Determination of Free Protein Mobilities by Paper Electrophoresis with Evaporation *

I. Evaluation of the Buffer Flow Due to Evaporation and Electroosmosis

KURT SCHILLING and HEINZ WALDMANN-MEYER

From the Biological Institute, Carlsberg Foundation, Copenhagen, Denmark

A procedure was devised for the determination of electrophoretic mobilities by means of open-strip paper electrophoresis.

An equation covering evaporation and electroosmosis was derived. The fundamental premise is the constancy of the electric current during the experiment. Evaporation and electroosmosis are represented by the parameters f and e, respectively. The determination of these parameters may be omitted in the calculation of electrophoretic mobilities, since a correction for both evaporation and electroosmosis is also obtained by running a single aliquot of an uncharged substance parallel to the sample.

The equation was tested in an experimental series where current and concentration were systematically varied. It was thus confirmed that the migration takes place in a zone of increasing, but uniform, salt concentration. This was further substantiated by independent procedures. The migration of dextran spots placed evenly along the strip was found to be in agreement with the theoretical basis. Straight lines were invariably obtained when the migration distance was plotted against the position of the application points. When the migration distance was first divided by time and voltage, all the lines intersected the ordinate at the same point, and the slopes were proportional to the electric current, thus demonstrating the constancy of the parameters f and e.

Problems arising from the presence of evaporation in paper electrophoretic mobility determinations are discussed. It is emphasized that a satisfactory method is obtained by using constant electric current, instead of the constant voltage hitherto considered essential.

Since the appearance in 1937 of the first report on zone electrophoresis [1] numerous technical modifications, aiming at the achievement of greater reproducibility and precision, have been introduced by various authors in order

* Presented at the Meeting of the Kemisk Forening, Copenhagen, March 25th, 1958.

to raise the reliability of the method to the level attained by free electrophoresis.

Undoubtedly this object has been accomplished as far as fractionation and clinical analysis of proteins are concerned, where zone electrophoresis, especially on paper strips, has even proved superior in several aspects to the classical Tiselius technique. However, serious difficulties are encountered in determinations of the electrophoretic mobility since interfering factors unknown from the Tiselius method, *i. e.* the electroosmotic flow, the evaporation of the buffer due to heat development and the influence of the carrier medium, have to be taken into account.

On the other hand, paper electrophoresis offers so many advantages, one of them being the minimal amount of substance required, that it may be considered a matter of great interest to arrive at a satisfactory method for the determination of mobilities and isoelectric points by means of this technique.

The mobility obtained in free solution at a defined pH and temperature, although in some degree dependent on the type and concentration of the buffer used, may be considered a characteristic property of a protein and is referred to as *free mobility* in the following. In order to have any practical value, a method using paper electrophoresis would have to yield the same free mobilities.

Previous approaches are scarce and seem in several respects open to criticism. In the present study the effects of the interfering factors have been evaluated quantitatively and a procedure developed yielding results identical with those obtained by free electrophoresis. In the first part of this investigation the buffer flow caused by the combined effects of evaporation and electroosmosis has been studied, and it is shown that, when a constant current is used throughout the experiment, a simple expression can be derived for the mobility of a migrating substance.

MATERIALS AND METHODS

Apparatus. Horizontal open strip electrophoresis sets with buffer cells of about 1 000 ml capacity were employed, each holding two paper strips. The height of the buffer levels was equalized by means of leveling glass tubes prior to equilibration of the strip. The paper rested upon nylon threads between two 29 × 8.5 cm glass plates, kept 6 mm apart and tightened at the edges by plastic borders which held the nylon threads. At all times the strip was in strictly horizontal position. The length of the vertical paper section to the buffer surface was 4.5 cm. The voltage gradient over the paper was measured by secondary platinum electrodes fixed to two of the nylon threads at 15.0 cm distance from each other. The power supply was a valve rectifier in conjunction with an adjustable electronic current stabilizer, giving a constancy of about 0.1 %.

Solutions. Sodium acetate buffers of pH 5.10 and of 0.045 and 0.09 ionic strength.

4 % solutions of dextran (Pharmacia, Uppsala) in the buffer, prepared by gentle heating.

Procedure. Two 8 × 39 cm strips of Munktell paper No. 20/150 were used per cell unit. The strips were immersed in buffer for a few seconds and blotted on crepe-paper before being placed into the apparatus. After a minimum of 3 h equilibration, six 10 μl spots of dextran solution were applied at 3 cm distance from each other measured along the longitudinal axis of the paper. In order to avoid interference, they were placed alternately to the right and the left at 2.5 cm distance from the paper edge.

The current was switched on immediately after the application of the solution to the paper, and the experiments were run for 17 to 20 h at room temperature ranging from 20.8 to 21.5°C. Current and voltage were recorded at the beginning and conclusion of the experiment. Corrections for voltmeter resistance were introduced and a correction of 0.8 V (0.053 V · cm^{-1}), due to the polarization of the secondary platinum electrodes was added to all readings. The polarization was estimated by measuring the voltage between 3 platinum electrodes A, B, and C on the paper with constant current. The difference between the voltage readings AB + BC and AC would be equal to the polarization potential. The same value was obtained from rapid reversal of the electrode polarization.

After conclusion of the experiment, the vertical paper ends were cut off, and the strips dried horizontally in the air at room temperature, after which they were placed for 30 min in a hot air oven at 110°C and then stained for 25 min with a 1 % bromo phenolblue (Merck) solution in 95 % ethanol containing about 10 % (w/v) $HgCl_2$. Since the dextran spots appeared most clearly during the first few minutes of staining, their centers were marked with a pencil during the process. Finally, the strips were washed several times with methanol until the appearance of a white background, and the migration distance measured.

THEORY

The equations derived below are based on a few simple assumptions which, as well as the conclusions drawn from them, have been experimentally tested, as described in the next paragraph.

The symbols used will be defined below in connection with the explanations. Distances and velocities are considered positive in the direction anode to cathode, according to the usual convention.

It is assumed that the migration velocity ds/dt is made up of three separate components in the following way:

$$\frac{ds}{dt} = m \cdot V + e \cdot V + (a - s)\ \mathrm{L} \qquad \text{(I,1)}$$

The first term gives the migration rate due to the influence of the electric field on the migrating particle and is proportional to the potential gradient V. It appears as $m \cdot V$ in equation I,1. The factor m used for the mobility differs from the free mobility u on account of the retarding effects of the carrier medium. This problem will be treated in the subsequent communication [2].

The two other terms express the migration velocity caused by the buffer flow. $e \cdot V$ represents the electroosmotic flow, which too is approximately proportional to V. The last term of the equation gives the migration velocity due to evaporation. Assuming uniform evaporation along the strip and that the capillary forces keep the amount of solution in the paper constant, this component of the migration velocity will be proportional to the distance

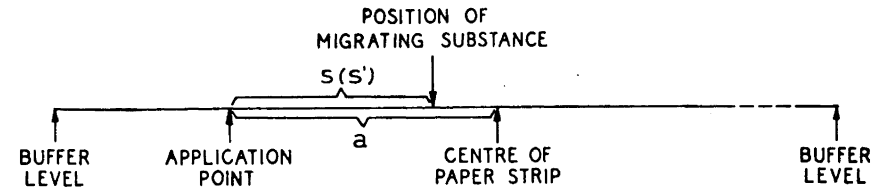

Fig. 1. Schematic presentation of the experimental arrangement.

between the sample and the center of the paper strip, as expressed by $(a—s)$, where a is the distance from the point of application to the paper center and s the distance of migration (Fig. 1).

L denotes the intensity of evaporation and may be assumed to be proportional to the wattage dissipation $(i \cdot V)$ in the paper:

$$L = f \cdot i \cdot V \tag{I,2}$$

The increase of the salt concentration caused by the evaporation from the strip produces a corresponding increase of the buffer conductivity. Working with constant current this results in a steadily decreasing voltage V. To obtain the correct time function we again consider Fig. 1. s' now represents the distance which the buffer has migrated by evaporation alone. The concentration has increased by the factor $\frac{a}{a—s'}$, and, assuming that the activity coefficients remain practically constant, as in the case of monovalent ions in the concentration range usual in electrophoresis, the voltage has dropped correspondingly from its initial value V_0:

$$V = V_0 \frac{a—s'}{a} \tag{I,3}$$

The migration velocity ds'/dt of the buffer as caused by evaporation will, in analogy to the third term of eqn. 1, be determined by

$$\frac{ds'}{dt} = (a—s')\ L \tag{I,4}$$

and substituting eqns. 2 and 3 we obtain

$$\frac{ds'}{dt} = fiV_0 \frac{(a—s')^2}{a} \tag{I,5}$$

Integration and combination with eqns. 2 and 3 result in

$$\frac{a}{a—s'} = 1 + fiV_0t \tag{I,6}$$

$$V = \frac{V_0}{1 + fiV_0t} \tag{I,7}$$

$$L = \frac{fiV_0}{1 + fiV_0t} \tag{I,8}$$

Substituting eqns. 7 and 8 in eqn. 1 we arrive at

$$\frac{ds}{dt} = \frac{m \cdot V_0}{1 + fiV_0t} + \frac{eV_0}{1 + fiV_0t} + \frac{(a—s)fiV_0}{1 + fiV_0t} \tag{I,9}$$

which after integration gives

$$s = (m+e+afi)\ \frac{V_0 t}{1 + fiV_0 t} \qquad \text{(I,10)}$$

A more convenient expression is obtained by substituting eqn. 7, resulting in

$$s = (m+e+afi)V_t t \qquad \text{(I,11)}$$

where the voltage V_t at the time t has to be used in the calculation.

When an uncharged substance such as dextran is used, eqn. 11 reduces to

$$s_d = (e+afi)V_t t \qquad \text{(I,12)}$$

When protein and dextran are run under identical conditions and applied at the same distance from the center, the difference in migration distance is given by

$$s_p - s_d = mV_t t \qquad \text{(I,13)}$$

obtained by subtracting eqn. 12 from eqn. 11.

It appears from this fundamental equation that by running an uncharged substance parallel to the protein, not only is it possible to correct for electroosmosis but also for the more complicated effects of evaporation. The voltage referred to in eqn. 13 is that measured at the end of the experiment, and a necessary condition for the validity of this equation is the use of a constant current during the whole run.

Once the parameters e and f have been determined, it should be possible to obtain mobility values corrected for evaporation and electroosmosis from eqn. 11, without the use of an uncharged indicator substance. However, since e and f may vary with the experimental conditions, we have preferred to apply dextran spots in each mobility determination, and to use eqn. 13 in the calculations.

EXPERIMENTAL VERIFICATION

The validity of the propounded equations was tested in a number of experiments in sodium acetate buffer of pH 5.1. To visualize the movement of the buffer solution, dextran spots were placed at various positions. In chromatographic experiments with the same buffer and the same paper [3] dextran yielded a R_F-value of approximately 1.0. It may thus be concluded that dextran follows the surrounding fluid and that its displacement closely reflects the movement of the buffer solution. This is further substantiated by voltage measurements described below. The slight electrophoretic mobility of dextran can be neglected, since it amounts to only $-0.16 \times 10^{-5} \cdot \text{cm}^2 \cdot \text{V}^{-1} \cdot \text{sec}^{-1}$ in pH 8.8 barbital buffer [4] and may be expected to be even less at pH 5.1.

When the migration distance of the dextran spots was plotted as function of their starting positions, straight lines were obtained (Fig. 4). Similar experiments have been performed by other authors [5,6,12] and they prove that the salt distribution remains uniform within the dextran zone. This was controlled in

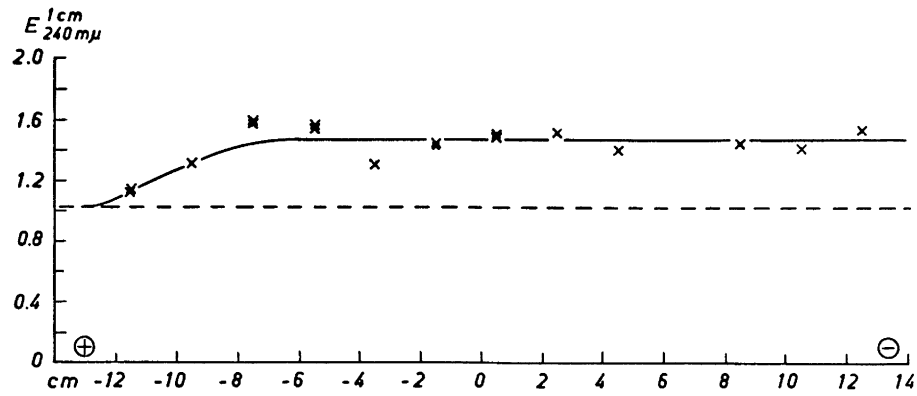

Fig. 2. The concentration increase caused by evaporation. The dotted line represents the original concentration. Determinations by U.V. absorption. pH 8.8 barbital buffer of $\Gamma/2$ 0.08 employed.

an experiment with 5 secondary platinum electrodes placed at various positions along the paper. The conductivity was measured at several time intervals. It rose twofold during the run, but was at any time uniform along the strip. Moreover, it was found by weighing that the amount of buffer in the paper — 27.5 μl/cm^2 — did not change during the experiment.

In an experiment with pH 8.6 barbital buffer, the paper strip was cut in sections perpendicular to the electric field after the current had passed for 19 h. The paper sections were eluted and the barbital concentration determined by measuring the extinction at 240 mμ. The results are shown in Fig. 2, and it is evident that there is a broad zone of increased, but uniform, concentration.

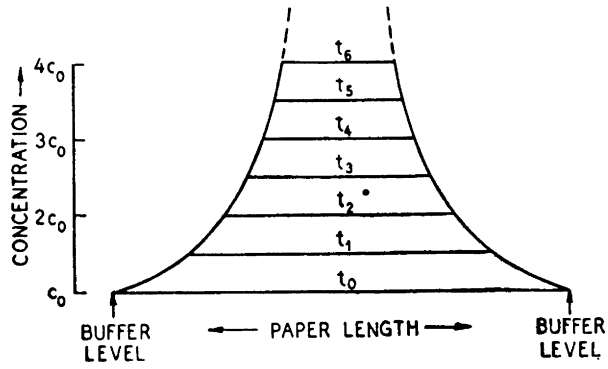

Fig. 3. Schematic presentation of the uniform concentration zone according to theory showing the shrinkage with time and the concentration increase owing to evaporation. The additional effect of electroosmosis will produce a certain skewness varying with the experimental conditions. The t values recorded are arbitrary.

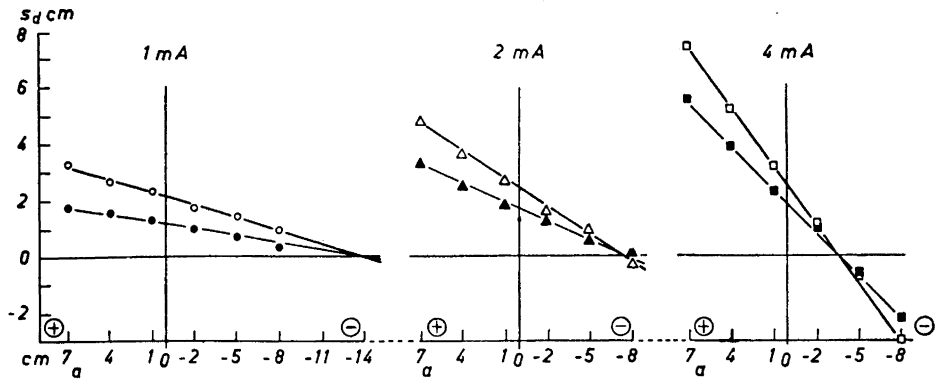

Fig. 4. Dextran migration with different currents and buffer concentrations. Migration distance (s_d) plotted against the position of the application points (a). The scale of the abscissa of this and the following figure reads from right to left because a is measured from application point to paper center.

2.0	△	▲
4.0	□	■

The only possible explanation of all these findings is a homogeneous evaporation from the strip together with a fluid displacement resulting in uniform buffer distribution.

It is clear that toward each end of the paper we come to a point where the concentration begins to fall off until, at the buffer level, we reach the original concentration. This is seen in Fig. 2 and schematically presented in Fig. 3, where it is shown how the zone of uniform concentration shrinks with time.

It is essential that the substance, the mobility of which is to be determined, as well as the electrodes used for voltage measurements are within this zone. This condition can easily be fulfilled. In our mobility measurements [2] performed over 16—19 h with 2.5 mA and 2—3 V/cm, the evaporation amounted to about 30 % of the buffer solution in the paper with a corresponding reduction in length of the uniform concentration zone. In recent experiments even 10 mA/strip have been routinely employed for the same length of time. By increase of the strip length still wider ranges of current and time could be used.

Uniform buffer distribution and straight lines when plotting dextran migration against starting positions will be obtained regardless of any variations in voltage and current during the experiment. Under defined conditions, however, it is possible to calculate the position of the spots at a certain time. The assumptions made in the theoretical part thus led to eqn. 12. In order to test this equation, experiments were performed at different currents and buffer concentrations. Representative results are shown in Fig. 4.

The point of intersection of the dextran lines with the abscissa gives the position on the paper termed π by Macheboeuf *et al.*[7,8] At this point the buffer displacement caused by evaporation is exactly counterbalanced by the electro-osmotic flow. It is apparent that the lines obtained at different ionic strengths but identical current intersect the abscissa at the same point. This is in accordance with eqn. 12. With $s_d = 0$, also $(e+afi)$ must be equal to zero, and therefore the corresponding application distance

$$a_0 = -\frac{e}{fi} \qquad \text{(I,14)}$$

As e and f are constants, a_0 will be constant with constant current, irrespective of variations in the other conditions. It follows further from eqn. 14 that a_0 will be inversely proportional to i. Comparison of the values of a_0 obtained from Fig. 4 at 1.0, 2.0 and 4.0 mA demonstrates that this is indeed the case.

To evaluate the slopes of the various dextran lines, we write eqn. 12 in the form

$$\frac{s_d}{V_t t} = e+afi \qquad \text{(I,12a)}$$

In Fig. 5, $\frac{s_d}{V_t t}$ *viz.* the migration distance divided by time and final voltage, is plotted against a.

As to be expected from eqn. 12a, lines from experiments with the same current coincide, and the slopes are proportional to the current applied. Further, the intersection with the ordinate is very nearly the same with all currents, indicating the constancy of e, and thereby the validity of the second term of eqn. 1.

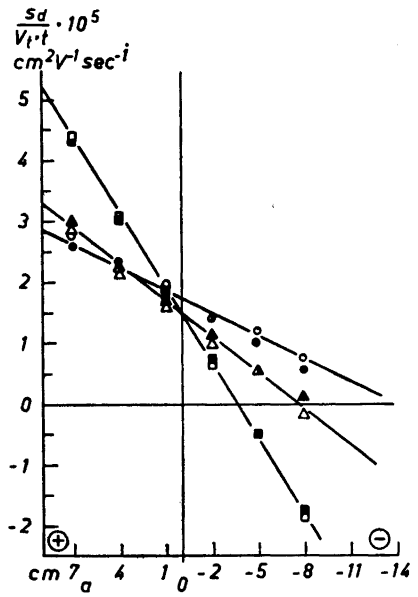

Fig. 5. Dextran migration distance divided by time and final voltage as function of the position of the application points.

The value of e can be obtained from Fig. 5. It is found to be about 1.6 $cm^2 \cdot sec^{-1} \cdot V^{-1}$ and shows the magnitude of the electroosmotic flow under the experimental conditions. The small deviations observed in these and similar experiments indicate that the electroosmotic flow is rather sensitive to minor experimental variations.

It has been claimed that the electroosmotic flow may vary along the length of the paper strip. With uniform evaporation and buffer distribution, as demonstrated by our experiments, it follows from obvious reasons that the electroosmotic flow must be uniform even if the driving force varies along the paper. The constant amount of buffer held in the paper by capillary forces behaves like a fluid in a tube with a uniform cross sectional area.

The concentration being uniform in the central part of the strip, the evaporation can be followed by the voltage decrease as well as through the slope of the dextran lines. Comparisons made according to eqn. 3 revealed a scattering of a few per cent, but on an average the agreement between V_0/V_t and the "dextran shrinkage" (ratio of distance between starting positions to distance between final positions) was excellent.

The fact that the slopes in Fig. 5 are indeed proportional to the current demonstrates that the factor f in eqn. 2 is constant with different currents. Experiments covering a 50 fold variation of the initial watt input showed only minor deviations in the value of f.

It follows from eqn. 2 that f indicates the fraction of the watt input consumed by evaporation. When the buffer has moved the distance s' (Fig. 1), an amount of water equal to $w \cdot s'$ has evaporated, w being the amount of water present in 1 cm length of paper. $585\ w \cdot s'$ cal or $585 \times 4.18\ w \cdot s'$ W sec. are used for evaporation, and the dissipation of electrical energy is determined by $\int (a - s')\ iV dt$. After substituting eqn. 6 and integrating, the ratio is found to be $585 \times 4.18\ w \cdot f$. w was determined separately by weighing in a number of experiments and found to be 0.22 g at the employed paper width of 8 cm.

Taking $f = 1.1 \times 10^{-3}$ cm/watt · sec. from the dextran experiments, we find that about 60 % of the electrical input is consumed for evaporation within wide limits of current and voltage. This value probably will vary considerably with the type of apparatus and the ambient temperature. It was estimated at about 70 % by Macheboeuf *et al.* in their experiments [8].

According to eqn. 7, the reciprocal voltage plotted against time should result in a straight line. A typical example is shown in Fig. 6 where a perfectly straight line is obtained. Only in the beginning a greater increase in $1/V$ is noted. This undoubtedly is caused by an initial temperature increase. Extrapolation of the straight line to the ordinate gives the initial conductivity value at equilibrium temperature and the difference from the measured value indicates the temperature increase which here amounts to $\Delta T = 1.75$°C. It is apparent that temperature equilibrium is established within one hour after starting. The straight line of Fig. 6 proves the time relationship expressed in eqn. 7, which was used in the derivation of the final equations.

DISCUSSION

In developing a procedure for the determination of free mobilities on paper strips, the most important requirement is to establish a quantitative relation which makes it possible to correct for the effects of evaporation. The evapora-

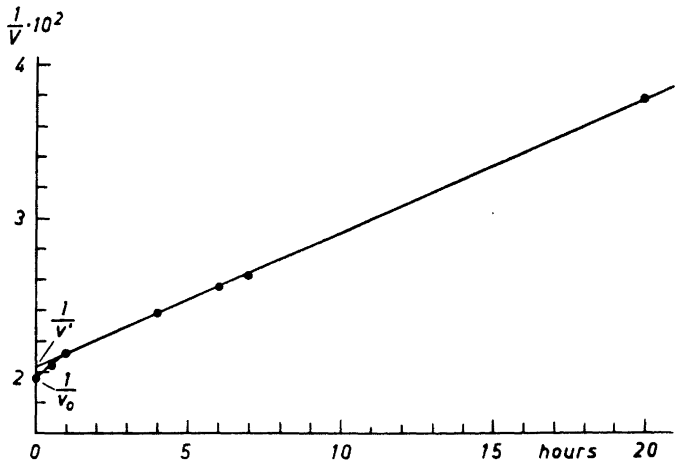

Fig. 6. Voltage decrease due to evaporation as function of time. Experiment carried out in $\Gamma/2$ 0.09 sodium acetate, pH 5.10. Current 3.0 mA; V: Voltage over 15 cm.

tion from the paper causes a continuous change in the salt concentration on the strip and thereby of the voltage gradient acting on the migrating substance, even if the voltage on the apparatus as a whole is kept constant. Furthermore, evaporation causes a flow toward the center of the paper. Since the velocity of this flow increases with the distance from the center its effect on the migration distance cannot be simply corrected for by comparison with that of an uncharged substance, because specimens differing in their migration velocities will be under the influence of different flow rates. Finally, the intensity of evaporation will change during the run because of variations in voltage and current.

In fact, most authors are of the opinion that a reliable method can only be worked out by suppressing evaporation. Low temperatures and very low currents or the addition of substances able to reduce the vapor pressure, such as glycerol [9] have been used to this effect. Even thus it is difficult to eliminate the evaporation to a degree where it may be fully neglected. The closed strip apparatus operated at low temperatures [4], in which the paper is compressed between glass plates and, in most cases, made air-tight by chemical seals, seems to be the best way to avoid distillation from the paper surface.

On the other hand, the open strip technique with free evaporation is claimed to give a much clearer resolution of the protein pattern [11] aside from preventing contact of the specimens with glass plates or alien substances used as seals, which might modify their migration rates. Also in experiments which employ the tracer technique, a contact with the enclosing plates should preferably be avoided. Any method which makes it possible to determine free mobilities using an open strip in the presence of evaporation would therefore be of great value.

An attempt to correct for the effects of evaporation was made by Woods and Gillespie [6] who, although working with a closed strip apparatus, found evaporation to be present in their experiments. The correction applied, however, is empirical and does not appear convincing. Moreover, as shown in the following communication [2], their mobility value for albumin in pH 8.6 barbital buffer is about 25 % lower than the corresponding free mobility.

An interesting approach to the problem of mobility determination with open paper strips was made by Macheboeuf *et al.*[7,8] This method even takes advantage of evaporation for the calculation of free mobility values. It had previously been pointed out by Durrum [10] that in the presence of evaporation a substance will finally reach an equilibrium position where the migration in the electric field is counterbalanced by the buffer flow caused by evaporation and electroosmosis. A necessary condition is that the evaporation remains constant with time. The time for the attainment of this equilibrium position is theoretically infinite and, as the duration of the experiment is limited on account of the increasing buffer concentration, satisfactory results cannot always be obtained. In Macheboeuf's method the substance is placed as a diagonal streak across the paper and the point is noted where it does not move to either side, this being the equilibrium position which can be discerned after a few hours. By applying an uncharged substance on the same paper, correction can be made for the effect of electroosmosis. The equilibrium position is, of course, dependent on the intensity of evaporation and, in order to obtain the electrophoretic mobility, a reference substance of known mobility is required.

In their calculations Macheboeuf *et al.* postulate a constant evaporation as well as a constant voltage gradient. On account of the increasing buffer concentration on the paper these two assumptions are incompatible. The theoretical basis of this approach is therefore more complex than apparent from Macheboeuf's equations. The equilibrium position will thus generally vary in the course of an experiment. Although the conditions are not defined as a function of time, in the determination of mobility the deviation will cancel out due to the use of a reference substance and correct values should be obtained. It should be pointed out that to ensure a uniform voltage gradient, also in Macheboeuf's method, all readings must be performed within the central zone of uniform concentration shown in Fig. 3.

In these, as in all other previous procedures aiming at the determination of free mobilities, a constant voltage was applied, and it seems generally accepted that a reliable determination of electrophoretic mobilities can only be achieved by the maintenance of a constant voltage throughout the experiment. It must be emphasized that this is not the case. The only necessary condition is a knowledge of the voltage as a function of time. Moreover, the maintenance of a constant voltage in experiments with evaporation presents difficulties of practical as well as of theoretical nature. In spite of a constant voltage between the electrode vessels, the concentration changes along the paper result in a continuous decrease of the voltage gradient in the central part where the measurements are performed. Even if this voltage should be kept constant by a suitable regulation, very complicated functions would determine the migration of a substance. A thorough calculation with experimental verification has as yet not appeared.

In the present paper it is demonstrated that all the described difficulties can be overcome by application of a constant current during the whole experiment. This has previously been recommended in order to minimize the influence of the temperature on the migration distance [11]. The application of a constant current in the present method differs fundamentally from this, since its object is the determination of the free mobility of the migrating substance. Under these conditions it has been possible to arrive at a simple expression for the mobility, taking into account the effects of both evaporation and electroosmosis.

In addition to the effect of the buffer flow thus established, the migration velocity of a protein depends on the properties of the carrier medium. It should, however, be stressed that the equations derived above for a medium where retarding factors do not exist, are still valid when these factors come into play as far as dextran is concerned. The influence of the carrier medium as well as of the temperature increase and change in ionic strength will be evaluated in the subsequent communication [2], together with the actual determination of serum protein mobilities.

Acknowledgments. We wish to thank Dr. Tage Astrup of this Institute for his interest and stimulating discussion. This work was supported by grants from the *Teknisk-Kemisk Fond* and the *Rask-Ørsted Foundation*, to whom we are indebted.

Determination of Free Protein Mobilities by Paper Electrophoresis with Evaporation *

II. Evaluation of Temperature and Concentration Increases, Influence of the Carrier Medium, and Measurement of Serum Protein Mobilities

HEINZ WALDMANN-MEYER and KURT SCHILLING

The Biological Institute, Carlsberg Foundation, Copenhagen, Denmark

After the determination of the joint effect of evaporation and electroosmosis by means of an uncharged substance had been established, the final equation for the calculation of free solution mobilities was obtained by introduction of correction factors for the influence of the carrier medium.

A direct quantitation of *protein adsorption* was achieved on basis of the actual electrophoretic experiment. The presence of evaporation is indispensable for this evaluation. This emphasizes the value of evaporation for accurate mobility determinations, in contrast to hitherto prevailing opinions. Differing from γ-globulin, serumalbumin was not adsorbed in the media employed.

The *path-length increase* owing to the paper structure was calculated by means of the paper/buffer conductivity ratio and found to be a paper constant. The final, uniform *salt concentration* of the migration zone was evaluated by the migration of an uncharged substance or by the voltage drop. The *temperature increase* on the strip was determined through conductivity measurements at several time intervals and appears as a function of the watt input.

42 samples of human serumalbumin and γ-globulin were run in sodium acetate and barbital buffers of 0.10 ionic strength from pH 4.0 to 8.8, and the free mobilities calculated according to the derived equation. The results were converted to their values at 1°C and compared to moving-boundary data. Absolute agreement between our values and the free electrophoresis mobilities is found.

In view of the advantages inherent to paper electrophoresis, the development of the open-strip technique into an accurate method for mobility determinations may open new perspectives for enzymological, clinical and interaction studies.

* Presented at the Meeting of the Kemisk Forening, Copenhagen, March 25th, 1958.

In spite of an immense amount of work on paper electrophoresis, very few attempts have been made to adapt this method for the estimation of protein mobilities. Presumably this is due to the prevailing opinion that any such attempt has to fail, because of the complicated effects produced by evaporation. Even when evaporation was suppressed, adsorption of the proteins to the filter paper seemed to prevent mobility determinations.

In the preceding paper [1] it was shown that the buffer flow caused by evaporation and electroosmosis can be calculated and the results experimentally confirmed. It is one of the objects of the present communication to describe how the temperature increase and the changes in the medium, inherent to the open-strip technique with free evaporation, can be evaluated and taken into account in mobility determinations.

However, the sole presence of a carrier medium produces some complications which have to be dealt with in the first instance. The migration rate of a given substance, moving on a semisolid support such as moist filter paper, would obviously differ from that found in free solution even if all other conditions could be kept identical. The rate must be lower due to the retarding effect connected with the intricate geometrical structure of such a supporting medium, and to a possible adsorption of the proteins to the carrier medium.

The results presented here demonstrate that both the geometrical factor and the adsorption can be evaluated, and that mobilities identical with those obtained in free solution — subsequently called *free mobilities* — can be calculated when corrections are introduced for these effects.

MATERIALS AND METHODS

Apparatus. As described [1].

Buffers. Sodium acetate buffers of $\Gamma/2$ 0.08 were used over the whole acid range in order to maintain a constant buffer composition. Above pH 5.3 barbital was added to 0.025 M. Experiments carried out at pH 8.6 – 8.8 were performed in Longsworth's sodium barbital buffer of the same ionic strength.

Proteins and dextran. Normal human serum albumin and γ-globulin prepared by ethanol fractionation were obtained by kindness of Dr. Albert Hansen, Statens Serum Institut, Copenhagen. 5 % (w/v) solutions in the respective buffers were prepared at 4°C and dialyzed for 24 h in the refrigerator. γ-globulin solutions were prepared once a week. The albumin was electrophoretically homogeneous, whereas a small albumin impurity was present in the γ-globulin preparation.

4 % dextran (Pharmacia, Uppsala) solutions in the corresponding buffer were prepared by gentle heating.

Procedure. As described [1], except for specimen apposition: Two transversal lines were drawn on the paper at 7 and 8 cm from the center of the strip toward the anode and the cathode, respectively. After immersion in buffer and blotting off excess fluid from the strip, the paper was placed in the apparatus. After equilibration, albumin, γ-globulin and dextran solutions were applied, each as one individual 5 μl aliquot to both of these lines, the distance between the 3 spots on a line being 2.5 cm.

For photometric evaluation of the protein migration, the paper was kept overnight in liquid petrolatum and scanned with an EEL (Harlow, Essex) Densitometer, employing a green glass filter (OGR-1). The apex of the absorption peak was taken as the end point of protein migration.

pH Measurements. The pH values were measured potentiometrically with a glass electrode, using a calomel reference electrode (Radiometer, Copenhagen), after calibration with standard phosphate. Controls were performed immediately after the run by cutting a 1×15 cm segment from the strip, which then was thoroughly eluted with boiled

distilled water, the pH measured, and compared to the same dilution of the original buffer solution. The average value, corrected for dilution, was taken as the experimental pH. Experiments showing an increase larger than 0.30 units were discarded.

Temperature. The starting and final, as well as the maximum and minimum ambient temperatures were recorded. Experiments where the maximum variation exceeded 2.5°C were discarded. The temperature on the paper was obtained by adding to the mean ambient temperature the increase (ΔT) taken from Fig. 2.

Determination of the conductivity ratio. The *electrical resistance of the moist paper* strip was found by measuring current (D.C.) and voltage after 3 h equilibration in the apparatus, at constant temperature. The *buffer content* per cm length of paper was obtained by weighing the horizontal part of the strip immediately afterwards. After drying, the difference – corrected for buffer salt content – was divided by the specific gravity and the strip length. The *conductivity* of the free solution was determined for the same temperature by means of an alternating current bridge (Danbridge, LB-1). The conductivity ratio, q, was then calculated according to eqn. II, 8.

RESULTS

A. Adsorption

Adsorption of proteins to filter paper, manifesting itself through "protein-tailing", has been considered one of the main obstacles in the determination of mobilities by paper electrophoresis. However, this problem has apparently not always been critically analysed, since it is necessary to distinguish between the effect on migration rates of reversible adsorption on one hand, and of irreversible adsorption on the other. Depending upon medium and pH, most proteins will probably undergo both processes. The "tail" left by the irreversibly adsorbed proteins does not necessarily signify a retardation of the migration rate, and Durrum's idea [2] that it might be compared to the "unrolling of a carpet" appears to give an adequate picture of the process. Provided that a sufficient amount of substance is available for migration, as it was the case in the present experiments, the "head" will reach its final position, unhindered by a possible irreversible adsorption of excess protein, and enough material will assemble at the end point as to grant the measurement of the migration distance.

On the other hand, protein migration rates would be decreased by reversible adsorption processes occurring during paper electrophoresis. Since chemical pretreatment of the paper made in order to eliminate adsorption might interfere with the protein mobilities, we have suggested the use of chromatographic R_F-values as correction factors [3]. However, a critical reappraisal of this idea showed that, although the chromatographic R_F-values possess general interest as protein-constants, the conditions in chromatography are too different from those existing in electrophoresis to allow the use of these values for correction. In ascending chromatography 19.8 μl buffer were absorbed per cm^2 paper, which is about 30 % less than the amount of fluid present during electrophoresis under our experimental conditions. Another factor which undoubtedly plays a major role is the difference between chromatographic and electrophoretic migration rates. In chromatography [3] the proteins moved at 15 cm/h, whereas the range in the electrophoretic experiments here described varied from 0.05 to 0.30 cm/h.

It was thus fundamental to evaluate the adsorption directly from the actual paper electrophoretic experiment. The following considerations demonstrate the feasibility of such a determination. The close correspondence of the "dextran shrinkage" with the ratio of initial to final voltage between the secondary electrodes in all our electrophoretic experiments [1] demonstrates that dextran is not significantly adsorbed to filter paper in the conventional buffers. This has also been substantiated by chromatographic experiments [3,4].

On this basis, a preliminary approach to the evaluation of protein adsorption was made by submitting albumin, γ-globulin and dextran to *alternating current* (50 cycles/sec.) in an electrophoresis set. Under these conditions, the migration of both protein and dextran is caused exclusively by the buffer displacement produced by evaporation. Accordingly, for an unadsorbed protein we find that the migration distances of this specimen (s_p) and of dextran (s_d) are identical:

$$s_p = s_d \qquad \text{(II,1)}$$

When adsorption occurs, the migration of the protein is delayed and a factor ($\varrho \leqq 1$) has therefore to be introduced:

$$s_p = \varrho \; s_d \qquad \text{(II,2)}$$

Thus, in alternating current experiments, the adsorption factor (ϱ) can be determined by means of one protein-dextran pair. A number of such experiments are summarized in Table 1, where it is shown that albumin and dextran migrated invariably almost equal distances, while γ-globulin was significantly adsorbed to the filter paper. A schematic presentation of an alternating current experiment is given in Fig. 1(a).

Table 1. Protein adsorption in alternating current experiments. s_p protein migration distance; s_d dextran migration distance; adsorption factor $\varrho = s_p/s_d$; σ_m standard deviation of the mean.

Buffer	Ionic strength	pH	Albumin			γ-Globulin		
			Nr. expt.	ϱ	σ_m	Nr. expt.	ϱ	σ_m
Sodium acetate	0.025—0.30	5.20	8	1.01	0.02	8	0.95	0.02
Zinc acetate	0.025—0.30	6.00	8	1.02	0.01	6	0.95	0.04

ϱ-Values corresponding to the specific experimental conditions, however, are obtained directly from the actual *electrophoretic experiment* (*i. e. direct current*), by the use of two protein dextran pairs per strip (cf. Materials and Methods). According to eqn. 13 of the preceding communication [1], which gives an expression of the mobility of an unadsorbed substance:

$$s_p - s_d = m \; V_i t \qquad \text{(I, 13)}$$

For an adsorbed protein, the equation becomes:

$$\frac{s_p}{\varrho} - s_d = m\ V_t t \qquad \text{(II,3)}$$

As eqn. II, 3 is valid irrespective of the point of application of the samples, we find that

$$\frac{s_{p1}}{\varrho} - s_{d1} = \frac{s_{p2}}{\varrho} - s_{d2} \qquad \text{(II,4)}$$

p_1d_1 and p_2d_2 indicating the two protein-dextran pairs. This relation is schematically presented in Fig. 1(b).

In consequence,

$$\varrho = \frac{s_{p1} - s_{p2}}{s_{d1} - s_{d2}} \qquad \text{(II,5)}$$

In mobility experiments described below (Fig. 3) it was seen that albumin has a mean ϱ-value of 1.025, as compared to a value of 0.903 found for γ-globulin. It is interesting to note the close correspondence of these results with those obtained in the alternating current experiments (Table 1). The scattering observed cannot be attributed to the pH, as no clear correlation between pH and ϱ is found. On the other hand, later experiments indicate that the adsorption increases parallel to the buffer concentration. The results of these investigations will be published elsewhere.

It has thus been shown how the adsorption factor can be determined both in a system based upon evaporation alone (A.C.), and in "open-strip" electrophoresis (D.C.), where evaporation, electroosmosis and protein charge contribute to the migration. The latter, direct, determination has to be preferred, as it corresponds to the specific conditions of the experiment.

In *electrophoretic systems devoid of evaporation*, however, the adsorption factor cannot be evaluated, as shown by the following considerations. Evaporation produces a liquid flow converging from both ends toward the center of the strip and diminishing in intensity as this point is approached. This flow adds to the electroosmotic flow and to the electrophoretic migration, thus giving rise to a marked asymmetry between the anodic and the cathodic side of the strip [Fig. 1(b)]. When this asymmetry is lacking, identical specimens will obviously migrate the same distances, irrespective of their starting positions on the paper [Fig. 1(c)]. In consequence, for experiments where evaporation is suppressed, it is seen that

$$s_{p1} = s_{p2} \qquad \text{and} \qquad s_{d1} = s_{d2} \qquad \text{(II,6)}$$

and, in accordance with eqn. II,5,

$$\varrho = \frac{0}{0}$$

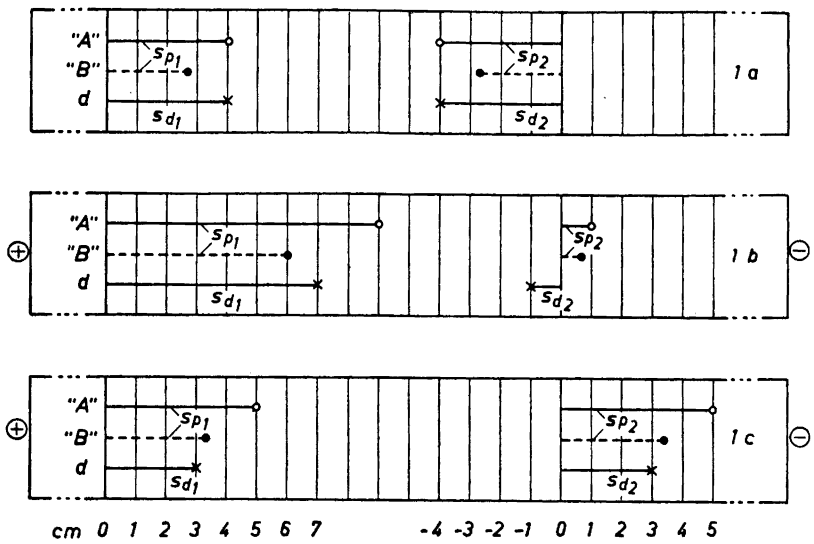

Fig. 1. Schematic illustration of migration relationships with protein adsorption. —○ Unadsorbed "A"-protein. ———● Adsorbed "B"-protein, adsorption factor $\varrho = 0.666$. —× Uncharged substance (dextran). – Assumed migration distances valid for the 3 experiments: Owing to evaporation ± 4 cm, – to electroosmosis 3 cm, and to protein charge 2 cm. (*cf.* eqn. I, 11). For simplicity, "A" and "B"-proteins are given the same charge. The points of application appear as zero. Migration to the cathode is considered positive.

1 a. Alternating current experiment. (Substances subject to evaporation only.) "A"-protein: $s_p = s_d$. "B"-protein: $s_p/\varrho = s_d$. Both sides yield the same result.
1 b. Open-strip electrophoresis. (Evaporation, electroosmosis and electrophoretic migration taking place.) "A"-protein: $s_{p_1} - s_{d_1} = s_{p_2} - s_{d_2}$. "B"-protein: $s_{p_1}/\varrho - s_{d_1} = s_{p_2}/\varrho - s_{d_2}$.
1 c. Electrophoresis devoid of evaporation. (Substances under the influence of electroosmosis and electrophoretic migration.) "A" and "B"-proteins: $s_{p_1} = s_{d_1}$. ϱ cannot be calculated.

Hence, this direct determination of the adsorption factor is not feasible in systems devoid of evaporation. From the schematic illustration in Fig. 1(c), the same conclusions can be drawn by geometrical considerations.

The result is of fundamental significance, since it is generally assumed that a possible determination of free mobilities by paper electrophoresis can be carried out only when evaporation is suppressed [2,5a]. In view of our results, it becomes clear that the presence of evaporation is even of advantage, as it allows the direct estimation of the adsorption factor. Moreover, the accuracy of the ϱ-values will increase in proportion to the migration distance due to evaporation. In order to introduce the adsorption factor into results obtained from systems devoid of evaporation, parallel alternating current experiments would have to be performed. On this ground it can be concluded that for an accurate calculation of mobilities, the open-strip method is to be preferred.

Attention should finally be drawn to the adsorption problem when protein mixtures, such as sera, are analyzed. If it is assumed that some protein is irreversibly held by the paper, the foremost specimen would saturate a number of paper centers and hereby possibly "accelerate" the fractions following behind, the ϱ-values of which thus would become higher than those of their isolated counterparts. Observations in this sense were made in our chromatographic investigations [3]. In practice, however, it is noted that the ϱ-values of albumin and γ-globulin do not differ by more than 10 % in the conventional buffers. Moreover, when — as described — two serum spots are applied, and if the order in which the fractions migrate is identical for both spots, ϱ-values different from the isolated fractions will be found, but the calculated free mobilities will be the same.

B. The influence of paper-structure

The concept of a "tortuous path" was first envisaged by Kunkel and Tiselius [6]. According to their idea, the distance covered by the migrating substance is in reality longer than that measured on the paper because of the intricate channel system proper to the filter paper texture. The observed migration distance has thus to be divided by a factor smaller than 1.0 to get the real path-length. Due to the increased path length, the measured voltage gradient has to be multiplied by the same factor in order to obtain the voltage acting on the migrating substance.

The problem is considered by McDonald *et al.*[7] under a somewhat different viewpoint in their "barrier theory". The supporting medium is supposed to act as a mechanical barrier slowing down the velocity of the migrating substance through repeated collisions. Such an effect should be more pronounced with increasing molecular weight of the migrating substance. In view of the R_F-values of approximately 1.0 found for dextran [3,4] and the correspondence between "dextran shrinkage" and the V_o/V_t ratio [1], it is apparent that the influence of the geometrical factor is the same in the case of the buffer solution as with dextran. The concept of a "tortuous path" in the sense of Kunkel and Tiselius would therefore seem more adequate than the barrier theory by McDonald *et al.*

Kunkel and Tiselius determined the real path length by comparing the conductivity of the moist paper with that of a buffer column of the same length and same amount of buffer. According to their calculations the conductivity ratio represents the ratio of the measured to the true length. This value was squared to get the correction factor for the calculation of the free mobilities. We have used the same experimental approach but applied the conductivity ratio directly to the conversion of the measured mobilities. Kunkel and Tiselius, in their paper [6], overlooked the fact that an increased path length with constant buffer content involves a corresponding reduction of the cross-sectional area, causing the resistance to increase with the square of the path length. The conductivity ratio thus gives the square of the ratio between the measured and the true length, and should be applied directly.

It is also evident that, as far as factors of identical influence, such as path-length, are concerned, the reduction in the mobility of a protein migrating on paper will be equal to that of the buffer ions and thereby to the conductivity. The free mobility, u, is thus obtained by dividing the mobility, m by the conductivity ratio, q.

$$u = \frac{m}{q} \tag{II,7}$$

The conductivity ratio q, which was used in our calculations, was determined according to the following equation:

$$q = \frac{\text{Paper conductivity}}{\text{Buffer conductivity}} = \frac{\frac{i}{V/l \cdot w}}{\varkappa} = \frac{i \cdot l}{V \cdot w \cdot \varkappa} \tag{II,8}$$

i = current employed, after equilibration of the strip (A)
l = distance between the secondary electrodes (cm)
V = voltage over distance l at current i, corrected for polarization and voltmeter resistance (V)
w = buffer per cm length of paper (ml . cm $^{-1}$)
$\varkappa$ = buffer conductivity (Ω^{-1} cm^{-1})

The value obtained from 22 experiments was 0.740 (S.D.M. $\pm$ 0.0047). Since q is equal to the square of the ratio of measured to true length, the latter is found to be 16.3 % longer than the distance measured. As observed from Table 2, q remains constant for a given brand of paper, in spite of varying buffer type, pH and ionic strength. This is in full agreement with Kunkel and Tiselius' results [6] and shows that this factor depends solely on the type of paper used. A standard error below 1 % (Table 2) indicated that small differences between different batches [5b] are without significance in the present case.

It was mentioned [1] that the "wetness" w, on which special emphasis is laid by McDonald *et al.*[7], remains constant during an experiment. That is further evidenced by the fact that the different buffer concentrations, given in Table 2, resulted in practically identical w values, and shows that no variations in q owing to wetness changes [8] occur during the experiment. Temperature increases within the observed range do not appear to influence the outcome of the q-value.

Since the different types of buffer used yielded the same q values, it can be concluded from Table 2 that reversible ion adsorption does not take place during the process. The absence of an irreversible ion adsorption was independently demonstrated by eluting a known amount if buffer from a paper strip and comparing the conductivity of the eluate with a solution of the same ion concentration as directly prepared. The difference was within the experimental error (<1 %) in the sodium and zinc buffers employed.

The q value of 0.740 (Table 2) has been applied to all subsequent mobility calculations in the following way. According to eqn. II,3:

$$m = \frac{\frac{s_p}{\varrho} - s_d}{V_t t} \tag{II,3}$$

Table 2. Conductivity ratio, q, calculated according to eqn. II,8. Muncktell paper No. 20/150 employed.

			MEAN	0.740
			σ_m	0.005

By introducing the conductivity quotient according to eqn. II,7, it is found that

$$u^{T°C} = \frac{m}{q} = \frac{\frac{s_p}{\varrho} - s_d}{q \cdot V_t t} \qquad \text{(II,9)}$$

$u^{T°C}$ = free mobility at experimental temperature T°C ($cm^2V^{-1}sec^{-1}$)
s_p = protein migration distance measured (cm)
s_d = dextran migration distance measured (cm)
ϱ = adsorption factor (eqn. II,5)
q = conductivity ratio (eqn. II,8)
V_t = voltage/cm at the conclusion of the experiment, corrected for polarization and voltmeter resistance ($V \cdot cm^{-1}$)
t = duration of the experiment (sec)

Eqn. II,9 is the final formula employed in the calculation of free mobilities.

The correction factors for adsorption and increased path length may also be introduced into the equation I, 11 of the previous communication [1], resulting in

$$u = \frac{1}{q}\left(\frac{s}{\varrho V_i t} - e - afi\right) \qquad \text{(II, 10)}$$

From this equation it would be possible to determine free mobilities on paper without the use of an uncharged reference substance provided that the constants e, f, and ϱ had been determined beforehand. Because of the obvious uncertainty of such a procedure, the use of dextran cannot be dispensed with, and the present method has to be preferred.

C. Temperature determination

Since the use of thermocouples during an experiment would produce considerable technical difficulties, the determination of the actual temperature on the strip indicated the convenience of an evaluation of the temperature increase (ΔT) as function of the watt input.

It has been shown in the preceding communication [1] that in experiments with constant current the reciprocal voltage plotted against time gives a straight line (Fig. 6 in Ref.[1]). By extrapolation to the ordinate an expression of the initial conductivity at the temperature prevailing during the experiment is obtained ($1/V'$). The difference between $1/V'$ and $1/V_0$ is directly proportional to the conductivity increase caused by the temperature rise.

The viscosity of the buffer solution used is nearly identical with that of pure water, and the temperature function of the latter was therefore employed to convert the conductivity increase to temperature. This conversion is performed as follows: The reciprocal viscosity of water corresponding to the mean ambient temperature during such an experiment, is taken from a table. This value is increased by the percentage of conductivity increase found as described above, and the corresponding temperature read from the table. ΔT is then obtained by subtracting the mean ambient temperature from this value.

In Fig. 2 the temperature increase found in 16 buffers of widely varying ionic strengths and different composition by plotting the reciprocal voltage against time, is correlated with the initial watt input ($V_0^{(15cm)} \times$ mA per strip). In spite of some scattering, it appears justified to accept a ΔT-value of 3°C per $W_0^{(15cm)}$/strip.

In the experiments which laid the basis for Fig. 2 no substances were applied to the strips after equilibration, as it was the case in the mobility determinations. Since the equilibrium undoubtedly will be disturbed by the opening of the covering plates, as required with our apparatus, the voltage before and after protein and dextran application was measured. It was seen that the difference between the two values is of no significance at all, as even 5 min opening, together with the application of six 5 μl-aliquots, does not produce a voltage decrease greater than 1 %, which in the present series would mean a maximum error of 5×10^{-3} °C.

The $\Delta T/W_0$ correlation will obviously vary with the apparatus used and is the only function here described which will have to be determined at each laboratory.

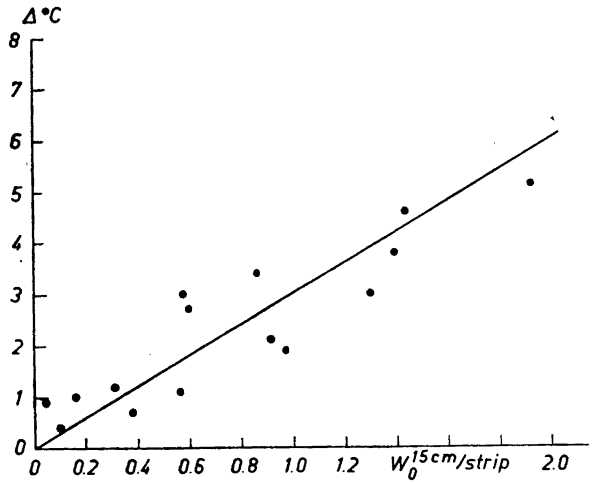

Fig. 2. The temperature increase as function of the initial watt input. $W^{15\ cm}$: Watt per 15 cm strip length (120 cm^2). Sodium acetate, barbital and zinc acetate buffers, ranging from $\Gamma/2 = 0.025$ to 0.30, used. Experimental points obtained by extrapolation procedure (see p. 22).

When highly concentrated or viscous buffers are employed, the conductivity should be measured as function of the temperature, and the resulting curve used as reference for exact temperature conversions. In the ordinary concentration range, however, the difference would be negligible.

From the described experiments it has been seen that the temperature increase occurs within the first hour, and it appears therefore justified to add ΔT, taken from the $\Delta T/W_0$ plot, directly to the mean ambient temperature. The resulting value is then used for the conversion of the mobilities to their values at 1°C. The viscosity ratio was used to this end. This is in accordance with Tiselius' procedure [9] and it has been shown by McDonald *et al.*[7] that the free mobility as function of the temperature is, in fact, proportional to the reciprocal viscosity. Deviations from this relation, which have been mentioned for certain inorganic ions [10], do apparently not apply to serum proteins. We used 1°C for comparison, since, although not always clearly stated, most free electrophoresis data are obtained at a temperature of about 1°C within the cell. A variation of 1°C in this range changes the mobility value by about 2 %.

D. The concentration increase and its effects

Open-strip electrophoresis suffers from the characteristic inherent to all procedures with evaporation, that the salt concentration on the strip increases during the run. The final ionic strength can easily be calculated by multiplying the initial concentration by the "dextran shrinkage" (distance between the starting positions divided by the distance between the final positions). The mean ionic strength ($\Gamma/2_m$) is then considered valid for the whole experiment.

In our mobility determinations an initial ionic strength of $\Gamma/2 = 0.080$ to 0.084 was used, which increased to about 0.12, thus resulting in a mean concentration of $\Gamma/2_m = 0.102$ (S.D. = ± 0.0036).

The error involved by taking the average ionic strength is rather insignificant, since the mobility changes only slightly with the ionic strength in monovalent ion buffers [11]. According to our own determinations, the mobilities of both serum albumin and γ-globulin in sodium acetate buffer of $\Gamma/2_m = 0.08$ differ by about 5—7 % from the values found in the same buffer of $\Gamma/2_m = 0.12$, the change becoming less pronounced in higher concentrations. These determinations were made at pH 4.75 and 5.65. It is evident that the average concentration ($\Gamma/2_m$) would differ even much less from the real value.

pH changes measured on the strip could not be caused by a concentration increase of the magnitude observed. Since the buffer capacity was sufficient and electrolysis products were prevented from diffusing into the paper, the pH variations were produced by the evaporation of volatile buffer components. Routine controls were therefore especially required in sodium acetate buffers. No pH gradients can be supposed to occur within the uniform concentration zone.

E. The mobilities of human serum albumin and γ-globulin from pH 4.0 to 8.8. Determination and calculation

The crucial test for the validity of the considerations set forth above is the determination of a number of mobilities and their comparison with results obtained by free electrophoresis.

As shown in the preceding chapters, the final eqn. II,9 for the computation of mobilities has been derived from eqn. 13 in Ref.[1] by gradual introduction of correction factors for adsorption and paper structure. The migration distance of the protein is divided by the corresponding ϱ-value, the dextran migration then subtracted, and the difference divided by the conductivity ratio, final voltage and time.

The temperature conversion to 1°C is then performed as described above.

It will be noted that two protein-dextran pairs were applied per strip in order to evaluate the adsorption factor ϱ. Once this factor has been calculated, it is seen from eqn. II,4 that either pair can be used for the mobility calculation according to eqn. II,9.

The mobilities of human serum albumin and γ-globulin were determined over a pH range from 4.0 to 8.8, and the results calculated according to eqn. II,9.

In Fig. 3 the mobilities are presented as function of the pH, together with previous findings by other authors working with free electrophoresis (moving boundary). Values obtained from media other than those employed in this investigation were disregarded.

A full accordance between free and paper electrophoretic results is observed. Isoelectric points of pH 4.68 for albumin and of pH 6.83 for the γ-globulin preparation were obtained by our method, the scattering of the experimental points being less than to be expected from a corresponding study employing free electrophoresis.

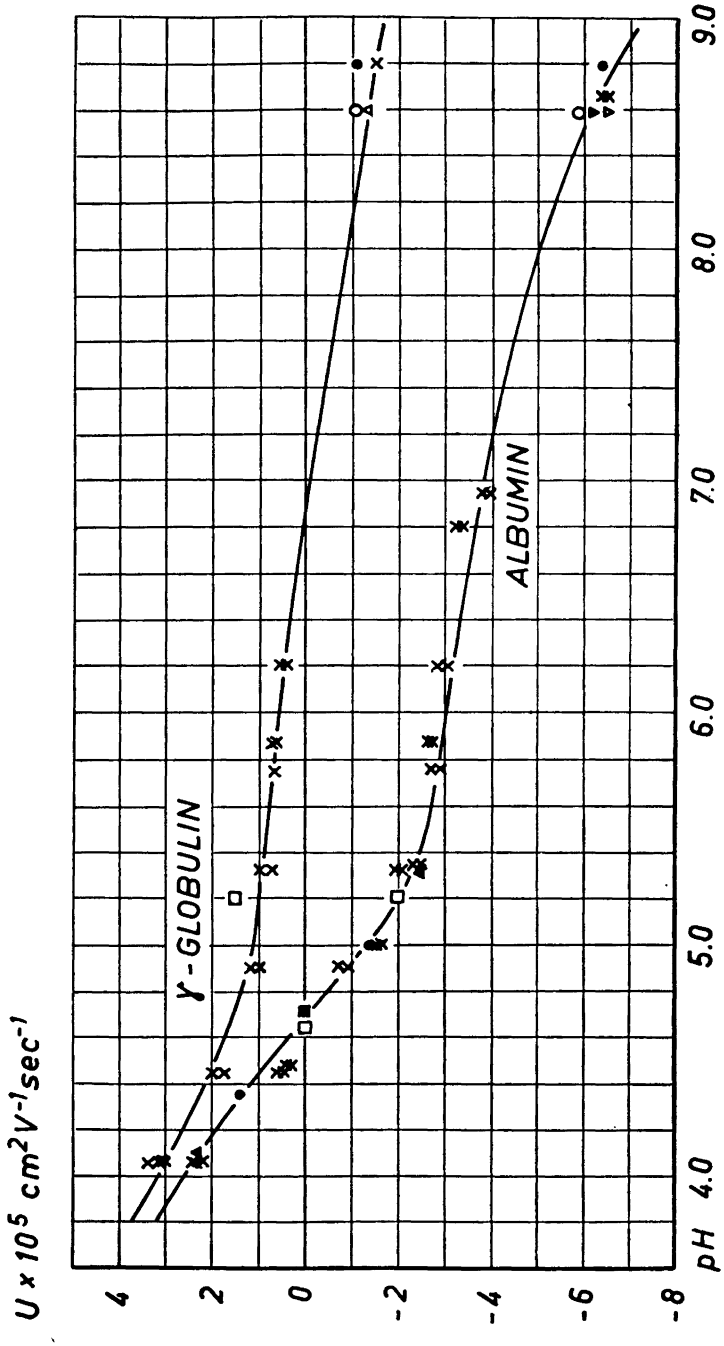

Fig. 3. The electrophoretic mobilities of human serumalbumin and γ-globulin at 1°C in 0.10 ionic strength buffers. pH 4.0—5.5 sodium acetate; pH 5.5—7.0 sodium acetate + barbital; pH 8.6—8.8 barbital.

The excellent agreement of the paper electrophoretic results with those obtained in free solution establishes the value of the present procedure.

DISCUSSION

In view of the reported results, previous work by other authors on the determination of free mobilities by means of paper electrophoresis is discussed first.

Procedures working without evaporation were described by Kunkel and Tiselius [6] and McDonald *et al.*[7] In experiments by Woods and Gillespie [12] a correction was introduced. The only method working with uninhibited evaporation has been published by Macheboeuf *et al.*[13,14] who even take advantage of this factor.

In the first group mentioned, the sole complications are the electroosmotic flow and the influence of the supporting medium. In the fundamental study of Kunkel and Tiselius [6] — the only publication giving a comparison with moving boundary data for more than one pH value — the uncharged dextran was used as indicator of the electroosmotic flow. Correct mobilities for serumalbumin were obtained at three pH values, in spite of the fact that the square of the conductivity ratio was erroneously applied as tortuous path factor. It might be presumed that this was compensated by a retarding of the protein migration owing to the silicone employed in Kunkel and Tiselius' closed-strip system. No correction for adsorption effects was introduced. In this specific case, however, this does not influence the final mobility values, since — as shown above — serumalbumin remains unadsorbed in the conventional media.

McDonald *et al.*[7] describe several approaches to the attainment of free mobilities, all of them obligatorily working at low temperatures. In a method working with slight evaporation the mobility of serumalbumin at pH 8.6 was obtained by extrapolation of mobility *vs.* time to zero time on the basis of about 50 experiments, whereas γ-globulin could not be estimated because of its low mobility. In a "direct method" requiring 24—36 h per determination, the maximum voltage applicable is 0.5 V/cm. Apparently, no account is taken of the electroosmosis nor of the "barrier effect", so strongly emphasized by the authors. Since it is furthermore shown that a change in the type of paper may change the results by a factor of about 2.0, the agreement with free mobility values appears rather fortuitous. In a third approach, where ionic strengths of 0.0125 may not be exceeded, a reference substance of known mobility is required to correct for the effects of electroosmosis and paper interaction. In an empirical equation various constants are determined using results obtained with the reference protein. When the migration velocity of an unknown substance is then introduced into this equation, it is claimed to yield the free mobility. The different interaction with the paper is estimated separately in conductivity measurements which require a considerable amount of the substance tested. The procedure presents appreciable technical difficulties, and the results reported for γ-globulin, showing 20 % deviation from the free mobility value after determining the parameters by means of albumin, cannot be considered to establish the validity of the proposed equation.

According to McDonald [5c] mobilities may be defined as specific for a given support. This was actually done in a later publication [15], and means — in

our view — a virtual abandonment of the attempts to determine free mobilities by paper electrophoresis, since the mobility is only significant when considered as a physical constant independent of the carrier employed.

Mobility determinations in the presence of evaporation, reported by Woods and Gillespie [12], contain an empirical correction for evaporation effects. It should be noted that the comparison with free mobilities is based on an erroneous temperature correction, since a 2 % change of the mobility value per °C, as derived from the viscosity, is only valid when converting from 25°C to 0°C, and not in the opposite sense. Their value would thus be 27.2 % lower than that found by free electrophoresis. The authors do not consider any corrections for the paper structure. If this is done, the discrepancy would be reduced.

Important investigations have been carried out by Macheboeuf *et al.* [13,14]. The procedure called "electrorheophoresis" has been discussed in the preceding communication. An example of its practical application has been published by Meulemans [23].

Both in Macheboeuf *et al.*'s method and in McDonald *et al.*'s third approach, proteins of known mobility are used as reference substances, in order to correct for buffer flow and carrier medium effects. However, the fact is neglected that, as shown above, the adsorption depends on the specific protein, and some doubts concerning results thus obtained must be expressed.

In this connection, it should be pointed out that the use of dextran, too, involves a series of problems which remain to be solved. Our calculations are based on the assumption that no interaction between the dextran indicator and neither the carrier nor the buffer takes place. While this holds true in the present experiments, conditions may be conceived where dextran is adsorbed or acquires a significant charge. In experiments aiming beyond the conventional media it may therefore be necessary to gain a previous knowledge of the electrochemical behavior of dextran under these conditions. An approach to this problem is at present being worked out and will be published. It does not appear probable that dextran can be easily replaced by a more appropriate indicator, but a final solution might possibly be found by resorting to labelled molecules.

It is evident that paper electrophoresis shares with the moving boundary method certain problems, inherent to the migration of colloidal particles in the electric field, which await further elucidation. Preliminary observations indicate that the mobility of albumin, at a given pH, decreases with increasing protein concentration, which is in agreement with Svensson's results in moving-boundary electrophoresis [16]. Nevertheless, extrapolation to zero protein concentration is not usual in routine mobility determinations and the protein concentration is simply stated together with the other parameters.

One of the most significant advantages of paper electrophoresis being the minute quantity of specimen required, the present results open new ways for studies on the electrochemical properties of enzymes and pathological samples only available in scanty amounts.

An interesting application of the new procedure lies in the field of ion interaction studies. As stressed by Steinberg and Mihalyi [17], some of the subfractions observed in the moving-boundary method may be artifacts produced by

incomplete ion binding resulting from the high protein/free ion ratio. In paper electrophoresis, on the other hand, a considerable and constant excess of the free ion assures the displacement of the equilibrium toward protein-ion binding. By computation of the changes produced in the mobility through addition of increasing ion concentrations to the buffer, binding constants and charge of the different fractions can be evaluated. When working with ions whose activity coefficients change appreciably with the concentration increase caused by evaporation, corrections would have to be introduced. The open-strip technique offers the possibility of further implementing such studies by the introduction of labelled ions.

On this ground it is hoped that the present results, aside from providing an exact micromethod for mobility determinations, may contribute to the attainment of new insights into protein binding and structure.

Acknowledgments. The authors express their gratefulness to Dr. Tage Astrup of this Institute for his most valuable advice and constant encouragement. The skillful technical assistance of Miss Jytte Walter is acknowledged. Thanks are due to Miss Mary A. Bloomstrom for aid with the manuscript. We are indebted to the *Rask-Ørsted Foundation* and the *Teknisk-Kemisk Fond* for grants supporting this investigation.

N-Substituted Alkyltriaminosilanes

II. On the Reaction of N-Substituted *n*-Propyltriaminosilanes with Amines

LEWI TANSJÖ

Department of Organic Chemistry, University of Lund, Lund, Sweden

As a part of an investigation on aminosilanes the reaction between N-substituted *n*-propyltriaminosilanes and some amines was studied. These reactions are apparently catalyzed by hydrogen ion and observations were made which indicate influence by the steric properties of the reagents.

The preparation of *n*-propyltri-(*n*-amylamino)-silane, *n*-propyltri-(*n*-hexylamino)-silane and *n*-propyltri-(benzylamino)-silane is described.

In Part I[1] of this work the author described the reaction of *n*-propyltrichlorosilane with various primary and secondary amines to give N-substituted *n*-propyltriaminosilanes. The great reactivity of the Si—N bonds in these compounds has now been used for the preparation of some compounds of this type by an exchange reaction according to the formula

$$n\text{-}C_3H_7Si(NHR')_3 + 3R''NH_2 \rightarrow n\text{-}C_3H_7Si(NHR'')_3 + 3R'NH_2 \qquad (A)$$

The method has earlier been extensively used for the preparation of N-substituted trialkylaminosilanes, dialkyldiaminosilanes and diphenyldiaminosilanes [2-8].

As it can be assumed that reaction (A) is reversible, it is desirable — in order to obtain good yields — to employ an excess of $R''NH_2$ and to choose R′ so that liberated $R'NH_2$ can be easily removed from the reaction mixture. Of the compounds described in Part I, therefore, only *n*-propyltri-(methylamino)-silane and *n*-propyltri-(ethylamino)-silane were used. They reacted on heating with an excess of *n*-butylamine, *n*-amylamine, *n*-hexylamine, benzylamine, *cyclo*hexylamine and aniline to give the following compounds

I n-$C_3H_7Si(NHC_4H_9$-$n)_3$
II n-$C_3H_7Si(NHC_5H_{11}$-$n)_3$
III n-$C_3H_7Si(NHC_6H_{13}$-$n)_3$
IV n-$C_3H_7Si(NHCH_2C_6H_5)_3$
V n-$C_3H_7Si(NHC_6H_{11})_3$
VI n-$C_3H_7Si(NHC_6H_5)_3$

II—IV have not earlier been reported in the literature. Their physical constants and analyses are given in Table 1. I, V and VI were earlier prepared in Part I of this work.

Table 1. Physical constants and analyses of n-$C_3H_7Si(NHR')_3$

No.	M	B.p. °C	Pressure mm Hg	n_D^{20}	d^{20}_4	MR_D	% Si		Equiv.wt.	
							found	calc.	found	calc.
II	329.64	164–65	3	1.4503	0.8516	104.08	8.6	8.5	110.2	109.9
III	371.72	182–83	2	1.4527	0.8507	118.04	7.6	7.6	123.6	123.9
IV	389.60	216–18	1	1.5665	1.0503	121.09	7.2	7.2	131.5	129.9

n-Propyltri-(methylamino)-silane and n-propyltri-(ethylamino)-silane both failed to react with N-methylaniline, which may be ascribed to the steric requirement of the bulky groups in this amine. That reaction (A) is influenced by steric effects is also supported by the fact that *cyclo*hexylamine which reacted with n-propyltri-(ethylamino)-silane failed to react with n-propyltri-(*iso*propylamino)-silane.

Addition of a proton donator to the reaction mixture considerably accelerated reaction (A). Thus with a small amount of ammonium chloride or ammonium sulfate present, there was in all reactions a pronounced increase in the rate of liberation of $R'NH_2$. In the presence of one of these proton donators *cyclo*hexylamine reacted readily even with n-propyltri(*iso*-propylamino)-silane. With still more bulky groups around the silicon atom, however, as in n-propyltri-(*tert.*-butylamino)-silane, the reaction with *cyclo*hexylamine seemed to be quite impeded even in the presence of these accelerators. With a small amount of ammonium sulfate added, even N-methylaniline liberated some ethylamine from n-propyltri-(ethylamino)-silane, but complete reaction was not obtained even on prolonged heating of the reaction mixture. In general ammonium sulfate was found to be more convenient as proton donator than amine hydrochlorides which during the course of the reactions partly sublimed into the reflux condensor.

The accelerating effect of protons on the reactions of aminosilanes with amines has been reported in the literature prior to this work. Thus Langer, Conell and Wender [8] recently demonstrated a pronounced catalytic effect by hydrogen or ammonium ion on the reaction between hexamethyldisilazane and primary amines, and Speier, Zimmerman and Webster [9] recognized this catalysis in the preparation of allylaminotrimethylsilane from hexamethyldisilazane and allylamine.

In the presence of a proton donator the initial step in reaction (A) seems to be the formation of an ion, $Si—\overset{+}{N}H_2R'$, which on the following nucleophilic attack from $R''NH_2$ splits off $R'NH_2$. The fact that aminosilanes do not give hydrochlorides with hydrogen chloride but are spontaneously converted to chlorosilanes by this reagent demonstrates clearly the great reactivity of the $Si—\overset{+}{N}$ bond.

n-Propyltri-(methylamino)-silane and *n*-propyltri-(ethylamino)-silane could both be refluxed for several hours without any liberation of methylamine or ethylamine, which indicates that the rate of the intermolecular condensation reaction, the first step of which would be

$$2n\text{-}C_3H_7Si(NHR')_3 \rightarrow n\text{-}C_3H_6Si(NHR')_2 - NR' - Si(NHR')_2 - C_3H_7\text{-}n + R'NH_2$$

is very low. Thus it is evident that such a reaction will not accompany reaction (A) to any great extent. As can be expected, however, also the condensation reaction is catalyzed by hydrogen ion. This will be further described in a later part of this work.

Reaction (A) can be considered as the sum of three consecutive competitive reactions:

$$n\text{-}C_3H_7Si(NHR')_3 + R''NH_2 \xrightarrow{k_1} n\text{-}C_3H_7Si(NHR')_2(NHR'') + R'NH_2$$

$$n\text{-}C_3H_7Si(NHR')_2(NHR'') + R''NH_2 \xrightarrow{k_2} n\text{-}C_3H_7Si(NHR')(NHR'')_2 + R'NH_2$$

$$n\text{-}C_3H_7Si(NHR')(NHR'')_2 + R''NH_2 \xrightarrow{k_3} n\text{-}C_3H_7Si(NHR'')_3 + R'NH_2$$

Therefore, if the reaction is performed with a mole ratio $R''NH_2$: $n\text{-}C_3H_7(NHR')_3$ less than 3:1, a mixture of four compounds will result. The relative amounts of these compounds will depend on the ratio $k_1:k_2:k_3$ between the rate constants of the competitive reactions above. This was demonstrated in the case of *n*-hexylamine and *n*-propyltri-(ethylamino)-silane, which were mixed in the mole ratio 1:1 and heated in the presence of some ammonium chloride giving a mixture containing all the expected compounds.

The conceivable redistribution between two aminosilanes of the type $n\text{-}C_3H_7Si(NHR')_3$ with different R'-groups was studied in the case of *n*-propyltri-(ethylamino)-silane and *n*-propyltri-(*n*-amylamino)-silane. These compounds could be refluxed together for several hours without any noteworthy change. In the presence of some ammonium sulfate, however, heating to reflux temperature for a few hours caused redistribution resulting in a mixture of the expected four compounds.

EXPERIMENTAL

The method of the determination of the physical data of the compounds and the analyses have been previously described [1]. The preparation of *n*-propyltri-(*tert.*-butylamino)-silane will be described in the next part of this work.

n-*Propyltri-(*n-*butylamino)-silane (I).* A mixture of 3.2 g (0.02 mole) of *n*-propyltri-(methylamino)-silane and 5.9 g (0.08 mole) of *n*-butylamine was heated to reflux temperature for one hour in the presence of 0.1 g of ammonium chloride. Distillation of the reaction mixture gave 4.0 g (70 %) of I, b.p. 159—161°/12 mm, n_D^{20} = 1.4472, d^{20} = 0.8525, equiv. wt. 96.0 (calc. 95.9).

n-*Propyltri-(*n-*amylamino)-silane (II).* A mixture of 3.2 g (0.02 mole) of *n*-propyltri-(methylamino)-silane and 8.7 g (0.1 mole) of *n*-amylamine was heated in a flask equipped with thermometer and reflux condensor. Liberated methylamine was titrated with standard hydrochloric acid using methyl red as the indicator. Sixty five per cent of the expected amount of methylamine escaped from the reaction vessel during a period of 1.5 h, and during that time the reflux temperature rose from 108 to 122°. After cooling about 0.1 g of methylamine hydrochloride was added to the reaction mixture. On heating methylamine evolution began below 100° and the expected amount of it was liberated within 15 min. Distillation of the reaction mixture gave 4.9 g (74 %) of II.

In another experiment a mixture of 2.0 g (0.01 mole) of *n*-propyltri-(ethylamino)-silane and 4.4 g (0.05 mole) of *n*-amylamine was heated to reflux temperature for one hour. Only about 30 % of the calculated amount of ethylamine were liberated. On addition of 10 mg of ammonium sulfate to the reaction mixture, however, the rest of the ethylamine disappeared within 30 min.

n-*Propyltri-(*n-*hexylamino)-silane (III).* 3.1 g (0.015 mole) of *n*-propyltri-(ethylamino)-silane and 7.6 g (0.075 mole) of *n*-hexylamine were heated at about 125° for one hour. The liberated amount of ethylamine during that period corresponded to only 20 % of the expected amount. After addition of 50 mg of ammonium sulfate to the reaction mixture gas evolution began at about 100° and the rest of the ethylamine disappeared within 25 min. Distillation of the reaction mixture gave 4.2 g (75 %) of III.

n-*Propyltri-(benzylamino)-silane (IV).* A mixture of 2.0 g (0.01 mole) of *n*-propyltri-(ethylamino)-silane, 4.3 g (0.04 mole) of benzylamine and 20 mg of ammonium sulfate gave upon heating to reflux temperature for 45 min the expected amount of ethylamine. On distillation of the reaction mixture 3.0 g (77 %) of IV were obtained.

n-*Propyltri-(*cyclo*hexylamino)-silane (V).* 7.9 g (0.08 mole) of *cyclo*hexylamine liberated on heating to reflux temperature for one hour about 30 % of the expected amount of ethylamine from 4.1 g (0.02 mole) of *n*-propyltri-(ethylamino)-silane. On addition of 50 mg of ammonium sulfate to the reaction mixture complete reaction was obtained after reflux for one hour. Distillation gave 6.1 g (83 %) of V, b.p. 192—93°/3 mm, n_D^{20} = 1.4918, d^{20} = 0.9479, equiv. wt. 121.6 (calc. 121.9).

n-*Propyltrianilinosilane (VI).* 3.2 g (0.02 mole) of *n*-propyltri-(methylamino)-silane and 7.4 g (0.08 mole) of aniline were heated to reflux temperature for one hour. About 50 % of the expected amount of methylamine were evolved. On addition of 50 mg of ammonium sulfate the rest of the methylamine evolved in 20 min on heating to reflux temperature. Distillation gave 5.4 g (78 %) of VI, b.p. 220°/2 mm, equiv. wt. 115.3 (calc. 115.8).

Reaction with N-methylaniline. A mixture of *n*-propyltri-(methylamino)-silane and N-methylaniline did not react after 6 h of reflux. In another experiment 3.1 g (0.015 mole) of *n*-propyltri-(ethylamino)-silane and 8.0 g (0.075 mole) of N-methylaniline were heated to reflux temperature for 8 h without reaction. On addition of 50 mg of ammonium sulfate to the reaction mixture 50 % of the amount of the ethylamine, calculated for complete reaction, were liberated on heating to reflux temperature for 6 h. On fractionation of the mixture most of the N-methylaniline was recovered. Between 160 and 200° at 10 mm Hg 2.0 g of a substance was obtained which contained N-methylaniline and may have been a mixture of *n*-propyl-(N-methylanilino)-di-(ethylamino)-silane and *n*-propyldi-(N-methylanilino)-(ethylamino)-silane. It is probable that the evolution of ethylamine was partly due to an intermolecular condensation of *n*-propyltri-(ethylamino)-silane.

Reaction of cyclo*hexylamine with* n-*propyltri-(*iso*propylamino)-silane and* n-*propyltri-(*tert.-*butylamino)-silane.* No *iso*propylamine distilled from the reaction mixture when

7.9 g (0.08 mole) of *cyclo*hexylamine and 4.9 g (0.02 mole) of *n*-propyltri-(*iso*propylamino)-silane were heated to 125° for 4 h. On addition of 50 mg of ammonium sulfate to the reaction mixture more than 90 % of the calculated amount of *iso*propylamine distilled over on heating to 115° for one hour. From *n*-propyltri-(*tert.*-butylamino)-silane, however, under the same conditions no liberation of *tert.*-butylamine occurred on prolonged heating to 125°, even in the presence of some ammonium sulfate.

n-*Propyltri-(ethylamino)-silane and* n-*hexylamine.* 30.5 g (0.15 mole) of *n*-propyltri-(ethylamino)-silane and 15.2 g (0.15 mole) of *n*-hexylamine were heated for 2 h to reflux temperature in the presence of about 0.1 g (0.002 mole) of ammonium chloride. The calculated amount of ethylamine (0.15 mole) was liberated, most of this during the first 45 min. The precipitate was filtered from the reaction mixture. On distillation at 11 mm Hg the following fractions were obtained:

A:	90— 95°	7.2 g	equiv.wt. = 68.1
B:	95—135	1.9 g	» = 82.7
C:	135—137	11.1 g	» = 86.3
D:	137—180	3.1 g	» = 89.7
E:	180—182	9.3 g	» = 105.3
F:	182—200	1.8 g	» = 111.3
G:	dist. residue	2.2 g	» = 179

The following compounds, E_i = equiv.wt., can be expected to be present in the reaction mixture:

n-$C_3H_7Si(NHC_2H_5)_3$	E_1 = 67.8
n-$C_3H_7Si(NHC_2H_5)_2(NHC_6H_{13}$-$n)$	E_2 = 86.5
n-$C_3H_7Si(NHC_2H_5)(NHC_6H_{13}$-$n)_2$	E_3 = 105.2
n-$C_3H_7Si(NHC_6H_{13}$-$n)_3$	E_4 = 123.9

The found equivalent weights of the fractions seem to indicate that:

A = E_1
B = E_1 (0.3 g) and E_2 (1.6 g)
C = E_2
D = E_2 (2.5 g) and E_3 (0.6 g)
E = E_3
F = E_3 (1.1 g) and E_4 (0.7 g)

If it is further assumed that G is a mixture of E_4 (1.5 g) and products of total hydrolysis (0.7 g) the following compounds seem to have been formed:

7.2 + 0.3	= 7.5 g of	E_1 = 0.037 mole
11.1 + 1.6 + 2.5	= 15.2 g »	E_2 = 0.059 »
9.3 + 0.6 + 1.1	= 11.0 g »	E_3 = 0.035 »
and about	2 g »	E_4 = 0.005 »
		Sum: 0.136 mole

If k_1:k_2:k_3 is 3:2:1, *i. e.*, if the difference in steric and polar properties of the species are neglected, it can be shown [10] that E_1:E_2:E_3:E_4 would be 8:12:6:1. For 0.15 mole of starting material this makes E_1 = 0.044; E_2 = 0.067; E_3 = 0.033 and E_4 = 0.006 mole.

Fraction C, which was assumed to be E_2, had n_D^{20} = 1.4455; d^{20} = 0.8532; MR_D = 81.02; E, which was assumed to be E_3, had n_D^{20} = 1.4499; d^{20} = 0.8521; MR_D = 99.51.

Redistribution. 11.8 g (0.058 mole) of *n*-propyltri-(ethylamino)-silane and 15.3 g (0.041 mole) of *n*-propyltri-(*n*-amylamino)-silane were heated to reflux temperature for 3 h. On distillation most of the starting materials were recovered. Less than one g of substance was obtained between 100—200° at 12 mm Hg, so it is evident that redistribution had occurred only to a very small extent. In another experiment, however, 8.1 g (0.04 mole) and 13.2 g (0.04 mole), respectively of the compounds were heated to reflux

temperature for 3 h in the presence of 20 mg of ammonium sulfate. Now distillation of the reaction mixture gave: 92—127°: 1.0 g, E = 72.3; 127—136°: 2.4 g, E = 82.2; 136—162°: 2.7 g, E = 86.5; 162—170°: 4.3 g, E = 95.0; 170—185°: 2.8 g, E = 98.2; 185—205°: 2.4 g, E = 100.1, and distillation residue 3.0 g, so it is evident that under these conditions redistribution had occurred. Some ethylamine was liberated during the course of reaction, which seems to indicate that the reaction was accompanied by an intermolecular condensation reaction.

The author is indebted to Professor E. Larsson for his kind interest in this work.

N-Substituted Alkyltriaminosilanes

III. On the Preparation of Some Sterically-Hindered Compounds

LEWI TANSJÖ

Department of Organic Chemistry, University of Lund, Lund, Sweden

n-Propyltribromosilane and *n*-propyltriiodosilane were shown to react more readily than *n*-propyltrichlorosilane with *tert.*-butylamine and diethylamine.

Some N-substituted alkyltriaminosilanes which could not be prepared by the direct treatment of halosilanes with the bulky amines in question could be obtained from the corresponding amine magnesium halogenides.

The preparation of fifteen compounds which have not earlier been reported is described.

Part 1. In a previous paper [1] it was shown that only two chlorine atoms are replaced when *n*-propyltrichlorosilane reacts with *tert.*-butylamine, diethylamine and N-methylaniline. This was ascribed to the steric hindrance exerted by the bulky groups in these amines, for the remaining chlorine atom could readily be exchanged by ammonia and amines with less bulky groups, such as ethylamine and even *iso*propylamine.

Thus the reactivity of the Si—Cl bond is not sufficient to give the N-substituted *n*-propyltriaminosilanes with the amines above even on prolonged reflux. In order to obtain these triaminosilanes, two other methods have been tried, both giving the desired result.

A. From the fact that in general the reactivity of halosilanes increases in the order F, Cl, Br, I, it could be expected that *n*-propyltribromosilane and *n*-propyltriiodosilane would give a better yield of the triaminosilanes than *n*-propyltrichlorosilane does in their reaction with the amines in question. This assumption was verified by the fact that *n*-propyltriiodosilane reacted completely with *tert.*-butylamine and *n*-propyltribromosilane gave a good yield of *n*-propyltri-(diethylamino)-silane. N-Methylaniline, however, replaced only two bromine atoms in *n*-propyltribromosilane; the second one not readily.

Previously [1] it has also been reported that di-*iso*propylamine only exchanged one chlorine atom in *n*-propyltrichlorosilane. Now it was shown that even in *n*-propyltribromosilane only one halogen atom was replaced by di-*iso*propylamine, illustrating the great steric requirement of this amine.

B. Breederveld and Waterman [2-3] used *tert.*-butylamine magnesium bromide and diethylamine magnesium bromide for the preparation of tetra-*tert.*-butylaminosilane and the corresponding diethylamine compound, and this method was successful also in this work. Thus *n*-propyltri-(*tert.*-butylamino)-silane was obtained in good yield by heating a mixture of *n*-propyldi-(*tert.*-butylamino)-chlorosilane and *tert.*-butylamine magnesium bromide at about 160°C for several hours, and the corresponding diethylamine compound was obtained in an analogous way from diethylamine magnesium bromide. *n*-Propyltri-(N-methylanilino)-silane was prepared directly from *n*-propyltrichlorosilane and N-methylaniline magnesium iodide. Prolonged heating of a mixture of *n*-propyl-(di-*iso*propylamino)-dichlorosilane and di-*iso*propylamine magnesium bromide seems to make possible the exchange of two chlorine atoms in *n*-propyltrichlorosilane, but no pure compound was isolated in this case.

Part 2. Whereas *n*-propyltrichlorosilane gives N-substituted *n*-propyldiaminochlorosilanes with *tert.*-butylamine and diethylamine and practically no triaminosilanes, silicon tetrachloride reacts with these amines to give the N-substituted triaminosilanes in good yield [4-5]. It must be concluded, therefore, that the reactivity of the compounds $(t\text{-}C_4H_9NH)_2SiClX$ and $[(C_2H_5)_2N]_2SiClX$ is much greater for X = Cl than for X = n-C_3H_7 in the reaction

$$(t\text{-}C_4H_9NH)_2SiClX + 2t\text{-}C_4H_9NH_2 \longrightarrow (t\text{-}C_4H_9NH)_3SiX + t\text{-}C_4H_9NH_3Cl \quad (1)$$

and the analogous reaction for diethylamine. The influence on the reactivity for some different X in the reaction above has now been qualitatively investigated in the following way. Compounds of the type $(t\text{-}C_4H_9NH)_2SiClX$ and $[(C_2H_5)_2N]_2SiClX$ were prepared with X = n-C_3H_7, C_2H_5, CH_3, H and Cl, and

Table 1. $(t-C_4H_9NH)_2SiClX + t-C_4H_9NH_2$.

X	Hydrochloride g	Per cent reaction
$n-C_3H_7$	<0.2	<2
C_2H_5	1.4	13
CH_3	5.3	48
H	10.4	95
Cl	10.1	92

Table 2. $[(C_2H_5)_2N]_2SiClX + (C_2H_5)_2NH$

X	Hydrochloride g	Per cent reaction
$n-C_3H_7$	<0.2	<2
C_2H_5	0.4	4
CH_3	1.4	13
H	9.8	89
Cl	10.0	91

these were refluxed with an excess of *tert.*-butylamine and diethylamine, respectively, in benzene solution. The amount of hydrochloride precipitated after ten hours was taken as a measure of the per cent reaction. From the results presented in Tables 1 and 2, it is seen that the reactivity increases in the order n-C_3H_7, C_2H_5, CH_3, H and that X = Cl gives a greater reactivity than any alkyl group. It also appears that *tert.*-butylamine reacts more readily than diethyl amine, probably due to the difference in steric requirement between these amines.

From the compounds, prepared in part 1 and 2 the following have not been described before (the Arabic figures refer to the numbering in the experimental part):

I	(1)	n-$C_3H_7Si(NHC_4H_9$-$t)_3$
II	(2)	n-$C_3H_7Si[N(C_2H_5)_2]_3$
III	(4)	n-$C_3H_7Si[N(CH_3)(C_6H_5)]_3$
IV	(9)	$C_2H_5Si(NHC_4H_9$-$t)_3$
V	(9)	$C_2H_5Si[N(C_2H_5)_2]_3$
VI	(9)	$CH_3Si(NHC_4H_9$-$t)_3$
VII	(9)	$CH_3Si[N(C_2H_5)_2]_3$
VIII	(7)	$C_2H_5Si(NHC_4H_9$-$t)_2Cl$
IX	(7)	$C_2H_5Si[N(C_2H_5)_2]_2Cl$
X	(7)	$CH_3Si(NHC_4H_9$-$t)_2Cl$
XI	(7)	$CH_3Si[N(C_2H_5)_2]_2Cl$
XII	(7)	$HSi(NHC_4H_9$-$t)_2Cl$
XIII	(7)	$HSi[N(C_2H_5)_2]_2Cl$
XIV	(3)	n-$C_3H_7Si[N(CH_3)(C_6H_5)]_2Br$
XV	(5)	n-$C_3H_7Si[N(C_3H_7$-$i)_2]Br_2$

Their physical constants and analyses are given in Table 3.

EXPERIMENTAL

The method of the determination of the physical data of the compounds and the analyses have been previously described [1] and also the general performance of the syntheses. The preparation of n-propyltribromosilane and n-propyltriiodosilane will be described in a later paper.

1. n-*Propyltri-(*tert.-*butylamino)-silane (I). A.* 18.1 g (0.04 mole) of n-propyltriiodosilane in 50 ml of benzene were added dropwise to 21.9 g (0.3 mole) of *tert.*-butylamine in 75 ml of the same solvent, and then the mixture was refluxed for 10 h. Filtration left 24.1 g (calc. for the replacement of three halogen atoms 24.1 g) of *tert.*-butylamine hydroiodide, and fractionation of the filtrate gave 9.8 g (85 %) of I with the data given in Table 3.

B. 12.0 g (0.11 mole) of ethylbromide in 25 ml of ether were added dropwise to 2.7 g (0.11 mole) of magnesium in 15 ml of ether. After the addition the mixture was stirred for 15 min. Thereafter 8.8 g (0.12 mole) of *tert.*-butylamine in 20 ml of ether were slowly added, and the mixture was gently refluxed for 15 min. To the suspension of *tert.*-butylamine magnesium bromide formed, 25.1 g (0.1 mole) of n-propyldi(*tert.*-butyl-

amino)-chlorosilane were added. The ether was distilled off, and then the mixture was heated for 14 h at 125°C. On distillation 15 g of a liquid were obtained between 114° and 116°C at 10 mm Hg with a neutralization equivalent of 106 (calc. for I 95.9) and n_D^{20} = 1.4437; d^{20} = 0.8572. To complete the reaction this product was again heated with a small quantity of *tert.*-butylamine magnesium bromide for 14 h at 160°C. Distillation now gave 12.0 g (42 %) of a compound freed from chlorine and with the same data as the compound obtained in A.

2. n-*Propyltri-(diethylamino)-silane (II).* *A.* 9.3 g (0.03 mole) of *n*-propyltribromosilane in 40 ml of benzene were added to 16.1 g (0.22 mole) of diethylamine in 75 ml of benzene. The mixture was refluxed for 4 h. Filtration left 12.3 g diethylamine hydrobromide on the filter (calc. for complete reaction 13.9 g). 10 g of diethylamine were added to the filtrate, and the mixture was then refluxed overnight. Filtration now left 1.5 g of hydrobromide. Fractionation gave 5.0 g (58 %) of II with the data given in Table 3.

B. 25.1 g (0.1 mole) of *n*-propyldi-(diethylamino)-chlorosilane were added to diethylamine magnesium bromide obtained in the same way as the corresponding *tert.*-butylamine compound. After evaporation of the ether the mixture was heated for 4 h at 130°C. Distillation at 9 mm Hg gave three fractions: 110–120°C, 4 g, n_D^{20} = 1.4560; 120–127°C, 4 g, n_D^{20} = 1.4575; 127–135°C, 10 g, n_D^{20} = 1.4590. After a new treatment with about 0.05 mole of diethylamine magnesium bromide for 10 h at 160°C, 9.1 g (32 %) of II and 6 g of a first fraction with E = 103 were obtained.

3. n-*Propyldi-(N-methylanilino)-bromosilane (XIV).* 9.3 g (0.03 mole) of *n*-propyltribromosilane in 40 ml of benzene were added to 22.5 g (0.21 mole) of N-methylaniline in 50 ml of benzene. After the addition some hydrobromide had precipitated, but on warming this was quantitatively dissolved. The solution was refluxed overnight, and the hydrobromide precipitated after cooling was filtered off. The benzene and the excess of N-methylaniline were distilled off. On fractionation of the residue, 3.3 g (30 %) of XIV were obtained. 4.5 g of a product distilled between 160° and 180°C at 10 mm Hg and presumably contained *n*-propyl-(N-methylanilino)-dibromosilane. Only a small residue was left in the distillation flask, showing that *n*-propyltri-(N-methylanilino)-silane cannot be obtained in this way.

4. n-*Propyltri-(N-methylanilino)-silane (III).* 8.9 g (0.05 mole) of *n*-propyltrichlorosilane in 25 ml of ether were slowly added to N-methylaniline magnesium iodide obtained from 3.9 g (0.16 mole) of magnesium, 22.7 g (0.16 mole) of methyliodide and 21.4 g (0.2 mole) of N-methylaniline. After refluxing for 30 min, the ether was distilled off and

the residual mixture was heated for 6 h at 130°C. Fractionation gave 7.0 g (36 %) of III as a very viscous syrup and a first fraction of about 6 g between 160° and 200°C at 2—3 mm Hg.

5. n-*Propyl-(di-*iso*propylamino)-dibromosilane (XV).* 31.1 g (0.1 mole) of *n*-propyltribromosilane in 100 ml of benzene were added dropwise to 50.6 g (0.5 mole) of di-*iso*propylamine in 100 ml of the same solvent. The mixture was then refluxed for 4 h. Filtration left 18.9 g (calc. for the replacement of one bromine atom 18.2 g) of di-*iso*-propylamine hydrobromide on the filter. Further refluxing of the filtrate for 30 h gave only 0.3 g more hydrobromide, so it is seen that the diaminosilane cannot be obtained in reasonable yield by this method. The yield of XV was 22.5 g (68 %). It is immediately hydrolyzed in contact with moist air and was never quite freed from hydrobromide.

6. 24.2 g (0.1 mole) of *n*-propyl-(di-*iso*propylamino)-dichlorosilane were heated for 22 h at 150°C with di-*iso*propylamine magnesium bromide obtained from 2.7 g (0.11 mole) of magnesium, 12.0 g (0.11 mole) of ethylbromide and 12.1 g (0.12 mole) of di-*iso*propyl-amine. On fractionation of the mixture at 9 mm Hg most of the dichlorosilane was recovered, but at 120—135°C there were obtained 5.1 g of a product which consumed acid to an extent corresponding to about 75 % *n*-propyldi-(di-*iso*propylamino)-chloro-silane and 25 % of the dichlorosilane. No further attempts were made to isolate a pure compound from this fraction.

7. The compounds VIII—XIII used for the investigation in part 2 were all prepared by addition dropwise of 59 g (0.8 mole) of *tert.*-butylamine or diethylamine in 100 ml of ether to 0.2 mole of the appropriate trihalosilane in 100 ml of the same solvent and refluxing for 2 h. The amine hydrochlorides precipitated (43.8 ± 0.5 g; calc. 43.8 g) were filtered off. The yields of diamino compounds ranged from 55 to 70 %.

The preparation of *n*-propyldi-(*tert.*-butylamino)-chlorosilane and the corresponding diethylamine compound, which were also used in part 2, has been earlier described [1]. Di-(*tert.*-butylamino)-dichlorosilane and di-(diethylamino)-dichlorosilane have been prepared by Breederveld and Waterman [4-5]. Here they were prepared in the same way as VIII—XIII, and the data of the compounds obtained were in good agreement with those given in Refs.[4-5].

8. The experiments in part 2 were performed by refluxing a mixture of 0.10 mole of the compounds $(t\text{-BuNH})_2SiClX$ or $[(C_2H_5)_2N]_2SiClX$ with 21.9 g (0.3 mole) of *tert.*-butyl-amine respectively diethylamine in 100 ml of benzene for 10 h. After cooling, the precipitated amine hydrochloride was separated from the reaction mixture, carefully washed with benzene and dried. The appropriate filtrates were used for the syntheses below.

9. As is seen from Tables 1 and 2 the direct treatment of ethyltrichlorosilane or methyltrichlorosilane with *tert.*-butylamine or diethylamine will not give the compounds IV—VII in good yields. These compounds were more easily obtained according to method B in part 1:

Ethyltri-(tert.-*butylamino)-silane (IV).* After the benzene had been distilled off from the filtrate, mentioned in 8, the residue was added to 0.1 mole of *tert.*-butylamine magnesium bromide and the mixture was heated for 12 h at 160°C. On the following fractionation 10.2 g (37 %) of IV were obtained.

Ethyltri-(diethylamino)-silane (V) (9.8 g; 36 %), *methyltri-*(tert.-*butylamino)-silane* (VI) (10.5 g; 40 %) and *methyltri-(diethylamino)-silane* (VII) (9.6 g; 37 %) were obtained in exactly the same way as IV.

The author is indebted to Professor E. Larsson for his kind interest in this work.

Studies on Succinic Acids

I. Preparation of α,α′-Dialkyl- and Tetraalkyl-Substituted Succinic Acids by Kolbe Electrolysis

LENNART EBERSON

Department of Organic Chemistry, Chemical Institute, University of Lund, Sweden

This paper is the first one in a series dealing with problems concerning the stereochemistry of alkyl-substituted succinic acids. The preparation of α,α′-dimethyl-, α,α′-diethyl-, α,α′-di*iso*propyl-, α,α′-di-(*tert.*-butyl)-, α,α′-di*neo*pentyl-, α,α′-di*cyclo*hexyl-, α,α′-dimethyl-α,α′-diethyl-, tetraethyl-, α,α′-diethyl-α,α′-di*iso*propyl-, α,α,α′,α′-bis-(ethylene)-, α,α,α′,α′-bis-(trimethylene)-, and α,α,α′,α′-bis-(tetramethylene)-succinic acids by Kolbe electrolysis of the corresponding malonic monoesters in methanolic solution and subsequent hydrolysis of the coupled products is described. Treatment with concentrated sulphuric acid at moderate temperatures has been found to be an effective and rapid hydrolysis method for the sterically hindered succinic esters. The melting points of the acids are found to be dependent on the method of determination, generally being appreciably higher when determined with a Kofler apparatus than with the conventional capillary method in an electrically heated block.

The Kolbe electrolysis method has frequently been used for the preparation of α,α′-dialkyl- and tetraalkyl-substituted succinic acids from half esters of mono- and dialkylmalonic acids [1–6]. Most of these electrolyses have been carried out in aqueous solution and a reinvestigation with methanol as solvent seemed desirable, as the conditions for obtaining optimum yields are less critical in this medium [7]. Moreover, the electrolysis of malonic esters containing alkyl groups of more varying type should give a better understanding of the scope and limitations of the reaction.

The electrolyses were carried out in methanolic solution at a smooth platinum anode with a current density of about 0.5 A/cm^2. The pH of the solution was below 7 and the temperature was kept below 35° by external cooling. The results of the present and earlier investigations are summarized in Table 1.

Table 1. Yield of coupled products.

[a] Based on unrecovered malonic diester. [b] Product of unspecified purity. [c] *Trans*-esterification occurred.

The complication that *trans*-esterification occurred with some of the esters investigated was not serious, as no difficulties in the purification of the coupled products were introduced by this reaction, especially as the preparation of the acids was the main purpose.

HYDROLYSIS OF THE SUCCINIC ESTERS

Diethyl α,α'-dimethyl- and α,α'-diethylsuccinate were hydrolyzed by boiling with concentrated hydrochloric acid and 50 % sulphuric acid, respectively, and separated into diastereoisomers by fractionated crystallization from water. Diethyl α,α'-di*iso*propylsuccinate on hydrolysis with 78 % sulphuric acid exclusively gave the anhydride of the low-melting form of α,α-di*iso*-propylsuccinic acid. Hydrolysis by warming the ester with concentrated sulphuric acid for a few minutes gave a mixture of the high-melting acid and the anhydride of the low-melting acid. The product from the electrolysis of monoethyl *tert.*-butylmalonate was first purified by distillation *in vacuo* and then separated into two solid diethyl α,α'-di-(*tert.*-butyl)-succinates, m.p. 85—87°

and 36—40°, and a liquid dimethyl ester. The ester with m.p. 85—87° on treatment with concentrated sulphuric acid at 80° for 5 min gave a mixture of high-melting α,α′-di-(*tert.*-butyl)-succinic acid and the anhydride of the low-melting diastereoisomer which was converted into the corresponding acid by boiling with 20 % potassium hydroxide. The ester with m.p. 36—40° on treatment with concentrated sulphuric acid gave the anhydride of the low-melting form, while the liquid dimethyl ester gave a mixture of high-melting acid and anhydride of the low-melting acid.

Diethyl α,α′-di*neo*pentylsuccinate and its silicon analogue, diethyl α,α′-bis-(trimethylsilylmethyl)-succinate [2], were readily hydrolyzed by boiling with ethanolic potassium hydroxide, and the acid mixtures obtained were separated into diastereoisomers by fractionated crystallization from suitable solvents.

Murray and Taylor [3] separated the solid diethyl esters of α,α′-di*cyclo*hexyl-succinic acid and found that they were difficult to hydrolyze in alkaline media, and instead used heating with a mixture of concentrated sulphuric acid, acetic acid, and water. However, warming with concentrated sulphuric acid for a few minutes again was found to effect hydrolysis. The high-melting ester gave the high-melting acid, whereas the low-melting one gave the anhydride of the low-melting acid. No interconversion of the diastereoisomers was observed, which was the case under the vigorous conditions used by Murray and Taylor.

The α,α′-dimethyl-α,α′-diethyl-, tetraethyl-and α,α′-diethyl-α,α′-di*iso*propylsuccinates all were very resistant to hydrolysis in alkaline media, but they were easily converted into the corresponding anhydrides by concentrated sulphuric acid at 70—80°. The anhydrides on boiling with strong potassium hydroxide solution and subsequent acidification gave the acids. The α,α,α′,α′-bis-(ethylene)- and α,α,α′,α′-bis-(trimethylene)-succinates were hydrolyzed by boiling with 10 % ethanolic potassium hydroxide. The α,α,α′,α′-bis-(tetramethylene)-succinate required treatment with concentrated sulphuric acid for effecting hydrolysis and then gave α,α,α′,α′-bis-(tetramethylene)-succinic anhydride, m.p. 62—63°. The anhydride readily dissolved in warm 20 % potassium hydroxide solution and on acidification the corresponding acid was obtained.

DETERMINATION OF THE MELTING POINTS

It is well known that an alkyl-substituted succinic acid decomposes into the corresponding cyclic anhydride and water on heating near its melting point. This phenomenon lowers the melting point and makes it dependent on the rate and time of heating and the method of determination. This is clearly shown in Table 2, which gives melting points for the above acids plus tetramethylsuccinic acid under varying conditions. The first column refers to determination with the Kofler apparatus, the heating block being pre-warmed to about 30° below the melting point before introduction of the sample, and then heated at a rate of about 2°/min. The second and third columns give melting points by the conventional capillary method with open and sealed capillaries, respectively, under the same heating conditions as above. The sealed capillaries were wholly immersed into the electrically heated block to

Table 2. Melting points of alkyl-substituted succinic acids.

Succinic acid	Melting point, °C, Kofler apparatus	Melting point, °C, open capillary	Melting point, °C, sealed capillary	Melting point, °C, from the literature	Reference

[a] Tetramethylsuccinic acid was prepared from *iso*butyric acid and potassium persulphate according to Fichter and Heer [14].

prevent the decomposition products from distilling to the cold parts of the capillary. The last column gives melting points from the literature, the most recent values having been selected all of which have probably been determined by the capillary method.

The rather large discrepancy between the Kofler and capillary method is readily explained by the fact that the decomposition products can escape almost freely from the unchanged acid in the Kofler apparatus, while this is more difficult in an open capillary and impossible in a sealed one. Even the Kofler method may give melting points differing by as much as 15° for different samples from the same bulk of a substance, dependent on the rate of heating, especially for the tetra-alkylated acids. The values in Table 2 may therefore be too low, and it is possible that other investigators will find still higher melting points. However, the melting point determined in a sealed capillary (which is not a real melting point but a mixed melting point between acid and anhydride under the pressure of acid, anhydride, and water in the vapour phase) was found to be comparatively insensitive to the heating conditions and thus is of value for identification purposes.

Tetraethyl and α,α′-diethyl-α,α′-di*iso*propylsuccinic acids in the solid phase slowly pass into their anhydrides on standing even at room temperature, while the low-melting forms of α,α′-di*iso*propyl-, α,α′-di-(*tert.*-butyl)-, and α,α′-di*cyclo*hexylsuccinic acids, and α,α′-dimethyl-α,α′-diethyl- and α,α,α′,α′-bis-(tetramethylene)-succinic acids tend to lose water during recrystallization.

CONFIGURATIONS OF THE DIASTEREOISOMERS

The low-melting forms of α,α′-dimethyl- and α,α′-diethylsuccinic acid have previously been shown to be *racemic* by resolution with appropriate alkaloids [15,16]. In this paper it is shown by means of partial resolution with brucine that the low-melting forms of α,α′-di*iso*propyl- and α,α′-di-(*tert.*-butyl)-succinic acid possess *racemic* configurations; knowledge of the configuration is necessary for the discussion in coming papers of this series. By analogy in melting points, solubility, and especially the behaviour on anhydrization by heat the low-melting forms of α,α′-di*neo*pentyl- and α,α′-bis-(trimethylsilylmethyl)-succinic acid [2] are tentatively ascribed the *racemic* configuration, as also Murray and Taylor [3] have done in the case of α,α′-di*cyclo*hexylsuccinic acid.

Stefl [17] has stated that an α,α′-dimethyl-α,α′-diethylsuccinic acid with m.p. 173° prepared by him was partially resoluble into optically active components by means of brucine. However, the structure of this acid is questionable, as Stefl has shown it to undergo conversion into an anhydride, claimed to be of opposite configuration, which requires the assumption of breaking and recombination of C—C bonds in good yields if actually α,α′-dimethyl-α,α′-diethylsuccinic acid should be involved. It has been shown that optically active compounds which have no possibility to enolize at the asymmetric center, cannot be racemized even under very vigorous conditions [18]. The present author has not been able to reproduce this conversion with a sample of the acid prepared by the Kolbe method. No resolution experiments have been attempted, and as only one isomer has been obtained any conclusions regarding the configuration cannot be drawn. The same applies to α,α′-diethyl-α,α′-di*iso*propylsuccinic acid.

EXPERIMENTAL

Preparation of the succinic esters

Preparation of the monoethyl malonates. The malonic diester, 0.5 mole, was dissolved in 200 ml of absolute ethanol and a solution of 0.5 mole of potassium hydroxide in 300 ml of absolute ethanol added with good agitation during 5 min. The mixture was allowed to stand over night, whereupon the ethanol was distilled off with gradual addition of water. Unreacted diester was removed by extraction with ether, and the aqueous layer was acidified with concentrated hydrochloric acid. The monoester was extracted with ether and the ether solution thoroughly washed with water. Benzene (about one third of the volume of the solution) was added and finally the solvents were distilled off under reduced pressure at 40–50° to avoid decomposition. By this procedure dry crude monoester was obtained which was sufficiently pure to be directly used in the electrolysis experiments.

Electrolysis of the monoethyl malonates. The electrolysis of a substituted malonic monoester was carried out according to the following procedure: Dry crude monoester, prepared from 0.5 mole of diester according to the above method, was dissolved in 150–200 ml of methanol together with 0.5–1 g of sodium. The mixture was placed in a cell consisting of a 400 ml beaker fitted with a water cooling jacket, a mechanical stirrer, a platinum spiral anode (surface area 3.0 cm^2), a platinum net cathode (total surface area *ca.* 50 cm^2), and a thermometer reaching into the liquid. A current of 1.5–2.0 A was passed through the solution until it became neutral. Rapid agitation and passing a rapid stream of tap water through the cooling jacket was necessary to keep the temperature of the electrolyte below 35°.

Table 3. Physical constants and analyses of substituted succinic esters.

[a] The separation of these esters is described below.
[b] Calculated for dimethyl ester.
[c] The crude product was separated into two forms according to Murray and Taylor [3]. They found m.p.'s 120° and 60°, respectively.

The reaction product was isolated by dilution of the cell contents with water, distilling off the methanol on a water-bath, and taking up the organic layer in ether. The ether solution was washed with 5 % aqueous sodium carbonate and water and finally dried with anhydrous magnesium sulphate. The ether was distilled off and the residue fractionated *in vacuo*. In most cases also low-boiling material, probably consisting of disproportionation products from intermediate radicals [7], was obtained, but it was not further investigated.

Yields of coupled products are given in Table 1, and physical constants and analyses in Table 3.

*Separation of the esters of α,α'-di-(*tert.*-butyl)-succinic acid.* The crude product, isolated as above, was first purified by distillation, b. p. 102—110°/2 mm, whereby a semi-solid crystal mass was obtained. It was dissolved in boiling 90 % methanol and the solution allowed to cool slowly. The crystals were collected, m. p. 83—85°, m. p. after another recrystallization from the same solvent 85—87° (yield 31 %). The mother liquor was freed from solvent and vacuum-distilled, b. p. 109—112°/2.5 mm. This product was liquid but gradually deposited crystals on standing at 0° for one month, after which time the crystals were filtered on a sintered glassfunnel and sucked as dry as possible, m. p. 33—38°. They were dissolved in petroleum ether, the solution cooled to —80° and the solid rapidly filtered, m. p. 36—40° (yield 15 %).

The mother liquor from the filtration of the crystals with m. p. 33—38° was then very carefully fractionated in an efficient column and a fraction with b. p. 111—112°/2.5 mm was collected, according to analyses consisting of nearly pure dimethyl α,α'-di-(*tert.*-butyl)-succinate (yield 39 %).

Hydrolysis of the succinic esters

Melting points of the acids, determined as described above, are given in Table 2. Other melting points in the experimental part were determined with the Kofler apparatus unless otherwise stated. The neutralization equivalent weight of an acid was determined by potentiometric titration in 50 % ethanol (by weight) with standard alkali in the same solvent and was calculated from the most distinct break in the titration curve. The behaviour of these acids on titration will be discussed in a coming paper of this series.

α,α'-Dimethylsuccinic acid. Diethyl α,α'-dimethylsuccinate, 10.0 g, was hydrolyzed by boiling with concentrated hydrochloric acid for 8 h. After cooling the crystal mass was filtered off and the mother liquor extracted with ether. The ether was distilled off and the remaining solid combined with the first crystal crop dissolved in hot water. *Meso*-α,α'-dimethylsuccinic acid (4.1 g) crystallized out and was further purified by two recrystallizations from water.

The mother liquor was evaporated to dryness and the residue recrystallized four times from concentrated hydrochloric acid to give almost pure *racem*-α,α'-dimethylsuccinic acid (2.0 g).

α,α'-Diethylsuccinic acid. The diethyl ester was hydrolyzed by boiling with 50 % sulphuric acid over night and the acid mixture separated into *meso* and *racemic* forms according to Schotte and Rosenberg [9].

α,α'-Diisopropylsuccinic acid. A. Diethyl α,α'-di*iso*propylsuccinate, 10.0 g, was boiled for 20 min with a mixture of concentrated sulphuric acid, 40 ml, and 20 ml of water. During this procedure the mixture became dark, probably due to oxidation. After cooling, it was diluted with water and the organic layer taken up in ether. The ether was distilled off and the residual oil (crude anhydride) dissolved in warm 10 % aqueous potassium hydroxide and finally the acid liberated by acidification with concentrated hydrochloric acid. Crude *racem*-α,α'-di*iso*propylsuccinic acid (7.8 g) was obtained, which was purified by recrystallization from ethyl acetate. It was necessary to keep the heating time as short as possible to avoid too much anhydrization.

B. Diethyl α,α'-di*iso*propylsuccinate, 10.0 g, was dissolved in 20 ml of concentrated sulphuric acid and warmed on a water-bath for 10 min. After cooling, the mixture was diluted with water and the organic components taken up in ether. The ether solution was extracted twice with 10 % sodium carbonate solution, which then on acidification gave crude *meso*-α,α'-di*iso*propylsuccinic acid (2.7 g). This acid was purified by recrystallization from hot glacial acetic acid.

The ether solution with the same treatment as above gave *racem*-α,α'-di*iso*propylsuccinic acid.

Partial resolution of low-melting α,α'-diisopropylsuccinic acid. Low-melting α,α'-di*iso*propylsuccinic acid, 4.04 g, and brucine, 7.88 g, were dissolved in 250 ml of hot water and the solution filtered warm. After standing for four days at room temperature the crystals formed were filtered off (6.3 g) and recrystallized twice from hot water. The acid was liberated by treatment with dilute hydrochloric acid, dried and recrystallized from ethyl acetate. It showed $[\alpha]_D^{20} = +1.5°$ in absolute ethanolic solution. The rotation was small but significant, as the rotation of the alkaloid is of opposite sign.

α,α'-Di-(tert.-*butyl*)-*succinic acid.* High-melting diethyl α,α'-di-(*tert.*-butyl)-succinate, 5.0 g, was warmed with 10 ml of concentrated sulphuric acid at about 80° for 5 min. The solution was diluted with water and after cooling the crystal mass was filtered off, washed with water and finally dried. It was treated with 25 ml of boiling ethyl acetate, which left the *meso*-α,α'-di-(*tert.*-butyl)-succinic acid undissolved. The acid (1.2 g) was filtered from the hot solution and then recrystallized from boiling glacial acetic acid. (Found: C 62.6; H 9.6; equiv. wt. 116.1. Calc. for $C_{12}H_{22}O_4$: C 62.6; H 9.6; equiv. wt. 115.2.)

The mother liquor was evaporated to dryness leaving behind *racem*-α,α'-di-(*tert.*-butyl)- succinic anhydride (2.5 g), a small sample of which was recrystallized from 80 % aqueous acetone, m. p. 114—115°. (Found: C 67.9; H 9.5. Calc. for $C_{12}H_{20}O_3$: C 67.9; H 9.5.)

Crude anhydride, 2.0 g, was boiled with 20 % aqueous potassium hydroxide until it had completely dissolved, which required about 2 h. Acidification yielded an oil from which the aqueous layer was decanted and replaced by water. The mixture was heated to 80—90° whereby the oil quickly solidified and could be filtered off. It was recrystal-

lized from ethyl acetate or benzene. Care must be exercised in recrystallizing this compound, since prolonged boiling resulted in partial anhydrization. (Found: C 62.8; H 9.6; equiv. wt. 231.0. Calc. for $C_{12}H_{22}O_4$: C 62.6; H 9.6; equiv. wt. 230.3.)

The liquid dimethyl ester on the same treatment gave both *meso* acid and *racemic* anhydride, whereas the low-melting diethyl ester only gave *racemic* anhydride.

Partial resolution of low-melting α,α'-di-(tert.-butyl)-succinic acid. Low-melting α,α'-di-(*tert.*-butyl)-succinic acid, 8.3 g, and brucine, 14.2 g, were dissolved in 200 ml of boiling water, filtered, and allowed to cool slowly. The salt (11.1 g) was collected and recrystallized once from water. The acid was liberated by treatment with dilute hydrochloric acid and showed after recrystallization from benzene $[\alpha]_D^{20} = +6.1°$ in absolute ethanolic solution. In spite of further recrystallizations of the brucine salt higher rotations could not be achieved.

α,α'-Dineopentylsuccinic acid. Diethyl α,α'-di-*neo*pentylsuccinate, 10.0 g, was boiled with excess of 10 % ethanolic potassium hydroxide over night. The ethanol was distilled off with gradual addition of water, and on acidification a solid was obtained, which was filtered off and dried. The acid mixture was dissolved in boiling ethyl acetate, filtered, and allowed to cool slowly. *Meso-α,α'-dineo*pentylsuccinic acid (3.7 g) crystallized out. It was recrystallized once from ethyl acetate. (Found: C 64.9; H 10.1; equiv. wt. 129.5. Calc. for $C_{14}H_{26}O_4$: C 65.1; H 10.1; equiv. wt. 129.2.)

The mother liquor from the above filtration was freed from ethyl acetate and the residue boiled with 15 ml of acetic anhydride for 3 h. The acetic anhydride together with acetic acid formed was distilled off *in vacuo* and the remaining oil dissolved in warm 10 % aqueous potassium hydroxide. On acidification the *racemic* form (3.1 g) was obtained, which was recrystallized from benzene. Before analysis it had to be dried at 105° for 2 h. (Found: C 65.3; H 10.2; equiv. wt. 130.0. Calc. for $C_{14}H_{26}O_4$: C 65.1; H 10.1; equiv. wt. 129.2.)

On anhydrization by heat the two isomers behaved analogously with the two forms of α,α'-bis-(trimethylsilylmethyl)-succinic acid [2], the high-melting form giving the anhydride of the low-melting acid and the low-melting form its own anhydride.

α,α'-Bis-(trimethylsilylmethyl)-succinic acid. The two forms of these acids have been prepared previously [2].

α,α'-Dicyclohexylsuccinic acid. High-melting diethyl α,α'-di-*cyclo*hexylsuccinate, 5.0 g, was heated on a boiling water-bath with 10 ml of concentrated sulphuric acid for 4 min. A longer heating time caused isomerization. Cooling and dilution with water precipitated a solid which was filtered, dried and recrystallized from glacial acetic acid to give 3.1 g of pure *meso-α,α'-dicyclo*hexylsuccinic acid.

Low-melting diethyl ester, 5.0 g, was heated on a boiling water-bath with 10 ml of concentrated sulphuric acid for 10 min. After cooling and dilution with water an oil was obtained which was taken up in ether, the ether distilled off, and the residue dissolved in boiling 10 % aqueous potassium hydroxide. Acidification gave an oil which did not solidify when trying the usual methods for effecting crystallization. However, boiling with water for a few minutes caused the oil to crystallize. The acid was collected, dried and recrystallized from benzene to give 2.8 g of *racem-α,α'-dicyclo*hexylsuccinic acid. Care was required during this procedure, as prolonged boiling in benzene resulted in anhydrization.

α,α'-Dimethyl-α,α'-diethylsuccinic acid. Dimethyl α,α'-dimethyl-α,α'-diethylsuccinate, 10.0 g, was heated on a boiling water-bath with concentrated sulphuric acid for 15 min. Cooling and dilution with water yielded an oil which was taken up in ether. The ether was distilled off and the residue boiled with 10 % aqueous potassium hydroxide until it had dissolved, which required about 45 min. Acidification gave 7.1 g of α,α'-dimethyl-α,α'-diethylsuccinic acid, which was recrystallized from ethyl acetate. (Found: C 59.2; H 9.0; equiv. wt. 203.1. Calc. for $C_{10}H_{18}O_4$: C 59.4; H 9.0; equiv. wt. 202.2.)

Stefl [17] described one liquid and one solid form of α,α'-dimethyl-α,α'-diethylsuccinic anhydride and also found that the liquid form dissolved on boiling with aqueous potassium hydroxide. On acidification an acid with m. p. 173° was obtained. If the liquid anhydride was dissolved in 40 % aqueous potassium hydroxide and the solution kept at reflux temperature for three days it was stated that the solid anhydride was obtained directly on acidification of the reaction mixture. No acid corresponding to this anhydride could be obtained. However, the present author was not able to reproduce this conver-

sion with α,α′-dimethyl-α,α′-diethylsuccinic anhydride prepared by the Kolbe method. Only α,α′-dimethyl-α,α′-diethylsuccinic acid with m. p. 155—159° was recovered in 85 % yield.

Tetraethylsuccinic acid. Diethyl tetraethylsuccinate on treatment with concentrated sulphuric acid as described in the foregoing preparation gave tetraethylsuccinic anhydride, m. p. 86—87°, in almost quantitative yield. The anhydride was converted into the acid by boiling with 40 % aqueous potassium hydroxide for 4 h. The yield of crude acid was 95 % and it was recrystallized from ethyl acetate, though with considerable loss due to anhydrization. After standing for about two years the solid acid had transformed into anhydride to an extent of about 30 %.

α,α′-Diethyl-α,α′-diisopropylsuccinic acid. Diethyl α,α′-diethyl-α,α′-di*iso*propylsuccinate, 10.0 g, was heated on a boiling water-bath with 20 ml of concentrated sulphuric acid for 5 min. Dilution with water produced an oil which was taken up in ether. The ether solution was washed with water and dried with anhydrous magnesium sulphate. The ether was distilled off and the anhydride distilled *in vacuo*, the main fraction (5.1 g) being collected at 140—143°/3 mm. The oil soon solidified and was recrystallized from petroleum ether at −80°, m. p. 44—50°. (Found: C 69.8; H 10.0. Calc. for $C_{14}H_{24}O_3$: C 70.0; H 10.1.)

α,α′-Diethyl-α,α′-di*iso*propylsuccinic anhydride, 2.0 g, was boiled with 20 % ethanolic potassium hydroxide for 2 h. The solution was evaporated to dryness and the residue treated with ice-cold dilute hydrochloric acid. The solid (1.8 g) was filtered, washed with water and rapidly dried in a vacuum-desiccator. A small sample was recrystallized from ethyl acetate as rapidly as possible and then analyzed immediately. (Found: C 65.5; H 10.2; equiv. wt. 261. Calc. for $C_{14}H_{26}O_4$: C 65.1; H 10.1; equiv. wt. 258.4).

The solid acid spontaneously lost water on standing. After one month the m. p. (in a sealed capillary) was 80—105°, the depression being due to the presence of anhydride.

α,α,α′,α′-Bis-(ethylene)-succinic acid. Dimethyl α,α,α′,α′-bis-(ethylene)-succinate, 5.0 g, was boiled with 10 % ethanolic potassium hydroxide over night, the ethanol distilled off and the residue acidified with dilute hydrochloric acid. The solid was collected and recrystallized from 50 % acetic acid to give pure α,α,α′,α′-bis-(ethylene)-succinic acid (3.1 g). (Found: C 56.3; H 5.8; equiv. wt. 84.5. Calc. for $C_8H_{10}O_4$: C 56.5; H 5.9; equiv. wt. 85.1.)

α,α,α′,α′-Bis-(trimethylene)-succinic acid. Dimethyl α,α,α′,α′-bis-(trimethylene)-succinate, 5.0 g, was boiled with 10 % ethanolic potassium hydroxide over night, the ethanol distilled off and the residue acidified with dilute hydrochloric acid. The solid was filtered and recrystallized from 50 % acetic acid to yield pure α,α,α′,α′-bis-(trimethylene)-succinic acid (2.3 g). (Found: C 60.5; H 7.2; equiv. wt. 198.0. Calc. for $C_{10}H_{14}O_4$: C 60.6; H 7.1; equiv. wt. 198.2.)

α,α,α′,α′-Bis-(tetramethylene)-succinic acid. Dimethyl α,α,α′,α′-bis-(tetramethylene)-succinate, 5.0 g, was heated on a boiling water-bath together with 10 ml of concentrated sulphuric acid for 5 min. On dilution with water an oil separated which solidified upon cooling. The solid (3.6 g) was filtered and a small sample recrystallized from light petroleum, m. p. 65—66°. According to analyses it consisted of α,α,α′,α′-bis-(tetramethylene)-succinic anhydride. (Found: C 69.4; H 7.8; Calc. for $C_{12}H_{16}O_3$: C 69.2; H 7.8.)

Crude anhydride, 3.1 g, was dissolved in 20 % aqueous potassium hydroxide by boiling for 15 min. Acidification yielded a solid which was recrystallized from 90 % acetic acid, though with loss due to anhydrization. According to analyses it was α,α,α′,α′-bis-(tetramethylene)-succinic acid. (Found: C 63.7; H 8.1; equiv. wt. 225.3. Calc. for $C_{12}H_{18}O_4$: C 63.7; H 8.0; equiv. wt. 226.3.)

Overberger *et al.*[13] found m. p. 63—64° for the anhydride.

The author wishes to express his sincere gratitude to Professor Erik Larsson for his kind interest in this work. A grant from *Doktor P. Håkanssons Stiftelse* is gratefully acknowledged.

ACTA CHEMICA SCANDINAVICA 13 (1959) 50—59

On the Complex Formation of Nickel with Dimethylglyoxime

DAVID DYRSSEN, FRANC KRAŠOVEC and LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The distribution of $^{63}Ni^{2+}$ at 25°C between chloroform and 0.1 M perchlorate solution has been studied as a function of the concentration of H^+ and of dimethylglyoxime (HA) in the aqueous phase. The data may be completely explained with the equilibria; $NiA_2 \rightleftharpoons NiA_2$ (in $CHCl_3$), $\log \lambda_2 = 2.51 \pm 0.10$; $Ni^{2+} + 2HA \rightleftharpoons NiA_2$(in $CHCl_3$) + $2H^+$, $\log K = -1.17 \pm 0.10$. Previous solubility [1] and emf [2] data have been recalculated.

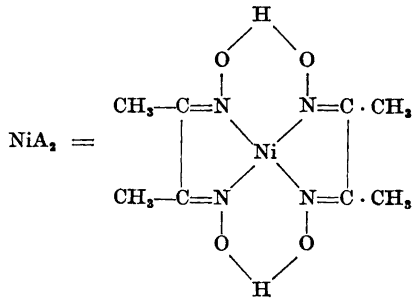
The present distribution data give no evidence for the presence of significant amounts of NiA^+. By curve-fitting it is concluded that $\log K_1 \leq \log K_2 - 1.2$; the same conclusion is drawn from the solubility data [1]. By using the value for K_a(HA) calculated from Ref[1], β_2 is obtained as 17.24 ± 0.07 (at $I = 0.10$) from the distribution data, and 17.23 ± 0.05 from the solubility data.

Charles and Freiser's emf data [2] would indicate $\log K_1 \sim 10.55$, $\log K_2 \sim 11.15$ in their medium, 50 % dioxane.

Dimethylglyoxime (HA) is a well-known reagent for nickel. The complex NiA_2 has a very low solubility in water but may be extracted, presumably as NiA_2 molecules, with organic solvents such as chloroform.

The crystal structure of NiA_2 (s) has been studied by Godycki and Rundle[3] and its infrared spectrum by Rundle and Parasol [4]. The molecule is planar. There are two very strong, probably symmetrical, hydrogen bonds between the two A groups in each molecule, and metal-metal bonds between neighboring NiA_2 molecules. From a discussion of the properties of NiA_2 and a number of related compounds, Sharpe and Wakefield [5] conclude, as was already suggested by Rundle [3,4], that the metal-metal bonds are the main factor in making NiA_2 insoluble.

It might be of interest to know to what extent the intermediate complex NiA^+ is formed in aqueous solution. Christopherson and Sandell [1] could explain their solubility data assuming only Ni^{2+} and NiA_2 in the aqueous phase; however, we shall see that their experiments were perhaps not ideally designed for a search for NiA^+. On the other hand, Charles and Freiser [2],



from pH measurements (presumably in 50 % dioxane-water), give complex formation constants K_1 and K_2 for A^-—Ni^{2+}, indicating $K_1 \sim 4K_2$. They point out, quite correctly, that a more accurate calculation of their data would give a lower K_1 and a higher K_2.

To study the importance of NiA^+, we have applied the distribution method (for surveys, see Rydberg [6], Dyrssen [7]). In this case, we have measured how the distribution ratio, q, for Ni between chloroform and an aqueous solution varies with the concentrations [HA] and $[H^+] = h$, in the aqueous solution.

GENERAL EQUATIONS

There is no evidence that the aqueous solutions with which we are concerned should contain Ni^{2+} and A^- in any species other than Ni^{2+}, NiA^+, NiA_2, A^-, and HA. With the usual definitions of the acidity constant, K_a, and the complex formation constants, $\beta_1 = K_1$ and $\beta_2 = K_1K_2$ we have:

$$[A^-] = K_a[HA]h^{-1}\,;\ [NiA^+] = \beta_1[Ni^{2+}][A^-]\,;\ [NiA_2] = \beta_2[Ni^{2+}][A^-]^2 \quad (1)$$

Our equations will be transformed to use h and [HA] as variables; in general, [HA] is more accurately known than $[A^-]$, since $[HA] \gg [A^-]$ in the solutions. We shall find it convenient to introduce an auxiliary variable, v, and a constant parameter, p:

$$v = [A^-]^{-1}\beta_2^{-\frac{1}{2}} = h[HA]^{-1}K_a^{-1}\beta_2^{-\frac{1}{2}}\,;\ p = \beta_1\beta_2^{-\frac{1}{2}} = \sqrt{K_1/K_2} \quad (2)$$

The paramter, p, indicates the tendency towards formation of NiA^+. In Dyrssen and Sillén's »two-parameter» notation [8], $\beta_1 = 10^{a+b}$, $\beta_2 = 10^{2a}$ and $p = 10^b$. If the distribution of A over the Ni atoms were statistical, one would have $p = 2$.

From (1) and (2) we may easily derive

$$[Ni^{2+}] = [NiA_2]h^2[HA]^{-2}\beta_2^{-1}K_a^{-2} = [NiA_2]v^2$$
$$[NiA^+] = [NiA_2]\,h\,[HA]^{-1}\beta_1\beta_2^{-1}K_a^{-1} = [NiA_2]pv$$

The total amount of Ni in the aqueous solution is thus

$$[NiA_2] + [NiA^+] + [Ni^{2+}] = [NiA_2]\,(1 + pv + v^2) \tag{3}$$

Solubility data. In Christopherson and Sandell's experiments [1], solutions of ionic strength 0.05 M were brought to equilibrium with NiA_2 (s) and HA (s) at 25°C. At equilibrium with these solids we have

$$[HA] = s_1 = \text{constant};\ [NiA_2] = s_2 = \text{constant}$$

Thus the total solubility of NiA_2 in the solution is

$$S = [NiA_2] + [NiA^+] + [Ni^{2+}] = [NiA_2]\,(1 + pv + v^2) = s_2\,(1 + pv + v^2) \tag{4a}$$

$$v = hs_1^{-1}\,K_a^{-1}\beta_2^{-\frac{1}{2}} = h \cdot \text{constant} \tag{4b}$$

To find the unknown constants we may plot the experimental data in a diagram log S (log h) and move it along a family of standardized curves $Y\ (X)$

$$Y = \log\,(1 + pv + v^2);\ X = \log v \tag{5}$$

which may easily be constructed (Sillén [9]). From the curve that gives the best fit, one may obtain the parameter, p. From the positions of the coordinate axes at the best fit one obtains from (4) and (5).

$$\log S - Y = \log s_2;\ \log h - X = \log s_1 + \log K_a + \tfrac{1}{2}\log \beta_2 \tag{6}$$

Distribution data. When an aqueous solution with Ni^{2+} and HA is equilibrated with chloroform, the chloroform takes up NiA_2 and HA; the experiments have given no reason to assume any other species in the organic phase. Denoting by λ_2 the real equilibrium constant for the distribution of NiA_2 and by q the total distribution ratio for Ni, we have

$$[NiA_2]_{org} = \lambda_2\,[NiA_2] = q([NiA_2] + [NiA^+] + [Ni^{2+}]) = q[NiA_2]\,(1 + pv + v^2) \tag{7}$$

This gives immediately

$$q^{-1} = \lambda_2^{-1}\,(1 + pv + v^2) \tag{8}$$

Since $v = h\,[HA]^{-1}$. constant, (2), we may make a plot of $(-\log q)$ as a function of $\log (h\,[HA]^{-1})$ and compare it with the same family (5) of normalized curves as before, Y (X). From the position at the best fit we obtain

$$-\log q - Y = -\log \lambda_2;\ \log (h[HA]^{-1}) - X = \log K_a + \tfrac{1}{2}\log \beta_2 \tag{9}$$

Emf data. Charles and Freiser [2] made pH titrations in 50 % dioxane and calculated log $[A^-]$ at the two points where $\bar{n}$, the average number of A bound per Ni, is 0.5 and 1.5. We have the equation

$$\bar{n} = \frac{2\,[NiA_2] + [NiA^+]}{[NiA_2] + [NiA^+] + [Ni^{2+}]} = \frac{2 + pv}{1 + pv + v^2} \tag{10}$$

From (10) we may derive the values for v where $\bar{n} = 0.5$ and 1.5:

$$v_{0.5} = (\sqrt{12 + p^2} + p)/2 \; ; \; v_{1.5} = (\sqrt{12 + p^2} - p)/6$$

$$v_{0.5}v_{1.5} = 1 \; ; \; v_{0.5}/v_{1.5} = (\sqrt{12 + p^2} + p)^2/4$$

Inserting the definition (2) of v we find

$$\log [A^-]_{0.5} + \log [A^-]_{1.5} = -\log \beta_2$$

$$\log [A^-]_{1.5} - \log [A^-]_{0.5} = 2 \log (\sqrt{12 + p^2} + p) - \log 4 \qquad (11)$$

CHRISTOPHERSON AND SANDELL'S SOLUBILITY DATA

Christopherson and Sandell [1] determined the solubility at 25°C of HA(s) in dilute $NaHCO_3$-Na_2CO_3 buffers, or NaOH, of ionic strength 0.05(NaCl), and of NiA_2(s) in KCl-HCl mixtures of ionic strength 0.05, when saturated with HA(s), and also in some other solutions of pH between 5.6 and 8.9 and the same ionic strength, all saturated with HA(s). They gave the »pH» of the solution,

$$\text{»pH»} = -\log h - \log f$$

where f is the activity factor of the H^+ ion. In the following we shall give the equilibrium constants as the concentration quotients at the corresponding ionic strength. As long as f remains constant (constant ionic strength), many of the conclusions are independent of any uncertainty that may exist in the f assumed.

For the solubility of HA, Christopherson and Sandell found a linear plot, solubility *versus* $(fh)^{-1}$, with the equation

$$\text{solubility} = 10^{-2.268} (1 + 10^{-10.585} (fh)^{-1})$$

Now it may easily be seen that the solubility is

$$[HA] + [A^-] = s_1 (1 + K_a h^{-1})$$

whence we deduce

$$s_1 = 10^{-2.268} \; ; \; K_a = f^{-1} \cdot 10^{-10.585} \; (I = 0.05(\text{NaCl}))$$

The solubility, S, of NiA_2 is plotted in Fig. 1 as log S (log (fh)). Over these experimental points is placed the family of curves, $Y(X)$, in the position of best fit. The full-drawn curve is the one calculated for $p = 0$, and the dotted one for $p = 1$. The broken lines are the asymptotes. It is readily seen that most of the experimental points are in parts where the curves differ very little on varying the value for p. Only one point is in the region with maximum influence of p, and thus of the intermediate complex NiA^+, and this point

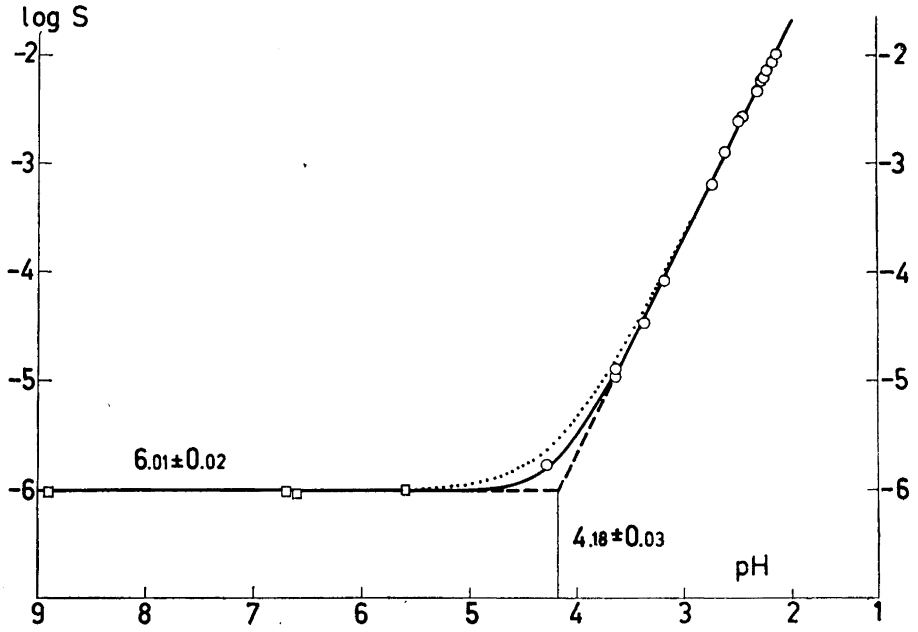


Fig. 1. Solubility of NiA_2 (25°C, $I = 0.05$, saturated with HA(s)) according to Christopherson and Sandell [1]). Experimental data: $\log S$ *versus* — "pH" = $\log h + \log f$. "Normalized curves" $Y(X)$, eqn. (5), in position of best fit, for $p = 0$ (full-drawn) and $p = 1$ (dotted). The broken lines are the asymptotes.

agrees well with $p \sim 0$. The data hence give no certain evidence for the existence of NiA^+. Assuming $p = 0$, we obtain at the best fit (see eqn. 6):

$$\log S - Y = -6.01 \pm 0.02 = \log s_2$$

$$\log (fh) - X = -4.18 \pm 0.03 = \log s_1 + \log K_a + \tfrac{1}{2} \log \beta_2 + \log f$$

Combining this with the above values for s_1 and K_a we obtain

$$\log s_2 = -6.01 \pm 0.02; \log \beta_2 = 17.35 \pm 0.04 \ (I = 0.05)$$

It may be noted that the value for β_2 is independent of any uncertainty in f; so is the conclusion that $p \sim 0$.

We might have obtained the same result and the following equation for S by using for the two constants average values from the data near to each of the asymptotes

$$S = 10^{-6.013} + 10^{+2.340} (fh)^2 = [NiA_2] + [Ni^{2+}]$$

Applying the activity factors given by Kielland [10] for the ions, and by Christopherson and Sandell [1] for the uncharged species, we may calculate, from their data, the following equilibrium constants for the ionic strengths 0, 0.05, and 0.10:

		$I = 0$	$I = 0.05$	$I = 0.10$
$HA(s) \rightleftharpoons HA$	$\log s_1 =$	− 2.26	− 2.27	− 2.28
$HA \rightleftharpoons H^+ + A^-$	$\log K_a =$	−10.67	−10.52	−10.46
$NiA_2(s) \rightleftharpoons NiA_2$	$\log s_2 =$	− 6.00	− 6.01	− 6.03
$Ni^{2+} + 2A^- \rightleftharpoons NiA_2$	$\log \beta_2 =$	17.83	17.35	17.23

Reference[1] seems to have used the activity factors for 0.025 M instead of 0.05 M, which is easily done since Kielland's table gives f as a function of $2I$.

For distribution between chloroform and water, Christopherson and Sandell [1] moreover give

$$HA \rightleftharpoons HA(\text{in } CHCl_3) \qquad \log K_d = -1.08$$
$$NiA_2 \rightleftharpoons NiA_2(\text{in } CHCl_3) \qquad \log \lambda_2 = 2.61$$

In water, saturated with $CHCl_3$, the equilibrium constants may differs slightly from those in aqueous solution free from $CHCl_3$. For instance, in the presence of $CHCl_3$, $\log s_2 = -5.92$.

DISTRIBUTION EXPERIMENTS

Experimental. The experiments were made in a room thermostated at 25°C. All the reagents used were of analytical grade, and the chloroform was made alcohol-free by washing it with water. The ionic strength was kept constant at 0.1 M using $HClO_4$, $NaClO_4$, and NaOH. In some experiments, small amounts of acetate ($\leqq 0.01$ M) were added to buffer the aqueous phase.

The distribution ratio, q, was measured using ^{63}Ni (half-life 80 years, 0.063 MeV β). The two phases had equal volumes, 15 ml. HA and Ni^{2+} were originally present in the aqueous phase, at concentrations $[HA]_{total} = 0.001$ to 0.0032, and $[Ni]_{tot} = 1.30 \times 10^{-4}$M. After equilibration and separation of the phases, 1 ml of the chloroform phase was taken out, evaporated in a cup of stainless steel, and counted in a Tracerlab Flow Proportional Counter SC-16. The aqueous phase could not be evaporated directly, since it contained $NaClO_4$; to 5 ml aqueous phase, ammonia was added to pH $\sim$ 9, and the nickel was extracted with 5 ml of chloroform, 1 ml of which was then evaporated, and the Ni counted as before.

In the aqueous phase, $[H^+] = h$ was measured with a glass electrode and a Radiometer pHM3i valve potentiometer, standardized against 0.01 M $HClO_4$ + 0.09 M $NaClO_4$. To obtain the real [HA] in the aqueous phase, from the $[HA]_{tot}$ added originally, it was necessary to introduce corrections for $[HA]_{org}$ and in some parts of the experimental range also for $[A^-]$ and $[NiA_2]_{org}$. The amounts of NiA_2 and NiA^+ in the aqueous phase were always negligible in comparison to $[HA]_{tot}$. We easily obtain

$$[HA] = ([HA]_{tot} - 2\,[Ni]_{tot}\, q(1+q)^{-1})\,(1 + K_d + K_a h^{-1})^{-1}.$$

The values for K_d and K_a were taken from Christopherson and Sandell's data [1]. K_d is small, only 1/12, and any slight error in it will mean only a constant shift along the log (h[HA]$^{-1}$) axis. The correction for K_a is negligible for most points, and the exceptions are not in the critical part of the curve.

The data ([HA]$_{tot}$, log h, log q) are given in Table 1; Fig 2 gives (log q) as a function of (log h — log [HA]). As in Fig 1, the calculated curves for $Y(X)$ with $p = 0$ (full-drawn) and $p = 1$ (dotted), and the asymptotes (broken) are given in the position of best fit. The spread is seen to be greater than for the solubility measurements, which is due to the difficulty of measuring dry samples with the very weak α-emitter ^{63}Ni (0.063 MeV). On the other hand, a much larger number of experimental points has been placed in the critical region from which the value of p can be deduced. As seen from Fig. 2, the data agree, within the experimental error, with the curve for $p = 0$, and thus give no evidence for the existence of NiA^+ in appreciable amounts.

