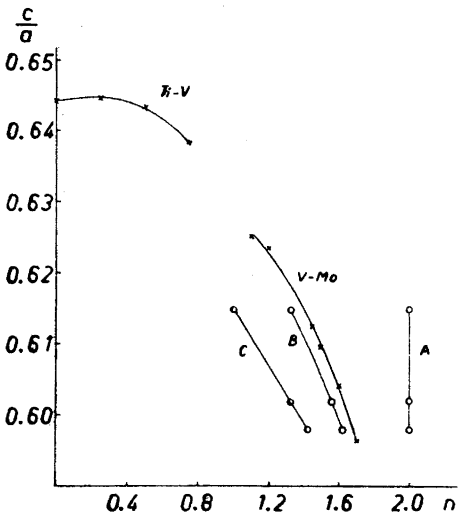

Fig. 1.

with the corresponding data for chromium dioxide (V = 57.06 Å^3 for rutile type cell [1]) and molybdenum dioxide (V = 65.03 Å^3 for subcell of distorted rutile type [2]). The decrease, with the molybdenum content, of the c axis (*i.e.* the shortest metal-metal distance of the structure) is the reverse of what would be expected from the relative sizes of the component atoms. This is taken as an indication of bonding forces acting between the neighbouring metal atoms of the mixed oxide as has previously been found for molybdenum dioxide (shortest metal-metal distance = 2.50 Å[2,3]) and several other compounds of transition metals when in valency states lower than their maximum ones [4]. The long metal-metal distance in chromium dioxide (c = 2.917 Å) [1] shows that no such bonding is present in this substance. This interpretation of the meaning of the intermetallic distances is supported by the magnetic data reported for the chromium and molybdenum dioxides [5]. It is also of interest to note that the metal atoms are "non-bonding" in the $Cr_2Cl_9^{3-}$ ion [6] while structural and magnetic data indicate bond formation in the $W_2Cl_9^{3-}$ ion [7,8].

It was shown in a previous article [4] that the axial ratio c/a provides an acceptable "normalized" measure of the metal-metal distance and this makes possible a comparison of rutile structures containing atoms of different sizes. On plotting the axial ratio against the number of excess valency electrons available per close metal-metal contact (n) (*i.e.* the number of valency electrons of the transition metal atoms which are not engaged in metal oxygen bonding) smooth curves are obtained.

Fig. 1 shows the curves thus derived for rutile type phases occurring in the systems (Ti,V)O_2 and (V,Mo)O_2. A few rutile type preparations in the systems (V,Re)O_2, (V,Mo,Re)O_2 and (Nb,Mo)O_2 give further data in fair agreement with the (V,Mo)O_2 curve or its extrapolation towards higher n values. For the (Cr,Mo)O_2 preparations, the following alternatives are indicated in the figure:

A. The excess valency electrons of both chromium and molybdenum are available for the formation of metal-metal bonds.

B. The excess chromium electrons are "non-bonding". All the metal atoms are tetravalent.

C. The excess chromium electrons are "non-bonding". The chromium atoms are trivalent and the corresponding proportion of the molybdenum atoms pentavalent or hexavalent.

It appears that curve *B* is in the best agreement with the data for other rutile phases containing molybdenum. This may be taken as an indication that the excess chromium electrons do not contribute to the metal-metal bonding and that the chromium atoms are probably in a tetravalent state.

This investigation forms part of a research program on metal oxides and related compounds financially supported by the *Swedish Natural Science Research Council*.

Rutile-Type Phases in Some Systems of Mixed Transition Metal Dioxides

BENGT-OLOV MARINDER and ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

It has previously been pointed out that, in some dioxides of transition metals, very short metal-metal distances are present, indicating the existence of bonds between the metal atoms. This is the case for the dioxides of MoO_2-type [1] and for orthorhombic rhenium dioxide [2]. In the search for further substances exhibiting such bonds, one pseudo-ternary and several pseudo-binary systems of transition metal dioxides have been studied. Since the intention was principally to find the metal-metal distances, it was natural to concentrate the interest on the occurrence of phases of rutile type, where the intermetallic distances are simply connected with the unit cell dimensions. A comprehensive knowledge of the phase relations in the various systems was not aimed at. This article presents the findings obtained during these studies. Discussions of the occurrence of metal-metal bonds in the various systems have been given elsewhere [3-5].

The samples investigated comprised mixed dioxides of titanium, vanadium, niobium, chromium, molybdenum, wolfram and rhenium. The starting materials were all of high purity. The samples were generally prepared by heating appropriate mixtures of oxides and sometimes also metals in sealed, evacuated silica tubes and keeping the temperature at about 1 000°C for several days. This treatment was with few exceptions found satisfactory for the attainment of equilibrium conditions.

The preparations were studied by means of X-ray powder photographs obtained in a Guinier focusing camera with strictly monochromatized Cu$K\alpha_1$ radiation. Potassium chloride ($a = 6.2919$ Å at 20°C) [6] was always added to the powder specimens as an internal standard. The results of the phase analysis are summarized in Table 1 which also includes some data reported by Schönberg [7].

A noticeable feature of several of the systems investigated is the occurrence of rutile-type phases (r) existing over wide ranges of composition (*cf.* Fig. 1). This

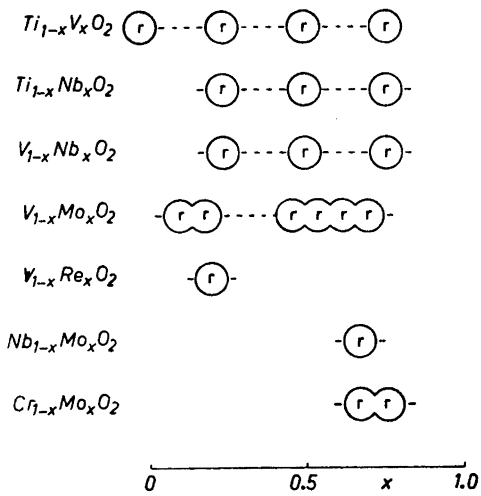

Fig. 1.

is the case not only in systems containing a component of rutile structure (*i.e.* the systems with titanium dioxide). Systems formed with components of other crystal structures, including vanadium and molybdenum dioxide (MoO_2-structure) [1], niobium dioxide (superstructure of distorted rutile) [5] and rhenium dioxide (orthorhombic ReO_2-type) [2] also show intermediary regions of ideal rutile type. These results evidently add further examples to the data given by Brandt [8], of the pronounced adaptability of the rutile structure to a variety of metal atom species.

In no case were indications observed of superstructures like those reported by Byström, Hök and Mason [9] for the large group of mixed oxides of ordered trirutile type. No attempts were made in this study to find out if such ordering occurs at lower temperatures.

The occurrence at an intermediary composition in the molybdenum dioxide-wolfram dioxide system of a MoO_2-type phase (which may extend over the entire range of composition) is evidently rather exceptional. Probably a mixed MoO_2-type structure will form over a wide range of composition only if the structures of the two components are similar.

This investigation forms part of a research program on metal oxides and related com-

The Preparation of Some Naphthylselen-carboxylic Acids

BERNDT SJÖBERG and STEFAN HERDEVALL

Chemical Institute, University of Uppsala, Uppsala, Sweden

In connection with the studies on synthetic plant growth regulators going on at this institute some naphthylsulphide-carboxylic acids have previously been prepared [1,2] and the plant growth regulating activity has been investigated by Professor B. Åberg at the Royal Agricultural College, Uppsala [3]. We have now extended these studies to some naphthylselen-carboxylic acids.

Some phenylselenacetic acids and 1-naphthylselenacetic acid have previously been prepared by reacting the Grignard reagents with selenium and then adding dilute alkali solution and bromoacetic acid [4]. As bromobenzene and 1-bromonaphthalene are readily available this method seems to be convenient for the preparation of phenylselen-carboxylic acids and for 1-naphthylselen-carboxylic acids. For the syntheses of the 2-naphthylselen-carboxylic acids we have tried three methods:

Acid	Method	Yield	M.p.
1-Naphthylselen-acetic	2	50	66—67°*
2-Naphthylselen-acetic	1	26	89—90°
2-Naphthylselen-acetic	2	20	89—90°
2-Naphthylselen-acetic	3	75	89—90°
α-(2-Naphthylselen)-propionic	1	20	118—119°
α-(2-Naphthylselen)-propionic	2	15	118—119°
α-(2-Naphthylselen)-propionic	3	77	118—119°
β-(2-Naphthylselen)-propionic	2	14	105—106°

* Morgan and Porritt reported m.p. 54°.

1. Hydrolysis of 2-naphthylselenocyanate [5] and direct reaction with different bromosubstituted acids.
2. Reaction of selenium with the Grignard reagent of 2-iodonaphthalene and further reaction with halogen substituted acids.
3. Reduction with sodiumborohydride of 2,2'-dinaphthyldiselenide dissolved in a benzene-alcohol mixture followed by reaction with haloesters.

As can be seen in the table above, method 1 has given a somewhat higher yield (counted on 2-naphthylselenocyanate) than method 2 (counted on 2-iodonaphthalene). However, 2-iodonaphthalene is much easier to prepare than 2-naphthylselenocyanate, and so method 2 is to be preferred. Both in method 1 and 2 some diselenide is formed from which the acids can be obtained in very good yield. If the diselenide is accessible, this method is certainly the best.

Experimental. Method 1. 2-Naphthylselenocyanate was prepared according to Loevenich, Fremdling and Föhr [5]. The naphthylselenocyanate was dissolved in hot alcohol, some glucose and excess of concentrated potassium hydroxide solution were added and the mixture boiled until a homogeneous phase had been obtained. The mixture was cooled and the neutralised bromosubstituted acid was added. After standing in a closed bottle for 12 h warm water was added, the mixture filtered and the solution acidified with hydrochloric acid.

The naphthylselenocyanate was dissolved in hot alcohol, some glucose and excess of concentrated potassium hydroxide solution were added and the mixture boiled until a homogeneous phase had been obtained. The mixture was cooled and the neutralised bromosubstituted acid was added. After standing in a closed bottle for 12 h warm water was added, the mixture filtered and the solution acidified with hydrochloric acid.

Method 2. 2-Iodonaphthalene was prepared in the usual way [6]. However, the yield and the quality of the product were improved when excess of nitrous acid was removed by potassium permanganate and the diazotized solution filtered before it was treated with potassium iodide [7].

The Grignard reagent of 0.2 mole 2-iodonaphthalene was prepared in a nitrogen atmosphere using a mixture of dry ether and benzene as solvent. Selenium (0.18 g-atom) was added and the mixture refluxed for 2 h. The flask was then cooled and 200 ml of about 3 M potassium hydroxide was added. A neutralised solution of the bromosubstituted acid was added with vigorous stirring. The stirring was continued for 12 h, the mixture was then treated with hydrochloric acid. The organic phase was extracted with ammonia and the naphthylselen-carboxylic acid was precipitated with hydrochloric acid. From the ether-benzene phase about 8 g of 2,2'-dinaphthyldiselenide was isolated.

Method 3. The diselenide was dissolved in boiling benzene and alcohol was added until starting turbidity. Sodiumborohydride was added until the solution was almost colourless. After addition of excess of haloester the mixture was refluxed for 2 h, potassium hydroxide solution was added and the alcohol and the benzene were distilled off. The alkaline solution was extracted with ether and then acidified.

All the naphthylselen-carboxylic acids were recrystallised from carbon tetrachloride and from formic acid. Yield and melting points are given in the table above.

Mass Spectrometric Studies on Bile Acids and Other Steroid Derivatives

Sune Bergström*

Institute of Physiological Chemistry, University of Lund, Lund, Sweden

Ragnar Ryhage

Laboratory for mass spectrometry, Kemiska Institutionen I, Karolinska Institutet, Stockholm, Sweden

and Einar Stenhagen

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

The mass spectra of the methyl esters of the bile acids show several characteristic features which render them useful for analytical purposes. The methyl ester of cholanic acid shows an intense peak of *m/e* 374 corresponding to the unfragmented ionized molecule $C_{25}H_{42}O_2^+$. This peak is the largest in the spectrum. When the sterol nucleus carries one or more hydroxyl groups the molecular peaks ("parent peaks") are either very small or absent because the hydroxyl groups are easily eliminated as water with the formation of double bonds. The side chain is also readily split off and in the mass spectrum there occurs a peak corresponding to the ionized unsaturated nucleus. For methyl esters of monohydroxycholanic acids such as 3-hydroxycholanic (lithocholic) acid this peak occurs at *m/e* 257. For 3,7,12-trihydroxycholanic (cholic) acid the "nuclear peak" is at *m/e* 253. For a saturated bile acid the nuclear peak thus indicates the number of hydroxyl groups present in the sterol ring system.

If the ring system contains both hydroxyl groups and double bonds the nuclear peak indicates their sum. Thus stigmasterol and β-sitosterol, which both have one hydroxyl group and one double bond in the ring system, give a characteristic nuclear peak at *m/e* 255.

The saturated monohydroxy tetracyclic triterpene tetrahydrodammaradienol [1] which possesses a trimethyl-substituted steroid nucleus gives a nuclear peak at *m/e* 299 = (257 + 3 × 14).

Peaks due to methoxycarbonyl-containing fragments are less prominent in the spectra of methyl esters of bile acids than they are in the spectra of methyl esters of aliphatic acids [2], but the intensity distribution among these peaks depends on the structure of the side chain in a manner analogous to that found in the case of methyl esters of branched chain aliphatic acids.

Positional isomers such as 3-hydroxy- and 12-hydroxycholanic acid give very different mass spectra.

The methyl ester of triacetoxycholic acid gives a very good spectrum in which the last peak observed is a strong peak at *m/e* 428 = (M—120). This fragment has evidently been formed by the elimination of two of the three acetyl groups in the form of acetic acid. The acetic acid is indicated by its strong molecular peak at *m/e* 60.

On the Mechanism of Deoxycholic Acid Formation

S. Bergström, S. Lindstedt and B. Samuelsson

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Recent work has shown that deoxycholic acid is formed from cholic acid by the action of intestinal microorganisms [1-3]. The aim of the present investigation was to study the reaction mechanisms of this transformation with the aid of cholic acid labelled with tritium in the 7β-position. The acid was prepared by reduction of 3α, 12α-dihydroxy-7-ketocholanic acid with sodium borohydride earlier exposed to tritium gas for 6 days. This compound was first administered together with cholic acid-24-^{14}C to rabbits. A bile fistula was made after two days. Practically all of the cholic acid had then been transformed into deoxycholic acid. The ratios of isotopes (^{3}H/^{14}C) in this acid and in the administered cholic acid were determined and found to be equal, thus demonstrating complete retention of the 7β-hydrogen during the elimination of the 7α-hydroxyl group.

The doubly labelled cholic acid was then given to rats and allowed to take part in the enterohepatic circulation for 1—7 days. Determinations of isotope ratios in the cholic acid samples isolated from the animals showed that a progressive loss of tritium had occurred.

It is known that in the rat deoxycholic acid is hydroxylated to cholic acid in the liver [4] and it was assumed that the loss of the 7β-^{3}H had taken place during the reaction sequence: cholic acid → deoxycholic acid → cholic acid. Norman and Sjövall [3] have isolated labelled deoxycholic and 3α, 12α-dihydroxy-7-ketocholanic acid from feces of rats that had received labelled cholic acid, and have further shown that the keto acid can be transformed into deoxycholic acid in the gut. If the 7-keto acid was an obligatory intermediate in the reaction cholic acid → deoxyholic acid this would explain the loss of the 7β-^{3}H. To clarify this point doubly labelled cholic acid was injected into the coecum of rats with a bile fistula and deoxycholic acid isolated from the feces. This acid retained 80 % of the tritium activity indicating that 3α,12α-dihyroxy-7-ketocholanic acid is only of minor importance as an intermediate in the formation of deoxycholic acid, the main path probably leading *via* the stereospecific elimination of water with the formation of an unsaturated acid as an intermediate.

The loss of tritium activity might also have occurred in the step deoxycholic acid → cholic acid which occurs in the liver. The doubly labelled deoxycholic acid obtained in the aforementioned experiments was therefore injected intraperitoneally into rats with a bile fistula. The ratio of T/^{14}C in the isolated cholic acid was then found to be less than 4 % of that in the injected deoxycholic acid.

The 7α-hydroxylation of cholesterol and the 11α- and 11β-hydroxylation in the pregnane-3,20-dione series have been found to proceed by direct replacement of the 7α-, 11α- and 11β-hydrogen, resp.[5-7] and it seems plausible that the 7α-hydroxylation of deoxycholic acid proceeds by a similar reaction, in which the 7β-hydrogen would not be labelized.

One explanation of these results is that the 7-hydrogen of the possible unsaturated intermediate formed by the elimination of water is brought into the 7α-position at the reduction of the double bond.

Determination of the Position of Carbon-Carbon Double Bonds by Mass Spectrometry

Nguyen Dinh-Nguyen

Department of Medical Biochemistry, University of Gothenburg, Sweden

The position of the double bond in methyl oleate may be determined by comparing the mass spectra of methyl stearate and methyl 9,10-dideuterostearate. The latter compound was prepared by reduction of methyl oleate with deutero-hydrazine.

The extension of the method to poly-unsaturated fatty esters is under investigation.

The Effect of Parathyroid Extract on Oxidative Phosphorylation

Carl-Henric de Verdier

Institute of Medical Chemistry, University of Uppsala, Sweden

In a previous communication the *in vivo* effect of a parathyroid extract was studied on the incorporation of ^{32}P labelled phosphate into different phosphorus compounds in rat kidney and liver [1]. Additional experiments have been made with kidney slices and liver mitochondria *in vitro*. The kidney slices were incubated in a medium containing different ions (Ca^{++} 2.5 mM) and glucose as a substrate. In this system parathormone (Lilly) in a concentration of 0.2 U. S. P. units per ml partly inhibited the incorporation of labelled phosphate into some nucleotides and phosphorylthreonine isolated from phosphoprotein. The effect on oxidative phosphorylation has been tested in a system of liver mitochondria similar to that of Dawson and Jones [2] by working on the assumption that although kidney and bone are the main target organs, the action of the hormone must be demonstrable in most cells. The mitochondrial suspension was obtained after homogenization in 0.25 M sucrose containing 0.001 M EDTA followed by centrifugations; the final two washings were performed in sucrose without EDTA. The result of a typical experiment is shown in Table 1.

Table 1. Effect of parathormone on oxidative phosphorylation in rat liver mitochondria. Each sample contained mitochondria from 0.5 g wet weight liver, 40 μmoles potassium orthophosphate, 5 μmoles ATP, 17 μmoles $MgCl_2$, 30 μmoles pyruvate, 0.04 μmoles cytochrome c, 295 μmoles sucrose, 60 μmoles glucose and hexokinase, pH 7.4. About 0.1 mC ^{32}P per flask. Final volume 3.0 ml. Incubation in open vessels with shaking at 30°C.

Hormone concentration units per ml	Ca^{++} concentration mM	Organic phosphate formed % of total labelled phosphate 7 min	18 min
0	0	42	98
0	0.33	40	98
0.025	0.33	32	77
0.05	0.33	31	72
0.10	0.33	30	69
0.20	0.33	30	55

The effect is obtained only when Ca^{++} is present in a concentration of about 3×10^{-4} M. The necessary presence of calcium ions seems to indicate that the hormone exerts its effect *via* these ions. Their inhibitory effect on oxidative phosphorylation in different mitochondrial systems is well-known[3]. Experiments with $^{45}Ca^{++}$, however, did not reveal any significant effect of the extract on the distribution of calcium ions between intra- and extramitochondrial space.

On the Use of Gas Chromatography and Mass Spectrometry in the Analysis of the Fatty Acids Found in Butter and Margarine

B. Hallgren and S. Stenhagen

Department of Medical Chemistry, University of Gothenburg, Gothenburg

R. Ryhage

Laboratory for Mass Spectrometry, Kemiska Institutionen I, Karolinska Institutet, Stockholm, Sweden

Under standardized operational conditions in gas chromatography the retention volume or retention time is characteristic of a certain component. When investigating mixtures of several components it is, however, necessary to use additional identification methods. In analysing mixtures of esters of fatty acids we have submitted them to both gas chromatography and mass spectrometry. If the gas chromatograms and the mass spectra of the mixtures are compared it is sometimes possible to identify the components. The mass spectrum of a mixture of many components will, however, become too complex. We have then collected fractions coming out from the gas chromatography column and identified the components of the fractions by a mass spectrometer run.

Using these methods we have analysed the complex mixtures of fatty acids present in butter and margarine.

The Isolation of Phosphorylhexosamine from the Rest Protein Fraction of *Escherichia coli* B

Gunnar Ågren

Institute of Medical Chemistry, University of Uppsala, Sweden

In earlier communications [1,2] it has been shown that acid hydrolysates of the Schneider rest protein fractions from mammalian organs contain O-phosphorylserine and O-phosphorylthreonine. Phosphorylserine has also been isolated from the corresponding fraction of yeast [3]. In other microorganisms phosphorylated hydroxy-amino acids of different composition seem to dominate in the acid hydrolysates. From *L. casei* O-phosphorylmuramic acid has recently been isolated [4], and from *E. coli* in the same way O-phosphorylethanolamine [5].

It has now been possible to isolate chromatographically pure phosphorylhexosamine from the acid hydrolysate of the rest protein of *E. coli*. Previously published methods for cultivation and isolation have been followed[6]. The bacteria were harvested at the end of the lag phase. They had been cultivated for about 2 h on a medium containing 1 mC ^{32}P per liter to facilitate the identification of phosphorus compounds. After lyophilization the cells were disrupted in a Raytheon 50-watt 9 kc magnetostriction oscillator during continuous cooling. The cell walls were separated by fractionated centrifugation [6]. The elution curve of the acid hydrolysate of cell walls passing through a Dowex 50-column was given in a previous paper [5].

By paper ionophoretic analysis it was found that the material from peak No. III on the curve was a mixture of at least three ninhydrin-positive compounds which at pH 5 migrated slower than phosphorylserine or phosporylthreonine. Sufficient amounts of material for analysis of peak No. III was obtained by mixing radioactive bacteria with large amounts of unlabeled cells. For large scale cultivation the bacteria were incubated in a 1 000 liter tank on the same medium for about 20 h. The usual yield of fresh bacteria from a single cultivation was about 2.5 kg. Material from two cultivations was used in this study. The hydrolysates of the rest protein fractions were separated on 10 Dowex-50 columns. Column dimensions were 6.5 × 55 cm.

Preparative paper ionophoresis of all material from peak No. III was carried out for 4 h in a 0.1 N pyridine-acetate buffer of pH 5 using Whatman paper No. 3. Two large ninhydrin-positive spots were found close to each other and well separated from a weaker spot with a more rapid migration. The phosphorus contents were 2.7 %, 0.71 %, and 0.16 %, respectively. Material from the slowest moving spot with the highest phosphorus content was eluted from the paper with water and purified by chromatography first on a small Dowex-50 column as a single peak with 0.01 N HCl and then on a small (0.9 cm × 25 cm) Dowex-1 formate column where the material could be eluted with water. Two rather well separated peaks were observed. Only a few mg were obtained from the first fraction with a phosphorus content of 6.0 %. The second peak had a phosphorus content of 11.6 %. In all about 40 mg of material was obtained from 5 kg of fresh bacteria.

The identity of this material with phosphorylhexosamine was verified by paper ionophoresis at pH 5 and paper chromatography in two solvent systems[1] where the compound moved as a single green-coloured ninhydrin-positive spot parallel with glucosamine-6-phosphate. This was prepared by incubating a yeast hexokinase preparation with equimolar amounts of glucosamine and radioactive ATP followed by purification on Dowex-1 formate column. Elementary analysis of the compound from *E. coli* gave the following values (Found: C 27.5; H 5.8; N 5.2; P 11.6. Calc. for $C_6H_{14}O_8NP$ (259): C 27.8; H 5.5; N 5.4; P 11.9). The position of the phosphate group must probably be in the primary alcoholic group. Only a phosphate group attached here would seem to resist the acid hydrolysis used in the isolation procedure [7].

Phosphorylhexosamine may not be present only in the cell walls. Water soluble fractions of proteins were obtained after centrifugation of the vibrated bacteria at 105100 *g* for 30 min at 0°C and precipitation with ethanol or acetone [6]. The acid hydrolysates of these purified fractions also gave the same types of elution curves on Dowex-50 columns with peaks in the same column volumes as No. III from the hydrolyzed cell walls. The function of phosphorylhexosamine in bacterial phosphoproteins is not clear. It could connect some peptide chains by diester bonds as in casein or pepsin [8], or possibly represent the active site in a transphosphorylating mechanism. A preliminary note has been published that galactosaminephosphate should be present in the hydrolysate of bone tissue [9].

Mass Spectrometric Studies on Amino Acid and Peptide Derivatives

Carl-Ove Andersson

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden, and Laboratory for Mass Spectrometry, Kemiska Institutionen I, Karolinska Institutet, Stockholm, Sweden

In the mass spectrum of a methyl ester of the type RCH_2COOCH_3 the most prominent peak is normally found at *m/e* 74 and is due to a rearranged fragment $^1C_3H_6O_2^+$. A prominent peak due to the alkyl fragment R^+ is only observed when carbon atom 3 is quaternary. The mass spectrum of the methyl ester of an *α*-amino acid $RCHNH_2COOCH_3$ shows, on the other hand, a very large peak due to the ionized fragment $RCHNH_2^+$. The mass number of this fragment is different for all amino-acids except the isomeric valines and leucines.

The parent peaks are small but in the cases so far examined allow a direct determination of the molecular weight of the esters. A further prominent peak occurs at *m/e* 88 corresponding to the fragment $-CHNH_2COOCH_3^+$.

Although several free amino-acids and simple peptides can be brought into the gas phase without decomposition [2] compounds with the zwitterion structure have been found less suitable for mass spectrometric analysis than compounds in which either the amino group or the carboxyl is protected. It has been found possible to analyze peptides with protected amino- and carboxyl groups. Thus N-trifluoroacetyl-L-alanyl-L-phenylalanine methyl ester [3] gives an excellent mass spectrum with a parent peak at *m/e* 346 (calculated molecular weight 346.3).

The high-mass, high-resolution mass spectrometer thus seems to offer interesting possibilities in the analysis of amino-acids and peptides.

It is intended to extend this work to other amino-acid derivatives and to study the possibility of analyzing mixtures. As carried out at present one analysis requires about 100 micrograms of material.

Infrared-spectroscopic Studies on Bile Acids

I. Fischmeister

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Sweden

The poor solubility of the bile acids in the nonpolar solvents required for infrared spectroscopy prevents their investigation in solution. We have therefore examined the spectra of the solid substances pressed in potassium bromide pellets. In the case of the bile acid esters which can be examined both in solution and in the solid state, the solid state spectra are found to be more distinct, owing to the fixed positions of the molecules in the crystal.

The spectra are sufficiently specific to allow identification of each bile acid by infrared spectroscopy. They are especially sensitive to the number and position of the hydroxyl groups in the skeleton. This is shown for the series of cholanic acid and its hydroxy derivatives, for coprostanic acid and its 3,7- and 3,7,12-hydroxy derivatives as well as for peptide conjugates of cholanic acid and its hydroxy derivatives with glycine and taurine. The length of the side chain affects not only the CH_2-vibrations but also those of the hydroxyl- and carboxyl group, indicating differences in the hydrogen bond pattern and/or different degree of hydrogen bonding in the crystallized compounds with different side chains.

Cellular Localisation and Specificity of Intestinal Invertase

Bengt Borgström and Arne Dahlqvist

Department of Physiological Chemistry, University of Lund, Lund, Sweden

In homogenates from intestinal mucosa (swine), invertase has been found exclusively localized in the microsome fraction, obtained by differential centrifugation. By treating the microsomes with a solution of desoxycholate the invertase activity was obtained in a clear solution which, however, did not prove to be a true solution, as dialysis lead to a recovery of the enzyme in the particulate form.

When isolated microsomes were digested by trypsin, invertase was rapidly inactivated parallel with the hydrolysis of proteins. In the beginning of this reaction, a solubilisation of invertase was observed. Phosphate buffer was found to protect invertase against the inactivation by trypsin, without affecting its solubilisation. In the presence of desoxycholate, it is therefore possible to use trypsin digestion for preparation of soluble invertase.

The relation of invertase to other α-glucosidases of intestinal mucosa is not known. According to the theory of Weidenhagen [1], the animal intestine should contain only one α-glucosidase, hydrolyzing maltose, sucrose, and other α-D-glucopyranosides. Enzyme preparations from animal intestine have, however, no action upon α-methylglucoside [2] and recently two α-glucosides have been demonstrated to be hydrolyzed by enzymes different from maltase, namely *iso*maltose and nigerose [3,4].

During the further purification of solubilized invertase, we have found that the trehalase activity is rapidly lost during ethanol fractionation while invertase and maltase activity are not affected during this procedure. Intestinal trehalase must therefore be an enzyme separate form maltase and invertase.

The further separation of invertase and maltase activity is explored by the use of DEAE-cellulose columns and these results will be discussed.

Fractionation of Enzymes from Ringhals Venom

Walter Björk and Hans G. Boman

Institute of Biochemistry, University of Uppsala, Uppsala, Sweden

Venom from the South African ringhals cobra *(Hemachatus haemachates)* has been studied by anion exchange chromatography and column electrophoresis.

Early results showed considerable differences in the chromatograms for different batches of venom and it was found that storage and autoincubation of the venom would alter the chromatographic behaviour of especially the phosphodiesterase. These results indicated that the procedure for the collection of the venom might be of significant importance for a successful fractionation. We have later by the kind cooperation of Dr. J. H. Mason at The South African Institute for Medical Research, been able to compare venom collected in the ordinary way (dried at room temperature) and venom "milked" down in a container cooled by dry ice and immediately freeze-dried. The chromatograms of these two materials showed that the main part of the phosphodiesterase is present in different forms depending on the collection procedure and that chromatography of the freeze-dried venom gives about 7 times better purification for the phosphodiesterase than obtained for venom collected in the ordinary way. It has also been found that the successful chromatographic separation of the diesterase is dependent on a sort of double fronting of the developing agent. The phosphodiesterase was separated from lecithinase A and cholinesterase, but the chromatography so far used did not separate the two latter enzymes from each other. However, column electrophoresis at pH 5.5 effects a complete separation of cholinesterase from both lecithinase A and phosphodiesterase. It thus appears that a combination of chromatography and electrophoresis may offer possibilities for an efficient purification of all three enzymes.

Inhibition of DNA-Synthesis by Deoxyadenosine

Hans Klenow and Lorna Langer

The Fibiger-Laboratory, University of Copenhagen, Denmark

The effect of some purine derivatives on the incorporation of ^{14}C-formate into DNA (deoxyribonucleic acid) and of ^{32}P-orthophosphate into DNA and RNA (ribonucleic acid) of ascites tumor cells *in vitro* has been investigated.

When Ehrlich's ascites tumor cells were incubated *in vitro* with ^{14}C-formate it was found that adenine, adenosine and deoxyinosine had some stimulatory effect or no effect on the incorporation of ^{14}C into DNA-thymine (measured a specific activity) when these compounds were added in concentrations of 2.3—3.9 μmoles per ml cell suspension. In the presence of added deoxyadenosine, however, the specific activity of DNA-thymine was only 6—15 % of that of the control. This effect was found both in the presence and in the absence of added deoxycytidine or deoxycytidylic acid. The total radioactivity of the pooled acid-soluble thymine compounds from cells incubated in the presence of ^{14}C-formate and deoxyadenosine for about 3 h, was about twice as high as that of the control experiment without added deoxyadenosine. The specific radioactivity of these thymine compounds were, however, about the same in the two cases. It is likely, therefore, that deoxyadenosine inhibits the biosynthesis of DNA and that this inhibition is not due to a block of the biosynthesis of the thymine part of DNA.

Experiments with ^{32}P-orthophosphate have shown a similar inhibitory effect by deoxyadenosine on the incorporation of ^{32}P into DNA. Fifty per cent inhibition was obtained with about 1 μmole of deoxyadenosine per ml cell suspension. Incorporation of ^{32}P into RNA was slightly increased under these conditions.

Experiments with suspensions of Yoshida's ascites tumor cells showed that addition of deoxyadenosine in concentrations of 3.5—3.9 μmoles per ml cell suspension had only a modest inhibitory effect in incorporation of ^{14}C-formate into DNA-thymine, while deoxyinosine showed a consistent stimulation of this incorporation, suggesting that the rate of DNA-synthesis is increased by about 50 %.

Table 1. Rate of incorporation of ^{32}P-orthophosphate into RNA and DNA of Ehrlich's ascites tumor cells.

Each vessel contained 0.4 g packed cells, suspended in 1.2 ml Tyrode's solution, deoxycytidine 5 μmoles, $H_2^{32}PO_4^-$ 12 μC, glucose 55 μmoles, and sodium succinate 37 μmoles. To the experimental vessels were further added 5 μmoles of adenine compounds as indicated; final volume 2.25 ml. Incubated at 37°C with shaking. The figures are averages of two experiments.

Additions	Rate of incorporation in per cent of the control	
	RNA	DNA
Adenine	99	105
Adenosine	105	122
Deoxyadenosine	94	14

Mass Spectrometric Studies on Esters of Rosin Acids

Henrik H. Bruun

Institute of Wood Chemistry, Åbo Akademi, Åbo, Finland

Ragnar Ryhage

Laboratory for mass spectrometry, Kemiska Institutionen I, Karolinska Institutet, Stockholm

and Einar Stenhagen

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

A mass spectrometric study has been performed on the methyl esters of the following rosin acids: *d*-pimaric, levopimaric, *iso*-*d*-pimaric, podocarpic, palustric, abietic, neoabietic, dihydroabietic, tetrahydroabietic and dehydroabietic (nomenclature of Simonsen and Barton [1], as well as on the related hydrocarbons fichtelite and retene.

All the methyl esters give excellent mass spectra showing a very strong peak due to the ionized unfragmented molecule. All the spectra differ markedly from each other and a rosin acid may be readily identified by the mass spectrum of its methyl ester. Methyl tetrahydroabietate and fichtelite have several strong peaks in common, a feature to be expected as the hydrocarbon skeleton of tetrahydroabietic acid is identical with that of fichtelite.

The Vitamin B_{12}-Content of Human Fetal Tissues

Johan Killander

Department of Microbiology, Institute of Medical Chemistry, University of Uppsala, Sweden

Deficiency of B_{12} during fetal life has been suggested to cause malformation or death of the fetus [1]. Moreover the fetal erythroblasts have been considered to be related to the megaloblasts occurring in anemias caused by B_{12} deficiency. It was therefore of interest to study the B_{12}-content of fetal tissues.

Method. 25—500 mg of tissue was homogenised; crude papain and sodium cyanide were added. The volume was made up to 25 ml with phosphate-citric acid buffer, pH 5.0. One hour's digestion at + 60°C was followed by heating at 100°C for 15 min. After filtration or centrifugation the B_{12} content of the extract was assayed microbiologically using *Euglena gracilis* z[2]. The recovery of added B_{12}-^{60}Co was nearly complete as determined by both radioactivity and microbiological measurements. Extracts of liver and muscle from a hog previously injected with B_{12}-^{60}Co contained close to 100 % of the radioactivity of the organ.

Material. Liver, spleen, kidney, adrenals, heart, lung, thymus, brain, spinal cord and muscle from 28 fetuses of 6—25 cm length were analysed. *Results*, See Table 1.

Conclusions. No changes in B_{12} concentration of fetal organs were observed over the period of life investigated except for brain and spinal cord in which the vitamin was found to decrease with age. The data on fetuses will be compared with those on prematures, children and adults.

Table 1. Mean and range of the vit. B_{12} content of human fetal tissues in mμg/g fresh weight.

Tissue	Fetal length 6—15 cm No. of observations		Fetal length 16—25 cm No. of observations	
Liver	17	360 (250—490)	6	340 (230—530)
Spleen	6	59 (48—79)	11	50 (37—72)
Kidney	14	140 (115—170)	7	130 (75—230)
Adrenals	15	180 (120—270)	7	180 (130—260)
Lung	2	77 (55—99)	2	87 (82—92)
Heart	17	45 (39—62)	8	41 (32—54)
Thymus			4	23 (14—30)
Brain	14	25 (13—38)	8	9,7 (5,3—15)
Spinal cord	14	63 (36—106)	11	36 (14—51)
Muscle	13	39 (23—44)	6	29 (21—35)

A Twin Microscope for the Perkin-Elmer Model 21 Infra-red Double-Beam Spectrophotometer

Fredrik Möhl

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Uppsala, Uppsala, Sweden

In our laboratory a Perkin-Elmer 21 infra-red double-beam spectrophotometer is employed. As the need arose for a microscope attachment to it, we began constructing such a device in the autumn of 1956.

The instrument now completed consists of 2 parallel microscopes lying horizontally directly in the beams. Each microscope has 10 mm reflecting Schwarzschild aplanats for objective and condenser. A lamp was built into the monochromator of the spectrometer to project its entrance slit upon the sample. The latter is observed through a retractable viewer with a semi-reflecting right-angle prism.

The stage is vertical, it has right-angle slides and moves axially for focusing. It can also be swung upwards-outwards for attention.

The whole microscope attachment forms a unit. It is easily removed and replaced with accuracy, being secured in position by two pins.

It is, however, still our opinion that no satisfactory device for infra-red double-beam microspectrophotometry has yet been made [1,2]. In our microscope too much energy is lost at the entrance. Had this not been the case, an excessive heating of the sample would have been unavoidable.

The remedy should be to reverse the beam path by interchanging the energy source and the detector of the spectrometer. Thus the sample would be placed in a monochromatic beam causing little heat. We have, however, not been able to solve this problem practically. It seems a task for the makers.

The Nucleophilic Reactivity of Biological Thiols with Respect to Thiol-Disulphide Exchange Reactions *

Alexander Pihl, Lorentz Eldjarn and Karl F. Nakken

Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway

The biological significance of thiols can to a considerable extent be explained by the nucleophilic reactivity of their thiol group. It has generally been felt that in most of the nucleophilic exchange reactions of thiols the mercaptide ion is the active molecular species. Recently this mechanism has been proven in the case of thiol-disulphide exchange reactions [1,2]. At pH 7.4 the concentrations of the ionized forms of the physiological thiols are not inconsiderable as their pK values prove to be much lower than previously realized [3,4].

In the present investigation the relative nucleophilic reactivity of a series of biologically important thiols has been studied. The initial rate of interaction of the thiols (cysteine, glutathione, homocysteine, cysteamine, diethylcysteamine, and penicillamine) with cystine at pH 7.4 and 37°C was measured using ^{35}S-labeled cystine followed by paper electrophoretic separation of the reaction products [5]. The unexpected observation was made that the observed initial reaction rates (k_{SH}) were approximately equal in spite of the very large differences in the concentrations of the ionized thiols (pK varied from 7.7 to 9.75). The rate constants for the respective ionized thiols (k_{S^-}) were found to obey the Brönsted equation with the following parameters:

$$\log k_{S^-} = 0.73\ pK_{SH} - 1.88$$

The above k values (expressed in liter $\times$ moles^{-1} $\times$ min^{-1}) refer to the interaction of the thiols with the one of the sulphur atoms of cystine. Since cystine contains two symmetrical sulphur groups which are equivalent in these exchange reactions, the observed rates were actually twice the one given in the equation. The above presentation was preferred for thermodynamic reasons.

Several thiols tested did not obey the above equation but reacted at distinctly slower rates. This was the case with certain N-acyl derivatives (N-acetylcysteamine, aletheine, and coenzyme A). Compounds where the ionized thiol is part of a resonating system (thiocyanide, *o*-aminothiophenol, ergothionine, thiolhistidine, *etc.*) did not interact at all with cystine.

Thiol-disulphide exchange reactions play an important part in the enzymatic reduction of disulphides [6] and similar reactions may be envisaged to occur in the establishment and the splitting of disulphide cross linkages in proteins. The fact that a series of thiols obey the above equation strongly indicates that in such reactions the pK value of the attacking thiol is of minor significance with regard to the reaction rates. This finding may be interpreted to mean that with increasing pK_{SH} value the decrease in the concentration of the ionized thiol at a given pH is effectively counteracted by a concurrent increase in the nucleophilic reactivity of the ionized thiol.

The Nucleophilic Reactivity of Biological Thiols with Respect to Thiol-Disulphide Exchange Reactions *

Alexander Pihl, Lorentz Eldjarn and Karl F. Nakken

Norsk Hydro's Institute for Cancer Research, The Norwegian Radium Hospital, Oslo, Norway

The biological significance of thiols can to a considerable extent be explained by the nucleophilic reactivity of their thiol group. It has generally been felt that in most of the nucleophilic exchange reactions of thiols the mercaptide ion is the active molecular species. Recently this mechanism has been proven in the case of thiol-disulphide exchange reactions [1,2]. At pH 7.4 the concentrations of the ionized forms of the physiological thiols are not inconsiderable as their pK values prove to be much lower than previously realized [3,4].

In the present investigation the relative nucleophilic reactivity of a series of biologically important thiols has been studied. The initial rate of interaction of the thiols (cysteine, glutathione, homocysteine, cysteamine, diethylcysteamine, and penicillamine) with cystine at pH 7.4 and 37°C was measured using ^{35}S-labeled cystine followed by paper electrophoretic separation of the reaction products [5]. The unexpected observation was made that the observed initial reaction rates (k_{SH}) were approximately equal in spite of the very large differences in the concentrations of the ionized thiols (pK varied from 7.7 to 9.75). The rate constants for the respective ionized thiols (k_{S^-}) were found to obey the Brönsted equation with the following parameters:

$$\log k_{S^-} = 0.73\ pK_{SH} - 1.88$$

The above k values (expressed in liter $\times$ moles^{-1} $\times$ min^{-1}) refer to the interaction of the thiols with the one of the sulphur atoms of cystine. Since cystine contains two symmetrical sulphur groups which are equivalent in these exchange reactions, the observed rates were actually twice the one given in the equation. The above presentation was preferred for thermodynamic reasons.

Several thiols tested did not obey the above equation but reacted at distinctly slower rates. This was the case with certain N-acyl derivatives (N-acetylcysteamine, aletheine, and coenzyme A). Compounds where the ionized thiol is part of a resonating system (thiocyanide, *o*-aminothiophenol, ergothionine, thiolhistidine, *etc.*) did not interact at all with cystine.

Thiol-disulphide exchange reactions play an important part in the enzymatic reduction of disulphides [6] and similar reactions may be envisaged to occur in the establishment and the splitting of disulphide cross linkages in proteins. The fact that a series of thiols obey the above equation strongly indicates that in such reactions the pK value of the attacking thiol is of minor significance with regard to the reaction rates. This finding may be interpreted to mean that with increasing pK_{SH} value the decrease in the concentration of the ionized thiol at a given pH is effectively counteracted by a concurrent increase in the nucleophilic reactivity of the ionized thiol.

On the Metabolism of Thiosulfate Esters

Bo Sörbo

Research Institute of National Defence, Dept. 1, Sundbyberg, and Nobel Medical Institute, Biochemical Dept., Stockholm, Sweden

When sodium sulfocysteine [$NaS_2O_3CH_2CH(NH_2)COOH$] or aminoethylthiosulfuric acid [$NH_2C_2H_4S_2O_3H$] were incubated with rat liver homogenates under aerobic conditions, sulfate was formed. Under anaerobic conditions sulfite was formed instead of sulfate, but sulfite is oxidized to sulfate in the presence of oxygen by the action of sulfite oxidase [1]. The formation of sulfite was a non-enzymic reaction involving protein-bound sulfhydryl groups. The other reaction product was a protein-bound mixed disulfide. As the protective properties of certain sulfur compounds against ionizing radiation have been attributed to their capacity to form mixed disulfides [2], the possibility was considered that thiosulfate esters should also protect against ionizing radiation. This has been experimentally verified in the case of aminoethylthiosulfuric acid [3]. The presence of an enzyme in rat liver, which forms thiosulfate from sulfocysteine (but not from aminoethylthiosulfuric acid) was also found and this supports earlier work of Cavallini and Stirpe [4], who observed an increased excretion of thiosulfate in rats injected with sulfocysteine.

ACTA CHEMICA SCANDINAVICA 12 (1958) 1359—1363

Pyrazole Studies

XI.* Oxidation by Air of 1:4-Disubstituted Pyrazolidine-3:5-diones

STIG VEIBEL, S. LINHOLTER and P. SØRENSEN

Department of Organic Chemistry, University of Technology, Copenhagen, Denmark

Previously reported studies on the triethylaminecatalysed oxidation by air of 4-alkylsubstituted pyrazol-5-ones have been extended to embrace 1:4-disubstituted pyrazolidine-3:5-diones. These substances are oxidised to the corresponding 4-hydroxysubstituted compounds considerably faster than the pyrazolones, and the scheme followed is another, no triethylamine oxide being formed simultaneously and further oxidation to unidentified products taking place more readily than in the case of the pyrazolones.

The identity of a substance mentioned by Gagnon *et al.* as 1:4-diphenylpyrazolidine-3:5-dione with phenylacetic acid phenylhydrazide has been suggested and the genuine 1:4-diphenylpyrazolidine-3:5-dione has been prepared.

In a previous communication [1] we were able to show that 4-alkylsubstituted pyrazol-5-ones in methanolic solution are oxidised by air to 4-alkyl-4-hydroxysubstituted pyrazol-5-ones, this oxidation, in the presence of triethylamine in excess and at constant concentration of oxygen, following a first order scheme, one molecule of oxygen being absorbed per molecule of pyrazolone and one molecule of triethylamine oxide being formed simultaneously.

In view of the growing significance of substituted pyrazolidine-3:5-diones we decided to investigate the oxidation of these substances under conditions similar to those being in force in the investigations mentioned. We found that the pyrazolidine-3:5-diones are oxidised extremely readily under these conditions, but the scheme is not so clear-cut as in the instance of the pyrazol-5-ones where a first order scheme was followed usually at least up to 80 % completion and the hydroxy-compound could be isolated in 95—100 % yield. With the pyrazolidine-3:5-diones the absorption of oxygen usually comes to an end when about 66—75 % of the calculated volume of oxygen has been absorbed, presuming the absorption of one mole of oxygen per mole of pyrazolidinedione. The velocity with which oxygen is absorbed is considerably greater

* X: *Acta Chem. Scand.* **9** (1955) 970.