From the position at the best fit we find, using points close to the asymptotes

$$q^{-1} = 10^{-2.51} + 10^{1.17}\,(h/[HA])^2$$

We may also read directly (see eqn. 9)

$$-\log q - Y = -\log \lambda_2 = -2.51 \pm 0.10$$

$$(\log h - \log [HA]) - X = \log (h/[HA]v) = \log K_a + \tfrac{1}{2} \log \beta_2 = -1.84 \pm 0.07$$

which gives, for 25°C and $I = 0.1$, the following equilibrium constants:

$$NiA_2 \rightleftharpoons NiA_2 \text{ (in } CHCl_3) \quad ; \log\lambda_2 = 2.51 \pm 0.10$$

$$Ni^{2+} + 2HA \rightleftharpoons NiA_2 \text{ (in } CHCl_3) + 2H^+ \quad ; \log K = \log\lambda_2 + 2 \log K_a + \log \beta_2 = -1.17 \pm 0.10$$

Inserting the value log $K_a = -10.46$, calculated from the solubility data [1], we obtain

$$Ni^{2+} + 2A^- \rightleftharpoons NiA_2 \; ; \log\beta_2 = 17.24 \pm 0.07$$

which is seen to agree very well with the estimate from the solubility data [1], 17.23.

The crossed and solid symbols in Fig. 2 denote experiments where up to 0.01 M acetate was added for buffering. A comparison with the open symbols indicates that the acetate had no perceptible influence, which is reasonable in view of the equilibrium constants given by Fronæus [11] (log $K_1 \sim 0.7$, log $\beta_2 \sim 1.25$ for Ac^--Ni^{2+} in 1 M $NaClO_4$ at 20°C).

Estimates of p and K_1

We have seen from Figs. 1 and 2 that both the solubility and the distribution data, when plotted and compared with »normalized curves», $Y(X)$, give good agreement with the curve for $p = 0$. A deviation of p from the value 0

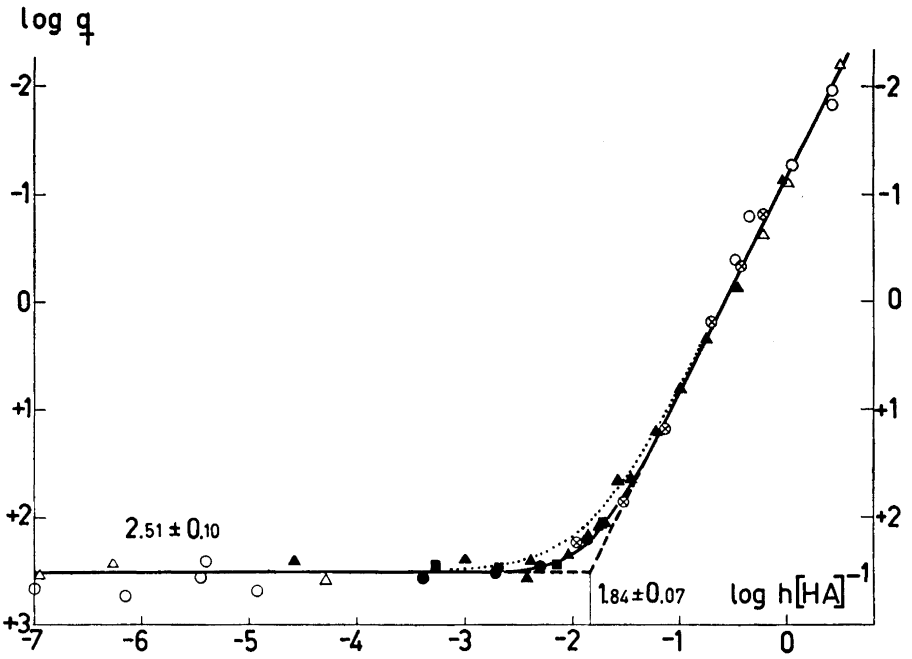

Fig. 2. Distribution data (present work). Experimental points: (— log q), distribution ratio, *versus* (log h — log [HA]). "Normalized curves" $Y(X)$ in position of best fit, for $p = 0$ (full-drawn) and $p = 1$ (dotted). The broken lines are the asymptotes.

Table 1. Distribution of Ni^{2+} between chloroform and 0.1 M perchlorate solutions at 25°C. Initial concentrations in the aqueous phase $[Ni]_{tot} = 1.30 \times 10^{-4}$ M, $[HA]_{tot} =$ 0.0032 (○ ⊗ ●), 0.002 (■) or 0.001 (△ ▲) M. Acetate concentrations: 0 (○, △), 0.004 (⊗), or 0.010 (●, ■, ▲) M.

+ 2.244	4.54				

would cause the largest deviation in the curve at the abcissa corresponding to $X = 0$ (intersection point of the asymptotes). Here, $Y = \log (2 + p)$. as seen from eqn. (5). Fron the data it may be estimated that the deviation from the curve with $p = 0$, denoted by Δ by Dyrssen and Sillén [8], is probably less than 0.05:

$$\Delta = \log (2 + p) - \log 2 \leq 0.05$$

thus $p \leq 0.25$, or $\log K_1 \leq \log K_2 - 1.2$

From Charles and Freiser's data [2] for 50 % dioxane (25° to 39.6°C) we obtain, using eqns. (11)

$$\log\beta_2 = -\log([A^-]_{0.5}\,[A^-]_{1.5}) = 21.7 \pm 0.1$$

$$\log ([A^-]_{1.5}/[A^-]_{0.5}) = 2 \log (\sqrt{12 + p^2} + p) - \log 4 = 0.60 \pm 0.02$$

thus $p = 0.5 \pm 0.1$, $\log K_1 \sim 10.55$, $\log K_2 \sim 11.15$ (in 50 % dioxane)

Charles and Freiser have also measured the complex formation between Ni^{2+} and the O-monomethyl ether of dimethylglyoxime, HA_{Me} in 50 % dioxane at 25°C. Applying the same eqns. (11) to their single set of $[A^-_{Me}]$ values, we obtain

$$\text{for } A^-_{Me}\text{—}Ni^{2+}\text{: } \beta_2 = 12.07\,;\ 2 \log (\sqrt{12 + p^2} + p) - \log 4 = 0.69$$

thus $p \sim 0.85$, $\log K_1 = 5.97$, $\log K_2 = 6.10$

Accordingly we would have for A^-_{Me}—Ni^{2+}, $K_1 \sim 10^{6.0}$ and $K_2 \sim 10^{6.1}$. Even in this case, the second complex would be favored since p is less than the »statistical» value, 2. This is remarkable, since with A^-_{Me} the formation of the second complex cannot be favored by hydrogen bonds as with A^-. The great difference makes one suspect for a moment that there might be in the aqueous phase a complex where Ni is bound to the doubly charged ion of HA; we might formally write this complex as $NiH_{-1}A$, and it could have no counterpart with HA_{Me}. For such a complex we would have

$$[NiH_{-1}A] = K\,[NiA_2]\,[HA]^{-1}$$

In the solubility experiments, with [HA] = constant, considerable amounts of such a complex might have passed as »NiA_2». In the distribution experiments, however, it would make q shift with [HA], whereas really q is found to be a function of $h/[HA]$ only, so this complex does not seem to be important.

On the other hand, one might disbelieve completely the p obtained from Charles and Freiser's data but still put some confidence in their β_2. Estimating that K_1 for A^-_{Me} is $\sim 10^6$ and that K_1 for A^- has the same order of magnitude, we would have K_2 for A^- about 10^{16}, and $p \sim 10^{-5}$, in 50 % dioxane. This is, however, a very uncertain estimate.

Returning to our first treatment: if Charles and Freiser's data [2] are taken at their face value, the first complex of the methyl ether, A^-_{Me}, would be much

less stable than that of A^-. One possible reason is a steric hindrance, or strain in the chelate ring caused by the CH_3 group. It would be interesting to know the crystal structure of $Ni(A_{Me})_2$, and also to have more accurate equilibrium data on the A_{Me}—Ni^{2+} complexes.

The only conclusion that the present data allow us to draw about p for A^-—Ni^{2+} in aqueous solution is that it is certainly less than 1, and probably less than 0.25. At any rate, p is thus less than would be expected from a statistical distribution of A^- over Ni^{2+} ions: 2.0 at $I = 0$, 1.65 at $I = 0.05$, and 1.55 at $I = 0.10$, corrected with Kielland's activity coefficients [10].

Finally, we should like to remark that the quite good agreement of the experimental data with the calculated curve over a wide range of concentrations has added to our confidence in the distribution method as a way of studying equilibria. If there had been any serious systematic errors, they would have been likely to show up in this very simple system which contains only two adjustable parameters, λ_2 and the product $K_a^2\beta_2$.

ACTA CHEMICA SCANDINAVICA 13 (1959) 60—74

The Effect of Some Pro-oxidants and Antioxidants on the Stability of Natural Vitamin A

KARL BÄCK*

Division of Food Chemistry, Royal Institute of Technology, Stockholm, Sweden

A study was made on the influence of some pro-oxidants (metal ions) and antioxidants on the stability of vitamin A in fish liver oils and vitamin A concentrates from fish liver oils. The destruction of vitamin A and the change in peroxide number were determined in oil samples stored at 34.5°C.

Under the conditions used, the effects of the pro-oxidants and antioxidants were small. Iron and copper had the greatest pro-oxidative effect of the metal ions tested. Among the antioxidants tested, NN′-diphenyl-*p*-phenylene diamine was the best stabilizer.

Fish liver oils are the best natural sources of the vitamins A and D and are extensively used to supply these essential compounds. When the oils turn rancid, their vitamin contents are destroyed. Rancidity in fish liver oils is mainly due to atmospheric oxidation. As vitamin D has been found to be more stable to oxidation than vitamin A, most of the work in this field has been devoted to studies of the stability of vitamin A.

In this investigation, the catalytic effect of various concentrations of the metal ions Al^{3+}, Cu^{2+}, Fe^{3+}, Ni^{2+}, Sn^{4+} and Zn^{2+} on the destruction of vitamin A was studied. The pro-oxidative effect observed with the metal ions was weak compared to those reported by other investigators.

The stabilizing effect of the following antioxidants and synergists was also investigated: ascorbic acid, ascorbyl palmitate, citraconic acid, citric acid, BHA,** BHT, lecithin, NN′-diphenyl-*p*-phenylene diamine, NDGA, tiodiphenylamine and some commercial antioxidant mixtures. NN′-diphenyl-*p*-phenylene diamine was the best stabilizer and on the whole the effects of the antioxidants were comparatively small.

* Present address, Blå Band Produkter AB, Halmstad, Sweden.

** The abbreviations BHA, BHT and NDGA denote butylated hydroxy anisole, butylated hydroxy toluene and nordihydroguaiaretic acid respectively.

EXPERIMENTAL

The properties of the vitamin oils used in these experiments are summarized in Table 1. Investigations were made on fish liver oils and on vitamin A concentrates obtained by molecular distillation of low potency fish liver oils. In the oils A, C, F and M the contents of the trace metals Cu, Mn, Ni and Fe were estimated. The amount of iron was in the range 0.1—0.5 p.p.m. and the amounts of the other metals were in the range 0.00—0.05 p.p.m. After the oils had been percolated through an ion exchange resin column, the amounts of Cu, Mn and Ni were in the range 0.00—0.01 p.p.m. and the amount of iron was less than 0.1 p.p.m.

Analysis

Vitamin A analysis. Vitamin A was determined using a method which closely resembles that given by Dowler and Laughland [1].

Adsorbent. Commercial bone meal was extracted in a Soxhlet apparatus with hexane and then with acetone in order to remove fatty material soluble in these solvents. The bone meal was dried in an oven at 110°C and the fraction which passed a 100 mesh but was retained by a 200 mesh sieve was used. To remove the finest particles the sieving on the 200 mesh sieve was made with the bone meal suspended in water. After this treatment, the adsorbent was again dried at 110°C.

Procedure. The chromatographic tube used had a length of 120 mm and an internal diameter of 8 mm. At the lower end it had a constriction. A plug of glass wool was placed in the tube and the bone meal adsorbent poured into the tube in the form of a suspension in hexane. After settling the height of the adsorbent column was 60 mm. Without further arrangements the rate of flow of the solvent through this column was 40—60 drops per min.

A 2 ml solution of oil in hexane which contained approximately 100 IU of vitamin A per ml was placed on the top of the column. The vitamin A esters were eluted by three successive portions of 2, 5, and 10 ml of hexane. As no vitamin A alcohol could be detected in any of the batches of oil used in these experiments, no measures were taken to elute this substance in the routine analyses.

The vitamin A in the eluate was determined by measuring the absorbancies at 312, 325 and 335 mμ in a Beckman spectrophotometer model DU. A corrected value for the absorbancy at 325 mμ was calculated by using the formula

$$A_{corr} = 7\ A_{325} - 3.045\ A_{312} - 3.955\ A_{335}.$$

Using this corrected value, the $E^{1\%}_{1\,cm}$-value was calculated and the vitamin A contents were determined by using a conversion factor of 1 900. This method has certain limitations especially when the oil is oxidized. Components initially present in the oil or developing during its oxidation and having a relatively high absorbancy in the interval 290—325 mμ are not quantitatively removed by the simple purification on the bone meal column. On the other hand, it is not possible to use a method involving saponification when the oil has a high content of peroxides.

Peroxide value. The peroxide value was determined essentially as suggested by Wheeler [2]. Samples (1 g) of oil were dissolved in 25 ml of a mixture of 60 % glacial acetic acid and 40 % chloroform in 200 ml conical flasks. A saturated solution of potassium iodide (0.5 ml) was added, and the flask gently rotated for 1 min. Distilled water (50 ml) was then added and the liberated iodine titrated immediately with 0.02 N sodium thiosulphate. Starch was used as an indicator. The results are expressed in millimoles of peroxide per kg of oil.

Estimation of trace metals. The metals Cu, Fe, Mn and Ni were detected and semi-quantitatively estimated by a method given by Täufel [3]. Oil (20 g) was weighed in a thoroughly cleaned quartz crucible with a diameter of about 50 mm and a height of about 50 mm. The crucible was placed on an electric heating plate and when the oil had reached its ignition temperature, the vapours were ignited. The energy input to the electric plate was regulated to keep the flame of the burning oil as small as possible.

Table 1. Properties of the different oils tested

Oil	Vitamin A contents IU/g × 10^3	Initial peroxide value	Time for 50 % destruction of vitamin A, hours	Peroxide value in the oil when 50 % of the vitamin A initially present is destroyed

O	72.4	2.3	264	70
P	39.8	0.5	204	59

The 20 g of oil were usually burnt to a coke-like residue in about 1—2 h. The crucible was then placed in an electric oven, where the combustion was completed at 500°C in 3—4 h.

The ash was dissolved in 0.5 ml of 6 N HCl. The resulting solution was evaporated to dryness by placing the quartz crucible in a slanting position on a sand bath in order to keep the resulting dry chloride in as small an area as possible. The dry chloride was dissolved in 0.2 ml of 6 N HCl. Sheets of Whatman No. 4 filter paper (230 × 420 mm) were washed to remove metal ions which might be present, by passing a solvent system of *n*-butanol (83 %) and 6 N HCl (17 %) through them by using a descending technique. The paper sheets were dried in a stream of warm air.

The hydrochloric acid solution of ash from the oil was placed in two spots on the starting line of two of the above mentioned washed paper sheets. The total amount of the solution was equally divided between the two spots. On each sheet four more spots with known amounts of metal chlorides were placed for comparison. On one sheet the chlorides of copper and nickel were placed and on the other the chlorides of iron and manganese. The paper sheets were chromatographed with the above mentioned solvent system for 5—7 h. During this time the solvent front had moved 200 — 300 mm. The paper sheets were dried in a stream of warm air. The sheet with the control spots of copper and nickel was sprayed with a solution of rubeanic acid (0.05 %) in 99 % ethanol and then treated with ammonia vapour. Copper gave a grey to green spot with an R_F-value of 0.1—0.2 and nickel a violet spot with an R_F-value of 0.02—0.08. Amounts of 0.05 μg of copper and nickel were easily detected. The sheet with the control spots of iron and manganese was sprayed near the starting line (to $R_F = 0.3$) with a water solution of sodium cyanide (15 %) in order to bind the nickel ion in a complex that would not interfere with the determination of manganese. This metal was detected as a brown spot (R_F-value 0.05—0.15) after spraying the upper part of the sheet with a solution of formaldoxim according to Hecht and Gottlieb [4*]. The sheet was subsequently treated with ammonia vapour. The method readily permits the detection of 0.05 μg of manganese.

* The formaldoxim solution according to Hecht and Gottlieb is prepared by dissolving hydroxylamine hydrochloride (19.95 g) and paraformaldehyde (10 g) in distilled water (100 ml).

Iron present in amounts of approximately 5 μg could easily be seen as a yellow spot. Even 1 μg quantities were easily detected if the sheets were sprayed with a methanolic solution of ammonium rhodanide (5 %) and subsequently treated with hydrochloric acid vapours. The R_F-value of iron was 0.5—0.7.

Recovery experiments in which Cu, Mn and Ni were added to the oil in amounts of 0.1 p.p.m. showed that complete recovery was obtained with Mn and Ni, whereas a negligible loss of Cu occurred during the analytical process.

Procedure

The testing of the oil was performed according to a method used by Simons *et al.*[5] Oil (2 ml) was carefully measured into several beakers, 23 mm in diameter and 27 mm in height, which had been thoroughly cleaned just prior to use. Care was taken to avoid smearing the oil on the walls of the beakers. The samples were placed in a constant temperature oven at 34.5 ± 0.5°C. At recorded intervals, three (in some experiments two) beakers of each sample of oil were removed and individual determinations of the peroxide values and vitamin A contents were immediately performed.

Metallic ions were removed from the oils in the following way: A chromatographic tube, approximately 400 mm in length and 22 mm in diameter, was used. At its lower end there was a glass filter plate and a stopcock. The tube was filled with a slurry of an ion exchange resin (Amberlite IR 100, analytical quality) in distilled water to give a bed approximately 320 mm deep. The level of the liquid was not allowed at any time to fall below that of the resin. Percolation of 5 % HCl (1 800 ml) through the column over a period of at least 15 min ensured that the resin was in the hydrogen form. The column was washed with successive portions of distilled water (10 ml) until the effluent had a pH of about 4. The column was then prepared for the oil by percolating 100 ml of 2-propanol through it in order to remove water from the resin, followed by 100 ml of a mixture of 85 % 2-propanol and 15 % benzene.

Fifty ml of oil was mixed with 15 ml of benzene and 35 ml of 2-propanol and the mixture percolated through the column. Fifty ml of 30 % benzene in 2-propanol and then pure 2-propanol were added until all the oil had passed through the column. The solvents were removed from the oil-2-propanol-benzene mixture by evaporation under vacuum.

Metal ions were usually incorporated in the oil samples as chlorides dissolved in absolute ethanol. These solutions were added to the oil to give a final concentration of 2 % of the total amount of oil. In two experiments the ions of copper and iron were incorporated in the oils as stearates dissolved in paraffin oil. The solutions were added to give a final concentration of 2 % of the vitamin A oil. Antioxidants were added as solutions in propylene glycol or ground-nut oil and these solutions were always added to give a concentration of 2 % of the total amount of the vitamin A oil. Citric acid was added as a 30 % solution in absolute ethanol. As citric acid was usually added to a total concentration of 0.01 %, the amount of ethanol added in this way seldom exceeded 0.05 %.

RESULTS

The experiments are summarized in Tables 2—20.

In the tables the term "relative stability" means ratio of the time for 50 % destruction of vitamin A in oil containing metal ion or antioxidant, to the time for the same distruction of vitamin A in the same oil containing no metal ion or antioxidant.

Figs. 1—4 are typical diagrams showing peroxide value relative to time, percentage destruction of vitamin A relative to time, and percentage destruction of vitamin A relative to peroxide value.

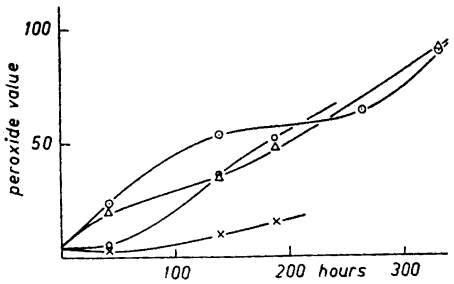

Fig. 1. Increase in peroxide value in oil from which metal ions had been removed and to which various amounts of Cu had been added (as $CuCl_2$). The samples were kept in the dark and exposed to air at 34.5°C for different lengths of time.

Not only did the metal ions increase the destruction rate of vitamin A, they also decreased the peroxide value for the oil at a certain percentage of vitamin A destruction. When the metal ions were added as stearates, as in the two experiments with iron and copper, their catalytic effect was not so pronounced as when they were added as chlorides.

Table 2. Effect of $Al^{3}+$

Oil	Concentration of $Al^{3}+$ p.p.m.	Time for 50 % destruction of vitamin A, hours	Peroxide number in the oil when 50 % of the vitamin A initially present is destroyed	Relative stability

C	100	379	12	0.38

Aluminium ions markedly increased the rate of vitamin A destruction and this effect was noticeable even at concentrations of 1 p.p.m. (Table 2).

At concentrations of 1 p.p.m. and 10 p.p.m., copper was the strongest accelerator of the destruction of vitamin A of all the metals tested. The addition of 10 p.p.m. and 100 p.p.m. of copper ions caused the same rate of destruction, but the peroxide value for the same percentage of vitamin A destruction was much lower in the oil with 100 p.p.m. of copper (Table 3).

* The ferric ions were added as stearates dissolved in paraffin oil.

Ferric ions at a concentration of 100 p.p.m. caused more rapid destruction of vitamin A than any concentration of the other metals tested. Iron did not accelerate the breakdown of vitamin A at 1 p.p.m. but increased its detruction at 6 p.p.m. The decrease in peroxide value at 50 % destruction of vitamin A was less pronounced when iron was added to the oil than when copper was added (Table 4).

Nickel ions had a moderately accelerating effect on the destruction of vitamin A. The decrease in peroxide value for 50 % destruction of vitamin A with nickel ions was less than for ions of copper and iron. It was confusing to notice that in oil C, which was found to be extremely sensitive to the

Table 5. Effect of Ni^{2+}

C	100	385	9	0.40

presence of all the other metal ions tested, the effect of nickel was comparatively small (Table 5).

The pro-oxidative effects of tin and zinc were weak. The increase in vitamin A destruction and the decrease in peroxide value were hardly detectable when these metal ions were added at concentrations of 1 p.p.m. At 10 p.p.m. these metals had a noticeable effect (Tables 6 and 7).

Table 8 shows that citric acid definitely stabilized vitamin A. In the range 0.1—0.01 %, the effect was practically independent of the concentration. Citric acid was effective in "trapping" copper ions which is shown in Table 12. Ascorbic acid had good antioxidant properties. The addition of 0.01 % of ascorbic acid to one of the tested oils increased the time for 50 % destruction of vitamin A by about 20 %. Ascorbyl palmitate had no effect (Tables 9 and 10).

Citraconic acid is considered to be a powerful antioxidant for margarine [6]. In these experiments, however, citraconic acid had no antioxidant properties

(Tables 11 and 12). Table 12 shows the effects of citric, ascorbic and citraconic acids in an oil in which 10 p.p.m. of copper was incorporated.

Lecithin was found to be a very good antioxidant for stabilizing vitamin A. In the concentration range 0.01—0.1 % the stabilizing effect increased approximately linearly with the concentration. The effect of lecithin was added to the effect of phenolic antioxidants present but, as could be expected, the combined effect of citric acid and lecithin was less than the sum of the effects for each of them (Table 13).

DPPD (NN'-diphenyl-*p*-phenylene diamine) was the most powerful stabilizer of vitamin A of all the antioxidants tested. In the range 0.001—0.01 %,

its effect increased approximately linearly with the logarithm of the concentration (Table 14).

The results from the experiments made with BHA and BHT are summarized in Tables 15, 16, and 17. Table 15 shows that BHA and a mixture of equal amounts of BHA and BHT were inferior to BHT in their ability to stabilize vitamin A.

In this experiment the temperature in the constant temperature oven fell to room temperature and remained at that level for 24 h. The figures are valid only when compared with each other.

Some experiments were made with propyl gallate, NDGA and tiodiphenylamine. The results are summarized in Tables 18 and 19. NDGA and propyl gallate had distinctly antioxidative effects but tiodiphenylamine had no effect. The latter substance even seemed to be antagonistic to lecithin.

Some commercial antioxidant mixtures were also tested. The results from these experiments are summarized in Table 20. A mixture containing BHT, BHA, propyl gallate and lecithin citrate gave the best results. When added at a concentration of 0.05 %, as recommended by the manufacturer, this mixture increased the time for 50 % destruction of vitamin A by 50 %.

DISCUSSION

The effect of metal ions on the oxidation of various fats and oils has been studied by Lea [7], Morris *et al.*[8], and Evans *et al.*[9] and others. Lea studied the accelerating effect of metal ions at room temperature in the presence of an aqueous phase while the other investigators used an A.O.M. stability test. Lea found that 1 p.p.m. of Fe and 0.1 p.p.m. of Cu greatly enhanced the oxidation of herring oil. Morris *et al.* found that the same amounts of these metals decreased the stability of lard by 50 %. Evans *et al.* found that 0.3 p.p.m. of Fe greatly accelerated the oxidation of soya-bean oil.

Under the conditions of this investigation the effect of trace metals is less pronounced. To double the rate of destruction of vitamin A, 10 p.p.m. of copper or iron has to be added to the oil when stored in the dark at 34.5°C. Aluminium or nickel must be present at a concentration of about 100 p.p.m. in order to accelerate the destruction to the same extent. As much as 100 p.p.m. of tin or zinc do not usually increase the rate of vitamin A destruction by 100 %. Metal ions seem to have at least two different effects on the oxidation of vitamin A in fish liver oil. One is a direct enhancement of the oxidation of vitamin A. The other is an acceleration of the breaking down of the peroxides formed. This second reaction seems to decrease the rate of oxidation of vitamin A *via* peroxides.

The effects of various antioxidants on the stability of vitamin A have previously been studied by Buxton [10,11], Caspe and Hadjopoules [12], Kring [13], Swain and Idler [14], Kamath and Magar [15], Spruyt [16], and Wodsack [17] and others. Different methods have been tried for testing and determining the vitamin A and peroxide values.

In this investigation, citric acid was found to act as a good stabilizer of vitamin A. It is not considered to be a true antioxidant [6,9], but is effective as an inactivator of trace metals and as a synergist for true antioxidants. As the fish liver oils tested contained detectable amounts of trace metals and as fish liver oils have been shown to contain antioxidants [10], it is understandable that citric acid should have some stabilizing effect.

Antioxidative properties have been reported for ascorbyl palmitate [17] and for citraconic acid [6]. In the experiments with fish liver oils reported here, however, no antioxidative effect could be detected.

Lecithin has a comparatively good stabilizing effect on vitamin A in fish liver oil. This effect is, however, only slightly increased by the addition of citric acid. The phosphorous acid group of lecithin is itself able to inactivate trace metals and therefore no additional effect of citric acid can be expected.

Acknowledgements. The author wishes to express his thanks to Professor H. Lundin, Head of the Division of Food Chemistry, for his valuable advise in the preparation of this paper. Thanks are due to Miss M. Ahrens, Mr. E. Kivisäkk, and Mr. E. T. Okine for technical assistance. The financial support of Kjellbergs Successors AB is greatfully acknowledged.

Zur Kenntnis der Carbonylgruppen im Lignin. I

ERICH ADLER und JOSEF MARTON

Institutionen för organisk kemi, Chalmers Tekniska Högskola, Göteborg, Schweden

Die Reduktion verschiedener Aldehyde und Ketone der Guajacylpropanreihe mittels Natriumborhydrid in alkalischer Lösung wurde spektrophotometrisch untersucht und die Veränderungen des Absorptionsspektrums der Lösungen beim Übergang der Carbonylverbindungen in die entsprechenden Alkohole wurden in Form der Borhydridreduktions-$\Delta\varepsilon$-Kurven ($\Delta\varepsilon_r$-Kurven) dargestellt.

Die $\Delta\varepsilon_r$-Kurven für Björkman-Lignin und dessen durch Behandlung mit Diazomethan erzeugtes Derivat wurden, ausgehend von den $\Delta\varepsilon_r$-Kurven der Modellsubstanzen, in qualitativer und quantitativer Hinsicht analysiert. Als Ergebnis wurden folgende Werte für die Anzahl von carbonylhaltigen Einheiten per OCH_3-Gruppe im Björkman-Lignin gefunden: <0,01 phenolische Coniferylaldehydeinheiten (Typ I), 0,03 verätherte Coniferylaldehydeinheiten (Typ II), 0,005—0,01 phenolische 4-Ketoguajakolgruppen (Typ III) und 0,05—0,06 verätherte 4-Ketoguajakolgruppen (Typ IV). Neben diesen konjugierten Carbonylgruppen (insgesamt 0,09—0,11/OCH_3) dürften etwa ebensoviele isolierte Ketogruppen (in der β-Stellung der Propanseitenkette) vorkommen.

Durch Oximierung von Björkman-Lignin (= "Milled wood lignin", M.W.L.)[1,2] aus Fichte mit Hydroxylaminhydrochlorid und potentiometrische Titrierung der freigelegten Salzsäure wurde gefunden, dass dieses Lignin auf etwa jede fünfte Guajacylpropaneinheit eine Carbonylgruppe enthält (0,18—0,21 CO/OCH_3)[3,4]. Auch wenn die Feinmahlung des Holzes vor der Extraktion des Lignins in Stickstoffatmosphäre vorgenommen wurde [2], liessen sich die Carbonylgruppen nachweisen, woraus hervorgehen dürfte, dass die lezteren tatsächlich dem nativen Lignin angehören und nicht erst während des Isolierungsprozesses (oxydativ) gebildet werden.

Für die nähere Kenntnis der Biosynthese und der Struktur des Lignins wäre es von Bedeutung, Aufschluss über die Lokalisierung und Verteilung der Carbonylgruppen im Ligninmolekül zu gewinnen. Qualitative Hinweise liefert das Infrarotspektrum. Im IR-Spektrum des Björkman-Lignins (Fig. 1) zeichnen sich zwei für Carbonyle typische Bandengruppen ab. Die längerwellige (1 690—1 660 cm^{-1}, Schwerpunkt bei 1 675 cm^{-1}) kann die konjugierten Aldehydgruppen der phenolischen and verätherten Coniferylaldehydeinheiten (I, II) sowie Arylketone (III, IV) umfassen. Die kürzerwellige und schwächere

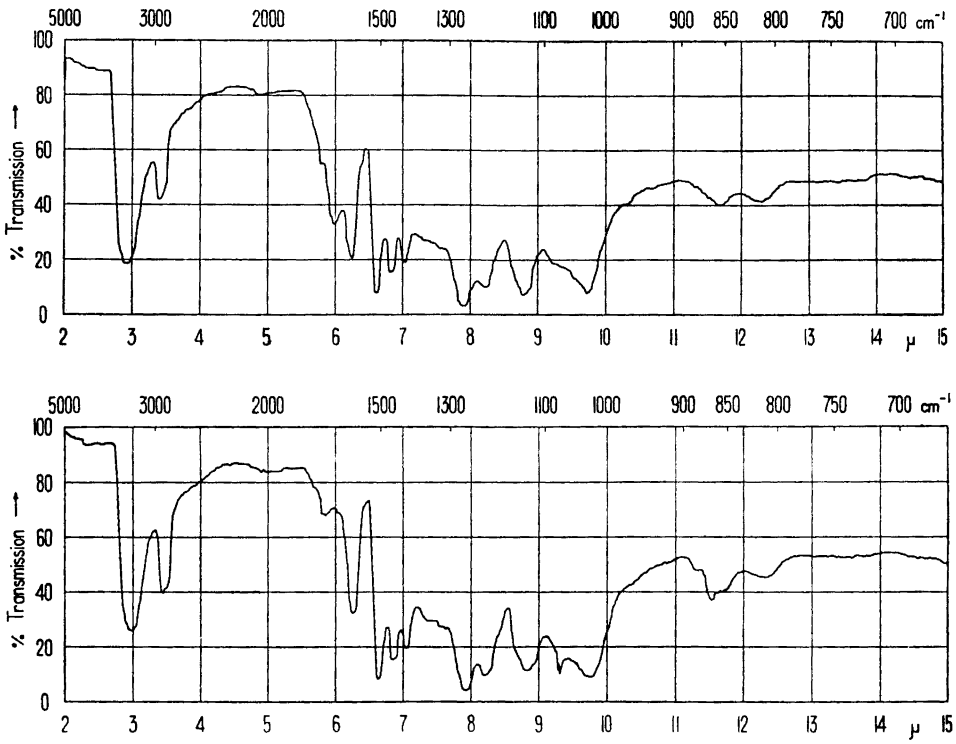

Fig. 1. Oben: IR-Spektrum von Björkman-Lignin L II *(Picea abies). Unten:* IR-Spektrum eines mit $NaBH_4$ reduzierten Björkman-Lignins.

Absorption (1 725—1 710 cm^{-1}) lässt isolierte, d. h. in der Mitte der Propanseitenkette stehende Ketogruppen (V, VI) erkennen. Nichtkonjugierte Aldehydgruppen, die bei 1 740—1 720 cm^{-1} absorbieren sollten, können nicht streng ausgeschlossen werden. War die Feinmahlung des Holzes unter Stickstoff ausgeführt worden, so zeigte daraus isoliertes Björkman-Lignin keine merkbare Absorption für nichtkonjugierte Aldehydgruppen. Eine Zusammenstellung der C=O-Streckungsfrequenzen für eine Reihe von Modellsubstanzen findet sich in Tab. 1. (S. 86).

Aus Tab. 1 ist zu entnehmen, dass die für Arylketone normalerweise bei 1 700—1 680 cm^{-1} liegende Carbonylbande in einigen Fällen nach niedrigerer Frequenz verschoben ist. Dies gilt besonders für die Oxyketone XI, XX und XXa, mit Frequenzen von 1 668—1 665 cm^{-1}, und für die Diketone XIV und XV (1 665—1 660 cm^{-1}). Die Banden solcher α-Ketone würden also mit denen der Coniferylaldehydgruppen zusammenfallen.

Im Spektrum eines mit Natriumborhydrid reduzierten Björkman-Lignins [5] (Fig. 1) fehlt die längerwellige Bandengruppe. Die Intensität der kürzerwelligen Bandengruppe ist herabgesetzt; die restliche Absorption (bei 1 725—1 700 cm^{-1}) ist vielleicht auf Spuren von Carboxylgruppen zurückzuführen.

V : R = H
VI : R = C-Atom einer Seitenkette

Für den qualitativen und quantitativen Nachweis der im IR-Spektrum erkennbaren ungesättigten Aldehydgruppen vom Coniferylaldehydtyp (I und II) stehen mehrere schon bekannte Methoden zur Verfügung. Björkman-Lignin zeigt die Wiesner'sche Reaktion (Rotfärbung mit Phloroglucin-Salzsäure) sowie Gelbfärbung mit aromatischen Aminen, z. B. *p*-Aminobenzoesäure, Reaktionen, die für Gruppen vom Typus I und II charakteristisch sind [6,7]. Der kolorimetrische Vergleich der durch *p*-Aminobenzoesäure hervorgerufenen Färbung des Björkman-Lignins (λ_{max} in 60 %-iger Essigsäure bei 445 mμ) mit den entsprechenden Farbstoffen aus Coniferylaldehyd oder dessen Äthern deutet darauf hin, dass auf etwa 35 Guajacylpropaneinheiten im Lignin eine Coniferylaldehydgruppe (I + II) trifft (etwa 0,03 Gruppen I + II per OCH_3)[4]. Derselbe Wert wurde für Brauns-Lignin erhalten, und Aulin-Erdtman und Hegbom [8] geben auf Grund von Messungen der spektralen Veränderungen bei Ionisierung, Sulfonierung und alkalischer Desulfonierung ($\Delta\varepsilon$-Methoden) von Brauns-Lignin *(Picea abies)* die Werte für I und II zu 0,01 bzw. 0,02 per OCH_3 an.

Die Aldehydgruppen in Einheiten vom Coniferylaldehydtyp (I und II) machen somit nur einen kleinen Teil des Gesamtcarbonyls aus. Auch der Anteil von 4-Ketoguajakolgruppen (mit freiem Phenolhydroxyl) (Typ III) scheint sehr begrenzt zu sein. Solche Gruppierungen verursachen beim Übergang von neutraler zu alkalischer Lösung eine Extinktionserhöhung im Gebiet um 350 mμ, und aus den Ionisierungs-$\Delta\varepsilon$-Werten für diesen Bereich hat Aulin-Erdtman [8] auf das Vorkommen von 0,02—0,03 Gruppen III per OCH_3 (in Brauns-Lignin aus *Picea abies*) geschlossen. Björkman-Lignin gibt bei 350 mμ ungefähr dieselben Ionisierungs-$\Delta\varepsilon$-Werte [2]. Aulin-Erdtman [8] hat schliesslich auch versucht, die Menge von verätherten 4-Ketoguajakolgruppen (Typ IV) zu schätzen und gibt für Brauns-Lignine aus *Picea mariana* und *Tsuga heterophylla* Werte von 0,02 bzw. 0—0,01 Gruppen IV per OCH_3 an.

Wir haben nun die Frage der differenzierten Bestimmung der verschiedenen Typen von Carbonylgruppen, besonders im Björkman-Lignin, mit Hilfe einer neuen Methode angegriffen. Die Methode schliesst sich an Beobachtungen an, die kürzlich von D. C. C. Smith [9] mitgeteilt wurden. Smith fand, dass *p*-Oxyaryl-aldehyde und -ketone sowie Coniferylaldehyd von Natriumborhydrid in 0,01 N NaOH langsam reduziert werden, während die Reduktion

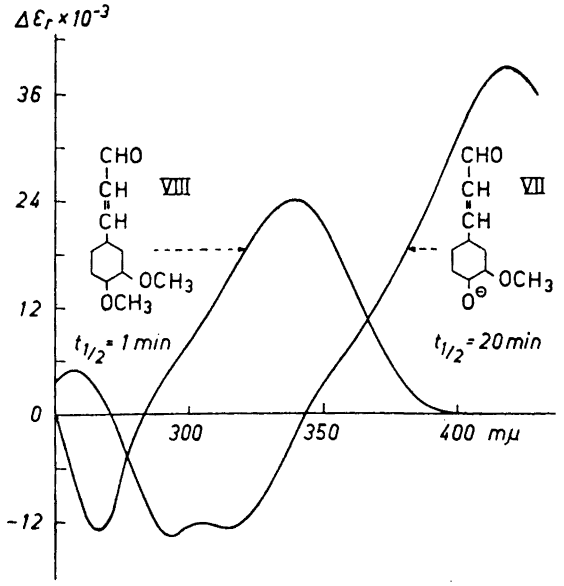

Fig. 2. $\Delta\varepsilon_r$-Kurven für Coniferylaldehyd (VII) und Methylconiferylaldehyd (VIII) nach 100 min Reduktionsdauer (Versuchsbedingungen, siehe Experimenteller Teil).

entsprechender Carbonylverbindungen mit verätherten Phenolhydroxyl rasch verläuft. Reduktion von vier verschiedenen Brauns-Ligninen verursachte einen Abfall der Extinktion der Lösungen bei 350 mμ; eine rasch verlaufende Anfangsphase wurde der Reduktion von verätherten Coniferylaldehydeinheiten (Typ II), eine folgende langsame Phase der Reduktion von 4-Ketoguajakolgruppen (III) zugeschrieben.

Es war nun zu erwarten, dass ein genauerer Vergleich der spektralen Veränderungen bei der Borhydridreduktion von Lignin bzw. von geeigneten Modellsubstanzen in alkalischer Lösung eine quantitative Bestimmung der carbonylhaltigen Gruppierungen I—IV erlauben würde, da diese als konjugierte Chromophore in spezifischer Weise zur Ultraviolettabsorption des Ligninmoleküls beitragen. Eine direkte Erfassung der Gruppierungen V und VI mit nicht-konjugierter Ketogruppe erschien weniger aussichtsreich. Wie weiter unten gezeigt wird, gaben jedoch auch Modellsubstanzen vom Typ V und VI bei der Borhydridreduktion spektrale Änderungen, die bei der Deutung der mit Lignin erhaltenen Befunde berücksichtigt werden mussten.

Dem Vergleich zwischen Lignin und Modellverbindungen wurden die Differenzkurven zugrundelegt, die durch Subtraktion der ε-Werte der reduzierten Lösung von den ε-Werten der (alkalischen) Lösung ohne Borhydrid konstruiert wurden. (Die so erhaltenen "Borhydridreduktions-$\Delta\varepsilon$-Kurven" werden im folgenden kurz als "$\Delta\varepsilon_r$-Kurven" bezeichnet.) Durch diese Anwendung der von Aulin-Erdtman [10] eingeführten $\Delta\varepsilon$-Methode auf die Borhydridreduktion des Lignins werden die konjugierten Carbonylsysteme (I—IV) von übrigen Chromophoren gesondert sichtbar und der Auswertung zugänglich gemacht.

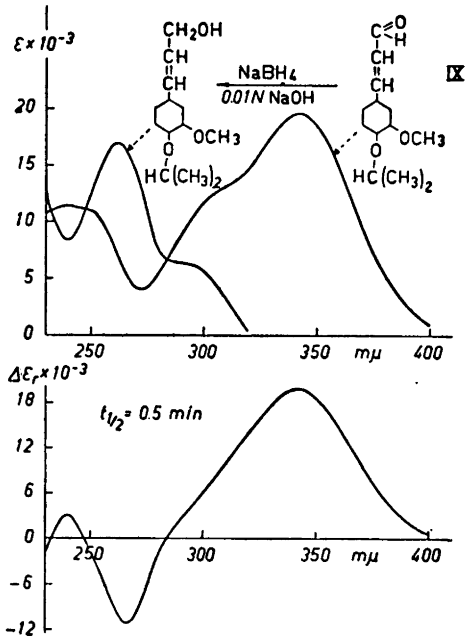

Fig. 3. Oben: Absorptionskurven von *Iso*propylconiferylaldehyd (IX) und dessen Borhydridreduktionsprodukt (50 min Reduktionsdauer). *Unten:* $\Delta\varepsilon_r$-Kurve.

Borhydridreduktion von Modell-Carbonylverbindungen

Coniferylaldehyd (VII) — als Vertreter des Strukturtyps I — zeigt in alkalischer Lösung eine intensive Absorption mit einem Maximum bei 418 mμ (ε_{max} = 39 000) (vgl. auch [11]). Bei Zusatz von überschüssigem Natriumborhydrid verschwand das langwellige Absorptionsband und es bildeten sich neue Maxima bei 290 und 315 mμ aus, die dem Übergang in Coniferylalkohol (vgl.[12]) entsprechen. Die Absorptionsänderung war nach 100 Min. fast beendet, und die Halbwertzeit ($t_{½}$) für den Extinktionsabfall bei 420 mμ war 20 Min. Subtraktion der Extinktionswerte der reduzierten Lösung von den Ausgangswerten lieferte die in Fig. 2 angegebene $\Delta\varepsilon_r$-Kurve.

In Tab. 1 sind die langwelligen Maxima der $\Delta\varepsilon_r$-Kurven für die untersuchten Modelle zusammengestellt. Dieselbe Tabelle gibt auch Aufschluss über die Geschwindigkeit der Borhydridreduktion (Halbwertzeiten), ermittelt aus dem zeitlichen Verlauf des Extinktionsabfalls im Absorptionsmaximum.

Coniferylaldehyd-methyläther (VIII) und der entsprechende *Iso*propyläther (IX) — als Vertreter des Strukturtyps II — haben im Gegensatz zu dem ionisierbaren Coniferylaldehyd in alkalischer Lösung dasselbe Absorptionsspektrum wie in neutraler Lösung ($\lambda_{max.}$ 340 bzw. 342 mμ) und die sehr rasch verlaufende $NaBH_4$-Reduktion liefert das Spektrum der entsprechenden ver-

ätherten Coniferylalkohole. Die $\Delta\varepsilon_r$-Kurve für VIII ist ebenfalls in Fig. 2 wiedergegeben; für IX sind in Fig. 3 als Beispiel für die Konstruktion der $\Delta\varepsilon_r$-Kurven sowohl die Absorptionskurven vor und nach der Reduktion sowie die Differenzkurve dargestellt.

Als Modelle für den phenolischen 4-Ketoguajakoltyp (III) wurden die Verbindungen X—XIII und als Sonderfall das Diketon XIV untersucht. Die Hauptmaxima der Absorptionsspektren für die ionisierten Phenolketone X—XIII (in 0,01 N NaOH) liegen zwischen 345 und 356 mμ, und da die ent-

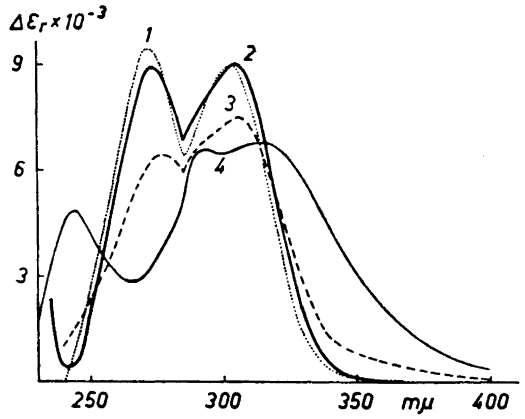

Fig. 8. $\Delta\varepsilon_r$-Kurven für *1)* 4-Propioveratron (XVI); *2)* β-Oxy-propioveratron (XX); *3)* α-Oxy-propioveratron (XVII); *4)* Veratroylmethylketon (XV), nach 100 min Reduktionsdauer.

sprechenden Phenolalkohole auch in alkalischer Lösung bei diesen Wellenlängen nicht mehr absorbieren, erhalten die $\Delta\varepsilon_r$-Kurven die Maxima und die Intensitäten der langwelligen Banden der ionisierten Phenolketone. Die Reduktion der Phenolketone verläuft sehr langsam. Nach 100 Min. Reduktionsdauer in 0,01 N NaOH war bei X und XIII der Extinktionsabfall nur sehr geringfügig, und erst nach etwa 70 Stunden hatte die Reaktion ihr Ende erreicht. Vanilloylmethylketon (XIV) unterliegt einer stufenweisen Reduktion, indem zunächst die β-ständige Carbonylgruppe sehr rasch reduziert wird, wobei sich das Ketol XI bildet, das langsam weiterreagiert.

Die $\Delta\varepsilon_r$-Kurven für die Ketone X, XI, XIII und XIV sind in den Fig. 4—7 wiedergegeben. (Langwellige Maxima der $\Delta\varepsilon_r$-Kurven und Halbwertzeiten für X—XIV, vgl. Tab. 1.)

Die Substanzgruppe XVI—XXI umfasst Vertreter des verätherten 4-Ketoguajakol-Typs (IV), zu dem auch das verätherte Diketon XV zu rechnen ist. Die $\Delta\varepsilon_r$-Kurven für Propioveratron (XVI), α-Oxy-propioveratron (XVII), β-Oxy-propioveratron (XX) und Veratroylmethylketon (XV) sind in Fig. 8 dargestellt. Für α-Guajakoxy-β-oxy-propioveratron (XXI) sind in Fig. 9 teils die Absorptionskurven der alkalischen Lösung vor und nach der Reduktion, teils die daraus konstruierte $\Delta\varepsilon_r$-Kurve wiedergegeben. (Vgl. auch Tab. 1.) Noch stärker ausgeprägt als in der Gruppe der Coniferylaldehyde verläuft bei den α-Ketonen die Reduktion relativ sehr viel rascher, wenn die phenolische Hydroxylgruppe verätherт ist (Tab. 1).

Überraschenderweise unterschied sich die Absorption der alkalischen Lösung des Ketols XXI (Fig. 9), obwohl es keine freie Phenolhydroxylgruppe enthält, von derjenigen seiner neutralen Lösung. In 0,1 N NaOH (in 50 proz. Äthanol) waren die Extinktionswerte (ε), verglichen mit der neutralen Lösung, bei 247 mμ um einen Betrag von 950, bei 340 mμ um 900 erhöht, während sie bei 280 mμ um 400, bei 310 mμ um 200 vermindert waren. Die entsprechenden Extinktionsänderungen in 1 N NaOH waren +3 000,

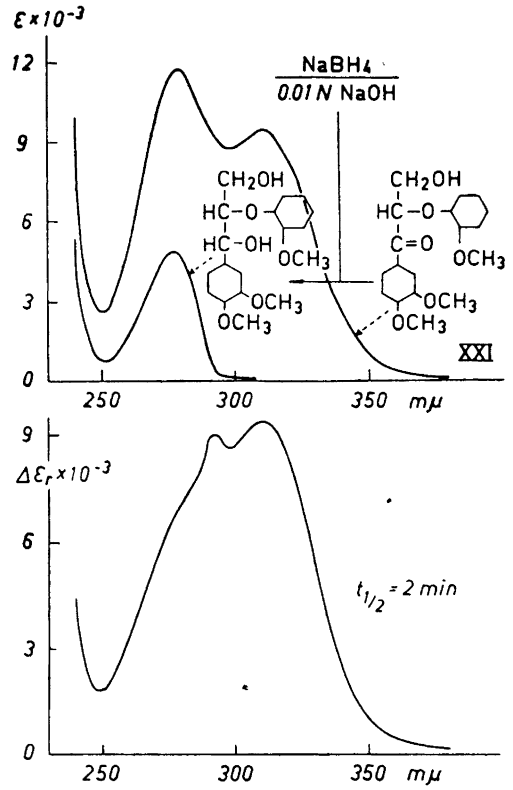

Fig. 9. Oben: Absorptionskurven von α-Guajakoxy-β-oxy-propioveratron (XXI) und dessen Borhydridreduktionsprodukt (50 min Reduktionsdauer). *Unten:* $\Delta\varepsilon_r$-Kurve.

+1 800, −1 300 und −440. Diese Alkaliverschiebung erinnert an die bei der Ionisierung von konjugierten Phenolen auftretende — jedoch sind die $\Delta\varepsilon$-Werte dort viel höher (vgl.[10]) —, und es lag daher der Verdacht nahe, dass das verwendete Präparat Spuren des entsprechenden Phenols als Verunreinigung enthielt. Die Alkaliverschiebung des Spektrums blieb jedoch nach Reinigung der Substanz (Ausschütteln ihrer ätherischen Lösung mit verdünnter Lauge) erhalten. Bei einigen anderen verätherten α-Ketonen, z. B. α-Oxypropioveratron (XVII), und weniger ausgeprägt bei den Ketonen XVIII und XIX, wurde ein ähnlicher Effekt beobachtet. Möglicherweise handelt es sich hier um eine Enolisierung.

Die Substanzen XXII, XXIV, XXV und XXVI [14] wurden als Modelle für die β-Ketongruppierung mit phenolischer Hydroxylgruppe (Strukturtyp V) untersucht. Obwohl bei diesen Verbindungen die Reduktion des Ketons zum sekundären Alkohol nicht mit der Aufhebung einer Konjugation verknüpft ist, bedingt sie doch eine gewisse Änderung des Absorptionsspektrums. Die β-Ketogruppe steht über das α-Kohlenstoffatom mit dem aromatischen Kern in Beziehung (vgl.[15]). In neutraler Lösung ist ihr Einfluss allerdings so gering,

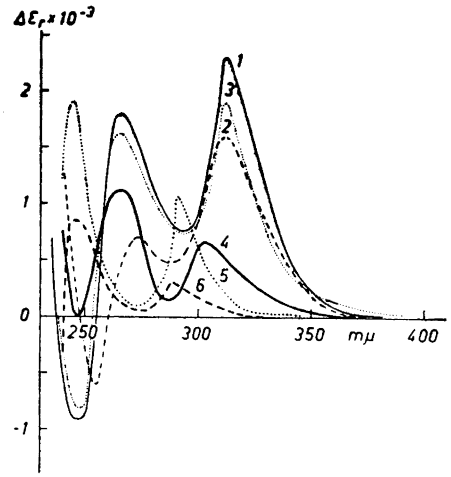

Fig. 10. $\Delta\varepsilon_r$-Kurven für *1)* Guajacylaceton (XXII); *2)* Syringylaceton (XXIV); *3)* ω-Oxyguajacylaceton (XXV); *4)* 4-Oxy-2,6-dimethoxyphenylaceton (XXVI); *5)* Veratrylaceton (XXIII); *6)* 2,4,6-Trimethoxyphenylaceton (XXVII), nach 100 min Reduktionsdauer.

dass die Absorption der β-Ketone derjenigen von unkonjugierten Guajacylpropanen weitgehend ähnlich ist. In alkalischer Lösung dürfte jedoch infolge der erhöhten Polarisation der Ketogruppe deren Einfluss auf die chromophoren Eigenschaften der Gesamtstruktur deutlicher werden; auch an eine schwache Enolisierung, die dem Auftreten einer *Iso*eugenolstruktur entspräche, könnte man denken. Die Abwesenheit solcher Effekte im entsprechenden sekundären Alkohol dürfte die Absorptionsänderung erklären. Die $\Delta\varepsilon_r$-Kurven von Guajacylaceton (XXII), Syringylaceton (XXIV) und ω-Oxyguajacylaceton (XXV) sind einander sehr ähnlich (Fig. 10); ihre Intensitäten sind aber ungefähr zehnmal kleiner als die der phenolischen α-Ketone (Typ III). Das Phloroglucinderivat XXVI schliesst sich den übrigen Acetonverbindungen gut an. (Siehe auch Tab. 1.)

ω-Oxyguajacylaceton (XXV), das im allgemeinen als "β-Oxyconiferylalkohol" (vgl. z. B.[16]), d. h. als die Enolform von XXV, bezeichnet wird, zeigt im IR-Spektrum (in fester Phase) eine normale C=O-Bande (1 718 cm^{-1}) und in neutraler Lösung (95 % Äthylalkohol) das UV-Spektrum einer unkonjugierten Guajakolverbindung, besitzt also unter solchen Bedingungen die Ketonstruktur (XXV). In alkalischer Lösung wird es ziemlich rasch oxydativ verändert, was sich in einer fortschreitenden Erhöhung der Extinktion im Bereich um 350 mμ zu erkennen gibt. Die Bestimmung der Absorptionskurven des Ketols XXV — sowie der übrigen phenolischen β-Ketone — erforderte deshalb besondere Vorsichtsmassnahmen (N_2-Atmosphäre).

Veratrylaceton (XXIII) und 2,4,6-Trimethoxyphenylaceton (XXVII)[14] dienten schliesslich als Modelle für die verätherte β-Ketongruppierung (Typ VI). Der Unterschied zwischen der Absorption dieser Ketone und derjenigen der entsprechenden Alkohole ist, besonders im Bereich höherer Wellenlänge, sehr geringfügig (Fig. 10, Tab. 1).

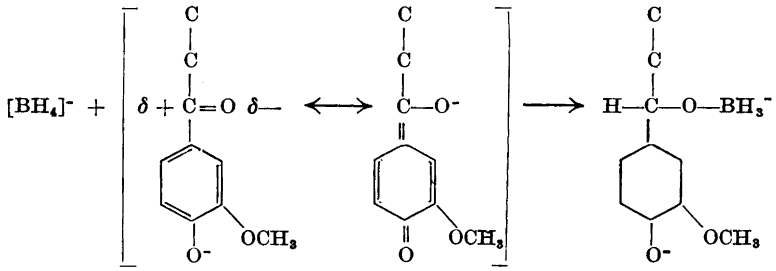
a Feste Substanzen wurden in KBr-Tabletten, Öle zwischen NaCl-Platten gemessen.
b Versuchsbedingungen, siehe Experimenteller Teil.
c Wenn andere Zeitangaben fehlen, war die Reduktion nach 100 min vollständig.

Die Abhängigkeit der Reduktionsgeschwindigkeit von der Struktur der Carbonylverbindung (vgl. Tab. 1) ist vereinbar mit der Annahme eines nucleophilen Angriffs durch das $[BH_4]^-$-Ion oder das $H:^-$-Ion auf das Kohlenstoffatom der Carbonylgruppe; die Reduktion verläuft umso schneller, je stärker positiv dieses C-Atom ist. Bei den sehr langsam reagierenden phenolischen α-Ketonen (Typ III) ist durch die Resonanz des Phenolatketon-anions der positive Charakter des Carbonyl-C-Atoms stark abgeschwächt; bei den entsprechenden Äthern ist die Resonanz zwischen dem substituierten Kern und der Ketogruppe weniger ausgeprägt und sie reagieren deshalb rascher.



Ähnliches gilt für Coniferylaldehyd (Typ I) bzw. dessen Äther (Typ II).

Elektronenanziehende Substituenten an dem der Carbonylgruppe benachbarten C-Atom wirken positivierend und erhöhen die Reduktionsgeschwindigkeit sowohl in der Reihe der phenolischen wie der verätherten 4-Ketoguajakole (OH > Guajacyl > OC_2H_5); ein OH-Substituent am ω-C-Atom wirkt schwächer beschleunigend (vgl. XX resp. XVII mit XVI). Andrerseits setzen elektronenabstossende (negativierende) Substituenten an der Carbonylgruppe die Reduktionsgeschwindigkeit herab, wie aus folgenden Beispielen hervorgeht:

	Halbwertzeit in 0,01 N NaOH
Vanillin	127 Min.
Propioguajakon (X)	24 Std.
Veratrumaldehyd	2 Min.
Propioveratron (XVI)	18 Min.

Erhöhung der Alkalikonzentration im Reaktionsgemisch der Borhydridreduktion (von der in der vorliegenden Arbeit angewandten 0,01 N NaOH auf 0,1 N NaOH) wirkte stark verlangsamend sowohl auf die Reduktion der phenolischen wie der verätherten

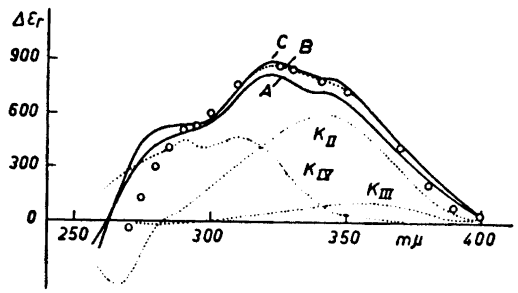


Fig. 11. $\Delta\varepsilon_r$-Kurven von Björkman-Lignin L I (vgl. Text), nach 50 min (A), 22 h (B) und 46 h (C) Reduktionsdauer, sowie berechnete $\Delta\varepsilon_r$-Kurven für 0,03 Mol/l *Iso*propyl-coniferylaldehyd IX (K_{II}), 0,005 Mol/l α-Guajakoxy-propioguajakon XIII (K_{III}) und 0,05 Mol/l α-Guajakoxy-β-oxy-propioguajakon XXI (K_{IV}). Addition der $\Delta\varepsilon_r$-Werte von K_{II}, K_{III} und K_{IV} ergibt die mit O bezeichneten Werte. Versuchsbedingungen, siehe Experimenteller Teil.

α-Ketone. Die in Tab. 1 angegebenen Halbwertzeiten wurden mindestens auf das 2—4-fache erhöht. (Propioguajakon X lässt sich durch mehrtägige Einwirkung von Borhydrid in 0,01 N NaOH präparativ sehr gut in Guajacyl-äthyl-carbinol überführen; in 0,1 N NaOH dagegen ist die Methode praktisch kaum mehr anwendbar.) Auch dieser Effekt scheint sich in die oben dargestellten Zusammenhänge einzufügen; bezüglich des Alkalieinflusses auf die Reduktion der verätherten α-Ketone sei auch auf die durch steigende Alkalikonzentration hervorgerufene successive Änderung der UV-Absorption des Ketons XXI hingewiesen (Enolisierung? vgl. S. 83—84).

Borhydridreduktion von Björkman-Lignin

Die Borhydridreduktion wurde an zwei unbehandelten Präparaten aus *Picea abies*, L I (14,84 % OCH_3) und L II (15,23 % OCH_3), sowie an einem mit Diazomethan methylierten [17] Präparat, DL III (19,41 % OCH_3), spektrophotometrisch verfolgt. Präparat L I entstammte einem Holzmehl, dessen Feinmahlung in der Schwingmühle unter Stickstoff vorgenommen worden war [2].

Die Einwirkung von Borhydrid auf das in 0,01 N NaOH (Lösungsmittel: Monomethylglykol-Äthanol-Wasser 4:6:5) gelöste Björkman-Lignin L I verursachte einen raschen Abfall der Extinktion im Bereich von 270—400 mμ. Nach 50 Min. Reduktionsdauer hatte die $\Delta\varepsilon_r$-Kurve das in Fig. 11, Kurve A, angegebene Aussehen. Die Reduktion verlief danach so langsam weiter, dass eine nach 100 Min. ausgemessene Kurve sich von Kurve A kaum unterscheiden liess. Nach 22 Stunden dagegen waren die $\Delta\varepsilon_r$-Werte deutlich erhöht (Kurve B), und nach 46 Stunden (Kurve C) war die Reaktion offenbar zum Stillstand gekommen.

Auf Grund der Modellversuche sollte Kurve A die (rasch verlaufende) Reduktion von verätherten Coniferylaldehydgruppen (Typ II) sowie von verätherten 4-Ketoguajakolgruppen (Typ IV) wiederspiegeln. Die Schulter bei etwa 342 mμ stimmt mit den Maxima der $\Delta\varepsilon_r$-Kurven der verätherten Coniferylaldehydmodelle (Fig. 2, 3) überein. Das Maximum bei 320—322 mμ ist

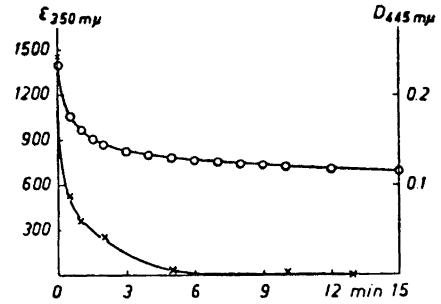

Fig. 12. Borhydridreduktion von Coniferylaldehydgruppen in Björkman-Lignin L II: Abfall der Extinktion bei 350 mμ (Kurve O und linke Ordinate). Farbreaktion mit *p*-Aminobenzoesäure, gemessen bei 445 mμ (Kurve × und rechte Ordinate). Versuchsbedingungen, siehe Exp. Teil.

gegenüber dem für das $\Delta\varepsilon_r$-Maximum der Ketone vom Typ IV erwarteten (305—310 mμ, vgl. Fig. 8, 9) nach Rot verschoben; wie weiter unten gezeigt wird, kann dies auf Überlagerung der $\Delta\varepsilon_r$-Kurven von Typ II und Typ IV zurückgeführt werden. Nach 50—100 Min. langer Reduktion müssten auch bereits phenolische Coniferylaldehydgruppen (Typ I) in der $\Delta\varepsilon_r$-Kurve sichtbar werden. Sie würden verhältnismässig hohe $\Delta\varepsilon_r$-Werte am langwelligen Ende der Kurve verursachen. Da aber die $\Delta\varepsilon_r$-Werte in diesem Gebiete sehr niedrig sind, können Coniferylaldehydgruppen mit freiem Phenolhydroxyl nur in Spuren im Präparat L I vorhanden sein. Aus demselben Grunde kann auch die Anwesenheit von Vanilloylmethylketongruppierungen (XIV) (vgl. Fig. 7) ausgeschlossen werden.

Der geringe Extinktionsabfall während der langsamen Reduktionsphase (Erhöhung der $\Delta\varepsilon_r$-Werte von A nach B und C), besonders im Bereich um 350 mμ, kann nach den Modellversuchen auf die Reduktion phenolischer 4-Ketoguajakolgruppen (III) zurückgeführt werden.

Die oben vorgenommene Zuordnung des langwelligen Teils der $\Delta\varepsilon_r$-Kurve A zur Reduktion von (verätherten) Coniferylaldehydeinheiten konnte auf folgende Weise gestützt werden. Für eine Lösung von Björkman-Lignin in 0,01 N NaOH wurde teils der Extinktionswert bei 350 mμ gemessen, teils wurde in einer mit Essigsäure angesäuerten Probe der Lösung die Intensität der durch Zusatz von *p*-Aminobenzoesäure hervorgerufenen Gelbfärbung bestimmt. Die alkalische Lösung wurde hierauf mit $NaBH_4$ versetzt und es wurde teils der Abfall der Extinktion bei 350 mμ, teils, in abpipettierten Proben, die *p*-Aminobenzoesäurereaktion zeitlich verfolgt. Hierbei zeigte sich, dass die Intensität der Farbreaktion parallel mit dem Abfall der Extinktion abnimmt und Null wird, wenn die rasche Phase des Extinktionsabfalls im Reduktionsgemisch abgeschlossen ist (Fig. 12).

Durch Vergleich der $\Delta\varepsilon_r$-Werte der Kurven A—C (Fig. 11) mit den $\Delta\varepsilon_r$-Kurven der Modellsubstanzen lässt sich nun auch eine mengenmässige Schätzung der verschiedenen Carbonyltypen in dem untersuchten Ligninpräparat vornehmen.

Wie bereits erwähnt, kann man vom Vorkommen merklicher Mengen von Coniferylaldehydgruppen mit freiem Phenolhydroxyl (Typ I) im Präparat L I

absehen. Kurve A kann man sich aus den $\Delta\varepsilon_r$-Werten für die zwei rasch reagierenden Carbonyltypen, nämlich verätherte Coniferylaldehydgruppen (Typ II) und verätherte 4-Ketoguajakole (Typ IV) zusammengesetzt denken. Als Vergleichssubstanzen für diese Gruppierungen wählten wir den *Iso*propylconiferylaldehyd (IX) und das α-Guajakoxy-β-oxypropioveratron (XXI). Substanz IX besitzt ein $\Delta\varepsilon_r$-Maximum von 19 800 bei 342 mμ (Fig. 3 und Tab. 1); das $\Delta\varepsilon_r$-Maximum von Substanz XXI ist 9 400 bei 310 mμ. (Fig. 9 und Tab. 1.) Bei 310 mμ hat Substanz IX $\Delta\varepsilon_r = 10\,500$, während Substanz XXI bei 342 mμ ein $\Delta\varepsilon_r$ von 2 020 besitzt. Kurve A (Fig. 11) hat bei 310 mμ den $\Delta\varepsilon_r$-Wert 750, bei 342 mμ den $\Delta\varepsilon_r$-Wert 720. Bezeichnet man die Anzahl verätherter Coniferylaldehydgruppen (II) in Lignin (in Mol per OCH_3) mit x, die der verätherten 4-Ketoguajakolgruppen (IV) mit y, so gilt:

$$\text{bei } 310 \text{ m}\mu\text{:} \quad 10\,500\ x + 9\,400\ y = 750,$$
$$\text{bei } 342 \text{ m}\mu\text{:} \quad 19\,800\ x + 2\,020\ y = 720.$$

Hieraus ergibt sich $x = 0{,}031$ Gruppen II per OCH_3, und $y = 0{,}046$ Gruppen IV per OCH_3 in Präparat L I.

Die Anzahl phenolischer 4-Ketoguajakolgruppierungen (Typ III) lässt sich direkt aus der Grösse des langsamen Extinktionsabfalls ermitteln. Bei 356 mμ z. B. ist die Differenz zwischen den $\Delta\varepsilon_r$-Werten von Kurve A und Kurve C 110; wählt man als Modell das α-Guajakoxy-propioguajakon (XIII) mit $\Delta\varepsilon_r = 24\,600$ im Maximum (356 mμ), so ergibt sich ein Wert von 110/24 600 = 0,005 Gruppen III per OCH_3.

Um die Zuverlässigkeit der voranstehend beschriebenen quantitativen Auswertung zu prüfen, wurden $\Delta\varepsilon_r$-Kurven für die ermittelten Anteile der 3 Komponenten gesondert konstruiert, indem man die $\Delta\varepsilon_r$-Werte der Modelle IX (für Typ II), XIII (für Typ III) und XXI (für Typ IV) mit 0,03, 0,005 bzw. 0,05 multiplizierte. Die so erhaltenen $\Delta\varepsilon_r$-Kurven der einzelnen Komponenten sind in Fig. 11 als K_{II}, K_{III} und K_{IV} bezeichnet. Addition der $\Delta\varepsilon_r$-Werte dieser drei Kurven bei verschiedenen Wellenlängen ergab die mit o bezeichneten Werte. Diese fallen im Bereich zwischen 290 und 370 mμ mit der experimentell erhaltenen Kurve C zusammen. Die geringfügige Abweichung oberhalb 370 mμ dürfte auf dem Vorkommen sehr kleiner Mengen phenolischer Coniferylaldehydgruppen, die hier vernachlässigt wurden, beruhen. Die mangelnde Übereinstimmung im Bereich unterhalb 290 mμ kann durch die Wahl des Vergleichsmodells XXI bedingt sein; andere Modelle, wie Propioveratron (XVI) und β-Oxy-propioveratron (XX), haben in diesem Bereich höhere $\Delta\varepsilon_r$-Werte. Möglicherweise macht sich hier auch der Einfluss von nicht-konjugierten (β)-Ketonen geltend (s. unten).

Die $\Delta\varepsilon_r$-Kurven für das Björkman-Lignin-präparat L II (Fig. 13) zeigen etwas höhere $\Delta\varepsilon_r$-Werte als die Kurven für L I. Da Präparat L II aus einem Holzmehl stammte, dessen Schwingmahlung in gewöhnlicher Weise in Luft vorgenommen worden war, während bei L I die Mahlung unter Stickstoff erfolgte, deuten die erhöhten $\Delta\varepsilon_r$-Werte auf eine oxydative Neubildung von konjugierten Carbonylgruppen hin. Einen Hinweis hierauf hatte bereits der Vergleich der Ionisierungs-$\Delta\varepsilon$-Kurven geliefert [2]. Die Hydroxylaminmethode gab einen kleinen aber eindeutigen Unterschied im Gesamt-Carbonylgehalt (0,18 CO/OCH_3 in L I; 0,21 CO/OCH_3 in L II), und wie die Auswertung der $\Delta\varepsilon_r$-

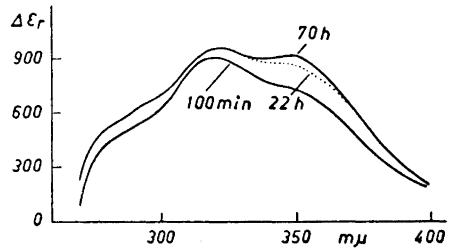

Fig. 13. $\Delta\varepsilon_r$-Kurven von Björkman-Lignin L II.

Kurven zeigt, hält sich auch die Neubildung von konjugiertem Carbonyl innerhalb bescheidener Grenzen.

Am langwelligen Ende der $\Delta\varepsilon_r$-Kurven für L II (Fig. 13) sind die $\Delta\varepsilon_r$-Werte deutlich höher als bei L I (Fig. 11). Würde man den bei 400 mμ gefundenen Wert (180) auf phenolische Coniferylaldehydeinheiten zurückführen, so würde sich, da Coniferylaldehyd bei 400 mμ $\Delta\varepsilon_r = 32\,000$ besitzt, ein Gehalt von $180/32\,000 = 0{,}006$ phenolischen Coniferylaldehydgruppen per OCH_3 ergeben.

Die weitere Analyse der $\Delta\varepsilon_r$-Kurven für L II lieferte folgende Werte: 0,03 verätherte Coniferylaldehydgruppen (Typ II), 0,01 phenolische 4-Ketoguajakolgruppen (Typ III) (gegenüber 0,005 bei L I) und 0,05—0,06 verätherte 4-Ketoguajakolgruppen (Typ IV) per Methoxyl (Summe: 0,09—0,10 konjugierte Carbonylgruppen per OCH_3; unter Einbeziehung der oben diskutierten phenolischen Coniferylaldehydgruppen würde sich diese Summe auf 0,10—0,11 konjugiertes CO/OCH_3 erhöhen).

Die bei der Borhydridreduktion des mit Diazomethan methylierten Björkman-Lignins (DL III) erhaltenen Resultate stehen in guter Übereinstimmung mit den oben beschriebenen. Methylierung mit Diazomethan beeinflusst die in Frage stehenden konjugierten Carbonyleinheiten in verschiedener Weise. Nach

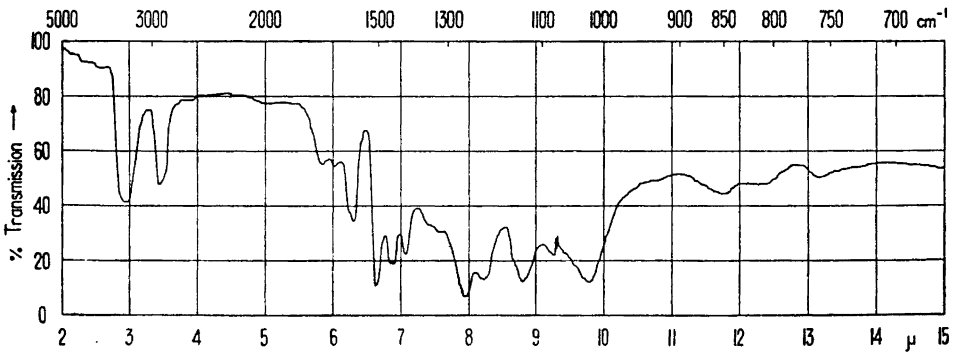

Fig. 14. IR-Spektrum eines mit CH_2N_2 methylierten Björkman-Lignins (Präparat DL III).

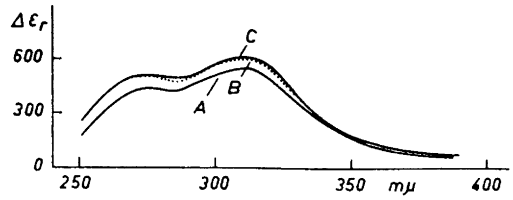

Fig. 15. $\Delta\varepsilon_r$-Kurven eines mit CH_2N_2 methylierten Björkman-Lignins (DL III) nach 100 min (A), 22 h (B) und 46 h (C) Reduktionsdauer.

Kratzl und Wittmann [18] lagert sich Diazomethan an die Äthylenbindung der Coniferylaldehydseitenketten unter Bildung eines Pyrazolinrings an. Hierbei wird die Konjugation der Aldehydgruppe mit dem aromatischen Kern aufgehoben; die typischen Farbreaktionen werden nicht mehr gegeben. Ferner werden phenolische Ketongruppierungen (III und V) durch Methylierung des Phenolhydroxyls in verätherte (IV und VI) übergeführt.

Im IR-Spektrum von DL III (Fig. 14) ist die langwellige Carbonylbande infolge der Umsetzung der Coniferylaldehydgruppen mit Diazomethan viel schwächer als im Spektrum des unbehandelten Lignins (vgl. Fig. 1, oben). Die vorhandene Absorption um 1 665 cm^{-1} kann mit dem Vorkommen von Arylketongruppierungen mit 1,3-Ketolstruktur, wie z. B. beim β-Oxypropioveratron (XX), erklärt werden (vgl. S. 76 und Tab. 1). Auch Spuren von Coniferylaldehydgruppen, welche der Anlagerung von Diazomethan entgangen sein mögen, könnten zu dieser Absorption beitragen. Die Absorptionsbande für isolierte Carbonylgruppen liegt im Bereich von 1 725 — 1 705 cm^{-1}.

Die Effekte der Diazomethanbehandlung auf die carbonyltragenden Einheiten des Lignins zeichnen sich auch in der Borhydridreduktions-$\Delta\varepsilon$-Kurve des Präparats DL III (Fig. 15) deutlich ab. Die für die nicht methylierten Präparate (L I, L II) charakteristische Schulter mit relativ hohen $\Delta\varepsilon_r$-Werten bei 340—350 mμ fehlt in der Kurve für DL III infolge der Absättigung der Coniferylaldehydseitenketten durch die Anlagerung von Diazomethan. Die nach 100 Min. erhaltenen $\Delta\varepsilon_r$-Werte um 350 mμ erhöhen sich nicht bei verlängerter Reduktionsdauer, da nun die Phenolhydroxyle der ursprünglichen 4-Ketoguajakole vom Typ III methyliert sind.

Das bei den unmethylierten Präparaten bei 322—325 mμ liegende Maximum ist im Falle des methylierten Lignins DL III nach etwa 310 mμ gerückt, d. h. in den für das $\Delta\varepsilon_r$-Maximum der verätherten 4-Ketoguajakole (Typ IV) charakteristischen Bereich. Diese Verschiebung des Maximums ebenso wie die Erniedrigung der $\Delta\varepsilon_r$-Werte ist ohne weiteres durch das Wegfallen der Überlagerung mit den $\Delta\varepsilon_r$-Werten der verätherten Coniferylaldehydgruppen zu verstehen (vgl. Fig. 11). Für die geringfügige Erhöhung der $\Delta\varepsilon_r$-Werte im kürzerwelligen Gebiet bei verlängerter Reaktionsdauer gibt es gegenwärtig keine auf Modellversuche zu stützende Erklärung.

Der quantitative Vergleich der $\Delta\varepsilon_r$-Werte um 310 mμ für das methylierte Lignin DL III mit den entsprechenden Werten für das Modell XXI gibt an,

dass DL III 0,06—0,07 verätherte 4-Ketoguajakolgruppen (Typ IV) per OCH_3 enthält. Dieser Wert stimmt überein mit der Summe der Anzahl von verätherten (0,05—0,06) und phenolischen (0,01) 4-Ketoguajakolgruppen im nicht-methylierten Lignin.

Wir haben bei der Analyse der $\Delta\varepsilon_r$-Kurven der untersuchten Ligninpräparate bisher den eventuellen Beitrag durch β-Ketongruppierungen (Typ V und VI) unberücksichtigt gelassen. Wie oben gezeigt (S. 84—85, Fig. 10), geben phenolische β-Ketone, wie Guajacylaceton (XXII) und ω-Oxy-guajacylaceton (XXV), $\Delta\varepsilon_r$-Kurven mit Maximum bei 312 mμ, d. h. im selben Bereich wie die verätherten 4-Ketoguajakole, z. B. das Modell XXI (310 mμ). Wollte man das Hauptmaximum der $\Delta\varepsilon_r$-Kurven der unmethylierten Lignine (L I und L II) anstatt auf verätherte 4-Ketoguajakole (Typ IV) ausschliesslich auf die Anwesenheit von phenolischen β-Ketonen (Typ V) zurückführen, so würde dies bedeuten, dass die Ligninpräparate statt 0,05 Gruppen vom Typ IV etwa 0,25 Gruppen vom Typ V per OCH_3 enthalten. (Die $\Delta\varepsilon_r$-Werte der phenolischen β-Ketonmodelle XXII und XXV, 2 300 bzw. 1 900 bei λ_{max} = 312 mμ, sind etwa fünfmal kleiner als die Maximum-Werte der verätherten 4-Ketoguajakolmodelle, s. Tab. 1.) Es kann jedoch ausgeschlossen werden, dass phenolische β-Ketone nennenswert zum $\Delta\varepsilon_r$ im Maximum der Ligninkurven beitragen. Bei der Methylierung von Lignin mit Diazomethan würden nämlich die phenolischen β-Ketongruppen (Typ V) in verätherte (Typ VI) übergehen, und die letzteren sollten im Bereich von 310—312 mμ nur noch kaum messbare $\Delta\varepsilon_r$-Werte geben (vgl. z. B. Veratrylaceton, XXIII, Fig. 10). In Wirklichkeit bleibt aber, wie oben gezeigt, der $\Delta\varepsilon_r$-Wert bei 310 mμ (nach Abzug des Beitrags durch verätherte Coniferylaldehydeinheiten, s. Fig. 11) beim Übergang von Lignin zu methyliertem Lignin erhalten.

Es wurde gefunden, dass ω-Oxy-guajacylaceton (XXV) mit Diazomethan unter Verschwinden der Carbonylfunktion reagiert (IR-Spektrum). Wären phenolische β-Ketone von der Struktur XXV in grösserer Menge im Lignin vorhanden, so könnte man also auch aus dem eben genannten Grunde erwarten, dass beim diazomethan-methylierten Lignin der $\Delta\varepsilon_r$-Wert bei 310—312 mμ deutlich niedriger wäre als beim unbehandelten Lignin, was jedoch nicht der Fall ist.

Es mag schliesslich noch erwähnt werden, dass Brauns-Lignin *(Picea abies)* und diazomethan-methyliertes Brauns-Lignin bei der Borhydridreduktion ähnliche $\Delta\varepsilon_r$-Kurven lieferten wie die untersuchten Björkman-Ligninpräparate. Entsprechend dem höheren Totalgehalt an phenolischen Einheiten [5] sind auch die phenolischen 4-Ketoguajakolgruppen im Brauns-Lignin etwas reichlicher vertreten. Neben 0,03 verätherten Coniferylaldehydeinheiten (Typ II) und 0,04—0,05 verätherten 4-Ketoguajakoleinheiten (Typ IV) wurden 0,015—0,02 phenolische 4-Ketoguajakolgruppen (Typ III) per OCH_3 gefunden. Aulin-Erdtman [8] fand mit anderen $\Delta\varepsilon$-Methoden — neben 0,01 phenolischen Coniferylaldehydgruppen (Typ I) — 0,02 Gruppen von Typ II und 0,02—0,03 Gruppen vom Typ III.

Zusammenfassung und Diskussion

Unsere mit der Borhydridreduktionsmethode für Björkman-Lignin erhaltenen Resultate können folgendermassen zusammengefasst werden.

Das Lignin enthält per OCH_3 folgende Mengen mit dem aromatischen Kern konjugierte Carbonylgruppen:

a) in phenolischen Einheiten
<0,01 Aldehydgruppen in Coniferylaldehydeinheiten (I),
0,005—0,01 α-ständige Ketogruppen (III);
b) in nicht-phenolischen Einheiten
0,03 Aldehydgruppen in verätherten Coniferylaldehydeinheiten (II),
0,05—0,06 α-ständige Ketogruppen (IV).

Insgesamt sind damit 0,09—0,11 (konjugierte) Carbonylgruppen per OCH_3 lokalisiert. Dies ist ungefähr die Hälfte der Gesamtmenge von Carbonylgruppen (0,18—0,21 CO/OCH_3), bestimmt mittels der Hydroxylaminmethode [3,4]. Da β-ständige Carbonylgruppen in phenolischen Einheiten (Typ V) nicht in fassbarer Menge vorzukommen scheinen (s. S. 93) und da nicht-konjugierte Aldehydgruppen auf Grund des IR-Spektrums wenig wahrscheinlich sind, sollte die fehlende Hälfte der Carbonylgruppen der Hauptsache nach aus β-ständigen Ketogruppen in nicht-phenolischen Einheiten (Typ VI) bestehen. Auf sie spricht die $\Delta\varepsilon_r$-Methode nicht an (s. S. 85 und 93).

Gierer und Söderberg [19,20] haben neuerdings die gasvolumetrische Messung des Borhydridverbrauchs nach Lindberg [21] auf die Bestimmung des Gesamtcarbonylgehaltes von Lignin angewandt und kamen für Björkman-Lignin *(Picea abies)* zu Werten von 0,41—0,45 CO/OCH_3. Diese Werte sind etwas mehr als doppelt so hoch wie die von uns und auch von Gierer und Söderberg mittels der Hydroxylaminhydrochlorid-Methode gefundenen. Zur Erklärung der Diskrepanz zwischen den beiden Methoden weisen Gierer und Söderberg darauf hin, dass gewisse Modell-Carbonylverbindungen nur sehr langsam oximiert werden. Besonders langsam reagierte das sowohl in β- wie in γ-Stellung substituierte α-Keton XXI ("sterische Hinderung").

Auch im hiesigen Institut war, im Zusammenhang mit der Bestimmung des Gesamtcarbonyls in Lignin, die Geschwindigkeit der Oximierung mehrerer der auf S. 80 angegebenen Modellsubstanzen geprüft worden [3]. Unter den angewandten Bedingungen, die den von Gierer und Söderberg [20] angegebenen ähnlich waren, waren die am langsamsten reagierenden Verbindungen (gewisse α-Ketone) erst nach 300 Stunden voll oximiert; beim Vanilloylmethylketon (XIV), reagierte das erste Carbonyl ziemlich rasch, das zweite jedoch erst im Laufe von etwa 600 Stunden. Die von Gierer und Söderberg [19,20] gefundene Ausnahmestellung des α-Ketons XXI wurde nachträglich bestätigt; es war nach 500 Stunden erst zu 60 % oximiert. Für die Ligninpräparate wählten wir eine Oximierungsdauer von 500 Stunden (die Anwesenheit nennenswerter Mengen von Vanilloylmethylketongruppierungen konnte aus spektrochemischen Gründen ausgeschlossen werden).

Da nun mit Hilfe der in der vorliegenden Arbeit beschriebenen spektrophotometrischen Borhydridmethode festgestellt wurde, dass die Gesamtmenge von α-Carbonylgruppen (in phenolischen und verätherten Einheiten, III und IV) nicht mehr als 0,06—0,07/OCH_3 beträgt, kann ausgesagt werden, dass solche Gruppen nicht oder jedenfalls nur zu einem kleinen Teil für die Differenz zwischen den mit der Hydroxylaminmethode und der gasvolumetrischen Borhydridmethode erhaltenen Werten für das Gesamtcarbonyl verantwortlich gemacht werden können. Coniferylaldehydgruppen werden mit Hydroxylamin

sehr rasch umgesetzt, und ihre Menge (0,03—0,04/OCH_3) ist ausserdem durch verschiedene Methoden übereinstimmend festgelegt.

Will man daher annehmen, dass die Differenz zwischen den mit der Hydroxylaminmethode und den mit der gasvolumetrischen Borhydridmethode erzielten Werten darauf beruht, dass gewisse Typen von Carbonylgruppen durch die erstgenannte Methode nicht erfasst werden, so hätte man diese nicht-oximierbaren Carbonyle in der Reihe der β-Ketone zu suchen. Die Menge solcher Carbonyle sollte dann 0,20—0,25/OCH_3 betragen. Modellsubstanzen mit β-ständiger, nicht oximierbarer (aber durch Borhydrid reduzierbarer) Ketogruppe sind bisher nicht angetroffen worden; es wäre von Interesse, die Oximierbarkeit von Derivaten des ω-Oxyguajacylacetons (XXV), die am ω-Hydroxyl veräthert und eventuell auch am α-C-Atom substituiert sind, zu untersuchen. Auch an irgendwie "maskierte" Carbonylgruppen, die zwar Borhydrid verbrauchen aber nicht mit Hydroxylamin reagieren, wäre vielleicht zu denken.

Herrn Dr. J. C. Pew, Madison, Wisconsin, U. S. A., danken wir für die Überlassung von Coniferylaldehyd-*iso*propyläther, Herrn Dr. J. A. F. Gardner, Vancouver, Canada, für eine Probe von ω-Oxy-guajacyl-aceton. Herrn Docent A. Björkman, Säffle, Schweden, verdanken wir das Ligninpräparat L I.

Bei der Ausführung der Versuche erfreuten wir uns der Mitarbeit von Frau Terezia Marton.

Wir danken *Statens Tekniska Forskningsråd* für die Gewährung eines Forschungsbeitrags.

EXPERIMENTELLES

$\Delta\varepsilon_r$-Kurven der Modellsubstanzen. Das UV-Spektrum der Substanzen wurde gemessen in einer Lösung, die durch Mischen von 2 ml einer 0,1—0,4 mM Lösung der Substanz in Äthanol mit 1 ml 0,03 N wässriger Natronlauge bereitet wurde. In einem zweiten Reaktionsgemisch wurde anstelle der Natronlauge 1 ml einer 50 mM oder 100 mM Lösung von $NaBH_4$ in 0,03 N NaOH verwendet und das Absorptionsspektrum nach verschiedenen Zeiten gemessen. Die Stabilität des Spektrums der alkalischen Lösung ohne $NaBH_4$ wurde ebenfalls nach verschiedenen Zeiten geprüft. Als Vergleichslösungen dienten die entsprechenden Gemische ohne Substanz.

$\Delta\varepsilon_r$-Kurven der Ligninpräparate. Als Lösungsmittel für die Ligninpräparate diente ein Gemisch von 40 Volumteilen Monomethylglykol und 60 Volumteilen Äthanol. Die Konzentration der Lösungen war 0,1 g/l (für L I und L II) bzw. 0,2 g/l (für DL III). Die Messlösungen wurden bereitet aus 2 ml der Ligninlösung und 1 ml 0,03 N NaOH bzw. 1 ml einer 50 mM, im Falle von DL III einer 100 mM Lösung von $NaBH_4$ in 0,03 N NaOH. Die Extinktion ε ist auf die Konzentration an OCH_3 bezogen.

Die *p-Aminobenzoesäurereaktion* auf Coniferylaldehydgruppen (vgl. S. 89 und Fig. 12) wurde folgendermassen ausgeführt: Von der mit Borhydrid versetzten alkalischen Lösung des Lignins (Zusammensetzung wie voranstehend, jedoch Dioxan als Lösungsmittel) wurden nach verschiedenen Zeiten Proben von 1 ml abpipettiert und sofort mit 1 ml Eisessig vermischt. Die erhaltene Lösung wurde mit 2 ml *p*-Aminobenzoesäurereagens (1,65 g *p*-Aminobenzoesäure, 60 ml Eisessig und 25 ml 4 N HCl, mit Wasser auf 100 ml verdünnt) versetzt. Die optische Dichte der Lösung bei 445 mμ wurde gegen eine Vergleichslösung ohne Lignin gemessen. Der *D*-Wert für die Zeit Null wurde mit einer Ligninlösung ohne Borhydridzusatz bestimmt.

Die Messungen der Ultraviolettabsorption wurden mit einem Beckman DU-Gerät ausgeführt.

Zur Aufnahme der Infrarotspektren (KBr-Methode) diente ein Perkin-Elmer Instrument, Modell 21. Von den Modellsubstanzen wurden 1—1,5 mg, von den Ligninpräparaten 1,8 mg per 500 mg KBr verwendet.

On the Design and Efficiency of Isothermal Reaction Calorimeters

S. SUNNER and I. WADSÖ

Thermochemistry Laboratory, University of Lund, Lund, Sweden

A number of isothermal reaction calorimeters have been designed, built and tested. From an initial, very simple Dewar-type calorimeter a system was developed that showed an accuracy of 0.1 % and an equilibration time less than 2 minutes. To check the accuracy of the electrical calibrations, the heat of solution of potassium chloride was measured. The results obtained were compared with those of previous investigators.

In principle, changes in enthalpy accompanying a chemical reaction can always be calculated from heat of formation data, given that these are available for all the participating substances. In most cases this is not so — even the determination of a single heat of combustion value can be a laborious and very time-consuming task. Besides, in some reactions one (or more) of the participants may be too unstable for investigation by the combustion method [1]. A few years ago we therefore began to develop suitable apparatus for reaction calorimetry.

The variety in types of chemical reactions makes it impossible to design a more or less universally useful reaction calorimeter (in the same sense as a bomb calorimeter can be constructed). We therefore restricted the methodological work to calorimetric equipment suited to reactions obeying the following limiting conditions:

1. The reactions should be reasonably fast, the duration of the reaction period not exceeding one hour.
2. The total amount of heat evolved (or absorbed) during the reaction should be 50 cal. or less.

Further, the following conditions should be emphasized:

3. The size of the calorimeter should be *ca.* 100 ml.
4. The calorimeter should be simple in design and easy to operate, and
5. The accuracy achieved should be 0.1 % or 0.05 cal. whichever is larger.

Having these conditions in mind it was felt that a calorimeter of the "constant-temperature environment" (isothermal) type should be adopted. Furthermore,

there being no systematic treatise on reaction calorimeters available, it was decided to start by assembling a very simple Dewar-type calorimeter, and from the experience gained with this, to develop a more elaborate apparatus.

Altogether five different calorimeters have been built and tested, and the present paper reports briefly on the experience gained with these.

CALORIMETERS IN THE DEVELOPMENT STAGE

The essential features of design of the calorimeters are shown in Fig. 1. The second earliest type (A) consisted of a silvered Dewar vessel with an inner thin-walled glass-shield (e) and an inner socket standard joint *. All connections were made through the cone-joint: the thermistor (a) (in the beginning a Beckmann thermometer was used); the calibration element (b) and two short glass tubes carrying the stirrer (c) and the ampoule holder (d). A rigid mounting was achieved by use of sheets of cork interspaced by cork crumbs as insulating materials. The inner end of the standard cone-joint was protected against absorption of moisture from the calorimeter liquid by a paraffin wax-poly*iso*butene coating.

The temperature was measured by use of a thermistor (Stantel F 2311/300) in a conventional Wheatstone bridge arrangement. The thermistor was sealed into a glass tube; only the small thermistor bead extruded into the calorimeter liquid. The stirrer hung freely through the glass tube into the calorimeter liquid and was mounted directly on the shaft of a 600 rpm synchronous motor. At the start of an experiment, the Dewar-vessel was completely submerged in a thermostat, the temperature of which was constant to within 0.002°C. After equilibration the measurement was performed in the usual way by observing the temperature during the initial, reaction and final periods. The reaction was started by breaking a sealed glass ampoule on the bottom of the Dewar.

The heat equivalent of the calorimeter was determined by passing a known current through the known calibration resistance for a known length of time.

Although this common type is very easy to build and operate, it suffers from several weaknesses. The reproducibility was not very high, $\pm$ 0.5 %. The reasons for this are several. The mounting of the stirrer was not rigid enough to ensure an even heat of stirring. The ampoule, which was positioned very near the stirrer, broke irregularly causing a sudden change in the heat of stirring. The most serious disadvantage, however, was that the time for reaching thermal equilibrium was very long mainly due to the slow equilibration. This calorimeter has been used for several measurements [2,3].

In order to overcome these difficulties a new calorimeter was built (Fig. 1). This consisted of a steel can (B) which could be used together with one of three different surrounding systems — a solid copper block (B 1), a double walled glass flask (B 2) or a single-walled glass flask (B 3).

The calorimeter can was made out of high grade stainless steel and consisted of a thin-walled cylinder to which a lid and a bottom had been soldered. A

* The first calorimeter built consisted of an ordinary Dewar vessel, volume 150 ml, fitted with a heavy rubber stopper.

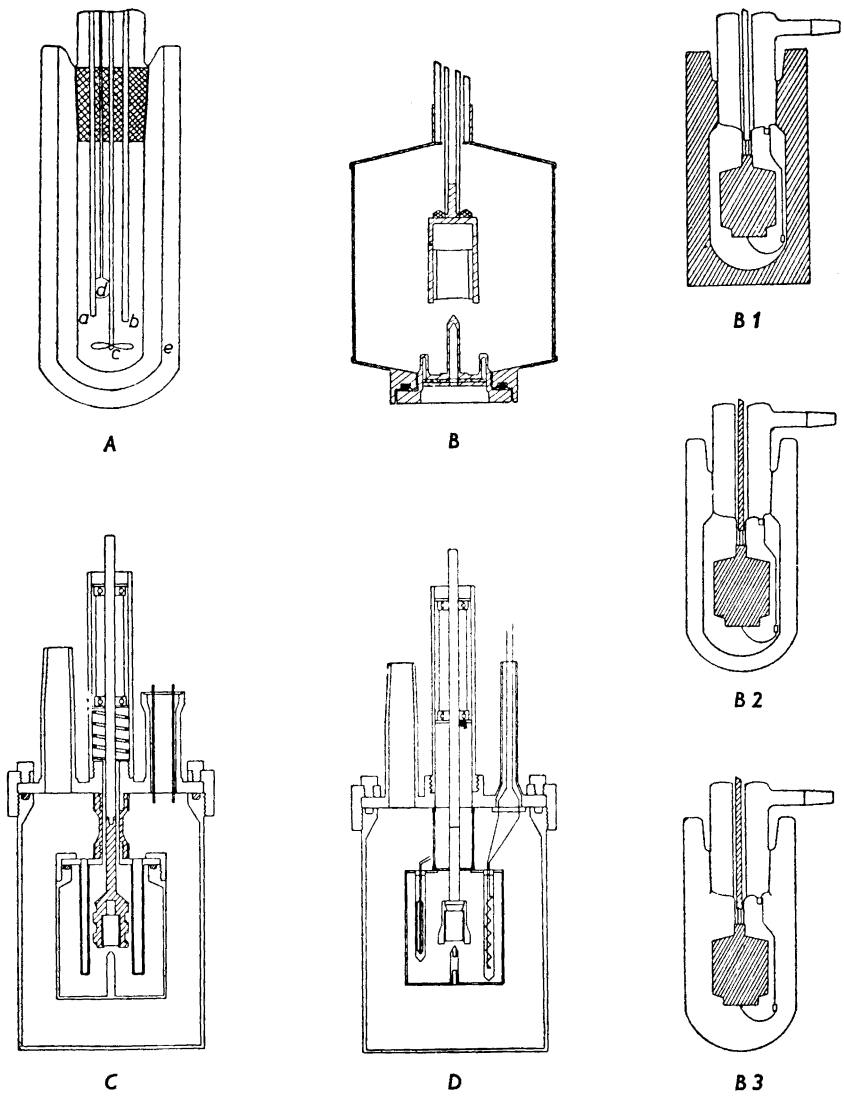

Fig. 1. Principle design of the calorimeters.

plug, machined from one piece of steel and having two wells was screwed into the bottom, and a high-vacuum tight seal was achieved by use of an O-ring gasket. The central well served to house the thermistor and the concentric well contained the calibration heater. This consisted of a 2 mm strip of thin mica on which a 0.15 mm manganin wire was wound (resistance 15 Ω). The strip was inserted into the bottom of the well and insulated from the walls by

use of mica. The lower part of the well was closed by a PVC ribbon; further insulation between the heater and the outside of the plug was effected by a PVC disk kept in place by a steel plate.

The calorimeter can was sealed to a tube extruding from a hollow glass stopper. Through the stopper, the space between the calorimeter can and the surrounding flask could be evacuated. The electrical connections were carried from the plug in the calorimeter can to four terminals placed on a strip of phosphor-bronze, and then passed through the stopper to the outside of the calorimeter.

The stirrer was made of steel and shaped like a three-armed clutch grasping the ampoule and provided with small wings for the stirring. It was sealed with sulphur to a short glass tube, the upper end of which was sealed to a steel rod. The stirrer and shaft were precisely centered during the sealing operation. The steel rod was mounted in two ball bearings outside the hollow stopper and could be moved up and down during a run.

At the start of an experiment, the calorimeter was held in an upside down position. The stirrer shaft was moved so that the ampoule holder projected from the can. The ampoule was inserted and the stirrer was moved back to give a leak-proof seal between the lid of the can and the ampoule holder by means of a small rubber gasket. The calorimeter can was filled with 90 ml of solution, the plug was screwed tight and the can was inserted into the jacket, which was afterwards submerged in the thermostat.

This calorimeter can together with the surrounding system (B 1) fulfilled the given conditions reasonably well and was used for several measurements [4-8]. It was, however, not convenient for reactions with a heavy second reaction component (bromine, or certain solids) as the stirring did not affect the liquid in the ditch between the thermistor and the calibration element wells. Further, the stainless steel was corroded by bromine or showed catalytic activity in the reaction $SO_2 + Br_2$ or I_2. Finally, with certain calorimeter liquids, *e. g.* amines, the rubber-gasket did not always give a leak-proof seal due to swelling or dissolution processes.

We therefore built a third calorimeter (Fig. 1, C), of a rather common design (*e. g.* Ref.[9]). This was machined from stainless steel and consisted of a body, a lid with tubes for the thermistor and the calibration element and a screw-nut ring. The high-vacuum seal was made with an O-ring gasket. All inner parts were coated with several layers of teflon, of total thickness 0.12 mm. The stirrer was made from a teflon-rod. The calorimeter can hung from the lid of the surrounding chromium-plated brass can in a tube of teflon.

This calorimeter was tested and immediately rejected because the equilibration was very slow, particularly if the calorimeter can was not completely or almost completely filled by liquid.

THE FINAL CALORIMETER

Finally, a calorimeter (Fig. 1, D), was built according to the main principles of the design of calorimeter B.

A thin-walled (0.5 mm) open can machined from one piece of brass was silver soldered to a brass lid. The bottom had a central rod to support an

ampoule-breaking pin. The lid was provided with two thin-walled tubes, and had a central, wide opening surrounded by two concentric thin brass-rings. After being chromium-plated, all interior parts of the can were coated with teflon as described above.

The calorimeter can hung from the lid of a surrounding brass can in a thin-walled (0.7 mm) glass tube which was sealed to the metal parts by Araldite applied to groves between the brass-rings. Thus, a rigid mounting as well as a high-vacuum tight seal were attained. In order to minimize the air gap between the stirring rod and the walls of the opening in the calorimeter can, a snugly fitting teflon coated brass gasket was introduced into the glass tube. The only free space between the gas phase in the calorimeter and the surrounding air was thus reduced to a 0.5 mm air gap around the stirring shaft.

The combined ampoule holder and stirrer was made of teflon-coated stainless steel and fastened to a teflon rod, the upper end of which was screwed on to the steel spindle of the stirring device. The whole stirrer was exactly centered and could be easily unscrewed from the lid of the outer brass can.

The thermistor was introduced into one of the tubes in the calorimeter can. The calibration element was placed in the second tube and both tubes were vacuum-tightly sealed with Araldite. The electrical connections were passed through the outer can by metal-glass seals soldered to the lid of the can.

The interspace was evacuated through a B19 standard cone, using a mechanical rotary pump and a three stage glass mercury pump attached to a liquid air trap. The evacuation was very rapid and a vacuum better than 10^{-4} mm Hg was reached within a few minutes after the start of the pumping.

This calorimeter was very easy and rapid to operate, one experimental cycle being completed within *ca.* 1 h.

Technique of mixing

The reaction period was started by breaking a glass ampoule and mixing the liquid or solid contents with the calorimeter liquid. In order to achieve rapid mixing a modification has been developed of a well-established procedure [9–12], in which the stirrer performs the breaking of the bulb.

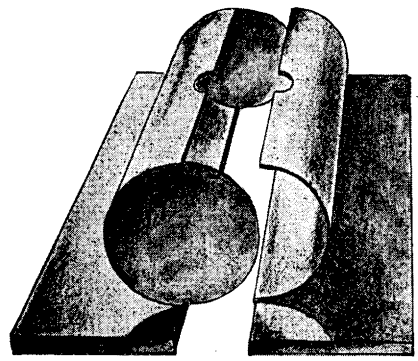

Fig. 2. Ampoule mould.

The ampoules were blown in a mould (Fig. 2) from selected thin-walled glass tubing. The method has two advantages: the ampoules are of uniform and predetermined size, and the end walls are very thin, facilitating the breaking and minimizing possible heat effects. For liquid samples, the ampoule shaft was drawn to a fine capillary as near the bulb as possible and for solid samples, the shaft was only slightly narrowed. When the sample had been introduced, the bulb was placed in a small copper block which was cooled by dry ice and the shaft was sealed very close to the bulb wall with a micro flame. The ampule was inserted centrally in the stirrer which during rotation gave the liquid an upward motion. By lowering the stirrer, a steel or platinum needle was forced to break through the end walls of the ampoule and a rapid mixing was achieved, the contents of the bulb being thrown out into the calorimeter liquid.

Heat effects arrising from bulb breaking

Many authors have pointed out that the breaking of a bulb may give rise to one or more small heat effects [11-13]. Principally such a heat effect can be traced back to one or several of the following causes:

1. The heat of stirring is dependent on the environmental situation — other conditions being equal. If the bulb is situated close to the stirrer the heat generated by friction between the liquid and the unbroken bulb might be significantly different from that generated between the liquid and the remaining parts of the broken bulb. This effect is the only one which is dependent on the speed of stirring and can therefore easily be detected by observing the time-temperature curves before and after breaking an empty bulb [12]. By varying the speed of stirring the highest rpm value can be found at which the change in the heat of stirring is insignificant.

It is of course desirable to make the breaking of the bulbs as uniform as possible. This is difficult when using the type of bulb which is very common and which we used in our first apparatus. However, a moulded bulb tends to break very uniformly. In our first calorimeter we found a varying and sometimes quite appreciable heat effect of this kind. It was not detectable in calorimeters B and D.

2. The heat of rupture of the bulb depends on the mechanical properties of the glass: wall thickness, internal strain *etc.* With rather large and rigid ampoules, the heat of rupture may be considerable [11].

In our case, in which the volume of the bulb is only *ca.* 1 ml and the end walls break through for a pressure of about 10 g this effect is negligible.

3. The heat of wetting of the inner surface of the glass bulb is usually a negligible quantity. Only in microcalorimetric measurements of, *e. g.*, heats of adsorption is it necessary to take this effect into consideration [13].

4. Heat effects due to a change of state of one or two of the phases in the calorimeter may or may not be significant depending on the experimental conditions. Bartell and Suggitt [11] have pointed out that the breaking of an evacuated bulb is followed by an evaporation. In the same way, the rupture of a bulb partly filled by a volatile liquid is accompanied by a condensation process.

5. The vaporized reactant in a partly filled ampoule may partly escape the surrounding liquid when the bulb is broken.

The magnitude of both effects 4 and 5 are easily estimated from vapor pressure data and the volume of the gaseous phase in the bulb. With 1 ml bulb they are usually negligible.

Time of equilibration

In high precision calorimeters it is of great importance to minimize the time of equilibration as much as possible. The method of comparative measurements is not rigorously applicable as the heat cannot be generated at the same rate in the calibration experiment as in the actual measurement. Evidently, a simultaenous measurement of the kinetics and exothermicity of a particular reaction also requires a small time lag of the apparatus compared to the total time of reaction.

The time of equilibration was experimentally determined for the different calorimeters by studying the heat transfer constant, K, as a function of time in a calibration experiment. K is defined as

$$K = \frac{| g_f - g_i}{| \Theta_i - \Theta_f}$$

where

g_i is the rate of temperature change during the initial period,
g_f is the rate of temperature change during the final period,
Θ_i is the mean temperature during the initial period and
Θ_f is the mean temperature during the final period.

By chosing different reaction times in one and the same experiment, different values of K were obtained and plotted against the time elapsing from the moment when the calibration current was shut off until the middle of the final period. In such a way the curves in Fig. 3 were obtained.

The following conclusions can be drawn from the results: Any construction which creates an indetermined boundary of the calorimeter system towards the surroundings leads to a slow equilibration. A stopper which is in reasonably good contact both with the calorimeter system as well as with the surroundings and which contains insulating materials (in order to slow down the heat transfer) introduces an appreciable time lag. Also, a radiation shield with a not negligible heat capacity compared to that of the calorimeter increases the time of equilibration. The three-parted calorimeter C was slow, due to the low heat conductivity of steel together with the fact that the lid and the screw-nut ring represent rather heavy masses far removed from the liquid phase. When the amount of liquid in the calorimeter was increased from 90 to 110 ml (the vessel was then almost full), the time of equilibration dropped from 40 to 15—20 min. Both calorimeter B with single glass wall (B 3) or copper block (B 1) as well as calorimeter D reached equilibrium rapidly. Indeed, D equilibrated within 2 min, as is best seen from the curve in Fig. 4.

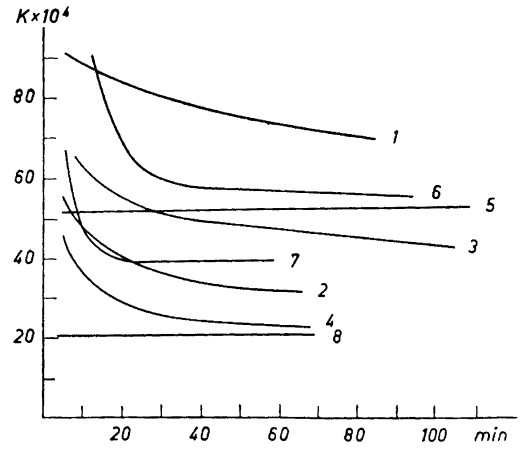

Fig. 3. *K*-values *versus* time. At time zero the input of *ca.* 50 cal of electrical energy was completed.

1) Ordinary Dewar, fitted with a heavy rubber stopper. 100 ml of water.
2) Calorimeter A. 75 ml of water.
3) Calorimeter B 2. 90 ml of water, 10^{-1} mm Hg.
4) Calorimeter B 2. 90 ml of water, 10^{-4} mm Hg.
5) Calorimeter B 1 and B 3. 90 ml of water, 10^{-1} mm Hg.
6) Calorimeter C. 90 ml of water, 10^{-1} mm Hg.
7) Calorimeter C. 110 ml of water, 10^{-1} mm Hg.
8) Calorimeter D. 100 ml of water, 10^{-4} mm Hg.

Temperature measuring system

The temperature was measured by a thermistor (Stantel F 2311/300) in a conventional D.C. bridge circuit [14]. Instead of using a high current sensitivity galvanometer together with scale and lamp outfit we have used a spotlight galvanometer (Cambridge Spot Galvanometer, 41159/2, sensitivity 0.03 μA/scale division for calorimeters A—C; Sullivan T 2001/D, sensitivity 0.005 μA/scale division for calorimeter D) together with a 40 × microscope. The sensitivity corresponds to a temperature change of the thermistor of less than 0.0001°C. The galvanometer was placed on a heavy iron plate resting on rubber knobs directly on a table. The mounting is simple and sturdy and the galvanometer is reasonably insensitive to vibrational disturbances.

The uncertainty in the determination of a temperature difference is estimated to $\pm$ 0.0002°C.

Electrical calibration system

The calibration resistance was wound from 0.15 mm lacquered and silk spun manganin wire on a thin-walled glass tube, coated with an epoxy resin and inserted into a glass or metal tube, which was then carefully sealed. The resis-

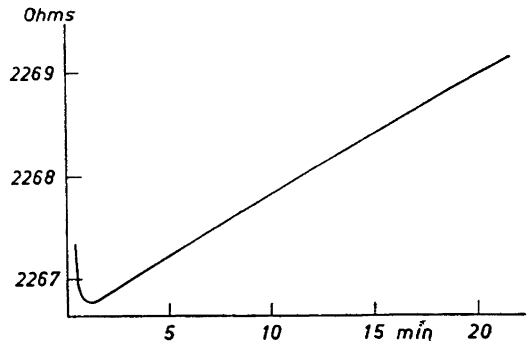

Fig. 4. Time of equilibration for calorimeter D, with water as calorimetric liquid. At time zero the input of *ca.* 50 cal of electrical energy was completed.

tance of the heater was measured between the leads to the heater at the midpoints between the calorimeter can and the outer jacket. The resistance was about 15 Ω (calorimeter B) and 65 Ω (calorimeter D). By separate experiments it was found that the resistance did not change within 0.001 Ω during a run.

The calibration was performed by the substitution method. The current from a 12 V storage battery was passed through a dummy heater, of the same resistance as the calibration resistance. When the current became constant, as found from the potential drop over a standard resistor in series with the dummy heater, the calibration was started by switching over to the calibration heater for a fixed time. The current was measured as above at regular intervals by use of a potentiometer (Leeds — Northrup Student Potentiometer, calorimeters A—C, and Rubicon High Precision Type B Potentiometer, calorimeter D).

The time during which the current was passed through the heater was chosen to equal the time of an actual experimental determination, if possible, the shortest time being *ca.* 240 sec. and the longest *ca.* 1 000 sec. The current was chosen to produce a temperature increase as near to that in an actual run as possible. The total input of electrical energy was usually kept at *ca.* 200 J. The uncertainty of the electrical calibration as calculated from the errors in the determinations of voltage, resistance and time was ±0.15 % for calorimeters A—C, and ± 0.05 % for calorimeter D.

All heat quantities are given in thermochemical calories, defined by 1 calorie = 4.1840 abs. joules.

Heat of solution measurements of potassium chloride

Mishchenko and Kaganovich [15] suggested in 1949 the solution of potassium chloride in water be used as a standard process to calibrate reaction calori-

meters. The authors critically examined the relevant literature and concluded that the best value for the integral heat of solution according to the equation

$$KCl\ (c) + 200\ H_2O\ (l) \rightarrow KCl,\ 200\ H_2O$$

is $\Delta H_{25°} = 4\,194 \pm 3$ cal.mole^{-1}.

In order to check the reliability of our calorimeters we therefore made heat of solution measurements with calorimeters B 1 and D.

A sample of pure KCl (Merck's pro analysi) was pulverized, carefully dried at 105°C for 2 h and stored in vacuum over phosphorus pentoxide. About 800 mg were weighed out, corresponding to a molar ratio KCl to H_2O of *ca.* 1 to 450. With calorimeter B 1 two sets of calibration experiments were performed (Table 1), one with pure salt and pure water (I) and the second with potassium chloride solution (II). The first set together with the dissolution experiments (Table 2) gave ΔH(soln) at 24.73°C and the second set gave ΔH(soln) at 25.17°C. In calculating the results in Table 2 the average value from Table 1 was used and the heat of solution values therefore refer to 24.95°C.

In Table 1, the first column gives the corrected logarithmic resistance ratio value (which is proportional to the temperature increase), the second column the input of electrical energy in calories and the third column the value of the heat capacity in calories per unit of $\log(R_i/R_f)$. In Table 2, the first column gives the amount of KCl (vacuum weight), the second the corrected temperature increase as above, the third column gives the heat absorbed, the forth

column gives the uncorrected heat of solution in cal.mole^{-1} and the last column gives the heat of solution value corrected to KCl, 450 H_2O and 25.00°C. The magnitudes of the corrections were obtained from the literature [16,17].

The same series of experiments were performed with calorimeter D, although only one set of calibration experiments was taken. The results are shown in Tables 3 and 4.

The agreement shows that systematic errors are either absent or equal in the two calorimetric systems. However, the difference between our value and that recommended by Mishchenko and Kaganovich, corrected to KCl, 450 H_2O, 4 196 ± 3 cal.mole^{-1}, is more than twice the sum of the standard deviations and therefore seems to be significant [18].

The recent careful investigation by Coops *et al.*[12] gives a heat of solution value of 4 126 cal.mole^{-1} for KCl, 5 170 H_2O. Corrected [16] to KCl, 450 H_2O this value becomes 4 165 cal.mole^{-1}.

From a comparison of the results given, it is obvious that systematic errors are present in one or more of the determinations. With calorimeters of an expected accuracy of *ca.* 0.1 %, the agreement between values obtained in different laboratories for a standard reaction should definitely be better. For the following reasons we question if the solution of KCl in water is really suitable for calibration purposes:

1. ΔH(soln)/ΔT at room temperature is too high (36 cal.mole^{-1} per centigrade).

2. On a molar basis, the heat of solution of KCl is inconveniently low. It might therefore easily be influenced by impurities, crystal shape and size, and dissolved gases in the water phase.

3. When used in connection with a measured reaction having a large temperature change, a rather large amount of KCl must be used. The con-

centration of the KCl solution will be high and the differential heat of solution for concentrated solutions is high. Thus not only has the temperature to be known with an accuracy of *ca.* 0.005°C but also the concentration must be very well defined in each experiment.

The Crystal Structure of Ru_7B_3

BERTIL ARONSSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The crystal structure of Ru_7B_3 has been determined from single crystal data. There are two formula units in the unit cell, which Åselius [14] has determined to be hexagonal with $a = 7.467$ Å and $c = 4.713$ Å. The space group is $P6_3mc$. The ruthenium atoms are situated in two six-fold positions 6 (*c*) with $x_I = 0.4563$, $z_I = 0.318$, and $x_{II} = 0.1219$, $z_{II} = 0.000$ and one two-fold position 2(*b*) with $z_{III} = 0.818$. The structure of Ru_7B_3 is very closely related to that of the trigonal chromium carbide Cr_7C_3.

Very little is known about the borides of the platinum metals. Buddery and Welch [1] have shown that a number of such borides exists and are easily prepared by direct combination of the elements. These authors have given the approximate compositions of many borides of the platinum metals and, in some cases, also have established the unit cell dimensions. Later Mooney and Welch[2] determined the crystal structure of Rh_2B from single crystal data. Rh_2B seems to be the only noble metal boride with known crystal structure and, as Geller [3] points out, it is isomorphous with Rh_2Ge[3], δ-Ni_2Si[4] and Co_2Si[5].

Since a knowledge of the platinum metal borides is very essential for a better understanding of the transition metal borides, X-ray investigations in this group of compounds have been started at this institute. The borides of ruthenium were supposed to be those most related to the well-known molybdenum and iron borides and were therefore chosen as the first object of investigation. In an investigation of the Ru-B system, Åselius [14], confirming the results of Buddery and Welch, has found that the most metal-rich intermediate phase in this system has the approximate composition Ru_2B. He was able to index the powder photograph, chosing a hexagonal unit cell with $a = 7.467$ Å, $c = 4.713$ Å and $c/a = 0.631$. The density was found to be 10.7 g/cm^3, showing that there are 14 ruthenium atoms in the unit cell and indicating that the formula should be written Ru_7B_3 rather than Ru_2B. Åselius [14] has also found the isomorphous phase Rh_7B_3 with $a = 7.47$ Å, $c = 4.78$ Å and $c/a = 0.640$.

The crystal structure of Ru_7B_3 has been determined with single crystals kindly donated by Åselius. The relation of this structure to that of the trigonal chromium carbide [6], Cr_7C_3, and to other transition metal borides will be discussed.

EXPERIMENTAL

Some small single crystals were picked out of an arc melted alloy. By use of Mo$K\alpha$-radiation, Weissenberg photographs around the a- and c-axes were taken of two crystals which were found to be free from satellites. The multiple film technique (with thin iron foils between the films) was used and the intensities were estimated visually. With the exception of a few low angle reflexions from the larger crystal (rotated around the a-axis), no serious influence from absorption or extinction could be detected. Log I_o/I_c decreased linearly with $\sin^2\Theta/\lambda^2$, and for both crystals the temperature constant B was found to be 0.42 Å^2. The $\varrho_o(xy)$ and $\varrho_c(xy)$ electron density projections were computed on the Hägg-Laurent [7] machine and with Beevers-Lipson strips. Twenty eight nonequivalent $hki0$ reflexions were used in these calculations.

DETERMINATION AND DESCRIPTION OF THE STRUCTURE

The Weissenberg photographs showed that the crystals were hexagonal. There was no evidence that the symmetry should be lower. The systematic extinctions of $hh\bar{2}\bar{h}l$ reflexions for l odd gave the possible space groups $P6_3/mmc$, $P\bar{6}2c$ and $P6_3mc$. The approximate positions of the 14 ruthenium atoms in the unit cell were deduced from the following two conditions:

(1). The ruthenium atoms cannot all have the z-parameters 0, 1/4, 1/2 and 3/4. This is a consequence of the relation $|F|_{0008} < |F|_{0002} < |F|_{0004} < |F|_{0006}$ which was found from the intensities of the $000l$-reflexions.

(2). No Ru-Ru contacts are shorter than 2.5 Å. This seems a reasonable assumption since the shortest Ru-Ru distance in pure ruthenium is 2.65 Å. In particular, this condition establishes that two ruthenium atoms cannot have the same x- and y-parameters but different z-parameters because such a situation would imply Ru-Ru contacts shorter than 2.36 Å ($c/2 = 2.357$ Å).

These two conditions eliminate all the positions of space group $P6_3/mmc$. Condition (2) rules out 12(k), 12(i), 6(g), 4(f), 4(e), 2(b) and 2(a). Condition (1) rules out any combination of 12(j), 6(h) and the remaining two-fold positions. In the same way any combination of the positions of space group $P\bar{6}2c$ violates one or both of the above conditions. Only the space group $P6_3mc$ then remains. Of the positions in this space group condition (2) eliminates 12(d) and 2(a). The only alternative remaining is to put the 14 ruthenium atoms into two six-fold positions 6(c) and one two-fold 2(b) position. An evaluation of the threedimensional Patterson function in the section $P(xy0)$ and along $P(00z)$ showed that no Ru-Ru contacts shorter than 2.7 Å exist in the basal plane or in the direction of the c-axis. This supports the correctness of condition (2). In addition, the Patterson function gave approximate x-parameters of the ruthenium atoms. Approximate z-parameters could be obtained from space considerations.

The x-parameters were refined from successive $\varrho_o(xy)$ and $\varrho_c(xy)$ syntheses until the final "backshift"-corrections were less than $\pm$ 0.001. The final x-parameters (Table 1) are estimated to be reliable to within $\pm$ 0.002. No

Table 1. Final atomic parameters of Ru_7B_3. Space group $P6_3mc$. (Estimated accuracy of x-parameters $\pm$ 0.002, of z-parameters $\pm$ 0.003.)

6 Ru_I in 6(*c*)	$x_I = 0.456_3$	$z_I = 0.318$
6 Ru_{II} in 6(*c*)	$x_{II} = 0.121_9$	$z_{II} = 0.000$
2 Ru_{III} in 2(*c*)	$x_{III} = 1/3$	$z_{III} = 0.818$
6 B in 6(*c*)	$x_B = 0.18_7$	$z_B = 0.58_0$

significant difference in the scattering parameters (number of electrons) of the different ruthenium atoms was revealed in the Fourier projections. The z-parameter of the Ru_{II} atom (Table 1) was chosen to be zero. The z-parameter of the Ru_I atom was obtained by comparison between calculated and observed $|F|$ values of $3n0\bar{3}nl$ reflexions ($l = 5, 7, 9$), the contribution of the Ru_{III} atom to these reflexions being zero. In the same way the z-parameter of the latter was obtained from inspection of $20\bar{2}l$ reflexions ($l = 5, 7, 9$) since the contribution of the Ru_I atom to the intensities of these reflexions was found to be very small. A variation of $\pm$ 0.001 in the z-parameters changed the $|F|_{calc}$ values by 1—5 %, and the final z-parameters are estimated to be reliable to within $\pm$ 0.003. With the final atomic parameters given in Table 1, the reliability index of the observed 28 nonequivalent $hki0$ reflexions was found to be 8.2 % while that of the observed 64 nonequivalent $h0\bar{h}l$ reflexions was 11.8 %.

As seen from Fig. 1 the ruthenium skeleton of Ru_7B_3 is fairly densely packed and is built up mainly of metal tetrahedra, some of which are outlined in the figure. Besides the tetrahedra there are metal octahedra with their centres in 0, 0, 1/4 and 0, 0, 3/4 and sharing faces in the c-direction. Between

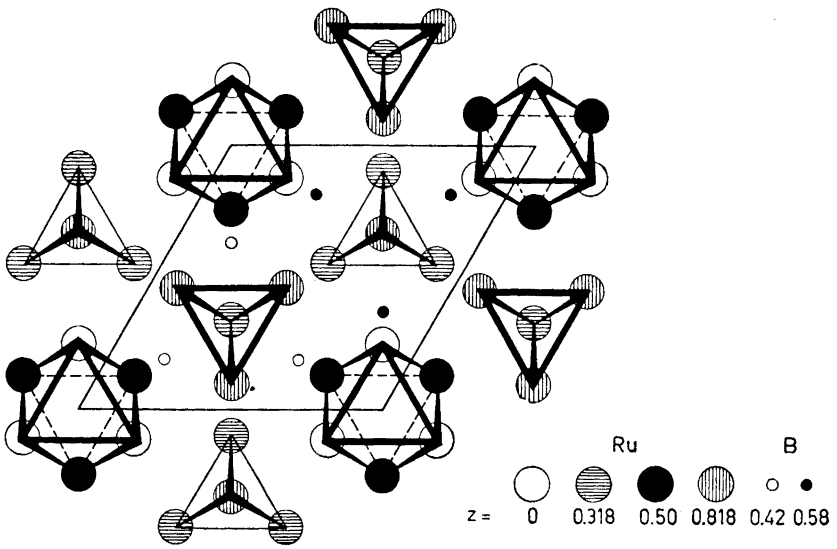

Fig. 1. The structure of Ru_7B_3 as seen along the hexagonal axis.

the octahedra and the tetrahedra there are two types of 'holes' whose centres in the mirror planes correspond to positions 6(*c*). The larger 'hole' has a roughly trigonal prismatic environment and the parameters of its centre are $x = 0.20$; $z = 0.58$. The smaller hole is more irregular and the parameters of its 'centre' are $x \sim 0.20$; $z \sim 0.42$. In addition to these two types of holes only the octahedral holes of the metal skeleton can possibly accomodate the boron atoms. (The tetrahedral interstices are much too small for a boron atom.)

The difference ($F_o - F_c$) synthesis (only the contribution from the ruthenium atoms was included in the F_c terms) was carried out in the *xy*-projection. No maximum was found in the origin, indicating that there are no boron atoms in the octahedral holes. The highest maximum of the difference synthesis (amounting to 5 % of the ruthenium maxima of the F_o synthesis) had the coordinates $x \sim 0.17$; $y \sim 0.83$, which indicates that one of the remaining 'holes' did contain boron atoms. An attempt has been made to obtain some experimental evidence showing which of the two holes is actually occupied. Since the x_B-parameter is about 0.20, the $50\bar{5}l$ ($l = 2, 4$) are the $h0\bar{h}l$ reflexions that are most likely to give some information about the *z*-parameter of the boron atom. Fortunately, these two reflexions are fairly weak and therefore a considerable influence of the boron atoms on their intensities can be anticipated. The $|F_o - F_c|/|F_o|$ values for the $50\bar{5}2$ and $50\bar{5}4$ reflexions are given below. The value of $|F_c|$ has been computed for the two alternative boron positions and also for the situation when the contribution from boron is neglected.

$|F_o - F_c|/|F_o|$ values for the $50\bar{5}2$ and $50\bar{5}4$ reflexions

	neglecting boron	with 6 boron atoms in 6(*c*) and $x_B = 0.20$, $z_B = 0.58$; $x_B = 0.20$, $z_B = 0.42$	
$50\bar{5}2$	0.21	0.11	0.31
$50\bar{5}4$	0.16	0.11	0.27

As seen from the table, a z_B value of 0.58 is strongly preferred over the value of 0.42. In fact, with $x_B = 0.20$ the only z_B parameters which will improve the agreement between observed and calculated structure factors for the above reflexions are $z_B \sim 0.1$ and $z_B \sim 0.6$, and the first of these is impossible since it would give a Ru-B distance of about 1 Å.

Thus, there is considerable experimental evidence that the boron atoms are situated in the largest hole of the ruthenium skeleton, corresponding to a position 6(*c*) with $x_B \sim 0.20$ and $z_B \sim 0.58$. Since the experimental material does not permit an accurate determination of the boron positions, the coordinates of the centre of the hole have been chosen as boron parameters. Aside from the experimental evidence, it is very unlikely from space considerations that boron atoms can occupy the 'smaller' holes of the metal skeleton since this would involve Ru-B distances shorter than 2.0 Å.

The final atomic parameters are given in Table 1. The interatomic distances (< 3.5 Å) are given in Table 2. A projection of the structure along the *c*-axis is shown in Fig. 1.

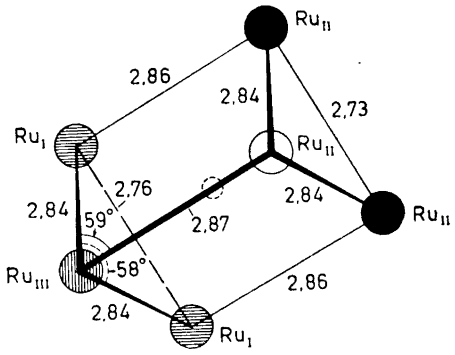

Fig. 2. The environment of the boron atoms in Ru_7B_3 as seen along the hexagonal axis.

DISCUSSION

The Ru-Ru contacts (Table 2) are on the average only 0.10 Å longer in Ru_7B_3 than in ruthenium where the average interatomic distance is 2.68 Å. There are also contacts shorter than those in pure ruthenium. The Ru_I atoms form zig-zag rows in the *c*-direction with an intermetallic distance of 2.61 Å. The boron atom has its six closest neighbours at an average distance of 2.16 Å. (With $r_{Ru} = 1.34$ Å, r_B will be 0.82 Å.) This value is rather small and is in accordance with the Me-B distances found in MoB (B-6 Mo 2.23 Å) [8] and in the recently discovered borides of the cementite (Fe_3C) type [9], *e.g.* in Ni_3B (B-6 Ni 2.04 Å). In these two phases the boron atoms have a trigonal prismatic environment as in Ru_7B_3. In Mo_2B[8] and Rh_2B[2] where the boron atoms have more than six close neighbours, the Me-B distances are considerably larger. In Mo_2B the boron atoms have eight metal neighbours at 2.37 Å; in Rh_2B nine at distances between 2.38 Å and 2.63 Å with an average value of 2.50 Å.

The most remarkable feature of the structure of Ru_7B_3 is its close similarity to that of the trigonal chromium carbide [6], Cr_7C_3. The formula and the unit cell of this carbide were determined by Westgren and Phragmén [10], who found the unit cell to be hexagonal with $a = 13{,}87$ kX, $c = 4.53$ kX and $2c/a = 0.654$. Later Westgren *et al.*[11] found a small deviation from the hexagonal symmetry and concluded that Cr_7C_3 was indeed trigonal. In a more recent paper on this

phase, Westgren [6] gave its approximate crystal structure. As *hki*0 reflexions appeared only when h was even and k was even, a projection on the basal plane could be divided into four identical parts. The atomic arrangements projected on such a part were determined by Westgren. Using the space group $P6_3mc$ he found 6 Cr_I in 6(c) with $x_I = 0.455$, 6 Cr_{II} in 6(c) with $x_{II} = 0.125$ and 2 Cr in 2(b). The chromium parameters of Westgren agree within 0.001 and 0.003 with those reported here for the ruthenium atoms of Ru_7B_3. Westgren did not try to determine the z-parameters but he gave a description of the complete structure using the hexagonal space group $P6_3mc$. In particular, he pointed out the trigonal prismatic environment of the carbon atoms. It is evident from Westgren's proposed structure that the near environment of the atoms in Cr_7C_3 and Ru_7B_3 is practically the same. The structure of Cr_7C_3 can be described as a slightly distorted superstructure of Ru_7B_3, making the unit cell four times larger and causing the symmetry to decrease to trigonal.

Ru_7B_3 is another example of a boride with close similarities to the 'complicated' carbides of chromium, manganese and iron. Other recently discovered examples are Co_3B and Ni_3B[9] which crystallize in the cementite (Fe_3C) structure. It has also been found that boron and carbon to a large extent can substitute for each other in the 'complicated' carbide structures, *e.g.* in $Fe_3(C, B)$[12] and in $Fe_{23}(C, B)_6$[13]. It does not seem unlikely that further studies on the platinum metal borides will reveal additional similarities between borides and carbides.

Chemistry of Arylboric Acids IX. Reaction of Arylboric and Alkylboric Acids with Mercuric Halides *

KURT TORSSELL

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Stockholm, Sweden

The reaction between mercuric salts and arylboric acids is an electrophilic displacement reaction. Electron attracting substituents hamper the boron-mercury exchange whereas electron releasing substituents facilitate the reaction. Most arylboric acids react readily in aqueous solution; unreactive arylboric acids are rapidly converted in excellent yield to the corresponding mercury compound in glacial acetic acid medium with perchloric acid as catalyst. Alkylboric acids are converted in acetic acid medium to alkylmercuric salts without any catalyst.

According to Michaelis [1] phenylboric acid is converted to phenylmercuric chloride by aqueous mercuric chloride:

$$C_6H_5B(OH)_2 + HgCl_2 \longrightarrow C_6H_5HgCl + HCl + H_3BO_3$$

The mercuration reaction has been proved to proceed quantitatively and has been used for analytical purposes [2,3]. Diarylboric acids,[4,5] triphenylboron [2] and lithium tetraphenylboron [2] react in the same manner:

$$(C_6H_5)_2BOH + 2HgCl_2 \longrightarrow 2C_6H_5HgCl + 2HCl + H_3BO_3$$
$$(C_6H_5)_3B + 3HgCl_2 \longrightarrow 3C_6H_5HgCl + 3HCl + H_3BO_3$$
$$(C_6H_5)_4BLi + 4HgCl_2 \longrightarrow 4C_6H_5HgCl + 3HCl + H_3BO_3 + LiCl$$

From lithium bis-(*o,o'*-diphenyl)-boron Wittig and Herwig [6] obtained *o,o'*-bis(chloromercuri) diphenyl in a yield of 51 %. Alkylboric acids react slowly [7] or not at all [8] with mercuric halides.

In alkaline solution diphenylmercury is obtained [7] and according to Nesmejanow *et al.*[9] asymmetrical diarylmercurials can be prepared by reacting arylmercuric halides with arylboric acid containing a different arylgroup:

$$ArHgX + Ar'B(OH)_2 \xrightarrow{NaOH} ArHgAr' + H_3BO_3$$

* Part VIII. *Acta Chem. Scand.* 12 (1958) 1373.

Johnson *et al.*[10,11] have used the reaction between arylboric acids and mercuric chloride for the structural determination of nitroderivatives obtained by nitration of arylboric acids. The corresponding mercury derivatives were formed in good yields.

In a series of papers, Torssell *et al.*[12–15] have shown that a number of reactions and rearrangements can be performed with arylboric acids, even under drastic conditions, without splitting off the dihydroxyboron group (borono group). The availability of new arylboric acids and their apparent ready conversion to mercury compounds by simple treatment with an aqueous mercury halide might therefore render this mercuration reaction of value as a preparative method.

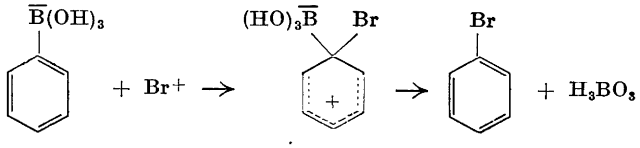
There seems to be one limitation. Arylboric acids containing many electron attracting substituents *e.g.* $-NO_2$, -COOR, react very slowly or not at all in aqueous solution. The unreactivity of certain compounds can, however, be easily overcome by using glacial acetic acid as medium and perchloric acid as catalyst. Klapproth and Westheimer [16] had found previously that the rate of mercuration of aromatic compounds increases with the acid concentration.

When, *e.g.*, 2-nitro-4-carbomethoxy-phenylboric acid, which is unaffected by aqueous mercuric chloride, is reacted with the mercuric halide in glacial acetic acid to which a small amount of perchloric acid is added, the corresponding mercuric organic compound is formed practically instantaneously in good yield. (Table 1, numbers 16 and 17.)

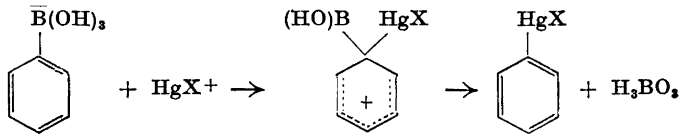
Mercuration of the aromatic nucleus is recognized as an electrophilic attack by positively charged mercuric ions [16]. Substituents increasing the electron density of the nucleus therefore facilitate the reaction, whereas substituents withdrawing electrons from the nucleus have the opposite effect.

The mercury-boron exchange seems to follow the same scheme. If mercuric chloride is added to a cold aqueous phenylboric acid solution, the mercury compound will be formed and precipitate immediately whereas a *m*-nitrophenylboric acid solution must be heated for a short time before precipitation occurs. From Table 1 it can be seen that 2-nitro-4-carbomethoxyphenylboric acid does not react and 3-nitro-5-carbomethoxyphenylboric acid gives only traces of the mercury compound. When 2-methyl-3,5-dinitrophenylboric acid is reacted with mercuric chloride for 20 min, only a part of the boron compound yields the mercury derivative and another part can be recovered as unreacted material. The ring carbon atom, to which the boron atom is attached, is electron deficient in these compounds. The mononitro [10] and monocarboxy derivatives [4], however, give the corresponding mercury compounds in good yield, which is also the case with all the other compounds tested in the present study.

Kuivila and Hendrickson [17] have shown that the bromolysis of arylboric acids is an electrophilic substitution:



The mercuration can be formulated in the same way:



The unreactivity of alkylboric acids towards mercuric salts has been reconfirmed. When *iso*-butylboric acid, for example, is heated with mercuric chloride in aqueous solution for 30 min no mercury organic compound can be detected. Part of the *iso*-butylboric acid decomposes into boric acid and butanol during the heating, a reaction that also takes place when no mercuric salt is present.

However, the corresponding alkylmercuric halide is formed in good yields when the reaction is carried out in acetic acid medium. No catalyst is necessary. Prolonged heating or presence of perchloric acid causes formation of yellow colored products difficultly soluble in ordinary solvents (M.p. > 260°).

EXPERIMENTAL

General procedure for converting an arylboric acid into the corresponding arylmercuric halide compound. The arylboric acid is dissolved in hot water. For compounds difficultly soluble in water a mixture of ethyl alcohol and water, 1:1, is employed. A sufficient amount of solvent is thereby used to ensure that no arylboric acid precipitates when the aqueous mercuric chloride is added. Mercuric chloride (25 % excess) is dissolved in warm water and added to the arylboric acid solution. Usually the arylmercuric halide precipitates after a few minutes or less. In order to ensure complete conversion, the mixture is boiled for *ca.* 15 min and left standing overnight in a refrigerator. The precipitate is filtered, washed with water and dried.

Conversion of less reactive arylboric acids into arylmercuric halide in glacial acetic acid medium with perchloric acid as catalyst. 3-Nitro-5-carbomethoxy-phenylboric acid, 0.1 g, is dissolved in 3 ml of glacial acetic acid at 80—90°; mercuric acetate, 0.16 g, is added and then 60 % perchloric acid, 0.05 ml. After 2 min at this temperature, the solution is poured into 15 ml of water containing potassium chloride, 0.2 g. A white precipitate of 3-nitro-5-carbomethoxyphenylmercuric chloride is formed immediately. Yield 97 %, m. p. 247—249°, from ethyl alcohol.

Conversion of alkylboric acids into alkylmercuric halides. n-Octylboric acid,[18] 0.10 g, is dissolved in 2 ml of cold glacial acetic acid. Mercuric acetate, 0.26 g, is added and the solution is warmed to 90—100° for 4—5 min whereafter it is poured into 12 ml water containing sodium chloride, 0.1 g. *n*-Octylmercuric chloride precipitates immediately, 0.18 g or 81 %, m. p. 115—116°.

iso-Butylmercuric bromide is prepared in the same way. Yield 50 %, m. p. 54—5°.

The Kinetics of Ox Liver Arylsulphatase A

S. O. ANDERSEN

Universitetets Fysisk-Kemiske Institut, Copenhagen, Denmark

The hydrolysis of 2-hydroxy-5-nitrophenyl sulphate catalyzed by ox liver arylsulphatase A was investigated by continued automatic titration of the liberated acid. It has been possible to keep the concentration of the substrate constant during an experiment, and the liberated sulphate has been precipitated as $BaSO_4$. It is shown that steady state is only reached after the course of more than one hour. A reaction mechanism is proposed involving slow, reversible inactivation of the enzyme.

Of the three arylsulphatases present in mammalian liver, arylsulphatase A has been found to exhibit anomalous kinetics when hydrolysing 2-hydroxy-5-nitrophenyl sulphate (nitrocatechol sulphate) [1–3]. The investigations reported in this paper have been performed with another technique than in the above mentioned investigations, in the hope that it would be possible to clarify some of the problems.

EXPERIMENTAL

Dipotassium nitrocatechol sulphate free from nitropyrogallol disulphate was prepared according to the method of Roy [4] and Dodgson and Spencer [5]. The equivalent weight determined by complete enzymic hydrolysis in a pH-state was found to be 347 (theoretical value for the dihydrate 347.3). A stock solution of nitrocatechol sulphate being 0.03 M and having pH 5.0 was prepared and stored in the refrigerator until use.

The enzyme was prepared from ox liver according to the method of Roy [2], with a few modifications. The acetone dried liver powder was extracted for 4 h with 0.1 M KCl at room temperature. After having performed the two fractionations with acetone the enzyme extract was heated at 65°C for 5 min and then centrifuged. The sulphatase activity was not affected by this procedure. The clear colourless supernatant was used without further purifications in the experiments described in this paper. It showed an enzyme activity towards nitrocatechol sulphate at about 10 000 units/mg N (one unit is defined as the amount of enzyme which liberates 1 μg of nitrocatechol from a 0.003 M nitrocatechol sulphate solution at pH 5.0 and 37°C in one hour [2]).

A diluted enzyme preparation was incubated at 20°C and pH 5.0. At suitable intervals samples were taken for determination of the enzyme activity. It was found that under these conditions the enzyme was stable for at least 48 h.

The hydrolysis of the nitrocatechol sulphate was followed by automatic titration of the liberated sulphuric acid in a pH-state. All experiments were performed at pH 5.0 and 20.0°C. A suitable amount of the enzyme preparation was diluted with so much 0.1 M

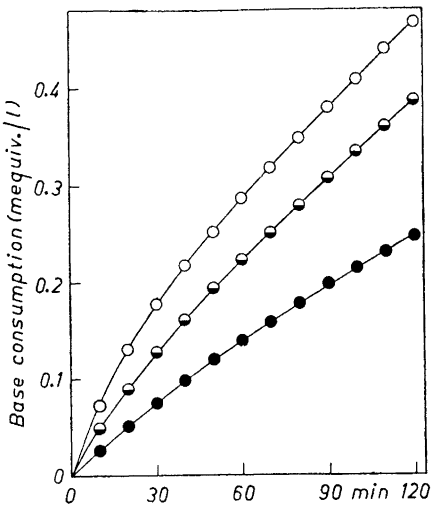

Fig. 1. Effect of addition of potassium sulphate on the enzymic hydrolysis of nitrocatechol sulphate. O—O—O: without sulphate, ◒—◒—◒: 0.3 mM K_2SO_4, ●—●—●: 1.5 mM K_2SO_4.

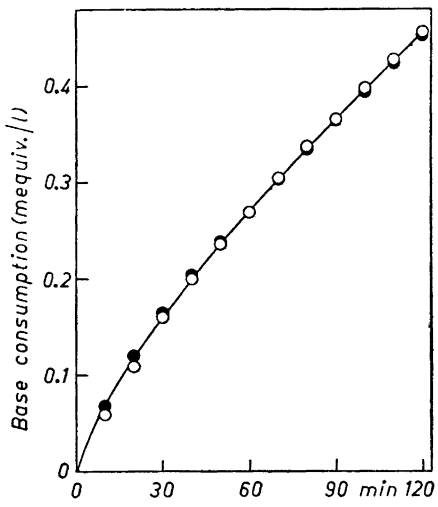

Fig. 2. Effect of addition of nitrocatechol on the enzymic hydrolysis of nitrocatechol sulphate. O—O—O: without nitrocatechol, ●—●—●: 3 mM nitrocatechol.