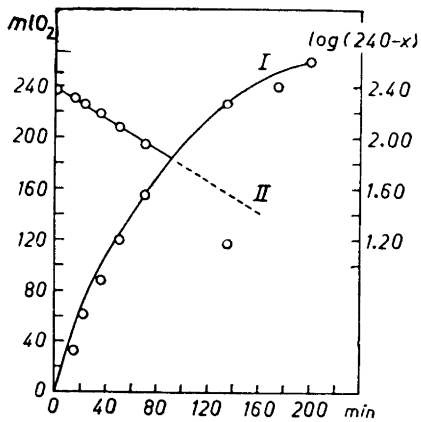

Fig. 1. Oxidation of a 0.02 M solution of 4-butylpyrazolidine-3:5-dione.
Curve I (ordinates left): Uptake of oxygen.
Curve II (ordinates right): log(240—x).

in the case of the pyrazolidinediones than in the case of the pyrazolones, and no triethylamine oxide can be isolated from the reaction products.

This means that only one *atom* of oxygen per molecule of pyrazolidinedione is demanded for the oxidation to the hydroxy compound, and the total consumption of oxygen is thus somewhat greater than calculated. As, however, the yield of hydroxy compound isolated is only some 50—75 %, and as the formation of oily products is always observed, we are of the opinion that the formation of the hydroxy compound is followed by a hydrolytic cleavage of the pyrazolidine-nucleus and possibly an oxidation of the substituted tartronic acid monophenylhydrazide formed (compare the following paper), this oxidation being responsible for the excess of oxygen consumed. As seen from Fig. 1, which is representative for all the oxidations, a first order scheme is followed up to some 60 % oxidation, presuming that only 1 atom of oxygen is used per molecule. This means that we here as in the case of the pyrazolones may compare the velocities of oxidation by indicating the time necessary for the absorption of 50 % of the calculated volume of oxygen.

A possible sequence of reactions might be:

$$\mathrm{PyRH} + (\mathrm{C_2H_5})_3\mathrm{N} \rightleftharpoons \mathrm{PyR^-} + (\mathrm{C_2H_5})_3\mathrm{NH^+}$$

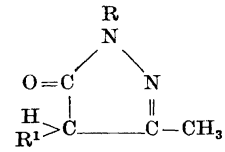
$$\mathrm{PyR^-} + \mathrm{O_2} \rightleftharpoons \mathrm{PyROO^-}$$

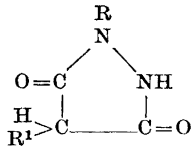
$$\mathrm{PyROO^-} + \mathrm{PyR^-} \longrightarrow 2\ \mathrm{PyRO^-},$$

PyRH meaning a 4-substituted pyrazolidine-3:5-dione.

The difference between the oxidation of pyrazolones and pyrazolidinediones should, thus, depend on the oxidation potentials of the pyrazolone anion, the triethylammonium ion and the pyrazolidinedione anion, decreasing in this order if the explanation given here is the correct one.

Table 1. Oxidation of different pyrazolones and pyrazolidine-diones with oxygen.





R	R^1	Time for 50 % oxidation	R	R^1	Time for 50 % oxidation
C_6H_5	CH_3	26 h	C_6H_5	CH_3	2 min
C_6H_5	C_2H_5	20 h	C_6H_5	C_2H_5	2.5 min
C_6H_5	C_3H_7*iso*	22.5 h	C_6H_5	C_3H_7*iso*	14 min
C_6H_5	C_4H_9	32 h	C_6H_5	C_4H_9	50 min
C_6H_5	C_6H_{11}	9 h	C_6H_5	C_6H_{11}	60 min
C_6H_5	$C_6H_5CH_2$	72 h	C_6H_5	$C_6H_5CH_2$	14 min
			C_6H_5	C_6H_5	4 min
			C_6H_5	$(C_6H_5)_3C$	—

The technique applied was that described previously [1]. Table 1 summarises the results obtained and gives a comparison of oxidation rates for corresponding pyrazol-5-ones and pyrazolidine-3:5-diones.

It is seen from Table 1 that we extended the investigation to the oxidation by air of 1:4-diphenylpyrazolidine-3:5-dione and of 1-phenyl-4-triphenylmethylpyrazolidine-3:5-dione. The former of these two substances was oxidised readily, the latter was not oxidised at all.

A comparison of columns 3 and 6 of Table 1 shows that not only are the rates of oxidation much higher for the pyrazolidinediones than for the pyrazolones, but the influence of the substituent present at C^4 is quite different in the two series. The 4-*cyclo*hexylpyrazolone is the one most rapidly oxidised, whereas the 4-*cyclo*hexylpyrazolidinedione is the one most slowly oxidised in the series of pyrazolidinediones investigated. So far, we have found no explanation covering this difference, but the mechanism followed in the two series is, as mentioned, quite different.

The presence of a phenyl group (or possibly also other substituents) at N^1 seems to be essential for the oxidisability of the pyrazolidinediones. 4-Benzylpyrazolidine-3:5-dione was not oxidised when the usual technique was applied. By addition of some crystals of cupric acetate, however, the absorption of oxygen was started and some 60 % of the volume calculated for the formation of the hydroxy compound was absorbed during 2 h. We did not succeed in isolating a definite oxidationproduct. Evidently an oxidative degradation of the cyclic compound takes place.

On the other hand, we succeeded, when oxidising 4-benzylpyrazolidine-3:5-dione in the absence of triethylamine, in isolating after 13 h, when 1 mole of oxygen per mole of pyrazolidinedione had been absorbed, a small quantity of a substance with m.p. 159—161° which contained 9.33 % of nitrogen, calculated for the 4-hydroperoxide of the pyrazolidinedione 9.28 % N. The main product was, however, an oil which was not further investigated but which,

in analogy to results obtained with butazolidine (see the following paper) might be impure benzyltartronic acid monophenylhydrazide or the free benzyltartronic acid.

EXPERIMENTAL PART *

The pyrazolidine-3:5-diones were prepared by current methods [2,3]. The yields obtained and the m. p.'s found as well as those indicated in the literature are tabulated in Table 2, whereas Table 3 contains the corresponding figures for the 4-hydroxypyrazolidine-3:5-diones.

The substance VII, 1-phenyl-4-triphenylmethylpyrazolidine-3:5-dione, was prepared in analogy to 1-phenyl-3-methyl-4-triphenylmethylpyrazol-5-one [7] by refluxing 1.95 g of triphenylcarbinol and 1.50 g of 1-phenylpyrazolidine-3:5-dione dissolved in 10 ml of glacial acetic acid and 3 drops of concentrated hydrochloric acid. After 45 min refluxing a substance precipitated which was not redissolved by addition of glacial acetic acid. After cooling some ml of water were added and the substance was isolated by suction, washed on the filter with methanol and dried.

* All microanalyses by Mr. Preben Hansen, Department of Organic Chemistry, University of Copenhagen.

In preparing VIII the yield was very poor, only some few (5) % of a substance with m. p. 218—220° and the composition calculated for 1:4-diphenylpyrazolidine-3:5-dione, $C_{15}H_{12}O_2N_2$ (252.3) as indicated in Table 2. This substance is soluble in alkali, leaving behind a substance insoluble in alkali. The alkali-insoluble substance was recrystallised from ethanol and isolated in a yield of 90 % with m. p. 166—167° (uncorr.). It was recognised as phenylacetic acid phenylhydrazide, $C_6H_5CH_2CONHNHC_6H_5$, $C_{14}H_{14}ON_2$ (226.3). (Found C 74.10; H 6.40; N 12.42. Calc. C 74.34; H 6.22; N 12.40.) The hydrazide has been prepared by Schott [8] who indicates m. p. 168—170°. Gagnon *et al.*[9] report the preparation of 1:4-diphenylpyrazolidine-3:5-dione which they describe as an alkali-insoluble substance with m. p. 172—173°, containing 11.60 % N. We think it reasonable to regard this substance as the phenylhydrazide, the cyclisation evidently taking place less readily in this instance than in the instance of alkylsubstituted malonic esters.

The formation of minor amounts of alkaliinsoluble substances was observed in the preparation of most of the substances I—IV. In one instance we isolated the alkali-insoluble substance which showed a composition in accordance with the corresponding phenylhydrazide, the formation of which may be explained by the scheme:

$$RCH{<}^{COOE}_{COOE} + C_6H_5NHNH_2 \longrightarrow RCH{<}^{CONHNHC_6H_5}_{COOE} \xrightarrow{NaOE}$$

$$RCH{<}^{CONHNHC_6H_5}_{COONa} + EOH \xrightarrow{HCl} RCH_2CONHNHC_6H_5 + CO_2 + EOH + NaCl.$$

Accordingly, we observed a slight liberation of carbon dioxide upon acidification of the reaction mixture when alkylmalonic esters were reacted with phenylhydrazine, but in the case of phenylmalonic ester the liberation of carbon dioxide was much stronger than usually.

Pyrazole Studies

XII.* The Hydrazobenzene-catalysed Oxidation of 1:2-Diphenyl-4-butylpyrazolidine-3:5-dione (Butazolidine)

STIG VEIBEL, S. LINHOLTER and P. SØRENSEN

Department of Organic Chemistry, University of Technology, Copenhagen, Denmark

The oxidation by air of alkaline-ethanolic solutions containing 1:2-diphenyl-4-butylpyrazolidine-3:5-dione and hydrazobenzene has been studied. The oxidation products were found to be butyltartronic acid mono-(N:N'-diphenyl)hydrazide and azobenzene. No 4-hydroxybutazolidine could be isolated.

It was found that the oxidation of butazolidine and of hydrazobenzene proceed simultaneously.

In previous papers the oxidation by air of 4-substituted pyrazol-5-ones [1,2] and 1:4-disubstituted pyrazolidine-3:5-diones [3] was studied. We found that triethylamine or sodium ethylate are catalysts for the oxidation, the result of which is the formation of 4-hydroxysubstituted pyrazolones or pyrazolidinediones.

Recently Sokolova and Magidson [4] announced that during the preparation of butazolidine from hydrazobenzene and ethyl butylmalonate a by-product was formed which they identified as 1:2-diphenyl-4-butyl-4-hydroxypyrazolidine-3:5-dione. This substance, they state, can be prepared, in a rather poor yield though, by dissolving butazolidine and hydrazobenzene (equimolar quantities) in ethanol, adding 1 equiv. of sodium ethylate and slowly distilling off the ethanol, passing a stream of air through the solution during the distillation. From the residue 60 % of butazolidine were recovered and the 4-hydroxy compound was isolated in a 9 % yield.

The hydroxy compound is very easily hydrolysed by aqueous bases to butyltartronic acid mono-(N:N'-diphenyl)hydrazide.

We tried to reproduce this result, following as exactly as possible the directions given by Sokolova and Magidson. We did not succeed, however, unchanged butazolidine, hydrazobenzene and azobenzene being the only crystalline products obtained by us.

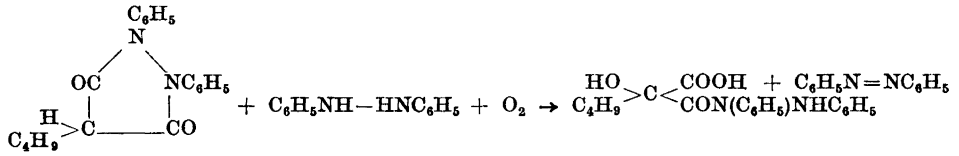
Using the oxidation-technique described previously [1] we were, on the other hand, able to establish the absorption of one molecule of oxygen per

* Part XI: Preceding paper.

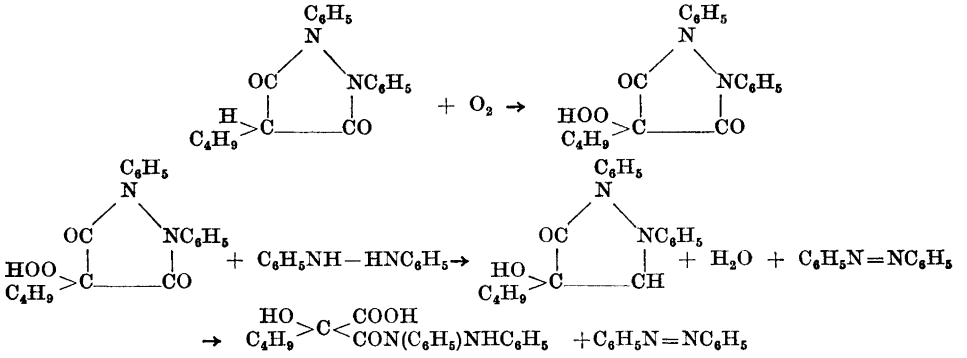
molecule of butazolidine when a solution of this substance and hydrazobenzene in absolute ethanol containing sodium ethylate is agitated in an oxygen atmosphere. The oxidation proceeds extremely slowly at room temperature, 6 days and nights being necessary for the absorption of the calculated volume of oxygen. This means that both the butazolidine and the hydrazobenzene must be oxidised during the absorption of oxygen, and we were able to establish that the two oxidations proceed simultaneously, as we in an experiment discontinued the oxidation after the absorption of 70 % of the volume calculated and isolated from the reaction mixture 30 % unchanged butazolidine and 70 % azobenzene.

Even with the technique employed here we were not able to isolate the hydroxybutazolidine, but only the hydrolysed substance, butyltartronic acid mono-(N:N'-diphenyl)hydrazide which was identified by its m.p. and by electrometric titration with sodium hydroxide.

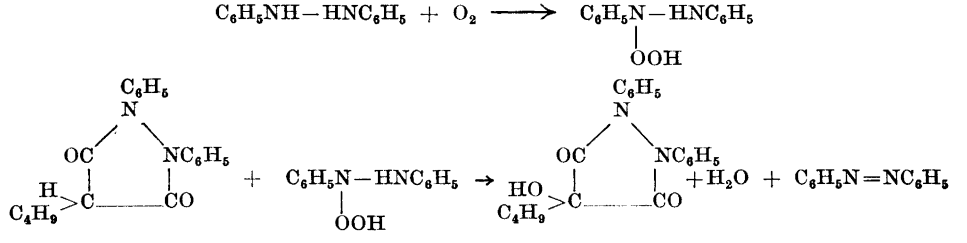
The overall reaction thus is represented by the equation:



Realising that the amine-catalysed oxidation proceeds through the formation of peroxides a possible sequence might be:



As, however, no oxidation takes place in the absence of hydrazobenzene, not even when azobenzene is added, the oxidation possibly starts with the formation of a hydroperoxide of hydrazobenzene so that the sequence might be:



It is seen that during the reaction sufficient water is formed to permit the hydrolysis of the hydroxybutazolidine. Sokolova and Magidson do not state how they have been able to suppress the hydrolysis but they mention that the hydroxy compound is extremely readily hydrolysed in alkaline solution.

EXPERIMENTAL PART

A solution of sodium ethylate was prepared from 0.75 g of sodium and 100 ml of absolute ethanol. In this solution 10 g of butazolidine (0.033 mole) and 6 g of hydrazobenzene (0.033 mole) were dissolved and the solvent slowly removed by distillation (5 h), a stream of air passing through the solution. From the residue 8.5 g of butazolidine, 1 g of azobenzene and 4.5 g of hydrazobenzene were recovered. If any, only an insignificant oxidation of butazolidine has thus taken place.

A similar solution was placed in a flask connected to an oxygen-reservoir, enabling the reading of the volume of oxygen absorbed. After 6 days and nights no more oxygen was absorbed, the total volume absorbed being 800 ml (at 20°) or 0.032 mole. The solution was diluted with 500 ml of water, precipitating azobenzene and hydrazobenzene if this substance remains unoxidised. The filtrate was acidified and the substance precipitated filtered off and dried.

The substance precipitated by water was dissolved in light petroleum and recrystallised by slowly evaporating the solvent. Different crops of crystals (*in toto* 5.1 g) were collected. They had the colour of azobenzene and m. p. 65° (azobenzene 68°). In this case practically quantitative oxidation of hydrazobenzene to azobenzene had taken place.

The substance precipitated by acid (9 g) had m. p. 128—132° (uncorr.). Sokolova and Magidson indicate for 4-hydroxybutazolidine m. p. 132—133°. Recrystallised from 50 % methanol, however, the m. p. of our substance was raised to 143—144° (corr.), whereas Sokolova and Magidson indicate the m. p. 145° for butyltartronic acid mono-(N:N′-diphenyl)hydrazide. 0.8600 g consumed (electrometric titration) 24.96 ml of 0.1029 N NaOH. Equiv. wt. found 335, calc. for the hydrazide 342.

In another experiment the reaction was interrupted when 70 % of the calculated volume of oxygen had been consumed. From the solution was recovered 3 g = 30 % of butazolidine, and a mixture of azo- and hydrazobenzene containing 4 g = 70 % of azobenzene was isolated. Besides, butyltartronic acid mono-(N:N′-diphenyl) hydrazide was isolated in a yield of 40 %. It is thus seen that the oxidation of butazolidine is coupled to the oxidation of hydrazobenzene.

Finally we tried to oxidise butazolidine with *tert*-butylhydroperoxide. 0.05 mole of butazolidine, 30 ml of 2 N sodium ethylate solution (0.06 mole) and 7.5 ml of *tert*-butylhydroperoxide (0.08 mole) were dissolved in 75 ml of *tert*-butylalcohol. After 20 min the experiment was discontinued. From the solution a solid was isolated, m. p. 145—46°, equiv. wt 330, titrated with sodium hydroxide (phenolphthalein). Here, again, the only oxidation product isolated was the butyltartronic acid mono-(N:N′-diphenyl)hydrazide.

Thanks are due to *Det Teknisk-Videnskabelige Forskningsråd* for a research-fellowship (P.S.) and to A. G. Geigy, for a gift of butazolidine generously placed at our disposal.

Viscosity of Binary Mixtures

THOR A. BAK and KNUD ANDERSEN

Universitetets Fysisk-Kemiske Institut, København, Denmark

The viscosities of the mixtures CCl_4—$CHCl_3$, C_6H_6—$CH_2(C_6H_5)_2$ and C_7H_{16}—$C_{16}H_{34}$ have been measured in an ordinary Ostwald viscometer. The deviation from linearity in the fluidity is positive in the first case, negative in the last two. The first case is discussed using the theorem of corresponding states, and it is shown that the dipole interaction is responsible for the asymmetry in the "excess fluidity".

In recent years the theory of liquid mixtures has reached a high degree of perfection. Using the average potential model of Prigogine and coworkers [1] one can predict, at least semi-quantitatively, the thermodynamic functions for mixtures when one knows the properties of the pure components.

With regard to a property like the viscosity of mixtures the situation is less satisfactory. The only workable theory of which we are aware is that of Eyring and coworkers [2] and its extensions by Grunberg [3]. This theory, however, contains an empirical correction term of appreciable magnitude, and in our opinion it can therefore primarily be considered as a convenient way of classifying experimental results.

The difficulty in setting up a theory for viscosity of mixtures is that one does not have a good theory for viscosity of pure liquids. A more promising way of attacking the problem for the time being is therefore to make a semi-phenomenological theory in which one uses the properties of the pure liquids without trying to account for them by means of a molecular model. The natural vehicle for such work is the theory of corresponding states, since the fluidity of a liquid can be described using only two parameters, *viz.* $\Phi = A \exp(-E/RT)$.

Such a development was suggested by K. Meyer [4] as early as 1909, but it was not until the idea of an average potential in liquid mixtures had been developed that it actually became possible.

The method we use has been developed by Thomaes [5] and used successfully on the mixture CCl_4—$C(CH_3)_4$. In order to test the method further we have measured the viscosity of a mixture where dipolar effects are predominant, namely CCl_4—$CHCl_3$ and two mixtures for which size effects dominate, namely C_6H_6—$CH_2(C_6H_5)$ and C_7H_{16}—$C_{16}H_{34}$. The ordinary thermodynamic properties of these mixtures are well known, and the surface tensions of the mixtures have recently been measured in this laboratory [6].

EXPERIMENTAL

The liquids were purified as described by Koefoed and Villadsen [6]. The viscosities were measured in an ordinary Ostwald viscometer which in each case was standardized on one of the pure liquids. The values for the viscosity of the pure liquids (CCl_4, C_6H_6 and C_7H_{16}) were taken from the book by Timmermans [7]. Table 1 gives the results obtained for the fluidity and its deviation from the linearly interpolated fluidity.

Table 1.

1. CCl_4-CHCl_3. (X is the mole-fraction of $CHCl_3$). $T = 25.01°C$.

X	Φ cp^{-1}	$\Phi-\Phi_{lin}$ cp^{-1}
0.000	1.103	0.000
0.151	1.226	0.011
0.328	1.367	0.020

0.803	1.716	0.017
1.000	1.845	0.000

2. $C_6H_6-CH_2(C_6H_5)_2$. (X is mole-fraction of diphenylmethane.) $T = 29.70°C$.

X	Φ cp^{-1}	$\Phi-\Phi_{lin}$ cp^{-1}
0.000	1.773	0.000
0.113	1.364	−0.253
0.204	1.140	−0.350
0.288	0.975	−0.398
0.523	0.666	−0.382
0.686	0.534	−0.285
0.801	0.469	−0.192
0.893	0.427	−0.106
1.000	0.383	0.000

3. $C_7H_{16}-C_{16}H_{34}$. (X is mole-fraction of $C_{16}H_{34}$.)

X	Φ cp^{-1} $T = 20.02°C$	$\Phi-\Phi_{lin}$ cp^{-1} $T = 20.02°C$	Φ cp^{-1} $T = 30.00°C$	$\Phi-\Phi_{lin}$ cp^{-1} $T = 30.00°C$
0.000	2.445	0.000	2.747	0.000
0.097	1.808	−0.429	2.062	−0.455
0.195	1.370	−0.655	1.582	−0.705
0.492	0.678	−0.707	0.811	−0.767
0.785	0.385	−0.371	0.481	−0.404
1.000	0.291	0.000	0.370	0.000

It should perhaps be remarked that in the last two cases, for which the 'excess fluidity" is negative, the "excess viscosity" is positive, as it is also in the case of CCl_4-CHCl_3.

THEORY

We want to treat the fluidity of mixtures by the method of corresponding states, *i.e.*, we want to get a dimensionless fluidity by multiplying it with a suitable combination of the molecular mass and the parameters which charac-

terize the intermolecular potential, ε and r. The dimension of fluidity is g^{-1} cm sec, and it is therefore reduced by multiplication with $(m\varepsilon)^{1/2} r^{-2}$. We shall neglect the pressure dependence of the viscosity, so that we can assume that two liquids at the same reduced temperature are at corresponding states as long as we only consider their viscosity.

For a mixture, ideal with respect to fluidity [2], we have

$$\Phi = X_1\Phi_{11} + X_2\Phi_{22}$$

where Φ_{11} and Φ_{22} are the fluidities of the pure components, and X_1 and X_2 are the mole-fractions. For a non-ideal solution we therefore set

$$\Phi = X_1\Phi_1 + X_2\Phi_2$$

where Φ_1 and Φ_2 are quantities to be determined.

Formally we have:

$$\Phi_{11}(T_1) = \frac{r^2_{11}}{(m_{11}\varepsilon_{11})^{1/2}}\,\widetilde{\Phi}(T_1)$$

$$\Phi_1(T) = \frac{r^2_1}{(m_1\varepsilon_1)^{1/2}}\,\widetilde{\Phi}(T)$$

where $\widetilde{\Phi}(T)$ denotes a reduced fluidity at the (non-reduced) temperature T, T_1 is an undetermined temperature, and T is the temperature of the mixture. Assuming that $m_1 = m_{11}$, that is, assuming that the effective mass of species 1 in the flow process is independent of the mole-fraction we have

$$\Phi_1(T) = \Phi_{11}(T_1)\left(\frac{\varepsilon_{11}}{\varepsilon_1}\right)^{1/2}\left(\frac{r_1}{r_{11}}\right)^2 \frac{\widetilde{\Phi}(T)}{\widetilde{\Phi}(T_1)}$$

If in this expression we choose $\widetilde{T}_1 = \widetilde{T}$, *i.e.*, $T_1 = T\,\frac{\varepsilon_{11}}{\varepsilon_1}$ the two reduced fluidities cancel, and we therefore can express $\Phi_1(T)$ in terms of the pure compound at another temperature:

$$\Phi_1(T) = \Phi_{11}\left(T\,\frac{\varepsilon_{11}}{\varepsilon_1}\right)\left(\frac{\varepsilon_{11}}{\varepsilon_1}\right)^{1/2}\left(\frac{r_1}{r_{11}}\right)^2$$

An analogous expression is found for Φ_2.

The quantities ε_1 and r_1 which we have introduced in this way are assumed to be "average potentials" and "average distances" in the liquid mixture, *i.e.*,

$$\varepsilon_1 = X_1\varepsilon_{11} + X_2\varepsilon_{12}$$

where ε_{11} is the maximum interaction energy between two 1-molecules, and ε_{12} is the maximum interaction energy between a 1-molecule and a 2-molecule. Analogous expressions are used for r_1, ε_2 and r_2. For r_{12} we take, as long as dipolar effects can be neglected $r_{12} = \frac{1}{2}(r_{11} + r_{22})$, and for ε_{12} we take, when no other information can be obtained,

$$\varepsilon_{12} = (\varepsilon_{11}\varepsilon_{22})^{1/2}$$

For the mixture CCl_4—$CHCl_3$ we have, when dipolar effects are neglected, $\varepsilon_{11} = \varepsilon_{22}$, $r_{11} \neq r_{22}$, but $|r_{11} - r_{22}| << r_{11} + r_{22}$. We shall therefore first investigate this case where the only differences which can cause non-ideal behaviour is a difference in size.

We set $2\,\frac{r_{22} - r_{11}}{r_{11} + r_{22}} = \varrho$ and have

$$\Phi_1 = \Phi_{11}(1 - \varrho X_2)$$
$$\Phi_2 = \Phi_{22}(1 + \varrho X_1)$$

neglecting higher powers of ϱ. Therefore

$$\Phi = X_1\Phi_1 + X_2\Phi_2 = X_1\Phi_{11} + X_2\Phi_{22} + (\Phi_{11} - \Phi_{22})\varrho X_1 X_2$$

The deviation from linearity is positive when $\Phi_{11} - \Phi_{22}$ has the same sign as ϱ, which is the most common thing. Its maximum value is $\frac{1}{4}\varrho(\Phi_{11} - \Phi_{22})$. For the mixture we consider $r_{11} = 6.62$ Å and $r_{22} = 6.10$ Å, so that $\varrho = -0.082$. The maximum deviation is then 0.015 cp^{-1}.

It is known, however, that for CCl_4 — $CHCl_3$ dipolar effects are predominant. From the measurements of McGlashan, Prue and Sainsbury [8] and Cheesman and Whitaker [9] one finds, for $X_1 = X_2 = \frac{1}{2}$, $h^E/g^E = 2.14$, where h^E stands for the excess molar enthalpy of mixing and g^E for the excess molar Gibbs function of mixing, and this almost satisfies the relation of Pople [10], $g^E = Ts^E = \frac{1}{2}h^E$, valid for mixtures where dipolar effects are predominant and differences in polarizability between the two species can be neglected.

To treat the dipolar effects we set

$$\varepsilon_{ij} = \varepsilon^0{}_{ij}(1 + \psi_{ij})$$
and
$$r_{ij} = r^0{}_{ij}\ (1 + \varphi_{ij})$$

where ψ_{ij} and φ_{ij} are small perturbations which stem from the dipole interaction. For details on this method, we refer to chapter 14 in the book by Prigogine [1].

Using the technique described there, we find

$$\psi_{11} = \psi_1 = \varphi_{11} = \varphi_1 = 0$$
$$\psi_{22} = \tfrac{2}{3}\Gamma \qquad \varphi_{22} = -\tfrac{1}{18}\Gamma$$
$$\psi_2 = \tfrac{2}{3}X_2\,(1 + 3\varrho X_1)\Gamma$$
$$\varphi_2 = \tfrac{1}{18}X_2\,(1 + 3\varrho X_1)\Gamma$$

with $\Gamma = \dfrac{\mu^4{}_2}{r^6{}_{22}\varepsilon_{22}kT}$ where μ_2 is the dipole moment of $CHCl_3$.

Therefore we have

$$\Phi_1 = \Phi_{11}\left(\frac{r_1}{r_{11}}\right)^2$$

$$\Phi_2 = \Phi_{22}\,(T + \tfrac{2}{3}\vartheta T)\left(\frac{r_2}{r_{22}}\right)^2(1 + \tfrac{4}{9}\vartheta)$$

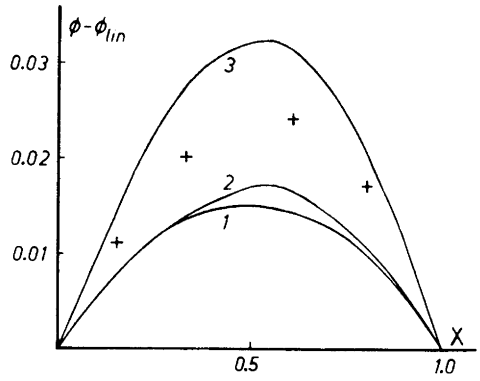

Fig. 1. Excess fluidity in reciprocal centipoise for the system CCl_4—$CHCl_3$. 1 size effect, 2 dipolar effect, 3 sum of 1 and 2, + experimental points.

with $\vartheta = (1 - X_2 + 3\varrho X_1 X_2)\Gamma$; $\Gamma = 0.013$ at 25°C. Here we have again neglected higher powers of ϱ and ϑ, and we shall therefore also expand Φ_{22} in a Taylor series from T retaining only the linear term. We then have

$$\Phi_2 = \Phi_{22}(T)\left(\frac{r_2}{r_{22}}\right)^2\left[1 + \vartheta\left(\tfrac{2}{3}\frac{T\Phi'_{22}}{\Phi_{22}} + \tfrac{4}{9}\right)\right]$$

$$= \Phi_{22}\left(\frac{r_2}{r_{22}}\right)^2 (1 + 2.47\ \vartheta)$$

at 25°C, using data from the book by Timmermans [7]. Substituting this into the expression for Φ we have $\Phi = \Phi_{\text{lin}} + 0.061\ X_1X_2 + 0.059\ X_2(1 - X_2 + 0.25\ X_1X_2)$

Within this approximation we see that the size effect and the dipolar effect simply add. Fig. 1 shows the experimental values of $\Phi - \Phi_{\text{lin}}$ and the curves for the size effect, the dipole effect and the sum of the two. Although the curve for the sum overshoots the mark considerably, it is seen that qualitatively it has all the right features including the asymmetry.

For the other two mixtures we have not so far been able to give a satisfactory theoretical development along these lines, but we hope to return to this problem in a later publication.

We are indebted to Dr. G. Thomaes for valuable discussions and for letting us see his paper before its publication.

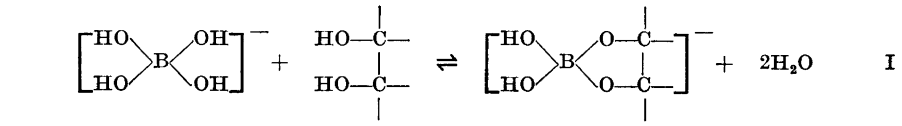
Chemistry of Arylboric Acids VIII. The Relationship between Physico-chemical Properties and Activity in Plants

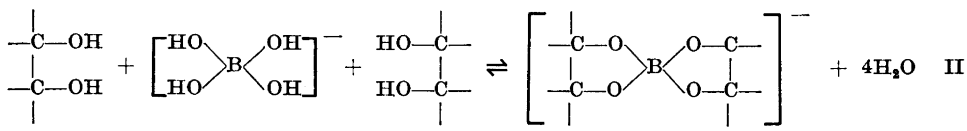
KURT TORSSELL, JOHN H. McCLENDON
and G. FRED SOMERS

Biochemical Institute, University of Stockholm, Stockholm, Sweden and Department of Agricultural Chemistry, University of Delaware, Newark, Delaware, U.S.A.

Ionization constants for a number of arylboric acids and their complexes with sugars have been measured. Further, the effect of arylboric acids on retrogradation of starch and viscosity of borax-galactomannan solutions have been investigated. Results of these physico-chemical investigations have been compared with the root cell elongation effect of the compounds in order to validate a hypothesis on the mode of action of arylboric acids in plants. Evidence is presented for a correlation between root growth promoting effect and ability of the compounds to form complexes with polyols.

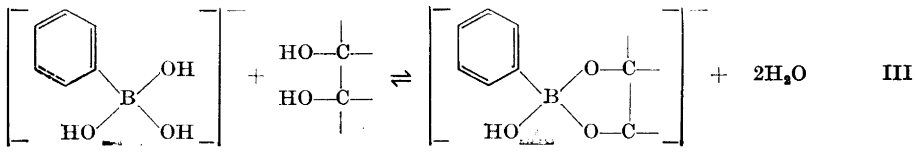
It has been known for a long time that polyhydroxy compounds enhance the acidity of boric acid through complex formation [1,2]. The following equilibria are involved:





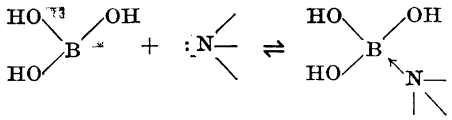
It is obvious that if compound I is a stronger acid than boric acid, the acidity must increase when the polyalcohol is added to a boric acid solution. For steric reasons compound II must be completely dissociated.

Phenylboric acid behaves in the same manner but can bind only one polyalcohol [3].



III

Boric acid can also interact with other functional groups, *i.a.* an amino group:



but in comparison to the B—O bond the B—N bond is much weaker [4].

From a chemical point of view it seems, therefore, reasonable to associate the plant physiological effects of boric acid and arylboric acids with an effect on hydroxyl-rich compounds. Thus we can expect that boric acid or arylboric acids may act upon: a) an enzyme system where either the coenzyme or the substrate contains a polyhydroxyl compound; b) the polysaccharide chains in the cell wall; Schmucker [5], Torssell [6], Odnoff [7] and O'Kelley [8*]; c) translocation of sugars; Gauch and Dugger [9].

a. *Effect of boric acid and phenylboric acid on enzymes.* The effect of boric acid on various enzymes has been tested by several workers (Ref.[10], reviews). As a general rule it may be said that boric acid has no or very little effect at low concentrations but inhibits enzyme activity at higher concentrations *in vitro*.

The action of phenylboric acid on the enzymes tested shows the same general picture but the inhibiting effect seems to be stronger than that of boric acid [11]. It was found that the activity of invertase, α-amylase and phosphorylase *in vitro* and the fermentation activity of baker's and brewer's yeast were not affected by phenylboric acid at concentrations less than 5×10^{-3} M. In the present paper three other enzymes have been tested: pectinase, pectin esterase and the "Zwischenferment" with its coenzyme TPN. Pectins presumably play a prominent role as cell wall constituents and as the boric acids seem to regulate the cell stretching it was of interest to test whether or not phenylboric acid has an influence on enzymes controlling the breakdown and de-esterification of pectins. In the first two enzyme systems phenylboric acid can couple with the substrate and in the third with both the coenzyme and the substrate, glucose-6-phosphate.

b. *Effect of boric acid and arylboric acids on the cell wall.* Schmucker [5] found that boron is essential for the germination of pollen and growth of the pollen tube and attributed this to an effect of the boric acid — polyalcohol complexes on cell wall formation. Boron deficiency symptoms appear first in meristematic tissues, root tips and buds, *i.e.* parts of the plant characterized

* *Added in proof.* Recently A. R. Spurr, *Am. J. Bot.* **44** (1957) 637, also hypothesized that boron affects the carbohydrate deposition into the cell wall.

by rapid growth rate. By discontinuous addition of boric acid to boron deficient bean plants, Odnoff [7] has shown the role of boron in the stretching process of the roots. On the basis of experiments with arylboric acids on wheat roots, Torssell [6] proposed the hypothesis that arylboric acids and boric acid control the deposition and orientation of polysaccharides in the cell wall through complex formation and thereby also regulate the stretching of the cell. More evidence for such a view is presented in the present work.

It has already been pointed out that the effects of arylboric acids on plants probably are not associated with an auxin effect [6]. The activity of synthetic auxin or antiauxin compounds strongly depends upon what kind of nuclear substituents they have and on the general structure of the molecule whereas this is of less importance in the arylboric acid series.

It is more likely that the effects of arylboric acids are associated with the properties of the dioxyboron group than with an overall effect of the molecule. The paper chromatographic experiments show, however, that an adsorption of arylboric acids on polysaccharides also may play a role. In order to explain the action of arylboric acids on amylose retrogradation, we have to take into consideration both complex formation and adsorption.

If now the arylboric acid-polyalcohol complexes play the proposed role in cell wall formation and in a wider sense in the cell stretching, we would expect to find a correlation between the plant physiological activity of different arylboric acids and their ability of form sugar complexes. The delaying effect of arylboric acids on amylose retrogradation [6] that served as a model experiment for the aging process of the polysaccharide chains in the cell wall, should further parallel their activity in plants.

In proposing this working hypothesis, however, we should not neglect two other factors that can greatly affect the activity of the compounds in plant. The uptake and translocation may be different with compounds that have the same intrinsic effect at the site of action. Secondly, the toxicity of some derivatives may be so high that side reactions completely counteract the cell elongation effect.

We have been looking for other model experiments more closely related to the proposed stabilization mechanism and have investigated the effect of arylboric acids on borax-galactomannan gels [12]. Galactomannan is a polysaccharide, consisting of a chain of 1,4′ linked D-mannopyranose units with single side units of D-galactopyranose linked 1,6′ to every other D-mannose unit [13]. The addition of borax to dilute solutions of this polysaccharide gives rise to an increased viscosity.

c. *Effect of boric acid and arylboric acid on sugar translocation.* Gauch *et al.*[9,14] have postulated that boric acid plays a role in the translocation of sugars in plants. There is evidence in favor of this hypothesis but other evidence is not in accord with it. McIlrath and Palser [15] found that in roots of boron deficient cotton plants, where no phloem necrosis was observed, the total sugar content was equal to that of normal plants and in the leaves it was lower. Spraying of buds with sucrose solution did not inhibit the boron deficiency symptoms. Odnoff [7] reported that the sugar level in the roots of boron deficient young bean plants was higher than in normal control plants.

Provided that the mechanism of action of arylboric acids and boric acid is the same, it is not possible to explain their cell stretching effect only on basis of an increased sugar translocation [14]. We probably have to account for several modes of action of boron in plants, of which the translocation effect may be one.

EXPERIMENTAL

Determination of enzyme activities in the presence of phenylboric acid

1. *Pectinase.* The effect of phenylboric acid on pectinase was tested viscosimetrically and by measurement of reducing groups produced.

a. *Viscosimetrically.* The following solutions were prepared: (I) sodium pectate, 1 %, (Sunkist Growers, Inc., Ontario, Calif., U.S.A.), buffered to pH 4.0 with acetate, 0.05 M. (II) Pectinase, 0.01 % (Nutritional Biochemicals Corp., Cleveland, Ohio). The crude pectinase was first purified by ultra filtration according to McClendon and Somers [16]. (III) Phenylboric acid 7.0×10^{-2}, 7.0×10^{-3} and 7.0×10^{-4} M. To 20 ml (I) + 2 ml (III) (or 2 ml water in the control run) equilibrated at 30° in a water bath were added 2 ml enzyme solution (II). The mixture was shaken rapidly. The time of efflux was measured at intervals with an Ostwald viscosimeter. In one experiment the enzyme was first incubated with 3.5×10^{-2} M phenylboric acid for 1.5 h and then added to the pectin solution. Fig. 1 shows the efflux time (extent of degradation) as a function of time.

b. *Measurement of reducing groups.* To 50 ml of sodium pectate (I) and 20 ml phenylboric acid (III) equilibrated at 30° 2 ml of 0.1 % enzyme solution was added. The time was noted and 10 ml aliquots were removed at various times and analyzed for reducing groups according to Willstätter and Schudel [17]. Fig. 2 shows the I_2 consumption (liberated reducing groups) as a function of time.

2. *Pectinesterase.* (Pectin from Nutritional Biochemicals Corp., Cleveland, Ohio and Pectinesterase from Worthington Biochemical Sales Co., Freehold, New Jersey.) The enzyme activity was tested according to the procedure of Kertesz [18]. Fifty ml of 1 % pectin solution containing 0.1 M NaCl and a suitable amount of phenylboric acid was equilibrated at 30° and adjusted to pH 6. Two ml of 0.01 % enzyme solution was added; followed by thorough mixing. Sodium hydroxide (0.01 M) was added at a rate to keep the pH constant at 6. In Fig. 3 the alkali consumption is plotted against time.

3. *Glucose-6-phosphate dehydrogenase (Zwischenferment).* The assay method, described by Kornberg and Horecker [19] was employed. The reduction of the coenzyme in presence of various phenylboric acid and boric acid concentrations was followed (Fig. 4) by measuring at various times the intensity of the absorption band (at 340 mμ) of the reduced form. (Zwischenferment from Sigma Chemical Co., St. Louis, Mo.; TPN, Nutritional Biochemicals Corp., Cleveland, Ohio). Veronal buffer pH 7.5 was used instead of glycylglycin.

Complex constant measurements

Complex constants of arylboric acids with fructose, maltose, starch (Lintner, potato) and galactomannan were measured. The method, described in an earlier paper [3], was employed with the difference that a saturated calomel electrode was used and the measurements were carried out in pure water instead of 0.1 M KCl. The constants in Table 1 are mean values from two or more runs. The arylboric acids tested were synthesized according to Torssell [20].

Effect of arylboric acids on amylose retrogradation

Because identically prepared amylose solutions may retrograde with different velocity, all substances were tested [6] at the same time with the same amylose solution in order to get comparable values of their inhibiting effect. Into 5 ml of 4×10^{-2} M arylboric acid

were pipetted 15 ml 0.5 % maize amylose containing 0.02 M buffer (pH 5.0 acetate; pH 6.5 and 6.9 phosphate; and pH 7.9 veronal). The final arylboric acid concentration was 10^{-2} M. Because of insolubility of some compounds (*p*-nitro-phenylboric acid, 3-nitro-4-carbomethoxy-phenylboric acid) they were tested at a concentration of 5×10^{-3} M. Intensity of the scattered light was measured at various times with a *Leifo*-photometer. The experiments were duplicated at various pH's.

Effect of arylboric acids on the viscosity of borax-galactomannan solutions

Galactomannan from guar seed (Stein Hall, New York, U.S.A.; trade name Jaguar A-20-D) was reprecipitated once [21] and 1.6 g of the dry ground product was dispersed in 400 ml vigorously stirred hot water (*ca.* 80°). After standing overnight the solution was heated to boiling for 10 min, filtered hot with suction through porous filter paper and was buffered to pH 8.9 with glycine buffer (0.02 M).

Four series of solutions were prepared: a) 10 ml galactomannan (I) + 10 ml borax of various concentrations ($10^{-3}-10^{-2}$ M); b) 10 ml (I) + 10 ml phenylboric acid (half neutralized in order to minimize pH changes) in various concentrations ($10^{-3}-10^{-2}$ M); c) 10 ml (I) + 10 ml of a mixture in various proportions of borax (10^{-2} M) + phenylboric acid (10^{-2} M); d) 10 ml (I) + 5 ml borax (3.0×10^{-3} M, final concn.) + 5 ml of various arylboric acids (half neutralized, 1.2×10^{-3} M, final concn.). The mixtures were shaken vigorously and equilibrated for 2 h at 25°. Their viscosity was measured with an Ostwald viscometer. Efflux times are shown for series a–c in Table 5. The decrease in efflux time (viscosity) caused by addition of various arylboric acids to the borax-galactomannan solution, series d, has been calculated as percent of the viscosity increase caused by borax alone, when added to the galactomannan solution, Table 1.

Paper chromatography

A technique, elaborated by Rockland and Dunn [22] was employed. R_F-values refer to pure water as solvent. The arylboric acids (0.3 % water-methanol solution) were placed upon the paper, W 52, by means of a drawn out melting point capillary. Colors were developed with 0.4 % alcoholic curcuma solution, which gives brown-red spots with boron on a yellow background when the paper strips were left to dry for 5 min in an oven at 90° [27].

RESULTS AND DISCUSSION

Effects on enzymes. Presence of phenylboric acid does not affect the time course of pectic acid degradation by pectinase when followed viscosimetrically (Fig. 1) but a slight inhibition (*ca.* 10 % after 20 h, 10^{-3} M) could be detected by measuring reducing groups, (Fig. 2). Rather high concentrations of phenylboric acid (10^{-2} M) must be used before the inhibiting effect on pectinesterase is significant (Fig. 3). Glucose-6-phosphate dehydrogenase is also left unaffected by phenylboric acid in concentrations $<10^{-3}$ M. Boric acid is less active (Fig. 4). Thus when summing up results from the enzymatic work carried out in previous [11] and present papers we find, with one exception — cholinesterase [11] (which, however, does not occur in plant tissues) — that phenylboric acid at concentrations $<10^{-3} - 5 \times 10^{-3}$ M has no effect on the tested enzymes and at higher concentrations acts as an inhibitor.

According to Eliasson [23] phenylboric acid has no effect on the respiration of excised wheat roots.

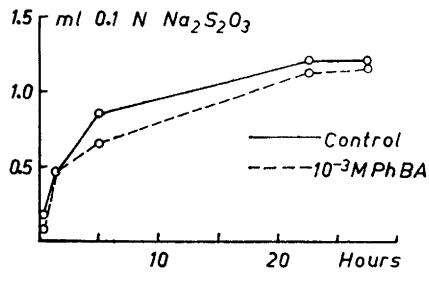

Fig. 2. Effect of phenylboric acid on the activity of pectinase. Degradation is followed by measurements of reducing groups, (equivalent to ml $Na_2S_2O_3$).

The effects of phenylboric acid on enzymes are in no cases striking and it seems to be difficult to draw any conclusions about relationships between the action of phenylboric acid on enzyme systems and its cell stretching effect in plants. However, the possibility may not be excluded that boric acid might be a constituent of an enzyme or act in some way *via* an enzyme.