KCl that a final volume of 30 ml was obtained, and the pH was adjusted to 5.0. The reaction was started by adding the desired amount of substrate solution. The amount of base necessary to keep the pH constant was added automatically from a syringe, and corresponding values of time and amount of base added were read. The small dilution of the reaction mixture caused by this addition of base has not been considered in the calculations as it only amounts to a few per cent.

Roy[6] and Dodgson and Spencer[1] has shown that the reaction is influenced by sulphate ions. To overcome this complication the equivalent amount of $BaCl_2$ was added to the base in the syringe, so that the liberated sulphate would be precipitated as $BaSO_4$. It was found necessary to use exactly the equivalent amount of $BaCl_2$, as barium ions in excess inhibit the enzymic reaction. Before an experiment was started, a small amount of $BaSO_4$ was added to the reaction mixture to avoid supersaturation.

In most of the experiments reported the substrate concentration was kept constant. This was done by titrating with a mixture of equivalent amounts of base and substrate. The substrate is sufficiently stable in alkaline solution at room temperature to make such a procedure possible.

RESULTS

Experiments with added sulphate or nitrocatechol show that sulphate in a concentration of 0.0003 M inhibits the reaction (Fig. 1), and that nitrocatechol in a concentration of 0.003 M has very little influence on the reaction velocity (Fig. 2).

Experiments, where the substrate concentration was kept constant and where the liberated sulphate was precipitated as $BaSO_4$, showed that the reaction velocity decreased to about half the initial velocity during the first hour

Table 1. Measured (ξ_{exp}) and calculated (ξ_{calc}) values of the amount of substrate split at the time t. ξ_{exp} and ξ_{calc} are expressed in 10^{-6} M. E_{rel} is the relative enzyme concentration.

of the experiment, after which the velocity was constant for at least seven hours.

Incubation of the diluted enzyme for one hour at 20°C and pH 5.0 before starting the experiment has no inluence on the reaction progress. This indicates that the substrate is among the factors involved in the initial decrease of the reaction velocity.

Increasing the substrate concentration in an experiment when the reaction velocity had been constant for some time, showed that the velocity increased suddenly and then decreased slowly again for about one hour, when it again became constant at a higher level than before.

Experiments were performed at five different enzyme concentrations, the substrate concentrations being kept constant at 0.002 M nitrocatechol sulphate. The liberated sulphate was precipitated as $BaSO_4$. It was found that

Table 2. The absolute and relative values of the parameters A, B and C used to calculate the values of ξ_{calc} in Table 1.

110	132	132	189	188	283	284	353	352	367	366
120	141	142	204	203	303	304	378	376	392	390

under these circumstances the progress of the reaction could be described by the expression:

$$\xi = At + B(1 - e^{-Ct})$$

where ξ is the amount of acid liberated at the time t, and A, B and C are parameters, the values of which were determined to give the best description of the reaction progress. The results are given in Tables 1 and 2. It is seen that A and B are proportional to, and C independent of the enzyme concentration.

Experiments were performed at five different substrate concentrations, and with the same enzyme concentration. The substrate concentrations were kept constant in the individual experiments, and the liberated sulphate was precipitated as $BaSO_4$. In these experiments too the reaction progress could be described by the expression:

$$\xi = At + B(1 - e^{-Ct})$$

as seen in Table 3. The values of the parameters A, B and C are given in Table 4.

Table 4. The values of the parameters A, B and C used to calculate the values of ξ_{calc} in Table 3.

a mM	A	B	C
	10^{-6} mole × l^{-1} × min^{-1}	10^{-6} mole × l^{-1}	min^{-1}
0.25	0.972	27.8	0.022

1.00	1.91	76.0	0.032
2.00	2.29	101.2	0.038
3.00	2.43	98.7	0.048

REACTION MECHANISM

To explain the results presented in this paper, it has been assumed that the active form of the enzyme can be transformed into an inactive form. This transformation proceeds slowly to an equilibrium, and the substrate seems to be necessary for this transformation.

The suggested reaction scheme can be represented in the following way:

$$\begin{aligned} X_1 + A &\rightleftharpoons X_2 && (\pm 1)\\ X_2 &\rightarrow X_1 + P && (+ 2)\\ X_2 &\rightleftharpoons X_3 && (\pm 3) \end{aligned}$$

where X_1, X_2 and X_3 are different forms of the enzyme, A is the substrate and P is the reaction products.

The two first reactions are the usual Henri-Michaelis scheme, and reaction ($\pm$ 3) is the slow, reversible inactivation of the enzyme here postulated.

If we assume steady state at any moment with respect to the two first reactions, we have

$$x_1 = (K_m/a)x_2 \tag{4}$$

where K_m is $(k_2 + k_{-1})/k_1$. Small letters are used to denote concentrations, and k_i is the velocity constant for reaction i.

Further we have for the total enzyme concentration

$$E = x_1 + x_2 + x_3 \tag{5}$$

and that

$$\mathrm{d}x_3/\mathrm{d}t = k_3x_2 - k_{-3}x_3 \tag{6}$$

From (4) and (5) we get

$$x_3 = E - (K_m/a + 1)x_2$$

and this together with (6) gives, if a is kept constant,

$$-(K_m/a + 1)\mathrm{d}x_2/\mathrm{d}t = (k_3 + k_{-3}(K_m/a + 1))x_2 - k_{-3}E \tag{7}$$

This equation can be solved with respect to x_2, and if we assume that the concentration of x_3 is zero at the beginning of the experiment, we get

$$x_2 = c_1 + c_2\mathrm{e}^{-\lambda t} \tag{8}$$

where $c_1 = k_{-3}E/(k_3 + k_{-3}(K_m/a + 1))$

and $c_2 = k_3E/(k_3 + k_{-3}(K_m/a + 1))(K_m/a + 1)$

and $\lambda = (k_3 + k_{-3}(K_m/a + 1))/(K_m/a + 1)$

The velocity of the reaction is

$$v = \mathrm{d}\xi/\mathrm{d}t = k_2x_2$$

hence

$$\xi/k_2 = c_1t + \frac{c_2}{\lambda}(1 - \mathrm{e}^{-\lambda t}) \tag{9}$$

This expression is of the same form as that determined from the results of the experiments:

$$\xi = At + B(1 - \mathrm{e}^{-Ct})$$

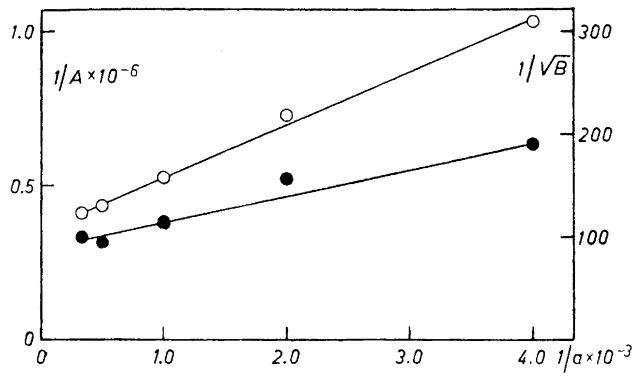

Fig. 3. The calculated values of 1/A and $1/\sqrt{B}$ plotted against the reciprocal substrate concentration.

In is seen that c_1 and c_2/λ are proportional to and λ is independent of the enzyme concentration, which is in accordance with the experiments. Moreover it can be found that there is a rectilinear relationship between $1/c_1$ and $1/a$ and between $\sqrt{\lambda/c_2}$ and $1/a$. In Fig. 3 the experimentally determined values of 1/A and $1/\sqrt{B}$ are plotted against $1/a$.

DISCUSSION

The experiments reported in this paper show that even when the substrate concentration is kept constant, and the liberated sulphate is precipitated as $BaSO_4$, the reaction velocity only reaches a constant value more than one hour after the beginning of the experiment. As it has been shown that the liberated nitrocatechol has only little influence on the reaction velocity, the cause of this phenomenon must be sought in the enzyme. A reaction mechanism has been proposed and shown to fit the experiments. The special feature of this reaction mechanism is a slow reversible inactivation of the enzyme, in which

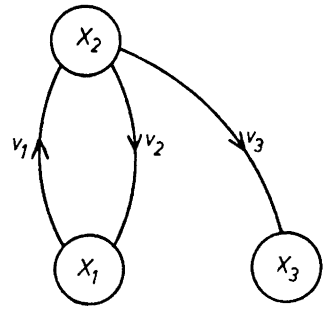

Fig. 4.

the substrate is involved. The reaction scheme can be expressed in the notation proposed by Christiansen [7,8] as in Fig. 4, where the circles symbolize the different enzyme forms.

It must be noted that there are some differences between the results obtained in other laboratories and those here reported. Roy [3] has found that free nitrocatechol causes an overall increase in the reaction velocity, and both Roy [3] and Dodgson and Spencer [1] report that there can be observed an increase in velocity after the initial decrease in the reaction velocity. Both groups have performed there experiments at 37°C and used an acetate buffer as medium, and they have followed the reaction spectrophotometrically. In this work 0.1 M KCl has been used as medium at 20°C, and the reaction was followed by titrating the liberated acid. Before more experiments have been performed it will not be possible to decide whether the cause of the discrepancies has to be sought in the different techniques used.

Über die Carbonylgruppen des Lignins

JOSEF GIERER und SIGURD SÖDERBERG

Schwedisches Holzforschungsinstitut, Holzchemische Abteilung, Stockholm, Schweden

Carbonyl group estimations, by a volumetric method involving the use of borohydride, indicate that in lignins isolated under mild conditions (Brauns "native lignin" and Björkmans "milled wood lignin") there are 0.41—0.48 CO groups/OCH_3 group. This contrasts with other determinations, in which hydroxylamine hydrochloride was used, where values of 0.12—0.19 were obtained.

The cause of this discrepancy has been sought in the present work. Similar types of determinations to those above have been carried out on compounds related to lignin and containing carbonyl groups. A study of the reaction of those compounds with hydroxylamine hydrochloride showed that the rate of reaction is highly dependent on the position of the carbonyl group in the side-chain and on the structure of the side-chain. Under the experimental conditions normally employed the use of hydroxylamine hydrochloride, therefore, resulted in values, which in many cases were too low, whereas the use of borohydride gave values near to the theoretical.

The possibilities to correlate the difference between the two carbonyl determinations with the position of the carbonyl groups in the side-chains and to reconcile the new findings with other experimental evidence are briefly discussed.

Seit dem Nachweis von Carbonylgruppen in Lignosulfonsäuren durch Klason [1] ist wiederholt wersucht worden, diese Gruppen in verschiedenen Ligninpräparaten auch quantitativ zu bestimmen. Die erhaltenen Werte schwankten innerhalb weiter Grenzen je nach Wahl des Untersuchungsmaterials und der Bestimmungsmethode [2]. Die Kenntnis des genauen Carbonylgehaltes ist jedoch von erheblicher strukturchemischer Bedeutung. Ausserdem zeigten vorläufige Versuche [3], in Übereinstimmung mit bereits früher gemachten Annahmen [4], dass Carbonylgruppen eine wichtige Funktion bei der Sulfitierung des Lignins ausüben dürften. Eine zuverlässige Bestimmungsmethode für diese Gruppen sollte daher auch das Studium des Verlaufes dieser technisch wichtigen Delignifizierungsreaktion wesentlich erleichtern.

Von den bekannten, analytisch auswertbaren Carbonylreaktionen (Zusammenfassung siehe [5]) wurde in letzter Zeit vor allem die Umsetzung mit Hydroxylamin-Chlorhydrat zur quantitativen Bestimmung der CO-Gruppen in unter schonenden Bedingungen isolierten Ligninpräparaten und in Ligno-

Tabelle 1. Mit Hilfe der Borhydrid-Methode ermittelte Carbonylgehalte verschiedener Ligninpräparate.

Ligninpräparat	Carbonylgehalt CO/OCH_3
Brauns' "native lignin"	0,48
Brauns' "native lignin", 24 Stunden bei Zimmertemperatur mit 0,5 %iger methanolischer Salzsäure methyliert [6,21]	0,45
Björkman-Lignin *	0,44, 0,43, 0,41
Björkman-Lignin, 2 Tage in der Schwingkugelmühle gemahlen	0,45
Björkman-Lignin, mit Natriumborhydrid reduziert und isoliert [21]	0,023
Björkman-Lignin, 24 Stunden bei Zimmertemperatur mit 0,1 N Natronlauge behandelt und wiederisoliert	0,48
Björkman-Lignin, 3 Tage lang bei Zimmertemperatur und pH 4,0 oximiert und wiederisoliert	0,21
Björkman-Lignin, 5 Stunden unter Rückflusskochung bei pH 4,0 oximiert und wiederisoliert	0,29
Björkman-Lignin, 24 Stunden bei Zimmertemperatur mit 0,5 %iger methanolischer Salzsäure methyliert [6,21]	0,40

Salzsäurelignin (Rheinau)	0,38

* verschiedene nach dem gleichen Verfahren hergestellte Präparate

sulfonsäuren herangezogen. Der bei der Oximbildung freiwerdende Chlorwasserstoff wurde potentiometrisch mit Natronlauge titriert, wobei sich in den Zeit - Umsatzkurven eine rasch und eine langsam verlaufende Phase abzeichnete. Die erstgenannte wurde der tatsächlichen Oximierungsreaktion, die letztgenannte hingegen einer oxydativen Zersetzung des überschüssigen Hydroxylamin-Chlorhydrates zugeschrieben [6]. Der Carbonylgehalt ergab sich daher durch Extrapolation auf die Zeit Null. In Brauns' "native lignin" [6] wurden auf diese Weise 0,12 CO/OCH_3, in Björkman-Lignin [7] 0,19 CO/OCH_3 und in einer Lignosulfonsäure [8] 0,10 CO/OCH_3 gefunden.

Vor kurzem teilten *Lindberg und Mitarbeiter* [9,10] eine neue Methode zur Bestimmung von Carbonylgruppen in Kohlenhydraten mit, die auf einer quantitativen Auswertung der Reduktion mit überschüssigem Borhydrid beruht. Der Verbrauch an Wasserstoff wird hierbei nach Ablauf einer bestimmten Reaktionszeit durch Zersetzung des Borhydridüberschusses (mit H_2SO_4) gegen eine entsprechende Blindprobe als Differenz ermittelt.

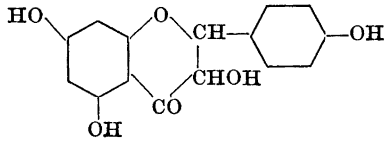
XX



XXI

Bei Anwendung dieser Methode auf schonend isolierte Ligninpräparate (aus Fichtenholz) wurden nun Carbonylgehalte gefunden, die, wie Tabelle 1 zeigt, durchwegs viel höher als die entsprechenden mit Hilfe der Hydroxylamin-Methode bestimmten Werte (siehe oben) liegen. Ein ähnlicher Unterschied im Ergebnis der beiden Bestimmungsmethoden konnte auch bei einem enzymatisch nach dem Zulaufverfahren [11] aus Coniferylalkohol synthetisierten

"Dehydrierungspolymerisat" (DHP) * beobachtet werden. Mit Hilfe der Hydroxylamin-Methode wurden nur 0,07 CO/OCH_3, mit Hilfe der Borhydrid-Methode hingegen 0,33 CO/OCH_3 gefunden (Tab. 1). Um sicherzustellen, dass der hohe Wasserstoffverbrauch tatsächlich auf eine Reduktion und nicht etwa auf eine Adsorption an dem bei Säurezusatz wieder teilweise ausfallenden Lignin (siehe experimenteller Teil) zurückzuführen ist, wurde die Bestimmungsmethode auch an einem mit Natriumborhydrid vorreduzierten und wiederisolierten Ligninpräparat ausgeführt. Der hierbei beobachtete Wasserstoffverbrauch war sehr gering (siehe Tab. 1) und dürfte durch eine partielle Reoxydation des vorreduzierten Lignins während und nach seiner Isolierung bedingt sein.

Für die auffallende Diskrepanz zwischen den Ergebnissen der beiden Carbonylbestimmungsmethoden müssen daher chemische Faktoren verantwortlich sein. Es muss angenommen werden, dass entweder die Umsetzung mit Hydroxylamin-Chlorhydrat nicht alle Carbonyle des Lignins erfasst oder dass die Borhydrid-Methode auch auf andere Gruppen (als Carbonylgruppen) anspricht. Um zwischen diesen Alternativen zu entscheiden, wurden die beiden Methoden an geeigneten Modellsubstanzen näher untersucht.

HYDROXYLAMIN-METHODE

Die Umsetzung der Modellsubstanzen und der Ligninpräparate mit Hydroxylamin-Chlorhydrat wurde mit Hilfe einer verbesserten Apparatur untersucht. Der Laugenzusatz wurde automatisch geregelt und der Luftsauerstoff von einem Stickstoffstrom durch das thermokonstant gehaltene Reaktionsgefäss verdrängt. Dadurch konnte die Zersetzung des überschüssigen Hydroxylamin-Chlorhydrates sehr vermindert werden (Blindversuch).

Selbst bei Anwendung dieser apparativen Ausrüstung zeigten jedoch die Zeit-Umsatzkurven im Falle der Ligninpräparate nach einer rasch verlaufenden Initialphase einen langsamen sich über Tage erstreckenden Anstieg, der wesentlich steiler als der des entsprechenden Blindversuches (Versuch nur mit Hydroxylamin-Chlorhydrat) war (siehe Abb. 1). Dies deutet darauf hin, dass der langsam freigelegte Chlorwasserstoff seine Entstehung nicht nur einer spontanen Zersetzung des Reagenzes, sondern teilweise auch einer Umsetzung des letztgenannten mit sehr träge reagierenden Carbonylgruppen verdankt.

Ein Studium der Oximierungsreaktion mit ligninverwandten Verbindungen u. a. vom Typus der 3-Methoxy-4-hydroxy- und der 3,4-Dimethoxy-phenylpropanone bzw.-propanale (I) ergab, dass β- und γ-ständige Carbonylgruppen (II—V) — wie auch aromatische Aldehyde, z. B. VI und VII — überaus rasch (siehe Abb. 2), α-ständige Carbonylgruppen (aromatische Ketone, VIII—XIX) hingegen langsam reagieren (Abb. 4). Die Reaktionsgeschwindigkeit der α-ständigen Carbonylgruppen ist stark abhängig von der Substitution am β-ständigen Kohlenstoffatom der Seitenkette und nimmt von Verbindungen mit einer der Ketogruppe benachbarten Methylengruppe (VIII, IX, X, XIII, XVIII, XX) über solche mit einer Hydroxymethylengruppe (z. B. XI) zu

* Für die freundliche Überlassung dieses Präparates danken wir Herrn Dr. G. Billek, Wien.

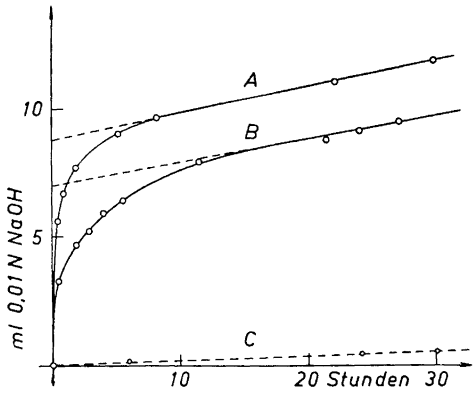


Abb. 1. Zeitlicher Verlauf der Oximierung von A) Björkman-Lignin (100 mg), B) Brauns' "native lignin" (100 mg), C) Blindversuch.

solchen mit einer Aroxymethylengruppierung (XIV—XVI) oder mit einer Arylmethylengruppierung (z. B. XIX) hin ab (siehe Abb. 4). Besonders langsam reagieren α-Carbonylgruppen in Einheiten, die ausser einer β-ständigen Aroxyl- oder Arylgruppe auch eine γ-ständige Hydroxylgruppe enthalten (z. B. XVI bzw. XIX). Derartige Substitutionstypen an den β- und γ-ständigen Kohlenstoffatomen der Seitenketten werden bekanntlich aufgrund biosynthetischer Modellversuche [11–14], sowie aufgrund von Untersuchungen über den Abbau von Ligninpräparaten durch Äthanolyse [15–18] und "Acidolyse" [19] als dominierend angesehen.

Hingegen ist offenbar die Oximierungsgeschwindigkeit unabhängig davon, ob die zur Seitenkette p-ständige phenolische Hydroxylgruppe frei oder veräthert (bzw. verestert) ist (vgl. II mit III, IV mit V und VI mit VII, Abb. 2, sowie IX mit X und XIV mit XV, Abb. 4).

Die grossen Unterschiede in der Oximierungsgeschwindigkeit verschiedener Carbonyle zeigen sich auch deutlich bei Substanzen, welche 2 Carbonylgruppen verschiedener Reaktionsfähigkeit im gleichen Molekül enthalten, wie z. B. bei den Verbindungen XII und XVII. Aufgrund der oben erwähnten Modellversuche konnte erwartet werden, dass die β-ständige Ketogruppe in XII (vgl. mit IV und mit V), sowie die Aldehydgruppe in XVII (vgl. mit VII) sehr rasch, die α-ständigen Ketogruppen in beiden Substanzen (vgl. mit XI bzw. mit XVI) hingegen nur langsam oximierbar sind. Der Verlauf der Zeit — Umsatzkurven stimmt hiermit überein. In beiden Fällen werden während der raschen Reaktionsphase nur ca 50 % des Totalcarbonyls erfasst (Abb. 3). Dass im Diketon XII tatsächlich die β-ständige Ketogruppe rasch und die α-ständige langsam oximiert wird, konnte auf folgende Weise gezeigt werden: Nach Ablauf der raschen Reaktionsphase wurde das partiell oximierte Produkt (Monoxim) isoliert (Schmp. 162—163°) und mit Natriumborhydrid reduziert. Das Reduktionsprodukt gab bei Kupplung mit Chinononochlorimid in schwach alkalischer Lösung eine intensive Farbreaktion, woraus auf das Vorkommen einer freien (nicht oximierten) α-ständigen Ketogruppe im ursprünglichen Monoxim geschlossen werden darf [20,21].

Die Carbonylgruppe der Substanz XX, welche einem Flavanonring angehört, ist mit ungefähr der gleichen Geschwindigkeit wie gewöhnliche α-Carbonyle mit benachbarter Methylengruppe (z. B. IX und X) oximierbar, die der Substanz XXI hingegen reagiert — vermutlich bedingt durch die Anwesenheit der beiden benachbarten Hydroxylgruppen — extrem langsam (Abb. 4).

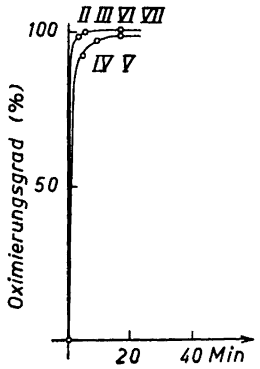

Abb. 2. Zeitlicher Verlauf der Oximierung von β- und von γ-Carbonylverbindungen des 3-Methoxy-4-hydroxy- und des 3,4-Dimethoxyphenylpropantypus (I), sowie von Vanillin (VI) und von Veratrumaldehyd (VII).

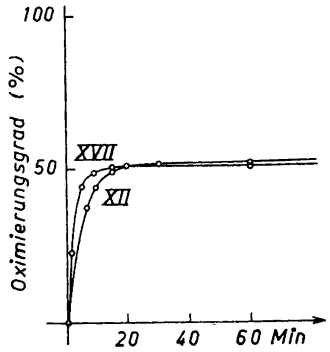

Abb. 3. Zeitlicher Verlauf der Oximierung zweier Dicarbonylverbindungen (XII und XVII) mit Carbonylgruppen verschiedener Reaktionsfähigkeit.

Wird die Oximierung anstatt bei Zimmertemperatur unter Rückflusskochung (5 St.) ausgeführt, so setzen sich auch die nur sehr träge reagierenden α-Carbonyle (z. B. in den Substanzen XII, XIV—XVII und XIX) zum grössten Teil um (Tab. 2).

Brauns "native lignin" und Björkman-Lignin ergaben unter diesen Reaktionsbedingungen höhere Carbonylwerte (0,3 bzw. 0,25 CO/OCH_3) als bei Zimmertemperatur (0,12 bzw. 0,19 CO/OCH_3). Die mit Hilfe der Borhydrid-Methode gefundenen hohen Carbonylwerte (0,48 bzw. 0,44 CO/OCH_3, siehe Tab. 1) konnten demnach durch Erhöhung der Oximierungstemperatur nicht erreicht werden.

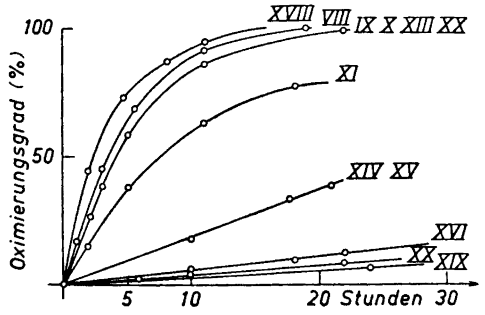

Abb. 4. Zeitlicher Verlauf der Oximierung von α-Ketoverbindungen des 3-Methoxy-4-hydroxy- und des 3,4-Dimethoxy-phenylpropantypus (I).

Tabelle 2. Vergleich der Oximierungsgrade (in Prozenten des theor. Wertes) nach 5-stündiger Reaktionszeit bei Zimmertemperatur und bei Rückflusskochung für die α-Ketone XII–XIX.

Substanz	Carbonyl (in % des theor. Wertes) gefunden nach 5-stündiger Reaktionszeit	
	bei Zimmertemperatur	unter Rückflusskochung
XII	52,1	93,5
XIII	58,0	94,7
XIV	10,1	97,5
XV	10,0	101,1
XVI	2,8	88,3
XVII	51,3	101,0
XVIII	74,4	99,8
XIX	1,2	87,1

BORHYDRID-METHODE

Während die untersuchten Carbonylverbindungen grosse Unterschiede in den Oximierungsgeschwindigkeiten zeigen (Abb. 2—4), sind sie durch Einwirkung von Kalium-borhydrid unter den im experimentellen Teil angegebenen Bedingungen vollständig reduzierbar. Eine Ausnahme bilden einige α-Carbonylverbindungen mit *p*-ständiger phenolischer Hydroxylgruppe, wie z. B. VI, VIII, IX und XIV. Sie benötigen zur vollständigen Reduktion längere Reaktionszeiten. Tabelle 3 zeigt eine Zusammenstellung der mit Hilfe der Borhydrid-Methode ermittelten Carbonylwerte für die wichtigsten Modellsubstanzen.

Zur Überprüfung der Spezifität der Borhydridreduktion wurden auch carbonylfreie Modellsubstanzen mit zum aromatischen Kern konjugierter Doppelbindung, mit Benzylalkylätherbindung, mit Esterbindung, mit Laktonbindung oder schliesslich mit freier Carboxylgruppe getestet (Tab. 4). Wie ersichtlich, werden unter den gewählten Bedingungen nur Ester- und Laktengruppen teilweise reduziert. Die Reduzierbarkeit dieser Gruppen wird durch Behandlung mit 0,1 N Natronlauge (Spaltung in Carboxyl- und Alkoholgruppe) aufgehoben. Da jedoch nach Alkalibehandlung und Wiederisolierung von Björkman-Lignin die Menge des bei der Borhydridreduktion verbrauchten Wasserstoffs ungefähr gleich gross wie beim unbehandelten Präparat ist, dürften derartige Struktur-elemente, wenn überhaupt, so nur in sehr geringer Menge im Lignin vorkommen.

Auch das Infrarot-Spektrum des Lignins, sowie die Ergebnisse des Studiums der Alkylierungsreaktion durch Einwirkung von alkoholischer Salzsäure [6] gaben keine Anhaltspunkte für das Vorkommen nennenswerter Mengen freier oder veresterter Carboxylgruppen im Fichtenholzlignin.

Tabelle 3. Mit Hilfe der Borhydrid-Methode ermittelte Carbonylgehalte verschiedener Modellsubstanzen.

* teilweise Reduktion der Estergruppe.
** Zur quantitativen Bestimmung ist eine bedeutende Verlängerung der Reaktionszeit erforderlich.

Bisher sind keine anderen, durch Borhydrid reduzierbaren Gruppen (als Carbonylgruppen) im Lignin aufgefunden worden. Es darf daher gefolgert werden, dass der hohe Wasserstoffverbrauch ausschliesslich durch Carbonylgruppen verursacht wird.

Tabelle 4. Wasserstoffverbrauch carbonylfreier Substanzen.

Substanz	Wasserstoffverbrauch (ml) von 1 Mmol	
	berechnet (für Reduktion aller) ev. reduzierbaren Gr.	gefunden

Vanillinoxim	22,4	0,8
3,4-Dimethoxy-zimtaldehydoxim	44,9	1,4

Durch die Auffindung wesentlich grösserer Mengen Carbonylgruppen in "nativen" Ligninen, als bisher angenommen wurden, erhält das Problem der Aufteilung dieser Gruppen auf die drei Kohlenstoffatome der Propanseitenketten erhöhte strukturchemische Bedeutung. Wie bereits gezeigt wurde, erlaubt die Oximierungsreaktion eine grobe Differenzierung in zwei Kategorien verschiedener Reaktionsfähigkeit.

Die rasch verlaufende Phase der Oximierung könnte nach Aussage der Modellversuche (siehe oben) auf das Vorkommen von Aldehyd- und von "sterisch nicht gehinderten" β-Ketogruppen zurückzuführen sein. Die Hydroxylamin-Methode dürfte in ihrer bisherigen Ausführungsform (Zimmertemperatur, Extrapolation des Laugenverbrauchs auf die Zeit 0) — im Gegensatz zur Borhydrid-Methode — nur solche oder ähnliche rasch reagierende Carbonylgruppen im Lignin erfassen. Diese Deutung der Diskrepanz zwischen den Ergebnissen der beiden Bestimmungsmethoden wird auch durch den Befund gestützt, dass ein nach Ablauf der raschen Reaktionsphase isoliertes "oximiertes" Björkman-Lignin bei nachfolgender Borhydrid-Reduktion ungefähr soviel Wasserstoff verbraucht, wie der Differenz zwischen den Carbonylwerten der beiden Bestimmungsmethoden entspricht (Tab. 1). (Modelloxime erwiesen sich unter den Bedingungen der Bestimmungsmethode gegenüber Borhydrid stabil, siehe Tab. 4).

Die Zuordnung der langsam mit Hydroxylamin-Chlorhydrat reagierenden Carbonylgruppen zu bestimmten Strukturelementen des Lignins gestaltet sich schwieriger. Als einziger Strukturtyp, der in Bezug auf Oximierungsgeschwindigkeit mit der beim Lignin beobachteten langsamen Reaktionsphase vergleichbar ist, wurden bisher "sterisch gehinderte" α-Carbonylgruppen, wie z. B. in den Verbindungen XIV—XVI, sowie in XIX und XX (siehe Abb. 4), festgestellt.

Im "Dehydrierungspolymerisat" könnten derartige α-Ketogruppen eventuell durch sekundäre Oxydation benzylalkoholischer Hydroxylgruppen in entsprechenden Struktureinheiten entstanden sein (siehe z. B. den in einem Zwischenstadium der DHP-Herstellung isolierbaren Guajacyl-β-coniferyläther [11], sowie die im Zusammenhang mit oxydativen Abbauversuchen an einem DHP-Präparat diskutierten β-Arylstrukturen [12]). Die beiden anderen in einer Zwischenphase der DHP-Herstellung isolierbaren, dimeren Hauptprodukte, Pinoresinol und Dehydro-diconiferylalkohol [11-14], repräsentieren weitere mögliche Verknüpfungsstrukturen, die bei analoger Oxydation am α-ständigen Kohlenstoffatom Monoalkyl- bzw. Monoarylacetalgruppierungen (siehe unten) liefern würden.

Man wäre daher zunächst geneigt, die langsame Oximierungsphase des Lignins und damit den Unterschied in den Ergebnissen der beiden Bestimmungsmethoden auf derartige "sterisch gehinderte" α-Ketogruppen zurückzuführen. Gegen das Vorkommen bedeutender Mengen α-Carbonylgruppen sprechen jedoch spektrophotometrische Befunde. So konnte durch Messungen im Ultraviolett mit Hilfe der sogenannten $\Delta\varepsilon$-Methode [22] gezeigt werden, dass nur ein geringer Teil der phenolischen Einheiten des Lignins (in Brauns'"native lignin" aus *Picea mariana* 0,01—0,02/OCH_3 [23]) eine dem aromatischen Kern benachbarte Carbonylgruppen enthalten dürfte (siehe auch Ref.[24,21]). Auch in den nicht-phenolischen Einheiten des Lignins konnten auf spektrophotometrischem Weg keine grösseren Mengen α-Carbonylgruppen gefunden werden. Aus den Absorptionsänderungen im Ultraviolett, welche durch Reduktion

mit Borhydrid hervorgerufen werden, errechneten Adler und Mitarbeiter [25,26] die Frequenz derartiger Gruppen in Björkman-Lignin zu 0,05—0,06/OCH_3. Die Gesamtmenge α-ständiger Carbonylgruppen (in phenolischen und nicht-phenolischen Einheiten) beträgt nach dieser Bestimmungsmethode bei Björkman-Lignin nur 0,06—0,07/OCH_3 [26].

Eine Möglichkeit, diese spektrophotometrischen Resultate mit dem Vorkommen grösserer Mengen α-Carbonylgruppen im Lignin in Einklang zu bringen, besteht in der Annahme, dass diese Gruppen zu einem beträchtlichen Teil "maskiert", d. h. sowohl im Ultraviolett als auch im Infrarot nicht erkennbar vorliegen könnten (siehe oben, vgl.[27]). So wären z. B. Carbonylgruppen in Halbacetalform in Betracht zu ziehen, die wohl von der Borhydrid-Methode, nicht aber von der Hydroxylamin-Methode erfasst würden. Für das Vorkommen solcher Gruppen konnte jedoch in vorläufigen Versuchen bisher keine experimentelle Stütze erbracht werden. Durch Einwirkung von methanolischer Salzsäure auf Brauns"native lignin" und auf Björkman-Lignin bei Zimmertemperatur wurde nämlich die Menge der durch die Borhydrid-Methode bestimmbaren Carbonylgruppen nicht wesentlich vermindert (Tab. 1). Eine derartige Behandlung sollte eventuell vorhandene Halbacetalgruppen in Vollacetalgruppen überführen, welche auch gegenüber Borhydrid stabil sind. Die Richtigkeit dieser Schlussfolgerung müsste allerdings noch durch entsprechende Modellversuche gezeigt werden.

Die langsam oximierbaren Carbonylgruppen scheinen demnach in anderer Weise "maskiert" vorzuliegen. Zu ihrer Lokalisierung und Charakterisierung wird es zusätzlicher Modellstudien unter Heranziehung weiterer Carbonylreaktionen bedürfen.

EXPERIMENTELLER TEIL

Die verwendeten Modellsubstanzen und Ligninpräparate wurden nach in der Literatur beschriebenen Methoden dargestellt bzw. isoliert *.

Hydroxylamin-Methode. Rund 0,2 Millimole Modellsubstanz bzw. rund 200 mg Ligninpräparat wurden genau eingewogen und in 10 ml 95 %igem Äthanol (bei Ligninpräparaten, wenn erforderlich, unter Zusatz von etwas Wasser) gelöst. Die Lösung wurde auf pH 4,0 eingestellt (Glaselektrode) und zur Zeit Null einer in einem thermokonstant (25°C) gehaltenen Titrationsgefäss befindlichen Lösung von 138 mg (2 Millimole) Hydroxylamin-Chlorhydrat in 40 ml 95 %igem Äthanol vom pH 4,0 zugesetzt. Die bei konstanter Temperatur (25°C) unter ständigem Durchleiten eines mit Alkohol gesättigten Stickstoffstroms und unter magnetischer Umrührung vor sich gehende Oximierungsreaktion wurde durch automatische Titration (Autotitrator der Fa. Radiometer, Kopenhagen) des freigesetzten Chlorwasserstoffs mit 0,01 N Natronlauge laufend gemessen.

In der Abb. 1, welche den zeitlichen Verlauf der Oximierungen von Björkman-Lignin und von Brauns' "native lignin" wiedergibt, ist der Verbrauch an Natronlauge in Millilitern, in den Abb. 2—4, die sich auf die Oximierungen der Modellsubstanzen beziehen, in Prozenten des theoretischen Wertes gegen die Zeit aufgetragen.

Bei den Umsetzungen der Modellsubstanzen und Ligninpräparate mit Hydroxylamin-Chlorhydrat durch 5-stündiges Kochen unter Rückfluss wurden die gleichen Mengenverhältnisse wie oben angegeben angewandt. Das Reaktionsgemisch wurde nach Abkühlen auf 25°C in das Titrationsgefäss übergeführt und bis zum pH-Wert einer entsprechenden

* Die Substanzen XIV und XV wurden uns freundlicherweise von Herrn Prof. E. Adler, Göteborg, die Substanzen XVII—XIX von Herrn Doz. B. Lindgren, Stockholm, zur Verfügung gestellt, wofür auch an dieser Stelle bestens gedankt sei. Die Darstellungen dieser Verbindungen sind z. T. noch nicht veröffentlicht.

Blindprobe (erhalten durch 5-stündiges Kochen einer Lösung von 138 mg Hydroxylamin-Chlorhydrat im gleichen Alkohol-Wassergemisch unter Rückfluss) titriert.

Borhydrid-Methode. Rund 0,2 Millimole Modellsubstanz bzw. rund 100 mg Ligninpräparat wurden genau eingewogen, in den mittleren Teil des dreiteiligen Reaktionsgefässes [10] übergeführt und in 20 ml alkoholischer Borsäurelösung (9,27 g/l) gelöst bzw. suspendiert. Die Bestimmungen wurden im übrigen nach der von Lindberg und Theander [10] beschriebenen Arbeitsweise ausgeführt. Die Ligninpräparate gingen bei Zusatz von 20 ml Kaliumborhydridlösung (1,35 g/l 0,1 N Natronlauge) restlos in Lösung und wurden erst bei Abbruch der Bestimmung, d. h. bei Zusatz von 5 ml 2 N Schwefelsäure, wieder teilweise ausgefällt. Die Reaktionszeit betrug 5 Stunden, die Reaktionstemperatur 25°C (thermostatierter Raum).

Das als Differenz gegen eine entsprechende Blindprobe gemessene Volumen des verbrauchten Wasserstoffs wurde auf Normalbedingungen (760 Torr, 0°) reduziert und daraus der Carbonylgehalt der Probe errechnet (1 ml Wasserstoff entspricht 1,249 mg = 0,0446 Milliäquivalente Carbonyl). Das Verhältnis des bei der Reduktion verbrauchten Wasserstoffs zum Wert der Blindprobe schwankte zwischen ungefähr 1 : 10 und 1 : 6. Die mit Hilfe der Borhydrid-Methode ermittelten Carbonylwerte sind in den Tabellen 1 und 3 zusammengestellt.

Alkaline Hydrolysis of Glycosidic Linkages

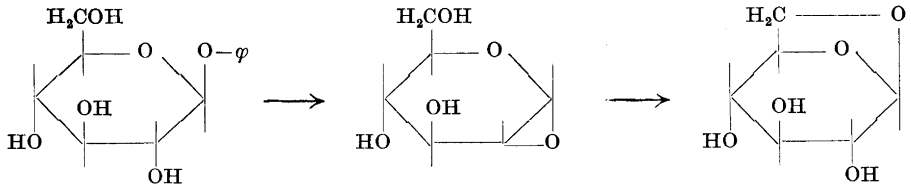
IV. The Action of Alkali on Some Glucopyranosides

JAN JANSON and BENGT LINDBERG

Institutionen för träkemi, Kungl. Tekniska Högskolan, Stockholm, Sweden

The alkaline hydrolysis of a number of glucopyranosides has been investigated. The results show that the hydrolysis may proceed by a number of different routes of comparable importance; one of those probably involves the intermediate formation of 1,2-anhydroglucose. Attempted transglycosidation of one β-glucoside and two β-xylosides by treatment with sodium methoxide in methanol at 170° yielded only traces of the corresponding methyl β-glycoside.

It is thought probable that the route by which 1,6-anhydro-D-glucose (III) is formed on the alkaline hydrolysis of phenyl β-D-glucoside (I) involves the intermediate formation of 1,2-anhydro-D-glucose (II). (For details of this and other reactions of glycosides with alkali, see Ref.[1])



I II III

Such a hypothesis offers an explanation of why the β-glucoside is much more sensitive to alkali than is the α-glucoside. The hydroxyl group at $C_{(2)}$ is in the *trans*-position to the phenoxyl group at $C_{(1)}$ and this makes it sterically possible for the first step in the reaction (I → II) to take place. McCloskey and Coleman [2] noted that phenyl 2,3-di-*O*-methyl-β-D-glucoside was quite stable to alkali. This may be explained in terms of the above mechanism. With different phenyl-β-glucosides, substituted in the *meta*- or *para*-position it was observed that the more acidic the phenol corresponding to the aglucone,

that is, the greater the electron attracting power of the phenoxyl group, the higher was the sensitivity to alkali [3].

It has been shown that alkyl glycosides are attacked by alkali only at higher temperatures [4]. Of the various methyl glycopyranosides studied, the "*trans*"-glycosides were always more reactive than were the "*cis*"-anomers, but this difference in reactivity was much less pronounced than in the case of the phenyl glycosides. The reactivity was also found to increase with the conformational instability of the most stable chair form of the glucoside (Part III) [5].

In the present paper the investigation of a number of glucopyranosides is reported. The method was the same as that previously used, that is treatment of the glucoside with 10 % aqueous sodium hydroxide at 170° and estimation of the percentage of unchanged starting material. The data for the various glucosides are summarised in Table 1.

Table 1. Rate and extent of hydrolysis of D-glucopyranosides with 10 % sodium hydroxide.

	Glucoside	Neutral residue, %			$10^3 \times k$ *
		6 h	24 h	48 h	
a	Methyl β-	98.2	88.3	73.9	2.6
b	Methyl 2-*O*-methyl β-	98.6	92.7	87.3	1.2
c	Methyl α-	96.4	93.8	89.6	1.0
d	Methyl 2-*O*-methyl α-	98.3	95.8	91.2	0.8
e	Ethyl β-	95.9	84.9	72.2	2.9
f	*Iso*propyl β-	93.8	80.1	61.6	3.9
g	*Tert.*-butyl β-	79.4	44.5	30.9	12.0
h	2-Methoxyethyl β-	95.6	90.6	81.3	1.7
i	2-Hydroxyethyl β-	89.7	73.6	58.0	4.5
j	2-Hydroxyethyl α-	97.0	90.1	81.0	1.8
k	2-Methoxyethyl α-	97.7	94.4	88.6	1.0

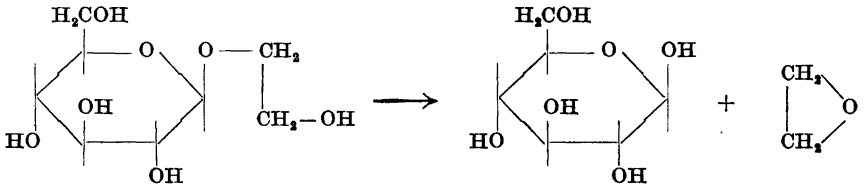
* Rate constants are expressed in Briggs logarithms and in hours.

If the hydroxyl at $C_{(2)}$ in methyl β-D-glucopyranoside (a in Table 1) is replaced by a methoxyl group (giving compound b), then the rate of alkaline hydrolysis is reduced by more than a half. In the α-series (compounds c and d) a similar substitution produced a much smaller effect. This observation, and the differences mentioned above between the reactivity of "*trans*"- and "*cis*"-glycosides, strongly support the view that, during the alkaline hydrolysis of *trans*-glycosides, an important route is that by way of the 1,2-anhydride. But as "*cis*"-glycosides and compound b show considerable reactivity, there must be other routes of importance.

The reaction velocities increase in the order methyl<ethyl<*iso*-propyl<*tert.*-butyl β-D-glucopyranoside (a,e,f,g resp.) and 2-methoxyethyl β-D-glucopyranoside (h) is even less reactive than is methyl-β-D-glucopyranoside. It is generally assumed that the electron attracting power decreases from methyl to *tert.*-butyl and therefore, by analogy with the phenyl glycosides, the reversed

order of reactivity would be expected. There are several competing mechanisms involved during alkaline hydrolysis and it is difficult to distinguish between the polar and the steric influence of alkyl groups. For these reasons, and without further studies, it is not at present possible to fully interpret the results.

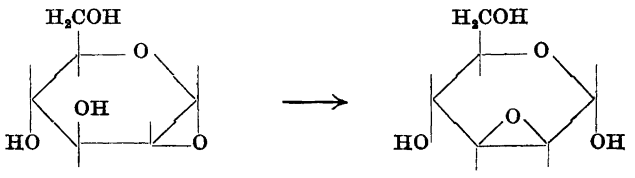
When cellobiitol was heated with alkali one of the main reaction products was 1,4-anhydro-D-glucitol [6]. This observation indicated the existence of another reaction route. The 1,4-anhydro-D-glucitol is probably formed by a nucleophilic attack on $C_{(4)}$ in the glucitol residue, either by the primary hydroxyl group at $C_{(1)}$ or by a hydroxyl group adjacent to that on $C_{(4)}$. In this last case there would be the intermediate formation of an ethylene oxide ring. Those possibilities have been studied by examining the alkaline hydrolysis of the α- and β-glucopyranosides both of ethylene glycol (monoglucosides, i and j) and of its monomethyl ether (compounds h and k). As expected, the glycol glucosides reacted much faster than did the glycol monomethyl ether glucosides. This indicated that in the hydrolysis of the former a major route involved the intermediate formation of an ethylene oxide ring (IV—V)



IV V

It is highly possible that this mechanism also operates under the conditions obtaining during sulphate and soda pulping and then leads to the hydrolysis of glycosidic linkages.

By treatment of suitable phenyl glycosides with alkali in the presence of an alcohol, transglycosidation reactions have been effected [1,7]. These reactions obviously proceed by way of the 1,2-anhydro sugars, and the possibility of transglycosidation reactions during the alkaline treatment of alkyl glycosides was inferred from previous investigations [6]. The formation of 1,6-anhydro sugars is of course an intramolecular transglycosidation. *Tert.*-butyl β-D-glucopyranoside was treated with sodium methoxide in methanol at 170° until about half of the starting material had been changed into acidic products. Only traces of methyl β-D-glucopyranoside and 1,6-anhydro-D-glucose could be chromatographically detected in the deionised reaction mixture. In similar



II VI

experiments with ethyl and *tert.*-butyl β-D-xyloside only traces of methyl β-D-xyloside were detected. These results are rather unexpected and the reason for the low yields of transglycosidation products is uncertain. One possible explanation is that the intermediate 1,2-anhydride (*e.g.* II) may preferably rearrange to a 2,3-anhydride (VII), which in turn is transformed into acidic products.

The rate constant for the hydrolysis of methyl β-D-glucopyranoside was in good agreement with that determined previously (Part III[5]) but the constant for methyl α-glucoside was found to be much higher than that recorded earlier. The amount of unchanged starting material in the hydrolysates of the various glucosides was previously determined gravimetrically. Those determinations suffered from the drawback that significant errors might be introduced due to imperfect drying or to the presence of small amounts of impurities praticularly when, as in case of methyl α-glucoside, only a small percentage of the material was hydrolysed. In the present work the quantitative determinations of the rate and degree of hydrolysis were made polarimetrically. This method would be expected to yield more reliable results especially for the α-glucosides with their high specific rotation. Some of the glycosides studied in this investigation had not been hitherto prepared. They, and the others, were prepared by conventional methods, outlined in the experimental part.

EXPERIMENTAL

All melting points are corrected. All distillations were carried out under reduced pressure. Unless otherwise stated, optical rotations were determined in aqueous solutions, $c \simeq 2$.

For chromatography, Whatman No. 1 paper and the following irrigants were used.

A. Ethyl acetate-acetic acid-water 3:1:1
B. Butanol-pyridine-water 6:2:3
C. Methyl ethyl ketone, saturated with water.

Those synthesis are described below which are of new glycosides or of glycosides prepared by methods other than those given in the literature.

2-Hydroxyethyl α-D-glucopyranoside. A mixture of glucose (57 g), glycol (500 g) and Amberlite IR 120 (H^+) (120 g) was heated on the steam bath with stirring for 72 h. The ion exchange resin was then filtered off and the solution was concentrated to a syrup, which was dissolved in 2 N aqueous sodium hydroxide (250 ml) and kept at 100° overnight. After deionisation and concentration a syrup was obtained which did not crystallise. Chromatographic investigation revealed that, amongst several compounds present, one was chromatographically indistinguishable from the expected β-glucoside. Part of the syrup was fractionated by carbon column chromatography, using aqueous ethanol as irrigant and the gradient elution technique. The main fraction did not crystallise but was chromatographically pure and both its R_F-value and its high specific rotation (98°) accorded with the high calculated approximate values for hydroxyethyl-α-glucoside. The β-anomer was obtained in lower yield from another fraction and had a rather higher mobility on electrophoresis in borate buffer.

A few months after the investigation of this substance was completed, it crystallised. Recrystallisation from ethyl acetate-ethanol yielded the pure substance, m. p. 99°—101°, $[\alpha]_D^{23}$ +139° (*c* 0.05, in water). (Found C 42.5; H 7.1. Calc. for $C_8H_{16}O_7$: C 42.9; H 7.2).

2-Methoxyethyl α-D-glucopyranoside was prepared in the same way as the above substance. It was purified by carbon column chromatography and gave a homogeneous syrup having $[\alpha]_D$ +94°.

Methyl 2-O-methyl-α-D-glucopyranoside. 2-*O*-methyl-D-glucose (6 g) prepared by the method of Lock and Richards [8], and *p*-toluene sulphonic acid (2.2 g) were dissolved in anhydrous methanol (20 ml) and the solution boiled overnight under reflux. The methanol was distilled off, the syrup dissolved in water, and acid removed by passing the solution through a column of IR 4B. The concentrated eluate was treated overnight with 2 N aqueous sodium hydroxide and after deionisation was again concentrated. The product was crystallised (1.9 g) from ethyl acetate. It had m. p. 146°–150° and $[\alpha]_D^{20}$ +155°.

Methyl 2-O-methyl-β-D-glucopyranoside. 2-*O*-Methyl-D-glucose (4 g), dissolved in a mixture of acetic anhydride (8 ml) and pyridine (25 ml), was heated on a steam bath for 30 min. The reaction mixture was taken to dryness and traces of pyridine were removed by co-distillation with acetic acid. The syrup was dissolved in a mixture of acetic acid (20 ml) and acetyl bromide (1.75 ml). This solution was cooled in ice-water and a solution of water (0.38 ml) in acetic acid (2 ml) was added over 30 min. The reaction mixture was kept at room temperature for 2 h. Then chloroform (25 ml) was added and the mixture, after being washed successively with ice-water, sodium hydrogen carbonate solution and water, was firstly dried over calcium chloride and calcium carbonate and then concentrated to a thick syrup (7.6 g). The syrup was dissolved in a mixture of anhydrous benzene (10 ml) and anhydrous methanol (20 ml). After the addition of anhydrous calcium sulphate (3 g) small portions of silver carbonate (9.5 g) were added and the flask was shaken for 90 min and then allowed to stand overnight. After filtration, the solution was concentrated, then treated with sodium hydroxide and the reaction mixture deionised as described above and concentrated to a syrup. The product, after crystallisation from ethyl acetate, had m. p. 95°–97°, $[\alpha]_D^{20}$ −38°. Yield 1.4 g.

Tert.-*butyl β-D-xyloside.* Tri-*O*-acetyl-α-D-xylopyranosylbromide (11.2 g) was dissolved in a mixture of benzene (15 ml) and *tert.*-butanol (15 ml). Silver carbonate (27 g) was added and the mixture was shaken overnight. After filtration and concentration the resultant syrup was dissolved in ethyl ether and the solution extracted with water. Crystalline 2,3,4-tri-*O*-acetyl-D-xylose, m. p. 136°–139°, $[\alpha]_D^{20}$ +45° (equilibr.) was isolated from the aqueous phase. The ether phase on concentration yielded a syrup which, on crystallisation from 50 % ethanol gave *tert.*-butyl 2,3,4-tri-*O*-acetyl-β-D-xylopyranoside (2.6 g). After recrystallisation the substance had m. p. 132°–134° and $[\alpha]_D^{25}$ −45° (*c*, 1.5 in chloroform). (Found C 54.4; H 7.2. Calc. for $C_{15}H_{24}O_8$: C 54.2; H 7.3.) The product on deacetylation yielded the free xyloside, which was crystallised from methyl ethyl ketone. M. p. 122°–123°, $[\alpha]_D^{25}$ −29°. (Found C 52.5; H 8.6. Calc. for $C_9H_{18}O_5$: C 52.4; H 8.8.)

Ethyl β-D-xylopyranoside was prepared by deacetylation of the corresponding acetate [9] and was crystallised from methyl ethyl ketone. M. p. 95°–96°, $[\alpha]_D^{25}$ −38°. (Found: C 47.0; H 7.6. Calc. for $C_7H_{14}O_5$: C 47.2; H 7.9.)

Alkaline hydrolysis. The samples (0.5 g) of glucoside were separately dissolved in 2.65 N sodium hydroxide (5 ml) and the solutions, in stainless steel bombs and under nitrogen, were heated at 170° in a thermostat oil bath for different times. When cold the solutions were deionised by filtration through a mixed bed of Amberlite IR 120 (H^+) and Dowex 2 (OH^-). The bed was thoroughly washed with water and the filtrate and washings were combined and concentrated. A chromatographic investigation, in the irrigants listed earlier, showed that the reaction mixtures contained unchanged starting material and, amongst the faint traces of other components, one which was chromatographically indistinguishable from 1,6-anhydro-D-glucose. The glycol glucosides yielded substantial amounts of ethylene glycol in addition. The recovery of unchanged starting material was determined polarimetrically.

A recovery of 98–100 % was achieved in control experiments in which the glucoside was treated as above but omitting the heating stage.

Transglycosidation reactions. Samples of the glycosides were separately dissolved in 2.65 N methanolic sodium methoxide and the solutions heated at 170° as previously. The reaction mixtures were then treated in the same way as those obtained by alkaline hydrolysis. The *tert.*-butyl β-glucoside, *tert.*-butyl β-xyloside and ethyl β-xyloside were heated for 48, 27 and 48 h, respectively, and the recoveries of unchanged starting materials were 43, 60 and 54 %, respectively. All products crystallised and, after recrystallisation, small

amounts of the corresponding methyl β-glycosides were chromatographically detected in the mother liquors. The glucoside gave in addition a compound chromatographically indistinguishable from 1,6-anhydro-D-glucose.

*iso*Thiocyanates XXXIV *. The Absolute Configuration of (–)-5-Vinyl-2-oxazolidinethione (Goitrin) and its Glucosidic Progenitor (Progoitrin)

ANDERS KJÆR, BO W. CHRISTENSEN and SVEND E. HANSEN

Organic Chemical Laboratory of the Royal Veterinary and Agricultural College, Copenhagen V, Denmark

The antithyroid factor, (–)-5-vinyl-2-oxazolidinethione (I), produced by enzymic hydrolysis of a glucoside (progoitrin) present in roots and seeds of, *e. g.*, rape and turnips, has been demonstrated to possess the absolute configuration depicted as (II). The salt of (–)-1-amino-3-buten-2-ol and (+)-α-bromocamphor-π-sulphonic acid, formerly employed for the synthesis of (I), has been transformed into the *dextro*rotatory acid oxalate of 1-amino-2-butanol.

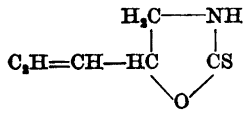
The latter salt has also been prepared from (–)-2-hydroxybutyric acid of known absolute configuration by a sequence of reactions not involving chemical bonds attached to the asymmetric carbon atom. (+)-1-Amino-2-butanol acid oxalate has been transformed into (–)-5-ethyl-2-oxazolidinethione of known absolute configuration.

On the likely assumption that enzymic hydrolysis of progoitrin proceeds with retention of configuration the above correlation further establishes the stereochemistry of the parent glucoside.

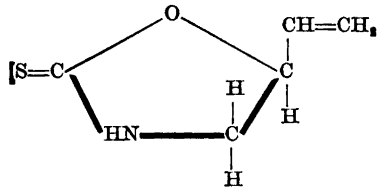
The presence of a goitrogenic factor in roots and seeds of various cruciferous species had long been suspected at the time Astwood *et al.*[1] succeeded in isolating from yellow turnip (rutabaga) a *levo*rotatory, crystalline compound to which the structure (I) was attributed and which upon ingestion elicited goitrous symptoms in animals and human subjects. The same authors [2] presented evidence for (I) being a secondary component produced by enzymic fission of a parent substance, possibly a glycoside. This view was supported by spectroscopic evidence in our laboratory and one of the stereoisomeric 2-hydroxy-3-butenyl *iso*thiocyanates, enzymically liberated from a glucoside, was suggested as a likely progenitor of (I)[3]. A similar conclusion was reached by Schultz and Wagner [4] who isolated a crystalline tetraacetate of the parent glucoside ('glukorapiferin') from seeds of a rape variety. Shortly thereafter, Greer [5] announced the isolation of progoitrin, the crystalline sodium salt of

* Part XXXIII of this series: *Acta Chem. Scand.* **12** (1958) 1693.

the glucosidic precursor of (I), which was enzymically hydrolyzed to glucose, sulphate and (-)-5-vinyl-2-oxazolidinethione (goitrin) *. The structure of the latter was substantiated by Ettlinger [6] who synthesized (I) by a series of reactions which left the configuration around the asymmetric carbon atom as the sole undecided structural feature. In connexion with current studies in this laboratory, knowledge of the absolute configuration of (I) became desirable. The present paper records experimental data supporting (II) as a correct expression for the *levo*rotatory 5-vinyl-2-oxazolidinethione (goitrin).

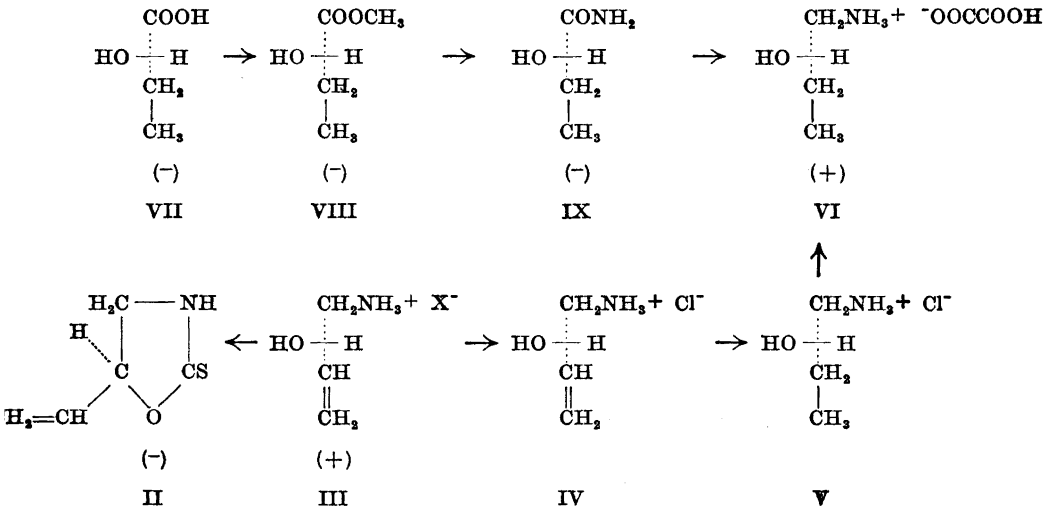


I



II

In his synthesis, Ettlinger [6] transformed the salt (III) of (-)-1-amino-3-buten-2-ol and (+)-α-bromocamphor-π-sulphonic acid into (-)-5-vinyl-2-oxazolidinethione (II). From the same salt, prepared in essentially the same way, we obtained by ion exchange the corresponding hydrochloride (IV). Catalytic hydrogenation of this afforded the hydrochloride of the corresponding 1-amino-2-butanol (V), which was, in turn, transformed into the *dextro*rotatory acid oxalate of the same amino-alcohol (VI).



* Greer, as well as Virtanen *et al.*[17], used the prefix L to denote this *levo*rotatory enantiomorph, a specification which should be dismissed in this context because of its generally accepted usage in expressing generic relationship within a particular configurational series. In the present case, however, such a correlation has not been previously established. Even if it had, the prefix would be an ambiguous or, at best, arbitrary specification.

The steric relationship of the salt (VI) was established by an alternative synthesis departing from a configurationally known compound. As such served *levo*rotatory 2-hydroxybutyric acid (VII), prepared by resolution of the racemic acid with brucine [7]. The acid was transformed into the previously unknown (-)-methyl 2-hydroxybutyrate (VIII) and thence into the more strongly *levo*rotatory 2-hydroxybutyramide (IX), which was reduced with lithium aluminium hydride to give an optically active 1-amino-2-butanol, characterized as the *dextro*rotatory acid oxalate (VI). The latter possessed the same rotation, both with regard to magnitude and sign, as the salt prepared as described above. Idential melting point, undepressed on admixture, and coinciding infra-red spectra further served to corroborate the identity of the two preparations.

The literature contains abundant evidence to support the assignment of the Fischer projection formula (VII) to the *levo*rotatory enantiomorph of 2-hydroxybutyric acid. Thus, Levene and Haller [8] correlated chemically, through the enantiomeric 2-butanols, (+)-lactic acid and (-)-2-hydroxybutyric acid.*

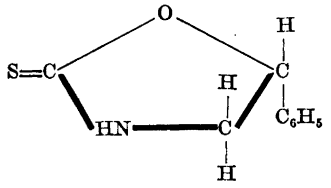
Szarvas [9] adduced good evidence for the configurational relationship of the two acids by rotatory dispersion studies, whereas Fredga *et al.*[10] demonstrated the same generic connexion by utilizing the quasi-racemate method. Supplementary evidence for (-)-2-hydroxybutyric acid being generically related to (+)-lactic acid is available by the fact that the rotations of both are similarly displaced on salt formation in accord with the general rule of Clough, which has been demonstrated to apply for monoasymmetric 2-hydroxy-substituted carboxylic acids [11]. Again, a direct correlation of (—)-hydroxybutyric acid with (—)-malic acid of ascertained configuration has been established by Horn and Pretorius [12] through an anodic coupling process.

The above correlations place the spatial representation of (—)-2-hydroxybutyric acids as (VII), and hence its absolute configuration, beyond any doubt. The same applies for the amine salt (VI) because the subsequent transformations into ester (VIII), amide (IX) and amine salt (VI) proceed without participation of bonds extending from the asymmetric carbon atom. In addition, Noyce and Denney [13] demonstrated an asymmetric center next to a carboxyl or carbonyl grouping to be unaffected by lithium aluminium hydride reduction. Again, inversion can safely be excluded in the catalytic hydrogenation and ion exchange reactions utilized in transforming the sulphonate (III) into the oxalate (VI). Although no rigorous proof is available of the mechanisms by which an optically active 2-amino-alcohol is transformed into an active 2-oxazolidinethione such as (II), there can hardly be any doubt that in the present case a base-induced cyclization of an intermediate *iso*thiocyanate represents the actual events. This further implies that no rupture of the C-O-linkage, or any other bond attached to the asymmetric center, occurs;

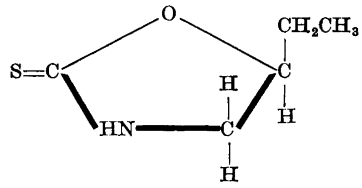
* In fact, the authors reported this acid as a *dextro*rotatory compound. Szarvas [9] subsequently demonstrated it to be slightly *levo*rotatory when measured in pure water, and further pointed out that Levene and Haller's measurement was performed in a solution of 0.58 M barium chloride and excess hydrochloric acid, resulting in an inversion of the sign of rotation. Similar conclusions were reached by other groups also [10, 12].

a conclusion which establishes the absolute configuration of goitrin (II) * relative to that of the salt (III) and, hence, of the acid (VII).

In previous communications from this laboratory the presence in seeds of *Barbarea vulgaris* R.Br.[15] and inflorescenses of *Reseda luteola* L.[16] of a glucoside (glucobarbarin) furnishing (–)-5-phenyl-2-oxazolidinethione (barbarin) upon enzymic hydrolysis, was demonstrated. Stereospecific synthesis of barbarin [16] further showed it to possess the absolute configuration depicted as (X)**



X



XI

It is interesting that goitrin and barbarin, both *levo*rotatory in methanolic solution, contain the substituents at the asymmetric carbon atom in opposite spatial positions. It hence became of interest to transform *levo*rotatory 1-amino-2-butanol acid oxalate (VI) into the corresponding 5-ethyl-2-oxazolidinethione possessing the absolute configuration (XI)***. The latter turned out to be *levo*rotatory in methanolic solution like the configurationally analogous goitrin. The ultra-violet absorption spectrum of (XI) was of the expected type and very similar to that of goitrin, a fact which supports the recent conclusion by Virtanen *et al.*[17] that (XI) can be excluded as the substance responsible for the absorption pattern observed in a milk fraction from a cow which was fed progoitrin-containing rape seed in amounts corresponding to 4.5 g of goitrin. Experimental details for the synthesis of (XI) will appear in a forthcoming communication.

The above determination of the absolute configuration of goitrin also establishes the configuration around the asymmetric carbon atom in the side-chain of progoitrin, because there can hardly be any doubt that cyclization of the intermediate 2-hydroxy-3-butenyl *iso*thiocyanate proceeds with full retention of configuration. The possible consequences of the above stereochemical studies for the biogenesis of the ring-producing *iso*thiocyanate glucosides are being considered at the present.

EXPERIMENTAL

All melting points are uncorrected and determined in capillary tubes in a slowly heated bath. Microanalyses were performed by Mr. P. Hansen at the Chemical Laboratory of the University of Copenhagen.

(±)-*1-Amino-3-buten-2-ol.* This unsaturated amino-alcohol was prepared by the route developed by Ettlinger [6] and the various synthetic reactions proceeded essentially as

* In the system for specification of absolute, asymmetric configuration proposed by Cahn *et al.*[14], goitrin (II) is (*S*)-5-vinyl-2-oxazolidinethione.

** (*R*)-5-Phenyl-2-oxazolidinethione in the specification system of Cahn *et al.*[14]

*** (*S*)-Ethyl-2-oxazolidinethione in the specification of Cahn *et al.*[14]

described. 3,4-Epoxy-1-butene, serving as the starting material, was prepared from butadiene as reported by Kadesch [18]. It was found advantageous, as proposed by Raciszewski *et al.*[19], to add a trace of pyrogallol to the 1-amino-3-buten-2-ol prior to distillation, resulting in a 74 % yield of distilled amino-alcohol based on the acid oxalate. Without polymerization inhibitor the yield was considerably lower (*cf.* also Ref.[19]) than that (79 %) reported by Ettlinger [6].

Salt of (—)-1-Amino-3-buten-2-ol and (+)-α-bromocamphor-π-sulphonic acid. Resolution of the above racemic amino-alcohol with (+)-α-bromocamphor-π-sulphonic acid (British Drug Houses) proceeded as reported by Ettlinger [6]. After recrystallization from wet ethyl acetate the monohydrate of the slightest soluble salt, m. p. 98—102°, possessed the rotation data: $[\alpha]_D^{21}$ +64° (H_2O, *c* 2.3), $[\alpha]_D^{21}$ +55° (0.5 % NaOH, *c* 2.1). A subsequent preparation, conducted at a time when the relative humidity in the laboratory was lower, resulted in isolation of the lower-melting [6], anhydrous salt.

Acid oxalate of (—)-1-amino-2-butanol (VI). The above bromocamphorsulphonate (3 g), dissolved in water (200 ml), was percolated slowly through a column containing an anion exchange resin (Amberlite IR-4B, about 120 mequiv.) in the chloride form. The combined filtrate and washing was concentrated to dryness when the hydrochloride (IV) remained as a viscous oil. Without further purification, the hydrochloride was dissolved in 96 % ethanol (20 ml), containing a few drops of water, and the solution was subjected to catalytic hydrogenation at atmospheric pressure in the presence of 10 % palladium charcoal (1 g). Hydrogen (140 ml) was rapidly taken up and after about 10 min. the absorption came to a stop. After filtration, the filtrate was concentrated *in vacuo* to an oil, consisting of (V), which was dissolved in water. The solution was made alkaline with NaOH, saturated with NaCl and subjected to continuous extraction with ether in a liquid-liquid extractor. To the ether-containing distillation flask was added oxalic acid dihydrate (950 mg) before extraction was initiated. After 3 h, the crystalline acid oxalate (500 mg) was removed by filtration. Two recrystallizations from absolute ethanol, with the use of a little charcoal, afforded a pure specimen of *dextro*rotatory acid oxalate of 1-amino-2-butanol (VI) (330 mg), m. p. 149—150°, $[\alpha]_D^{21}$ +11.3° (H_2O, *c* 0.69).

The substance showed no melting point depression on admixture with a specimen synthesized by another route described below. The infra-red spectra of the two preparations were coinciding throughout the wave-length range (650—4 000 cm^{-1}) examined.

(—)-2-Hydroxybutyric acid VII. 2-Bromobutyric acid (271 g), prepared in 76 % yield according to the directions for the synthesis of 2-bromo*iso*caproic acid [20], was transformed into (±)-2-hydroxybutyric acid in 67 % yield by the method of Bischoff and Walden [21].

The racemic acid (250 g), dissolved in water (1 300 ml), was resolved by means of brucine (966 g of anhydrous alkaloid base), as described by Guye and Jordan [7, 22]. The salt (410 g) was recrystallized from water (700 ml) to give a product (270 g), which possessed rotation values in accord with those reported [7]. To a solution of the salt in water (300 ml), conc. ammonia (50 ml) was added and the precipitated brucine was filtered off and washed. The filtrate was acidified with conc. HCl, saturated with NaCl, and subjected to continuous extraction with ether [9] for 6 h. After removal of the solvent from the dried ether solution, the crystalline (—)-2-hydroxybutyric acid remained (45 g). It was purified by distillation, b. p. 97° at 1.2 mm, and was obtained as hygroscopic, colourless needles (32 g), m. p. 53°, unchanged on recrystallization from a mixture of chloroform and pentane, $[\alpha]_D^{21}$ −15.3° (172 mg of acid in water, containing 1.3 equiv. of ammonia; total volume 5.00 ml). Literature values: m. p. 55—55.5° (recryst. from CCl_4)[10], 52.7—53.5° (from CCl_4: hexane) [12], $[\alpha]_D^{25}$ −15.9° (NH_4-salt in H_2O, *c* 2.7)[10].

(±)-Methyl 2-hydroxybutyrate. Because attempts to esterify 2-hydroxybutyric acid by the method of Clemmensen and Heitman [23] and by the customary hydrochloric acid-catalyzed procedure were unsatisfactory, due to the large amounts of by-products formed by intra- and inter-molecular condensations, special conditions were worked out with the racemic acid as a model in order to minimize the undesired side reactions. The following procedure was eventually adopted:

To a refluxing solution of anhydrous methanol (700 ml), containing dry HCl (6.7 g), was added in 7 portions, and with 0.5 h intervals, a total of 35 g of (±)-2-hydroxybutyric acid. The solution was refluxed for another 2 h when ether (100 ml) and enough water to

produce an aqueous phase of a few ml, were added, followed by solid $NaHCO_3$ until neutralization. The organic layer was removed by decantation, dried over Na_2SO_4 and freed of ether by distillation. The methyl ester distilled as a colourless liquid, b. p. 69° at 30 mm, n_D^{25} 1.4170. The yield was 19.8 g (50 %). Reppe [24] reports: b. p. 68° at 30 mm.

(−)-Methyl 2-hydroxybutyrate (VIII). The above procedure, applied to (−)-2-hydroxybutyric acid (32 g), afforded the corresponding optically active methyl ester (16.8 g) with the same b. p., n_D^{25} 1.4171, D_4^{24} 1.048, $[\alpha]_D^{24}$ −2.30° (neat). (Found: C 51.30; H 8.89. Calc. for $C_5H_{10}O_3$: C 50.85; H 8.53.)

(−)-2-Hydroxybutyramide (IX). A solution of (−)-methyl 2-hydroxybutyrate (10.0 g) in conc. aqueous ammonia (330 ml) was left standing in a closed vessel at room temperature for 3 days, whereupon it was concentrated *in vacuo* to a viscous oil. This was refluxed for one hour with sodium-dried ether (200 ml) which was decanted hot from undissolved material, and the process was repeated with a fresh portion of ether (200 ml). The combined ether solutions deposited on cooling overnight a crop of the hygroscopic amide as colourless small prisms (2.85 g). An additional crop of the same quality (2.26 g) separated from the concentrated mother liquor. An analytical specimen was secured by an additional recrystallization from anhydrous ether. Due to hygroscopicity it proved necessary to determine the m. p. in capillary tubes, sealed after drying over P_2O_5, m. p. 61−62°, $[\alpha]_D^{23}$ −45° (H_2O, *c* 1.15). (Found: C 46.65; H 8.72; N 13.40. Calc. for $C_4H_9NO_2$: C 46.60; H 8.80; N 13.59.) It is interesting to notice that the higher-melting racemic 2-hydroxybutyramide (m. p. 105° [25], 108° [26]) does not possess hygroscopic properties, a finding paralleled in the lactamide series.

Reduction of (−)-2-hydroxybutyramide to (VI). In a three-necked flask, provided with magnetic stirring, dropping funnel, nitrogen inlet and a Soxhlet-type extractor was placed a solution of lithium aluminium hydride (6.0 g) in dry ether (660 ml). (−)-2-Hydroxybutyramide (4.0 g) was placed in the extractor and washed down in the course of 2 h by the refluxing ether, during which time the reaction mixture was stirred in a slow stream of dry nitrogen. Excess reagent was then destroyed by addition of wet ether, whereafter a saturated solution (300 ml) of potassium sodium tartrate was introduced. The ether layer was combined with three 250 ml-extracts of the aqueous phase. The amine content in the dried ether solution was determined by titration to 1.21 g, corresponding to a 34 % yield.

Addition of the amine solution to an ethereal solution of oxalic acid (2.05 g) resulted in the separation of the acid oxalate in crystalline form (1.76 g), m. p. 150°. An analytical specimen was produced on recrystallization from absolute ethanol, m. p. 150°, alone or in admixture with the sample described above; $[\alpha]_D^{22}$ +11.8° (H_2O, *c* 0.71). (Found: C 40.30; H 7.27; N 7.91. Calc. for $C_6H_{13}NO_5$: C 40.21; H 7.31; N 7.82). As further criterion of identity of the two independently synthesized specimens served the coinciding infra-red spectra which, in addition to numerous expected bands, displayed an unidentified, characteristic peak at 718 cm^{-1} (KBr-disc).

Acid oxalate of (−)-1-amino-3-buten-2-ol. This salt was desired particularly for the purpose of studying its infrared spectrum. It was prepared from the above α-bromocamphor-π-sulphonate by liberation of the amino-alcohol with strong base, a process accompanied by unknown secondary reactions, followed by treatment with one equivalent of oxalic acid. The salt crystallized from absolute ethanol in colourless prisms, m. p. 134°, $[\alpha]_D^{23}$ −5.9° (H_2O, *c* 1.0). (Found: N 7.60. Calc. for $C_6H_{11}NO_5$: N 7.90). Reported m. p. for the racemic salt: 130.5−132° [6].

The infra-red spectrum, was very similar to that of the acid oxalate of the saturated amino-alcohol (VI), having in common with the latter the band at 718 cm^{-1}. Significant deviations were noted, however, particularly in the 800−1 100 cm^{-1} region.

The authors are indebted to Dr. J. Villadsen of the H. Topsøe Laboratory for the loan of a butadiene tank.

The work is part of investigations supported by *Statens Almindelige Videnskabsfond (The Danish State Research Foundation)* and *Carlsbergfondet (The Carlsberg Foundation)*. A special grant from *Kai Hansen's Fond* is gratefully aknowledged.

The Addition of Dimethylamine to Propylene Sulphide

BERTIL HANSEN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The product of the reaction between dimethylamine and propylene sulphide in ether has been studied in several ways, and found to be 2-dimethylamino-propanethiol. Based on a comparison with the opening of alkene oxide and alkene immonium rings, it is proposed that the opening of the propylene sulphide ring includes a cyclic sulphonium intermediate, $CH_3-CH-CH_2$ (S$^+$, R).

For the preparation of derivatives of α- and β-methyl-thiocholine esters 2-dimethylamino-propanethiol-(1) and 1-dimethylamino-propanethiol-(2) are useful starting materials [1]. As 2-dimethylamino-ethanethiol is easily obtained from ethylene sulphide and dimethylamine [2], it seemed obvious to investigate if one of the dimethylamino-propanethiols could be prepared from propylene sulphide and dimethylamine. This paper describes the work carried out to find out which of the two possible thiols I and II was formed in this reaction(1).

$$CH_3CH\text{-}CH_2 + (CH_3)_2NH \rightarrow \begin{cases} (CH_3)_2NCHCH_2SH & (I) \\ \quad\quad CH_3 & \\ (CH_3)_2NCH_2CHSH & (II) \\ \quad\quad CH_3 & \end{cases} \qquad (1)$$

The reaction between propylene sulphide and an amine is described in the literature, but nobody has shown how the ring ruptures. Reppe and Nicolai [3] say that they have obtained a primary mercaptan by treating propylene sulphide with *n*-butylamine. On the other hand Snyder *et al.*[4] guess that they got a secondary thiol when di-*n*-amylamine reacted with propylene sulphide, because they could show that the same amine with *iso*-butylene sulphide gave a tertiary mercaptan.

Regarding other reactions with propylene sulphide it has been found that hydrogen chloride, acetyl chloride and acetyl bromide [5] open the ring

at the centre carbon atom, while acetic anhydride [5] and lithium aluminium hydride [6] destroy the bond between the sulphur atom and the terminal carbon atom. There is, in other words, no general rule for the opening of the propylene sulphide ring which can be applied to reactions between amines and propylene sulphide.

EXPERIMENTAL

Propylene sulphide was prepared from propylene oxide and thiourea [1]. B. p. 74—76°.

Addition of dimethylamine to propylene sulphide. The reaction was carried out in anhydrous ether as described in Ref.[1] Physical data for the dimethylamino-propanethiol are b. p. 71°/88 mm; $n_D^{25} = 1.4538$; $d^{25} = 0.8693$ g/cm³.

The hydrochloride when crystallized from a mixture of *iso*propanol/ligroin gave needles which, after being dried in a vacuum desiccator, melted at 167°. (Found: C 38.6; H 9.1. Calc. for $C_5H_{14}ClNS$ (155.7): C 38.6; H 9.1.) The picrate, recrystallized from *iso*propanol/petroleum ether and dried in air, melted at 94.5°. (Found: C 38.1; H 4.5. Calc. for $C_{11}H_{16}N_4O_7S$ (348.3): C 37.9; H 4.6.)

1-Dimethylamino-2-chloropropane hydrochloride. See Ref.[1] M. p. 185°. Schultz and Sprague [7] observed 185—186°.

2-Dimethylamino-1-chloropropane hydrochloride was prepared from thionyl chloride and 2-dimethylamino-propanol-(1) which was obtained by reducing ethyl-α-dimethylamino-propionate with lithium-aluminium hydride. M. p. 102°. Schultz and Sprague [7] observed 103—104°.

Iso*thiuronium compounds.* Dimethylamino-chloropropane hydrochloride and thiourea were refluxed in abs. ethanol [1]. For the product from 1-dimethylamino-2-chloropropane hydrochloride see Ref.[1]

From 2-dimethylamino-1-chloropropane hydrochloride a crude product in 54 % yield was obtained, which, after recrystallization, melted at 152°. (Found: C 30.6; H 7.4. Calc. for $C_6H_{17}Cl_2N_3S$ (234.2): C 30.8; H 7.3.)

Hydrolysis of iso*thiuronium salts.* The reaction was carried out as described in Ref.[1] For the hydrolysis of the isothiuronium compound from 1-dimethylamino-2-chloropropane hydrochloride see Ref.[1] The hydrochloride of the hydrolysis product after reprecipitation by ether from a solution in absolute ethanol/ligroin (1:1) melted at 114—115°. (Found: C 38.5; H 9.4. Calc. for $C_5H_{14}ClNS$ (155.7): C 38.6; H 9.1.)

The picrate, after recrystallization from absolute ethanol, melted at 168°. Renshaw *et al.*[8] reported 159—166°. (Found: C 38.0; H 4.6. Calc. for $C_{11}H_{16}N_4O_7S$ (348.3): C 37.9; H 4.6.)

The *iso*thiuronium compound from 2-dimethylamino-1-chloropropane hydrochloride gave thiol in 48 % yield. B. p. 55.5°/27 mm. $n_D^{25} = 1.4678$. (Found: C 50.1; H 11.0. Calc. for $C_5H_{13}NS$ (119.2): C 50.4; H 10.8.)

S-Acetylation and N-methylation of the dimethylamino-propanethiols. The reactions with acetic anhydride and methyl bromide were carried out as reported in Ref.[1] The dimethylamino-propanethiol from propylene sulphide gave a product melting at 188°. The dimethylamino-propanethiol from the *iso*thiuronium salt gave a product melting at 168°. For analyses see Ref.[1]

Treatment of the dimethylamino-propanethiols with a Raney nickel catalyst. To 2 ml of dimethylamino-propanethiol in 100 ml of absolute ethanol Raney nickel catalyst, W 5[9], was added in portions, with shaking, until the gas evolution ceased. At the same time the red colour formed during the reaction disappeared. The catalyst was removed by filtration, and a saturated solution of picric acid in absolute ethanol was added. To avoid excess of picric acid the E.M.F. of a glass-calomel electrode system was plotted against the volume of the picric acid solution. When the curve showed that the equivalence point had almost been reached, the addition was stopped. The solution was evaporated to dryness under reduced pressure at a temperature below 40°. The residue was crystallized once from water. The yield of the crude product was about 50 %.

The dimethylamino-propanethiol from the *iso*thiuronium salt gave a product which melted at 110—115°. Recrystallization gave flakes which melted at about 110°. (Found: C 41.6; H 5.2. Calc. for $C_{11}H_{10}N_4O_7$ (316.3): C 41.8; H 5.1.)

The dimethylamino-propanethiol from propylene sulphide gave a product which melted at 130—150°. Recrystallization gave flakes which melted at about 110°. (Found: C 41.6; H 5.2. Calc. for $C_{11}H_{16}N_4O_7$ (316.3): C 41.8; H 5.1.)

Treatment of quaternary nitrogen compounds with a Raney nickel catalyst. One gram of the nitrogen compound and 20 g of catalyst were shaken for 1 h in 75 ml of absolute methanol. After filtration the solution was evaporated to dryness under reduced pressure at room temperature. The reaction was carried out with the two acetyl methyl-thiocholine iodides [1], acetyl choline iodide and choline iodide. In all cases the residues amounted to only a few mg.

Dimethylpropylamine picrates. One mole of propyl iodide was dissolved in 1.5 l of dry ether and cooled to −10°. Three moles of anhydrous dimethylamine were added, and the mixture was placed in an ice-water bath, which was allowed to come to room temperature. After 6 days a precipitate, consisting mainly of dimethylamine hydroiodide and possibly a little dimethyldipropylammonium iodide, was filtered off. The excess dimethylamine in the filtrate was bound as amide by adding acetic anhydride in portions until no increase in the temperature could be observed. The dimethylpropylamine was then precipitated with hydrogen chloride. The precipitate was filtered off by suction, washed with ether and dried in a vacuum desiccator. The picrate was obtained on cooling a solution of the crude hydrochloride and an equivalent amount of picric acid in the smallest possible amount of hot water. It was recrystallized once from water. Dimethyl-*n*-propylamine picrate: flakes, m. p. 109°. (Found: C 41.8; H 5.1. Calc. for $C_{11}H_{16}N_4O_7$ (316.3): C 41.8; H 5.1.) Dimethyl-*iso*propylamine picrate: needles, m. p. 239°. (Found: C 41.8 H 5.1. Calc. for $C_{11}H_{16}N_4O_7$ (316.3): C 41.8; H 5.1.)

Infra-red spectra. Samples were prepared from about 2 mg of the compound to be investigated and 300 mg of potassium bromide.

The spectra were recorded with a Perkin-Elmer spectrophotometer, Model 21, equipped with a rock-salt prism. The following settings of the instrument were used: resolution 927, response 2:1170, gain 6, scale 5 cm/μ, speed about 1 μ/min.

RESULTS

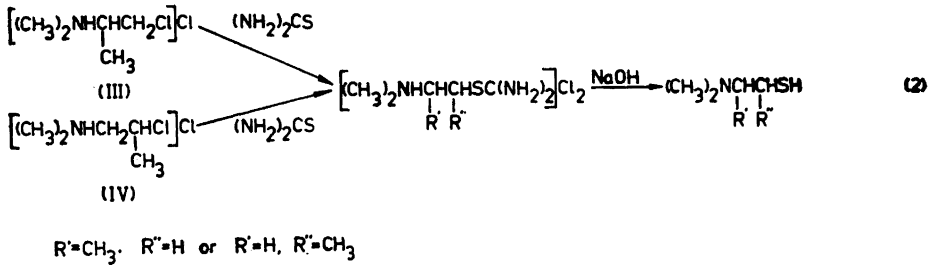
Preparative work. The addition of dimethylamine to propylene sulphide (reaction (1)) in ether gives a product which seems to consist of only one of the isomers I and II. It distils at constant temperature and the melting points of the hydrochloride and the picrate change only slightly on recrystallization (Table 1).

Table 1. Physical data for the products of the reactions (1) and (2) and derivatives.

Product of reaction	B.p./mm Hg	n_D^{25}	d^{25}g/cm^3	Melting-points			
				hydro-chloride	picrate	derivative *	
						pure	mixed with V
(1)	71°/88	1.4538	0.8693	167°	94.5°	187°	187°
(2)	78.5°/70	1.4684	0.9046	114—115°	168°	168°	135—140°

* Acetyl methyl-thiocholine bromide.

As the analytical literature gives no test that is characteristic for primary or secondary thiols, an attempt was made to synthesize I and II. A possible way for the dimethylamino-propanethiols was to synthesize them from the hydrochlorides of the corresponding chlorides, III and IV. However, when



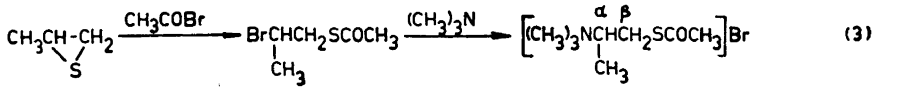
(2)

R'=CH_3. R''=H or R'=H, R''=CH_3

these compounds were refluxed with thiourea in ethanol the resulting *iso*-thiuronium compounds were found to be identical (from III m.p. 152°; from IV m.p. 154°). The refractive index of the thiols formed on hydrolysis of the *iso*thiuronium salts also indicated the formation of only one isomer (from III $n_D^{25} = 1.4678$; from IV $n_D^{25} = 1.4684$).

The fact that only one *iso*thiuronium salt was obtained from III and IV is not astonishing, as Schultz and Sprague [7] have found that III when melted rearranges into IV. As IV is the stable isomer, it seems most likely that an isomerisation occurs in the reaction between III and thiourea giving a compound with the *iso*thiuronium group bonded to the centre carbon atom. However, the possibility of an isomerisation in the reaction with IV could not be excluded at this point.

As the dimethylamino-propanethiols resulting from the reactions (1) and (2) have different physical properties themselves and as salts (Table 1), one of the thiols must have the structure I and the other II. By treatment first with acetic anhydride and then with methyl bromide they were transformed into N-(S-acetyl-mercaptopropyl)-trimethylammonium bromides (acetyl methyl-thiocholine bromides) and a comparison could thus be made with the product of reaction (3) (m.p. 187°). V was known to be acetyl α-methyl-thiocho-



(3)

(V)

line bromide, as Davies and Savige [5] have been able to elucidate the direction of the first step of reaction (3). From the values in Table 1 the conclusion can be drawn that the product of reaction (1) has the structure I and that (2) gives II. A study of the infra-red spectra of the acetyl methyl-thiocholine bromides confirms the correctness of the conclusion.

Degradations with a Raney nickel catalyst. In the hope of finding other ways of confirming the structures of the dimethylamino-propanethiols they were hydrogenated with a Raney nickel catalyst, a method that has been widely used for replacing the sulphur atom of organic sulphur compounds

with hydrogen atoms [10,11]. The amines formed were isolated as picrates and compared with the picrates of the tertiary amines of reaction (4).

$$2(CH_3)_2NH + RI \rightarrow RN(CH_3)_2 + [(CH_3)_2NH_2]\ I \qquad (4)$$

R = *n*-propyl or *iso*propyl

Contrary to the picrates of (4) (*n*-propyl m.p. 109°; *iso*propyl m.p. 239°) the two picrates from the hydrogenation reactions showed no distinct melting-points indicating that they were not pure. After one recrystallization from water both melted at about 110°. The melting-points and the analyses indicate a rearrangement of the *iso*propylamine derivative into the *n*-propyl one during the hydrogenation. Further confirmation for the rearrangement was obtained from the infrared spectra of the four picrates.

No rearrangement has been observed on treating benzoyl-L(—)-cystine with Raney nickel, and benzoyl-L(+)-alanine is formed [11]. A possible explanation of the difference between the reactions lies in the character of the unshared electron pair of the nitrogen atom, which in benzoyl-cystine is strongly attrac-

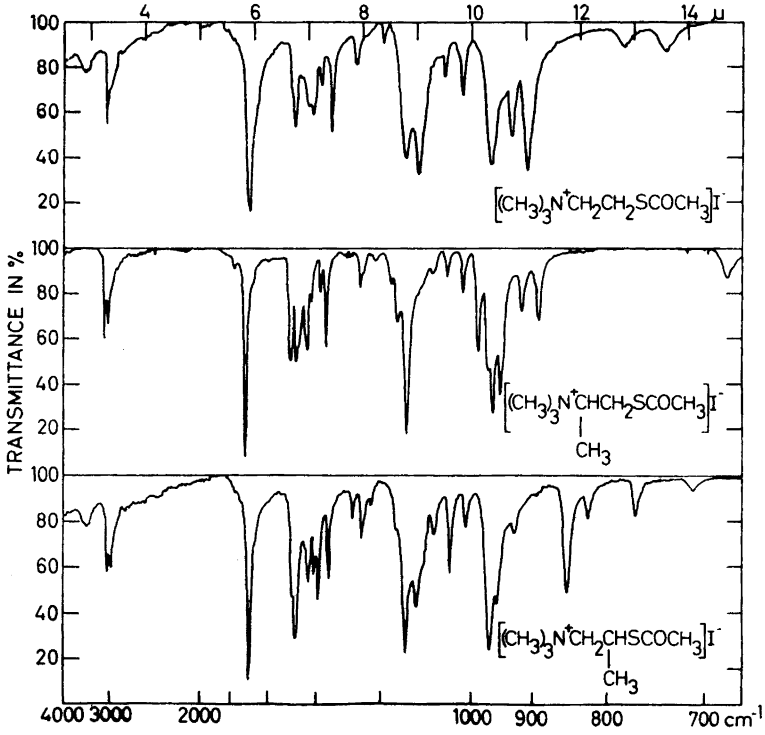


Fig. 1. Infra-red spectra of acetyl thiocholine iodide (first spectrum) and of the acetyl methyl-thiocholine iodides prepared from the dimethylamino-propanethiols derived from propylene sulphide and dimethylamine (second spectrum) and from S-(dimethylamino-propyl)-isothiuronium chloride hydrochloride.

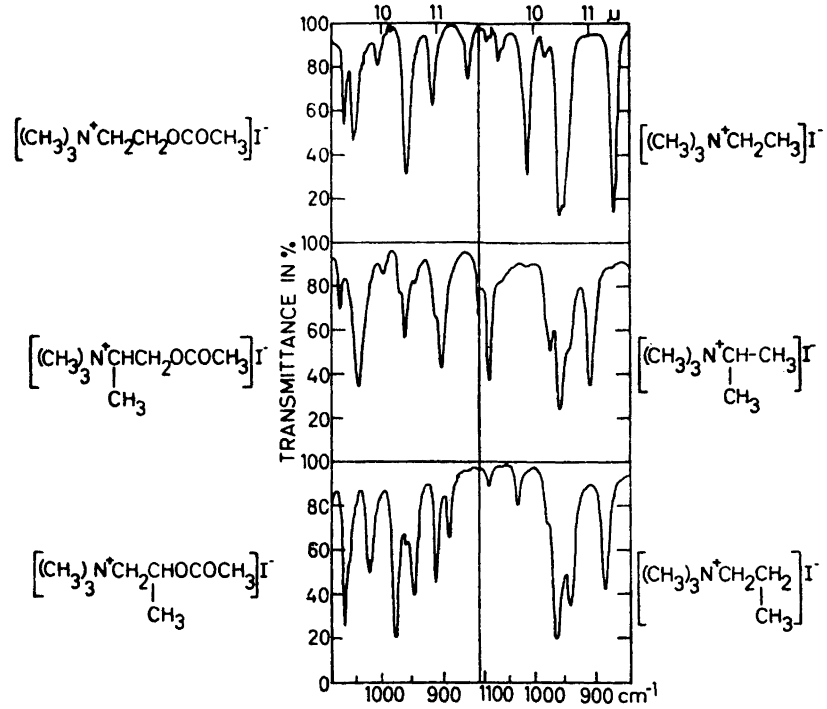

Fig. 2. Infra-red spectra of some derivatives of choline and of some tetraalkylammonium iodides.

ted by the benzoyl and the carboxylic groups and thus has a reduced ability to take part in reactions. If all the electron pairs of the nitrogen atom are occupied, as in a quaternary ammonium compound, no rearrangement would be expected. The acetyl methyl-thiocholine iodides prepared from the two dimethylamino-propanethiols [1] were therefore treated in ethanol solution with Raney nickel. The reactions were supposed to give *n*-propyl- and *iso*-propyltrimethylammonium iodide. However, when the solutions were evaporated to dryness at room temperature almost no residue was left, showing that the quaternary ammonium group must have been degraded by the Raney nickel. This behaviour was also found on treating choline iodide and acetyl choline iodide with Raney nickel. Consequently, the hydrogenation reactions could not give any information on the structures of the dimethylamino-propanethiols.

Infra-red spectra. The spectra of the acetyl methyl-thiocholine iodides derived from the two dimethylamino-propanethiols and of acetyl thiocholine iodide [2] are shown in Fig. 1. The compounds are differently substituted in the carbon chain between the nitrogen and the sulphur atoms and must therefore exhibit dissimilarities in the C—N^+ and C—S(—CO) bands. The C—S stretching bands which are expected to appear at 600—660 cm^{-1} (15—

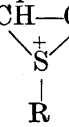
17 μ)[12] could not be recorded. As tetramethylammonium iodide has strong absorbtion in the range 900—1 000 cm^{-1} (11—10 μ) which can be ascribed to the C—N^+ bond, this range has also been recorded (Fig. 2) for some other compounds related in the same way as the thiocholine esters. In all cases the compounds with the simplest structure have the simplest spectra in this range, while the most complicated spectra are found for the compounds having an additional methyl group at the carbon atom adjacent to the nitrogen atom. This result shows that the infra-red spectra give some information about the actual structures and is a support for the formation of 2-dimethylamino-propanethiol-(1) in the addition of dimethylamine to propylene sulphide.

DISCUSSION

The only direct proof that the opening by dimethylamine of the propylene sulphide ring leads to a primary mercaptan (1) is the identification, by comparison of the melting-points, of the acetyl methyl-thiocholine bromide obtained from the reaction product with that obtained from the addition product of propylene sulphide and acetylbromide (3). This result is, however, more or less clearly supported by the other experiments, and nothing points to a rupture of the terminal C—S-bond. Only the rates of hydrolysis of the two acetyl methyl-thiocholine bromides, which have been studied by Heilbronn [13,14], seem strange. She found that the compound prepared from the product of (2) was hydrolyzed somewhat faster than V, while the reverse relationship was observed for the corresponding oxygen compounds. No explanation of the difference has been found.

It is interesting to compare the ring opening of propylene oxide and propylene sulphide. The propylene oxide ring is, in almost every reaction, destroyed at the terminal carbon atom, while the propylene sulphide ring generally ruptures at the centre carbon atom. The difference is probably due to different reaction mechanisms. The first step in the addition to propylene oxide is often a nucleophilic attack, for instance the additions of acetic acid [15], phenol [16] and methanol [17] which all are catalyzed by alkali.

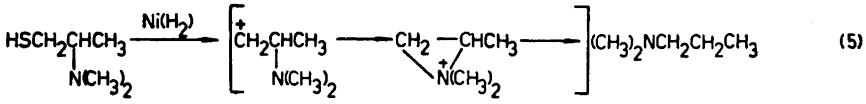
As sulphur atoms give onium compounds much more easily than oxygen atoms, it seems probable that additions to propylene sulphide involve the formation of an intermediate cyclic sulphonium ion, $CH_3CH—CH_2$,



which then opens at the centre carbon atom while capturing a negative ion. Support for this theory is obtained from ring ruptures of nitrogen compounds. Schultz and Sprague [7] found that (1-chloropropyl-(2))-dimethylamine cannot be distilled without rearrangement to (2-chloropropyl-(1))-dimethylamine. It is very likely that this rearrangement involves the formation of the cyclic quaternary ammonium ion, $CH_3CH—CH_2$, which opens at the centre carbon atom.

Another reaction showing that an *iso*propyl amino compound is less stable than a *n*-propyl amino compound is the reaction of 2-dimethylamino-propane-

thiol-(1) with Raney nickel catalyst, $Ni(H_2)$, which gives dimethyl-*n*-propylamine as described above. This reaction also throws some light on the mechanism of the removal of the sulphur atom by the Raney nickel catalyst. The



(5)

first step seems to be a rupture of the C—S-bond in such a way that the shared electron pair goes to the sulphur atom. Thus a carbonium ion is formed which can react with the unshared electron pair of the nitrogen atom, resulting in a cyclic quaternary immonium ion. This finally opens at the centre carbon atom.

The formation of a cyclic sulfonium ion intermediate in some addition reactions with propylene sulphides has also been proposed by Davies and Savige [5,18]. For the reaction between propylene sulphide and an amine they propose, however, a ring-opening at the terminal carbon atom. It is certainly difficult to find a source for the first hydrogen ions required for the intermediate sulphonium ion $CH_3CH(\overset{+}{S}H)CH_2$, but once some mercaptan has formed it can give rise to the hydrogen ions necessary.

To Professor G. Ljunggren, the Head of this Institute, I wish to express my gratitude for his kind interest in this work.

The Preparation of Thiocholine Esters

II. Esters of α- and β-Methyl-thiocholine

BERTIL HANSEN

Research Institute of National Defence, Dept. 1, Sundbyberg 4, Sweden

The paper describes the preparation of α-methyl- and β-methyl-thiocholine halide esters of the lower fatty acids and of benzoic acid. The α-methyl compounds were prepared from propylene sulphide either by addition of acid bromide and then trimethylamine or preferably by addition of dimethylamine, acid anhydride and finally methyl halide. The last two steps were also used for the synthesis of the β-methyl compounds from 1-dimethylamino-propanethiol-(2).

The preparation of thiocholine esters in two ways from ethylene sulphide has been described earlier [1]. This paper gives methods for the syntheses of α- and β-methyl-thiocholine esters, which were of interest for biochemical, physicochemical [2,3] and pharmacological comparisons with the thiocholine esters.

The 1-dimethylamino-propanethiol-(2) required for the preparation of the β-methyl-thiocholine derivatives was synthesized as described by Renshaw *et al.*[4] from 1-dimethylamino-2-chloropropane hydrochloride and thiourea. The melting-point of the intermediate *iso*thiuronium compound could not, even after several recrystallizations, be raised above 154°, and the value 201—2° found by Renshaw *et al.*[4] seems doubtful.

An attempt to prepare 2-dimethylamino-propanethiol-(1) in the same way from 2-dimethylamino-1-chloropropane hydrochloride and thiourea failed and resulted in 1-dimethylamino-propanethiol-(2)[5]. However, the 2-dimethylamino-propanethiol-(1) was easily obtained as the only product from the addition of dimethylamine to propylene sulphide in ether solution [5].

The esters of the α- and β-methyl-thiocholine halides were prepared in good yields from the thiols by esterification with acid anhydride and quaternization with methyl halide. Another method for the α-methyl-thiocholine esters was based on the addition of an acid bromide to propylene sulphide, which gave a 2-bromo-*n*-propyl-thiolo ester [6]. This was quaternized with trimethylamine.

All the α-methyl-thiocholine compounds, independent of the method of preparation, at once formed crystals, whereas some of the β-methyl-thiocholine

iodides could not be obtained in crystalline form. Thus the esters of the *iso*-butyric, *n*-butyric and *n*-valeric acids were obtained as oils of which the last-mentioned partially crystallized after one or two days. The melting-points of the aliphatic esters of the α-methyl-thiocholine were higher than those of the corresponding β-methyl-thiocholine derivatives. The compounds were found to be hygroscopic, and even a few minutes exposure to moist air produced, in some cases, enough hydrolysis to give, some time later, a smell of the acid component. Owing to the formation of iodine the iodides assumed a yellow discolouration when stored in light. The solubility of the salts decreased in water and increased in ethanol with increasing molecular weight.

The acetyl and benzoyl β-methyl-thiocholine iodides have been described by Renshaw *et al.*[4] The melting-points given by them were found to be a few degrees below those now reported.

Ivin [7] has prepared a compound which, according to him, is acetyl α-methyl-thiocholine iodide. The compound was obtained by treating propylene sulphide with acetyl iodide and then adding trimethylamine. It gave acceptable nitrogen and sulphide analyses, but its iodine content was in accordance with a wrongly calculated value (found 35.5, calc. 35.3; correctly calc. 41.9). Furthermore the melting-point 238° is much higher than that for the compound prepared in this institute, 164°. It thus seems clear that Ivin's compound cannot have been acetyl α-methyl-thiocholine iodide or that he by mistake has reported some erroneous values.

EXPERIMENTAL

Propylene sulphide. Propylene oxide and thiourea gave propylene sulphide (b.p. 74—76°; yield 58 %) when treated as described for the preparation of ethylene sulphide[1].

Esters of 2-bromo-propanethiol-(1). The esters were obtained from propylene sulphide and acid bromides in the same way as the esters of 2-bromo-ethanethiol-(1)[1]. The boiling points and yields are given in Table 1. The products were not analysed.

Table 1. Esters of 2-bromo-propanethiol-(1).

Acid	Formula	Mol.wt	B.p./mm Hg	Yield in %
Acetic	C_5H_9BrOS	197.1	72—73°/6 *	73
Propionic	$C_6H_{11}BrOS$	211.1	93—96°/9	66
n-Butyric	$C_7H_{13}BrOS$	225.1	99.5—100.5°/8	53
n-Valeric	$C_8H_{15}BrOS$	239.2	125—126.5°/10	53

* Davies and Savige [6] found 45°/0.2.

Esters of α-methyl-thiocholine bromide. The esters of 2-bromo-propanethiol-(1) were allowed to react in dry acetone (the valeric derivative in dry acetone/ligroin 1:1) with excess of trimethylamine. The precipitates were recrystallized, the acetic ester from dry ethanol/ligroin and the other ones from dry acetone/ligroin. Analyses and melting-points are given in Table 2.

Table 2. Esters of α-methyl-thiocholine bromide.

Acid	Formula	Mol. wt.	M. p.	C		H		Br		Yield in %
				calc.	found	calc.	found	calc.	found

2-Dimethylamino-propanethiol-(1). A solution of 46 g (0.63 mole) of propylene sulphide dissolved in 65 ml of dry ether was cooled to 0° and 75 ml (1.05 mole) of anhydrous dimethylamine were added. The mixture was stored at room temperature for two days and then distilled through a 25 cm Widmer column, the excess of dimethylamine and the ether being removed at ordinary pressure and the 2-dimethylamino-propanethiol-(1) being distilled under reduced pressure. Yield 51.5 g (69 %) at 71°/88 mm; $n_D^{25} = 1.4538$; $d^{25} = 0.8693$ g/cm³. (Found: C 50.4; H 10.8. Calc. for $C_5H_{13}NS$ (119.2): C 50.4; H 11.0.)

1-Dimethylamino-2-chloropropane hydrochloride was prepared from thionyl chloride and 1-dimethylamino-propanol-(2), obtained by adding dimethylamine to propylene oxide. M. p. 185°. Schultz and Sprague [8] observed 185—186°.

S-(1-Dimethylaminopropyl-(2))-isothiuronium chloride hydrochloride. One mole of 1-dimethylamino-2-chloropropane hydrochloride and 1.02 mole of thiourea in 600 ml of absolute ethanol were refluxed for 65 h. The solution was cooled to room temperature and ethyl acetate then added in small portions until the first permanent opalescence was obtained. The vessel was scratched with a glass rod and two days later crystals had formed. They were removed by suction, washed with absolute ethanol/ethyl acetate (1:1) and dried in air. Yield 122 g (52 %). After being recrystallized from *n*-propanol and dried at 75° the compound melted at 154°. (Found: C 30.4; H 7.3. Calc. for $C_6H_{17}Cl_2N_3S$ (234.2): C 30.8; H 7.3.)

By performing the reaction in *n*-propanol Renshaw *et al.*[4] obtained the *iso*thiuronium compound in 92 % yield. Their method was tried without success, nor could their melting-point, 201—202°, be reproduced.

1-Dimethylamino-propanethiol-(2). One mole of the *iso*thiuronium compound was dissolved in 280 ml of water. The solution was covered with ether in an extraction apparatus. With cooling, a solution of 2.0 moles of sodium hydroxide in 80 ml of water was added in portions. The reaction mixture was continously extracted with ether until there was no further change in the volume of the water phase. The ether solution was dried with calcium chloride and distilled through a 25 cm Vidmer column, the ether at ordinary and the thiol under reduced pressure. Yield 64 %; b. p. 78.5°/70 mm; $n_D^{25} = 1.4684$; $d^{20} = 0.9046$ g/cm³.

Esterification of the dimethylamino-propanethiols. The reactions between the thiols and the acid anhydrides were carried out as described for 2-dimethylamino-ethanethiol [1]. The boiling ranges are given in Table 3.

Table 3. B.p./mm Hg of esters of x-dimethylamino-propanethiol-(y).

Esters of methyl-thiocholine iodides and bromides. The esters of the dimethylaminopropanethiols were quaternized with methyl bromide or iodide according to the method used earlier[1]. Of the α-methyl esters the acetic, butyric and benzoic compounds were recrystallized from dry acetone/ligroin (2:1). The acetyl β-methyl-thiocholine bromide was recrystallized from dry acetone/absolute ethanol (3:1) and the benzoic ester from water. Table 4 contains the melting-points, analyses and yields of the compounds.

All melting-points have been determined with a »Kofler Hot Bench».

My thanks are due to the Head of this Institute, Professor G. Ljunggren, for his interest in this work.

Composition of Products Formed by Thermal Neutron Fission of ^{235}U

III. Isotopic Composition and Atomic Weight of the Fission Product Elements

JAN PRAWITZ

Research Institute of National Defence, Dept. 1, Sundbyberg 4, and Institute of Inorganic and Physical Chemistry, University of Stockholm, Sweden

The isotopic composition and atomic weight of the fission product elements have been calculated for seven different irradiation times between one day and two years, two cooling times, 100 and 3 000 days, and three thermal neutron fluxes 10^{12}, 10^{13} and 10^{14} n cm^{-2} sec^{-1}. Some applications of the difference in composition between the natural and fission product elements are discussed.

Since more accurate nuclear data of the fission products are available, many calculations of their properties have appeared in the literature [1–12]. Most of these works only consider the radioactive isotopes. Calculations on the stable isotopes and their poisoning effect in thermal reactors have been performed by Blomeke and Todd [9], Robb *et al.*[7], Lock [3], and Walker [8]. Part II[12] of this series considers the fission products, both radioactive and stable, from a chemical point of view. Atomic weights of artificially produced elements in the transmercury region are discussed by Glass *et al.*[16]

At the moment of "shut down" of a reactor the fission fragments are highly radioactive, but after moderate cooling times the major part of them has become stable. After 100 days 80 % and after 10 years 90 % of the nuclei are stable or have half-lives longer than 10^{10} years. The fission product elements have other isotopic compositions and therefore also differing atomic weights than the natural elements. These two properties are functions of the irradiation and cooling time. Except for the effect of neutron absorption by the fission products themselves the isotopic composition is independent of the thermal neutron flux.

Presentation. In this paper the isotopic abundances in atomic per cent and the atomic weights have been calculated for all fission product elements for seven irradiation times, (1 and 7 days, 1, 2 and 6 months, 1 and 2 years) and two cooling times, 100 days, a practical moment for fuel reprocessing, and 3 000

Table 1. Isotopic composition of the fission product elements in atomic per cent for seven different irradiation times and two different cooling times. Thermal neutron flux $\leq 10^{14}$ n cm^{-2} sec^{-1}. In those cases where the neutron flux influences the results, values are given for three fluxes, 10^{12}, 10^{13}, and 10^{14} n cm^{-2} sec^{-1}, equal flux for values on the same line. If the compositions after 3 000 days cooling time are not independent of the irradiation time, values are given for two irradiation times: 7 days and depending on the neutron fluxes (10^{12}, 10^{13}, or 10^{14} n cm^{-2} sec^{-1}) 2 years, 6 months, or 1 month. Isotopic abundances of the natural elements are also given. In the half life column y stands for years, d for days, and h for hours.

*** Values on this line are calculated for a thermal neutron flux of 10^{14} n cm^{-2} sec^{-1}.

days, a moment when the isotopic composition in most cases has become stabilized and independent of the irradiation times considered (See Part II[12], Fig. 8). In those cases where the thermal neutron flux influences the result three fluxes, 10^{12}, 10^{13} and 10^{14} n cm^{-2} sec^{-1}, have been considered. For the two higher fluxes the calculation has been limited to irradiation times up to 6 and 1 month, respectively, because the burn up makes longer times impractical.

The isotopic compositions are summarized in Table 1 together with the natural isotopic abundances taken from Strominger *et al.*[13]. If no value is given for an isotope after a time, the value is either very small or the isotope does not belong to the fission products. The calculated atomic weights are given in Table 2 together with the atomic weights (1955) of the natural elements. The atomic weights are independent of the irradiation time except for seven elements, which are to be found in Table 3.

For a few elements with highly neutron absorbing isotopes, the compositions are also after 3 000 days cooling time strongly dependent on the irradiation time. In these cases two values are given for 7 days, and depending on neutron flux, 2 years, 6 months, or 1 month.

Method of calculation. The number of atoms of the fission product isotopes were calculated for the different irradiation and cooling times and neutron fluxes mentioned above with the modified Rubinson [14] formulae given in Part II[12]. The calculations assume constant thermal neutron flux, constant fission rate, and no fission product removal during irradiation. The required data of fission yields, half-lives, and neutron absorption cross sections are taken from Part I[15]* of this series except for a few more recent data. The isotopic abundances within the elements are then easily computed. By multiplying the abundances of the isotopes of an element with their atomic masses, adding the results, and dividing by 1.000275 the atomic weight on the chemical scale of the element is obtained. Nuclide masses are taken from Wapstra and Duckworth [17]. For five isotopes, where no data are available, the integral mass numbers are used. This uncertainty is negligible because the difference between the integral mass numbers and the corresponding measured nuclide masses in the fission product region is <0.1 %, and the abundances of these elements are low. For some elements, monoisotopic both in Nature and as fission products, the atomic weights adopted for the natural elements have been used.

Errors. The accuracy of the results depends directly on the accuracy of the parameters used. In this work fission yields and cross sections give the largest contributions to the errors, while half-lives and nuclide masses have little influence. The best values of the abundances have a standard deviation of 1 %, while others may have 20 %. However, most values have a standard deviation better than 10 %. Such a deviation will in general only cause a minor deviation in the atomic weights, but is larger than the difference between the physical and the chemical scale, except in the case of elements consisting of mainly one isotope, where the small errors of the nuclide masses dominate.

* This compilation is in good agreement with that of Katcoff [18], but uses a fission yield of 6.32 % for ^{140}Ba as a standard value instead of Katcoff's 6.44 %. However, the choice of standard value has no or little effect on calculated isotopic compositions.

DISCUSSION

The main difference in isotopic composition between the natural and the fission product elements is the lack of light stable isotopes for most of the fission product elements. The reason for this is that such a light isotope is shielded from build-up from beta-decaying radioactive fission products by a stable isobar with lower atomic number. These fission product elements, therefore, have higher atomic weights than the natural ones. Furthermore, long-lived radioactive isotopes not occurring in Nature due to too short half-lives cause considerable differences in the atomic weights. The elements Tc and Pm with no stable isotopes are included among the fission products. Zn and Ga are not considered here, because only short-lived isotopes of these elements belong to the fission products. The reported results for the element Dy may be of limited value, because the isotope ^{162}Dy not yet reported as a fission product, may be formed in quantities as large as 10 % of ^{161}Dy.

Some fission product elements differ from those in Nature by consisting of one isotope only. These isotopes are ^{81}Br, ^{99}Tc, ^{109}Ag, ^{115}In, and ^{139}La. Other pure isotopes may be produced by chemical separation at a moment when they, or their radioactive precursors, make up 100 % of a chemical element, or else by many consecutive separations at special moments. Such procedures will be investigated in a later work.

About 25 % of the fissions result in stable Xe-isotopes. If the known world reserve of uranium in ores (25 Mton [20]), *i. e.* both ^{235}U and ^{238}U, was burnt up

Table 2. Atomic weights of the fission product elements after an irradiation time $\leq$ 2 years. Cooling time 100 and 3 000 days. Thermal neutron flux $\leq 10^{14}$ *n* cm^{-2} sec^{-1}. Atomic weights of natural elements (1955) are included.

§ The Cd and Xe values also hold for cooling times >100 days, but they depend upon the the thermal neutron flux.
* Values on this line are calculated for a neutron flux of 10^{12} n cm^{-2} sec^{-1}.
** Values on this line are calculated for a neutron flux of 10^{13} n cm^{-2} sec^{-1}.
*** Values on this line are calculated for a neutron flux of 10^{14} n cm^{-2} sec^{-1}.

and the Xe produced was distributed in the atmosphere, the natural atomic weight of Xe would not be notably changed. However, if the uranium in the oceans (2 100 Mton) was burnt up, the atomic weight of Xe would change from 131.3 to 131.5. As Xe belongs to the rare elements in Nature the above result indicates that fission products evenly distributed among the natural elements will not cause a change of the atomic weights. However, concentrated deposits may cause local variations.

If ^{12}C instead of natural O is used as standard value for the atomic weights, this will change the values for six fission product elements only (Br, Nb, Tc, Ag, In, and Pm).

Applications. Since the first self-sustaining nuclear reactor was realized in the Chicago Pile-1 on December 2, 1942 [19], large amounts of fission products have been accumulated. Their isotopic composition differs from the natural elements which means different and sometimes useful nuclear properties. Isotope dilution, activation, and nuclear magnetic resonance analysis methods are favoured, when the desired isotope is present in high concentration and especially when undesired isotopes are not present at all. Mo with high neutron absorption cross section and Pd with low may be useful in nuclear energy facilities. Another useful construction metal is Zr, and as a fission product (yield 35 %) it is completely free from Hf but slightly radioactive due to the isotope ^{93}Zr with 950 000 years half-life. The cross section of fission product Cd generated during 7 days irradiation at a neutron flux of 10^{13} n cm^{-2} sec^{-1} is

4 700 barns, while natural Cd has 2 550 barns. The fission product Ag, consists of 100 % ^{109}Ag, whereas in Nature only 49 % ^{109}Ag, may be useful for the production of 253 days ^{110}Ag. A detailed penetration of Table 1 would certainly show further applications similar to the examples above. Some other utilizations have been pointed out by Glueckauf [21].

Acknowledgements. The author wishes to thank Prof. G. Ljunggren for his large interest in and support of these calculations, Prof. A. Ölander, Doc. J. Rydberg, Doc. D. Dyrssen, Tekn.lic. L. W. Holm, Fil.mag. Brita Bernström, Ass. S. Andersson, and Fil.kand. B. Collén for valuable discussions in the planning of this work and for criticism of the manuscript. The author also wishes to thank Mr. C. Roering for correcting the English text.

Synthesis of 4-Antipyryl Alkamine Ethers *

JAAKKO HUKKI and JORMA MYRY

Lääketehdas Orion Oy, Helsinki, Finland

A number of basic ethers have been prepared by the reaction of 4-hydroxyantipyrine with alkamine halides commonly used for the production of antihistamines.

Only a few ethers of 4-hydroxyantipyrine are reported in the literature. Of these, two alkyl ethers (a methyl and an ethyl ether) are described by Knorr and Pschorr [1]. The rest are nitrophenyl and substituted nitrophenyl ethers prepared by Kaufmann *et al.*[2] In all these cases, the method of etherification was the same. 4-Hydroxyantipyrine was allowed to react with the requisite alkyl or nitrophenyl halide in the presence of sodium methoxide or ethoxide.

In the hope of obtaining compounds with a simultaneous antipyretic and antihistaminic effect, some alkamine ethers of 4-hydroxyantipyrine were prepared for pharmacologic evaluation. The present paper is concerned with the synthesis of these compounds.

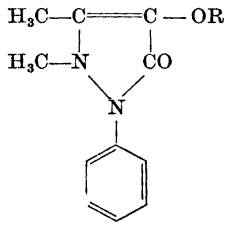
An attempt to use 4-bromoantipyrine for the etherification failed, obviously owing to the poor reactivity of the "aromatically" substituted bromine atom. After reflux with dimethylaminoethanol or its sodium compound in dry toluene for 24 h, the 4-bromoantipyrine was recovered unchanged.

The method used by Knorr and Pschorr [1], with 4-hydroxyantipyrine as starting material, although successfully employed by us for the preparation of 4-antipyryl benzyl ether, did not work with alkamine halides. In spite of the markedly phenolic character of the 4-hydroxyantipyrine, the formation of N,N,N′,N′-tetra-alkylpiperazinium dihalides quite outbalanced the etherification reaction. An attempt to carry out the condensation of 4-hydroxyantipyrine with an alkamine halide in the presence of pyridine was also unsuccessful. In this case, an alkamine pyridinium halide hydrohalide was formed, as observed already by Kratzl and Berger [3] when studying the corresponding condensation with 4-aminoantipyrine.

The etherification could be effected satisfactorily, if the sodium compound of 4-hydroxyantipyrine was prepared by means of sodium amide in dry toluene and the condensation carried out under anhydrous conditions (method A).

* New features disclosed in this paper are covered by a pending Finnish patent application.

Table 1. Alkamine ethers of 4-hydroxyantipyrine



R	Free amine	Mono-oxalate								
		Formula	Yield[e] %	M.P. °C	Analyses

[a] From petroleum ether. [b] From this compound a dihydrochloride, m.p. 180° (from ethanol), was also obtained. [c] From ethanol. [d] From acetone-methanol. [e] Calculated on the basis of 4-hydroxyantipyrine.

It turned out, however, that the best results in regard to both the yield and purity of the products could be obtained simply by refluxing 4-hydroxyantipyrine with the appropriate alkamine halide hydrohalide in dry acetone in the presence of anhydrous potassium carbonate (method B).

The ethers obtained were viscous liquids or low-melting solids, which were difficult to purify. For analysis they were converted into their mono-oxalates. Some data relating to these new compounds, all prepared according to method B, are presented in Table 1.

For further characterization, ultraviolet absorption spectra of the ethers were determined. These are represented in Fig. 1. For comparison, the corresponding spectra of 4-hydroxy-, -ethoxy- and -benzyloxyantipyrine are included.

One of the ethers, 4-antipyryl 2-dimethylaminoethyl ether, was allowed to react with methyl iodide at room temperature to give the corresponding quaternary ammonium salt. It has been shown by Knorr [4] that at 60° antipyrine also reacts with methyl iodide to form 1-phenyl-2,3-dimethyl-5-methoxypyrazolium-2 iodide. In order to decide, which of these two courses the reaction had taken, a test was made with antipyrine for comparison. It turned out that under the same reaction conditions, no iodide formation was observed

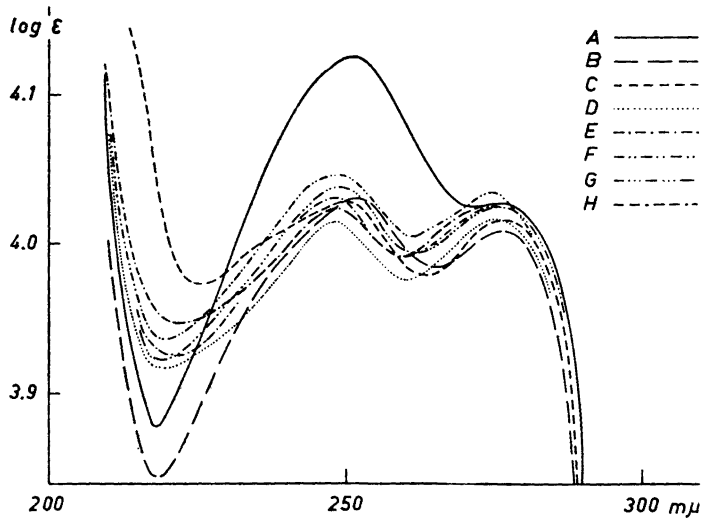

Fig. 1. Ultraviolet absorption spectra of 4-hydroxyantipyrine (A) and the following of its ethers: ethyl (B), benzyl (C), 2-dimethylaminoethyl (D), 2-diethylaminoethyl (E), 3-dimethylaminopropyl (F), 2-dimethylamino*iso*propyl (G) and 2-(N-piperidino)ethyl (H).

between antipyrine and methyl iodide after 3 days at room temperature, while from 4-antipyryl 2- dimethylaminoethyl ether an almost quantitative yield of the salt was obtained within one day. Accordingly, the salt in question must be β-(4-antipyryloxy)ethyltrimethylammonium iodide.

EXPERIMENTAL

All melting points were determined on a Kofler hot stage and are corrected. The microanalyses were performed by the Microanalytisches Laboratorium im Max-Planck-Institut, Mülheim (Ruhr), Germany. The ultraviolet data, from the Analytical Laboratory of Lääketehdas Orion Oy, are for solutions in ethanol (concentration 0.010—0.025 g per liter).

4-Hydroxyantipyrine. This was prepared from 4-dimethylaminoantipyrine (pyramidon) by the general route devised by Bockmühl [5]. Because no detailed information is to be found in the literature, a description of the procedure used by us is given:

Pyramidon (0.5 mole) was dissolved in a mixture of 200 ml of conc. hydrochloric acid (37.8 %) and 85 ml of water. This solution was added dropwise and with continuous agitation to a solution of sodium nitrite (2.0 mole) in 250 ml of water, while the temperature was kept below 0°. After the addition, the mixture was allowed to stand in the refrigerator overnight to complete the crystallization of the resultant intermediate, 1-diketobutyryl-1-phenyl-2-methyl-2-nitrosohydrazide monohydrate. This was filtered off, washed with 200 ml of cold water and then added to a solution of 130 g of sodium bisulfite in 700 ml of water. The mixture was allowed to stand at room temperature overnight. The crystallized 4-hydroxyantipyrine was filtered, washed with water and dried. The yield was 92 %, m. p. 182°.

4-Antipyryl alkamine ethers. Method A: 4-Hydroxyantipyrine (0.1 mole) and sodium amide (0.1 mole) in 300 ml of anhydrous toluene were heated and stirred for 4 h at 80°, all moisture being excluded. To this mixture a carefully dried solution of the appropriate

alkamine chloride (0.12 mole) in toluene was added. The mixture was heated at 80° for 25 h. The residue, after evaporation of the solvent *in vacuo*, was dissolved in chloroform, washed with dilute sodium hydroxide and water and dried over anhydrous sodium sulfate. After evaporation of the solvent, the ether remained as a viscous liquid. This was dissolved in ethanol, oxalic acid was added and the resulting oxalate was precipitated from the solution with ethyl ether.

Method B: A mixture of 4-hydroxyantipyrine (0.1 mole), an alkamine chloride hydrochloride (0.1 mole) and freshly ignited, fine-ground potassium carbonate (0.3 mole) was added to 350 ml of dry acetone. The mixture was refluxed for 2 days with continuous agitation. After cooling, the anorganic salts were filtered off. The filtrate was evaporated *in vacuo*, after which the remainder was worked up as in A.

4-Benzyloxyantipyrine. To a solution of 0.01 mole of sodium ethoxide in ethanol 0.01 mole of benzyl chloride and 0.01 mole of 4-hydroxyantipyrine were added. The mixture was refluxed for 4 h, after which it was evaporated to dryness and the remainder worked up as in the case of alkamine ethers. The yield was 79 %, m. p. 71—72° (from a mixture of petroleum ether and acetone). With method B, a yield of 72 % was obtained. (Found: C 73.63; H 6.29; N 9.71. Calc. for $C_{18}H_{18}N_2O_2$: C 73.45; H 6.16; N 9.71.)

4-Ethoxyantipyrine. To a solution of 0.25 mole of 4-hydroxyantipyrine in an equivalent amount of 0.1 N aqueous sodium hydroxide, 0.25 mole of diethyl sulfate was added gradually with shaking. After half an hour's heating at 60—70°, the mixture was extracted with chloroform and the chloroform solution worked up as in method A. The yield was 65 %, m. p. 53—54° (from a mixture of petroleum ether and acetone)(lit[1]. m. p. 60).

β-(4-Antipyryloxy)ethyltrimethylammonium iodide. To a solution of 2.75 g (0.01 mole) of 4-antipyryl 2-dimethylaminoethyl ether in 30 ml of absolute ether was added 1.42 g (0.01 mole) of methyl iodide. After one day standing at room temperature, the crystals formed were filtered off, washed with 10 ml of absolute ether and dried. The theoretical yield was obtained, m. p. 187°. After recrystallization from a mixture of acetone and methanol the salt was analyzed. (Found: C 45.90; H 5.73; N 10.12; I 30.38. Calc. for $C_{16}H_{24}O_2N_3I$: C 46.05; H 5.80; N 10.07; I 30.42.)

Ozonolysis of *p*-Benzoquinone II

ERLING BERNATEK and KNUT ASBJØRN STRAUMSGÅRD

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

The ozonolysis of *p*-benzoquinone in chloroform at 3—4° has been studied. By decomposition of the ozonized solution with water the following compounds were formed: Formic acid, glyoxylic acid, oxalic acid, maleic acid, mesoxalic dialdehyde, formaldehyde and carbon dioxide. A quantitative study of these compounds has been undertaken, and possible mechanisms for their formation are presented.

In a preliminary communication [1] (Part I of this series) one of the present authors discussed some aspects of the ozonolysis of *p*-benzoquinone in chloroform. The main result was the tentative establishment of the unsaturated aldehyde CHOCOCH=CHCOCHO as a decomposition product. An earlier investigation by Fichter, Jetzer and Leepin [2] had led to the identification of formic acid among the products of this ozonolysis.

It soon became clear that the ozonolysis of *p*-benzoquinone was a rather complex affair and that the reaction products might be numerous. We have therefore performed a more detailed investigation of the products which occurred when the ozonolysis was carried out under certain specified conditions. It is appropriate to remark at this point that the qualitative and quantitative composition of the reaction mixture seems to be highly susceptible to even minor alterations in reaction conditions. We have thus in the present investigation not isolated any unsaturated aldehyde although the conditions of ozonolysis were not very different from those of the earlier investigation.

During the ozonization an ozonide separated as described before [1,2], but no attempts were made to characterize this unstable and highly hydrolysable substance. If kept in air at room temperature for instance, it soon became a dark syrup in which after some time long needles of oxalic acid appeared.

The ozonized mixture was decomposed by shaking with cold water when the ozonide quickly went into solution and the active oxygen disappeared. The aqueous extract had a strong acidic reaction but contained only traces of hydrochloric acid (which have resulted from decomposition of the chloroform). In order to identify and determine the amount of volatile acids the aqueous solution was distilled at room temperature by passing nitrogen through it at low pressure and collecting the distillate in aqueous sodium hydroxide.

Only formic acid could be found. A neutral substance in the decomposition solution was isolated by removing the acidic products in a column of a weakly basic ion-exchange resin. In the neutral eluate there was a substance which instantly reduced Tollens' reagent and which through its *p*-nitrophenylhydrazone was identified as mesoxalic dialdehyde. As it was found that the reaction mixture also contained non-volatile acid substances, the ion-exchange column after removing quantitatively the mesoxalic dialdehyde with water, was treated with 5 % aqueous formic acid. The eluate contained a carbonyl compound which reacted with 2,4-dinitrophenylhydrazine to give a derivative in the form of yellow needles. The melting point of this product (190° decomp.) was not changed after recrystallization so it may be concluded that only one carbonyl compound had been eluted with the dilute formic acid, *viz.*, glyoxylic acid. Elution of the ion-exchange column with 2 N hydrochloric acid afforded finally oxalic and maleic acids. These two acids were, however, more easily isolated directly from the decomposition solution.

Beside the two aldehydes, mesoxalic dialdehyde and glyoxylic acid, a third aldehyde was found but only in very small amounts. The derivative with dimedone and the colour with chromotropic acid proved that this third aldehyde was formaldehyde. It could be shown that this compound did not result from decomposition of the solvent or of impurities.

During the decomposition of the ozonized solution with water an evolution of carbon dioxide could be noticed. The aqueous extract gave only a very faint reaction on hydrogen peroxide.

In order to get a better picture of the fate of benzoquinone during ozonolysis and the mode of formation of the fragments, it was necessary to undertake a quantitative determination of the products. Some of the analytical methods available were not very accurate but it is felt that a fairly good estimate of the relative amounts in which the above-mentioned degradation products occurred has been secured.

Formic acid was determined as mentioned before by distillation into aqueous sodium hydroxide at low temperature and pressure.

Mesoxalic dialdehyde was determined by evaporation of the eluate from the ion-exchange column and weighing the residue. This is clearly a minimum value as there always is a certain loss of substance in the column. Furthermore the aldehyde is somewhat volatile with water vapour and in addition to this only that part of the eluate which contained appreciable amounts of the aldehyde was evaporated. To concentrate the total volume of the neutral eluate would have been almost a practical impossibility.

Glyoxylic acid could be precipitated as the dinitrophenylhydrazone but the precipitation was far from quantitative. To avoid this source of error and to avoid the loss in the column glyoxalic acid was determined by difference. The decomposition solution was in this case evaporated directly in a vacuum desiccator over potassium hydroxide to constant weight. From this value were subtracted the amounts of the non-volatile products mesoxalic dialdehyde, oxalic acid and maleic acid. The amount found in this way must be a maximum value since contaminations and eventual minor amounts of unidentified substances are included and — which is important — because the mesoxalic dialdehyde is represented by a minimum value.

Oxalic acid was precipitated in accordance with the usual analytical method as the calcium salt.

Maleic acid was determined in the filtrate from the oxalate determination by precipitation as the barium salt. This salt has the drawback to be somewhat soluble in water so the filtrate had to be measured and the amount of dissolved barium maleate calculated. An alternative method of analysis was to oxidize the concentrated decomposition solution

with hydrogen peroxide. Maleic acid is much slower oxidized by this reagent than the other compounds present. The residue after evaporating the oxidation mixture consists of pure maleic acid. Some loss is inevitable in this last procedure but the two methods give results of the same order of magnitude.

Several methods were tried for the determination of carbon dioxide. Absorption in barium hydroxide followed by a rapid filtration of the precipitated barium carbonate was chosen.

In Table 1 the analytical results are given in relation to one mole of benzoquinone and in addition the percentages of recovered carbon are calculated.

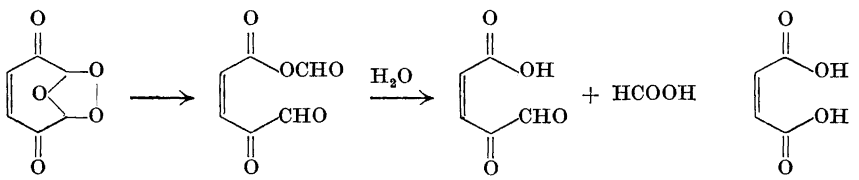
Table 1.

Product	Mole/mole benzoquinone	Recovered carbon, %
Formic acid	1.65	27.3
Mesoxalic dialdehyde	0.13	7.7
Glyoxylic acid	1.16	39.0
Oxalic acid	0.03	1.4
Maleic acid	0.06	4.5
Carbon dioxide	0.16	2.7

It will be seen that account can be made for about 83 % of the carbon in the starting material. The deficiency of about 17 % may in part be explained by imperfection of our analytical methods, but it is also highly probable that some of the benzoquinone is oxidized directly to water and carbon dioxide during the ozonization. As ozone is not absorbed quantitatively by benzoquinone some of it escapes with the effluent oxygen and interferes with attempts to determine directly formed carbon dioxide. In addition to this comes a small amount of material still contained in the chloroform layer after extraction with water. Per gram of benzoquinone this amounts to about 20 mg.

The maleic acid can only be derived from a monozonide of benzoquinone. In the diozonide of course both carbon-carbon double bonds are broken and no maleic acid can result. During ozonolysis there was always passed through the solution ozone in excess of that calculated for reaction with both double bonds but nevertheless some monozonide must have existed. This is evidently due to the already mentioned incomplete absorbtion of ozone by benzoquinone and to the fact that some ozone is decomposed by the solvent before it can react with the quinone.

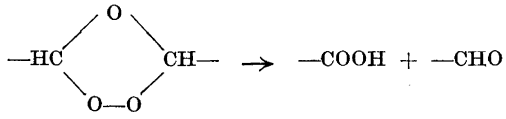
The monozonide of benzoquinone may be a normal ozonide like I.



I II III IV

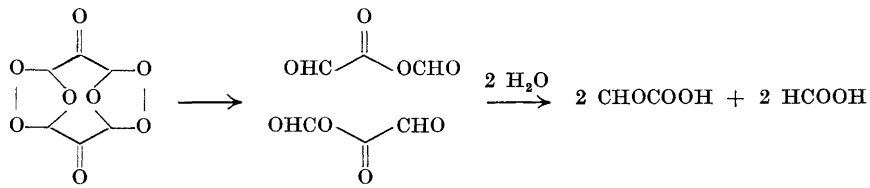
It is well known that normal ozonides like other peroxy compounds may undergo rearrangements, which in our case would lead from I to II. Another possibility is that benzoquinone *via* anomalous ozonolysis more directly is converted to II. The latter structure will be recognized as a mixed anhydride between formic acid and the unsaturated ketoaldehydic acid III. By treatment with water these two acids will be set free. Transformation of III into maleic acid (IV) obviously involves an oxidation. This may be effected by ozonide still present or, since maleic acid is formed only in minor amounts, by those small quantities of hydrogen peroxide present in the decomposition solution or maybe already during the ozonization. The aldehyde group is most probably oxidized to formic acid, less likely it seems to carbon dioxide and water. This last statement is in part based upon the fact that Dallwigk and Briner [3] who investigated the ozonolysis of cinnamaldehyde found that the glyoxylic acid which was formed by treatment of the ozonide with water was further oxidized to formic acid and carbon dioxide by undecomposed ozonide.

When discussing the formation of the other products several reaction paths must be taken into consideration, the most conspicious of which are the two already mentioned, *viz.*, formation of the normal ozonide with subsequent rearrangement and anomalous ozonolysis. Further may be mentioned direct hydrolytic cleavage of the ozonide and the so-called "acid-rearrangement" which is well known to occur among aldozonides and which may be represented as follows:



Still more numerous are of course the combinations of these reactions which may be possible with a diozonide. To postulate such combinations will, however, be rather speculative and therefore left out of serious consideration.

The main products, formic acid and glyoxylic acid, which are formed in rather overwhelming molar quantities as compared with the other products are most probably formed by symmetrical * double rearrangement of the normal diozonide or by symmetrical anomalous ozonolysis:

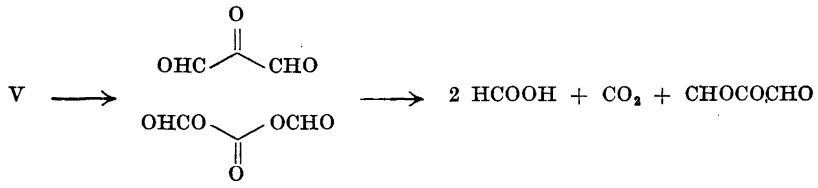


V VI

* Symmetrical in the sense that the two migrating oxygen atoms become adjacent to different carbonyl groups. In the same sense unsymmetrical rearrangement means that the two oxygens become adjacent to the same carbonyl group.

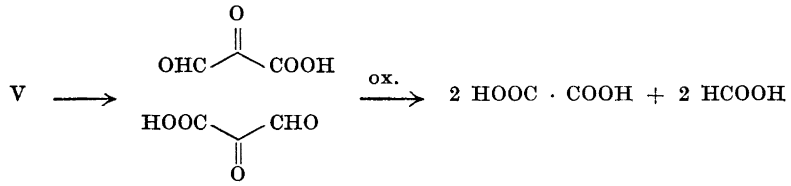
It is difficult to discern between the two mentioned possibilities, but it may be concluded that at least a part of the reaction goes *via* the normal diozonide as the peroxidic substance which separated during ozonization could be kept for some time at 0° without decomposition. At room temperature, however, it dissolved in the chloroform after a short time. Simultaneously carbon monoxide began to evolve which can be taken as an indication of the actual existence of structures like VI. Mixed anhydrides of formic acid are known to decompose with the evolution of carbon monoxide under anhydrous conditions. If 0.58 mole of benzoquinone undergoes the above degradation there will be produced the 1.16 moles of glyoxylic acid actually found and 1.16 moles of formic acid.

Carbon dioxide and mesoxalic dialdehyde are formed in roughly equimolecular amounts (especially if we take into account that the found amount of mesoxalic dialdehyde is a minimum value) and very likely through an unsymmetrical double rearrangement of the normal ozonide or by unsymmetrical anomalous ozonolysis:



Assuming that 0.16 moles of benzoquinone reacts in this way the products will be 0.16 moles of carbon dioxide, 0.16 moles of mesoxalic dialdehyde and 0.32 moles of formic acid.

Oxalic acid contains carbon in a higher oxidation state than the other products (except carbon dioxide) and its formation is difficult to explain without further oxidation of the decomposition products. A possible mechanism is the symmetrical double acid-rearrangement of the normal diozonide:



Oxidation of the primarily formed mesoxalic monoaldehyde probably takes place during the ozonization. If the rearrangement starts at an early stage of the reaction, ozone and small amounts of water formed by complete breakdown of benzoquinone may easily convert the ketoaldehydic acid to oxalic acid and formic acid. 0.015 moles of benzoquinone reacting as described give 0.03 moles of oxalic acid and 0.03 moles of formic acid.

When adding together the mentioned molar amounts of formic acid and remembering that 0.06 moles of maleic acid are accompanied by 0.12 moles

of formic acid we get the total of 1.63 moles of formic acid. This figure corresponds very well with the found amount of 1.65 moles and therefore lends support to the soundness of the presented paths of reaction. Addition of the consumed molar amounts of benzoquinone gives 0.82 moles. (Compare *ca.* 83 % recovered carbon).

The problem of formaldehyde formation has not been discussed yet, mainly because the amount of this aldehyde is so small that it does not affect the overall picture of degradation. If we regard the molecular formulae for benzoquinone and formaldehyde $C_6H_4O_2$ and CH_2O, it will be noticed that carbon in both compounds has the formal oxidation stage zero. That means that the particular carbon atom in the benzoquinone skeleton going to form formaldehyde must be severed retaining the mean formal oxidation stage. Obviously this can only be attained by hydrolytic cleavage of at least one carbon-carbon bond, for instance in the following way:

$$HOH + —CO—CHO \longrightarrow —COOH + HCHO$$

The fragment to be hydrolysed must be a rearrangement product from one of the ozonides.

EXPERIMENTAL

Ozonization procedure. The source of ozone was an apparatus built in this institute and consisted of ten Berthelot tubes; voltage 11 000 V. Through the apparatus was led a stream of dry tank oxygen at the rate of 30 l/h. At this rate of flow a yield close to 2 g O_3/h was obtained which corresponds to an ozone concentration of *ca.* 4.8 % (weight).

A good commercial grade of chloroform was used as a solvent. This was dried with calcium chloride and distilled with rejection of rather large head and tail fractions. The *p*-benzoquinone was a recrystallized Eastman-Kodak product.

As reaction vessel a gas washing bottle with fritted bottom for the distribution of gas was employed. During ozonization the bottle was placed in an ice-bath. The ozonization mixture (usually 5 g of quinone in 150 ml of chloroform or 1 g of quinone in 50 ml of chloroform) would then during the reaction attain a temperature of 3 to 4°. The end point of the reaction could not be determined by the sudden appearance of unreacted ozone (as ozone was passing through the solution already from the outset) but could be judged with fair accuracy from the disappearance of the yellow quinone colour. At this point an ozonide had separated at the walls of the vessel as a white sticky mass, the solution being light greenish. If this mixture was kept at room temperature the separated ozonide went into solution. Strips of filter paper moistened with a palladium chloride solution, which were suspended in the reaction vessel above the liquid, blackened in a short time.

The reaction mixture was decomposed by shaking with ice-cold water and the chloroform layer was extracted a few more times with additional amounts of water. The ozonide went quickly into solution and the chloroform thereafter gave no reaction on active oxygen. On the other hand the aqueous solution (hereafter referred to as "decomposition solution") gave a faint reaction on hydrogen peroxide with titanium reagent. If the extracted chloroform was dried with sodium sulphate and evaporated to dryness there remained a solid brownish residue amounting to about 20 mg/g benzoquinone. The nature of this residue has so far not been investigated.

Formic acid. Some of the decomposition solution was distilled and the distillate exactly neutralized with aqueous sodium hydroxide. To this was added a hot concentrated solution of S-benzylthiouronium chloride. The mixture was immediately cooled and inoculated with a small crystal of S-benzylthiouronium formate. In a few hours white crystals had separated which had m. p. 146°. Mixed m. p. with an authentic sample showed no depression.

For the quantitative determination aliquots of the decomposition solutions from ozonization of 1.000 g portions of benzoquinone were distilled. The distillations were in this

case performed at low pressure and room temperature while a slow stream of nitrogen was passed through the solution. Formic acid was absorbed directly in a 0.1000 N solution of sodium hydroxide and the resulting mixture back-titrated with hydrochloric acid. As a mean of the determinations it was found that 1.000 g of benzoquinone produced 15.2 mmoles of formic acid.

Mesoxalic dialdehyde. The decomposition solution from 5.00 g of benzoquinone was added to the same volume of ethanol and the mixture passed through a column of De-Acidite G (3 × 30 cm). Before use the ion exchange resin had been treated with 1 N sodium hydroxide and washed neutral, first with tap water and finally with distilled water. The ethanolic decomposition solution was left in the column for about one hour and thereafter eluted with 50 % ethanol. About 500 ml of a neutral eluate which showed a strong reaction with Tollens' reagent was collected. A faint but very persistent tailing was characteristic of the elution and the volume of eluate actually containing traces of a neutral carbonyl compound was very large. The 500 ml of eluate was evaporated to dryness *in vacuo* and formed a dry brittle mass of only faint colour. It could not be brought to crystallization and was difficult to purify in this state. The mean yield of the product was 500 mg. In order to prepare the *p*-nitrophenylhydrazone, an aqueous solution of the aldehyde was added to a hot solution of *p*-nitrophenylhydrazine in glacial acetic acid and the mixture heated on a water-bath for about one hour when a dark red substance separated. This substance was digested three times with glacial acetic acid and the undissolved part recrystallized from nitrobenzene. The dark brick-red derivative had no melting point but decomposed at about 297°; the decomposition point was, however, rather dependent upon the rate of temperature increase. (Found: C 52.0; H 3.8; N 24.4. Calc. for $C_{21}H_{17}N_9O_6$: C 51.3; H 3.5; N 25.7.) The analytical values were rather high in carbon and low in nitrogen content, a fact which is attributed to the tenacious retaining of nitrobenzene by the tris-*p*-nitrophenylhydrazone. An authentic sample of mesoxaldialdehyde was prepared by ozonization of phorone and a derivative with *p*-nitrophenylhydrazine was made as described above. Also here a decomposition point of about 297° was found and the analytical figures were close to those already mentioned. (Found: C 52.0; H 3.7; N 24.1.) The infrared spectra of the two derivatives proved that they were identical.

From the first acetic acid extract of our original *p*-nitrophenylhydrazone mixture a dark red substance separated. Decomposition occurred in the range 260 to 270°. (Found: C 50.0; H 3.8; N 21.8. Calc. for $C_9H_7N_3O_4$ (mono-*p*-nitrophenylhydrazone): C 48.9; H 3.2; N 19.0. Calc. for $C_{15}H_{12}N_6O_5$ (bis-*p*-nitrophenylhydrazone): C 50.6; H 3.4; N 23.6).

Glyoxylic acid. After removing the mesoxalic dialdehyde completely the ion-exchange column was treated with 5 % aqueous formic acid. In the eluate a carbonyl compound appeared which reacted with 2,4-dinitrophenylhydrazine to give yellow needles; m. p. 190° decomp. Recrystallized twice from water the melting point was unchanged. Mixed melting point with an authentic sample of glyoxylic acid 2,4-dinitrophenylhydrazone was undepressed. (Found: C 37.3; H 2.8; N 22.1. Calc. for $C_8H_6O_6N_4$: C 37.8; H 2.4; N 22.1.) The eluate and an aqueous solution of phenylhydrazine hydrochloride gave brownish orange needles. Recrystallized from water (charcoal) they became light yellow; m. p. 137—138° decomp. (Found: C 58.5; H 4.9; N 16.6. Calc. for $C_8H_8N_2O_2$: C 58.5; H 4.9; N 17.1.)

The decomposition solution from 1.000 g of benzoquinone was evaporated in a vacuum desiccator over potassium hydroxide to constant weight. Weight of the residue 1.197 g. From this value was deducted the sum of the found amounts of mesoxalic dialdehyde, oxalic acid and maleic acid, in all 202 mg, which leaves us 995 mg of glyoxylic acid monohydrate, *i. e.* 800 mg of the anhydrous acid.

Oxalic acid. The decomposition solution from 1.000 g of benzoquinone was added to a solution of 2 g calcium chloride in 50 ml of water and dilute aqueous ammonia added until pH reached *ca.* 6. The crystalline precipitate was collected after one hour and dried at 110°: 52 mg of calcium oxalate monohydrate which corresponds to 32 mg of oxalic acid. A larger amount of calcium oxalate prepared in this way was dissolved in 2 N hydrochloric acid and extracted with ether. The dried ethereal extract was evaporated when white crystals remained. These had m. p. 101°, undepressed upon admixture of an authetic sample of oxalic acid.

Maleic acid. The filtrate from the oxalate precipitation was concentrated to a small volume and a hot solution of 0.5 g of barium chloride in a few ml of water added when a

white precipitate was formed. The mixture was cooled to about 15° and filtered rapidly by suction. In a typical run the dried barium maleate weighed 44 mg and the filtrate from this salt measured 20 ml. Now it is found in the literature [4] that 100 parts of water at 14.5° dissolves 0.584 parts of barium maleate monohydrate. The filtrate contains therefore 108 mg of the anhydrous salt and the total of 153 mg of barium maleate corresponds to 72 mg of maleic acid. From the barium salt maleic acid could be set free and isolated. It was identified by the melting point which was undepressed upon admixture of an authentic sample.

Maleic acid could also be determined more directly. The decomposition solution from 1.000 g of benzoquinone was mixed with 2 ml of 40 % hydrogen peroxide and evaporated slowly on a water-bath. The residue weighed 70 mg, but was somewhat contaminated with a yellow peroxidic syrup. A further 0.5 ml of hydrogen peroxide was therefore added together with some water and the mixture again evaporated to dryness. The residue consisted this time of pure, white maleic acid, but weighed only 50 mg.

Carbon dioxide. 1.000 g of benzoquinone was ozonized as usual and the dissolved ozone swept out quantitatively with oxygen. Water was added and the liberated carbon dioxide was carried into a solution of barium hydroxide by the oxygen stream. The precipitated barium carbonate was rapidly filtered off by suction, dried and weighed. Found: 294 mg of barium carbonate which corresponds to 66 mg of carbon dioxide.

Formaldehyde. 260 ml of the chloroform ordinarily used in these experiments were treated with ozone for 6 h and thereafter extracted five times with 25 ml portions of water. Especially the first extract gave a positive reaction on formaldehyde with chromotropic acid reagent. Further it gave a small crystalline precipitate with an ethanolic solution of dimedone. This product had m. p. 189.5° which was undepressed upon admixture of an authentic sample.

500 ml of chloroform were extracted five times with the same volume of water, dried over calcium chloride and distilled. A part of the distillate was treated for 6 h with ozone and extracted with water. The aqueous extract gave a negative test for formaldehyde. If a small amount of ethanol was added to the purified chloroform and treated with ozone as before, formaldehyde reappeared in the aqueous extracts.

Benzoquinone was dissolved in the purified chloroform and ozonized as usual. The decomposition solution was passed through an ion-exchange column and the neutral eluate collected. With an ethanolic solution of dimedone it gave sparingly a precipitate of white needles. Recrystallized from a small amount of ethanol they had m. p. 190.5° which was undepressed upon admixture of an authentic sample of formaldehyde dimedone derivative. Also the test with chromotropic acid reagent was positive.

Short Communications

Least Square Method for Computor Calculation of Stability Constants *

JAN RYDBERG** and JAMES C. SULLIVAN

Chemistry Division, Argonne National Laboratory Lemont, Illinois, USA

Although a number of investigators have been concerned with the problem of calculation of stability constants, the methods presented have in general been approximation techniques (*cf. e. g.* Ref.[1]). With the growing use of high-speed computors, it becomes feasible to re-examine some of the data in the literature using a least square technique to calculate such stability constants. In addition, the use of such a computor enables the experimentalist to assign standard deviations to constants so calculated. This feature of computor calculation is a valuable contribution, since it provides an objective measure of the precision associated with such constants.

The necessity for such an approach is rather pointedly illustrated when one considers the compilation prepared by Bjerrum, Schwarzenbach and Sillén [2], where, for example, in the system Fe(III)-SCN^- there are 35 different investigations tabularized. In the absence of any measure of precision (not considering systematic errors) of the calculated stability constants, the user of this compilation is forced to *ad hoc* considerations.

The authors have therefore started a series of studies in order to reveal the advantage and precision of using least square methods in combination with high-speed digital computors for the calculation of stability constants. The results of our studies will be given in a series of papers dealing with the application of the method to systems containing simple complexes (one central atom and one type of ligand, *e. g.* MA_n), composite complexes (one central atom and several different types of ligands, *e. g.* MA_nB_p) and polynuclear complexes (several central atoms of same kind for each kind of ligand, *e. g.* M_mA_n) as studied by means of solvent extraction, ion exchange, spectrophotometric and e.m.f. methods.

In the present paper, as an example, the treatment of a simple system will be briefly described.

The U(IV)-acetylacetone system

This system, which has been studied by means of solvent extraction [3], was chosen partly because of its familiarity to one of the authors, and partly because of its regular behavior in the present treatment.

Outline of the mathematical treatment. U(IV), here abbreviated to M^{+4}, is assumed to form a series of complexes, MA_n^{4-n}, with acetylacetone, HA, in aqueous solutions. The uncharged complex MA_4 can be extracted into inert organic solvents like C_6H_6, and it is assumed that this complex is the only extractable one of M. The distribution ratio, q, of all species of M between the organic and aqueous solvents will then be

$$q = \frac{[M]_{org}}{[M]_{aq}} = \frac{\lambda_N \cdot \varkappa_N [A^-]^N}{\sum_0^n \varkappa_n [A^-]^n} \qquad (1)$$

where λ_N is the distribution constant of the uncharged complex MA_N between the organic and aqueous phases, and $\varkappa_n$ is the over-all stability constant for the n:th complex:

* Based on work performed under the auspices of the U.S. Atomic Energy Commission.

** On leave of absence from the University of Stockholm, and Research Institute of National Defence, Stockholm, Sweden.

$$\varkappa_n = \frac{[MA_n^{N-n}]}{[M^N]\,[A^-]^n} \qquad (2)$$

If we introduce the following notations

$$y = \frac{[M]_{aq}}{[M]_{org}}\ ,\ x = [A^-],\ a_n = \frac{\varkappa_n}{\lambda_N \varkappa_N}\ ,\ \text{and}\ z = \frac{[M]_{aq}}{[M]_{org}}\,[A]^N = y\,x^N$$

into eqn. (1), it will yield

$$z = \sum_0^n a_n x^n \qquad (3)$$

This can be solved for a_n, provided n combinations of $z(x)$ are available. Usually the number L of experimental points is $\gg n$, and the L equations of type 3 can therefore be solved with a least square technique. However, x and z are experimentally determined quantities and therefore have associated with them errors, which makes it necessary to properly weight the equations. The details of the procedures will be described in a later paper.

Computer operations. In the U(IV) case it was assumed that the errors in $[A^-]$ could be neglected compared to the errors in $[M]_{org}$ and $[M]_{aq}$, which will be called σ_{org} and σ_{aq}. The computer was therefore programmed for these five kinds of data: $[A^-]$, $[M]_{org} \pm \sigma_{org}$ and $[M]_{aq} \pm \sigma_{aq}$, which were punched on cards together with information of N, L and maximum number of n. In the programming, the computor was ordered, 1) to print the best combination of positive a_n for a minimum number of n, 2) to print the standard deviations of a_n, 3) to print the z_i values, calculated according to eqn. (1) with the a_n given by the computor, for the various input x_i values, 4) to print the standard deviations of these z_i, 5) to print the over-all accuracy of the computation. This latter information is given in the form of S_{min}/k*, which should have a value between 1.5 and 0.5 for reliable data.

For $n = N = 4$, and $L = 35$, the time of the whole operation (*i. e.* putting in program and data cards, running the computor and printing out) is about 5 min for the computer used (an I.B.M. 704).

Results of the computations. In the U(IV)-acetylacetone system [3], it was felt that there was no obvious way to unambigously establish the analytical errors in the determinations of $[M]_{org}$ and $[M]_{aq}$. Therefore, the error in log q was estimated from the spread of the individual points; see Fig. 1. For this purpose, points with very close lying log $[A^-]$ values were chosen. From 6 such groups, comprising altogether 14 points, at various log $[A^-]$, an average error of ± 0.04 in log q was estimated, which corresponds to a ± 10 % error in q on a linear scale. For the sake of simplicity, and also in order to make the data more suitable to the input form of the computor, the whole error was attributed to $[M]_{aq}$. Thus the data put into the machine were $[M]_{org} = q \pm 0.00$, $[M]_{aq} = 1.00 \pm 0.10$, and $[A^-]$.

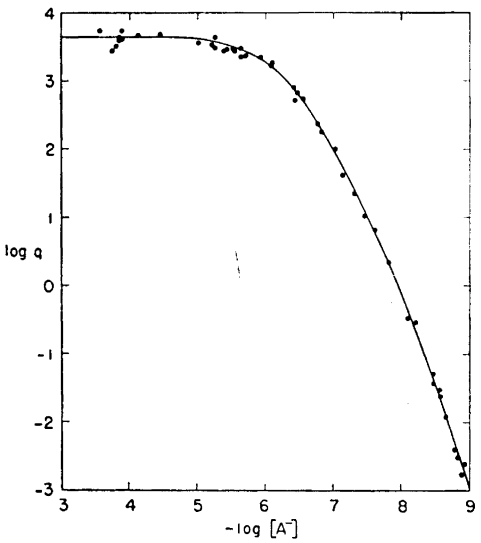

Fig. 1.

* The significance of the function

$$S_{min}/k = \frac{\sum \omega_i \sum (a_n x_i^n - z_i)^2}{L - N - 2},$$

where ω_i is the weight of the point i, will be fully discussed in a subsequent paper.

Table 1. Equilibrium constants calculated by the least square method.

Reaction	Constants
$U^{4+} + A^- \rightleftharpoons UA^{3+}$	$(1.04 \pm 0.69)\ 10^9$
$UA^{3+} + A^- \rightleftharpoons UA_2^{2+}$	$(1.80 \pm 0.64)\ 10^8$
$UA_2^{2+} + A^- \rightleftharpoons UA_3^{+}$	$(3.31 \pm 0.72)\ 10^6$
$UA_3^{+} + A^- \rightleftharpoons UA_4$	$(0.95 \pm 0.19)\ 10^6$
UA_4 (aq.) $\rightleftharpoons UA_4$ (C_6H_6)	$(4.38 \pm 0.25)\ 10^3$

In addition to the 10 % error in $[M]_{aq}$, a number of other errors were also tested. The S_{min}/k values of these runs were 15.5 (for a 5 % error), 3.9 (10 % error), 1.0 (20 % error) and 0.4 (30 % error), indicating that the 10 % error first assigned to the experimental points was too small.

In this particular system, it turned out that the best fit of the experimental data to the curve given by eqn. (1) is obtained when all constants $\varkappa_1$,.....$\varkappa_4$ and λ_4 are present. The stepwise formation constants k_n as well as the distribution constant λ_4 are given in Table 1. It is seen that the standard deviation is very large for k_1 (about 70 %), but diminishes successively up to k_4 (about 20 %). The precision in λ_4 is unusually good. With these values (or rather $\varkappa_n = \prod_1^n k_n$), the curve in Fig. 1 is calculated.

In Table 2, the log $\varkappa_n$ and log λ_4 values are given in order to compare them with the constants manually calculated in the original paper [3]. There, two different sets of constants were given for the two-parameter method; here, the average values are given, and the errors are the spread between these two values. When comparing the constants, the agreement between the constants calculated with the least square method and those of the two-parameter method is rather good, while it is less good for the ligand number method. Since both these latter methods are graphical in nature, the better agreement of the two-parameter method probably stems from the fact that the experimental data in that method are used directly for the estimation of the stability constants, and that the sequence-values of the stability constants are of the suitable two-parameter type. In the ligand number method, the graphical derivation of the smoothed curve through the experimental points makes possible the introduction of large errors.

From Table 2 it is further seen that the precision assigned to the constants obtained by the two graphical methods is far too small. While all errors in the primary data are considered in the least square computations, only errors in a very narrow range of data can be regarded for estimating the errors of the constants obtained by the graphical methods. This illuminates one of the statements made in the introduction, namely the inherent difficulty of the approximation methods in making valid estimates of the precision of the stability constants.

Table 2. Comparison of equilibrium constants (log $\varkappa_n$) obtained with three different calculation procedures.

Reaction	Least square method	Ligand number method	Two-parameter method
$U^{4+} + A^- \rightleftharpoons UA^{3+}$	9.02 ± 0.29	8.6 ± 0.2	9.05 ± 0.1
$U^{4+} + 2A^- \rightleftharpoons UA_2^{2+}$	17.27 ± 0.26	17.0 ± 0.2	17.02 ± 0.15
$U^{4+} + 3A^- \rightleftharpoons UA_3^{+}$	23.79 ± 0.26	23.4 ± 0.1	23.92 ± 0.1
$U^{4+} + 4A^- \rightleftharpoons UA_4$	29.77 ± 0.29	29.5 ± 0.1	29.76 ± 0.1
UA_4 (aq.) $\rightleftharpoons UA_4$ (C_6H_6)	3.64 ± 0.025	3.62 ± 0.05	3.62 ± 0.05

The Presence of Pyruvate as a Source of Error in Ammonia Determination by Means of Nessler's Reagent

G. STEENSHOLT and L. ROTNES

Department of Biochemistry, University of Oslo, Norway

A simple and rapid method for estimating the pyruvate-activated glutaminase II activity of rat liver was described by Beaton [1] in 1954. During experiments with glutaminase II, using exactly the same procedure [1], we found that sodium pyruvate reduced the colour of Nessler's reagent even in the presence of Archibald's persulphate-gluconate stabilizer [2]. Comparing standard curves made with and without pyruvate, we found about 50 % reduction when using Vanselow's [3] Nessler reagent. Utilizing Kolthoff's [4] Nessler reagent, the reduction amounted to about 24 %.

Standard curves were made according to Beaton [1], using the same quantities of pyruvate as in the enzyme activity determinations. A set of tubes was prepared as shown in Table 1.

Table 1. Preparation of standard curves. Each tube contained 1 ml veronal-acetate buffer, pH 7.7 (31.8 μmole sodium pyruvate) and 1 ml glutamine solution (20.4 μmole). Tube 1 is the blank.

Tube No.	Water ml	$(NH_4)_2SO_4$ standard solution containing 3.598 μmole per ml ml
1	2.0	0
2	1.8	0.2
3	1.6	0.4
4	1.5	0.5
5	1.4	0.6
6	1.2	0.8

A similar set of tubes was prepared in identically the same manner, except that the pyruvate was omitted. After incubation for 1 h at 37°C, 2 ml 0.7 N sulphuric acid and 2 ml 7 % sodium tungstate were added. A 4 ml sample was removed from each tube. To each sample were then added 4 ml of a freshly prepared Archibald's stabilizer diluted 2 : 1 with water. 1 ml of Nessler's reagent was rapidly added and after 5 min the colour was read at 450 mμ in a Coleman spectrophotometer. Three different sodium pyruvate preparations were tried. One preparation had been obtained from Boehringer & Soehne, Mannheim, and two were prepared according to Greenstein [5]. They gave the same results in all our experiments. The results obtained are shown in Fig. 1.

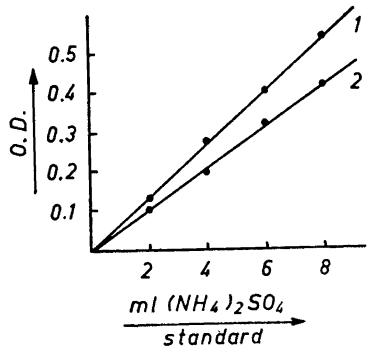

Fig. 1. The reduction of the colour of Kolthoff's form of Nessler's reagent. Curve 1, samples without pyruvate read against blank without pyruvate. Curve 2, samples containing pyruvate read against blank containing pyruvate.

When estimating glutaminase II activity we might use curve 2 adding adequate amounts of pyruvate to the blank after incubation. According to Refs. [6,7] 80—90 % of the pyruvate is recovered at the end of the incubation period. In experiments with varying pyruvate concentrations we found that the reduction in colour intensity reached its maximum at a pyruvate concentration of approximately 50 % of that used in the experiments reported in Table 1.

A reasonable procedure consists in adding 80 % of the initial amount of pyruvate to the blank after adding the sulphuric acid on termination of the incubation. This preserves the rapidity and convenience of the method, especially when series of analyses have to be carried out.

On the Relative Donor Strengths of $POCl_3$ and $PO(CH_3)_3$. A Ramanspectroscopic Study

PER-OLOF KINELL, INGVAR LINDQVIST and MARGARETA ZACKRISSON

Institute of Physical Chemistry and Institute of Chemistry, University of Uppsala, Uppsala, Sweden

A very important problem in the study of addition compounds is the determination of the relative acceptor and donor strengths of the reacting molecules.

The relative donor strenghts of two donor molecules D_1 and D_2 are only defined for a given acceptor molecule A. The free energy changes of the two reactions $A(g) + D_1(g) = AD_1(g)$ and $A(g) + D_2(g) = AD_2(g)$ should be compared in an exact study. If liquid or solid phases appear in either of these reactions the discussion is complicated by the large variations in cohesive energies. These depend very much upon the dipole moments of the different molecules, and bear no obvious relation to the strengths of the acceptor-donor bonds. The same difficulty prevails if a solvent with an appreciable dipole moment is used for the study. In an ideal solvent the differences between the solvation energies for D_1 and AD_1, and for D_2 and AD_2 should be equal. It is rather difficult to find such a solvent but the use of different types of solvents which may interact more or less favourably with the different molecules might lead to a rather safe assessment of the relative donor strengths.

If such solvents can be selected a suitable method of studying the reactions taking place remains to be found so that at least the order of donor strength can be determined. The molecular spectra are then of an especial interest although they do not seem to have been used much for this purpose. Infrared spectra and Raman spectra each have their advantages and disadvantages in this connection. IR is sensitive to low concentrations of the dissolved molecules if the solvent has a low absorption in the spectral regions where the molecules to be studied absorb. Raman spectra are more difficult to measure in dilute solutions but have fewer absorption bands with less risk for overlap between the spectra of the different molecules or with the solvent spectrum. In this first study we have investigated the usefulness of the Raman method.

For this purpose we have tried to find a test pair of donor molecules with well known donor functions for which a rather safe prediction about the relative donor strengths could be made, so that the difficult search for a number of different, suitable solvents could be omitted as an unnecessary precaution. This requirement is fulfilled by the pair $POCl_3$ and $PO(CH_3)_3$. The donor function of the oxygen atom in such compounds has recently been definitely established by X-ray and spectroscopic work[1,2]. It can also be safely predicted that $PO(CH_3)_3$ should be a better donor molecule than $POCl_3$. The larger electronegativity of chlorine causes a drift of electrons from oxygen in $POCl_3$ compared with $PO(CH_3)_3$ and thus a lower dipole moment and a lower tendency to donate an electron pair.

1,2-Dichlorethane was used as a solvent and the following solutions were studied (mole fractions within brackets): $POCl_3$ (0.10), $PO(CH_3)_3$ (0.10), $SbCl_5$ + $POCl_3$ (0.10 + 0.10), $SbCl_5$ + $PO(CH_3)_3$ (0.02 + 0.02) and $SbCl_5$ + $POCl_3$ + $PO(CH_3)_3$ (0.02 + 0.02 + 0.02). The solution of $SbCl_5 \cdot POCl_3$ was supersaturated. The preparation of the mixture of all three molecular species must be made in such an order that $POCl_3$ and $PO(CH_3)_3$ are not permitted to react with each other. The products of that complicating reaction are not known but the reaction is prevented by the presence of $SbCl_5$.

On the Relative Donor Strengths of $POCl_3$ and $PO(CH_3)_3$. A Ramanspectroscopic Study

PER-OLOF KINELL, INGVAR LINDQVIST and MARGARETA ZACKRISSON

Institute of Physical Chemistry and Institute of Chemistry, University of Uppsala, Uppsala, Sweden

A very important problem in the study of addition compounds is the determination of the relative acceptor and donor strengths of the reacting molecules.

The relative donor strenghts of two donor molecules D_1 and D_2 are only defined for a given acceptor molecule A. The free energy changes of the two reactions $A(g) + D_1(g) = AD_1(g)$ and $A(g) + D_2(g) = AD_2(g)$ should be compared in an exact study. If liquid or solid phases appear in either of these reactions the discussion is complicated by the large variations in cohesive energies. These depend very much upon the dipole moments of the different molecules, and bear no obvious relation to the strengths of the acceptor-donor bonds. The same difficulty prevails if a solvent with an appreciable dipole moment is used for the study. In an ideal solvent the differences between the solvation energies for D_1 and AD_1, and for D_2 and AD_2 should be equal. It is rather difficult to find such a solvent but the use of different types of solvents which may interact more or less favourably with the different molecules might lead to a rather safe assessment of the relative donor strengths.

If such solvents can be selected a suitable method of studying the reactions taking place remains to be found so that at least the order of donor strength can be determined. The molecular spectra are then of an especial interest although they do not seem to have been used much for this purpose. Infrared spectra and Raman spectra each have their advantages and disadvantages in this connection. IR is sensitive to low concentrations of the dissolved molecules if the solvent has a low absorption in the spectral regions where the molecules to be studied absorb. Raman spectra are more difficult to measure in dilute solutions but have fewer absorption bands with less risk for overlap between the spectra of the different molecules or with the solvent spectrum. In this first study we have investigated the usefulness of the Raman method.

For this purpose we have tried to find a test pair of donor molecules with well known donor functions for which a rather safe prediction about the relative donor strengths could be made, so that the difficult search for a number of different, suitable solvents could be omitted as an unnecessary precaution. This requirement is fulfilled by the pair $POCl_3$ and $PO(CH_3)_3$. The donor function of the oxygen atom in such compounds has recently been definitely established by X-ray and spectroscopic work[1,2]. It can also be safely predicted that $PO(CH_3)_3$ should be a better donor molecule than $POCl_3$. The larger electronegativity of chlorine causes a drift of electrons from oxygen in $POCl_3$ compared with $PO(CH_3)_3$ and thus a lower dipole moment and a lower tendency to donate an electron pair.

1,2-Dichlorethane was used as a solvent and the following solutions were studied (mole fractions within brackets): $POCl_3$ (0.10), $PO(CH_3)_3$ (0.10), $SbCl_5$ + $POCl_3$ (0.10 + 0.10), $SbCl_5$ + $PO(CH_3)_3$ (0.02 + 0.02) and $SbCl_5$ + $POCl_3$ + $PO(CH_3)_3$ (0.02 + 0.02 + 0.02). The solution of $SbCl_5 \cdot POCl_3$ was supersaturated. The preparation of the mixture of all three molecular species must be made in such an order that $POCl_3$ and $PO(CH_3)_3$ are not permitted to react with each other. The products of that complicating reaction are not known but the reaction is prevented by the presence of $SbCl_5$.

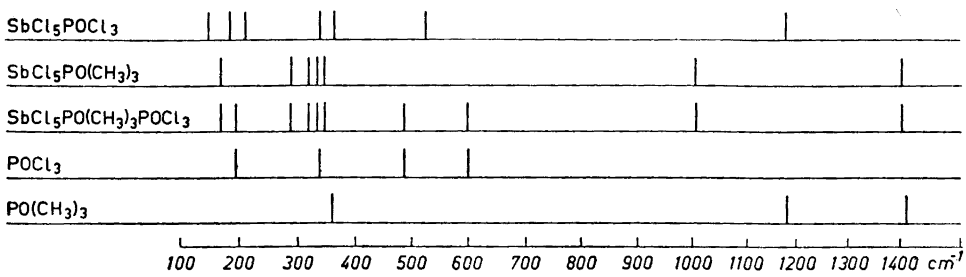

Fig. 1. The Raman spectra of the different solutions.

The Raman spectra were taken with a redesigned spectrograph of the type described by Kinell [3]. The photographic technique using Ilford Zenith plates was applied. The spectra were excited by the 4 358 Å Hg-line, and saturated $NaNO_2$ solution was used to filter away the UV part of the Hg-spectrum.

The results are shown in the simplified Fig. 1 where the spectrum of 1,2-dichlorethane is omitted together with those bands which overlap with it (the intensities are not indicated).

The interpretation is obvious: all the $SbCl_5$ in the ternary mixture has reacted with $PO(CH_3)_3$ to form $SbCl_5 \cdot PO(CH_3)_3$, leaving $POCl_3$ unreacted in the solution. This confirms that $PO(CH_3)_3$ is a better donor molecule than $POCl_3$ in the reaction with $SbCl_5$ (at these concentrations in 1,2-dichlorethane, strictly speaking).

The very distinct determination of the relative donor strengths achieved by this method in this case gives good hope for its application to problems with a less obvious solution. Such work is in progress in these Institutes.

Electroorganic Preparations

VII. Reduction of a Compound Containing a Trifluoromethyl Group

HENNING LUND

Leo Pharmaceutical Products, Copenhagen, Denmark

Several compounds are reducible at the dropping mercury electrode due to an electrochemical fission of a carbon-halogen bond. The reductive splitting of such bonds have been studied by means of polarography and controlled potential reductions and in most cases the halogens have been iodine, bromine or chlorine. Apparently only in the reduction of one compound,[1] phenacyl fluoride, the electrochemical fission of an aliphatic carbon-fluorine bond has been reported. In this communication the polarography and reduction of a compound containing a trifluoromethyl group is investigated.

The trifluoromethyl group which has received considerable attention as a substituent in various drugs is not generally reducible at the dropping mercury electrode, as no reduction between 0 and −2.0 V *vs.* S.C.E. was observed for trifluoroacetic acid, trifluoromethylbenzene, 3-trifluoromethylaniline, or 3-trifluoromethyl-4-sulphamyl-aniline. However, the introduction of two sulphamyl groups in 3-trifluoromethylaniline renders the compound reducible. In Table 1 is reported the polarographic behaviour of 6-trifluoromethyl-7-sulphamyl-3,4-dihydro-1,2,4-benzothiadiazine-1,1-dioxide (6-TFM).

Table 1. Diffusion currents in μA and half-wave potentials *vs.* S.C.E. for 6-trifluoromethyl-7 - sulphamyl - 3,4 - dihydro - 1,2,4 - benzothiadiazine-1,1-dioxide. Concentration 0.60 × 10^{-3} M. 0.01 % gelatine added as maximum suppressor.

pH	i_d μA	$E_{\frac{1}{2}}$ V
6.28	8.4 *	1.67
7.35	7.7	1.67
8.30	7.1	1.67
8.80	7.0	1.67$_5$
9.75	6.7	1.70
10.50	6.6	1.75
10.75	6.5	1.78

* merges with the hydrogen wave.

The compound yields in the pH-interval 6 to 11 a well-defined, diffusion controlled, irreversible wave. By comparison of the wave height with that of 2,4-disulphamyl-5-bromo-aniline, which was assumed to be reduced in a two-electron reduction to 2,4-disulphamyl-aniline, it was found that the wave height of 6-TFM corresponded to a comsumption of 5−6 electrons per molecule. As seen from Table 1 the half-wave potentials of 6-TFM are constant at pH-values lower than about 8.5, whereas they at higher pH-values become more negative. This pH-dependence of the half-wave potentials is connected with the presence of the two sulphamyl groups. Each sulphamyl group contains a weakly acidic hydrogen atom. The *pK*-values of the groups are 8.9 and 10.7. At pH-values lower than 8.5 the undissociated sulphamyl groups strongly attract electrons from the benzene ring and the trifluoromethyl group, thus making an attack of electrons more easy. At pH-values higher than 8.5 an increasing part of the sulphamyl groups are dissociated into anions which attract electrons much less than does the undissociated sulphamyl group. The potential required to promote an attack of electrons thus becomes more negative.

A similar dependence of the half-wave potentials upon pH has been found for many halogen compounds containing a dissociable group, such as α-halogenated acids [2,3], iodophenols [4], and iodoanilines [4]. A plot of the half-wave potentials of these compounds against pH normally yields an S-shaped curve with one pH-independent branch in acid solution and one in alkaline solution. The pK_a value of the acid is found in the rising part of the curve; the midpoint of the S-shaped curve is generally found at a pH somewhat higher than the pK_a of the acid. This is probably due to recombination of the anion with hydrogen ions at the electrode surface.

As the half-wave potential of both the acid and the anion are pH-independent one might have expected a pH-interval in which two waves were observed due to the reduction of the acid and of the anion, respectively. This is the case in the reduction of, *e. g.*, pyruvic acid [5]. The pH at which the wave due to the reduction of the acid is of equal height as that due to the reduction of the anion is somewhat higher than the pK_a of pyruvic acid and is determined by the rate of the recombination at

the electrode surface [5]. A difference between pyruvic acid and the halogenated acids lies in the fact that the reduction of the reducible group in pyruvic acid (the carbonyl group) generally is pH-dependent in acid solution, whereas the reduction of a carbon-halogen bond as such is pH-independent. It seems that the half-wave potentials of the halogen compounds by some as yet undetermined feature of the electrode process kinetics reflects the average electronic interaction between the dissociable group and the carbon atom, at which the fission of the carbon-halogen bonds takes place.

Controlled potential reduction of 6-TFM and its parent disulphonamide, 5-trifluoromethyl-2,4-disulphamyl-aniline, showed that the electrode reaction was a six-electron reduction and the methyl compounds, 6-methyl-7-sulphamyl - 3,4 - dihydro - 1,2,4 - benzothiadiazine-1,1-dioxide and 5-methyl-2,4-disulphamyl-aniline, respectively, were isolated from the reaction mixture. A photometric determination with zirconiumeriochrome cyanine of the fluoride ions produced showed the presence of about 95 % of the total original fluorine content as fluoride ion. The overall reaction thus is

$$R—CF_3 + 6e^- + 3\ H_2O \rightarrow R—CH_3 + 3\ F^- + 3\ OH^-$$

Although a stepwise reduction of a polyhalogenated carbon atom is the most common reaction path a few examples of polarographic waves due to a complete reduction of a polyhalogenated compound are reported. Chloral hydrate [6] thus produces a single wave which corresponds to a reduction to acetaldehyde.

Elving and Leone [1] point to the fact that the carbon-fluorine bonds in F_3CH are considerably shorter than in FCH_3, which is reflected in the greater stability of the polyfluoromethanes. They conclude that if this behaviour is generally true for the trifluoromethyl group, the stepwise fission of the carbon-halogen bonds would not be observed as in the case of trichloro- and tribromoacids, but all of the bonds would probably be ruptured in a single step at a potential more negative than that at which the one carbon-fluorine bond in the monofluoro compound would be reduced. The results of the present investigation fully substantiate the conclusion of Elving and Leone.

As 6-TFM can be determined spectrophotometrically after alkaline hydrolysis, diazotization and coupling we have a means of determining in a solution both the concentration of the primary, aromatic amine and of trifluoromethyl groups bonded to a benzene ring containing two sulphamyl groups. This has been applied to the determination of 6-TFM in the urine from persons given 6-TFM perorally, and has shown that the concentrations of the amine and the trifluoromethyl compound found in the urine were the same, which strongly suggests that the trifluoromethyl group remains intact during the passage through the body.

Experimental. The polarograph was a recording polarograph Radiometer Type PO 3a. The capillary delivered 2.16 mg of mercury per second at a corrected mercury height of 48.5 cm. The drop time 3.90 sec (water, open circuit). The capillary constant $m^{2/3}t^{1/6} = 2.13$ $mg^{2/3}\ sec^{-\frac{1}{2}}$. The apparatus used for the controlled potential reductions was an electromechanical potentiostat of the Lingane-Jones type.

The buffer solutions used were below pH 8 sodium phosphate-citric acid buffers and from pH 8 to 11 sodium borate buffers. The medium employed was 40 % alcohol containing 1 M potassium chloride and 0.01 % gelatine. The pH-values were measured with a glass electrode; in the medium used they have only relative value.

Reduction of 6-trifluoromethyl-7-sulphamyl-3,4 - dihydro - 1,2,4 - benzothiadiazine - 1,1 - dioxide. A suspension of 1.0 g of 6-TFM in 180 ml 30 % aqueous methanol containing 20 g of potassium hydrogen carbonate was reduced at a cathode potential of —1.70 V *vs.* S.C.E.; the reduction was completed after the consumption of 6.3 electrons per molecule. Small amounts of hydrochloric acid were added during the electrolysis to compensate for the hydrogen ions used in the reduction; the consumption of hydrogen ions was calculated from the reading of the coulometer. After completion of the reduction the reaction mixture was extracted several times with ethyl acetate, which was evaporated. The residue was recrystallized from dilute methanol yielding 600 mg of a compound with an IR-spectrum identical with that of actual 6-methyl-7-sulphamyl-3,4 - dihydro - 1,2,4 - benzothiadiazine - 1,1 - dioxide. (Found: C 34.53; H 4.04; N 15.12; S 22.99. Calc. for $C_8H_{11}N_3O_4S_2$: C 34.64; H 3.99; N 15.16; S 23.13.)

From a similar reduction of 5-trifluoromethyl-2,4-disulphamyl-aniline were isolated 650 mg of a compound with an IR-spectrum identical with that of 5-methyl-2,4-disulphamyl-aniline. (Found: C 31.79; H 4.22; N 15.92; S 24.02. Calc. for $C_7H_{11}N_3O_4S_2$: C 31.69; H 4.18; N 15.84; S 24.17.)

Separation of Hg^{++} from Active Carbon by Extraction with EDTA

HARALD HOVDEN

Norsk Hydros Forskningslaboratorium, Porsgrunn, Norway

In the synthesis of vinyl chloride from acetylene and hydrogen chloride active carbon impregnated with mercuric chloride is used as a catalyst. The catalyst usually contains 8—10 % by wt. of mercuric chloride. The mercuric chloride content of catalyst samples drawn from a reactor which has been in use for a certain length of time, varies between zero and a value higher than the original one.

A producer of vinyl chloride is of course highly interested in a rapid and fairly accurate method for the determination of the mercury content of the catalyst. The present work was initiated some 20 months ago, at which time no publications dealing with this special problem could be found in available literature.

In our first experiments we investigated several procedures based on initial oxidation of the carbon, *e.g.* combustion in a Parr bomb, oxidation with fuming sulphuric acid and potassium persulphate and the method described by Schöniger[1,2] where the sample is burned in a conical flask filled with oxygen. By all these methods, however, the recovery of mercury was too low. This was also the case when the catalyst was extracted with acetone, while extraction with nitric acid or a mixture of nitric and hydrochloric acid seemed more promising. Another possible way of separating the mercury from the carbon may be distillation in a quartz apparatus, a method worked out for the determination of mercury in organic matter.[3]

During our further work, however, we were led to the conclusion that the most convenient method would be direct extraction of the mercury by means of EDTA. Check analysis by the aqua regia/H_2O_2 extraction method described in Ref.[4] have shown that this extraction is complete also when applied on spent catalyst samples. In the extract the mercury content is easily determined photometrically as mercury dithizonate. For a more detailed description of the dithizone procedure, Ref.[5] may be consulted.

Experimental. All of the solutions are made up with glass distilled water.

Buffer solution, pH = 10. 70 g NH_4Cl and 610 ml 12 N NH_4OH, diluted to 1 000 ml.

EDTA-solution. Disodiumsalt of ethylenediaminetetraacetic acid, 0.1 M.

Procedure. 20—30 mg of ground catalyst is transferred to a centrifuge tube together with 5 ml of EDTA-solution and 15 ml of buffer solution and extracted for 30 min with moderate shaking. The complexing of Hg^{++} with EDTA is considered a very rapid reaction and it therefore seems probable that complete extraction is achieved in considerably less than 30 min. The extraction is followed by settling of the carbon, which is most conveniently done by means of centrifuging. 5 ml of the supernatant liquid is pipetted into a volumetric flask and the volume is adjusted to 100 ml. An aliquot of this solution is used for the subsequent determination with dithizone.

Synthesis of *o*-Phthalic Acid Di-Esters of Choline and Related Compounds

SVERRE ØKSNE

Norwegian Defence Research Establishment, Toxicological Group, Lilleström, Norway

The preparation and physiological effects of a large number of choline esters and other types of quaternary alkylammonium compounds are dealt with in the literature.[1,2] Fusco *et al.*[3] prepared the bis-choline esters of the three phthalic acids and Bovet-Nitti[4] reported that β-diethylaminoethyl phthalate bis-ethiodide (306 I.S.) was a powerful inhibitor of pseudocholinesterase but not of true cholinesterase.

$$o\text{-}C_6H_4(COOCH_2CH_2\overset{+}{N}(C_2H_5)_3)_2\ 2I^-$$

306 I.S.

As part of an investigation on the inhibition of cholinesterases carried out by our institute,[5] the bis-methiodides and bis-ethiodides of the tertiary amines I, II and III were prepared.

$o\text{-}C_6H_4R_2$ I R = $COOCH_2CH_2N(CH_3)_2$
II R = $COOCH(CH_3)CH_2N(CH_3)_2$
III R = $COOCH(CH_3)CH_2N(C_2H_5)_2$

Experimental *. *Phthalyl chloride.* This was prepared as described by Kyrides[6], from phthalic anhydride and thionyl chloride. B. p. 119—122°/4 mm.

β-Dimethylaminoethyl phthalate (I)[3]. A solution of phthalyl chloride (0.04 mole) in dry ether (75 ml) was added dropwise to a solution of 2-dimethylaminoethanol (0.1 mole) in dry ether (50 ml) under vigorous stirring and cooling in cold water. The mixture was heated under reflux for 2 h and left overnight at room temperature. After evaporating the ether under reduced pressure, the residue was dissolved in water (20 ml). A chilled solution of potassium carbonate (15 g) in water (20 ml) was then added, and the mixture was extracted with five portions of 25 ml of ether. The combined ether extracts were dried for two days with anhydrous potassium carbonate, filtered and the ether evaporated under reduced pressure. Distillation of the residue *in vacuo* gave a light yellow oil. Yield 7.3 g (59 %); b. p. 168—169°/0.55 mm. (Reported by Fusco: 187°/2.5 mm.) No analyses were taken of this compound.

α-Methyl - β - dimethylaminoethyl phthalate (II). The ester II was prepared from 10.3 g (0.1 mole) of 1-dimethylamino-2-propanol and 8.1 g (0.04 mole) of phthalyl chloride in the same way as described for the preparation of I. Distillation *in vacuo* gave a colourless oil. Yield 7.0 g (52.5 %); b. p. 132—134°/0.1 mm. The dipicrate of II was prepared with a saturated solution of picric acid in absolute ethanol,

* Melting points and boiling points are uncorrected.

α - Methyl - β - diethylaminoethyl phthalate (III). The ester III was prepared from 26.2 g (0.2 mole) of 1-diethylamino-2-propanol and 16.2 g (0.08 mole) of phthalyl chloride following the same procedure as for I. The ester seemed to be partly decomposed by distillation. It was a yellow oil. B.p. 145—147°/0.05 mm. The dipicrate was recrystallized from absolute ethanol. M. p. 148—149.5°. (Found: N 13.50 and 12.73. Calc. for $C_{34}H_{42}O_{18}N_8$: N 13.18.)

Bis-methiodides and bis-ethiodides of I, II and III. The bis-quaternary alkyliodides of I, II and III were prepared in an acetone solution. The alkyliodides formed were dissolved in hot methanol and ethyl acetate was added slowly until a precipitate appeared. The solution was then chilled overnight in a refrigerator. For the preparation of the compounds IV, V and VI a solution of the tertiary amine and excess of methyl iodide or ethyl iodide in acetone was left overnight at room temperature. Compound VII was formed when a solution of II in acetone was heated with ethyl iodide under reflux for 3 h. In preparing the ethiodide of III (VIII), the reaction mixture was left at room temperature for eight days, and the methiodide of III (IX) was prepared by keeping the reaction mixture at 37° for three days. All the quaternary compounds (IV—IX) prepared, decomposed on melting. They were analysed for iodine by potentiometric titration with silver nitrate.

Melting points and analytical data of the bis-quaternary compounds are listed in Table 1.

M. Delépine's Nitrido-Iridium(III,IV) Sulphate Complexes with Nitrogen Bound to Three Iridium Atoms

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

Delépine [1] prepared green salts from $(NH_4)_3IrCl_6$ boiled with concentrated sulphuric acid. These salts are aquo acids, forming red-brown hydroxo complexes in alkaline solution by a reversible reaction, consuming one OH^- per Ir. They are distinctly different from Lecoq de Boisbaudran's blue-green sulphates,[2] formed by boiling, *e.g.*, K_3IrCl_6 with H_2SO_4 without the presence of NH_4^+. The latter salts can have the composition $K_{10}Ir_3(SO_4)_9O,H_2O$ (private communication from Professor Delépine) and may have further H_2O of crystallization. Delépine [3] found later that the green salts, prepared in the presence of NH_4^+, contain one nitrogen atom for each three iridium atoms. Then, he proposed one of two formulae:

I. $K_4[N\{Ir(H_2O)(SO_4)_2\}_3]$
II. $K_4H_2[N\{Ir(H_2O)(SO_4)_2\}_3]$

I contains two tetravalent and one trivalent iridium atom, while II assumes that all three iridium atoms are trivalent. Since Pascal and Pacault found that the nitrogen salts are diamagnetic, while Lecoq de Boisbaudran's salts are paramagnetic and according to the analysis contains one Ir(IV) and two Ir(III), it was concluded that II was probably true. During the study of the absorption spectra of Delépine's many interesting complexes,[4] the present author was surprised by the strong colour of a pure Ir(III) salt as II, and further by the presence of two hydrogen ions even in the hydroxo salts $K_7H_2[N\{Ir(OH)(SO_4)_2\}_3]$. This note shall present evidence that I is correct. The magnetochemical criterion is not very certain; even compounds with an odd number of electrons may be diamagnetic in certain cases (*e.g.* NO at low temperatures) where the gyromagnetic factor g accidentally is zero. But the case of I with an even number of electrons has a great chance for

and recrystallized from dry ethanol. M. p. 136—146°. (Found: N 13.92. Calc. for $C_{30}H_{30}O_{18}N_8$: N 14.10.)

α - Methyl - β - diethylaminoethyl phthalate (III). The ester III was prepared from 26.2 g (0.2 mole) of 1-diethylamino-2-propanol and 16.2 g (0.08 mole) of phthalyl chloride following the same procedure as for I. The ester seemed to be partly decomposed by distillation. It was a yellow oil. B.p. 145—147°/0.05 mm. The dipicrate was recrystallized from absolute ethanol. M. p. 148—149.5°. M. Delépine's Nitrido-Iridium(III,IV) Sulphate Complexes with Nitrogen Bound to Three Iridium Atoms

CHR. KLIXBÜLL JØRGENSEN

Chemistry Department A, Technical University of Denmark, Copenhagen, Denmark

Delépine [1] prepared green salts from $(NH_4)_3IrCl_6$ boiled with concentrated sulphuric acid. These salts are aquo acids, forming red-brown hydroxo complexes in alkaline solution by a reversible reaction, consuming one OH^- per Ir. They are distinctly different from Lecoq de Boisbaudran's blue-green sulphates,[2] formed by boiling, *e.g.*, K_3IrCl_6 with H_2SO_4 without the presence of NH_4^+. The latter salts can have the composition $K_{10}Ir_3(SO_4)_9O,H_2O$ (private communication from Professor Delépine) and may have further H_2O of crystallization. Delépine [3] found later that the green salts, prepared in the presence of NH_4^+, contain one nitrogen atom for each three iridium atoms. Then, he proposed one of two formulae:

I. $K_4[N\{Ir(H_2O)(SO_4)_2\}_3]$
II. $K_4H_2[N\{Ir(H_2O)(SO_4)_2\}_3]$

I contains two tetravalent and one trivalent iridium atom, while II assumes that all three iridium atoms are trivalent. Since Pascal and Pacault found that the nitrogen salts are diamagnetic, while Lecoq de Boisbaudran's salts are paramagnetic and according to the analysis contains one Ir(IV) and two Ir(III), it was concluded that II was probably true. During the study of the absorption spectra of Delépine's many interesting complexes,[4] the present author was surprised by the strong colour of a pure Ir(III) salt as II, and further by the presence of two hydrogen ions even in the hydroxo salts $K_7H_2[N\{Ir(OH)(SO_4)_2\}_3]$. This note shall present evidence that I is correct. The magnetochemical criterion is not very certain; even compounds with an odd number of electrons may be diamagnetic in certain cases (*e.g.* NO at low temperatures) where the gyromagnetic factor g accidentally is zero. But the case of I with an even number of electrons has a great chance for

being diamagnetic; the platinum group complexes with bridge atoms between the heavy atoms seem to utilize all possibilities of spin-pairing.[5]

The green salts do not react with most reducing agents. However, the present author found that vanadous ions (prepared from NH_4VO_3 and Zn in HCl) reduces the green solution to a straw-yellow colour, having only a weakly increasing absorption in the ultraviolet. Metallic zinc may act directly on the green solution in H_2SO_4. Uranium(III) in 2 M HCl reduces also quantitatively, and H_2O_2 restores at least 90 % of the original green colour, as measured on a recording Cary MS-11 spectrophotometer. The band maxima (shoulders in parenthesis) are at wavelengths in mμ with the extinction coefficients ε given per iridium atom present:

Green aquo form		Red-Brown hydroxo form		Blue-green Lecoq de Boisbaudran's salt	
(661)	ε = 450	653	ε = 470	(800)	ε = 350
582	530	562	910	701	770
439	1 260	452	1 500	306	1 250
(356)	465	335	710		
(311)	850	(298)	1 300		
(276)	1 220	269	1 850		

The special type of absorption bands in polynuclear complexes with the same metal in different oxidation states have often smaller wavenumbers than the electron transfer bands of mononuclear complexes.[4] The bands of the iridium complexes given above, are more narrow than the bands of iron(II,III) cyanides or molybdenum-(V,VI) blue. This may simply be connected with the fact that we have well-defined iridium compounds. The wavenumbers of the first bands are smaller [6] than of $IrCl_6^{--}$ and resemble those of $IrBr_6^{--}$. The absorption spectra are probably related to the formation of molecular orbitals of the nitrogen lone-pair (mainly a p_z-orbital) interacting with some of the iridium d-electrons, as will be discussed later.

The stability of the bonding of the nitrogen atom to the three iridium atoms, which even may survive the reduction to three Ir(III), is rather surprising. Werner prepared many cobalt (III) with NH- and NH_2-bridges, but the bonding of three metal atoms is rather exceptional. By X-ray crystallography, Scavnicar and Grdenic [7] found that $HgO,2HgCl_2$ contains oxygen atoms, surrounded in a plane by three rectilinear HgCl groups. The nitrogen-atom in Delépine's green salts may be nearly co-planar with the iridium atoms, forming a structure of the type of triphenylamine without tendency to co-ordinate a fourth group. That such »nitrido» complexes are formed in concentrated H_2SO_4, is rather remarkable. The oxygen atom (which also may be two OH^-) in Lecoq de Boisbaudran's salts may also co-ordinate three Ir. These salts are less stable; with alkalis or by standing with water, they precipitate violet, basic salts, and they are easily reduced by vanadium(II). On the other hand, the green nitride salt does not decompose to any great extent, if stored in aqueous solution at 25°C for 15 months.

Analysis. Since it is only possible to reduce the green nitrogen compound with ions, evolving hydrogen with water, it is not easy to make a direct titration, involving the reduction of iridium. However, the vanadium content [8] of the mixed $(NH_4)_2$ (V; Zn) $(H_2O)_6$ $(SO_4)_2$ was found by potentiometric titration with $KMnO_4$ in 1 M H_2SO_4 (showing distinct potential shifts at each of the oxidized forms (III), (IV), (V)) to have the effective molecular weight M = 2 090 (while a pure V (II) salt would have M = 387). To each 1 ml of a solution, 0.5 M in HCl and 0.0150 M in total Ir from the green salt, was added 10, 15, 20, 25, and 30 mg of the V (II), Zn (II) salt, which is remarkably stable in air [8]. The solutions were diluted to 10 ml with 0.5 M HCl, and the decrease of ε at several wavelengths was found to be a linear function of the reducing agent added, corresponding to complete reduction for 20.5 mg. This is 98 % of the value expected for a Ir (III, IV, IV) compound, proving the formula I discussed above.

Acknowledgements. I am very much indebted to Professor Marcel Delépine of College de France for many valuable informations and for the precious samples of iridium complexes.

Cuprous Chloride Catalysed Dimerisation of Methyl Propiolate

LARS SKATTEBÖL

SINTEF, Norges Tekniske Högskole, Trondheim, Norway

In an attempt to prepare methyl deca-2:4-diynoate by the so-called Glaser coupling [1] of methyl propiolate with *n*-hept-1-yne, Christensen and Sörensen [2] were able to obtain only tetradeca-6:8-diyne and two crystalline substances which analysed for $C_8H_8O_5$ and $C_8H_8O_6$, respectively. In order to determine the structures of these two anomalous products the Glaser coupling of methyl propiolate was investigated.

The reaction of methyl propiolate in slightly acidic aqueous cuprous chloride-ammonium chloride solution, with air as the oxygen source, gave a crystalline compound in 36 % yield. The substance

$$H_3COOC \cdot C \equiv C - H + HC \equiv C \cdot COOCH_3 \xrightarrow[NH_4Cl]{Cu_2Cl_2} H_3COOC \cdot C \equiv C \cdot CH = CH \cdot COOCH_3$$

(I)

was obtained as colourless thick needles from ether-petroleum ether, m.p. 57°. (Found: C 57.40; H 5.04. Calc. for $C_8H_8O_4$; C 57.14; H 4.80). U.V.-absorption, in ethanol: λ_{max} 2 660, 2 540, 2 440 (inflexion) Å. ε 12 900, 17 500, 16 300. The infrared spectra showed the presence of acetylenic- and ethylenic bonds in addition to bands characteristic of an ester. A strong band at 958 cm^{-1} indicated that the double bond had the *trans* configuration. [3] On the basis of this evidence we concluded that the substance was dimethyl hex-2-en-4-yne-1:6-dioate (I). This compound has been reported in the literature. [4] There are, however, small discrepancies in the melting points and ultraviolet spectra of the two compounds, but these may be due to a difference in the configuration about the double bond.

The formation of the compound can be explained by addition of one molecule of methyl propiolate to another, thus being an example of a substituted acetylene undergoing the Nieuwland dimerisation. [5] Accordingly oxygen should not play any part in the reaction. This was confirmed by running the reaction under pure nitrogen, when practically the same yield of (I) was obtained.

Just after the completion of this work, Akhtar and Weedon [6] published a report on the reaction of substituted copper acetylides with oxygen in hot acetic acid. They obtained the corresponding vinyl acetylenic compounds in good yields.

Further work on this reaction is in progress.

Acknowledgement. I am indebted to Professor N. A. Sörensen for his interest in this work.

Scavenging of Free Radicals and Radiation Protection by Nitric Oxide in Plant Seeds

B. SPARRMAN, L. EHRENBERG and A. EHRENBERG

Institute for Organic Chemistry and Biochemistry, University; and Biochemical Department, Nobel Medical Institute, Stockholm, Sweden

Under anoxic conditions nitric oxide (NO) is noteworthily untoxic to living tissue. In an exploratory study (unpublished) a treatment of resting barley seeds with NO at atmospheric pressure for several days was found neither to induce growth inhibition nor to raise the mutation rate significantly. Being a simple, fairly stable and easily diffusing free radical, *i. e.*, with possible ability to combine quantatively with free radicals in the tissue, NO is of potential value in radiobiological experiments. NO reacts in a 1:1 ratio with reactive free radicals [1]. This fact makes its modifying influence on radiation sensitivity more suited to interpretation on a quantitative basis than the corresponding [2-5] effects of the diradical oxygen, which might start chain reactions [1] and, in addition, affects the radiation sensitivity *via* its metabolic action [6].

In the present investigation the reactions of NO with free radicals was used to shed light on the mechanism by which water exerts an action on the radiation sensitivity of plant seeds. This effect consists of a decrease of the radiation sensitivity with increasing water content with a minimum at some value between 12 and 20 % water, dependent on the system studied (*cf.* Ehrenberg and Ehrenberg [7] and quoted literature).

In the latter publication measurements of electron spin resonance (esr) demonstrated that the same amount of free radicals is produced initially, irrespective of the water content, when seeds of *Agrostis stolonifera* are exposed to X-rays. In very dry seeds the radicals remain unchanged but, as the water content increases, an increasing proportion of the radicals decays in a second order reaction. The fact that the growth inhibition induced at the different water contents is found to be proportional to the (semiconstant) level of radical concentration after the decay, indicates that the protective action of water is due to an increasing recombination of free radicals.

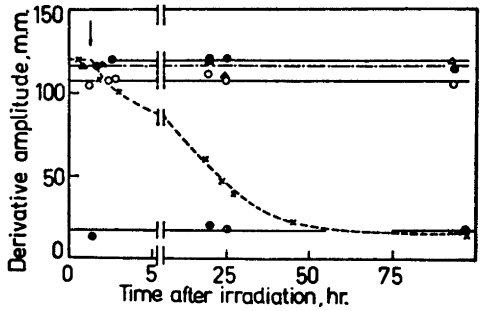

Fig. 1. Time dependence of derivative amplitude of esr absorption in dry seeds (4.5 % H_2O) of *Agrostis stolonifera*, X-irradiated and stored in different atmospheres. ◑ unirradiated seeds stored in N_2; ● irradiated in air, stored in air; ○ irradiated in N_2, stored in air; △ irradiated in N_2, stored in N_2; × irradiated in N_2, stored in NO. The arrow indicates the moment when the gas was changed over the three latter samples.

In the present studies we determined the rate of entrance into the seeds of NO and/or its rate of reaction with radiation produced paramagnetic centers. Dry seeds (4.5 % H_2O) were irradiated with 150 000 r of X-rays (185 kV, 2 mm Al filtration, 800 r min^{-1}) in N_2. After determination of the esr absorption the N_2 filling of the glass tube was replaced by NO, and the decay of the signal was followed for a few days. Total decay down to the control value [8] required about 48 h at 20°C (Fig. 1), at higher water contents the reaction was more rapid. The fact that the signal height was equal to the (stable) N_2 value when N_2 was replaced by air after irradiation or when irradiation was performed in the presence of air, indicates that free oxygen is not present in the tissue [7] or that the radicals are changed into an equal amount of peroxy radicals.

In a second experiment seeds were irradiated at different water contents, and the influence of the gas (N_2, NO, or air) present during irradiation was studied by determination of the dose causing 50 % reduction of the seedling growth (measurement at 15 mm control height). In order to secure penetration of NO into the tissue

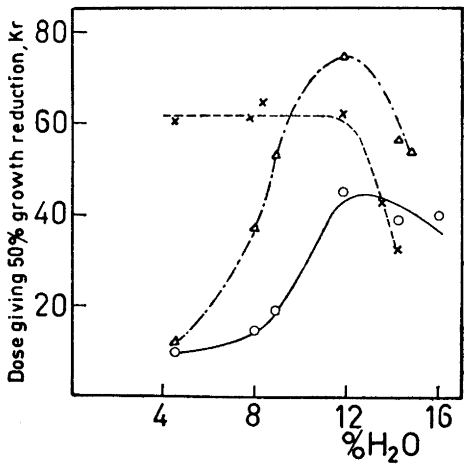

Fig. 2. The dose of X-rays required for 50 % growth inhibition of seeds of *Agrostis stolonifera* as a function of their water content. The seeds were irradiated and stored (see text) in air O, in N_2 △, and in NO ×.

and a quantitative reaction with the radicals, the seeds were kept in the different gases for 48 h, and irradiation was performed in the middle of that period.

In Fig. 2 the radiation sensitivities are shown. In N_2 and air a clear minimum sensitivity (*i. e.*, maximum of 50 % dose) is registered at 12 % H_2O. In the presence of NO, however, about maximal protection was found at all water contents below 12 %, and under these conditions esr signals close to the control values were invariously found.

This influence of the radical scavenger, NO, connects directly the radiation produced free radicals with a large part of the biological effect. Within this range of water content the destruction of radicals leads to a protection, either this occurs by a recombination (which is facilitated by the presence of hydration water) or by reaction with a scavenger. The sensitivity increasing effect of oxygen does not necessarily depend on immediate reactions with radicals, since the air was not removed by evacuation before sowing. Thus the seeds irradiated in air had a higher oxygen content than the N_2 seeds, at the start of germination. Under similar conditions after-effects of O_2 have been observed [9].

At water contents above the minimum, where the radiosensitivity is again higher, NO increases the radiosensitivity in a manner similar to that of O_2, and in agreement with results of other investigators [2-5]. When the H_2O content exceeds 12 %, more loosely bound H_2O becomes present, permitting new types of reactions. Below 12 % H_2O, the reaction constant for radical recombination is independent of the water content [7], indicating that H_2O is exclusively present as a single, more or less complete layer of hydration water. Above 12 % H_2O, the reaction constant increases with increasing water content.

These preliminary investigations are being continued on a quantitative basis.

The investigation was aided by grants from the *Swedish Agricultural Research Council*, the *Swedish Natural Science Research Council*, and the *Magnus Bergvall Foundation*.

Structure of the Hexathionate Ion in the *trans*-Dichloro-dien-cobalt(III) Salt

OLAV FOSS and KJARTAN MARØY

Chemical Institute, University of Bergen, Bergen, Norway

In the potassium barium salt, $K_2Ba(S_6O_6)_2$, the sulphur chain of the hexathionate ion has a *cis-cis* configuration as in the S_8 ring of orthorhombic sulphur.[1] It has now been found that the extended *trans-trans* rotational isomer occurs in the crystals of *trans*-dichloro-dien-cobalt(III) hexathionate monohydrate.

This salt, $(Coen_2Cl_2)_2S_6O_6.H_2O$, is orthorhombic, with the unit cell dimensions:[2] a = 12.12 Å, b = 19.13 Å, c = 6.43 Å, and two formula units per unit cell. The space group is C_{2v}^8 — $Pba2$, which requires that the hexathionate ions and the water molecules lie on twofold axes of symmetry.

The intensities of 149 observed $hk0$ reflections out of 187 attainable with Fe$K\alpha$ radiation were estimated visually from zero-layer Weissenberg photographs, taken of a prism {110} with edges 0.08 × 0.09 mm (μr approx. 0.7). The cobalt x and y coordinates were found from the $hk0$ Patterson map, the Co-Co $2x,2y$ vector being also the centre vector of the centro-symmetric cation and the peak therefore large. Using cobalt as a searcher atom, the two chlorine atoms were located by means of the vector convergence method.[3] The cobalt and chlorine contributions gave the probable signs of one fourth (37) of the strongest $hk0$ reflections, and a Fourier synthesis based on these indicated the positions of the three sulphur atoms of the asymmetric unit and thereby the signs of 40 additional reflections; none of the signs changed later. The second Fourier map allowed the location of the lighter atoms, and Fourier refinement and next Fourier difference refinement were then carried out.

The $hk0$ Fourier map is shown in Fig. 1, and the x and y coordinates of the heavier atoms are listed in Table 1, together with the temperature constants B used in the calculation of structure factors. The B values, assigned on the basis of the differ-

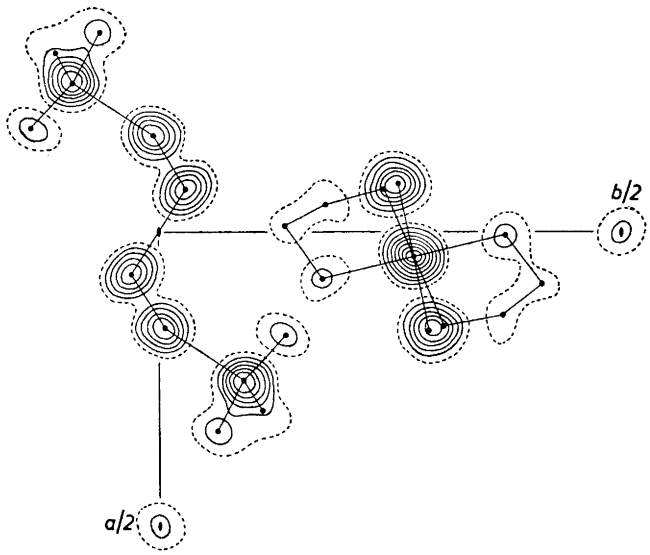

Fig. 1. Electron density projection of *trans*-dichloro-dien-cobalt(III) hexathionate monohydrate along the c axis. Contours are at intervals of 4 e · Å^{-2} for the cobalt and chlorine atoms and 3 e · Å^{-2} for the other atoms, beginning with 4 e · Å^{-2} (dashed).

Table 1. Atomic coordinates, in fractions of cell edges, and temperature constants B, in Å^2. Origin on a twofold axis.

	x	y	B
Co	0.0410	0.2757	
Cl_1	0.1660	0.2930	3.5
Cl_2	—0.0840	0.2584	
S_1	0.2530	0.0917	3.0
S_2	0.1638	0.0050	3.5
S_3	0.0722	—0.0289	4.0

ence maps, indicate an increased thermal vibration of atoms at the middle of the sulphur chain relative to the ends. Ignoring contributions from the 17 hydrogen atoms of the asymmetric unit, the reliability index R is 0.10 for the $hk0$ data.

The z coordinates of the atoms will be determined later from a projection along the a axis. The middle sulphur-sulphur bond of the hexathionate ion lies across the twofold axis and the length is independent of the sulphur z coordinate; the x and y coordinates of S_3 give a length of 2.07 ± 0.02 Å for this bond.

Studies on Succinic Acids

II.* Equilibrium Constants for the Interconversion of *Meso*- and *Racem*-α,α'-dialkylsuccinic Acids

LENNART EBERSON

Department of Organic Chemistry, Chemical Institute, University of Lund, Sweden

This paper deals with the determination of the equilibrium constants of the reaction *meso* acid $\rightleftharpoons$ *racemic* acid for α,α'-dimethyl-, α,α'-diethyl-, and α,α'-di*iso*propylsuccinic acid at 170° in the solvents dioxane, water, and 5 N aqueous hydrochloric acid. In certain cases the interpretation of the results is complicated by the occurrence of simultaneous anhydrization, but it is clearly established that the *racemic* forms are relatively more stable, contrary to the findings of several other investigators. The stability order found can be explained by assuming the existence of an intramolecular hydrogen bond which selectively stabilizes one of the *racemic* acid conformations. A similar stabilizing effect is not probable for any of the *meso* acid conformations.

It has been known for a long time that diastereoisomers of α,α'-disubstituted succinic acids can be converted into each other under certain conditions, *e. g.* by heating with hydrochloric acid at elevated temperatures. Wagner-Jauregg [1] has cited a number of cases of such interconversions, which all point to the *meso* forms being the most stable ones. Linstead and Whalley [2] have stated without experimental proof that the *meso* form of α,α'-dimethylsuccinic acid should be the more stable isomer. Later on, Golden and Linstead [3] have semiquantitatively investigated the equilibration of *mesoid* and *racemoid* α-methyl-α'-ethylsuccinic acid under varying conditions. In two cases the equilibrium mixture contained more than 50 % of the *racemoid* form, *i. e.*, the stability order was in line with that of the corresponding anhydrides and contrary to the cases cited above. Barton and Cookson [4] used the data of Wagner-Jauregg as evidence for the stability order of *erythro* and *threo* isomers predicted from the conformational point of view. According to this reasoning the *erythro (meso)* form should be the more stable one.

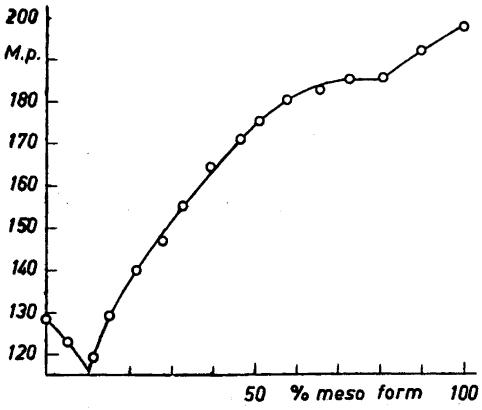

Fig. 1. Melting point diagram for *meso*- and *racem*-α,α′-dimethylsuccinic acid.

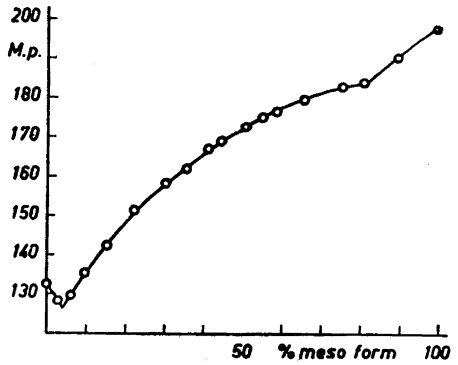

Fig. 2. Melting point diagram for *meso*- and *racem*-α,α′-diethylsuccinic acid.

However, a critical examination of the original literature [5–13] on equilibrations of α,α′-dialkylsuccinic acids revealed that the table set up by Wagner-Jauregg was based on an unreliable experimental material of great inhomogeneity. Thus, in most cases it has not been established whether the inversions are reversible or not, the analysis of the equilibrated samples has been made by

preparative methods, which only qualitatively give the direction of the changes, the temperatures and times used for equilibration have been extraordinarily varying, and the inversions have been carried out with strong hydrochloric acid as solvent, which might influence the equilibrium state. Besides, in several cases the equilibria actually were at about 50 % inversion [7,8] and in one case (α,α'-di*iso*propylsuccinic acid) in favour of the *racemic* acid [11].

This paper, which is part of an investigation on the stereochemistry of alkylsubstituted succinic acids, describes an attempt to measure the equi-

acid $\rightleftharpoons$ *racemic* acid at 170° in various solvents.

% *meso* acid in the equilibrium mixture			Equilibrium constant K_0

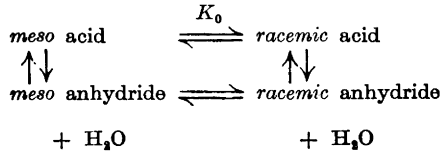
librium constants for the interconversion of the *meso* and *racemic* forms of α,α′-dimethyl-, α,α′-diethyl-, and α,α′-di*iso*propylsuccinic acids at 170° in the solvents dioxane, water, and 5 N hydrochloric acid. The composition of the equilibrium mixtures was determined by thermal analysis and/or by potentiometric titration in the case of α,α′-di*iso*propylsuccinic acid. The shape of the melting point curves and the states of the equilibria are such as to permit the evaluation of the constants in an unambiguous manner. The melting point diagrams are shown in Figs 1, 2, and 3, and the results of the inversion experiments in Table 1.

These data clearly indicate that the inversions really are reversible and that the equilibrium mixtures in all cases contain 50 % or more of the *racemic* acid. Furthermore, there is a trend to an increase of the constant when the steric requirements of the substituents are enhanced. Unfortunately, the two forms of α,α′-di-(*tert.*-butyl)-succinic acid do not equilibrate at 170°, but experiments carried out at 220—230° showed that both isomers are converted into the *racemic* anhydride with no observable contamination of *meso* acid. The values for α,α′-di*iso*propylsuccinic acid are probably somewhat too small as the analytical method necessitated treatment of the equilibrated samples with aqueous base and subsequent acidification with dilute hydrochloric acid, filtration, and washing with water. This procedure should be expected to influence the final result in direction towards lower constants, as the *meso* acid is less soluble in water than the *racemic* acid.

DISCUSSION

The reason for putting some values in Table 1 in parentheses is the complication introduced in these cases by the formation of anhydride during equilibration, which makes the significance of the corresponding equilibrium constants somewhat questionable. The procedure has been to convert the mixture of acid and anhydride into acids by treatment with water or aqueous base and then analyzing the product of hydrolysis as outlined above. The measured constant will then refer to the system *meso* material ⇌ *racemic* material. This behaviour immediately actualizes the question: Could not the stability order found be explained in all cases, even when anhydride formation is not observed, by assuming the existence of the equilibrium in aqueous or dioxane



solution at 170°? In that case the driving force would be the formation of the *racemic* anhydride, which is the stable form of the anhydrides. When the equilibrium has been frozen in and the system returned to room temperature, the anhydrides would have the possibility of passing into the acids again during the analytical work, except when their rate of hydrolysis is low. There is

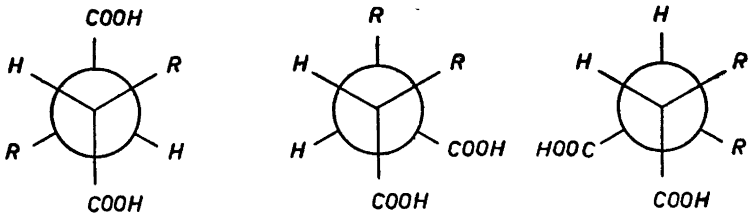
evidence for the existence of an equilibrium between acid and anhydride in aqueous solution at elevated temperatures in a number of cases [14]. For example, steam-distillation of an aqueous solution of tetramethylsuccinic acid gives tetramethylsuccinic anhydride, which is then slowly hydrolyzed by cold water again.

It would hardly be possible to develop a method for the unambiguous determination of an eventual equilibrium between acid and anhydride at 170° which does not interfere with the reaction. However, the fact that equilibration of the α,α'-dimethylsuccinic acids in absolute dioxane yields acid mixtures with no contamination of anhydride makes it probable that the equilibrium *meso* acid $\underset{\rightleftharpoons}{\overset{K_0}{}}$ *racemic* acid is not influenced to any appreciable extent by anhydrization in those cases where it has not been observed.

Koskikallio [15] has measured the rate of hydrolysis of acetic anhydride in dioxane containing 0.07 % of water and found a second order rate constant of about 10^{-5} l · mole^{-1} · sec^{-1} at 100° and 10^{-7} l · mole^{-1} · sec^{-1} at 40°. Comparison of the rate constants for the hydrolysis of acetic anhydride in various solvent mixtures with those of succinic anhydride under similar conditions indicates that they always are of the same magnitude [15]. The rate constants of the hydrolysis of the two α,α'-dimethylsuccinic anhydrides in water at 25° in turn are of roughly the same order as those of acetic and succinic anhydride [14,16]. If now the equilibration of α,α'-dimethylsuccinic acids in dioxane would lead to partial anhydride formation, the anhydride portion would not have time to be hydrolyzed during the working-up period (about 4 h), provided the above reasoning holds. In fact, even if an average rate constant of 10^{-3} l · mole^{-1}·sec^{-1} for hydrolysis during this period is allowed, the half-life time would still be about 4 h. Thus it can be concluded with tolerable certainty that those equilibrium constants which have not been put in parentheses actually refer to the reaction *meso* acid $\underset{\rightleftharpoons}{\overset{K_0}{}}$ *racemic* acid, and that the others must be interpreted with regard to the complication discussed above.

As already mentioned the results of the earlier investigations in this field have been explained on the basis of conformational analytical considerations [2,4]. Accordingly, the *meso* acid would be the more stable isomer, as in its most favoured conformation (I a) all substituents are situated in *trans* staggered positions, thereby allowing a minimum of non-bonded interactions.

The conformations of the *racemic* acids (II, a—c) are all energetically less favoured than I a, provided these interactions are *repulsive*, *i. e.*, it must be assumed that the carboxyl groups behave like alkyl groups in this connection. This reasoning cannot be true, as the relative stabilities of the acids reported in this paper are the same as those of their anhydrides. The departure from the expected behaviour must be due to *attractive* forces between the carboxyl groups, and it is plausible to assume that intramolecular hydrogen bonding is responsible for this effect. The *racemic* acid conformation II b would then be the most favourable arrangement, as it contains a ring system with two *trans*-situated alkyl substituents. The concept of a seven-membered hydrogen-bonded ring system existing in aqueous solution is perhaps not quite acceptable on these grounds alone, and the topic will be discussed more in detail in



I a *I b* *I c*

The conformations of the *racemic* acid.

papers III[17] and IV[18] of this series, where dissociation constants and infra-red data will be presented. In fact, the infra-red spectra give further evidence for the existence of an intramolecular hydrogen bond in solutions of peralkyl-substituted succinic acids.

EXPERIMENTAL

Materials. Commercial dioxane of *purissimum* quality was purified according to Vogel [19] but the treatment with sodium was repeated once more. The α,α'-dialkylsuccinic acids were prepared and purified as described in paper I [20].

Determination of the melting point diagrams. It has been pointed out earlier that the melting points of alkyl-substituted succinic acids are rather sensitive to the method of determination and the heating conditions owing to the decomposition into anhydride and water near the melting point [20]. However, if the melting point was determined in a sealed capillary, it was found to be satisfactorily reproducible. Naturally the true melting point is not measured by this procedure but instead a mixed melting point for a complex system with the components acid, anhydride, and water. The good reproducibility points to an equilibrium being established, but this problem requires further investigation before it can be fully discussed. For analytical purposes the method is satisfactory provided all determinations are made as identical as possible. Each point of the diagrams was obtained in the following way:

The mixture of the *meso* and *racemic* acid (total 20 mg) was accurately weighed into a small weighing-glass, and one ml of analytical grade acetone was added. If the acids did not dissolve immediately, the mixture was warmed for a few seconds, until complete solution was achieved. The acetone was evaporated in a slow stream of air and the residue finally dried over concentrated sulphuric acid *in vacuo* for 10—12 h. The crystal mass was finely ground and introduced into melting point capillaries (two determinations

were made for each mixture) which were sealed in a micro-burner. The whole capillary must be immersed into the heating-block in order to avoid distillation or sublimation during the heating period. The capillary was introduced into the melting point apparatus at a temperature about 10° below the melting point, which was first roughly estimated in the Kofler apparatus. The heating rate was 1°/min. The melting point was taken as the temperature at which the last crystals disappeared, and this value was generally reproducible within ± 1°.

Equilibration of meso- *and* racem-*α,α'-dialkylsuccinic acids.* Samples of *meso* and *racemic* acid, 20 mg of each, were introduced into glass ampoules made from 10 mm Pyrex tubing and with a volume of about 3 ml. The solvent (dioxane, water, or 5 N hydrochloric acid), 2.0 ml, was added and the ampoules were sealed in a burner. The thermostat consisted of a large brass block which was heated electrically by means of two heating spirals of Kanthal wire, and was fitted with a contact thermometer (graded in 0.1° in the range 150−200°) and a calibrated thermometer (gradation as above). The block was very carefully isolated with diabas wool and placed in a sheet container. Preliminary experiments had indicated that equilibration occurred with reasonable speed at 170°. With the described apparatus this temperature was maintained within 0.1°, which was quite sufficient for the purpose of this study. The sealed ampoules were placed in a small steel-bomb, which fitted snugly into a hole in the brass block. After some experiments the times for reaching equilibrium were established at 120 h with dioxane as solvent, and 48 h with water or 5 N hydrochloric acid. After the heating period the bomb was removed and rapidly cooled in ice-water (this procedure lasts about 1 min), the ampoules were opened and the contents poured into small beakers. The ampoules were rinsed with a few ml of dioxane. The solvent was then evaporated *in vacuo* over concentrated sulphuric acid and sodium hydroxide pellets for 4 h in the case of dioxane and 12 h in the case of water and 5 N hydrochloric acid. The procedure then differed somewhat for different acids.

For α,α'-dimethylsuccinic acid the residue in all cases consisted of a mixture of the acids with no contamination of anhydride, which is shown by the fact that another treatment with water and subsequent evaporation did not change the melting point.

For α,α'-diethylsuccinic acid the residue from equilibration in dioxane was a mixture of water and anhydride, which first had to be converted into acids by treatment with water and subsequent evaporation. From the equilibrations in water and 5 N hydrochloric acid mixtures of the acids were directly obtained. Consequently, the melting points of these mixtures, determined as described above in connection with the melting point diagrams directly give the composition of equilibrium for α,α'-dimethylsuccinic and α,α'-diethylsuccinic acid.

For α,α'-di*iso*propylsuccinic acid the residue was in two cases a mixture of acid and anhydride. As the anhydride portion could not be hydrolyzed by water alone a small amount of aqueous potassium hydroxide was added. When the anhydride had dissolved, the acid mixture was precipitated by the addition of a few drops of dilute hydrochloric acid, the crystals were filtered, washed with some water and finally dried *in vacuo*. However, the melting points of these mixtures were too low to be compatible with the melting point diagrams, which was probably due to the presence of minute amounts of anhydride. Fortunately, the dissociation constants of *meso*- and *racem*-α,α'-di*iso*propylsuccinic acid in 50 % ethanol (see paper III[17]) are of an order to permit analysis by means of potentiometric titration. Experiments with mixtures of known composition gave results with an accuracy of about ± 2 %. As is seen from Table 1, the two methods of analysis give agreeing results in the case where both have been applied.

The author wishes to express his sincere gratitude to Professor Erik Larsson for his kind interest in this work. A grant from *Kungliga Fysiografiska Sällskapet* is gratefully acknowledged.

Studies on Succinic Acids

III.* Application of the Kirkwood-Westheimer Theory to the Anomalously High K_1/K_2-Ratios Exhibited by Certain Alkylated Succinic Acids

LENNART EBERSON

Department of Organic Chemistry, Chemical Institute, University of Lund, Sweden

The first and second dissociation constants of a number of 1,2-dicarboxylic acids have been measured in 50 % ethanol. It was found that *racem*-α,α'-dialkylsuccinic acids, containing alkyl groups with large steric requirements, and tetraalkylsuccinic acids have K_1/K_2-ratios of very great magnitudes, the ratio for *racem*-α,α'-di-(*tert.*-butyl)-succinic acid being the highest ever observed. By application of the Kirkwood-Westheimer theory to these molecules it is found that electrostatic effects alone cannot be responsible for this anomaly, but together with the assumption of an intramolecularly hydrogen-bonded monoanion the theory is in satisfactory agreement with experimental data.

The ratio between the first and second dissociation constants of a dibasic acid has been the basis of several attempts to calculate the distance between the dissociating protons [1–6]. This topic has been reviewed by Brown, McDaniel, and Häfliger (up to 1953) [7] and earlier by Adell [8] and Kortüm [9]. The high K_1/K_2-ratios exhibited by certain highly alkylated short-chain dicarboxylic acids which could not be accounted for by the original simple theory have given rise to a more complicated treatment by Kirkwood and Westheimer [10–12]. This theory treats the molecules as spherical or ellipsoidal cavities of low dielectric constant (assigned a value of 2.0, as for *n*-paraffines), imbedded in a medium of high dielectric constant, *i. e.*, the concept of an "effective" dielectric constant, which is a function of the size and shape of the molecule, was introduced. According to this treatment, the accommodation of alkyl groups in the carbon chain increases the size of the molecule, thereby allowing a greater part of the electrostatic effect to be transmitted through the cavity of low dielectric constant. With this theory reasonable values of the interprotonic

* Part II. *Acta Chem. Scand.* 13 (1959) 203.

distances could be calculated even for acids with high K_1/K_2-ratios, though it involved a number of important assumptions regarding the size and shape of the molecules. For instance, the calculations were based on molecules with the carboxyl groups in *trans* position, though chemical evidence pointed to other models with the carboxyl groups in *gauche* position. Furthermore, the theory has been critisized for the fact that it does not explain the influence of solvent and temperature on the K_1/K_2-ratio in a satisfactory manner [13, 14]. Peek and Hill [15] have considered the effect of rotation about the central carbon-carbon bond in succinic acid, and stated that the Kirkwood-Westheimer theory, together with an acceptable value of the energy barrier against internal rotation (about 2 kcal/mole) was in good agreement with experiment.

Davison [16], Hunter [17], McDaniel and Brown [18], and Brown, McDaniel, and Häfliger [7] have discussed hydrogen bonding as a factor in the ionization of dicarboxylic acids and proposed that an anomalously high K_1/K_2-ratio was best explained by assuming the existence of an intramolecular hydrogen bond in the monoanion. As a summary of the discussions of these authors the formation of such a structure should be favoured by the following factors:

1. The fixation of the carboxyl groups in *cis*-position.
2. The prevention of rotation of the carboxyl groups.
3. The existence of steric strain in the molecule, which should in part be relieved by the formation of a cyclic structure.
4. Lowering of the dielectric constant of the solvent.

The investigations by, among many others, Wotiz and Merrill [19] on highly branched malonic acids, Cookson and Trevett [20] on a dicarboxylic acid derived from a *Delphinium* alkaloid and having the carboxyl groups rigidly held in positions near each other, and Mizutani [21] on the strength of maleic acid in methanol-water mixtures of varying composition, confirm these statements.

However, Westheimer and Benfey [22] recently have shown that the ratio K_1/K_E, where K_E is the ionization constant of the monomethyl ester of the acid in question, forces an upper limit upon the effect of hydrogen bonding on the K_1/K_2-ratio, so that it should contribute only to a fraction of the total observed effect.

These discussions have been based on essentially the same material, published before 1940, and surprisingly few new data have appeared since that time. In paper I of this series [23] the author has described the preparation of a number of α,α'-dialkyl- and tetraalkyl-substituted succinic acids with structures suitable for obtaining more information regarding the factors which influence the K_1/K_2-ratio. The thermodynamic dissociation constants of these acids have now been measured in 50 % ethanol by weight by the electrometric titration method in cells with liquid junctions. The experimental conditions were mainly those used by Speakman [24, 25] in the determination of K_1 and K_2 for a few dibasic acids in aqueous ethanol, but a simpler calculation method was used. The use of 50 % ethanol was necessary, as a number of the investigated acids were almost insoluble in water. Succinic, *cis*- and *trans*-caronic acid, maleic and fumaric acid have been included for comparison. The author has previously reported the preparation of a number of α,α'-dialkylglutaric acids [26, 27], from which the two forms of α,α'-di-(*tert.*-butyl)-glutaric acid were

chosen for pK-measurement, representing glutaric acids with a large bulk of alkyl substituents. The values of pK_1, pK_2, ΔpK and K_1/K_2 are shown in Table 1 together with the results of earlier determinations in water.

The monomethyl esters of *meso*- and *racem*-α,α'-dimethyl-, *meso*- and *racem*-α,α'-diethyl-, *meso*- and *racem*-α,α'-di*iso*propyl-, *meso*- and *racem*-α,α'-di-(*tert.*-butyl)-, tetramethyl-, and tetraethylsuccinic acid have been prepared and their pK_E-values determined in 50 % aqueous ethanol, as shown in Table 2. Furthermore, some of the acids listed in Table 1 were titrated electrometrically in pyridine with tetrabutylammonium hydroxide (TBAH)* in methanol-benzene solution. This titration method has recently been applied to dibasic acids [29–31] and has been found to give two sharp inflection points in the titration curves of a number of acids, namely *m*- and *p*-hydroxybenzoic, malic,

* These titrations were carried out at the Department of Analytical Chemistry, University of Lund.

oxalic, malonic, maleic, fumaric, succinic, *o*-phthalic, and sulphuric acid. Salicylic acid titrated as a monobasic acid and had a very large break in the titration curve. The results of the TBAH-titrations are given in the form of titration curves in Figs 1 and 2.

The most striking fact in Table 1 is the enormous increase of the K_1/K_2-ratio of the *racemic* acids when the steric requirements of the alkyl substituents are increased, the value for *racem*-α,α′-di-(*tert.*-butyl)-succinic being the highest ever observed, while on the contrary the corresponding *meso* forms have ratios of about the same relatively small magnitude. The K_1/K_E-values listed in Table 2 show the same general trend. Among the tetra-alkylated acids the trend is a substantial increase of the K_1/K_2-ratio with higher "degree of alkylation" and a much greater ratio for the open-chain acids than the cyclic ones. As is seen from Fig. 1, this corresponds to a change in titration curve type for the *racemic* acids from a curve with two inflection points to a curve with one

very strong break (compare salicylic acid). The curves of the *meso* acids all have two inflection points. Fig. 2 shows the titration curves of the tetra-alkylated acids, which all have very strong breaks for the first equivalence point but the second ones either very small or totally absent. Also in 50 % ethanol *racem*-α,α'-di-(*tert.*-butyl)-succinic acid titrates as a monobasic acid, thus resembling the highly branched malonic acids investigated by Wotiz and Merrill [19].

DISCUSSION

Kirkwood and Westheimer based their calculations of interprotonic distances in symmetrical dibasic acids on the formula

$$\log \frac{K_1}{\sigma K_2} = \frac{e^2}{2.303\, k\, T\, R\, D_E} \qquad (1)$$

where K_1 and K_2 are the first and second dissociation constants, e the electronic charge, k the Boltzmann constant, R the interprotonic distance, and σ a statistical factor, in this instance equal to four. D_E is the effective dielectric constant and is a function of the shape of the molecule, the positions of the protons within the molecule, the dielectric constant of the solvent, and the dielectric constant of the acid molecule. For the calculations of D_E it was necessary to assume the shape of the molecule to be either a sphere or a prolate ellipsoid of revolution, owing to the mathematical difficulties associated with other models. In the former case D_E is calculated as a function of the positions of the protons within the sphere, in the latter as a function of the excentricity of the ellipsoid. An intersection of the spherical model is shown schematically in Fig. 3.

In this Figure b is the radius of the sphere (estimated from the partial molar volume obtained according to Traube [32]), r the distance from the center of the sphere to the ionizable protons, ϑ the angle between the distances r, and R the interprotonic distance. In the case of the ellipsoidal model the mathematical treatment requires the protons to be placed at the foci of an ellipsoid of revolution with the excentricity λ_0. The interfocal distance is R, and λ_0 is obtained from the formula

$$\lambda_0^3 - \lambda_0 = \frac{6\, V}{\pi\, R^3} \qquad (2)$$

where V is the partial molar volume.

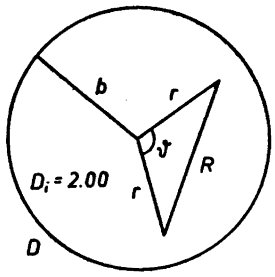

Fig. 3.

For a number of succinic acids (*meso-* and *racem-α,α'*-diethylsuccinic acid, tetramethylsuccinic acid) the spherical model was used and in other cases (*meso-* and *racem-α,α'*-dimethylsuccinic acid, succinic acid) the ellipsoidal one, but in all cases the carboxyl groups were supposed to be *trans* to each other [12].

Now there is evidence that a number of the acids investigated in this paper and also some of those treated by Kirkwood and Westheimer should have *gauche* carboxyl groups *in their most favoured conformations.* Thus equilibration of *meso-* and *racem-α,α'*-dialkylsuccinic acids indicates that the *racemic* form is the more stable isomer [33] contrary to the stability order predicted by conformation analytical reasoning [34,35]. The presence of an intramolecular hydrogen bond in the preferred conformation of the *racemic* acid could explain this anomaly. The extreme ease of anhydrization of certain succinic acids [23] also makes it reasonable to assume that the carboxyl groups have been forced into *gauche* position, partly by the possibility of an intramolecularly hydrogen-bonded ring structure being formed, which should relieve part of the steric strain in the open-chain acid, partly by the orienting effects of large alkyl groups. For example in *α,α'*-di-(*tert.*-butyl)-succinic acid the bulky alkyl groups should entirely determine the conformation of the molecule, and consequently in the *meso* acid the carboxyl groups become orientated *trans* to each other, and in the *racemic* from *gauche* to each other.

Table 3 gives the calculated ΔpK-values in 50 % ethanol for a number of the acids investigated in this paper. D_E-functions were worked out for the solvent 50 % ethanol *. These curves are shown in Figs 4 and 5. The geometrical

* The author wishes to express his thanks to Laborator C.-E. Fröberg and Fil.mag. E. Larsson at the Institute of Numerical Analysis, University of Lund, for their kind help with the calculation of the D_E-function in the ellipsoidal case.

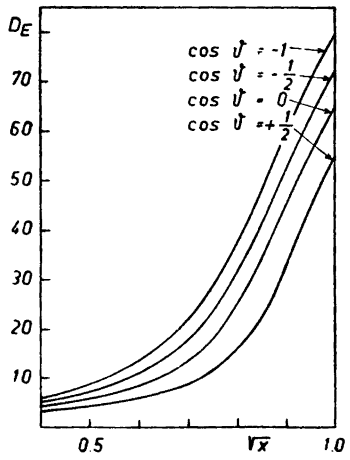

Fig. 4. Plot of D_E *versus* $\sqrt{x} = r/b$ for $\cos\vartheta = +\frac{1}{2}, 0, -\frac{1}{2}, -1$. $D_i = 2.00$; $D = 50.4$.

relations between the carboxyl groups were obtained from the bond lengths and angles in succinic acid. The proton was placed on the extension of the bond between the carboxyl carbon atom and its nearest carbon neighbor at a distance of 1.45 Å from the former one. The factors for the correction of the effect of hydrogen bonding in the monoanion were calculated from the K_1/K_E-values in Table 2 according to Westheimer and Benfey. This correction is calculated for the case that hydrogen bonding exists in the monoanion but not in the free acid and its monomethyl ester. As mentioned above, available data [33, 36] point to the existence of an intramolecular hydrogen bond also in the diacid, which should reduce the magnitude of the correction. However, with regard to the approximate nature of this theory, no attempt was made to estimate this effect. It is also quite obvious that a measured Δ pK in reality does not refer to a single conformation but to an equilibrium mixture between several rotation isomers of acids and ions with or without interactions between

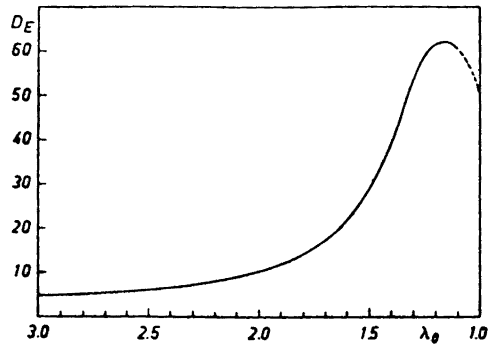

Fig. 5. Plot of D_E *versus* λ_ϑ. $D_i = 2.00$; $D = 50.4$.

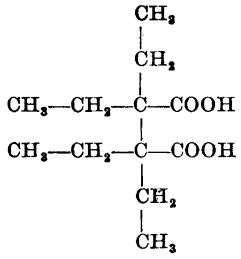
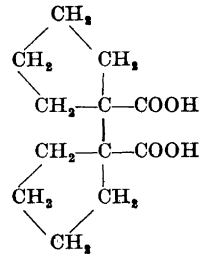
the carboxyl groups. By comparing calculated and measured ΔpK-values it should, however, be possible to get an idea about which conformations are the most preferred ones.

Turning to Table 3, it must first be established by examination of molecular models whether the various conformations approximate the shapes of spherical or ellipsoidal molecules. It is found that the spherical model is best suited for conformations with *gauche* carboxyl groups and that the ellipsoidal model with the protons at the foci is difficult to associate with the shape of these molecules. For the conformations with *trans* carboxyl groups it was similarly found that both models could be used. By inspection of Table 3 it is obvious that a preferred conformation with *gauche* carboxyl groups together with the assumption of an intramolecular hydrogen bond in the monoanion is in satisfactory agreement with the observed ΔpK-values for the *racem*-α,α'-dialkyl- and tetraalkylsuccinic acids. Electrostatic effects alone cannot account for the large K_1/K_2-ratios in these cases. Likewise, it is probable that the *meso* acids have *trans* carboxyl groups in their most favoured conformations, though *meso*-α,α'-dimethylsuccinic acid appears to be capable of existing also in a conformation with *gauche* carboxyl groups.

Thus, the main cause of an anomalously high K_1/K_2-ratio appears to be steric in origin. If the steric properties of a dibasic acid are such as to permit a close approach of the carboxyl groups, the pure electrostatic effect transmitted through the solvent and the molecule itself will increase. Besides, formation of an intramolecular hydrogen bond will be possible, which further magnifies the K_1/K_2-ratio. In the case of highly alkylated dibasic acids it is tempting to compare this effect with the empirically found rule that accommodation of alkyl substituents in a carbon chain capable of ring closure facilitates ring formation [37]. The theoretical background of this rule is not entirely understood, but probably steric strain in the open-chain compound, which is relieved in part in the cyclic structure, together with the existence of preferred conformations with the reacting groups in *gauche* position, is responsible for this effect. The behaviour of the tetraalkylated succinic acids investigated in this paper is consistent with this hypothesis. For example, if in tetraethylsuccinic acid the ethyl groups on each carbon atom are bent back and united with a C—C bond we obtain the structure of $\alpha,\alpha,\alpha',\alpha'$-bis-(tetramethylene)-succinic acid





By analogy with the investigations on the base strengths of triethylamine and quinuclidine carried out by Brown and Sujishi [38] it may be concluded that the

steric strain should be diminished by this structural change. Actually a much smaller K_1/K_2-ratio is found for $\alpha,\alpha,\alpha',\alpha'$-bis-(tetramethylene)-succinic acid *.

Lastly, it must be pointed out that the above discussion has neglected the effect of interactions between solvent and solute and of medium changes in the vicinity of the carboxyl groups. As very little is known about the conditions at the boundary surfaces it is, however, difficult to include such a discussion. At present the Kirkwood-Westheimer theory, together with the assumption of an intramolecularly hydrogen-bonded monoanion for molecules with carboxyl groups near each other, accounts for the observed effects, though in a crude manner. Specifically, the theory constitutes a valuable tool for the assignment of conformations in dibasic acids.

EXPERIMENTAL

Materials. Commercial absolute ethanol was freed from water by the magnesium ethylate method and distilled. Equal weights of the ethanol and carbon dioxide-free water were mixed and stored in a container protected from the carbon dioxide of the air. To prepare the standard sodium hydroxide solution the calculated volume of 50 % aqueous carbonate free sodium hydroxide for obtaining a 0.05 N solution was added, followed by the amount of absolute ethanol needed for restoring the original solvent composition.

The preparation and purification of the acids have been described (except those mentioned below) by the author in earlier papers. Before pK-measurement they were recrystallized once more from the appropriate solvents and dried *in vacuo* over concentrated sulphuric acid. Succinic acid was analytical grade reagent, *cis*- and *trans*-caronic acid were prepared and purified according to Fredga and Sikström [39] and commercial samples of maleic and fumaric acid were recrystallized twice from benzene and water, respectively.

The monomethyl esters listed in Table 3 were prepared according to either of the following methods. *Meso*-α,α'-di-(*tert.*-butyl)-succinic acid which does not form an anhydride, was converted into the monosilver salt (contaminated by the disilver salt) and

treated with methyl iodide. A fair yield of the monomethyl ester was obtained, which was recrystallized twice from methanol.

The other acids were converted into anhydrides by boiling with acetyl chloride, the excess of acetyl chloride was removed *in vacuo*, and the crude anhydride allowed to react with the calculated amount of sodium methylate in absolute methanol. The solution was evaporated to dryness in a vacuum desiccator at room temperature and the residue acidified with dilute hydrochloric acid. The monomethyl ester was then isolated and purified by distillation or recrystallization from aqueous methanol. Melting points and analyses are shown in Table 4.

Method. Speakman [24] has developed a graphical method for the evaluation of the dissociation constants of dibasic acids from pH-measurements which is especially well adapted for acids with small K_1/K_2-ratios, say < 50. As the purpose of the present investigation was more to get an idea of the relative magnitudes of K_1 and K_2 for a series of dibasic acids rather than to make very precise measurements, and as the K_1/K_2-ratios in question are generally $\gg 50$, the author has used the simple formulae (3) and (4) for the calculations of K_1 and K_2,

$$K_1 = \frac{a_{H^+} (b + [H^+]) f_1}{(a - b - [H^+]) f_0} \quad (3)$$

$$K_2 = \frac{a_{H^+} (b - a - [OH^-]) f_2}{(2a - b + [OH^-]) f_1} \quad (4)$$

where a_{H^+} is the hydrogen ion activity, as measured by the glass electrode, a the total molar concentration of acid, b the molar concentration of added base, and f_0, f_1, and f_2 the activity coefficients of diacid, monoanion, and dianion, respectively.

For acids with $K_1/K_2 > 10^3$ the calculations of K_1 and K_2 are totally independent of each other, and they were based on 5—6 pH-measurements in each of the ranges of 15—35 and 65—85 % neutralization. For acids where $50 < K_1/K_2 < 10^3$ it can be shown that the influence of the separate dissociation stages on each other is negligible in this connection if K_1 and K_2 were computed from pH-measurements in the ranges of 10—20 and 80—90 % neutralization. As has been shown by Bacarella *et al.*[42] the glass electrode correctly measures a_{H^+} in aqueous organic solvents, provided that certain conditions for the handling of the glass electrode are fulfilled. Thus, in this work the glass electrode was standardized before use with an acetate buffer of pH 4.11 and a borate buffer of pH 9.08. It was then equilibrated with 50 % ethanol for several hours before the beginning of the electrometric titrations. It was stored in 50 % ethanol when not in use. No correction was made for the liquid junction potentials. As $[H^+]$ normally makes only a small contribution to the expressions $(b + [H^+])$ and $(a - b - [H^+])$ a_{H^+} was used in its place. $[OH^-]$ could not be neglected in a few cases where K_2 was very small, and it was calculated from the expression $[OH^-] = K_w/[H^+]$. A rough estimate of K_w (7.2×10^{-16}) was obtained from titration of the pure solvent with standard sodium hydroxide. No correction was made for the presence of ethoxide ions, a and b were corrected for dilution during the titration, f_0 was assumed to be unity, and f_1 and f_2 were computed by the Debye-Hückel limiting law, $\log f_i = -A z_i^2 \sqrt{I}$, where $A = 1.01$ in 50 % ethanol at 20°, and I was approximated as $(b + [H^+])$ when $a < b$ and as $(2b - a)$ when $b > a$ [24, 25].

The dissociation constants of the monomethyl esters were calculated as for monobasic acids.

The accuracy of the pK-values of Tables 1 and 2 is estimated at ± 0.15 unit in pK except for those pK_2-values which have been corrected for $[OH^-]$, where the error may be as high as ± 0.30 unit. For comparison within the material of this paper the accuracy is probably rather better. Speakman [25] has determined the pK-values of succinic acid in 50 % ethanol by weight at 20° and found $pK_1 = 5.48 \pm 0.05$ and $pK_2 = 7.24 \pm 0.05$ (calculated on the basis of molalities). For comparison, the pH-data for succinic acid were also put into the equations given by Speakman and then the pK-values graphically determined. This method gave $pK_1 = 5.43$ and $pK_2 = 7.36$, which is in satisfactory agreement with those calculated according to formulae (3) and (4).

pH-Measurements. Solutions of the acids in 50 % ethanol (0.004—0.005 M), were electrometrically titrated with standard sodium hydroxide in the same solvent (about 0.05 N), and pH-readings were made for various volumes of added base in the ranges mentioned above. The following cell was used

Glass electrode	solution under investigation	satd. KCl	satd. KCl	Hg	Hg_2Cl_2

The glass electrode was Radiometer Type G 202 B. The titrations were run in a carbon dioxide-free atmosphere and the temperature was 20 ± 0.5°. The titrations were run up to the equivalence points to check the purity of the acids; neutralization equivalents always agreed with the calculated ones within ± 1 %.

The author wishes to express his sincere gratitude to Professor Erik Larsson for his kind interest in this work.

Studies on Succinic Acids

IV.* Evidence for the Existence of Intramolecular Hydrogen Bonding in Certain Highly Alkylated Succinic Acids by Infra-Red Spectra

LENNART EBERSON

Department of Organic Chemistry, Chemical Institute, University of Lund, Sweden

The infra-red spectra of *racem*-α,α'-di*iso*propyl-, *racem*-α,α'-di-(*tert.*-butyl)-, *racem*-α,α'-di*cyclo*hexyl-, and tetraethylsuccinic acid and their monopotassium salts have been found to be consistent with an intramolecularly hydrogen-bonded structure. All these acids have very large K_1/K_2-ratios. The infra-red spectra of *meso*-α,α'-di*iso*-propyl-, *meso*-α,α'-di-(*tert.*-butyl)-, and *meso*-α,α'-di*cyclo*hexylsuccinic acid and their monopotassium salts are compatible with a structure containing one carboxyl group and one carboxylate ion which are essentially independent of each other.

There is chemical and physico-chemical evidence for the existence of an intramolecular hydrogen bond in certain dibasic acids and their monoanions [1–4]. These include highly branched malonic acids (I), *racem*-α,α'-dialkylsuccinic acids (II) with bulky alkyl groups, tetraalkylsuccinic acids (III), β,β-dialkylglutaric acids (IV), *cis*-1,2-*cyclo*propanedicarboxylic acids (V), *cis*-1,2-dicarboxyethylenes (VI), and others.

In all these cases the steric relationships probably play an important role. For example, it is well known that the accomodation of alkyl groups in a carbon chain capable of ring closure will increase the ease of formation and stability of the corresponding cyclic compound [5]. In an alkylated dibasic acid the formation of a cyclic structure can be accomplished by the formation of an intramolecular hydrogen bond, provided the arrangement of alkyl groups will be energetically favoured. In the other types of dibasic acids the carboxyl groups are rigidly held at distances which make hydrogen bonding possible. The most

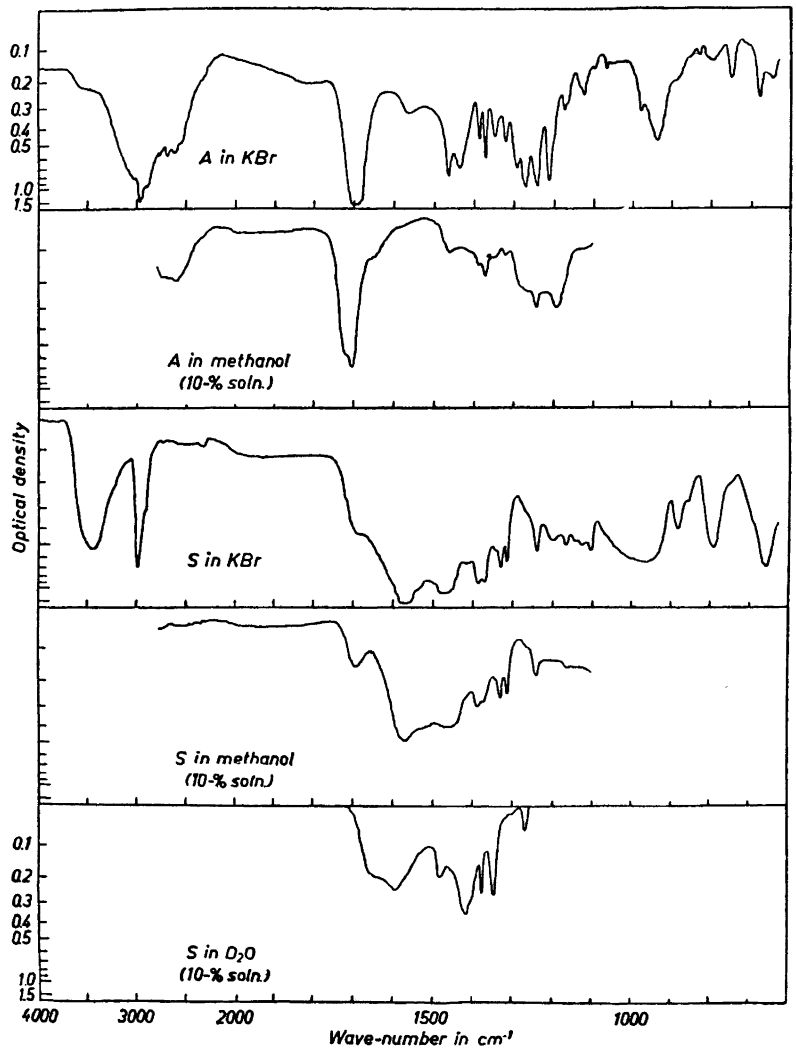

Fig. 1. Infra-red spectra of *racem*-α,α'-di*iso*propylsuccinic acid (A) and its monopotassium salt (S).

important arguments for the existence of an intramolecular hydrogen bond in dibasic acids of these kinds are:

1. They have anomalously high ratios between their first and second dissociation constants, which cannot be explained on the basis of electrostatic effects alone [1,3].

2. Measurements of the equilibrium constants of the reaction *meso*-acid ⇌ *racem*-acid for α,α'-dialkylsuccinic acids indicate that the *racemic* form is the

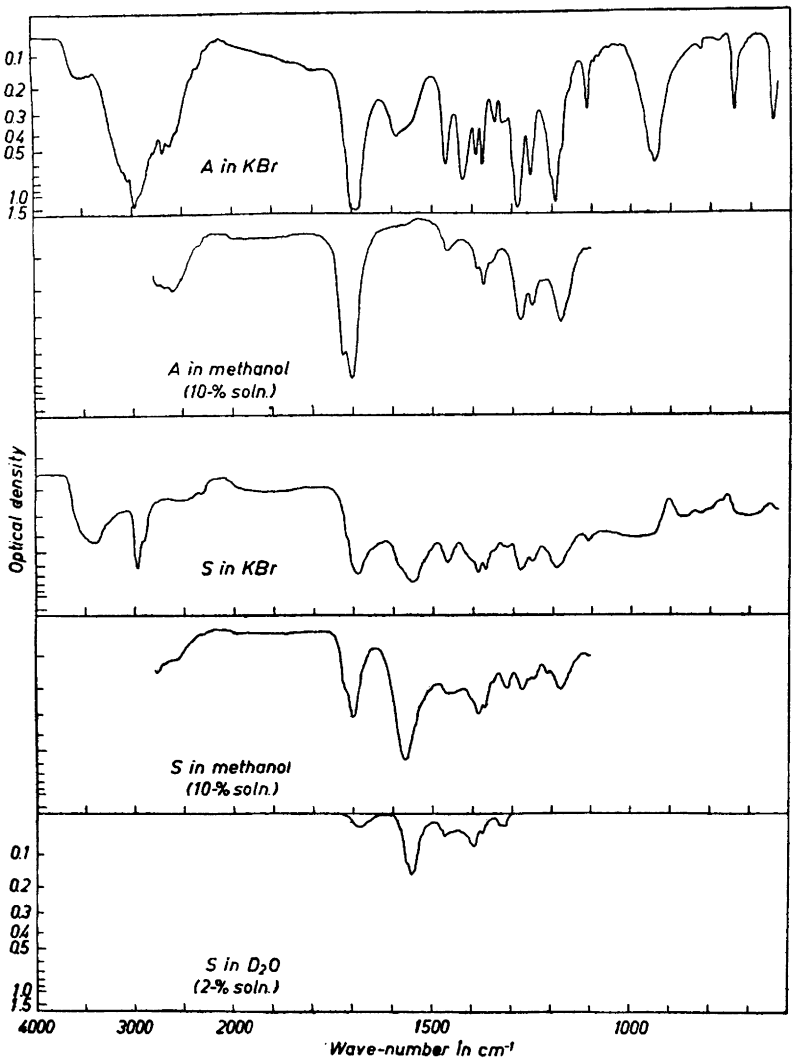

Fig. 2. Infra-red spectra of *meso*-a,a'-di*iso*propylsuccinic acid (A) and its monopotassium salt (S).

more stable isomer [2], *i. e.*, the stability order is the reverse of that predicted from conformational analytical considerations.

3. They are very easily anhydrized, some of them even in aqueous solution or in the solid state [4].

Shahat [6] has shown by X-ray analysis that in crystalline maleic acid there exists an unsymmetrical hydrogen bond. Cardwell *et al.*[7] have investigated maleic acid and its monopotassium salt in the solid state by means of infra-red

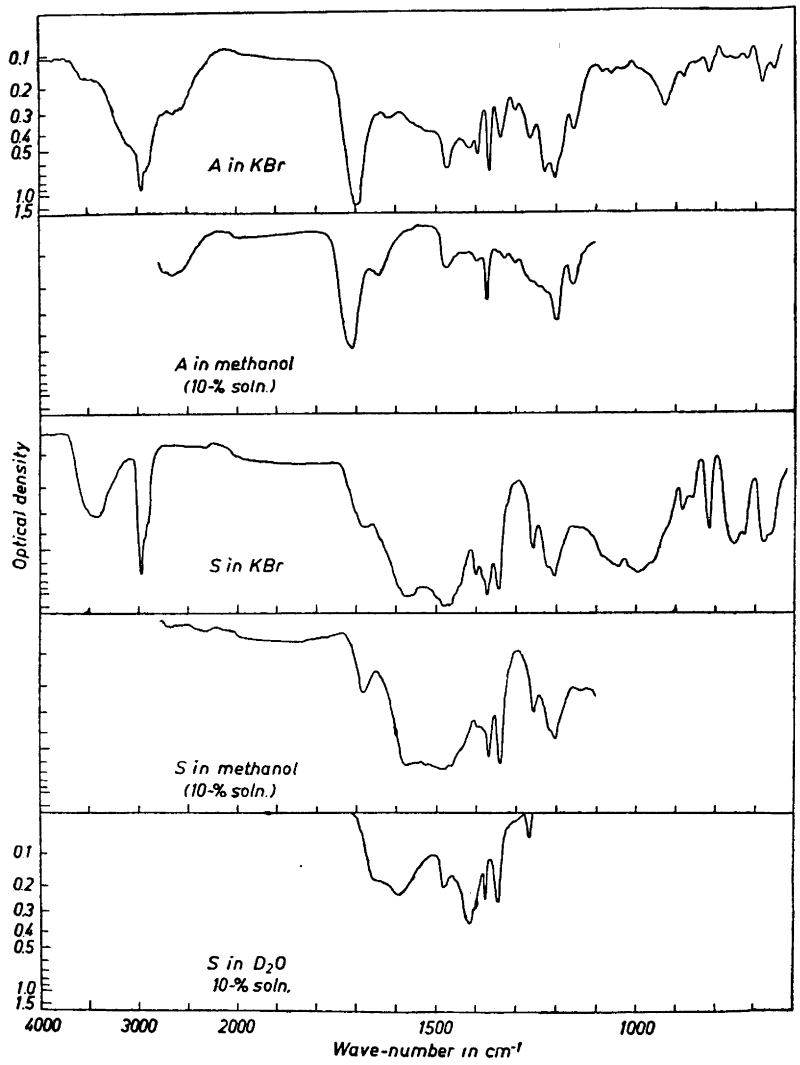

Fig. 3. Infra-red spectra of *racem*-α,α'-di-(*tert.*-butyl)-succinic acid (A) and its monopotassium salt (S).

spectra and found evidence for an intramolecular hydrogen bond in both acid and salt. In the latter case the absence of the carbonyl band indicated that the hydrogen bond might be symmetric.

The purpose of the present investigation was to study the infra-red spectra under various conditions for a series of alkylsubstituted succinic acids and their monopotassium salts. Four acids, *racem*-α,α'-di*iso*propyl-, *racem*-α,α'-di-(*tert.*-butyl)-, *racem*-α,α'-di*cyclo*hexyl-, and tetraethylsuccinic acid, which exhibit very high K_1/K_2-ratios (4×10^6—3.5×10^9 in 50 % aqueous ethanol) and three acids, the *meso* forms of the above acids, with low K_1/K_2-ratios (about 100) have been selected, and the infra-red spectra of the acids and their monopotassium salts have been examined in the solid state and in methanolic solution. Some of the salts were also studied in deuterium oxide solution. Methanol is the only solvent which meets the requirements of being transparent in the double bond stretching frequency region and of dissolving both

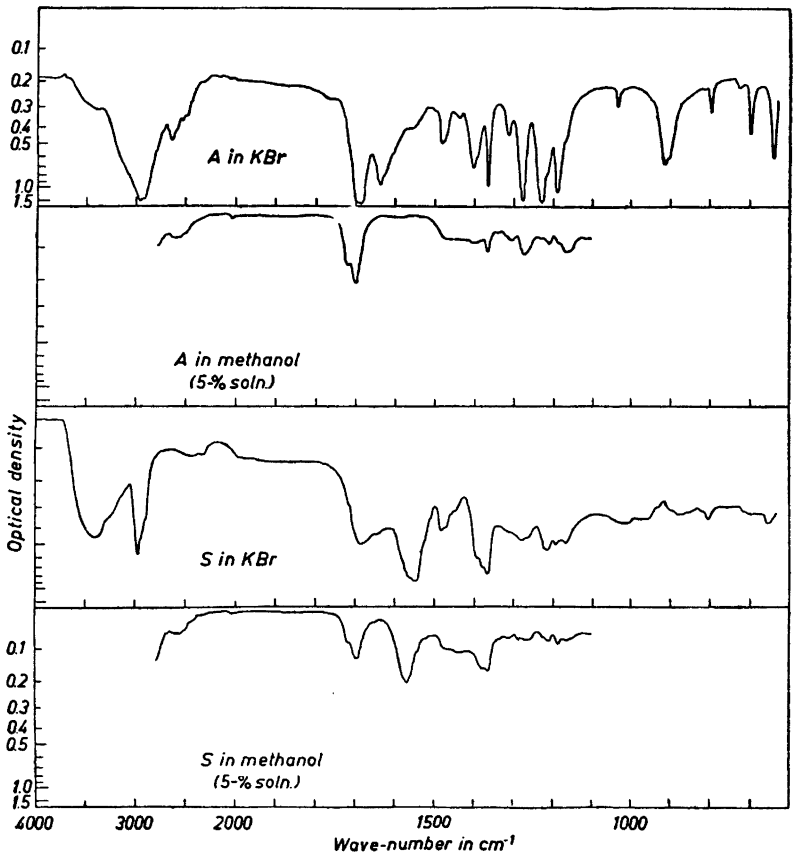

Fig. 1. Infra-red spectra of *meso*-α,α'-di-(*tert.*-butyl)-succinic acid (A) and its monopotassium salt (S).

acids and salts in sufficient concentrations. The discussion will be limited to a consideration of the carbonyl stretching frequency and the carboxylate asymmetric stretching frequency, as the other bands associated with these groups either are difficult to recognize or fall in a region where the solvent has a large absorption. The results are shown in Figs 1—7 and in Table 1, which gives the wave-numbers of the bands in the double bond region together with the approximate molar extinction coefficients in methanolic solution.

At a first glance it is seen that the spectra of the low-ratio acids and their salts are consistent with the structure VII for the acids and VIII for the monoanions.

Thus, in the solid state the carbonyl stretching frequency of the acids has a single peak at about 1 695 cm^{-1}, and no significant shift occurs in the spectra of the corresponding salts. In methanolic solution the situation is similar;

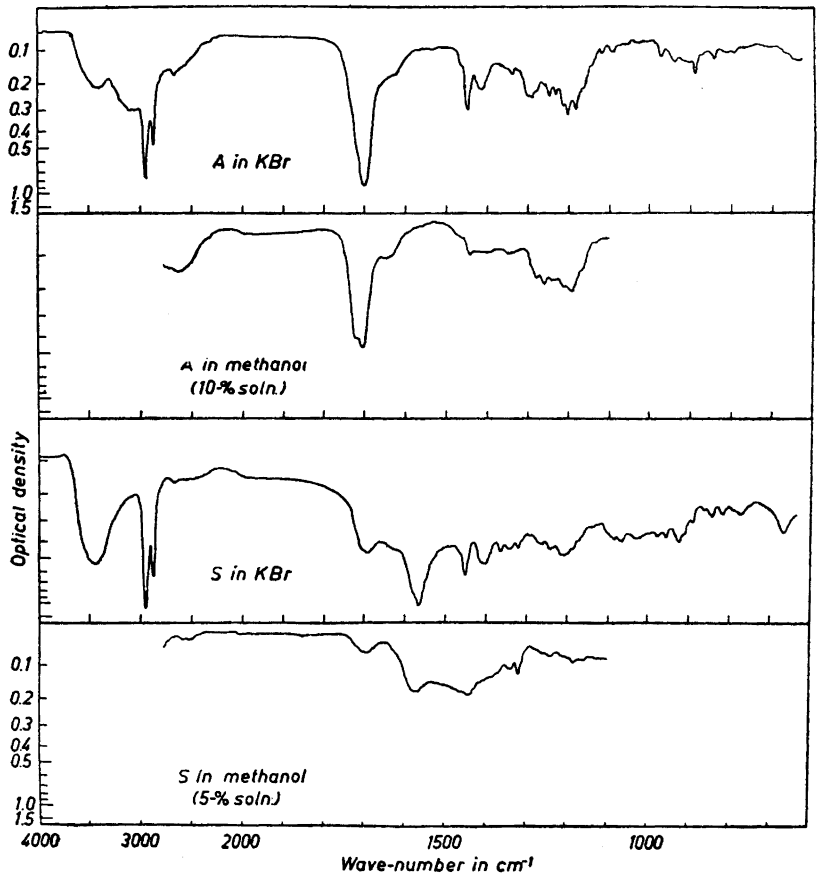

Fig. 5. Infra-red spectra of *racem-a,a'*-di*cyclo*hexylsuccinic acid (A) and its monopotassium salt (S).

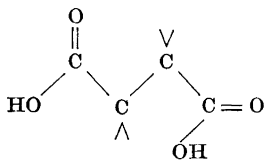
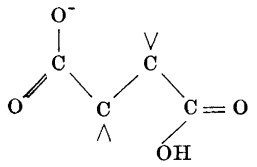


VII



VIII

however, the carbonyl band has split into two peaks at about 1 720 and 1 700 cm^{-1}. These peaks are not shifted in the spectra of the salts in methanol, but the molar extinction coefficients are reduced to about half their values in the acids. The carboxylate asymmetric stretching frequency occurs in the solid state at 1 550—1 560 cm^{-1} and in methanol it is shifted to about 1 570 cm^{-1}. The only *meso* acid salt which has been studied in deuterium oxide solution

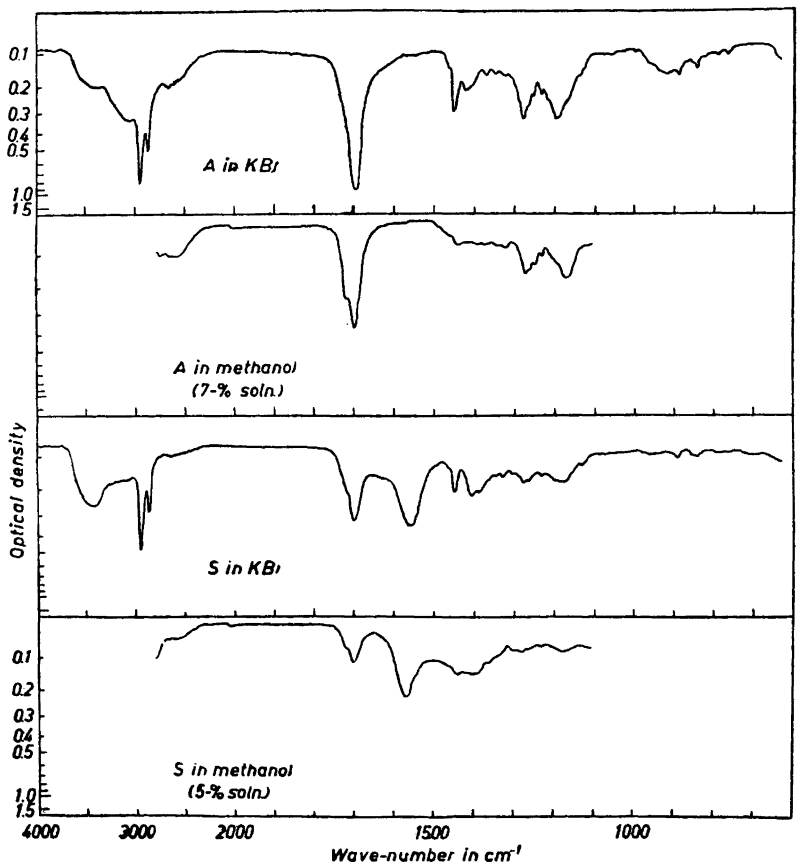


Fig. 6. Infra-red spectra of *meso*-α,α'-di*cyclo*hexylsuccinic acid (A) and its mono-potassium salt (S).

(the others are too slightly soluble) shows a single carbonyl peak at 1 680 cm^{-1} and the carboxylate band at 1 550 cm^{-1}, *i. e.*, both bands have shifted about 20 cm^{-1} towards lower wave-numbers as compared with the spectra in methanol. Summarizing, the double bond region of a low-ratio acid salt can be interpreted as a superposition of the carboxyl group and carboxylate ion spectra, and consequently the structure of the monoanions is best represented by VIII without interactions between the carboxyl groups.

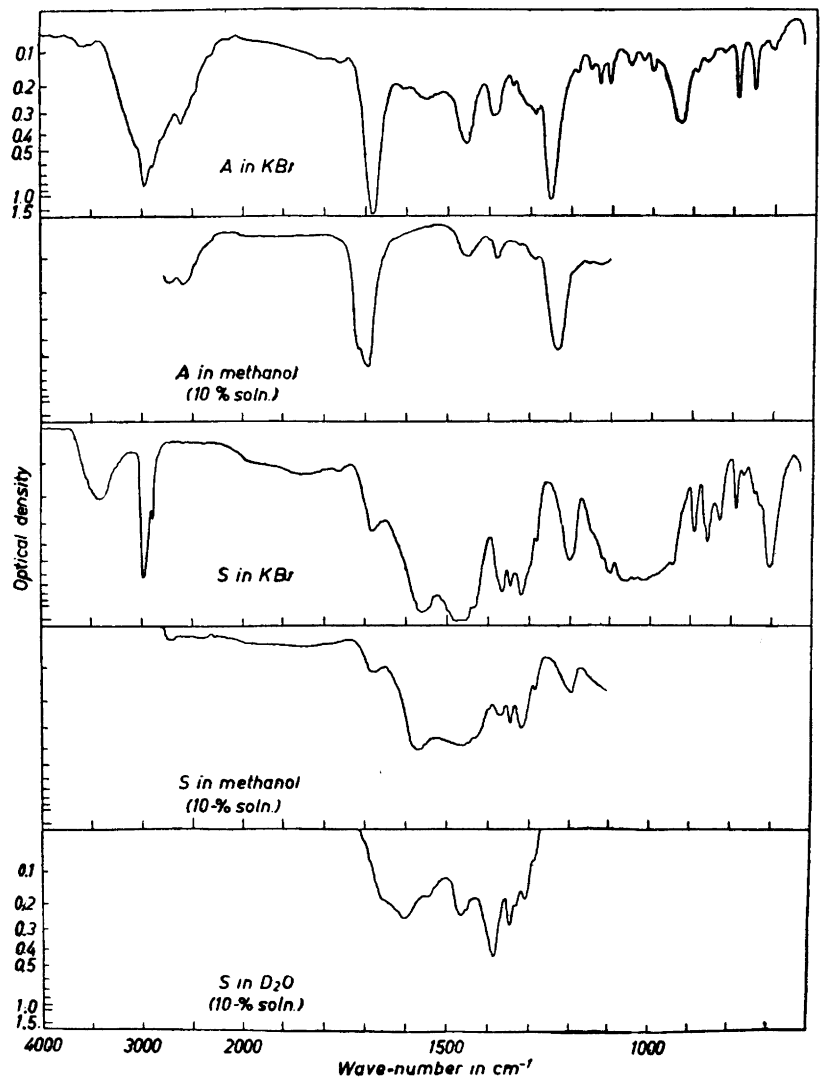

Fig. 7. Infra-red spectra of tetraethylsuccinic acid (A) and its monopotassium salt (S).

Table 1. Carbonyl frequencies of alkylsubstituted

Succinic acid	Carbonyl stretching frequency		
	In KBr, wave number in cm^{-1}	In methanol	
		wave number in cm^{-1}	Molar extinction coefficient ε
Racema-α,α'-di*iso*propyl-	1 695 vs	1 718 sh 1 704 1 650 sh	440 480 50
monopotassium salt	1 680 sh	1 690	110
Meso-α,α'-di*iso*propyl-	1 692 vs	1 723 1 701	350 510
monopotassium salt	1 687 sb	1 720 sh 1 700	150 250
Racem-α,α'-di-(*tert.*-butyl)-	1 695 vs 1 615 w	1 716 sh 1 708 1 640	390 110
monopotassium salt	1 675 mb	1 682	80
Meso-α,α'-di-(*tert.*-butyl)-	1 690 vs 1 635 s	1 720 1 700	330 500
monopotassium salt	1 687 sb	1 718 sh 1 695	170 270

monopotassium salt	1 690 sb	1 695	110
Meso-α,α'-di*cyclo*hexyl-	1 695 s	1 717 1 697	330 540
monopotassium salt	1 697 m	1 717 1 698	130 240
Tetraethyl-	1 683 vs	1 716 1 691	360 550
monopotassium salt	1 682 m	1 678	70

vs = very strong; s = strong; m = medium; w = weak; sh = shoulder; b = broad.

A similar interpretation is not possible for the spectra of the high-ratio acids and their salts. In methanolic solution all the *racem*-acids but not tetraethylsuccinic acid show a carbonyl band of low intensity at about 1 650 cm^{-1} (*racem*-α,α'-di-(*tert.*-butyl)-succinic acid has a weak band at 1 615 cm^{-1} also

succinic acids and their monopotassium salts.

In D_2O wave number in cm^{-1}	Carboxylate ion, asymm. stretching frequency				$\varepsilon_{C=O}$ (acid) / $\varepsilon_{C=O}$ (salt)

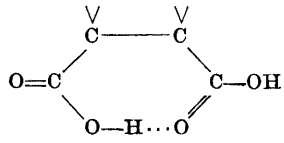
in the solid state). This band must be due to a carbonyl group taking part in an intramolecular hydrogen bond (IX). A band at 1 630 cm^{-1} in solid maleic acid has been explained in the same way [7]. Accordingly, the peaks at 1 720 and 1 700 cm^{-1} are assigned to the other carbonyl group which may take



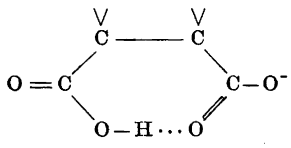
IX

part in an external hydrogen bond. The cause of the splitting around 1 700 cm^{-1} is probably coupling of the carbonyl frequencies[8-10], and not the existence of monomers and polymers in solution as the relative intensities of the two bands are independent of concentration.

The spectra of the *high*-ratio acid salts show the following main features. In both the solid state and in solution the salts have a large, almost continuous absorption in the region 1 600—1 400 cm^{-1}. In methanolic solution the carbonyl frequency has shifted by 10—25 cm^{-1} towards lower wave-numbers as compared with those of the acids, which is indicative of an intramolecular hydrogen bond [11]. The carbonyl band has been considerably reduced in intensity and its molar extinction coefficient is only a small fraction of that in the acid. In the hydrogen maleate ion the carbonyl band has completely disappeared [7], which points to the existence of a symmetric hydrogen bond in this ion with a structure intermediate between the extreme structures X a and X b.

X a X b

The fact that there actually is found a carbonyl peak in the spectra of the salts in question, though of appreciably reduced intensity, suggests that a structure for the monoanion with an unsymmetric intramolecular hydrogen bond (XI) is best compatible with the spectral data. In the deuterium oxide solution of a high-ratio acid salt the carbonyl peak has shifted towards lower wave-numbers and the carboxylate peak towards higher wave-numbers. This behaviour lends further support to an intramolecularly hydrogen-bonded structure.



XI

EXPERIMENTAL

The acids investigated in this paper were prepared and purified as described previously [4]. The monopotassium salts were prepared by dissolving accurately weighed amounts of acids and potassium carbonate (analytical grade reagent) in water or aqueous

ethanol by slight warming, filtering, and then evaporating *in vacuo* at room temperature. The last traces of solvent were removed by warming at 110° for 3 h. The purity was checked by analysis for carbon and hydrogen. It is by no means certain that a solid salt spectrum actually refers to the hydrogen potassium salt, but these spectra are given for comparison. The discussion above is based on the salt spectra in methanolic solution, where only the ion species HA^- is present.

The infra-red spectra were recorded by a Perkin Elmer model 21 spectrophotometer equipped with a sodium chloride prism. The solid samples of the acids and salts were examined in pressed potassium bromide plates. The wave-numbers given in Table 1 are accurate within ± 5 cm^{-1}.

The author wishes to express his sincere gratitude to Professor E. Larsson for his kind interest in this work.

The infra-red part of this work was carried out at the Chemical Institute, University of Copenhagen. I am greatly indebted to Professor B. Bak for placing these facilities at my disposal and to Civilingenjör D. Christensen for valuable discussions.

Grants from *Kungliga Fysiografiska Sällskapet* and *Matematisk-naturvetenskapliga Fakulteten*, University of Lund, are gratefully acknowledged.

The Metabolism of 7-Ketolithocholic Acid-24-^{14}C in the Rat *

Bile Acids and Steroids 70

BENGT SAMUELSSON**

Department of Physiological Chemistry, University of Lund, Lund, Sweden

The metabolism of intraperitoneally administered 7-ketolithocholic acid-24-^{14}C has been studied in bile fistula rats. This acid is partly transformed into 3α,6β,7β-trihydroxycholanic acid (Acid I) and 3α,7β-dihydroxycholanic acid (ursodeoxycholic acid). The results are discussed in relation to the metabolism of chenodeoxycholic acid.

Studies of the metabolism of chenodeoxycholic acid in the rat liver have shown that this acid is transformed into two more polar acids [1], which have recently been identified by Doisy *et al.* as 3α, 6β, 7β-trihydroxycholanic acid (Acid I) and 3α,6β,7α-trihydroxycholanic acid (Acid II) [2,3]. In the former metabolite an inversion of the original 7α-hydroxylgroup has occurred. Experiments with 7β-tritiochenodeoxycholic acid have shown that the 7β-hydroxy-acid is formed with loss of the tritium labell [4], and it was thus of interest to study the metabolism of carboxylabelled 7-ketolithocholic acid in the rat liver. Similar studies have been reported by Doisy *et al.*[5], who found that 7-ketolithocholic acid, intragastrically administered to rats, was converted into chenodeoxycholic acid, ursodeoxycholic acid, Acid I and Acid II.

EXPERIMENTAL

7-Ketolithocholic acid-24-^{14}C. 66.9 mg of methyl chenodeoxycholate-24-^{14}C[6] were treated with ethylchlorocarbonate in dioxane and pyridine [7], and the 3α-cathylate oxidized with 26 mg of sodium dichromate in aqueous acetic acid for 16 h at 25°C. After saponification the product was chromatographed with phase system F[9], yielding 50.5 mg of 7-ketolithocholic acid — 24—^{14}C. Specific activity 1.85 μC/mg. M.p. 200—202°.

* A preliminary report of this work was read at the meeting of the Danish Biochemica Society in Copenhagen, June 1957 [11].

** Present address: Department of Chemistry, Karolinska Institutet, Stockholm 60, Sweden.

Table 1. Recrystallizations of the radioactive material contained in peak A in the chromatogram shown in Fig. 2.

Inactive bile acid added	Crystallizing solvent	Weight mg	c.p.m. per mg
3α,6β,7β-Trihydroxy-cholanic acid (Acid I)		50	410
	Acetone/light petroleum	40	415
	Methanol/water	31	390
	Acetone	23	395
	Methanol/ethyl acetate	19	410
	Acetone/light petroleum	12	400

0.8 mg of this acid was neutralized with sodium hydroxide and injected intraperitoneally in 0.9 % sodium chloride solution into each of two 200—250 g white male rats of the institute stock on which the common bile duct had been cannulated 24 h before the administration. The rats had free access to white bread and oats and 0.9 % sodium chloride solution. The bile was collected, hydrolyzed, extracted with ether and chromatographed on hydrophobic supercel as described earlier [8,9]. The following systems were used.

System	Moving phase	Stationary phase
C[8].	150 ml of methanol	15 ml of *iso*octanol
	150 ml of distilled water	15 ml of chloroform
F[9].	165 ml of methanol	45 ml of chloroform
	135 ml of distilled water	5 ml of heptane

4 ml of the stationary phase were used per 4.5 g hydrophobic supercel. All chromatograms were run at a constant temperature of +23°C.

Reference substances used for identification of the metabolites

3α,6β,7β-Trihydroxycholanic acid (Acid I) was isolated from rat bile after hydrolysis and chromatography with phase system C. 0.084 g was obtained from the bile of 10 rats, collected during the first 12 h after the bile duct cannulation, at which time the concentration of this acid is maximal. M. p. 226—227°, $[\alpha]_D^{23} = +62° \pm 2°$ (*c* 0.51, methanol). The m. p. was not depressed by synthetic Acid I, prepared through hydroxylation of methyl-3α-acetoxy-Δ^6-cholenate with osmium tetroxide [3].

Table 2. Recrystallizations of the radioactive material contained in peak B in the chromatogram shown in Fig. 1.

Inactive bile acid added	Crystallizing solvent	Weight mg	c.p.m. per mg
Ursodeoxycholic acid		60	690
	Acetic acid/water	50	710
	Ethyl acetate/light petroleum	44	730
	Acetone/water	35	700
	Methanol/water	22	725
	Ethyl acetate/light petroleum	14	705

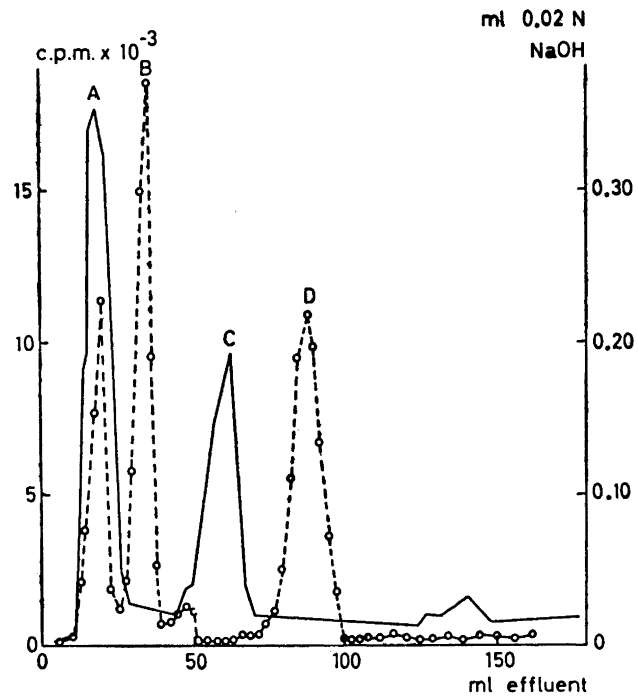

Fig. 1. Chromatography of acids from hydrolyzed bile, excreted during 24 h following intraperitoneal administration of 0.8 mg of 7-ketolithocholic acid —24—^{14}C. Column: 4.5 g hydrophobic supercel. Phases: Type F, see page 237. Solid line: Titration values. Broken line: Radioactivity.

Ursodeoxycholic acid was prepared through reduction of 7-ketolithocholic acid with sodium in *n*-propanol and chromatography with phase system F[10]. M. p. 201—202°, $[\alpha]_D^{23} = +56° \pm 2°$ (*c* 0.50, methanol).

RESULTS AND DISCUSSION

The carboxylabelled 7-ketolithocholic acid was injected intraperitoneally into two rats with bile fistulas and the bile was collected daily. The administered ^{14}C was almost completely recovered in the bile within the first 24 h. A chromatographic separation of the hydrolyzed bile with phase system F is shown in Fig. 1. The front peak (A) was rechromatographed with phase system C, Fig. 2. The activity is then eluted immediately after the band of inactive cholic acid. The radioactive material (105—140 ml) was diluted with inactive Acid I and the identity established by recrystallizations from different solvents and determination of the specific activity of the material from each recrystallization. (Table 1). About 2—3 % of the total radioactivity was eluted at about 50 ml, but the amount of this material was insufficient for identifica-

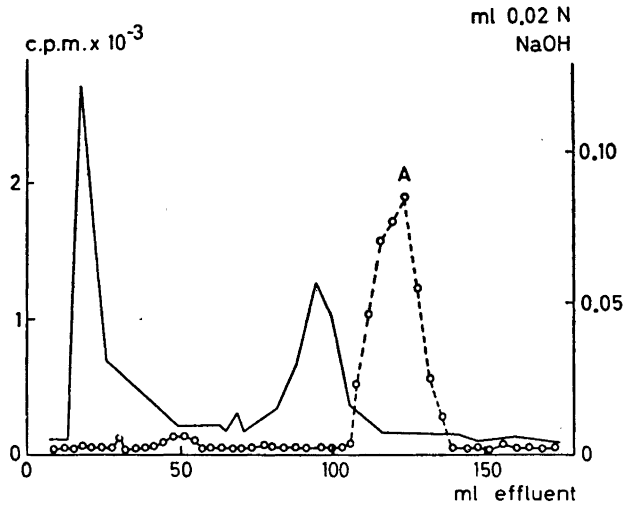

Fig. 2. Chromatography of peak A in the chromatogram shown in Fig. 1. Column: 4.5 g hydrophobic supercel. Phases: Type C, see page 237. Solid line: Titration values. Broken line: Radioactivity.

tion. With phase system C, Acid II (65—85 ml) is eluted before and Acid I (105—140 ml) after cholic acid (85—105 ml). The second peak (B) in the chromatogram shown in Fig. 1 was diluted with inactive ursodeoxycholic acid and recrystallized from different solvents. There was no depression of the specific activity (Table 2). Peak C in the chromatogram in Fig. 1 represents inactive chenodeoxycholic acid, normally present in the bile, and peak D consists of unchanged 7-ketolithocholic acid-24-^{14}C. This compound was also identified through isotope dilution. The composition of the labelled products was calculated from determinations of the total activity of the material and the ^{14}C contained in peak A, B and D. The results from two rats are shown in Table 3.

The ketogroup of 7-ketolithocholic acid is thus reduced in the liver to a 7β-hydroxylgroup and any formation of the 7α-epimer could not be demon-

Table 3. Percentage composition of the labelled products excreted in the bile during 24 hours after intraperitoneal administration of 7-ketolithocholic acid-24-^{14}C to two rats with bile fistulas.

Compound	Per cent		
	Rat I	Rat II	Average
3α,6β,7β-Trihydroxycholanic acid	24.2	29.3	26.8
Ursodeoxycholic acid	38.1	33.4	35.8
7-Ketolithocholic acid	32.8	33.7	33.3
Total	95.1	96.4	95.9

strated. The pathway for the formation of 3α,6β,7β-trihydroxycholanic acid (Acid I) may either be an initial hydroxylation of 7-ketolithocholic acid in the 6β-position and a later reduction of the 7-ketone, or a 6-hydroxylation of ursodeoxycholic acid. The facts that 7-ketolithocholic acid and ursodeoxycholic acid are only formed in small amounts in the metabolism of chenodeoxycholic acid, and that they are only partly metabolized, when injected intraperitoneally into a bile fistula rat [4], suggest that these acids constitute only a minor pathway in the formation of Acid I from chenodeoxycholic acid. Furthermore, evidence for the direct conversion of Acid II into Acid I will be presented in a subsequent publication [4].