(RBH = Phenylboric acid; RB^- = ionized acid; D = polyalcohol) have been measured for a number of arylboric acids which show various degrees of cell stretching effect (Table 1). When comparing the complex formation ability of arylboric acids ($k_s \times k_1$) with their action in plants, the assumption has to be made that the relative magnitude of complex constants for one sugar, in this case fructose, is about the same for another polyalcohol. This has been proved to be true for maltose, which forms much weaker complexes than fructose (Table 2). The systems, Lintner starch-phenylboric acid and galactomannan-phenylboric acid have also been investigated. Calculation of complex constants can be only very approximate as the units within the chain differ in complex forming ability. Galactose residues do not form as strong complexes as the mannose units of galactomannan. Also at end groups or at groups where branching occurs, the conditions for complex formation are different. As a first approach toward an investigation of the nature of these complexes, an end group determination (reducing groups) was carried out according to Willstätter and Schudel. This gives some idea concerning the average molecular weight (lower limit). It was found with starch that the concentration of the complex always was less than the reducing group concentration and calculation of the complex constant on the basis of reducing group concentration gave a more constant value than a calculation on a basis that every glucose unit takes part in complex formation to the same degree. The fact that methyl glucoside [1] gives very weak complexes with boric acid in comparison with glucose favors the idea that in starch the end groups preferentially combine with phenylboric acid. The complex constant for the starch-phenylboric acid system when only end groups are taken into consideration is of the same magnitude as that of the maltose-phenylboric acid system, in which the formation of a complex containing two phenylboric acid per maltose seems to be negligible, Table 2. It may therefore be assumed that complex formation between starch and phenylboric acid preferably takes place at the end groups and that to some extent weaker complexes are formed with the other units of the chain. Willstätter-Schudel end-group determination of starch usually gives too high values. According to the analysis, the starch molecule contains on an average 15—20 units, which seems to be too low for this kind of starch (Lintner potato starch). A lower end group concentration gives a higher complex constant k_1 but on the other hand a formation of weak complexes between phenylboric acid and some of the units in the chain has the opposite effect on k_1.

In the galactomannan-phenylboric acid system it was found that the complex formation is higher than the amount of reducing groups, *i.e.* the units in the chain are as important as the end groups for complex formation. This is to be expected from steric reasons; mannose and galactose have adjacent *cis*-hydroxyl groups at carbon atoms 2,3 and 3,4 respectively, which favors complex formation while the hydroxyl groups of the glucose unit in starch are all *trans* and only the end group has adjacent *cis*-hydroxyls (in 1,2 position). Table 3 shows some of the original measurements and in column 7 the concentration of the complex is calculated. A Willstätter-Schudel end group determination gave a polymerization degree of about 30, a value that for this kind of polysaccharide is too low. From the last row of column 7,

Table 3. 40.00 ml of a galactomannan-phenylboric acid solution is titrated with 0.1668 N NaOH. (D_{tot}) is the concentration of sugar residues = molecular concentration x degree of polymerization. Temp. 25° C.

ml NaOH	$[Na^+]$ $\times 10^2$	$[RBH_{tot}]$ $\times 10^2$	$[RBH]$ $\times 10^2$	$[D_{tot}]$ $\times 10^2$	$[D]$ $\times 10^2$	$[RBD^-]$ $\times 10^2$	pH	$[H^+]$ $\times 10^8$	k_1
—	—	2.18	2.18	1.50	1.50	—	5.75	178	—
1.20	0.486	2.12	1.63	1.46	1.42	0.041	8.30	0.501	6.5
2.20	0.869	2.07	1.20	1.42	1.34	0.084	8.68	0.209	8.0
3.47	1.332	2.01	0.68	1.38	1.25	0.130	9.11	0.0775	8.7

however, we find that the concentration of the complex is 0.130×10^{-2} M which is about one tenth of the total sugar concentration in the solution. That means that, as an average, every tenth sugar unit has formed a complex with phenylboric acid at this pH and we must therefore have more than one complex per molecule. The complex constant for galactomannan, Table 2, has been calculated on the assumption that every chain unit gives equally strong complexes and that already formed complexes do not affect the formation of adjacent ones. The complex constants for starch and galactomannan are not comparable as they are calculated on basis of different assumptions. In order to get an idea about their relative magnitude the galactomannan constant has to be multiplied by the polymerization number of galactomannan.

In the last column of Table 1 the activities of the compounds are tabulated according to an arbitrary scale: +++ means a root elongating effect of 175 % or more, ++ = 150—175 %, + = 125—150 % and 0 = 100 % (none) — 125 %. The values are taken from a previous paper [6] and by the gradation the position of the maximum (concentration at which maximum occurs) has been considered.

The active acids 3, 4, 6 and 14 (see Table 1 for identification) all have high ionization constants, k_s, and also high complex formation ability, $k_s \times k_1$, in comparison with the inactive acids 10, 11 and 12. The $k_s \times k_1$ values of the highly active 2, 5 and 9 are higher than that of the inactive 10 and 11 but of the same magnitude as 12. Numbers 7 and 8 also are strongly dissociated and have high $k_s \times k_1$ values and we would therefore expect that they should be active in plants which, however, is not the case. A closer examination of their activity curves shows that they are more toxic to the roots, than the other compounds. Number 8, for example, inhibits the root growth completely at a concentration of 10^{-5} M whereas 10, 11 and 12 at 10^{-4} M do not show any inhibiting effect. *o*-Hydroxymethyl-phenylboric acid, 8, shows in comparison with other tested arylboric acids a strong bacteriostatic effect [11]. Therefore, it is probable that they actually are active, but their toxicity reverses the cell elongating effect by disturbing other essential reactions of importance for root growth. It has already been pointed out in the introduction that uptake and translocation may influence the activity of the compounds. When these factors are of the same magnitude for different compounds the complex constant alone ought to determine the activity in plants. Isomeric compounds as the *o*-, *m*- and *p*-nitrophenylboric acids are probably affected

equally by the mentioned factors and we find that complex constants $k_s \times k_1$ and root growth promoting activity (Ref.[6], Fig. 1) increases in the same order:

$$o\text{-}NO_2 < m\text{-}NO_2 < p\text{-}NO_2\text{-phenylboric acid}$$

Thus, it may be concluded that a correlation exists between plant physiological action of arylboric acids and their ability to form complexes with polyalcohols.

Relation between retrogradation effect, degelation effect and growth promoting effect. The inhibiting effect of arylboric acids on amylose retrogradation decreases in the following order:

$$3\text{-}NO_2 > 4\text{-}OCH_3 > 2\text{-}CH_2OH > \text{-}H \geq 2\text{-}NO_2\text{-}5\text{-}NH_2 > 2\text{-}NO_2 \geq 2\text{-}CHO > H_3BO_3$$

Relative order for some compounds may slightly change from experiment to experiment; the main order, however, is the same. The sequence above represents an average obtained from several runs at various pH's. Some compounds were tested in 0.005 M solution (4-NO_2- and 2-NO_2-4-$COOCH_3$-phenylboric acid) as they precipitated at higher concentrations. Their activity decreased in the following order:

$$4\text{-}NO_2 > 2\text{-}NO_2\text{-}5\text{-}NH_2 > 2\text{-}NO_2\text{-}4\text{-}COOCH_3$$

In Fig. 5 the effect of phenylboric acid at various concentrations is demonstrated.

It is obvious that complex formation alone cannot be responsible for the retrogradation inhibiting effect, because 4-methoxy-phenylboric acid and phenylboric acid show stronger inhibitions than 2-formyl-phenylboric acid that has a higher complex constant $k_s \times k_1$. Adsorption of arylboric acids on the growing amylose aggregates probably plays a role. Therefore a similarly built aromatic compound, 3-nitrophenol, (inactive in plants) was tested and found to have the same activity as phenylboric acid; aniline, 0.01 M, has no activity.

The measurements of starch complexes show further that units in the chain form only very weak complexes and that phenylboric acid is mainly linked to the end groups, which explains the fact that correlation between complex constants and the effect on retrogradation is not good. Even if the compounds most active in root growth are found in the beginning of the sequences above, the value of the retrogradation experiment as a true model for deposition of cell wall material is decreased, because of the fact that other compounds inactive in plants, *e.g.* nitrophenol, also hamper the retrogradation.

The chromatographic behavior of arylboric acids demonstrates clearly the importance of adsorption effects. It is possible to separate arylboric acids on paper with pure water as eluent. R_F values of different derivatives are shown in Table 4.

Table 4. R_F values of arylboric acids. Water as solvent. Whatman 52. The numbers refer to compounds in Table 1.

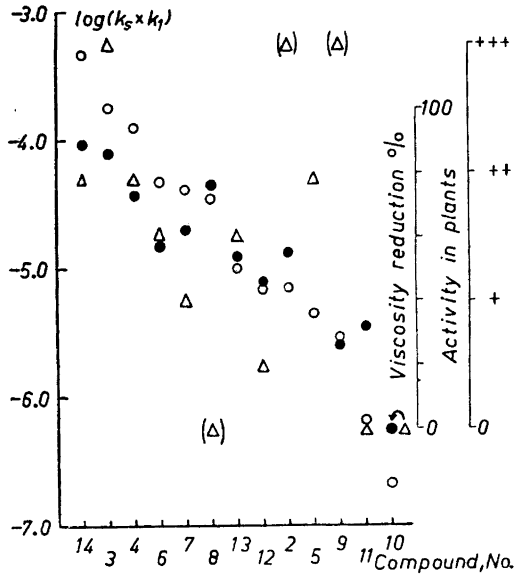

Fig. 6. Comparison of complex constants for arylboric acids, O, with their effect in plants, △, and on the viscosity of galactomannan-borax solutions, ●.

Borax forms gels with galactomannans; in dilute solution a viscosity increase takes place. Repeated cross linkages between galactomannan and and boric acid causes increased chain length and molecular weight, which results in an increased viscosity or, finally, in a gel formation [12]. Arylboric acids reduce the viscosity; probably in the following way. When an arylboric acid and boric acid are present in the polysaccharide solution at the same time, they will compete for the favorably oriented hydroxyl groups of the chain. As arylboric acids are not able to combine with more than one sugar residue, the formation of such complexes will decrease the chain length. The negatively charged arylboric acid-polysaccharide complexes have furthermore a repelling effect on other charged chains, which make it more difficult for boric acid to link them together.

Table 5. Effect of boric and phenylboric acids on the viscosity of galactomannan solutions (~ 0.15 %) pH 8.95.

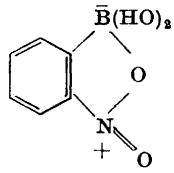
Phenylboric acid conc. M	—	—	—	—	10^{-2}	2×10^{-3}	2×10^{-3}
Efflux time, sec	37.2	43.2	248	∞	38.0	41.5	120

The galactomannan-boric acid-phenylboric acid system illustrates the proposed role of boric acid as a regulator of deposition and orientation of cell wall material and the role of arylboric acids as an inhibition in this process. Tables 1 and 5 show the effect of arylboric acids in decreasing the viscosity of a borax-galactomannan solution. Derivatives with high complex constant reduce the viscosity strongly and compounds low in complex forming ability have less effect (see also Fig. 6). Thus the degelation effect parallels complex formation and consequently the root growth promoting effect. Nitrophenol was also tested but showed here little effect in comparison with active compounds.

In order to clarify the relationship between complex constants of arylboric acids, their action on the viscosity of borax-galactomannan solutions and their activity in plants, the compounds have been arranged along the x-axis of Fig. 6 in the order of their ability to form complexes. log ($k_s \times k_1$) is plotted along the y-axis, open rings. Also along the y-axis are plotted: 1) The reduction in viscosity due to arylboric acids in the borax-galactomannan mixtures (as percent of the viscosity increase caused by borax alone, filled rings); 2) The cell elongating effect of the compounds (triangles). Results from the viscosity measurements parallel fairly well the complex constants. With three exceptions (triangles in parenthesis) the points for the cell elongating effect follow the pathway or the other two sets of data. The deviation of number 8 has already been discussed. 2 and 9, phenylboric acid and *p*-methoxy-phenylboric acid have in comparison with their complex constants, a very high action on roots. But here, as is pointed out earlier, uptake, transport and toxicity can play a role. The activity curves of these two compounds have a very broad maximum in comparison to the other tested compounds [6].

Note on the ionization constants of some arylboric acids

Ionization constants of a number of arylboric acids have been measured earlier and the results discussed on the basis of negativities and resonances of the groups involved [24-26]. Additional data for some new derivatives are presented here. From negativity and resonance interaction of the formyl group with the benzene ring it is to be expected that the *o*-compound should be a stronger acid than the *m*-compound and both of them stronger than phenylboric acid; this is the case (Table 1). The anomalous weakness of *o*-nitrophenylboric acid is ascribed to formation of a ring structure imposing a negative charge on the boron atom [25], a phenomenon which appears also with the three



other nitroderivatives 10, 11 and 12. As expected, the 3,5-dinitro compound is a strong acid in comparison with phenylboric acid — about 100 times stronger.

The k_s for *o*-amino-phenylboric acid has not been measured but it ought to be considerably weaker than phenylboric acid because of resonance interaction between the nitrogen and boron atoms. Its acetyl derivative, however, has a k_s value very slightly greater than that of phenylboric acid, which means that the free electrons at the nitrogen atom are completely neutralized by the carbonyl group. We can find the same general trend in the benzoic acid series.

Acknowledgments. This work has been supported by grants from *Statens Naturvetenskapliga Forskningsråd*, Sweden and Mr. Thomas Brittingham. We are indebted to Dr. G. Neumüller for a sample of maize amylose.

The Distribution of Polyalcohols between Organic Ion Exchangers and Water

MALTE MATTISSON and OLOF SAMUELSON

Department of Engineering Chemistry, Chalmers Tekniska Högskola, Göteborg, Sweden

The distribution of glycol, glycerol and sorbitol between an aqueous solution and different types of ion exchange resin has been studied. It has been found that the concentration is lower in the resin phase than in the outer solutions. The counter ions and the degree of cross-linking of the resin have a considerable influence. The application of the Gibbs-Donnan theory is discussed.

The distribution of non-electrolytes between an ion exchanger and an aqueous solution has been dealt with by many authors. Polyalcohols have been subjected to investigations with respect to their sorption as borate complexes on anion exchangers [1-3], and their distribution between ion exchangers and solutions in pure water has also been studied [4,5]. The aim of the present work is to give an idea of the factors which influence the distribution, through a more detailed investigation of a small number of compounds, namely ethylene glycol, glycerol and sorbitol using water as solvent.

EXPERIMENTAL PART

The ion exchanger was shaken with the solution for a time, long enough to attain equilibrium. The two phases were then separated by centrifugation and analysed. Experiments were performed with a single polyalcohol in the solution, not with mixtures of them.

Ion Exchange Resins. The anion exchanger Dowex 2 and the cation exchanger Dowex 50 were used. Of the latter, resins with varying degrees of cross-linking (X), 0.5, 1, 2 and 8 % DVB (divinylbenzene) were studied. In order to obtain as good reproducibility of centrifugation as possible, spherical resin particles were used. The anion exchanger and the cation exchanger, X8, with a normal degree of cross-linking had the particle size 0.2—0.4 mm (40/70 mesh) in an air-dried state and the other resins 0.14—0.29 mm (50/100 mesh). Very fine particles were washed out with water. The cation exchangers were washed with hydrochloric acid and the anion exchanger alternately with hydrochloric acid and sodium hydroxide solutions. The resins were transformed into their ionic states and air-dried in the usual way [6].

Equilibration. The equilibrium experiments were performed in 50 ml test tubes. The solutions of polyalcohols were freshly prepared from c.p. chemicals by dilution with

boiled-out distilled water. On prolonged storage at room temperature the solutions are liable to microbial destruction. In each experiment 40 ml solution and 0.5 – 2 g air-dried resin were added, the lower amount being used for the resins which swell most. The test tubes were rotated slowly in an air thermostat kept at 25.0 ± 0.1°C. The time of contact had to be chosen long enough to obtain equilibrium, but not so long that the polyalcohols were destroyed by microbes. Other authors have reported as short times as a few minutes for obtaining equilibrium between ion exchangers and aqueous solutions of non-electrolytes [4], but in the present work some systems were found to require longer times. The potassium form of normally cross-linked Dowex 50 and a solution of sorbitol attained equilibrium within one hour. The corresponding value for the perchlorate form of Dowex 2 was 10 h. The differences between various systems may be explained by differences in the molecular size of the solutes and in the swelling of the resins. To secure equilibrium the contact time was chosen as long as 40 h.

Separation of the Resin. After equilibration the resin was transferred to a weighed centrifuge basket, made of stainless steel and fitted with a bottom of wire-netting. The solution was collected in a 50 ml conical flask and stored in a refrigerator until analysed. The basket with the resin was placed in a centrifuge tube, closed with a rubber cap, and subjected to centrifugation for 40 min at 2 000 r/min, corresponding to a centrifugal acceleration of about 600 *g*. After the run, the basket with resin was weighed in a closed weighing bottle. Subsequently the resin was transferred by washing to a column of 10 mm diameter and 120 mm height fitted with glass filter bottom. The polyalcohol was eluted with water until the volume of the eluate was 100 ml. The solution was kept in a refrigerator until analysis could be performed.

Analyses. The concentration of glycol, glycerol and sorbitol in the equilibrium solution and in the eluate was determined by oxidation with periodic acid [*cf.* Ref.[7]]. Samples containing less than 30 mg ethylene glycol, 20 mg glycerol or 15 mg sorbitol were mixed in conical flasks with 25 ml of a solution of periodic acid, made by dissolving 5 g $HIO_4 . 2H_2O$ in 200 ml distilled water and filling up to one litre with glacial acetic acid. Fresh solution was made every day. The flasks were shaken vigorously and then kept well closed at room temperature. After 30 min, 10 ml potassium iodide solution (270 g/l) was added, and the liberated iodine was titrated with 0.1 N sodium thiosulfate solution. In order to obtain as good accuracy as possible, a 10 ml burette fitted with a 40 ml pipette on the top was used. As an indicator, 10 ml starch solution (2 g/l) was added. The discoloration was best observed in the light from a blue bulb. On each solution 2 or 3 determinations were made, and 4 to 7 blanks were run in each series of 17 to 25 titrations in all. For the calculation of the concentration of polyalcohol from the sodium thiosulfate consumption, factors taken from the literature were used [8]. These factors deviated only slightly from the theoretical ones. A control showed that they gave satisfactory results.

After the experiment, the resin was treated in the following manner: The cation exchangers were transformed into the hydrogen form and washed. The hydrogen ions were eluted with sodium chloride solution and titrated with 0.1 N sodium hydroxide solution to the color change of phenolphthalein. After being washed with water, the resin was transferred to a glass filter crucible and, after being dried for 6 days at 60 – 70°C over magnesium perchlorate under vacuum, the crucible and contents were weighed. In all cases the determinations of dry weight and capacity were checked by calculating the equivalent weight of the resin. The dry weight was recalculated to the actual ionic form.

The anion exchangers were transformed into the chloride form, washed and eluted with sodium nitrate solution. The chloride ions were determined by titration with silver nitrate solution according to Mohr [9]. After being washed, the resins were again transformed into the chloride form, washed, dried and weighed.

List of Symbols

x mole fraction of polyalcohol in the solution
x_r mole fraction of polyalcohol in the resin phase (ion exchanger not included)
K^* distribution coefficient ($= x_r/x$)
m molality of polyalcohol in the solution

m_r molality of polyalcohol in the resin phase
f practical activity coefficient of polyalcohol in the solution
f_r practical activity coefficient of polyalcohol in the resin phase
π swelling pressure of the resin, atmospheres
$\bar{v}$ partial molal volume of polyalcohol, ml
$\bar{v}_o$ partial molal volume of polyalcohol in an infinitely diluted aqueous solution at atmospheric pressure, ml
R gas constant, ml-atmospheres per degree per mole
T absolute temperature, degrees
k_s salting out parameter
n_r normality of resinate, equiv./1 000 ml water

RESULTS AND DISCUSSION

The experimental data are presented in Tables 1—3. The polyalcohol concentration in the solution and in the resin phase is given as mole fractions x and x_r. In the calculation of x_r the ion exchanger has not been included but only water and polyalcohol. The distribution coefficient K^*, *i.e.* the ratio x_r/x, is also given in the tables. Furthermore, figures are given for the total swelling, expressed in grams of water plus polyalcohol per equivalent of ion exchange resin, and for the water content and the polyalcohol content of the resin phase in moles per equivalent of resin. The water content is calculated by the difference.

The distribution coefficient is a function of solute concentration [4], but from the data given in Tables 1—3 it is evident that within the examined range of concentration — up to 3.5 mole per cent in the outer solution — this dependence is small. For the normally cross-linked cation exchange resins the

distribution coefficient increases slightly with increased concentration, but for the anion exchange resins and for the weakly cross-linked cation exchanger the variations are probably within the limits of experimental errors.

As may be seen, the concentration in the resin phase is in all cases lower than that in the outer solution. Thus the net effect may be considered as a salting out of the polyalcohol from the resin phase.

It may be of interest to apply the Gibbs-Donnan theory [10] to the distribution of the non-electrolyte between the two phases. Different approaches have recently been reviewed by Holm [11]. The distribution can be approximately represented by the following equation [cf. Ref. [11c] p. 464—465].

$$\ln \frac{m \cdot f}{m_r \cdot f_r} = \frac{\pi \cdot \bar{v}}{RT} \quad (1)$$

If the concentration of non-electrolyte is low in both phases, we may put m/m_r equal to x/x_r and $f = 1$. Consequently, the equation may be written

$$-\log K^* = \frac{\pi \bar{v}}{2.303\ RT} + \log f_r \quad (2)$$

The first term on the right-hand side of eqn. (2) (the pressure term) accounts for the influence of the swelling pressure upon the distribution, whereas the second term (the interaction term) accounts for the interaction between the non-electrolyte and a hypothetical strain-less ion exchanger. The salting-out effect on non-electrolytes in common electrolyte solutions can, as a good approximation, be represented by the following eqn. (12)

$$\log f_i = k_s\ m_s \quad (3)$$

where f_i is the practical activity coefficient of the non-electrolyte, k_s a salting-out parameter and m_s the molal concentration of the salt. This equation is valid only at fairly low concentrations of the non-electrolyte. If eqn. (3) is applied to our problem, eqn. (2) may be written:

$$-\log K^* = \frac{\pi \bar{v}}{2.303\ RT} + k_s \cdot n_r \quad (4)$$

The distribution coefficient, K^*, is obtained in the experiments. The swelling pressure, π, may be obtained from isopiestic measurements [13,14] and data for Dowex 50X8 have been taken from the paper by Boyd and Soldano [14]. A few isopiestic measurements were made with the resin (Li-form) used in the present work and it was observed that the calculated osmotic pressure was somewhat lower than the data given by these authors. The deviations were less than 10 %. The non-electrolyte has within the actual range of concentration only a slight influence upon the swelling, and so the swelling pressures determined for pure water can be used.

The partial molal volume, $(\bar{v}_o)$, in aqueous solution at infinite dilution is reported by Riiber, Sörensen and Thorkelsen to be 54.28 ml per mole for glycol, 70.59 ml per mole for glycerol and 117.86 ml per mole for sorbitol [15]. As no data are available for the calculation of the partial molal volume, $(\bar{v})$, in the resin, the values, $\bar{v}_o$, for pure aqueous solutions at atmospheric pressure have been inserted in eqn. (2).

From these data f_r has been calculated according to eqn. (2). The calculation is based upon the values for K^* obtained at the lowest concentration under investigation. The results are given in Table 4. Although several objections might be raised to the calculations, this approach may serve as a basis for a discussion of the results obtained in the present work. First of all, it may be

Table 4. The magnitude of the pressure term and the interaction term.

pointed out that the pressure term has a predominating influence upon the distribution coefficient for the non-electrolytes studied in the present work, whereas in ion exchange equilibria the influence of the pressure term upon the equilibrium distribution is fairly small [13].

For resins with lower degrees of cross-linking the swelling pressure is much lower than for the X8 resin, and for this reason the pressure term will have lower values for these resins. On the other hand it must be expected that the interaction term is also lower for these resins. Because of the experimental difficulties involved in the determination of the swelling pressure for these resins the data published by different authors are contradictory. An attempt has been made to calculate the pressure term for the X2 resin. This calculation, which is based upon isopiestic measurements by Boyd [16], indicates that the relative magnitude of the pressure term is fairly large for this resin also. As the probable errors are considerable, these calculations are not included in the table.

From eqn. (2) it may be predicted that, if the interaction term is small or of the same order of magnitude for different non-electrolytes, the distribution coefficient will decrease for an increase in molecular size. It might therefore be expected that for all forms of the resin the distribution coefficient should increase according to the following sequence

$$\text{sorbitol} < \text{glycerol} < \text{glycol}$$

This is in agreement with the experimental results.

The influence of the degree of cross-linking can be predicted from eqn. (4). The pressure term decreases rapidly for a decrease in the degree of cross-linking. At the same time there is an increase in swelling, which means that n_r decreases. Consequently, it must be expected that for strongly polar non-electrolytes K^* is increased and approaches the value of unity at low degrees of cross-linking. This is in agreement with the experimental results given in Tables 2 and 3. In this connection it may be mentioned that also for less polar solutes (acetic acid and butyric acid), where, because of a van der Waals' adsorption on the resin matrix, K^* is larger than unity, the distribution coef-

ficient has been shown to be equal to unity for resins with a low degree of cross-linking [17,18].

From Tables 2 and 3 it may also be seen that the degree of cross-linking does not affect the order of the effects of different counter ions upon the distribution of glycerol and sorbitol.

The influence of different counter ions upon the distribution coefficient compared at a constant degree of cross-linking is a more complicated matter. The swelling of the resin is dependent on the counter ions, which means that both π and n_r are affected. At a constant degree of cross-linking a higher swelling means an increase in swelling pressure but a decrease in inside concentration (n_r). This means that the pressure term and the interaction term are affected in opposite directions. Furthermore, it must be expected that, as in the case of normal electrolytes, the parameter, k_s, is different for different ions and also varies considerably for various non-electrolytes. Thus it might be expected that the effect of the counter ions upon the distribution coefficient might be different for different polar solutes. This is in agreement with the experimental data presented in the tables. This effect is most clearly demonstrated in the experiments with anion exchangers, where a reversed order between the counter ions is obtained for glycol and sorbitol.

It may be of interest to compare the results obtained in the present work with the data given in an earlier paper [19] on the distribution of glucose between different forms of the resins and an outer aqueous solution. The experimental technique was the same in both investigations and the results are comparable. It is found that the order of the different counter ions is the same for glucose as for sorbitol. For both solutes the distribution coefficients increase according to the following series:

For Dowex 50: $Li^+ < Na^+ < K^+$
For Dowex 2: $ClO_4^- < Cl^- < SO_4^{2-}$

For the cation exchanger the sequence is in agreement with the order which can be calculated from the swelling pressure according to the method used in the present work, whereas for the anion exchanger a reversed order has been observed. This shows that it is not permissible to neglect the interaction term even if it is only desired to make predictions of a qualitative kind.

Some conclusions about the possibilities of adopting ion exchange resins for the separation of glycol, glycerol and sorbitol in aqueous solution can be drawn from the data given in the present paper. The ratio between the distribution coefficients has a predominating influence upon the separation [cf. Ref.[20]]. For the anion exchanger in the perchlorate form this ratio (the separation factor) is 1.4 for glycol/glycerol and 1.6 for glycerol/sorbitol indicating that a good separation can be obtained provided that the flow rate is not too high. It may also be concluded that the forms of the cation exchanger used in the present work will be less suitable, but from the data given for different degrees of cross-linking it may be anticipated that an increase in the degree of cross-linking would give more favorable results.

The Sorption of Polyalcohols from Aqueous Alcohol by Cation Exchange Resins

MALTE MATTISSON and OLOF SAMUELSON

Department of Engineering Chemistry, Chalmers Tekniska Högskola, Göteborg, Sweden

The rate of sorption and the equilibrium distribution of glycol, glycerol, sorbitol and mannitol between aqueous alcohol and cation exchange resins has been studied. It has been found that the alcohol concentration has a predominating influence upon the rate of uptake. The equilibrium uptake increases considerably for an increase in alcohol concentration, but also the counter ions and the degree of cross-linking have an effect.

In earlier papers [1-3] it has been shown that sugars, dissolved in a mixture of water and ethyl alcohol, can be taken up by means of ion exchange resins. It was found that considerable amounts could be sorbed especially at low water concentrations in the solution. In the present work these investigations have been extended to include another group of polar non-electrolytes, namely polyalcohols, and it is shown that these behave in a similar manner. Because of the poor solubility of sugars in ethyl alcohol the earlier investigations were restricted to systems with a considerable water content. The higher solubility of certain polyalcohols has made it possible to study the uptake also from an almost water-free medium. As mentioned in a preliminary report, the sorption of polyalcohols is much larger in nearly water-free solutions than in solutions more rich in water [4]. Also, the rate of sorption is highly dependent on the water concentration.

EXPERIMENTAL PART

Preparation of ion exchange resins. The experiments were performed with the cation exchanger Dowex 50. The normally cross-linked resin (X8) with 8 % divinylbenzene as well as a resin (X2) with 2 % divinylbenzene were used. Most experiments were made with Dowex 50 X8 with a particle size of 0.2—0.4 mm obtained by grinding and screening in an air-dried condition (sodium form). In one experimental series (Table 1) the influence of the particle size upon the rate of sorption has been studied and in this case spherical beads of both types of resin have been used.

Before the experiments the resin was immersed in water and very fine particles removed by decantation. The resin was washed with hydrochloric acid and sodium hydr-

oxide solutions several times. The sodium state of the resin was air-dried and stored in tight bottles. When other ionic forms were needed the sodium form of the resin was weighed out and subsequently converted into the desired ionic form.

The exchange capacity was determined titrimetrically by treating the hydrogen form of the resin with potassium chloride solution and subsequently titrating with alkali [5].

In the experiments, samples of the air-dried ion exchanger (usually 7.80 mequiv.) were brought into equilibrium with aqueous alcohol of the same composition as that used as solvent. This equilibration was performed in columns of about 5 ml volume, by passing the aqueous alcohol through the resin. The apparatus used in the experiments with absolute ethanol permitted the ethanol to be supplied intermittently and the eluate collected without contamination by atmospheric humidity. Once or twice every day about 5 ml of ethanol was fed to each column until 100 ml effluent had been collected. Analysis of the effluent showed that its water content was about 3 % higher than it should be when calculated from the water content of the resin as determined by drying the resin over magnesium perchlorate at 60°C in vacuum. This would indicate that the last traces of moisture are not removed during the drying but there is also a possibility that — despite the precautions taken — water has been taken up from the atmosphere.

In the experiments presented in Table 1 the technique was altered in some respects. The ion exchangers were converted into the potassium form and air-dried samples weighed out in this state. Also in this series 7.8 mequiv. were transferred to each column, but all columns were treated simultaneously with absolute alcohol in a special apparatus. The time required to remove the water was around 40 days, but the treatment was continued for 60 days in order to make sure that all the samples were in equilibrium with the solvent.

Absolute alcohol was prepared from 99.5 % ethanol by treatment with magnesium powder [6].

The sorption of polyalcohol. After equilibration with the solvent, dried air was sucked gently through the columns at 30—40°C in order to remove the interstitial solution and to make it possible to empty the columns. The resin was transferred into 50 ml test tubes fitted with ground in stoppers. The empty columns were also placed in the test tubes in order to avoid any loss of resin. Into each test tube 40 ml of polyalcohol solutions were pipetted. The tubes were closed and rotated slowly in an air thermostat at 25.0 ± 0.1°C. After the desired contact time, the test tubes were taken out of the thermostat, and the solution was passed through a fritted glass filter, which had previously been dried.

Analyses. The water concentration in the solution was determined according to a modified Karl-Fischer method [7]. The concentration is expressed in weight per cent and all data given below refer to the solution after the contact with the resin.

The concentration of polyalcohol in the solution, before and after the experiments, was determined by oxidation with periodic acid [8]. The amount of sorbed polyalcohol was calculated from the decrease in solution concentration. No correction was applied for the change in volume of the solution.

RESULTS AND DISCUSSION

The sorption is characterized by the ratio m_r/m, where m_r is the amount of polyalcohol in the resin phase expressed in mmoles per equiv. ion exchanger and m is the concentration of polyalcohol in the solution in mmoles per 1 000 g solvent. Where equilibrium has been established, this ratio, which will be called the sorption coefficient (K_e), can be used to characterize the equilibrium distribution. The original concentration of the solution is denoted by m_o.

Rate of sorption. In order to establish the time required for obtaining equilibrium some kinetic experiments have been carried out. Fig. 1 demonstrates the rate of uptake of glycerol using the lithium form of Dowex 50. Similar curves for the potassium form of the resin are shown in Fig. 2. The glycerol concentration in the original solutions (20 mmole/1 000 g solvent) was the same in all experiments incorporated in Figs. 1 and 2. It may be seen that the rate of uptake depends markedly on the alcohol concentration. This is in

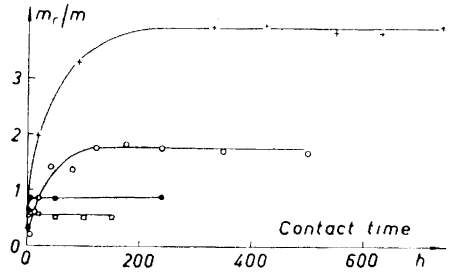

Fig. 1. The rate of glycerol sorption by the Li^+-form of Dowex 50 from various ethanol-water mixtures. % water at equilibrium 0.06 0.6 7.5 12.6
+ ○ ● □

+ ○ ● □

agreement with earlier observations on the sorption of sugars [2]. At the highest water concentration in the solution (12.6 %) equilibrium is reached within one hour, whereas several hundred hours are required in the experiments at the lowest water concentration. A comparison between Figs. 1 and 2 shows that the lithium form of the resin reacts more rapidly than the potassium form. In ethyl alcohol, as well as in water, lithium ions cause a higher swelling of the resin than potassium ions [9], and in general ion exchange reactions occur at a faster rate the higher the swelling. This is ascribed to differences in diffusion velocity inside the particles. If the particle diffusion is the rate determining step, this explains the difference between the two forms of the resin. Experiments with solutions of glycerol in alcohol containing 7.5 % water showed that within wide limits (20—1 200 mmole/1 000 g solvent) the concentration of glycerol had only slight influence upon the time required for equilibrium. This is an indication that the influence of the film diffusion step can be neglected in these systems.

It is interesting to note that the rate of glycerol uptake decreases to a marked extent when the water content of the solution is lowered from 0.6 % to 0.06 %. For this reason it was deemed to be of interest to study in more detail the rate of uptake in an almost water-free system. The results obtained with a resin in the potassium form are presented in Table 1. In agreement with the results presented in Fig. 2 it has been found that the time required to reach equilibrium is extremely long. This is true not only for the normal cation exchanger but also for the weakly cross-linked resin (X2). The uptake obtained after 1 198 h has been considered as the equilibrium uptake. As the rate of uptake is extremely slow the film diffusion step cannot be rate determining.

Table 1. The rate of glycerol sorption by the K^+-form of Dowex 50. 7.80 mequiv. resin + 40 ml alcohol (0.02 % water). Initial concentration: 2.018 mg glycerol per g solution.

Time of reaction h	Glycerol uptake, mg per 7.80 mequiv. resin			
	X2 0.037—0.074 mm	X2 0.14—0.29 mm	X8 0.300—0.385 mm	X8 0.75—1.02 mm
1	22.12	3.21	2.65	1.50
5	33.73	7.65	6.49	5.55
12	34.22	12.35	9.51	8.70
25	36.35	15.77	12.73	11.69
45	36.90	20.29	16.07	14.71
70	36.56	23.11	18.35	16.66
110	36.90	25.00	22.58	20.28
185	36.94	28.72	25.09	24.08
1 198	37.10	38.68	37.74	37.17
1 198	37.21	39.64	36.59	37.07

Consequently, either the diffusion within the particle or the sorption mechanism or these two factors together must determine the rate of uptake. From Table 1 it is evident that the particle size has a marked influence upon the rate of uptake, which excludes the possibility that the sorption mechanism is the rate determining step. This effect is most clearly demonstrated by the results obtained with the weakly cross-linked resin (X2), whereas with the normal resin (X8) this effect is surprisingly small. The explanation for the different behavior of the two types of resin is given by the micrographs presented in Fig. 3. It may be seen that the weakly cross-linked resin consists of intact spheres, whereas the normal resin contains a large number of cracked particles. Consequently, the sorbed molecules may have about the same way to diffuse within the particles of the two samples of the X8 resin.

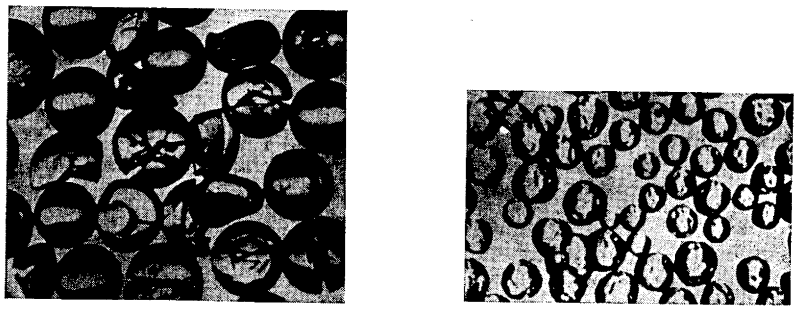

Fig. 3. Micrographs of the resins used in the kinetic experiment reported in Table 1. Magnification 25 times.
A: Normally cross-linked resin.
B: Weakly cross-linked resin.

An attempt has been made to apply the theory of particle diffusion according to Boyd, Adamson and Myers [10]. In the present case the solute concentration was not constant throughout the experiment, therefore it may be expected that the equation given by these authors can be applied only to the first part of the reaction. The particle size was not uniform, which has made it necessary to make the calculation for small fractions of each sample. The particle size distribution of the samples has been determined microscopically and the weight distribution curve has been calculated. The diffusion coefficient obtained in this way is around 10^{-10} — 10^{-11} cm^2/sec for both samples of the X2 resin. For a comparison it may be mentioned that the diffusion constant for glycerol in 96 % ethyl alcohol [11] is $5.3 \cdot 10^{-6}$ cm^2/sec. The results support the conclusion that the particle diffusion is the rate determining step.

As mentioned above, the differences in the rate of uptake between resins in different ionic forms can be explained by differences in swelling. The lowered swelling, which occurs when the water concentration is lowered, may to some extent explain the decrease in rate for a decrease in water concentration. However, the decrease in swelling corresponding to a change in the water concentration from 0.6 % to 0.06 % is so small that it can hardly be determined experimentally (less than 2 %). Consequently, the influence of the water concentration upon the swelling does not give the whole explanation of the differences in the rate of sorption in different solvent mixtures. It must be observed that the water content given in Figs. 1 and 2 refers to the outer solution. Within this range of concentration the water content in the resin phase is considerably higher [9]. From available data it can be roughly estimated that, at an outer concentration of 0.6 % water, the inside concentration is about 13 %, whereas for 0.06 % in the outer solution, the corresponding inside concentration is around 4 %. It is likely that this change in composition of the inside solution may also contribute to a decrease in the rate of diffusion inside the resin particles. A change in composition may have a considerable effect upon the structure of the inside solution. According to Sutra [12,13] the radii of the solvated alkali metal ions in ethyl alcohol are more than twice their size in water. It is known that in a mixture of alcohol and water the solvate sheaths of the alkali metal cations consist of both water and alcohol, water being held preferentially in the solvate sheath. When the alcohol concentration is increased a resolvation must occur, which in the case of ion exchange resins must result in a considerable decrease in the volume of the "free" inner solution. Probably this factor may contribute to a decrease in the rate of diffusion inside the resin particles, which would explain the lowered rate of sorption at extremely low water contents in the solution. It may also be pointed out that some of the glycerol molecules which diffuse into the resin phase must enter the solvate sheath, and that this resolvation may in some way have an influence upon the rate of uptake.

Equilibrium distribution. From Figs. 1 and 2 it is obvious that the solvent composition has a large effect upon the equilibrium. In agreement with earlier observations for sugar [2,3], the uptake of glycerol is found to increase when the relative amount of water in the solvent is decreased. It is interesting to note that the uptake is changed by a factor of about two, when the water content in the solvent is lowered from 0.6 % to 0.06 %. Also with glycol and sorbitol

Table 2. The effect of the counter ions and the degree of cross-linking upon the distribution equilibrium.

Polyalcohol	Water conc. %	m_o	%DVB in the resin	K_e						
				H^+	Li^+	Na^+	K^+	Rb^+	Cs^+	NH_4^+
Sorbitol	0.03–0.06	7.65	8	1.17	87	83	169	221	222	30.1
Glycerol	0.06	21.12	8	0.28	3.4	10.5	6.85	5.97	4.86	1.39
Glycerol	0.03–0.04	20.57	2	0.40	1.37	8.51	5.80	4.92	4.13	1.12
Glycol	0.04–0.08	13.87	8	0.23	1.32	2.35	1.36	0.84	0.86	0.51
Glycerol	7.5	12.00	8	0.24	0.89	1.11	0.95	0.87	0.79	0.62

it has been found that the uptake increases considerably for a decrease in water concentration in the solvent (*cf.* Tables 2 and 3). In pure water the net effect is a salting out, *i.e.* the concentration of polyalcohol in the resin phase is lower than in the outer solution [8].

The influence of the solute concentration upon the equilibrium distribution for glycerol in solutions with 7.7 % water is shown in Figs. 4 and 5. Fig. 4 also illustrates the uptake of glycerol from an almost water-free medium. All isotherms are convex, *i.e.* the sorption coefficient decreases for an increase in concentration. The effect of the solute concentration upon the sorption coefficient is largest in almost water-free solutions. This dependence on concentration must be remembered when comparing the sorption by different ionic states of a resin or by resins of different degrees of cross-linking. The rigorous method would be to make the comparison at constant equilibrium concentration in the outer solution. This would require measurements at different concentrations and such measurements have only been made in a few systems. Measurements are available, which permit a comparison between the effects of Li^+, Na^+ and K^+ upon the uptake of glycerol from a solution containing 7.7 % water. The data given in Fig. 4 show that at low solute concentrations the highest sorption is obtained with the Na^+-resin and the least sorption with the K^+-resin, whereas the Li^+-resin takes an intermediate

position. From Fig. 5 it may be seen that the order of the Li^+-resin and the Na^+-resin is reversed, *i.e.* the sorption isotherms for these two forms of the resin cross each other.

A reversed order of the effects of different counter ions can be obtained also when the relative amount of water in the solvent is changed. A comparison between Fig. 1 and Fig. 2 confirms that at higher water concentrations (7.5 and 12.6 %) the lithium form is a more effective sorbent than the potassium form. At low water concentrations (0.06 and 0.6 %) the order is reversed and the sorption is much higher for the potassium form.

In Table 2 further data are collected showing the influence of the counter ions upon the equilibrium uptake of different polyalcohols. The data refer to the solute concentration given in the table and, as already mentioned, the sorption coefficients are affected by changes in the solute concentration. Among the alkali metal resins the sodium form is the most effective sorbent for glycol and glycerol at the concentrations investigated. On the other hand, sorbitol is sorbed more strongly by the resin saturated with potassium ions and particularly with rubidium and cesium ions. In this respect sorbitol behaves like glucose [2]. The hydrogen and ammonium forms of the resin

sorb less than the alkali metal forms, which is in agreement with the results obtained with glucose.

The experiments with glycerol presented in Table 2 indicate that the degree of cross-linking has an influence upon the sorption. However, this factor is less important than the effect of the ionic form of the resin. This is in agreement with the results obtained with glucose [3].

The sorption differs considerably for various polyalcohols. Table 3, which contains data for the sorption from a solution with 12.5 % water shows that the uptake increases according to the following series: glycol < glycerol < mannitol < sorbitol. In an almost water-free medium only glycol, glycerol and sorbitol have been investigated and it has been found that the sorption increases according to this sequence. In water the sequence is reversed [8]. Evidently the number of hydroxyl groups in the sorbed molecule has a marked effect upon the distribution coefficient. The uptake of mannitol and sorbitol at various solute concentrations is demonstrated in Fig. 6. The two polyalcohols have the same number of hydroxyl groups in the molecule, but sorbitol is held more strongly than mannitol. Consequently, small differences in the structure between different solutes may have a considerable influence upon the sorption.

In a previous work on the distribution of polyalcohols between an aqueous solution and an ion exchange resin an attempt was made to split up the distribution coefficient into two parts, a pressure term and an interaction term [8]. The calculation was based upon the Gibbs-Donnan theory. It was found that both terms have a considerable influence upon the distribution. Because of the lack of data, *e.g.* swelling pressure data, no attempts will be made to perform such calculations for the uptake from the solvents used in the present work. However, some remarks of a qualitative kind may be made.

In aqueous solutions the distribution coefficient (K^*) is less than unity, which means that the concentration of polyalcohol is lower in the resin than in the outer solution. This net effect is explained by the contributions of the pressure term and the interaction term, which both have an influence in the same direction. The pressure term will always act in this direction and therefore it may be concluded that for solutions in ethanol, where the net effect is a considerable sorption, the pressure term is small compared with the interaction term. The pressure term has a larger influence upon large molecules than upon small ones, but despite this fact the larger molecules are, in alcohol solution, sorbed more strongly by the resin. This can only be explained if the interaction term has a higher numerical value for the larger molecules.

The interaction term accounts for the interaction between the solute and the ion exchanger and between the solute and the solvent. The interaction between the solute and pure solvent mixtures can be accounted for if the activity coefficients for the solute are known at different solvent compositions. Data, which show the solvent composition inside the resin as a function of the outer concentration, are given in an earlier paper [9]. Within the range of alcohol concentrations studied in the present work the water concentration inside the resin is higher than in the outer solution and therefore the polar solutes, preferring the better solvent, will accumulate in the resin phase. Based upon solubility measurements, an attempt was made in an earlier paper to estimate the relative magnitude of the solute-solvent interaction and the solute-resin interaction for glucose in aqueous alcohol. It was shown that both factors have to be taken into consideration. As to the solute-resin interaction it has been demonstrated that for sugars the interaction between the ions inside the resin and the solute is a more important factor than the interaction between the resin matrix and the solute [2,3]. For less polar solutes, *e.g.* acetic acid, the latter factor may predominate [5].

As demonstrated in earlier papers the uptake of polar non-electrolytes from aqueous alcohol can be used for analytical separations. Under suitable conditions non-electrolytes can be separated according to the chromatographic technique [4,1]. From the present work it is obvious that the separation factors, *i.e.* the ratio between the sorption coefficients (or distribution coefficients), differ much more in aqueous alcohol than in pure water [*cf.* Ref.[8]]. An increase in alcohol concentration causes an increased separation factor. For this reason it is advantageous to use a high alcohol concentration for chromatographic separations of polar non-electrolytes. As observed earlier for sugars [1,2] and confirmed in the present work for polyalcohols, the reaction equilibrium is reached slowly in aqueous alcohol and as demonstrated above the rate of reaction is extremely low in an almost water-free medium. This is a consider-

able disadvantage as far as chromatographic work is concerned, and for practical purposes the concentration cannot be chosen too high.

In this connection it may be mentioned that glycol, glycerol and sorbitol can be easily separated, *e.g.* by elution with 95 % ethyl alcohol from a column with the sodium form of Dowex 50 [4]. Glycol and glycerol appear as sharp peaks and sorbitol, which is bound much more strongly, appears as a broad band of low concentration. After glycol and glycerol have been eluted, sorbitol can be displaced quickly by means of water. The resin swells much more in water than in aqueous alcohol and so it might be necessary to break up the resin bed after the addition of water. Because of the influence of solvent composition upon the swelling, gradient elution based upon a gradient in solvent composition cannot be used as the changes in swelling causes channelling or even plugging in the column [14].

APPENDIX

An attempt was made to determine the swelling pressure of Dowex 50 in ethyl alcohol according to the isopiestic method [15,16]. Isotherms of the same shape as for water were obtained. The weakly cross-linked resin X0.5 sorbed considerably more than the normally cross-linked resin. The sequence of the ionic forms of the resin was the same as for water sorption, *i. e.* the lithium form sorbed more than the sodium form, which showed a stronger sorption than the potassium form. The order is the same as obtained for the swelling in alcohol solutions [9].

Considerable experimental difficulties arose in these experiments and only the results obtained with the sodium form of the resin will be given in the present paper. The isotherms are given in Fig. 7. The time of reaction in these experiments has been 3—6 days and no significant differences have been observed for different times of reaction. The isotherms for the sorption and desorption do not coincide, and for this reason it seems improbable that a true equilibrium has been reached. Furthermore, it is very difficult to prevent traces of water vapor from entering the system, so no swelling pressure data will be given here. It may only be mentioned that the lithium resin gave data of the same order of magnitude as for water [15,16], whereas higher pressures were calculated for the sodium and potassium forms of the resin.

Synthesis of Potential Hypnotics

POUL NEDENSKOV*, WILLIAM TAUB and DAVID GINSBURG

Department of Chemistry, Israel Institute of Technology, Haifa, Israel

Several 2,2-disubstituted *cyclo*hexanones were prepared and a number of their corresponding oximes was subjected to Beckmann rearrangement in order to obtain ε,ε-disubstituted caprolactams believed to possess hypnotic activity.

It was believed that lactams containing a quaternary carbon atom adjacent to the lactam moiety, *i.e.* the grouping —CO—NH—CRR'— within a cyclic system, might possess hypnotic activity. Such compounds would be available from 2,2-dialkyl-*cyclo*hexanones, for example, through Beckmann rearrangement of the corresponding oximes.

It has been shown [1] that such rearrangement leads exclusively to the above grouping rather than to the isomeric (—CRR'—CO—NH—) one. It was also expected [2] that the disubstituted caprolactams would be less prone to polymerization than caprolactam itself. However, this expectation was not realized. In fact, although some of the products synthesized did indeed possess hypnotic activity, polymerization occurred so readily that preparation of this type of compound was abandoned as impractical.

The difficulties in preparing 2,2-disubstituted *cyclo*hexanones in one step are well known. However, the availability of Stork's excellent method for the synthesis of monoalkyl*cyclo*hexanones [3] afforded the possibility of alkylating the latter derivative in the presence of sodium hydride in reasonable overall yield. The purification of the liquid products was effected by distillation through the efficient column described by Clauson-Kaas and Limborg [4].

The oximes were prepared in high yield by the pyridine procedure [5] and were rearranged by means of polyphosphoric acid [6]. The disubstituted caprolactams thus obtained polymerized very readily during distillation or even upon standing. Purification with lower loss of material could be effected chromatographically.

In the attempt to prepare 6,6-dialkylpyridones from the corresponding oximes of 2,2-disubstituted *cyclo*pentanones, the following approach was attempted but failed.

Chlorination of 2-ethyl*cyclo*pentanone with sulfuryl chloride afforded 2-chloro-2-ethyl*cyclo*pentanone. Treatment of the latter with diethyl cadmium indeed effected alkylation by replacement of the chlorine atom with an ethyl group without attack of the carbonyl group but unfortunately this cadmium alkyl was a sufficiently strong base so as to effect dehydrochlorination and 2-ethyl-*cyclo*pent-2-enone was formed concomitantly. Perhaps a different metal alkyl might be employed successfully but this was not pursued further.

EXPERIMENTAL PART *

*2-Ethyl*cyclo*hexanone.* A mixture of freshly distilled *cyclo*hexanone (108 g, 1.1 mole), pyrrolidine (156 g, 2.1 mole) and dry thiophene-free benzene (500 ml) was heated and stirred in a nitrogen atmosphere [7]. The water formed during the preparation of the enamine was collected in a calibrated moisture trap. Most of the benzene and excess pyrrolidine were removed at atmospheric pressure and the rest at the water pump. The flask containing the residual yellow oil was cooled to room temperature and ethyl iodide (187 g, 1.2 mole) was slowly added, causing a strong exothermic reaction. When stirring became difficult due to the thickness of the reaction mixture, absolute ethanol (125 ml) was added. After addition of the ethyl iodide was complete the mixture was heated under reflux overnight (under nitrogen).

The ethanol was removed at reduced pressure and the resulting crystalline mass was heated under reflux with water (200 ml) for 3 h. After cooling and separation of the oily phase, the aqueous phase was extracted twice with ether. The aqueous phase was then subjected to steam distillation; the distillate was saturated with sodium chloride and was extracted several times with ether. The oil and combined ether extracts were dried

(magnesium sulfate) and the ether was removed, leaving a brownish oil (140 ml) which when distilled through an efficient column [4] afforded 2-ethyl*cyclo*hexanone as a colorless oil, b. p. 88°/50 mm, n_D^{30} 1.4464 (71 g, 63 % based on unrecovered *cyclo*hexanone). Lit.[8] reports b. p. 67°/12 mm, n_D^{15} 1.4543.

*2-Allyl*cyclo*hexanone.* This ketone was similarly prepared from *cyclo*hexanone (49 g, 0.5 mole), pyrrolidine (71 g, 1 mole) in dry benzene (500 ml) and freshly distilled allyl bromide (73 g, 0.6 mole). Dry *n*-butanol was used instead of ethanol. The ketone had b. p. 90—98°/20 mm, n_D^{30} 1.4647 (42 g, 60 %). Lit.[9] reports b. p. 91—94°/12 mm.

*2-n-Butyl-2-methyl*cyclo*hexanone.* In a 1-liter 3-necked flask equipped with mechanical stirrer, reflux condenser and dropping funnel, a mixture of 2-methyl*cyclo*hexanone (56 g, 0.5 mole), dry toluene (500 ml) and sodium hydride (13.2 g, 0.55 mole) was heated and stirred under reflux for 15 h under nitrogen. The suspension of sodio-derivative was then cooled and *n*-butyl bromide (67.5 g, 0.5 mole) was added with stirring during 10 min and then heated under reflux for 2—3 h. After cooling to *ca.* 50°, the precipitated sodium bromide was removed by filtration and the salt was washed with two portions (50 ml) of dry ether. The solvents were removed at the water pump from the combined filtrates. The light yellow residue (*ca.* 90 ml) was distilled through an efficient column [4] affording 2-*n*-butyl-2-methyl*cyclo*hexanone, b. p. 96°/12 mm) n_D^{30} 1.4525 (52 g, 62 %) and 2,6-di-*n*-butyl-2-methyl*cyclo*hexanone, b. p. 144—145°/12 mm, n_D^{30} 1.4560 (9.0 g, 8 %). (Found: C 80.2; H 12.3; O 7.5. Calc. for $C_{15}H_{28}O$: C 80.3; H 12.6; O 7.1.)

The disubstituted ketone gave an orange 2,4-dinitrophenylhydrazone, m. p. 144—145° (from ethanol-ethyl acetate). (Found: C 58.5; H 6.9; N 16.6. Calc. for $C_{17}H_{24}O_4N_4$: C 58.6; H 6.9; N 16.1.) The trisubstituted ketone did not form the analogous derivative, presumably for steric reasons.

Other 2,2-disubstituted cyclo*hexanones.* These were prepared analogously employing the corresponding 2-substituted *cyclo*hexanone and alkyl bromide or iodide. The 2-ethyl-, 2-allyl- and 2-methyl-compounds served as starting materials except in the case of the preparation of 2-ethyl-2-phenyl*cyclo*hexanone, when 2-phenyl*cyclo*hexanone was alkylated as described above, with ethyl bromide. 2-Allyl-2-ethyl*cyclo*hexanone was prepared by alkylation of 2-allyl*cyclo*hexanone with ethyl iodide.

Oximes. The pyridine procedure was used. The ketone was heated under reflux with an equal weight of hydroxylamine hydrochloride in pyridine-absolute ethanol [5] for 3 h. The crystalline oximes were recrystallized from aqueous methanol and the liquid oximes were distilled in a high vacuum. They were obtained pure in at least 70 – 80 % yield.

The data pertinent to the ketones and oximes are summarized in Table 1.

ε,ε-Disubstituted caprolactams. It was found in this case that 85 % sulfuric acid and boron trifluoride [10] were inferior to polyphosphoric acid [6] as catalysts for Beckmann rearrangement of the oximes. The best experimental conditions found were the following.

In a 3-necked flask provided with a teflon-blade stirrer, calcium chloride tube and a flask with a connecting rubber sleeve containing phosphorus pentoxide (30 g) was placed orthophosphoric acid (85 %, 30 g). The solid pentoxide was added in small portions with vigorous stirring during 15 min. Its container was then replaced by a thermometer. The polyphosphoric acid thus prepared was heated in an oil bath to 100° and the oxime (2 g) was added, causing the temperature to rise to *ca.* 115° during the first minute after addition. When the temperature had dropped to 105°, the reaction mixture was heated to 115° and thus maintained for 10 min. After cooling to 90°, the slightly yellow mixture was poured on to cracked ice (150 g). The resulting turbid solution was cooled to −10° in an ice-salt bath and aqueous potassium hydroxide (40 %, 100 ml) was added dropwise with vigorous stirring, keeping the temperature below −5°. The pH was then *ca.* 6.5 and the lactam was readily extracted with chloroform-ethyl acetate (10:1; 150 ml + 100 ml). The bright yellow solution was dried (magnesium sulfate) under nitrogen in the refrigerator. A change of color to red indicates occurrence of polymerization. The solvents were removed at water pump pressure under nitrogen and the residual oil was dissolved in carbon tetrachloride in order to remove any insoluble polymer which may have formed. Removal of the solvent from the filtrate under nitrogen at water pump pressure usually affords a dark oil which can be further purified either by distillation of small portions (2 g) in a high vacuum or by chromatography. In the latter case a solution of the lactam in carbon tetrachloride is poured on to a column of florex-celite (5:1) with successive elution by carbon tetrachloride-benzene and chloroform. Analytically pure lactam is present in the chloroform fractions.

Table 2 records the data pertinent to the lactams.

Table 2. ε,ε-Disubstituted caprolactams.

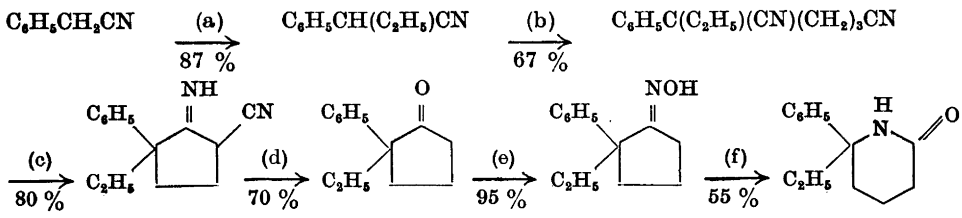
6-Ethyl-6-phenyl-2-piperidone. This compound was prepared *via* the following reaction scheme:[11]



(a) The procedure was exactly analogous to the synthesis of the corresponding methyl derivative [11]. The product had b. p. 115—120°/12 mm.

(b) The alkylation was carried out with γ-iodobutyronitrile (b. p. 72—73°/0.5 mm, n_D^{30} 1.5180), prepared from the γ-bromocompound [11].

The product was obtained after a forerun (b. p. 70—134°/0.01 mm), as an oil, b. p. 135.5—138°/0.01 mm, n_D^{30} 1.5040. (Found: C 78.7; H 7.5. Calc. for $C_{14}H_{16}N_2$: C 79.2; H 7.6.)

(c) Cyclization was effected by means of sodamide in dry benzene [11]. The major portion of the crystalline imine had m. p. 122° but an additional small amount of light brown crystals from the mother liquor, m. p. 112—116°, was sufficiently pure for further work. (Found: C 78.7; H 7.5; N 12.9. Calc. for $C_{14}H_{16}N_2$: C 79.2; H 7.6; N 13.2.)

(d) Hydrolysis of the imine (12.1 g) was effected by heating under reflux with acetic acid (100 ml), concentrated sulfuric acid (6 ml) and water (6 ml) for 4 h [11]. After dilution with water (120 ml), extraction with benzene and distillation, 2-ethyl-2-phenyl*cyclo*pentanone was obtained as an oil (7.5 g), b. p. 79—81°/0.01 mm, n_D^{30} 1.5283.

(e) A mixture of the above ketone (6.8 g), hydroxylamine hydrochloride (5 g), pyridine (20 ml) and absolute ethanol (20 ml) was heated under reflux for 4 h. After the usual workup, the colorless crystalline oxime (7.0 g) was obtained, m. p. 84—85° (from aqueous methanol). (Found: C 76.6; H 8.2; N 6.7. Calc. for $C_{13}H_{17}ON$: C 76.8; H 8.4; N 6.9.)

(f) Beckmann rearrangement with polyphosphoric acid (see above) gave the desired pyridone as a slightly yellow unstable oil, b. p. 120—125°/0.1 mm. It was best stored in the refrigerator under nitrogen. (Found: C 76.1; H 7.8; N 6.3. Calc. for $C_{13}H_{17}ON$: C 76.8; H 8.4; N 6.9.)

Attempted preparation of 2,2-diethylcyclopentanone. (a) To a solution of 2-ethyl*cyclo*pentanone [12] (22.4 g) in dry carbon tetrachloride (100 ml) was added a solution of sulfuryl chloride (18 ml) in dry carbon tetrachloride (30 ml) during 1 h. Stirring was continued for an additional 2 h and then the mixture was kept in the dark overnight. The solvent was removed at water pump pressure and the desired 2-chloro-2-ethyl*cyclo*pentanone was obtained as a colorless oil (22 g, 73 %), b. p. 78—82/20 mm, n_D^{30} 1.4658, which soon turned yellow. It was used immediately after distillation.

(b) Diethyl cadmium was prepared in the usual way by treating ethyl magnesium bromide (from ethyl bromide (32.7 g, 0.3 mole), magnesium (6.1 g, 0.25 g.atom) in dry ether (200 ml)) with anhydrous cadmium chloride (23.8 g, 0.13 mole). To this solution was added during 10 min a solution of freshly distilled 2-chloro-2-ethyl*cyclo*pentanone (15.1 g) in dry ether (80 ml). After stirring for 10 min at 0°, the dark gray suspension appeared greenish-white. Stirring at ice-bath temperature was continued for an additional 2 h and then the mixture was stirred overnight at room temperature. It was finally heated under reflux for 1 h. Ammonium chloride solution (0.5 M, 100 ml) was added with stirring at 0° followed by hydrochloric acid (10 %, 50 ml). The yellow ether layer was separated and the aqueous phase was extracted with several portions of ether. The combined ether extracts were washed with saturated sodium bicarbonate solution and dried (magnesium sulfate). Distillation gave a mixture of the desired but impure 2,2-diethyl*cyclo*pentanone (66 g), b. p. 82—92°/20 mm, after a forerun of 2-ethyl-*cyclo*pent-2-enone (2.8 g), b. p. 74—82°/20 mm, and higher boiling material (6 g).

Each of the first two fractions was treated with 2,4-dinitrophenylhydrazine. Chromatography of the benzene solutions on basic alumina showed that the first fraction consists mainly of the unsaturated ketone, whose red 2,4-dinitrophenylhydrazone had m. p. 200° (from ethanol-ethyl acetate). (Found: C 53.6; H 4.6; N 19.2. Calc. for $C_{13}H_{14}O_4N_4$: C 53.8; H. 4.9; N. 19.3.) However, this was accompanied by an orange-red 2,4-dinitrophenylhydrazone which formed the main component in the mixture of hydrazones obtained from the second fraction. This was the derivative of 2,2-diethyl*cyclo*pentanone and had m. p. 205° (from ethanol-ethyl acetate). (Found: C 56.2; H 6.2; N 17.5. Calc. for $C_{15}H_{20}O_4N_4$: C 56.2; H 6.3; N 17.5.)

This procedure is therefore impractical for obtaining the pure disubstituted ketone as dehydrochlorination of the starting material accompanied the desired alkylation reaction.

Fungus Pigments

IX.* Some Further Constituents of *Hydnum aurantiacum* Batsch

JARL GRIPENBERG

Department of Chemistry, Finland Institute of Technology, Helsingfors, Finland

Two further constituents of the fungus *Hydnum aurantiacum* Batsch have been isolated and identified as 1,2,4,5-tetrakis(benzoyloxy)-3,6-bis(*p*-hydroxyphenyl)benzene (dihydroaurantiacin dibenzoate) (II) and thelephoric acid.

The isolation of aurantiacin (I), the pigment of the fungus *Hydnum aurantiacum* Batsch has been described in a previous paper[1]. Another crystalline component has now been isolated from the same extract. This compound is colourless, and was finally shown to have the composition $C_{46}H_{30}O_{10}$, although it was at first difficult to get consistent analytical results owing to its great tendency to retain solvent of crystallisation. It was most conveniently recrystallised from dioxan which could be completely removed only by prolonged heating at 150°/0.01 mm.

When warmed with dilute alkali the compound dissolved and the solution eventually became dark brown. Acidification yielded a mixture of benzoic acid and atromentin. This together with the lack of colour indicated that the compound was a hydrogenated derivative of aurantiacin.

IV R = R′ = $COCH_3$
V R = R′ = H

* Part VIII, *Acta Chem. Scand.* 12 (1958) 603.

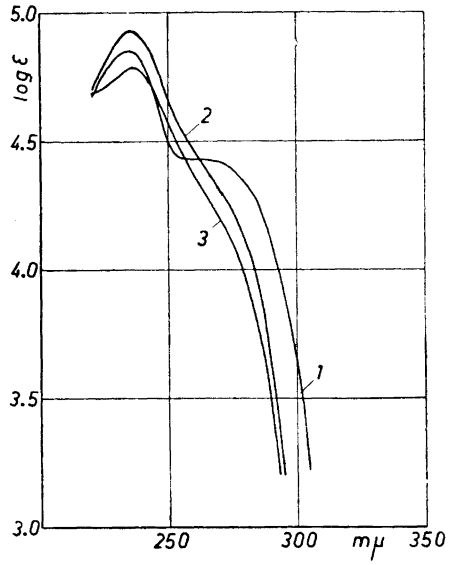

Fig. 1. Absorption spectra of: *1.* 1,2,4,5-Tetrakis(benzoyloxy)-3,6-bis(*p*-hydroxyphenyl)benzene (II) (in dioxan), *2.* 1,2,4,5-Tetrakis(benzoyloxy)-3,6-bis(*p*-acetoxyphenyl)benzene (III) (in dioxan) and *3.* aurantiacin leuco-acetate (IV) (in alcohol).

The composition $C_{46}H_{30}O_{10}$ corresponds to a dibenzoate of dihydro-aurantiacin. That the compound has free phenolic hydroxyl groups can be seen from the UV and IR spectra. The former (Fig. 1; curve. 1) has a strong inflexion at 270 mμ and the latter a strong peak at 3 420 cm^{-1}; both disappear on acetylation. The UV spetrum of the diacetate thus obtained (Fig. 1; curve. 2) is very close to that of aurantiacin leuco-acetate [1] (IV) (Fig. 1; curve 3).

The compound $C_{46}H_{30}O_{10}$ is very stable, but dihydroaurantiacin (V), prepared from aurantiacin by catalytic hydrogenation shows a great tendency to revert to aurantiacin by aerial oxidation. This indicates that the compound $C_{46}H_{30}O_{10}$ has no hydroquinone grouping. It should therefore be II (assuming that the two benzoyl groups are symmetrically situated). This view was confirmed by synthesis of III from aurantiacin diacetate by hydrogenation followed by benzoylation. This was identical with the acetate of the compound $C_{46}H_{30}O_{10}$ referred to above.

The presence of this leucobenzoate of aurantiacin together with aurantiacin recalls the simultaneous occurrence of leucomelone and its leucoacetate in *Polyporus leucomelas* Pers. ex Fries [2]. There are also a number of cases known where a quinone occurs in fungi together with the corresponding hydroquinone, sometimes forming a quinhydrone [3-5]. It is possible that the occurrence of the dihydroderivative either free or acylated, together with the corresponding quinone is more common than is usually appreciated because the dihydroderivatives which are usually colourless are easily overlooked.

Extraction of the ether-extracted fungus material with acetone gave a small amount of thelephoric acid. The occurrence of thelephoric acid is by no means surprising, since its presence in a number of *Hydnum* species has been reported before [6,7].

EXPERIMENTAL

(The analyses were carried out by Dr. A. Bernhardt, Mülheim, and the IR spectra were taken by Mr. B. C. Fogelberg, AB Centrallaboratorium, Helsingfors.)

*Isolation of 1,2,4,5-tetrakis (benzoyloxy)-3,6-bis (*p*-hydroxyphenyl)benzene* (II). The mother liquor from which aurantiacin had been filtered off [1] was evaporated under vacuum. The residue was extracted with benzene and then with a small amount of acetone. The grey insoluble powder was repeatedly recrystallised from dioxan giving 1,2,4,5-tetrakis(benzoyloxy)-3,6-(*p*-hydroxyphenyl)benzene as clusters of colourless needles, m. p. 305—307°. (Found: C 74.47; H 4.07; O 21.83. $C_{46}H_{30}O_{10}$ requires C 74.38; H 4.07; O 21.55 %.) The benzene and acetone solutions were evaporated to dryness under vacuum and repeated treatment with benzene and acetone gave further amounts of the same compound.

Further amounts of the compound were obtained by purification of aurantiacin by chromatography [1]. It was obtained by evaporation of the fraction just preceding aurantiacin. It was slightly contaminated with aurantiacin which could be removed by crystallisation from dioxan.

*Hydrolysis of 1,2,4,5-tetrakis (benzoyloxy)-3,6-bis (*p*-hydroxyphenyl)benzene.* The compound (30 mg) on warming with 2 N sodium hydroxide (5 ml) for a few minutes dissolved completely. The dark brown solution was acidified and extracted with ether. The ether was evaporated and the residue extracted with a little benzene. Evaporation of the benzene solution gave benzoic acid (12 mg) identified by mixed m. p. The dark brown benzene-insoluble material was acetylated with acetic anhydride and pyridine giving yellow needles, m. p. 242—244°/290—295°, unchanged by admixture of atromentin tetra-acetate.

*1,2,4,5-Tetrakis (benzoyloxy)-3,6-bis (*p*-acetoxyphenyl)benzene* (III) a). From 1,2,4,5-tetrakis(benzoyloxy)-3,6-bis(*p*-hydroxyphenyl)benzene. The compound was suspended in acetic anhydride, a drop of pyridine was added and the mixture was warmed to give a clear solution. On cooling the acetate crystallised out and was recrystallised from dioxan giving glass-like crystals which turned opaque on standing in air, m. p. 317—321°. (Found C 72.66; H 4.29; O 22.89. $C_{50}H_{34}O_{12}$ requires C 72.63; H 4.15; O 23.22 %.)

b) From aurantiacin. Aurantiacin diacetate [1] (220 mg) was suspended in alcohol and hydrogenated over PtO_2 catalyst. The originally yellow crystals turned slowly colourless, without ever completely dissolving. The consumption of hydrogen was about 10 ml (theor. 8 ml). The crystals and the catalyst were filtered off and the crystals were dissolved in pyridine. Excess of benzoyl chloride was added and the mixture allowed to stand for three days. It was then poured into water giving a colourless precipitate. Ether was added to the suspension and the precipitate was then filtered off and recrystallised from dioxan. The crystals were identical in appearance with those obtained according to b), m. p. 320—324°, mixed m. p. undepressed. The IR spectra of the two preparations were identical

Dihydroaurantiacin (V). Aurantiacin (50 mg) was hydrogenated over a prereduced Adams catalyst in dioxan. The uptake of hydrogen was 2.1 ml (theor: 2.1 ml) and the solution turned colourless. It was evaporated under vacuum at room temperature to give slightly yellow crystals of dihydroaurantiacin, m. p. 310—312°. On attempted recrystallisation from dioxan they turned much darker in colour, apparently re-oxidising to aurantiacin. The substance was not analysed.

Isolation of thelephoric acid. The ether extracted fungus material was further extracted with acetone in a Soxhlet apparatus giving a violet-red solution in which a small amount of grey precipitate formed during the extraction. This was removed and the solution allowed to stand. A dark blue precipitate gradually formed, which was almost insoluble in all organic solvents except pyridine in which it dissolved with a wine-red colour. Dilution with water gave a blue solution, from which a blue precipitate slowly formed. This had no m. p. but gradually decomposed above 350°. Acetylation with acetic anhydride and pyridine gave an orange-red acetate, which was recrystallised from dimethyl

succinate m. p. 330—335° (decomp.). Reductive acetylation with zinc, acetic anhydride and pyridine gave a colourless leuco-acetate, after recrystallisation from nitrobenzene m. p. 370—380° (decomp.). All these properties agree well with those given for thelephoric acid [7-9].

This investigation has been supported by a grant from *Statens Naturvetenskapliga Kommission*, which is gratefully acknowledged.

An X-Ray Study on the System Cu-S

SEVED DJURLE

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The phase relations in the system Cu—S have been investigated by X-ray diffraction methods. Phases of the following (approximate) compositions were found to exist:

Cu_2S, $Cu_{1.96}$ S, $Cu_{1.8}$ S and CuS.

All of these phases except CuS undergo one or more transitions at higher temperatures. Each ultimately transforms into a face-centred cubic phase which probably exists at least over the composition range Cu_2S to $Cu_{1.8}S$.

The previously unknown sulphide $Cu_{1.96}S$ seems to be low-symmetric at room temperature. A high-temperature modification of this sulphide is tetragonal and can be preserved as a metastable phase at room temperature, where its body-centred unit cell has the dimensions:

$a = 4.008$ Å, $c = 11.268$ Å.

The low-temperature modification of $Cu_{1.8}$ S is the only phase with a homogeneity range. The range seems to extend at least from the composition $Cu_{1.80}S$ to $Cu_{1.73}S$.

The following sulphides of copper are known as minerals: Cu_2S (chalcocite), $Cu_{1.8}S$ (digenite), CuS (covellite).

The binary system Cu-S has been the object of several studies. References to the earlier investigations are found in the bibliography of Haughton and Prince [1]. Different controversial opinions about the system have been put forward.

Buerger [2,3] studied the system Cu_2S—CuS with a controlled-temperature camera and found the compound $Cu_{1.8}S$, in addition to the earlier known Cu_2S and CuS. According to Buerger, $Cu_{1.8}S$ below approximately 78°C should have the ideal composition Cu_9S_5, and above 78°C have a range of homogeneity with both sulphur excess and sulphur deficit. Concerning Cu_2S, Buerger states that above 105°C it has a hexagonal basic structure and below 105°C an orthorhombic superstructure. The relations between the unit cells of the modifications and their probable space groups are given. According to Buerger the superstructure phase is capable of dissolving sulphur up to eight atomic per cent CuS, while the basic structure dissolves only up to two atomic per cent CuS.

Rühl [4] has also studied the system Cu_2S—CuS with a high-temperature camera. Contrary to Buerger, he found that $Cu_{1.8}S$ at room temperature has the homogeneity range $Cu_{1.81}S$—$Cu_{1.77}S$, and that at higher temperatures, the solid solution region is very much broadened, but only towards the copper side. He observed that the diffraction pattern of $Cu_{1.8}S$ at room temperature and up to about 75°C had superstructure lines. The phase in equilibrium with $Cu_{1.8}S$ was not Cu_2S, but a phase whose diffraction pattern had the strongest lines in places similar to Cu_2S. He thought it probable that Cu_2S had a small range of homogeneity (up to two atomic per cent CuS).

Jensen [5] has studied Cu_2S by differential thermal analysis and found a maximum melting temperature of 1 129°C for the composition $Cu_{1.989}S$. He could not observe the limits of solubility of sulphur in Cu_2S, nor any transformations in the solid state between 404°C and the melting points in the composition range 77.00 to 82.00 weight per cent copper.

Hirahara [6] has determined several physical properties of Cu_2S as a function of temperature and found two transition points, the lower one at about 110°C and the upper one at about 470°C.

X-Ray and thermal studies on the phase transitions of Cu_2S, performed by Ueda [7], gave results in good agreement with those of Hirahara. For the modification of Cu_2S above 470°C, Ueda could observe only two diffraction lines. He pointed out the similarity of the places of the lines with the strongest ones of high-temperature $Cu_{1.8}S$.

Further contributions to the knowledge of the electrical conductivity of the copper sulphides, together with X-ray work, has been given by Kamaigaichi [8].

Attempts to solve the structure of hexagonal Cu_2S have been made by Ueda [7], using powder data, and also by Belov and Butuzov [9]. The last two used the single crystal data given by Buerger and Buerger [10]. It seems to the present author that none of them has come to any quite satisfactory agreement between observed and calculated intensities, and hence the structure determination cannot be regarded as settled. For CuS, the structure has been determined by Oftedal [11], and later confirmed by Berry [12].

EXPERIMENTAL

Finely powdered Cu (electrolytically precipitated, E. Merck, Darmstadt) and S (sublimated sulphur, T. Schuchardt, Goerlitz) of better than 99.9 % purity were used as starting materials.

Samples were prepared by carefully mixing weighed amounts of the elements, pressing the mixtures to pellets at a pressure of up to 16 ton/cm² and sintering in evacuated Supremax or silica tubes at a temperature of 320 or 470°C. The heating time varied between 1 and 7 days. The samples were either quenched in cold water from the sintering temperature or allowed to cool slowly, within 24 h, in the furnace.

Visual examination or X-ray analysis indicated that some samples were heterogeneous after this treatment. They were then finely powdered, pressed into pellets and annealed in evacuated tubes for times up to 1 month.

No signs of contamination of the samples from the Supremax or silica tubes were detected.

In order to see if the preparation technique was satisfactory, selected samples were chemically analyzed. The sample was dissolved in fuming HNO_3 and the solution was evaporated to dryness on a steam bath. HNO_3 was removed by repeated evaporations

with HCl, and then the sample was diluted to 100 ml. SO_4 and Cu were determined in aliquote parts, the former gravimetrically as $BaSO_4$ and the latter by titration with 0.01 M EDTA with murexide as an indicator. The composition, calculated from the weighed amounts of the elements, was in good agreement with the chemical analysis. The deviation amounted to 0.5 weight per cent for copper and 0.2 weight per cent for sulphur.

The samples were investigated by taking X-ray powder photographs in Guinier type focusing cameras with quartsmonochromatized Cu-$K\alpha$ radiation (sometimes with Cr-$K\alpha$ radiation). KCl or CaF_2 were used as internal standards. The following constants of wavelengths and standards were used:

Cu$K\alpha$ = 1.5418 Å	$a_{KCl}21°$ = 6.29215 Å
Cr$K\alpha$ = 2.2909 Å	$a_{CaF_2}21°$ = 5.46300 Å

In order to investigate samples at higher temperatures in most cases from room temperature up to 500°C, X-ray measurements were made with an one-sided Debye-Scherrer heating camera of 4.55 cm film radius, registering reflexions between 2Θ = 26.456° and 2Θ = 157.15°. The radiation used was Cu-$K\alpha$ filtered with a Ni-foil. The camera and the X-ray technique used has been described by Fischmeister [13]. The thermocuple of the camera was calibrated against known melting points [14].

The temperature fluctuation limits were:

± 2°C below	300°C
± 3°C between	300°C and 400°C
± 4°C above	400°C

The samples, in the form of very fine powder, were mounted in thin-walled capillary tubes. The tubes used were of Pyrex glass, had an outside diameter of about 0.3 mm and walls about 0.01 mm thick. The capillaries were either sealed after evacuation to prevent decomposition of the samples when heated, or continually evacuated through the camera. In order to be sure that no abnormal changes took place during heating, room temperature powder patterns before and after the heat treatment were included in each run.

RESULTS

The present study has revealed the existence of several previously unknown phases in the system Cu—S. Table 1 summarizes the result of the analysis with the high-temperature camera. The modifications have been labelled with Roman numerals (I for the one which exists above the highest transition temperature). As will be shown later, all the I-modifications probably belong to the same high-temperature phase.

The approximate composition of the phases which could be preserved at room temperature was determined by means of Guinier photographs. The X-ray analyses showed that many of the samples were not in equilibrium. In spite of different heat treatment, this could often not be completely remedied. The result of the phase analysis of two groups of samples, one annealed at 400°C and the other at 75°C during one month is summarized in Table 2, in which the denomination of the phases is the one arrived at after the high-temperature studies had been made.

Data from powder photographs of the different phases are collected in Table 3. The crystallographic results are discussed in the following.

Table 1. The sulphides of copper.

Compound	Approximate range of existence *	Crystal system
Cu_2S III	<110°C	Orthorhombic
Cu_2S II	110°C–470°C	Hexagonal
Cu_2S I	>470°C	Cubic F.C.
$Cu_{1.96}S$ III	<100°C	"Low-symmetric"
$Cu_{1.96}S$ II	Metastable?	Tetragonal
$Cu_{1.96}S$ I	>100°C	Cubic F.C.
$Cu_{1.8}S$ II	<78°C	
$Cu_{1.8}S$ I	>78°C	Cubic F.C.
CuS	<500°C	Hexagonal

* Range of investigation 20–500°C.

The phases occurring at the composition Cu_2S

The high temperature X-ray analysis has revealed two transitions. The lower one takes place gradually at about 110°C in agreement with data published earlier [3,6], and the upper one occurs at 465 to 475°C, in agreement with the temperature reported by Hirahara [6].

Cu_2S III

Minerals of chalcocite (gratefully received from the Institute of Mineralogy and Geology in Uppsala) were examined by means of powder photographs, and a single crystal was selected from a sample giving the same diffraction lines as synthetic samples. The Weissenberg photographs gave an A-centred orthorhombic cell, and after indexing the powder photograph the cell dimensions were determined as:

$$a = 11.881 \pm 0.004 \text{ Å}, \qquad b = 27.323 \pm 0.008 \text{ Å},$$
$$c = 13.491 \pm 0.004 \text{ Å}.$$

The result is in good agreement with the works of Ueda [7], Buerger and Buerger [10] and Oftedal [11]. Buerger and Buerger give the lattice parameters:

$$a = 11.90 \text{ Å}, \qquad b = 27.28 \text{ Å}, \qquad c = 13.41 \text{ Å}$$

with an accuracy of about 1 %.

The method of Ueda to determine the c-axis from rotation photographs and the a- and b-axis from the reflexions |6.0.0| and |3.4.6.| is unsatisfactory, since with Cu-radiation the reflexion |6.0.0| cannot be separated from |3.12.0| and |3.4.6| is inseparable from |0.8.6|.

Cu_2S II

The powder photographs of Cu_2S II could be indexed with a hexagonal unit cell. The dimensions at different temperatures are:

152°	$a = 3.961$	$c = 6.722$		$c/c = 1.697$
300°	$a = 3.981$	$c = 6.761$		$c/a = 1.698$
460°	$a = 4.005$	$c = 6.806$		$c/a = 1.699$

± 0.004 Å $\qquad \pm 0.007$ Å

This is in fairly good agreement with the value of B. and B.[10], $a = 3.89$ Å, $c = 6.68$ Å, $c/a = 1.717$ at 112°C (accuracy 1 %) and the diagram of Ueda [7] (his Fig. 4).

Cu_2S I

The powder photograph of this modification has been indexed as the pattern of a face-centred cubic lattice with the cell edge at

465°C	$a = 5.725$	± 0.010 Å
500°C	$a = 5.735$	

A cell content of 4 Cu_2S is consistent with the cube edge.

The phases occurring around the composition $Cu_{1.96}S$

The photographs of samples of this composition have revealed that three modifications exist.

$Cu_{1.96}S$ III is stable up to at least 75°C and $Cu_{1.96}S$ II is a high temperature modification, metastable at room temperature. When heating pure $Cu_{1.96}S$ III in the high temperature camera it begins at about 100°C to transform slowly into $Cu_{1.96}S$ I. The transition from $Cu_{1.96}S$ III to $Cu_{1.96}S$ II has not been observed.

$Cu_{1.96}S$ II is formed together with $Cu_{1.96}S$ III when quenching samples of the right composition from above a temperature of at least 320°C. From Table 2 it seems that $Cu_{1.96}S$ II is metastable at room temperature and up to at least 75°C. In the high-temperature camera, its powder pattern can only be observed below 150°C. Owing to the sluggish transitions, the patterns taken in the high temperature camera probably do not correspond to equilibrium.

$Cu_{1.96}S$ III

The diffraction pattern of this phase has not been indexed. Its complexity indicates a low symmetry.

$Cu_{1.96}S$ II

The Guinier photograph, taken at room temperature corresponds to a primitive tetragonal lattice with a cell content of 4 $Cu_{1.96}S$ and with the dimensions:

$$a = 4.008 \pm 0.002 \text{ Å}$$
$$c = 11.268 \pm 0.006 \text{ Å}.$$

$Cu_{1.96}S$ I

This modification is cubic, and has a face-centred unit lattice with the cube edge $a = 5.707 \pm 0.006$ Å at 500°C and a cell content of 4 $Cu_{1.96}S$. The unit cells of $Cu_{1.96}S$ II and $Cu_{1.96}S$ I have the following relations:

$$a_{II} \approx 1/\sqrt{2} \times a_I; \qquad c_{II} \approx 2 \times a_I$$

The phases occurring around the composition $Cu_{1.8}S$

The high temperature investigation has established a transition at 78°C in agreement with the work of Rühl [4].

$Cu_{1.8}S$ II

The Guinier powder photographs of four samples with the composition $Cu_{1.82}S$, $Cu_{1.78}S$, $Cu_{1.74}S$ and $Cu_{1.70}S$ are listed in Table 3. It appears that line displacements occur for variation in the composition. As the displacements are regular and the lines, except for some very weak ones, can be followed through the series of samples, it seems that the most probable interpretation

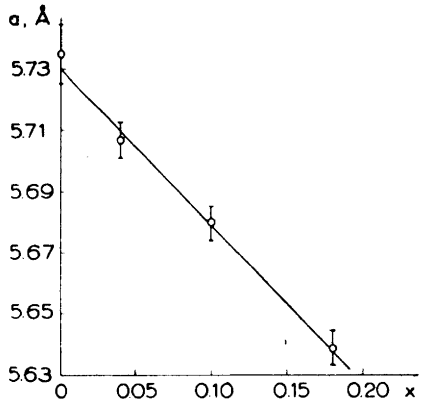

Fig. 1. Cube edge of $Cu_{2-x}S$ at 500°C as a function of x.

of the data implies the existence of a single phase, called $Cu_{1.8}S$ II, having a homogeneity range. The range extends surely from $Cu_{1.80}S$ to $Cu_{1.73}S$, and possibly from $Cu_{1.82}S$ to $Cu_{1.70}S$. The uncertainty is due to possible errors in the measurements.

Attempts to find a common indexing of the four photographs of $Cu_{1.8}S$ II have not been successful. However, most of the strongest lines of the photographs seem to correspond to a face-centred cubic basic lattice. The basic cube edge for the various compositions are:

$Cu_{1.82}S$	$Cu_{1.78}S$	$Cu_{1.74}S$	$Cu_{1.70}S$
$a = 5.570$	$a = 5.564$	$a = 5.556$	$a = 5.551 \pm 0.003$ Å

The displacements of most of the other lines when the composition is varied shows, however, that the real lattice cannot be cubic.

$Cu_{1.8}S$ I

The unit cell of this modification is face-centred cubic and is evidently closely related to the basic cell of $Cu_{1.8}S$ II. At the composition $Cu_{1.82}S$, it has the following cell constants,

at	80°C	$a = 5.577$	± 0.006 Å
	152°C	$a = 5.593$	
	300°C	$a = 5.610$	
	500°C	$a = 5.639$	

A cell content of 4 $Cu_{1.8}S$ is compatible with the cube edge.

The phase CuS

The powder photograph of this phase gave, for the hexagonal unit cell, the dimensions:

$$a = 3.794 \pm 0.003 \text{ Å}$$
$$c = 16.332 \pm 0.010 \text{ Å}$$

in close agreement with the values of Oftedal [11] and Berry [12]

$$\left.\begin{matrix} a = 3.80 \text{ Å} \\ c = 16.4 \text{ Å} \end{matrix}\right\} \text{ and } \left.\begin{matrix} a = 3.796 \text{ Å} \\ c = 16.36 \text{ Å} \end{matrix}\right\} \text{ respectively}$$

From the above it is evident that all the compounds, except CuS, have cubic, face-centred high-temperature modifications, whose diffraction lines show nearly the same relative intensity.

This points to a common high-temperature phase $Cu_{2-x}S$, where x can vary from 0 to at least 0.18 ($x > 0.18$ was not investigated). The variation of the unit cell edge of $Cu_{2-x}S$ with the composition at 500°C, as shown in Fig. 1, supports this view.

DISCUSSION

The results of the present study are contradictory to the phase diagram reported by Buerger [2,3].

The fact that Buerger's results do not agree with those of the present author is not surprising because of the way Buerger's samples were prepared. According to Buerger, chalcocite and synthetic CuS powders were compacted, placed in an *open* glass tube and heated at a temperature of about 110°C for at least 12 h. This treatment is so much more astonishing as Buerger himself, later in his paper, states: "When chalcocite is heated in direct contact with air, it begins to convert to digenite", and "It appears, then, that oxygen can proxy for sulphur".

The data reported by Rühl [4] are in good agreement with those of the present author. Thus he observed the diffraction pattern of Cu_2S only in the range Cu_2S—$Cu_{1.98}S$ (compare Table 2): and his Cu_2S-similar phase probably is the phase $Cu_{1.96}S$ III. The largest divergence between the work of Rühl and that of the present author concerns the homogeneity range of $Cu_{1.8}S$.

More work is needed to establish the composition-temperature phase diagram. Particular attention ought to be called to establishing the range of existence of the modifications of $Cu_{1.96}S$.

Acknowledgements. The author wishes to thank Professor G. Hägg for his encouraging interest in this investigation and Mr. H. Fischmeister and Mr. S. Rundqvist for stimulating discussions and valuable advice.

ACTA CHEMICA SCANDINAVICA 12 (1958) 1427—1436

An X-Ray Study on the System Ag-Cu-S

SEVED DJURLE

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The phase relations in the ternary system Ag-Cu-S have been investigated by X-ray diffraction methods. Ternary phases of the following approximate compositions were found to exist:

$Ag_{1.55}Cu_{0.45}S$ (α), corresponding to the mineral jalpaite

$Ag_{1.2}Cu_{0.8}S$ (β) and

$Ag_{0.93}Cu_{1.07}S$ (γ), corresponding to the mineral stromeyerite.

At room temperature the α phase is tetragonal and its body-centred unit cell has the dimensions:

$a = 8.673$ Å, $c = 11.756$ Å.

It transforms at 112°C into a body-centred cubic lattice, which transforms at about 300°C into a face-centred cubic lattice.

The β phase has two transition temperatures, the lower one at about 97°C and the upper one at about 130°C. Attempts to index its powder pattern have not been successful. At room temperature the γ phase is orthorhombic but transforms at 90°C into a hexagonal lattice. A second transition occurs at about 180°C.

Present evidence indicates that the modifications above the highest transition temperatures all belong to a face-centred cubic phase $(Ag,Cu)_2S$.

Previous investigators of the ternary system Ag-Cu-S have restricted themselves to the study of the "quasi-binary" system Ag_2S—Cu_2S.

Schwartz [1] examined the relations of chalcocite (Cu_2S)-stromeyerite (AgCuS)-argentite (Ag_2S), using both microscopic and X-ray techniques. He found the ternary compound AgCuS, which had a transition at a temperature of 93°C. He also stated that there was "considerable solubility of Ag_2S in Cu_2S and of Cu_2S in Ag_2S". The melting points of samples of various proportions of Ag_2S and Cu_2S followed a smooth curve, indicating complete solid solubility at high temperatures.

Suhr [2], contrary to Schwartz, could not find any extensive solid solution regions at room temperature. He found, in addition to Ag_2S, the compound AgCuS, the compound jalpaite, Ag_3CuS_2, and two unknown compounds, one silver-rich, which he thought was off the Ag_2S—Cu_2S join, and the other copper-rich, which was not Cu_2S.

Using a natural crystal of stromeyerite, AgCuS, Suhr found the unit cell to be orthorhombic with the cell dimensions:

$$a = 4.06, \qquad b = 6.66, \qquad c = 7.99 \text{ Å}.$$

A crystal structure determination of stromeyerite has been made by Frueh [3].

EXPERIMENTAL

The preparative methods and the X-ray technique used in this study were the same as in a preceding paper on copper sulphides [4].

As the third component of the system finely powdered Ag ("Finsilver", Grave, Stockholm) of better than 99.9 % purity was used.

The sintering temperature was 320, 470 or 500°C.

Selected samples were chemically analyzed. After the sample had been dissolved in fuming HNO_3 and the solution evaporated to dryness, the sample was dissolved in dilute HNO_3 and Ag was determined potentiometrically by titration with 0.1 M NaCl. The AgCl precipitate was filtered off and SO_4 and Cu were then determined as previously described [4].

The composition, calculated from the weighed amounts of the elements, was in good agreement with the chemical analysis. The maximum deviation for each element was ±0.5 atomic per cent.

RESULTS

The present study has revealed the existence of ternary phases at the approximate compositions

$Ag_{1.55}Cu_{0.45}S = \alpha$ phase (composition corresponding to the mineral jalpaite)
$Ag_{1.2}Cu_{0.8}S = \beta$ phase
$Ag_{0.93}Cu_{1.07}S = \gamma$ phase (composition corresponding to the mineral stromeyerite)

which all contain 33 1/3 atomic per cent sulphur *i. e.* lie on the "quasi-binary" line Ag_2S—Cu_2S of the ternary diagram. At each of these three compositions three different modifications appear when the temperature is raised from room temperature. These modifications are denoted by Roman numerals (I for the one existing above the highest transition temperature observed). All phases of the general formula $Ag_{2-x}Cu_xS$ ($0 \leq x \leq 2$) are listed in Table 1.