This work is part of an investigation supported by the *Medical Faculty of the University of Lund* and by a research grant (H 2842) to Prof. S. Bergström from the *National Institutes of Health, United States Public Health Service.*

Low Temperature Heat Capacities and Thermodynamic Properties of the Iron Selenides $Fe_{1.04}Se$, Fe_7Se_8 and Fe_3Se_4 from 5 to 350°K

FREDRIK GRØNVOLD

Kjemisk Institutt A, Universitetet i Oslo, Blindern, Norway

and

EDGAR F. WESTRUM, JR.

Department of Chemistry, University of Michigan, Ann Arbor, Michigan, USA

Heat capacities of three iron-selenide phases representing the tetragonal PbO-like structure with composition $Fe_{1.04}Se$ and the hexagonal and monoclinic NiAs-like structures with compositions Fe_7Se_8 and Fe_3Se_4, respectively, were measured in the range 5 to 350°K. Heat capacity values, enthalpy, and entropy increments are tabulated at different temperatures. At 298.15°K the entropies $(S°-S_0^\circ)$ are 8.437 eu for $Fe_{0.5103}Se_{0.4897}$ (*i. e.*, $Fe_{1.04}Se$), 9.780 eu for $Fe_{0.4667}Se_{0.5333}$ (*i. e.*, Fe_7Se_8), and 9.554 eu for $Fe_{0.4286}Se_{0.5714}$ (*i. e.*, Fe_3Se_4). A λ-type transition with a maximum at 34°C is found in Fe_3Se_4, associated with an order-disorder process of supposedly ferrimagnetic to paramagnetic nature. The entropy increment of transition is about 2 eu per mole of Fe_3Se_4.

It has been shown by Hägg and Kindström [1] that an intermediate phase with composition FeSe and a tetragonal structure of the PbO-type exists in the iron-selenium system below a temperature between 600 and 300°C. In addition, another intermediate phase with homogeneity range from about 50 to 57.5 atomic percent selenium exists in samples quenched from 600°C. This phase has a NiAs-like structure which is hexagonal only in the iron-rich range and becomes monoclinic above 54 atomic percent selenium. By combining X-ray and density data, Hägg and Kindström concluded that the solid solution takes place by subtraction of iron atoms with increasing selenium content. Thus, the structure deforms when about 20 % of the iron lattice sites are unoccupied. This extended solid solution exists only at high temperatures and the iron-rich selenide with PbO-type structure and composition $Fe_{1.04}Se$ is formed below about 490°C according to Grønvold and Haraldsen [2].

The iron-rich composition limit of the $Fe_{1-x}Se$-phase goes towards a higher selenium content as the temperature is lowered, and at about 350°C the limit is at $Fe_{0.88}Se$ or Fe_7Se_8. Furthermore, a two-phase region is observed in the range $Fe_{0.87}Se$ to $Fe_{0.80}Se$.

As the temperature is lowered another phenomenon is also observed, *i.e.*, the ordering of the vacancies after the iron atoms. Bertaut [3] has studied the ordering process in Fe_7S_8 with NiAs-like structure and found that the decrease in internal energy for an ordered arrangement of holes compared to a random distribution is so large that all ionic defect structures are expected to have ordered distribution of the holes. This picture has to be modified for phases like the FeSe-phase which are not typical ionic compounds. It is apparent that the concentration of holes must exceed a certain value for the ordering — and thus the superstructure formation — to take place at a given temperature. With an increasing number of holes another superstructure might be formed, and so on. In case of the FeSe-phase two such superstructure phases have been established by Okazaki and Hirakawa [4], one in the composition range Fe_7Se_8 to Fe_6Se_7, the other in the range Fe_4Se_5 to Fe_3Se_4.*

In addition to the phases mentioned, an iron diselenide also exists at lower temperatures. It was found [5] in samples heat-treated for 4 months at 250°C

In respect to their magnetic properties, the iron selenides are very interesting [6]. Ferrimagnetism is associated with the FeSe-phase, with a Néel temperature at about 150°C for samples in the range $Fe_{1.00}Se$ to $Fe_{0.79}Se$. By further increase in selenium content the Néel point decreases rapidly and reaches 30°C by $Fe_{0.74}Se$. The magnetization intensity at —195°C has its maximum at $Fe_{0.89}Se$, confirming the presence of only one phase in this region. The sharp and almost linear drop on the iron-rich side can be interpreted as due to a two phase region with a paramagnetic phase with composition $Fe_{1.04}Se$, and the curved region from $Fe_{0.79}Se$ to $Fe_{0.74}Se$ as the homogeneity range of the Fe_3Se_4-phase.

More recent work by Hirone and Chiba [7] by X-ray, thermal and magnetic methods confirms the non-existence of stoichiometric FeSe and places the selenium-rich composition limit of the tetragonal phase at $Fe_{1.05}Se$ and the iron-rich limit of the hexagonal phase at $Fe_{0.88}Se$ at temperatures below 350°C. They also found ferrimagnetism associated with the hexagonal phase and a spontaneous magnetization of 0.20 Bohr magnetons. The Néel point is at 174°C and increases gradually to 192°C with increasing selenium content, and then rapidly falls to 40°C at $Fe_{0.77}Se$.

The magnetic properties of single crystals of Fe_7Se_8 and Fe_3Se_4 were studied by Hirakawa [8] using a torque magnetometer. For Fe_7Se_8 the direction of easy magnetization is in the (00.) plane at room temperature, but changes into the [001] direction below about 150°K. No such change

* Note added in proof: Okazaki (*J. Phys. Soc. Japan* **14** (1959) 112) has just reported a triclinic superstructure for Fe_7Se_8 in samples annealed at 290°C and slowly cooled. The present authors have observed a similarly deformed structure on Fe_7Se_8 samples subjected to annealing after having been in contact with the atmosphere. The sample studied here did not show any line splitting characteristic of a monoclinic or triclinic cell, and its superstructure is probably based upon an orthorhombic cell with doubled *c*-axis.

was observed for Fe_3Se_4. The saturation magnetizations at liquid air temperature for Fe_7Se_8 and Fe_3Se_4 were 68 and 80 gauss cm^{-3}, respectively.

The structural and magnetic properties of the iron selenides are thus rather sensitive to changes in temperature, and in order to get a further understanding of the causes of these changes, a thermodynamic study of the iron-selenium system is being carried out. In this paper will be reported the results of heat-capacity measurements on three single-phase samples, one representing the tetragonal FeSe-phase with composition $Fe_{1.042}Se$, and two others representing the $Fe_{1-x}Se$ phase with NiAs-like structure and compositions Fe_7Se_8 and Fe_3Se_4, or $Fe_{0.875}Se$ and $Fe_{0.750}Se$, respectively.

EXPERIMENTAL

A. Preparation of the samples. The iron selenides were synthesized from high purity iron and selenium. "Ferrum reductum pro analysi" from Merck was reduced with dry purified hydrogen gas at 1 000°C until constant weight was attained. A spectrographic analysis showed the presence of about 0.01 % Ni and Si and about 0.001 % Mn. The high-purity selenium was a gift from Bolidens Gruvaktiebolag, and contained these

impurities (in ppm) according to their analysis: Cl(2), Fe(0.8), K(0.3), Na(0.4), non-volatile matter (12). The following elements were not detected (the numbers indicate the sensitivity limit in ppm): Ag(0.03), Al(0.3), As(1), Bi(0.1), Ca(1), Cr(0.3), Cu(0.1), Hg(0.5), Mg(0.3), Mn(0.1), Ni(0.3), Pb(0.3), S(5), Sb(1), Si(1), Sn(0.3), Te(1), Zn(1).

Accurately-weighed quantities of the elements corresponding to the compositions $FeSe_{0.96}$, Fe_7Se_8 and Fe_3Se_4 were heated in evacuated and sealed silica tubes. Because of the transitions in the solid selenides which sometimes causes cracking of the silica tubes on cooling, the silica tubes were put into larger silica tubes which were also evacuated and sealed. The samples were fused for 4 h at 1 050°C in an electric muffle furnace, cooled to room temperature and fragmented under dry nitrogen in an agate mortar. They were then homogenized at 350°C for 30 days and cooled down to room temperature over another 30 days. By means of X-ray powder photographs the samples were proved to be of identical nature to those obtained earlier [2].

B. *Cryostat and calorimeter.* The Mark I cryostat and technique employed for low-temperature adiabatic calorimetry are being described elsewhere [9]. The copper calorimeter (laboratory designation W-7) has a capacity of 40.33 cm^3; it is gold-plated inside and out and has only four vanes. A separate series of measurements were carried out to determine the heat capacity of the empty calorimeter, using the same thermometer and heater and exactly the same amount of indium-tin solder for sealing and Apiezon-T grease for thermal contact with the thermometer and heater. It represented from 11 to 35 % of the total heat capacity observed.

Temperatures were measured with a capsule-type platinum resistance thermometer (laboratory designation A-3) contained in an axial well in the calorimeter. A 150-ohm constantan heater was wound on a cylindrical copper tube surrounding the resistance thermometer. The thermometer has been calibrated by the National Bureau of Standards,

and the temperatures are judged to correspond with the thermodynamic temperature scale within 0.03°K from 10 to 90°K and within 0.04°K from 90 to 350°K. Precision is considerably better, and the temperature increments are probably correct to a millidegree after corrections for quasi-adiabatic drift.

The thermometer resistance and the power input were measured with a calibrated White double-potentiometer, calibrated resistances and a calibrated standard cell. An electric timer, operated by a calibrated tuning fork and amplifier, was automatically started at the beginning of the heating period and stopped at the end. The calorimeter was loaded with sample and evacuated, and helium was added at 4 cm Hg pressure at about 25°C to provide thermal contact between sample and calorimeter. It was then sealed, placed in the cryostat and cooled. The mass of sample used was 107.795 g $Fe_{1.04}Se$, 118.961 g Fe_7Se_8 and 132.015 g Fe_3Se_4.

RESULTS

The heat-capacity determinations are listed in Table 1 in chronological order, and expressed in terms of the thermochemical calorie, defined as 4.1840 abs joules. The ice point is taken to be 273.15°K, and the atomic weights of iron and selenium as 55.85 and 78.96, respectively. The data are expressed in terms of one mole of mixture ("mole"), equivalent to the gram formula weight of Fe_ySe_{1-y}; *i.e.*, 67.17 g $Fe_{1.04}Se$, 68.18 g Fe_7Se_8 and 69.06 g Fe_3Se_4. An analytically-determined curvature correction for the finite temperature increments was applied to the observed values of $\Delta H/\Delta T$. The approximate temperature increments can usually be inferred from the adjacent mean temperatures in Table 1.

The heat-capacity *versus* temperature curves are shown in Fig. 1. For $Fe_{1.04}Se$ it has the usual sigmoid shape up to 350°K, while for Fe_7Se_8 the curve shows pretransition effects and for Fe_3Se_4 a transition actually takes place at about 307°K or 34°C.

Values of C_p, $S°—S_0°$ and $(H°—H_0°)/T$ for the three samples are listed in Table 2 at selected temperatures. The reason for not giving the free-energy function is the uncertainty about complete ordering. The enthalpy and entropy increments were computed by numerical integration, using graphically interpolated values of heat capacity. The heat-capacity values are considered to have a probable error of 0.1 % above 25°K and 1 % at 10°K. The effects of nuclear spin and of isotope mixing are not included in the entropy function. The estimated probable error in the entropy and enthalpy functions is 0.1 % above 100°K, but some of the values are given to an additional digit because of their significance when the entropies or enthalpies at different temperatures or compositions are compared.

The entropy increment associated with the λ-transition in Fe_3Se_4 at 34°C is about 2 cal $mole^{-1}$ deg^{-1}. The transition temperature corresponds to that found [6,7] for the change from paramagnetism to ferrimagnetism in $Fe_{0.74}Se$ and the nature of the transition seems thus established.

It is known from X-ray work [4] that the structure of Fe_3Se_4 has an ordered distribution of vacancies, just as Fe_7S_8[3], Cr_3S_4[10] and $Ni_{0.80}Se$[11], but less is known about the valence states of the atoms. According to the electrostatic treatment of Yosida [12], Bertaut [3] and Lotgering [13], the distribution of Fe^{2+}

and Fe^{3+} ions in $Fe_{1-x}Se$ in the planes I and II normal to the c-axis of the NiAs-like structure is (when ϱ designates the fraction of Fe^{3+} ions in plane I, and all vacancies are in plane II):

Plane I	Plane II
$(\frac{1}{2}-2x\,\varrho)Fe^{2+} + 2x\varrho Fe^{3+}$	$(\frac{1}{2}-x-2x[1-\varrho])Fe^{2+} + 2x(1-\varrho)Fe^{3+}$

On the basis of spin-only magnetism the magnetic moment of Fe_7Se_8 resulting from antiparallel spin arrangement between lattice I and II is calculated to vary between 0.29 and 0.86 Bohr magnetons per iron atom as ϱ goes from 0 to 1, *i.e.*, as the number of Fe^{3+} ions in lattice I increases from zero to its maximum value. By assuming all Fe^{3+} ions and vacancies to be located in the same plane, the experimentally found moment of 0.2 Bohr magnetons is reasonably well explained.

For Fe_3Se_4 the same model predicts magnetic moments of 1.33 to 2.0 Bohr magnetons per iron atom as ϱ goes from its minimum value 0.5 (corresponding to equipartition of Fe^{3+} ions between lattice I and II) to its maximum value 1.0, when all Fe^{3+} ions are in lattice I. The magnetic measurements [6] are not in agreement with this, however, as the observed moment of Fe_3Se_4 is only 0.1 Bohr magneton. This shows that strong interactions are present between the paramagnetic ions and their neighbors so that the electrostatic description has to be modified.

Acknowledgment. The authors thank Bolidens Gruvaktiebolag for a generous supply of selenium and Roger Berg and Paul (Te Fu) Chang for assistance in the calorimetric measurements. One of us (F. Grønvold) expresses his appreciation to the *Nansen Foundation* for assistance. The partial support of the *Division of Research of the U. S. Atomic Energy Commission* is gratefully acknowledged.

VI. Reduction of Compounds Containing the Azomethine group

HENNING LUND

Leo Pharmaceutical Products, Copenhagen, Denmark

The polarographic reduction in buffered medium of a number of ketimines, aniles, oximes, azines, phenylhydrazones, and semicarbazones have been investigated by use of controlled potential reductions. The number of electrons participating in the electrode reactions and the reduction products are reported and some indications of a probable reduction path are presented.

Compounds containing the azomethine group >C=N— have mostly been of interest for polarography as a means of determining carbonyl compounds by converting them to a suitable azomethine derivative. Thus aliphatic ketones not reducible as such in buffered solutions can be determined as the ketimines [1,2] or Girard hydrazones [3–5]. Other derivatives as hydrazones [6], semicarbazones [7], and oximes [8–11] have been investigated. Of these especially the oximes have recieved attention from various workers.

The polarographic behaviour of most of the compounds containing a carbon-nitrogen double bond have some features in common. Of the molecules in the equation

$$A + H^+ \rightleftharpoons (AH)^+ \quad (1)$$

the $(AH)^+$ is reducible at a less negative potential than A and when $(AH)^+$ is removed from the reaction mixture by the reduction the equilibrium is forced to the right. The height of the polarographic wave is, therefore, in a certain pH-region determined by the rate of the recombination (1) of the molecules with the hydrogen ions [12]. The phenomenon of recombination is found in the reduction of other compounds [13,14], but the special feature of many of the azomethine compounds is that in neutral and weakly alkaline solution the wave height at a certain pH is not constant but decreases at more negative potentials until another electrode reaction takes place. The phenomenon has been explained by the assumption that a change in the structure of the carbon-nitrogen double bond at the surface of the electrode caused by the lowering of the electrode potential lowers the rate of the recombination. As the subject

of the recombination in the polarography of oximes have been treated elsewhere [9,10] only these introductory remarks have seemed warranted.

The purpose of the present work has been to investigate the electrode reactions which occur during the polarographic reduction of compounds containing a carbon-nitrogen double bond, and to this end a polarographic investigation of some aniles, oximes, amidoximes, azines, phenylhydrazones, and semicarbazones has been made together with preparative reductions at controlled potential of representatives from each group.

As the polarographic behaviour, especially the half-wave potentials, of the compounds is dependent upon the medium used all investigations were performed in 40 % alcohol containing 1 M potassium chloride as supporting electrolyte and the reducible compound in a concentration of 20 μg/ml. In order to facilitate the comparison of the compounds the limiting currents are reported for the concentration 10^{-3} M, which is calculated from the experimental data by assuming a linear dependence of limiting current on concentration.

Ketimines

Ketones as acetone and *cyclo*hexanone give rise to a polarographic wave in a medium containing a primary amine or ammonia and a salt of the amine due to the reduction of the ketimine [1,2] formed in the equilibrium:

$$RR'C{=}O + H_2NR'' \rightleftharpoons RR'C{=}NR'' + H_2O$$

Controlled potential reduction of a solution of *cyclo*hexanone in a large excess of methylamine and methylamine hydrochloride showed that the reduction consumed two electrons per molecule *cyclo*hexanone and the product was the expected N-methyl *cyclo*hexyl amine.

$$RR'C{=}NCH_3 + 2e^- + 2H_2O \rightarrow RR'CH{-}NHCH_3 + 2OH^-$$

Aniles

Only a few compounds of this class were investigated. Benzalaniline and salicylaldehyde anile were found to be too unstable both in alkaline and acid solution for a polarographic investigation. Benzophenone anile is rather unstable below pH 5, but at higher pH-values the stability is sufficiently high to allow both a polarographic investigation and a preparative reduction.

Table 1. Limiting currents in μA and half-wave potentials *vs* S.C.E. of benzophenone anile at different pH-values. Concentration 10^{-3} M. 0.01 % gelatine added as maximum suppressor.

pH	5.10		6.25		7.40		9.85		10.75		13	
	i_d	$-E_{\frac{1}{2}}$	i_d	$-E_{\frac{1}{2}}$	i_d	$-E_{\frac{1}{2}}$	i_d	$-E_{\frac{1}{2}}$	i_d	$-E_{\frac{1}{2}}$	i_d	$-E_{\frac{1}{2}}$
1. wave	2.2	0.82	2.4	0.89	2.4	0.96	4.8 [a]	1.10	4.8	1.13	2.4	1.21
2. wave	2.6	1.08	2.4	1.07	2.2	1.07					2.2	1.58

[a] slight tendency to minimum.

The polarographic behaviour of benzophenone anile is similar to that of benzophenone in that two waves are found at lower pH values and only one at higher values (Table 1). As for benzophenone the first wave is pH-dependent, whereas the second one is not, and the combined wave is less dependent upon pH than the first one. The half-wave potentials of the anile are, however, about 0.3 V more positive than those of benzophenone, and whereas the two waves of benzophenone merge about pH 5 the waves of the anile merge about pH 9. Furthermore, there are found two waves in strongly alkaline solution for the anile, which is not the case for benzophenone. In the pH-region 9—12 a small minimum is found about —1.5 V; this is similar to that found for oximes and hydrazones.

Controlled potential reduction at pH 10 showed that the electrode reaction was a two electron reduction and the isolated product was benzhydrylaniline.

$$(C_6H_5)_2C{=}NC_6H_5 + 2e^- + 2H_2O \rightarrow (C_6H_5)_2CH{-}NHC_6H_5 + 2OH^-$$

Attempts to reduce the anile at the plateau of the first wave at pH 6 were unsuccessful due to the difficulties of obtaining sufficient buffering in a medium in which the anile was appreciably soluble.

Oximes

Unconjugated oximes. The oximes of the following unconjugated carbonyl compounds were investigated polarographically: *Iso*butyraldehyde, phenylacetaldehyde, and benzylacetone (Table 2). They all show a single pH-dependent wave in acid solution and the height of the wave decreases at higher pH-values and disappears in alkaline solution. The polarographic wave shows, however, no minimum at higher pH-values.

Preparative reductions of *iso*butyraldoxime and phenylacetaldoxime showed that the electrode reaction was a four electron reduction, and from the latter reduction phenylethylamine was isolated.

$$C_6H_5CH_2CH{=}NOH + H^+ \rightleftharpoons (C_6H_5CH_2CH{=}NOH)H^+$$
$$+ 4e^- + 4H^+ \rightarrow C_6H_5CH_2CH_2NH_3^+ + H_2O$$

α,β-Unsaturated oximes. Oximes of the following α,β-unsaturated carbonyl compounds were investigated polarographically: Crotonaldehyde, mesityloxide, carvone, testosterone propionate, cinnamaldehyde, and benzalacetone. The polarographic behaviour of these oximes were rather different (Table 2).

Crotonaldoxime shows in acid solution a single pH-dependent wave with the height determined by the rate of the recombination. About pH 8 the first wave disappears without showing minima and a second wave of nearly the same height as the wave in strongly acid solution appears. The half-wave potentials of this wave is approximately independent of pH. The wave is probably due to the reduction of the unprotonated crotonaldoxime. This wave disappears in strongly alkaline solution which might be explained by the formation of the more difficultly reducible oxime anion R—NO^-. Controlled potential reduction in weakly acid solution showed the electrode reaction to be a four electron reduction.

Table 2. Limiting currents in μA and half-wave potentials *vs* S.C.E. of some oximes and N-benzylhydroxylamine. Concentration 10^{-3} M. 0.01 % gelatine added as maximum suppressor.

[a] Minimum.
[b] Drawn out wave
[c] The compound is hydrolyzed.
[d] Poorly defined wave which merges with the hydrogen wave.

Crotonaldoxime exists in a higher melting and a lower melting form. The higher melting isomer, which is investigated here, shows ressemblance with the *anti* cinnamaldoxime and the *anti* benzaldoxime in the behaviour in alkaline solution, where the higher melting form of crotonaldoxime and the mentioned *anti* oximes gives rise to a reduction wave due to the reduction of the unprotonated oxime of nearly the same heigt as that in acid solution, whereas the *syn* isomers give a smaller wave.

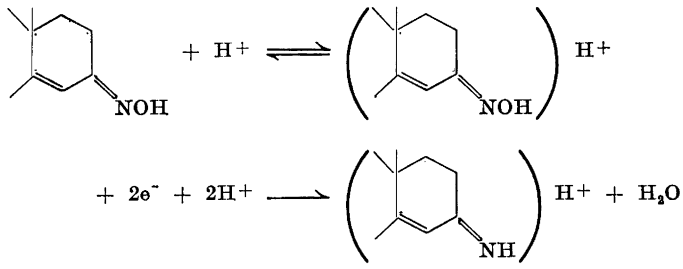
The polarographic wave of mesityloxide oxime is like the first wave of crotonaldoxime apart from a slight tendency to forming minimum. No wave appears in alkaline solution. The wave in acid solution was shown to be due to a four electron reduction.

Carvone oxime produces in mineral acid solution two two-electron waves which about pH 2 merge into one four-electron wave. This wave disappears

at higher pH-values and pronounced minima are found in this pH-interval. No reduction takes place in alkaline solution.

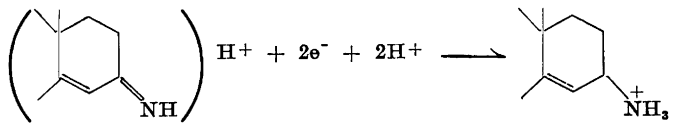
Testosterone propionate oxime is reduced in two two-electron reductions in acid solution until pH about 6, where the waves become deformed and diminish in height. The oxime is rather stable in acid solution at room temperature as the height of the waves at pH 1.0 is not diminished to any measurable degree during a period of 40 h.

Controlled potential reduction at pH 1 at —0.90 V *vs* S.C.E., which is the plateau of the first wave, showed that this wave was due to a two electron reduction. From the reaction mixture testosterone propionate could be isolated in good yield. The possibility that the oxime was hydrolyzed and the hydroxylammonium ion reduced must be excluded, as hydroxylamine is not reduced at that potential and the oxime was found to be stable at room temperature at pH 1. The reaction can thus be formulated:



followed by hydrolysis of the ketimine.

From controlled potential reduction at pH 1 at —1.2 V *vs* S.C.E., which is the plateau of the second wave, it was found that the total reduction of the oxime consumed four electrons and the second one thus two electrons. From this reduction was isolated an amine and the electrode reaction of the second wave, therefore, probably is the reduction of the formed ketimine to the amine:



The *anti* cinnamaldoxime shows a single pH-dependent wave at pH values lower than 6. At pH 1 the height of the wave varies with the height of the mercury reservoir as required for a diffusion controlled wave. About pH 6 the wave becomes drawn out and the wave diminishes somewhat. The height of the wave in strongly alkaline solution is, however, more than half of the height in acid solution. The height of the wave in strongly alkaline solution varies with the height of the mercury reservoir, but somewhat less than required for a diffusion controlled wave.

The *syn* cinnamaldoxime ressembles the *anti* isomer in acid solution but is different from it in alkaline medium. In strongly alkaline solution the wave disappears almost.

Controlled potential reduction in acid solution yielded some saturated aldehyde and the main product was cinnamylamine. The reaction consumed 3.8 electrons per molecule. In alkaline solution the *anti* cinnamaldoxime was reduced in a four electron reduction and hydrocinnamaldehyde was isolated in good yield.

Benzalacetone oxime shows in strongly acid solution a single wave the height of which varies linearly with the square root of the height of the mercury reservoir. The half-wave potentials of this wave vary linearly with pH from pH 0 to pH 6. At pH-values higher than 3 a second, smaller wave is found whose nature was not investigated further. In strongly alkaline solution a single wave is found, the height of which is somewhat bigger than half of the wave height in strongly acid solution. The height of the wave at pH 13 varies somewhat with the height of the mercury reservoir, but not as much as required by a diffusion controlled wave.

From controlled potential reduction in mineral acid solution of benzalacetone oxime it was found that the reaction consumed 3.5 electrons per molecule. The main product, 1-methyl-3-phenyl-allylamine, was accompanied by some benzylacetone and another saturated ketone. In view of the results obtained for testosterone propionate oxime the reaction might be formulated:

$$\begin{aligned} C_6H_5CH{=}CH{-}C(CH_3){=}NOH \; + \; H^+ \; &\rightleftharpoons \; (C_6H_5CH{=}CH{-}C(CH_3){=}NOH)H^+ \\ + \; 2e^- \; + \; 2H^+ \; &\rightarrow \; (C_6H_5CH{=}CH{-}C(CH_3){=}NH)H^+ \; + \; H_2O \\ +2e^- \; + \; 2H^+ \; &\rightarrow \; C_6H_5CH{=}CHCH(CH_3){-}NH_3{}^+ \end{aligned}$$

The formation of benzylacetone might be due to a reduction of the carbon-carbon double bond followed by hydrolysis of the benzylacetone oxime or to a reaction similar to that in alkaline solution.

In alkaline solution the benzalacetone oxime was reduced in a four electron reduction and besides the main product, benzylacetone, a very small amount of amine could be isolated. The reaction might be formulated to proceed in at least three ways:

A) $$R{-}CH{=}CH{-}C(CH_3){=}NOH \; + \; 2e^- \; + \; 2H_2O \; \rightarrow \; R{-}CH_2{-}CH_2{-}C(CH_3){=}NOH \; + \; 2 \; OH^-$$

followed by alkaline hydrolysis of the oxime and a two electron reduction of the formed hydroxylamine.

B) $$\begin{aligned} R{-}CH{=}CH{-}C(CH_3){=}NOH \\ + \; 2e^- \; + \; 2H_2O \; &\rightarrow \; R{-}CH_2{-}CH_2{-}C(CH_3){=}NOH \; + \; 2 \; OH^- \\ + \; 2e^- \; + \; 2H_2O \; &\rightarrow \; R{-}CH_2{-}CH_2{-}C(CH_3){=}NH \; + \; 2 \; OH^- \end{aligned}$$

followed by alkaline hydrolysis of the ketimine.

C) $$\begin{aligned} R{-}CH{=}CH{-}C(CH_3){=}NOH \\ + \; 2e^- \; + \; 2H_2O \; &\rightarrow \; R{-}CH{=}CH{-}C(CH_3){=}NH \; + \; 2 \; OH^- \\ + \; 2e^- \; + \; 2H_2O \; &\rightarrow \; R{-}CH_2{-}CH_2{-}C(CH_3){=}NH \; + \; 2 \; OH^- \end{aligned}$$

followed by hydrolysis of the ketimine to the ketone. It can not, however, be excluded that the hydrolysis precedes the last reduction which then would be the reduction of the benzalacetone to benzylacetone.

The first formulation is unlikely on the following grounds. Hydroxylamine is not reducible at the potential used in alkaline solution. Furthermore, benzylacetone oxime is not hydrolyzed easily in alkaline solution, which was shown by leaving a 10^{-3} M solution of benzylacetone oxime in 0.1 N sodium hydroxide for 18 h. The concentration of the oxime did not diminish to any appreciable degree which was found by polarography of the solution after lowering the pH to 3.

The second formulation (B) is unlikely, as benzylacetone oxime is not reduced in alkaline solution. No evidence has been found against the third formulation (C), why it must be regarded as the most likely approximation to the reaction path.

Aromatic oximes. The polarographic behaviour of oximes of simple aromatic carbonyl compounds have been thoroughly investigated elsewhere. Here the *syn* and *anti* benzaldoxime, which only seem to have been investigated in unbuffered systems [15,16], and oximes of some aminocarbonyl compounds have been included in the investigation.

The oximes of the aminocarbonyl compounds show a similar behaviour as, *e.g.*, acetophenone oxime and the electrode reaction was shown to be a four electron reduction to the amine.

The *syn* and *anti* benzaldoxime are very much alike in their polarographic behaviour below pH about 4, whereas at higher pH-values they behave differently from each other. The *syn* benzaldoxime produces in weakly alkaline solution only a small wave, whereas the reduction wave due to the reduction of the unprotonated oxime of the *anti* benzaldoxime is nearly as high as in weakly acid solution. In strongly alkaline medium the height of the wave of the *anti* benzaldoxime diminishes somewhat, probably due to the formation of the anion $R—CH=NO^-$.

Controlled potential reduction of benzophenone oxime at pH 3 yielded benzhydrylamine in a four electron reduction. *Anti* benzaldoxime was reduced at pH 9, where the unprotonated oxime is reduced, in a four electron reduction and benzylamine was the isolated product.

The reduction of aromatic oximes has been formulated [10] in the following way:

(A)
$$\begin{aligned} R'R''C{=}NOH + H^+ &\rightleftharpoons (R'R''C{=}NOH)H^+ \\ + 4e^- &\rightarrow (R'R''C{=}NOH)H^* \\ + 3H_2O &\rightarrow R'R''CH{-}NH_3^+ + 4\ OH^- \end{aligned}$$

where the symbol * represents an activation state or series of such states the charge type being unspecified.

An alternative formulation with two consecutive reductions occuring at the same potential (or at different potentials as in the cases of benzophenone oxime in strongly acid solution [10]), which evades the assumption of an electron uptake in aqueous solution of four electrons before an uptake of hydrogen ions, would be:

(B)
$$\begin{aligned} R'R''C{=}NOH + H^+ &\rightleftharpoons (R'R''C{=}NOH)H^+ \\ + 2e^- + 2H^+ &\rightarrow (R'R''CH{-}NHOH)H^+ \\ + 2e^- + 2H^+ &\rightarrow R'R''CH{-}NH_3^+ + H_2O \end{aligned}$$

$$\text{or (C)}\quad R'R''C=NOH + H^+ \rightleftharpoons (R'R''C=NOH)H^+$$
$$+ 2e^- + 2H^+ \rightarrow (R'R''C=NH)H^+ + H_2O$$
$$+ 2e^- + 2H^+ \rightarrow R'R''CH-NH_3^+$$

Of these (B) is unlikely as benzylhydroxylamine is not reduced in mineral acid solution (Table 2) and in slightly acid solution the reduction occurs at a potential appreciably more negative than the half-wave potential of benzaldoxime. Although the intermediate aldimine (C) is too unstable in acid solution to be investigated polarographically it seems not unlikely that the electron uptake is a faster reaction than the hydrolysis. In this connection it can be mentioned that benzylidene-methylamine in cold 50 % sulfuric acid has been reduced at a lead cathode in a two electron reduction to benzylmethylamine [17]. Although the postulated aldimine probably exists as an activated complex at the electrode surface it is believed that (C) gives a better approximation to the reaction path than (A) or (B).

N-benzylbenzaldoxime. The polarographic behaviour of this compound ressembles somewhat that of *anti* benzaldoxime (Table 3). In strongly acid solution, however, where the compound is hydrolyzed too rapidly for exact polarographic measurements, two waves are found, which merge into one wave about pH 3. About pH 8 the wave splits in two waves, but in more alkaline solution again one wave is found with a height somewhat lower than in weakly acidic solution.

Controlled potential reduction in neutral solution showed that the main reaction was a four electron reduction of the N-benzylbenzaldoxime to dibenzylamine. In mineral acid solution, where two waves are observed, the first wave is apparantly not corresponding to the reduction of the carbon-nitrogen double bond, as the expected product from such a reduction, dibenzylhydroxylamine, is not reducible in acid solution at the potential used. The reaction path in acid solution and probably also in neutral medium would thus be:

$$C_6H_5CH_2N(\rightarrow O)=CHC_6H_5 + H^+ \rightleftharpoons (C_6H_5CH_2N(\rightarrow O)=CHC_6H_5)H^+$$
$$+ 2e^- + 2H^+ \rightarrow (C_6H_5CH_2N=CHC_6H_5)H^+ + H_2O$$
$$+ 2e^- + 2H^+ \rightarrow (C_6H_5CH_2)_2NH_2^+$$

Table 3. Limiting currents in μA and half-wave potentials *vs* S.C.E. of N-benzylbenzaldoxime, N,N-dibenzylhydroxylamine, mesoxalic acid ester oxime, and benzamideoxime. Concentration 10^{-3} M. 0.01 % gelatine added as maximum suppressor.

[a] The compound is hydrolyzed.
[b] drawn out wave.

From a controlled potential oxidation at a mercury anode at —0.05 V *vs* S.C.E. in alkaline solution of dibenzylhydroxylamine was isolated N-benzylbenzaldoxime and benzaldehyde.

Ethyl ester of mesoxalic acid oxime. This compound has previously been investigated by Souchay and Ser [9] and the results obtained here are substantially in agreement with theirs. The half-wave potentials found in the medium used here are, however, somewhat more negative and the height of the wave corresponds nearly to a four electron reduction. The polarographic behaviour of the ester ressembles that of oximes containing two keto groups in the α-positions to the oxime group [9] and also that of N-benzylbenzaldoxime.

From the height of the wave of mesoxalic acid oxime Sartori *et al.*[18] concluded that the electrode reaction was a two electron reduction to the hydroxylamino malonic acid. Controlled potential reduction at pH 6 to the ester showed, however, that the electrode reaction in this case was a four electron reduction and aminomalonic acid ester was isolated from the reaction mixture. The electrode reaction is thus similar to that of other oximes.

Benzamideoxime. The polarographic behaviour of this compound resembles somewhat that of the unconjugated oximes. In strongly acid solution the wave is masked by the hydrogen wave but from pH about 2 a single wave is found. The height of this wave diminishes from pH about 6 and the wave disappears completely about pH 10. No minima has been observed in weakly alkaline solution. The height of the wave at pH 3 to 5 corresponds to a two electron reduction, whereas ordinary oximes are reduced by a four electron reduction.

Controlled potential reduction in aqueous solution at pH 4.8 of benzamideoxime confirmed that the electrode reaction consumed two electrons per molecule, and benzamidine, $C_6H_5C(NH_2) = NH$, was isolated in good yield as the picrate.

$$C_6H_5C(NH_2)=NOH + H^+ \rightleftharpoons (C_6H_5C(NH_2)=NOH)H^+$$
$$+ 2e^- + 2H^+ \rightarrow (C_6H_5C(NH_2)=NH)H^+ + H_2O$$

This reaction is similar to that postulated above as the first step of the reduction of ordinary oximes.

Benzalazine

Benzalazine has previously been investigated [6] in 70 % ethanol containing 0.5 M tetramethylammonium chloride. The results obtained in 40 % ethanol containing 1 M potassium chloride are somewhat different from those reported and are given in Table 4. The results of the polarographic investigation of benzaldehyde benzylhydrazone in the same medium are included in the table.

The benzalazine, which is rapidly hydrolyzed in mineral acid solution, shows a single pH-dependent wave at pH values lower than 7. Between 6 and 9 the height of the wave diminishes rapidly and shows a pronounced minimum. The height of the first wave is determined by the rate of some reaction which might be the recombination of the benzalazine and H^+ to the easier reducible protonated benzalazine or might rather be some reaction involving the primarily formed reaction product. The first wave degenerates to another pH-

Table 4. Limiting currents in μA and half-wave potentials *vs* S.C.E. at different pH-values of benzalazine and benzaldehyde benzylhydrazone. Concentration 10^{-3} M. 0.01 % gelatine added as maximum suppressor.

[b] Minimum.

dependent wave with a smaller wave height. This wave splits up in two waves in the pH-region 9.5—12. The wave with the most negative half-wave potential grows at the sacrifice of the other one in a manner, which resembles the reduction of *e.g.*, pyruvic acid.

The height of the wave about pH 4 is between 2.5 and 3 times the height of the wave in alkaline solution, where the wave is diffusion controlled. The height of the wave in alkaline solution corresponds to a two electron reduction, and a reduction requiring 5 to 6 electrons would then be expected in acid solution.

Benzaldehyde benzylhydrazone shows at about pH 1 two waves of equal height which merge to one wave about pH 3. Between pH 6 and 9 the height of the wave diminishes rapidly and disappears completely about pH 9. The height of the wave about pH 4 is between 1.5 and 2 times higher than the height of the wave of benzalazine in alkaline solution, and a reduction requiring 3 to 4 electrons per molecule would, therefore, be expected.

On comparing the half-wave potentials of benzalazine and benzaldehyde benzylhydrazone it is found that the half-wave potentials of the latter is equal to or less negative than the half-wave potentials of benzalazine, and in a mixture of the two compounds the benzaldehyde benzylhydrazone would thus be reduced before or simultaneously with benzalazine.

The polarographic behaviour of benzalazine could, therefore, be explained by assuming that the first wave was due to a reduction of benzalazine to benzaldehyde benzylhydrazone followed immediately by a reduction of this compound. If a two electron reduction wave is subtracted from the polarograms of benzalazine the resulting polarograms are very much like those of benzaldehyde benzylhydrazone.

Controlled potential reduction of benzalazine in alkaline solution showed that the electrode reaction consumed two electrons per molecule, and the isolated product was benzaldehyde benzylhydrazone

$$C_6H_5CH=N-N=CHC_6H_5 + 2e^- + 2H_2O \rightarrow C_6H_5CH_2NH-N=CHC_6H_5 + 2\ OH^-$$

Dibenzyl diimide, $C_6H_5CH_2—N = N—CH_2C_6H_5$ [6], has been suggested as the reduction product, but this compound is known to rearrange to benzaldehyde benzylhydrazone under the influence of alkali or acid. It cannot, however, be excluded that dibenzyl diimide is the primarily formed product, although in view of the reducibility of azobenzene it would not seem unlikely that dibenzyl diimide would be reduced further to dibenzylhydrazine.

At pH 5 benzaldehyde benzylhydrazone was reduced in a four electron reduction, and benzylamine was isolated from the reaction mixture. The reaction path is probably similar to that of benzaldehyde phenylhydrazone to be discussed later.

$$C_6H_5CH_2NH-N=CHC_6H_5 + 4e^- + 6H^+ \rightarrow 2\ C_6H_5CH_2NH_3^+$$

In weakly acid solution benzalazine was reduced consuming 5.5 electrons per molecule and benzylamine was isolated from the reaction. The main reaction is:

$$C_6H_5CH=N-N=CHC_6H_5 + 6e^- + 8H^+ \rightarrow 2\ C_6H_5CH_2NH_3^+$$

Phenylhydrazones

α,β-Unsaturated phenylhydrazones. Carvone phenylhydrazone produces in mineral acid solution two waves of equal height which merge into one wave about pH 3. This wave diminishes in height from pH about 5 and disappears completely about pH 8. Controlled potential reduction at pH 4 showed that the electrode reaction consumed four electrons per molecule and aniline was isolated from the reaction mixture indicating a reductive splitting of the nitrogen-nitrogen bond.

Aromatic phenylhydrazones. The phenylhydrazones of the following aromatic carbonyl compounds were investigated: benzaldehyde, benzophenone, N-*p*-dimethylamino benzaldehyde, and *p*-aminoacetophenone. As seen from Table 5 they all show a single, pH-dependent wave in acid solution, which diminishes in height at higher pH-values and disappears completely in alkaline solution. The half-wave potentials of the hydrazones were from 0.05 to 0.2 V more positive than those of the carbonyl compounds. In the table are included the data of N-benzyl-N′-phenyl-hydrazine.

In the pH-region where the wave height is approximately constant the half-wave potentials have a nearly linear dependence of pH. For the amino-compounds the influence of the amino group makes the pH-dependence more complicated in neutral solution. In alkaline medium are found pronounced minima as for the oximes. The explanation of these minima and the diminishing of the wave height at higher pH-values is probably the same as for the oximes [9].

Controlled potential reductions of benzaldehyde phenylhydrazone, benzophenone phenylhydrazone, and N-*p*-dimethylamino benzaldehyde phenylhydrazone in acid solution showed that the electrode reaction consumed four electrons per molecule and that the overall reaction could be formulated as follows:

$$RR'C=N-NHC_6H_5 + 4e^- + 6H^+ \rightarrow RR'CH-NH_3^+ + H_3N^+-C_6H_5$$

Table 5. Limiting currents in μA and half-wave potentials *vs* S.C.E. of some phenylhydrazones and N-benzyl-N′-phenylhydrazine at different pH-values. Concentration 10^{-3} M. 0.01 % gelatine added as maximum suppressor.

[a] Minimum.
[b] Merge with the sodium wave.

The same results were obtained by Tafel and Pfeffermann [19] from the reduction of the phenylhydrazones of acetaldehyde, acetone, and benzaldehyde in 50 % sulfuric acid at a lead cathode. In the last case a small amount of benzylaniline was isolated besides the benzylamine and aniline.

The reduction of benzaldehyde phenylhydrazone might proceed by a reduction to N-benzyl-N′-phenyl-hydrazine followed by a reductive splitting of the nitrogen-nitrogen bond or a disproportionating to the amines and the hydrazone. This seems, however, unlikely as N-benzyl-N′-phenyl hydrazine is not reducible at the dropping mercury electrode and the compound seems perfectly stable in acid solution.

The cleavage of the protonated nitrogen-nitrogen bond seems, therefore, to be the initial step in the reaction and this is followed by a reduction of the formed aldimine:

$$\begin{aligned} C_6H_5CH{=}N{-}NH{-}C_6H_5 + H^+ &\rightleftharpoons (C_6H_5CH{=}N{-}NH{-}C_6H_5)H^+ \\ + 2e^- + 3H^+ &\rightarrow (C_6H_5CH{=}NH)H^+ + H_3N^+{-}C_6H_5 \\ + 2e^- + 2H^+ &\rightarrow C_6H_5CH_2NH_3^+ \end{aligned}$$

The side reaction, which occurs in 50 % sulfuric acid and leads to the formation of benzylaniline, is also better explained on the assumption that benzaldimine is the intermediate product than if the reduction of the carbon-nitrogen double bond is assumed to be the initial step.

A reductive cleavage of a nitrogen-nitrogen bond has previously been reported for the reduction of 3-hydroxy-1,3-diphenyl-triazene, which in a four electron reduction followed by a two electron reduction forms aniline and phenylhydrazine [20].

Semicarbazones

α,β-Unsaturated semicarbazones. Cinnamaldehyde semicarbazone produces in acid solution a single wave the height of which diminishes at higher pH-values and disappears about pH 10. From pH about 8 another wave appears, which is found in both weakly and strongly alkaline solution. The half-wave potentials of the first wave is pH-dependent, whereas the second one is not. The height of the first wave is determined by the rate of the recombination of the semicarbazone and the hydrogen ion, whereas the second one is diffusion controlled. This second wave is due to the reduction of the unprotonated semicarbazone.

Table 6. Limiting currents in μA and half-wave potentials *vs* S.C.E. of some semicarbazones at different pH-values. Concentration 10^{-3} M. 0.01 % gelatine added as maximum suppressor.

* Minimum.

Controlled potential reduction of cinnamaldehyde semicarbazone in alkaline solution showed that the electrode reaction consumed two electrons and the isolated product was hydrocinnamaldehyde semicarbazone:

$$C_6H_5CH=CH-CH=N-NHCONH_2 + 2e^- + 2H_2O \rightarrow C_6H_5CH_2CH_2CH=N-NHCONH_2 + 2\ OH^-$$

Attempts to reduce cinnamaldehyde semicarbazone in mineral acid solution was unsuccessful due to a partial hydrolysis of the semicarbazone.

Benzalacetone semicarbazone shows a similar behaviour as cinnamaldehyde semicarbazone. The benzalacetone semicarbazone is hydrolyzed in mineral acid solution, whereas it is stable in alkaline solution. Controlled potential reduction in alkaline medium showed that the electrode reaction was a two electron reduction to benzylacetone semicarbazone.

Aromatic semicarbazones. The semicarbazones of benzaldehyde and *p*-aminoacetophenone were investigated. Both showed a single pH-dependent wave in acid solution and the wave height diminished at higher pH-values. No wave was observed in alkaline solution. As in the cases of phenylhydrazones and oximes the semicarbazones showed pronounced minima in neutral and weakly alkaline solution.

Controlled potential reduction in mineral solution showed that a reductive splitting of the nitrogen-nitrogen bond took place in a reaction consuming four electrons per molecule. For benzaldehyde semicarbazone the overall electrode reaction thus is:

$$C_6H_5CH{=}N{-}NHCONH_2 + 4e^- + 5H^+ \rightarrow C_6H_5CH_2NH_3^+ + H_2NCONH_2$$

The reduction path is probably similar to the that of the reduction of benzaldehyde phenylhydrazone.

From the reduction of benzophenone semicarbazone, for which Souchay and Graizon [7] from the height of the polarographic wave suggested a 2 electron reduction to 1-benzhydryl semicarbazide, benzhydrylamine was obtained in good yield (70 %) in mineral acid solution. In an acetate buffer, pH 4, however, the reduction required less than 4 electrons and 1-benzhydryl semicarbazide was isolated in 30 % yield.

DISCUSSION

From the data presented it appears that in the polarographic reduction of RR'C = NYR'' the reaction depends on the nature of Y. Is Y a carbon atom, then the reduction consumes two electrons per molecule and the saturated compound is the reaction product. When, however, Y is nitrogen or oxygen the most common overall reaction in acid solution consumes four electrons per molecule and a reductive splitting of the N—Y bond takes place together with a saturation of the double bond. It also appears, that in general the splitting of the N—Y bond precedes the reduction of the carbon-nitrogen double bond thus giving the following reaction path:

$$\begin{aligned} RR'C{=}N{-}Y{-}R'' + H^+ &\rightleftharpoons (RR'C{=}N{-}Y{-}R'')H^+ \\ + 2e^- + 2H^+ &\rightarrow (RR'C{=}NH)H^+ + H{-}Y{-}R'' \\ + 2e^- + 2H^+ &\rightarrow RR'CH{-}NH_3^+ \end{aligned}$$

In a few cases, *e.g.* benzophenone semicarbazone at pH 4, however, the four electron reduction is accompanied by a two electron reduction of the carbon-nitrogen double bond and the compound formed by this two electron reduction is not reduced further. This might also be the case in the reduction of dimethylglycylhydrazones of α,β-unsaturated steroid ketones [5], where the wave height of the hydrazones were found to be twice the wave height of the uncondensated steroid ketones. As α,β-unsaturated steroid ketones are reduced by a one electron reduction [21], this would suggest a two electron reduction of the hydrazones. However, no controlled potential reduction of the dimethylglycylhydrazones were made due to their low stability in acid solution, and the nature of the electrode reaction is, therefore, still uncertain.

EXPERIMENTAL

The polarograph was a recording polarograph Radiometer Type PO 3a. The capillary delivered 2.27 mg of mercury per second at a corrected mercury column height of 48.5 cm. The drop time 3.90 sec.(H_2O, open circuit). The capillary constant $m^{2/3}t^{1/6} = 2.17$ $mg^{2/3}sec^{-1/2}$.

The apparatus used for the controlled potential reductions was an electromechanical potentiostat of the Lingane-Jones type. For the oxidations performed at an anode potential of −0.05 to −0.5 V *vs* S.C.E. the manually operated apparatus employed in Part I[21] was found suitable.

The buffer solutions used were from pH 2.5 to 8 a sodium phosphate-citric acid buffer and from pH 8 to 11 a sodium borate buffer. The medium employed was 40 % alcohol containing 1 M potassium chloride and 0.01 % gelatine.

The carbonyl derivatives were prepared in the conventional way. The only derivative whose data apparently not have been reported previously is testosterone propionate oxime, which was prepared from 5 g of testosterone propionate, 5 g of hydroxylamine hydrochloride and 4 ml pyridine in methanol solution. After 3 days at room temperature the mixture was diluted with water and the precipitate recrystallized from dilute alcohol and benzene-hexane. M. p. 184°. $(\alpha)_D = +132°$ (1 % in $CHCl_3$).

Reduction of cyclo*hexanone in methylamine solution.* 1.0 ml of freshly redestilled *cyclo*hexanone was reduced in a mixture of 40 ml 33 % aqueous methylamine solution, 50 ml 4 N hydrochloric acid, and 100 ml water at −1.65 V *vs* S.C.E. After completion of the reduction which required 2 electrons per molecule *cyclo*hexanone the reaction mixture was extracted three times with ether, which was washed three times with dilute sodium hydroxide. After drying, the ether was evaporated, together with the remaining traces of methylamine. The residue was dissolved in ether and on addition of dry hydrogen chloride a precipitate, 925 mg, was obtained, which after recrystallization from alcohol-ether had m. p. 175−176°. It was identified as N-methyl *cyclo*hexylamine hydrochloride (m. p.[22] 175−178°). (Found: C 55.95; H 10.76; N 8.90; Cl 23.56. Calc. for $C_7H_{16}NCl$: C 56.16; H 10.79; N 9.36; Cl 23.70.)

Reduction of benzophenone anile. 1.0 g of benzophenone anile was reduced in a medium of 40 % peroxide free tetrahydrofurane, 20 % alcohol and 40 % water. The buffer was a borate buffer pH 10, the cathode potential −1.70 V *vs* S.C.E. Small amounts of acid were added during the reduction to compensate for the hydrogen ions used; the consumption of hydrogen ions was calculated from the reading of the coulometer. — The yellow colour of the solution disappeared during the reduction, which required two electrons per molecule. After completion of the reaction the mixture was diluted with water, made a little more alkaline and extracted three times with ether. The combined extracts were dried with potassium carbonate, and on addition of dry hydrogen chloride a precipitate, 1.05 g, was obtained, m. p. 203°, which was identified as benzhydryl aniline hydrochloride,[1] m.p.[23] 201−203°. (Found: C 76.98; H 6.12; N 4.90; Cl 11.54. Calc. for $C_{19}H_{18}NCl$: C 77.16; H 6.13; N 4.74; Cl 11.97.)

Reduction of testosterone propionate oxime (1). A solution of 0.5 g testosterone propionate oxime was reduced in 180 ml 50 % alcohol containing 0.5 N HCl at −0.90 V *vs* S.C.E. until the first wave disappeared on the polarograms, which required 2.1 electrons. The reaction mixture was then extracted with chloroform, which was evaporated. The residue was dissolved in alcohol and added to an acid alcoholic solution of 2.4-dinitrophenylhydrazine. A precipitate, 0.7 g, was obtained, m. p. 190−195°; it was recrystallized from butanol and tetrahydrofurane-alcohol, m. p. 212−215° after sintering about 210°. (Testosterone propionate 2,4-dinitrophenylhydrazone m. p. 209.9−210.5°[24], 217−218°[25]). The IR-spectrum of the obtained hydrazone was found to be identical with that of actual testosterone propionate 2,4-dinitrophenylhydrazone.

Reduction of testosterone propionate oxime (2). A solution of 0.5 g of testosterone propionate oxime was reduced in 180 ml 50 % alcohol containing 0.5 N HCl at −1.20 V *vs* S.C.E. In this case a motor driven stirrer was found more suitable than a magnetic stirrer due to the formation of a surface-active reaction product. At higher concentrations of this compound the mercury emulgated thus making a further use of the electrode impossible. The reduction required a little less than four electrons. The reaction mixture was diluted with water, extracted with ether, made alkaline and again extracted with ether, which was dried. On addition of dry hydrogen chloride a precipitate, 275 mg, was obtained, m. p. 235−240° (decomp.). The amine hydrochloride was rather slightly soluble in water. The amine was set free with carbonate and extracted with ether, which was evaporated. The amine had m. p. 218−222°. (Found: C 75.73; H 10.16; N 4.13. Calc. for $C_{22}H_{35}NO_2$: C 76.49; H 10.21; N 4.06.)

Reduction of anti *cinnamaldoxime (1).* 1.0 g of *anti* cinnamaldoxime was reduced in a mixture of 80 ml N H_2SO_4, 80 ml alcohol, and 20 g of Na_2SO_4 at −0.8 V *vs* S.C.E. The

reduction consumed 3.8 electrons. After completion of the reduction the reaction mixture was extracted with ether, which was dried and evaporated leaving 225 mg of a compound with an IR-spectrum indicating the presence of an unconjugated aldehyde group. The aqueous phase was then made alkaline and extracted with ether, which was dried. On addition of dry hydrogen chloride a precipitate, 525 mg, was obtained, which was identified as cinnamyl amine hydrochloride through the benzoyl derivative, m. p. 93—94° (94—95°). (Found: C 80.73; H 6.37; N 5.75. Calc. for $C_{16}H_{15}NO$: C 80.98; H 6.37; N 5.91.)

Reduction of anti *cinnamaldoxime (2).* 1.0 g of *anti* cinnamaldoxime was reduced in 150 ml aqueous alkaline solution, to which benzene was added to dissolve the reaction product. The reduction required 4 electrons per molecule. After completion of the reaction the layers were separated and the aqueous phase extracted with ether. The combined organic solvents were washed with aqueous acid, from which a small amount of amine could be isolated. The organic solvents were evaporated leaving 800 mg of a compound which was identified as hydrocinnamaldehyde through the 2,4-dinitrophenylhydrazone, m. p. 149—151°. (Hydrocinnamaldehyde 2,4-dinitrophenylhydrazone, m. p. 147°[26].)

Reduction of benzalacetone oxime (1). A suspension of 1.0 g of benzalacetone oxime was reduced at pH about 0.2 in 50 % alcohol containing sulfuric acid and sodium sulfate at −0.85 V *vs* S.C.E. The reduction consumed 3.5 electrons. The reaction completed, the mixture was diluted with water and extracted several times with ether, which was evaporated. The IR-spectrum (in chloroform) of the residue indicated the presence of benzylacetone. The residue, however, also contained another unconjugated ketone forming a 2,4-dinitrophenylhydrazone with m. p. 30—40° higher than that of benzylacetone. The reaction medium was then made alkaline and extracted several times with ether. The ether was extracted with dilute hydrochloric acid, and the amine benzoylated in alkaline solution, yielding 825 mg benzoyl derivative. It was identified as N-(methyl-cinnamyl)-benzamide from its m. p. 135—137° (N-(methyl-cinnamyl)-benzamide m. p. 136—137°). (Found: C 81.06; H 6.78; N 5.77. Calc. for $C_{17}H_{17}NO$: C 81.30; H 6.82; N 5.58.)

Reduction of benzalacetone oxime (2). A solution of 1.0 g benzalacetone oxime was reduced in 150 ml aqueous sodium hydroxide containing potassium chloride. 40 ml benzene were added to extract the reduction product as soon as it was formed. The compound was reduced at −1.70 V *vs* S.C.E. and the reduction required 3.9 electrons. After separation of the layers, the aqueous layer was extracted with ether, and the organic phase washed with acid, from which a small amount of amine (75 mg) could be isolated. The organic solvents were evaporated leaving 820 mg of a compound with an IR-spectrum identical with that of benzylacetone. On reaction with 2,4-dinitrophenylhydrazine a precipitate, m. p. 126°, was obtained (benzylacetone 2,4-dinitrophenylhydrazone, m. p. 125—126.3°[27]).

Reduction of anti *benzaldoxime.* 1.0 g of *anti* benzaldoxime was reduced at pH 9 in a mixture of 30 % peroxide free tetrahydrofurane and 70 % aqueous buffer at −1.7 V *vs* S.C.E. The reduction required 4.0 electrons per molecule. After completion of the reaction the mixture was extracted three times with ether, which was dried. On addition of dry hydrogen chloride a precipitate, 700 mg, was obtained which was identified as benzylamine hydrochloride through the benzoyl derivative, m. p. 104—6° (N-benzyl-benzamide, m. p. 105—7°). (Found: C 79.65; H 5.99; N 6.70. Calc. for $C_{14}H_{13}NO$: C 79.57; H 6.21; N 6.64.)

Reduction of N-benzyl benzaldoxime. 1.0 g of N-benzyl benzaldoxime was reduced in aqueous medium of pH 7 at −1.2 V *vs* S.C.E. The reduction required 3.8 electrons per molecule. After completion of the reduction the reaction mixture was extracted with ether which was dried. On addition of dry hydrogen chloride a precipitate, 740 mg, was obtained, which after recrystallization from alcohol had m. p. 257—258°. (Dibenzylamine hydrochloride, m. p. 256°.) (Found: C 71.75; H 6.96; N 5.99; Cl 14.90. Calc. for $C_{14}H_{16}NCl$: C 71.93; H 6.90; N 6.00; Cl 15.17.)

Reduction of mesoxalic acid ester oxime. 1.0 g of mesoxalic acid ester oxime was reduced in a sodium bicarbonate solution that was saturated with carbon dioxide during the reduction, which required four electrons. pH was then raised to 9 and the mixture extracted with ether and ethyl acetate, which was dried. After addition of alcoholic hydrogen chloride the organic solvents were evaporated *in vacuo* and the residue dissolved in a small amount of alcohol. On addition of ether a precipitate was obtained with m. p. 159°, which was identified as aminomalonic acid ethylester hydrochloride (m. p. 162°). (Found:

C 39.76; H 6.76; N 6.81; Cl 16.70. Calc. for $C_7H_{14}NClO_4$: C 39.72; H 6.67; N 6.61; Cl 16.75.)

Reduction of benzamide oxime. 1.0 g of benzamide oxime was reduced in aqueous acetate buffer pH 4.7 at −1.3 V *vs* S.C.E. The reduction required two electrons per molecule. After completion of the reduction picric acid was added and a precipitate, 2.1 g, was obtained, which after recrystallization from alcohol had m. p. 231−233°. It was identified as benzamidine picrate (m. p. 233°) by its m. p. and analysis. (Found: C 44.72; H 3.07; N 20.10. Calc. for $C_{13}H_{11}N_5O_7$: C 44.71; H 3.17; N 20.05.)

Reduction of benzalazine. A suspension of 2.0 g of benzalazine in alkaline 50 % ethanol was reduced at −1.60 V *vs* S.C.E. The yellow colour of the solution disappeared as the reduction proceeded, and a white compound crystallized out. After consumption of 2 electrons per molecule the reduction was finished and the crystalline compound filtered off, m. p. 68−70°. It was identified as benzaldehyde benzylhydrazone (m. p. 65°, 69−70°). This compound is known to be unstable in contact with air, and the compound was, therefore, further characterized by its picrate, m. p. 130° (130°). (Found: C 54.25; H 3.95; N 15.91. Calc. for $C_{20}H_{17}N_5O_7$: C 54.66; H 3.90; N 15.94.)

Reduction of benzaldehyde benzylhydrazone. 1.5 g benzalazine was reduced in alkaline solution as described above (2 electrons per molecule). pH was then lowered to 5 by addition of glacial acetic acid and the reduction product from the alkaline reduction, benzaldehyde benzylhydrazone, reduced at −1.2 V *vs* S.C.E. After completion of the reduction which required 4 electrons hydrochloric acid was added and most of the solution evaporated *in vacuo*. The residue was made alkaline and extracted with ether which was dried. On addition of gaseous hydrogen chloride a precipitate, 1.08 g, was obtained which was identified as benzylamine hydrochloride from the m. p. 250−254° (250−256°) and the m. p. 104−106° of the benzoyl derivative (N-benzyl benzamide, m. p. 105−107°).

Reduction of benzaldehyde phenylhydrazone. A suspension of 1.0 g of benzaldehyde phenylhydrazone in a mixture of 90 ml peroxide free dioxane, 50 ml alcohol, and 50 ml N HCl was reduced at −0.80 V *vs* S.C.E. The reduction was completed after the consumption of 4.2 electrons. The reaction mixture was evaporated to dryness *in vacuo* and the residue dissolved in buffer pH 5. This was extracted with ether, which was shown to contain an amine, that could be diazotized. The aqueous phase was made alkaline and extracted with ether, which was dried. On addition of alcoholic hydrogen chloride a precipitate was obtained, m. p. 253−255°, which was recrystallized from alcohol-ether. The compound was identified as benzylamine hydrochloride from its analysis: (Found: C 58.37; H 7.08; N 9.74; Cl 24.75. Calc. for $C_7H_{10}NCl$: C 58.54; H 7.02; N 9.76; Cl 24.68.)

Reduction of benzophenone phenylhydrazone. A suspension of 1.0 g of benzophenone phenylhydrazone was reduced at −0.75 V *vs* S.C.E. in a mixture of 80 ml peroxide free dioxane, 80 ml alcohol, and 40 ml 2 N HCl. After completion of the reduction, which consumed four electrons per molecule, the reaction mixture was diluted with water and extracted with ether. pH was raised to 4 and the aqueous layer extracted with ether. The aqueous phase was then made alkaline and extracted with ether. After drying of this ether extract a precipitate, 460 mg, was obtained on addition of hydrogen chloride. It sublimed about 280°. It was identified as benzhydrylamine hydrochloride from its analysis. (Found: C 71.04; H 6.59; N 6.28; Cl 16.15. Calc. for $C_{13}H_{14}NCl$: C 71.07; H 6.42; N 6.37; Cl 16.14.)

Reduction of p-*dimethylaminobenzaldehyde phenylhydrazone.* 1.0 g of N-dimethylaminobenzaldehyde phenylhydrazone was reduced at pH 0.5 in 50 % alcohol. The cathode potential was −0.8 V *vs* S.C.E. The reduction was completed after the consumption of four electrons per molecule, and pH was then adjusted to 5. The reaction medium was extracted with ether, made alkaline and extracted several times with ether. The ether was dried and on addition of dry hydrogen chloride a precipitate, 480 mg, was obtained, which was identified as N^4,N^4-dimethyl-toluene-α,4-diamine dihydrochloride from its analysis. (Found: C 48.33; H 7.28; N 12.56; Cl 31.51. Calc. for $C_9H_{16}N_2Cl_2$: C 48.44; H 7.23; N 12.56; Cl 31.79.)

Reduction of cinnamaldehyde semicarbazone. 1.0 g of cinnamaldehyde semicarbazone was reduced in alkaline, 50 % alcoholic solution at a cathode potential of −1.70 V. After consumption of two electrons per molecule the reaction was completed and the reaction mixture diluted with water. It was extracted with ether which was evaporated. The residue was recrystallized from dilute alcohol and benzene. It was identified as hydro-

cinnamaldehyde semicarbazone from the m. p. 124—126° (127°), and its analysis. (Found: C 63.16; H 6.95; N 21.58. Calc. for $C_{10}H_{13}N_3O$: C 62.80; H 6.86; N 21.97.) On boiling with 2,4-dinitrophenylhydrazine in dilute alcohol a 2,4-dinitrophenylhydrazone, m. p. 149—151° was obtained (Hydrocinnamaldehyde 2,4-dinitrophenylhydrazone, m. p. 147° [26]).

Reduction of benzalacetone semicarbazone. A suspension of 1.0 g of benzalacetone semicarbazone was reduced at pH 13 in 50 % alcohol at a cathode potential of −1.70 V. The reduction required 2 electrons per molecule. The reaction mixture was then diluted with water and extracted with ether, which was evaporated. The residue was recrystallized from benzene-petrol ether, 0.65 g, m. p. 112°. The m. p. was not raised by recrystallization from dilute alcohol, but on recrystallization from benzene and seeding with a crystal of actual benzylacetone semicarbazone the m. p. was raised to 141—142° (benzylacetone semicarbazone m. p. 142°). (Found: C 64.19; H 7.36; N 20.48. Calc. for $C_{11}H_{15}N_3O$: C 64.37; H 7.37; N 20.47.) On boiling with 2,4-dinitrophenylhydrazine in dilute alcohol a 2,4-dinitrophenylhydrazone, m. p. 125—26°, was obtained. (Benzylacetone 2,4-dinitrophenylhydrazone, 125—126,3° [27]).

Reduction of benzaldehyde semicarbazone. A solution of 1.0 g of benzaldehyde semicarbazone was reduced in a mixture of 70 ml peroxide free dioxane, 70 ml alcohol and 50 ml N HCl at a cathode potential of −0.85 V *vs* S.C.E. The reduction required four electrons. After completion of the reaction the solvents were evaporated *in vacuo* and the residue dissolved in alkali, which was extracted with ether. After drying dry hydrogen chloride was added and a precipitate m. p. 252—255° was obtained. The amine was benzoylated yielding a derivative m. p. 104—106° (N-benzyl benzamide m. p. 105—107°). (Found: C 79.54; H 6.04; N 6.30. Calc. for $C_{14}H_{13}NO$: C 79.57; H 6.21; N 6.64.)

Reduction of benzophenone semicarbazone. 1.0 g of benzophenone semicarbazone was reduced in 200 ml 50 % ethanolic 0.5 N HCl containing 3 g of semicarbazide hydrochloride at −0.9 V *vs* S.C.E. The reduction required four electrons per molecule. The reaction medium was extracted with ether after completion of the reduction, and 0.1 g of an unidentified compound was isolated from the ether. The aqueous phase was made alkaline and extracted with ether, which was dried. On addition of alcoholic hydrogen chloride a precipitate, 620 mg, was obtained, which was identified as benzhydrylamine hydrochloride from its analysis. (Found: C 70.85; H 6.60; N 6.40; Cl 16.00. Calc. for $C_{13}H_{14}NCl$: C 71.07; H 6.42; N 6.37; Cl 16.14.)

From the reduction of benzophenone semicarbazone at pH 4 a hydrochloride was isolated, which on recrystallization from water yielded a compound, that was identified as 1-benzhydrylsemicarbazide from its m. p. 165° (164—165°) and analysis. (Found: C 69.43; H 6.32; N 17.59. Calc. for $C_{14}H_{15}N_3O$: C 69.68; H 6.27; N 17.42.)

An X-Ray Analysis of the 1:1 Compound Trimethylamine-Iodine

KNUT O. STRØMME

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

The crystal structure of the 1:1 molecular compound trimethylamine-iodine has been determined by X-ray methods. The nitrogen-halogen arrangement is linear. A short N—I distance (2.27 Å) suggests a strong interaction between nitrogen and halogen. The observed I—I distance (2.83 Å) is 0.17 Å longer than the covalent I—I bond length observed in the "free" I_2 molecule.

Structure determinations of addition compounds between weak organic amines (with dissociation constants in water solution of the order 10^{-9}) and halogens [1,2] show the nitrogen-halogen-halogen arrangement to be linear. The interaction between the donor (nitrogen) atom responsible for the Lewis base properties of the amine, and the acceptor (halogen) atom is strong, and the nitrogen-halogen distance slightly larger than that to be expected for a normal covalent bond. It might be questioned whether or not appreciably stronger organic bases behave in a similar way towards halogens. According to Hantzsch [3] the addition reaction between trimethylamine (diss. const. 7.4×10^{-5}) and bromine leads to the formation of bromotrimethylammonium bromide.

$$[(CH_3)_3NBr]^+Br^-$$

Attempts to obtain single crystals of this compound were not successful. Using iodine instead of bromine, however, single crystals of the corresponding addition compound suitable for X-ray analysis could be grown without too great difficulty.

EXPERIMENTAL

The compound trimethylamine-iodine was obtained as an orange coloured precipitate by adding a solution of potassium triiodide to a solution of the amine in water [4]. After filtration the precipitate was dried over phosphorus pentoxide in a desiccator. The composition was determined by titration of iodine against a standardized solution of sodium thiosulphate. Decomposition point 66°C. Recrystallisation was effected by cooling a

solution of the compound in methylene chloride to −50°C. The crystals show a marked tendency to twin.

The rather unstable crystals were mounted in boronlithium capillaries before exposure to X-rays. Their cross-sectional dimensions perpendicular to the rotation axis were about 0.15 × 0.20 mm².

Weissenberg and oscillation photopgraphs were taken with Cu-$K\alpha$ radiation at about −20°C, the cooling being achieved by an adjustable stream of cold air. Using the double film technique two series of Weissenberg photographs were given exposure times from 1 to 100 h. The intensities estimated visually by comparison with a standard scale, were corrected for Lorentz- and polarization effects. No correction for absorption and secondary extinction effects was applied. 66 $hk0$ and 125 $h0l$ reflections are attainable with Cu-$K\alpha$ radiation. Actually, 50 and 92 were observed, respectively. The atomic scattering factors employed in the calculations of the structure factors are given by the Hartree and Thomas-Fermi f-curves [5]. A correction of the form exp. $(-B \sin^2 \Theta/\lambda^2)$ was applied to the calculated structure factors. The temperature factor, B, was found by inspection to be 1.70 Å² and 1.20 Å² for the ($hk0$) and ($h0l$) zones, respectively. Absorption effects are probably mainly responsible for the smallness of these figures.

CRYSTAL DATA

The crystals are orthorhombic with axial dimensions: $a = 11.37$ Å, $b = 8.30$ Å, $c = 8.34$ Å. With four $(CH_3)_3N.I_2$ molecules per unit cell the calculated density is 2.64 g/cm³, as compared to the experimental value of 2.57 g/cm³.

When twinning occurs the individual crystals retain a common orientation of the a axis, whereas the orientations of the b and c axes interchange. Since these axes differ only slightly in length, superposition of X-ray reflections may occur.

Absence of reflections excludes all space groups but $Pnma$ and $Pna2_1$. The former is centrosymmetric and was assumed to be the correct one. It demands that the four amine groups be situated in mirror planes.

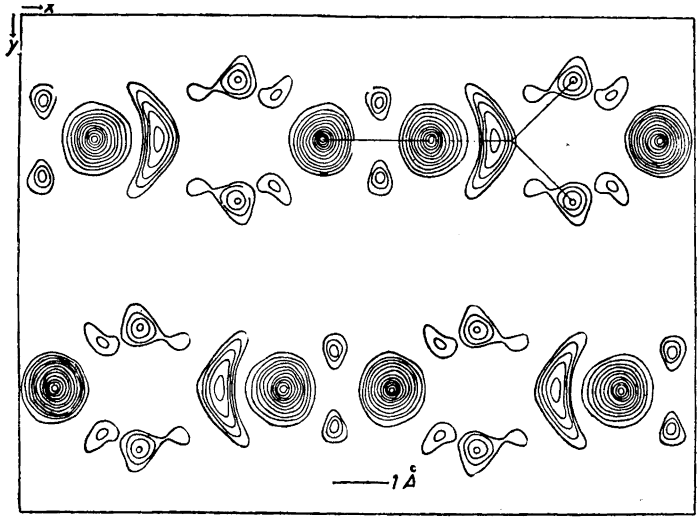

Fig. 1. Electron density projection along the c axis. Contour intervals: 10 e · Å⁻² for iodine atoms and 2 e · Å⁻² for nitrogen and carbon atoms. The first contour is the 6-electron line.

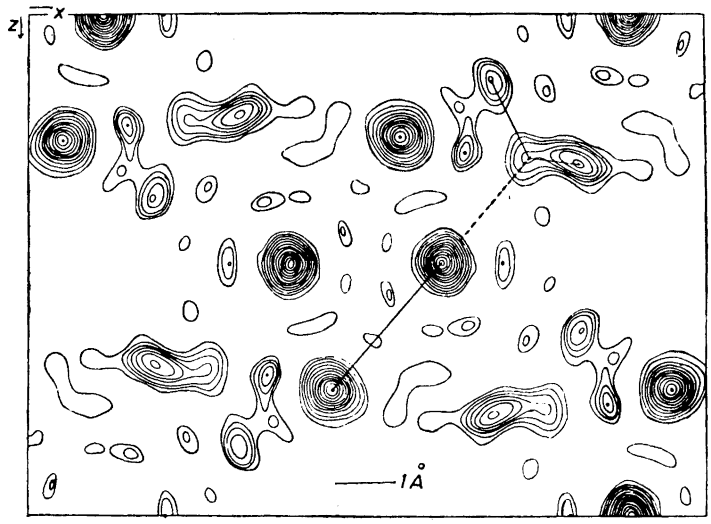

Fig. 2. Electron density projection along the *b* axis. Contours as in *Fig.* 1.

DETERMINATION OF THE STRUCTURE

The positions of the iodine atoms were found from two dimensional Patterson syntheses based on the (hk0) and (*h*0*l*) reflections, combined with trial and error computations. Using the heavy atom method for the sign determination, the electron density map, Fig. 1 was worked out. In this figure the full lines represent bonds within the amine and the halogen groups, whereas the broken line indicates the bond between the groups. The iodine atoms are seen to be situated in mirror planes, *i.e.* in fourfold positions.

For the (010) projection which is shown in Fig. 2, successive refinements had to be carried out. The small contributions of the heavy atoms to the structure factors with indices $h = 2n + 1$ and $l = 2n$ made the successive introduction of the light atoms necessary. Except for two crystallographically equivalent N—C distances the projection along the *b* axis on the mirror plane gives the intramolecular bond distances in their true lengths.

Table 1 contains a list of atomic parameters. The suffixes attached to the atomic symbols refer to the structure formula shown below. The *y* para-

Table 2. Standard deviations of peak positions [6].

I_1:	$\sigma(x) = 0.005$ Å;	$\sigma(z) = 0.006$ Å
I_2:	$\sigma(x) = 0.007$ Å;	$\sigma(z) = 0.007$ Å
N:	$\sigma(x) = 0.069$ Å;	$\sigma(z) = 0.073$ Å

meters of two carbon atoms situated outside the mirror plane are derived from a (F_{obs}—F_{hal}) synthesis using the ($hk0$) reflections. Almost identical values of the x parameters of the heavy atoms are obtained from the two projections.

The agreement factor, defined as $R = \Sigma \| F_{obs} | - | F_{calc} \| / \Sigma | F_{obs} |$, including not observed reflections when $| F_{calc} | > | F_{obs,\ min.} |$ is 0.13_7 for the ($hk0$) zone and 0.16_7 for the ($h0l$) zone. Observed and calculated F- values are listed in Table 3.

Table 3. Observed and calculated structure factors. The figures represent one fourth of the absolute values.

CONCLUSION

Table 4 contains calculated intramolecular distances and angles and some covalent bond lengths [7]. The suffixes attached to the atomic symbols refer to the structure formula

$$\begin{matrix} C_1 \diagdown \\ C_2 — N \ldots I_1 — I_2 \\ C_3 \diagup \end{matrix}$$

Intermolecular distances are found to be in satisfactory agreement with the sums of accepted van der Waals' radii [7]. Standard deviations in bond lengths [8] are as follows:

$$\sigma\ (I_1—I_2) = 0.009\ \text{Å}$$
$$\sigma\ (I — N) = 0.070\ \text{Å}$$

The structure of this compound is closely related to the structures of the 1:1 complexes between weak organic bases and halogen [1,2]. The nitrogen-halongen-halogen group is linear. The short N—I distance indicates a strong interaction between donor and acceptor atoms. At the same time the I—I bond is weakened, the bond being about 0.2 Å longer than in the "free" I_2 molecule. The values of the N—I bond lengths observed in the 1:1 compounds pyridine-iodomonochloride and trimethylamine-iodomonochloride are 2.26 Å [2] and 2.30 Å [10], respectively. A reinvestigation of the compound pyridine-iodomonochloride gave 2.30 Å for the N—I bond length [10].

The value of the dissociation constant of the amine or the nature of the second halogen atom appears to be of minor importance in determining the nitrogen-iodine bond length. The iodine atom directly linked to nitrogen is believed to possess in its valence shell five electron pairs in sp^3d_{z2} hybrid orbitals, whereas the second iodine atom retains its octet of electrons in its valence shell. The atomic arrangement to be expected is then a linear grouping of nitrogen-halogen-halogen. A more comprehensive discussion of these problems is given by Hassel [9,10].

Finally it should be stressed that the results of this investigation appear to contradict the assumption first expressed by Hantzsch that the addition compounds between trimethylamine or other tertiary amines and halongens [3,4] should be interpretated as salts of a halogen substituted ammonium cation.

The author is grateful to professor O. Hassel for his interest and advice throughout this work.

Crystal Structure of the 1:1 Addition Compound Formed by Acetone and Bromine

O. HASSEL and KNUT O. STRØMME

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

The crystal structure of the equimolecular compound containing acetone and bromine has been determined at temperatures near −30°C using Weissenberg technique (CuK-radiation) and precession technique (MoK-radiation). The space group is $C2/c$ and the lattice parameters: $a = 7.12$ Å; $b = 7.48$ Å; $c = 12.90$ Å; $\beta = 111.5°$. Endless chains are present in this structure, bromine atoms and the carbonyl carbon and oxygen atoms of each chain being coplanar. Each oxygen atom is linked to two neighbouring oxygen atoms of the same chain by halogen molecule bridges and the O—Br—Br—O arrangements are linear. The observed Br—Br distance was found equal to the distance observed in free bromine molecules (2.28 Å), the O—Br distance 2.82 Å. This structure affords the first example of two halogen molecule bridges starting from a common oxygen atom.

Results obtained in previous investigations of the crystal structure of addition compounds containing halogen molecules and electron donor molecules like ethers, amines and aromatic hydrocarbons made it appear of interest to include at least *one* addition compound between halogen and ketone in our research programme [1]. It would appear probable that in such compounds "halogen molecule bridges" are formed between keto oxygen atoms belonging to neighbouring ketone molecules. There is no doubt a marked tendency to establish endless chains of alternating halogen and donor molecules in addition compounds. In the case of ketones, however, such chains could not be formed unless both lone electron pairs of a particular keto oxygen atom are capable of forming electron transfer bonds at the same time.

We have chosen the 1:1 addition compound of acetone and bromine as an example. According to Mass and McIntosh [2] this compound has a melting point of —8°C and the X-ray analysis of single crystals should therefore not be more difficult than for several other substances which have already been successfully investigated.

On cooling equimolecular mixtures of the two components in thin capillary tubes it was found that single crystals could indeed be grown which appeared

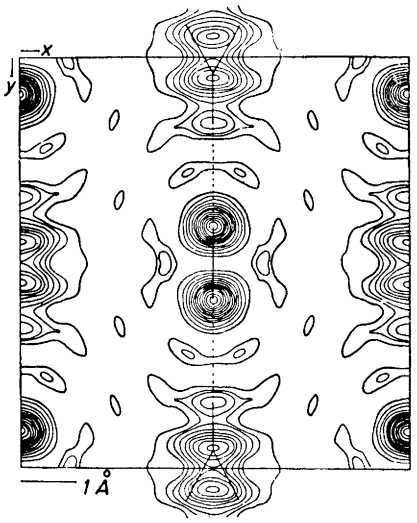

Fig. 1. Fourier projection along the *c* axis. First contour line represents 4 e · Å^{-2}. Contour intervals 2 e . Å^{-2} for light atoms, 10 e · Å^{-2} for bromine.

satisfactory for our purpose. When using Weissenberg technique, however, it is useful that crystals are available that have one of their crystallographic axes approximately parallel to the axis of the capillary tube. In our case we succeeded in producing crystals which fulfilled this requirement with respect to one crystallographic direction only, the *c*-axis. The material obtained from Weissenberg diagrams with Cu*K*-radiation had therefore to be supplemented by material obtained using a precession camera and Mo*K*-radiation.

No efforts were made in order to keep the crystal at a constant temperature during the exposure, but the temperature was never far from a mean value of about —30°C.

According to the X-ray data the addition compound is monoclinic and the space group either $C2/c$ or C/c. The lattice parameters are:

$$a = 7.12 \text{ Å}; \quad b = 7.48 \text{ Å}; \quad c = 12.90 \text{ Å}; \quad \beta = 111.5°$$

The density of the crystals was not determined experimentally, but a reasonable value is 2.1 which leads to a number of four molecules of each kind in the unit cell.

From a two dimensional Patterson synthesis preliminary x and y coordinates of the bromine atoms were determined and a Fourier map with projection along [001] was worked out. It was assumed that the space group is $C\ 2/c$ and the signs of the structure factors were determined from the coordinates of the bromine atoms alone, neglecting contributions from the lighter atoms. The resulting electron density map is reproduced in Fig. 1. No changes of structure factor signs occurred after introducing the contribution from carbon and oxygen atoms. Fig. 1 thus represents the final electron density projection along [001]. The R-factor of this projection is 0.13. The heavy peaks correspond to double bromine atoms, the overlapping of the atoms being complete or at least almost so. Approximate x and y coordinates of the lighter

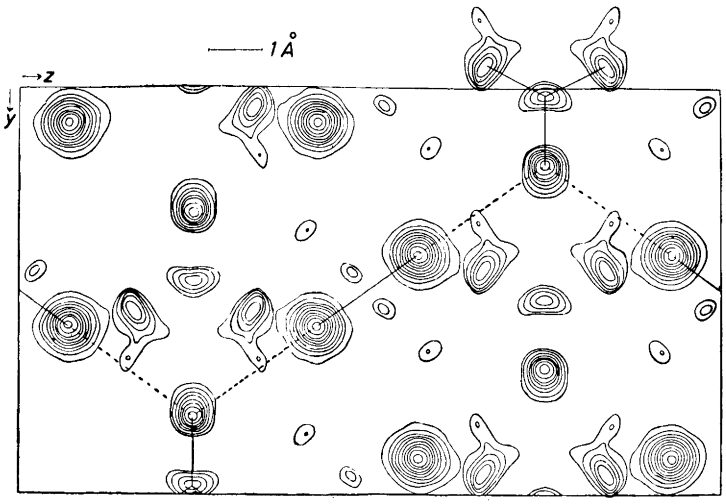

Fig. 2. Fourier projection along the *a* axis. First contour line represents 4 e · Å^{-2}. Contour intervals 1 e · Å^{-2} for light atoms, 6 e · Å^{-2} for bromine.

atoms may also be obtained from this projection. The C—O distance of the carbonyl group is in good agreement with the value deduced from the [100] projection (1.22 Å).

Before starting to work out the Fourier projection along [100] the corresponding Patterson map was computed in order to determine the *z* coordinates and verify the *y* coordinates already determined. Neglecting again the lighter atoms the Fourier chart reproduced in Fig. 2 was obtained. More accurate values for the coordinates of the light atoms were worked out by computing a difference synthesis with subtraction of the contribution from the bromine atoms. This procedure led to some modifications of the coordinates determined from the original map and also to minor corrections of the bromine parameters. With the new parameter values the *R* factor for the [100] projection dropped from 0.12 to 0.10. The final parameters for both the bromine and the light atoms are listed in Table 1.

The fall in observed X-ray intensities for increasing reflexion angles turned out to be smaller for the bromine acetone compound than for most addition

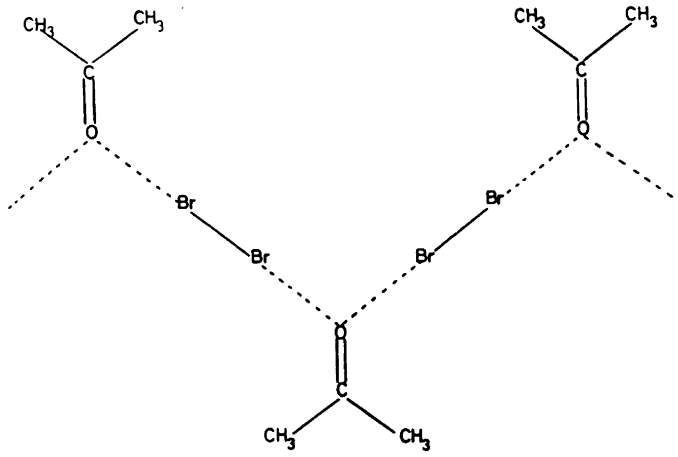

Fig. 3. The planar chains.

compounds with halogens previously investigated (*B* values 2.1 and 2.3 for the projection along [100] and [001]), respectively. This is probably due to the presence of the fairly rigid planar double chains present in the acetone-bromine structure (see below).

There is actually very strong evidence that not only are the bromine atoms lying in the (100) plane but also the carbon and oxygen atoms of keto groups belonging to a particular chain. The coordinate values of the latter atoms are listed in the upper part of Table 1. From these values follows a Br-Br bond distance of 2.28 Å. Allowing for probable errors in the bromine coordinates it may at least be stated that this distance cannot be substantially greater than the corresponding bond distance in the "free" molecule which is indeed 2.28 Å. The distance between a bromine atom and the nearest oxygen atom to which it is directly attached becomes 2.82 Å, a value somewhat larger than the O-Br distance observed in the addition compound between 1,4-dioxan and bromine namely 2.71 Å. The standard deviation in the Br-Br distance is 0.006 Å, in the O-Br distance 0.028 Å.

Table 2. Interatomic distances and angles.

Bond	Bond length (Å)	Sum of covalent radii (Å)	Angle	
Br—Br	2.28	2.28	Br—Br—O	180°

The O—Br—Br—O arrangement is linear. The angle between the two O—Br—Br—O lines meeting in a particular oxygen atom is 110°. The arrangement of the carbonyl and bromine atoms in the plane of the chains (*cf.* Fig. 3) thus appears to be determined in a very simple way by the position of the two lone electron pairs of the oxygen atom and the linearity of the O—Br—Br—O arrangement. The presence of halogen-molecule bridges between oxygen atoms of neighbouring acetone molecules was not unexpected; the new feature of this structure is the fact that a particular oxygen atom may indeed serve as a "bridge-head" for *two* such bridges.

The only atoms of the chains which do not appear to be situated in the (100) planes are those of the methyl groups. The angle between the C—C bonds and the plane of the chains is 16°. The reason for this tilting of the methyl groups is probably to be sought in the circumstance that only in this way the distance from the methyl carbon atom to the two nearest bromine atoms belonging to neighbouring chains will be of equal length and correspond to the accepted "van der Waals distance".

The relatively slow fall in X-ray intensities for increasing reflexion angles mentioned above indicates more moderate thermal vibrations than those met with in many other addition compounds. This finding must no doubt be a consequence of the particular form of chains present in the structure which should be expected to facilitate vibrations perpendicular to the plane. Actually, the observed anisotropy of the thermal vibrations is in accord with this view, the vibration parallel to the x-axis being more pronounced than in directions perpendicular to the x-axis.

Table 2 contains a list of observed interatomic distances and angles. In Table 3 observed and calculated structure factors are listed. The number of reflexions observed in the ($hk0$) zone is 37 (theor. 39), in the ($0kl$) zone 40 (theor. 60). The f-curves used in this calculations are those given in the *Internationale Tabellen* (1935).

This investigation has been sponsored by the United States Air Force Development Command under contract AF 61 (052)—71.

Aminosugars and Related Compounds

Part VI*. The Action of Alkali on Some Benzyloxycarbonylamino Derivatives

A. B. FOSTER, M. STACEY and S. V. VARDHEIM**

Chemistry Department, The University, Edgbaston, Birmingham 15, England

The action of aqueous ethanolic sodium hydroxide on methyl 2-benzyloxycarbonylamino-2-deoxy-6-*O*-toluene-*p*-sulphonyl-α-D-glucopyranoside (II) yields an unexpected product to which the structure methyl 2-amino-3:6-anhydro-2-*N*:4-*O*-carbonyl-2-deoxy-α-D-glucopyranoside (IV) has been allocated. The susceptibility of benzyloxycarbonylamino alkyl derivatives towards alkali appears to be influenced by the presence of hydroxyl groups in the same molecule. Benzyloxycarbonylamino*cyclo*hexane is converted to a mixture of di*cyclo*hexylurea and ethoxycarbonylamino*cyclo*hexane by the action of alkali. Several new derivatives of methyl 2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside are described.

The action of alkali on suitable 6-*O*-toluene-*p*-sulphonyl-D-glycopyranoside derivatives yields 3:6-anhydro-D-glucopyranoside compounds [1]. The reaction occurs in other hexopyranose derivatives and has been well studied [2]. 2-Amino-3:6-anhydro-2-deoxy-D-glucose and its derivatives are however unknown and an attempted synthesis of a derivative by the alkaline treatment of methyl 2-benzyloxycarbonylamino-2-deoxy-6-*O*-toluene-*p*-sulphonyl-α-D-glucopyranoside (II) gave unexpected results.

Treatment of methyl 2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside (I) with one mole of toluene-*p*-sulphonyl chloride in pyridine gave, as anticipated [3], the 6-*O*-toluene-*p*-sulphonate (II). That the C_6 hydroxyl group had been substituted in this reaction was indicated by the ready exchange of the toluene-*p*-sulphonyloxy residue for iodine on treatment of (II) with sodium iodide in acetone at 100° for 2 h to yield methyl 2-benzyloxycarbonylamino-2:6-di-deoxy-6-iodo-α-D-glucopyranoside (III). This type of exchange

* Part V. *Acta Chem. Scand.* **12** (1958) 1605.

** Present address (S.V.V.) Papirindustriens Forskningsinstitutt, Boks 250, Vinderen Oslo, Norway.

reaction is generally characteristic of primary toluene-*p*-sulphonates [3,4]. The consumption of approximately 1 mole of lead tetra-acetate by the 6-*O*-toluene-*p*-sulphonate (II) indicated the presence of a vicinal glycol grouping in the molecule and confirmed the allocated structure. When methyl 2-benzyloxycarbonylamino-2-deoxy-6-*O*-toluene-*p*-sulphonyl-α-D-glucopyranoside (II) was treated with 0.33 N sodium hydroxide in boiling aqueous ethanol (water-ethanol 1:2 v/v)* a rapid reaction took place ($[M]_D$ + 445° → + 93° during 30 min). An almost identical change in $[M]_D$ occurred during 36 h when the reaction was carried out at room temperature. Only one compound, *A*, could be isolated from the reaction and it appeared to be the major if not the sole product. Compound *A* has been allocated the structure methyl 2-amino-3:6-anhydro-2-*N*:4-*O*-carbonyl-2-deoxy-α-D-glucopyranoside (IV) on the basis of the following arguments and observations.

Elemental analysis was consistent with the formula $C_8H_{10}O_5N$ and the molecular weight (196) obtained by cryoscopy in water indicated a monomeric structure.

Evidence, which may be interpreted as indicating the presence of a 3:6-anhydro ring in compound *A*, is provided by infra-red spectra measurements. The spectra of a series of 3:6-anhydrohexopyranosides have been studied by Barker and Stephens [5], who found that, in general the spectrum of a 3:6-anhydro compound in the region 700—900 cm^{-1} was more complex than that of the parent glycoside. Further, the 3:6-anhydrohexopyranosides showed apparently characteristic absorptions in the ranges 870 ± 7, 838 ± 16, 798 ± 21 and 747 ± 11 cm^{-1} (for a discussion of the assignment of these absorptions reference should be made to the original paper [5]). The absorptions at 878, 860, 820 and 755 cm^{-1} shown by compound *A* provide a reasonably close parallel with these findings and are suggestive of a 3:6-anhydro hexopyranoside structure.

Table 1 illustrates the similarities in the infra-red spectra in the region 700—900 cm^{-1} of methyl 3:6-anhydro-α-D-glucopyranoside, Compound *A* and the respective parent compounds.

a Data taken from Ref.[5] and measured in "Nujol" mulls.
b Measured in KBr discs.
c Also showed absorption at 779 cm^{-1} (w).
Key: w week, m medium, s strong, v very.

* Unless otherwise stated, subsequent reference to alkali implies a reagent of this composition.

Further evidence suggesting the presence of a 3:6-anhydro-ring in compound *A* is the similar changes in optical rotation which occur when methyl 6-*O*-toluene-*p*-sulphonyl-α-D-glucopyranoside [1] and methyl 2-benzyloxycarbonylamino-2-deoxy-6-*O*-toluene-*p*-sulphonyl-α-D-glucopyranoside (II) are treated with alkali. The ready conversion, under these conditions, of the former compound to methyl 3:6-anhydro-α-D-glucopyranoside is well established [1].

Proof of the presence of a 3:6-anhydro ring in compound *A* followed when, on vigorous acidic hydrolysis a product *B*, presumably 2-amino-3:6-anhydro-2-deoxy-D-glucofuranose, was obtained which appeared homogeneous and displayed properties anticipated for an anhydro aminosugar on examination by paper chromatography and zone electrophoresis (ionophoresis). Reaction of *B* with phenylhydrazine yielded a compound identical with 3:6-anhydro-D-glucose phenylosazone obtained by treatment of authentic 3:6-anhydro-D-glucofuranose with phenylhydrazine.

Absorption in the range 1 700—1 736 cm^{-1} (amide I band) of a series of carbamates (R—O.CO.NH.R') has been associated with the carbonyl group [6]. Thus the strong absorption at 1 708 cm^{-1} in the spectrum of compound *A* is consistent with the presence of a carbamate grouping. However, the absence of absorption at *ca.* 1 540 cm^{-1} indicated that the carbamate grouping, if present, was part of a cyclic structure. Although an adequate explanation is lacking, it is well established [6] that the amide II band (N—H deformation) characteristic of acyclic amides is not shown when the NH—CO grouping is part of a cyclic system. This is true of tetrahydro-1:3-oxazine-2-one [7], the simplest cyclic carbamate analogue of compound *A*, and of a wide range of other related compounds [6,8]. The absorption at 3 280 cm^{-1} in the spectrum of compound *A* is therefore most likely due to an N—H bond and not to an O—H bond, an inference substantiated by the fact that compound *A* could not be converted to an *O*-acetate or *O*-toluene-*p*-sulphonate.

Since a 3:6-anhydro-ring is present in compound *A*, then, in a pyranoside structure, a cyclic carbamate grouping can involve only the amino and hydroxyl groups on C_2 and C_4 respectively. That the C_4-hydroxyl group is blocked is suggested by the resistance of compound *A* to cold dilute acid. Methyl 3:6-anhydro-α- and β-D-glucopyranoside [1] (and related compounds [2]) readily undergo an acid catalysed intramolecular rearrangement to yield the corresponding furanoside compounds. However, this rearrangement does not occur if the C_4-hydroxyl group is blocked, *e.g.* by methylation [1] (or in the galactose series [9] where the C_4-hydroxyl group is located in a sterically unfavourable position).

The presence of the carbamate grouping in compound *A* was confirmed when vigorous acidic hydrolysis liberated carbon dioxide.

Formation of the 3:6-anhydro-ring during the action of alkali on methyl 2-benzyloxycarbonylamino-2-deoxy-6-*O*-toluene-*p*-sulphonyl-α-D-glucopyranoside (II) probably precedes the formation of the cyclic carbamate since, under similar alkaline reaction conditions, methyl 2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside (I), in which 3:6-anhydro-ring formation is precluded, does not form a cyclic carbamate but undergoes rapid (*ca.* 30 min) decarboxylation (separation of sodium carbonate). Examination of accurate scale models shows that initial formation of the 3:6-anhydro-ring, following

the action of alkali on the 6-*O*-toluene-*p*-sulphonate (II), would bring the benzyloxycarbonylamino and hydroxyl groups at C_2 and C_4, respectively, into *meta* axial positions so that the hydroxyl group would be very favourably situated for nucleophilic attack on the carbonyl group of the benzyloxycarbonylamino residue with consequent expulsion of the benzyloxy group.

The stability of benzyloxycarbonylaminoalkyl groups towards alkali appears to be significantly influenced by the presence of hydroxyl groups in the same molecule. This is illustrated by the examples quoted above and by the facts that both 2-benzyloxycarbonylaminoethanol and 3-benzyloxycarbonylaminopropan-1-ol underwent rapid decarboxylation (30 min) on treatment with alkali. On the other hand benzyloxycarbonylamino*cyclo*hexane was much more resistant. Treatment of this compound (readily obtained from the reaction of *cyclo*hexylamine and benzylchloroformate) with alkali for 12 h did not cause complete reaction since 8 % of pure starting material could be recovered. The main product (59 %) formed together with benzyl alcohol was di*cyclo*hexylurea, identical with the compound obtained by the reaction of di*cyclo*hexyl carbodi-imide and phosphoric acid. Also produced in the reaction was ethoxycarbonylamino*cyclo*hexane (*N*-carbethoxy*cyclo*hexylamine) identical with the product obtained by the action of ethylchloroformate on *cyclo*hexylamine. No reaction occurred when benzyloxycarbonylamino*cyclo*hexane was treated with 0.33 N sodium hydroxide in aqueous dioxan (66 % dioxan).

The preceding observations indicate that care must be exercised in the selection of the amine protecting group in aminosugar syntheses where the use of alkaline reagents is contemplated.

Parallel with the above investigations a number of derivatives of methyl 2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside were prepared. Treatment [10] of methyl 2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside with benzaldehyde at 140° yielded methyl 4:6-*O*-benzylidene-2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside which gave a crystalline 3-*O*-methyl ether, 3-*O*-benzoate, 3-*O*-methanesulphonate and 3-*O*-toluene-*p*-sulphonate. The location of the benzylidene residue across the C_4:C_6-hydroxyl groups in these compounds was shown on acidic hydrolysis of the 3-*O*-methyl derivative when known [11] 2-amino-2-deoxy 3-*O*-methyl-D-glucose hydrochloride was formed. This latter compound was readily converted to crystalline *N*-(2:4-dinitrophenyl) and *N*-(2-hydroxynaphthylidene-1) derivatives.

EXPERIMENTAL

*Methyl 2-benzyloxycarbonylamino-2-deoxy-6-*O*-toluene-*p*-sulphonyl-α-*D*-glucopyranoside.* A solution of methyl 2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside[12] (1 g, m. p. 159°, $[\alpha]_D$ +89° in pyridine) in dry pyridine (10 ml) was cooled (0°) and treated gradually with a solution of freshly recrystallized toluene-*p*-sulphonyl chloride (0.58 g) in dry pyridine (2 ml). After storage at 0° for 2 h and then at room temperature overnight the reaction mixture was poured into ice water (150 ml). The oily compound which separated solidified after vigorous agitation of the suspension for 1 h. It was collected (0.73 g, 50 %) and recrystallized from aqueous-ethanol (50 %, v/v) to yield the product, m. p. 103°, $[\alpha]_D$ +96° (*c*, 1.0 in ethanol). Kyi[13] reports m. p. 103—104° for this product.

A solution of the above toluene-*p*-sulphonate (96 mg) in glacial acetic acid (20 ml) was treated with a 2.9 % solution (25 ml) of lead tetra-acetate in glacial acetic acid and the volume rapidly adjusted to 50 ml. Aliquots were withdrawn at suitable time intervals and the consumption of oxidant determined by a standard procedure[14]: the following results were obtained.

Time (h)	1	24	48	72	96	120
Oxidant consumed (mole)	0.096	0.29	0.483	0.725	0.918	0.918

Methyl 2-benzyloxycarbonylamino-2:6-dideoxy-6-iodo-α-D-glucopyranoside. A solution of methyl 2-benzyloxycarbonylamino-2-deoxy-6-*O*-toluene-*p*-sulphonyl-α-D-glucopyranoside (0.8 g) and sodium iodide (1.6 g) in acetone (16 ml) was heated in a sealed tube at 100° for 2 h. Sodium *p*-toluenesulphonate was precipitated. After filtration the reaction mixture was diluted to turbidity with water and stored at 0°. The *product* (0.7 g, 96 %) separated and after recrystallization from alcohol it had m. p. 156°, $[\alpha]_D$ +77° (*c*, 1.0 in acetone). (Found: C 41.5; H 4.7; N 3.1; I 29.0. $C_{15}H_{20}O_6NI$ requires C 41.2; H 4.6; N 3.2; I 29.1.)

*Action of alkali on methyl 2-benzyloxycarbonylamino-2-deoxy-6-*O*-toluene-*p*-sulphonyl-α-D-glucopyranoside.* A solution of methyl 2-benzyloxycarbonylamino-2-deoxy-6-*O*-toluene-*p*-sulphonyl-α-D-glucopyranoside (1 g) in ethanol (10 ml) and N sodium hydroxide (5 ml) was boiled under reflux. $[\alpha]_D$ changed +92.5 → +19.4° (based on the weight of the 6-*O*-toluene-*p*-sulphonate) during 30 min. After cooling and neutralisation with carbon dioxide the reaction solution was concentrated at 45° (bath)/15 mm, the residue extracted with boiling acetone (20 ml) for 15 min and the extract clarified by filtration through a carbon pad. Evaporation of the filtrate yielded a syrup which crystallized on trituration with ethyl acetate (3 ml) and heating. *Methyl 2-amino-3:6-anhydro-2-N:4-*O*-carbonyl-2-deoxy-α-D-glucopyranoside* (0.27 g, 65 %) obtained thus had m. p. 172°, $[\alpha]_D$ +46.4° (*c*, 1.0 in water). (Found: C 47.5; H 5.5; N 6.6. $C_8H_{11}O_5N$ requires C 47.8; H 5.5; N 7.0.)

When the reaction was allowed to proceed at room temperature $[\alpha]_D$ changed +92.5° → +19.2° (final constant value) during 36 h. From the solution a product (0.29 g, 69.5 %) was isolated and found to be identical with that described above.

A solution of methyl 2-amino-3:6-anhydro-2-*N*:4-*O*-carbonyl-2-deoxy-α-D-glucopyranoside (0.1304 g) in deionized water (4.8137 g) depressed the freezing point by 0.255°. Employing a freezing point constant of 18.5 (determined using 2-acetamido-2-deoxy-D-glucose as a standard) these results indicate a molecular weight of 196 (calc. 201).

*Acidic hydrolysis of methyl 2-amino-3:6-anhydro-2-N:4-*O*-carbonyl-2-deoxy-α-D-glucopyranoside.* A solution of (a) the cyclic carbamate (0.1 g) in 0.1 N sulphuric acid (5 ml) showed no change in $[\alpha]_D$ during 24 h storage at room temperature; neutralisation and evaporation of the solution gave unchanged starting material, (b) the cyclic carbamate (0.13 g) in 3 N hydrochloric acid (10 ml) was boiled under reflux in a stream of nitrogen for 3 h. The carbon dioxide evolved was collected as barium carbonate (105.4 mg, 83.5 %) which was formed on passage of the effluent gases through barium hydroxide solution.

The hydrolysate was freed from hydrochloric acid by prolonged codistillation with water at 40° (bath)/14—16 mm. Final evaporation yielded amorphous *B*, presumably 2-amino-3:6-anhydro-2-deoxy-D-glucofuranose hydrochloride (0.075 g). The infra red

spectrum (KBr disc) of the product showed absorption at 825 and 878 cm^{-1} indicative [5] of furanose configuration. The hydrolysate was examined by zone electrophoresis (ionophoresis) on Whatman No. 3 paper using the enclosed strip technique [15]. With a borate buffer [16] (pH 10) a single compact zone, M_G 0.9, was detected with aniline hydrogen phthalate. Under the same conditions 2-amino-2-deoxy-D-glucose affords a rather diffuse zone. In an acetate buffer (pH 5) a single zone of higher mobility than that of 2-amino-2-deoxy-D-glucose could be detected with ninhydrin.

Paper chromatographic analysis of the hydrolysate using the *tert*-butanol-acetic acid-water (2:1:1) solvent system [17] revealed a single component, detected with ninhydrin with R_F value (0.497) significantly higher than that of 2-amino-2-deoxy-D-glucose (0.327) but similar to that of 2-amino-1:6-anhydro-2-deoxy-D-gulopyranose [18] and the altrose analogue [18]. A solution of *B* (57.8 mg) in water (1 ml) was treated with acetic acid (0.1 ml), phenylhydrazine (0.12 g) and sodium acetate (0.18 g) and the mixture maintained at 95° for 1.5 h. The solid which separated on cooling was dissolved in methanol (2 ml) and diluted with water (20 ml). 3:6-Anhydro-D-glucose phenylosazone (5.9 mg) separated and after collection and washing with water it gave an infra-red spectrum (KBr disc) identical with that of authentic material described below.

Under identical reaction conditions 2-amino-2-deoxy-D-glucose hydrochloride (50 mg) yielded D-glucosephenylosazone (15.6 mg).

3:6-Anhydro-D-glucosephenylosazone. Crystalline 3:6-anhydro-D-glucose (50 mg) was treated at 75—80° for 2 h with a solution (3 ml) prepared from water (25 ml), sodium acetate (2 g), acetic acid (1 ml) and phenylhydrazine (1 g). On cooling a mixture of crystals and oil separated. The crystals were freed from oil by trituration with aqueous methanol yielding 3:6-anhydro-D-glucose phenylosazone (27.4 mg), m. p. 185—187°. A further amount (13.5 mg) of product was obtained on dilution of the combined mother liquors with water.

Benzyloxycarbonylaminocyclohexane. Sodium hydrogen carbonate (21 g) was added to a solution of *cyclo*hexylamine (25 g) in water (150 ml) followed by benzyl chloroformate (43 g) gradually during 1 h with continuous vigorous stirring. The crude product was collected, washed successively with light petroleum (60—80°) and water, then dissolved in ether and the solution dried ($MgSO_4$). Addition of light petroleum (60—80°) gave *benzyloxycarbonylaminocyclohexane.* (39 g, 66 %), m. p. 93° (Found: C 72.4; H 8.0; N 6.0. $C_{14}H_{19}O_2N$ requires C 72.1; H 8.15; N 6.0). Infra-red spectrum (KBr disc) showed absorptions at 1 545 cm^{-1} (amide II band) and 1 688 cm^{-1} (amide carbonyl).

Action of alkali on benzyloxycarbonylaminocyclohexane. (a) A solution of benzyloxycarbonylamino*cyclo*hexane (25 g) in N sodium hydroxide (125 ml) and ethanol (250 ml) was boiled under reflux for 12 h. On cooling sodium carbonate (2.4 g) separated. The solution was neutralised with carbon dioxide, freed from insoluble material and fractionally distilled using a 12″ column packed with nickel gauze. Ethyl alcohol was collected at 78° followed by a fraction at 98° which after condensation separated into three phases *B*, *C* and *D* of increasing density, respectively. *N:N'*-Di*cyclo*hexyl urea (7.1 g) separated after dissolution of the still residue in aqueous alcohol; it had, after recrystallization from alcohol, m. p. 236° alone or in admixture with an authentic specimen. (Found: C 69.4; H 10.75; Calc. for $C_{13}H_{24}N_2O$: C 69.5; H 10.7.) The identity of the compound was confirmed by infra-red spectroscopy. From the mother liquors by dilution with water unchanged benzyloxycarbonylamino*cyclo*hexane (1.6 g, 8 %) separated with m. p. 92° alone or in admixture with authentic material.

Examination of fractions *B* and *D* by gas phase chromatography (Perkin-Elmer apparatus with packing A at 155° with a flow rate of 15 ml/min) revealed a single component with properties closely similar to those of benzyl alcohol.

The infra-red spectra (liquid film) of fractions *B* and *D* revealed a very close similarity indeed and both showed strong absorptions at 1 692 (amide carbonyl [6]), 1 572 (amide II band, characteristic of acyclic amides) and 697 and 738 cm^{-1} (aromatic group).

Portions of fractions *B* and *D* were combined (2 ml total volume), diluted with 50 % aqueous ethanol (3 ml) and stored at 0°. Ethoxycarbonylamino*cyclo*hexane separated and after recrystallization from ethanol-ether it had m. p. 56° alone or in admixture with an authentic sample. Identity was confirmed by infra-red spectroscopy.

The infra-red spectrum (liquid film) of a solution of ethoxycarbonylamino*cyclo*hexane (1 g) in benzyl alcohol (2 ml) was virtually identical with the spectra of fractions *B* and *D*.

Ethoxycarbonylaminocyclohexane. To a solution of *cyclo*hexylamine (20 g) and sodium hydrogen carbonate (18 g) in water (100 ml), ethyl chloroformate (22 g) was gradually added during 1 h with constant vigorous stirring of the mixture. The crude product was collected, washed with water and a small volume of cold ethanol. Recrystallization from ethanol-ether afforded ethoxycarbonylamino*cyclo*hexane (23 g, 66.5 %) m. p. 55—56°. (Gillibrand and Lamberton [19] record m. p. 56° for this compound prepared by a different procedure.) The infra-red spectrum (KBr disc) showed absorptions at 1 537 cm^{-1} (amide II absorption) and 1 700 cm^{-1} (amide carbonyl).

N:N'-Dicyclohexylurea. A solution of di*cyclo*hexylcarbodi-imide (1 g) in ether (4 ml) was added to a solution of phosphoric acid (0.86 g) in ether (20 ml). Recrystallization, of the product which separated, after 30 min from ethanol yielded N:N'-di*cyclo*hexyl urea (0.7 g, 64 %), m. p. 235°. (Skita and Rolfes [20] record m. p. 230° for this compound prepared by a different method.) The infra-red spectrum (nujol mull) showed absorptions at 1 541 cm^{-1} (amide II absorption) and 1 633 cm^{-1} (amide carbonyl).

Methyl 4:6-O-benzylidene-2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside. Methyl 2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside (2 g) was heated with freshly distilled benzaldehyde at 140—145° for 5 h whilst a stream of carbon dioxide was passed through the reaction mixture. The cooled mixture was then diluted with light petroleum (10 vol, 60—80°) and the precipitate (2.0 g) collected, washed with light petroleum and recrystallized from chloroform-acetone. *Methyl 4:6-O-benzylidene-2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside* (1.82 g, 71.5 %) was obtained, m. p. 209—210° $[\alpha]_D$ +51° (*c*, 1.0 in chloroform). (Found: C 63.3; H 5.8; N 3.7. $C_{22}H_{25}O_7N$ requires C 63.6; H 6.0; N 3.4.)

By the usual methods the benzylidene compound was converted to a 3-*O*-toluene-*p*-sulphonate, m. p. 116°, after softening at 60—65°, $[\alpha]_D$ +8° (*c*, 1.0 in $CHCl_3$). (Found: C 61.1; H 5.5; N 2.2; S 5.9. $C_{29}H_{31}O_9NS$ requires C 61.2; H 5.45; N 2.5; S 5.6); 3-*O*-benzoate, m. p. 165—166°, $[\alpha]_D$ +43° (*c*, 1.0 in $CHCl_3$). (Found: C 67.3; H 5.6; N 2.4. $C_{29}H_{29}O_8N$ requires C 67.1; H 5.6; N 2.7); 3-*O*-methanesulphonate, m. p. 138—140°, $[\alpha]_D$ +38° (*c*, 1.0 in $CHCl_3$). (Found: C 55.7; H 5.3; N 2.8; S 6.7. $C_{23}H_{27}O_9NS$ requires C 56.0; H 5.5; N 2.8; S 6.5.)

Methylation of methyl 4:6-O-benzylidene-2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside. A solution of methyl 4:6-*O*-benzylidene 2-benzyloxycarbonylamino-2-deoxy-α-D-glucopyranoside (0.5 g) in methyl iodide (6 ml) was boiled under reflux in the presence of dry silver oxide (1 g) for 2 h. During this period two additional amounts (1 g) of silver oxide were added. After filtration through a carbon pad the reaction mixture was evaporated and the residue recrystallized from a methanol-chloroform mixture. *Methyl 4:6-O-benzylidene-2-benzyloxycarbonylamino-2-deoxy-3-O-methyl-α-D-glucopyranoside* (0.32 g) was obtained, m. p. 223—224°. (Found: C 64.3; H 6.2; N 3.1. $C_{23}H_{27}O_7N$ requires C 64.3; H 6.3; N 3.3.)

A solution of the above methyl ether (1 g) in 2.5 N hydrochloric acid (15 ml) was boiled under reflux for 4 h. After filtration through a carbon pad the hydrolysate was diluted with water and twice extracted with light petroleum (60—80°). Subsequent evaporation of the aqueous solution gave a syrupy residue which crystallized from methanol-acetone to yield 2-amino-2-deoxy-3-*O*-methyl-D-glucose hydrochloride (0.25 g, 47 %), m. p. 210—215° (decomp.) with discoloration at *ca.* 175°. (Neuberger [11] records m. p. 215° for this compound prepared by a different method.) Examination of the crystalline methyl ether by paper chromatography using the organic phase of a butanol-ethanol-water (4:1:5) system revealed that it contained a trace of the parent amino sugar.

2-Amino-2-deoxy-3-*O*-methyl-D-glucose hydrochloride was readily converted to an *N*-(2:4-dinitrophenyl) derivative which darkened at *ca.* 174° and had m. p. 184°. (Found: C 42.6; H 4.5; N 11.7. $C_{13}H_{17}O_9N_3$ requires C 43.45; H 4.7; N 11.7) and an *N*-(2-hydroxynaphthylidene-1) derivative, m. p. 184—185° (decomp.). (Found: C 62.6; H 6.0; N 4.1. $C_{18}H_{21}O_6N$ requires C 62.3; H 6.05; N 4.0.)

The authors thank Dr. D. H. Whiffen and Dr. K. J. Morgan for the infra-red spectra measurements and for valuable discussion, Mr. G. Durant for samples of 2-benzyloxycarbonylaminoethanol and 3-benzyloxycarbonylaminopropan-1-ol, and Miss B. Parkinson for experimental assistance. One of them (S.V.V.) thanks *Papirindustriens Forskningsinstitutt,* Oslo, Norway for a grant.

On the Kinetics of the Reaction of Cyanic Acid with Amines

MOGENS BALLUND JENSEN

The Royal Danish School of Pharmacy, Copenhagen, Denmark

The velocity constants, k_u, for the reactions: $RR'NH_2^+ + OCN^- \rightarrow RR'NCONH_2$ were determined for ammonium ion and a number of aminium ions. Assuming that the formation of urea or substituted urea is a result of a reaction between free ammonia or amine and free cyanic acid the velocity constants, $k_{OCNH\cdot Am}$, for the reactions: $RR'NH + OCNH \rightarrow RR'NCONH_2$ were calculated from $k_{OCNH\cdot Am} = k_u \cdot K_{Am} \cdot K_{OCNH}/K_{H_2O} \cdot f^2$ where K_{Am}, K_{OCNH} and K_{H_2O} are the dissociation constants for the amine, for cyanic acid and for water, respectively. f is an activity coefficient. The values of $k_{OCNH\cdot Am}$ show a simple relationship to the velocity constants, $k_{CO_2\cdot Am}$, for the analogous reactions between amines and carbon dioxide: $RR'NH + OCO \rightarrow RR'NCOOH$, *viz.* $\log k' = \log k'' - 1.08$ (18°C), where k' stands for $k_{OCNH\cdot Am}$ and k'' for $k_{CO_2\cdot Am}$.

The same relation is observed for the velocity constants for the reactions: $OH^- + OCNH \rightarrow NH_2COO^-$ and $OH^- + OCO \rightarrow HCO_3^-$ and for the velocity constants for the reactions: $H_2O + OCNH \rightarrow NH_3 + CO_2$ and $H_2O + OCO \rightarrow H_2CO_3$.

The present investigation is based on the assumption that the rate determining step for the reaction between ammonium ion and cyanate ion leading to the formation of urea in aqueous solution is a reaction between free ammonia and free cyanic acid. In the case of the analogous reactions between aminium ion and cyanate ion yielding substituted urea, the rate determining step is correspondingly assumed to be a reaction between free amine and free cyanic acid.

The purpose of the investigation has been to demonstrate that the velocity constants for the reaction of cyanic acid with amines (*incl.* ammonia) calculated from the velocity constants for the reaction between aminium ion and cyanate ion show a simple relationship to the velocity constants for the reaction of carbon dioxide with amines.

The reactions to compare are

$$RR'NH + OCNH \rightarrow RR'NCONH_2 \quad (I)$$

and

$$RR'NH + OCO \rightarrow RR'NCOOH \quad (II)$$

The reaction products are urea or substituted urea and carbamic acid or substituted carbamic acid, respectively.

For reaction I the velocity constants, $k_{OCNH\cdot Am}$, were obtained from the velocity constants, k_u, for the gross reaction

$$RR'NH_2^+ + OCN^- \rightarrow RR'NCONH_2 \qquad (III)$$

upon considering the equilibrium

$$RR'NH_2^+ + OCN^- \rightleftharpoons RR'NH + OCNH \qquad (IV).$$

The following relations will hold:

$$\text{rate} = k_{OCNH\cdot Am} \cdot c_{RR'NH} \cdot c_{OCNH} =$$

$$k_{OCNH\cdot Am} \cdot (K_{H_2O}/K_{Am} \cdot K_{OCNH}) \cdot f^2 \cdot c_{RR'NH_2^+} \cdot c_{OCN^-} = k_u \cdot c_{RR'NH_2^+} \cdot c_{OCN^-}$$

K_{H_2O} is the dissociation constant of water, K_{Am} is the basic dissociation constant of the amine, and K_{OCNH} is the acidic dissociation constant of cyanic acid. The activity coefficient of the aminium ion is set equal to that of the cyanate ion and is denoted f. The activity coefficients of the free amine and the free cyanic acid are put equal to unity.

From the above relations the following expression is obtained for $k_{OCNH\cdot Am}$:

$$k_{OCNH\cdot Am} = k_u \cdot K_{Am} \cdot K_{OCNH}/K_{H_2O} \cdot f^2$$

The values of k_u were determined for ammonia and some primary and secondary amines and the values of $k_{OCNH\cdot Am}$ were calculated from the above expression.

The experiments on the determination of k_u are given in the following section.

The velocity constants for reaction II, $k_{CO_2\cdot Am}$, have been determined previously for ammonia and a number of amines including the amines [1-7] here investigated.

The final section gives the results and a discussion.

The experiments were carried out at 18°C. The initial ionic strength was 0.2 and decreased only slightly during an experiment. The velocity constants were calculated on the basis of Napierian logarithms and refer to molar concentration, the unit of time being the minute.

ON THE REACTION: $RR'NH_2^+ + OCN^- \rightarrow RR'NCONH_2$

The formation of urea in solutions containing aminium ion and cyanate ion was followed by determing the content of cyanate at different times. The samples to be analyzed were brought to pH = approx. 5.5 by the addition of acetic acid. The cyanate was precipitated as silver cyanate by the addition of a relatively great excess of silver nitrate and back-titration with ammonium thiocyanate was carried out in a quota part of the filtrate from the silver cyanate [8].

* No ammonia added.

k_u (mean): 0.000577

The experiments with a few exceptions were carried out with solutions containing both aminium ion and free amine, *i.e.* with solutions being in most cases moderately basic. Under these conditions it was found that the concurrent formation of carbonate was only slight.

The experiments which were carried out in the case of the ammonium ion are listed in Table 1. In all the runs there was a relatively great concentration of ammonium ion compared to that of the cyanate ion, *i.e.* the concentration of ammonium ion varied only slightly during a run meaning that the reaction is approximately of the first order with respect to cyanate ion. The velocity constants, k, calculated from $k \cdot t = \ln a/a\text{-}x$ are also listed in Table 1. The value of k_u was obtained dividing the mean value of k with the mean value of the concentration of ammonium ion. The values of k_u calculated in this way are also given in Table 1 together with the mean value of the values of k_u obtained from the first four experiments.

nium ions and cyanate ions without addition of free ammonia, *i.e.* the pH of this solution was about 6 whereas the pH of the other solutions was about 9.

The formation of considerable amounts of carbonate in more acid solution can be explained through the more rapid decomposition of cyanate into carbon dioxide and ammonia at the lower pH [8].

The contents of carbonate were determined by acidimetric titration of the barium carbonate precipitated from the solutions upon addition of sodium hydroxide and barium chloride.

k_u (mean): 0.00637

The back-reaction, *viz.* the decomposition of urea into ammonium ion and cyanate ion, was neglected. The equilibrium constant for this reaction is reported [9] to be $10^{-4.52}$ (25°C).

From the first four experiments the mean value 0.000577 for k_u was obtained. Walker and Hambly [10] have determined k_u for temperatures between 25°C and 80°C. By extrapolation to 18°C the value 0.00085 is obtained at an ionic strength of 0.1 corresponding to approx. 0.00072 at the ionic strength 0.2. Wyatt and Kornberg [11], however, report the values of Walker and Hambly to be about 20 % too large (at 50°C) because of the concurrent formation of carbonate.

k_u (mean): 0.000992

concentration of aminium ion and the concentration of cyanate ion were of the same order of magnitude the values of k_u were calculated from the expressions for bimolecular reactions.

In the experiments with anilinium ion (Table 10) a few percent of the cyanate was present as free cyanic acid but this was not taken into consideration in the calculation of k_u.

Determinations of the contents of carbonate carried out in some of the experiments showed that only small amounts of carbonate were formed.

From the experiments with methylaminium ion (Table 2) the value 0.00103 was obtained for k_u. This value agrees well with the value 0.00109 calculated by extrapolation from the data of Miller [12] at an ionic strength of 0.082.

RESULTS AND DISCUSSION

In column 1 of Table 12 is given a survey on the values of k_u determined in the preceding section. Column 1 also gives the value of k_u for the reaction between hydrazinium ion and cyanate ion yielding semicarbazide, $H_2N{\cdot}NH{\cdot}CO{\cdot}NH_2$. The value of k_u for this reaction was calculated from the data of Baker and Gilbert [13].

Column 2 of Table 12 contains the pK_{Am} values for the amines. From the columns 1 and 2 can be seen that some correlation appears to exist between the values of k_u and pK_{Am}. The value of k_u for anilinium ion is for instance about 7×10^3 times greater than the value of k_u for ammonium ion. There are, however, large deviations from linearity in a plot of log k_u against pK_{Am}.

Column 3 of Table 12 presents the values of $k_{OCNH{\cdot}Am}$ calculated from

$$k_{OCNH{\cdot}Am} = k_u \cdot K_{Am} \cdot K_{OCNH}/K_{H_2O} \cdot f^2 = k_u \cdot K_{Am} \times 10^{11.03}.$$

The values $10^{-3.54}$ (Ref.[8]) and $10^{-14.22}$ have been used for K_{OCNH} and K_{H_2O}, respectively. From the expression of Svirbely and Warner [14] the value $10^{-0.35}$ is obtained for f^2 in the case of the ammonium ion. This value has been used for the aminium ions as well.

Column 3 also contains the velocity constants [8] at 18°C for the reactions

$$H_2O + OCNH \rightarrow NH_3 + CO_2 \qquad (V)$$

and

$$OH^- + OCNH \rightarrow NH_2COO^- \qquad (VI)$$

The velocity constants for the reactions V and VI are denoted k_{OCNH} and $k_{OCNH{\cdot}OH^-}$, respectively. The value of $k_{OCNH{\cdot}OH^-}$ has not been determined directly but was calculated from the previously determined velocity constant, k_{OCN^-}, for the gross reaction: $OCN^- + 2H_2O \rightarrow NH_3 + HCO_3^-$. ($k_{OCN^-}$ is $10^{-6.48}$ at 18°C). Assuming reaction VI to be the rate determining step for this reaction [15] the following equation will hold: $k_{OCNH{\cdot}OH^-} = k_{OCN^-} \cdot K_{OCNH}/K_{H_2O}$

For $k_{OCNH{\cdot}Am}$, $k_{OCNH{\cdot}OH^-}$ and k_{OCNH} the joint designation k' is used.

Column 4 of Table 12 presents the values of $k_{CO_2{\cdot}Am}$ at 18°C.

Table 12. Velocity constants for the reactions: $RR'NH^+ + OCN^- \rightarrow RR'NCONH_2$ (k_u), $RR'NH + OCNH \rightarrow RR'NCONH_2$($k_{OCNH\cdot Am}$) and $RR'NH + OCO \rightarrow RR'NCOOH$($k_{CO_2\cdot Am}$). 18°C.

Amine	1 k_u	2 pK_{Am}[a]	3 $k_{OCNH\cdot Am}$	4 $k_{CO_2\cdot Am}$
Ammonia	0.000577	4.76	$10^{3.03}$	$10^{4.02}$
Methylamine	0.00103	3.38	$10^{4.66}$	$10^{5.77}$ b
Dimethylamine	0.00338	3.22	$10^{5.34}$	$10^{6.18}$
Ethylamine	0.000583	3.34	$10^{4.46}$	$10^{5.55}$
Diethylamine	0.000923	3.00	$10^{5.00}$	$10^{5.82}$
Benzylamine	0.00672	4.74	$10^{4.12}$	$10^{5.42}$
Allylamine	0.00357	4.38	$10^{4.20}$	$10^{5.42}$
Glycinate ion	0.00637	4.34	$10^{4.32}$ c	$10^{5.41}$
tert.-Butylamine	0.000102	3.55	$10^{3.49}$	$10^{4.64}$
Aniline	3.8	9.46 d	$10^{2.15}$	$10^{3.2}$ e
Hydrazine	0.749 f	6.06	$10^{4.84}$	$10^{5.87}$
Piperidine	0.000992	2.95	$10^{5.08}$	$10^{6.25}$
Hydroxyl ion			$10^{4.20}$	$10^{5.38}$
Water			0.047	1.52 g 0.87 h

a The values of pK_{Am} are, with exception of the pK_{Am}-value for aniline, the same as have been used in the publications on the carbamates.

b Redetermined, not previously published value.

c In the case of glycine the value of $k_{OCNH\cdot Am}$ was calculated from $k_{OCNH\cdot Am} = k_u \cdot K_{OCNH} / K'_{AmH^+} \cdot f$ where $a_{H^+} \cdot c_{^-OOC\cdot CH_2NH_2} / c_{^-OOC\cdot CH_2NH_3^+} = K'_{AmH^+} = 10^{-9.88}$ and f was put equal to $10^{0.18}$.

d Value of Lundén [19].

e Only small amounts of phenyl carbamate are formed upon addition of carbon dioxide to solutions containing aniline. In a previous paper [5] values of $k_{CO_2\cdot Am}$ from $10^{2.64}$ to $10^{3.78}$ were reported. The listed value of $k_{CO_2\cdot Am}$ is the mean value of these values.

f Calculated from the data of Baker and Gilbert [13].

g Value of Faurholt [1]. h Value of Pinsent, Pearson and Roughton [16].

Column 4 also contains the velocity constants at 18°C for the reactions [1,16]

$$H_2O + OCO \rightarrow H_2CO_3 \qquad \text{(VII)}$$

and

$$OH^- + OCO \rightarrow HCO_3^- \qquad \text{(VIII)}$$

The velocity constants for the reactions VII and VIII are denoted k_{CO_2} and $k_{CO_2\cdot OH^-}$, respectively.

For $k_{CO_2\cdot Am}$, $k_{CO_2\cdot OH^-}$ and k_{CO_2} the joint designation k'' is used.

From the columns 3 and 4 can be seen that the values of k' are about a twelfth of the values of k''. Roughly, one can still say that the two set of velocity constants are of the same order of magnitude.

Fig. 1 shows that a straight line is obtained if log k' is plotted against log k''. The slope of the line is approx. 1 and the intersection with the ordinate axis is at — 1.08. This indicates the following relation between k' and k''

$$\log k' = \log k'' - 1.08$$

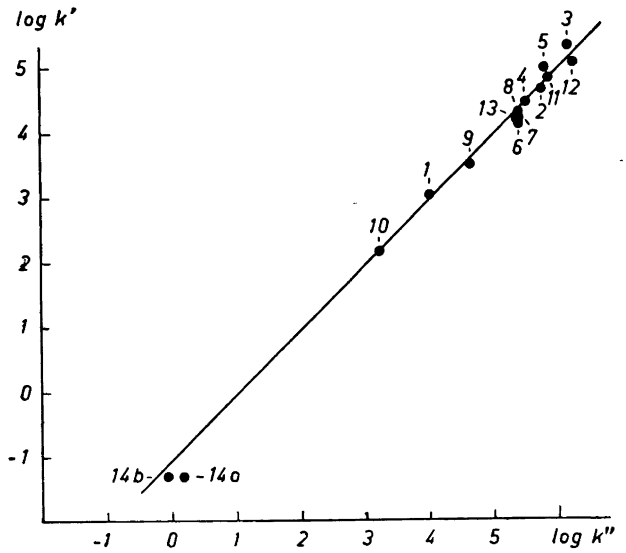

Fig. 1. Plot of log k' against log k''. k' and k'' are the velocity constants (18°C, min.) for the reactions between cyanic acid or carbon dioxide, respectively, and the following molecules and ions: 1) ammonia, 2) methylamine, 3) dimethylamine, 4) ethylamine, 5) diethylamine, 6) benzylamine, 7) allylamine, 8) glycinate ion, 9) *tert.*-butylamine, 10) aniline, 11) hydrazine, 12) piperidine, 13) hydroxyl ion, 14a) water (k'': value of Faurholt [1]) and 14b) water (k'': value of Pinsent, Pearson and Roughton [16]).

The largest deviations from the straight line are found in the case of the two secondary amines dimethylamine and diethylamine where the deviations amount to approx. + 0.2 units in the logarithm. In the case of the secondary amine piperidine the above stated expression fits well, however. In the case of benzylamine the deviation amounts to approx. — 0.2 units in the logarithm.

It should be noted that the reactions I and III are kinetically indistinguishable, because of the mobile equilibrium indicated in IV. Also the theoretical effect of changing ionic strength and dielectric constant will be the same for both mecanisms. As pointed out by Frost and Pearson [17] reaction I is, however, the most probable, seen from a stereochemical point of wiev. The reason is supposed to be that this reaction easily can take place by addition of the nitrogen atom's unshared pair of electrons to the positively polarized carbon atom of cyanic acid. In the case of ammonia the reaction is

$$\underset{\ddot{\text{H}}\text{NH}}{\overset{\curvearrowright}{\text{HN}=\text{C}=\text{O}}} \rightarrow \underset{\text{HNH}^+}{\text{HN}=\text{C}-\text{O}^-} \rightarrow \underset{\text{NH}}{\overset{\text{H}}{\text{HN}-\text{C}=\text{O}}}$$

A simple proton shift completes the transformation to urea. This is similar to a host of reactions involving addition of basic reagents to carbonyl groups.

Reaction II between amines and carbon dioxide is an example of such a reaction.

The above stated analogy between cyanic acid and carbon dioxide requires that at least a part of the cyanic acid exists as the imide form corresponding to the formula OCNH in aqueous medium. Electron diffraction appears to show that the acid has the imide structure (at least mainly) [18]. If only a minor part of the cyanic acid is present as OCNH in aqueous solution and if only the OCNH form is the one that reacts the values of $k_{OCNH \cdot Am}$ have to be multiplied with a common factor greater than 1 in order to give the true values of the velocity constants for reaction I. This is one possible reason which could explain the fact that the velocity constants for the reactions with cyanic acid are smaller than the velocity constants for the reactions with carbon dioxide. Another possibility, or at least a contributory cause, could be that the carbon atom in OCNH is less positively polarized than the carbon atom in OCO, *i.e.* a somewhat weaker attraction exists between the carbon atom and the nitrogen atom in the cyanic acid-amine reactions than is to be found in the carbon dioxide-amine reactions.

It should be added that a detailed discussion of the mecanism of the addition of amines to cyanic acid recently has been given by Johncock, Kohnstam and Speight [20].

Acknowledgements. The author wishes to express his gratitude to Professor Carl Faurholt for his kind interest in the investigation.

ACTA CHEMICA SCANDINAVICA 13 (1959) 301—311

The Oxidation of Emulsified 1-*p*-Menthene with Molecular Oxygen

VÄINÖ E. VEIJOLA and ATSO O. ILVESPÄÄ

Department of Chemistry, Finland Institute of Technology, Helsinki, Finland

1-*p*-Menthene prepared by hydrogenating purified *d*-limonene has been emulsified in water and oxidized at temperatures between 65 and 80° without any catalyst and at 10° with catalyst present.

Under the former conditions the oxidation of 1-*p*-menthene took place at position 6 while under the latter conditions it took place at positions 3 and 6. The hydroperoxides formed, 1-*p*-menthene-3-hydroperoxide and 1-*p*-menthene-6-hydroperoxide, were found to have the *trans* configuration.

The refractive index n_D^{25} of *trans*-carvotanacetol was found to be 1.4736. This alcohol underwent rearrangement to the *cis* form in both acid and alkaline media. The refractive index n_D^{25} of the resulting *cis*-carvotanacetol was 1.4772.

On chromic acid oxidation, both the *trans* and *cis* forms of carvotanacetol were converted into carvotanacetone ($n_D^{25} = 1.4785$). The infrared absorption spectrum of carvotanacetone was recorded. The infrared spectrum of the piperitone ($n_D^{25} = 1.4825$) derived from 1-*p*-menthene-3-hydroperoxide was identical with that reported by Le Fèvre *et al.* for the compound.

In all stages of the investigation the micro sorption method developed by Blohm proved very useful. With this method it was possible to separate, for example, the *trans* and *cis* forms of carvotanacetol from each other.

When unsaturated cyclic hydrocarbons are oxidized with molecular oxygen, the oxygen usually attacks the carbon atom or atoms in the alpha positions relative to the double bond.[1] When the oxidation is photosensibilized, the double bond is shifted at the same time [2]. In both cases the compounds first formed are hydroperoxides. The photosensibilized oxidations will not be discussed in this publication.

Because the oxidation of 1-*p*-menthene with molecular oxygen has not been reported before, the oxidation of a number of compounds similar in structure to 1-*p*-menthene will be first briefly examined. In the oxidation of limonene [3–7] the point of attack is primarily position 6 although according

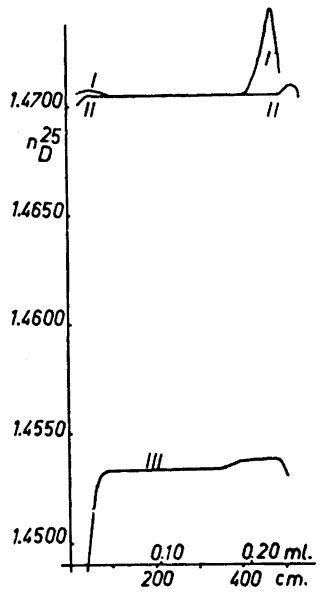

Fig. 1. Sorptograms. I, pomegranate oil; II, product isolated by steam distillation; III, hydrogenated product.

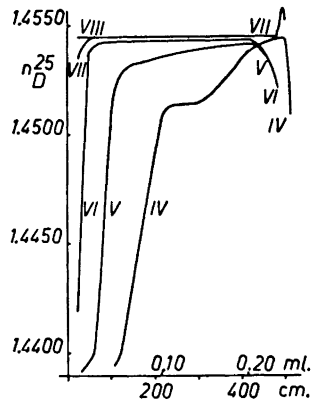

Fig. 2. Sorptograms. IV, initial fraction 1; V—VIII, fractions 2—5.

to Eschinazi [6] addition to position 3 also occurs to a slight extent. Fushizaki *et al.*[8] found that carbon 3 is attacked in the oxidation of terpinolene. The products of oxidation of 1-*p*-methyl*cyclo*hexene have indicated that both carbons 3 and 6 are attacked [9–12]. However, Cook [13] has reported that the oxidation occurs almost solely at carbon 3. He performed the oxidation at 70° with iron phthalocyanine as catalyst.

The results reported in the literature lead one to conclude that the oxidation of 1-*p*-menthene by molecular oxygen will involve the methylene groups in the alpha positions relative to the double bond, *i.e.* positions 3 and 6. The main purpose of the present study was to determine whether the oxidation takes place at one or both of these positions. To decide this, 1-*p*-menthene was emulsified in water and oxidized with molecular oxygen both with and without catalyst present and the reaction products or their derivatives identified. In addition to customary methods, the micro sorption method of Blohm [14] was used to separate the terpene alcohols and ketones from one another before identification.

Preparation of 1-p-*menthene.* 1-*p*-Menthene was prepared by hydrogenating *d*-limonene isolated from French pomegranate oil (Roure-Bertrand Fils, Grasse). According to Igolen *et al.*[15], pomegranate oil contains over 90 % *d*-limonene. The high *d*-limonene content of the oil used is shown by the sorptogram I (Fig. 1). The oil was first subjected to steam distillation. A part of the minor components passed over in the first fractions and a part remained in the distillation residue. In this and in subsequent stages the products

were protected by a carbon dioxide atmosphere. The distillate was separated from the condensed water and dried with sodium wire at room temperature. The refractive index n_D^{25} of the dried distillate was 1.47021, and its specific rotation $[a]_D^{25} = 97°5'$. The refractive indices of the fractions on the plateau of its sorptogram II (Fig. 1) were the same, $n_D^{25} = 1.47056$, as those of the fractions on the plateau of sorptogram I. Widmark [16] has reported for pure *d*-limonene a refractive index n_D^{25} of 1.4703.

The *d*-limonene fractions were hydrogenated [17,18] in absolute alcohol with Raney nickel as catalyst. The hydrogenation of *d*-limonene to 1-*p*-methene proceeded fairly rapidly, but the hydrogenation of the latter to *p*-menthane took place much more slowly. Since it is difficult to separate *d*-limonene and 1-*p*-methene by fractional distillation, whereas 1-*p*-menthene and *p*-menthane are readily separated, the hydrogenation was continued until the *d*-limonene had been completely hydrogenated. The progress of the reaction could be easily followed by recording sorptograms of samples taken during the reaction. As the unsaturation of *d*-limonene decreased, the refractive index of the reaction mixture decreased rapidly and at the same time the adsorption on the sorptogram column. Owing to this, the first sections of the sorptograms gave the refractive index of *p*-menthane, then that of 1-*p*-menthene, and finally that of *d*-limonene. The hydrogenation was terminated when the peak for *d*-limonene had disappeared from the sorptogram. Water, one tenth of the volume of the hydrogenated mixture, was added, whereupon the hydrogenation products rose to the surface and the product containing oxygen remained in solution[19]. The upper layer was washed with water and its sorptogram (Fig. 1, III, $n_D^{25} = 1.4533$) recorded.

The products of hydrogenation were fractionally distilled in a packed column with 10 theoretical plates. The distillate was separated into the fractions shown in Table 1. From the sorptograms IV—VIII for these fractions the 1-*p*-menthene contents were estimated by assuming the fractions to contain only 1-*p*-menthene, $n_D^{25} = 1.45445$, and *p*-menthane, $n_D^{25} = 1.4372$ ($n_D^{20} = 1.4395$ [18]).

The oxidation of 1-p-menthene with molecular oxygen. The oxidations with and without catalyst were conducted by passing oxygen into an emulsion of 1-*p*-menthene in water. The results are presented in Fig. 3 and Table 2.

The previously employed emulsion oxidation procedure [21] was slightly modified. To effect a vigorous mixing a vibrator mixer (Vibro-Mischer, A. G. für Chemie Apparatebau, Zürich) was employed. This made possible the use of a thermostat. As in the earlier experiments [21], a 0.5 % aqueous solution of sodium stearate, to which sodium carbonate had been added to give the pH indicated, was first used as emulsifying medium (Expts. Nos. 1—6). A 0.3 % sodium stearate solution proved to be more effective than the 0.5 % solution at the temperatures employed (*cf.* expts. Nos. 2 and 5, Fig. 3).

As shown by the curves for expts. Nos. 1, 2 and 3 in Fig. 3, the rate of oxygen absorption rose rapidly as the temperature was increased. The oxidation was interrupted in these experiments as soon as 10 % of the oxygen required

[d] Emulsifier 1 % Teepol (Shell Chem. Corp.; dry matter 40 %).

to oxidize 1-*p*-menthene to 1-*p*-menthene-hydroperoxide had been consumed. In these experiments the hydroperoxide values of the reaction products were equal, which indicates that the rate of oxidation and the rate of hydroperoxide decomposition increased in the same degree with increasing temperature. About 70 % of the oxygen added was found in the hydroperoxides formed in these experiments. When the reaction time was prolonged, the hydroperoxide content of the product increased, but at the same time the proportion of added oxygen that was bound as hydroperoxide decreased.

When the product of expt. No. 2 was stored at room temperature for four months, the hydroperoxide content fell gradually from 8.6 to 5.6 %.

In expt. No. 8 cobalt resinate was employed as catalyst and the temperature was only 10 °. Since even a dilute sodium stearate solution becomes viscous at this temperature, sodium secondary alkyl sulphate (Teepol 710) was

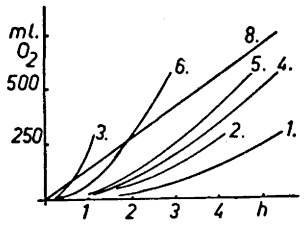

Fig. 3. Oxygen consumption as a function of time.

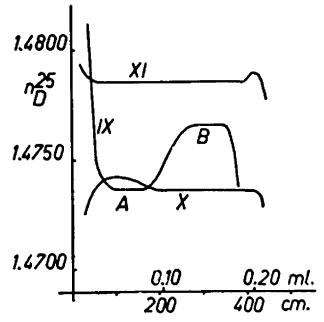

Fig. 4. Sorptograms. IX, expts. Nos. 1, 3—6, "ketone mixture"; X, expt. No. 7, "alcohol mixture"; XI, synthetic carvotan-acetone.

used as emulsifier. The rate of oxidation was nearly as great in this experiment as in expt. No. 2 at 70°. No induction period was observed as in the other experiments. Despite the low temperature, the hydroperoxide decomposed more rapidly than in the other experiments in which the temperatures were much higher. The higher rate of decomposition was evidently due to the presence of the catalyst.

Identification of oxidation products

The oxygen compounds formed in the emulsion oxidation were for the most part hydroperoxides in all experiments except No. 8. The other products formed were mainly alcohols, ketones and polymers.

The hydroperoxides in the reaction products were reduced in sodium sulphide[22] and sodium sulphite solutions [23]. The reduced oxidation products were separated from 1-*p*-menthene by passing their solution in petroleum ether through a column packed with silica gel (BDH, for chromatographic analysis) as proposed by Kirchner *et al.*[24] When this separation was performed on the oxidation product of expt. No. 8, a part of the oxidized material passed through the silica gel layer; this fraction was recovered subsequently by passing it a second time through a silica gel column. The oxygen-containing compounds were retained quantitatively by the silica gel and the sorptogram of the product that passed through the column revealed it to be pure 1-*p*-menthene. The oxidation products were eluted from the silica gel with anhydrous ether. The results are shown in Table 3.