Diffraction lines of the high temperature modifications of the ternary phases were only observed at elevated temperatures in the heating camera. Quenched specimens only showed lines of the III modifications at room temperature, which shows that the high temperature modifications transform too rapidly to be preserved by quenching. Data from powder photographs of the different phases are collected in Table 2.

The section of the phase diagram at 20°C which is given in Fig. 1 is based on Guinier powder photographs taken at room temperature of a great number of samples. All triangles of the diagram are three-phase regions except the one with the corners γ, $Cu_{1.80}S$ and $Cu_{1.73}S$, which represents a two-phase region. In his work on the system Cu—S the author[4] has found that the phase denoted as $Cu_{1.8}S$ has a homogeneity range at least existing between the compositions $Cu_{1.80}S$ and $Cu_{1.73}S$.

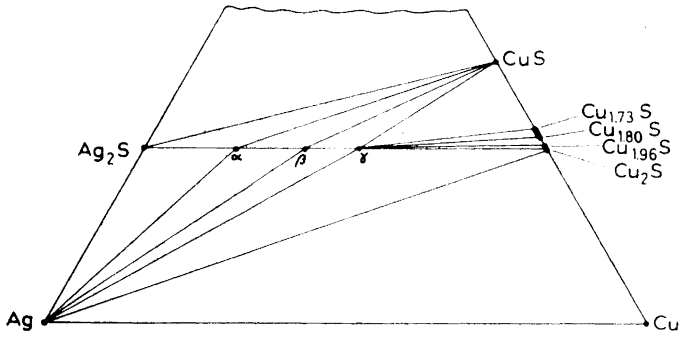

Fig. 1. The phase diagram of Ag-Cu-S. Isothermal section at 20°C.

The α phases

The two transition temperatures observed are: the lower one 112°C, and the upper one 290—310°C.

α III

This modification is tetragonal and has a body-centred unit cell with the dimensions, at room temperature:

$$a = 8.673 \pm 0.004 \text{ Å} \qquad c = 11.756 \pm 0.006 \text{ Å} \qquad c/a = 1.355$$

Table 1. The sulphides of the general formula $Ag_{2-x}Cu_xS$ $(0 \leqq x \leqq 2)$.

Compound	Composition (At.-%)			Approximate range of existence *	Crystal system
	Ag	Cu	S		
Ag_2S III	66.2/3	0	33.1/3	<177°C	Monoclinic
Ag_2S II				177—600	Cubic B.C.
Ag_2S I				>600	Cubic F.C.
α III	51.2/3	15	33.1/3	<112	Tetragonal
α II				112—300	Cubic B.C.
α I				>300	Cubic F.C.
β III	40	26.2/3	33.1/3	< 97	(Low-symmetric)
β II				97—130	
β I				>130	Cubic F.C.
γ III	31	35.2/3	33.1/3	< 90	Orthorhombic
γ II				90—180	Hexagonal
γ I				>180	Cubic F.C.
Cu_2S III	0	66.2/3	33.1/3	<110	Orthorhombic
Cu_2S II				110—470	Hexagonal
Cu_2S I				>470	Cubic F.C.

* Range of investigation 20—500°C, except for Ag_2S.

A Debye-Scherrer photograph taken at 105°C gave the values

$$a = 8.725 \pm 0.009 \text{ Å} \quad \text{and} \quad c = 11.74 \pm 0.01 \text{ Å}.$$

The fact that the a-axis expands and the c-axis contracts on heating, allows an unequivocal indexing.

The density, calculated from the cell constants, assuming 16 $Ag_{1.55}Cu_{0.45}S$ per unit cell, is 6.8 g/cm^3. Measuring of the density gave 6.9 g/cm^3.

α II

The diffraction pattern of this modification has been indexed as body-centred cubic. The cell constant measured at different temperatures is,

$$\left.\begin{array}{lll} \text{at} & 116°C & a = 4.825 \\ & 152°C & a = 4.836 \\ & 300°C & a = 4.870 \end{array}\right\} \pm 0.005 \text{ Å}$$

The cell volume is 1/8 of that of modification III, indicating 2 $Ag_{1.55}Cu_{0.45}S$ as the cell contents.

α I

Due to the high background blackening, only two lines of the pattern of this modification could be discerned.

As will be shown below, the highest temperature modifications between Ag_2S I and Cu_2S I can all be indexed on the basis of a face-centred cubic cell, giving a straight line relationship between cell edge and composition.

The two lines of α I have therefore been given indices consistent with a face-centred cubic lattice.

The cube edge at three different temperatures is as follows:

$$\left.\begin{array}{ll} 300°C & a = 6.110 \\ 400°C & a = 6.123 \\ 500°C & a = 6.140 \end{array}\right\} \pm 0.006 \text{ Å}$$

A cell content of 4 $Ag_{1.55}Cu_{0.45}S$ is consistent with the cell constants.

The β phases

Two transition temperatures have been observed, The lower one occurs at 95 to 99°C and the upper one at 120 to 143°C. No satisfactory indexing of the diffraction patterns of the modifications β III and β II has been found.

β I

The pattern of β I was indexed as derived from a face-centred cubic lattice. The edge of the unit cube was found to be,

$$\left.\begin{array}{lll} \text{at} & 151°C & a = 5.999 \\ & 300°C & a = 6.015 \\ & 500°C & a = 6.042 \end{array}\right\} \pm 0.006 \text{ Å}$$

This is consistent with a cell content of 4 $Ag_{1.2}Cu_{0.8}S$.

The γ phases

The examination has revealed two transition temperatures, the lower one at 90°C and the upper one at about 180°C.

The value of the lower transition temperature is in good agreement with the value 93°C given by Schwartz [1].

γ III

The Guinier photograph taken at room temperature gives an orthorhombic cell with the cell constants:

$$\begin{aligned} a &= 4.066 \pm 0.002 \text{ Å} \\ b &= 6.628 \pm 0.003 \text{ Å} \\ c &= 7.972 \pm 0.004 \text{ Å} \end{aligned}$$

as compared with the values reported by Suhr [2]

$$a = 4.06 \qquad b = 6.66 \qquad c = 7.99 \text{ Å}$$

γ II

This modification has been indexed hexagonally, giving a unit cell with a cell content of 2 $Ag_{0.93}Cu_{1.07}S$ and the dimensions

$$\left.\begin{array}{lll} \text{at} & 100°C & a = 4.138 \pm 0.004 \text{ Å} \\ & & c = 7.105 \pm 0.007 \text{ Å} \end{array}\right\} \quad c/a = 1.983$$

and at

$$\left.\begin{array}{ll} 152°C & a = 4.158 \pm 0.004 \text{ Å} \\ & c = 7.068 \pm 0.007 \text{ Å} \end{array}\right\} \quad c/a = 1.963$$

γ I

With the indexing chosen, the unit cell is face-centred cubic, has a cell content of 4 $Ag_{0.93}Cu_{1.07}S$ and the following cell constant,

$$\left.\begin{array}{lll} \text{at} & 196°C & a = 5.961 \\ & 300°C & a = 5.973 \\ & 500°C & a = 5.993 \end{array}\right\} \pm 0.009 \text{ Å}$$

The phases occurring at the composition Ag_2S

The transition temperatures as found in the present study are in complete agreement with the work of Kracek [5]. He states that there exist three modifications, the lower transition from Ag_2S III to Ag_2S II occurring between

176 and 178°C, the upper transition from Ag_2S II to Ag_2S I at a temperature of 586 ± 3°C in the presence of excess silver, and of 622 ± 3°C when sulphur is in excess.

Ag_2S III

The indexed Guinier photograph at room temperature gives a monoclinic unit cell with the following lattice parameters:

$$\left.\begin{array}{l} a = 9.531 \\ b = 6.925 \\ c = 8.278 \end{array}\right\} \pm 0.005 \text{ Å}$$
$$\beta = 123.85 \pm 0.10°$$

in fair agreement with the values of Ramsdell [6]

$$a = 9.47 \text{ Å}, \qquad b = 6.92 \text{ Å}, \qquad c = 8.28 \text{ Å}, \qquad \beta = 124°$$

Ag_2S II

Powder photographs of Ag_2S II were taken with the high-temperature camera, and the patterns have been indexed as belonging to a body-centred cube in accord with the work of Rahlfs [7]. Only the three strongest lines of the patterns have been used for evaluating the cell edge. This is,

$$\left.\begin{array}{lll} \text{at} & 189°C & a = 4.870 \\ & 300°C & a = 4.890 \\ & 500°C & a = 4.926 \end{array}\right\} \pm 0.008 \text{ Å}$$

The cell dimensions are in good agreement with the value 4.88 Å at 250°C given by Rahlfs.

Ag_2S I

A powder photograph of this modification was taken at 600°C. Due to the very high background blackening, only one line of the pattern could be seen With regard to the suspected isomorphism of the highest temperature modifications, discussed below, and the fact that all the I modifications have /220/ as their strongest diffraction line, this line has been indexed as /220/ of a face-centred cubic lattice, with the cube edge $a = 6.269 \pm 0.020$ Å.

The I-modifications

As has been mentioned above, and as can be seen from Tables 1 and 2 all the I-modifications of the sulphides on the "quasi-binary" line Ag_2S—Cu_2S give X-ray diffraction patterns which can be indexed with a face-centred cubic

Table 2. X-Ray diffraction data of the phases Ag_2S, α, β and γ.

unit cell. They also have comparable line intensities. The values of the cube edge, extrapolated to 600°C from values at different temperatures in order to be comparable, are as follows:

x in $Ag_{2-x}Cu_xS$	a, Å
0	6.269 ± 0.020
0.45	6.153 ± 0.006
0.80	6.055 ± 0.006
1.07	6.000 ± 0.009
2.00	5.752 ± 0.010

The value for Cu_2S I is extrapolated from measurements reported in Ref.[4]

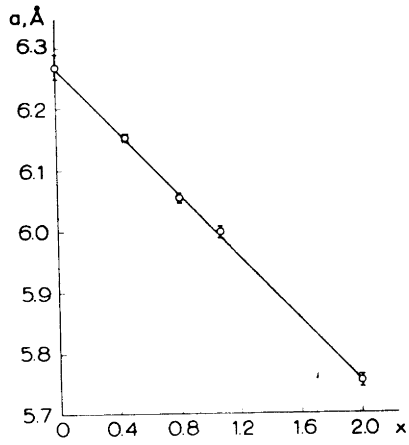

Fig. 2. Variation of cube edge of $Ag_{2-x}Cu_xS$ with x.

The values of the cell edge are plotted against the composition in Fig. 2, and within the errors of measurement, a straight line is obtained for the variation of the cell edge with the composition.

This indication of isomorphous phases with complete solid solubility is in accord with the melting point curve determined by Schwartz [1].

From the present investigation it thus seems probable that in the system Ag_2S—Cu_2S there is only one common highest temperature modification $Ag_{2-x}Cu_xS$, $0 \leq x \leq 2$.

With regard to the face-centred cubic phase $Cu_{2-y}S$, where y varies from 0 to at least 0.18, in the system Cu—S[4], there is a possibility, not investigated, that the ternary phase $Ag_{2-x}Cu_xS$ could also exist with a small deficit of copper and/or silver atoms.

Acknowledgements. The author wishes to express his sincere gratitude to Professor G. Hägg and Dr. H. Fischmeister for their encouraging interest in this investigation.

The Chemistry of Dicarboxylic Acids

I. A New Method for Quantitative Determination of Malonic Acid

AAGE JART

Danish Fat Research Institute, Copenhagen, Denmark

Malonic acid interacts with acetic acid anhydride to form a coloured compound on which it has proved possible to base a method for quantitative determination of the acid. A description is given of an analytical method depending on the absorption exhibited at 345 mμ by the compound produced. The influence of the presence of oxalic acid, succinic acid and citric acid on the reaction has been examined. In addition the ultraviolet and infrared spectra of the coloured compound formed are given.

Malonic acid can be determined quantitatively by direct titration; gravimetrically after precipitation of its barium salt [1]; by oxidation in sulphuric acid solution by means of potassium permanganate [2], sodium dichromate [3] or ceric sulphate [4]; and by measuring the areas of the coloured spots resulting from paper chromatography either of the acid or its salts.

The object of the present investigation is to develop a spectrophotometric method — as far as possible a method specific to malonic acid and enabling quantitative determination of the acid even when present in relatively small quantities. The interest in determining malonic acid arises in connection with ozonolysis of unsaturated fatty acid methyl esters. As in natural fatty acids the double bonds are often placed with a distance of three carbon atoms the ozonolysis gives rise to formation of malonic acid as an end product in the oxidation processes. The amount of malonic acid produced corresponds to the content of fatty acids with this configuration. A suitable chemical reaction on which to base the analytical method was found in the interaction between malonic acid and acetic acid anhydride which results in the appearance of a yellowish-green to yellowish-brown colour which — especially on dilution with glacial acetic acid — shows strong fluorescence [5].

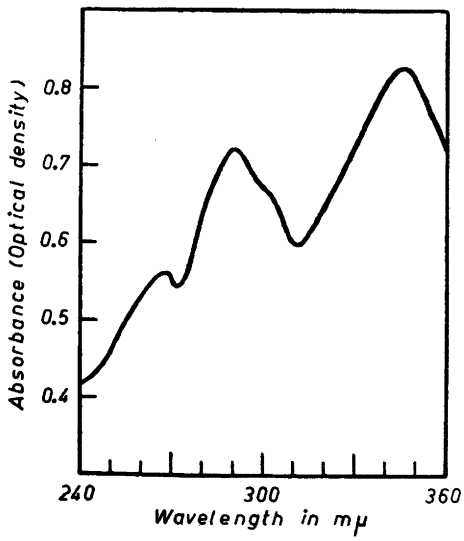

Fig. 1. The ultraviolet spectrum of "malonic colour".

PRELIMINARY INVESTIGATIONS

The ultraviolet spectrum of the coloured compound formed when crystalline malonic acid is heated with acetic acid anhydride shows a distinct absorption maximum at 290 mμ and likewise at 345 mμ (Fig. 1). The peak at 345 mμ is the highest and also the most stable, for which reason it was chosen as the basis of the present work. If D is the optical density measured in a 1 cm layer and c the corresponding concentration in mg/ml of the malonic acid used for the experiment, the reaction coefficient, α, is defined by the equation

$$\alpha = \frac{D}{c} \tag{1}$$

In order to examine the influence of the reaction time on α, a series of eight experiments at different but constant temperatures was made. The temperatures and quantities of malonic acid used appear from Table 1.

The reaction vessel used was a 250 ml round-bottom flask with a stoppered opening for drawing samples and with a reflux condenser, through which a thermometer was passed into the flask. The flask was completely immersed in a thermostat consisting of a 5 l beaker with oil and a contact thermometer with relay, heating element (150 W) and magnetic stirrer; the beaker was insulated by means of a 1 cm layer of cotton fabric.

To start the experiment 50 ml acetic anhydride (analytical grade, Merck) was transferred by means of a pipette to the preheated reaction flask. After a period of 20 min (15—20 min were necessary to establish constant temperature) the sample of crystalline malonic acid (analytical grade, Merck) was introduced by means of a 1 ml weighing cup, and the flask was swirled slightly to effect rapid solution of the sample. One minute after the introduction of the sample the thermometer reading was 0.5°C below the reaction

Table 1. Summary of the experiments at eight different temperatures (*cf.* Fig. 2).

Experiment	Temperature, °C	Malonic acid, mg
A	69.9	78.5
B	79.7	58.5
C	89.2	43.1
D	99.5	33.9
E	111.6	20.3
F	120.2	25.0
G	129.3	16.4
H	138.3	12.2

temperature, and after altogether 10 min the temperature had again reached the desired level.

During the individual experiments about 20 samples were drawn and, after dilution with glacial acetic acid (analytical grade, Merck), measured against corresponding mixtures of acetic acid anhydride and glacial acetic acid in a Beckman spectrophotometer model DU.

The reaction coefficient was calculated for the individual samples, and the results of the eight experiments are represented graphically in Fig. 2. It appears from the figure that the intensity of the absorption at 345 mμ increases with increasing temperature and reaction time. The only exception from this observation is graph H at which the temperature is 138.3°C. The reason is

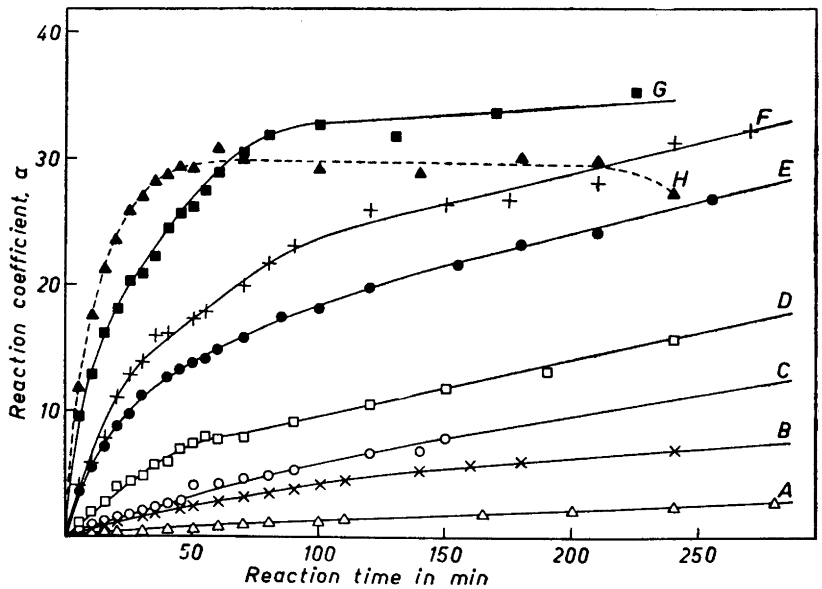

Fig. 2. The influence of the reaction time on the reaction coefficient at different temperatures (*cf.* Table 1).

that malonic acid decomposes at high temperatures to form acetic acid and carbon dioxide. The pure acid decomposes when heated to its melting point (135.6°C), while in solution the reaction often occurs at a lower temperature.

DEVELOPMENT OF ANALYTICAL METHOD

The object of the first experiments was to ascertain whether reproducible reaction coefficient values could be obtained at 100.0°C, 110.0°C, and 125.0°C.

The thermostat consisted of an enamelled tank, thoroughly insulated with glass wool and containing about 17 litres of oil. It was fitted with a stirrer, a contact thermometer with relay and an adjustable heating element. The heating element operated for about two thirds of the time, and the temperature was kept constant within ±0.1°C. The thermostat was arranged to hold four reaction vessels (test tubes).

By means of a pipette 5 ml acetic acid anhydride was transferred to each of the tubes, and after a preheating period of 20 min malonic acid was introduced by means of a little weighing cup into three of the vessels, the fourth serving as a blank. The reaction was allowed to proceed for 60 min and was then stopped by transferring the reaction vessels to a beaker with ice water. The four samples were now transferred quantitatively into 100 ml volumetric flasks by means of glacial acetic acid (the samples which had been kept at 125.0°C were further diluted five times) and measured in a Beckman spectrophotometer model DU (wavelength: 345 mμ, slit width: 0.18 mm with hydrogen lamp, and a 1 cm cuvette).

According to this procedure each experimental series provides three analytical results, and in Table 2 three series of this kind are given for each of the temperatures chosen. It will be seen that reproducibility is best at 110.0°C, the individual experimental series resulting in identical reaction coefficient values, although the thermostat used was not sufficiently stable to ensure that results obtained from day to day were in complete agreement. At 125.0°C the tendency of malonic acid to decarboxylation seems to be so pronounced that it is impossible to obtain reliable results, even though the relatively high value of the reaction coefficient, α, would enable a greater accuracy when

Table 2. Values of the reaction coefficient α at 100.0°C, 110.0°C and 125.0°C.

No.	100.0°		110.0°		125.0°	
	Malonic acid mg	α	Malonic acid mg	α	Malonic acid mg	α
1	10.5	3.77	11.6	6.43	13.1	18.6
2	14.2	3.95	13.2	6.39	10.8	18.9
3	11.3	4.15	8.6	6.38	10.2	18.0
4	12.3	3.97	14.6	6.73	11.3	17.0
5	11.5	4.02	11.1	6.77	12.9	17.5
6	11.4	3.96	12.7	6.69	12.1	19.0
7	11.4	3.66	13.6	6.54	6.8	17.7
8	12.6	3.66	11.4	6.60	11.9	17.3
9	13.0	4.22	11.6	6.57	10.5	18.7

working with small quantities of malonic acid. The lack of reproducibility of the results obtained at 100.0°C is due to the fact that at this temperature the viscosity of the thermostat oil is so high as to prevent sufficiently uniform transmission of heat to the four reaction vessels — this resulted in highly varying α values even within the same experimental series.

The conclusion to be drawn from this is that it is possible to perform the analysis at 110°C but that in case the thermostat available is not an extremely good one, it is necessary to include a control sample with malonic acid in each experimental series.

The influence of other compounds on the reaction

It is necessary to know whether other compounds which may be present in the sample to be analyzed have any influence on the reaction producing the coloured compound. It was examined whether the presence of oxalic acid and succinic acid, impurities which occur frequently together with malonic acid (for instance after chromatographic separation) will result in variations in the reaction coefficient values found. Table 3 shows that small quantities of these compounds (analytical grade, Merck) do not interfere in the malonic acid determination.

Table 3. The influence of the presence of oxalic acid and succinic acid on the malonic acid determination.

No.	Oxalic acid mg	Malonic acid mg	Succinic acid mg	α
1	2.9	11.2	1.55	7.14
2	—	10.3	—	7.10
3	5.1	9.7	4.4	7.01

In another experiment 11.7 mg citric acid monohydrate (analytical grade, Merck) was treated according to the described analytical method. This gave rise to a uniform absorption (D = about 0.1) between 240 mμ and 360 mμ, while a mixture of equal parts of citric acid and malonic acid resulted in a smaller absorption throughout the range 240—360 mμ than that produced by malonic acid alone. It is thus impossible to determine malonic acid in mixtures of malonic acid and citric acid without a preliminary separation, and samples to be analyzed must therefore in each individual case be examined to find out whether such a separation is necessary prior to the malonic acid analysis. The control sample should as far as possible be of the same composition as the mixture in which the content of malonic acid is to be determined.

THE RECOMMENDED ANALYTICAL METHOD

Use a thermostat with vigorous stirring and containing a liquid with good heat transmission characteristics. Adjust the temperature at 110°C and maintain this temperature within $\pm$0.1°C. As reaction vessels use three or

Table 4. Two series of malonic acid determinations. (Samples diluted to 100 ml before the measurement.)

Malonic acid mg	Optical density, D	α	Malonic acid found, mg
11.0	0.814	—	10.9
11.1	0.828	7.46	—
10.4	0.777	—	10.4
10.9	0.791	—	10.9
11.0	0.797	7.25	—
9.7	0.698	—	9.6

more absolutely identical test tubes (length 12 cm, external diameter 2 cm, Pyrex glass), and keep the test tubes half-way immersed in the thermostat liquid during the process.

By means of a pipette transfer 5 ml acetic acid anhydride, analytical grade, to each test tube. Place the test tubes in the thermostat at 0.5 min intervals. After a preheating period of 20 min transfer, by means of small weighing cups, the weighed samples (plus one standard sample with a known content of malonic acid) to the test tubes. One test tube is used for a blank determination, and in this test tube a weighing cup without malonic acid is placed. Exactly 60 min after the introduction of the samples into the reaction vessels remove the latter from the thermostat and place in a beaker with ice water. Allow the solutions to cool down to room temperature, and then dilute with sufficient glacial acetic acid, analytical grade, to produce solutions suitable for measurement in a spectrophotometer at 345 mμ. On the basis of the known content of malonic acid in the standard sample determine the reaction coefficient, α, using this coefficient and (1) for the subsequent calculation of the malonic acid content in the samples examined (*cf.* Table 4).

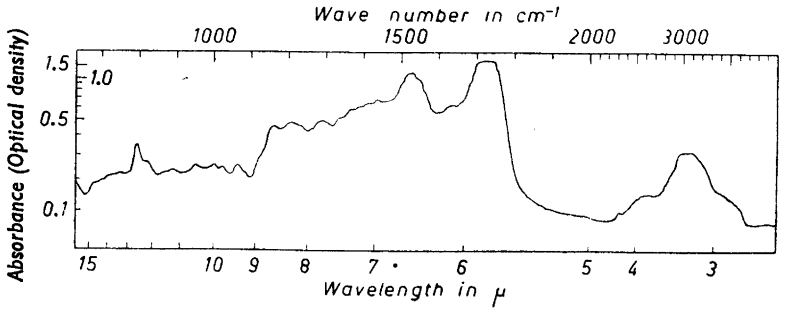

Fig. 3. The infrared spectrum of "malonic colour".

SPECTRA OF THE "MALONIC COLOUR"

The ultraviolet spectrum (Fig. 1) was obtained by means of a recording spectrophotometer (Beckman, DK-2, scanning time: 6—7 minutes); the material used being 12.2 mg malonic acid treated according to the above analytical method. After the peak at 345 mμ the absorption decreases uniformly with increasing wavelength ($D_{400\ m\mu} = 0.10$, $D_{450\ m\mu} = 0.02$, and $D_{500\ m\mu} = 0.00$). When the coloured solution is allowed to stand (after dilution with glacial acetic acid) the peak at 345 mμ becomes gradually smaller, but the change produced in the course of 24 h is hardly measurable; the reaction is not materially influenced by daylight.

The infrared spectrum (Fig. 3) was obtained from 1.1 mg "malonic colour" in 300 mg potassium bromide (Perkin-Elmer spectrophotometer, model 21).

The "malonic colour" was prepared by treating 1 g malonic acid with 50 ml acetic acid anhydride for 60 min at 110°C. The acetic acid anhydride was distilled off in vacuum, and the residue was dissolved in methyl acetate, filtered and evaporated to dryness in vacuum at a temperature not higher than 70°C, the treatment of the residue being repeated once.

The spectrum shows that the compound in question is a polymer with a considerable number of C=O bonds; it seems moreover to contain acid and ester groups, while the presence of more or less modified aromatic rings is likely.

V. On the Polarographic Determination of Phenols after Treatment with Nitrous Acid

HENNING LUND

Leo Pharmaceutical Products, Copenhagen, Denmark

It is shown that the polarographic wave obtained in the wellknown determination of morphine and other *p*-substituted phenolic compounds after treatment with nitrous acid is due to a nitro derivative rather than a nitroso derivative.

A number of *p*-substituted phenolic compounds and derivatives thereof which are not, themselves, reducible at the dropping mercury electrode can be determined polarographically after treatment with nitrous acid; such compounds are, *e. g.*, morphine [1], codeine [2], cephaeline [3], estrone [4,5], and estrogenic compounds [4,5]. The reaction has generally been formulated as a nitrosation of the phenolic compound to an *o*-nitroso derivative.

The reaction of phenolic compounds with nitrous acid [6] or nitric acid [7] has been applied to the colorimetric determination of phenols and the coloured compound obtained in alkaline solution has been regarded as a salt of the quinone oxime.

Ochiai and Nakamura [8], however, reported that the compound obtained by Wieland and Kapelmeier [9] on treatment of morphine with N_2O_3 was not 2-nitrosomorphine but 2-nitromorphine. Most recently Baggesgaard Rasmussen and Boll [10] have published results which strongly favour the formulation of the compound as 2-nitromorphine.

The formation of a nitro derivative is in agreement with the results of Philpot and Small [11] who examined the action of nitrous acid on *p*-cresol and tyrosine and found, that unless the nitroso compound was trapped as the stable copper derivative, very little of it accumulated, since it was rapidly transformed further. The products of further reaction was found to depend on the concentration of nitrous acid and phenols and on the temperature. At high concentrations of nitrous acid the formation of nitro compounds was suggested, whereas diazo derivatives were formed at somewhat lower concentrations of nitrous acid.

The purpose of the present investigation was to determine the nature of the derivative responsible for the polarographic wave obtained from morphine after treatment with nitrous acid. The investigation consists of a polarographic examination of "2-nitrosomorphine" and related compounds, and a preparative reduction at controlled potential of some of these compounds.

POLAROGRAPHIC INVESTIGATION

In Table 1 are listed the half-wave potentials at a few pH-values of 4-hydroxy-3-nitro-toluene, 4-hydroxy-3-nitroso-toluene, 3-hydroxy-6-nitro-toluene, 3-hydroxy-6-nitroso-toluene, "2-nitroso-morphine", prepared according to Wieland and Kappelmeier [9], and 4-nitro-estrone.

Table 1. Half-wave potentials (*vs.* S.C.E.) at different pH-values of "2-nitroso-morphine" and some reference compounds.

	4-Hydroxy-3-nitro-toluene	4-Hydroxy-3-nitroso-toluene	3-Hydroxy-6-nitro-toluene	3-Hydroxy-6-nitroso-toluene	"2-Nitroso-morphine"	4-Nitro-estrone

The polarographic behaviour of 4-hydroxy-3-nitro-toluene in the medium used was similar to that of *o*-nitrophenol found by Stocesova [12]. The wave obtained in acid and alkaline solution corresponded to a 6 electron reduction, which was verified by a controlled potential reduction at pH 1.5 and 10. This is in disagreement with the results of Astle *et al.*[13] who from the wave height in acid solution reported that 4 electrons were consumed in acid solution. In a pH interval around pH 5 the height of the wave corresponded to a consumption of less than 6 electrons (between 4 and 5) and the main wave was mostly succeeded by a drawn out wave. The sum of the waves nearly corresponded to a 6 electron reduction. The reason for this behaviour, according to Stocesova, is that the *o*-hydroxyphenylhydroxylamine which is primarily formed by a 4 electron reduction is converted to the quinoneimine, which is reduced by a 2

electron reduction. The conversion is acid-base catalyzed, and in a pH-interval around 5 the height of the wave is determined by the rate of the conversion.

The 4-hydroxy-3-nitroso-toluene showed at pH-values higher than 8 a single wave corresponding to a 4 electron reduction, which was verified by a controlled potential reduction at pH 10. In acid solution 2 waves occurred. The height of the first wave corresponded to between 2.5 and 3 electrons and the second one to about 1 electron. The second wave became more and more drawn out at higher pH values and disappeared almost at pH 6. The half-wave potential of the first wave was in the whole pH region 0.25—0.3 V more positive than that of the nitro compound.

The polarographic behaviour of 3-hydroxy-6-nitro-toluene was somewhat different from that of 4-hydroxy-3-nitro-toluene. The compound showed a single wave at pH-values lower than 7 corresponding to a 6 electron reduction, which was verified by a controlled potential reduction at pH 4. At pH 7 the wave was somewhat drawn out and in a small interval about pH 8 the wave split up in 2 waves. From pH 9 to 10 a single 6 electron wave again was found, but at higher pH values the wave split up in two waves. The height of these waves were dependent upon pH, but the nature of the phenomenon was not investigated further.

3-Hydroxy-6-nitroso-toluene was reduced in a single step at pH values higher than 7 and the wave corresponded to a 4 electron reduction, which was verified by a controlled potential reduction at pH 10. In an interval around pH 5 the height of the main wave decreased somewhat and a drawn out, second wave appeared.

"2-Nitroso-morphine" was reduced polarographically very similarly to 4-hydroxy-3-nitro-toluene. At pH-values higher than 7 a single wave was obtained, whereas the main wave decreased somewhat in a pH interval about pH 4 and a second wave appeared, which became more and more drawn out at higher pH-values. The difference between the half-wave potential of 4-hydroxy-3-nitro-toluene and that of "2-nitroso-morphine" was, except at pH about 6, less than 0.02 V.

4-Nitro-estrone was reduced in a single 6 electron wave in the whole pH region, except in a small interval about pH 5. The diminishing of the wave was not very pronounced.

Another series of experiments were performed in which morphine, estrone and a few of their derivatives together with some model compounds were treated with nitrous acid under the conditions used by Baggesgaard Rasmussen *et al.*[1] for the determination of morphine (N HCl, method A) and those described by Gry[4] for the determination of estrone (acetate buffer pH 3.2, method B). After treatment with nitrous acid excess of potassium hydroxide (method A) or ammonium hydroxide (method B) was added. In some cases no nitrite was present. The results are summarized in Table 2, where only the half-wave potentials of the main wave(s) is given.

Morphine treated with nitrite (method A) and "2-nitroso-morphine" without nitrite behaved very similarly; morphine only differed from "2-nitroso-morphine" by a small second wave succeeding the main wave. The height of this wave was about 5 % of the height of the main wave; the half-wave potential was about 1.0 V. The nature of this wave was not investigated further.

Table 2. Half-wave potentials of the main wave(s) obtained on treatment of some phenolic compounds with nitrous acid.

Compound	Method	Nitrite	pH	$E_{\frac{1}{2}}$ V
Morphine	A	+	14	0.84
"2-Nitroso-morphine"	A	–	14	0.84
p-Cresol	A	+	14	0.82_5
p-Cresol	B	+	10	0.76
4-Hydroxy-3-nitroso-toluene	A	–	14	0.56
4-Hydroxy-3-nitroso-toluene	B	–	10	0.36
4-Hydroxy-3-nitroso-toluene	B	+	10	0.75
4-Hydroxy-3-nitro-toluene	A	–	14	0.81
4-Hydroxy-3-nitro-toluene	B	–	10	0.75_5
4-Hydroxy-3-amino-toluene	B	+	10	0.54 1.02
Estrone	B	+	10	0.65
4-Nitro-estrone	B	–	10	0.64_5
m-Cresol	B	+	10	0.44 0.81 1.00
3-Hydroxy-6-nitroso-toluene	B	–	10	0.43
3-Hydroxy-6-nitroso-toluene	B	+	10	0.99
3-Hydroxy-6-nitro-toluene	B	–	10	0.98_5
2,4-Dinitro-phenol	B	–	10	0.69 0.97

Treatment (method A) of *p*-cresol with nitrite yielded a main wave very much like that of 4-hydroxy-3-nitro-toluene under the same conditions without nitrite, but different from the wave of 4-hydroxy-3-nitroso-toluene without nitrite. The main wave of the "nitrosated" *p*-cresol was preceded by a small wave (wave height about 5 % of the height of the main wave) with a half-wave potential about 0.47 V. This wave might have been due to the nitroso derivative or the "diazo-derivative" [11].

Estrone with nitrite in acetate buffer (method B) produced a wave similar to that of 4-nitro-estrone without nitrite.

p-Cresol nitrosated (method B) with potassium nitrite or amyl nitrite, 4-hydroxy-3-nitroso-toluene with nitrite and 4-hydroxy-3-nitro-toluene without nitrite showed very similar waves, which were different from the wave of 4-hydroxy-3-nitroso-toluene under the same conditions without nitrite.

m-Cresol on the same treatment produced 3 waves, a small wave at the same potential as did 3-hydroxy-6-nitroso-toluene without nitrite and a main wave at the same potential as that of 3-hydroxy-6-nitro-toluene. The nature of the third wave at a potential between the other two waves is not known. 3-Hydroxy-6-nitroso-toluene produced on treatment with nitrous acid a wave at the same potential as that of the nitro derivative; only a small part remained as the nitroso compound.

The spectra of the solutions used for polarography (method B) showed, that other compounds besides the nitro derivative were formed from *p*-cresol on treatment with nitrous acid. 4-Hydroxy-3-nitro-toluene showed under

these conditions (pH 10) an absorption maximum about 437 mμ, 4-hydroxy-3-nitroso-toluene (without nitrite) a maximum about 454 mμ and the maximum of the "nitrosated" *p*-cresol varied around 420 mμ.

PREPARATIVE REDUCTIONS

4-Hydroxy-3-nitro-toluene was reduced at pH 1.5 and 10. At pH 1.5 a small second wave was found on the polarograms taken in the strong solutions (5×10^{-2} M) used for the preparative reductions indicating that the rate of the conversion of the primarily formed phenylhydroxylamine derivative was not sufficiently high to secure a single 6 electron wave under these conditions. As the reduction, however, consumed 5.9 ± 0.1 electrons the intermediate formed product must be transformed in the bulk of the solution to a species reducible at the potential used, which is considerably more positive than the half-wave potential of the second wave. Some coloured compounds were formed during the reduction, but apparently not enough to influence the electron consumption to any appreciable degree. At pH 10 6.0 electrons were consumed, and in both cases the expected 4-hydroxy-3-amino-toluene was isolated. The same compound was obtained by the reduction at pH 10 of 4-hydroxy-3-nitroso-toluene. The reduction required 4 electrons. 3-Hydroxy-6-nitro-toluene was reduced at pH 4 consuming 6 electrons and 3-hydroxy-6-nitroso-toluene at pH 10 requiring 4 electrons for the reduction.

"2-Nitroso-morphine" was reduced at pH 10 at —0.85 V. The reduction consumed 5.95 ± 0.1 electrons and an aromatic amine could be detected in the reaction mixture.

DISCUSSION

The polarographic data presented in Tables 1 and 2 substantiate the assumption that *p*-substituted phenols on treatment with excess of nitrous acid form mononitro derivatives as a main product. The reaction, however, is not clean and various amounts of other phenolic derivatives are formed. The importance of these side reactions depends among other things on the structure of the phenolic compound; tyrosine, for instance, forms much more material of unidentified structure than does *p*-cresol under the same conditions. A special method, therefore, has to be developed for a given phenol, if a polarographic determination of the compound is to be worked out.

The question whether the nitro compounds are formed by a direct attack of N_2O_4 on the phenol or by an oxidation of a primarily formed nitroso derivative cannot be answered conclusively, although it can be pointed out, that both 4-hydroxy-3-nitroso-toluene and 3-hydroxy-6-nitroso-toluene on treatment with nitrous acid yield, more or less completely, the nitro derivative.

The investigation of Baggesgaard Rasmussen *et al.*[1] and the data presented here point to the conclusion that the wave obtained on treatment of morphine with nitrous acid is due to the compound formulated by Wieland and Kappelmeier as "2-nitroso-morphine". The reduction wave of this compound is found to represent a 6 electron reduction under conditions, where 4-hydroxy-

3-nitro-toluene consumed 6 electrons and 4-hydroxy-3-nitroso-toluene was reduced by 4 electrons per molecule. As it seems very unlikely that other parts of the molecule than the substituent in the 2 position are involved in the reduction the presented data are taken as strong evidence in favour of the formulation [8,10] of the compound obtained by Wieland *et al.* as 2-nitro-morphine.

The result of the present investigation is that the main polarographic wave obtained on treatment of morphine [1], estrone [4], or *p*-cresol with excess of nitrous acid is due to the reduction of the mononitro derivative rather than the mononitroso derivative.

EXPERIMENTAL

The polarograph was a recording polarograph Radiometer Type PO 3a. The capillary delivered 3.24 mg of mercury per second at a corrected mercury height of 48.5 cm; the drop time 5.82 sec (H_2O, open circuit); the capillary constant $m^{2/3}t^{1/6} = 2.94$ $mg^{2/3}sec^{-1/2}$.

The reference electrode, the buffer solutions and the apparatus used for the controlled potential reductions were the same as described in Part I [14] and III [15]. The medium used in the polarographic investigation was aqueous N KCl, except for the nitroestrone, where the solution contained 40 % alcohol.

4-Hydroxy-3-nitroso-toluene was made according to Philpot and Small [11]. It was recrystallized from petrol ether (b. p. 60°—80°) by cooling in a carbon dioxide-acetone cooling bath, m. p. 56°—58°.

"2-Nitroso-morphine" was prepared according to Wieland *et al.*[9] and the potassium salt purified after recrystallization from alcohol by chromatography [10]. The potassium salt was converted to the hydrochloride. (Found: C 49.75; H 5.94; N 6.90; Cl 9.38. Calc. for $C_{17}H_{19}N_2O_5$, 2 ½ H_2O: C 49.62; H 5.89; N 6.81; Cl 8.63.)

Reduction of "2-nitroso-morphine". 400 mg of the hydrochloride of "2-nitroso-morphine" was dissolved in 120 ml N NaCl containing 5 % sodium bicarbonate and 5 % sodium carbonate, which was deaerated and purified by electrolysis beforehand. The compound was reduced at −0.85 V (*vs* S.C.E.). The reduction was followed polarographically. It required 5.9_5 electrons. After completion of the reduction a small part of the reaction mixture was made acid and treated with sodium nitrite. After destruction of excess of nitrous acid with ammonium sulfamate, naphthylethylenediamine was added, and a violet colour slowly developed indicating the presence of an aromatic amine in the reduction medium. 2-Amino-morphine was found by Wieland *et al.* to couple slowly after diazotation. Attempts to isolate the diamine were not succesful.

ACTA CHEMICA SCANDINAVICA 12 (1958) 1451—1455

Localization of the C=S and the C—S Group Frequencies in Carboxymethyl Dithioesters

BØRGE BAK, LISE HANSEN-NYGAARD and CHRISTIAN PEDERSEN

Chemical Laboratory of the University of Copenhagen, Copenhagen, Denmark

Twenty-one carboxymethyl dithioesters were investigated spectrophotometrically in the infrared (400—4 000 cm^{-1}). Almost without exceptions intense bands were observed at 1 350—1 365, 1 290—1 325, 1 190—1 225, and 640—670 cm^{-1}. The bands close to 1 200 and 660 cm^{-1} were assigned to the C=S and the C—S stretching frequency modes.

The location of the C=S and the C—S group frequencies in organosulphur compounds has been a matter of considerable discussion. The literature concerned with this problem has lately been reviewed by Bellamy [1]. Both group frequencies are difficult to localize because they, unlike *e. g.* the characteristic C—H, C=N, and C=O frequencies, fall in a spectral region where "fingerprint frequencies" are numerous. Valuable guidance as to their approximate position may, however, be obtained by a simplified force-constant calculation. From this it follows, that the two frequencies must be looked for in the vicinity of 1 200 cm^{-1} (C=S) and 700 cm^{-1} (C—S). Probably, therefore, the somewhat meager literature on the localization of the latter frequency is caused by the fact that the usual rock-salt optics does not allow observations below *ca.* 700 cm^{-1}. Since a number (21) of new carboxymethyl dithioesters were prepared in this laboratory [2] we decided to determine their infrared absorption spectra. All dithioesters should possess the two group frequencies we are looking for. Recently, Brader *et al.*[3] have studied infrared spectra of a few (7) alkyl dithioesters. Tentatively they assigned the C=S frequency to 1 170—1 195 cm^{-1} for dithioesters but they were unable to identify the C—S frequency because of lack of KBr-optics. Felumb [6] located the C=S group frequency in dixanthogenes to the 1 210—1 230 cm^{-1} region. Schotte [7] has found the C—S group frequency in a series of dithiolane derivatives. Also, the paper by Mecke [8] on thiocarbonyl compounds discusses the position of the C=S band.

dithioesters ($R-CSSCH_2COOH$). Abscissa: wavenumber of radiation (400—1 500 cm^{-1}). millimole if less than 100. Higher densities recorded as 10 mm.

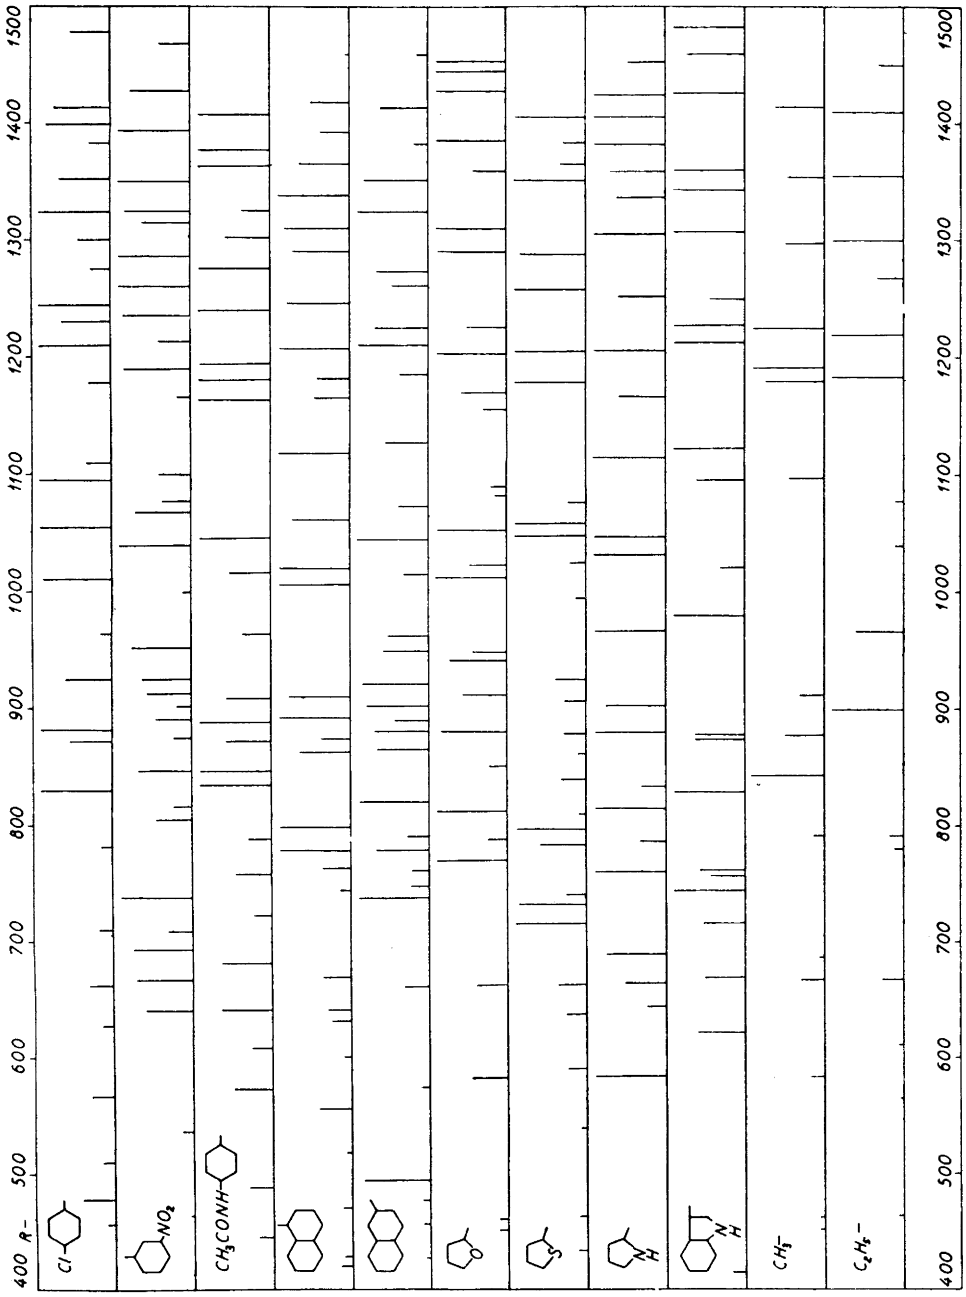

Table 1 (b)

EXPERIMENTAL

The spectra were obtained employing a Perkin-Elmer model 21 double beam infrared spectrophotometer equipped with NaCl, KBr, and CaF_2 optics. Since the compounds investigated are solids, KBr disk technique was applied (300 mg KBr mixed with 0.4—1.8 mg sample). The error in the frequency measurements is thought to be less than 2 cm^{-1}. For convenience the main features of the observed spectra are recorded graphically in Table 1. Although all the spectra were examined in the 400—4 000 cm^{-1} region it was not found useful to include more than the 400—1 500 cm^{-1} interval in Table 1. The spectra of all the compounds in question show, of course, the very broad and intense carboxyl band in the 2 400—3 400 cm^{-1} region and the intense carbonyl band at 1 700—1 725 cm^{-1}, these bands are of little diagnostic value.