Table 3. Reduced oxidation products after separation from 1-*p*-menthene.

[a] Oxidation product recovered in the second elution.

The reduced oxidation products, which mainly consisted of alcohols, were oxidized to the corresponding ketones with chromic acid in acetic acid solution [25,26] (Table 4). The ketones in the resulting mixtures were determined gravimetrically as their dinitrophenylhydrazones according to Scholtens [27] (Tables 3 and 4).

[b] Amount removed by steam distillation from products of chromic acid oxidation.

Oxidations without added catalyst. Expts. Nos. 1, 3—7. The ketones obtained in expts. 1 and 3—6 were combined and converted into a dinitrophenylhydrazone which melted at 187—190° after three crystallizations from ethanol. With synthesized carvotanacetone-2,4-dinitrophenylhydrazone (m.p. 191—192° [28,29]), this derivative gave a mixed melting point of 187—191°. Since the

solubility of piperitone dinitrophenylhydrazone in ethanol was much greater than that of the corresponding derivative of carvotanacetone, the original dinitrophenylhydrazone precipitate was fractionated by chromatography according to Montes [30]. The dinitrophenylhydrazone passed through the adsorbent as one zone, from which it was concluded that no appreciable amounts of 1-*p*-menthene-3-hydroperoxide corresponding to piperitone, but only 1-*p*-menthene-6-hydroperoxide corresponding to carvotanacetone, had been formed in the oxidation.

The sorptogram IX of the same ketone mixture is shown in Fig. 4. Two different sections, one (A) showing a minimum and the other (B) a maximum, are evident in the sorptogram.

The fractions of section A gave a copious dinitrophenylhydrazone precipitate which, after two crystallizations from ethanol, melted at 189—191°. The refractive index, $n_D^{25} = 1.4736$, of section A is much lower than the refractive index, $n_D^{25} = 1.47855$, of pure carvotanacetone (sorptogram XI, Fig. 4). Despite this large difference, the fractions giving section A can be concluded to have been impure carvotanacetone.

The fractions of section B, which yielded only a negligible amount of a dinitrophenylhydrazone, were concluded to be carvotanacetol that had not been oxidized to carvotanacetone in the chromic acid treatment [25]. On the other hand, the reduced oxidation product of expt. No. 7 gave the sorptogram X (Fig. 4), the refractive index of which was, however, much lower than the refractive index of section B in sorptogram IX. The only explanation for the difference between the sorptograms appeared to be that the alcohol (carvotanacetol) that had not been converted into ketone by chromic acid had undergone isomerization to another alcohol which had an appreciably higher refractive index than the alcohol formed in the reduction of the original hydroperoxide.

To decide this, the reduced oxidation product of expt. No. 7 was isomerized by boiling in glacial acetic acid. The resulting product gave the sorptogram XII in Fig. 5. This sorptogram consists of three separate sections. The refractive index of the first highest plateau was almost the same as that of section B in sorptogram IX. The refractive index of the third section or the second highest plateau was identical with that of sorptogram X for the reduced product of expt. No. 7. It is hence obvious that only a part of the alcohols had been isomerized. The section of the sorptogram between the two plateaus was evidently due to the acetate of one of the alcohols, as indicated by the strong odour of carvotanacetol acetate given off by the fractions.

All of the isomerized product was saponified with ethanolic potassium hydroxide, and the product liberated distilled with steam. The distilled alcohol gave the sorptogram XIII of Fig. 5. After a gradual rise the sorptogram levelled off, and the refractive index of this section was close to the refractive index of the isomerized carvotanacetol that was assumed to be present. It is thus obvious that not only were the esters saponified but also the unisomerized alcohol underwent isomerization. The refractive index in the main section of the sorptogram XIII for the distilled and isomerized alcohol was close to that for synthesized carvotanacetol [31], $n_D^{25} = 1.4772$ (Sorptogram XIV, Fig. 6).

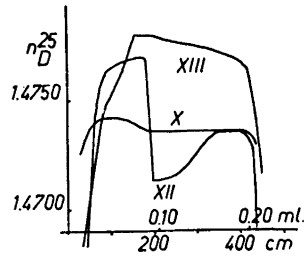

Fig. 5. X, expt. No. 7, "alcohol mixture"; XII, expt. No. 7, isomerized product; XIII, expt. No. 7, saponified product.

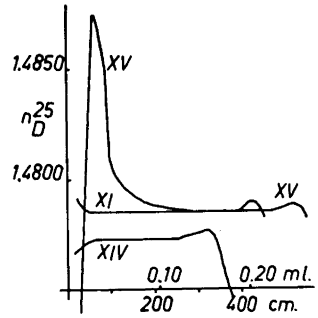

Fig. 6. XI, synthetic carvotanacetone; XIV, synthetic carvotanacetol; XV, expt. No. 7, "ketone mixture" prepared after saponification.

The saponified product contained 10 % ketone. This ketone evidently increased the refractive index of carvotanacetol, and since the ketone precedes the alcohol, as in sorptogram IX, the highest part in the sorptogram XIII is due to carvotanacetone.

Under the conditions where the isomerization was carried out [29], carvotanacetol is dehydrated to some extent and forms menthadienes. These hydrocarbons appear in the first fractions of the sorptograms (*e.g.* XII and XIII) and lower the refractive index. After the isomerized and saponified product was oxidized with chromic acid and isolated by steam distillation, it gave the sorptogram XV (Fig. 6) which shows first a high peak and then falls close to the refractive index of carvotanacetone (n_D^{25} for synthesized carvotanacetone [31] was 1.4785; sorptogram XI, Fig. 6). The refractive index, $n_D^{25} = 1.4875$, at the peak in sorptogram XV is very close to the refractive index, $n_D^{25} = 1.4883$, of *p*-cymene [32]. The fractions giving the peak had the odour of *p*-cymene. The *p*-cymene may have resulted from the oxidation of the menthadienes by chromic acid. It is obvious that for this reason there is a gradual decrease before the refractive index of the ketone is reached in all the sorptograms (IX, XV, XVII and XIX) of the products of the chromic acid oxidations.

According to the above, the alcohol with the lower refractive index is formed when the hydroperoxide formed in the emulsion oxidation is reduced, while the alcohol with the higher refractive index results from the isomerization of this alcohol. Synthesized carvotanacetol has the same refractive index as the isomerized alcohol. Hence, since the alcohols both yield carvotanacetone on oxidation with chromic acid, they are carvotanacetols.

According to the rule of Auwers-Skita [33], the alcohol with the higher refractive index must be the *cis* form. On the other hand, Gastambide [34] has stated that the sterically more hindered form, in this case the *cis* form, is less strongly adsorbed. Consequently the alcohol with the higher refractive index first appearing in the sorptogram XII was *cis*-carvotanacetol. The synthesized carvotanacetol is hence also the *cis* form. However, the carvotanacetol obtained by reducing the oxidation product was more strongly adsorbed than the

preceding and had a lower refractive index and was hence *trans*-carvotanacetol. From this it may be deduced that the main product of the oxidation under the chosen conditions was *trans*-1-*p*-menthene-6-hydroperoxide. This conclusion is confirmed by the nature of the oxidation products of certain terpenes, which products have been shown to have the *trans* configuration [22,35].

Oxidation at low temperature in the presence of catalyst. Expt. No. 8. The main part of the reduced oxidation products of this experiment contained 34 % ketone (Table 3). The dinitrophenylhydrazone of the ketone melted at 190—192° after two crystallizations from ethanol, which indicated that the ketone was carvotanacetone. The reduced product of expt. No. 8 gave the sorptogram XVI, which differed completely from the sorptogram X of the corresponding product of expt. No. 7. Certain observations at the time of the experiment and later led to the conclusion that the orptograms XVI had been formed by partly separated fractions consisting of carvotanacetone, *trans*-piperitol, *trans*-carvotanacetol and piperitone, in this order.

The product of the chromic acid oxidation of the main product of expt. No. 8 (Table 4) gave the sorptogram XVII. In this sorptogram a very high initial peak is followed by a sharp minimum and a fairly high, broad maximum. The minimum is evidently due to carvotanacetone. The mean refractive index of the fractions contributing to the initial peak, $n_D^{25} = 1.4818$, is close to the refractive index of piperitone ($n_D^{20} = 1.4848$ [36]; $n_D^{25} = 1.4823$). In addition, these fractions smelled strongly of piperitone.

This product of chromic acid oxidation of the main fraction was distilled in a spinning band column with 25 theoretical plates. The fractions shown in Table 5 were obtained.

Table 5. The distillation of the main product of expt. No. 8 after chromic acid oxidation.

Fraction	t°C at 3.4 mm Hg	ml	n_D^{25}
1	78.5—79.5	1.0	1.47787
2	—80.5	0.8	1.48082
3	—82.5	0.7	1.48190
4	82.5	0.1	1.48212

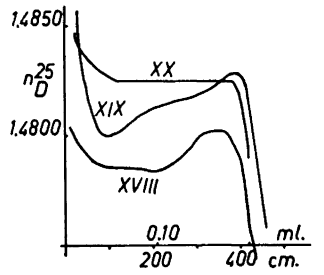

Fig. 8. XVIII, expt. No. 8, ketone fraction 1; XIX—XX, expt. No. 8, ketone fractions 2 and 3.

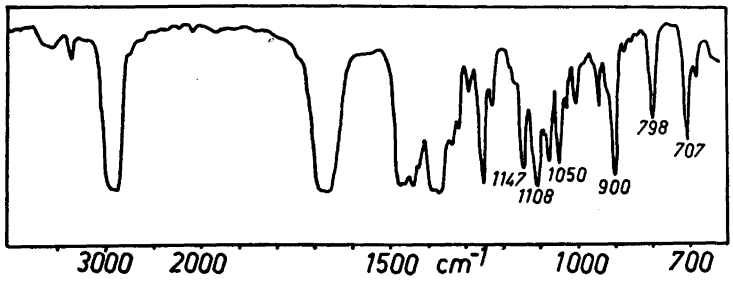

Fig. 9. Infrared spectrum of synthesized carvotanacetone.

The fractions 1, 2 and 3 yielded the sorptograms XVIII, XIX and XX (Fig. 8). The refractive index n_D^{25} of the horizontal section of the sorptogram XVIII was 1.4785, from which it was concluded that fraction 1 consisted mainly of carvotanacetone. The refractive index, $n_D^{25} = 1.4825$, of sorptogram XX suggested that the fraction 3 was almost pure piperitone. Fraction 2 evidently contained both these compounds.

The 2,4-dinitrophenylhydrazone prepared from fraction 3 melted at 113—116° after crystallization from an ethanol-ethyl acetate mixture. The corresponding derivative of piperitone has been reported [37] to melt at 116°.

The high yield of piperitone suggests that the oxidation at a low temperature with catalyst present involves addition to position 6, but also to position 3 to a considerable extent.

Infrared spectra

A 30-μl sample was taken from the middle fractions of sorptogram XX and its infrared spectrum recorded. This spectrum was identical with the spectrum recorded for piperitone by Le Fèvre *et al.*[38]

An infrared spectrum was also recorded for a sample from the middle fractions of synthetic carvotanacetone giving the sorptogram X. Since the infrared spectrum for carvotanacetone was not found in the literature, the recorded spectrum (Fig. 9) was compared with the Raman spectrum for the compound [39]. The two spectra for carvotanacetone were found to conform well with each other.

The infrared spectrum obtained for piperitone was also found to agree well with the Raman spectrum of this compound [40].

Micro sorption method

Blohm's micro sorption method [14] was employed in a slightly modified form. Whereas Blohm and Widmark employed sorptograms only in the analysis of hydrocarbons [14,16,32,41], the method was found in this study very suitable also for liquid alcohols and ketones. After the present work had been completed, Widmark published sorptograms for various liquid compounds including carvotanacetone [42]. The refractive index he obtained for

carvotanacetone, $n_D^{25} = 1.4782$, deviates slightly from the value, $n_D^{25} = 1.47855$, obtained in this work.

Commercially available silica gel (BDH, for chromatographic analysis) proved to be a suitable adsorbent. The sieve fraction passing through 200 mesh was employed. The sorptogram tube chosen after some experimentation was a capillary tube 150 cm long with an inner diameter of 1.5 mm. The fractions were collected into capillary tubes 0.76 mm in inner diameter (15—20 tubes). The volumes of the fractions were obtained by measuring the lengths of the liquid columns in the calibrated capillary tubes. In the sorptogram plots the abscissa is the cumulative length of the liquid column of the fractions (10 cm corresponds to 46.5 μl).

For the recording of each sorptogram an accurately measured 0.20-ml or 0.25-ml volume of the sample was taken. The sample volume was transferred to the top of the column with an injection syringe of 0.5-ml capacity with a scale graduated in 0.01-ml divisions. By using a needle of suitable length the sample could be added so that none of it adhered to the upper walls of the column. After the sample had penetrated into the column packing, alcohol was added from a side tube.

The pressure applied to the column varied from 1.5 to 4.5 atmospheres. Depending on the pressure and the nature of the sample, the passage of the sample through the column took from 3 to 5 h. The oxygen-containing terpenes are more viscous than the hydrocarbons and hence required higher pressures. The passage of synthetic carvotanacetol through the column took over 10 h under a pressure of 4 atm.

The refractive indices of the fractions were measured to the fifth decimal with an immersion refractometer (Eintauch-Refraktometer Nr. 67130, Carl Zeiss, Jena). The light source was a sodium lamp. When the refractive indices were measured the temperature was maintained at 25 ± 0.05°C with a thermostat (Colora, Ultrathermostat NB-26093).

ACTA CHEMICA SCANDINAVICA 13 (1959) 312—322

A Comparative Study on the Chelate Formation between Germanic Acid and Some Glycols and Polyalcohols in Aqueous Solutions

P. J. ANTIKAINEN

Institute of Chemistry, University of Helsinki, Helsinki, Finland

The influence of a series of glycols and polyalcohols (hexoses) on the ionization of germanic acid has been studied potentiometrically in aqueous solution at 25°C. Germanic acid displays a tendency to form one-to-one and one-to-two chelate compounds with glycols, while the polyalcohols and their derivatives (aldoses and ketoses) seem to yield solely one-to-two chelate acids (one molecule of germanic acid combined with two molecules of polyol). It thus appears that the number of hydroxyl groups present in the organic ligand plays a very important part in determining the structure of the chelates formed. On the other hand, an increase in the number of carbon atoms in the ligand chain seems to increase the values of the chelate formation constants but not to affect the structure of the chelate. Furthermore, an increase in the number of hydroxyl groups in the ligand (*e. g.* propylene glycol and glycerol) seems to lead to increased values for the chelate formation constants. Additional functional groups as well as different configurations of the hydroxyl groups in the ligands apparently affect the values of the chelate formation constants. Lactol forms may be partly responsible for the observed differences in the chelating ability of germanic acid with carbohydrate substances.

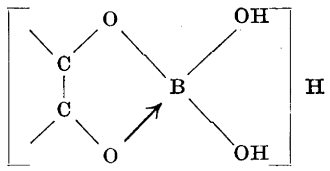
Analogously with boric acid [1] and telluric acid [2], germanic acid [3–7] forms chelate acids with di- or polyhydroxy compounds containing at least two hydroxyl groups in the *cis*-position. The structure and the formation constants of most of such chelate compounds of germanic acid seem to be still unknown. The object of the present investigation was to determine potentiometrically the structure and formation constants of the chelate acids formed by the interaction of germanic acid and the following alcohols in aqueous solutions: ethylene glycol, propylene glycol, 3-methoxy-1,2-propylene glycol, D-mannose, D-glucose and D-galactose. Furthermore an endeavour was made to establish the chelate-forming ability of germanic acid with these alcohols as related to that with glycerol, mannitol and fructose which has been studied previously by the author.

THEORY AND METHOD USED

The author [6] has previously observed that germanic acid is capable of forming one-to-one and one-to-two anionic chelate compounds with some polyalcohols:

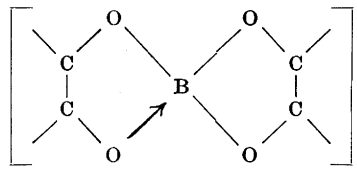
$$\underset{\text{one-to-one}}{HGeD} \qquad \underset{\text{one-to-two}}{HGeD_2} \tag{1}$$

These chelate compounds of germanic acid are generally strong mono-basic acids. However, germanium is also known to exhibit a cordination number six in complex formation, thus resembling boron, which has a tendency to form chelate acids with the co-ordination number four under corresponding conditions:



HBD

one-to-one



HBD_2

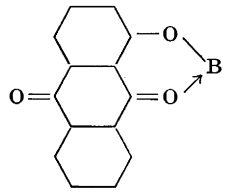
one-to-two

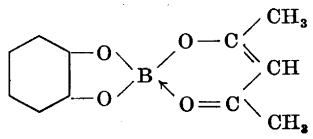
(2)

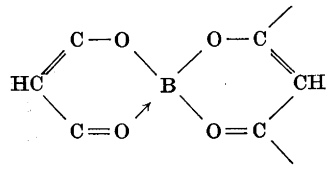
These configurations are in good agreement with the concepts regarding the structure of the acid anions of boron and germanium in which these elements exhibit tetra- and hexacovalency, respectively [8,9]:

$$B(OH)_4^- \qquad Ge(OH)_6^{--} \tag{3}$$

and also with the general tendency of these elements to form complex compounds with the co-ordination number four or six, *e. g.* the fluoborate and fluogermanate anions, BF_4^- and GeF_6^{--}. Chelates of type (2) require the hydroxyl groups to be of *cis*-configuration and attached to adjacent carbon atoms. Carbonyl groups may at times participate in chelate bonding as has been demonstrated for the following chelates of boric acid [10–13]

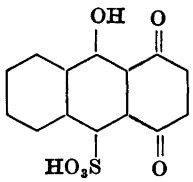




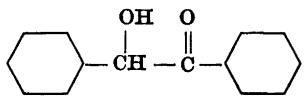


(4)

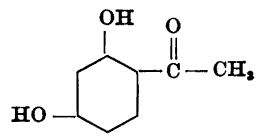
Germanic acid appears to behave in a similar manner as is evidenced by its reaction with the following compounds:



9-Hydroxynaphthacene-quinonesulphonic acid



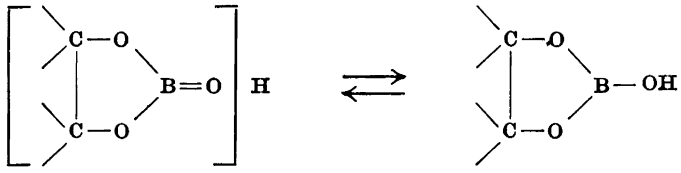
Benzoin



Resacetophenone

(5)

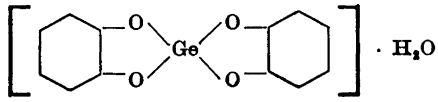
pH and conductivity measurements in general show the germanic acid-polyhydroxy chelates to be strong acids in aqueous solution. It has been noted that boric acid is also capable of forming neutral 1:1 chelates with certain glycols. In that case, according to Böeseken [14], a so-called pseudo acid is formed, which is in equilibrium with the strong chelate acid, the equilibrium being almost completely on the side of the pseudo acid



chelate acid — pseudo acid

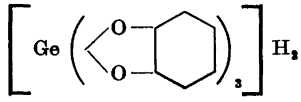
(6)

According to Bevillard [4] and others the existence of *o*-diphenol chelates of germanic acid, which possess the following structure



(7)

may be interpreted as indicating that similar neutral chelates may also be formed by this element. It has, however, not been possible to demonstrate the presence of such chelates in solution. It is thus obvious that germanic acid in solutions with polyhydroxy compounds generally forms strong chelate acids, the presence of which can be demonstrated, for instance, by pH measurements. Further, it is apparent from the above examples that the chelate acids formed are mono-basic acids. On the other hand, it is interesting to find that the germanic acid chelates which are formed with certain *o*-diphenols are of the following structure [4]



(8)

and act as strong di-basic acids. Summing up it may be said that the known polyhydroxy chelates of germanic acid are comprised of strong mono-basic acids of the one-to-one or one-to-two type and strong di-basic acids of the one-to-three type.

The author has previously used the so-called buffer capacity method [15,1,2] for the investigation of some polyhydroxy chelates of boric, telluric and germanic acid in aqueous solution. This method enables the stoichiometry of the reactions in question as well as the formation constants of the chelates formed to be determined.

When it is assumed that the germanic acid chelates formed are mono-basic acids, the reactions may be expressed as follows

$$H_2GeO_3 + nD \rightarrow HGeD_n$$

In this equation $HGeD_n$ designates the mono-basic acid formed and D the polyhydroxy compound; n represents the number of ligand molecules which combine with one molecule of germanic acid. If several different chelates are formed simultaneously, n designates the average number of ligand molecules per molecule of germanic acid. In such cases n is generally not a whole number. When the chelate formation reaction is expressed according to eqn. (9) the equilibrium constant for the reaction can be written as follows

$$K_k = \frac{[HGeD_n]}{[HGe] \cdot [D]^n} \tag{10}$$

When the real first-ionization constant of germanic acid is designated by K_1 and the corresponding constant for the chelate acid by K_1', the germanic acid solution containing chelate acids can be treated as an aqueous solution of an apparently mono-basic strong acid. The ionization constant, K^*, of this acid will consequently take the following form

$$K^* = K_k \cdot K_1' \, [D]^n + K_1 = K_n \cdot [D]^n + K_1 \tag{11}$$

It is therefore possible to determine the constants of this equation by measuring the apparent value of the ionization constant of germanic acid for various concentrations of the polyhydroxy compound. By using large concentrations of the ligand and small concentrations of germanic acid, it may be assumed that [D] is equal to the corresponding stoichiometric concentration, C_D, of the ligand and, eqn. (11) becomes

$$p(K^*—K_1) = pK_n—n \, . \log C_D \tag{12}$$

The expression $p(K^*—K_1)$ should, according to the above equation, be a linear function of $-\log C_D$, the slope of the curve giving the value of n, while the value of pK_n may be obtained from the point of intersection of this curve and the line obtained when $-\log C_D = 0$. The following assumptions have been made in the derivation of eqn. (12)

1. Both the germanic acid and its chelate acids are mono-basic acids.
2. $[D] = C_D$
3. Changes in the dielectric constants of the solutions as may possibly be caused by the ligand are too small to have any effect on the results. (High concentrations of the ligand have been avoided.)

In the event that these assumptions prove to be invalid eqn. (12) will, of course, no longer represent a straight line. This is especially true for assumption 2 (*cf.* Fig. 1).

If the chelate formation is almost complete, the apparent ionization constant, K^*, will approach the real ionization constant [1,2] of the chelate acid and the following equation is obtained

$$\lim K^* \rightarrow K_1' \qquad (13)$$

$$C_D \rightarrow >> C_{H_4GeO_4}$$

The graph of eqn. (12) may be curved for other reasons also. If, for instance, two chelates are formed simultaneously (one-to-one and one-to-two, for example) the graph takes a shape, in which the slopes of the ends of the curve approach the whole numbers. These slopes, n_1 and n_2, indicate the structures of the chelates formed in each reaction. Hence, eqn. (11) becomes

$$K^* = k_1 \cdot C_D^{n_1} + k_2 \cdot C_D^{n_2} + K_1 \qquad (14)$$

by the aid of which both formation constants of the apparent chelate formation reactions may be determined in the manner described above. In this equation k_1 and k_2 correspond to the constant K_n in eqn. (11). For the determination of these constants n_1 and n_2 and, in addition, the apparent ionization constant, K^*, must be known for at least two different concentrations of the ligand. In practice, however, it is best to determine several points along the curve corresponding to eqn. (14) as well as its asymptotes which have the slopes n_1 and n_2, and then to calculate the constants k_1 and k_2 with these values for several pairs of K^*'s.

According to eqn. (11) the chelate formation constant, K_n, is equal to the product of K_1' and K_k. Hence,

$$K_n = \frac{[H^+] \cdot [GeD_n^-]}{[HGe] \cdot [D]^n} \qquad (15)$$

The constants k_1 and k_2 of eqn. (14) also correspond to this equation. If the above equation is divided by the equation

$$K_1 = \frac{[H^+] \cdot [Ge^-]}{[HGe]} \qquad (16)$$

which represents the first ionization constant of germanic acid, the following new expression is obtained for the chelate formation constant

$$K_n' = \frac{[GeD_n^-]}{[Ge^-] \cdot [D]^n} = K_n/K_1 \qquad (17)$$

In eqns. (16) and (17) Ge^- designates the germanic acid anion ($H_2GeO_3^-$) and GeD_n^- the chelate acid anion formed. Again, both the germanic acid and its chelate acid are considered to be mono-basic acid. According to eqn. (17) the chelate formation reactions under investigation may be considered to take place between the germanic acid anion and the organic ligand as follows

$$Ge^- + nD \rightleftharpoons GeD_n^- \qquad (18)$$

This equation corresponds to eqn. (9). The constant, K_n', gives a good indication of the extent of the chelate formation reaction, and is therefore employed in the final considerations. It should also be noted that, according to eqn. (18), the value of the constant, K_n', is not dependent upon the ionic strength. The constants obtained are therefore comparable to the corresponding thermodynamic constants.

EXPERIMENTAL

All measurements were made by potentiometric titration using a quinhydrone electrode. A saturated calomel electrode served as reference standard. The temperature was regulated at 25 ± 0.05°C by means of a thermostat.

Carbon dioxide was removed from the test solutions effected by bubbling a stream of purified nitrogen through them for as many as 20 h previous to the titration. A slow, continuous flow of nitrogen was maintained during the titration. These precautions proved essential when working in ranges of small buffer capacity where the presence of even exceedingly low concentrations of carbon dioxide can lead to unreliable results.

The sodium hydroxide solution was added by means of a calibrated micro syringe designed by Ellilä [16]. With this syringe it was possible to attain an accuracy for small additions (0.0002—0.5 ml) of hydroxide solution that completely corresponded to the accuracy of the potentiometer. Addition of 0.003—0.08 ml of an approx. 0.1 N sodium hydroxide solution to the test solutions generally corresponded to a max. potential jump of 10—15 mV when the concentrations of germanic acid and polyhydroxy compounds were chosen to be within the molar ranges of 0.008—0.012 and 0.05—1.0, respectively.

The test solutions were prepared in 50 ml volumetric flasks by measuring with pipettes the appropriate amounts of germanic acid, polyhydroxylic compounds and potassium chloride from corresponding stock solutions. Small quantities of hydrochloric acid were also added before filling up the flasks. About 50 ml of these solutions were used for the titrations by emptying the calibrated volumetric flasks into the titration vessels. Whenever possible the reagents used were the best *pro analysi* products available. If these could not be obtained inferior products were purified.

The aqueous stock solution of germanic acid was prepared from Merck's germanium dioxide. Its concentration was determined by titration [3]. The stock solutions of the glycols were prepared by weighing out the appropriate quantities of dried glycols. The glycols were dried in small portions by being stirred on an oil bath at a temperature near the boiling point of each glycol (100—130°C) for about one hour and were then kept for a week in vacuum desiccators containing sulphuric acid and phosphorus pentoxide as drying agents. The molarities of the aqueous solutions prepared from these dried glycols were as follows:

ethylene glycol 2.290 (1.0160), propylene glycol 1.239 (1.0044),
butylene glycol 1.566 (1.0051), 3-methoxy-1,2-propylene glycol 2.422 (1.0347). (The numbers in brackets indicate the corresponding densities of the solutions.)

Because of the slow mutarotation of hexoses in aqueous solution, their solutions had to be prepared about 24 h before the measurements were made in order to permit the attainment of equilibrium.

Table 1. Values of the apparent ionization constant of germanic acid in approximately 0.1 M aqueous potassium chloride solutions with various concentrations of some di- and polyhydroxy compounds at 25°C. (In the calculations the value $K_1 = 2.63 \times 10^{-9}$ has been used [19].)

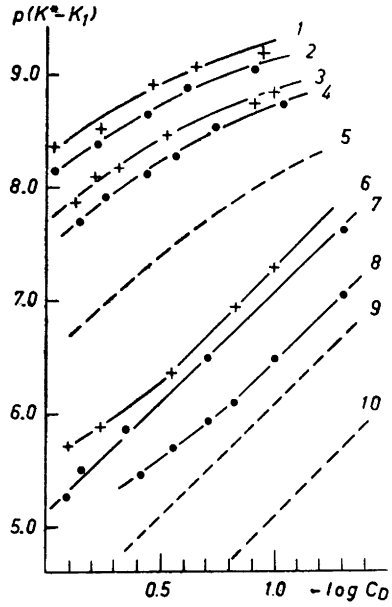

Fig. 1. The dependence of the apparent ionization constant of germanic acid on the concentrations of 1) ethylene glycol, 2) propylene glycol, 3) butylene glycol, 4) 3-methoxy-2,3-propylene glycol, 5) glycerol, 6) D-galactose, 7) D-glucose, 8) D-mannose, 9) D-mannitol, 10) D-fructose (*cf.* Table 1 and Ref.[6]).

RESULTS AND DISCUSSION

Table 1. gives the values of the apparent ionization constant of germanic acid in approx. 0.1 M potassium chloride solutions at different concentrations of various glycols and polyalcohols. These values are in good agreement with eqn. (14) as is illustrated by Fig. 1. Furthermore, it appears that the glycols have a weak tendency to form one-to-one and one-to-two chelates, while the polyalcohols (hexoses) seem to possess a strong tendency to form one-to-two chelates only, as has been expressed previously by the author [6] (*cf.* D-galactose and D-mannose and eqn. 13). Thus it appears that the chelate-forming abilities of the glycols and polyalcohols investigated increase in the order

ethylene glycol, propylene glycol, butylene glycol, 3-methoxy-1,2-propylene glycol, glycerol, D-galactose, D-glucose, D-mannose, D-mannitol, D-fructose. (19)

The different chelating abilities of these ligands with germanic acid may also be seen from Table 2 which lists the calculated values of pk_1, pk_2, $\log k_1'$ and $\log k_2'$ (employing eqn. 14). Here k_1 and k_2 correspond to the constants in eqn. (17). Thus it becomes apparent that the number of hydroxyl groups in the organic ligand has a very important influence on the structure of the chelates formed. In the case of aliphatic alcohols an increase in the number of hydroxyl groups in the ligand molecule apparently favours the formation of one-to-two chelates and also tends to increase the chelate formation constants (*cf.* propylene glycol, 3-methoxy-1,2-propylene glycol and glycerol). It is interesting to note here that according to Bevillard [4] the aromatic dihydroxy compounds

Table 2. Chelate formation constants of chelates formed by germanic acid and some di- and polyhydroxy compounds. The values in Table 1 and eqns. (12), (14) and (17) have been used in the calculations, the values of n, n_1 and n_2 being 2, 1 and 2, respectively, *c. f.* Ref.[6].

(*o*-diphenols) form solely one-to-three chelates in aqueous solutions. The occurrence of such one-to-three chelates has also been observed by the author and his co-worker [17] through potentiometric measurements.

Apart from the number of hydroxyl groups in the ligand molecule, the size of the carbon chain also seems to be an important factor in the stability of the chelates. An increase in the number of carbon atoms appears only to increase the stability of chelates but not to affect the structure of the chelates, as may be seen from the fact that all glycols as well as glycerol, independent of the number of carbon atoms, form both one-to-one and one-to-two chelates. On the other hand, an increase in the number of hydroxyl groups seems to favour the formation of one-to-two chelates, as has been found earlier [18].

In a more critical study of the observed differences in the stabilities of the chelates formed it must be born in mind that the hexoses will occur in aqueous solutions mainly in their lactol forms (*cf.* Ref.[6]). Thus, the real ligands in the case of hexoses consist of heterocyclic molecules. Such structural differences have naturally considerable influence on the stability of the chelates formed. In some cases the presence of the necessary hydroxyl groups in the *cis*-position depends on lactol formation, *e. g.* for D-glucose; of its two anomeric forms only the *α*-form possesses two hydroxyl groups in the *cis*-position. It is therefore apparent that glycosidic hydroxyl groups may also participate in chelate formation. Mutarotation alters the space configuration of the glycosidic hydroxyl groups and thus affects chelate formation. Since the mutarotation is dependent on pH, the chelate formation of hexoses will also be affected by pH and it is therefore important to mention the conditions under which the measurements were performed. In this investigation the measurements were made in acidic solutions, only exceedingly small quantities of base being added to germanic acid-ligand solutions.

From Fig. 1 and Table 2 it can be seen that of all the chelate formers investigated fructose showed the greatest chelating effect on germanic acid. This may be attributed to the fact that fructose, in contrast to the other hexoses, occurs in aqueous solution almost entirely in the open-chain form.

It may therefore be concluded that lactol formation diminishes the ability of the ligand to form chelates with germanic acid. This is supported by the fact that although D-mannitol and D-mannose have very similar space configurations with respect to the hydroxyl groups, mannose possesses a lower chelate-forming ability than mannitol. A similar reduction in chelate formation owing to lactol configuration has been observed earlier by the author [6] in the hexose chelates of boric acid. Boric acid and germanic acid display similar behaviour in chelate formation in other respects also. Thus, for instance, the chelating effect of the chelate formers seems to increase according to series (19) for both acids. It must, however, be noted that, as may be seen from the chelate formation constants obtained, the germanic acid chelates are more stable than the corresponding chelates of boric acid.

According to Saito [5], the hydroxyl groups in positions 1 and 2 play a very important part in the chelate formation between sugars and germanic acid. This becomes evident from the chelating ability of fructose as compared with its two glycosidic derivatives inuline and sucrose, which display a noticeably smaller chelating ability than does the parent sugar. Accordingly it is also possible that fructose undergoes chelation by virtue of its lactol form, even though this form may be present to only a minor extent in aqueous solution. The fact that the aldohexoses display a considerably smaller chelating ability than does fructose may possibly be explained that in the case of the aldoses C-atoms 1 and 2 are both incorporated in the rigid lactol ring, while C-atom 1 of fructose is outside the ring. The hydroxyl groups of C-atom 1 of the ketoses may therefore, owing to their less restricted state, assume a sterically more favourable position for chelate formation than is possible for the corresponding hydroxyl groups of the aldoses. That flexibility in structure plays an important part in chelate formation is furthermore evidenced from the chelate formation constants of D-mannitol and D-mannose. The great importance of the hydroxyl groups in positions 1 and 2 for the formation of germanic acid chelates of ketoses has also been observed polarographically by Saito [5].

This investigation has been supported by a grant from the *State Commission of Natural Sciences (Valtion Luonnontieteellinen Toimikunta)*, which is gratefully acknowledged.

Some Features of the Salts of Deoxyribonucleic Acid with Bivalent Metals in Relation to Deoxyribonuclease Activity

JORMA ERKAMA and PIRJO SUUTARINEN

Institute of Biochemistry, University of Helsinki, Finland

Mg++, Mn++, and Zn++ salts of deoxyribonucleic acid (DNA) were prepared from the sodium salt of calf thymus DNA. The products were characterized by ultraviolet absorption spectra, viscosity measurements and titration curves, in addition to nitrogen, phosphorus and metal analyses. From the pH titration curves it is apparent that bivalent metals may interact with the titratable groups of DNA to produce structures similar to the chelated complexes. Pancreas deoxyribonuclease I (DNase I) showed a pH optimum at 6.0 for ZnDNA and at 6.5 for NaDNA, MgDNA and MnDNA when tested without addition of bivalent ions. Mg++ at 0.003 M concentration (a considerable excess over the amount of stoichiometrically bound metal) increased the rate of hydrolysis of MgDNA and MnDNA but was without appreciable effect on the action of DNase I when ZnDNA was used as substrate. It can be assumed that complex formation between the metal and the enzyme may also be essential for the activity of DNase I.

Previous studies on the activation of pancreas deoxyribonuclease I (DNase I) indicate a correlation between metal-binding of deoxyribonucleic acid (DNA) and its rate of hydrolysis [1–4]. It has been suggested that magnesium and similar ions may form chelate bridges between an amino group and a phosphate group of DNA [5].

Jungner [6] has obtained large molecular aggregates on precipitation of sodium thymonucleate from aqueous solution with ethanol in the presence of some bivalent ions. It has been found in this laboratory that the content of sodium in these aggregates is rather low (< 0.1 %) when the precipitation procedure has been repeated several times. Thus, the aggregates, albeit artificial products, may also be considered as salts of DNA with bivalent metals.

In order to gain some qualitative information on the degree of chelation of the metals, potentiometric titration of the aggregate compounds was undertaken. In addition, a study was made of the action of DNase I on these "metallosubstrates".

MATERIALS AND METHODS

Salts of DNA. DNA was isolated from calf thymus as the sodium salt by the method of Kay, Simmons and Dounce [7]. The product was stored as a solution in the frozen state. Analysis of two different preparations: I, N 14.0; P 8.0; N/P 3.87; η_{rel} (0.1 %) 4.4; ε(P) 7 500. II, N 12.0; P 7.0; N/P 3.79; η_{rel} (0.1 %) 4.7; ε(P) 8 350.

Mg^{++}, Mn^{++}, and Zn^{++} salts of DNA were prepared mainly by Jungner's method [6]. To 300 ml of sodium deoxyribonucleate solution containing 0.50 g of NaDNA, NaCl was added to bring the NaCl concentration up to 1 M. The nucleate was precipitated with ethanol and dissolved with stirring in 50 ml of distilled water in the refrigerator. The solution was dialyzed for 9 h against ion exchange water and 18 h against re-distilled water. The chloride of the bivalent metal in 10 ml of water was added to the concentration of approximately 0.05 M and the mixture was shaken for several minutes and placed in the refrigerator. The nucleate was precipitated with 5 volumes of ethanol, washed with ethanol and dissolved in water. The precipitation process was repeated twice.

DNase I was the once crystallized preparation D537 from the Worthington Biochemical Corp. It was found that in the cold a stock solution, containing 0.14 mg of enzyme per ml, remained stable for several days.

Spectral measurements were carried out with a Unicam spectrophotometer, model S.P. 500, 1 cm silica cells being employed. The nucleate concentration was 0.03 %.

Viscosity measurements were made at 25 ± 0.05° in an Ubbelohde viscometer with distilled water as solvent. The data were plotted as relative viscosity.

Potentiometric titration. A sample containing 20 mg of nucleate in 12 ml of water was used in the titration experiments, carried out mainly by following the directions of Gulland, Jordan and Taylor [8]. No attempt was made to maintain the ionic strength constant during the titrations. All pH measurements were made with a Beckman Glass Electrode pH Meter.

Measurements of DNase I activity. The enzyme activity was measured by Kunitz's spectrophotometric procedure [9]. One ml of enzyme solution, containing 5 μg of DNase I, and 3 ml of substrate solution (2 mg of nucleate and 5 ml of phosphate buffer in 50 ml of H_2O or 0.005 M $MgSO_4$) was kept 10—15 min at 25°, then mixed and placed in a 1-cm quartz cell with mixing. The linear change in the optical density at 260 mμ was followed during 5—10 min against a substrate-water control. The DNase activity was expressed as the increase in absorption per min.

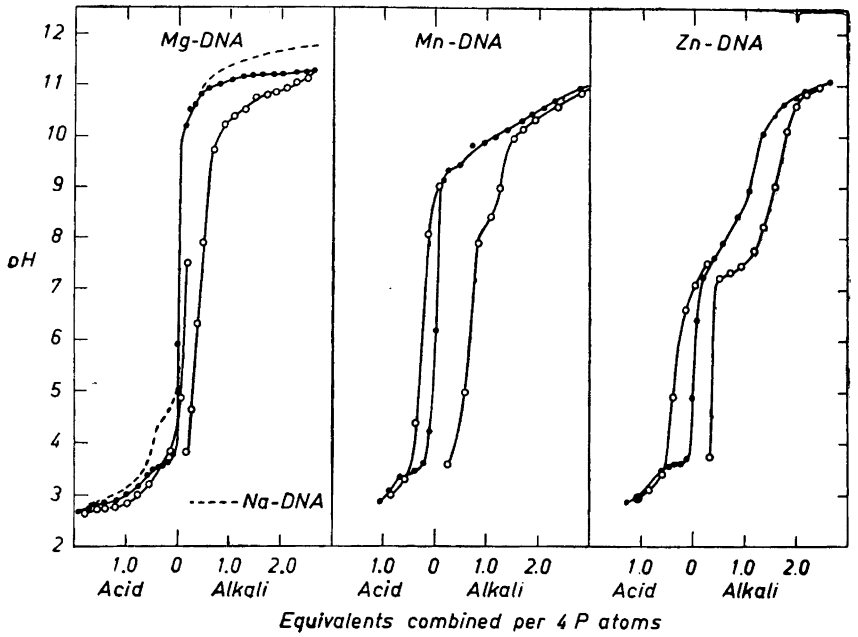

Fig. 1. Titration curves of the salts of DNA with bivalent metals. ● Forward-titration; O Back-titration.

RESULTS AND DISCUSSION

General properties of the preparations. The low nitrogen values of the preparations (Table 1) are probably due to the Kjeldahl procedure having been used. The atomic N/P ratio is in good agreement with the calculated figures. The protein content of the aggregates was not estimated, but in an earlier preparation of MgDNA, precipitated in a similar way, a protein content of about 3 % was found.

It can be seen from the analytical data that the molar ratio of metal to phosphorus is considerably greater than the theoretical value. One explanation, proposed by Jungner, is the possibility that the metal can also enter less acid radicals and not only the phosphoric acid groups. However, Shack, Jenkins and Thompsett [10] have reported data which suggest that there is no binding of metal on DNA with groups other than phosphorus. Cavalieri, Angelos and Balis [11] suggest that at least two types of sites, one with monovalent and one with divalent phosphate, may be involved. In our view, the excess of metal can also be interpreted as due to the retention of chloride ions.

A partial denaturation of the nucleate in dilute solutions during preservation and prolonged dialysis [12] may contribute to the rather high values of ε(P).

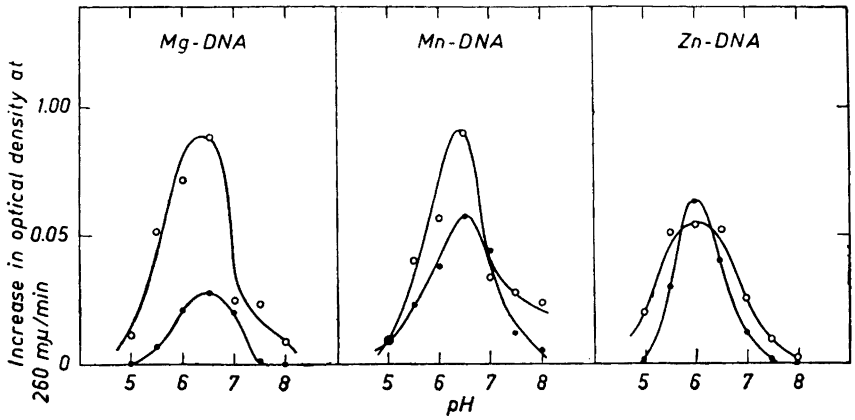

Fig. 2. Effect of pH on the rate of enzymatic digestion of salts of DNA. ● Without added Mg^{++}; ○ With 3.75×10^{-3} mmoles of Mg^{++}. Test solution: 0.03 mg DNA/ml; 5 μg DNase I; phosphate buffer; total volume 4 ml; 25°C.

Titration curves. Fig. 1 summarizes the changes in pH on forward- and back-titration of preparations. The titration curve for NaDNA is also included. All the preparations show a clear-cut pH drop in the acid range as compared with the titration curve of NaDNA. It can be concluded that some acidic protons of DNA, titrating between pH 5 and 3.5, have been displaced by the chelating bivalent metals, and that the amino groups of DNA are involved. This conforms with the views of Brown and Watson [5] who suggest the possibility that magnesium and similar ions may form chelate bridges between the amino group of guanine and a neighbouring phosphate group.

Neither in the sodium nucleate nor in the magnesium nucleate are any groups titrated in the alkaline region below pH 10. On the other hand, the titration curves of MnDNA and ZnDNA indicate that there is a very distinct tendency for Mn^{++} ions and especially for Zn^{++} ions to form chelates with the groups dissociating in the alkaline range. The different titration steps with distinct inflection points are most clearly separated in the titration curve of ZnDNA. The liberation of the titrating groups in the alkaline region begins at pH 7, and at approximately pH 7.3 the back-titration curve of ZnDNA shows a very steep bend. All this evidence indicates linkages of a different kind in ZnDNA as compared with the other preparations investigated.

Experiments with DNase I. Parallel studies (Fig. 2) were made without added Mg^{++} and with addition of 0.003 M Mg^{++}. The concentration of metal in the substrate solution without added Mg^{++} was 4.95×10^{-5} M for MgDNA, 4.12×10^{-5} M for MnDNA and 4.93×10^{-5} M for ZnDNA.

It will be noted that the optimal pH for the digestion of MgDNA and MnDNA is 6.5, as shown by Kunitz [9]. The same optimal pH was also obtained with NaDNA. With ZnDNA, however, the optimal pH for the action of DNase I is about 6.0. When no Mg^{++} is added to the digestion mixture, the reaction at the optimal pH range is most rapid with ZnDNA as substrate.

On the other hand, addition of Mg^{++} at 0.003 M concentration (a considerable excess over the amount of stoichiometrically bound metal in the substrate) increases the rate of hydrolysis of MgDNA and MnDNA but has no activating effect on the action of DNase I with ZnDNA at pH 6.0.

The activating effect of added Zn^{++} was not studied at the pH optimum of the DNase because free zinc ions cause precipitation of phosphate above pH 5.5. In an experiment made at pH 5.0 and with NaDNA as substrate, 0.003 M $ZnSO_4$ accelerated the reaction rate to approximately 200 % of that with 0.003 M $MgSO_4$ activation.

Our results are not in agreement with the observation of Gilbert, Overland, and Webb [13] that 0.01 M of zinc sulphate completely inhibited the action of deoxyribonuclease. These workers followed the course of the hydrolysis by measuring the increase in acid-soluble phosphorus. It seems possible that the increase in ultraviolet absorption, catalyzed by DNase I during the initial stage of the degradation, and the cleavage of the phosphate ester bonds are not simultaneous changes.

The formation of complexes of DNA with Mg^{++}, Ca^{++}, and Mn^{++} and the respective dissociation constants have been reported in the work of Wiberg and Neuman [3]. In a recent paper [4], Wiberg has studied the mechanism of metal activation of DNase I. He found that Ca^{++} is a potent synergist in the Mg-activated reaction.

The data reported here and the evidence presented by Wiberg indicate that the mechanism of the metal activation of DNase I cannot be explained satisfactorily by the concept of metallosubstrate alone.

DNase I is found to excercise its catalytic power within the pH range where no substrate groups are dissociated and where the hydrogen bonds of the Watson-Crick double-helical model are intact. The pH of optimum stability of the enzyme — from pH 5 to 6 — lies within the same pH range. Since the isoelectric point of DNase is in the region of pH 4.7 to 5.0 [9], the active form of the enzyme has a negative charge. It can be assumed that complex formation between the metal and the enzyme may also be essential for the activity of DNase I.

The chelation of the substrate with the bivalent metals may alter the substrate either in such a way that the enzyme system can function, as postulated by Weissman and Fisher [1], or also, we would add, in such a way that the combination of the metallosubstrate with the metalloenzyme is no longer possible. In this way the observations, to some extent contradictory, regarding the effect of the metals and the observed synergistic or antagonistic behaviour of the pairs of metals could be satisfactorily explained.

Synthesis of Phenolic Alkamine Ethers of Adrenaline and Some Related Compounds

JAAKKO HUKKI and ERKKI HONKANEN

Lääketehdas Orion Oy, Helsinki, Finland

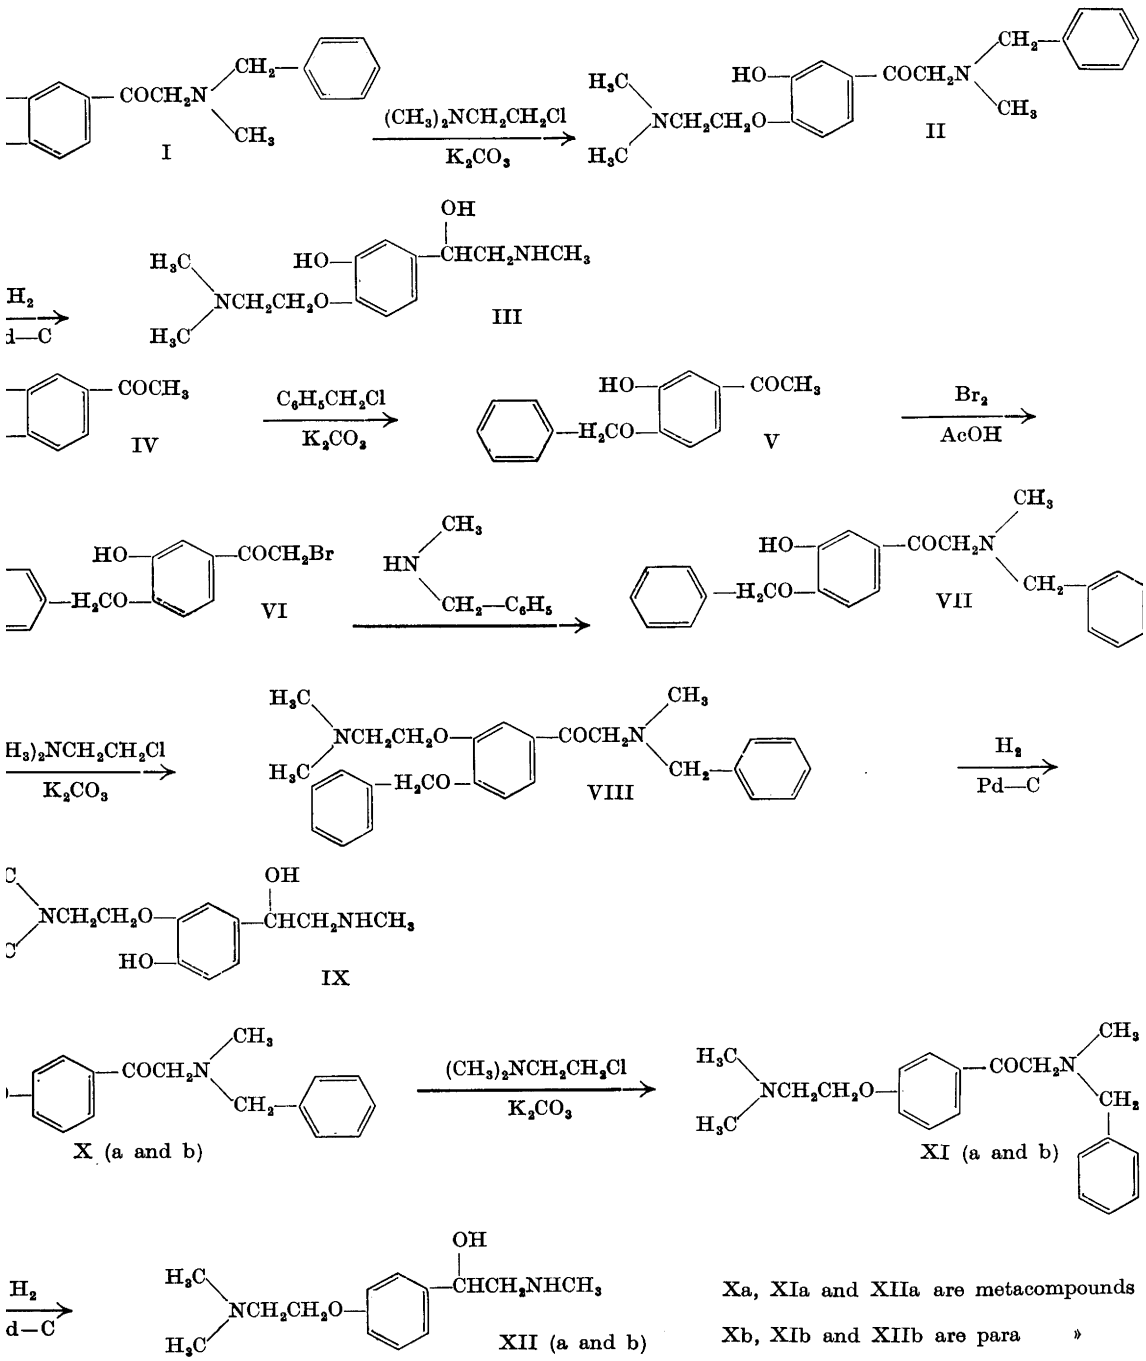
Both of the possible isomers of the phenolic dimethylaminoethyl monoethers of adrenaline (III and IX) were synthesized. The corresponding ethers of *meta* and *para*-synephrine (XIIa and XIIb) were also prepared.

In the hope of obtaining adrenaline-like substances possessing antihistamine activity the synthesis of phenolic dimethylaminoethyl ethers of adrenaline was attempted. Compounds of this type are not reported in the literature.

In the case of adrenaline, there are two possible isomeric phenolic monoethers (III and IX). To obtain each of these, the preferential reactivity of the hydroxyl group in the 4-position in 3,4-dihydroxyacetophenones was made use of. N-Benzyladrenalone (I), when allowed to react with one equivalent of dimethylaminoethylchloride in dry acetone in the presence of anhydrous potassium carbonate, was converted to the 4-dimethylaminoethyl ether (II). This, after subjection to simultaneous catalytic hydrogenation and hydrogenolysis, afforded the desired 4-dimethylaminoethyl ether of adrenaline (III).

In order to prepare the other isomer, an attempt was made to protect the hydroxyl group in the 4-position in N-benzyladrenalone by benzylation, after which the hydroxyl group in the 3-position would be amenable to selective etherification with dimethylaminoethylchloride. Unfortunately, the reaction of N-benzyladrenalone with benzyl chloride resulted in the formation of a dark resin, from which no individual compound could be isolated. Thus, a more complicated method of synthesis had to be devised:

From the reaction of 3,4-dihydroxyacetophenone (IV) with one equivalent of benzylchloride the 4-benzyl ether (V) was obtained. To confirm the position of the benzyl group this compound was methylated with diazomethane. A methyl ether was obtained which proved identical with one prepared by benzylation of acetovanillone (3-methoxy-4-hydroxyacetophenone). 3-Hydroxy-4-benzyloxyacetophenone was brominated to give the ω-bromoderivative (VI), which on condensation with methylbenzylamine formed the very compound (VII), which could not be obtained from N-benzyladrenalone by the direct



Xa, XIa and XIIa are metacompounds

Xb, XIb and XIIb are para »

procedure described above. Etherification of the 4-benzyl ether (VII) with dimethylaminoethylchloride and hydrogenation and hydrogenolysis of the resulting compound (VIII) afforded the desired 3-dimethylaminoethyl ether of adrenalone (IX). The above mode of synthesis being unequivocal at every step, the constitution of the final product (IX) is established. Hence the other monoether prepared earlier, being distinctly different, must have the alternative constitution III.

For comparative pharmacologic evaluation, the corresponding phenolic alkamine ethers of *meta*- and *para*-synephrine (XII) were also prepared. The principle in both syntheses was the same: *m*- or *p*-hydroxy-ω-methylbenzylaminoacetophenone (X) was etherified with dimethylaminoethylchloride and the resulting alkamine ether ketone (XI) subjected to simultaneous catalytic hydrogenation and hydrogenolysis.

As salts, these dimethylaminoethyl ethers of adrenaline, *m*- and *p*-synephrine, are stable, colorless, crystalline compounds, readily soluble in water.

EXPERIMENTAL

All melting points are uncorrected. Microanalyses were performed by the Microanalytisches Laboratorium im Max-Planck-Institut für Kohlenforschung, Mülheim, Germany.

N-Benzyladrenalone (I). This was prepared from 3,4-dihydroxy-ω-chloroacetophenone and methylbenzylamine according to Dalgliesh [1]. It was isolated as the monoethanolate.

3-Hydroxy-4-dimethylaminoethoxy-ω-methylbenzylaminoacetophenone (II). A mixture of 15.9 g (0.05 mole) of N-benzyladrenalone monoethanolate, 7.3 g (0.05 mole) of dimethylaminoethylchloride hydrochloride and 18.0 g (0.13 mole) of anhydrous potassium carbonate in 150 ml of dry acetone was refluxed for 24 h. The inorganic salts were filtered off and the solvent evaporated. The residue, upon admixture of ether saturated with hydrogen chloride, afforded the desired product as the dihydrochloride. The yield was 5.0 g (24 %), m. p. 235—236° (decomp.) (from dilute ethanol). (Found: C 57.48; H 6.95; N 6.51; Cl 16.74. Calc. for $C_{20}H_{28}O_3N_2$, 2HCl: C 57.80; H 6.78; N 6.74; Cl 17.08.)

α-(3-Hydroxy-4-dimethylaminoethoxyphenyl)-β-methylaminoethanol dihydrochloride (III). A solution of 1.04 g (0.0025 mole) of 3-hydroxy-4-dimethylaminoethoxy-ω-methylbenzylaminoacetophenone dihydrochloride in 20 ml of water was hydrogenated with 0.5 g of 10 % palladium-on-carbon catalyst at room temperature and atmospheric pressure. Two molar equivalents of hydrogen were absorbed in about 2 h. After removal of the catalyst by filtration, the solvent was evaporated under reduced pressure. The residue, after crystallization from acetone-methanol, afforded the dihydrochloride of the 4-dimethylaminoethyl ether of adrenaline, m. p. 225—226°. (Found: C 47.89; H 7.63; N 8.31; Cl 21.66. Calc. for $C_{13}H_{22}O_3N_2$, 2HCl: C 47.75; H 7.40; N 8.57; Cl 21.69.)

3,4-Dihydroxyacetophenone (IV). This was prepared from catechol diacetate by the method of Rosenmund and Lohfert [2].

3-Hydroxy-4-benzyloxyacetophenone (V). To a boiling solution of 15.2 g (0.1 mole) of 3,4-dihydroxyacetophenone and 12.7 g (0.1 mole) of benzylchloride in 250 ml of absolute ethanol, 2.3 g (0.1 mole) of sodium in 100 ml of absolute ethanol was added gradually during 1 h, after which time boiling was continued for a further 4 h. After filtration the solvent was evaporated. The residue was dissolved in 80 ml of 2 N sodium hydroxide solution and extracted with chloroform to remove the dibenzyl ether formed (about 7.5 g). Upon neutralization of the aqueous layer with carbon dioxide, 3-hydroxy-4-benzyloxyacetophenone was precipitated. The yield, after crystallization from ethanol, was 12.7 g (52.5 %), m. p. 119—120°. (Found: C 74.10; H 5.94. Calc. for $C_{15}H_{14}O_3$: C 74.36; H 5.83.)

From the above compound the following derivatives were prepared:

The *benzoate*, m. p. 76—77°. (Found: C 76.59; H 5.42. Calc. for $C_{22}H_{18}O_4$: C 76.28; H 5.24.)

The *methyl ether*, m. p. 83—84° (from methanol), was obtained with diazomethane. (Found: C 74.38; H 6.25. Calc. for $C_{16}H_{16}O_3$: C 74.98; H 6.29.) It was shown by mixed melting point determination to be identical with 3-methoxy-4-benzyloxyacetophenone. This was prepared by benzylation of acetovanillone obtained from veratrole by the method of Pratt and Robinson [3].

3-Hydroxy-4-benzyloxy-ω-bromoacetophenone (VI). A solution of 12.1 g (0.05 mole) of 3-hydroxy-4-benzyloxyacetophenone in 250 ml of glacial acetic acid (99—100 %) was cooled below +10°. To this solution 8.0 g (0.05 mole) of bromine in 50 ml of glacial acetic acid was added in the course of half an hour with stirring. The solvent was evaporated under reduced pressure. The residue, upon trituration with water, deposited crystals, which were recrystallized first from benzene, then from methanol. The yield was 8.0 g (50 %), m. p. 143—144°. (Found: C 55.84; H 4.13; Br 25.09. Calc. for $C_{15}H_{13}O_3Br$: C 56.09; H 4.08; Br 24.90.)

From the above compound the *benzoate*, m. p. 104—106°, was also prepared.

3-Hydroxy-4-benzyloxy-ω-methylbenzylaminoacetophenone (VII). A mixture of 3.21 g (0.01 mole) of 3-hydroxy-4-benzyloxy-ω-bromoacetophenone and 2.42 g (0.02 mole) of methylbenzylamine in 50 ml of benzene was shaken for 4 h and allowed to stand at room temperature overnight. The separated methylbenzylamine hydrochloride (1.55 g = 98 %) was filtered off and the solvent evaporated. The residue was a reddish brown oil, which did not crystallize. It was used without further purification for the following reaction.

3-Dimethylaminoethoxy-4-benzyloxy-ω-methylbenzylaminoacetophenone dihydrochloride (VIII). A mixture of 3.6 g (0.01 mole) of the crude 3-hydroxy-4-benzyloxy-ω-methylbenzylaminoacetophenone, 2.16 g (0.015 mole) of dimethylaminoethylchloride hydrochloride and 5.6 g (0.04 mole) of anhydrous potassium carbonate in 100 ml of acetone was refluxed for 48 h. After filtration the solvent was evaporated. The residue, upon addition of absolute ethanol and ether saturated with hydrogen chloride, afforded the desired product as the dihydrochloride. The overall yield from 3-hydroxy-4-benzyloxy-ω-bromoacetophenone (VI → VIII), after recrystallization from acetone-methanol, was 2.0 g (40 %), m. p. 202—204°. (Found: N 5.86; Cl 14.77. Calc. for $C_{27}H_{32}O_3N_2$, 2HCl: N 5.53; Cl 14.10.)

α-(3-Dimethylaminoethoxy-4-hydroxyphenyl)-β-methylaminoethanol dihydrochloride (IX). A solution of 1.0 g (0.002 mole) of 3-dimethylaminoethoxy-4-benzyloxy-ω-methylbenzylaminoacetophenone dihydrochloride in 20 ml of water was hydrogenated at room temperature and atmospheric pressure in the presence of 0.5 g of 10 % palladium-on-carbon catalyst. Three molar equivalents of hydrogen were absorbed in 2 h. After filtration, the solvent was evaporated under diminished pressure. The residue, upon trituration with acetone-methanol, yielded the desired product as the crystalline dihydrochloride, m. p. 248—249° (decomp.). (Found: C 47.50; H 7.46; N 8.59; Cl 21.92. Calc. for $C_{13}H_{22}O_3N_2$, 2HCl: C 47.75; H 7.40; N 8.57; Cl 21.62.)

3-Hydroxy-ω-methylbenzylaminoacetophenone hydrochloride (Xa). The synthesis of this compound was carried out by the sequence of reactions devised by Sergievskaya and Ravdel [4]. The starting material, 3-hydroxyacetophenone (a product of Winthrop Products Co.), was brominated after protection of the phenolic hydroxyl group by benzoylation, to give 3-benzoyloxy-ω-bromoacetophenone. This, by condensation with methylbenzylamine and subsequent debenzoylation, afforded 3-hydroxy-ω-methylbenzylaminoacetophenone hydrochloride, m. p. 202—203°, in 46 % overall yield (based on 3-hydroxyacetophenone).

3-Dimethylaminoethoxy-ω-methylbenzylaminoacetophenone hydrochloride (XIa). A mixture of 2.92 g (0.01 mole) of 3-hydroxy-ω-methylbenzylaminoacetophenone hydrochloride, 2.16 g (0.015 mole) of dimethylaminoethylchloride hydrochloride and 6.9 g (0.05 mole) of anhydrous potassium carbonate in 100 ml of dry acetone was refluxed for 48 h. After filtration the solvent was evaporated under reduced pressure. The residue was dissolved in ethanol. This solution, upon addition of ether saturated with hydrogen chloride, deposited crystals of dihydrochloride, which were recrystallized from acetone-methanol. The yield was 3.5 g (88 %), m. p. 198—200°. (Found: C 59.59; H 7.46; N 6.88; Cl 17.87. Calc. for $C_{20}H_{26}O_2N_2$, 2HCl: C 60.00; H 7.07; N 7.02; Cl 17.77.)

α-(3-Dimethylaminoethoxyphenyl)-β-methylaminoethanol dioxalate (XIIa). A solution of 2.00 g (0.005 mole) of 3-dimethylaminoethoxy-ω-methylbenzylaminoacetophenone dihydrochloride in 30 ml of water was hydrogenated with 0.5 g of 10 % palladium-on-carbon catalyst at room temperature and atmospheric pressure. Two molar equivalents of hydrogen were absorbed in 2 h. After removal of the catalyst and evaporation of the solvent under reduced pressure, the remainder, a viscous, colorless, non-crystallizable oil, was dissolved in 5 ml of 2 N aqueous sodium hydroxide solution and extracted with ether. The ethereal layer was dried over anhydrous sodium sulfate. After evaporation of the solvent the residue was dissolved in methanol. This solution, after addition of 0.9 g (0.01 mole) of anhydrous oxalic acid, was heated to boiling. On cooling, the dioxalate of the desired amine was obtained as colorless crystals, m. p. 156–158°. (Found: C 48.40; H 6.31; N 6.59. Calc. for $C_{13}H_{22}O_2N_2$, 2(COOH): C 48.79; H 6.27; N 6.70.)

4-Hydroxy-ω-methylbenzylaminoacetophenone monohydrate (Xb). A mixture of 3.41 g (0.02 mole) of 4-hydroxy-ω-chloroacetophenone (prepared by the method of Tutin *et al.*[5]) and 4.84 g (0.04 mole) of methylbenzylamine in 20 ml of benzene was shaken for 4 h and allowed to stand overnight at room temperature. After removal of the methylbenzylamine hydrochloride formed and evaporation of the solvent, the residue was crystallized from dilute ethanol. The yield was 5.2 g (95 %) and m. p. 106–109°. This same compound has been prepared previously by Asscher [6] from phenol and methylbenzylaminoacetonitrile. The yield and melting point recorded by this author are 16.5 % and 102–110°, respectively.

4-Dimethylaminoethoxy-ω-methylbenzylaminoacetophenone dioxalate (XIb). A mixture of 2.73 g (0.01 mole) of 4-hydroxy-ω-methylbenzylaminoacetophenone monohydrate 2.16 g (0.015 mole) of dimethylaminoethylchloride hydrochloride and 5.60 g (0.04 mole) of anhydrous potassium carbonate in 100 ml of acetone was refluxed for 48 h. The inorganic salts were filtered off, the solvent evaporated and the residue dissolved in ethanol. After addition of 1.80 g (0.02 mole) of anhydrous oxalic acid, the alkamine ether separated as the dioxalate. The yield was 2.7 g (52 %), m. p., after recrystallization from ethanol, 148–150°. (Found: N 5.42. Calc. for $C_{20}H_{26}O_2N_2$, 2(COOH): N 5.54.)

α-(4-Dimethylaminoethoxy)-β-methylaminoethanol dihydrochloride (XIIb). A solution of 2.53 g (0.005 mole) of 4-dimethylaminoethoxy-ω-methylbenzylaminoacetophenone dioxalate in 30 ml of water was hydrogenated at room temperature and atmospheric pressure in the presence of 0.5 g of 10 % palladium-on-carbon catalyst. Two molar equivalents of hydrogen were consumed in 2 h. After removal of the catalyst and evaporation of the solvent the hydrogenation product was obtained as crystalline dioxalate, m. p. 153–154°. By treatment with ether saturated with hydrogen chloride, this was converted to the corresponding dihydrochloride, m. p., after recrystallization from acetone-methanol, 200–201°. (Found: C 50.02; H 7.86; N 9.04; Cl 22.49. Calc. for $C_{13}H_{22}O_2N_2$, 2HCl: C 50.16; H 7.78; N 9.04; Cl 22.78.)

Calculated Mean Amplitudes of Vibration in Boron Trihalides

S. J. CYVIN

Institutt for teoretisk kjemi, Norges tekniske høgskole, Trondheim, Norway

The mean amplitudes of vibration from spectroscopic data in boron trifluoride, trichloride and tribromide are recalculated. The results are presented together with new calculations for boron triiodide.

Bakken [1] has presented a list of mean amplitude values for a number of four-atomic molecules including boron trifluoride, trichloride and tribromide. Professor Morino during his stay in Trondheim pointed out a discrepancy between Bakken's values and unpublished values obtained by T. Iijima for the non-bonded distances in boron trifluoride and trichloride. In the present work a recalculation of the mean amplitudes of the three mentioned

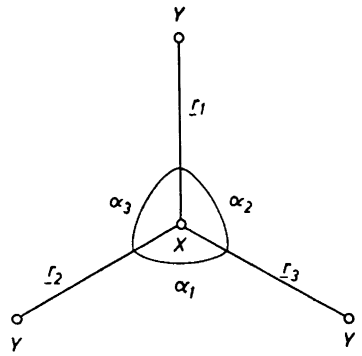

Fig. 1. Internal coordinates for plane symmetrical XY_3 molecules. The symbols denote displacements from the equilibrium distances and angles. Symmetry coordinates:

$$\text{Symm.species } A'_1: \quad S_1 = 3^{-\frac{1}{2}}(r_1 + r_2 + r_3)$$

$$\text{Symm.species } E': \begin{cases} S_3 = 6^{-\frac{1}{2}}(2r_1 - r_2 - r_3) \\ S_4 = 6^{-\frac{1}{2}}(2\alpha_1 - \alpha_2 - \alpha_3) \end{cases}$$

R denotes the equilibrium X—Y distance.

molecules has been performed together with the calculations for boron triiodide. These calculations revealed an error in the numerical calculations of Bakken.

General treatment [2-5]. The molecular model (XY_3) is that of D_{3h} symmetry in the equilibrium position. Small harmonic vibrations are assumed. It is found that only 3 symmetry coordinates (see Fig. 1) are needed for setting up the energy matrices for the in-plane vibrations. The adopted symbols for the force constants of the symmetrized potential energy matrix are given by

$$K_1 \text{ (symmetry species A'}_1\text{)}; \quad \begin{bmatrix} K_2 & \Gamma \\ \Gamma & \Phi \end{bmatrix} \text{ (symmetry species E')}.$$

The secular equation yields the following equations for the vibrational frequencies ($\lambda = 4\pi^2\nu^2$),

$$\lambda_1 = K_1\mu_Y$$

$$\lambda_3 + \lambda_4 = \tfrac{1}{2}(K_2 + 3\Phi)\ (3\mu_X + 2\mu_Y) + 3\tfrac{3}{2}\Gamma\mu_X$$

$$\lambda_3\lambda_4 = 3(K_2\Phi - \Gamma^2)\ (3\mu_X + \mu_Y)\ \mu_Y$$

where μ_X and μ_Y denote the inverse masses of X and Y, respectively. The two types of interatomic distance deviations will be represented by $r_{XY} = r_1$

Table 1. Experimental fundamental frequencies and calculated force constants of boron trihalides.

Fundamentals (gaseous state) in cm^{-1} units [a]				
	$^{11}BF_3$	$^{11}BCl_3$	$^{11}BBr_3$	$^{11}BI_3$
ν_1	888	471	278	190
ν_3	1 453.5	954.2	819.8	704.1
ν_4	480.4	243	148	100
	$^{10}BF_3$	$^{10}BCl_3$	$^{10}BBr_3$	$^{10}BI_3$
ν_3	1 504.7	993.7	856.1	737.0

Force constants in mdyne/Å units [b]				
	BF_3	BCl_3	BBr_3	BI_3
K_1	8.8236	4.6324	3.6374	2.6984
K_2	7.4068	3.3424	3.3021	1.7292
Φ	0.50013	0.23082	0.18071	0.15079
Γ	−0.63980	−0.19575	−0.34545	−0.03493

[a] The data for BF_3 and BCl_3 are from Ref.[6]; those of BBr_3 and BI_3 from Ref.[7].

[b] The additional solutions arising from the quadratic secular equation yield unreliable force constant values which have been rejected.

Table 2. Mean amplitudes of vibration in boron trihalides.

Mean amplitude (Å)	Abs. temp. °K	Molecule $^{11}BF_3$	$^{11}BCl_3$	$^{11}BBr_3$	$^{11}BI_3$
u_{XY}	0	0.0424	0.0478	0.0479	0.0508
	298	0.0425	0.0491	0.0506	0.0570
u_{YY}	0	0.0517	0.0536	0.0461	0.0449
	298	0.0552	0.0689	0.0726	0.0848

and $r_{YY} = \frac{1}{2}\,3^{\frac{1}{2}}\,(r_2 + r_3) + \frac{1}{2}Ra_1$. They are connected with the symmetry coordinates by the following linear combinations.

$$r_{XY} = 3^{-\frac{1}{2}}S_1 + 6^{-\frac{1}{2}}2S_3$$

$$r_{YY} = S_1 - 2^{-\frac{1}{2}}S_3 + 6^{-\frac{1}{2}}S_4$$

To compute the corresponding mean amplitudes, *viz.* $u_{XY} = < r_{XY}^2 >_{Av}^{1/2}$ and $u_{YY} = < r_{YY}^2 >_{Av}^{1/2}$, the interatomic distance deviations need be expressed in terms of the normal coordinates. Consequently the transformation between the symmetry coordinates and the normal coordinates is required. (For a detailed theoretical treatment, see especially Refs. [4,5]).

Numerical computations. The applied experimental values of vibrational frequencies are given in Table 1. Calculated force constants which are consistent with these frequency values are also included in the table.

The data from Table 1 have been used for computations of the mean amplitudes of vibration (u) for the boron halides of the ^{11}B isotope. The resulting values of u at the absolute zero point and the temperature 298 °K are given in Table 2.

Acknowledgement. I wish to express my best thanks to Professor Yonezo Morino, who pointed out the error in Bakken's paper, for interesting discussions during his visit in Trondheim.

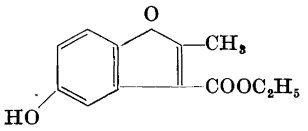
Ozonolysis and Structure of Some Benzofurans

ERLING BERNATEK and INGE BØ

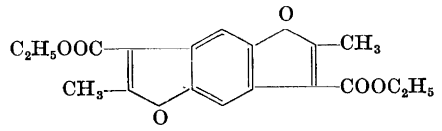
Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

Stable, crystalline ozonides have been obtained by ozonisation of 2-methyl-3-carbethoxy-5-acetoxybenzofuran and 2,7-dimethyl-3-carbethoxy-5-acetoxybenzofuran. The structure of reaction products from toluquinone and ethyl acetoacetate and acetylacetone, respectively, has been determined. Further the ozonolysis of 2-methyl-3-carbethoxy-5-hydroxybenzofuran, 2-methyl-3-acetyl-5-hydroxybenzofuran and 2-methyl-3-acetyl-5-acetoxybenzofuran is described.

By the reaction between ethyl acetoacetate and *p*-benzoquinone in the presence of anhydrous zinc chloride there is formed a mixture of a benzofuran and a benzodifuran. The synthesis was first described by v. Pechmann [1] and Ikuta [2], the latter author providing the proof for the structures (I and II) of the products.



I



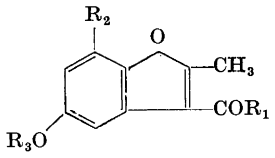
II

Some years later Graebe and Levy [3] extended the synthesis to include toluquinone and proposed a revision of some of Ikuta's structural formulae. These have, however, been corroborated by more recent work by Bernatek [4]. Further extensions of the synthesis have been made through the investigations of the latter [4–6] and by Grinev and his collaborators [7,8].

Ozonolysis of benzofurans was originally established by v. Wacek, Eppinger and v. Bezard [9] but the reaction seems not to have been exploited until some benzodifurans were ozonised by Bernatek and Thoresen [10] in 1955. That investigation was from the outset aimed at structural problems but as an interesting sideline it was found that when suitably substituted a benzodifuran would yield very stable and excellently crystallising ozonides.

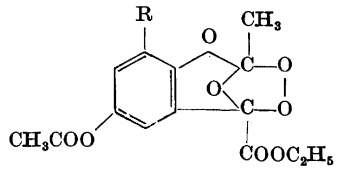
The present paper deals with the ozonolysis of I and III (a product from benzoquinone and acetylacetone) as well as their homologs IV and V contain-

ing a methyl group in the benzene ring. IV was prepared by Graebe and Levy but no attempts to determine the position of the methyl group were made at that time. Our interest is therefore in part directed towards structural problems and in part towards the possible formation of stable ozonides.



IA: $R_1 = OC_2H_5$, $R_2 = H$, $R_3 = CH_3CO$
III: $R_1 = CH_3$, $R_2 = R_3 = H$
IIIA: $R_1 = CH_3$, $R_2 = H$, $R_3 = CH_3CO$
IV: $R_1 = OC_2H_5$, $R_2 = CH_3$, $R_3 = H$
IVA: $R_1 = OC_2H_5$, $R_2 = CH_3$, $R_3 = CH_3CO$
V: $R_1 = R_2 = CH_3$, $R_3 = H$
VA: $R_1 = R_2 = CH_3$, $R_3 = CH_3CO$

The ozonolyses were performed in ethyl acetate at 0°. In order to isolate stable ozonides it was found necessary to ozonise the acetates rather than the free hydroxybenzofurans. Thus substance I gave no ozonide when concentrating the reaction mixture, but a yellow, peroxidic syrup which decomposed violently at room temperature. No definite decomposition products were isolated. It is believed that the presence of a free hydroxyl group enhances combustion of the molecule. IA on the other hand yielded a stable, monomeric ozonide $C_{14}H_{14}O_8$ (VI).

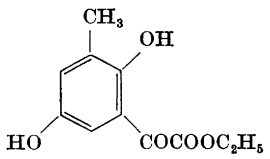


VI: R = H
VII: R = CH_3

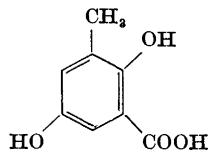
Ozonolysis of III gave a light brown syrup which was decomposed with aqueous sodium carbonate and acidified with hydrochloric acid. After several days in a refrigerator a small amount of crystals appeared and were identified as gentisic acid (hydroquinone carboxylic acid).

The immediate ozonisation product of IIIA was also a brownish, peroxidic syrup which was rather stable and may have contained an ozonide, but no such was isolated. After some time the syrup deposited white crystals of gentisic acid diacetate. From these results it is clear that the hydroxyl in III must be in *para*-position to the oxygen bridge of the furan ring. We have thus another support for the original formula of Ikuta in contrast to the proposals of Graebe and Levy where the hydroxyl and the oxygen bridge would have been in *meta*-position to each other.

IV gave after ozonisation a colourless syrup which decomposed slowly with evolution of gas. After some days white crystals separated which were identified as oxalic acid. The degradation had in this case evidently gone very far. IVA yielded as expected a stable ozonide $C_{15}H_{16}O_8$ (VII). On treatment with sodium iodide in glacial acetic acid it was reduced to a monoacetate of ethyl 2,5-dihydroxy-3-methylphenylglyoxalate (VIII).



VIII



IX

Whether the acetoxy group is attached to the 2- or 5-position cannot be proved conclusively, but the latter position is considered the more likely one. If the ozonide (VII) had been reduced without complications, the diacetate of VIII would have formed. During the reaction the new acetoxy group probably has been split off *in statu nascendi*. The acetate of VIII was boiled with glacial acetic acid and sodium acetate to give the free ketoacid. This was in turn oxidised with hydrogen peroxide and hydrolysed with hydrochloric acid to the methyl gentisic acid IX (2,5-dihydroxy-3-methyl-benzoic acid). Proof is hereby secured for the position of the methyl group *ortho* to the oxygen bridge in the reaction product from toluquinone and ethyl acetoacetate (IV).

Of V (the product from toluquinone and acetylacetone) only its acetate VA was ozonised. No ozonide was obtained from this compound but a peroxidic syrup which deposited crystals of 2,5-diacetoxy-3-methylbenzoic acid (diacetate of IX). The position of the methyl group in the benzene ring of V must consequently be the same as in IV.

Regarding the course of ozonolysis it is obvious that IA and IVA mainly undergo the normal reaction. The same probably holds true also for I and IV, but here the free hydroxyl group is responsible for a secondary and far-reaching decomposition. III, IIIA and VA all lose their 3-acetyl groups which is consistent with an anomalous ozonolysis. The fact that the peroxidic syrups resulting from the ozonisation had any stability at all at room temperature, however, makes it more probable that the ozonisation proper was a normal one and followed by a rearrangement.

EXPERIMENTAL

(Melting points not corrected)

Ozonisation procedure. The substance was usually dissolved in about 50 times its weight of pure ethyl acetate and the solution cooled in an ice-bath. A current of oxygen containing 4.5 % (wt) of ozone was passed through the solution at a rate of 30 l/h. Some ozone always escaped from the reaction mixture and the reagent was therefore passed through in excess of the calculated amount. The ozonised solution was concentrated *in vacuo* and worked up as described below.

2-Methyl-3-carbethoxy-5-hydroxybenzofuran (I) and its acetate (IA). I (3.0 g) in ethyl acetate (150 ml) was ozonised for 60 min. During the reaction a strong yellow colour appeared but vanished towards the end. After concentration *in vacuo* at room temperature a yellow syrup remained which almost immediately decomposed violently.

IA (3.0 g) in ethyl acetate (150 ml) was ozonised for 60 min. Transitory yellow colour. After concentration a yellow syrup remained which crystallised after two days in a refrigerator. Recrystallised from ethanol, m. p. 105° (1.2 g). (Found: C 54.2; H 4.7; act. O 5.2; M (benzene) 290. Calc. for $C_{14}H_{14}O_8$: C 54.2; H 4.6; act. O 5.2; M 310.)

2-Methyl-3-acetyl-5-hydroxybenzofuran (II) and its acetate (IIA). II (2.5 g) in ethyl acetate (100 ml) was ozonised for 30 min. Transitory yellow colour. After concentration the brownish syrup did not crystallise after one week in a refrigerator. The syrup was treated with aqueous sodium carbonate until a clear solution remained. Upon acidification white crystals slowly began to separate. Recrystallised from a small amount of water, m. p. 199°. Mixed m. p. with an authentic sample of gentisic acid showed no depression. IIA (3 g) in ethyl acetate (150 ml) was ozonised for 60 min. Concentration gave a brownish syrup which after being kept in a refrigerator overnight deposited white crystals. Recrystallised from ethyl acetate-petrol ether m. p. 122° (0.35 g). Mixed m. p. with an authentic sample of diacetylgentisic acid (m. p. 119°) showed no depression. (Found: C 55.5; H 4.1; E 237. Calc. for $C_{11}H_{10}O_6$: C 55.5; H 4.2; E 238.)

2,7-Dimethyl-3-carbethoxy-5-hydroxybenzofuran (IV) and its acetate (IVA). IV (1.5 g) in ethyl acetate (75 ml) was ozonised for 30 min. Concentration *in vacuo* afforded a syrup which at room temperature underwent a slow decomposition with evolution of gas. After two days in a refrigerator white crystals separated. Recrystallised from water, m. p. *ca.* 102° (0.05 g). Mixed m. p. with oxalic acid was undepressed. (Found: C 19.2; H 4.9. Calc. for $C_2H_2O_4 \cdot 2H_2O$: C 19.1; H 4.8).

IVA (2.5 g) in ethyl acetate (150 ml) was ozonised for 60 min. During concentration a yellowish substance separated. M. p. 109—111° (1.7 g). Recrystallised from ethanol, m. p. 112°. (Found: C 55.6; H 5.0; act. O 4.9. Calc. fo · $C_{15}H_{16}O_8$: C 55.6; H 5.0; act. O 5.0.) The ozonide (VII) (0.8 g) was treated overnight with sodium iodide (0.75 g) in glacial acetic acid and the liberated iodine removed with aqueous sodium sulphite. A yellow oil separated and crystallised on scratching. Recrystallised from dilute ethanol, yellowish needles of m. p. 69°, gave an orange-coloured precipitate with 2,4-dinitrophenylhydrazine. (Found: C 58.6; H 5.3. Calc. for $C_{13}H_{14}O_6$: C 58.6; H 5.3.)

$C_{13}H_{14}O_6$ (monoacetate of VIII) (0.20 g), anhydrous sodium acetate (0.25 g) and glacial acetic acid (5 ml) were refluxed for one hour and evaporated to dryness *in vacuo*. The yellow residue (sodium salt) was taken up in water and acidified with hydrochloric acid when a yellow substance separated. Recrystallised from benzene, yellow-orange needles, m. p. 132° (0.15 g). Red precipitate with 2,4-dinitrophenylhydrazine. (Found: C 55.4; H 4.6. Calc. for $C_{11}H_{10}O_6$: C 55.5; H 4.2.)

The ketoacid $C_{11}H_{10}O_6$ (0.15 g) and hydrogen peroxide (5 ml, 1 %) were stirred at room temperature for 2 h and left for another 17 h. The yellow colour had disappeared and a white substance separated. Recrystallised from ethyl acetate-ligroin and from dilute ethanol, m. p. 146°. This substance was refluxed with hydrochloric acid (5 ml, 1 N) for 30 min. On cooling yellowish needles separated. Recrystallised from a small amount of water. White needles, m. p. 216°. Mixed m. p. with an authentic sample of 2,5-dihydroxy-3-methylbenzoic acid (prepared from *o*-cresotic acid by persulphate oxidation [11]) showed no depression. Also the I.R.-spectra of the two samples were identical.

2,7-Dimethyl-3-acetyl-5-hydroxybenzofuran (V) and its acetate (VA). To a mixture of acetylacetone (8 ml), acetone (30 ml) and anhydrous zinc chloride (11 g) was added toluquinone (4 g) in small portions. The mixture was refluxed for 30 min and on cooling a white substance separated. Recrystallized from acetone, m. p. 235° (4 g). The red colour characteristic for benzofurans was produced by heating with concentrated sulphuric acid. With 2,4-dinitrophenylhydrazine a red substance was formed, m. p. 255°. (Found: C 70.7; H 5.9. Calc. for $C_{12}H_{12}O_3$: C 70.6; H 5.9.)

V (3 g) in acetyl chloride (15 ml) was refluxed for 15 min. The mixture was poured into 600 ml of ice-water and stirred vigorously. The separated substance was washed thoroughly and recrystallised from 50 % ethanol, 2.7 g, m. p. 97°. (Found: C 68.2; H 5.6. Calc. for $C_{14}H_{14}O_4$: C 68.3; H 5.7.)

VA (2.7 g) in ethyl acetate (150 ml) was ozonised for 60 min. On concentration a light yellow syrup remained which after some days in a refrigerator deposited a white substance. Recrystallised from ethyl acetate-ligroin and from dilute ethanol, m. p. 148°. (Found: C 57.0; H 4.7; E 252. Calc. for $C_{12}H_{12}O_6$: C 57.2; H 4.8; E 251.) Mixed m. p. with an authentic sample of 2,5-diacetoxy-3-methylbenzoic acid was undepressed. Also the I.R.-spectra of the two compounds were identical.

On the Acid-Catalysed Rearrangement of Ozonides *

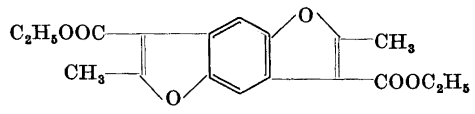
ERLING BERNATEK and FREDRIK THORESEN

Universitetets Kjemiske Institutt, Blindern-Oslo, Norway

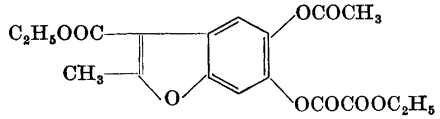
An acid-catalysed rearrangement of two stable, crystalline ozonides is described. The reaction is intramolecular and the reacting entities are probably the conjugate acids of the ozonides.

It has been reported [1] that suitably substituted benzo [1,2—b:4,5—b'] difurans yield stable, crystalline ozonides. This is also the case with some benzofurans [2]. Criegee's statement [3] that stable ozonides often can be obtained from unsaturated five-membered rings is consequently further amplified. Ozonides can, like other peroxy compounds, undergo rearrangements where one of the "peroxidic" oxygen atoms is interposed between two carbon atoms. Undoubtedly such rearrangements often have been confused with anomalous ozonolysis because the net results of the reactions generally are identical. Only in the later years when really pure, stable and monomeric ozonides have become available, such rearrangements have been studied in some detail. Thus, Criegee [4] has reported on the rearrangement of ozonides from 2,3-disubstituted indenones, while Witkop [5] described a rearrangement of 2-phenylskatole ozonide.

We wish to describe the acid-catalysed rearrangement of the monozonide and diozonide of diethyl 2,6-dimethylbenzo [1,2—b:4,5—b'] difuran-3,7-dicarboxylate (I).



I



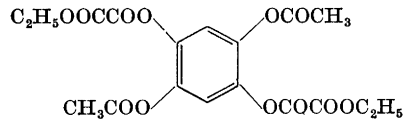
II

When the ozonides were dissolved in acetic anhydride containing a small amount of perchloric acid, the content of active oxygen disappeared rapidly. From the monozonide ($C_{18}H_{18}O_9$) two products could be isolated. A very small amount of an acid which could not be identified and a substance $C_{18}H_{18}O_9$.

* Presented at the 9. *Nordiske Kemikermöde*, Aarhus 1956.

The latter contained one O-acetyl group, split off one mole of oxalic acid on alkaline hydrolysis and could be alcoholysed to diethyl oxalate and a substance $C_{12}H_{12}O_5$. The latter could in turn be acetylated to a diacetate $C_{16}H_{16}O_7$. These results are only compatible with the structure II for the rearrangement product $C_{18}H_{18}O_9$.

Also the diozonide ($C_{18}H_{18}O_{12}$) yielded two products; an acid $C_{12}H_{10}O_8$ and a substance $C_{18}H_{18}O_{12}$. The acid gave a dimethyl ester and was identified as 2.5-diacetoxyterephthalic acid. $C_{18}H_{18}O_{12}$ contained two O-acetyl groups and by alkaline hydrolysis split off two moles of oxalic acid. Treatment with sodium acetate in acetic anhydride gave 1,2,4,5-tetracetoxybenzene. Evidently $C_{18}H_{18}O_{12}$ has the structure III.



III

The rearrangements are isomeric and most probably intramolecular since the same products in approximately the same yields were obtained by rearrangement in propionic anhydride. Further it is likely that the first step in the reaction is an addition of a proton, *i.e.* the reacting entities are the conjugate acids of the ozonides. A semiquantitative experiment shows that that with perchloric acid the reaction is very fast at 0°. With sulphuric acid it is somewhat slower but still fast and with hydrogen chloride very slow. The rate of the reaction is apparently dependent on the proton-donating strength of the catalyst. Witkop [5] has outlined a probable mechanism for the rearrangement of 2-phenylskatole ozonide but did not support it with any special experimental evidence. Especially is the point of protonation arbitrarily chosen. No mechanism will be propounded here (several can be written), but it ought to be mentioned that the point of attack may as well be the ether bridge in the trioxolane ring of an ozonide as the peroxy bridge.

The formation of 2,5-diacetoxyterephthalic acid may be a result of a different course of the rearrangement. In this case the primary product is not an ester but a mixed anhydride of diacetoxyterephthalic acid and ethyl carbonate which is hydrolysed during isolation.

In the experimental part is further described the reduction of the ozonides to the corresponding α-ketoesters.

EXPERIMENTAL

(Melting points are not corrected)

Rearrangement of monozonide. Monozonide (0.90 g) was added in small portions to an ice-cooled mixture of perchloric acid (3 drops, 70 %) and acetic anhydride (10 ml). After 30 min the content of active oxygen had disappeared and the mixture was poured into ice-water. A white substance (0.82 g) separated and was recrystallised from petrol ether, m. p. 89—90°. (Found: C 57.4; H 4.7; O-acetyl 11.5. Calc. for $C_{18}H_{18}O_9$ (II): C 57.2; H 4.8; O-acetyl 11.4.) A small amount of the raw product did not dissolve in petrol ether. It was an acid and decomposed at 197—198°.

II (86.7 mg) was boiled with sodium carbonate (10 ml, 2 N) for 60 min in a hydrogen atmosphere. The solution was analysed for oxalic acid. Found: Calcium oxalate dihydrate 30.0 mg. Calc. for $C_{14}H_{13}O_5(OCOCOOC_2H_5)$: 33.5 mg. The calcium oxalate was dissolved in dilute hydrochloric acid, extracted with ether and the isolated oxalic acid identified by its X-ray powder diagram.

II (0.98 g) was refluxed with anhydrous ethanol (50 ml) containing hydrogen chloride (3 %) for 60 min). The mixture was evaporated to dryness and extracted with several portions of petrol ether and the extracts concentrated on a water-bath. The residue smelled like an ester and by means of its I.R.-spectrum was identified as diethyl oxalate. From the petrol ether extractions a white substance remained (0.60 g, 98 %). Recrystallised from dilute ethanol, colourless crystals m. p. 182°. (Found: C 61.2; H 5.1. Calc. for $C_{12}H_{12}O_5$: C 61.0; H 5.1.)

$C_{12}H_{12}O_5$ (0.24 g) and acetic anhydride (10 ml) were refluxed for 4 h and poured into ice-water. The separated substance (0.3 g) was recrystallised from benzene. Yellowish crystals, m. p. 158°. (Found: C 60.1; H 5.1; O-acetyl 27.0. Calc. for $C_{16}H_{16}O_7$: C 60.0; H 5.0; two O-acetyl 26.9.)

Rearrangement of diozonide. Diozonide (2.0 g) was rearranged as described for the monozonide. The product was an oil which solidified after two days in a refrigerator. The product (1.2 g) was extracted with hot benzene and the undissolved part (0.4 g) recrystallised from dilute ethanol. Decomp. $>300°$. (Found: C 50.9; H 3.9. Calc. for $C_{12}H_{10}O_8$: C 51.1; H 3.6.) This substance (0.28 g) was methylated with diazomethane and the product recrystallised from ethanol, m. p. 164—165°. Mixed m. p. with an authentic sample of 2,5-diacetoxyterephthalic acid dimethyl ester was undepressed.

The benzene extract was evaporated and washed with aqueous sodium bicarbonate, the residue being recrystallised from benzene, m. p. 138° (0.6 g). (Found: C 50.7; H 4.3; O-acetyl 20.5. Calc. for $C_{18}H_{18}O_{12}$ (III): C 50.7; H 4.3; two O-acetyl 20.2.)

III (0.23 g), acetic anhydride (10 ml) and sodium acetate (0.5 g) were refluxed for 3 h. Poured into ice-water when a brownish substance separated (0.17 g). Recrystallised from glacial acetic acid (charcoal), m. p. 227—228°. Mixed m. p. with an authentic sample of 1,2,4,5-tetracetoxybenzene was undepressed.

III (268 mg) was hydrolysed with sodium hydroxide and the solution analysed for oxalic acid. Found: calcium oxalate dihydrate 188 mg. Calc for $C_{10}H_8O_4(OCOCOOC_2H_5)_2$ 184 mg.

The rearrangements were performed in propionic anhydride and the results were found to be essentially the same as described above.

Reduction of the ozonides. Monozonide (1.8 g) was dissolved in ethyl acetate (100 ml) and a solution of sodium iodide (3 g) in glacial acetic acid (15 ml) was added and the mixture shaken well. After 10 min the liberated iodine was removed with aqueous sodium sulphite. The ethyl acetate was washed with water, dried and concentrated when a dark oil (1.6 g) remained. This crystallised after some time and was recrystallised from dilute ethanol. White crystals, m. p. 99°. Gives a precipitate with 2,4-dinitrophenylhydrazine. (Found: C 59.5; H 5.0. Calc. for $C_{18}H_{18}O_8$: C 59.7; H 5.0.) The substance is regarded as ethyl 2-methyl-3-carbethoxy-5-acetoxybenzofuranyl-6-glyoxalate (normal reduction product of the monozonide).

Diozonide (1.9 g) in chloroform (100 ml) was chilled to $-23°$ and mixed with sodium iodide (6 g) in glacial acetic acid (30 ml). After 10 min the iodine was removed with aqueous sodium sulphite and the chloroform washed with aqueous sodium bicarbonate, dried and concentrated. A brown oil remained and crystallised in needles (1.4 g). Recrystallised from benzine, m. p. 135°. Positive reaction on carbonyl with 2,4-dinitrophenylhydrazine. (Found: C 54.9; H 4.6; O-acetyl 22.2. Calc. for $C_{18}H_{18}O_{10}$: C 54.8; H 4.6; two O-acetyl 21.8.) The substance is the expected reduction product of the diozonide: Diethyl 1,4-diacetoxybenzene-2,5-diglyoxalate.

One of the authors (E.B.) wishes to express his gratitude to *Fridtjof Nansens Fond* for a grant.

The Crystal and Molecular Structure of Acetyl Choline Bromide

HARALD SÖRUM

Forsvarets Forskningsinstitutt, Kjeller, Norway
and
Fysisk Institutt, Norges Tekniske Högskole, Trondheim, Norway

The crystal and molecular structure of acetyl choline bromide has been determined by the aid of X-ray methods. The crystals are monoclinic with $a = 11.10$ Å, $b = 13.67$ Å, $c = 7.18$ Å and $\beta = 110°$. The space group is $P2_1$ and there are four molecules per unit cell. It is shown that the acetyl choline ion is present in the structure in two distinct structural forms, one of which is the previously assumed extended form, the other being a sort of "ring" structure, where the choline radical, including the oxygen, forms a roughly planar "ring" with a distance from the ester oxygen to the methyl group in the "ring" plane of ~3 Å. Shortened intermolecular distances of ~3 Å link the molecules together to form double strings of molecules running in the direction of the crystallographic a-axis. Atomic coordinates, interatomic distances and bond angles are given. It is suggested that the ability of acetyl choline to exist in two different structural forms may be of primary importance for its behaviour at lipoid-water interfaces, possibly also for its specific action in the transfer of nerve impulses.

Choline, $(HO{\cdot}CH_2{\cdot}CH_2{\cdot}N(CH_3)_3)^+OH^-$, is the parent compound of a series of physiologically active derivatives, widely distributed in plants and animals. The most important one of these derivatives may be acetyl choline, to which is ascribed the formula $(CH_3{\cdot}CO{\cdot}O{\cdot}CH_2{\cdot}CH_2{\cdot}N(CH_3)_3)^+OH^-$, and which is known to play a specific role in the cholinergic nerve system, besides other physiological activities.

The choline derivatives or "cholines" form, along with the acid and dipolar derivatives named "betaines", an interesting type of compounds characterized by the tetra-substituted ammonium group. Accurate determinations of the structures of such compounds are rare in the literature. X-Ray investigations on the crystal structures of the iodides and bromides of palmityl and stearyl cholines have been reported by Stora [1], but accurate atomic positions were not derived in these works. Jellinek [2] has recently reported a structure determination of muscarine iodide, a substance which is related to acetyl choline bromide.

The understanding of the specific actions of acetyl choline is apparently closely connected with a detailed knowledge of the structure of the acetyl choline ion. The present structure determination was therefore undertaken to provide as complete a description of the acetyl choline ion and of the molecular packing as possible, and it is intended to carry out structure determinations for several characteristic compounds of related type.

EXPERIMENTAL

Crystallographic data of acetyl choline bromide have been given in a preliminary account of this work [3]. Repeating here the values of the lattice constants, correcting a misprint in a and choosing the obtuse angle we obtain: $a = 11.10$ Å, $b = 13.67$ Å, $c = 7.18$ Å, $\beta = 110.0°$. There are four molecules per unit cell. The space group is $P2_1$.

Relative intensities of the $hk0$-reflexions were obtained by visual estimation from multiple film Weissenberg photographs, taken with Cu$K\alpha$-radiation. As the specimen used was very small and of fairly spherical form, no correction has been applied for absorption. After corrections for Lorentz and polarization factors the intensities were brought to an approximately absolute scale by the method of Wilson [4]. The scale factor thus found was later on by comparison with calculated intensities found to be correct within 4 %. Intensities of the reflexions on the equatorial layer lines with rotation around the [010]- and the [100]-axis, respectively, and on the first seven layer lines around the [010]-axis were recorded in the same way. These intensities were transferred directly to an absolute scale by comparison with calculated intensities.

The X-ray photographs show subsidiary reflexions [3], indicating some sort of long range modulation of the structure amplitude of the pseudo-cell. It has, however, been assumed that the structure of the pseudo-cell, representing an average structure, could be derived from the intensities of the main reflexions, disregarding those of the subsidiary reflexions. This "anomaly" has greatly complicated the derivation of the structure, and also impeded an ultimate refinement of the atomic coordinates. On the other hand, it may well be that the actual structure found in this work may reveal characteristic and important features of the acetyl choline ion, which might have been lost if a "normal" crystal, showing no subsidiary X-ray reflexions, had been obtained by crystallization under different conditions. In the continued work on this problem it is intended to investigate if this is possible.

The extrapolation graph for determination of the scale factor indicates rather strong thermal vibrations, the derived constant in the temperature factor being about 5 Å^2. This temperature factor has not been used in preparing the data for the Fourier syntheses, but has been introduced in comparing observed and calculated structure factors and amplitudes. Atomic scattering factors are taken from *Internationale Tabellen* 1935 and from Viervoll and Ögrim [5].

DETERMINATION OF THE STRUCTURE PROJECTED ON (001)

A Patterson projection on (001) is shown in Fig. 1. There is only one high and sharp maximum with coordinates u, $b/2$ and this maximum must therefore correspond to interaction between bromine atoms connected by the screw axis. Since there are four molecules in the unit cell, and the space group has twofold general positions, there must be two independent molecules in the asymmetric unit. The only maximum which may be assumed to correspond to interactions between independent bromine atoms is the apparent double maximum around the position $a/2,b/4$ in the Patterson projection. These

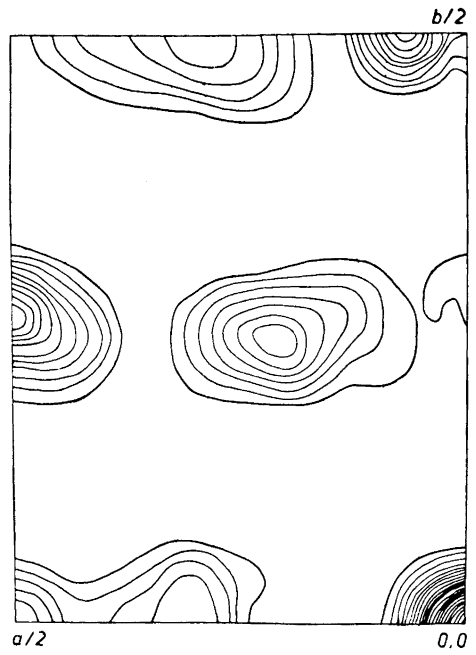

Fig. 1. Asymmetric part of the Patterson projection on (001) of acetyl choline bromide.

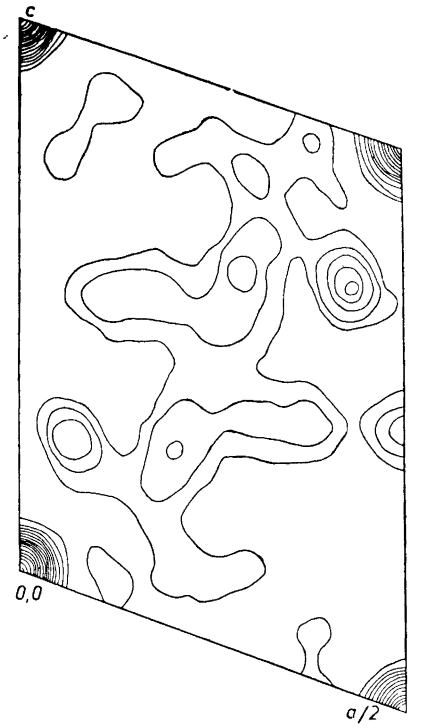

Fig. 2. Patterson projection on (010) of acetyl choline bromide.

maxima indicate the following approximate coordinates for the bromine atoms: $x_1 = \pm 0.036$, $y_1 = 0$ and $x_2 = 0.5 \pm 0.036$, $y_2 = 0.25 \pm 0.015$. The number of possible sign combinations is reduced by the choice of origin, and calculation of some structure amplitudes enabled a choice between the remaining possibilities; thus, the coordinates $x_1 = 0.036$, $y_1 = 0$ and $x_2 = 0.536$, $y_2 = 0.265$ were derived for the independent bromine atoms.

Derivation of coordinates of the light atoms from the Patterson projection would be rather fortuitous, but the projection clearly suggests that the molecules are arranged in layers parallel to (010) and interspaced approximately $b/4$. The square of the bromine scattering factor is about 1.6 times the sum of the squares of the scattering factors of the lighter atoms, and it might thus be expected that the knowledge of the bromine positions would lead to a recognizable structure of the acetyl choline ion in a Fourier synthesis calculated on this basis, although in this case the heavy atom may have a somewhat too strong influence. Only the (010)-projection, however, is centrosymmetric, and in this projection the overlapping of four molecules would be a serious obstacle for a straigt-forward derivation of the structure.

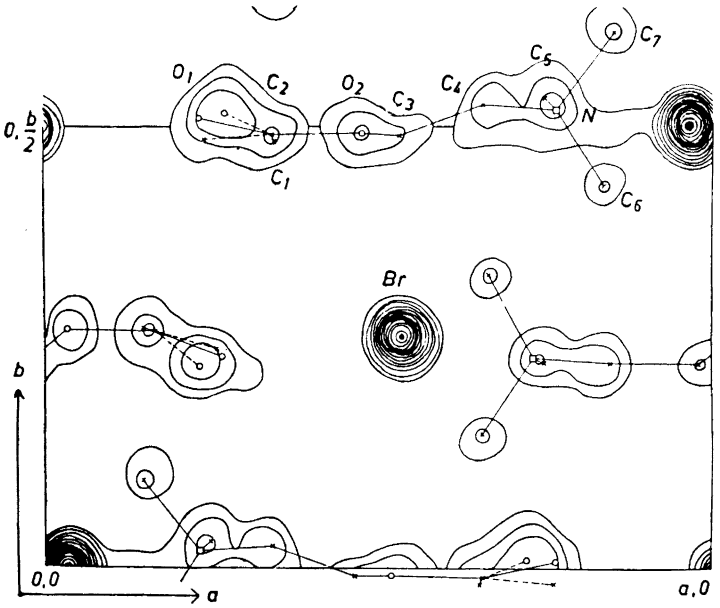

Fig. 3. Projection of electron density on (001) of acetyl choline bromide. Contour lines are drawn at equal but arbitrary intervals. Full circles, open circles, squares and crosses indicate bromine, oxygen, nitrogen and carbon atoms, respectively. Dashed lines indicate an alternative orientation of the acetyl groups.

The proposed layer structure and spatial considerations suggest that the independent acetyl choline ions were to be placed between bromine atoms in the direction of the a-axis, and having their long directions running in the same direction. Tentative coordinates of the lighter atoms, except hydrogen, were derived in this way and were included in the calculation of the first complete set of structure amplitudes and phases of the $hk0$-reflexions, leading to a value of R of 0.32, which is only slightly lower than the value of R (0.35) when the bromine atoms only are included in the calculations. Two ambiguities had to be reckoned with in the derivation of the tentative coordinates, *first*, the direction of the molecules with respect to the positive a-axis direction, and *secondly*, whether independent molecules should run in the same or in opposite direction.

The first Fourier projection gave a fairly clear picture of the structure, but maxima corresponding to the two methyl groups, lying outside the approximate plane of the rest of the molecule, indicated that the directions of both molecules should be reversed. This feature is noteworthy as it indicates that the influence of the bromine atoms is strong enough to lead to a correct structure, even if some of the lighter atoms were included with wrong positions. The coordinates derived from the first Fourier projection led to a marked drop in the value of R, from 0.32 to 0.23, and the second Fourier projection gave a

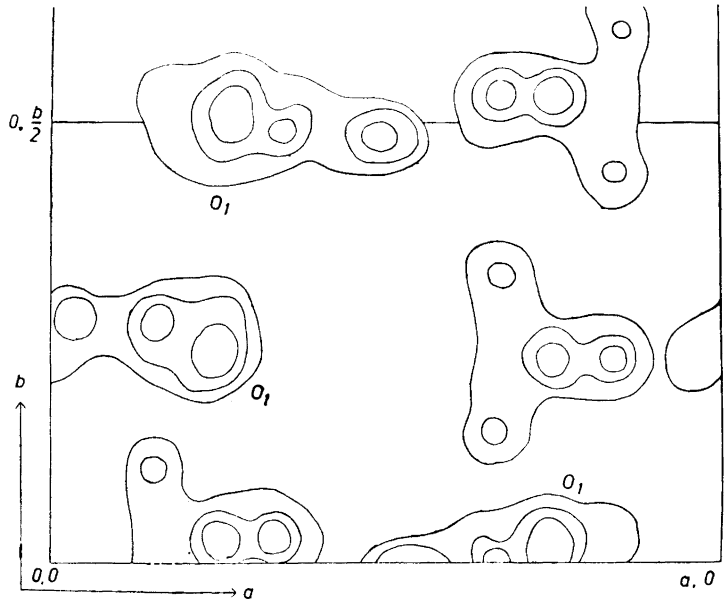

Fig. 4. Projection of electron density on (001) of acetyl choline bromide after subtraction of the bromine peaks. Contour lines at arbitrary intervals. The maxima corresponding to the O_1-positions are broadened considerably in the direction of the *b*-axis.

substantially better picture of the molecular structure. In solving this projection the independent acetyl choline ions were, in the first stage, assumed to have approximately similar structures. This assumption had later on to be abandoned, though the corrections for this projection proved to be rather small (see next section). A map of electron density after subtraction of the bromine peaks has been calculated in order to correct for diffraction effects of the heavy bromine atoms. Four cycles of Fourier synthesis — structure factor calculation were carried out, and the resulting values of R are given in Table 1. Non-observed reflexions were included in evaluating R as far as the calculated structure amplitude exceeds the minimum value observed.

The projection of electron density on (001) is shown in Fig. 3, and the same projection, after subtraction of the bromine peaks, is shown in Fig. 4. Calculated structure amplitudes are compared with the observed ones in Table 4.

DETERMINATION OF THE STRUCTURE PROJECTED ON (010)

The projection of electron density on (001) in Fig. 3 shows that very pronounced overlapping of atoms of the individual molecules must be expected in a projection on (100), and overlapping of four different molecules in a projection on (010). The latter one, has, however, the advantage of being centrosymmetrical, and offers, furthermore, the possibility of improving the resolu-

tion by sectional syntheses along the b-axis, such that the projections of single molecules could be obtained. The projection on (010) was therefore chosen for the next stage in deriving the structure. The strong overlapping of the molecules in this projection impedes taking the full advantage of the heavy atom method. On the other hand the sectional syntheses involve too many tedious calculations to be used as a method of refinement. This projection was therefore, in the first stage, solved from the Patterson projection on (010) together with trial and error methods, using structure factor graphs, refined in the next stage as far as possible by the method of least squares, and finally three different sectional syntheses were computed as a check on the proposed structure. The Patterson projection on (010) is shown in Fig. 2. Since the x-coordinates of the bromine atoms were known from the (010)-projection, the maxima corresponding to Br-Br interactions were easily located, indicating z-coordinates of approximately 0.14 for both of the independent bromine atoms. The maximum at 1/2, 0, 0 is only slightly lower than the origin peak as (010) is an *approximate* glide plane with translation $a/2$. The rest of the Patterson projection shows strongly overlapping maxima, and could not give any detailed informations as to the position of the acetyl choline ion. In the first attempts to derive the structure in this projection an extended model of the molecule was assumed, in accordance with the generally accepted point of view, the direction of the molecules being approximately parallel to the [101]- direction (see next section). This assumption could in effect lead to a reasonable packing of the molecules. Calculation of structure factors revealed, however, very serious contradictions for some low order reflexions. By turning the part of the molecule containing the acetyl group about 180° around the C_4—C_3-bond, such that $C_5 \cdot N \cdot C_4 \cdot C_3 \cdot O_2$ form an approximately planar ring with a distance of about 3 Å from C_5 to O_2, reasonably good agreement for all $h0l$-reflexions could be obtained. A difficulty in deriving the structure lies in the small but significant difference between the two independent molecules, which are to a rough approximation related by a glide-plane of symmetry. The intensities of, *e.g.* the $h0l$-reflexions with h odd (the values of h deviate slightly from odd integral values [3]), show that such differences exist, but do not give very much clue to the real nature of these differences.

THE SECTIONAL SYNTHESES

The projection of the structure on (001) clearly shows that a projected section between the limits $-b/8$ and $b/8$ could be expected to yield the structure of one of the molecules without serious overlapping. Similarly, a section between the limits $b/8$ and $3b/8$ would give the structure of the other molecule. Because of the screw axis, however, a calculation of, *e.g.*, the first of these sections, would also include the section between the limits $3b/8$ to $5b/8$, whereas the latter would also comprise the section between $5b/8$ to $7b/8$. This makes, however, no difference as the first molecule in either case is placed at such a distance from the screw axis that it does not overlap with the equivalent molecule in the projected section, which comes out as centrosymmetrical. In order to reduce the overlapping of the methyl groups

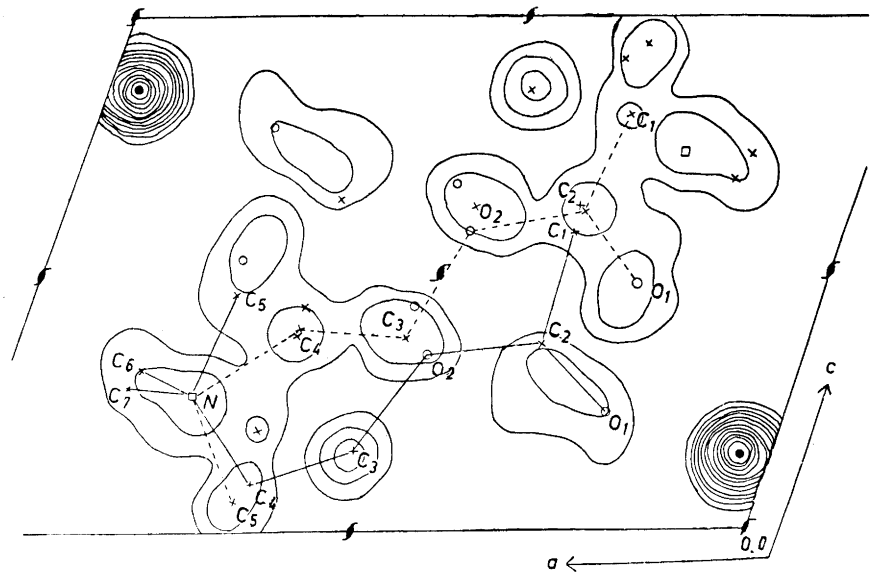

Fig. 5. Projected section of electron density on (010) between the limits $-b/16 - +b/16$ with the equivalent section between the limits $7b/16 - 9b/16$. The calculation of this section is based exclusively on the bromine positions. Filled circles, open circles, squares and crosses indicate bromine, oxygen, nitrogen and carbon atoms respectively. An acetyl choline ion, lying roughly in the plane at $y = 0$, is indicated by dashed lines for the extended form, and with full lines for the "ring" form. The maxima of both forms will appear in this projection (see text). The maxima corresponding to C_3-positions are too high, probably because of bromine atoms lying just above in the adjacent section. Atomic positions for the equivalent section are shown, but are not connected by lines.

a section was also calculated for the limits $-b/16$ to $b/16$ with its equivalent section form $7b/16$ to $9b/16$. The reflexions on the equatorial layer line and on the seven lowest layer lines around the [010]-axis were used for these sectional syntheses, comprising about 1 200 reflexions.

These sections, which appeared as very similar except for a translation of $a/2$ of the second section, showed maxima as expected for the assumed structure, but in addition there appeared some maxima which could not be very well accounted for. Some improvement could be obtained by assuming two possible orientations of the acetyl groups. More serious difficulties were encountered in calculation of interatomic distances between atoms of adjacent molecules, showing that a methyl group of one molecule would approach the acetyl group of another molecule to a distance of about 2.5 Å, which seems to be unreasonably short. To check the proposed structure once more, the section between the limits $-b/16$ to $b/16$ with the equivalent section from $7b/16$ to $9b/16$ was recalculated with amplitudes based exclusively on the bromine positions. This new section is closely similar to the section previously calculated, but it might be noticed that the heights of the additional maxima were slightly increased when using Br-positions only. This similarity is not surprising,

considering the strong influence of the bromine atoms, for example, the bromine atoms determine the signs of all the *h*0*l*-reflexions (with *h* even) except for one extremely weak term.

It may be seen from this section, which is reproduced in Fig. 5, that the presence of two different structures of the acetyl choline ion, from consideration of peak heights both being of the same probability, would be necessary to account satisfactorily for the maxima in this section, *i.e.* the "ring" form, as previously assumed, and an extended form having its long direction approximately parallel to the crystallographic [101]-direction. The arguments for assuming such a mixed structure may be summarized as follows:

1. *h*0*l*-reflexions with *h* close to an odd integral value are present in the X-ray photographs, but these reflexions are rather weak. This shows that the actual structure deviates from an "ideal" structure with a glide-plane parallel to (010) and translation $a/2$, the observed intensities of these reflexions being a measure of this deviation. $F(h0l)$'s with *h* odd, calculated on the assumption of "ring" form only, or extended form only, show in both cases calculated values which, on the average, are only about one tenth of the observed average value. If a structure with the independent molecules being of the "ring" form and the extended form, respectively, is assumed, calculated $F(h0l)$'s with *h* odd are of the same magnitude (or somewhat higher) as the observed ones. Some agreement between observed and calculated values is also obtained, the *R*-factor being 0.42 for these weak reflexions, which is not too bad, considering that the bromine atoms contribute practically nothing to these reflexions, and that their intensities may be more or less influenced by the apparent long range modulation of the structure.

2. As mentioned above the maxima of both forms show up in a section along the [010]-axis based exclusively on the bromine positions. Both forms are likely to appear in this section, since weak reflexions such as the *h*0*l*-reflexions with *h* close to an odd integral value, and which would differentiate between the two forms, were not included in the calculation of the section.

3. The agreement between observed and calculated structure factors and amplitudes is considerably improved by assuming the presence of the two forms, both for an ordered structure of the two forms and for a disordered structure of the same forms.

4. All the interatomic distances lie within reasonable limits for a structure consisting of the two forms of the acetyl choline ion, whereas some unreasonably short distances are found in the case of "ring" form only or extended form only.

The coordinates of the atoms for an ordered structure of the two forms of the acetyl choline ion are given in Table 2, and interatomic distances within each ion may be found in Fig. 6 together with the bond angles. Observed and calculated structure factors of the *h*0*l*-reflexions are compared in Table 3. The reliability index *R* is surveyed in Table 1.

Table 1. Survey of the values of the reliability index R for different sets of reflexions and for different assumed structures of acetyl choline bromide. The structure with the acetyl choline ion of the "ring" form is designated by I, and the structure with the extended form of the acetyl choline ion is designated by II. The value of R, when the Br-atoms only are included in the calculations, is included for comparison.

DESCRIPTION AND DISCUSSION OF THE STRUCTURE

i) *The acetyl choline ion.* A drawing of the acetyl choline ion, as resulting from the present determination, is shown in Figs. 6 *a* and 6 *b* for the "ring" form and the extended form, respectively. The atoms of the ion lie in both cases approximately in a plane, except for those of the methyl groups C_6 and C_7. In contradiction to the previously accepted point of view of an extended form only, the acetyl choline ion is consequently able to exist also in a sort of "ring" structure with the atoms C_5, N, C_4, C_3 and O_2 lying approximately in a roughly planar ring, the distance between C_5 and O_3 being close to 3 Å. It is then likely that both of these forms exist in solutions in polar solvents. While preparing this article a paper appeared on the structure of the related molecule of muscarine iodide [2], for which a closely similar "ring" structure was found. The deviation from a tetrahedral arrangement around the nitrogen

Table 2. Atomic coordinates of the two independent molecules of acetyl choline bromide, assuming that the first molecule corresponds to the extended form and the second molecule corresponds to the "ring" form, *i. e.* for an ordered structure.

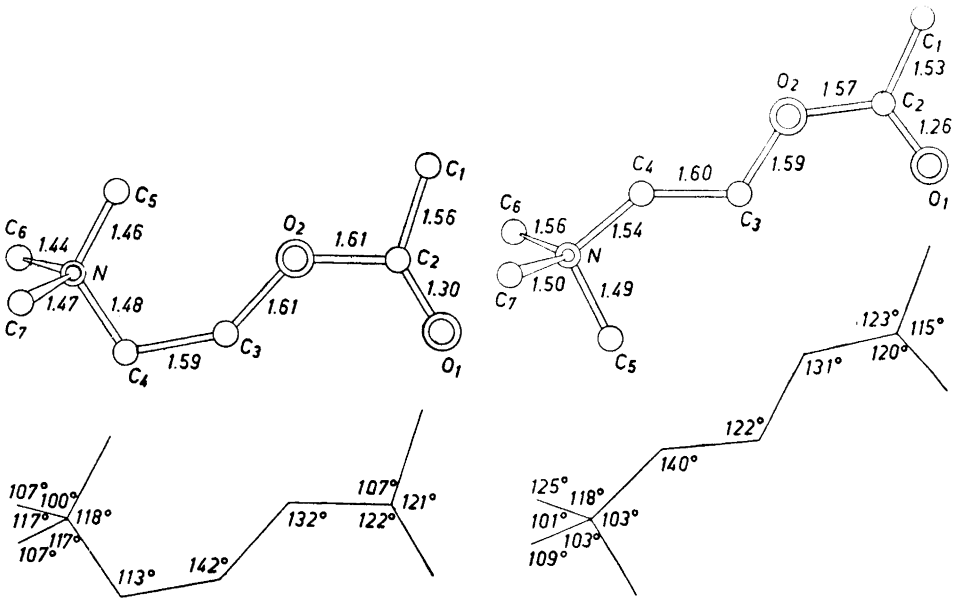

Fig. 6. a. Schematic drawings of the "ring" form of the acetyl choline ion showing interatomic distances and bond angles. Interatomic distances are given in Å.

b. Schematic drawings of the extended form of the acetyl choline ion with interatomic distances in Å and bond angles.

atom may be slightly more pronounced in the structure of the acetyl choline bromide than in muscarine iodide, and this may possibly be a consequence of a tighter packing due to the smaller size of the bromine atom. The distance in muscarine iodide corresponding to the C_5—O_2 distance in acetyl choline is reported by Jellinek to be 2.87 Å, a value close to that quoted above. The interatomic distances and bond angles within the "onium" group and the first bond in the chain show normal values within the limits of accuracy, though the values of the bond angles are spred from about 100° to about 120°. The shortest distances between non-bonded atoms belonging to the same molecule lie in the range 2.3—2.5 Å.

The bond lengths from the O_2-atoms are considerably longer than usually found for C—O single bonds, thus C_3—O_2 is 1.59 Å and 1.61 Å, C_2—O_2 1.57 Å and 1.61 Å for the extended form and the "ring" form, respectively. The anomaly in these bond lengths may to some extent be due to inaccuracies in the derivation of the atomic coordinates, but it seems rather unlikely that the anomaly should be solely due to inaccuracies. The observed bond lengths from the ester oxygens would therefore suggest that these bonds were in some way affected by the neighbouring charged groups and ions. The bond angles also show some anomalous values, thus in the extended form the angle C_3C_4N is 140° and the angle $C_3O_2C_2$ is 131°, in the "ring" form the angle $C_4C_3O_2$ is

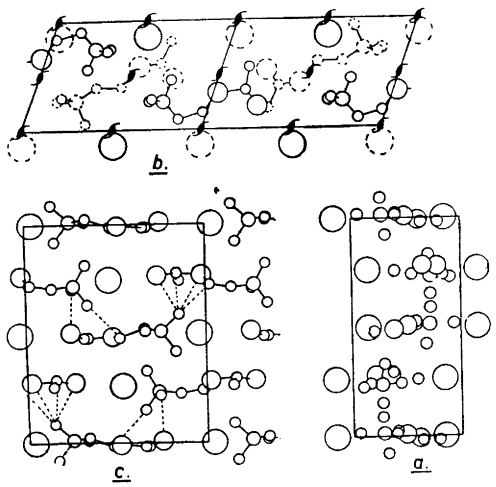

Fig. 7. The packing of the molecules of acetyl choline bromide as viewed along the *a*-axis direction (*a*), the *b*-axis direction (*b*) and along the *c*-axis direction (*c*). Bromine, oxygen, nitrogen and carbon atoms are represented by circles, the radius of which decreases from bromine to carbon, and in *b* dashed circles are used to indicate atoms of a molecule lying close $y = 0$ or $y = 1/2$ (in the unit cell on the right side) whereas circles in full lines indicate the atoms of molecules close to the plane through $y = 1/4$ or $y = 3/4$ (in the top left corner). Bonded atoms are connected by full lines. Some relatively short interatomic distances between neighbouring molecules, the lengths of which are about 3 Å, are indicated by dashed lines in *c*. These shortened interatomic distances link the molecules together to form endless double strings running in the direction of the *a*-axis.

142° and angle $C_3O_2C_2$ is 132°. It is likely that the high values of these bond angles originate from the same reasons as the large values of the bond lengths. It may be noted that bond angles of approximately the same magnitude have been found in other molecules showing Zwitter-ion character, *e.g.*, in cysteylglycine [6]. The structures of the acetyl groups are normal within the limits of accuracy.

ii) *The packing of the molecules.* The packing of the molecules in the crystal lattice is indicated in Figs. 7 *a*, *b* and *c* as viewed in the direction of the *a*-, *b*- and the *c*-axis, respectively. The Br_1-ion has 9 nearest neighbours within a distance below 4 Å, these are two O_2'-atoms at distances 3.36 and 3.43, two C_3'-atoms at 3.51 and 3.92, one C_4'-atom at 3.96, one C_7'-atom at 3.85, one C_4-atom at 3.91, one C_6-atom at 3.94 and one C_7-atom at 3.76, a prime denoting that the atom belongs to an adjacent molecule. Two N-atoms are at distances 4.11 and 4.37 and two N'-atoms at distances 4.30 and 4.88. There are five more nearest neighbours in the range from 4 to 4.5 Å, thus C_1, C_5, C_6, C_7 and O_1'.

The Br_2-ion has eight nearest neighbours within a distance of 4 Å, thus C_3' at 3.54, C_4' at 4.00, C_5' at 3.83, C_6' at 3.76, O_1 at 3.22, C_7 at 3.88, O_6 at 3.89 and C_5 at a distance of 3.05. Two N-atoms are found at a distance of 4.17 and 4.14, and two more N'-atoms at distances of 4.08 and 4,89. The

Br_2-ion has seven neighbours within distances lying in the range from 4.0 to 4.5 Å, thus C_4, C_6, C_7, O_2', C_5', $2C_1'$. There are thus four "onium"-groups around each Br-atom, and the arrangement of these groups are approximately tetrahedral with the Br-atoms in the space center of the tetrahedra.

The methyl group C_7 of one molecule and the methyl group C_6 of the other molecule approach the acetyl group, C_3 and O_2 of an adjacent molecule to distances, which are somewhat below the normal van der Waals distances. The shortest of these distances lie between 2.9 and 3.0 Å, and it may be seen from Fig. 7 *c*, where they are indicated by dashed lines, that these short intermolecular distances connect the molecules to form double strings of

molecules in the direction of the a-axis. The methyl group C_5 of the extended form is also at a distance of 3 Å from the O_1-atom of the "ring" form.

All the distances between atoms or groups of molecules belonging to different double strings are about or above the normal van der Waals distances, thus, for example, the distance $O_1—O_1'$ is 3.8 Å.

The origin of the subsidiary reflexions, with non-integral values of the indices, has not as yet been investigated in detail. The existence of the acetyl choline ion in two different forms in the structure may perhaps offer an explanation, which might serve as a possible working hypothesis. In the calculation of the structure factors for an ordered structure of the two forms, it was assumed that the extended form is located about the position x from 0 to 0.7, $y \simeq 0$, whereas the "ring" form is located about the position x from 0.5 to 1.2 and $y \simeq 0.25$. The y-coordinates of the C_3-groups give a slight preference for this arrangement as it leads to slightly more reasonable interatomic distances, else the positions of the different forms could just as well be interchanged. It is then reasonable to suggest that stacking faults in the sequence extended form — "ring" form produce a long range modulation of the structure, which gives rise to the observed subsidiary reflexions. Such a partially disordered structure would be in accordance with the observation that the averages of the structure factors for the two forms agree just as well with the observed values as those calculated for the ordered structure, and appreciably better than for either of the forms separately. Another observation pointing in the same direction is the marked broadening of the maxima of the O_1-atoms in the direction of the b-axis. This broadening is especially pronounced in the difference map, reproduced in Fig. 4. Such a broadening might be expected for a disordered structure as the y-coordinates for the O_1-atom would differ considerably for the two forms of the acetyl choline ion.

It is not unlikely that the ability of the acetyl choline ion to exist in two distinct structural forms may account for some of its specific activities. The extended form would be likely to prevail in solution in polar media, whereas the "ring" form might be the prevalent form in unpolar media. Such an ability of the acetyl choline ion would evidently have a strong bearing on its characteristic behaviour at lipoid-water interfaces, and possibly also on its specific action in the transfer of nerve impulses.

The present work was begun in the Department of Chemistry at *Forsvarets Forskningsinstitutt*, Kjeller, where the experimental part and the first stages of the structure determination were carried out. The work has been continued at *Fysisk Institutt, Norges Tekniske Högskole*, with financial support from *Forsvarets Forskningsinstitutt*, which is gratefully acknowledged.

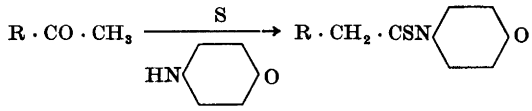
Preparation of 3-Reteneacetic Acid by the Willgerodt-Kindler Reaction

EYLIF DYNESEN

Chemical Institute, Aarhus University, Denmark

3-Reteneacetic acid has been prepared through the Willgerodt-Kindler reaction. By hydrolysis of the crude thiomorpholide two by-products, retene-3-carboxylic acid and retene-3-glyoxylic acid were isolated. The precursor of these byproducts, 3-reteneglyoxylmorpholide has been isolated by chromatography of the crude thiomorpholide. 3-Reteneacetomorpholide can be obtained by partial hydrolysis of the thiomorpholide.

In a synthetic program 3-reteneacetic acid was required as starting material and as 3-acetylretene can be prepared in good yield [1,2], the Willgerodt reaction seemed promising. The Kindler procedure [3,4] in the Schwenk-Bloch modification [5] using morpholine as the amine was selected. The main reaction product then is the thiomorpholide:



The mole ratios applied were 1:2.5:2 for ketone, sulphur and morpholine, respectively, in accordance with King and McMillan [6].

In a preliminary experiment the crude reaction product was hydrolyzed directly in a mixture of acetic acid and sulfuric acid. The purification of the reteneacetic acid met, however, with great difficulties. Next, a recrystallization of the thiomorpholide from alcohol was tried. When cooling the hot solution an oil separated at first, but by careful work a 75—80 % yield of light yellow crystals could be obtained. The melting point of this material was, however, far from sharp, even after several recrystallizations.

Next, hydrolysis of the thiomorpholide by means of alcoholic potassium hydroxide was tried. After boiling for a short time much crystalline material separated in the reaction mixture. The substance was colourless and contained no sulphur. It could be hydrolyzed to 3-reteneacetic acid and was thus shown to be the morpholide of this acid.

Under suitable conditions the partial alkaline hydrolysis gave a satisfactory yield of almost pure morpholide, and for the purpose of preparation of pure 3-reteneacetic acid it is advantageous to isolate the morpholide and afterwards bring the hydrolysis to completion. It turned out, that it was unnecessary to recrystallize the crude Willgerodt reaction product. Partial alkaline hydrolysis of this material gave an about 70 % yield of almost pure morpholide. The second step in the hydrolysis was most advantageously carried out by means of a solution of potassium hydroxide in *n*-propanol. By this procedure an overall yield of 60 % of 3-reteneacetic acid could be obtained.

By examination of the alkaline mother liquor from partial hydrolysis of the crude thiomorpholide two by-products were isolated and identified, *viz.* 3-retenecarboxylic acid and 3-reteneglyoxylic acid. The latter acid could not be obtained in quite pure condition but could be identified by conversion to the phenylhydrazone and the methyl ester, which was characterized through the dinitrophenylhydrazone.

In order to isolate the precursors of these by-products in the Willgerodt reaction and to isolate the thiomorpholide in pure condition, the crystalline product from the Willgerodt reaction was chromatographed on alumina. In this way 3-retenethioacetomorpholide could be isolated as a pure white compound composing the bulk of the crystalline product, but two other substances which were stronger adsorbed than the thiomorpholide were isolated as white compounds constituting about 10 % of the impure thiomorpholide. One of these compounds could be identified as 3-reteneacetomorpholide. The other substance was a neutral compound, which contained no sulphur.

The ultraviolet absorption spectrum was quite different from the spectra of 3-retenethioacetomorpholide and 3-reteneacetomorpholide, which were very similar and showed a typical retene structure, while the spectrum of the by-product showed a broad absorption band at 320—340 mμ. Hydrolysis of this product with alcoholic potassium hydroxide gave 3-retenecarboxylic acid and 3-reteneglyoxylic acid. As the spectrum of methyl-3-reteneglyoxylate is almost identical with that of the by-product, it is reasonable to assume, that the by-product is 3-reteneglyoxylmorpholide. The elementary analysis supports this assumption.

EXPERIMENTAL

3-Acetylretene was prepared by the method of Dodd, Schramm and Elderfield [2] with the modification, that acetic anhydride was used instead of acetyl chloride in the Friedel-Crafts reaction. The yield of pure 3-acetylretene was 61 %.

Willgerodt-Kindler reaction. A mixture of 3-acetylretene (24.0 g, 0.087 mole), sulphur (7.05 g, 0.22 g-atom) and morpholine (15.2 ml, 0.174 mole) was heated under gentle reflux for 5 h, during which time a considerable amount of hydrogen sulphide was evolved. The dark coloured viscous product was poured in hot alcohol (200 ml) and left standing overnight. Crystals and oily material had now separated in the solution. The solution and the main part of the crystalline material was decanted from the oil, which was redissolved in alcohol. On cooling, some substance at first separated as an oil but later crystalline material separated. By warming the solution gently, more of the oil crystallized. The solution with the crystalline material was again decanted from residual oil and by repeating this process twice, 23 g of crystalline light yellow material was isolated, melting point 110—114°, yield 75 % calculated as pure 3-retenethioacetomorpholide.

3-Reteneacetomorpholide. The crystalline thiomorpholide (23 g) was dissolved in hot alcohol (100 ml), and a solution of potassium hydroxide (17.1 g) in water (17 ml) was added. The solution turned immediately black and subsequently red. The solution was refluxed. After 4 min boiling much precipitate suddenly separated in the reaction mixture. The precipitate was filtered by suction and washed with alcohol. Yield of 3-reteneacetomorpholide 17.1 g (78 %, calc. from the thiomorpholide), m. p. 184.5—185.5°. Recrystallization from *n*-propanol gave white crystals, m. p. 187—188.5°. (Found: C 79.5; H 7.55; N 3.90. Calc. for $C_{24}H_{27}NO_2$ (361.5): C 79.7; H 7.53; N 3.88.) U.V. absorption (in ethanol): λ_{max} 260.5 (log ε 4.81); 282 (4.13); 291 (4.01); 303.5 (4.13); 329 (2.41); 335.5 (2.51); 352 mμ (2.19). λ_{min} 234; 278; 287.5; 297; 325; 331.5; 341—345 (shoulder); 349.5 mμ.

Alkaline hydrolysis of 3-reteneacetomorpholide. The morpholide (1.8 g, 0.005 mole) was dissolved in *n*-propanol (10 ml). To the warm solution was added a solution of potassium hydroxide (1.4 g, 0.025 mole) in water (1—2 ml). The mixture was refluxed for 5.5 h. After dilution with water (200 ml) the clear solution was acidified with hydrochloric acid. A white precipitate separated (1.4 g, m. p. 209—213°). The product was recrystallized from *n*-propanol (15 ml) giving 3-reteneacetic acid 1.15 g (78.8 %), m. p. 210—212.5° (subl.). (Found: Equiv.wt.: 293.3; C 82.1; H 6.84. Calc. for $C_{20}H_{20}O_2$ (292.4): C 82.2; H 6.90.)

Synthesis of 3-reteneacetic acid. A mixture of 3-acetylretene (41.4 g, 0.15 mole), sulphur (12.03 g, 0.375 g-atom) and morpholine (26.1 ml, 0.3 mole) was heated under gentle reflux for 5 h. The dark reaction mixture was dissolved in alcohol (150 ml). To the warm mixture was added a solution of potassium hydroxide (20 g) in water (10 ml) and alcohol (20 ml). The solution was refluxed for 8 min and then cooled. The precipitate was filtered by suction and washed with alcohol. The alkaline filtrate was further boiled for 15 min and left overnight. A second crop of morpholide was obtained. The crude morpholide was treated twice with boiling water. Yield of crude morpholide 38.1 g (70.2 % calc. from 3-acetylretene), m. p. 177—184°.

The morpholide (38.1 g) was dissolved in hot *n*-propanol (200 ml), and potassium hydroxide (17.7 g) in water (12 ml) was added. The mixture was boiled under reflux for 4 h. The slightly soluble potassium salt separated in the mixture. Water (300 ml) was added, and propanol was removed by distillation. The aqueous solution was boiled with charcoal, filtered and acidified. 3-Reteneacetic acid separated as colourless crystals (30.3 g). The crude product was recrystallized from a mixture of alcohol and acetone. Yield 26.8 g (61.2 % calc. from 3-acetylretene), m. p. 209—212.5° (subl.).

3-Retenecarboxylic acid. To the dark brown alkaline mother liquor from the partial hydrolysis of the crude Willgerodt reaction product was added potassium hydroxide (10 g), and the solution was refluxed for 2 h. The main part of the alcohol was removed by distillation *in vacuo*. To the residue was added water, and the solution was acidified with hydrochloric acid. A brown precipitate separated (7.5 g) and was dissolved in hot benzene. On cooling crystalline material separated (1 g). Two further recrystallizations from benzene gave 3-retenecarboxylic acid (0.3 g), m. p. 242—244° (subl.); gives no depression when mixed with an authentic specimen. (Found: C 82.1; H 6.45. Calc. for $C_{19}H_{18}O_2$: C 82.0; H 6.52.)

3-Reteneglyoxylic acid. The aqueous filtrate, resulting from digestion of the crude morpholide with hot water, was yellowish and gave on cooling a precipitate of a potassium salt. Acidification gave a yellow precipitate (2 g), which was recrystallized from a mixture of benzene and hexane and gave yellow crystals (1 g), m. p. 144—148.5°. One further recrystallization from benzene-hexane gave 3-reteneglyoxylic acid (0.8 g), m. p. 147—150°. (Found: C 78.8; H 6.15. Calc. for $C_{20}H_{18}O_3$ (306.3): C 78.4; H 5.92.)

Phenylhydrazone of 3-reteneglyoxylic acid. The keto acid (0.4 g) was dissolved in alcohol (7 ml). To the solution was added phenylhydrazine hydrochloride (0.3 g) and potassium acetate (0.2 g). The mixture was refluxed for one hour and cooled. The precipitate was washed several times with hydrochloric acid, recrystallized from glacial acetic acid. The phenylhydrazone (0.1 g) formed yellow crystals m. p. 166—168.5°. (Found: Equiv.wt. 403; N 6.9. Calc. for $C_{26}H_{24}N_2O_2$ (396.5): N 7.1.)

Methyl ester of 3-reteneglyoxylic acid. 3-Reteneglyoxylic acid (0.6 g) in methanol (25 ml) and concentrated sulfuric acid (0.1 ml) was refluxed for 8 h. The excess of methanol was distilled off and the residue dissolved in ether-benzene. The solution was washed with water, potassium bicarbonate and saturated sodium chloride. After drying with anhydrous calcium chloride the solvent was distilled off and the residue dissolved in hot

alcohol. After some time crystalline light yellow material had separated. Recrystallized from alcohol the methyl-3-reteneglyoxylate (0.08 g) had m. p. 101—102°. (Found: C 78.7; H 6.12. Calc. for $C_{21}H_{20}O_3$ (320.4): C 78.7; H 6.29.) U.V. absorption (in cyclohexane): λ_{max} 248.5 (log ε 4.61); 264 (4.58); 289—92 (shoulder) (3.82); 336 mμ (4.18); λ_{min} 223 (4.13); 256 (4.56); 299 mμ (3.74).

Dinitrophenylhydrazone of methyl-3-reteneglyoxylate. 2,4-Dinitrophenylhydrazine (0.2 g) and alcohol (10 ml) was heated to boiling. To the hot solution was gradually added concentrated sulfuric acid until clear solution. To this solution was added a solution of the keto ester (0.2 g) in alcohol (5 ml). A reddish orange precipitate at once separated. The dinitrophenylhydrazone (0.2 g) was recrystallized from xylene. Yield 0.1 g, m. p. 293—294.5°. (Found: C 64.3; H 4.85; N 10.9. Calc. for $C_{27}H_{24}N_4O_6$ (500.5): C 64.8; H 4.83; N 11.2.)

Chromatography of the crude thiomorpholide. From the Willgerodt-Kindler reaction of 3-acetylretene (16.6 g, 0.06 mole) 18.4 g of crystalline light yellow material was isolated, consisting of several fractions with the main fraction melting at 110—114°. As purification through fractional crystallization was unsuccessful, a fraction (11 g, m. p. 105—116°) was chromatographed on a column (21 × 6.5 cm) of alumina, solvent petroleum ether (600 ml) + carbon tetrachloride (400 ml).

The chromatogram was developed by the same solvent containing increasing amounts of carbon tetrachloride, and subsequently with carbon tetrachloride.

The surface of the column became strongly coloured. Next came a light yellow zone gradually changing to light grey. Next followed a broad pure white zone containing the thiomorpholide and finally a narrow yellow layer.

The column was fractionally eluted by washing with benzene. In the filtrate 3-retenethioacetomorpholide could be isolated by evaporation of the solvent and recrystallization of the residue. Yield: 7.2 g, m. p. 119.5—122°. Two further recrystallizations gave white crystals, m. p. 120—121.5°. (Found: C 76.6; H 7.18; N 3.70; S 8.44. Calc. for $C_{24}H_{27}NSO$ (377.5): C 76.4; H 7.21; N 3.71; S 8.49.) U.V. absorption (in ethanol): λ_{max} 261.5 (log ε 4.83); 282 (4.46); 303.5 (4.19); 329 (2.51); 335.5 (2.60); 352.5 mμ (2.37) λ_{min} 233.5; 278; 299; 325.5; 331.5; 341—345 (shoulder); 350 mμ.

From the column the surface layer was discarded, and the rest of the column was divided into two nearly equal parts, which were eluted separately with boiling alcohol. The eluate from the upper half was stronger yellow than that from the lower half of the column. From these two eluates two white crystalline neutral substances could be isolated. One of these, isolated from the lower half of the column, has been identified as 3-reteneacetomorpholide, yield 0.2 g, m. p. 186.5—188.5°; gives no depression, when mixed with an authentic specimen, prepared by alkaline desulphurization of 3-retenethioacetomorpholide.

The eluate from the upper half of the column was concentrated. From the yellow solution crystalline material separated (1 g), m. p. 147.5—152°. Fractional crystallization of this fraction gave a white compound (0.4 g), m. p. 175—178°. One further recrystallization from alcohol gave 3-reteneglyoxylmorpholide, m. p. 176—178°. (Found: C 76.6; H 6.79; N 3.77. Calc. for $C_{24}H_{25}NO_3$ (375.5): C 76.8; H 6.71; N 3.73.) U.V. absorption (in cyclohexane): λ_{max} 248 (log ε 4.59); 264.5 (4.60); 289—92 (shoulder) (3.93); 334 mμ (4.18). λ_{min} 223 (4.19); 254 (4.57); 300 mμ (3.84).

Alkaline hydrolysis of 3-reteneglyoxylmorpholide. A mixture of 3-reteneglyoxylmorpholide (0.3 g) potassium hydroxide (0.2 g) and alcohol (15 ml) was refluxed for about one hour. The potassium salt of 3-reteneglyoxylic acid partly separated in the boiling liquid and more was obtained on cooling. The salt was filtered off and washed with ether. On acidification of an aqueous solution of the salt, a yellow product was obtained, which after recrystallization from benzene-hexane had m. p. 148—151°, yield 0.1 g. (Found: Equiv.wt. 301.5. Calc. for $C_{20}H_{18}O_3$: 306.3.) The acid, which was not quite pure, was shown to be 3-reteneglyoxylic acid by conversion to the methyl ester.

After filtration of the potassium salt the alkaline filtrate was evaporated to dryness. The residue was dissolved in boiling water and the solution acidified. The brownish precipitate was dissolved in benzene. On cooling a small white precipitate separated. One further recrystallization from benzene gave 3-retenecarboxylic acid, m. p. 239.5—242°; gives no depression in m. p. when mixed with an authentic specimen.

Analyses and U.V. spectra were performed in this laboratory by miss B. Møller.

On the Defect Structure of Rutile

TOR HURLEN

Central Institute for Industrial Research, Blindern, Oslo, Norway

From the point of view of its importance to the understanding of the oxidation behaviour of titanium and titanium alloys, a theoretical reinvestigation is made of the defect structure of rutile with special emphasis on what is to be expected from the ideal rutile structure itself.

A discussion is moreover given of previous experimental results on the subject, and it is concluded that most of the available data are possibly best explained by assuming the defect structure to be a combination of a non-stoichiometric and a stoichiometric one, both involving titanium interstitial ions.

1.0 INTRODUCTION

It is well known that the oxidation of a metal usually leads to the formation of a more or less compact oxide film on the metal surface, and that the further oxidation requires passage through this film either of metal outwards or of oxygen inwards. Very often, the rate of transport of material through the oxide lattice itself (volume diffusion) is found to be determining for the oxidation resistance of the metal (Wagner [1] mechanism of oxidation).

It is further known that the volume diffusion in ionic crystals depends on the defect structure of the crystals, and that the defect structure in many cases may be partly controlled by the incorporation of foreign ions in the lattice (Wagner-Hauffe [2] approach to alloy oxidation).

The application of this basic knowledge to the oxidation resistance of a special metal and to its improvement by alloying, is greatly facilitated by the understanding of the defect structure of the pure oxide(s) in question.

Rutile has been shown [3,4] to be the main oxide formed on titanium under the most actual oxidation conditions. This oxide is of an *n*-conducting [5], oxygen deficient [5–7] type. It does not seem well recognized, however, whether the latter is due to the presence of oxygen vacancies or of titanium interstitials in the rutile lattice.

The purpose of the present work is to elucidate this matter and to gain the best possible understanding of the defect structure of rutile from already known experimental data. Our hope is that this might facilitate the interpretation and understanding of the oxidation behaviour of titanium and titanium alloys.

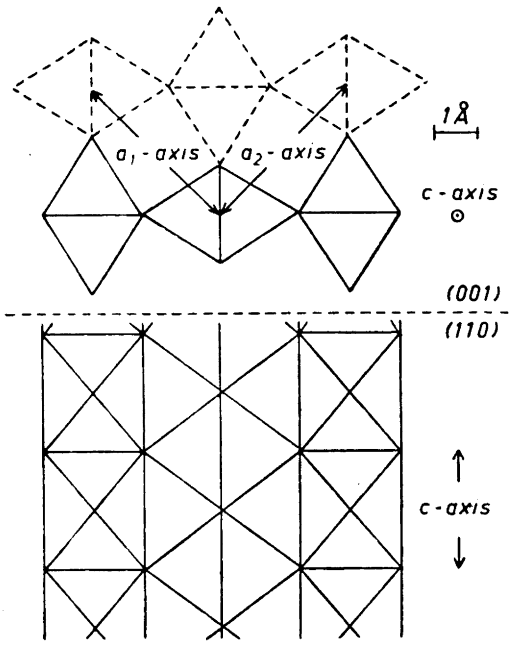

Fig. 2. The octahedron model of rutile.

2.0 THE RUTILE STRUCTURE

Titanium forms a number of different oxides, and so far the following ones have been identified [7]: Ti_2O, Ti_3O_2, TiO, Ti_2O_3, Ti_3O_5, Ti_nO_{2n-1} (n = 4, 5, 6, 7, 8, 9 and 10), and TiO_2. The lowest of these oxides, Ti_2O, has a structure which may be represented by OTi_6-octahedra sharing corners and edges. The other titanium oxides may be considered to consist of TiO_6-octahedra sharing corners, edges, and possibly faces in various ways.

From X-ray data on TiO_2 (rutile) is found that its TiO_6-octahedra are not exactly regular. Fig. 1 shows a rutile octahedron in two projections, and the dimensions given are those determined by Magnéli and co-workers [7], which are in close agreement with those determined by Cromer and Herrington [8]. The octahedra are characterized by:

4 Ti—O distances of 1.946 Å
2 Ti—O distances of 1.984 Å
8 O—O distances of 2.779 Å
2 O—O distances of 2.959 Å
2 O—O distances of 2.526 Å

In rutile, these octahedra are joined by edges and corners in such a way as to make each oxygen ion belong to three neighbouring octahedra. This type of octahedron coupling is shown in Fig. 2, where also the direction and length of the crystallographic axes in relation to the octahedra are indicated.

From Fig. 2 is easily seen that this type of coupling between the octahedra results in a kind of parallel octahedron chains in which neighbouring octahedra have an edge in common. These chains are further joined to each other so that the side corners in one chain's octahedra become top corners in a neighbouring chain's octahedra and *vice versa*. In rutile, the *c*-axis becomes parallel to the octahedron chains.

From Fig. 2 is further seen that this type of coupling between the chains results in the existence of just as many "open" channels parallel to the *c*-axis as there are octahedron chains, and in Fig. 3 is shown that such a channel contains a row of octahedral interstitial positions for titanium. The distance between these positions (in direction of the *c*-axis) is half only of that between normal titanium lattice positions in an octahedron chain. The "interstitial" oxygen octahedra are all of the same shape and size, and along the channels every second one is turned 90° around the *c*-axis in relation to the rest of them, and they are placed half way into each other. From Fig. 3 is further seen that an "interstitial" O_6-octahedron shares two faces and four edges with neighbouring TiO_6-octahedra.

The shape and size of the "interstitial" O_6-octahedra are shown in Fig. 4. By comparing with Fig. 1, it is seen that these O_6-octahedra differ distinctly from the normal TiO_6-octahedra in rutile, especially in being larger. The volume of a TiO_6-octahedron is about 9.89 Å^3, whereas the volume of an "interstitial" O_6-octahedron is about 10.91 Å^3.

The rutile structure also contains tetrahedral interstitial positions, and it is easily seen that there are just as many of these as there are octahedral interstitial positions (twice that of normal titanium lattice positions). The tetrahedral positions are not arranged along channels of any kind, and as titanium is not known to occur with the coordination number *four*, these positions seem to be of minor interest.

3.0 THE DEFECT STRUCTURE OF RUTILE

The defects or imperfections which can exist in crystal lattices can be classified as reversible (ions in interstitial positions and ion vacancies connected with an equivalent number of quasi-free electrons and electron holes) or irreversible (flaws, cracks, dislocations). The present discussion is confined to the former class of defects.

Ehrlich [6] reported that rutile exists over a rather wide oxygen concentration range ($TiO_{1.90}$—$TiO_{2.00}$), whereas Magnéli and coworkers [7] found that the minimum content of oxygen is higher than that corresponding to $TiO_{1.96}$. These investigators seem to agree, however, that the higher oxygen limit corresponds to the stoichiometric composition $TiO_{2.00}$.

The possible *non-stoichiometric* defect equilibria in rutile may be represented by the following equations:

$$\text{Nil} \rightleftharpoons O_v^{\cdot\cdot} + 2e^- + \tfrac{1}{2}O_2(g) \quad (1a)$$
$$\text{Nil} \rightleftharpoons O_v^{\cdot\cdot} e^- + e^- + \tfrac{1}{2}O_2\ (g) \quad (1b)$$
$$\text{Nil} \rightleftharpoons O_v^{\cdot\cdot} 2e^- + \tfrac{1}{2}O_2\ (g) \quad (1c)$$

for anion vacancies ($O_v^{\cdot\cdot}$) with or without trapped electrons (*AV-type* defects), and by

$$TiO_2 \rightleftharpoons Ti_i^{n+} + ne^- + O_2\ (g) \quad (2)$$

for cation interstitials (Ti_i^{n+}) with n positive charges (*CI-type* defects). As to n-values other than four, see under section 3.4 below.

In addition, there is also a hypothetical possibility of a *stoichiometric* defect equilibrium:

$$\text{Nil} \rightleftharpoons Ti_v^{''''} + Ti_i^{++++} \quad (3)$$

involving titanium vacancies ($Ti_v^{''''}$).

The symbols $'$ and $\cdot$ mean a negative and a positive surplus charge, respectively. e^- means a quasi-free electron, and "Nil" designates an ideal stoichiometric crystal.

In the following, we shall discuss the above possibilities on the basis of the ideal rutile structure itself and of other available data pertinent to the subject.

A critical discussion of results obtained up to 1954 has previously been given by Hauffe [5], who concludes that the defect structure most likely is of the AV-type.

3.1 Structural considerations

Under section 2.0 is shown that the rutile structure contains favourable octahedral interstitial positions for titanium, and on this basis it seems likely that rutile should be an oxide of the metal excess type (CI-type) rather than of the oxygen deficient type (AV-type), and also that stoichiometric defects (Eqn. 3) could be present in rutile.

An interesting fact in this connection is that a Ti_nO_{2n-1}-crystal structurally may be described [7,9] as being composed of parallel sheet crystals of rutile, the "grain boundaries" between which are free of misfit and differ from the ideal rutile structure mainly in containing titanium in octahedral interstitial positions. At these "grain boundaries", the rutile layers are slightly displaced in relation to each other (see below). Were it not so, the Ti_nO_{2n-1}-structures would have been identical to rutile with an ordered arrangement of titanium interstitials. It seems thus the most natural that in removing oxygen from rutile, one should go directly towards the Ti_nO_{2n-1}-structures by forming titanium interstitials, and not make a roundabout way by first forming oxygen vacancies which then have to be eliminated (at least to a large extent) when the oxygen content of the highest member of the Ti_nO_{2n-1}-series is reached (see under section 2.0).

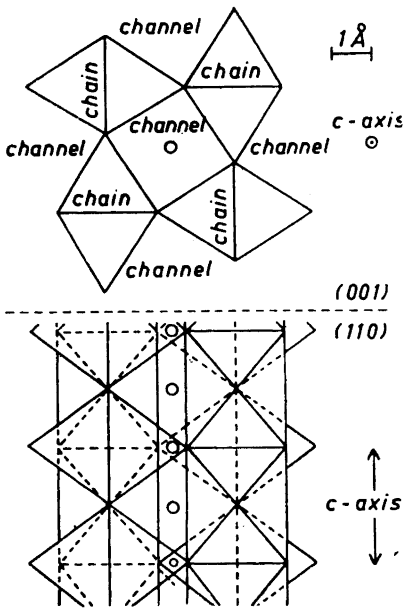

Fig. 3. Octahedral interstitial positions for Ti-ions in rutile.

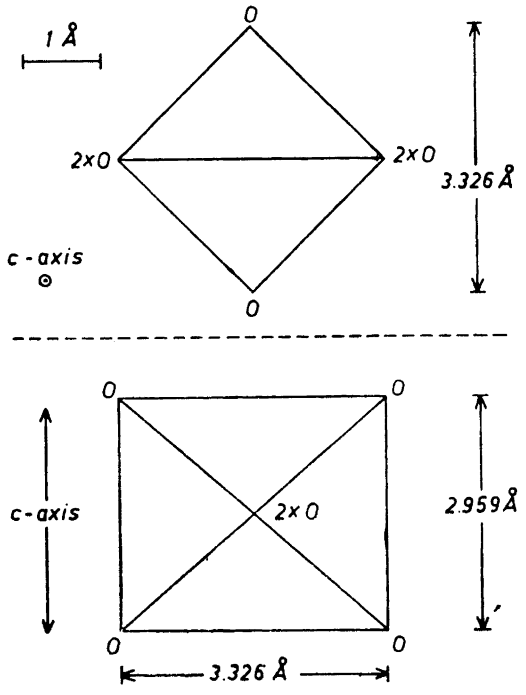

Fig. 4. The shape and size of the O_6-octahedra surrounding interstitial positions in rutile.

Magnéli and coworkers [7] have further found that the rutile lattice is slightly expanded, especially normal to the *c*-axis, with decreasing oxygen content:

$a = 4.584$ Å,	$c = 2.959$ Å	for maximum O-content
$a = 4.603$ Å,	$c = 2.960$ Å	for minimum O-content

It is difficult to judge what this expansion might really mean. If we assume, however, that rutile is a normal ionic crystal in which the lattice dimensions are mainly determined by the size of the ions, it is difficult to understand how the formation of oxygen vacancies may give such an effect. It is easier to imagine that the formation of titanium interstitials might cause a lattice expansion. The radius of the fourvalent titanium ion is namely about 20 % too large to allow six surrounding oxygen ions to come into contact with each other. From Figs. 3 and 4, it is further seen that a titanium interstitial should be expected to expand the lattice mainly in directions normal to the *c*-axis (just as observed).

It may seem that the above-mentioned displacement of the rutile layers at the "grain boundaries" or Magnéli-Andersson planes — as they better are

called — in the Ti_nO_{2n-1}-structures, is merely so that the octahedron chains on one side of such a plane fit into the open octahedron channels on the other side of the plane and *vice versa* (see Fig. 3). The oxygen framework of the rutile structure is thus maintained essentially unaltered all through a Ti_nO_{2n-1}-lattice. It is mainly the relative positions of the titanium ions in this framework that are changed at a Magnéli-Andersson plane. The titanium ions on one side of this plane are normally in positions which may be regarded as interstitial in relation to the rutile lattice on the other side of the plane and *vice versa*. Just at the plane, both the normal and the interstitial octahedron positions are occupied.

On this basis, the Ti_nO_{2n-1}-structures could possibly be described as a rutile structure with ordered arrangements of titanium vacancies and titanium interstitials, the latter in excess. This may suggest that rutile itself also could have defects of this kind more or less randomly distributed in the lattice (see eqns. 2 and 3).

3.2 Density measurements

Ehrlich [6] reports to have found a slightly lower density for $TiO_{1.97}$ than for TiO_2 by pycnometric measurements on powders. These results are used by Hauffe [5] as one of the main arguments for the existence of AV-defects in rutile.

Ehrlich himself pointed out that his $TiO_{1.97}$-sample was not quite a sound one. Pycnometric density measurements on powders are moreover easily affected with both systematic and accidental errors. As a comparison, we shall here give some density values determined by Magnéli and coworkers [7]:

$$d(TiO) = 4.95, \quad d(TiO_{1.67}) = 4.20, \quad d(TiO_{1.80}) = 4.29 \text{ gcm}^{-3}$$

and by Ehrlich [6]:

$$d(TiO) = 4.89, \quad d(TiO_{1.70}) = 4.21 \quad d(TiO_{1.80}) = 4.17 \text{ gcm}^{-3}$$

all of them on powders.

The inconsistence of these results should make it clear that, so far, one has to be careful in using the density data in elucidating the defect structure of rutile.

3.3 Colour observations

It is well known (see, *e.g.*, Ref.[5]) that rutile acquires a dark grey-blue colour when kept in a reducing atmosphere at high temperatures, and that it is slightly coloured in this way also by the incorporation of a higher-valent metal oxide (Ta_2O_5, Nb_2O_5, Sb_2O_5 or WO_3).

Hauffe [5] has suggested that this may be due to a formation of Pohl-Schottky colour centres, the so-called F-centres. Such a centre is equivalent to an oxygen vacancy with a trapped electron ($O_v^{\cdot\cdot}e^-$). The colouring of rutile, therefore, has naturally been used as another argument in favour of a defect structure of the AV-type.

A threevalent titanium ion in rutile may also give rise to a blue colour, however, and — in our opinion — the significance of the colour change is not understood well enough for the present to be used as an argument in this discussion.

3.4 Conductivity measurements

According to the Schottky-Frenkel theory of reversible defects [10,11], a defect equilibrium is given by the mass action law in quite an ordinary way. The equilibria of the defect systems (1), (2), and (3) above, should thus be represented by the following equations:

$$(O_v^{\cdot\cdot})(e^-)^2 p^{1/2} = \text{const.} \tag{4a}$$

$$(O_v^{\cdot\cdot} e^-)(e^-) p^{1/2} = \text{const.} \tag{4b}$$

$$(O_v^{\cdot\cdot} 2e^-) p^{1/2} = \text{const.} \tag{4c}$$

and

$$(Ti_i^{n+})(e^-)^n p = \text{const.} \tag{5}$$

and

$$(Ti_i^{++++})(Ti_v^{\prime\prime\prime\prime}) = \text{const.} \tag{6}$$

where p means the partial pressure of O_2 in the gas phase, and the brackets indicate that it is the concentration of the defect species we are dealing with in these equations. The constants are of course temperature dependent.

If we now assume that the conductivity (q) of rutile is proportional to the concentration of quasi-free electrons, we easily have by combining the eqns. (1) and (4) that

$$q = \text{const. } p^{-1/6} \tag{7a}$$

$$q = \text{const. } p^{-1/4} \tag{7b}$$

$$q = \text{const. (independent of } p) \tag{7c}$$

in the case of oxygen vacancies with none, one, or two trapped electrons, respectively.

In the case of a defect structure of the CI-type, we have

$$q = \text{const. } p^{-1/n+1} \tag{8}$$

This is easily seen by combining the eqns. (2) and (5).

Hauffe and coworkers [5,12] have found that the conductivity of rutile is proportional to $p^{-1/4.5}$ to $p^{-1/5}$ in the temperature range 800—1 000°C. This may be explained on the assumption of three- and fourvalent titanium ions in interstitial positions ($n = 3$ and 4 in eqn. 8). The results are not compatible with a defect structure of the AV-type.

It could here possibly be argued that a threevalent titanium ion is equivalent to a quasi-free electron and that it has no sense to use other n-values than four in eqns. (2), (5), and (8). This cannot be quite correct, however.

Cronemeyer [13] has namely shown that the electronic conductivity of rutile is distinctly higher in direction of the *c*-axis than in a direction normal to this axis, and as there is practically no possibility for interstitial titanium ions to take part in an electron exchange in the *c*-direction, whereas this may seem a preferred exchange direction for titanium ions in normal lattice positions when judging from interatomic distances (see Fig. 3), a threevalent titanium interstitial ion cannot be regarded synonymous with a quasi-free electron. There is at least a distinct difference between interstitially and normally placed titanium ions in this respect. This may easily be seen from the description of the rutile structure under section 2.0 above.

A combined stoichiometric and non-stoichiometric defect equilibrium in rutile should be defined by the following simultaneous equations:

$$\begin{aligned} (\mathrm{Ti_i^{++++}})(\mathrm{Ti_v^{''''}}) &= k_1 \\ \mathrm{Ti_i^{++++}})(e^-)^4 p &= k_2 \\ 4(\mathrm{Ti_i^{++++}}) &= 4(\mathrm{Ti_v^{''''}}) + (e^-) \end{aligned} \tag{9}$$

The two first equations are the same as (5) and (6) above. The last equation is required by the electroneutrality principle, and the two last equations imply the simplifying assumption that $n = 4$ in eqn. (2).

By solving this equation system, we easily have:

$$(e^-)^5(4k_1(e^-)^3 p + k_2) = 4k_2^2 p^{-1} \tag{10}$$

which should represent the conductivity/oxygen pressure relationship in this case, when the conductivity is assumed proportional to the concentration of quasi-free electrons.

In case $4k_1(e^-)^3 p \ll k_2$, this equation reduces to:

$$(e^-) = (4k_2)^{1/5} p^{-1/5} \tag{11}$$

which is equivalent with the previous eqn. (8), showing the conductivity to vary inversely with the 1/5-power of the oxygen partial pressure when $n = 4$.

In case $4k_1(e^-)^3 p \gg k_2$, eqn. (10) reduces to:

$$(e^-) = (k_2^2/k_1)^{1/8} p^{-1/4} \tag{12}$$

whereby it is seen that the presence of a stoichiometric defect equilibrium in addition to a non-stoichiometric one should make the conductivity q to be relatively more sensitive ($d \log q$) to relative changes ($d \log p$) in the oxygen pressure p.

The conductivity/pressure relationships found by Hauffe and coworkers [12] could possibly be interpreted also along this line of thought.

The conductivity measurements referred to, have been made on powders. The above discussion does show, however, that even single crystal data of this kind may not be quite conclusive in determining the defect structure of rutile.

3.5 Weight change measurements

From eqns. (1) and (2) is seen that a rutile crystal should loose some oxygen and, thereby, decrease in weight on the formation of defects. By also taking eqns. (4) and (5) into consideration, we easily have for the equilibrium weight:

$$w = w_0 - \text{const. } p^{-1/6} \quad (13a)$$

$$w = w_0 - \text{const. } p^{-1/4} \quad (13b)$$

$$w = w_0 - \text{const. } p^{-1/2} \quad (13c)$$

in the case of AV-defects with none, one, and two trapped electrons, respectively, and

$$w = w_0 - \text{const. } p^{-1/n+1} \quad (14)$$

in the case of CI-defects with n positive charges.

w_0 means here the weight of the crystal when without defects. Buessem, Förland, T., Förland, K.S., and Marshall [14] have studied the equilibrium weight of a rutile sample (powder) as a function of the oxygen pressure (from about 10 to 760 torr) at temperatures from 860 to 1 050°C. Their results are apparently best in agreement with (13a) above, thereby indicating a defect structure of the AV-type.

As their rutile sample was not quite pure, and, considering the very small difference between a 1/6- and a 1/5-power relationship, we don't feel quite convinced that the former and not the latter is the correct one. The latter relationship is more consistent with the results of the conductivity measurements (see above), and is the one to be expected if the defect structure is of the CI-type ($n = 4$ in eqn. (14) above).

Förland [15] is now making renewed and extended weight change measurements on a high purity rutile sample, and it shall be interesting to see the results of these measurements.

3.6 Incorporation experiments

It is well known that an incorporation of even small amounts of foreign ions into a host lattice may drastically change its defect equilibrium, and that a knowledge of the effect of such incorporations on various properties of a crystal may assist in elucidating its original defect structure (see, *e.g.*, Ref.[5]).

In the case of rutile, we are only aware of data on the effect of incorporations on its electronic conductivity and on its oxidation protective properties when present as a film on titanium. The latter effect will be discussed under a later section (3.7), and we shall here only deal with the former effect.

If rutile should have a defect structure purely of the AV-type, it seems natural to assume that the cation interstitial positions in this lattice — for one reason or another — must be so unfavourable that not even incorporated cations will make use of them. An incorporation of a foreign metal oxide must then take place in a way as here exemplified by Cr_2O_3:

$$Cr_2O_3 + 2e^- + \tfrac{1}{2}O_2 = 2Cr_S'(Ti) + 2TiO_2 \quad (13)$$

$Cr_S'(Ti)$ means here a threevalent chromium ion substituting a fourvalent titanium ion, and this represents one negative surplus charge in the lattice.

From this equation is seen that the incorporation of a cation of lower valence than four should lead to a consumption of free electrons and, thereby, to a *decrease* in electronic conductivity in the case of AV-defects in rutile. Small amounts of Ga_2O_3, Al_2O_3, and NiO have been found [5], however, to have almost no effect on the conductivity, and Cr_2O_3 even to increase the conductivity at temperatures below 900°C.

These observations are perhaps easier explained on the assumption of a defect structure of the CI-type in rutile. In this case we should be allowed to assume that also foreign cations could enter into interstitial positions in the rutile lattice. Thus, by once more taking Cr_2O_3 additions as an example, and by assuming this oxide to be built into the rutile lattice in such a simple way as to give a fraction x of the Cr^{+++}-ions as substitutes for Ti^{++++}-ions in normal lattice positions:

$$x\,Cr_2O_3 + 2x\,e^- + \tfrac{x}{2}O_2 = 2x\,Cr_S'(Ti) + 2x\,TiO_2 \qquad (14)$$

and the remaining fraction $(1-x)$ of the Cr^{+++}-ions, in interstitial positions:

$$(1-x)Cr_2O_3 = 2(1-x)Cr_i^{+++} + 6(1-x)\,e^- + \frac{3(1-x)}{2}O_2 \qquad (15)$$

the total incorporation is represented by:

$$Cr_2O_3 = 2x\,Cr_S'(Ti) + 2(1-x)\,Cr_i^{+++} + 2(3-4x)\,e^- + 2x\,TiO_2 + \frac{3-4x}{2}O_2 \qquad (16)$$

From this equation is seen that the effect of Cr_2O_3-additions on the conductivity of rutile in this case should depend on the fraction factor x (for $x \gtreqless \frac{3}{4}$ we will have for the conductivity $\Delta q \lesseqgtr 0$). This factor may very well be a function of both Cr_2O_3-concentration, temperature, and oxygen pressure, and eqn. (16) could thus possibly explain the observed effects of these variables on the conductivity of the TiO_2/Cr_2O_3 mixed oxides (see Ref.[5]).

A similar treatment could be given also to other rutile/foreign oxide systems.

3.7 Oxidation studies

Through studies of the oxidation of titanium under conditions at which rutile is formed on the metal surface, it should also be possible to gain some information as to the defect structure of rutile.

Most of the previous work on the oxidation of titanium is reviewed by Kofstad and Hauffe [3] and by Kofstad, Hauffe, and Kjöllesdal [4]. Some further work is now being prepared for publication by Hurlen, Kjöllesdal, Markali and Norman.

In this latter work, rather strong evidence is found that the oxidation, at temperatures from 300 to 500°C, is governed by a cavity formation at the metal oxide interface. Such a cavity formation is probably most easily understood by assuming the occurrence and growth of cavities to be due to a reten-

tion at the metal/oxide interface of inward diffusing metal ion vacancies or of vacancies left behind in the metal when metal ions enter into interstitial positions in the oxide and migrate outwards.

In the same work is also found that rutile whiskers sometimes are formed on top of the rutile film, and Kinna and Knorr [16] have found that platinum markers placed on a titanium surface, are deeply buried by the rutile layer formed during oxidation at 1 000 and 1 200°C. All these observations are difficult to understand without assuming a preferential titanium diffusion in rutile.

Also Gulbransen and Andrew [17] assume mainly a titanium diffusion in the oxide film all over the temperature region (250—600°C) covered by their oxidation experiments, and, in the relatively high negative activation entropy of oxidation calculated from the results of these authors, Moore [18] finds theoretical evidence for the validity of this assumption.

Most of the workers within this field seem to assume a preferential oxygen diffusion in rutile, however, and, from marker studies with radioactive silver at 900°C, Davies and Birchenall [19] got some results which have been taken as being in favour of this assumption even though they are not quite conclusive.

As the diffusion in solids may be regarded a diffusion of defects, it seems that the results of the oxidation studies are more in accordance with a defect structure of the CI-type (or a combined CI/CV-type) than with one of the AV-type.

The fact that the Wagner-Hauffe [2] approach to alloy oxidation has proved unsuccessful in the case of titanium [20] may also have some explanation [21] on the assumption of a combined CI/CV defect structure in rutile. The Wagner-Hauffe theory does not take such a combined defect structure into account. It only applies to cases in which the oxide has a single defect system.

4.0 CONCLUSION

The defect structure of rutile has here been discussed on the basis of structural considerations, density measurements, colour observations, conductivity measurements, weight change measurements, incorporation experiments, and oxidation studies.

It has been shown that some of the available data are inconclusive, that some data (especially those by Marshall and Förland [14] on the equilibrium weight of a rutile sample as a function of the oxygen pressure) may indicate a defect structure of the anion vacancy type (AV-type), but that the majority of the data is most easily interpreted on the assumption of a defect structure of the CI-type (or a combined CI/CV-type).

The strongest evidence in favour of this assumption is that the rutile structure contains apparently very favourable octahedral interstitial positions for titanium ions, and that positions of this kind actually are being occupied in an ordered way in the rutile-like oxides belonging to the homologous series of formula Ti_nO_{2n-1} (see Ref.[7]). This series of oxides extends directly up to the lower O-limit of the homogeneity range of the TiO_2 (rutile), and it seems logical and natural that we here should have just a transition from an ordered to a random occupancy of such sites.

Short Communications

The Crystal Structure of $K_3V_5O_{14}$ *

ANN MARIE BYSTROM and
HOWARD T. EVANS, Jr.

Geological Survey of Sweden, Stockholm 50, Sweden, and
U. S. Geological Survey, Washington 25, D. C., U.S.A.

As a part of a study of the system $K_2O-V_2O_5-H_2O$ at the U.S. Geological Survey, Washington, D.C., the crystal structure of $K_3V_5O_{14}$ has been worked out. $K_3V_5O_{14}$ crystallizes in red hexagonal prisms by rapid evaporation of dilute solutions of V_2O_5 and K_2O above 40°C. (R. Marvin, U.S. Geological Survey, written communication.) The crystals, which are often twinned, show strong dichroism, brown to dark red, with absorption $\varepsilon < \omega$; ω = dark red and ε = greenish yellow. They are optically uniaxial, negative, with refractive indices $\omega = 2.42$ and $\varepsilon = 1.748$. The habit clearly indicates that the point group symmetry is ditrigonal pyramidal, C_{3v}.

From photographs of the (*hk*0), (*hhl*), and (*h*0*l*) zones, made with a Buerger precession camera and MoKα radiation, and the habit of the crystal, the space group was established as $P31m$ (C_{3v}^2). The cell dimensions were determined with an x-ray single crystal goniometer using a scintillation counter. The following values were obtained:

$a = 8.6796 \pm 0.0020$ Å MoKα_1 = 0.70926 Å
$c = 4.9914 \pm 0.0008$ MoKα_2 = 0.71354
$V = 325.65$ Å^3 MoKβ = 0.63225

Density (observed) = 3.01 g cm^{-3}
Density (calculated) = 3.03 g cm^{-3}.

Intensities were recorded for (*hk*0), (*hk*1), and (*h*0*l*) zones on a Weissenberg camera using unfiltered MoK radiation. The multiple film technique was used and intensities were measured by visual comparison with a calibrated strip.

* Publication authorized by the Director, U.S. Geological Survey.

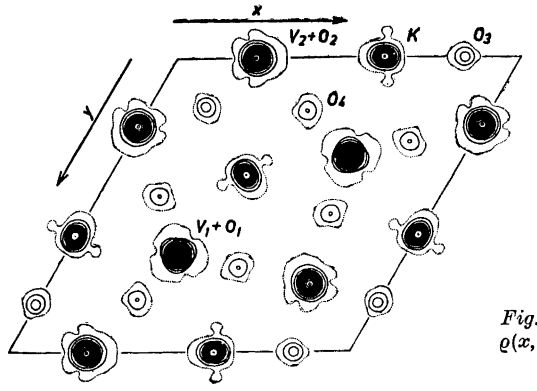

Fig. 1. Electron density projection of $K_3V_5O_{14}$, $\varrho(x, y)$. Dotted contour, 4 electrons/Å^2; contour interval 4 electrons/Å^2.

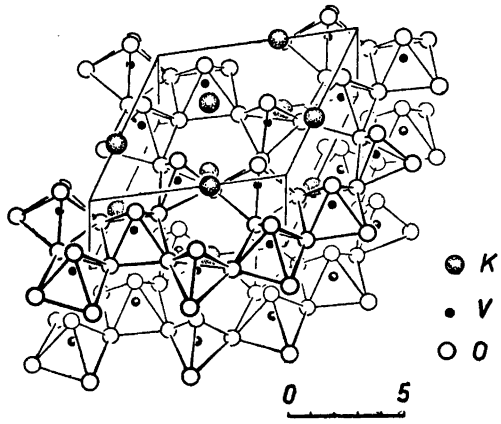

Fig. 2. View of the crystal structure of $K_3V_5O_{14}$, showing triangular and square pyramids linked into a sheet. Scale in Ångström units.

Owing to difficulties involved in getting a pure sample for chemical analysis, the cell content was uncertain at the outset. Thus, all attempts to interpret the Patterson function $P(u,v)$ in terms of 3K and 6V atoms failed. A solution was readily found for 3K and 5V atoms, however, and the resulting model was confirmed by the Patterson $P(u,w)$. The oxygen locations were then found mainly by space reasoning. From the preliminary positions of the atoms, electron density maps of the functions $\varrho(x,y)$ and $\varrho(x,z)$ were prepared, and by successive steps of refinement, the following coordinates were determined:

Atom	x	y	z
3 K in (*c*)	0.605	0	0
2 V_1 in (*b*)	1/3	2/3	0.471
3 V_2 in (*c*)	0.231	0	0.472
2 O_1 in (*b*)	1/3	2/3	0.796
3 O_2 in (*c*)	0.240	0	0.782
3 O_3 in (*c*)	0.838	0	0.367
6 O_4 in (*d*)	0.469	0.177	0.366

For these coordinates the reliability factors and temperature coefficients have been found as follows:

(*hk*0) (63 obs. data) $R = 0.116$, $B = 1.59$ Å^2;
(*hk*1) (51 obs. data) $R = 0.145$, $B = 0.77$;
(*h*0*l*) (93 obs. data) $R = 0.164$, $B = 0.90$.

In Fig. 1 the electron density projection $\varrho(x,y)$ is illustrated.

The five vanadium atoms lie very nearly in the same *z*-plane forming almost regular pentagons. The fourteen oxygen atoms are bound to the vanadium atoms in rather an unusual way, reminiscent of the bonding in V_2O_5 (Byström *et al.*[1]) and $KVO_3 \cdot H_2O$ (Christ *et al.*[2]). They form nearly square pyramids around the V_2 atoms and trigonal pyramids around the V_1 atoms, the pyramids all with apices pointing in the same direction along the *c*-axis and joined by sharing neighboring basal corners. Each hollow space resulting from the five-ring configuration is occupied by a potassium atom, placed about half way between the layers. Each potassium is surrounded by 10 oxygens, five from the apex oxygens of the polyhedra in the lower layer and five from basal corners of polyhedra in the layer above.

The V—O bonds in the *c*-direction of $K_3V_5O_{14}$ may be compared with the situation along the *b*-axis in V_2O_5 (Byström *et al.*[1]). In both cases there is a short V—O distance of 1.5—1.6 Å within the layer and then a long distance to the neighboring layer. In V_2O_5 the long distance is still short enough, V—O = 2.81 Å, to act as a weak bond, giving the structure a three dimensional network character. In $K_3V_5O_{14}$ the corresponding distance is considerably prolonged, of the order of 3.4 Å, too long for a bond. The vanadium-oxygen polyhedra thus form a two dimensional network, now held together by the interfoliated potassium ions. The nine V—O distances range from 1.55 to 1.87 Å and the K—O distances from 2.72 to 3.36 Å.

A pictorial view of the structure is given in Fig. 2, where the V—O polyhedra have been especially emphasized.

The work on the structure is being continued and a full report will appear at a later date.

An Infra-red Spectroscopic Study of the Structural Relationships of Dextropimaric, *Iso*dextropimaric, and Cryptopimaric Acids

HENRIK H. BRUUN

Institute of Wood Chemistry, Åbo Akademi, Åbo, Finland

INGRID FISCHMEISTER and EINAR STENHAGEN

Department of Medical Biochemistry, Institute of Medical Chemistry, University of Upsala, Upsala, Sweden

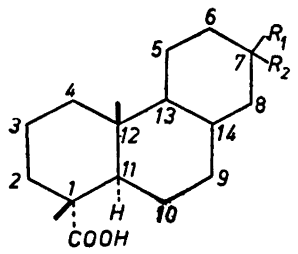

Fig. 1. Ring system numbering of rosin acids. Stereochemical configuration at the carbon atoms 1, 11, and 12 indicated.

Recent mass spectrometric investigations[1] of the structural relations between dextropimaric, *iso*dextropimaric, and cryptopimaric acid have led to the conclusion that dextropimaric acid and cryptopimaric acid can be structurally different only with regard to the orientation of the methyl and vinyl group attached to C_7 (Fig. 1; R_1 = vinyl, R_2 = methyl), whereas the difference between dextropimaric acid and *iso*dextropimaric acid must also involve the geometry of the ring system. In the present study the infra-red spectra of these compounds and their methyl esters have been recorded, and it will be shown that the vinyl group absorption and a skeletal vibration at 8.4 μ exhibit evidence of differences which are in accordance with the above conclusions. Moreover, they show that dextropimaric and *iso*dextropimaric acid are epimeric not only at C_{13} but also at C_7.

The absorption band due to the $=C\begin{matrix}H\\H\end{matrix}$ out-of-plane deformation vibration is found at 10.90 μ for dextropimaric acid and at 10.94 μ for both *iso*dextro- and cryptopimaric acid. In the spectra of the methyl esters the same band occurs at 10.92 μ for dextropimaric acid and at 10.98 μ for the other acids. In both cases the band for dextropimaric acid is shifted *ca.* 0.05 μ towards shorter wavelengths as compared with the (coincident) bands of *iso*dextro- and cryptopimaric acid.

The slightly weaker band at 10 μ due to the $-CH=$ out-of-plane deformation of the vinyl group only shows differences within the experimental error of the apparatus.

For the acids in the solid state (in KBr) the position of the vinyl group absorption deviates somewhat from that shown by the acids in solution and by the methyl esters. Again, dextropimaric acid differs from the two others with regard to the $=CH_2$ out-of-plane vibration, but here the shift is towards longer wavelengths (*cf.* Table 1). Cryptopimaric acid shows a double band, and the others single maxima with inflexions. The 10 μ band, again, exhibits only differences lying within the experimental error of the apparatus.

These spectral differences indicate that the vinyl group in dextropimaric acid has a different molecular environment, *i. e.* a different stereochemical position, than in *iso*dextro- and cryptopimaric acid. Since surface-film measurements[2] suggest that the position is quasi-axial for dextropimaric acid and quasi-equatorial for *iso*dextropimaric acid, these absorption differences seem to correspond to axial and equatorial positions of the vinyl group, respectively (see also an earlier infra-red investigation of the solid state spectra of dextro- and *iso*dextropimaric acid[3]). Spectral differences for substituents in axial and equatorial position are well known in steroid chemistry. For instance, hydroxyl groups[4], as well as carbonyl groups in the neighbourhood of halogen atoms[5], exhibit such shifts. Also, the acetate band at 8 μ [6,7] is single when the group is in the equatorial position, but splits into several peaks when it is in the axial position.

The medium-intensity band at about 8.4 μ is common to the spectra of the CCl_4 solutions of dextro-, *iso*dextro-, and cryptopimaric acids, to the spectra of the esters, and to those of the solid acids in KBr. In

Table 1.

Acid	Skeletal vibration, λ (μ)			RHC=C(H)(H) out-of-plane deformation vibration λ (μ)		
	Acid, in CCl_4-soln.	Ester, liquid	Acid, in KBr	Acid, in CCl_4-soln.	Ester, liquid	Acid, in KBr
Dextropimaric	8.44	8.40; 8.50	8.42	10.90	10.92	— (11.02)* 11.09
*Iso*dextropimaric	8.38	8.39; 8.45	8.39	10.94	11.00	10.88 (11.00) —
Cryptopimaric	8.44	8.40; 8.51	8.45; 8.49	10.94	10.97	10.88 11.02 (11.09)

* Values in parentheses signify inflexions.

each case this band has the same position for dextro- and cryptopimaric acid, but appears at a shorter wavelength in the spectrum of *iso*dextropimaric acid. The numerical values are listed in Table 1. A skeletal vibration in this region occurs for branched-chain alkanes [8]. In alkanes with the general structure  the band is at 8.39—8.44 μ [9], *i. e.* it is in the same position as found in our spectra, and it is therefore possible that one of the methyl-substituted carbon atoms (see Fig. 1) in our substances is involved in this vibration. Skeletal vibrations are known to be very sensitive to changes in the immediate environment of the vibrating group. We should therefore have a methyl substituted carbon atom whose environment is the same in dextro- and cryptopimaric acid but different in *iso*dextropimaric acid. This is the case for C_{12}, taking into account the mass spectrometric evidence of different ring fusion between rings B and C in dextropimaric and *iso*dextropimaric acid.

In summary, we can state that the spectral shifts discussed above suggest that dextropimaric and *iso*dextropimaric acid are epimeric at C_7 and C_{13}, while dextropimaric and cryptopimaric acid are epimeric at C_7. These results agree with the conclusions drawn by Bruun, Ryhage, and Stenhagen [1] from mass spectrometric data, and with the chemical evidence recently reported [10,11].

Experimental. The apparatus employed is described in Ref.[3], and the physical and chemical properties of the acids studied are given in Ref.[1]. The wavelength measurements are accurate to $\pm$ 0.015 μ.

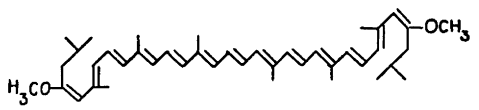
A Note on the Constitutions of Spirilloxanthin and P-481

SYNNÖVE LIAAEN JENSEN

Institutt for Organisk Kjemi, Norges Tekniske Högskole, Trondheim, Norway

The molecular formula of the carotenoid spirilloxanthin, shown to be identical with that of rhodoviolascin [1], was established by Karrer *et al.*[2,3] and van Niel *et al.*[4,1]. The following constitution (I) was suggested by Karrer *et al.*[5], who isolated from the potassium permanganate oxidation products,



(I)

bixindialdehyde and a methoxyl-free dialdehyde with eleven conjugated double bonds. Karrer *et al.* preferred a symmetrical molecule, and by analogy with the generally occurring 3-substituted carotenoids, they placed the methoxyl groups in the 3,3′-positions. This formula (I) does not contain any *iso*propylidene end groups. Karrer *et al.*[6], however, obtained 0.60–0.73 moles of acetone by ozonolysis. Carotenoids of the lycopene type (two *iso*propylidene end groups) have given 1.24–1.68 moles of acetone by ozonolysis [7,8]; the corresponding values for the γ-carotene type (one *iso*propylidene end group) ranging from 0.6–0.94 [9,10]. The values reported by Karrer *et al.* are unexpectedly high for the structure given (I). By ozonolysis (I) would give two moles of methyl *iso*valerate, from which no measurable quantity of acetone is to be expected. The failure of formula (I) to account for the acetone formed by ozonolysis has already been pointed out by van Niel [11].

Micro determination of *iso*propylidene has been repeated, using the method of Kuhn and Roth [12], on crystalline, chromatographically purified spirilloxantin isolated from *Rhodospirillum rubrum*. The result is presented in Table 1 together with values simultaneously obtained for the carotenoid P-481 [13] from the same source and for chromatographically pure lycopene from tomatoes.

Table 1.

Carotenoid	Found: Moles acetone/mole	Number of *iso*propylidene groups
Spirilloxanthin	0.42	0
P-481	0.82	1
Lycopene	1.70	2

Although our value for spirilloxanthin is appreciably lower than the values found by Karrer *et al.*, it still exceeds the amount found for carotenoids of the β-carotene type (no *iso*propylidene groups). The reported value for *iso*propylidene determination of β-carotene is 0.2 [9]. We therefore assume that the methoxyl groups of spirilloxanthin belong to a structural element from which some acetone is formed upon ozonolysis.

Assuming a symmetrical formula, Karrer's potassium permanganate oxidation data restrict the location of the methoxyl groups to positions 1, 2 or 3 and 1′, 2′ or 3′. As already mentioned the *iso*propylidene determination does not favour a 3-methoxy-structure. In addition, if the methoxyl groups were placed in the 3,3′-positions the stability of the so-called OH-spirilloxanthin [14] would be difficult to explain. This compound is a bacterial carotenoid with a visible spectrum similar to that of spirilloxanthin, but which according to partition tests and chromatographic behaviour contains one hydroxyl group [15,14]. It has been regarded by Goodwin [15] as a mono-demethylated spirilloxanthin. This assumption seems to agree with the results from kinetic studies of carotenoid synthesis in *Rhodospirillum rubrum* [14]. Mono-demethylated spirilloxanthin, according to formula (I) would be an enol, rearranging in neutral or acidic media to a carotenoid with twelve conjugated double bonds and an isolated keto group. OH-Spirilloxanthin should thus differ remarkably from spirilloxanthin in its visible spectrum. On addition of alkali a pronounced bathochromic shift in the visible spectrum should occur; this is not the case. It may be mentioned that 4,4′-dihydro-rhodoxanthin has a pure β-carotene spectrum [16] with no tendency to prolongation of the chromophore by enolization in neutral solvents.

Carotenoids with allylic methoxyl groups are known to yield products with extended conjugated chains by treatment with

chloroform-hydrochloric acid [17,7]. A series of experiments with chloroform-hydrochloric acid treatment [18] of spirilloxanthin, resulted only in a certain *trans-cis* isomerization of spirilloxanthin and gave no product with an extended conjugated chain. Methoxyl groups are therefore not likely to be present in the 2,2′-positions.

The arguments presented above indicate, by elimination, positions 1,1′ as the most likely sites for the methoxyl groups of spirilloxanthin. Further support for this hypothesis may be obtained from the IR-absorption bands of the methoxyl groups of a series of related compounds (Table 2), although very little data are available.

Table 2.

Compound	C—O Stretching Vibration Frequency cm^{-1}
Spirilloxanthin (KBr)	1 080
4,4′-dimethoxy-β-carotene (KBr) [18] *	1 082—1 097
Pigment Y [7]	1 064
Spheroidenone [7]	1 066
=C—O—C [19]	near 1 250

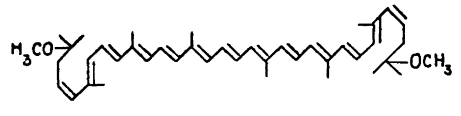
* Private communication from Dr. R. Entschel.

The frequency of the C—O—C stretching vibration of spirilloxanthin is different from that of an enolic methoxyl group.

A relatively intense band around 1 660 cm^{-1} has been shown by Rosenkrantz and Gut [20] to be characteristic for compounds containing the —CH=C—O— grouping. Spirilloxanthin has no absorption band in this region. IR-data are thus not in accordance with formula (I).

As a consequence of the above discussion the constitution (II) is suggested for spirilloxanthin.

As long as the elementary composition of P-481 is unknown, it is premature to indicate a structure for this carotenoid. As seen from Table 1 this carotenoid seems to contain one *iso*propylidene group. A chromophore of twelve conjugated double bonds [14] and the presence of one methoxyl group [21] have already been reported. The IR-absorption band of the methoxyl group [21] at 1 078 cm^{-1} has the same position as that of spirilloxanthin.



(II)

The biological role of P-481 as an intermediate between lycopene and spirilloxanthin in the biosynthesis of carotenoids of *Rhodospirillum rubrum* has been established by Stanier *et al.*[14].

Combining chemical and biological evidence, it is tentatively suggested that the P-481-molecule consists of half a lycopene molecule and half a spirilloxanthin molecule.

The author is gratefully indebted to Prof. N. A. Sörensen for helpful advice and valuable discussions throughout this work.

Synthesis of Certain S-Substituted L-Cysteines

DIMITRIOS THEODOROPOULOS*

Department of Medical Biochemistry, University of Gothenburg, Sweden

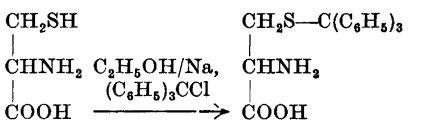
Twenty years ago du Vigneaud [1] introduced the benzylation of the thiol group of cysteine by adding benzyl chloride to the liquid ammonia solution of the sodium salt of cysteine. The S-benzyl group was reversibly split off by reduction with sodium in liquid ammonia. This method has played a fundamental role in the synthesis of various cysteinyl peptides and more recently in the dramatic synthesis of oxytocin [2].

Since the discovery by Weisberger and Levine [3] that leukaemic leukocytes have a high initial cystine-cysteine requirement, several S-cysteine analogues have been synthesized and tested as possible anticancer agents [4]. In most cases du Vigneaud's method has been employed with excellent results. Thus, S-dichlorovinyl-L-cysteine was prepared by McKinney [5] *et al.* in 60—70 % yield.

An alternative procedure for the synthesis of S-alkyl cysteines has been introduced by Zahn and Traumann [6]. Cysteine hydrochloride was treated with the appropriate alkyl bromide in a bicarbonate solution in the presence of nitrogen. Among the products thus produced, S-methyl-L-cysteine and S-ethyl-L-cysteine were obtained in 20 and 10 % yield, respectively. In a similar manner, but in alkaline solution with sodium hydroxide instead of bicarbonate, aminoethylcysteine[7] was synthesized.

In this respect it was found that treatment of cysteine in absolute ethanol with sodium, followed by addition of the appropriate alkyl or phenyl halide, results in the production of the desired S-derivative in excellent yield. Thus, S-benzyl-L-cysteine was synthesized in 70 % yield and its optical value shown to be identical to that reported. Excellent yields were also obtained in the cases of S-butyl-L-cysteine, S-ethyl-L-cysteine and S-methyl-L-cysteine. The thus obtained products were found to be homogeneous according to paper chromatography, as far as the method can detect. This finding suggests that the oxidation of cysteine to cystine is extremely limited or avoided under the experimental conditions described here. On the contrary, the diazonium salt procedure [8,9] for the preparation of S-aryl-L-cysteines gives products always contaminated with cystine, which is difficult to remove.

Treatment of cysteine hydrochloride with trityl chloride in a similar manner, produces S-trityl-L-cysteine in about 20 % yield.



A similar product has been synthesized by selective detritylation of S,N-ditrityl-L-cysteine [10], prepared by direct tritylation [11] of cysteine in the presence of diethylamine, but its reported optical value is entirely different to that described in this parer (see Experimental).

Experimental. S-Benzyl-L-cysteine. To a suspension of 1.75 g (0.01 mole) of L-cysteine hydrochloride monohydrate in 30 ml of absolute ethanol, 0.92 g (0.04 mole) of sodium was added within 10 min at room temperature. When the last piece of sodium was about to disappear, 1.26 g (0.01 mole) of benzyl chloride was added with stirring. After 2 min the reaction mixture was poured into 50 ml of water * and the solution acidified with acetic acid to pH 5—5.5. The desired product precipitated immediately. It was cooled in the refrigerator, filtered and washed successively with water and ethylether. Yield 1.5 g (71 %) m. p. 216—218° (decomp.), reported [1] 216—218° (decomp.),

* Swedish Medical Research Council Postdoctoral Fellow.

* Provided that all the sodium had disappeared.

Synthesis of Certain S-Substituted L-Cysteines

DIMITRIOS THEODOROPOULOS*

Department of Medical Biochemistry, University of Gothenburg, Sweden

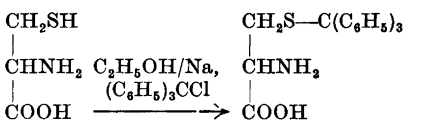
Twenty years ago du Vigneaud [1] introduced the benzylation of the thiol group of cysteine by adding benzyl chloride to the liquid ammonia solution of the sodium salt of cysteine. The S-benzyl group was reversibly split off by reduction with sodium in liquid ammonia. This method has played a fundamental role in the synthesis of various cysteinyl peptides and more recently in the dramatic synthesis of oxytocin [2].

Since the discovery by Weisberger and Levine [3] that leukaemic leukocytes have a high initial cystine-cysteine requirement, several S-cysteine analogues have been synthesized and tested as possible anticancer agents [4]. In most cases du Vigneaud's method has been employed with excellent results. Thus, S-dichlorovinyl-L-cysteine was prepared by McKinney [5] *et al.* in 60—70 % yield.

An alternative procedure for the synthesis of S-alkyl cysteines has been introduced by Zahn and Traumann [6]. Cysteine hydrochloride was treated with the appropriate alkyl bromide in a bicarbonate solution in the presence of nitrogen. Among the products thus produced, S-methyl-L-cysteine and S-ethyl-L-cysteine were obtained in 20 and 10 % yield, respectively. In a similar manner, but in alkaline solution with sodium hydroxide instead of bicarbonate, aminoethylcysteine[7] was synthesized.

In this respect it was found that treatment of cysteine in absolute ethanol with sodium, followed by addition of the appropriate alkyl or phenyl halide, results in the production of the desired S-derivative in excellent yield. Thus, S-benzyl-L-cysteine was synthesized in 70 % yield and its optical value shown to be identical to that reported. Excellent yields were also obtained in the cases of S-butyl-L-cysteine, S-ethyl-L-cysteine and S-methyl-L-cysteine. The thus obtained products were found to be homogeneous according to paper chromatography, as far as the method can detect. This finding suggests that the oxidation of cysteine to cystine is extremely limited or avoided under the experimental conditions described here. On the contrary, the diazonium salt procedure [8,9] for the preparation of S-aryl-L-cysteines gives products always contaminated with cystine, which is difficult to remove.

Treatment of cysteine hydrochloride with trityl chloride in a similar manner, produces S-trityl-L-cysteine in about 20 % yield.



A similar product has been synthesized by selective detritylation of S,N-ditrityl-L-cysteine [10], prepared by direct tritylation [11] of cysteine in the presence of diethylamine, but its reported optical value is entirely different to that described in this parer (see Experimental).

Experimental. S-Benzyl-L-cysteine. To a suspension of 1.75 g (0.01 mole) of L-cysteine hydrochloride monohydrate in 30 ml of absolute ethanol, 0.92 g (0.04 mole) of sodium was added within 10 min at room temperature. When the last piece of sodium was about to disappear, 1.26 g (0.01 mole) of benzyl chloride was added with stirring. After 2 min the reaction mixture was poured into 50 ml of water * and the solution acidified with acetic acid to pH 5—5.5. The desired product precipitated immediately. It was cooled in the refrigerator, filtered and washed successively with water and ethylether. Yield 1.5 g (71 %) m. p. 216—218° (decomp.), reported [1] 216—218° (decomp.),

* Swedish Medical Research Council Postdoctoral Fellow.

* Provided that all the sodium had disappeared.

$[\alpha]_D^{20}$ +21.9° (*c*, 2 in N NaOH), reported [1] $[\alpha]_D^{26.5}$ +23.5° (*c*, 1 in N NaOH).

S-Butyl-L-cysteine. It was prepared from cysteine hydrochloride and butyl bromide in a similar manner as described for the S-benzyl-cysteine derivative. Yield 1.6 g (94 %), m. p. 218—220° (decomp.), $[\alpha]_D^{20}$ —11.2° (*c*, 1 in 2 N HCl). (Found: N 7.50; S 17.82. Calc. for $C_7H_{15}O_2NS$: N 7.89; S 18.08.)

S-Ethyl-L-cysteine. This product was synthesized from L-cysteine hydrochloride and ethyl iodide as previously described, but the reaction mixture was diluted with no more than the necessary amount of water to form a clear solution. The desired product then precipitated upon acidification with acetic acid and cooling. Yield 1 g (82 %), m. p. 226—229° (decomp.), reported [6] m. p. 229°, $[\alpha]_D^{20}$ —27.9° (*c*, 2 in water), reported [6] $[\alpha]_D^{20}$ —25.8° (*c*, 5 in water). (Found: N 9.60; S 21.2. Calc. for $C_5H_{11}O_2NS$: N 9.39; S 21.40.)

S-Methyl-L-cysteine. Methyl iodide was used as the alkylating agent. The product being soluble in water was isolated in a similar manner as described for the S-ethylcysteine derivative. Yield 60 %, m. p. 245—250° (decomp.), reported [6] 251°, $[\alpha]_D^{20}$ —32.3° (*c*, 1 in water), reported [6] $[\alpha]_D^{20}$ —34.5° (*c*, 5 in water). (Found: N 10.15; S 23.20. Calc. for $C_4H_9O_2NS$: N 10.35; S 23.74.)

S-Trityl-L-cysteine. L-Cysteine hydrochloride monohydrate (1.75 g, 0.01 mole) was suspended in absolute ethanol and treated with sodium as described before. Trityl chloride (2.88 g, 0.01 mole) diluted in 6 ml of dry and freshly distilled tetrahydrofuran was added in 4—5 portions during 10 min with stirring. The reaction mixture was then acidified with acetic acid and diluted by addition of 100 ml of dry ether. Upon cooling for 1 h a white precipitate was deposited, which was filtered, washed well with water and finally with ethyl ether. Yield 0.8 g (20 %), m. p. 198—202° (decomp.), reported [10] 202—205° $[\alpha]_D^{20}$ —11.3° (*c*, 1 in 0.1 N NaOH), reported [10] $[\alpha]_D^{20}$ +19°± 1 (*c*, 2 in 0.1 N NaOH). (Found: N 3.5; S 8.6. Calc. for $C_{22}H_{21}I_2NS$: N 3.8; S 8.8.)

Foot note added in proof. Replacement of tetrahydrofuran by ethylether increased the yield in S-trityl-L-cysteine up to 60—70 %. It has also been found that the S-trityl group splits off by reduction with sodium in liquid ammonia at its boiling point. Thus, S-trityl-L-cysteine was converted to S-benzyl-L-cysteine and the optical rotation of the latter was in agreement with that reported above. However, the S-trityl group survives almost completely under the conditions used for the acidic hydrolysis of N-tritylamino acids and peptides [11].

Enthalpy Titrations with Temperature Adjustment

KURT SCHLYTER and
LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

With the revival of interest in complicated solution equilibria in the last two decades, a considerable amount of data has been collected about systems with several species formed (step-wise complex formation, polynuclear complexes) [1]. In many systems, there is very good evidence for the formulas of the species formed; the equilibrium constants of their formation, and thus the ΔG's of the reactions, are moreover known with a fair accuracy. In order to get a better understanding of such reactions, it would be desirable to break up the ΔG's into their ΔH and ΔS parts; many attempts have been made to calculate these from the variation of equilibrium constants with temperature. However, with the accuracy at present obtainable in systems with several species, and the limited temperature range available, the data of different careful workers very often disagree, even as to the sign of the quantities [2].

One might hope to get much better values for ΔH with a calorimeter, even of moderate accuracy. The traditional way of mixing two solutions, T and S, containing the reagents, would be keeping solution S and solution T in a sealed tube, in a calorimeter, until they have the same temperature, then mixing the solutions by breaking the tube with T and measuring the change of temperature. If only one reaction occurs, its ΔH may be obtained from the average of a relatively small number of such measurements.

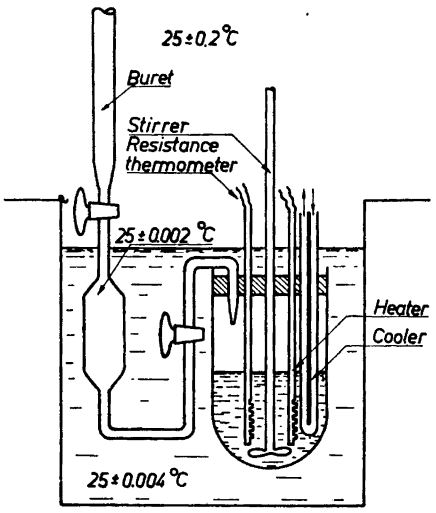

Fig. 1. Principle of calorimeter.

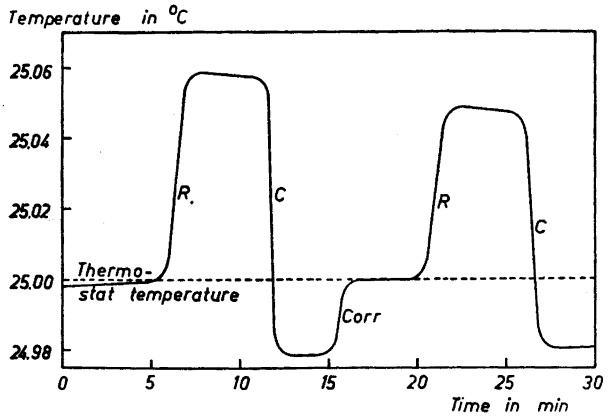

Fig. 2. Temperature history of part of a titration: R = reaction heat evolved; C=cooling applied; corr = temperature corrected by means of heater *etc.*

If, on the other hand, several reactions must be considered simultaneously, a much larger number of experiments of this type, varying the concentrations of both the reactants, would be needed and the method would become rather laborious and time-consuming.

We would suggest, for ΔH work, a titration technique which might give similar advantages over "point measurements" as does the titration technique introduced by Leden [3] for determining equilibrium constants: a much larger number of data for a given amount of time and labor, and a better check for small analytical errors.

It would, however, not be perfectly satisfactory to keep S in a calorimeter, and T in a buret (albeit thermostated), to add T portion-wise to S and measure the temperature in S after each addition. The temperature in S would naturally change during the reactions, so that one would have to make an increasing correction for the temperature difference between T and S. Moreover, the temperature in S might finally drift several degrees from the original one, say 25.0°C. Even if one knows the equilibrium constants for the various reactions at 25.0°C, the constants would now be different, which one would have to consider in the calculations.

These considerations have led us to try another simple device which we think has not been described before. The main parts are shown in Fig. 1, and a typical temperature history during the titration in Fig. 2.

The apparatus is kept in a thermostated room of approximately the standard temperature desired, 25.0°C. The upper part of the buret with solution T is thus air-thermostated. From the buret, T passes through a bulb, which is immersed in a water thermostat which keeps the temperature more accurately, and which also contains the calorimeter with S. The calorimeter is, as usual, provided with a thermometer and an electric heater, used for calibration. The unusual feature is a cooler of thin glass tubing, through which cool air may be blown; heat is then conducted away from the solution through the tube wall to the air. The temperature of S may be adjusted with any reasonable accuracy to equal the standard temperature of the thermostat bath and T; in practice, the final adjustment is best made with the heater, so the cooler is applied to produce a temperature somewhat below the standard one, after which the heat is applied.

The temperature history of the solution S will be as is seen in Fig. 2. Before each addition, the temperature in S is made equal to that in T; the addition is made, the temperature rise is recorded, and then the temperature of S is again brought back to the standard.

In this way, there will be practically no correction for temperature difference between S and T, and the temperature in S, even after an addition, may be kept within, say, 0.1° from the standard so that the equilibrium constants for the standard temperature may be used in the calculations.

An apparatus has been constructed according to these principles by one of us (K.S.) and is now being used to study a number of equilibrium systems. The main advantage is the increased speed of working, and the accuracy is quite satisfactory. A detailed description of the apparatus will appear elsewhere [4].

The Occurrence of Endocrocin in *Penicillium islandicum*

STEN GATENBECK

Institute of Biochemistry, University of Lund, Lund, Sweden

Earlier investigations of the biogenesis of polyhydroxyanthraquinones have shown that the anthraquinone molecule originates from acetate through head to tail couplings of acetate units. As discussed in another paper the experiments with labelled acetate as substrate do not explain the formation of the ring system since the intramolecular

condensation of a C—16 polyketoacid and the condensation of two C—8 benzene derivatives will give rise to the same isotopic pattern [1]. In both cases one has to presume a polyhydroxyanthraquinone-carboxylic acid as an intermediate step in the formation of the polyhydroxyanthraquinone. The biological formation of the anthraquinones *via* anthraquinone-carboxylic acids is indicated by the occurrence in nature of a polyhydroxyanthraquinone-carboxylic acid with the carboxyl group in the expected position in the molecule.

Asahina and Fuzikawa [2] have found 4,5,7 - trihydroxy - 2 - methylanthraquinone-3-carboxylic acid (endocrocin) in the lichen *Nephromopsis endocrocea*. The same lichen also produces physcion, the 7-methylether of the decarboxylated endocrocin. Shibata and Natori [3] have isolated endocrocin from the mold *Aspergillus amstelodami*, which also produces catenarin. The formation of catenarin from endocrocin is easily explained by hydroxylation at the 1-position and decarboxylation of endocrocin.

Endocrocin has now been found in a UV-mutant of *Penicillium islandicum*. This strain produces in addition both emodin [4], *i. e.* decarboxylated endocrocin, and catenarin as well as islandicin. This gives further support to anthraquinone-carboxylic acids being intermediates in the formation of the anthraquinones.

In spite of the slight solubility of endocrocin in water, it was mainly found (about 3 mg/l) in the culture medium (pH 4.5) of *Penicillium islandicum*.

The isolated endocrocin decomposed slowly over the range 290—320°C. Asahina and Fuzikawo describe the melting point of endocrocin as decomposition up against 318°C.

The isolated product was soluble in 0.5 N $NaHCO_3$ with a brown red color and gave all the color reactions reported by Asahina and Fuzikawa (ethanolic ferric chloride, a red brown coloration; concentrated H_2SO_4, a red coloration; methanolic magnesium acetate, an orange red coloration). It had an absorption curve that was very close to that of emodin in appearance. The acetylated product was soluble in $NaHCO_3$ and had m. p. 212°C (Asahina and Fuzikawa 212°C).

Thermal decomposition of the isolated endocrocin yielded emodin. The emodin was identified by its absorption spectrum and its m. p. (257°C) which was not depressed on admixture with authentic emodin.

Experimental. Culture conditions. Fourteen flasks, each containing 500 ml of Czapek-Dox medium were cultivated according to Howard and Raistrick [5] for thirty days. The mycelium was filtered off and washed with distilled water.

Isolation of endocrocin. The culture medium was acidified with concentrated HCl and extracted with ether (3 l). After concentrating to about 500 ml the ether solution was treated with 0.5 N $NaHCO_3$ until no more pigment could be removed. The pigments in the aqueous solution were taken up in ether after acidification of the solution with HCl. The ether phase was dried over anhydrous Na_2SO_4 and evaporated to dryness. The residue was purified by developing on a thick paper chromatogram (Whatman 3 MM) in chloroform-methanol-formic acid (4 %) (10:1:1). The region containing endocrocin (R_F 0.75) was extracted with acetone. The endocrocin was with difficulty recrystallized from glacial acetic acid, m.p. 290—320°C (decomp.).

Decarboxylation of endocrocin. A small portion of the endocrocin was heated at 320°C for half an hour in a test tube. The emodin which sublimed on the walls of the test tube was rinsed out with acetone and resublimed in vacuum at 200—220°C. The emodin had m.p. 257°C.

Acetylation of endocrocin. About 20 mg of endocrocin were boiled for 2 min with 2 ml of acetic anhydride and a few drops of concentrated H_2SO_4. The reaction solution was poured onto crushed ice after cooling to room temperature. The precipitate formed was filtered off and recrystallized twice from methanol yielding small pale yellow needles with constant melting point (212°C).

Über die equatoriale oder axiale Anknüpfung der Hydroxylgruppe bzw. der Alkoxylgruppe am glycosidischen Kohlenstoffatom der α- und β-D-Glucopyranosen und der α- und β-D-Galactopyranosen

JAKOB BLOM

Laboratorium der Brauerei Tuborg, Kopenhagen, Dänemark

In sechsgliedrigen Ringsystemen, ob carbocyclisch oder heterocyclisch, sind die stabileren Strukturen als Stuhl-Konformationen aufgebaut. In einer Stuhl-Konformation können die Substituenten entweder eine axiale a- oder eine equatoriale e-Anknüpfung am Ring haben [1]. Die stabilere Stuhl-Konformation ist diejenige, welche die grösste Anzahl von e-Substituenten trägt. In einer Stuhl-Konformation des *Cyclo*hexans oder des Tetrahydropyrans stehen 1—4, 2—5, 3—6, also *para* Substituenten paarweise in *cis* Stellung, wenn die Anknüpfung e, a oder a, e ist, in *trans* Stellung, wenn die Anknüpfung e, e oder a, a ist [2].

I. Physikalisch - chemische Methoden

Schmelzpunkte (Tab. 1). Bekanntlich hat eine *trans*-Äthylenverbindung einen höheren Schmelzpunkt als die isomere *cis*-Verbindung. Erweitert man die Doppelbindung zu einem *Cyclo*hexanring hat man dasselbe Bild. Selbst bei hexa- und pentasubstituierten *Cyclo*hexanen gilt diese Regel: Eine Verbindung mit einer höheren Anzahl von *para-trans*-Substituenten hat einen höheren Schmelzpunkt als die isomere Verbindung mit einer geringeren Anzahl. In Verbindungen mit einem Tetrahydropyranring wie Methyl- und Äthyl-Glycoside der α- und β-D-Glucose und der α- und β-D-Galactose gilt dieselbe Regelmässigkeit, wenn man der Alkoxylgruppe in den α-Derivaten eine equatoriale, in den β-Derivaten eine axiale Anknüpfung gibt. Alle α-Methyl-Glycoside der D-Aldopyranosen haben dieselbe Konfiguration bei C_1, alle β-Methyl-Glycoside dieselbe aber umgekehrte Konfiguration bei C_1 [3]. D-Glucose und D-Galactose unterscheiden sich nur durch die e- bzw. a-Anknüpfung der Hydroxylgruppe bei C_4. Diese beiden Facta bedingen, dass von den Glycosiden der D-Glucose das Glycosid mit equatorialer Alkoxylgruppe den höheren Schmelz-

punkt haben muss, während von den Glycosiden der D-Galactose das Glycosid mit axialer Alkoxylgruppe diese Position einnimmt.

Molekulare Drehung, $[M]_D$. (Tab. 2). Ersetzt man in der Ring-Methylen-Gruppe, von Monodeoxy-*Myo*inositol oder von 2-Deoxy-Glycosiden [4] von D-Glucose und D-Galactose ein Wasserstoffatom mit einer Hydroxylgruppe so steigt $[M]_D$ bei Einführung einer e-Hydroxylgruppe und fällt bei Einführung einer a-Hydroxylgruppe. Dieser Schluss lässt sich ziehen, da die e- bzw. die a-Anknüpfung der Hydroxylgruppe bei C_2 in den gebildeten Inositolen und Zuckerderivaten bekannt ist. Um ein entsprechendes Steigen oder Fallen von $[M]_D$ bei Einführung einer Hydroxylgruppe in der Ring-Methylengruppe von 1-Deoxy-D-Glucose und 1-Deoxy-D-Galactose zu erreichen, muss in der α-D-Glucose und in der α-D-Galactose die Hydroxylgruppe bei C_1 equatorial, in der β-D-Glucose und in der β-D-Galactose axial gebunden sein.

II. Biochemische und chemische Methoden

Oxydation. Bei der chemischen Oxydation einer sekundären Alkoholgruppe in einem *Cyclo*hexan-Ringsystem werden Verbindungen, welche eine a-Hydroxylgruppe tragen, schneller oxydiert als ihre Epimere, welche eine e-Hydroxylgruppe tragen [5]. Man ist der Ansicht, dass dieses Faktum darauf beruht, dass ein e-Wasserstoffatom sterisch leichter zugänglich ist als ein a-Wasserstoffatom. Bei der Oxydation von Inositolen und Monodeoxy-Inositolen durch *Acetobacter suboxydans* hat man gewisse Relationen zwischen Oxydabilität und Konstitution ableiten können [6]. In diesem Zusammenhang ist der wichtigste Punkt, dass in der vorgezogenen Konformation nur sekundäre Alkoholgruppen mit einer a-Hydroxylgruppe oxydiert werden. Durch Sauerstoff und Platinoxyd wird in *Myo*inositol dieselbe sekundäre Alkoholgruppe oxydiert als durch *Acetobacter suboxydans*.

Glucoseoxydase [7] ist ein specifisch wirkendes Enzym, es oxydiert α-D-Glucose zu D-Glucono-δ-Lacton, während es α-D-Glucose kaum angreift [8]. Die Oxydation von D-Aldohexosen durch Bromwasser zu δ-Lactonen, verläuft bei den β-Anomeren weit schneller als bei den α-Anomeren [9]. β-Methylglycoside werden bei C_1 durch Chlorwasser oxydiert, α-Methylglycoside langsam oder nicht [10].

Wenn es die leichtere Zugänglichkeit eines e-Wasserstoffatoms ist, welche die Oxydationsgeschwindigkeit von Derivaten von sowohl *Cyclo*hexan als von Tetrahydropyran bestimmt, müssen β-Verbindungen der Zucker am glycosidischen Kohlenstoffatom ein e-Wasserstoffatom tragen, da β-Verbindungen ja weit schneller oxydiert werden als die anomeren α-Verbindungen. β-D-Glucose und β-Methylglucosid haben demnach eine axiale Hydroxylgruppe oder Methoxylgruppe bei C_1.

Hydrolyse von 1,2-Anhydro-D-Glucose. 1,2-Anhydro-D-Glucose-3,4,6-triacetat wird Brigl-Anhydrid [11] genannt. Es enthält einen Äthylenoxyd- oder Epoxyd-Ring. Sowohl in *Cyclo*hexan- als in Tetrahydropyransystemen haben Epoxydringe einen a- und einen e-Brückenkopf. 1,2-Anhydro-D-Glucose hat bei C_2 einen e-Brückenkopf und muss daher bei C_1 einen a-Brückenkopf haben. Bei lang andauerndem Erhitzen (16—104 St.) auf 100° oder 120° addiert das Brigl-Anhydrid verschiedene Verbindungen unter Bildung von α-Glucosiden (Maltose, α,α-Trehalose, Saccharose). Die Ausbeute ist meistens nur gering. Das Brigl-Anhydrid addiert Alkohole mit ausserordentlicher Leichtigkeit. Die Reaktionsprodukte sind sterisch einheitliche β-D-Glucoside. Aus dem Brigl-Anhydrid werden also einerseits α-Glucoside andererseits β-Glucoside gebildet. Eine der Reaktionen muss unter Umlagerung verlaufen: die Frage ist: Welche? Die Umsetzung mit Carbinol verläuft schon bei Zimmertemperatur in wenigen Stunden quantitativ [12]. Unter diesen milden Bedingungen erscheint eine Umlagerung unwahrscheinlich. Es gibt nur eine plausible Erklärung: β-Methyl-D-Glucosid wird ohne Umlagerung gebildet; es hat eine axiale Methoxylgruppe.

Das *Resultat* dieser Untersuchungen steht im Widerspruch mit der heutigen Anschauung. Auf Grund der Übereinstimmung der Ergebnisse mehrerer von einander unabhängigen Methoden möchte ich schon jetzt die Resultate meiner Untersuchungen als "kurze Mitteilung" veröffentlichen. Ein ausführlicher Bericht wird in *Acta Chem. Scand.* erscheinen.

Column Electrophoresis of Nucleotides from Ribonucleic Acid of Brain Microsomes

NORA FRONTALI*

Institute of Biochemistry, University of Uppsala, Sweden

Analysis of the nucleotide composition of ribonucleic acids (RNA) is usually accomplished by ion exchange chromatography or by paper electrophoresis. This latter technique is extremely simple and quick, but it allows the handling of only limited amounts of material. In the present work column electrophoresis has been used, and has proved a good tool for this purpose. It has been employed for analysing the nucleotide composition of RNA from brain microsomes, which are similar to liver and pancreas microsomes in showing a high content of RNA [1].

The separations were performed on a cellulose powder column according to Porath [2], and with elution beginning before the end of the electrophoretic run for better resolution [3]. Samples of hydrolysates from about 6 mg RNA were handled in the present experiments, but at least four times higher amounts can be as well separated on the same column (2 cm diameter, 70 cm length). Microsomes were prepared by

Column Electrophoresis of Nucleotides from Ribonucleic Acid of Brain Microsomes

NORA FRONTALI*

Institute of Biochemistry, University of Uppsala, Sweden

Analysis of the nucleotide composition of ribonucleic acids (RNA) is usually accomplished by ion exchange chromatography or by paper electrophoresis. This latter technique is extremely simple and quick, but it allows the handling of only limited amounts of material. In the present work column electrophoresis has been used, and has proved a good tool for this purpose. It has been employed for analysing the nucleotide composition of RNA from brain microsomes, which are similar to liver and pancreas microsomes in showing a high content of RNA [1].

The separations were performed on a cellulose powder column according to Porath [2], and with elution beginning before the end of the electrophoretic run for better resolution [3]. Samples of hydrolysates from about 6 mg RNA were handled in the present experiments, but at least four times higher amounts can be as well separated on the same column (2 cm diameter, 70 cm length). Microsomes were prepared by

* Permanent adress: Istituto Superiore di Sanità, Rome.

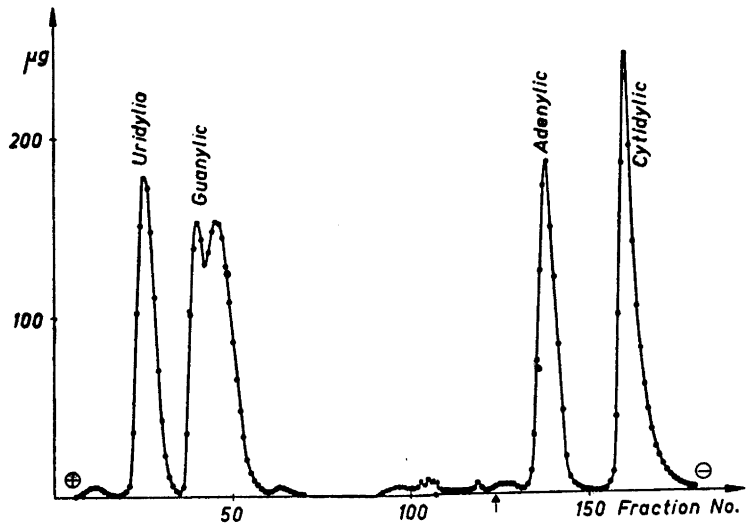

Fig. 1. Electrophoresis of an alkaline hydrolysate of RNA from brain microsomes on a 2 × 70 cm cellulose column with continuous elution device; 0.05 ammonium formate buffer, pH 3.5; 750 V, 22 mA. (Rubber or plastic joints or tubing were avoided as far as possible, as they were found to release UV absorbing material in the formate buffer.) Elution was started after 22 h, collecting fractions of 5 ml every 20 min for 19 h, fractions of 3 ml every 30 min for the next 20 h, and then fractions of 4 ml every 60 min till the end of the electrophoretic run, which lasted 88 h. From that point, marked by an arrow, elution in the usual way was started. The pattern is expressed as μg present in each fraction.

differential centrifugation from a homogenate of rat brain in 0.25 M sucrose. The fraction sedimenting between 18 000 × *g* (15 min) and 105 000 × *g* (60 min) was immediately precipitated with trichloroacetic acid (10 % final concentration). The precipitate was washed with trichloroacetic acid and extracted thoroughly with organic solvents. All these operations were performed keeping the temperature as close as possible to 0°, in order to minimize any possible enzymic RNA hydrolysis. The dry precipitate was hydrolysed with 0.3 M KOH at 37° for 18 h. The hydrolysate was neutralized with perchloric acid, and deproteinized by adding more perchloric acid (0.4 M final concentration). The supernatant after centrifugation was neutralized with KOH, and the perchlorate which precipitated overnight at −5° was discarded. This supernatant was used for electrophoresis, either as such or after freeze-drying.

The results of one electrophoretic separation with 0.05 M ammonium formate buffer pH 3.5 are shown in Fig. 1. The peaks of the four nucleotides, which have been identified from their relative mobilities in comparison with pure compounds, and from their spectra, are completely separated under these conditions. There is in addition an incomplete separation of the two isomers of guanylic acid, as has already been observed by paper electrophoresis at the same pH [4]. The small peaks are probably formed by a small aliquot of oligonucleotides.

The spectrophotometric measurement of the optical densities at 260 mμ of the fractions collected permitted the calculation of the relative amounts of the four nucleotides, as reported in Table 1. The extinction coefficients given by Beaven *et al.*[5] were used. The total sum accounts for 90 % of the total nucleotide content of the original hydrolysate, calculated according to Scott *et al.*[6] If the minor peaks are also taken into account, and their amount approximately calculated with the same factor, then the recovery is 94 %. The table reports for

Table 1. Nucleotide composition (in moles per 100 moles) of RNA of brain microsomes, compared with data on other tissues.

	rat brain microsomes	cat brain Ref.[7]	calf thymus microsomes *Ref.[8]*	rat liver Ref.[9]
Uridylic acid	19.7	20.6	19.3	20
Guanylic acid	32.5	31.8	33.6	32
Adenylic acid	18.1	21.6	19.1	21
Cytidylic acid	29.7	26.0	28.0	28

* These data have been recalculated, in order to render them comparable.

comparison the only available data on brain RNA [7]. They concern a purified preparation of RNA, obtained from slices of tissue after prolonged incubation. The way of preparation, besides the difference in species, can be the reason for the difference in nucleotide composition. The table reports also some recent data obtained by other authors who have performed, as we have done, direct hydrolysis of the RNA-protein. Although they concern different tissues, they show a close similarity with the present data on brain microsomes.

The fractions corresponding to each peak were pooled and lyophilized twice, in order to remove the ammonium formate. The dry powders, redissolved in a small volume, were used for further analysis. The four recovered nucleotides were submitted to chromatography with various solvents, in order to test their homogeneity. With the solvent *iso*butyric acid-ammonia [10] the uridylic acid gave rise to an additional spot. Its spectrum and chromatographic behaviour correspond to those of the "fifth nucleotide" described by Davis and Allen [11].

The same nucleotides were submitted to electrophoresis on paper at pH 2.5. One new spot separated ahead of guanylic acid. When a sample of guanylic acid was submitted to electrophoresis at similar conditions on a small cellulose column, a small faster migrating peak separated, as can be seen in Fig. 2. Its amount, calculated with the same extinction coefficient as guanylic acid, is 2.3 % of the total guanylic acid, and its spectrum is similar to that of the unknown component 1 B obtained by Kemp and Allen [12] by paper electrophoresis at pH 2.5 of guanylic acid from pancreas RNA.

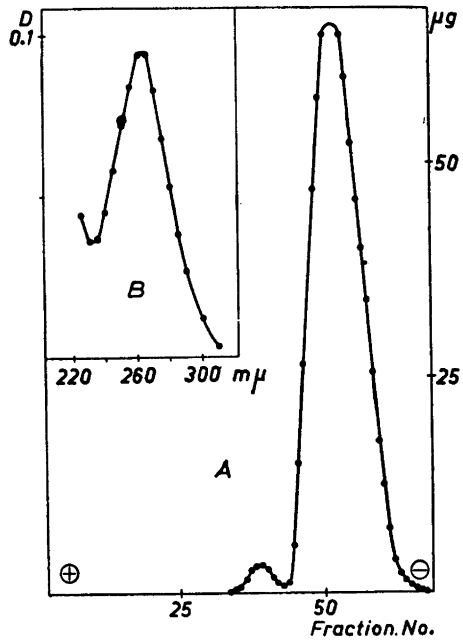

Fig. 2. a) Electrophoresis of brain RNA guanylic acid on a 2 × 18 cm cellulose column, with 0.2 M ammonium formate buffer pH 2.5; 600 V, 70 mA. The elution (5 ml every 5 min) was completed during the electrophoretic run, which lasted 6 h. b) Spectrum of the small, faster migrating peak obtained in a).

Paper electrophoresis of the four nucleotides was performed in borate buffer pH 9.2. One slower migrating compound separated from uridylic acid. It was present also in uridylic acid already deprived from the "fifth nucleotide" by chromatography.

The author wishes to express her gratitude to Dr. J. Porath for constant interest and advice.

Adenosine Triphosphatase in Chloroplasts

HERRICK BALTSCHEFFSKY

Wenner-Gren Institute, University of Stockholm, Sweden

The following two hypotheses are strongly supported by experimental evidence. 1. Light-induced phosphorylation (LIP) is an electron transport phosphorylation [1,2]. 2. The ATP-ase * reactions in mitochondria mirror oxidative phosphorylation (OP) reactions, in the reverse direction, going from ATP towards the electron transport chain [3].

Assuming that hypothesis 1 is correct, the question arises as to what extent similar or identical mechanisms are operating in the generation of ATP in OP and in LIP. Assuming that hypothesis 2 is correct, an investigation of the ATP-ase reactions in LIP systems should give information about the possible similarity between the two phosphorylation mechanisms.

Of the two known LIP systems, plant chloroplasts and bacterial chromatophores, the former have been obtained free from respiratory activity. In spinach, the most investigated plant, this activity is found in the mitochondria, which can be removed. In the photosynthetic bacteria, those fractions which show LIP have not yet been obtained free from the respiratory system. Thus the ATP-ase activity found in these bacteria [4-6] may reflect, at least partly, the OP rather than the LIP system.

A study was made of the ATP-ase activity in isolated spinach chloroplasts. They were prepared ** by the method of Allen, Whatley and Arnon [7]. Chloroplasts, freed of mitochondria, do not respire, according to these authors. In agreement with this, the oxygen uptake was zero with succinate as substrate and very low with DPNH. Arnon [8] has reported that the chloroplasts seem to be rather free of ATP-hydrolyzing enzymes. We obtain, however, a considerable ATP-ase activity in the presence of added Mg++.

The Mg++-dependent ATP-ase activity of whole chloroplasts and chloroplast fragments, prepared as in Ref.[8], and the strong inhibition caused by atebrin are shown in Table 1. Löw [9-11] has shown that atebrin and chloropromazine inhibit mitochondrial Mg++-activated ATP-ase and that some other ATP-hydrolyzing enzymes, which are not connected with electron transport systems, are unaffected. 1 mM chloropromazine gave about 85 % inhibition with chloroplast fragments.

Table 1. Mg++-dependent ATP-ase in spinach chloroplasts. Medium: 0.3 ml 0.1 M tris-(hydroxymethyl)aminomethane pH 7.5, 10 μmoles ATP, 8 μmoles $MgCl_2$. Where added: whole chloroplasts or chloroplast fragments equivalent to 0.5 mg chlorophyll, 14 μmoles atebrin. Final volume 2 ml, 20 min incubation, 30°C. Phosphate was measured according to Lindberg and Ernster [12].

Adenosine Triphosphatase in Chloroplasts

HERRICK BALTSCHEFFSKY

Wenner-Gren Institute, University of Stockholm, Sweden

The following two hypotheses are strongly supported by experimental evidence. 1. Light-induced phosphorylation (LIP) is an electron transport phosphorylation [1,2]. 2. The ATP-ase * reactions in mitochondria mirror oxidative phosphorylation (OP) reactions, in the reverse direction, going from ATP towards the electron transport chain [3].

Assuming that hypothesis 1 is correct, the question arises as to what extent similar or identical mechanisms are operating in the generation of ATP in OP and in LIP. Assuming that hypothesis 2 is correct, an investigation of the ATP-ase reactions in LIP systems should give information about the possible similarity between the two phosphorylation mechanisms.

Of the two known LIP systems, plant chloroplasts and bacterial chromatophores, the former have been obtained free from respiratory activity. In spinach, the most investigated plant, this activity is found in the mitochondria, which can be removed. In the photosynthetic bacteria, those fractions which show LIP have not yet been obtained free from the respiratory system. Thus the ATP-ase activity found in these bacteria [4-6] may reflect, at least partly, the OP rather than the LIP system.

A study was made of the ATP-ase activity in isolated spinach chloroplasts. They were prepared ** by the method of Allen, Whatley and Arnon [7]. Chloroplasts, freed of mitochondria, do not respire, according to these authors. In agreement with this, the oxygen uptake was zero with succinate as substrate and very low with DPNH. Arnon [8] has reported that the chloroplasts seem to be rather free of ATP-hydrolyzing enzymes. We obtain, however, a considerable ATP-ase activity in the presence of added Mg++.

The Mg++-dependent ATP-ase activity of whole chloroplasts and chloroplast fragments, prepared as in Ref.[8], and the strong inhibition caused by atebrin are shown in Table 1. Löw [9-11] has shown that atebrin and chloropromazine inhibit mitochondrial Mg++-activated ATP-ase and that some other ATP-hydrolyzing enzymes, which are not connected with electron transport systems, are unaffected. 1 mM chloropromazine gave about 85 % inhibition with chloroplast fragments.

Table 1. Mg++-dependent ATP-ase in spinach chloroplasts. Medium: 0.3 ml 0.1 M tris-(hydroxymethyl)aminomethane pH 7.5, 10 μmoles ATP, 8 μmoles $MgCl_2$. Where added: whole chloroplasts or chloroplast fragments equivalent to 0.5 mg chlorophyll, 14 μmoles atebrin. Final volume 2 ml, 20 min incubation, 30°C. Phosphate was measured according to Lindberg and Ernster [12].

	μmoles P liberated/h/mg chlorophyll
Whole chloroplasts	9
» » + atebrin	0.7
Chloroplast fragments	9
» » + atebrin	0.4

* Abbreviations: P, orthophosphate; ATP, adenosine triphosphate; ATP-ase, adenosine triphosphatase; DPNH, reduced diphosphopyridine nucleotide; M, moles per liter.

** Many thanks are due to Dr. M. B. Allen for showing the author how to isolate spinach chloroplasts.

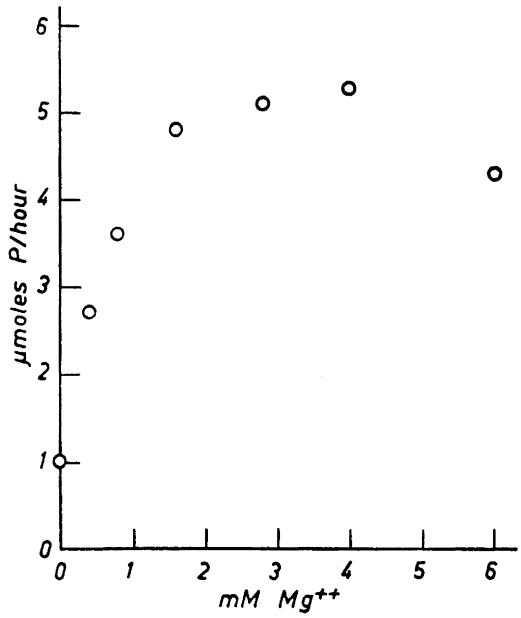

Fig. 1. Conditions as for Table 1, except that $MgCl_2$ was added as is shown in the figure, the amount of chloroplast fragments in each sample was equivalent to 0.68 mg chlorophyll and the incubation time was 30 min.

The requirement of added Mg++ is shown in Fig. 1. The chloroplast fragments used had been given two extra washings before the fragmentation in order to remove even more efficiently any mitochondrial contamination. No oxygen uptake was obtained with these fragments. The ATP-ase activity was optimal with 4 mM Mg++ and it was of roughly the same magnitude as after only one washing.

2,4-Dinitrophenol had no effect on the ATP-ase, neither in the presence nor in the absence of added Mg++.

The results reported show that isolated spinach chloroplasts exhibit a Mg++-dependent ATP-ase activity. As revealed by its sensitivity to atebrin and chloropromazine this reaction is similar to the Mg++-dependent ATP-ase of animal mitochondria. It is tempting to think that the ATP-ase found in chloroplasts is connected with LIP and that the results obtained support both hypotheses 1 and 2, showing a similarity between the phosphorylation mechanisms in OP and LIP.

Acid-Soluble Nucleotides in the Unfertilized Eggs of the Sea-Urchin *Paracentrotus lividus*

ROY NILSSON

Department of Zoophysiology, University of Lund, Sweden

The acid-soluble nucleotides of the unfertilized eggs of the sea-urchin *Paracentrotus lividus* have been analysed by ion-exchange and paper chromatography. The following compounds have been identified: AMP*, ADP, ATP, GMP, GDP, GTP, UMP, UDP, UTP, CMP, CTP and inosine. An UDP-derivative and two compounds containing CMP have not been fully identified.

In their recent work on the RNA and DNA content of the sea-urchin embryo during early embryonic life Agrell and Persson [1] have also studied the variations in the acid-soluble nucleotide fraction. Only optical densities in the ultraviolet were measured and no attempt was made to identify the components of this fraction. Other authors, however, have identified some of the nucleotide compounds in the unfertilized echinoderm egg. Chambers and Mende [2] have shown by the use of barium-precipitation and differential spectrophotometrical methods that the eggs of *Asterias forbesii* and *Strongylocentrotus dröbachiensis* contain ATP, ADP, and AMP. Whithley [3] using the same methods found that *S. purpuratus* contains ATP and White and Chambers [4] have shown that purified actomyosin dephosphorylates the calcium salt derived from the trichloroacetic acid extract of *Arbacia punctulata*. The methods hitherto applied do not, however, separate similar components, especially those occuring in small amounts; these disadvantages can be overcame by the use of chromatographic methods. In a recent analysis by ion-exchange chromatography of embryos of *Psamechinus miliaris* the presence of uridine- and guanosine derivatives as well as adenosine compounds was

* AMP = 5′-adenosinemonophospate
ADP = 5′-adenosinediphosphate
ATP = 5′-adenosinetriphosphate
GMP = 5′-guanosinemonophospate
GDP = 5′-guanosinediphosphate
GTP = 5′-guanosinetriphosphate
UMP = 5′-uridinemonophosphate
UDP = 5′-uridinediphosphate
UTP = 5′-uridinetriphosphate
CMP = 5′-cytidinemonophosphate
CTP = 5′-cytidinetriphosphate
TMP = 5′-thymidinemonophosphate
RNA = ribonucleic acid
DNA = deoxyribonucleic acid

demonstrated [5]. The present paper is concerned with an analysis of the acid-soluble nucleotides from sea-urchin eggs by ion-exchange and paper chromatography.

MATERIAL AND METHODS

The sea-urchin species used was *Paracentrotus lividus* collected at *Station Biologique Roscoff*. Most of the animals were of a shallow water form taken at low water; some were a deep water form taken from outside the harbour of Roscoff. The ovaries were placed in beakers containing sea water where the eggs were shed. The egg suspension was filtered through gauze to remove the rests of the ovaries. The eggs were then washed several times (4—5) with sea-water and then twice with a solution of 3.5 % sodium chloride. Before the last washing samples were taken for the counting of the eggs. The last washing was ended by gentle centrifugation (200 g for 2 min) to concentrate the eggs.

Preparation of the acid extract. The washed egg suspension was homogenized in a glass homogenizer or a Waring blendor with an equal volume of 10 % cold trichloroacetic acid and filtered through Hyflo Supercel. The extraction was repeated three times with 5 % trichloroacetic acid. The filtrates were pooled and extracted 6 times with ether to remove the bulk of the trichloroacetic acid, neutralized with a few drops of ammonia and freed from ether by aeration. All operations were performed in the cold (1—2°C).

Ion-exchange chromatography. Dowex-1 (200—400 mesh) in the formate form was used. The pH of the solution to be chromatographed was brought to 9—11 by addition of ammonia. After adsorption the column was washed with water to neutrality and elution was performed by the formic acid — sodium formate system previously used [6]. The effluent was fractionated by a time-operated fraction collector. The optical density of every fraction was read at 250, 260 and 270 mμ. Appropriate fractions were pooled and the nucleotides were concentrated by adsorption on norite from acid solution followed by elution with 50 % ethanol containing 1 % ammonia.

For re-chromatography of some of the most complex fractions obtained in the formate system, a chloride system was used [7], it having been found that nucleotides with identical or very similar elution positions in the formate system were generally well separated in the chloride system.

Paper chromatography. For determination of the purine or pyrimidine components in the different nucleotide fractions one dimensional chromatography in *iso*propanol-hydrochloric acid-water (98:25:27) was used after hydrolysis of the fraction in N hydrochloric acid at 100°C for one hour. For identification of the unhydrolysed fractions they were chromatographed in at least three different solvent systems, in general the following: propanol-ammonia (*d* 0.880)-water (60:30:10), *iso*butyric acid-ammonia (*d* 0.880)-water (66:1:33) and ethanol- M ammonium acetate pH 7.5 (75:30). Descending or ascending chromatography on Whatman No 1 paper was used with developing times of 20—70 h. In some cases the chromatogram was developed twice to secure better separation. The spots were located by photography in ultraviolet light. For quantitative estimations, the spots were cut out and eluted with 0.1 N hydrochloric acid. Phosphorus was located by spraying with the molybdate reagent of Hanes and Isherwood [8]. The chromatograms were further sprayed with ninhydrine to reveal amino acids, and with anilinium hydrogen phthalate to demonstrate the sugar components.

Analytical procedures. Phosphorus was determined by the method of Allen [9]; acid-labile phosphorus was determined after hydrolysis for 10 min at 100°C in N hydrochloric acid.

Purine-bound pentose was estimated by the orcinol method according to Albaum and Umbreit [10] and pyrimidine-bound pentose by the same method after treatment of the nucleotide with bromine according to Massart and Hoste [11]. For the determination of phosphorus and pentose a Klett-Summerson photoelectric colorimeter was used with a red filter.

Optical densities were measured in a Beckman Universal Spectrophotometer, model DU or in a Hilger Uvispek Spectrophotometer. The following extinction coefficients were used: 14 500 for adenosinephosphates at 258 mμ, 10 500 for guanosine phosphates at 256 mμ, 10 080 for uridine phosphates at 262 mμ and 13 000 for cytidine phosphates at 280 mμ. The measurements were generally made in 0.1 M hydrochloric acid.

Oxidation with periodate was carried out according to Dixon and Lipkin [12].

Dephosphorylation with 5'-nucleotidase. For these experiments dehydrated venom of *Crotalus adamenteus* (Ross Allen Reptile Institute, Silver Spring, Florida) was used, following the procedure of Johnson *et al.*[13] The reaction products were identified by paper chromatography and phosphorus analysis.

Determination of the egg count. During constant stirring of the egg suspension a sample was taken with a spoon and quantitatively transferred to a graduated cylinder, where its volume was estimated. The sample was then diluted to appropriate volume from which a 2-ml sample was taken and counted under a microscope with low magnification. The values obtained from triplicate samples agreed within 5 %.

RESULTS

Most of the phosphorus in the trichloroacetic acid extract from unfertilized *P. lividus* eggs was determined as inorganic phosphate. This fraction amounts to about 60 % of the total phosphorus, with the remaining 40 % equally distributed between acid-labile and acid-stable phosphates. The analytical data are shown in Table 1.

Table 1. Determination of the phosphorus content of the trichloroacetic acid extract from unfertilized *Paracentrotus lividus* eggs.

$\mu g/10^6$ eggs				
P_0	P_{10}	P_T	$P_{10}-P_0$	P_T-P_{10}
515	735	915	220	180
537	671	791	134	120
529	707	869	178	162
612	769	982	157	213
765	1 050	1 325	285	275

The phosphorus contents of different batches of eggs are in reasonable agreement with exception of the last one, which shows a considerably higher concentration of phosphorus (Table 1). But the eggs giving this value came from sea-urchins taken from deep water while the other samples originated from the shallow water form.

The ultraviolet absorption spectrum of the neutralized trichloroacetic acid extract had a maximum around 265 mμ and a minimum around 240 mμ (Fig. 1) indicating that the extract might contain ultraviolet absorbing components other than adenosine derivatives. Paper chromatography of the hydrolysed extract in *iso*propanol-hydrochloric acid-water showed that the extract contained derivatives of adenine, guanine, 5'-uridylic acid and 5'-cytidylic acid. Spraying with ninhydrine revealed several amino acids, which impaired the quantitative evaluation of the ultraviolet absorbing spots. It was possible, however, to obtain a rough estimation of the components by two dimensional paper chromatography (Fig. 2). This figure shows strong spots corresponding to AMP, ADP, and ATP and weaker spots with R_F-values which indicate guanosine-, cytidine-, and uridine derivatives.

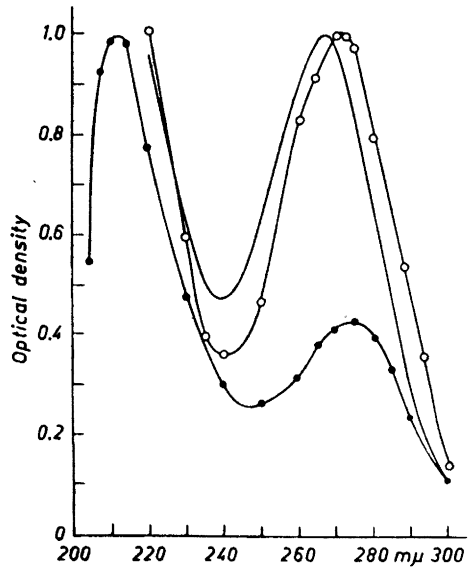

Fig. 1. Ultraviolet absorption curves 1) for the trichloroacetic acid extract from *P. lividus* eggs (—), 2) for the filtrate from the ion-exchange chromatogram of the extract (O—O) and 3) for the norite-eluate derived from the ion-exchange filtrate (●—●).

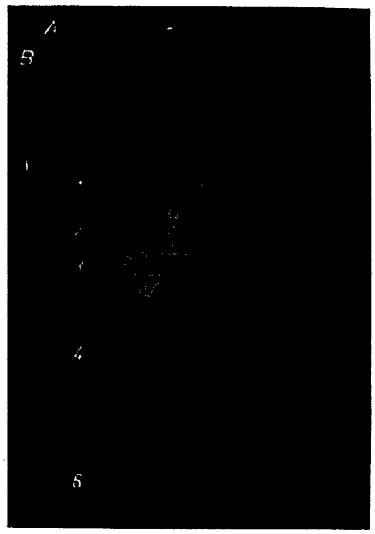

Fig. 2. Two-dimensional paper chromatogram of the extract from *P. lividus* eggs. Solvent: (A) *n*-propanol-ammonia-water (60:30:10) 72 h, (B) saturated ammonium sulphate-*iso*propanol-water (79:2:18) 12 h, Whatman No. 1 paper. (1) AMP, (2) ADP, (3) ATP, (4) guanosine derivatives, (5) uridine derivatives, and (6) cytidine derivatives.

The separation of the different components in the extract can be accomplished by ion-exchange chromatography on Dowex-1; Fig. 3 shows such a separation. While all the nucleotide material was adsorbed on the resin, most of the ultraviolet absorbing non-nucleotide components were removed in the filtrate. The present results indicate that about half of the ultraviolet absorption at 260 mμ in the acid extract is ascribable to non-nucleotide material; of an optical density at 260 mμ of 16 800 put on the column 8 600 were recovered in the filtrate and wash-water giving an ultraviolet absorption curve with a maximum around 273 mμ (Fig. 1). This fraction might contain purine and pyrimidine bases and ribosides which should be adsorbed on norite and then eluated with ammoniacal ethanol or with pyridine. Only about 40 % of the ultraviolet-absorbing material at 260 mμ from the filtrate and wash-water from the column was, however, adsorbed on norite in acid solution, and of the adsorbed material less than 10 % was eluted with 50 % ethanol (2 % ammonia) or with 25 % pyridine indicating the absence of any appreciable amounts of bases or nucleosides. Furthermore the eluates showed a strong ninhydrine reaction and an ultraviolet spectrum in 0.1 N hydrochloric

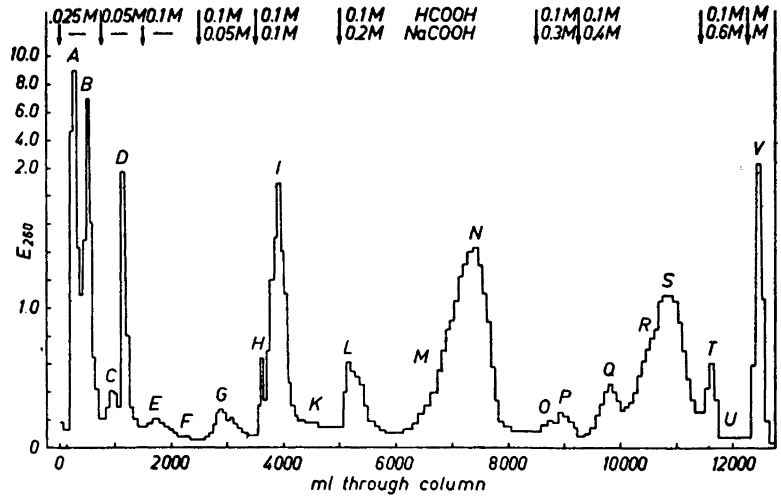

Fig. 3. Ion-exchange chromatogram of a trichloroacetic acid extract from *P. lividus* eggs on a Dowex-1 column (200—400 mesh, 2 cm² × 40 cm) in the formate system. Adsorbed material: extract with optical density E_{260} = 16 800. Recovery 103 %.

acid with maxima at 212 mμ and 275 mμ and a minimum at 250 mμ corresponding to the spectrum of tyrosine (Fig. 1).

Fractional elution of the nucleotides adsorbed on the column gave the separation shown in Fig. 3, resulting in the fractions indicated by the letters A—V. The fractions were concentrated by treatment with norite as described above. The concentrated eluates were then submitted to further analysis.

The different purine and pyrimidine components in the ion-exchange fractions were determined by paper chromatography of the hydrolysed fractions. R_F-values and ultraviolet absorption curves of the eluted spots were used for identification (Table 2).

It is clear from the table, that some of the fractions contained more than one component showing that the ion-exchange separation of the complex mixture of nucleotides in the acid extract of sea-urchin eggs had not been complete. In the first half of the chromatogram the separation was good but some overlapping had occurred between consecutive fractions, *e.g.* between B and C, C and D *etc.* In these cases complete separation could be achieved by preparative paper chromatography in the propanol-ammonia-water system. The mixture was applied to the paper as a line and after development, the formed zones were eluted with 0.01 N hydrochloric acid and concentrated by the norite-method. In those cases where it was obvious that the same components were present in more than one fraction, the eluates were pooled; in other cases the components were analysed separately. In the later part of the ion-exchange chromatogram the separation was not good, and some of the fractions were composed of a mixture of two compounds (fractions R and V)

Table 2. Paper chromatography of the hydrolysed fractions from the ion-exchange chromatogram shown in Fig. 3. R_F-values and ultraviolet-maxima of the eluted spots, together with those of authentic substances. Solvent: *iso*propanol-hydrochloric acid-water (98:25:27). Time: 24 h.

which could not be separated by paper chromatography in the propanol-ammonia system. In these cases the separation was achieved by re-chromatography of the fraction on Dowex-1 in the chloride system previously used (Fig. 4).

By these further partitions most of the fractions obtained in the original ion-exchange chromatogram could be divided into subfractions which were homogeneous in the following respects: On paper chromatography in propanol-ammonia-water they gave only one spot, their ultraviolet absorption spectra corresponded to one of the four ribosides adenosine, guanosine, uridine, and cytidine and after hydrolysis they gave only one ultraviolet absorbing spot on paper chromatography in *iso*propanol-hydrochloric acid-water (Table 3). Most of the original ion-exchange fractions were thus divided into components which were well separated and characterized at least with regard to the purine and pyrimidine part of the nucleotides. In some of the smaller fractions, however, the amounts available were not large enough to permit a final identification of the base-component. After hydrolysis fraction F gave a spot with an R_F-value identical with that of adenine; the spot, however, was too weak for determination of the ultraviolet absorption curve. The unpurified fraction did not give any definite nucleotide absorption spectrum; no maximum was obtained, only a shoulder between 250 and 265 mμ indicating the presence of a nucleotide heavily contaminated with non-nucleotide impurities. On

hydrolysis fraction C gave not only 5'-UMP but also a faint spot corresponding to TMP, and the same spot was also found when the unhydrolysed fraction was chromatographed in *iso*propanol-hydrochloric acid-water. The ultraviolet absorption curve of the eluted spot had the same shape as that of thymidine with a maximum between 265 and 270 mμ. The amount obtained was, however, too small for further analysis. Fraction A was not included in the table, as it consisted of a mixture of at least four components which could not be resolved by the propanol-ammonia-water solvent. This fraction will be dealt with separately below.

Further identification of the purified fractions was then carried out by determination of acid-labile and total phosphorus and of pentose. The results of the analyses are shown in Table 4.

Some of the fractions from Table 3 are not mentioned in Table 4. Fractions E and F could not be analysed on account of the small amounts available. Furthermore, as mentioned above, some of the consecutive ion-exchange fractions contained the same component; on paper chromatography before and after hydrolysis they thus gave one and the same ultraviolet absorbing spot. Such cases are H_1 which is identical with G, H_2, identical with I, M_2 and O identical with N and fraction R_1, identical with S. T is probably the same substance as S; it appeared as a well defined fraction as the elution solution was changed before the base absorption in fraction S was low enough. Fraction V_2 gave the same analysis and R_F-value as fraction S.

The analysis of the purified ion-exchange fractions together with the establishment of the products of hydrolysis resulted in the identification of the different nucleotide compounds with reference to the purine or pyrimidine

Table 4. Analysis of the purified fractions from the ion-exchange chromatogram shown in Fig. 3.

component and to the degree of phosphorylation. The identification was finally checked by paper chromatography in three different solvent systems together with authentic compounds. As developing systems an alkaline, an acid and a neutral solvent were used. The R_F-values in the different systems are shown in Table 5, which also gives the identification of the fractions.

Most of the fractions have been definitely identified as the nucleotides indicated in Table 5 by the analyses shown in Table 4 and by chromatography. Some of the fractions may, however, need some further comments.

Fraction C was eluted from the ion-exchange column by the same eluent as D, which it preceded as a small peak. The main component of C showed the same analytical results and the same R_p-values in four solvent systems as fraction D, a fraction in all respects identical with authentic 5′-UMP. Fraction C also contained AMP but the occurrence of thymidylic acid or some other tymidine derivative as indicated by paper chromatography after hydrolysis in *iso*propanol-hydrochloric acid-water, mentioned above, could not be confirmed by chromatography before hydrolysis in the systems used in Table 5.

On paper chromatography fractions E and F behaved like 5′-AMP but their elution positions on ion-exchange were different from that of 5′-AMP. They may possibly be labile derivatives of 5′-AMP, transformed to 5′-AMP during the working up of the original ion-exchange fractions. They cannot be 2′- or 3′- derivatives as by treatment with 5′-nucleotidase they were completely dephosphorylated to adenosine.

The peak represented by fraction H was possibly a consequence of a premature change of eluting solution resulting in a nearly equimolar mixture of H_1 identical with GMP (G) and H_2 identical with I. Fraction I appeared as a well defined peak entirely free from interfering ultraviolet absorbing compounds. It is a derivative of UDP containing ninhydrine positive components; it has not yet been fully identified. L is also a complex fraction with an analysis suggesting a mixture of several components. The fraction gave, however, only one spot on paper chromatography in the three systems mentioned above. The R_p-values corresponded to those of 5′-AMP, indicating in fraction L the presence of a compound containing the 5′-AMP moiety which probably was released by the norite treatment. ATP was found to occur in several fractions, R_1, S, T, U, and V_2. The ATP samples recovered from all these fractions were, however, in all tested respects identical with ATP isolated from muscle. It was probably the unsatisfactory resolution in the formate system of a mixture of higher phosphorylated nucleotides which was the cause of the broad elution of ATP. The separation was further impaired by the high background absorption given by non-nucleotide components present in the crude extract. If, however, an extract purified by norite treatment was used an ion-exchange chromatogram was obtained in which ATP was eluted only in fractions R and S, T and U were absent and V consisted entirely of GTP.

To complement the identification described above, the fractions were also tested to verify the position of the phosphate groups in the 5′-position. Two analytical methods were used; periodate oxidation and the action of a specific 5′-nucleotidase from snake venom. The results of the analysis are shown in Table 6.

All fractions analysed by periodate oxidation and with 5′-nucleotidase were established as 5′-phosphates; no evidence was obtained for the occurrence of 2′- or 3′-derivatives. Dephosphorylation by snake venom 5′-nucleotidase resulted — under the conditions used — in the liberation of one mole of orthophosphate per mole of mono- or triphosphate, while two moles were liberated from one mole of nucleoside diphosphate. These findings are in agreement with the results of Johnson *et al.*[13]

Table 6. Action of periodate and 5′-nucleotidase on the purified nucleotides from unfertilized *P. lividus* eggs. Oxidation with periodate: the reaction mixture contained in 0.4 ml 0.050 μmole of nucleotide and 0.100 μmole of periodate. The change in extinction at 227 mμ was read against a periodate blank and a water blank. Reaction time 45 min. Action of 5′-nucleotidase: 0.5—1.0 μmole of nucleotide, 0.5 mg of snake venom, 10 μl of 0.5 M $MgCl_2$ and 0.05 M Tris-hydroxymethylaminomethane buffer (pH 8.5) to 2 ml. After 2 h at 38—39°C the reaction mixture was cooled to 0°C and deproteinized by the addition of 0.2 ml of 50 % trichloroacetic acid. After centrifugation the supernatant was analysed for total and inorganic phosphorus. The reaction products were determined by paper chromatography in butanol-formic acid-water (77:10:13).

Fraction	Oxidation with periodate μmole		Action of 5′-nucleotidase μmole

Fraction A has hitherto only been mentioned in Table 2 where it was shown that on paper chromatography in *iso*propanol-hydrochloric acid-water the hydrolysed fraction gave three ultraviolet absorbing spots. The spot with the lowest R_F-value was not of purine or pyrimidine type since it did not show any maximum in the region between 220 and 300 mμ. The second spot corresponded to hypoxanthine possibly contaminated with small amounts of adenine, according to the R_F-values and ultraviolet spectra in acid and alkali. The third spot was 5′-CMP according to R_F-values and ultraviolet maxima at 280 mμ and 270 mμ at pH 1 respectively 11.

The components of the unhydrolysed fraction A were then separated by paper chromatography in butanol-formic acid-water (77:10:13). Four spots were obtained; spot I with $R_F = 0.03$, containing cytidylic acid and ninhydrine positive compounds, spot II ($R_F = 0.15$) with hypoxanthine spectrum, spot III ($R_F = 0.28$), a faint spot with an absorption maximum around 260 mμ

and spot IV ($R_F = 0.35$), also a faint spot which on account of the spectrum — maxima at 275 mμ and 213 mμ — and its positive reaction with ninhydrine was identified as tyrosine.

From spot I 5′-CMP was isolated free from ninhydrine reactive components by paper chromatography in *iso*propanol-hydrochloric acid-water and was further characterized by its R_F-values in propanol-ammonia-water (0.22) and *iso*butyric acid-ammonia-water (0.50). Analysis of the pure fraction gave the ration of 1:1.05:0:1.07 for cytosine:pentose:labile phosphate:total phosphate. Furthermore, a consumption of 0.98 moles of periodate per mole base was obtained and on treatment with 5′-nucleotidase 1.00 mole orthophosphate was released with cytidine as the other reaction product. As mentioned above, small amounts of cytidine compounds were also found in fractions B, C, and D and in two other ion-exchange chromatograms larger amounts of three cytidine derivatives were eluted before AMP. One of these was 5′-CMP; on hydrolysis the other two gave 5′-CMP but before hydrolysis they moved differently from 5′-CMP on paper chromatography in ethanol-ammonium acetate (pH 7.5). Both these substances contained phosphorus and pentose and are possibly cytidine derivatives of the type reported by Baddiley *et al.*[14] and by Kennedy and Weiss.[15] Further identification of these compounds had to be postponed.

Spot II obtained from fraction A was identified as inosine. The R_F-values obtained by paper chromatography in four different solvent systems, — propanol-ammonia-water $R_F = 0.35$ (0.36), butanol-formic acid-water (77:10:13) $R_F = 0.15$ (0.15), butanol saturated with 10 % urea $R_F = 0.18$ (0.19) and ethanol-M ammonium-acetate pH 7.5 $R_F = 0.31$ (0.30) — were the same as those of authentic inosine, shown within the brackets. The ultraviolet spectrum of the eluted spot in acid and alkali was identical with that of inosine. The ratio 1:0.95 was obtained for hypoxanthine and pentose; no phosphorus was found. In the same way, spot III was identified as adenosine.

Extracts from four different batches of unfertilized sea urchin eggs were analysed by ion-exchange either as the crude extract (3) or after treatment

with norite and with essentially the same results. The amounts of the nucleotide derivatives obtained are shown in Table 7.

The nucleotide content had the following general pattern: nearly one half of the nucleotides consists of adenosine derivatives (49 %) and the other half of equal amounts of uracil- and cytosine compounds (22 % respectively 17 %) and a smaller quantity of guanine nucleotides (10 %).

Even if adenine nucleotides dominate, the distribution of the nucleotides from the different purine- and pyrimidine base is fairly even. The pattern of acid-soluble nucleotides is quite different from that of *e.g.*, skeletal muscle [16] and the body wall musculature of *Annelida* [6] where the nucleotide fraction consists of adenine compounds to 90 %, or from that of the oviduct of the hen which has a high content of uridine nucleotides [17]. Muscle and the oviduct may be taken as examples of organs with a higly specialized function, a function which is reflected in the nucleotide composition; in muscle, which for its work needs easily accessible energy, adenine nucleotides, especially ATP, predominate, while the oviduct — whose main function is thought to be the synthesis of glycoproteins containing hexosaminederivatives — has a high content of uridine compounds, particularly in the form of different UDP-derivatives, which are thought to participate in the biosynthesis of mucopolysacharides.

As an example of reversed conditiones, *i.e.* an organ with a variety of functions, the liver can be taken. The more even composition of the nucleotide fraction of the liver [16] with regard to the different purines and pyrimidines, compared with that of the muscle and the oviduct, may be taken as a consequence of the multiplicity of functions.

Even the unfertilized egg which shall develop into a complex organism, has to have a manifold equipment of different nucleotides as a consequence of the multiplicity of processes essential for the differentiation and development of the embryo. Interesting is the occurrence of rather large amounts of cytosine derivatives, a type of nucleotides until recently not found to be present in biological material in higher concentrations. Kennedy and Weiss isolated different cytidine nucleotides from the liver of the hen and the rat, and have also shown that these compounds take part in the biosynthesis of phospholipids [15]. Furthermore, in a preliminary note Sugino *et al.*[18,19] have reported the occurrence of deoxycytidine derivatives in several organisms, among others in sea-urchin eggs. The unidentified cytosine compounds in the present investigation may consist of similar substances.

The only nucleosides found in the ion-exchange fractions were inosine and traces of adenosine. Part of the ultraviolet absorbing compounds from the extract was, however, not retained by the ion-exchange column; bases and nucleosides could be included in this fraction. But, as mentioned above, the major part of the ultraviolet absorption in the filtrate and wash water from the column consisted probably of amino acids and the only purine or pyrimidine compounds found were small amounts of substances — detected by paper chromatography — with spectra resembling those of uracil and cytosine. Therefore it seems unlikely that the unfertilized sea urchin egg contained larger amounts of free bases and nucleosides.

The further identification of the unknown fractions and the variations in nucleotide content during the mitotic cycle and the early development of the sea-urchin embryo is receiving attention.

I wish to thank the staff of the *Station Biologique, Roscoff*, for their kind help in supplying the sea-urchin material. I also wish to thank Laborator A. Deutsch, Statens Mejeriförsök, Alnarp, for valuable discussions.

The Degradation Product from Male Sperm Antagglutin with Molten Potassium Bisulphate

SVANTE ROSS

Institute of Zoophysiology, University of Uppsala, Sweden

The degradation product from male sperm antagglutin with molten potassium bisulphate has been compared with the corresponding products from some model compounds, especially tocopherols and hydroquinone. Some reactions taking place in the molten potassium bisulphate have been studied. The chemical structure of the antagglutin product has been discussed.

Male sperm antagglutin, a substance which in mammalian spermatozoa [1,2], prevents head-to-head agglutination, is a proteid containing sugar [2], sulphuric acid residues [3], and a further component which, probably in a somewhat modified form has been sporadically extracted with ethyl ether from antagglutin preparations. Judging from its ultra-violet spectrum this extractable artefact seems to be an aromatic compound of diphenolic character. It is easily oxidized to a quinone-like substance [4,5].

Heating of male sperm antagglutin in molten potassium bisulphate at 220°C gives a product which is soluble in ethanol and water, and which after oxidation shows a rather high optical density in ultra-violet light with a maximum at 256 mμ. The transformation of the antagglutin into this oxidized compound has been used as a method for quantitative determination of male sperm antagglutin [6]. This oxidized product is very similar to the oxidized form of the above mentioned aromatic substance which was extracted from the antagglutin solutions. As this degraded substance is rather easily formed under controlled conditions, experiments have been performed in order to obtain information about its properties and its precursor in the antagglutin molecule. Unfortunately the formed product is very easily further oxidized and therefore difficult to isolate. For this reason some model substances have been treated in the same way as the antagglutin, and the properties of the obtained products compared with those of the product from antagglutin. Some information about the chemical reactions that may occur in the molten potassium bisulphate have also been obtained from this model experiments.

EXPERIMENTAL AND RESULTS

The treatment of the male sperm antagglutin and the model substances with molten potassium bisulphate has been performed according to the method of quantitative determination of male sperm antagglutin [6], but with some modifications: about 1—3 μg male sperm antagglutin or 0.1—1 mg of the model substance is mixed with a large quantity (1—2 g) of dried, ether-extracted potassium bisulphate. This is done in a test tube with a diameter of one cm and a length of six cm. This reaction tube is placed in a bigger tube in which it is held upright by a layer of glass beads at the bottom. The bigger tube is immersed for one hour into an oil bath of 220°C. After cooling the reaction tube is cleaned externally with ethyl ether, and then reduced to powder in a mortar together with its contents. The powder is extracted with 3 ml of absolute ethanol in a centrifuge tube with a glass stopper. The centrifugated ethanol extract is evaporated under vacuum at 50°C, and the residue extracted several times with 3 ml of freshly distilled, dried ethyl ether. The residue in the distillation flask is taken up in 3 ml of absolute ethanol or distilled water, and its absorption spectrum in ultra-violet light read, especially between 250 and 260 mμ, where the degradation product from male sperm antagglutin has a maximum at 256 mμ. In some cases manganese dioxide is added to the powder during the extraction in order to act as an oxidizing agent, but in other cases the oxidation is performed through aeration in presence of platinum black. A Beckmann DU spectrophotometer was used for the absorption readings.

Hydroquinone disulphonic acid has been synthetized according to v. Hesse [7]. The identity and purity of the obtained product was acertained spectrophotometrically. The other chemicals used are commercial preparations of *pro analysi* purity.

Besides the male sperm antagglutin only few of the tested compounds give products after treatment with molten potassium bisulphate which have absorption maxima at 256 mμ (Table 1), *viz.* α- and δ-tocopherol on the one side, and hydroquinone and some substances which in molten potassium bisulphate may be transformed into hydroquinone, on the other.

The absorption maximum at 256 mμ of the degradation product from male sperm antagglutin disappears, when the solution is made alkaline, but reappears again when the solution is acidified (Fig. 1). The absorption maximum also disappears after hydrogenation with hydrogen and a quantity of platinum black, but reappears after aeration of this solution. The compound with absorption maximum at 256 mμ is very easily oxidized, and the maximum is then

irreversibly lost. The degraded product from antagglutin is soluble in water and ethanol, but not in ethyl ether (Table 2).

The products from α-tocopherol and its acetate and phosphate-esters and δ-tocopherol after treatment with molten potassium bisulphate have the same properties as those of the degradation product from male sperm antagglutin (Fig. 2 and Table 2). The yields of the products are, however, very poor, only about one hundreth (w/w) of that of the degraded product from antagglutin. Trials to isolate the product from α-tocopherol have failed owing to its sensitivity to further oxidation.

From Table 1 it is obvious that hydroquinone as well as compounds that in molten potassium bisulphate may be transformed into hydroquinone, like quinic acid, inositol, and 2,5-dihydroxybenzoic acid, give a product with an absorption maximum at 256 mμ (Fig. 3:I). With these compounds also a maximum at 312 mμ is obtained which has never been observed with the products from antagglutin or the tocopherols. This absorption maximum at 312 mμ is identical with that of hydroquinone disulphonic acid (Fig. 3:II) which after oxidation with manganese dioxide in 80 % ethanol gives a compound with an absorption maximum at 256 mμ (Fig. 3:III).

This compound is *p*-benzoquinone disulphonic acid, the dipotassium salt of which in aqueous solution at pH 4 has a molar extinction at 256 mμ of about 14 500. Hydroquinone is hence sulphonated in the molten potassium bisulphate which explains the non-solubility of the reaction product in ethyl ether (Table 2).

The product obtained from hydroquinone, although not identical with the product obtained from antagglutin, shows qualities which are similar to those of the latter (Table 2). Thus the absorption maximum at 256 mμ disappears,

Table 2. Some properties of the compounds that give products with an absorption maximum at 256 mμ after treatment with molten potassium bisulphate.

Before treatment			After treatment

when the solution is made alkaline, and reappears again, when the solution is acidified. The synthetic *p*-benzoquinone disulphonic acid likewise shows the same qualities (Fig. 4). These substances also agree in being very easily further oxidized, even at room temperature. By this reaction the absorption maxima are lost (Table 2).

DISCUSSION

The experiments with the hydroquinone group yield some information of the reactions that can take place in the molten potassium bisulphate. Sulphonation of hydroquinone in this milieu always gives the disulphonic acid. The wellknown dehydration reaction (compare the acrolein formation from glycerol in molten potassium bisulphate) occurs, when inositol and quinic acid are treated with the molten potassium bisulphate. Thus, by this treatment, an aliphatic carbocyclic structure with several hydroxylic groups can thus be transformed into an aromatic one. Sugars do not seem to react in this way (Table 1). The decarboxylation of 2,5-dihydroxybenzoic acid is certainly effected by the rather high temperature in the molten potassium bisulphate.

Of the tested compounds the products from α- and δ-tocopherol are most similar to the antagglutin degradation product. Yet it is surprising that both α- and δ-tocopherol give the same product, although there are three methyl groups in the benzene nucleus in the former, and only one in the latter substance. Durohydroquinone, that has the same benzene nucleus as α-tocopherol, does not give after corresponding treatment any product similar to the degradation product of antagglutin. It is therefore probable that the chromane structure of the α-tocopherol is at least partly retained in the product from α-tocopherol after heating in molten potassium bisulphate.

The aromatic compound of the male sperm antagglutin has been compared with tocopherols [4,5], and it has been shown that the derivative extracted from antagglutin is not identical with any of the known tocopherols [5]. It also appears most probable that this aromatic compound is an artefact originating from an aliphatic precursor constituent bound in the antagglutin molecule [5]. In fact, the intact antagglutin has no specific absorption in ultra-violet light like that of aromatic compounds.

The many resemblances between quinone disulphonic acid and the antagglutin degradation product point (Table 2) to a quinone-like structure, but no absorption maximum after reduction related to a hydroquinone has been detected. The situation of the absorption maximum of the antagglutin degradation product at 256 mμ in connection with the fact that an oxidation

is necessary in order to obtain this maximum makes it reasonable to propose that the chemical structure underlying the spectrum may be a carbonylic substance with two conjugated ethylenic bounds. The transformation in the molten potassium bisulphate of carbocyclic compounds like quinic acid and inositol into hydroquinone disulphonic acid suggests that the precursor constituent of the antagglutin degradation product and also of the extractable aromatic compound mentioned above is a carbocyclic residue with some hydroxylic groups.

Acknowledgment. The author is very much indebted to Professor P. E. Lindahl for advice and valuable discussions and for reading of the manuscript. This study was aided by grants from the *Population Council, New York*, and from the *Swedish Natural Scienes Research Council.*

The Crystal Structure of the So-Called δ-Titanium Oxide and Its Structural Relation to the ω-Phases of Some Binary Alloy Systems of Titanium *

STEN ANDERSSON

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

The crystal structure of the so-called δ-titanium oxide has been determined using X-ray powder techniques. The structure may be described as a deficient interstitial solution of oxygen in a metal atom lattice of the type present in the ω-phases of binary alloy systems of titanium.

In 1953 it was reported by Bumps, Kessler and Hansen [1] that, when titanium oxide preparations of compositions ranging from $TiO_{0.66}$ to $TiO_{0.75}$ are annealed at temperatures below 900°C, a previously unknown phase (called δ-titanium oxide) is formed in addition to the solid solution of oxygen in α-titanium and titanium monoxide. Possible formulae suggested for the δ-oxide were Ti_3O_2 or Ti_4O_3. The powder pattern with the exception of one reflexion was said to be in conformity with a tetragonal unit cell with the dimensions $a = 5.333$ Å and $c = 6.645$ Å. Schofield and Bacon [2] confirmed the data given by Bumps *et al.*

Koncz and Koncz-Déri [3] observed the formation of δ-titanium oxide when oxidizing titanium metal at low oxygen pressures within the temperature region 570—820°C. They reported a different tetragonal unit cell ($a = 3.20$ Å and $c = 5.12$ Å) and suggested the composition Ti_3O_2.

EXPERIMENTAL

In the present investigation, samples of compositions ranging from $TiO_{0.5}$ to $TiO_{1.0}$ were kept in sealed, evacuated silica tubes at temperatures between 600° and 800°C for a month. (Details about the titanium oxide specimens employed in this investigation have been given in a previous report [4].) The identification of the samples was performed by means of the X-ray powder patterns obtained in a Guinier focusing camera of 80 mm

* Research sponsored by the Office, Chief of Research and Development, U. S. Department of Army, through its European Office, under contract number DA-91-508-EUC-245.

diameter using strictly monochromatized Cu$K\alpha_1$ radiation and potassium chloride added to the specimens as an internal standard.

The intensities of the powder reflexions were measured by means of an X-ray diffractometer registering the pattern up to $2\Theta = 160°$ with Cu$K\alpha$ radiation. The specimen was diluted with gum arabic in order to avoid orientation as far as possible. The positive effect obtained in this way was strikingly demonstrated when observing the intensities of the reflexions of the Ti_2O oxide which was always present in the sample *(v. infra)*. While the latter intensities were highly anomalous when using an undiluted specimen, the addition of gum arabic lead to values close to the ideal ones.

For studying the oxide at elevated temperatures, the diffractometer was provided with an electric vacuum furnace which allowed the specimen to be heated to 1 000°C.

DETERMINATION OF THE STRUCTURE

The results of the phase analysis of the composition region $TiO_{0.5}$-$TiO_{1.0}$ reported in a previous article [4] were confirmed by the additional experiments included in the present study. Thus the δ-oxide was never obtained pure but was mixed with considerable amounts of the Ti_2O phase in preparations $TiO_{\sim 0.55}$ and with Ti_2O and TiO (low-temperature form) in samples $TiO_{0.6-0.9}$. Evidently it has not been possible to obtain the δ-oxide under equilibrium conditions.

As it was not possible to prepare single crystals of the δ-oxide, the structure determination had to be based exclusively on powder data. The specimen found to be the most suitable for this purpose was $TiO_{0.55}$. After subtracting the Ti_2O lines from the pattern given by this sample, all the remaining reflexions, which should be those of the δ-oxide, could be indexed assuming a hexagonal unit cell with the dimensions

$$a = 4.991_5 \text{ Å}, \qquad c = 2.879_4 \text{ Å}, \qquad V = 62.13 \text{ Å}^3$$

The powder pattern is given in Table 1.

The positions of the lines of the δ-oxide were not perceptibly different in samples of other gross compositions which shows that the homogeneity range of this phase must be narrow.

Table 1. The Guinier powder pattern of δ-TiO_x. Dimensions of the hexagonal unit cell: $a = 4.991_5$ Å, $c = 2.879_4$ Å.

I	$\sin^2\Theta_{obs}$	hkl	$\sin^2\Theta_{calc}$
st	0.09526	110	0.09525
st	0.10332	101	0.10331
w	0.16678	111	0.16681
m	0.19856	201	0.19856

		002	0.28623
w	0.29385	211	0.29381
w	0.38136	220	0.38100
		112	0.38148

The following structure was derived from the powder diffractogram:
Unit cell content: 3 TiO_x
Space-group: $P6/mmm$ (No. 191)
1 Ti in 1(*a*): 0,0,0
2 Ti in 2(*d*): $\frac{1}{3},\frac{2}{3},\frac{1}{2}$; $\frac{2}{3},\frac{1}{3},\frac{1}{2}$
3*x*O in 3(*f*): $\frac{1}{2},0,0$; $0,\frac{1}{2},0$; $\frac{1}{2},\frac{1}{2},0$

An attempt was made to estimate the oxygen content (x) of the δ-oxide by calculating the intensities corresponding to various values of x and comparing these data with the observed ones (*cf.* Table 2). This comparison was performed by means of an index of agreement

$$R = \frac{\Sigma \left| \sqrt{I_{obs}} - \sqrt{I_{calc}} \right|}{\Sigma \sqrt{I_{calc}}}$$

In this way the following values for R were obtained

composition	Ti	$TiO_{0.4}$	$TiO_{0.5}$	$TiO_{0.6}$	TiO
R	0.115	0.075	0.070	0.075	0.095

Table 2. Observed intensities and also calculated ones for different values of x in the formula δ-TiO_x. A temperature factor of $B = 1.2$ Å^2 was used.

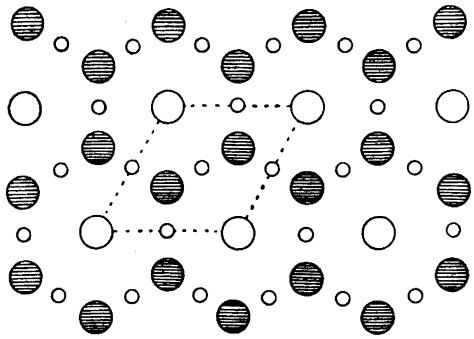

Fig. 1. The crystal structure of δ-TiO_x. Projection after c-axis. Large and small circles represent titanium and oxygen atoms, respectively. Open circles have $z = 0$ and shaded ones $z = \frac{1}{2}$. The oxygen positions are partly vacant in a random distribution.

The best fit should thus correspond to the composition $TiO_{0.5}$. The experimental evidence given above suggests a higher content of oxygen but it may be that the actual composition is not very different from $TiO_{0.5}$.

The thermal expansion of the δ-oxide, which was obtained from the diffractometer data at elevated temperatures (20°—800°C), was found to be 10×10^{-6}/°C in the *a* direction and 9×10^{-6}/°C in the *c* direction.

DISCUSSION OF THE STRUCTURE

The structure thus derived is illustrated in Fig. 1 and the interatomic distances are given in Table 3. The metal atoms of the two atomic positions have rather different environments. The Ti atom in 1(*a*) has two close Ti neighbours at a distance equal to the *c* axis (2.88 Å) and twelve additional Ti atoms at a considerably longer distance (3.22 Å) forming a hexagonal prism. Six oxygen atom positions in the equator plane of this prism occur at a distance of 2.50 Å from the central Ti atom. Each of the Ti atoms in the position 2(*d*) is situated at the common center of a trigonal Ti bipyramid, a trigonal Ti prism and a trigonal O prism (randomly defective). The distances from the central Ti atom to the various atoms of these coordination polyhedra are 2.88, 3.22 and 2.04 Å respectively. The O atoms are surrounded by six Ti atoms, four forming a square and the other two completing an elongated Ti octahedron.

A structure analogous to the one thus derived for δ-titanium oxide but with all the non-metal positions filled is represented by the ε-TaN studied by Brauer [7,8] and Schönberg [9]. The δ-oxide may evidently be considered as having a non-metal deficient ε-TaN structure.

The structure can also be described as an interstitial solution of oxygen in the metal atom structure. This metal atom structure is actually present in the ω-phases occurring in the binary systems of titanium with vanadium [5] and chromium [6]. Thus it seems natural to describe δ-titanium oxide as an interstitial solution of oxygen in a titanium structure of ω-type (ω-TiO_x).

Table 3. Interatomic distances in δ-TiO_x.

Atom	Surrounding atoms	Interatomic distances, Å
Ti in 1(*a*)	2 Ti in 1(*a*)	2.879_4
	12 Ti in 2(*d*)	3.221_4
	6 O in 3(*f*)	2.495_8
Ti in 2(*d*)	2 Ti in 2(*d*)	2.879_4
	3 Ti in 2(*d*)	2.881_8
	6 Ti in 1(*a*)	3.221_4
	6 O in 3(*f*)	2.037_6
O in 3(*f*)	4 Ti in 2(*d*)	2.037_6
	2 Ti in 1(*a*)	2.495_8

Relationships between the structure of the δ-oxide and those of other phases occurring in various titanium systems will be discussed elsewhere.

The shorter Ti-Ti distances of δ-titanium oxide (2.88 Å) are similar in length to those observed for the ordered Ti_2O structure of *anti*-$Cd(OH)_2$ type (2.85 Å) [10]. In the δ-oxide, these close metal-metal contacts are present both parallel and normal to the *c* axis. In Ti_2O the short Ti-Ti distances are inclined to the *c* axis. The similarities between the coefficients of thermal expansion observed for the δ-phase (*v. supra*) and for Ti_2O ($\alpha_c = 10.3 \times 10^{-6}$/°C and $\alpha_a = 9.2 \times 10^{-6}$/°C within the temperature range 20°—500°C) are probably connected with the occurrence of these close metal-metal contacts.

Acknowledgement. The author wishes to express his sincere gratitude to the principal investigator of this research program, Dr. Arne Magnéli, for having suggested this investigation, for his never-failing interest and for many valuable discussions.

Addition Compounds of Antimony Chlorides with Sulfoxides and Sulfones

INGVAR LINDQVIST and PALL EINARSSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The liquidus curves have been studied for the systems $SbCl_5$—$SO_2(CH_3)_2$, $SbCl_3$—$SO(CH_3)_2$ and $SbCl_3$—$SO_2(CH_3)_2$. The following new compounds have been prepared: $SbCl_5 \cdot SO(CH_3)_2$, $SbCl_5 \cdot SO(C_6H_5)_2$, $SbCl_5 \cdot SO_2(CH_3)_2$, $SbCl_5 \cdot SO_2(C_6H_5)_2$, $SbCl_3 \cdot 2SO(CH_3)_2$ and $SbCl_3 \cdot SO_2(CH_3)_2$. The melting point relations between these compounds have been discussed.

The suggestion by Groeneveld [1] that in the oxychlorides in many cases the oxygen atoms function as electron pair donors by the formation of solid addition compounds has recently been confirmed by X-ray work [2] on $SbCl_5.POCl_3$ and by infrared spectroscopy on different addition compounds [3]. These results have led to further studies of the occurrence of addition compounds which might be of the same type. It was proved by Groeneveld in his thesis that $SbCl_5$ forms 1:1 addition compounds with $SOCl_2$ and SO_2Cl_2. His results have been confirmed by us (congruent melting points of +6°C and —22°C were found). A stronger tendency to compound formation should be expected with sulfoxides and sulfones where chlorine is replaced by the less electronegative alkyl and aryl groups, resulting in a drift of electrons towards the oxygen atom and thus increasing its donor properties. We have therefore studied the system $SbCl_5$—$SO_2(CH_3)_2$ and have made additional experiments with $SO(CH_3)_2$, $SO(C_6H_5)_2$ and $SO_2(C_6H_5)_2$. As a complement the systems $SbCl_3$—$SO(CH_3)_2$ and $SbCl_3$—$SO_2(CH_3)_2$ have also been investigated, $SbCl_3$ in contrast to $SbCl_5$ being a dipole molecule.

EXPERIMENTAL

Chemicals used. $SbCl_5$ was purified by vacuum distillation and $SbCl_3$ by sublimation directly into a cool glass bulb placed 3 cm above the bulk of impure solid. $SO(CH_3)_2$ was repeatedly distilled until it had a final melting point of +19°C. The other sulfoxide and the sulfones were prepared and purified by Dr. B. Sjöberg whose help is gratefully acknowledged. They had the following melting points: $SO(C_6H_5)_2$ +70°C, $SO_2(CH_3)_2$ +108—109°C and $SO_2(C_6H_5)_2$ +125°C.

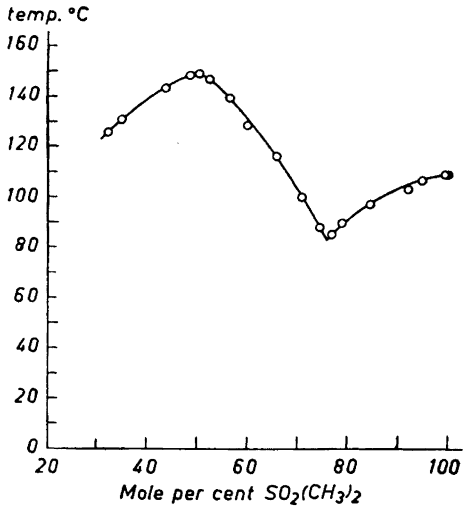

Fig. 1. The system $SbCl_5-SO_2(CH_3)_2$.

Phase diagrams. The liquidus curves were studied by the same methods as described earlier [4]. The reaction vessel was cooled down below 0°C before every addition of a reactant in order to prevent irreversible side reactions (elimination of organic halides, oxidation, *etc.*). If such precautions are not taken very vigorous reactions take place.

RESULTS

1. The liquidus curve of the system $SbCl_5$-$SO_2(CH_3)_2$ is given in Fig. 1. The addition compound $SbCl_5 \cdot SO_2(CH_3)_2$ has a congruent melting point of +149°C. This compound can also be prepared from solutions in carbon tetrachloride. The crystals are very hygroscopic.