DISCUSSION

The analysis was started by localizing a number of group frequencies that must be present in the spectra of these compounds according to their composition (*e. g.* the CH_3-, the CH_2-, the C_6H_5-, and the OH-group frequencies). It was, *i. a.*, noted that the two low-frequency COOH-bands appeared rather persistently in the 1 400—1 425 cm^{-1} and the 880—945 cm^{-1} intervals.

Two other bands of rather constant frequency throughout the series were observed, *viz.* bands at 1 350—1 365 and 1 290—1 325 cm^{-1}. The present spectroscopic material is insufficient for an identification of the mechanical

Table 2. Observed optical densities per mmole (D_{obs}) for C=S and C—S group frequencies.

2-Pyrryl-	200	1 206	60		665	
3-Indolyl-	294	1 213	57		670	
Methyl-	130	1 225	34		668	
Ethyl-	100	1 220	31		668	

character of these modes of vibration. They must, however, somehow be characteristic for the —$CSSCH_2COOH$ grouping since the radicals attached to the group are rather different. Neither of the two bands can be attributed to the C=S stretching vibration because of their position at too high a frequency.

Table 2 gives the observed optical density (D_{obs}) per mmole substance for bands in the 1 190—1 225 cm^{-1} interval finally assigned as the C=S stretching frequency, and for bands in the 640—670 cm^{-1} interval assigned as the C—S stretching frequency.

The result fits well with the assignment given by Mecke and Spiesecke for CH_3CSSH [4]. They found ν (C=S) = 1 216 cm^{-1}. Also there is substantial agreement with Sheppards paper [5] in which "primary" mercaptans, sulphides and disulphides all were shown to absorb in the 630—660 cm^{-1} region.

The C—S band is, therefore, unobservable by means of the ordinary NaCl optics.

Acknowledgment. We are indebted to professor K. A. Jensen of this laboratory for making the dithioesters investigated here available to us.

Kristallviolett. Eine quantitative Untersuchung über die Protolysenverhältnisse in Wasserlösungen

RUNE CIGÉN

Abteilung für anorganische und physikalische Chemie des Chemischen Instituts der Universität Lund, Schweden

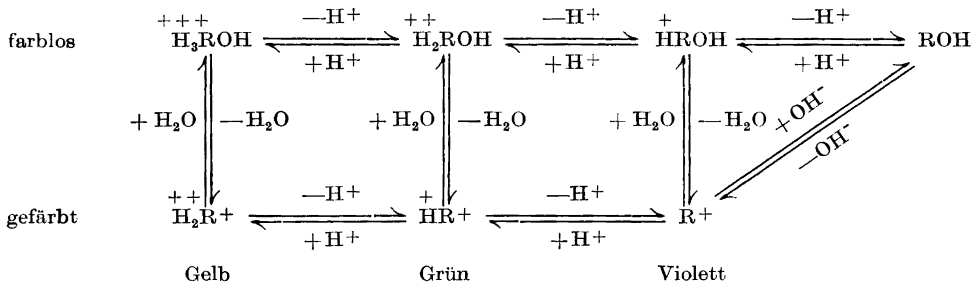
Die Protolysenreaktionen des Kristallviolett, KV, wurden quantitativ untersucht. KV bildet eine Reihe gefärbte Formen, die in Protonengleichgewicht miteinander stehen. Diese gefärbten Formen stehen in Hydratationsgleichgewicht mit einer Reihe farbloser Formen, die ihrerseits miteinander in Protonengleichgewicht stehen. Die Protonengleichgewichte stellen sich momentan ein, während die Hydratationsgleichgewichte messbare Zeit brauchen, um sich einzustellen. Ein Protolysenschema wurde aufgestellt, und die in diesem Schema enthaltenen 5 Dissoziations-, 4 Hydratations- und 8 Geschwindigkeitskonstanten wurden bestimmt. Ferner wurden die Absorptionskurven der drei gefärbten Formen des KV bestimmt.

Die Messungen wurden spektrophotometrisch bei 20°C und mit konstanter Ionenstärke = 0,5 M durchgeführt.

Von den zahlreichen Untersuchungen über basische Triphenylmethanfarbstoffe, die in den letzten fünfzig Jahren durchgeführt worden sind, behandeln nur wenige ihre Protolysenverhältnisse quantitativ. Vor kurzem publizierte Cigén [1] eine Dissertation, in der die Protolysenverhältnisse von zehn basischen Triphenylmethanfarbstoffen mit zwei reaktiven Aminogruppen genau untersucht worden waren. Sämtliche untersuchte Farbstoffe folgten demselben Reaktionsschema, und die zum Protolysenschema gehörenden Dissoziations-, Hydratations- und Geschwindigkeitskonstanten konnten bestimmt werden. Als eine Fortsetzung dieser Arbeiten ist nun das Kristallviolett, das drei reaktive Aminogruppen hat, untersucht worden. Das Kristallviolett wird in der Folge KV geschrieben. Das Perchlorat hat die Formel $[(CH_3)_2NC_6H_4]_3C\,ClO_4$.

Adams und Rosenstein [2] haben einen Versuch gemacht, Dissoziationsgleichgewichte und Reaktionsgeschwindigkeiten von KV zu bestimmen. Die Zahlenwerte, die diese erhalten haben, sind zwar wegen mangelhafter Methodik im grossen und ganzen irreführend und unterscheiden sich, in den wenigen Fällen, wo ein Vergleich möglich ist, stark von denen, die in dieser Arbeit vorgelegt werden.

Es ist schon lange bekannt, dass Farbstoffe, die zu dem jetzt untersuchten Typus gehören, in einer Reihe gefärbter und einer Reihe farbloser Formen auftreten können, wobei das pH der Lösung die Verteilung unter die verschiedenen Komponenten bestimmt. Man kann schematisch die Reaktionen auf folgende Weise schreiben: $R = [(CH_3)_2NC_6H_4]_3C$



Das aufgestellte Schema ist das denkbar einfachste. Es berücksichtigt nicht die Isomeriemöglichkeiten [3] oder den Umstand, dass die Reaktionen sicher über Zwischenformen gehen. Frühere Untersuchungen [1] über Farbstoffe mit zwei reagierenden Aminogruppen zeigten, dass die Protonengleichgewichte sich "momentan", d.h. mit nicht messbarer Geschwindigkeit, einstellen, während die Zeitreaktionen im Bereich $pH<10$ Hydratationen sind, deren wirkliche Geschwindigkeitskonstanten unabhängig von dem pH sind. Für $pH > 10$ bekommt man Zeitreaktionen, deren Geschwindigkeiten zeigen, dass OH^--Ionen an der Protolyse teilnehmen.

Man kann annehmen, dass KV ein Protolysenschema hat, welches im Prinzip dem gleicht, das früher für die nahe verwandten Farbstoffe aufgestellt worden ist (Cigén [1]). Wir nehmen demnach an, dass KV eine Reihe von gefärbten Formen bilden kann, die durch rasche Protonenaufnahme oder Protonenabspaltung ineinander übergehen, und eine Reihe von farblosen Formen, die auch in sich schnell einstellenden Protonengleichgewichten miteinander stehen. Zwischen den drei farblosen Salzen und den drei gefärbten Formen herrschen Hydratationsgleichgewichte, deren Zustandekommen eine gewisse messbare Zeit beansprucht. Zwischen dem farblosen nicht geladenen Carbinol und der violetten Form herrscht bei hohem pH ein OH^--Gleichgewicht, das, um sich einzustellen, eine messbare Zeit beansprucht.

Wenn man die Protolysenreaktionen quantitativ untersuchen will, muss man mathematische Beziehungen zwischen Reaktionsgeschwindigkeiten, Farbennuancen, Farbenintensitäten und pH ableiten. Um solche Ableitungen bequemer zu erzielen, werden folgende Bezeichnungen und Kürzungen eingeführt:

$$ROH = C, \quad \overset{+}{H}ROH = S_1, \quad \overset{++}{H_2}ROH = S_2, \quad \overset{+++}{H_3}ROH = S_3$$

$$R^+ = B, \quad \overset{+}{H}R+ = G, \quad \overset{++}{H_2}R+ = Y, \quad [H^+] = h, \quad [OH^-] = oh$$

Ferner werden folgende Konstanten definiert:

a) Dissoziationskonstanten: $K_1 = \frac{h[G]}{[Y]}$, $K_2 = \frac{h[B]}{[G]}$,

$K'_1 = \frac{h[S_2]}{[S_3]}$, $K'_2 = \frac{h[S_1]}{[S_2]}$, $K'_3 = \frac{h[C]}{[S_1]}$

b) Hydratationskonstanten (Gleichgewichtskonstanten):

$K_4 = \frac{[S_3]_\infty}{[Y]_\infty}$, $K_5 = \frac{[S_2]_\infty}{[G]_\infty}$, $K_6 = \frac{[S_1]_\infty}{[B]_\infty}$

c) Geschwindigkeitskonstanten (Gk):

k_1 = die Gk der Reaktion $Y + H_2O \rightarrow S_3$
k_2 = » » » » $S_3 \rightarrow Y + H_2O$
k_3 = » » » » $G + H_2O \rightarrow S_2$
k_4 = » » » » $S_2 \rightarrow G + H_2O$
k_5 = » » » » $B + H_2O \rightarrow S_1$
k_6 = » » » » $S_1 \rightarrow B + H_2O$
k_7 = » » » » $B + OH^- \rightarrow C$
k_8 = » » » » $C \rightarrow B + OH^-$

Die Untersuchungen wurden mit einem Spektrophotometer durchgeführt, weshalb spezifische Extinktionen benutzt wurden, um die Konzentrationen der verschiedenen Farbstoffskomponenten auszudrücken. Hierbei bedeuten:

ε_B,	ε_G,	ε_Y	die molekularen Extinktionskoeffizienten für B, G und Y.
e_o,	e_t,	e_∞	die spezifische Extinktion einer Lösung bei der Zeit 0 und t und bei Gleichgewicht (die Schichtdicke $d = 1$ cm).
E_o,	E_t,	E_∞	die abgelesenen Extinktionen, wenn $d \neq 1$.
e_B,	e_G,	e_Y	die spezifischen Extinktionen für B, G und Y.

ABLEITUNG VON NÖTIGEN FORMELN

Vorbereitende Untersuchungen über KV zeigten, dass KV im pH-Gebiete 5—6 bei Gleichgewicht in Form von B bis sehr nahe an 100 % vorliegt. Dies bedeutet, dass das Gleichgewicht $B + H_2O \rightleftharpoons S_1$ gegen das gefärbte B stark verschoben ist. Dagegen ist das Gleichgewicht $Y + H_2O \rightleftharpoons S_3$ stark gegen das farblose S_3 verschoden, und eine Lösung mit einem pH < 1 ist bei Gleichgewicht nahezu völlig entfärbt. Das Gleichgewicht $G + H_2O \rightleftharpoons S_2$ nimmt eine Zwischenstellung ein, und die vorbereitenden Untersuchungen deuteten an, dass es relativ stark gegen das gefärbte G verschoben ist. Alkalische Lösungen, mit pH > 11, sind nahezu entfärbt wegen des entstandenen farblosen Carbinols, C.

Die Bestimmung von K_1 und K_2. Man geht von einer Wasserstammlösung des KV, pH ~ 5, aus, wo [B] = die Totalkonzentration, C_M, des Farbstoffes. Diese Stammlösung wird mit Puffern von HCl + KCl von verschiedenem pH gemischt. Hierbei stellen sich die Gleichgewichte zwischen den verschiedenen

gefärbten Formen B, G und Y "momentan" ein. Wir bekommen, wenn sich diese schnellen Gleichgewichte eingestellt haben, bei $t = 0$

$$C_M = [B]_o + [G]_o + [Y]_o \tag{1}$$

$$e_o = [B]_o\varepsilon_B + [G]_o\varepsilon_G + [Y]_o\varepsilon_Y \tag{2}$$

Aber

$$C_M = [B]_o\left(1 + \frac{h}{K_2} + \frac{h^2}{K_1K_2}\right) \tag{3}$$

und

$$e_o = [B]_o\left(\varepsilon_B + \frac{h}{K_2}\varepsilon_G + \frac{h^2}{K_1K_2}\varepsilon_Y\right) \tag{4}$$

Nun ist $C_M\varepsilon_B = e_B$, $C_M\varepsilon_G = e_G$, $C_M\varepsilon_Y = e_Y$, und wir können also schreiben

$$e_o = \frac{e_B + \frac{h}{K_2}e_G + \frac{h^2}{K_1K_2}e_Y}{1 + \frac{h}{K_2} + \frac{h^2}{K_1K_2}} \tag{5}$$

(5) kann man folgendermassen schreiben

$$\frac{h}{e_o - e_B} = \frac{K_2 + h\left(1 + \frac{h}{K_1}\right)}{e_G + \frac{h}{K_1}e_Y - e_B\left(1 + \frac{h}{K_1}\right)} \tag{6}$$

Anfangs kann man in der Gleichung (6) nur h und e_B bestimmen. Man bekommt e_B, indem man eine Absorptionskurve für KV in Wasserlösung, pH $\sim$ 5, aufnimmt. e_G und e_Y können nicht unmittelbar bestimmt werden. Man kann aber eine Auffassung von der Grössenordnung des e_Y bei verschiedenen Wellenlängen bekommen, wenn man eine Absorptionskurve für KV in stark saurer Lösung aufnimmt, wo der Farbstoff bei Gleichgewicht hauptsächlich in Form von Y und S_3 vorliegt. Um K_2 zu bestimmen, wählt man eine Wellenlänge, wo $\varepsilon_Y << \varepsilon_B$. Man kann dabei $\frac{h}{K_1} \cdot \varepsilon_Y$ im Nenner der Gleichung (6) vernachlässigen. Die Messungen werden ferner bei solchen pH-Werten durchgeführt, dass $h < K_1$. In einem Diagramm trägt man $\frac{h}{e_o - e_B}$ als Funktion von h auf und bekommt so eine schwach gebogene Linie, deren Abschnitt auf der Ordinatenachse, y, und deren Winkelkoeffizient, l, wenn $h \to 0$, die Gleichungen $y = \frac{K_2}{e_G - e_B}$ und $l = \frac{1}{e_G - e_B}$ ergeben. Man bekommt also $K_2 = y/l$ und $e_G = 1/l + e_B$. Danach kann man K_1 entweder algebraisch oder graphisch bestimmen. Im ersten Falle löst man K_1 aus der Gleichung (5) heraus

$$K_1 = \frac{h^2(e_o - e_Y)}{K_2(e_B - e_o) + h\,(e_G - e_o)} \tag{7}$$

Im zweiten Falle verfährt man folgenderweise. Die Messungen werden für $h \geq K_1$ durchgeführt und bei einer Wellenlänge λ, wo e_B bedeutend kleiner als e_G ist und wo e_Y an der Seite von e_o vernachlässigt werden kann. Wenn $K_1 > 10 \cdot K_2$, kann man $K_2(e_B - e_o)$ im Nenner der Gleichung (7) vernachlässigen, die sich danach als

$$\frac{1}{e_o} = \frac{h}{K_1 e_G} + \frac{1}{e_G} \tag{8}$$

schreiben lässt. Falls die vorgenommenen Approximationen erlaubt sind, bekommt man eine Gerade, wenn man $1/e_o$ als Funktion von h aufträgt. Man erhält $e_G = 1/y$ und $K_1 = y/l$.

Die Farbintensität, die man durch Mischung der Stammlösung mit (HCl + KCl)-Puffern erhält, nimmt mit der Zeit ab. Die Farbe verbleicht, weil sowohl G als Y sich zu den farblosen S_2 und S_3 hydratisieren. Um die e_o zu bestimmen, aus welchen man K_1 und K_2 erhält, muss man also der Verbleichung kinetisch folgen und aus den Kinetikmessungen e_o durch Extrapolation der Extinktion zu der Zeit $t = 0$ bestimmen. Der Kontrolle wegen sollen die Messungen von e_o wenn möglich bei einigen verschiedenen Wellenlängen durchgeführt werden.

Die Bestimmung von K_4, K_5 und K_6. Diese Konstanten sind Gleichgewichtskonstanten und werden aus Lösungen bestimmt, die Gleichgewicht erreicht haben. Man hat dann

$$C_M = [B]_\infty + [S_1]_\infty + [C]_\infty + [G]_\infty + [S_2]_\infty + [Y]_\infty + [S_3]_\infty \tag{9}$$

$$= [B]_\infty \left[1 + K_6 + \frac{K_6 K_3'}{h} + \frac{h}{K_2}(1 + K_5) + \frac{h^2}{K_1 K_2}(1 + K_4) \right] \tag{10}$$

$$e_\infty = [B]_\infty \cdot \varepsilon_B + [G]_\infty \cdot \varepsilon_G + [Y]_\infty \cdot \varepsilon_Y \tag{11}$$

$$= [B]_\infty \left(\varepsilon_B + \frac{h}{K_2} \varepsilon_G + \frac{h^2}{K_1 K_2} \varepsilon_Y \right) \tag{12}$$

Aus (10) und (12) erhält man, da $C_M \cdot \varepsilon_B = e_B$ etc., die Gleichgewichtsextinktion e_∞

$$e_\infty = \frac{e_B + \frac{h}{K_2} e_G + \frac{h^2}{K_1 K_2} e_Y}{1 + K_6 + \frac{K_6 K_3'}{h} + \frac{h}{K_2}(1 + K_5) + \frac{h^2}{K_1 K_2}(1 + K_4)} \tag{13}$$

Aus (13) können K_4, K_5 und K_6 nur unter speziellen Voraussetzungen aufgelöst werden. In alkalischen Lösungen hat man bei Gleichgewicht das KV nur in Form von B, S_1 und C. Man kann da alle Glieder in (13), die K_1 und K_2 enthalten, vernachlässigen, und man bekommt

$$e_\infty = \frac{e_B}{1 + K_6 + \frac{K_6 K_3'}{h}} \tag{14}$$

(14) wird umgeformt zu

$$\frac{h}{e_\infty} = \frac{h(1 + K_6)}{e_B} + \frac{K_6 K_3'}{e_B} \tag{15}$$

Man bekommt eine Gerade, wenn man h/e_∞ als Funktion von h aufträgt. Der Abschnitt auf der Ordinatenachse $y = K_6 K_3'/e_B$ und der Winkelkoeffizient $l = (1 + K_6)/e_B$. Wir haben früher gesagt, dass bei pH $\sim$ 4—6 das KV nur in Form von B vorliegt, und wir können e_B aus einer Absorptionskurve, aufgenommen bei pH 4—6, erhalten. Aber hieraus folgt, dass $K_6 \ll 1$, und wir können also K_6 aus $l = (1 + K_6)/e_B$ nicht bestimmen. Dagegen können wir aus l eine Kontrolle unseres früher bestimmten Wertes von e_B erhalten, da $e_B \simeq 1/l$. Aus $y = K_6 K_3'/e_B$ bekommen wir nur $K_6 K_3' = y \cdot e_B$.

In stark sauren Lösungen kann man in erster Linie in der Gleichung (13) K_6 und $K_6 K_3'/h$ vernachlässigen. Wenn wir λ so wählen, dass e_Y neben e_B und e_G vernachlässigbar ist und K_4 auflöst, dann bekommen wir

$$K_4 = \frac{e_B + \frac{h}{K_2} \cdot e_G - e_\infty \left[1 + \frac{h}{K_2}(1 + K_5)\right]}{e_\infty \cdot h^2/K_1 K_2} - 1 \tag{16}$$

Die vorbereitenden Untersuchungen zeigten, dass das Gleichgewicht $G + H_2O \rightleftharpoons S_2$ verhältnismässig stark gegen das gefärbte G verschoben ist, weshalb es wahrscheinlich wirkt, dass $K_5 < 0{,}1$ ist. K_5 hat deshalb den Charakter eines Korrektionsgliedes in (16). In stark sauren Lösungen kann man K_4 berechnen, ohne einen genaueren Wert von K_5 zu kennen, als dass $K_5 < 0{,}1$ ist. In schwach sauren Lösungen kann man verschiedene Werte von K_5 versuchen, um zu prüfen, ob man einen konstanten K_4-Wert erhalten kann, der mit dem in stark sauren Lösungen gewonnenen K_4-Wert übereinstimmt. Auf diese Weise kann man einen approximativen Wert von K_5 berechnen.

Wenn man K_5 und K_6 genau bestimmen will, muss man ganz andere Methoden als die bisher durchgegangene ergreifen, nämlich Methoden, die sich auf die pH-Abhängigkeit der Reaktionsgeschwindigkeiten gründen. Dabei kann man auch die Geschwindigkeitskonstanten k_1—k_8 bestimmen.

ABLEITUNG VON KINETIKFORMELN

Frühere Untersuchungen über nahe verwandte Farbstoffe [1] zeigten, dass die Geschwindigkeitskonstanten bei den Hydratationen in dem Reaktionsschema unabhängig von dem pH sind. Dagegen wird die Geschwindigkeit, mit der eine Lösung ihre Farbintensität ändert, wegen des komplizierten Reaktionsschemas von dem pH abhängig. Wenn man annimmt, dass dasselbe auch für das KV gilt, kann man folgende Beziehungen zwischen Geschwindigkeits-, Hydratations-, Dissoziationskonstanten und $[H^+]$ ableiten. Man muss aber daran denken, dass das aufgeschriebene Schema den geschwindigkeitsbestimmenden Bruttoverlauf angibt. Der Reaktionsmechanismus ist komplizierter als was aus dem Schema hervorgeht.

Wir leiten Kinetikformeln ab, die für das ganze pH-Intervall 1—13 gelten. Die Reaktionen verlaufen als pseudomonomolekulare, da die Totalkonzentration des Farbstoffes $C_M \leq 10^{-5}$ M ist und Pufferlösungen bei den Messungen benutzt werden.

Wenn man die oben eingeführten Bezeichnungen verwendet, kann man die Bildungsgeschwindigkeit für B + G + Y folgendermassen schreiben

$$\frac{d([B] + [G] + [Y])}{dt} = k_2[S_3] - k_1[Y] + k_4[S_2] - k_3[G] + k_6[S_1] - \\ - k_5[B] + k_8[C] - k_7[B]oh \qquad (17)$$

oder

$$\left(1 + \frac{h}{K_2} + \frac{h^2}{K_1K_2}\right)\frac{d[B]}{dt} = \left(k_2 + k_4 \cdot \frac{K_1'}{h} + k_6 \cdot \frac{K_1'K_2'}{h^2} + k_8 \cdot \frac{K_1'K_2'K_3'}{h^3}\right)[S_3] - \\ - \left(k_1 \cdot \frac{h^2}{K_1K_2} + k_3 \cdot \frac{h}{K_2} + k_5 + k_7 \cdot oh\right)[B] \qquad (18)$$

die

$$\frac{d[B]}{dt} = k'[S_3] - k''[B] \qquad (19)$$

geschrieben werden kann.

Nun ist

$$C_M = [B] + [G] + [Y] + [S_3] + [S_2] + [S_1] + [C] \qquad (20)$$

und man kann

$$C_M = \left(1 + \frac{h}{K_2} + \frac{h^2}{K_1K_2}\right)[B] + \left(1 + \frac{K_1'}{h} + \frac{K_1'K_2'}{h^2} + \frac{K_1'K_2'K_3'}{h^3}\right)[S_3] \qquad (21)$$

schreiben, und bekommt also

$$[S_3] = \frac{C_M - \left(1 + \frac{h}{K_2} + \frac{h^2}{K_1K_2}\right)[B]}{1 + \frac{K_1'}{h} + \frac{K_1'K_2'}{h^2} + \frac{K_1'K_2'K_3'}{h^3}} = \frac{C_M - A[B]}{R} \qquad (22)$$

Aus (19) und (22) erhält man

$$\frac{d[B]}{dt} = \frac{k'A + k''R}{R}\left(\frac{k'C_M}{k'A + k''R} - [B]\right) = k(a - [B]) \qquad (23)$$

Integration von (23) ergibt

$$\ln(a - [B]_t) = -k\ t + I \qquad (24)$$

Für $t = 0$ ist $[B] = [B]_o$ und also $I = \ln(a - [B]_o)$

Bei Gleichgewicht ist $d[B]/dt = 0$ und aus (23) erhält man dann $a = [B]_\infty$. Dies ergibt schliesslich

$$k = \frac{1}{t} \ln \frac{[B]_\infty - [B]_o}{[B]_\infty - [B]_t} \tag{25}$$

Aus (18), (19), (22), (23) und (25) bekommen wir nach Vereinfachung die zusammenfassende Kinetikformel

$$k = \frac{h^3 k_2 + h^2 k_4 K_1' + h k_6 K_1' K_2' + k_8 K_1' K_2' K_3'}{h^3 + h^2 K_1' + h K_1' K_2' + K_1' K_2' K_3'} + \frac{h^2 k_1 + h k_3 K_1 + k_5 K_1 K_2 + k_7 K_1 K_2 \cdot oh}{h^2 + h K_1 + K_1 K_2} = \frac{1}{t} \ln \frac{[B]_\infty - [B]_o}{[B]_\infty - [B]_t} \tag{26}$$

Man kann zeigen, dass $\frac{[B]_\infty - [B]_o}{[B]_\infty - [B]_t} = \frac{[G]_\infty - [G]_o}{[G]_\infty - [G]_t} = \frac{[S_3]_\infty - [S_3]_o}{[S_3]_\infty - [S_3]_t}$ etc.

$$= \frac{e_\infty - e_o}{e_\infty - e_t}$$

. Bei den Messungen setzt man deshalb

$$k = \frac{1}{t} \ln \frac{e_\infty - e_o}{e_\infty - e_t} \text{ oder } k = \frac{1}{t} \ln \frac{e_o - e_\infty}{e_t - e_\infty} \tag{27}$$

In einem Diagramm trägt man z.B. $\log(e_t - e_\infty)$ als Funktion von t auf. Hierbei erhält man eine Gerade, deren Winkelkoeffizient $= -k \cdot \log e$, und k kann berechnet werden. Da k davon unabhängig ist, bei welcher Wellenlänge man die Messungen durchführt, wählt man die Wellenlänge, die am besten in das pH-Gebiet passt, in dem man sich gerade befindet.

Bei Gleichgewicht ist $[Y]_\infty k_1 = [S_3]_\infty k_2$, $[G]_\infty k_3 = [S_2]_\infty k_4$, $[B]_\infty k_5 = [S_1]_\infty k_6$ und $[B]_\infty oh k_7 = [C]_\infty k_8$. Wie man S. 1458 sieht wird $k_1 = k_2 K_4$, $k_3 = k_4 K_5$, $k_5 = k_6 K_6$ und $k_7 = k_8 K_6 K_3'/K_w$. (28)

Um sämtliche zu dem Protolysenschema gehörende Konstanten aus (26) und (28) zusammen mit den früher abgeleiteten (5) und (13) bestimmen zu können, ist es notwendig, dass man die Gleichung (26) approximieren kann. Im Zusammenhang mit der Beschreibung des experimentellen Verfahrens werden eine Anzahl verschiedener Approximationen behandelt.

EXPERIMENTELLES

Chemikalien und Lösungen. Kristallviolett: Das Handelspräparat in Form von Hydrochlorid (Merck's Reagenzien) wurde in das entsprechende schwerlösliche Perchlorat übergeführt, das dreimal aus Eisessig und einmal aus Wasser umkristallisiert wurde. Weitere Umkristallisation war wirkungslos, was sich dadurch feststellen liess dass eine Absorptionskurve nach jedem Schritt des Prozesses aufgenommen wurde.

Zu Pufferlösungen wurden *Salzsäure, Natriumacetat, Dinatriumhydrogenphosphat, Kaliumdihydrogenphosphat, Borsäure* und *Natriumhydroxyd*, die sämtliche von pro Analysi Qualitet waren, verwendet.

Man kann kaum thermodynamische Konstanten in einem so komplizierten Reaktionsschema wie das von KV bestimmen. Darum wählen wir die Methode, Konzentrationskonstanten zu bestimmen, die bei der Ionenstärke 0,5 M gelten, und mit Kaliumchlorid p.a., als Neutralsalz. Durch Zusatz von Neutralsalz kann man die Aktivitätskoeffizienten der an den Reaktionen teilnehmenden verschiedenen Arten von Ionen und Molekylen konstant halten, so lange ihre Konzentration im Verhältnis zur Ionenstärke klein ist.

Von dem KV wurden Stammlösungen durch Abwiegen des Perchlorates bereitet, das danach im Wasser aufgelöst wurde. Die Totalkonzentration des Farbstoffes war $(1-2) \times 10^{-5}$ M. Aus konzentrierteren Lösungen kristallisiert allmählich das Perchlorat des KV. Die Stammlösungen wurden in Polyäthylenflaschen aufbewahrt, die zuerst mit der Farbstofflösung mehrmals gespült worden waren.

Wie schon u.a. Turgeon und LaMer [4] hervorheben, hat das KV eine ausserordentlich grosse Neigung, sich an den Wänden der benutzten Gefässe zu adsorbieren. Um die Adsorption, die bei genauen Messungen sehr lästig ist, zu eliminieren oder wenigstens zu verringern, wurden folgende Methoden ergriffen. Nur Quarzküvetten bester Qualität wurden gebraucht. Wenn es experimentell möglich war, konnte man die Küvettenwände vor den Messungen mit dem KV "sättigen", indem man die Messlösung in der Küvette einige Minuten stehen liess, wonach die Messlösung mit einer neuen Portion davon ersetzt wurde. Die Adsorption ist in neutralen und schwach alkalischen Lösungen am lästigsten, wo das äusserst schwerlösliche Carbinol des KV sehr stark adsorbiert wird. Alle benutzten Glasgefässe waren aus Pyrexglas. Die Küvetten und Glasgefässe wurden äusserst genau gereinigt.

Apparatur. Bei den Extinktionsmessungen wurde ein Beckman Quarzspektrophotometer Modell DU benutzt, das umgebaut worden war, um die Temperatur im Küvettenhaus mit grösserer Genauigkeit konstant zu halten, als was mit dem Standardmodell möglich war. Der Apparat war in einem Zimmer aufgestellt, dessen Temperatur auf (20,0 ± 0,5)°C gehalten wurde, während temperiertes Wasser von (20,00 ± 0,02)°C durch die Wände des Küvettenhauses gepumpt wurde. Alle Messungen wurden bei 20°C durchgeführt.

Die $[H^+]$-Bestimmungen wurden titrimetrisch oder potentiometrisch ausgeführt. Bei den potentiometrischen Messungen wurde als Referenzlösung eine Lösung der Zusammensetzung 10 mM HCl + 490 mM KCl benutzt, deren pH gleich 2 gesetzt wurde. In vorliegender Arbeit bedeutet pH immer $-\log [H^+]$ und nicht $-\log a_{H^+}$. Als Elektroden wurden für pH <8 vergoldete Platinbleche und Chinhydron verwendet, Reproduzierbarkeit 0,1 mV. Für pH > 8 wurden Wasserstoffgaselektroden benutzt, Reproduzierbarkeit ~0,3 mV.

MESSUNGEN UND ERGEBNISSE

Die Bestimmung der verschiedenen Konstanten

Zuerst wurden drei Absorptionskurven von der blauen Form B des KV in Acetatpuffern, pH = 5, aufgenommen. $C_M = 1 \times 10^{-5}$, 8×10^{-6} bzw. 4×10^{-6} M. Dieselben ε-Werte wurden bei den verschiedenen C_M erzielt. Kurve B in Fig. 1. B hat ein Absorptionsmaximum für $\lambda = 590$ mμ. In einer Reihe von Lösungen wurde die Stammlösung mit Acetat- und Phosphatpuffern gemischt, wonach ein genauer Wert von ε_B bei 590 mμ bestimmt wurde. Das Resultat war $\varepsilon_B = (1{,}000 \pm 0{,}002) \times 10^5$.

Danach wurde eine Reihe von Boratpuffern mit der Farbstoffsstammlösung so gemischt, dass in den Messlösungen $C_M = 2 \times 10^{-6}$ M war. Die Lösungen verblassten langsam wegen der Carbinolbildung. Die Gleichgewichtsextinktionen $E_\infty = 2\, e_\infty$ wurden nach zwei Tagen abgelesen, $\lambda = 590$ mμ. Man kann die Messungen bei solchem pH, dass $[C]_\infty > 0{,}5 \times C_M$, nicht durchführen, weil das Carbinol so schwerlöslich ist, dass es ausfällt. Verringert man anderseits C_M, um die Gefahr der Ausfällung von Carbinol zu mindern, be-

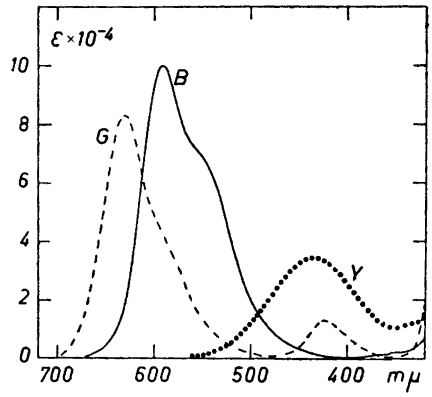


Fig. 1. Absorptionskurven von Kristallviolett in Wasserlösungen. Kurve B entspricht dem violetten Ion $[(CH_3)_2NC_6H_4]_3\overset{+}{C}$, Kurve G dem grünen $[(CH_3)NC_6H_4]_2\overset{+}{C}C_6H_4N\overset{+}{H}(CH_3)_2$, Kurve Y dem gelben $(CH_3)_2NC_6H_4\overset{+}{C}[C_6H_4N\overset{+}{H}(CH_3)_2]_2$.

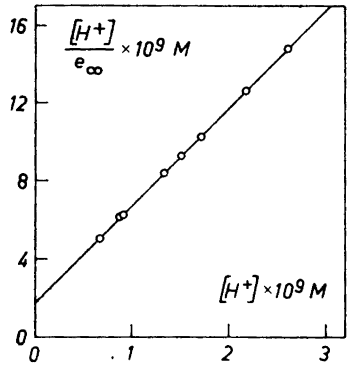

Fig. 2. $[H^+]/e_\infty$ als Funktion von $[H^+]$ für die Bestimmung von K_6K_3' und ε_B. $\lambda = 590$ mμ.

kommt man eine grössere Ungenauigkeit in den Messungen, indem die prozentuelle Adsorption von Farbstoff mit dessen Verdünnung steigt. In Fig. 2 ist $[H^+]/e_\infty$ der Gleichung (15) gemäss als Funktion von $[H^+]$ aufgetragen. Aus der erhaltenen Geraden bekommt man $y = K_6K_3'/e_B = 1{,}72 \times 10^{-9}$ und $l = (1 + K_6)/e_B = 5{,}00$. Man findet, da $K_6 \ll 1$, also $e_B = 0{,}200$, was $\varepsilon_B = 1{,}00 \times 10^5$ ergibt. Die Übereinstimmung mit dem früher erhaltenen $\varepsilon_B = 1{,}000 \times 10^5$ ist folglich sehr gut. Dies zeigt, dass $K_6 \ll 1$, denn falls K_6 nicht $\ll 1$, kann man zeigen, dass das graphisch erhaltene $e_B = (1 + K_6)/l$ grösser wird, als das e_B', das man aus einer Absorptionskurve, in Acetatpuffer aufgenommen, bekommt, wo $[S_1]$ und $[S_2]$ bei Gleichgewicht neben [B] nicht vernachlässigbar sind. Man kann also K_6 nicht aus diesen Messungen bestimmen, aber die Kenntnis davon dass $K_6 \ll 1$ ist, wird im folgender benutzt. Dagegen geben die Messungen $K_6K_3' = 3{,}44 \times 10^{-10}$.

Die Bestimmung von K_1 und K_2. Zwischen pH 3 und pH 2 schlägt die Farbe des KV von blauviolett in grün um, wegen der Reaktion $B + H^+ \rightleftharpoons G$. Aus Absorptionskurven, bei pH ~ 2 aufgenommen, findet man, dass die grüne Form G ein Absorptionsmaximum für etwa $\lambda = 635$ mμ und eines für etwa $\lambda = 420$ mμ hat. Zwischen pH 1 und pH 0 schlägt die Farbe des KV von grün in gelb um, wegen der Reaktion $G + H^+ \rightleftharpoons Y$. Eine Absorptionskurve, in 2 M HCl aufgenommen, zeigt, dass die gelbe Form Y ein Absorptionsmaximum für $\lambda = 434$ mμ hat.

Um K_1 und K_2 genau bestimmen zu können, führt man die Messungen bei solchen Wellenlängen aus, wo der Unterschied zwischen ε_B, ε_G und ε_Y so gross wie möglich ist. Es zeigte sich als zweckmässig, K_2 bei $\lambda = 635$ mμ $= \lambda_{G\ max}$

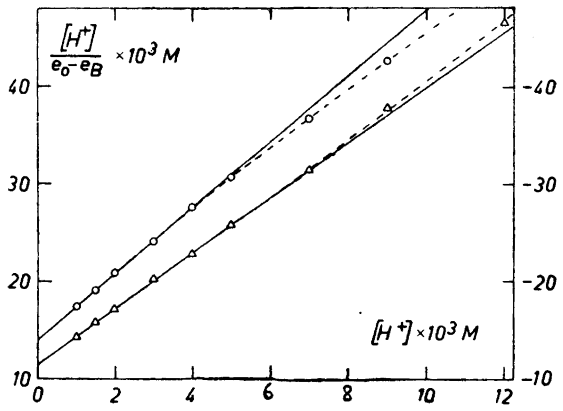

Fig. 3. $[H^+]/(e_0-e_B)$ als Funktion von $[H^+]$ für die Bestimmung von K_2, ε_B und ε_G. ○ $\lambda = 590$ mμ, Ordinate rechts, und △ $\lambda = 635$ mμ.

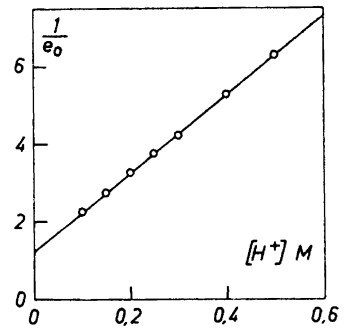

Fig. 4. $1/e_0$ als Funktion von $[H^+]$ für die Bestimmung von K_1 und ε_G. λ = 635 mμ.

und $\lambda = 590$ mμ $= \lambda_{B\ max}$ und K_1 bei $\lambda = 635$ mμ zu bestimmen. Da ε_B für $\lambda = 590$ mμ schon bekannt war und ε_B für $\lambda = 635$ mμ auf entsprechende Weise bestimmt werden konnte, wurde die Gleichung (6) verwendet.

Eine Reihe Messlösungen wurde dadurch bereitet, dass die Farbstammlösung mit verschiedenen Pufferlösungen von HCl + KCl schnell in Y-geformten Mischröhren gemischt wurde. Die Extinktionen wurden zur Zeit $t = 0$ extrapoliert. Für die Messlösungen war $C_M = 5 \times 10^{-6}$ M, $d = 2$ cm und $[H^+] =$ 1—12 mM. In Fig. 3 ist $[H^+]/(e_0-e_B)$ als Funktion von $[H^+]$ aufgetragen. Man erhält für $\lambda = 590$ mμ: $y = -0{,}0139$ M und $l = -3{,}40$ und für $\lambda = 635$ mμ: $y = 0{,}0115$ M und $l = 2{,}85$. Dies ergibt für 590 mμ: $K_2 = \mathbf{0{,}00409}$, $e_G = 0{,}206$, $\varepsilon_G = 4{,}12 \times 10^4$ und für 635 nμ: $K_2 = \mathbf{0{,}00404}$, $e_G = 0{,}409$, $\varepsilon_G = 8{,}18 \times 10^4$.

Die Absorptionskurve von B hat einen sehr steilen Verlauf um $\lambda = 635$ mμ, und dasselbe gilt für G um 590 mμ. Man muss deshalb alle Messungen bei der einen Wellenlänge zu Ende führen, bevor man die Messungen bei der anderen beginnt, da auch kleine Differenzen der Einstellung von λ grosse Fehler in den Berechnungen veranlassen können.

K_1 wurde für $\lambda = 635$ mμ bestimmt, wo $\varepsilon_Y \ll \varepsilon_G$ und ε_B ist. $C_M = 1 \times 10^{-5}$ M, $d = 2$—5 cm, $[H^+] = 100$—500 mM. In Fig. 4 ist $1/e_0$ als Funktion von $[H^+]$ der Gleichung (8) gemäss aufgetragen. Man bekommt $y = 1{,}23$ und $l = 10{,}10$ woraus $K_1 = \mathbf{0{,}122}$, $e_G = 0{,}813$, $\varepsilon_G = 8{,}13 \times 10^4$. Die Übereinstimmung mit dem ε_G, das oben in schwach sauren Lösungen bei $\lambda = 635$ mμ bestimmt wurde, ist folglich gut.

Die Bestimmung von K_4 und K_5. Gleichung (16) wurde benutzt. Eine Reihe Lösungen von KV in HCl + KCl standen so lange, bis sie nach 1—12 Stunden Gleichgewicht erreichten. Das C_M war $(0{,}5—1) \times 10^{-5}$ M. Die Messungen wurden durchgeführt, teils für $[H^+] = 1$—15 mM bei $\lambda = 590$ mμ, wo e_B und e_G aus $\varepsilon_B = 9{,}98 \times 10^4$ und $\varepsilon_G = 4{,}12 \times 10^4$ berechnet wurden, und teils

Tabelle 1. Berechnung von K_4.

$\lambda = 590$ mμ, $C_M = 5 \times 10^{-6}$ M

[H$^+$] mM	E_∞ (d = 2 cm)	K_4
1	0,774	79
1,5	0,652	82
2	0,553	80
3	0,407	77
4	0,307	78
5	0,239	78
7	0,157	81
9	0,116	79
	$C_M = 1 \times 10^{-5}$ M	
12	0,159	81
15	0,120	81

$\lambda = 635$ mμ, $C_M = 1 \times 10^{-5}$ M

[H$^+$] mM	E_∞ (d = 5 cm)	K_4
12	0,458	80
15	0,383	78
20	0,295	78
25	0,238	79

100	0,064	76
150	0,042	77
200	0,032	76
250	0,025	78
300	0,021	78

Mittelwert $K_4 = 79$

für [H$^+$] = 12—300 mM bei $\lambda = 635$ mμ, wo $\varepsilon_B = 1{,}17 \times 10^4$ und $\varepsilon_G = 8{,}16 \times 10^4$ sind.

Da die vorbereitenden Untersuchungen darauf deuteten, dass $K_5 < 1$ und möglicherweise $\ll 1$ ist, wurde versuchsweise $K_5 = 0{,}05$ gesetzt. Die Resultate sind in Tabelle 1 zusammengestellt. Man bekommt eine gute Konstanz für K_4. Der Mittelwert wird $K_4 = 79$. Für die sauersten Lösungen ist die Messgenauigkeit weniger gut, wegen der niedrigen Gleichgewichtsextinktionen. Der Wert des K_5 ist äusserst approximativ. Einen genaueren Wert für K_5 bekommt man aus den folgenden Kinetikmessungen.

KINETIKMESSUNGEN

In stark alkalischen Lösungen findet die Reaktion B + OH$^-$ $\rightleftharpoons$ C statt. Diese Reaktion, deren Gleichgewicht in stark alkalischen Lösungen fast vollständig gegen das farblose Carbinol, C, verschoben ist, ist von mehrere Forschern [4-8] für KV und andere basische Triphenylmethanfarbstoffe untersucht worden. Die Bleichungsgeschwindigkeit der Reaktion ist eine lineare Funktion von [OH$^-$]. In einer Reihe von Versuchen wurde die Farbstammlösung mit NaOH + KCl gemischt, und die Bleichung wurde kinetisch verfolgt. $C_M = 5 \times 10^{-6}$ M, $\lambda = 590$ mμ, [OH$^-$] = 25—250 mM. Die Entfärbung geschieht schnell und vollständig in stark alkalischen Lösungen. Mit Kenntnis von $K_6 K_3'$ kann man e_∞ berechnen, das in den am stärksten alkalischen Lösungen ganz vernachlässigbar ist. Wenn $C_M = 5 \times 10^{-6}$ M ist, fällt das Carbinol nicht augenblicklich aus, sondern man kann die Entfärbung wenigstens etwa 15 Minuten kinetisch verfolgen, was genügt, obwohl die Lösung hinsichtlich

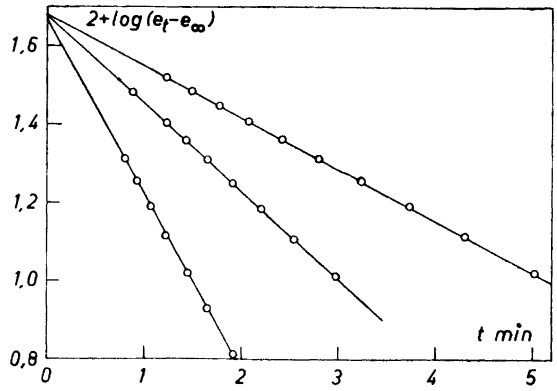

Fig. 5. Kinetikmessungen in NaOH + KCl, λ = 590 mμ, T = 20.0°C. [OH⁻] ist von oben nach unten 75, 125 und 250 mM.

des Carbinols übersättigt wird. In Fig. 5 ist $\log(e_t - e_\infty)$ als Funktion von t bei drei verschiedenen [OH⁻] aufgetragen. Man erhält Gerade, deren Winkelkoeffizienten, l, $-k \cdot \log e$ ergeben, wo k = die Geschwindigkeitskonstante der pseudomonomolekularen Reaktion ist. In stark alkalischen Lösungen kann die Gleichung (26) folgendermassen approximiert werden

$$k = k_8 + k_5 + k_7 \cdot \mathrm{oh} \tag{29}$$

In Fig. 6 ist k als Funktion von [OH⁻] bei fünf verschiedenen [OH⁻] aufgetragen. Man bekommt in Übereinstimmung mit (29) eine Gerade. Diese geht aber approximativ durch Origo, weshalb man $k_5 + k_8$ nicht aus dem Abschnitt auf der Ordinatenachse bestimmen kann. Dagegen erhält man $k_7 = \mathbf{4.12\ min^{-1}}$ aus dem Winkelkoeffizient der Gerade.

k_8 kann man folgenderweise bestimmen: Bei Gleichgewicht gilt

$$k_7 \cdot \mathrm{oh}\ [\mathrm{B}]_\infty = k_8\ [\mathrm{C}]_\infty \tag{30}$$

Aber $\mathrm{h}[\mathrm{C}]_\infty = K_3'[\mathrm{S}_1]_\infty$ und $[\mathrm{S}_1]_\infty = K_6[\mathrm{B}]_\infty$ weshalb $k_8 = k_7 K_w / K_6 K_3'$, wo K_w das Ionenprodukt des Wassers ist. Durch Messungen mit Wasserstoffgaselektroden in Lösungen vom Typus x mM NaOH + (500-x) mM KCl wurde K_w zu $1{,}24 \times 10^{-14}$ bestimmt. Man erhält $k_8 = \mathbf{0{,}000148\ min^{-1}}$.

Um k_5 zu bestimmen, kann man in schwach alkalischen Lösungen die Gleichung (26) zu

$$k = \frac{\mathrm{h} \cdot k_6 + k_8 K_3'}{\mathrm{h} + K_3'} + k_5 + k_7 \cdot \mathrm{oh} \tag{31}$$

approximieren. Wenn man annimmt, dass K_3' von derselben Grössenordnung, 10^{-6}, ist, wie die entsprechenden Diss.konstanten der früher untersuchten basischen Triphenylmethanfarbstoffe [1], kann man das h im Nenner vernach-

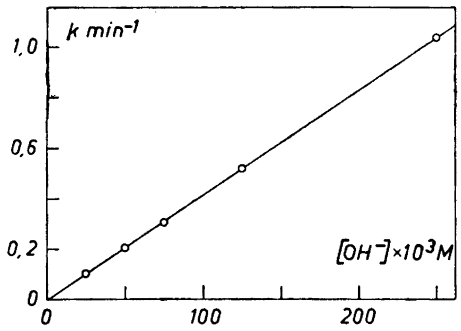

Fig. 6. Die Geschwindigkeitskonstante k als Funktion von $[OH^-]$ für $[OH^-]$ = 25—250 mM.

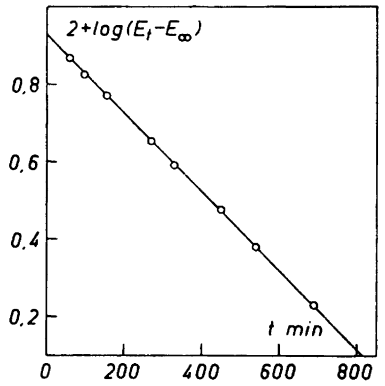

Fig. 7. Eine Kinetikreihe in Boratpuffer pH = 8,77. λ = 590 mμ, $C_M = 1 \times 10^{-6}$ M, d = 5 cm, T = 20.0°C.

lässigen, wenn pH > 8.5 ist. Ferner gilt ja bei Gleichgewicht $k_5[B]_\infty = k_6[S_1]_\infty$ und $[S_1]_\infty = K_6[B]_\infty$. Man kann dann (31) folgendermassen schreiben:

$$k = k_5(h/K_6K_3' + 1) + k_8 + k_7 \cdot oh \qquad (32)$$

Aus (32) kann k_5 durch Kinetikmessungen in geeigneten Boratpuffern bestimmt werden. Hier entsteht die experimentelle Schwierigkeit, dass wenn eine Farbstammlösung mit Boratpuffer, pH 9—10, gemischt wird, die Lösung sehr langsam verbleicht, und das schwerlösliche Carbinol ausfällt. Wenn man dies verhindern will, indem man das C_M genügend vermindert, bekommt man statt dessen grosse Unsicherkeit wegen der Adsorption. Man wählt zweckmässigerweise ein pH, wo nur ein kleinerer Teil von B zu C übergeführt wird. Zwar wird die Änderung der Extinktion klein, aber die Reaktion geht so langsam, dass man für jeden Messpunkt zu vielen Ablesungen Zeit hat. Man erreicht ausserdem, dass das Glied $k_7 \cdot oh$ den Charakter eines Korrektionsgliedes bekommt. Fig. 7 zeigt eine Kinetikreihe für pH 8,77, die k = 0,00236 min^{-1} ergibt, und aus (32) bekommt man danach $k_5 = 0{,}000367$ min^{-1}. Die Reproduzierbarkeit der Kinetikgerade war gut.

Um k_1 und k_2 zu bestimmen, wird (26) in stark sauren Lösungen folgenderweise approximiert

$$k = k_2 + \frac{k_1 \cdot h}{h + K_1} \qquad (33)$$

Nun ist $k_1[Y]_\infty = k_2[S_3]_\infty$ und $[S_3]_\infty = K_4[Y]_\infty$, weshalb man (33)

$$k = k_1\left(\frac{h}{h + K_1} + \frac{1}{K_4}\right) \qquad (34)$$

schreiben kann.

In Tabelle 2 ist k_1 aus (34) durch Kinetikmessungen mit $[H^+]$ = 100—300 mM berechnet. Der Wert von k_1 steigt etwas, wenn $[H^+]$ sinkt. Dies beruht

Tabelle 2. Approximative Berechnung von k_1.

[H+] mM	k min^{-1}	k_1 min^{-1}
100	0,0589	0,127
150	708	126
200	771	121
250	821	120
300	853	118

teils darauf, dass (33) eine immer schlechtere Approximation wird, je niedriger [H$^+$] wird, und teils möglicherweise darauf, dass das Ionenmedium sich merkbar verändert, wenn KCl in höherem Grade von HCl ersetzt wird. Aus Gründen, die sich im folgenden ergeben, wurde der Wert $k_1 = 0{,}117$ min^{-1} gewählt; dabei wird $k_2 = 0{,}00148$ min^{-1}. In Fig. 8 sind als Beispiel sechs Kinetikreihen eingezeichnet. $C_M = 1 \times 10^{-5}$ M, $\lambda = 635$ mμ, [H$^+$] = 80—300 mM, $d = 2$ cm.

Die restlichen Konstanten des Protolysenschemas sind wesentlich schwieriger zu bestimmen als die schon bestimmten. Man kann keine einfache und gleichzeitig gute Approximation von (26) in schwach und sehr schwach sauren Lösungen erzielen. Als eine grobe Approximation kann man um pH 5 schreiben

$$k = \frac{hK_6K_2'}{h^2 + hK_2' + K_2'K_3'} + k_5 \qquad (35)$$

Durch Derivierung von (35) hinsichtlich [H$^+$] findet man, dass die Reaktionsgeschwindigkeit durch ein Maximum geht, wenn $h^2 = K_2'K_3'$. Man kann danach mit verschiedenen Werten von K_3' probieren, wobei man K_6 aus dem schon

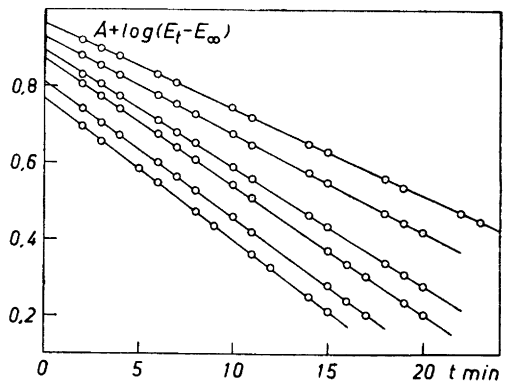

Fig. 8. Kinetikmessungen in HCl + KCl, $\lambda = 635$ mμ, $C_M = 1 \times 10^{-5}$ M, $d = 2$ cm, $T = 20$°C. Von oben nach unten sind die zusammengehörigen Werte für [H+] und A in A + log($E_t - E_\infty$):

[H+]	80	100	150	200	250	300 mM
A	1	1	1,05	1,1	1,1	1,1

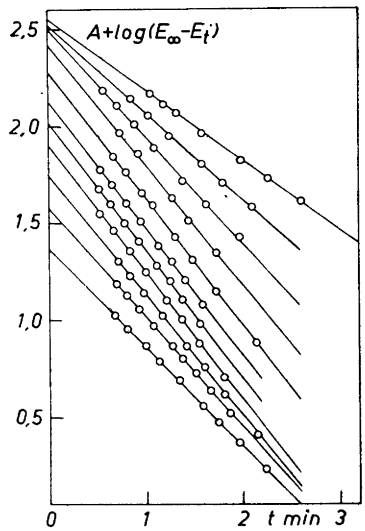

Fig. 9. Kinetikmessungen in Acetatpuffern, $\lambda = 590$ mμ, $C_M = (1-5) \times 10^{-6}$ M, $d = 1-5$ cm, T = 20°C. Von oben nach unten sind pH und A

pH	5,94	5,77	5,59	5,45	5,35	5,26	5,18	5.11	4,98	4,88	4,78
A	3,1	3,1	3,1	3,0	2,8	2,6	2,5	2,5	2,2	2	1,8

bekannten $K_6'K_3'$ und k_6 aus $k_6 = k_5/K_6$ bekommt. Ausserdem gilt dem Reaktionsschema gemäss

$$K_5K_2' = K_6K_2 \text{ und } K_4K_1' = K_5K_1 \qquad (36)$$

weshalb man approximative Werte von K_5 und K_1' erhält, wenn man K_3' festgelegt hat. Da $k_3 = k_4K_5$, vgl. (28), kann man dann durch Kinetikmessungen bei pH 1—3 approximative Werte für k_3 und k_4 aus (26) bestimmen.

In experimenteller Hinsicht verfährt man folgenderweise: Man bereitet eine Stammlösung von KV in 20 mM HCl. Eine solche Lösung wird wegen der Reaktionen $G + H_2O \rightleftharpoons S_2$ und $Y + H_2O \rightleftharpoons S_3$ bis zu $e_o/10$ entfärbt. Diese schwach gefärbte Stammlösung wird dann mit einer Reihe von Acetat- oder Phosphatpuffern gemischt, deren Zusammensetzungen so sind, dass man pH 3.2—6.3 bekommt. Hierbei wird B mit einer Geschwindigkeit, die k in der Gleichung (26) ergibt, wiedergebildet. Bei höherem pH wird im Mischungsaugenblick Carbinol in so hohem Grade gebildet, dass seine Schwerlöslichkeit die Messungen schwerreproduzierbar und unsicher macht. Eine andere Schwierigkeit liegt darin, dass die Reaktionsgeschwindigkeit um pH 5 so gross ist, dass sich die Kinetikmessungen nur schwer ausführen lassen. Bei k_{max} verläuft die Reaktion bis 50 % in nur 30 Sek. Trotzdem kann man gute Kinetikgeraden erhalten, was aus Fig. 9 hervorgeht, die eine Reihe von Kinetikmessungen, pH 4.78—5.94, zeigt. Indem man mehrere Kinetikreihen für jedes benutzte pH aufnimmt, kann man die Genauigkeit von k erhöhen. Bei den Messungen war $C_M = 1 \times 10^{-6}$ M für die meisten Messlösungen und 5×10^{-6} M für einige. $\lambda = 590$ mμ. Im Gebiete pH 1—3 wurde die Ge-

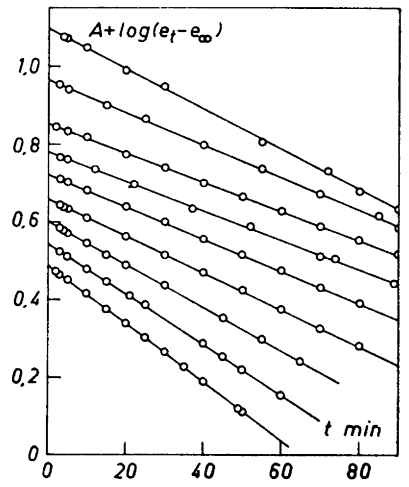

Fig. 10. Kinetikmessungen in HCl + KCl, $\lambda = 590$ mμ, $C_M = 1 \times 10^{-5}$, $d = 1$ cm, $T = 20°C$. Von oben nach unten sind [H$^+$] und A:

[H$^+$]	1,5	2	3	4	5	7	9	12	15 mM
A	1,9	1,6	1,35	1,2	1,1	1	0,95	0,9	0,85

schwindigkeit der Bleichung gemessen, die stattfindet, wenn die ursprüngliche Farbstammlösung, deren [B] = C_M, mit Lösungen von HCl + KCl gemischt wird. Die Messlösungen hatten $C_M = 1 \times 10^{-5}$ M, $\lambda = 590$ mμ. Fig. 10 gibt eine Reihe Kinetikgeraden für [H$^+$] = 1.5—15 mM.

In Fig. 11 und Fig. 12 sind die aus den Kinetikmessungen erhaltenen k-Werte als Funktion von pH aufgetragen. Die Kinetikmessungen wurden bei 48 verschiedenen [H$^+$] durchgeführt. Für jedes [H$^+$] wurden 2—4 Kinetikreihen durchgeführt, wonach man Mittelwerte für k erhielt. Die Bedeutung der verschiedenen Zeichen geht aus den Figurtexten hervor. Die ausgezogenen Kurven sind aus der Gleichung (26) berechnet, wobei die Konstanten benutzt wurden, die man auf direktem Wege bestimmen kann, und die Konstanten, die man durch sukzessive Approximationen bekommt. Nachdem man, S. 1471 gemäss, approximative Werte von K_3', K_2', K_1', K_5, k_3 und k_4 bestimmt hat, kann man diese Konstanten in (26) verwenden und sie justieren, bis man die denkbar beste Übereinstimmung bekommt zwischen den in Fig. 11 und Fig. 12 experimentell gefundenen k-Werten und den aus (26) berechneten. Die ausgezogenen Kurven wurden also aus der nicht approximierten Gleichung (26) berechnet.

Folgende Konstantwerte wurden benutzt:

$K_1 = 0{,}122$	$K_2 = 0{,}00406$			M
$K_1' = 4{,}86 \times 10^{-5}$	$K_2' = 1{,}78 \times 10^{-5}$	$K_3' = 2{,}46 \times 10^{-6}$		M
$K_4 = 79$	$K_5 = 0{,}0319$	$K_6 = 1{,}4 \times 10^{-4}$		
$k_1 = 0{,}117$	$k_3 = 0{,}00660$	$k_5 = 0{,}000367$	$k_7 = 4{,}12$	min^{-1}
$k_2 = 0{,}00148$	$k_4 = 0{,}207$	$k_6 = 2{,}62$	$k_8 = 0{,}000148$	min^{-1}

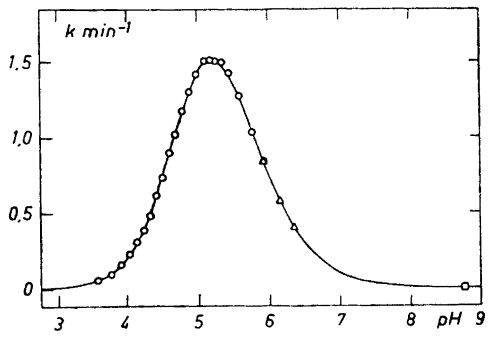

Fig. 11. Kinetikmessungen in Acetat- O, Phosphat- △ und Boratpuffern □. $\lambda = 590$ mμ, $C_M = 1 \times 10^{-6}$ M und 5×10^{-6} M, $d = 1$ und 5 cm, T = 20°C. Die Geschwindigkeitskonstante als Funktion von pH. Die ausgezogene Kurve wurde aus der Gleichung (26) berechnet.

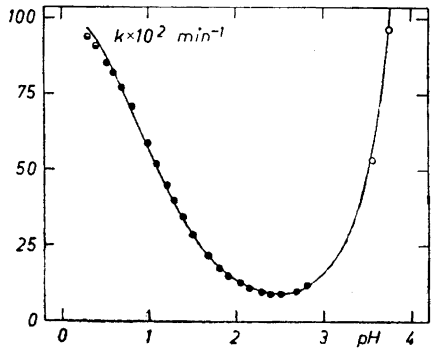

Fig. 12. Kinetikmessungen in Acetatpuffern O und in HCl + KCl ● und ◒. $\lambda = 635$, 590 und 434 mμ, $C_M = 5 \times 10^{-6}$ M und 1×10^{-5} M, $d = 1$, 2 und 5 cm, $T = 20$°C. Die Geschwindigkeitskonstante als Funktion von pH. Die ausgezogene Kurve wurde aus (26) berechnet.

Diese Konstanten satisfieren teils die Gleichung (26) und teils die Beziehungen, die in den Gleichungen (28) und (36) zusammengestellt sind.

Die Übereinstimmung zwischen experimentell gefundener und aus der Gleichung (26) berechneter Reaktionsgeschwindigkeit ist sehr gut. Versuche wurden unternommen, die ausgezogene Kurve unter Verwendung anderer Konstantenwerte als die oben gegebenen zu berechnen, aber schon die Änderung von einigen Prozenten in einem Konstant führt entweder dazu, dass die Kurve die experimentellen Punkte verlässt, oder dazu, dass die Beziehungen von (28) und (36) nicht erfüllt werden. Die Genauigkeit der bestimmten Konstanten variiert und lässt sich nur schwer exakt schätzen, sie liegt aber zwischen 1 und 5 %.

Absorptionskurven von G und Y sind auch in Fig. 1 eingezeichnet. Sie wurden folgendermassen berechnet: ε_G und ε_Y wurden für gewisse Wellenlängen, durch Extrapolation der Extinktion auf $t = 0$, aus der Gleichung (5) bestimmt. Danach wurden Absorptionskurven bei Gleichgewicht in schwach sauren Lösungen aufgenommen, nämlich $[H^+] \sim 4$ mM für die Bestimmung der Absorptionskurve von G, wobei e_G und ε_G aus (13) berechnet wurden, wo man ε_B im Gebiet $\lambda = 320$—700 mμ aus Kurve B in Fig. 1 kennt und ε_Y vernachlässigen kann. Danach wurde die Absorptionskurve von Y durch Messungen in stark sauren Lösungen auf entsprechende Weise bestimmt, nämlich $[H^+] \sim 250$ mM und ähnliche Berechnung aus (13), wo man nun sowohl e_B als e_G kennt.

G hat ein Absorptionsmaximum für $\lambda = 631$ mμ, $\varepsilon_G = 8{,}3 \times 10^4$, und eines für $\lambda = 424$ mμ, $\varepsilon_G = 1{,}40 \times 10^4$. Y hat ein Absorptionsmaximum für $\lambda = 434$ mμ, $\varepsilon_Y = 3{,}5 \times 10^4$.

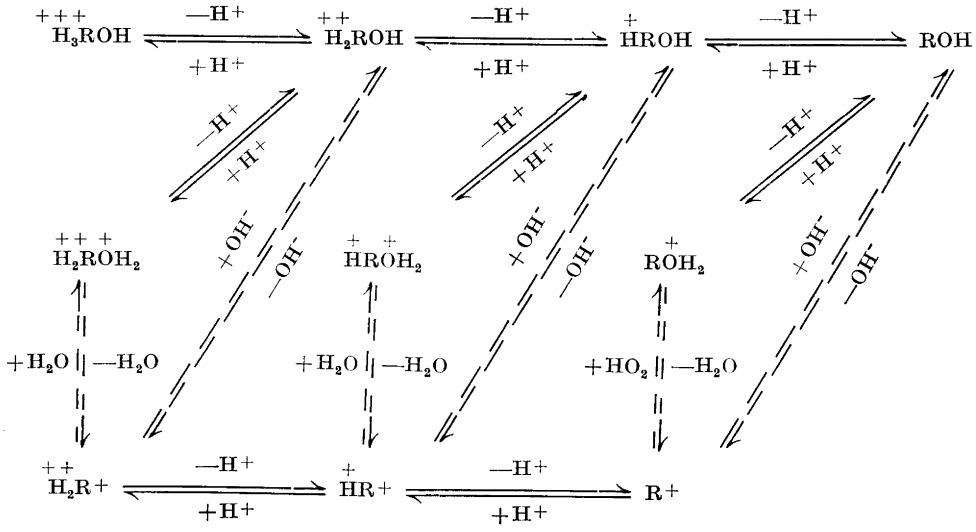
DISKUSSION DER ERGEBNISSE

Die früher von Adams und Rosenstein [2] unternommenen Versuche, Ionisationskonstanten für KV zu bestimmen, ergaben u.a., dass die Absorptionskurve von G eine höhere Extinktion in Abs.max. hat als die Absorptionskurve von B in Abs.max. $\varepsilon_{G\ max} = 11{,}3 \times 10^4$, $\lambda_{G\ max} = 635$ mμ, $\varepsilon_{B\ max} = 8{,}8 \times 10^4$, $\lambda_{B\ max} = 590$ mμ. Die Lagen der Maxima stimmen mit denen dieser Untersuchung überein, aber die von Adams und Rosenstein erhaltenen ε sind unwahrscheinlich. G soll nämlich eine Absorptionskurve haben, deren Abs.max. niedriger ist als die von B. Die Absorptionskurve von G soll der des primären gefärbten Ions von Malachitgrün, $[(CH_3)_2NC_6H_4]_2\overset{+}{C}C_6H_5$, ähnlich sein, und dasselbe gilt in noch höherem Grade für das entsprechende Farbion des Methylgrün, $[(CH_3)_2NC_6H_4]_2\overset{+}{C}C_6H_4N(CH_3)_3\overset{+}{C}lO_4^-$. Von meinen früheren Untersuchungen und den nun durchgeführten findet man für

	λ_{max}	ε_{max}	λ_{max}	ε_{max}
KV sekundäres Farbion G	631 mμ	$8{,}3 \times 10^4$	424 mμ	$1{,}40 \times 10^4$
Methylgrün primäres Farbion	633 »	$9{,}0 \times 10^4$	422 »	$1{,}85 \times 10^4$
Malachitgrün » »	618 »	$8{,}6 \times 10^4$	430 »	$1{,}8 \times 10^4$

Die Lagen der Maxima für G und das primäre Farbion des Methylgrün stimmen also nahe überein.

Die Ergebnisse von Adams und Rosenstein beruhen auf ihrer mangelhaften Methodik. Deshalb sind ihre Ergebnisse betreffs der Ionisationskonstanten und Reaktionsvorgänge nicht nur unvollständig, sondern auch quantitativ



Ausgezogene Pfeile bedeuten, dass die Reaktionen sehr rasch, "momentan", verlaufen, während gestrichelte Pfeile bedeuten, dass die Reaktionen mit messbarer Geschwindigkeit verlaufen.

irreführend. Man kann daher ihre Ergebnisse nicht mit den jetzt publizierten Ergebnissen für Kristallviolett vergleichen.

Zu Beginn wurde hervorgehoben, dass das jetzt für KV aufgestellte Protolysenschema als ein vereinfachtes Reaktionsschema zu betrachten ist, das nur den Bruttoverlauf und die geschwindigkeitsbestimmenden Reaktionen angibt. Hier folgt ein Protolysenschema, das die wahrscheinlichen Reaktionswege besser deckt.

Wenn dem Carbinol, ROH, ein Proton hinzugefügt wird, kann es entweder zum Stickstoff in einer Aminogruppe, $\overset{+}{\mathrm{H}}\mathrm{ROH}$ treten, oder zum Sauerstoff in der OH-Gruppe bei dem zentralen Kohlenstoffatom, $\mathrm{R}\overset{+}{\mathrm{O}}\mathrm{H}_2$. Im letzteren Falle kann ein $\mathrm{H_2O}$ abgespaltet werden, und wir erhalten das gefärbte R^+. $\overset{+}{\mathrm{H}}\mathrm{ROH}$ dürfte OH^- abspalten und $\overset{+}{\mathrm{H}}\mathrm{R}^+$ bilden können, gleich wie R^+ aus ROH gebildet werden kann. Wie aus dem Schema hervorgeht, soll dasselbe Reaktionsprinzip für das ganze Schema gelten. In neutralen und sauren Lösungen erfolgt zwar die Abspaltung des OH^- von $\overset{+}{\mathrm{H}}\mathrm{ROH}$ und $\mathrm{H_2}\overset{++}{\mathrm{R}}\mathrm{OH}$ so langsam, dass die Hydratations- und Dehydratationsgeschwindigkeiten geschwindigkeitsbestimmend werden. Nur in stark alkalischen Lösungen werden die Reaktionen, die OH^- mit einbegreifen, die Reaktionsgeschwindigkeit dominieren.

Da die Messungen mit der Ionenstärke 0.5 M durchgeführt wurden, wurden keine quantitativen Messungen in z.B. konz. $\mathrm{H_2SO_4}$ unternommen, wo KV wahrscheinlich das Ion $\mathrm{H_3}\overset{+++}{\mathrm{R}}^+$ bilden kann.

The Effect of Boron on the Formation of σ-FeCr at 700° C

B. ARONSSON and J. ÅSELIUS

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

Iron-chromium-boron alloys with the atomic ratio Fe/Cr = 54/46 and containing varying amounts of boron (0—26 at %) have been melted twice in an arc-furnace and subsequently annealed for 40—48 days at 700°C in evacuated silica tubes. It has been found that chromium is concentrated in the $(Cr, Fe)_2B$ phase, thereby lowering the amount of Cr available for the formation of σ-FeCr. In the presence of >8 at % B no sigma phase is found in the samples. The solubility of boron in σ-FeCr is probably very small. Thus, the influence of boron on the formation of σ-FeCr is analogous to that of carbon and nitrogen.

It has been assumed[1,2] that the bonding strength between a transition metal (Me) and one of the nonmetals boron, carbon or nitrogen (X) decreases with increasing atomic number of the transition metal in a given transition period. This assumption has been useful when systematizing general features and properties of systems containing the mentioned elements. The decreasing stability of the binary borides, carbides and nitrides of the transition metals with increasing group number of the metal is in accordance with this assumption as are the observations that in Me_1—Me_2—X systems (Me_1 and Me_2 from the same transition period) the lower atomic number metal is always concentrated in the phase richest in nonmetal [3-6].

The influence of carbon on the formation of σ-FeCr is one example of this general behaviour. In the metal rich part of the Fe-Cr-C system (15—43 weight % Cr). Shortsleave and Nicholson [7] found that Cr-rich $(Cr, Fe)_{23}C_6$ carbide is formed, thereby lowering the amount of chromium available for sigma formation. The higher the carbon content of the Fe-Cr-C alloy, the higher the *total* chromium content which is necessary for σ-FeCr to be found. The effect of nitrogen on sigma formation in Fe-Cr-Ni steels is quite analogous, Cr-rich nitrides being formed [8].

The present investigation has been undertaken in order to study if the effect of boron on the formation of σ-FeCr could be explained as depending on higher affinity of B for Cr than for Fe. We also wanted to know if boron, like silicon [9,10], could be dissolved in σ-FeCr to any considerable extent.

EXPERIMENTAL

The metals used in this investigation had a claimed purity of 99.7 %. The boron was analysed and found to contain 94 % B. 2—3 g samples were melted twice in an arc furnace. The samples contained 0, 4.0, 8.5, 13.2, 16.9, 22.5 and 26.0 atomic % B, and within 2 % the Fe/Cr atomic ratio was 54/46 in all of them. The melts were cold worked by hammering with a sledge and subsequently annealed in evacuated silica tubes for 40 days at 700°C and quenched in oil. After this annealing time the powder photographs showed sharp lines and no changes were observed after annealing another 8 days. Filings of the samples were recovered for 1—2 h at 600°C in vacuum. X-Ray photographs were taken in a Guinier type powder camera using Cr$K\alpha$ radiation and NaCl as calibration standard. (a_{NaCl} has been assumed to be = 5.6400$_6$ Å at 21°C.) Measurements of the cube edge of the α-phase could be reproduced within ± 0.01 %. The accuracy of the l.p. (lattice parameters) of the other phases present is estimated to be 0.02—0.03 %.

The samples were chemically analysed for B, Fe and Cr. After dissolving in HCl (under reflux) boron was determined by titration with sodium hydroxide after addition of D-mannitol. Iron and chromium were determined with standard volumetric methods. The result of the chemical analyses (in weight %) is given in Table 1.

Table 1.

Sample No.	% B	% Fe	% Cr	Σ
0		55.2	43.2	98.4
1	0.82	54.8	43.1	98.7
2	1.83	53.5	42.6	97.9
3	2.92	53.1	42.5	98.5
4	3.85	52.9	41.3	98.0
5	5.40	51.5	41.1	98.0
6	6.40	50.5	40.9	97.8

In order to identify the expected boron-rich phases, some alloys in the Cr—B system ($\leq$ 33 at % B) were prepared by arc-melting. They were investigated with X-ray powder methods both in the unannealed state and after annealing in vacuum for 3—4 weeks at 1150°C.

RESULTS

I. *The Cr-B system.* Only one intermediate phase was observed in the region 0—33 at % B. Its composition was approximately Cr_2B. The positions and intensities of all the X-ray powder lines could be explained assuming the crystal structure to be isomorphous with that of Mn_4B[11]. Sufficiently small single crystals gave very nice Weissenberg photographs which definitely showed that the Cr_2B phase in our samples had the Mn_4B structure. "Our" Cr_2B is evidently identical with the Cr_4B phase reported by Bertaut and Blum [12] but as we found the composition to be much nearer to $CrB_{0.50}$ than to $CrB_{0.25}$ it will be referred to as Cr_2B in the following. Two additional phases with the composition Cr_2B have earlier been reported, namely one orthorhombic [13] (space group *A b m m* or *A b m* 2) and one having the $CuAl_2$ structure [12]. Neither of these phases were observed in this investigation.

II. Except the ferrite (α) and sigma phases, only Cr_2B (with some dissolved Fe) was found in the Fe-Cr-B alloys. (Two or three very weak lines from samples 1, 2 and 3 probably originate from impurities.) The phases observed in the different samples and the l.p. of the α and Cr_2B phases are collected in

Table 2.

Sample	at % B	obs. phases	Lattice parameters in Å				at % Cr in α-phase
			Cr_2B			α	
Fe	—	α				2.8662	
Cr	—	α				2.8857	
0	—	σ				—	
1	4.0	α +σ+Cr_2B				2.8736	29
2	8.6	α+Cr_2B	a= 14.63	b = 7.37	c = 4.23	2.8731	24
3	13.2	α+Cr_2B	14.63	7.36	4.23	2.8729	22
4	16.9	α+Cr_2B	14.61	7.36	4.22	2.8721	16
5	22.5	α+Cr_2B	14.60	7.34	4.22	2.8697	7
6	26.0	α+Cr_2B	14.58	7.33	4.21	2.8681	3
Cr_2B	33	Cr_2B	14.71	7.41	4.25		

Table 2. The l. p. of the Fe and Cr used in the preparation of the samples 0—6 and those of pure Cr_2B are also given in the table.

The variation of the l. p. of the α-phase with the Cr content has been determined by Preston [14] (Fig. 1). From Fig. 1 the Cr content of the α-phase of the different samples has been determined and is given in Table 2.

The following observations should be made. With no boron present only the sigma phase is found in the 54/46 (Fe/Cr) sample; with 4 at % B present so much Cr has been bound in the Cr_2B boride that both ferrite (α) and sigma are found. At higher boron concentrations too little Cr is available for any sigma phase to be formed at all, and the α-phase is gradually depleted of Cr with further increasing boron content. The composition of the α-phase at the $\alpha/(\alpha + \sigma)$ boundary (700°C) obtained from sample 1 is 29 at. % Cr in good agree-

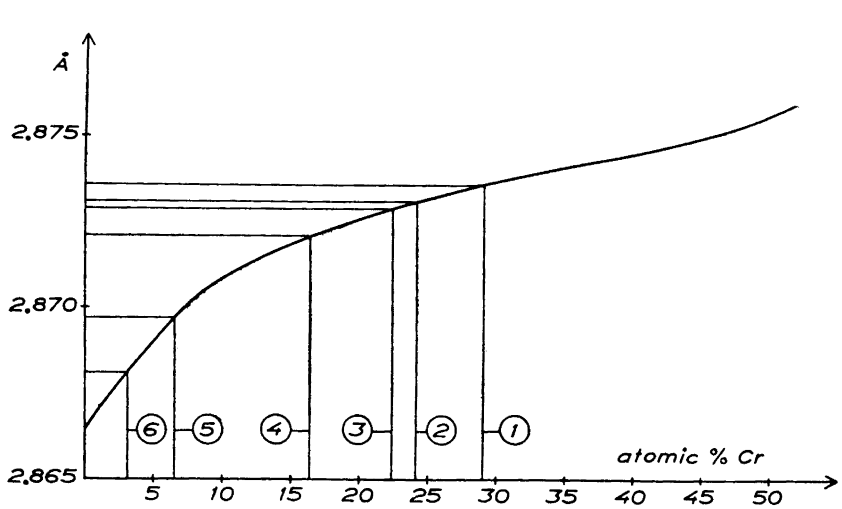

Fig. 1. Cube edge of α-phase as function of Cr content [14]. The numbers in circles refer to samples.

ment with the value of 31 at. % Cr which Cook and Jones [15] give for the binary Fe-Cr system. Thus, boron seems to have very little influence on the position of this boundary. In the samples 2—6 the l. p. of the (Cr, $Fe)_2B$ phase are smaller than those of pure Cr_2B showing that considerable amounts of Fe are dissolved in this phase. The atomic ratio Cr/(Cr + Fe) is estimated to be about three times as great in Cr_2B as in the α-phase.

If there is any appreciable solubility of boron in σ-FeCr it should influence the l. p. of this phase, and a closer study of these parameters is appropriate. The l. p. of the sigma phases in the samples 0 and 1 together with those earlier given by Lundström and Aronsson [10] are collected in Table 3.

Table 3.

Sample	Composition	l.p. of the sigma phase	
	$Fe_{0.504}$ $Cr_{0.496}$	a = 8.798 Å	c = 4.558 Å
0	$Fe_{0.551}$ $Cr_{0.449}$	a = 8.787 Å	c = 4.560 Å
1	$Fe_{0.56}$ $Cr_{0.44}$	a = 8.784 Å	c = 4.562 Å

The compositions have been obtained from chemical analyses except for sample 1. Cook and Jones [15] have found that the Fe-rich $\sigma/(\sigma + \alpha)$ limit in the Fe-Cr system occurs at 43.5—44 at % Cr (700°C). We have assumed that the composition of the sigma phase of sample 1 (containing both ferrite and sigma) is the same as at the $\sigma/(\sigma + \alpha)$ boundary of the binary Fe-Cr system.

The l. p. of the different sigma phases show that the a-axis of σ-FeCr decreases and the c-axis increases with increasing Fe content. The l. p. vary in the same directions when Si is dissolved in σ-FeCr[10]. These similarities are not unexpected as it has been assumed the Si and Fe are similarly distributed in the sigma structure. We think that the differences in l. p. of the sigma phases are entirely explained by the variations in Fe content and that they are not due to the solubility of boron in σ-FeCr. This solubility is likely to be very small.

CONCLUSIONS

We have found that the influence of boron on the formation of σ-FeCr is similar to that of carbon and nitrogen. With increasing boron content of a Fe-Cr-B alloy (the atomic ratio Fe/Cr = 54/46), increasing amounts of Cr-rich $(Cr, Fe)_2B$ are formed and less Cr is available for sigma formation. We have found no evidence that there is any appreciable solubility of boron in σ-FeCr.

Hydrolysis of Carboxylic Acid Esters of Thiocholine and its Analogues

1. Acid Hydrolysis

EDITH HEILBRONN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The hydrolysis of thiocholine esters, α-methylthiocholine esters and β-methylthiocholine esters was studied by a colorimetric method at pH-values 1.07, 1.65 and 2.20. First and second order rate constants are given. The temperature dependence of the hydrolysis was studied at 55°C, 75°C and 90°C at pH 1.2. The constants in Arrhenius' equation and activation energies are given.

The products of hydrolysis were studied by means of paper chromatography. Cleavage between the sulphur atom and the carbonyl group was found for all the esters investigated. R_F-values for choline and its analogues, choline esters, thiocholine and its analogues, thiocholine esters and the oxidation products of thiocholine and its analogues are given.

The results are discussed and a possible reaction mechanism for the hydrolysis of thioesters is given.

In the course of investigations, in this institute, concerning the relationship between the structure and cholinesterase affinity of substrates and inhibitors, series of carboxylic acid esters of thiocholine, α-methylthiocholine and β-methylthiocholine were synthesized [1,2].

Before a study of any enzyme kinetics or pharmacology with these compounds, it was considered necessary to study the dependence of their acid and alkaline hydrolysis on pH and temperature. Since up till now there has been relatively little known about the mechanism of hydrolysis of thioesters, it also seemed to be of interest to compare the hydrolysis of the thiocholine esters with the hydrolysis of the corresponding choline esters [3].

Earlier data reported on the hydrolysis of thioesters seem mostly to refer to studies carried out in water-acetone or water-dioxan solutions. Morse and Tarbell [4] describe the hydrolysis in hydrochloric acid in 62 % acetone of allyl, benzyl and trityl thioacetates. They found cleavage between the carbonyl group and the sulphur atom with allyl and benzyl thioacetates, but cleavage between the alkyl group and the sulphur atom with trityl thioacetate. Noda

et al. [5], Rylander and Tarbell [6] and Schaefgen [7] have investigated the hydrolysis of several thioacetates, among them *n*-butyl, *iso*butyl, *n*-amyl and *iso*amyl, in hydrochloric acid. They found the hydrolysis to be first order with respect to ester concentration and hydronium ion concentration. However, Böhme and Schran [8], who have studied the hydrolysis of some thioesters in water-dioxan and found a cleavage between acyl and sulphur, report catalysis by the hydronium ion which was not first order with respect to hydronium ion concentration, but dependent upon the type of acid used.

The dependence on pH and temperature of the hydrolysis of thiocholine and methylthiocholine esters reported in this paper was studied in acid buffer solutions. The products of hydrolysis were analyzed after hydrolysis in 0.1 M hydrochloric acid in a nitrogen atmosphere.

EXPERIMENTAL

Materials. Thiocholine, thiocholine esters, α-methylthiocholine esters and β-methylthiocholine esters were synthesized by Hansen [1,2]. Choline, β-methylcholine and acetyl-α-methylcholine were synthesized according to a method described by Tammelin [9] for the synthesis of acetylcholine and acetyl-β-methylcholine. The esters were iodides or bromides. The thioacetic acid was commercial (Fluka A.G.).

Paper chromatography. Five solvents were used for the chromatography of the products of hydrolysis and their reference substances. The compositions of these solvents were

1) *n*-butanol saturated with water [10],
2) *n*-butanol:ethanol:acetic acid:water (8:2:1:3) [11],
3) *n*-propanol:1 M acetic acid (3:1) [12],
4) diethylene glycol:*n*-butanol:water (1:4:1) [13],
5) 2 M ammonium hydroxide:*iso*propanol (1:3) [14].

Solvents 2—4 were used in descending technique, 1 and 5 in ascending technique. The filter paper used was Whatman No. 1. With the aid of a micropipette, 10—50 μl of the solutions were placed in small portions on the filterpaper, which was dried between each addition. Duplicate spots were run. The reference substances were dissolved in water to determine their R_F-values and in 0.1 M hydrochloric acid, when they accompanied the hydrolysates. Mixtures of hydrolysate and reference substance were also run.

The esters were hydrolyzed in sealed tubes containing 0.1 M hydrochloric acid in a nitrogen atmosphere at 35°C for several days. Hydrolysates were analysed by chromatography. A hydrolysis where the solutions were kept at 80°C in a nitrogen atmosphere was followed by determining the amount of unhydrolyzed ester as iron-hydroxamate complex [15].

The investigation of the spots was carried out by inserting the sheets into a chamber of iodine vapour in order to find the spots. Quaternary ammonium compounds were identified by spraying the chromatograms with dipicrylamine (DPA) [16] which gave yellow spots or by immersing the chromatograms in a solution of phosphomolybdic acid with subsequent reduction with stannous chloride (PMA) [13] which gave blue spots. Unhydrolyzed esters and thioacids were found as iron-hydroxamate complexes [17]. Thiols and also sometimes disulphides could be located with N-ethyl maleinimide (NEM) [18], which gave red spots. This reagent reacted also with the unhydrolysed esters, which apparently were hydrolysed by the reagent. Hydroxyl groups usually gave yellow-coloured spots.

Kinetic measurements. Acid hydrolysis was studied in Clark and Lubs standard buffer solutions [19] at 55°C, 75°C and 90°C. The pH-values of the solutions were determined with a Radiometer pH-meter 23, type PHM 23C, and are given in Table 6. A saturated calomel electrode and a glass electrode, G302A, were used for measurements at high temperature. The instrument was standardised against a citrate buffer, pH 2.75 ± 0.02 (55°C) (P-H Tamm, Svenska Finkemikalier).

Table 1. Chromatogram following oxidation of thiocholine, acetyl-α-methylthiocholine and acetyl-β-methylthiocholine. Solvent No. 4. Solvents are described in the experimental part.

4.0×10^{-3} M solutions of the compounds were hydrolysed in a thermostat. The pH of the solution was measured at the beginning and at the end of each kinetic experiment. The ester concentration in solutions was determined as iron-hydroxamate complex [15] and measured with a Beckman B spectrophotometer at 540 mμ.

Preparation of disulphide compounds. Bis (trimethyl ammonium ethyl) disulphide (oxidised thiocholine): 100 mg of thiocholine iodide were dissolved in 25 ml of 48 % hydrogen bromide, *d* 1.49. The solution was refluxed at the boiling point and a stream of oxygen was led in. The progress of the oxidation was followed with hydroxamate-$FeCl_3$ and also by chromatography. In this way it was made clear which spot was the thiol and which was the disulphide. After 60 h all the thiocholine was oxidised. Bis(trimethyl ammonium 2-methyl ethyl) disulphide, oxidised α-methylthiocholine, and bis(trimethyl ammonium 1-methyl ethyl) disulphide, oxidised β-methylthiocholine, were prepared in the same way, but here the starting material was the corresponding acetyl ester. Chromatograms are shown in Table 1.

RESULTS

Products of hydrolysis

The hydrolysis of thiocholine and its analogues can be expected to proceed according to one of the following reaction schemes:

$$R_1\overset{\overset{O}{\|}}{C}-SR_2 + H_2O \longrightarrow R_1\overset{\overset{O}{\|}}{C}-OH + HSR_2 \qquad (1)$$

or

$$R_1\overset{\overset{O}{\|}}{C}-SR_2 + H_2O \longrightarrow R_1\overset{\overset{O}{\|}}{C}-SH + HOR_2 \qquad (2)$$

where R_1 = alkyl or phenyl and

$$R_2 = -CH_2-CH_2-N^+(CH_3)_3,\ -CH_2-\underset{\displaystyle CH_3}{\underset{|}{CH}}-N^+(CH_3)_3 \text{ or } -\underset{\displaystyle CH_3}{\underset{|}{CH}}-CH_2-N^+(CH_3)_3$$

$$R_1\overset{\displaystyle O}{\overset{\|}{C}}-SH \text{ in acid medium splits into } R_1\overset{\displaystyle O}{\overset{\|}{C}}-OH \text{ and } H_2S, \text{ but } HSR_2N^+(CH_3)_3$$

probably is stable at least at moderate temperatures, the hydrolysates were analysed with respect to choline and thiocholine or their analogues.

Table 2. R_F—values for several quaternary ammonium compounds and thioacetic acid in 5 different solvents, described in the experimental part.

Before starting the chromatograms of the products of hydrolysis, the R_F-values for the expected reference substances were determined. Values are given in Table 2. Observed variation of R_F-values in different runs was about $\pm$ 10 %. It is seen that R_F-values for thioesters increase in the order chlorides, bromides, iodides. This has also been observed for quaternary ammonium compounds by Sheppars *et al.*[20].

A chromatogram following hydrolysis of acetylthiocholine iodide is shown in Table 3. Blue colour with phosphomolybdic acid and stannous chloride

Table 4. Chromatogram of hydrolysate of acetyl-β-methylthiocholine after hydrolysis in 0.1 M HCl in sealed tubes filled with nitrogen.

2	0.45 (0.21 + 0.34)	PMA, Nem PMA	α-methylthiocholine (oxidised α-methyl-thiocholine)
3	0.53 (0.45)	PMA, Nem PMA	α-methylthiocholine (oxidised α-methyl-thiocholine)
4	0.64 (0.31)	PMA, Nem PMA	α-methylthiocholine (oxidised α-methyl-thiocholine)

(PMA) indicates a quaternary ammonium group or a tertiary amino group. For the esters analysed the identification of a quaternary ammonium group was accepted. The iron-hydroxamate complex (FeH) indicates an ester linkage and a colour reaction with N-ethyl-maleinimide (NEM) indicates a thio group. However, in a few cases red colour with NEM was observed also with the disulphide compounds. The colour of the spots and their R_F-values identify them as acetylthiocholine (R_F 0.66), thiocholine (R_F 0.62) and probably oxidised thiocholine (R_F 0.21).

The hydrolysates of acetyl-β-methylthiocholine bromide gave, after 3 days at 55°C, β-methylthiocholine and very small amounts of oxidised β-methyl-thiocholine, as seen in Table 4. In the same way hydrolysis of acetyl-α-methylthiocholine bromide was shown to give α-methylthiocholine and small amounts of oxidised α-methyl-thiocholine, as seen in Table 5. For some unknown reason oxidised α-methyl-thiocholine often gave two spots.

Thus chromatograms of the products of acid hydrolysis of acetylthiocholine, acetyl-α-methylthiocholine and acetyl-β-methylthiocholine show that, for all three types of esters, cleavage occurs between the carbonyl group and the sulphur atom. This was also shown to be true for the other thioesters analysed, including the benzoyl thioesters.

Rate of hydrolysis

The rate of hydrolysis for thiocholine esters and their analogues was determined in buffer solutions at pH—values 1.07, 1.65 and 2.20 at 55°C. The ionic strengths (μ) of the solutions were estimated to be 0.142 at pH 1.07, 0.077 at pH 1.65 and 0.057 at pH 2.20. Straight lines were obtained when the logarithm of the ester concentration at constant pH was plotted against time as is seen

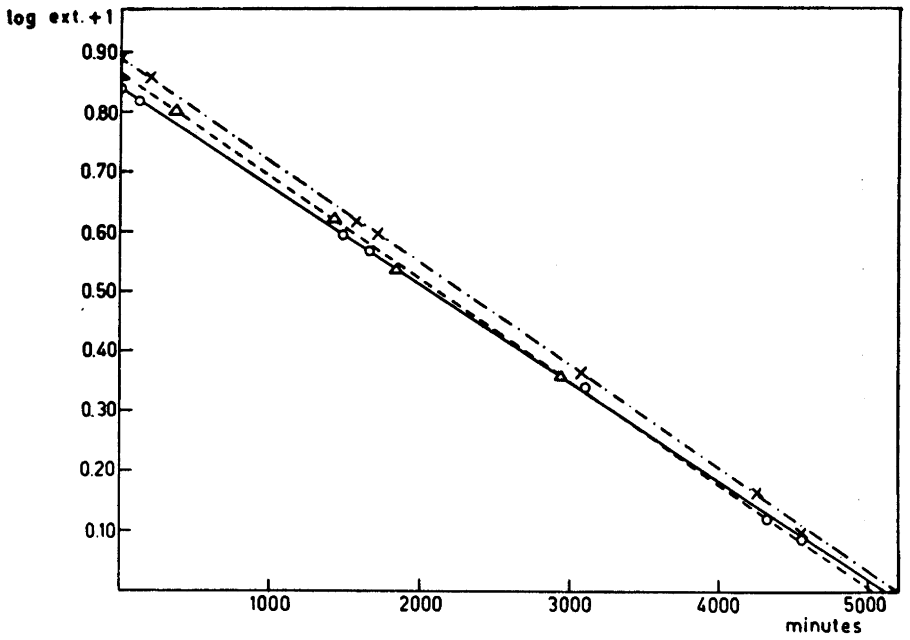

Fig. 1. Hydrolysis at pH 1.07. Logarithm of ester concentration, expressed as logarithm of optical density of iron-hydroxamate complex, plotted against time. × = acetylthiocholine, O = acetyl-α-methylthiocholine, △ = acetyl-β-methylthiocholine.

in Fig. 1, indicating a first order reaction. First order rate constants in minutes were calculated according to equation

$$k_1 = \frac{1}{t} \ln \frac{c_0}{c}$$

where c_0 and c are the optical densities at zero time and time t, respectively. It was shown earlier [15] that Lambert-Beer's law is obeyed. Second order rate constants in $1 \cdot \text{mole}^{-1} \cdot \text{min}^{-1}$ were calculated according to equation

$$k_2 \cdot a_{H^+} = k_1$$

as the catalysis by hydroxyl ions can be neglected at the pH—values investigated. Second order rate constants at ionic strength = 0 were not calculated, as Nilsson (Olered) [21,22] has shown that the ionic strength does not seem to influence the rate of the acid hydrolysis of choline esters.

Rate constants given in Table 6 show that the rate is proportional to hydrogen ion activity with a slight tendency to increase at the highest pH used.

Table 6. Pseudo first order rate constants and second order rate constants for several carboxylic acid esters of thiocholine, α-methylthiocholine and β-methylthiocholine, determined at pH 1—2.2, $t = 55°C$.

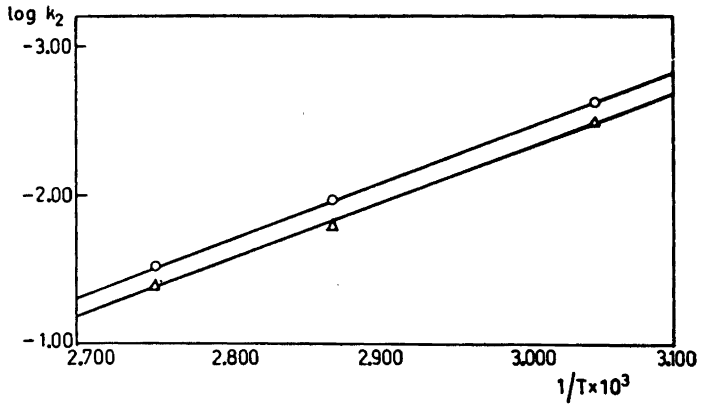

Fig. 2. Temperature dependence of hydrolysis. Second order rate constants in $1 \times \text{mole}^{-1} \times \text{min}^{-1}$ plotted against $1/T$. Lines calculated by method of least squares. △ = acetylthiocholine, ○ = acetyl-α-methylthiocholine.

Temperature dependence

Temperature dependence of the acid hydrolysis was determined for four esters of each of the thiols at pH 1.2 at 55°C, 75°C and 90°C. Difficulties in the determination of the exact pH at the high temperatures which were necessary to speed up hydrolysis, influence the accuracy of the calculated values. The logarithms for second order rate constants in $1 \cdot \text{mole}^{-1} \cdot \text{min}^{-1}$ were calculated as described earlier and plotted against $1/T$ as seen in Fig 2. The line

$$\log k_2 = A_H+ + B_H+/T$$

representing Arrhenius' equation, was calculated by means of the method of least squares, and the activation energies were calculated. The logarithm for the collision factor, PZ, is equal to A_H+ · Arrhenius' constants and activation energies are shown in Table 7.

Table 7. Constants in Arrhenius' equation and activation energies for several carboxylic acid esters of thiocholine, α-methylthiocholine and β-methylthiocholine at pH 1.2.

DISCUSSION

The rate of hydrolysis of the thioesters studied is rather low compared with the rate of the corresponding choline esters, determined in the same medium by Larsson [3]. The thiocholine esters hydrolyse at 75°C about 3 times slower than their choline analogues. The same phenomenon has been found by other authors [7], who have compared the rate of hydrolysis of thioesters with that of the corresponding oxygen esters. Sulphur is considered to be less negative than oxygen, which results in a less positive carbon in the C—S bond than in the C—O bond. This would retard the water attack on the carbon, supposed to be the rate determining step in acid hydrolysis. Even hydrogen ion attack on the sulphur would be slower than on the oxygen.

A comparison of activation energies found for thiocholine esters with those found for choline esters [3] shows no difference in these values, indicating that the two types of ester may hydrolyse by the same mechanism.

The effect of the substituent on the thiol on the rate of hydrolysis is not great. The esters of the unsubstituted thiocholines hydrolyse fastest, immediately followed by β-methyl substituted esters. The α-methyl substituted esters show the slowest rate of hydrolysis. No steric effect of the β-methyl group could be observed. The reason for this may be the length of the C—S—C bond, according to Pauling 2.58 Å. A methyl group in the β-position to the ammonium group in the thiol would be far enough away from the attacked carbon atom to have little chance of hindering the water molecule from reaching the carbon. Also the small hydrogen ion would easily reach the sulphur atom for an attack in the second step of the hydrolysis.

It is more difficult to explain the small but obvious retardation of hydrolysis found for the α-substituted esters. Several anomalies in the behaviour of these esters were observed. They were found to be the least water-soluble esters and they showed a different behaviour in chromatography from that of the choline esters. Thus it was found that the R_F-values for choline esters increase in the order unsubstitued, α-methyl substituted, β-methyl substituted ester, but for the thiocholine esters the order was found to be unsubstituted, β-methyl substituted, α-methyl substituted ester. This indicates that α-methyl substituted thiocholine esters have a lower affinity for water than the other thioesters and would be in agreement with the observed lower rate of hydrolysis.

The substituent on the carboxy group of the thioesters seems to be important for the rate of hydrolysis of the esters. The rate decreases as the carbon chain grows longer, and bulky substituents retard hydrolysis more than their straight analogues. Thus the rate of hydrolysis for the *iso*butyryl substituted thioester is lower than for *n*-butyryl substituted thioester. It is remarkable that the benzoyl thioester is practically not hydrolysed at all at 55°C. The effect of these substituents may be explained as a steric as well as an inductive and mesomeric (*e.g.* phenyl) effect. If the attack of water at the carbonyl carbon is the rate determining step, bulky substituents on this atom should retard the hydrolysis and thus have a greater influence upon the reaction rate than substituents at the thiol, which is in agreement with the experimental results. The electron releasing effect of the substituents increases with the length

of their carbon chain, leaving the carbonyl carbon less positive, thus retarding the attack of water at this atom.

From the observed data on the rate and products of hydrolysis of thiocholine esters and their analogues it seems probable that the mechanism for their hydrolysis is the same as for choline esters and for esters in general and thus can be described by

Hydrolysis of Carboxylic Acid Esters of Thiocholine and its Analogues

2. Alkaline Hydrolysis

EDITH HEILBRONN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The hydrolysis of thiocholine esters, α-methylthiocholine esters and β-methylthiocholine esters was studied with an automatic recording titrator at pH values 9.00, 9.50, 9.75 and 10.00 at 35°C and with a colorimetric method at pH 6.0, 7.0 and 8.0 at 55°C. First and second order rate constants are given.

The dependence of the hydrolysis rate on temperature was studied at 25°C, 30°C, and 35°C at pH 10.00. Arrhenius' constants and activation energies are given. The products of hydrolysis were studied by means of paper chromatography and paper ionophoresis and found to be fairly complex. Cleavage between the sulphur atom and the carbonyl group was found.

The hydrolysis of acetylcholine, acetyl-α-methylcholine and acetyl-β-methylcholine was studied with an automatic titrator at pH 9.00, 9.50 and 10.00 at 35°C. First and second order rate constants, Arrhenius' constants and activation energies are given. The results and possible reaction mechanisms are discussed.

Previous studies on the alkaline hydrolysis of thioesters [1-7] refer mostly to hydrolysis in various amounts of sodium hydroxide. Most experiments were carried out under conditions, to which the mathematical treatment of second order kinetics could be applied. Some experiments [3, 5, 6] were, however, carried out in large excess of hydroxyl ion, thus keeping the pH approximately constant. The authors have found agreement with the theory for second order reactions up to 60—80 % completion of hydrolysis. Cleavage between acyl and sulphur was found in all cases. However, Morse and Tarbell [4] found after hydrolysis of tritylthioacetate certain amounts of triphenylcarbinol, but this seems to be a secondary product, as mainly material of disulphide type, among others probably ditrityl disulphide, was obtained.

The only papers known to the present author and treating hydrolysis of thioesters at lower, exactly defined pH-values are by Koningsberger and Overbeek [8-11]. They studied the hydrolysis of ethyl thioacetate between pH 8

and 12 in 0.2 M borate buffer and found that the rate of hydrolysis was directly proportional to the hydroxyl ion concentration up to pH 8.6, as is usually the case with oxygen esters. Above this pH the second order rate constant started to decrease rapidly down to about 10 % of its original value, thereafter proportionality to hydroxyl ion concentration was again observed. They explained this observation by assuming two competitive reactions, a hydroxyl ion catalysed hydrolysis prevailing at high pH and another type of hydrolysis, prevailing at lower pH. Several ways were proposed for the latter type of hydrolysis.

In the preceding paper [12] the acid hydrolysis of carboxylic acid esters of thiocholine and two methylthiocholines is described. The study of the alkaline hydrolysis of these compounds was started with the methods [12] already described. However, complications occurred when the hydroxamate-$FeCl_3$ method [13] was used for kinetic measurement at higher pH-values and so it was decided to use an automatic recording titrator [14]. The dependence of the reaction rate on pH and temperature was also measured for some corresponding choline esters.

EXPERIMENTAL

Materials. The same preparations as for the study on acid hydrolysis [12] were used.

Paper chromatography. Solvents, paper and technique as described earlier [12].

The esters were hydrolysed in excess of 0.1 M sodium hydroxide in an atmosphere of nitrogen previous to chromatography with procedure as described earlier [12]. Hydrolysates from titrations at pH 9.0 were also subject to chromatographic analysis. The hydrolysates were acidified to prevent oxidation during chromatography.

High voltage paper ionophoresis. Hydrolysates from kinetic measurements were used. Paper ionophoresis was carried out with an apparatus according to Foster [15] on Whatman paper No. 1 at a voltage of 2 000 V, 40 V/cm. A 0.1 M borate buffer solution of pH 10.0 was used. Spots were placed on dry paper with a micropipette. After being air dried the papers were immersed in the buffer solution. Excess buffer solution was removed with filter papers. After ionophoresis the papers were air dried and the spots were developed as described earlier for paper chromatography [12].

Kinetic measurements. The alkaline hydrolysis was at first studied in modified Clark and Lubs standard buffer solutions [16] at 55°C. The pH-values of the solutions were determined against a standard buffer of pH 6.95 ± 0.02 (55°C) (P-H Tamm) as described earlier [12].

Automatic titration at constant pH was carried out at constant ionic strength in 0.1 M potassium chloride. The titrator was a 0.098 M solution of sodium hydroxide. The glass electrode used was a Radiometer G 202B and the reference electrode was a saturated calomel electrode, Radiometer K 300. In most experiments 2.77×10^{-5} moles of thiocholine esters were titrated. The same method was used for the determination of the rate constants of some corresponding choline esters. 5.54×10^{-5} moles of these compounds were titrated.

In a few experiments at pH 9.00 and 35°C the titrator was used to keep the pH constant and the amount of unhydrolysed ester was determined as iron-hydroxamate complex [13] in a Beckman apparatus at 540 mμ. In these experiments the concentration of the esters was 2.77×10^{-4} M and the titrator was 0.502 M sodium hydroxide.

RESULTS

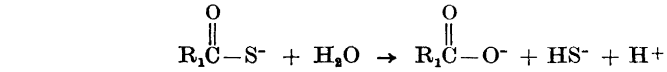
Products of hydrolysis

The following reaction schemes are possible for the alkaline hydrolysis of thiocholine esters and analogues at high pH:

(1)

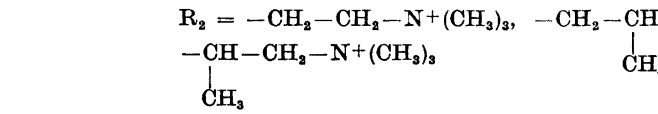
or

(2a)



(2b)

where R_1 = alkyl or phenyl and



In the first reaction two moles of alkali for each mole of hydrolysed ester would be consumed. In the second reaction one mole of alkali would be used in step a. The reaction described in step b has been found to be incomplete [18] and would thus consume less than one mole of alkali.

It was shown by titration that the esters hydrolysed at pH 10.00 used 2 moles of alkali. However, at pH 9.00 this could not be shown to be true for β-methylthiocholine esters, which used somewhat less than two moles of alkali. Because of the low rate of hydrolysis at this pH, the exact amount of sodium hydroxide used could not be determined.

The hydrolysates were analysed with respect to choline and thiocholine or their analogues. The reference substances described earlier [12] accompanied the chromatograms. The results of the chromatograms of the hydrolysates of acetylthiocholine and acetyl-α-methylthiocholine are given in Table 1. A chromatogram of valeryl-β-methylthiocholine after hydrolysis at pH 9.00 is also given in Table 1. An attempt to identify the source of the unknown spots in these chromatograms was made by studying the products of thiocholine after storage for 4 days in 0.1 M sodium hydroxide at 35°C. The results of this chromatogram are given in Table 2. Acidification by hydrochloric acid after the 4 days of storage gave traces of hydrogen sulphide.

The paper chromatograms were too complex to allow complete identification of the products of hydrolysis. It was, *e.g.*, not possible to decide if any choline compounds were formed as the R_F-values of choline and thiocholine and of their analogues are close to each other [12], which would make it possible for the thio compounds to "mask" spots of the corresponding oxygen compounds.

To determine the products of hydrolysis it was decided to use high voltage paper ionophoresis at a pH above the pK'_a of thiocholine and methylthiocholine. The pK'_a of thiocholine was found to be ~ 7.7 by titration at ionic strength $\mu = 0.1$ with an automatic recording titrator [14]. The values for the other two compounds had to be approximated from the pK'_a-values of analogous dimethylamino compounds. They were found by Hansen [17] to be 7.84 for dimethylamino ethanthiol, 7.59 for dimethylamino-α-methylethanthiol and 7.62 for dimethylamino-β-methylethanthiol.

It was therefore decided that a borate buffer solution of pH 10 should be used. At this pH it can be expected that thiocholine and its analogues will be dissociated and, owing to their state of "Zwitterion", $^-SRN^+(CH_3)_3$, will not move far from the starting point of the ionophoresis, but choline and its analogues, which are not dissociated at this pH, will move rapidly towards the negative pole because of their positive charge, $HORN^+(CH_3)_3$. Secondary oxidation products, having two positive charges, can also be expected to move rapidly towards the negative pole.

The results of the ionophoresis of the products of hydrolysis are given for valeryl-β-methylthiocholine in Fig. 1. It is clearly seen that no β-methylcholine is obtained, whereas β-methylthiocholine is. Hydrolysates of thiocholine esters and α-methylthiocholine esters showed spots indicating thiocholine and α-methylthiocholine, respectively. A spot of unknown origin was sometimes obtained between spots of unhydrolysed ester and thiol. It thus seems that cleavage between the sulphur atom and the carbonyl group occurs in alkaline hydrolysis, but that the products are somewhat complex even when oxidation is prevented during hydrolysis.

Rate of hydrolysis

The rate of hydrolysis for choline and thiocholine esters and their analogues was determined at the pH-values 9.00, 9.50, 9.75 (only α-methyl and β-methylthiocholine esters) and 10.00 at 35°C and at constant ionic strength, $\mu = 0.1$. The pseudo first order rate constant in min^{-1} was calculated according to the method of Guggenheim [19] except for β-methylthiocholine esters at pH 9.00. Second order rate constants were calculated according to the equation

$$k_2 \cdot a_{OH^-} = k_1 \qquad (3)$$

Table 3. Pseudo first order rate constants, second order rate constants, and second order rate constants at ionic strength = 0 for acetylcholine, acetyl-α-methylcholine and acetyl-β-methylcholine.

	R_2	$-CH_2-CH_2-N^+(CH_3)_3$			$-CH_2-CH(CH_3)-N^+(CH_3)_3$			$-CH(CH_3)-CH_2-N^+(CH_3)_3$		
R_1	pH	9.00	9.50	10.00	9.00	9.50	10.00	9.00	9.50	10.00
CH_3-	k_1 $min^{-1} \times 10^3$	4.75	13.9	46.9	4.05	12.4	41.3	1.10	3.40	11.4
	k_2 $l \times mole^{-1} \times min^{-1}$	220±8			193±5			52.9±1.7		
	k_2° $l \times mole^{-1} \times min^{-1}$	302±12			269±7			72.4±3.2		

and k_2° was calculated according to

$$\log k_2 + \log f_{OH} = \log k_2^\circ + z_a z_b \sqrt{\mu} - 0.6 z_a z_b \mu \quad (4)$$

where z_a and z_b are the charges of the reacting ions and 0.6 is a constant found and used by Olered [20] and shown by him to be valid for acetylcholine and some of its analogues. The value for log f_{OH^-} used in the equations was estimated to be — 0.12. The error in k_2, given in Table 3, is a maximum error.

Choline esters. The constant values of k_2 obtained for choline esters and their analogues and given in Table 3, show that the rate of hydrolysis of these esters depends only upon hydroxyl ion activity. The use of eqn. (3) is thus justified for these esters.

Thiocholine esters. Table 4 shows k_2 for thiocholine esters and their analogues. It is seen that k_2 for thiocholine esters is practically constant, though there seems to be a very slight tendency towards a higher value at lower pH. The logarithm of ester concentration, calculated from the amount of sodium hydroxide consumed, plotted against time, shows a straight line, indicating a pseudo first order reaction. Thus it is justified to use eqn. (3) also for these esters.

α-Methylthiocholine esters. The "k_2" values found for α-methylthiocholine esters, given in Table 4, show a tendency to decrease at lower pH. Plots of log c against time show no perfectly straight lines. It is questionable if the method of Guggenheim can be used for calculations of these reaction rates.

β-Methylthiocholine esters. The "k_2" values for β-methylthiocholine esters increase with decreasing pH. A check of the assumed pseudo first order rate of hydrolysis at constant pH, again done by plotting log c against time (Fig. 2), showed no straight line for any β-methylthiocholine ester at pH below 9.50. The method of Guggenheim could thus not be used for calculating the reaction

Table 4. Pseudo first order rate constants, "second order rate constants", and "second order rate constants" at ionic strength = 0 for several carboxylic acid esters of thiocholine, α-methylthiocholine and β-methylthiocholine, determined at pH 9—10, $t = 35°C$.

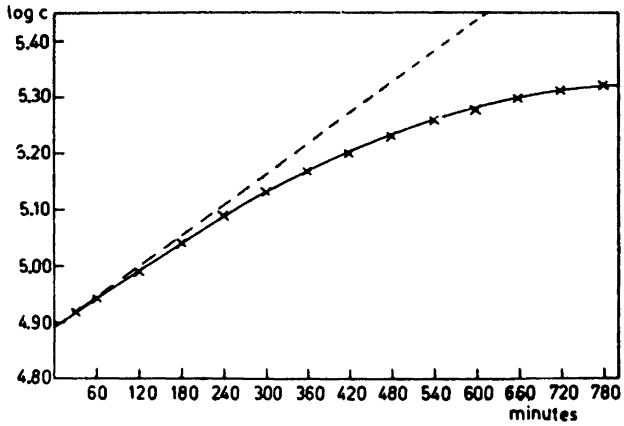

Fig. 2. Hydrolysis at pH 9.00. Logarithm of ester concentration for acetyl-β-methylthiocholine, calculated from consumed amount of sodium hydroxide, plotted against time. Dotted line shows, how ester concentration should decrease, if the reaction was pseudo first order. $t = 35°C$.

rates of these compounds at pH 9.00. The other values are shown in Table 4. The observed deviation from pseudo first order kinetics may depend upon another type of hydrolysis or upon secondary reactions, disturbing in the chosen method of analysis. To see if the hydrolysis of β-methylthiocholine esters at pH 9.00 proceeded as a first order reaction with respect to ester concentration,

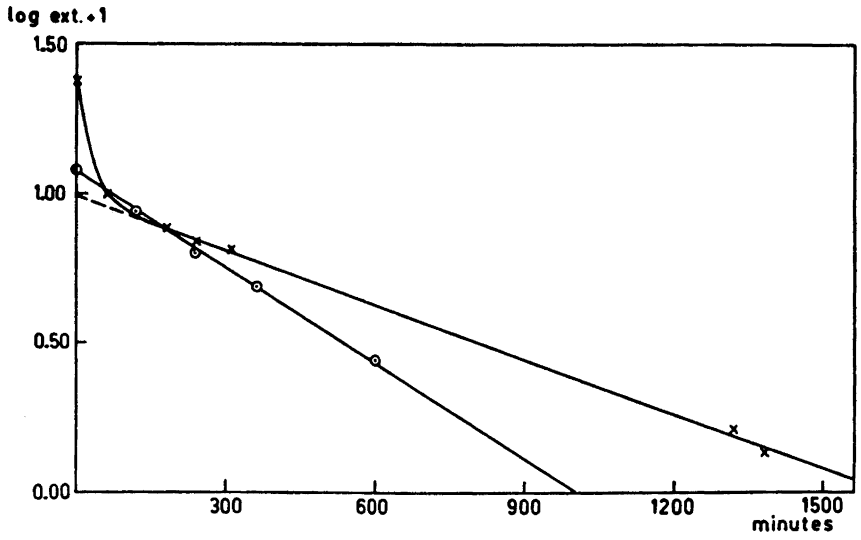

Fig. 3. Hydrolysis at pH 9.00. Logarithm of ester concentration for acetyl-β-methylthiocholine (⊙) and butyryl-β-methylthiocholine (×), expressed as logarithm of optical density of iron-hydroxamate complex, plotted against time. $t = 35°C$.

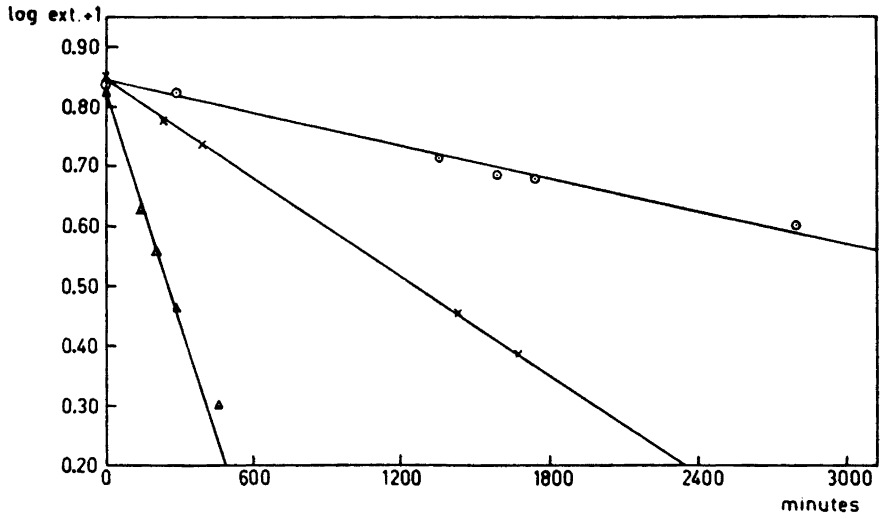

Fig. 4. Hydrolysis at pH 6 (⊙), 7 (×) and 8 (△). Logarithm of ester concentration of acetyl-α-methylthiocholine, expressed as logarithm of optical density of iron-hydroxamate complex, plotted against time. $t = 55°C$.

the automatic recording titrator was used to keep the pH constant and the amount of unhydrolysed ester was measured as iron-hydroxamate complex. The initial concentration of the ester had to be higher than in earlier experiments because of the unsensitivity of the colorimetric method. As Fig. 3 shows, the pseudo first order rate constant for acetyl-β-methylthiocholine was in this case 0.00248 min^{-1}, which would be the expected value, if the hydrolysis was dependent only upon hydroxyl ion activity. The hydrolysis seems to be first order with respect to ester concentration. The pseudo first order rate constant for butyryl-β-methylthiocholine was, by the same method, found to be 0.00137 min^{-1}. The bend at the beginning of the curve may indicate that the sample, which was slightly hydroscopic, was not pure. The same type of curve was obtained with valeryl-β-methylthiocholine.

Hydrolysis of the thioesters at lower pH. The rate of hydrolysis of thiocholine esters and their analogous was also determined in phosphate buffers at pH 6.0, 7.0 and 8.0 at 55°C. These buffer solutions could not keep the pH completely constant during hydrolysis. Owing to the acid character of the hydrolysis products a decrease of 0.10—0.15 pH units was observed. It is seen in Fig. 4 that the hydrolysis was first order with respect to ester concentration. First order rate constants, "second order rate constants", calculated according to eqn. (3), and "k_2^o" calculated according to eqn. (4), are given in Table 5. The ionic strenth is calculated from logarithm diagrams and the values were ~ 0.12 at pH 6, ~ 0.20 at 7 and ~ 0.31 at pH 8. The value used for pK_w was 13.13. It is seen that proportionality to hydroxyl ion activity is not obtained: k_2^o increases as pH decreases.

Temperature dependence

The temperature dependence of the rate of hydrolysis for choline and thiocholine esters and methyl substituted analogues of both was determined at pH 10.00 at 25°C, 30°C and 35°C. The logarithms of the second order rate constants, calculated as described earlier, were plotted against $1/T$ as shown in Fig. 5. The line

$$\log k_2 = A_{OH^-} + B_{OH^-}/T \qquad (3)$$

representing the Arrhenius' equation, was calculated by means of the method of least squares. The activation energy was also calculated. The logarithm for the collision factor, PZ, is equal to A_{OH^-}. The following values for pK_w were used: pK_w 25°C = 14.00, pK_w 30°C = 13.83 and pK_w 35°C = 13.68. The constants in the Arrhenius' equation and the activation energies are given in Tables 6 and 7.

DISCUSSION

Only a slight difference in the rate of hydrolysis of the thiocholine esters and the two methylthiocholine esters was found at pH 10.00 as long as the acid residue of the esters was the same. The unbranched thiocholine esters were found to hydrolyse fastest, followed by β-methyl substituted esters. Slowest hydrolysis showed the α-methyl substituted esters. Even activation energies and PZ factors were found to be almost equal for the three types of esters. This is obviously different from the corresponding choline esters. The hydrolysis of unsubstituted and α-methyl substituted choline esters was found to proceed faster than that of β-methylcholine esters. This is also indicated by the activation energies of the choline esters, which were found to be about 12.6 kcal/mole for unsubstituted and α-methyl substituted esters, but 16.2 kcal/mole for β-methylsubstituted esters. The reason for this difference may be found in the steric effect of the β-methyl group. The radius of the oxygen atom, according to Pauling 0.66 Å, and the resulting length of the

C—O—C bridge (2.20 Å) seems to make it possible for the β-methyl group to provide a screen against an approaching hydroxyl ion, but the bigger sulphur atom, according to the same author 1.04 Å, and giving rise to a greater length of the C—S—C bridge (2.58 Å) leaves more space for the attack of the approaching hydroxyl ion at the carbonyl carbon and seems to counteract the effect of the β-methyl group. The observed influence of the substituents of the acid residue upon the rate of hydrolysis is greater than the effect of the substituents of the thiol residue. The reaction rate decreases with the length of the carbon chain, methyl and ethyl showing nearly the same rate, and then the reaction rate falling to about 50 % of the value found for methyl, when the substituents are propyl or butyl; phenyl and *iso*propyl substituted esters showing a still smaller rate of reaction. These observations may be explained by the combined steric (*e.g.*, *iso*propyl) and inductive (*e.g.*, phenyl) effects of the substituents upon the attacked carbonyl carbon.

The observed deviations at lower pH, especially with the β-methyl-thiocholine esters, from pseudo first order kinetics in experiments with the automatic recording titrator seem to depend upon secondary reactions, probably by the products of hydrolysis. This is indicated by the unknown spots in the paper chromatograms and ionophoretograms of the hydrolysates. A possible reaction would be

$$HS-\underset{\displaystyle CH_3}{\underset{|}{CH}}-CH_2-N^+(CH_3)_3 \rightarrow CH_3-S-\underset{\displaystyle CH_3}{\underset{|}{CH}}-CH_2N(CH_3)_2 + H^+ \rightleftharpoons$$

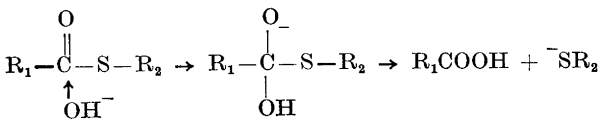
$$\rightleftharpoons CH_3-S-\underset{\displaystyle CH_3}{\underset{|}{CH}}-\overset{\displaystyle H}{\overset{|}{CH_2N^+}}(CH_3)_2$$

The pK_a of the latter compound is probably more than 9, which would offer an explanation of the smaller amount of alkali used by β-methyl-thiocholine esters for complete hydrolysis at pH 9.

The found activation energies for choline esters and thiocholine esters are near the activation energies found by other workers [1,3] for other thioesters. Together with the found pseudo first order hydrolysis and the found products of hydrolysis this indicates, that the mechanism of the alkaline hydrolysis of the studied esters may be described by the Lowry mechanism for ordinary ester hydrolysis, *viz.*

$$R_1-\underset{\displaystyle \uparrow OH^-}{\overset{\displaystyle O}{\overset{\displaystyle \|}{C}}}-\overset{\displaystyle \downarrow H_2O}{S}-R_2 \rightarrow R_1-\underset{\displaystyle OH}{\overset{\displaystyle O^-H}{\overset{|}{C}}}-S^+-R_2 + OH^- \rightarrow R_1COOH + HSR_2 \qquad (5)$$

However, the bond S- - -HOH should be weaker[21] than O- - -HOH, so perhaps solvation is less influential for thioesters. In this case the mechanism of alkaline hydrolysis could perhaps be described by



(6)

Such a mechanism would make it still easier to understand the nonexistent steric effect of the β-methyl group in the thiol.

The increasing value for "k_2^o" observed in rate reactions in phosphate buffer solutions may indicate catalysis by phosphate ions. In earlier studies on choline esters, performed with the same methods and in the same medium by Larsson [22], this effect was not observed. However, there is a factor of about two between the rate constants for choline esters found by Larsson and those found now with the automatic titrator, which supports the possibility of a catalysis by phosphate ions. In that case the catalytic activity comes from the ions $H_2PO_4^-$ and HPO_4^{2-} and their effect seems to be greater upon thioesters than upon oxygen esters. There is also the possibility of explaining the increasing "k_2^o" values by assuming two competitive reactions, each with a reaction rate proportional to ester concentration. These reactions could for instance be hydrolysis according to eqns. (5) and (6) described earlier, where reaction (6) would prevail at higher pH-values.

My sincere thanks are due to the Director of the Research Institute of National Defence, Dept 1, Professor G. Ljunggren, to Professor A. Tiselius, Director of the Institute of Biochemistry, University of Uppsala, for their kind interest in this work, and to Professor A. Fredga, Director of the Institute of Organic Chemistry, University of Uppsala, for instructive discussions.

The Oxidation of Glycosides

VI. Oxidation of Methyl 4,6-*O*-Ethylidene-β-D-glucopyranoside with Chromium Trioxide

ANDERS ASSARSSON and OLOF THEANDER

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan and Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

Methyl 4,6-*O*-ethylidene-β-D-glucopyranoside was oxidised with chromium trioxide in acetone and, after removal of the ethylidene groups, oxo-glucosides were isolated; the principal one being the 3-oxo-glucoside. Fractionation on a charcoal column yielded, *inter alia*, methyl 2-oxo-glucoside admixed with methyl glucoside. Those components were separated by chromatography on a carbon column using an irrigant containing sodium hydrogen sulphite. Small amounts of D-arabinose, D-erythrose and D-erythrono-γ-lactone were also isolated. The oxidation of methyl β-D-glucopyranoside was studied in an analogous experiment.

Amongst the products formed on the oxidation of the anomers of methyl 6-*O*-trityl-glucopyranosides with chromium trioxide are the corresponding 2-oxo-, 3-oxo- and 4-oxo-derivatives (Part V[1]). The present investigation was undertaken to simplify the preparation of methyl β-D-2-oxo-glucopyranoside and of methyl β-D-3-oxo-glucopyranoside. The hydroxyl group at C-4 and that at C-6 were protected by an ethylidene group prior to the oxidation. After removal of the ethylidene groups the mixtures of neutral oxidation products were fractionated on carbon columns and subfractionated by chromatography and by electrophoresis on thick filter papers. When 1.5 moles of oxidant per mole of sugar were used, the yield of 3-oxo-glucoside (5.4 %) was only slightly higher than that obtained (4.7 %) under similar conditions from methyl 6-*O*-trityl-β-D-glucopyranoside. The ethylidene derivative is prepared more easily than is the trityl derivative and the former gives a less complex mixture of products (in the present work no 4-oxo- or 6-oxo-glucosides were detected). The present procedure is then to be preferred to that used earlier. The yield of oxo-glucosides was not increased when a higher proportion of oxidant to sugar was used.

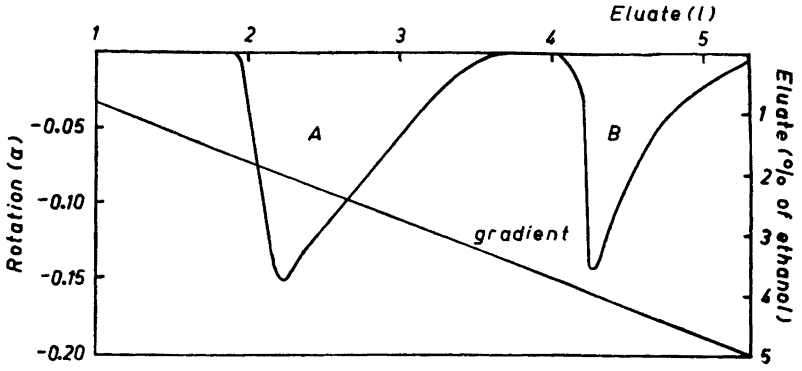

Fig. 1. Separation of methyl β-D-2-oxo-glucopyranoside (A) from methyl β-D-glucopyranoside on a carbon-Celite column using an irrigant containing sodium hydrogen sulphite.

The 2-oxo-glucoside was eluted from the carbon column together with the methyl glucoside. These two substances are easily separated by paper electrophoresis in sulphite buffer [3]. Barker *et al.*[4] used an irrigant containing borate for the carbon column chromatography of some sugars which were difficult to separate by ordinary carbon column chromatography, but which had different electrophoretic mobilities in borate buffer. In the present work the analogous use of sodium hydrogen sulphite in the irrigant resulted in the separation of methyl glucoside and methyl 2-oxo-glucoside (1.2 %) (see Fig. 1).

Many other components were chromatographically indicated to be present and the principal ones were isolated. They included D-glucose (principally from the hydrolysis of part of the methyl glucoside), D-arabinose (0.05 %), D-erythrose (0.13 %) and D-erythrono-γ-lactone (0.20 %) and a trace of a compound chromatographically indistinguishable from ribulose. Small amounts of a neutral and reducing compound (A) were isolated, which gave colour reactions with *p*-anisidine hydrogen chloride and with resorcinol-hydrochloric acid. It had a high electrophoretic mobility in hydrogen sulphite and on reduction with borohydride it gave mainly erythritol.

Another compound (B) giving a characteristic red-violet coloration with resorcinol was isolated. Some properties are given in the experimental part. A compound having similar properties was formed when methyl β-glucoside or its 6-*O*-trityl ether [1,2] was oxidised.

The arabinose and erythrose may have been formed *via* oxoaldonic acids. Whistler *et al.* recently showed that D-erythrono-γ-lactone was formed in relatively large amount when starch was oxidised with hypochlorite [5,6].

Methyl-β-glucoside on oxidation by dichromate in the presence of oxalic acid, yielded 6-oxo- and 3-oxo-glucosides as the principal neutral products [2]. In the present work methyl-β-glucopyranoside was oxidised with trioxide using conditions similar to those above and the following substances were isolated: arabinose (0.1 %), glucose (0.25 %) and the 2-oxo- (0.5 %), 3-oxo- (3.3 %), 4-oxo- (0.3 %) and 6-oxo- (1.3 %) derivatives of methyl glucoside.

Those results were unlike those obtained when an aqueous solution of chromate and oxalic acid was used as the oxidant [2]. In that case there was obtained a larger amount of aldehydo-glucoside than of keto-glucosides. The final yields will of course depend not only on the rate of formation of oxo-groups, but also upon any secondary reactions. The results obtained in the present and in an earlier investigation [1] showed that the 3-oxo-glucoside is the predominating neutral product obtained on oxidation with chromium trioxide. It is unlikely that under the oxidation conditions used one oxo-compound could be transformed into another by enolisation. No chromatographically detectable formation of 3-oxo-glucoside from 2-oxo-glucoside took place during the treatment of the oxidation products prior to fractionation. Recrystallisation of 2-oxo-glucoside from hot *n*-propanol, however, resulted in the formation of 3-oxo-glucoside and of unidentified compounds.

A small amount of methyl glucoside and, in a separate experiment, of methyl 4,6-ethylidene glucoside were oxidised with *t*.-butyl chromate in a mixture of acetone and *t*.-butanol. The yields of oxo-glucosides were lower, and that of the acids higher, than when chromium trioxide in acetone was used as oxidant.

EXPERIMENTAL

Melting points are corrected. All distillations were carried out under reduced pressure (bath temperature $<40°$) or by lyophilisation. Papers and spray-reagents used in the paper chromatography and electrophoresis were as given in Part. V[1].

Irrigants and buffers used:

A. Ethyl acetate-acetic acid-water, 3:1:3 (the upper phase).
B. Butanol-pyridine-water, 3:1:1.5.
C. Hydrogen sulphite buffer pH 4.7, 0.1 M[3].
D. Borate buffer pH 10.0, 0.1 M.

Oxidation of methyl 4,6-*O*-ethylidene-β-D-glucopyranoside with chromium trioxide and fractionation of the product

The methyl 4,6-*O*-ethylidene-β-D-glucopyranoside was made by a slight modification of the method of Helferich and Appel [7].

The oxidation and fractionation procedures were essentially as described in Part V[1] and accordingly only an abbreviated description is given. The percentage yields quoted are based upon the original weight of the starting-material calculated as methyl-β-glucoside.

Methyl 4,6-ethylidene-glucoside (80.0 g) was oxidised by boiling it under reflux, for 30 min, with acetone (4 l) and chromium trioxide (55.0 g). The brown chromium oxides were filtered off from the oxidation mixture and boiled with successive volumes of acetone with intermediate filtrations. During the evaporation of the combined filtrate, crystals of pure starting-material (31.0 g, m. p. 187—188°) separated and were filtered off. To the filtrate there were added ethanol (100 ml) and dilute sulphuric acid to give an 0.3 N solution (600 ml). The solution was kept at 100° for 30 min and then extracted with chloroform. The acidity was reduced to pH 5 by the addition of barium carbonate, the mixture being stirred and the temperature kept below 10°. After filtration, the solution was deionised and the solvent distilled off. The product, a light-yellow syrup (20.2 g), was fractionated on a carbon-Celite column (48 × 6 cm) using the linear-gradient elution technique (ethanol: 0—15 %, 10 l and 50 % 4 l). The following main fractions were obtained:

Fraction I (1.8 g) contained glucose and smaller amounts of other components. The material was sub-fractionated by paper chromatography and electrophoresis on thick filter papers, and the following components were obtained: D-erythrono-γ-lactone (0.20 %), D-arabinose (0.05 %), D-ribulose (<0.02 %), D-erythrose (0.13 %) and an unidentified compound A (0.1 %). The first three were chromatographically and electrophoretically indistinguishable from reference substances. The compound A was neutral and was rapidly oxidised by the alkaline silver reagent and also gave a yellow coloration with *p*-anisidine hydrogen chloride and a faint pink coloration with resorcinol-hydrochloric acid. Compound A had: $R_{Glucose}$ = 2.03 (irrigant A), $R_{Glucose}$ = 1.28 (irrigantB), M_V [3] (buffer C at 50°) = 1.70 and M_G (buffer D) = 0.66. On reduction with borohydride it gave erythritol which had m. p. and mixed m. p. 119—120°.

D-*Erythrose*. The amorphous sugar had $[\alpha]_D^{22}$ −14° (*c*, 2.2 in water), $R_{Glucose}$ = 2.35 (irrigant A), M_V = 0.18 (Buffer C at 50°) and M_G = 0.80 (buffer D). A sample of the sugar was reduced with borohydride. After deionisation and recrystallisation of the product from ethanol it had m. p. 120—120.5°, not depressed on admixture with erythritol. It was paper chromatographically and electrophoretically indistinguishable from erythritol. It was acetylated in the usual way and the product, after recrystallisation from ethanol, had m. p. 84—85°, not depressed on admixture with erythritol tetra-acetate.

D-*Arabinose*. The specific rotation of the amorphous sugar was $[\alpha]_D^{22}$ −100 (*c*, 0.8 in water).

D-*Erythrono-γ-lactone*. It was recrystallised from ethyl acetate and had m. p. 104—105° (*Lit.*[5] 104—105°) and $[\alpha]_D^{21}$ −74° (*c*, ? in water), *Lit.*[5] −72). The equivalent weight by titration was 114 (calc. 116).

Fraction II (11.5 g) consisted mainly of methyl β-glucoside and methyl 2-oxo-glucoside. After recrystallisation from aqueous ethanol, pure methyl glucoside (8.7 g) was obtained. The components in the mother liquor were fractionated on a carbon-Celite column (40 × 3 cm) using aqueous ethanol (0—10 %, 4 l and 50 %, 2 l) to remove both traces of glucose and of products which had been formed in small amounts from the labile 2-oxo-glucoside during the crystallisation of the methyl glucoside. A mixture (2.15 g) of methyl 2-oxo-glucoside and methyl glucoside was eluted with *ca.* 4 % aqueous ethanol. It was refractionated on the same column which had been thoroughly washed with 0.1 M sodium hydrogen sulphite. The column was irrigated with 0—5 % ethanol (5 l) using 0.1 M aqueous sodium hydrogen sulphite solution instead of water. The fractionation was followed polarimetrically (2 dm tube, Fig. 1) and by electrophoretic examination using buffer D. The methyl 2-oxo-glucoside was completely separated from the methyl glucoside and, after deionisation and evaporation of the solutions, the two components (0.85 g and 0.96 g, respectively) were obtained chromatographically and electrophoretically pure. Part of the 2-oxo-glucoside crystallised (for data *cf.* part V[1]). Paper chromatographic examination of the mother liquor showed that some rearrangement had taken place during the crystallisation.

Fraction III (4.0 g) consisted mainly of 3-oxo-glucoside which crystallised on removal of the solvent. It was recrystallised from *n*-propanol and had m. p. 130—131°, $[\alpha]_D^3$ −63 (*c*, 2 in water), The yield of this material plus that recovered from the mother liquors was 5.3 %.

Fraction IV (1.6 g) contained an unidentified neutral compound (B), isolated in amorphous state (0.2 %). It gave a distinctive red-violet coloration with resorcinol-hydrochloric acid, a yellow coloration with *p*-anisidine hydrogen chloride and was acid sensitive but alkali-stable. It had $R_{Glucose}$ = 2.98 (irrigant A) and 1.48 (irrigant B), M_V = 0 (Buffer C) and M_G = 0.42 (buffer D). It had OCH_3 *ca.* 14 % and $[\alpha]_D^{21}$ −29° (*c*, 1.4 in water).

The fraction also contained other components most of which could be chromatographically correlated to substances obtained in the previous fractions, while others were probably condensation products formed from the oxo-glucosides.

Oxidation of methyl β-D-glucopyranoside with chromium trioxide and fractionation of the product

The oxidation and fractionation procedures were essentially as described previously, but the reduction of the chromium compounds in aqueous solution by the ethanol was carried out at room temperature and after slight acidification with sulphuric acid. Methyl β-glucoside (20.2 g) was oxidised with chromium trioxide (15.6 g) in acetone (1.20 l) and the product was fractionated on a carbon-Celite column. After sub-fractionation by chromatography and electrophoresis on thick filter paper the following substances were obtained: arabinose (0.1 %), glucose (0.25 %) and the 2-oxo- (0.5 %), 3-oxo- (3.3 %), 4-oxo- (0.3 %) and 6-oxo- (1.3 %) derivatives of methyl β-glucoside. The substance B (see earlier) was obtained in 0.15 % yield.