2. Analogous compounds were also prepared with $SO(CH_3)_2$, $SO(C_6H_5)_2$ and $SO_2(C_6H_5)_2$ by melting the reactants together or by precipitation from carbon tetrachloride solutions. The melting points of the colorless addition compounds, $SbCl_5 \cdot SO(CH_3)_2$ $SbCl_5 \cdot SO(C_6H_5)_2$ and $SbCl_5 \cdot SO_2(C_6H_5)_2$ are +135 C°, +150—155°C and +141°C. The compound $SbCl_5 \cdot SO(CH_3)_2$ is partially decomposed by melting and its melting point is continuously decreasing by remelting.

3. These addition compounds can all be dissolved in ethylene chloride and in benzene. It was observed that they give colourless solutions with benzene while the corresponding addition compounds with $POCl_3$ and $SeOCl_2$ give the same kind of dark colour as $SbCl_5$ itself.

4. The liquidus curve of the system $SbCl_3$-$SO(CH_3)_2$ is shown in Fig. 2*a*. At mole fractions of $SO(CH_3)_2$ smaller than 0.60 strong supercooling prevents a reliable study of the phase diagram. The addition compound $SbCl_3 \cdot 2SO(CH_3)_2$ has a congruent melting point of +70°C. Attempts to prepare the compound by precipitation from chloroform solution ($SbCl_3$ does not dissolve in carbon tetrachloride) only led to the formation of a liquid phase dispersed as oil drops in the solution.

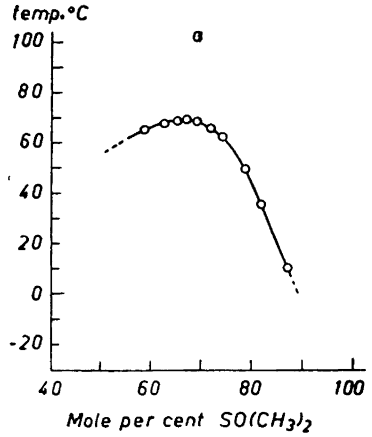

Fig. 2a. The system $SbCl_3$—$SO(CH_3)_2$.

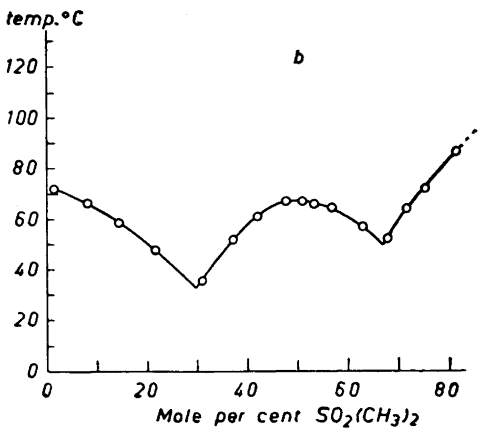

Fig. 2b. The system $SbCl_3$—$SO_2(CH_3)_2$.

5. The liquidus curve of the system $SbCl_3$—$SO_2(CH_3)_2$ is given in Fig. 2*b*. The addition compound $SbCl_3 \cdot SO_2(CH_3)_2$ has a congruent melting point of +67°C. The direct precipitation from chloroform solution offered the same difficulties as with the sulfoxide.

DISCUSSION

The melting points of compounds with appreciable dipole moments are mainly determined by two factors, the dipole moment and the mole volume. (The shape of the molecule is also of importance as it might permit or prevent particularly favourable packings of the dipole molecules. In the cases discussed here that effect will, however, probably parallel the effect of increasing volume if it is of any importance at all.) With low dipole moments the variations in the London-van der Waals attraction forces also play an important role. The effect of the two factors is clearly demonstrated in the sequence SO_2Cl_2, $SO_2(CH_3)_2$, $SO_2(C_2H_5)_2$ and $SO_2(C_6H_5)_2$ where the dipole moments are 1.80, 4.41, 4.41 and 5.04 while the melting points are —54°C, +109°C, +74°C and +125°C. The big difference in dipole moment between SO_2Cl_2 and the sulfones is reflected in a big difference in melting points. Within the sulfones with rather similar dipole moments the mole volumes are of larger importance and $SO_2(C_2H_5)_2$ has a appreciably lower melting point than $SO_2(CH_3)_2$. Of the sulfoxides only the dipole moment of $SO(C_6H_5)_2$ is known (~4), which is much larger than the value 1.44 for $SOCl_2$. The melting points are also very different: +70°C and —105°C.

If we now consider the addition compounds, the same effects should determine the melting points. (If the molecule is dissociated into one acceptor and one donor molecule by melting this is not true. In that case, with very weak acceptor-donor interaction, lower melting points might be obtained than would be expected from the total dipole moment and mole volume of the

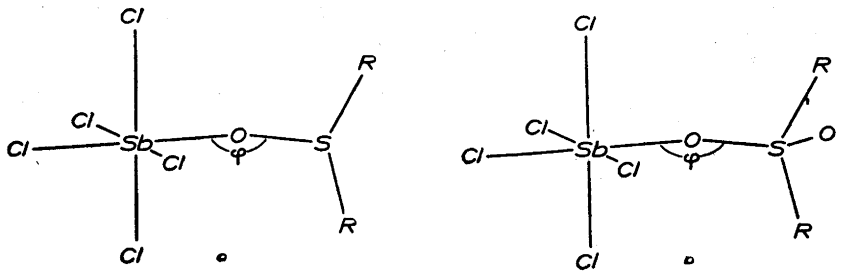

Fig. 3. *a* The probable structure of the addition compounds of $SbCl_5$ with $SOCl_2$ and the sulfoxides, *b* The probable structure of the addition compounds of $SbCl_5$ with SO_2Cl_2 and the sulfones.

addition compound molecule.) In the common case when the interaction between the complex molecules is the determining factor for the cohesion in the solid and liquid state we will first discuss the resultant dipole moment. Addition compounds with different donor molecules and the same acceptor molecule are easiest to compare. As a rule the donor molecules are not very much changed in structure by the complex formation while the acceptor molecules always are changed in shape because the acceptor atom has increased its coordination by new bonds to the donor atoms in the donor molecules. This is demonstrated in Fig. 3 for addition compounds with $SbCl_5$. The angle φ is generally not 180°. (For $SbCl_5 \cdot POCl_3$ the angle 146°5 is reported [2].) As a first approximation the dipole moment of the complex molecule is the vector sum of the dipole moments of the acceptor molecule (in the configuration which it has in the complex molecule) and of the donor molecule. The resultant dipole moment thus depends on the angle between the two vectors and it is obvious that the coupling probably will be less favourable for the sulfones than for the sulfoxides. The acceptor-donor bonds Sb-O will modify the results obtained by simple vector addition in such a way that the dipole moment is further increased by a strong acceptor-donor bond. Knowledge of the structures *and* the dipole moments might thus give information about the acceptor-donor bond. The resultant dipole moment is, however, mainly determined by the vector addition.

In the systems discussed here this would imply that the melting points of the addition compounds of $SbCl_5$ with $SOCl_2$ and sulfoxides would show a larger increase compared with the simple donor molecules than SO_2Cl_2 and the sulfones would do. The values are: +111°C for $SOCl_2$, +115°C for $SO(CH_3)_2$ and +80—85°C for $SO(C_6H_5)_2$, +32°C for SO_2Cl_2, +40°C for $SO_2(CH_3)_2$, +22°C for $SO_2(C_2H_5)_2$ and +16°C for $SO_2(C_6H_5)_2$. (The addition compound $SbCl_5 \cdot SO_2(C_2H_5)_2$ with a melting point of +96°C has been prepared by Klages [5].) The result is thus what could be expected from the simple considerations although a strong Sb—O bond might also have enhanced the effect.

With $SbCl_3$ one must also take into account the dipole moment of the free acceptor molecule (~4) and the possibility that the two dipole moments will be coupled in a very unfavourable way in the addition compound. The mole

volume increase might then be the dominating factor. The compounds $SbCl_3 \cdot 2SO(CH_3)_2$ and $SbCl_3 \cdot SO_2(CH_3)_2$ have thus both melting points below that of $SbCl_3$.

One should not try to elaborate too much on qualitative discussions of this type until the structures are known. The contribution of the London-van der Waals forces to the cohesion energy has also been considered to be equal for similar addition compounds. It is clear, however, that the strength of the acceptor-donor bond is not reflected in an obvious way in the melting point relations discussed here.

One indication about the strength of the bonds might be offered by the absence of colour in benzene solution. A dark colour is obtained with free $SbCl_5$ in benzene which readily leads to the conclusion that the acceptor-donor bond Sb-O in the addition compounds with sulfoxides and sulfones are stronger than with $POCl_3$ and $SeOCl_2$ which give a darker colour. Further studies are required, however.

An interesting feature is that $SbCl_3$ forms a 1:2 addition compound with $SO(CH_3)_2$. The same tendency for $SbCl_3$ to form 1:2 compounds has been observed in other connections. The compound $SbCl_3 \cdot 2POCl_3$ has thus been prepared [6] in contrast to only $AsCl_3 \cdot POCl_3$ described earlier [4].

This work has been sponsored by the *Air Force Office of Scientific Research of the Air Research and Development Command, United States Air Force*, through its European Office under contract No. AF 61(052)-43. This support is gratefully acknowledged.

Finally we wish to thank Professor G. Hägg for the facilities put at our disposal.

The Structures of Ni_6Si_2B, Fe_2P and Some Related Phases

STIG RUNDQVIST and FRANZ JELLINEK*

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

It has been found that the Fe_2P (*C* 22) structure previously proposed must be revised. The true symmetry is hexagonal, rather than trigonal. The phases Ni_6Si_2B, Mn_2P, and Ni_2P are isotypic with Fe_2P, but Co_2P possesses a different — orthorhombic — structure. Some structurally related phases are also discussed.

In the course of a study of the system Ni-B [1] it was observed that Ni-B mixtures containing more than approximately 35 at % of B, attack silica tubes at elevated temperatures. A ternary phase of composition Ni_6Si_2B is formed. The structure of the compound was determined and found to be very closely related to the Fe_2P structure (*C* 22-type) as proposed by Hendricks and Kosting [2], the only difference being that — while in Ni_6Si_2B the Si atoms are surrounded by 9 Ni — the corresponding P I atoms in the *C* 22-type are shifted 0.43 Å in the *c* direction in order to obtain a distorted octahedral environment. This shift lowers the symmetry of the structure from hexagonal (space group $P\bar{6}2m$) to trigonal (space group $P321$). As experimental evidence confirming this lowering of the symmetry was lacking, and the structural arguments which led Hendricks and Kosting [2] to their structure proposal are not longer very convincing, it was considered worth while to reinvestigate the structure of Fe_2P. Indeed it was found that the *C* 22-type must be revised: Fe_2P actually is isotypic with Ni_6Si_2B. The same applies to Mn_2P and Ni_2P, but for Co_2P a different structure — already determined by Nowotny [3] — was confirmed.

EXPERIMENTAL

The Ni_6Si_2B samples were prepared by heating mixtures of nickel powder (99.9 %), boron powder (99.7 %) and silicon powder (99.9 %) in evacuated and sealed silica tubes at 950°C. These mixtures did not attack the silica tubes appreciably, while mixtures of nickel and boron only, containing more than 35 at % boron attacked the tubes severely

* On leave from Anorganisch- en Fysisch-Chemisch Laboratorium der Rijksuniversiteit, Groningen, the Netherlands.

at temperatures above 900°C. The attack resulted in formation of Ni_6Si_2B, often in the form of needle-like crystals.

Fe_2P was prepared by dropping pellets of red phosphorus (99 %) into molten iron (97.5 %; main impurity oxygen). The iron was melted in an induction furnace under nitrogen atmosphere.

Weissenberg diagrams around the c axes of Ni_6Si_2B (layer lines 0—3) and Fe_2P (layer lines 0, 3, 4) were taken with MoK radiation; in the case of Fe_2P an equatorial diagram about the a axis was also made. Intensities were estimated visually. Some very weak reflexions were estimated only in a qualitative way; these were not used in the structure refinements. As the crystals used were quite small, no absorption correction was considered necessary.

Powder photographs were taken in Guinier-type cameras, using Cr$K\alpha$ (for Fe_2P, Mn_2P and Co_2P) and Cu$K\alpha$ (for Ni_6Si_2B and Ni_2P) radiations. The phosphides possess rather narrow homogeneity ranges, while in the case of Ni_6Si_2B a limited Si-B substitution was found. The unit-cell dimensions given in this paper are believed to correspond closely to the ideal compositions indicated. The accuracy of the lattice-parameter measurements is better than 0.05 %.

DETERMINATION OF THE Ni_6Si_2B STRUCTURE

The unit-cell dimensions of Ni_6Si_2B were found as $a = 6.105$ Å; $c = 2.895$ Å; $c/a = 0.4742$; $U = 93.4$ Å^3; with one formula unit in the cell. The density is calculated to be 7.45 g.cm^{-3}.

An inspection of the Weissenberg diagrams showed that — apart from normal decline — the intensities of ($hk2$) reflexions are the same as those of the corresponding ($hk0$) reflexions, while the same holds for ($hk3$) and ($hk1$). This indicates that all atoms (except possibly B) are arranged in layers with $z = 0$ and $z = 1/2$, respectively. Therefore, a Patterson section ($xy0$) was calculated. This section proved to be compatible with space group $P\bar{6}2m$, if 3 NiI are placed in 3(f), 3 NiII in 3(g) and 2 Si in 2(c). From structural arguments B was placed in 1(b) and, indeed, the Patterson synthesis gave support to this hypothesis.

Approximate Ni parameters were read from the Patterson map. Structure factors of the ($hk0$) reflexions were calculated; the scattering factors of Ni were interpolated from tables given by Thomas and Umeda [4], those of Si from Tomiie and Stam [5], and B scattering factors from Ibers [6]; the small correction for dispersion and anomalous scattering was neglected. Refinement of the Ni parameters by an algebraic method led to an R value of 5.5 % for the 23 measured ($hk0$) reflexions, when a temperature factor with $B = 0.52$ Å^2 was applied. Using the same temperature and scale factors, R was calculated to be 5.1 % for the 25 observed ($hk1$) reflexions. Therefore, no further refinement was considered worth while. Observed and calculated structure factors are compared in Table 1.

The final structure is the following:

Space group $P\bar{6}2m$ — (D^3_{3h});

3 NiI in 3 (f): $x00$; $0x0$; $\bar{x}\bar{x}0$ with $x = 0.247$

3 NiII in 3(g): $x0\frac{1}{2}$; $0x\frac{1}{2}$; $\bar{x}\bar{x}\frac{1}{2}$ with $x = 0.608$

2 Si in 2(c): $\frac{1}{3}\,\frac{2}{3}0$; $\frac{2}{3}\,\frac{1}{3}0$

1 B in 1(b): $00\frac{1}{2}$.

Table 1. Observed and calculated ($hk0$) and ($hk1$) structure factors for Ni_6Si_2B.

* The reflexions designed by w. were discernible above the background, but it was not possible to estimate them with any accuracy.

Interatomic distances are listed in Table 2; the accuracy of the given values is better than 0.01 Å. Fig. 1 shows the environment of the B and Si atoms. Si is surrounded by 6 NiII forming a trigonal prism and by 3 NiI in a triangle, situated outside the centers of the rectangular prism faces; the 9 Ni atoms forming the described tetrakaidecahedron around Si are approximately equidistant from the central atom. The B environment is similar, but the 3 Ni in the triangle are much farther away than those forming the trigonal prism and cannot be regarded as true neighbours. Adopting r_{Ni} as 1.24 Å the plausible values of $r_{Si} = 1.12$ Å and $r_B = 0.84$ Å are derived.

Table 2. Interatomic distances in Ni_6Si_2B.

Si	—	3 NiI	2.34 Å	B	—	6 NiI	2.08 Å

	—	2 NiI	2.895		—	4 NiII	3.26

REDETERMINATION OF THE Fe_2P STRUCTURE

For Fe_2P we found the unit-cell dimensions as $a = 5.865$ Å; $c = 3.456$ Å; $c/a = 0.5893$; $U = 103.0$ Å^3; in close agreement with the values given by Hägg [7] and Friauf [8], less so with the values by Nowotny and Henglein [9]. With three formula units in the cell the calculated density is 6.90 g.cm^{-3}, which compares favourably with the observed values of 6.83 [7], 6.89 [8] and 6.77 [10] g.cm^{-3}.

In the structure Hendricks and Kosting [2] proposed for Fe_2P, using Hägg's [7] experimental data, the Fe atoms occupy the same sites as the Ni atoms in Ni_6Si_2B, PII is situated in $00\frac{1}{2}$, but PI is shifted from the plane $z = 0$ to the position $\frac{1}{3}\,\frac{2}{3}\,\frac{1}{8}$, $\frac{2}{3}\,\frac{1}{3}\,\frac{7}{8}$. This shift lowers the symmetry from space group $P\bar{6}2m$ to $P321$.

A comparison of the intensities of ($hk0$) and ($hk4$) reflexions showed at once that Hendricks and Kosting's structure cannot be the correct one;

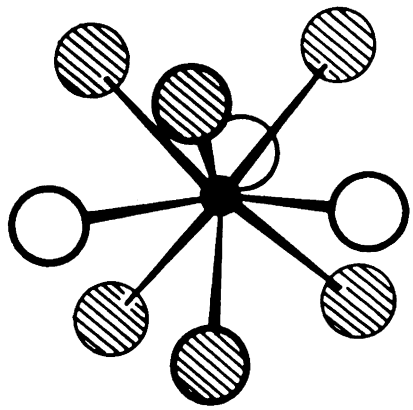

Fig. 1. The Si and B environments in Ni_6Si_2B. The nonmetal (black) is surrounded by six metal atoms (shaded) forming a trigonal prism, and by three metal atoms (white) in a triangle. The resulting coordination figure (a tetrakaidecahedron) is built up by fourteen triangles sharing all edges. The nine Ni atoms around Si are approximately equidistant from the central atom. The B environment is more distorted, as the three Ni in the triangle are much farther away from the central atom than the six Ni forming the trigonal prism.

adopting their proposed structure the intensity sequences in the zero and fourth layer lines about the c axis should be quite different, while actually they were identical. Furthermore, within experimental accuracy it was found that $|F(hkl)| = |F(\bar{h}kl)|$, indicating that the symmetry of Fe_2P is hexagonal and that PI lies in the plane $(xy0)$.

Nevertheless, we tried to interpret the small differences between $F(\bar{h}kl)$ and $F(hkl)$ as due to a minor deviation from hexagonal symmetry (and not to experimental inaccuracy), but no selfconsistent result was possible. Therefore, space group $P\bar{6}2m$ was adopted. Structure factors for $(h0l)$ reflexions were computed, using Fe scattering factors from Thomas and Umeda [4] and P scattering factors from Tomiie and Stam [5]. The Fe parameters derived by Hendricks and Kosting were provisionally adopted, and they proved to be surprisingly accurate. Refinement by an algebraic method indicated only minor shifts, the final structure being:

Space group $P\bar{6}2m$ — (D_{3h}^3);

3 FeI in 3(f): $x00$; $0x0$; $\bar{x}\bar{x}0$ with $x = 0.256$

3 FeII in 3(g): $x0\frac{1}{2}$; $0x\frac{1}{2}$; $\bar{x}\bar{x}\frac{1}{2}$ with $x = 0.594$

2 PI in 2(c): $\frac{1}{3}\frac{2}{3}0$; $\frac{2}{3}\frac{1}{3}0$

1 PII in 1(b): $00\frac{1}{2}$

A temperature factor with $B = 0.67$ Å^2 was employed, giving $R = 6.1$ % for the 34 measured $(h0l)$ reflexions. A comparison of observed and calculated structure factors is given in Table 3. In Table 4 interatomic distances are listed; the standard deviations are calculated to be less than 0.01 Å. The structure of Fe_2P is isotypic with that of Ni_6Si_2B and both PI and PII possess a distorted tetrakaidecahedral environment. However, the distortions are quite different in the two cases: while the three Fe atoms surrounding PI in a triangle are much closer to the central atom than the six Fe atoms forming the trigonal prism, just the opposite is true for the PII environment.

THE STRUCTURES OF SOME RELATED PHASES

Several binary phases have been described as isotypic with Fe_2P; as the isotypism generally was derived from a comparison of powder photographs, it is highly probable that the revised Fe_2P structure also applies to β-Co_2As [11], Pd_2Si [12,13], Pd_2Ge [12], and Pt_2Ge [12]. This was actually proved to be the case for Mn_2P and Ni_2P. The unit-cell dimensions were found to be:
for Mn_2P: $a = 6.074$ Å; $c = 3.454$ Å; $c/a = 0.5687$;

$U = 110.4$ Å^3; $Dx = 6.36$ g.cm^{-3};

in agreement with values by Fylking [14], Wiechmann [15], and Årstad and Nowotny [16];
for Ni_2P: $a = 5.864$ Å; $c = 3.385$ Å; $c/a = 0.5772$;

$U = 100.8$ Å^3; $Dx = 7.33$ g.cm^{-3};

Table 3. Observed and calculated (*h0l*) structure factors for Fe_2P.

* The reflexions designed by w. (weak) or v.w. (very weak) were observable on the diagrams, but it was not possible to estimate them with any accuracy.

which differs somewhat from Nowotny and Henglein's [17] values. There are reasons to believe that the phase "Pd_3B_2", which Buddery and Welch [13] prepared by heating Pd and B in silica tubes and to which a Fe_2P structure is ascribed, actually is the Pd analogue of Ni_6Si_2B. Indeed, in view of the structural non-equivalence of PI and PII in Fe_2P, it may be expected that several ternary phases containing two kinds of non-metals, crystallize in isotypic structures. FeI and FeII are also non-equivalent in Fe_2P, but — as far as we are aware of — no isostructural ternary phase containing two different transition metals, has yet been described. However, a superstructure of the Fe_2P type results, if in the structure proposed by Perlitz and Westgren [18] for $Al_8FeMg_3Si_6$ the Si positions and part of the (Al,Fe) positions are interchanged; such a change would be compatible with the published experimental data.

Table 4. Interatomic distances in Fe_2P.

PI	− 3 FeI	2.22 Å	PII	− 6 FeI	2.29 Å
	− 6 FeII	2.48		− 3 FeII	2.38
FeI	− 2 PI	2.22	FeII	− 1 PII	2.38
	− 2 PII	2.29		− 4 PI	2.48
	− 2 FeI	2.60		− 2 FeI	2.63
	− 2 FeII	2.63		− 4 FeI	2.71
	− 4 FeII	2.71		− 4 FeII	3.08

In agreement with Nowotny [3] we found for Co_2P an orthorhombic unit-cell, but the lattice dimensions observed by us are much smaller than those given by him. For the composition Co_2P we determined: $a = 6.608$ Å; $b = 5.644$ Å; $c = 3.512$ Å; $U = 131.0$ Å^3; $Dx = 7.55$ g.cm^{-3}. With increasing P content the unit-cell contracts in all directions, contrary to Nowotny's [3] observations.* Co_2P is isotypic with Co_2Si[19] — a limited mutual solubility exists — with δ-Ni_2Si [20], Rh_2Ge [21], Ru_2Si [23], Rh_2Si [23] (the alleged phase Rh_2B[22] probably actually was Rh_2Si too) and several Pd compounds [26]. The P environment is similar to that in Fe_2P, but the packing is different. This structure type is a distortion of the Ni_2In type, but — as was already pointed out by Nowotny [3] — the Co_2P structure can also be regarded as an anti-$PbCl_2$-type.

It is noteworthy that both the revised and the old — incorrect — Fe_2P structures also have their counterparts in inorganic-salt structures: β_1-K_2ThF_6 and β_1-K_2UF_6[24] are formally isotypic with Ni_6Si_2B and Fe_2P, while $SrCl_2.6H_2O$[25], β_2-Na_2ThF_6[24] and isotypes possess structures which are the anti-types to Hendricks and Kosting's [2] proposal for the *C* 22 structure.

X-Ray Investigations on Me-Si-B Systems (Me = Mn, Fe, Co)

I. Some Features of the Co-Si-B System at 1 000° C. Intermediate Phases in the Co-Si-B and Fe-Si-B Systems

BERTIL ARONSSON and (Miss) GUNVOR LUNDGREN

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

Some features of the Co-Si-B system at 1000°C have been determined with X-ray methods. It is found that the homogeneity ranges of the intermediate phases are small. The crystal structure of the ternary phase $Co_{4.7}Si_2B$ (isomorphous with $Fe_{\sim 4.7}Si_2B$) has been established from single crystal data and is closely related to the W_5Si_3($T1$) structure.

The Fe-Si-B system contains several ternary phases, the most remarkable of which is a cementite (Fe_3C) type phase, while the crystal structures of Fe_5SiB_2 and Mn_5SiB_2 are shown to be of the Cr_5B_3($T2$) type.

Since there are many similarities in the crystal chemistry of the borides and silicides of the transition metals, it seems very likely that a systematic study of the intermediate phases of Me-Si-B systems will give valuable information about both groups of compounds.

Investigations on Me-Si-B systems have been made by Nowotny and coworkers [1,2] who have been particularly interested in the Me_5X_3 phases (X = B, Si). At this Institute studies on Me-Si-B systems with Me = manganese, iron, and cobalt are in progress. This paper will deal with the Co-Si-B system and will also give some preliminary information about the intermediate phases of the Fe-Si-B and Mn-Si-B systems. In a second paper a more detailed account of the Fe-Si-B system will be given.

Our primary interest has been the crystal structures of the intermediate phases, and our investigations have been carried out chiefly by means of X-ray methods. However, no accurate determinations of the phase diagrams have been made. Before proceeding to the results of the present study of the Co-Si-B system, some reference to previous work on the Co-B and Co-Si systems will be given.

Table 1. Crystallographic data on intermediate phases in the Co-Si and Co-B systems.

	Lattice parameters (in Å)			Structure type	Ref.
	a	*b*	*c*		
Co_3B	4.408	5.225	6.629	*D* $O_{11}(Fe_3C)$	4
Co_2B	5.016		4.220	*C* 16 ($CuAl_2$)	3
CoB	5.253	3.043	3.956	*B* 27 (FeB)	3
Co_2Si	4.918	3.737	7.109	*C* 23 ($PbCl_2$)	5,6
CoSi	4.447			*B* 20 (FeSi)	7
$CoSi_2$	5.366			*C* 1 (CaF_2)	8,9

PREVIOUS WORK ON THE Co-B and Co-Si SYSTEMS

Reported crystallographic data on the intermediate phases of the binary Co-Si and Co-B systems are collected in Table 1. Bjurström [3] determined the structures of Co_2B and CoB to be of the *C* 16 ($CuAl_2$) and *B* 27 (FeB) types, respectively. Co_3B was recently discovered by Rundqvist [4,5]. Borén [6] determined the unit cell dimensions of Co_2Si and CoSi and found that the structure of the latter was of the *B* 20 (FeSi) type. Borén *et al.*[7] also gave a structure for Co_2Si, and this has recently been corrected by Geller [8]. The correct Co_2Si structure, which Geller [8] has shown to be isomorphous with δ-Ni_2Si [10], has been pointed out [9] to be indeed that of the *C* 23 ($PbCl_2$) type. Finally, $CoSi_2$ is of the *C* 1 type (Schubert and Pfisterer [11], Bertaut and Blum [12]). A hightemperature modification of Co_2Si has been reported [13,14], as well as a phase with the composition Co_3Si [13,14]. None of these phases is stable below 1 170°C and no crystallographic constants have been published for them. The solid solubility of silicon in cobalt has not been determined accurately but Hashimoto [14] reported a solubility of about 10 at % Si at 1 000°C.

No studies on ternary Co-Si-B alloys have been noted in the literature.

EXPERIMENTAL

The following chemicals were used:

Cobalt (99.2 %, containing 0.45 % Ni) kindly donated by Societé Générale Metallurgique de Hoboken.

Silicon (99.9 %) obtained from Pechiney & C:ie, Paris.

Boron (99 %) kindly donated by Borax Consolidated Ltd., London.

When a rough knowledge of the system had been obtained from arc melted and sintered alloys, 2—3 g samples of suitable compositions were prepared by sintering pressed pellets of the elements in evacuated silica tubes at 1 000°C. After four days, each sample was crushed, thoroughly mixed, then sintered for another two days and finally quenched in oil. After this treatment, all samples gave very sharp powder diffraction lines and the l.p. (lattice parameters) of the phases in a three phase region were found to be the same in different samples from this region. Therefore, it was concluded that equilibrium had been attained.

The powder photographs were taken in a Guiniertype powder camera using Cr*Ka* radiation and employing CaF_2 (a = 5.4630 Å at 21°C) as a calibration standard. The l.p. are estimated to be accurate to ± 0.03 %.

The oxygen content (weight percent) of two 2—3 g samples, determined by a vacuum fusion technique, was found to be 0.211 and 0.212, respectively. Since the composition of all samples was approximately Co_2Si_2B and the method of preparation was the same, the oxygen content of all samples has been assumed to be 0.21 % by weight. The analyses for cobalt and boron were carried out by Dr. L. Gustafsson at the Analytical Department of this Institute. For the cobalt analyses, the samples were dissolved in a mixture of nitric and hydrofluoric acid. The hydrofluoric acid was then removed by evaporating with sulfuric acid and the cobalt content (including traces of other heavy metals) was subsequently determined by titration with EDTA. For the boron determinations, the samples were first dissolved in dilute hydrochloric acid plus chlorine (0.3 g samples were

completely dissolved within 7—10 h). Cobalt was removed from the acid solution by passing the solution through a cationic exchanger (Dowex 50) and the cobalt-free solution was then neutralized to pH 6.80. After addition of mannitol, the solution was again titrated to pH 6.80. The results of the chemical analyses are given below (weight %).

Sample	Co *	B	Si as difference	Σ (see text)
1	79.75 ± 0.17	2.99 ± 0.20	16.7	99.4
2	77.51	4.61	17.3	99.4
4	83.30	5.33	10.8	99.4
6	82.45	3.34	13.6	99.4
9	79.58	2.13	17.7	99.4

* Traces of nickel and iron computed as cobalt are included in the values of this column.

The accuracy of the cobalt analyses is estimated to be ± 0.2 %, and that of the boron analyses ± 0.4 %. The impurities of the original chemicals (except oxygen and nickel) amounted to about 0.4 % by weight. By adding 0.2 % oxygen, a total of 0.6 % impurities is obtained. The silicon content has been obtained as the difference between 99.4 % and the sum of the cobalt and boron contents. This procedure was unsatisfactory, but any direct analysis for silicon would not give more reliable results unless much larger samples were available. However, very accurate analytical figures are of questionable value since the form in which oxygen is present in the sample is unknown. Oxygen may be bound to boron and silicon, and this would slightly reduce the amounts of the latter elements which actually participate in the Co-Si-B equilibria. Therefore, an alloy for which the analytical composition has been found to be $Co_{4.60}Si_2B$ plus traces of oxygen should rather be written $Co_{4.65}Si_2B$ plus traces of B_2O_3 and SiO_2. In addition, a spectrographic analysis of one sample revealed the presence of traces of nickel and iron. Small amounts of these metals can probably substitute for cobalt in the different alloys and therefore should be added to the cobalt content.

The densities of two samples which contained 80—90 % of the ternary phase $Co_{4.7}Si_2B$ were determined by weighing in air and benzene. The amounts of other phases present in the samples were estimated from the powder photographs, while the density of the ternary phase could be calculated. The values were reproducible to within 0.5 % and a test of the method on some known substances proved satisfactory. The results of the determination of the densities are given below:

	Density of sample	Calculated density of $Co_{4.7}Si_2B$
Sample 36 (arc melted, contained $Co_{4.7}Si_2B + CoB$)	7.27 g/cm³	7.26 g/cm³
Sample 10 (sintered, contained $Co_{4.7}Si_2B + Co_2B + Co_2Si$)	7.21 g/cm³	7.16 g/cm³
	Average	7.21 g/cm³

A small single crystal of the $Co_{4.7}Si_2B$ phase was picked out of an arc melted alloy that contained $Co_{4.7}Si_2B$ and small amounts of CoB. The l.p. of $Co_{4.7}Si_2B$ of this alloy were found to be $a = 8.615$ Å and $c = 4.250$ Å. These values are intermediate between those found in the neighbouring three-phase triangles. Weissenberg photographs were taken around the tetragonal axis by use of Mo$K\alpha$ radiation, and intensities of 92 nonequivalent reflexions from the layer lines 0—4 were visually estimated. An empirical correction for thermal movement and Θ-dependent absorption was obtained by plotting log F_o/F_c against $\sin^2\Theta$. The Fourier summations were made on the Hägg-Laurent [15] machine.

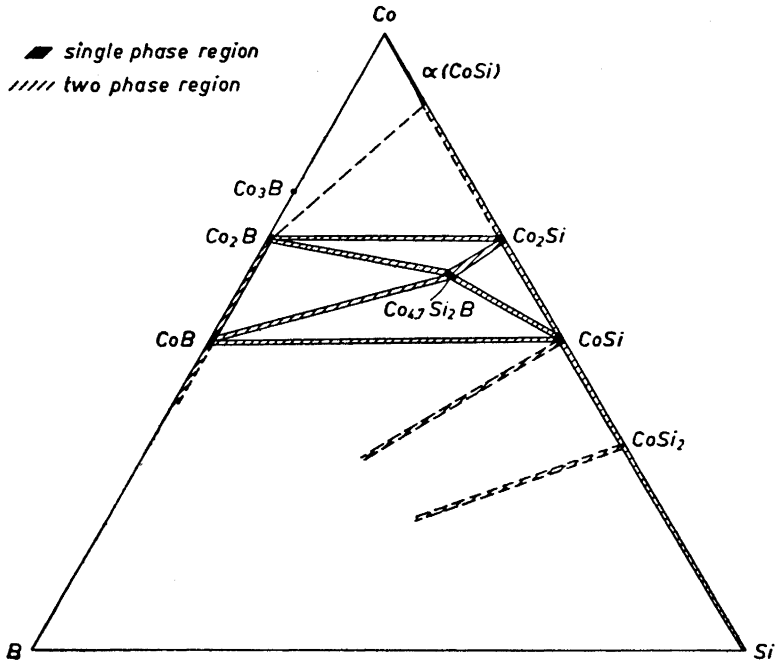

Fig. 1. Some features of the Co-Si-B system at 1 000°C. The one- and two-phase regions are greatly exaggerated for clarity.

RESULTS

The Co-Si-B system at 1 000°C. The results of the present investigation have been used for the construction of a partial isothermal section of the Co-Si-B system at 1 000°C (Fig. 1). The quasi-binary systems Co_2B-Co_2Si and CoB-CoSi divide the section into three parts. The main interest has been devoted to the Co_2X-CoX (X = Si,B) region, which was found to contain a ternary phase.

The l.p. (lattice parameters) reported for the binary phases Co_2B, CoB, Co_2Si and CoSi are given in Table 1. In ternary Co-Si-B alloys, the l.p. of these phases differ only slightly (not more than 0.2 %) from the values of Table 1, indicating that at 1 000°C the homogeneity ranges of Co_2B, CoB, Co_2Si and CoSi are small in the ternary Co-Si-B system.

In the metal-rich part of the system (> 66.7 at % Co) hexagonal cobalt with dissolved silicon was found. This phase will be called α(CoSi) in the following. (It has not been determined if the hexagonal α(CoSi) phase is stable up to 1 000°C or if it is formed during quenching.) The three-phase region Co_2B-Co_2Si-α(CoSi) and the two-phase region Co_2B-α(CoSi) were established. In Co_2B-Co_2Si-α(CoSi) alloys the l.p. of the hexagonal α(CoSi) phase were found to be $a = 2.502$ Å and $c = 4.062$ Å. These values are smaller

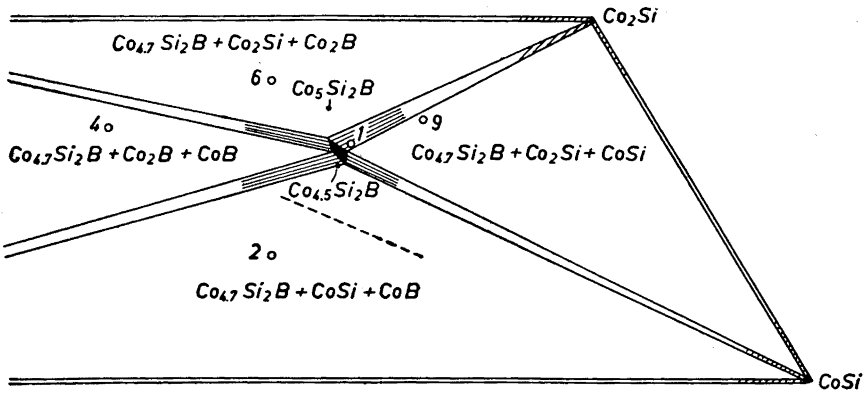

Fig. 2. The Co-Si-B system around Co_5Si_2B. The numbers refer to samples the analyses of which are given in the text.

than those reported for pure α-Co($a = 2.507$ Å, $c = 4.069$ Å)[16] and show that the α(CoSi) phase in equilibrium with Co_2B and Co_2Si contains considerable amounts of silicon. The existence of Co_3B was confirmed in binary Co-B alloys. No attempt was made to determine the equilibria in the Co-Si-B system in which this phase was involved. Evidently, the phase appears only in silicon-poor alloys.

The composition of the ternary phase could be determined quite well from analysed samples of approximate composition Co_5Si_2B (Fig. 2). The two-phase sample 1 (the l.p. of the $Co_{4.7}Si_2B$ phase in this sample were intermediate between those found in neighbouring three-phase regions) contained only small amounts of Co_2Si(~ 5 %). The limit between the two phase range $Co_{4.7}Si_2B$-Co_2Si and the three-phase region $Co_{4.7}Si_2B$-Co_2Si-CoSi was obtained from samples 1 and 9. These facts established the composition of the ternary phase to be $Co_{4.6}Si_2B$ (Fig. 2). This composition was further supported by the observation (from the intensities of the powder lines) that samples 6 and 9 were situated nearer to the ternary single-phase range than samples 2 and 4. As pointed out in the preceding paragraph, some boron and silicon are probably bound to oxygen and the amounts of these elements which actually participate in the Co-Si-B equilibria are slightly smaller than the analytically obtained values used in the construction of Fig. 2. Therefore, we have assigned the formula $Co_{4.7}Si_2B$ to the ternary phase. This composition gives a better agreement between observed and calculated densities than does $Co_{4.6}Si_2B$. The calculated density of $Co_{4.7}Si_2B$ is 7.24 g/cm^3 and that of $Co_{4.6}Si_2B$ is 7.09 g/cm^3 as compared with the observed value of 7.21 g/cm^3. The results of the single crystal investigation are also more consistent with the formula $Co_{4.7}Si_2B$ rather than with the formula $Co_{4.6}Si_2B$.

The l.p. of $Co_{4.7}Si_2B$ (Table 2) are nearly the same in the different three-phase regions indicating a small homogeneity range of this phase. It seems reasonable to assume that the homogeneity range depends on a variation in

Table 2. Lattice parameters of the $Co_{4.7}Si_2B$ phase. (Estimated accuracy ± 0.03 %.)

Three-phase region	Lattice parameters in Å			
	a	*c*	*c/a*	*V*
$Co_2B-Co_2Si-Co_{4.7}Si_2B$	8.624	4.248	0.4926	316.0 Å³
$Co_2Si-CoSi-Co_{4.7}Si_2B$	8.618	4.252	0.4934	315.8
$Co_2B-CoB-Co_{4.7}Si_2B$	8.621	4.247	0.4926	315.6
$CoSi-CoB-Co_{4.7}Si_2B$	8.605	4.249	0.4938	314.6

cobalt content (meaning a varying amount of vacancies in the cobalt skeleton) and on a B-Si substitution. Increasing the cobalt content should increase the volume of the unit cell while this should decrease with increasing B/Si ratio. As the unit cell volume is nearly constant for the first three of the three-phase regions shown in Table 2, we have sketched the single-phase range (Fig. 2) so that with increasing cobalt content, the B/Si ratio also increases. With a simultaneous increase of these two parameters, the volume of the unit cell will be very little affected.

Alloys of approximate composition Co_5Si_2B were annealed at temperatures between 950°C and 1 150°C, but no transformation of the ternary phase was observed, showing that $Co_{4.7}Si_2B$ is probably stable up to the melting point. Since a phase with the composition Me_5SiB_2 has been found both in the Fe-Si-B and in the Mn-Si-B systems, alloys of approximate composition Co_5SiB_2 were also annealed between 950°C and 1 150°C. However, only the three phases Co_2B, CoB and $Co_{4.7}Si_2B$ were found in the samples and it was concluded that no phase with the composition Co_5SiB_2 exists above 950°C.

Some alloys were prepared in the "cobalt-poor" part of the system (< 50 at % Co). CoSi and $CoSi_2$ were found to be in equilibrium with some very "boron-rich" phase, but no lines from this phase were observed on the powder photographs. The phase is amorphous and possibly is amorphous boron.

The crystal structure of $Co_{4.7}Si_2B$. The powder photograph of $Co_{4.7}Si_2B$ showed that the crystal structure of this phase must be very similar to that found for the tetragonal Me_5Si_3 silicides of the W_5Si_3($T1$) type [17–19]. It was considered important to study the $Co_{4.7}Si_2B$ structure more closely for two reasons. Firstly, it would be of interest to know whether the metal skeleton of $Co_{4.7}Si_2B$ is, in fact, entirely analogous to that of the W_5Si_3 type silicides

Table 3. Results of the single crystal investigation on $Co_{4.7}Si_2B$. (Space-group $D_{4h}^{18}-I4/mcm$.)

Atomic parameters		Relative scattering parameters from the $\varrho(xy)$ proj.	$\varrho(xy0)$ and $\varrho(xy1/4)$ sections	Corresponding parameters in W_5Si_3	Corresponding parameters in Cr_5Si_3
16 Co_I in 16(k)	$x = 0.0757$	27.4	27.0	$x = 0.074$	$x = 0.075$
	$y = 0.2036$			$y = 0.223$	$y = 0.224$
2.5–3 Co_{II} in 4(b)		18.0	19.6		
8 Si in 8(h)	$x = 0.162$	14.0		$x = 0.17$	$x = 0.165$
4 B in 4(a)		4.8			

as this situation would imply the existence of Co-Co contacts shorter than 2.13 Å (= $c/2$). Secondly, it would be interesting to know whether or not the boron and silicon atoms are statistically distributed in the structure. A detailed study of the crystal structure of $Co_{4.7}Si_2B$ might also give some explanation for the deviation from stoichiometry.

The result of the single crystal investigation is shown in Table 3. (For comparison some data on W_5Si_3[17] and Cr_5Si_3[18] are included.) The systematic extinctions were consistent with the space-group D_{4h}^{18}—$I\ 4/mcm$. The atomic parameters were refined from successive twodimensional $\varrho_o(xy)$ and $\varrho_c(xy)$ syntheses with the last backshift-corrections being 0.0003 for the cobalt parameters and 0.001 for the silicon parameter. This procedure gave the final parameters $x_{Co} = 0.0757$, $y_{Co} = 0.2035$ and $x_{Si} = 0.162$ in excellent agreement with the values $x_{Co} = 0.0758$, $y_{Co} = 0.2037$, and $x_{Si} = 0.162$ derived from the threedimensional ϱ_o ($xy0$) section. The scattering parameters were obtained from the $\varrho(xy)$ projection. By choosing the scattering parameters proportional to 27.0, 18.0, 14.0 and 5.0 the final (ϱ_o—ϱ_c) synthesis was very nearly zero for all values of x and y. The final R-value of the 26 observed nonequivalent $hk0$ reflexions was 6.1 %. A temperature factor with $B = 0.72$ Å^2 was employed. If the scattering parameters were assumed to be proportional to 27.0, 27.0, 14.0 and 5.0 respectively the R-value did not drop below 16 %.

Evidently, the 16(k) positions are occupied mainly by cobalt atoms; the 8(h) positions, mainly by silicon atoms and the 4(a) positions, mainly by boron atoms. The number of electrons found in the 4(b) positions, however, is much smaller than one would expect if this position was entirely occupied by cobalt atoms. (A reinspection of the ϱ_o (xy) projection which was evaluated during the determination [17] of the structure of W_5Si_3 showed that in W_5Si_3 there is no significant difference in the scattering parameters for atoms occupying 16(k) and 4(b), respectively.) The small number of electrons found in the 4(b) position can be explained either by assuming that this position is only partly (to 70 %) occupied by cobalt atoms or that it is occupied by a mixture of cobalt, silicon, and boron atoms. The composition of the ternary phase required for the second alternative is shown by the dotted line in Fig. 2. This line has been constructed with the assumption that the 4(b) positions are occupied

Table 4. Interatomic distances in $Co_{4.7}Si_2B$. (Estimated accuracy ± 0.03 Å.) (Distances have an asterisk when one of the atoms are in the partly occupied position 4(b).)

			Average (Å)
Co_I	— 9 Co	2.49(2); 2.69; 2.64(2); 2.65(2); 2.84(2) *	2.66
	— 4 Si	2.29; 2.35; 2.53(2)	2.42
	— 2 B	2.15 (2)	2.15
Co_{II}	— 10 Co	2.13(2) **; 2.84(8) *	2.70
	— 4 Si	2.24(4) *	2.24
Si	— 10 Co	2.24(2) *; 2.29(2); 2.35(2); 2.53(4)	2.38
	2 Si	3.02(2)	
B	— 8 Co	2.15(8)	2.15
	— 2 B	2.13(2)	2.13

by a mixture of cobalt, silicon and boron with a weighted mean atomic number of 20. Evidently this alternative is not the correct one. The first alternative corresponds to a composition of $Co_{4.67}Si_2B$, in excellent agreement with the formula $Co_{4.7}Si_2B$ arrived at in the preceding paragraph.

The atomic parameters in $Co_{4.7}Si_2B$ are different from those in W_5Si_3[17] and Cr_5Si_3[18], which means that the antiprismatic holes of the metal skeleton (where the boron atoms are situated in $Co_{4.7}Si_2B$) are relatively smaller in $Co_{4.7}Si_2B$ than in W_5Si_3 and Cr_5Si_3. The distance from the centre of the antiprismatic hole to the eight neighbouring metal atoms is only 2.15 Å in $Co_{4.7}Si_2B$ while the corresponding distance in Cr_5Si_3[18] is 2.46 Å. The different atomic parameters also imply that Si-Me distances much shorter than in Cr_5Si_3 and W_5Si_3 have been created in $Co_{4.7}Si_2B$. The distance between the silicon atoms and the cobalt atoms in the partly occupied position is only 2.24 Å while the shortest Me-Si contact in Cr_5Si_3 is 2.42 Å[18]. The *average* Co-B and Co-Si distances in $Co_{4.7}Si_2B$ (2.15 Å and 2.38 Å) are very similar to those found in Co_2B[3] (2.15 Å) and Co_2Si (2.42 Å)[8].

This detailed inspection of $Co_{4.7}Si_2B$ has revealed some significant differences between the crystal structure of this phase and that of the $W_5Si_3(T1)$ type silicides. The deviation from stoichiometry for $Co_{4.7}Si_2B$ is dependent upon the fact that the 4(*b*) positions are only partly (to 65—70 %) occupied by cobalt atoms, thus leaving vacancies in the structure. The difference in sizes of the two types of holes in the metal skeleton is larger in $Co_{4.7}Si_2B$ than in the binary Me_5Si_3 phases of $W_5Si_3(T1)$ type. The boron and silicon atoms are ordered in $Co_{4.7}Si_2B$ with the boron atoms occupying the smaller holes of the metal skeleton and the silicon atoms, the larger.

INTERMEDIATE PHASES OF THE Fe-Si-B AND Mn-Si-B SYSTEMS

The Fe-Si-B system is more complicated than the Co-Si-B system. In the metal-rich (> 50 at % Fe) part of the system, four ternary phases have been found in alloys sintered at 975°C (Table 5). One of these phases is isomorphous with $Co_{4.7}Si_2B$ and probably has a similar composition. Fe_5SiB_2 crystallizes in the $Cr_5B_3(T2)$[20,19] structure and thus is isomorphous with Mo_5SiB_2[21] and Fe_5PB_2[22]. The crystal structure of a phase with the approximate composition Fe_4BSi is apparently unknown. A cementite (Fe_3C) type phase with slightly varying l.p. has also been found. Since the volume of the unit cell has been found to be smaller for this phase than for $Fe_3C_{0.2}B_{0.8}$[23],

Table 5. Intermediate phases in the Fe-Si-B and Mn-Si-B systems at 975°C.

	Approximate compositions and lattice parameters (in Å)	Structure type
$Fe_{4.7}Si_2B$	$a = 8.82$; $c = 4.34$	$Co_{4.7}Si_2B$ ($T1$)
Fe_5SiB_2	$a = 5.54$; $c = 10.32$	Cr_5B_3 ($T2$)
$Fe_3(Si,B)$ or		
$(Fe,Si)_3B$ (boron-rich)	$a = 4.46$; $b = 5.36$; $c = 6.66$; $V = 159$ Å^3	Fe_3C (cementite)
(boron-poor)	$a = 4.47$; $b = 5.30$; $c = 6.67$; $V = 158$ Å^3	
Fe_4BSi		unknown
Mn_5SiB_2	$a = 5.61$; $c = 10.44$	Cr_5B_3 ($T2$)

it has been assumed that the formula should be written $(Fe, Si)_3B$. However, the small unit cell volume could also be explained by assuming the formula to be $Fe_3(Si, B)$ with vacancies in the iron skeleton.

In the Mn-Si-B system Mn_5SiB_2 (isomorphous with Fe_5SiB_2) has been found but no phase analogous with $Co_{4.7}Si_2B$ seems to exist in this system.

A more detailed account of the Fe-Si-B system will soon appear in this journal.

Acknowledgements. The research described in this paper was sponsored by the *European Commission of Air Research and Development Command* under Contract no. AF61(052)-40. The financial support from this authority is gratefully acknowledged.

We want to thank professor G. Hägg for many valuable suggestions and Dr. S. Rundqvist for stimulating discussions. We want to express our gratitude to Dr. Lilly Gustafsson who devoted much time to the chemical analyses. The oxygen analyses were performed at the Analytical Department of Avesta Jernverk and we are much indebted to Dr. G. Liljekvist and Mr. E. Gunnarsson of this factory. Thanks are also due to Mr. K. Nordgren who carried out the density determinations.

Absorption Spectra of Alkyl *iso*Thiocyanates and N-Alkyl Monothiocarbamates *

EMIL SVÁTEK, RUDOLF ZAHRADNÍK and ANDERS KJÆR

Research Institute for Pharmacy and Biochemistry, Prague, Czechoslovakia; Institute of Industrial Hygiene and Occupational Diseases, Prague, Czechoslovakia; Organic Chemical Laboratory of the Royal Veterinary and Agricultural College, Copenhagen, Denmark

Ultra-violet absorption spectra of twenty-two *iso*thiocyanates and N-alkyl monothiocarbamates have been determined. Whereas the former class of substances invariably displays a maximum of moderate intensitity ($\varepsilon \sim 10^3$) in the 244—248 mμ region, the N-alkyl monothiocarbamates possess absorption bands in the range 226—232 mμ and an attempt has been made to correlate the wave-length position of the absorption maximum with the structure of the substituents.

In the infra-red range of the spectrum, alkyl *iso*thiocyanates exhibit characteristic bands in two regions. The asymmetric stretching mode of the cumulative double bond system of the —N=C=S-grouping produces a moderately intense band at 2 170—2 221 cm^{-1}, accompanied by a group of two to three strong bands at 2 050—2 150 cm^{-1}, as well as a very weak band in the 2 000 cm^{-1} region. The position and intensity of the bands depend on the polarity of the solvents employed. The second characteristic frequency of alkyl *iso*thiocyanates occurs at 1 318—1 347 cm^{-1} and is assigned to the bending vibrations of —CH- atoms adjacent to the -N=C=S-grouping. This very strong band has been observed in all compounds possessing the RCH_2-N=C=S grouping, whereas methyl, *tert.*-butyl, phenyl and α-naphthyl *iso*thiocyanates do not exhibit typical absorption in the vicinity of 1 330 cm^{-1}.

The electronic spectra of alkyl *iso*thiocyanates have attracted only little attention heretofore. Kremann and Riebl [1] determined the absorption curve of allyl *iso*thiocyanate, whereas Pestemer and Litschauer [2] in addition to this mustard oil studied the spectroscopical properties of the ethyl- and monomethoxy-derivatives. According to these authors, *iso*thiocyanates possess absorption maxima at approximately 250 mμ with log $\varepsilon \sim 3$. Although the absorption properties of N-alkyl monothiocarbamates in the ultra-violet region have been utilized analytically they do not seem to have been subjected to detailed studies previously.

* Part III of the series: Reaction Kinetics and Properties of Compounds Belonging to Homologous Series of Nonaromatic Compounds. Part II: *Collection Czechoslov. Chem. Communs. In press.*

There does not exist any comprehensive treatise of the infra-red spectra of alkyl *iso*thiocyanates. The first data on the frequencies characteristic for such compounds were presented by Coblenz [3] who studied methyl, ethyl, allyl and phenyl *iso*thiocyanate. In view of the imperfect technique used in 1905, however, these frequencies can hardly be considered as too reliable. Gordy and Williams [4] later reported methyl and ethyl *iso*thiocyanate to possess bands at (3 012 cm^{-1}, 2 127 cm^{-1}) and (3 039 cm^{-1}, 2 205 cm^{-1}), respectively. Williams [5] recorded frequencies of the phenyl *iso*thiocyanate bands in the 650—3 000 cm^{-1} range but payed particular attention to the vibration of the —N=C=S-grouping, which displayed a broad band at 2 100 cm^{-1}. This consists, according to geometrical analysis, of three bands at 2 130, 2 080 and 1 950 cm^{-1}. As an explanation of this phenomenon the author considered Fermi resonance of the —N=C=S-group vibration, accompanied by an overtone of the fundamental frequency at 685 cm^{-1}.

More recently, frequency values of some *iso*thiocyanates have been listed in the papers by Ettlinger *et al.* (3-butenyl, *trans*- and *cis*-crotyl [6], *m*-methoxybenzyl [7]), Kjær and colleagues (*trans*-crotyl [8], *p*-methoxy-benzyl [9] and *o*-methoxybenzyl [10]) and Luskin *et al.*[11] The last authors summarized previous data and quoted the range 2 040—2 180 cm^{-1} for the strong NCS-group absorption. On basis of own experiments they concluded that *iso*thiocyanates in carbon tetrachloride solution display a strong band at 2 095 $\pm$ 15 cm^{-1}, frequently accompanied by a weak band at 2 000 cm^{-1}.

Attention should be drawn also to the Raman spectra of *iso*thiocyanates. In these, two especially intensive lines were observed at 2 100 and 2 170 cm^{-1}, both attributable to the —N=C=S group, rather than the expected single line [12,13]. Bagder [14] explained this doubling of the line of the —N=C=S mode in terms of Fermi resonance of the —N=C=S vibration with an overtone of the fundamental line at 1 070 cm^{-1}. This explanation, however, was later criticized by Kohlrausch [13] because it only applies in some cases (methyl and ethyl *iso*thiocyanate), whereas it does not hold for other derivatives. On basis of the Raman spectra a strong contribution of the mesomeric structure $R—\overset{\oplus}{N} \equiv C—S^{\ominus}$ to the *iso*thiocyanate structure has been suggested.

The present paper records the results from investigations of the absorption spectra of a series of alkyl *iso*thiocyanates and N-alkyl monothiocarbamates in the ultra-violet region between 220 and 350 mμ. It further presents the infra-red spectra of twenty-two *iso*thiocyanates in the region of the —N=C=S vibration (2 100 cm^{-1}). Of these, twelve selected species were further studied in the 1 600—650 cm^{-1} region where the —N=C=S grouping has not formerly been characterized.

EXPERIMENTAL

Apparatus and methods. Absorption curves in the ultra-violet region were recorded with the Sowiet spectrophotometer SF 4 at 21 $\pm$ 2°. All solutions were measured in 1.00 cm cells. The concentrations employed were usually 10^{-3} M or 10^{-4} M, depending on whether *iso*thiocyanates or N-substituted monothiocarbamates were being examined. Extinction readings were taken with 1 mμ intervals in the vicinity of absorption maxima, otherwise in steps of 5 mμ. Wave-length values were controlled by a mercury lamp and

are regarded as accurate within ± 0.5 mμ in the 250 mμ region. Extinction values are considered accurate to ± 3 %. Most absorption curves of alkyl *iso*thiocyanates were recorded in dioxane solution, whereas samples of the N-alkyl monothiocarbamates were prepared *in situ* by allowing such an amount of alkyl *iso*thiocyanate to react with 0.1 N NaOH that the resulting solution became 10^{-4} M. Four hours later, the absorption curves of the N-alkyl monothiocarbamates, resulting from the reaction of alkyl *iso*thiocyanates with the OH-ions [15], were determined. At the end of this time, the reaction had proceeded virtually to completion in all cases except when the slower reacting *tert.*-butyl *iso*thiocyanate was employed.

Infra-red spectra were determined with a Perkin-Elmer Model 12 B single-beam spectrophotometer with rock salt optics, and with a Zeiss Jena UR 10 double-beam spectrophotometer equipped with a lithium fluoride prism (for the range 1 900—2 300 cm^{-1}). The accuracy of frequencies in well-developed bands is ± 1 cm^{-1}. The instrument was calibrated against ammonia, atmospheric water and carbon dioxide, as well as polystyrene, benzene, pyridine and chloroform. The spectra were registered at constant temperature (25°), maintained by a room thermostate.

Reagents. The alkyl *iso*thiocyanates examined were the same substances as those studied in a preceding paper [15]. Dioxane (Lachema, reagent grade) was refluxed prior to use with a tenth of a volume of 4 % hydrochloric acid in a stream of nitrogen. Water and hydrochloric acid were then removed by shaking with solid potassium hydroxide. Thereafter, the dioxane was boiled for 9 h with metallic sodium, the precipitate and excess sodium were removed and the product distilled over fresh sodium. The main run was used in the experiments. Every third day, the dioxane was redistilled over sodium and the solvent was stored in the solid state in a refrigerator.

Other solvents employed were purified by standard procedures. All materials used were of reagent grade purity (Lachema).

RESULTS

Ultra-violet spectra of alkyl iso*thiocyanates and N-alkyl monothiocarbamates.* In the region of electronic spectra alkyl *iso*thiocyanates are characterized by a single absorption band of medium intensity ($\varepsilon \sim 10^3$) possessing a maximum between 244 and 248 mμ. Absorption curves of all mustard oils examined display the same general pattern, exemplified by the absorption curve (No. 1)

[a] Measured in 10^{-3} M solutions in dioxane. [b] The relative absorption maxima $\Delta\lambda_{max, Et} = \lambda_{max, i} - \lambda_{max, Et}$, where $\lambda_{max, i}$ is the position of the absorption maximum of the i[th] derivative and $\lambda_{max, Et}$ is a similar symbol for the reference derivative (ethyl). [c] The same symbol as defined for [b], yet with the allyl derivative as the reference compound. [d] λ_{max} (ethyl) = 245 mμ; [e] λ_{max} (allyl) = 246 mμ; [f] Measured in 10^{-4} M solution in 0.1 N NaOH; [g] λ_{max} (ethyl) = 226 mμ. [h] λ_{max} (allyl) = 227 mμ.

of Fig. 1. The influence of solvent composition was investigated in the case of ethyl *iso*thiocyanate (Table 1). The position and intensity of the absorption maxima of all species studied are summarized in Table 2.

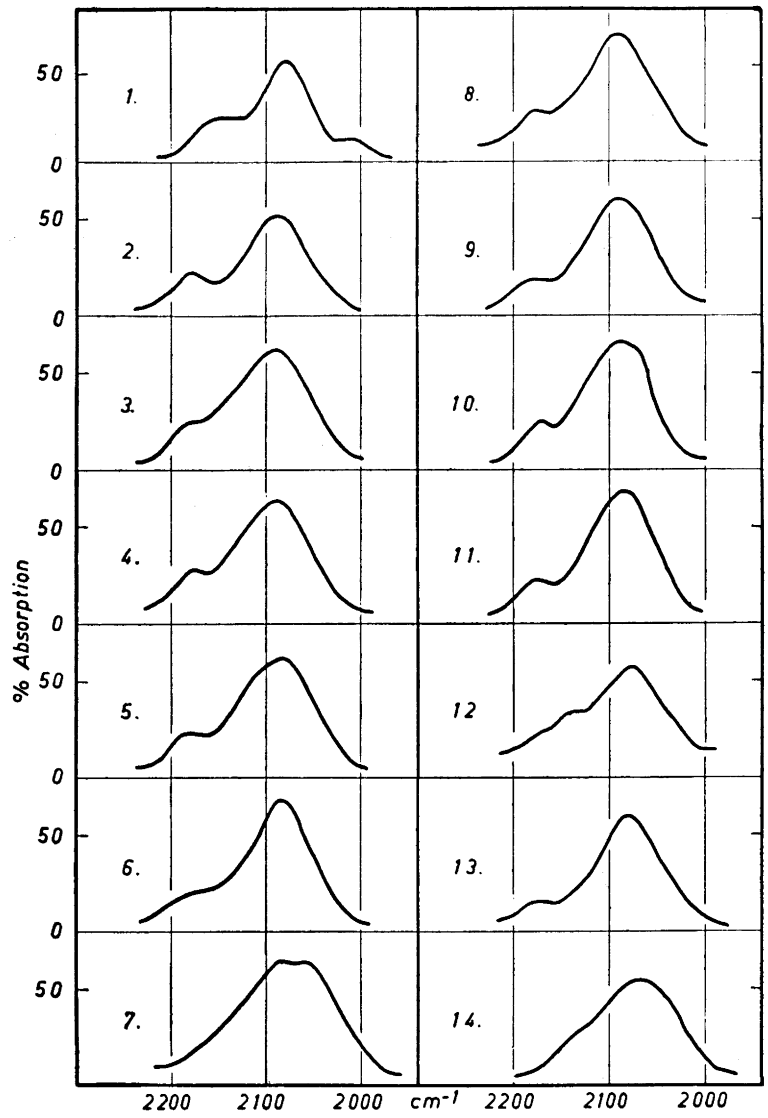

Fig. 2. Infra-red absorption bands of various *iso*thiocyanates in the 1 900—2 300 cm^{-1} region. (The thickness of the cell is 0.10 mm, concentration: 0.1 M in CCl_4, sodium chloride prism). 1. *iso*Propyl-, 2. *iso*butyl-, 3. *n*-hexyl-, 4. *n*-amyl-, 5. *iso*amyl-, 6. β-methallyl-, 7. DL-α-methallyl-, 8. *n*-octyl-, 9. 3-methylthiopropyl-, 10. 4-methylthiobutyl-, 11. 3-butenyl-, 12. *trans*-crotyl-, 13. benzyl-, 14. DL-α-phenethyl-*iso*thiocyanate.

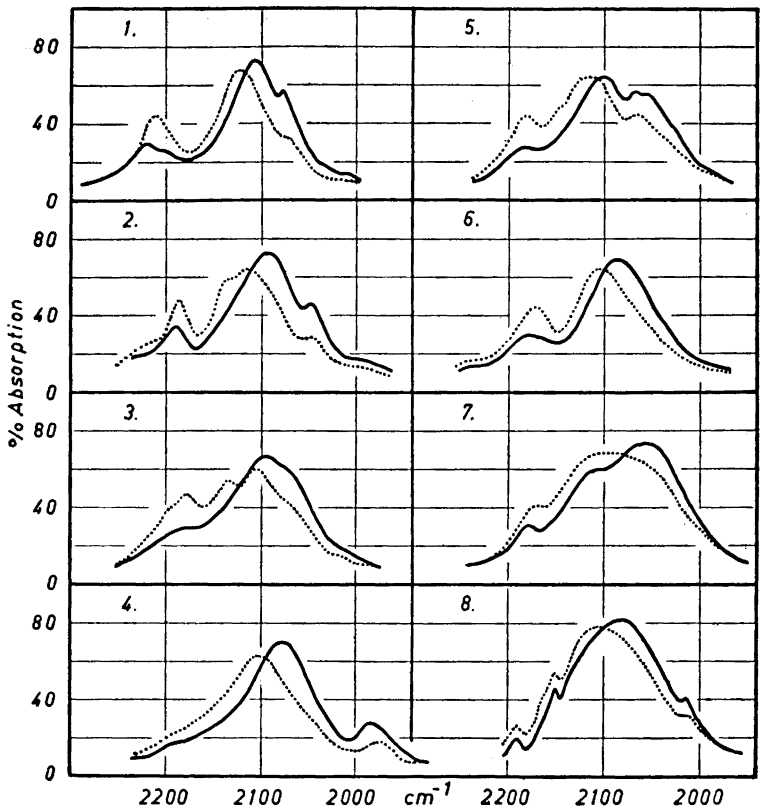

Fig. 3. Infra-red absorption bands of various *iso*thiocyanates in the 1 900—2 300 cm^{-1} region. (Concentration 0.1 M; in CCl_4-solution: full line; in $CHCl_3$: dotted line; absorption cell 0.10 mm, lithium fluoride prism). 1. Methyl-, 2. ethyl-, 3. *n*-butyl-, 4. *tert.*butyl-, 5. *cyclo*hexyl-, 6. allyl-, 7. phenyl-, 8. *α*-naphthyl- *iso*thiocyanate.

The general shape of the absorption curves of N-alkyl monothiocarbamates are similar to those of the mustard oils except for their higher intensity of the maximum absorption bands ($\varepsilon \sim 10^4$) (*cf.* Fig. 1, curve 2) which are located between 226 and 232 mμ (Table 2).

Infra-red spectra of alkyl *iso*thiocyanates

The 1 900—2 300 cm^{-1} region. In this region the spectra of twenty-two different *iso*thiocyanates were measured in carbon tetrachloride solution (0.1 M) in an 0.1 mm absorption cell (sodium chloride prism). Within this group, eight selected compounds were studied under comparable conditions at the higher resolving power of a lithium fluoride prism, and, in addition, in chloroform solution. Spectra of ethyl *iso*thiocyanate were recorded also

Table 3. Position (cm^{-1}) and intensity (% absorption) of bands of the —N=C=S-grouping in the 1 900—2 300 cm^{-1} region. (Concentration 0.1 M. (a): in CCl_4; (b): in $CHCl_3$. Thickness of the absorption cell 0.10 mm, lithium fluoride prism.)

in two extreme concentrations, *viz.* 0.01 M (1 mm cell) and 1.00 M (0.03 mm cell), as well as in the undiluted liquid and vaporous phase. The experimental curves are presented in Figs. 2 and 3, and the main frequencies and absorption data of eight selected compounds are reviewed in Table 3.

A typical feature of all the above compounds is the appearance of three to four bands which can be well differentiated: (i) a band of medium intensity in the 2 170—2 221 cm^{-1} region, (ii) a group of two to three strong bands in the range 2 050—2 150 cm^{-1}, and (iii) a weak band around 2 000 cm^{-1} which, in most cases, is poorly distinguishable and hence has not been studied in detail.

In chloroform solution a striking change of band intensities was observed on comparison with experiments where carbon tetrachloride served as the solvent. The band at 2 170—2 221 cm^{-1} rose at the expense of that located at 2 050—2 080 cm^{-1} whereas the strong band at 2 100 cm^{-1} was displaced towards higher wave-numbers ($\Delta\nu \sim 20$ cm^{-1}) and slightly decreased in intensity. The total band intensity, however, expressed as $\int A \, d\nu$ (the area of all bands from 1 950 cm^{-1} through 2 350 cm^{-1}), remained the same in carbon tetrachloride and chloroform.

In the above-mentioned region the spectra of the whole series of mustard oils are essentially identical, yet with three striking exceptions, *viz.* methyl, *tert.*-butyl and phenyl *iso*thiocyanate. Among all compounds examined, the methyl derivative displays bands at the highest frequencies. Tertiary butyl *iso*thiocyanate is devoid of any maximum in the 2 180 cm^{-1} region (in chloroform a shoulder only), but displays a maximum at 1 985 cm^{-1}. Finally, phenyl

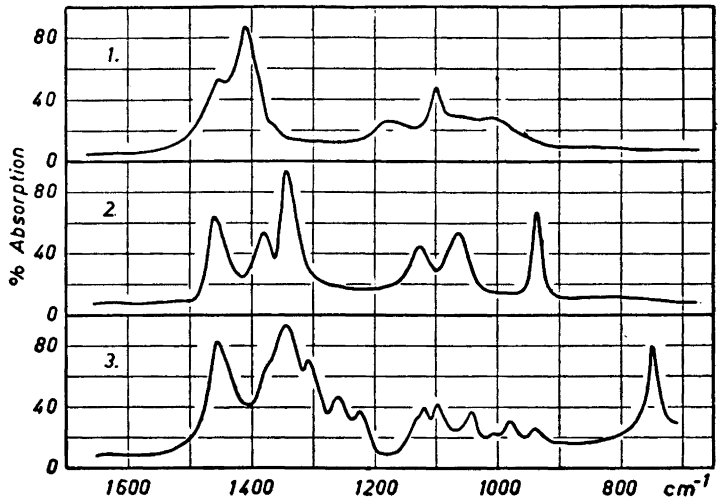

Fig. 4. Infra-red spectra of various *iso*thiocyanates. (5 % solutions in CCl_4 or CS_2). 1. Methyl *iso*thiocyanate. 2. Ethyl *iso*thiocyanate. 3. *n*-Butyl *iso*thiocyanate.

*iso*thiocyanate has its predominant bands at 2 054 cm^{-1} (in CCl_4) and also absorbs most intensely of all compounds listed in Table 3 in terms of $\int A\, d\nu$.

Ethyl *iso*thiocyanate, a typical representative of the present series, served as a model compound for the study of the dependence of the position and intensity of absorption bands on concentration, in carbon tetrachloride as

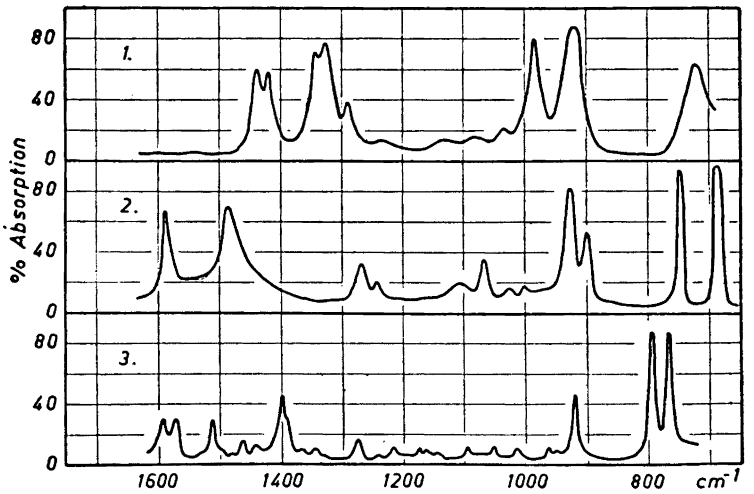

Fig. 5. Infra-red spectra of various *iso*thiocyanates (5 % solutions in CCl_4 or CS_2). 1. Allyl *iso*thiocyanate. 2. Phenyl *iso*thiocyanate. 3. α-Naphthyl *iso*thiocyanate.

well as chloroform. No conspicuous changes were noted, however. The spectra of the ethyl derivative as a film (liquid state) and in the vaporous phase did not deviate from those determined in solution.

The 1 800—1 500 cm^{-1} region. In this "double bond range" we have found no bands in the alkyl *iso*thiocyanates. Only derivatives of unsaturated alkyls and aromatic derivatives display absorption in agreement with literature assignments [18].

The 1 500—650 cm^{-1} region. Some typical regularities characteristic for the presence of the —N=C=S grouping were observed in this spectral range (Figs. 4 and 5). In the homologous series of normal substituents from ethyl to *n*-octyl, a strong absorption band at 1 346—1 348 cm^{-1} was apparent (ethyl 1 346 cm^{-1}, *n*-butyl 1 347 cm^{-1}, *n*-amyl 1 347 cm^{-1}, *n*-hexyl 1 348 cm^{-1}, *n*-octyl 1 347 cm^{-1}). Similarly, the allyl and benzyl derivatives displayed a band at 1 345 and 1 347 cm^{-1}, respectively. In *iso*propyl and *cyclo*hexyl *iso*thiocyanate the position of this band shifted to 1 329 and 1 318 cm^{-1}. Methyl, *tert.*-butyl, phenyl and α-naphthyl mustard oil again showed anomalous behaviour in this region compared with other compounds. None of them absorbed in the 1 350—1 300 cm^{-1} range, whereas methyl *iso*thiocyanate exhibited an intensive band at 1 412 cm^{-1} and the *tert.*-butyl derivative at 1 205 cm^{-1}. The position of the 1 347 cm^{-1}-band appeared to be independent of the polarity of the solvent and the concentration.

DISCUSSION

Ultra-violet spectra

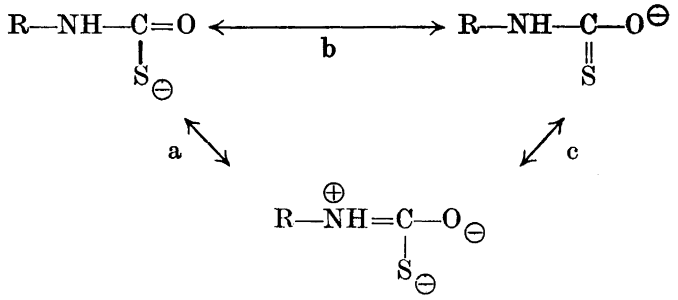
The molecular extinctions of the absorption maxima of alkyl *iso*thiocyanates (244—248 mμ) are approximately 10^3, a value intermediate between those characteristic for allowed and forbidden transitions. For the following reasons we believe that the absorption is assignable to the allowed N → V transition. An analysis of Raman as well as infra-red spectra suggests that the electron distribution in the NCS-grouping is approximately that of the dipolar form $R—\overset{\oplus}{N}\equiv C—\overset{\ominus}{S}$. The only likely N → V-transition in the present structure, however, is associated with the creation of cumulated double bonds ($R—\overset{\oplus}{N}\equiv C—\overset{\ominus}{S} \rightarrow R—N=C=S$) and such transitions are known to result in rather low extinction values [16]. The occurrence of an N → V-transition in the present case is supported also by the position of the absorption maximum. The range 245—260 mμ can be considered as the customary location for absorption bands attributable to transitions of the present type.

In this connexion attention should be drawn to the ultra-violet spectrum of the isomeric alkyl thiocyanates which exhibit [2] an absorption maximum of weak intensity ($\varepsilon = 30$) in the 240 mμ region, apparently belonging to a forbidden transition. This deviating pattern is not unexpected because the electron shift, characteristic for the N → V-transition, in this case would

imply not only the formation of cumulated double bonds but also, and more importantly, the participation of a polar ion containing trivalent sulphur.

$$R{-}S{-}C{\equiv}N \rightarrow R{-}\overset{\oplus}{S}{=}C{=}\overset{\ominus}{N}$$

The situation is more complicated in the N-alkyl monothiocarbamate series because three significant $N \rightarrow V$ transitions can be vizualized in molecules of this type, *viz.*:



It may be of interest to attempt an assignment of the absorption band (λ = 226—232 mμ) of high intensity ($\varepsilon \sim 10^4$), characteristic for alkyl monothiocarbamates, to one of these transitions (a, b, c). That represented by (a) is not active in the near ultra-violet region, as can be inferred, *inter alia*, from the insignificant absorption of N-alkyl carbamates in the 220—400 mμ region. Comparison of the position of the absorption maximum of N-alkyl monothiocarbamates with that of compounds containing N—C=S groupings (Fig. 6) suggests that the absorption maximum of the monothiocarbamates should be attributed to the transition (b) above. This interpretation, however, does not account for the fact that N-alkyl monothiocarbamates do not exhibit an additional maximum in the 245—260 mμ range, expectable from the transition (c) above. This is surprising, particularly because the formally similar dithiocarbamates and xanthogenates display maxima ascribable to the CSS- as well as to the N—C=S- or O—C=S-groupings.

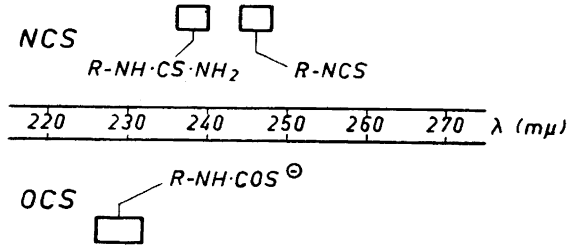


Fig. 6. Absorption maxima ranges of the —NCS and —OCS groupings in the ultra-violet region.

Influence of the structure of the R-group of iso*thiocyanates and monothiocarbamates on the position of the absorption maximum.* From Table 2 it can be seen that the introduction of any substituent in the methyl derivative in both series results in a bathochromic shift of the absorption maximum. This means that groups characterized by an $-I_S$ effect (*e.g.* allyl, benzyl, phenyl) as well as those displaying an $+I_S$ effect (*e.g. tert.*-butyl) displace the absorption maximum towards higher wave-lengths, *i.e.* the N → V-transition associated with the appearance of the absorption band requires lower energy. As both types of substituents ($+I_S$, $-I_S$) produce a qualitatively similar shift, we conclude that the extension of conjugation (due to hyperconjugation) is responsible, rather than the inductive effect. The data in Table 2 disclose the fact that replacing of the first hydrogen of the methyl grouping results in a shift of 1 mμ, whereas substitutions of the second and third hydrogens cause displacements of 2-4 mμ. Substitution at the β- and γ-carbon atom is not reflected by changes of absorption maxima, but in the case of "medium-size" *n*-alkyls (C_5, C_6, C_8) a shift of 1 mμ relative to the ethyl derivative was noticed in the monothiocarbamate series. In the *iso*thiocyanates these derivatives do not differ from the ethyl compound.

In the mustard oil series we consider hyperconjugation to be involved:

$$H_3\text{—}CH_2\text{—}\overset{\oplus}{N}\equiv C\text{—}\overset{\ominus}{S} \overset{h}{\longleftrightarrow} H\ \overset{\ominus}{\overline{C}}H_2\text{—}CH_2\text{—}\overset{\oplus}{N}\equiv C\text{—}\overset{\ominus}{S} \overset{(N\rightarrow V)}{\longleftrightarrow} H\ \overset{\oplus}{\overline{C}}H_2\text{—}CH_2\text{—}\overset{\ominus}{\overline{N}}=C=S$$

where h indicates a hyperconjugation displacement. Further substitution at the α-carbon atom of the ethyl derivative facilitates an extension of conjugation, whereas hyperconjugation in the methyl derivative operates less favourably, resulting in cumulation rather than conjugation of p electrons:

$$CH_3\text{—}\overset{\oplus}{N}\equiv C\text{—}\overset{\ominus}{S} \overset{h}{\longleftrightarrow} H\ \overset{\ominus}{\overline{C}}H_2\text{—}\overset{\oplus}{N}\equiv C\text{—}\overset{\ominus}{S} \overset{(N\rightarrow V)}{\longleftrightarrow} H\ \overset{\oplus}{\overline{C}}H_2\text{—}\overset{\ominus}{\overline{N}}=C=S$$

In both series, the ω-methylthioalkyl derivatives (XIX, XX and XXI) are closely comparable to the ethyl compound.

Apart from the number of substituents on the α-carbon atom (Table 2), the presence of π-electronic bonds in the substituting groups influences the magnitude of the bathochromic shift. Introduction of a double bond in β,γ-position (allyl derivatives) results in a shift equivalent to that produced by substitution of a hydrogen atom in the methyl derivative by a methyl grouping. Whereas in N-methallyl monothiocarbamate substitution at the α-carbon atom exclusively causes a bathochromic shift, the corresponding methallyl *iso*thiocyanate is changed by β-substitution as well. In the α-substituted mustard oil (XII) this displacement amounts to 3 mμ, which is more than the added influences of the allyl- (1 mμ) and the methyl-grouping (1 mμ) (estimated from the displacement on going from ethyl to *iso*propyl *iso*thiocyanate). However, considering the error attached to these measurements this difference does not warrant a more detailed discussion. It is interesting that the presence of a γ,δ-double bond, as in (XV), in both series produces an effect comparable to that observable in the allyl series. Previous examples of a corres-

ponding interaction between unconjugated chromophores across a dimethylene bridge have been recorded [17]. The presence of a δ,ε-double bond ((XVI) in Table 2) is without influence on the absorption pattern as estimated from the similarity between the spectra of (XVI) and the ethyl derivatives. In alkenyl *iso*thiocyanates the spectral displacement can again be ascribed to hyperconjugation, represented in the case of allyl *iso*thiocyanate by the following scheme:

$$CH_2{=}CH{-}CH_2{-}\overset{\oplus}{N}{\equiv}C{-}\overset{\ominus}{S} \xleftrightarrow{h} CH_2{=}CH{-}\overset{\ominus}{\underset{\oplus}{\underset{|}{CH}}}{-}\overset{\oplus}{N}{\equiv}C{-}\overset{\oplus}{S} \xleftrightarrow{(N \rightarrow V)}$$

$$\overset{\oplus}{H}\ \overset{\ominus}{\underset{|}{CH_2}}{-}CH{=}CH{-}\overset{\ominus}{N}{=}C{=}S$$

Besides *tert.*-butyl mustard oil, the benzyl and α-phenylethyl derivatives display the largest bathochromic displacement for reasons which we consider to be similar in nature to those suggested above for the alkenyl *iso*thiocyanates. A slight hypsochromic effect of the α-phenylethyl grouping, relative to benzyl mustard oil, rather than an expected displacement towards longer wave-lengths may be interpretable in terms of partial inhibition of the hyperconjugation effect or, rather, by steric interference of the conjugation between the aromatic ring and the NCS-grouping. The bathochromic shift associated with the introduction of a methyl-grouping in α-position of the allyl chain renders steric influence more likely as a deciding factor.

When the relative deviations in wave-lengths of maximum absorption in the *iso*thiocyanate and N-alkyl monothiocarbamate series are plotted (Fig. 7), a linear dependence appears. In case of unsaturated side chains the line acqui-

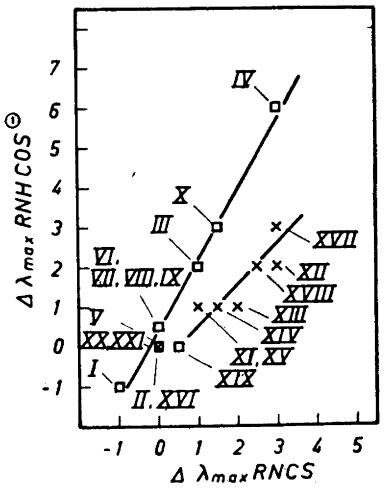

Fig. 7. Relationship between the relative absorption maxima of N-alkyl monothiocarbamates and alkyl *iso*thiocyanates (□ : compounds with saturated substituents; × : compounds with unsaturated substituents). The numbers of the compounds refer to Table 2.

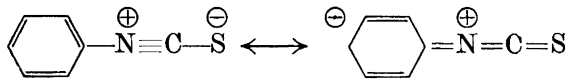
res a different slope, a deviation paralleling that observed in studies of the relative reaction velocities of alkyl *iso*thiocyanates.

Infra-red spectra

The 1 900—2 300 cm^{-1} region. In this wave-length region an increase of the absorption band at about 2 180 cm^{-1}, accompanied by an intensity decrease of the 2 090 cm^{-1} peak, is consistently observed on changing the solvent from CCl_4 to $CHCl_3$ (Fig. 3). The effect is presumably ascribable to an enhanced polarization of the NCS-grouping in the more polar solvent. The lacking band around 2 180 cm^{-1} in the spectrum of *tert.*-butyl *iso*thiocyanate (Fig. 3) is probably caused by steric influences.

The multiplet character of the band in this spectral region, attributed to the asymmetric stretching vibration of the —N=C=S grouping, is difficult to explain, for reasons similar to those outlined in the case of the Raman spectra [13]. Supplementary investigations of the Raman spectra are planned in order to clarify this problem. Association effects can hardly be responsible for the doubling of the bands, in view of the spectral independence of concentration or phase condition. Again, such phenomenons as tautomerism, hydrogen bonding or rotational isomerism seem very unlikely in case of the NCS-grouping.

The displacement of the absorption band from 2 100 cm^{-1} to 2 054 cm^{-1} in phenyl *iso*thiocyanate (Fig. 3) is explainable in terms of a conjugation effect diminishing the contribution from the triple-bonded hybride to the molecule which is assumed to be planar:



A qualitatively similar but less pronounced displacement is observable in the spectrum of α-naphthyl *iso*thiocyanate (Fig. 3), as would be expected.

The 1 500—650 cm^{-1} region. A strong band at 1 348—1 318 cm^{-1} can be assigned to the $-CH_2N=C=S$ or $>CH-N=C=S$ groupings. In the given region there has not been described, thus far, any intense, characteristic frequencies. Weak C—H-deformation modes (wagging and twisting) reaching into the 1 300 cm^{-1} region, such as those operating here, have received only little attention, particularly regarding the influence of substituents. The symmetric stretching vibration of the —N=C=S-grouping, which in Raman spectra gives rise to a strong line at 1 070 cm^{-1} (methyl and ethyl mustard oil) is, according to our findings, inactive or slightly active in the infra-red spectra examined. The strong band at 1 348—1 318 cm^{-1} can hardly be assigned to the symmetric stretching mode of the —N=C=S grouping, since methyl, *tert.*-butyl, phenyl and α-naphthyl *iso*thiocyanate do not absorb in this region. Furthermore, the Raman spectrum displays, in addition to the symmetric stretching vibration of the —N=C=S grouping at 1 070 cm^{-1}, a relatively strong line (in the ethyl derivative) of non-identified origin in the same region (1 340 cm^{-1}) where we find the band in the infra-red spectrum. It

is highly improbable that the stretching mode would be susceptible to that extent to the influence of substituents and be displaced only in methyl, *tert.*-butyl, phenyl and *α*-naphthyl *iso*thiocyanate from 1 340 cm^{-1} to another region. The most plausible interpretation of the latter bond is therefore that it represents a deformation vibration of the C—H grouping, the force constant of which is influenced by the presence of the polar $-N\overset{\oplus}{\equiv}C-\overset{\ominus}{S}$-grouping. A more exact characterization of the vibrational type would require a study of further derivatives. The introduction of deuterium to furnish the $-CD_2-N=C=S$-grouping would, of course, be advantageous in such investigations.

Methyl *iso*thiocyanate displays a strong band at 1 412 cm^{-1}, representing the symmetric deformation vibration of the methyl group and displaced by the influence of the —N=C=S-grouping from its normal position at 1 380 cm^{-1} in the linear aliphatic chain. Corresponding shifts of the methyl grouping, conditioned by the influence of polar substituents, have been reported and studied in detail [19–21]. The band at 1 453 cm^{-1} represents the asymmetric deformation vibration of the methyl group, practically unaffected by the —NCS-substitution (normal position: 1 450 cm^{-1}).

Tertiary butyl *iso*thiocyanate exhibits a broad, strikingly high band at 1 205 cm^{-1} within the region of the characteristic frequency of the *tert.* butyl-grouping. The intensity is probably influenced by the NCS-substitution.

The Binding of Chromate to Red Corpuscles, Haemoglobin and Globin

BENGT ZACHARIAS

Institute of Organic Chemistry and Biochemistry, University of Stockholm, Stockholm, Sweden

This investigation has shown that the presence of calcium in the incubation fluid promotes ^{51}Cr loss by chromate-labelled erythrocytes and blocks chromate uptake by red corpuscles. A site is suggested for the binding of chromate to the globin molecule.

The practice of labelling red corpuscles with radio chromate has become considerably wide-spread in recent years [1]. In contrast to other *in vitro* labelling methods employing radioactive substances — such as have been applied in the determination of the circulating red corpuscle mass [2–5] — the binding of ^{51}chromate to the red corpuscles is so stable that not only the corpuscle volume can be determined, making use of ^{51}chromate-labelled red corpuscles, but even information concerning the lifespan of the erythrocytes can be obtained [6,7].

The chromate loss from the circulating red corpuscles is, however, only a relative measure of the lifespan of the erythrocytes owing to a leakage of about 1 % per day from viable erythrocytes, apart from the 0.85 % loss per day due to red corpuscle physiological destruction [8].

In the healthy human organism, half of the chromate taken up by the red corpuscles is given off in the course of about one month, whereas in many pathological cases the chromate loss from the erythrocytes has been found to be far more rapid [7].

In vivo-labelling of red corpuscles by radiochromate shows an uptake of about 10 % only of the amount injected [9–11].

The uptake of radiochromate by red corpuscles *in vitro* increases with increasing temperature and increasing acidity [8,12,13]. It is also increased when an isotonic acid citrate solution (called ACD solution) is used instead of heparin as an anticoagulant [14,15].

It is reported that when ^{51}chromate-labelled red corpuscles are incubated in plasma, the ^{51}Cr loss is larger than when incubated in saline [16].

One of the aims of this investigation is to explain the above-mentioned difference in the rate of ^{51}Cr loss by the erythrocytes. The other is to determine the site of the binding of the chromate in the globin molecule, which is known to be responsible to a very large extent for the fixation of the chromate.

Gray and Sterling found already that, under optimal conditions *in vitro*, 80—90 % of the added radiochromate is taken up by the erythrocytes [6]. About 97 % of the radiochromate taken up by the erythrocytes is bound to the haemoglobin and only 2 % to the stroma.

EXPERIMENTAL

Materials. Blood was drawn by heart puncture from rats and rabbits of our laboratory strain. Horse blood was supplied by the Royal Veterinary Institute and human blood was supplied by the Karolinska Hospital. The radiochromate used had a specific activity of 1 mC per 23.76 μg chromium.

Determinations. Protein concentration of the globin solutions was determined according to the method of Warburg as modified by Kalckar [17]. The haemoglobin was determined as alkaline oxyhaemoglobin as described by Evelyn [18]. While the molecular weight [19] of haemoglobin is 66 700, that of globin is 66 000. Radioactivity was determined in a scintillation crystal counter, the samples having a volume of 10 ml.

Preparations. Haemoglobin was prepared by haemolysing the red corpuscles after repeated washings. Haemolysis was carried out by adding the same volume of distilled water and 0.2 volume of toluene. The haemolysate was centrifuged and the clear supernatant withdrawn. Rat and horse haemoglobin was crystallized from the clear haemolysate as described by Drabkin [20]. The haemolysates prepared from human and rabbit blood were filtered through Celite No. 545, as described by Boyd [21].

Native globin was prepared according to the method described by Rossi-Fanelli *et al.*[22], at a temperature of −15°C.

Activation. 5—12 ml whole blood were incubated for 1 h at room temperature with sodium chromate having an activity of 0.125—0.250 μC. After incubation, the percentage of uptake of sodium chromate by the erythrocytes was determined.

5—10 ml of haemoglobin and globin solutions were incubated in the same way as blood (above). The pH of the acid globin solutions was adjusted to 7.4 by 1 N NaOH.

After 1 h of incubation at room temperature the percentage of protein-bound chromium was determined, as described by Clegg [23], the sample being centrifuged for 1.5 h at 6 000—7 000 r.p.m.

RESULTS

Table 1 demonstrates that no difference can be detected in the uptake of chromate by the red corpuscles and by globin isolated from human, rabbit, horse or rat blood. It can be seen from Fig. 1 how the presence of 10 mg of

Table 1. Comparison of chromate binding of red corpuscles and the corresponding amount of globin.

Animal	% Chromate bound to red corpuscles	% Chromate bound to globin
Human	58.5	62.5
Rabbit	59.0	63.2
Horse	61.1	64.2
Rat	60.7	63.6

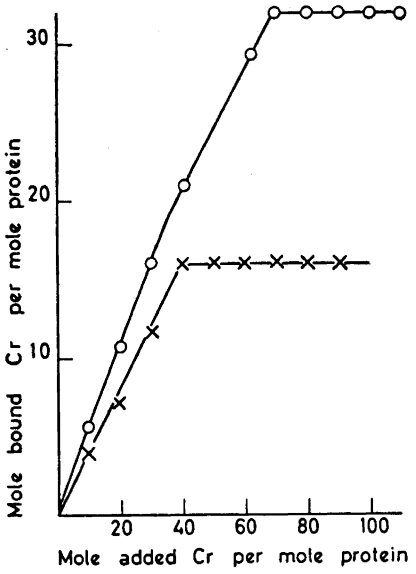

Fig. 1. The binding of ^{51}Cr by red corpuscles incubated in the presence of various amounts of chromate and in the presence and absence of calcium. Whole blood, haemoglobin and globin in the absence of calcium —O—O—; whole blood, haemoglobin and globin in the presence of calcium —×—×—.

calcium per 100 ml solution influences the uptake of chromate by human red corpuscles, haemoglobin and globin. The amount of chromate bound per molecule protein increases with increasing amounts of added chromate. In these experiments also, the presence of calcium ions reduces the amount of ^{51}chromium bound to about half of the amount fixed in the absence of cal-

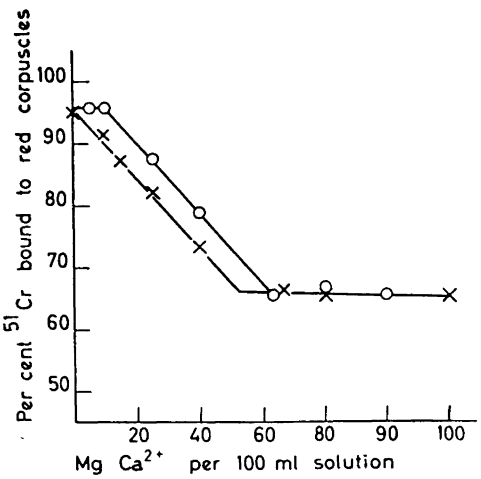

Fig. 2. The influence of varying amounts Ca^{2+} on the uptake of chromate by the red corpuscles. Saline —×—×—; ACD-plasma —O—O—.

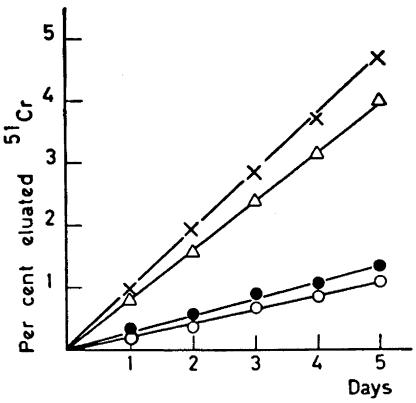

Fig. 3. Elution of ^{51}Cr from chromate labelled red corpuscles in the presence and absence of Ca^{2+} at 5°C. Saline —O—O—; Ca^{2+}-saline —×—×—; ACD-plasma —●—●—; Ca^{2+}-ACD-plasma —△—△

cium. In the presence of calcium ions, one molecule of protein can bind up to 16 molecules of chromate. In the absence of calcium, one molecule of protein can bind as much as 32 molecules of chromate.

The influence of varying amounts of calcium ions on the uptake of chromate by human red corpuscles in saline and ACD plasma is shown in Fig. 2. In calcium-free medium, the red corpuscles take up almost 100 % of the added chromate. Increasing amounts of calcium ions reduce the uptake of chromate until a plateau is reached at 60 %. In saline, this point is reached at a calcium concentration of 52 mg per 100 ml blood, and in ACD plasma at a calcium concentration of 64 mg per 100 ml. The fact that a part of the calcium is bound to the citrate of ACD-plasma explains the above difference. The amount of ionised calcium bound to ACD plasma was determined by conductometrical titration to be 12 mg per 100 ml.

Fig. 3 shows the elution of chromium from ^{51}Cr-labelled human red corpuscles incubated in different media at 5°C. Corrections were made for the small haemolysed fraction. The experiments, which took 5 days, were carried out at a low temperature as, when 37°C was sustained for 5 days, a marked haemolysis could not be avoided. The uptake of chromate by erythrocytes is known to depend very little on temperature. The elution rate in saline and ACD plasma was found to be 0.2 % per day. In saline containing 10 mg of calcium per 100 ml blood, the elution rate was 0.8 % per day, thus very much larger, and in ACD plasma containing 10 mg free calcium per 100 ml, the percentage was 0.75 per day.

DISCUSSION

We found that the presence of calcium in blood reduces the uptake of chromate by red corpuscles [15]. The uptake of chromate by haemoglobin and globin is also reduced to the same extent in the presence of calcium. This result suggests that globin and calcium compete for the chromate present and correspondingly the erythrocytes take up more chromate in the absence of calcium. This conclusion is supported by the observation that the elution

of chromate from the red corpuscles is increased when calcium is added to the blood. Cohn *et al.*[24] and Cannan [25] have determined the amino-acid groups present in haemoglobin and found among other amino-acid groups present a total of 33 histidine groups, all of which were dissociated at a physiological pH.

This result, and our finding that the number of chromate molecules bound by the globin molecule amounts to 32, suggests that the chromate is fixed to the histidine groups.

Acknowledgements. The author's thanks are due to Professor G. de Hevesy for the encouraging interest which he has taken in this work; to Dr. G. von Ehrenstein for stimulating discussions; to Dr. B. Gullbring for kindly supplying the human blood needed; and to the *Swedish Natural Science Research Council* for its generous support of this investigation.

On the Isomerism of Hydroxyurea

XI. Absorption Spectra in the Infra-Red

HELMER KOFOD

The Royal Danish School of Pharmacy, Chemical Laboratory B, Copenhagen, Denmark

A brief survey of the Raman and infra-red spectroscopy of urea is presented. On this background recorded infra-red spectra of the hydroxyurea isomerides are discussed and assignments of the principal absorption frequencies have been attempted. Although no rigorous proof has been furnished the results are compatible with the proposed constitutions carbamhydroxamic acid (I) and O-carbaminoyl-hydroxylamine (II), respectively.

In a preliminary communication [1] the absorption in the frequency region 3 600—600 cm^{-1} of the two isomerides were briefly described. In the present paper a first attempt has been made at a more detailed interpretation of the spectra in terms of structure.

The compounds, as well as urea, which may be regarded as the mother substance of at least one of the isomerides, belong to the medium-size molecules, which are too complicated for a complete theoretical treatment by the spectroscopist, but which are nevertheless too small to leave them entirely to the purely empirical approach of the organic chemist.

The structure of urea has been extensively studied by several authors. The Raman spectrum was recorded in 1934 by Kohlrausch and Pongratz [4] and also investigated in 1939 by Otvos and Edsall [5]. The latter work included a comparative investigation of deutero-urea. The absorption spectrum in the infra-red was recorded in 1941 by Kellner [2], who also subjected the molecule to a theoretical treatment [3]. Kellner found it possible to assign the observed frequencies to definite modes of vibration. The theoretical frequencies, calculated as usual from the evaluated force constants, were compared with the experimental infra-red and Raman frequencies, obtained by Kellner [2] and previous investigators [4,5]. Although quite satisfactory agreement was observed, Kellner pointed out that the proposed interpretation was by no means definite. The results of Kellner are compatible with the hypothesis advanced in 1935 by

This picture is also in agreement with X-ray measurements of the nuclear distances [9], $r(C{=}O) = 1.25$ Å and $r(C{-}N) = 1.37$ Å, and with the coplanarity of the carbon, oxygen and nitrogen atoms, as first deduced from crystallographic data [9], and later confirmed by absorption spectroscopy with polarized infra-red radiation by Keller [10] and by Waldron and Badger [11] from more

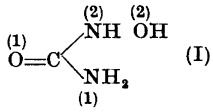
accurate measurements. Further corroboration of the latter work was presented in 1953 by Robinson and Price [6] who deduced the IR-absorption spectrum from the reflection spectrum using a single-crystal technique. Vaughan and Donohue [28] in 1952 obtained evidence that not only are the principle atoms coplanar but the hydrogen atoms lie in the plane of the rest of the molecule. Indications of this position had been observed in earlier work [10,11] and the coplanarity of the entire molecule was further supported by proton magnetic resonance studies [29] and by neutron diffraction work [27]. Davies and Hopkins [26] have recently reinvestigated the absorption of urea in the infra-red (solid and vapour state) and also recorded the spectrum of the uronium ion. Their frequency data, obtained with urea, are given in Table 1 together with the values and assignments by the previously quoted authors. Davies and Hopkins presented a detailed discussion of the bonding in urea in the solid state. The qualitative picture is in agreement with previous information, but the authors give revised values of the N—H bond lengths. They

state that only weak hydrogen bonding exists in the urea molecule, and their computation of the delocalization ("resonance"-) energy based upon the spectroscopic data yielded a value, which is considerably lower than the thermochemical value of 37 kcal/mole. The discrepancy is explained by the fact that the thermochemical value includes contributions from changes in the σ-bonds and from additional hydrogen bond energy made available by the planar configuration.

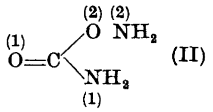
The absorption spectra of urea and of the isomeric "oxyureas", are reproduced in Fig. 1. A catalogue of frequencies of the principle absorption-bands is given in Table 2.

Among the proposed constitutions, those which seem to account for most chemical and physical properties of the oxyureas are



(I)

OU_{140}, Carbamhydroxamic acid



(II)

OU_{72}, O-Carbaminoylhydroxylamine

There is ample evidence that (I) represents the correct constitution of OU_{140}, *vide, e.g.*, parts III, IV, VI in the present series. Formula II was proposed by Exner [12] mainly from classical chemical arguments and on the basis of the results of the present author. It was, however, felt desirable to obtain further support by physical methods. At the time, when the preliminary communication [1] on the infra-red absorption appeared, only two O-acylated hydroxylamines were described in the literature, *viz.* O-anthranoyl-hydroxylamine [31] and the proposed structure II for OU_{72}. Since then the preparation of further two representatives of this type of compounds [30] has been reported, and this adds considerably to the probability of formula II. The need for a rigorous proof and the general interest [18] in the infra-red absorption of the biochemically important groupings CO—NH and NHOH is the author's justification for the following attempt at a detailed discussion of the spectra of the hydroxyureas.

The observed frequencies listed in Table 2 will be discussed with particular reference to the compatibility with the proposed constitutions I and II.

In the frequency region A all three compounds show an intense, partly resolved doublet with a slightly less intense shoulder on the low-frequency side. This is the region, where the N—H stretching vibration of amides are normally found, and the duplex nature of the peak is characteristic for the unsubstituted NH_2-group. The A-region of the urea spectrum has been carefully studied by many investigators [2-7,11], and there is general agreement that the frequencies are N—H stretching fundamentals *cf* Table 1. Mathis [13] reported a characteristic, intense band at 3 μ (3 333 cm^{-1}) in the spectra of hydroxamic acids in the solid state. He too regards it as being due to N—H stretching vibrations and takes the absorption bands as a proof of the constitution $R—C\langle^{O}_{NHOH}$. In 1958 Jencks [30] has recorded the absorption spectra

Table 2. Principle infra-red frequencies (cm^{-1}) of urea and the isomeric "oxyureas" in the solid state, *cf.* Fig. 1.

of various hydroxamic acids and a few O-acylhydroxylamines in chloroform solution. The data obtained with benzohydroxamic acid and O-benzoylhydroxylamine are representative and of interest in the present discussion, since the formulae of the compounds are analogous to I and II, respectively. The wave lengths, converted to wave numbers, are quoted in Table 3, and the assignments by Jencks are included. There is good agreement between the N—H stretching frequencies in Tables 2 and 3.

Table 3. Infra-red frequencies of benzoyl-hydroxylamines in chloroform-solution. Data and assignments by W. P. Jencks [30].

The assignment of the third (low-frequency) band is uncertain. In the urea molecule (*cf.* Table 1) it has been interpreted as the first overtone of the frequencies around 1 600 cm^{-1}. In benzohydroxamic acid on the other hand (*cf.* Table 3) a corresponding band has been assigned to a hydrogen bonded O—H group and in O-benzoyl hydroxylamine to a hydrogen bonded N—H group. It is emphasized that the latter assignments refer to solution spectra.

Since it is virtually impossible to distinguish between N—H and O—H bonds in this region the presence of a hydroxy-group in OU_{72} is not directly disproved; it is, however, unlikely for chemical reasons.

In the frequency-region B there is a broad band at 2 800 cm^{-1} in the spectrum of OU_{140}. It is one of the most intense bands in the spectrum and is absent or extremely weak in U and OU_{72}. It has therefore tentatively been assigned to the hydroxy-group [1]. Since this assignment would rule out all the possible formulations of OU_{72} containing free hydroxy-groups and would be in favour of the set of formulae I/II its validity has to be carefully considered. The normal stretching vibration of the unassociated O—H group is found at much higher frequencies in the A region. It is, however, well known [14] that the frequency is very considerably lowered by hydrogen bonding, of which there are ample possibilities in OU_{140}. For the O—H....O bond in the crystalline state the O—H frequency shift has been shown to be a monotonic and nearly linear function of the H....O distance [15,16]. Similar regularities have been demonstrated [17] for a number of other "straight" hydrogen bonds, such as OH....N, NH....O, NH....N, which may also be present in crystals of OU_{140}. The linear relationship is valid only up to a distance of *ca.* 2.8 Å. For short,

i. e. strong hydrogen bonds the OH frequency is reduced very considerably. When straight OH....O bonds are involved, stretching frequencies of the O—H bond as low as 2 000 cm^{-1} have in fact been recorded in the crystalline state. The observed frequency of 2 800 cm^{-1} is, therefore, by no means exceptionally low. Taking 3 700 cm^{-1} as the normal frequency of the non-hydrogen-bonded O—H group, 2 800 cm^{-1} would correspond [17] to a hydrogen bond distance OH....O of 2.67 Å.

The flattened shape of the maximum at 2 800 cm^{-1} in Fig. 1 is also in accordance with general experience concerning the hydrogen-bonded OH group in this frequency region [17, Fig. 2].

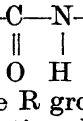
Mathis [13] has recorded the IR-spectra of a number of hydroxamic acids, which are, of course, closely related to the proposed formula (I) for OU_{140}. He reported "une bande d'absorption intense et très large" at 3.6 μ corresponding very closely to 2 800 cm^{-1}. This band is visible in the solid state only, *cf* Table 3. In carbon tetrachloride solution it disappeared and was replaced by a new, intense band at 3 450 cm^{-1} (2.9 μ). From these observations Mathis concluded that the 2 800 cm^{-1} band was *not* due to a hydrogen-bonded OH group and assigned it tentatively to a C—H stretching vibration, perturbed by the proximity of an oxygen atom, a proximity, which Mathis assumed to exist in the solid state only. The new band at 3 450 cm^{-1}, appearing in solution, was assigned to a hydrogen bonded hydroxy-group, intermolecular hydrogen bonds being postulated in solution only.

In the opinion of the present author the observations of Mathis might equally well be explained by assigning the band at 2 800 cm^{-1} to a hydrogen-bonded OH group in the crystalline state. Since the N—H group too may be involved in hydrogen bonds in the crystalline state, it would be reasonable to assume, that the new bond appearing at 3 450 cm^{-1} in solutions of hydroxamic acids represents the normal frequency of either the non-bonded OH group or of an unassociated N—H group.

Unfortunately the insolubility of OU_{140} in non-polar solvents prevents the recording of a solution spectrum, which might otherwise throw further light upon the origin of the 2 800 cm^{-1} band. Some further support for the assignment of the band at 2 800 cm^{-1} to a strongly hydrogen-bonded hydroxy-group is provided by observations by Nightingale and Wagner [34]. They reported a broad, intense band at 2 876 cm^{-1} in the infra-red spectrum of solid hydroxylamine at low temperature and attributed it to the O—H stretching vibration. The surprisingly low frequency was interpreted as indicating extremely strong hydrogen bonding in the crystal.

In the double-bond region C urea as well as the two oxyureas show an intense, broad absorption band, consisting of two incompletely resolved maxima.

This feature corresponds closely to what is known from amides of the general formula



in which the R groups must have a carbon adjacent to the amide group and cyclic connections by way of the R groups must be absent. These compounds all display two typical bands in the double-bond region. One is located at approximately 1 650 cm^{-1} ("Amide I") and is assigned to the carbonyl stretch-

ing vibration. For the other one at approximately 1 550 cm^{-1} ("Amide II") three different explanations have been proposed, the most probable one assigning it to the stretching vibrations of the C—N bond, which is supposed to be enhanced in bond strength by a mesomerism involving the adjacent C=O bond [25].

Hydroxamic acids similarly show an intense absorption in this region. In benzohydroxamic acid (*cf.* Table 3) the frequency of 1 666 cm^{-1}(6.0 μ) has been reported in the solid state [13] and 1 660 cm^{-1} in solution [30]. Both authors assigned it to carbonyl stretching vibration.

In urea a Raman frequency, which has been assigned to C=O, occurs at 1 680 cm^{-1}, other authors report the value of 1 665 cm^{-1} (*cf.* Table 1). Thompson *et al.*[18] have demonstrated that in the infra-red spectra of nearly all mono-, di- and tetra-substituted ureas the C=O absorption is located close to 1 660 cm^{-1}. The normal frequency in aldehydes, ketones and fatty acids is approximately 1 700 cm^{-1}. The reason for the value being considerably lower in amides, hydroxamic acids and ureas obviously is the weakening of the C=O bond by delocalisation.

We assume that the high frequency component of the intense, broad bands in OU_{72} and OU_{140} similarly represents a C=O stretching frequency. According to the above hypothesis the fact that in OU_{140} the high frequency component is 1 650 cm^{-1}, very close to the urea value, suggests that the delocalization and hence the bond length r(C=O) are nearly equal. In OU_{72}, on the other hand, the supposedly corresponding band is located at a considerably higher frequency than in urea, in fact very close to the normal value of 1 700 cm^{-1}, observed for simple ketones. Consequently the C=O bond should be very nearly a pure double bond. This trend might be expected from the proposed constitutions, since the symmetrical arrangements of two equivalent C—N bonds in urea and OU_{140} in all probability will cause more delocalization of the C=O bond than will the $C\begin{smallmatrix}O\\ \diagup\\ \diagdown\\ N\end{smallmatrix}$ arrangement in OU_{72}. On the assumption that formula II represents the correct constitution of OU_{72}, the carbonyl bond is in fact of the ester-type and the location of its frequency fit quite well with general experience. Furthermore the observation of a strong absorption at 1 730 cm^{-1} in O-benzoylhydroxylamine (*cf.* Table 3) assigned to the carbonyl group [30] may be taken as further corroboration of the assignment of the frequency.

The relation between bond length and stretching frequency of the carbonyl group has been studied by Rundle *et al.*[19]. For bond lengths ranging from 1.13 to 1.31 Å the points were found to fit a smooth curve, from which the C=O bond lengths in OU_{140} and OU_{72} may be read as 1.25 Å and 1.22 Å, respectively; that of urea is 1.26 Å.

Although the assignment of the high frequency absorption bands in region C to a carbonyl group is compatible with the formulae I and II it should be pointed out that no direct proof is delivered. This should be particularly emphasized with respect to formula II. The reason for this is that the C=N bond is known to produce a stretching frequency in the same region and of similar intensity, and it is virtually indistinguishable from that of C=O.

Molecular structures containing a C=N bond instead of a C=O bond, which have been proposed for both oxyureas, are therefore not entirely ruled out by the present results. Relatively few investigations have been carried out on the infra-red absorption of acyclic C=N compounds. Bonino and Manzoni-Ansidei [20] reported an absorption band at 1 650—1 660 cm^{-1} in acyclic oximes and assigned it to the C=N bond. Mathis [13] similarly observed a characteristic band at 5.95 —6 μ (1 680—1 666 cm^{-1}) in acyclic oximes and made the same assignment. Duyckaerts [21] reported the value 1 630 cm^{-1} in free oximes and assigned it to the C=N—OH group without specification; in salts and complexes of oximes he observed a band at 1 550 cm^{-1}, which he assigned to $\overset{+}{N}—\overset{-}{O}$. Borello and Henry [22] have investigated glyoximes and assigned a frequency at 1 625 cm^{-1} to the C=N bond. Some iminoethers and guanidines have also been investigated. It appears from the above and is generally agreed that the C=N absorption occurs at somewhat lower frequencies (1 625—1 650 cm^{-1}) than that of the C=O group, although values up to 1 683 cm^{-1}, have been found (acetoxime, Ref.[25], p. 182). It will be noticed that some of the values reported of the C=N frequency are very close to the low frequency component of the composite bands in region C in Table 2. This component at 1 620, 1 610 and 1 600 cm^{-1}, respectively, has therefore tentatively been assigned to the C—N bond, which is assumed to be enhanced in bond strenght by mesomerism involving the carbonyl group. It may possibly be identified with the "Amide II" band, for which a similar interpretation has been presented [25]. The fact that in OU_{72} the supposed "Amide II" band is distinctly separate from the C=O band, whereas in U and OU_{140} it is poorly resolved, may be correlated with the smaller degree of bond delocalization or "resonance" in the OU_{72} molecule as discussed above.

The alternative explanations [25] of the "Amide II" band may also be considered as a possibility, particularly the one assigning the band to NH_2 deformation, *cf.* Table 1.

As an aid in the assignment of the frequencies in region C the absorption of O-methyl-isourea might be of interest, since the contribution from structures containing C=N double bonding should be even more pronounced in this compound than in urea and the oxyureas. The Raman spectrum of an aqueous solution containing 50 % by weight of O-methylisouronium chloride has been determined by Edsall [23], but the results obviously refer to the cation, in which the delocalization of the C=N bonds is large, and no assignments have been made by the author except for some lines arising from the methyl-group. Investigations of the infra-red spectrum of the base are in progress in this laboratory.

Finally in the C region there is a shoulder at 1 565 cm^{-1}, also observed in O-benzoylhydroxylamine (*cf.* Table 3). In benzohydroxamic acid it is absent.

It is obvious from the discussion that at present a completely reliable assignment of the bands in the double-bond region C is hardly possible from the spectroscopic data alone, and the possibility is left open that the bands may

be entirely or partly due to C=N stretching vibrations and deformation of NH_2*.

In the frequency region D urea and OU_{140} display certain similarities, whereas the absorption curve of OU_{72} is much more complex. This is to be expected on the basis of the formulae I and II since it is the region, in which the C—N and C—O stretching frequencies normally appear, and with respect to these bonds U and OU_{140} are related and fundamentally different from OU_{72}.

At 1 470 cm^{-1} an intense band is noticed in urea (Table 2). It probably corresponds to the Raman lines observed at 1 458 and 1 478 cm^{-1}, respectively, by two different investigators (Table 1). These lines have been assigned to $C\langle^{N}_{N}$ asymmetric stretching. It is probably this band that reappears in OU_{140} at 1 490 cm^{-1}, but is absent or considerably displaced in OU_{72} in accordance with formula II, containing one C—N only.

At 1 415 cm^{-1} there is an intense band common to OU_{72} and OU_{140} but absent in U. If this band too be assigned to a C—N stretching vibration a reasonable explanation of the four bands appearing in the region 1 490—1 415 would be, that the two separate peaks in the "unsymmetric" OU_{140} are due to the two C—N bonds (formula I), and that these peaks in the symmetrical urea molecule coincide at the intermediate frequency 1 470. In OU_{72} in accordance with formula II there is one C—N band at 1 415 (in common with OU_{140}). The fact that all these frequencies are displaced from the normal C—N stretching frequency region (900—1 300 cm^{-1}) toward the double bond region may be understood as a result of the partial double bond character of the existing C—N bonds in all three compounds. In reasonable accordance with the results deduced from the C-region the relative displacement of the C—N frequencies indicate considerable bond delocalization in U and OU_{140} and much less in OU_{72}.

The low frequency part of the fingerprint-region D is still more difficult to interpret, and only vague suggestions may be attempted.

It would be reasonable to assign the bands located round 1 100 cm^{-1} in OU_{140} and OU_{72} to N—O stretching vibrations. Some support for this assignment is provided by investigations of Borello and Henry [22] who assigned a frequency at 1 150 cm^{-1} in a glyoxime to the N—O bond. Some evidence against this assignments is, however, found in the fact that absorption at 1 100 cm^{-1} is not completely absent in urea, the formula of which is devoid of N—O bonds. The frequency in question is of course in the normal position of C—N stretching vibrations (900—1 300) and this should be taken into account as an alternative assignment. A symmetrical stretching vibration of C—N has been reported at 1 000 cm^{-1} in urea (Table 1).

---

* *Added in proof.* A publication in Czech by O. Exner (*Chem. Listy* **52** (1958) 1613) has come to the author's knowledge after this paper had been delivered for publication. Exner has recorded the IR-absorption in the carbonyl-region of a number of hydroxylamine derivatives, *inter alia* the hydroxyureas. Exner reports a carbonyl frequency of 1 750 cm^{-1} in OU_{72} and a double band at 1 660 and 1 695 cm^{-1}, respectively, in OU_{140}. The numerical deviations from the values reported in Table 2 are probably due to the fact that Exner's measurements are carried out on dioxane solutions.

Formula II requires C—O single bond frequencies to exist in OU_{72}, and since this bond has no equivalent in the conventional formula of urea and probably not in that of OU_{140} either, any frequency assignable to C—O should be chosen amongst OU_{72}-bands, which are absent in U and OU_{140}. Three intense bands meeting these requirements, fall within the normal region of C—O stretching vibrations, namely those at 1 210 cm^{-1}, 950 cm^{-1} and at 885 cm^{-1}, respectively. It should be pointed out, however, that a band at 950 cm^{-1} observed in β-oximes in the solid state has been assigned to the N—O bond [24]. Since furthermore the band at 1 210 cm^{-1} has an equivalent in O-benzoylhydroxylamine (Table 3) we suggest that this band be assigned to the C—O stretching vibrations.

Finally the *E-region* is the one in which N—H rocking is normally observed and the band around 800 cm^{-1} observed in all three compounds may tentatively be assigned accordingly.

Summarizing the discussion of the absorption spectra it may be said that no details have been found, which are incompatible with the formulae I and II. Some observations are in favour of them, but no unambigous proof has been delivered as far as absorption spectroscopy in the infra-red is concerned.

EXPERIMENTAL

The preparation and characterization of the hydroxyureas (Fig. 1, curves *c*, *d*, and *f*) have been described in a previous communication [32]. The sample of the higher melting isomeride employed for the recording of curve *e* was prepared according to Runti and Deghenghi [33]. It is regarded as having a higher degree of purity than that used for curve *f*. The urea sample was a commercial analytical-grade product.

All results in Fig. 1 and Table 2 refer to the crystalline state. The pressed disc technique was used and the disc contained 1 mg substance dispersed in 300 mg of potassium bromide. The instrument was a Perkin Elmer double beam infra-red spectrophotometer model 21, equipped with sodium chloride optics. Resolution 927, response 1, gain 6.5, speed 5, suppression 2.

Acknowledgements. The author is grateful to professor, dr. Børge Bak for his kind interest and for valuable criticism. My thanks are also due to Mr. Henry E. Andersen for assistance in the recording of the spectra.

Attempts to Prepare Heparin from Ox Liver Capsules with a Mild Method

ROLF OTTOSON* and OLLE SNELLMAN

Institute of Biochemistry, University of Uppsala, Uppsala, Sweden

Heparin has been prepared almost quantitatively by a very mild method from ox liver capsules. It has, however, not been freed from a phosphorus containing component of unknown nature which seems to be firmly bound to the heparin.

The aim for the present study has been to develop a mild method for the preparation of heparin in order to obtain it in an as undamaged state as possible. Previous attempts to fractionate commercial heparin with fractionated alcohol precipitation resulted in several fractions with decreasing anticlotting activities but with almost constant sulfur contents. It would be interesting to see whether these activity differences are a result of using too violent preparation methods or if they exist *in vivo*. Efforts have been made to avoid extreme pH values, high temperatures and enzymatic degradation resulting from the presence of carbohydrate attacking enzymes possibly admixed. Acetone denaturation and zone electrophoresis have been very effective in removing the proteins.

METHODS

The ox liver capsules were removed from the livers immediately after slaughter, put into Dewar bottles with ice and transported to the Institute. There they were cleaned from other tissue by scraping with a knife, chopped, weighed and frozen in fine-ground carbon dioxide ice. The mixture was ground to a fine powder in a plate mill and left at -10°C until the carbon dioxide had evaporated. The capsule powder was treated at $+2$°C for about 5 min in a porcelain mortar with a solution 0.10 M in potassium thiocyanate and 0.05 M in potassium hydrogen phosphate (K_2HPO_4). The result was a paste which was diluted with about five times its volume of buffer solution. The pH was adjusted to 7.7—7.9, usually with 0.10 M sodium hydroxide in

* Present adress: Research Institute of National Defence, Sundbyberg 4, Sweden.

the first extraction of a capsule batch and with acetic acid diluted about twenty times in the third and following extractions. The mixture was slowly stirred over night at +2°C. After centrifugation in an International Centrifuge, Model FS, size 3, for about one hour, the supernatant was spared and the residue was stirred with the same volume buffer solution two times more in the same way as before. In some cases the residue was treated with buffer solution several times more in order to control the efficiency of the extractions. The results for two preparations are shown in Table 1. The anticlotting activities are measured with the thrombin method described by Jaques and Charles [1]. In order to avoid delicate standardizations, commercial heparin (Vitrum) has been used as standard, and the activity of this heparin dried in vacuum over P_2O_5 has been set to 100. In Table 1 the activity measured directly on the extract neutralized to 7.2 has been recounted as mg heparin.

Table 1. Yields in the extracts from two preparations. Starting weight 83 g and 120 g capsules wet weight. Yield in mg heparin.

Extract number	Yield in mg heparin	
1	32	63
2	11	16
3	2	2
4	1	4
5	1	0
Mg per kg wet weight	567	708

The three first extracts were pooled, the pH adjusted to 7.0—7.2 with acetic acid diluted tenfold, and an equal volume acetone was added, and the precipitation mixture left at room temperature over night. The precipitate was centrifuged down and treated with about ten times its volume of distilled water with a Potter-Elvehjem homogenizing apparatus. The pH was kept at 7.7—7.9 during this procedure. The insoluble proteins were removed by centrifugation in a Spinco centrifuge, Model L, rotor 20, at 20 000 *g* for one hour. The residue was washed once with a small amount of water, centrifuged again and the two supernatants were combined. The pH was adjusted to 7.0—7.2, an equal volume acetone was added, the precipitate centrifuged down at about 2 000 *g* for one hour and then washed with acetone. The precipitate was treated with a homogenizer, Spinco centrifuged, washed with water and Spinco centrifuged once more. The supernatants were combined and dialysed in a cellophane bag (Visking Co) against several changes of distilled water for about 24 h altogether. During the dialysis the pH was controlled and kept at 7.5—7.9.

The residues after the extractions and the Spinco centrifugations were pepsin incubated at 38°C at pH 2 for about 3 days, with addition of chloroform to prevent bacterial growth. Part went into solution and all except some small grains dissolved when the pH was increased to 7.5. The total anticlotting activity in this fraction corresponded to at most 10 mg heparin Vitrum per kg capsule wet weight.

The supernatants after the acetone precipitations of the extracts were collected and concentrated in air stream at about 45°C, dialysed and investiga-

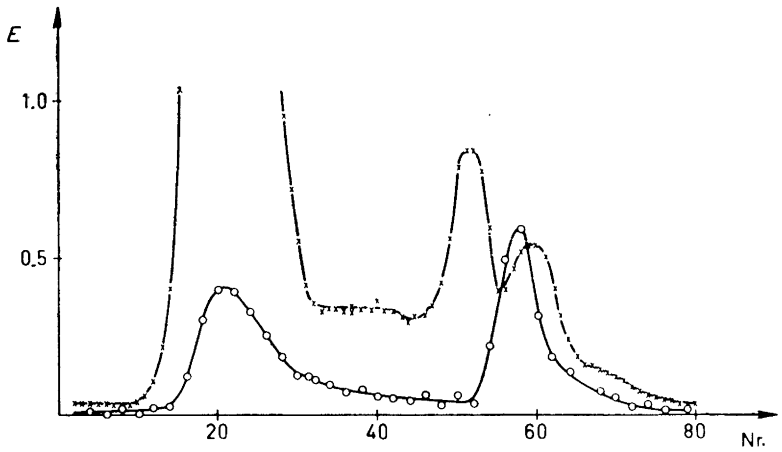

Fig. 1. Zone electrophoresis of two times acetone precipitated capsule extract: —o—o— = carbazole test curve; —x—x— = absorption at 280 mμ. Nr = number of eluated tubes, E = extinction.

ted for anticlotting activity. The activity corresponded to about 1 mg heparin Vitrum per kg capsule wet weight.

The dialysates were controlled for activity after concentration as described and redialysing in extra fine porous bags (Visking Co) but no heparin was found.

The activity not extracted with buffer and the activity lost in the precipitations correspond together to about 1 or 2 % of the total amount heparin activity in the capsules.

The dialysed crude heparin was subject to zone electrophoresis as described by Porath [2,3] with a cellulose powder, described by Flodin and Kupke [4], as supporting medium. The cellulose column was 70 cm long and 4.5 cm in diameter. The buffer used was 0.10 M potassium phosphate at pH 6.8. As DNP-leucine moves about half as fast as heparin at this pH and has a strong yellow colour, a little of this substance was added to make it possible to see how far the electrophoresis had proceeded. The sample was made only 0.03 M in phosphate buffer, which had a zone sharpening effect. This effect could be increased further by adding 5 ml distilled water to the sample. The starting zone contained about 50 ml solution. Each electrophoresis took about 80 h with a current of 0.1 A. After this time the zones were eluated with buffer in test tubes in a fraction collector changing tube every fifth minute. 15 ml was collected in each tube. One ml was taken from every second tube and tested for hexuronic acid with the Dische carbazole method [5]. All fractions were measured in a Beckman spectrophotometer, model DU, at 280 mμ.

A typical run is shown in Fig. 1. The first peak in the ultraviolet absorption curve is mainly due to nucleic acids, the second to DNP-leucine, and the third to the bulk of the proteins. In the carbazole reaction curve, the first peak (tubes 16—32) contained all the anticlotting activity. This fraction was

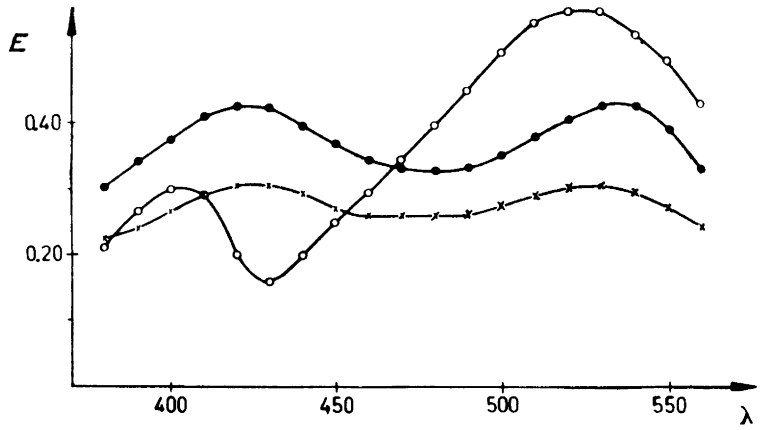

Fig. 2. Spectrophotometric absorption diagrams of carbazole tests on heparin = —o—o—; glycogen = —●—●—; the substance in peak 2 = —×—×—. E = extinction, λ = wavelength in mμ.

collected. Absolute alcohol was added until the alcohol concentration was 25 %. The precipitate, which formed after some hours, was discarded since a test for hexuronic acid was negative. Acetone was added to the supernatant to 50 %. The precipitate formed was centrifuged down, redissolved in a small volume of water and dialysed against distilled water in order to remove the precipitated phosphates.

The second zone (tube 53—64 in Fig. 1) was precipitated by adding 1 ml 4 M sodium chloride per 25 ml solution and two volumes alcohol. The precipitate formed was dried over P_2O_5 in vacuum and analyzed with the carbazole method. The absorption curve was compared with those of heparin and glycogen. The nitrogen content was 6.5 %. The data obtained indicated that this zone contained about 60 % glycogen and 40 % proteins.

The dialysate from zone one was run once more in zone electrophoresis. The result is shown in Fig. 3, which shows carbazole tests on the eluate. After this second electrophoresis the heparin containing zones from several preparations were pooled, dialysed against several changes of distilled water, and precipitated by adding 1 ml 4 M sodium chloride per 25 ml dialysate and two volumes alcohol. The precipitate was washed with alcohol and acetone and dried in vacuum over P_2O_5. The weight was 114 mg.

The final purification was made by dissolving the crude heparin in 26 ml distilled water and 20 ml of a buffer 0.05 M in sodium phosphate, pH 6.8, and 0.20 M in sodium chloride. Three fractions were obtained by adding absolute alcohol to 25, 54 and 66 %. The fraction before 25 % and the supernatant after 66 contained no hexuronic acid and were discarded. The fractions between 25 and 54 % and 54 and 66 % were washed with alcohol and acetone, dried and weighed. The fraction between 25 and 54 % weighed 104 mg. The fraction between 54 and 66 % weighed 3 mg, had an anticlotting activity of 8

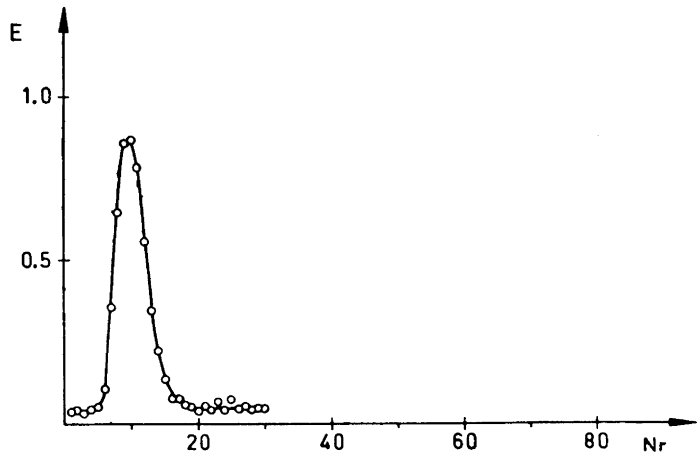

Fig. 3. Reelectrophoresis curve of the tubes No. 16—36 in the carbazole curve from the experiment shown in Fig. 1. Nr, *E* and —o—o— the same as in Fig. 1.

and a colour yield in the carbazole test of 36 % of that of commercial heparin (Vitrum).

The fraction between 25 and 54 % was subject to the following investigations, the results of which are tabulated in Table 2.

The ultraviolet absorption at 260 and 280 mμ was measured in a Beckman spectrophotometer, Model DU, in a 1 cm cuvette in order to get an estimation of the content of nucleic acid and proteins.

Ninhydrin tests were performed by taking some drops of a 3 % solution of the fraction, adding some drops of 0.2 % ninhydrin and heating in a water bath for 10 min.

The sulfur content was measured according to Ottoson and Snellman [6].

The anticlotting activity was measured.

The colour yield in per cent of the colour yield of the same weight commercial heparin (Vitrum) was measured with the carbazole method [5]. This measurement does not necessarily give even a relative value for the hexuronic acid content since the colour yield per mole hexuronic acid depends on how it is bound. Glucuronic acid in heparin gives a colour about 50 % more intense than that of free glucuronic acid.

Phosphorus was determined using a modification of a method described by Scheel [7]. In order to determine whether the phosphorus was organically bound or was a coprecipitation of inorganic phosphorus, tests were made without hydrolysis in sulfuric acid-perchloric acid mixture. The procedure exhibits a strong reaction for inorganic phosphorus in about one tenth of the phosphorus quantity present in the sample taken for analysis. The test was, however, negative.

One mg heparin was tested with the fuchsin-sulfurous acid test for aldehydes according to Feulgen, Boguth and Andresen [8]. The positive reaction for capsule heparin could, however, not be transferred by shaking into octyl alcohol.

To 1 mg heparin in 2 ml water 2.5 ml 0.1 % anthrone solution in concentrated sulfuric acid was added. The colour caused by hexoses is clearly visible for a few micrograms of glucose and strong for 50 μg micrograms.

Table 2. Data for capsule heparin and commercial heparin (Vitrum).

Determination	Capsule heparin	Heparin Vitrum
UV absorption at 260 mμ 1 mg per ml	0.304	0.360
UV absorption at 280 mμ 1 mg per ml	0.171	0.300
Ninhydrin test	negative	negative
Sulfur content, %	10.05	13.1 [a]
Anticlotting activity	112	100
Colour yield in the carbazole test	84	100
Phosphorus, %	1.10	—
Inorganic phosphorus	nil.	—
Fuchsin-sulfurous acid test	positive	negative
Anthrone test for hexoses	very weak	very weak

[a] Reprecipitated heparin Vitrum contains 12.2 % sulfur.

The results in Table 2 indicate that capsule heparin contains a component missing in the commercial heparin. Efforts to remove this component by refluxing a sample of heparin with ether-ethanol 5:1 or benzene-ethanol 5:1 on a water bath had no effect on the phosphorus content or the colour yield after 20 h refluxing. Shaking a heparin solution with phenol or reprecipitating it as barium salt has also without effect.

DISCUSSION

On comparing the commercial heparin and the capsule heparin here prepared, it seems probable that this heparin contains organically bound phophorus. The results indicate that this substance is not nucleic acid or a nucleotide, a protein or peptide or some hexose compound. The phosphorus content gives an equivalent weight of about 500.

The ratios of activity to sulfur content and to colour yield in the carbazole test seems to be almost the same as the corresponding ratios for one of the fractions of commercial heparin obtained by fractionated alcohol precipitations [9]. The heparin prepared has not yet sufficed for fractionation studies.

Analysis of Aqueous Mixtures by Gas Chromatography

BENGT SMITH

Institutionen för Organisk Kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

The utilization of some liquids as stationary phases in the analysis of various water-containing mixtures by gas liquid partition chromatography is described and examples given of the separations obtained. The application of the method to quantitative analysis is discussed.

Because of the rapidity with which water can be determined using gas-liquid partition chromatography (GLPC), this method has received considerable attention recently. In order to get good results, the liquid phase should preferably be able to dissolve some of the water. A too high solubility, however, is unsuitable because it results in long elution times. Examples of stationary phases previously used with success are polyethylene glycols [1,2] and a mixture of glycerol and tricresyl phosphate [3]. Data for the columns employed in this work and recommendations for their use are summarized in Table 1.

Polyethylene glycols. In the previous investigations [1,2] polyethylene glycols with an average molecular weight of 600 were used. Here, polymers with an average molecular weight of 200 and 400 were tried. There does not seem to be any special advantage in using the higher polymer since the thermal stability diminishes with increasing molecular weight and the vapour pressure of the lower ones is small enough to permit operation at 100°C for long periods. Fig. 1 shows the separation of an aqueous alcoholic mixture on column No. 1. As can be seen, the water band interferes with the *n*-butyl alcohol band. Water travels relatively more rapidly than the alcohols on polyethylene glycol 400 and this causes it to interfere, on column No. 2, with the *n*-propyl alcohol band as well as with the *n*-butyl alcohol band. The separation of an aqueous aldehydic mixture using column No. 1 is shown in Fig. 2. On all columns which are recommended for aldehydes (*cf.* Table 1), formaldehyde travels more slowly than acetaldehyde in spite of its lower boiling point. Obviously the hydrogen bonding forces are responsible for this effect. Examples of the separation of aqueous mixtures of ketones and aqueous mixtures of acids using polyethylene glycols as stationary phases are given in Figs. 3 and 4. The separation of the components in technical diethyl ether using 1 m of column No. 1 and 1 m of column No. 2 in series is shown in Fig. 5. Since this work was completed, Bodnar and Mayeux [4] have reported the use of

polyethylene glycol 400 and triethylene glycol for the analysis of aqueous mixtures.

Glycerol/tricresyl phosphate. Browning and Watts [3] recommended the use of a stationary phase containing 40 % by weight of glycerol and 26 % by weight of tricresyl phosphate on 34 % by weight of Celite for the analysis of aqueous mixtures. This composition was tried in this laboratory but it was found to be not specially satisfactory. The high liquid content makes the carrier greasy and difficult to pack evenly in the column. Furthermore, high gas velocities are necessary in order to complete the analysis in a reasonable time. However, by diminishing the liquid content to 10 % by weight of glycerol and 10 % by weight of tricresyl phosphate applied on 80 % by weight

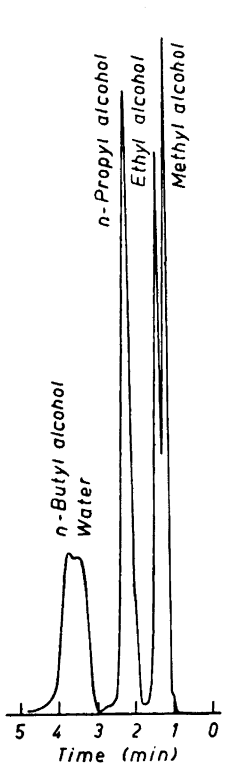

Fig. 1. Water-alcohol mixture. Column No. 1. Temperature 100°C. Flow of He 50 ml/min.

of Silocel, an easily packed, dry powder with a good separating power was obtained. Because of the relatively long retention time for water on this column (No. 3), it can be used to determine water in all the lower alcohols, including all the C_4-alcohols.

Diglycerol. The performance of column No. 4 was similar to that of No. 3. The lower alcohols appeared a good distance before the water band. The selectivity of this column for the lower alcohols was low. Thus, methyl, ethyl and *n*-propyl alcohol were not separated but gave instead only one peak. The good thermostability and low volatility of this stationary phase make it very suitable for use in series analyses extending over long periods.

Hexantriol. Water and *n*-propyl alcohol appeared in the same place when using this column.

Triethanolamine. According to Harvey and Chalkley [5], triethanolamine is unsuitable as a stationary phase for the analysis of aqueous mixtures. This

point of view seems to result from the use of too large a percentage of liquid on the carrier and the use of conditions favouring long retention times. By using 20 % by weight of liquid on Celite and changing the operating conditions, it was found that triethanolamine could be used for the determination of water in all the lower alcohols and in ketones, amines and ethers.

Tween 80. Water was eluted rapidly from column No. 7 (*cf.* Table 1). This column seems to be well suited for the determination of small amounts of low boiling alcohols or ketones in aqueous solution (*cf.* Fig. 6). Column No. 8, where the liquid content is diminished to 5 % by weight and the length of the column increased to 2 m, is suitable for the determination of water in the lower fatty acids (*cf.* Fig. 7). If the separation of formic and acetic acid is unnecessary, then a 1 m column is sufficient.

Glycerol monooleate. This substance may be used for the analysis of aqueous mixture of fatty acids in the same manner as Tween 80. Only a partial separation of formic and acetic acids can be obtained using column No. 9.

Columns with hydrophobic stationary phases have also sometimes been used. Thus Haskin *et al.*[6] utilized a column packed with di(2-ethylhexyl) phthalate for the analysis of an aqueous mixture of ethanol, acetonitrile and triethyla-

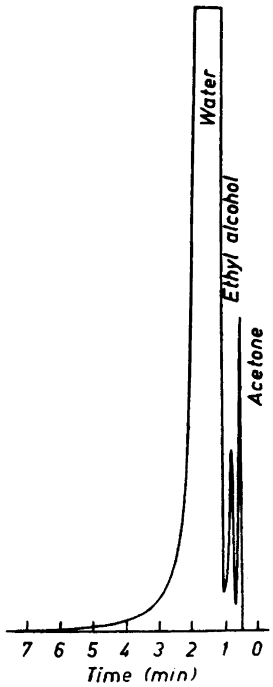

Fig. 6. Small amounts of ethyl alcohol and acetone in water. Column No. 7. Temperature 100°C. Flow of He 50 ml/min.

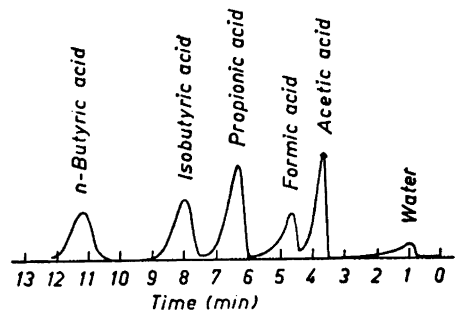

Fig. 7. Water-fatty acid mixture. Column No. 8. Temperature 100°C. Flow of He 100 ml/min.

amine. On this column, water is eluted first as a relatively narrow band with a steep front and a tail. We have tried to determine small amounts of water in ethanol by means of a 2 m column containing 30 % by weight of dioctyl phthalate on Celite. It was found, however, that the retention time for water varied with the amount of water in the mixture and increased as the water content decreased. While a good separation was obtained for mixtures containing several per cent water, the separation became bad, thus making quantitative measurements impossible, when the water content was decreased to a few tenths of a per cent.

In the foregoing, a few examples of separations of aqueous mixtures have been given. It should be pointed out, however, that, by varying the column length and using different columns in series and choosing suitable operating variables, aqueous mixtures of almost any kind can be treated successfully.

Quantitative analysis. The internal normalization method is very applicable for the quantitative analysis of water in aqueous mixtures. Although it is best suited for the assay of moderate amounts of water, even relatively small amounts of water can be determined by making proper use of the sensitivity switch of the gas chromatograph. In Fig. 8, the chromatogram, using column

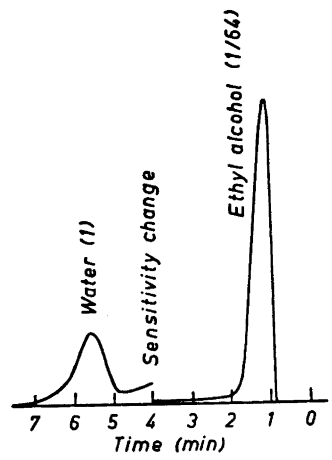

Fig. 8. Absolute ethyl alcohol. Column No. 6. Temperature 100°C. Flow of He 50 ml/min. Recorder attenuation shown in brackets.

No. 6, for absolute ethyl alcohol containing about 0.6 % of water is given. The water peak was run at full detector sensitivity and the alcohol peak at 1/64 of its maximum output. By this procedure, the areas under the two peaks are kept similar in size in spite of the large difference in the contents of the two components.

In the internal normalization method, the areas under the peaks are measured. In order to get a reasonably accurate value for the area, the peak should not be too narrow. Several methods are available for broadening a narrow peak, *e.g.* by increasing the paper speed of the recorder, by decreasing the flow of the carrier gas or by decreasing the temperature. It is also possible to increase the length of the column. It has been recommended when using this last method not to add a length of column containing the same stationary phase as the original column but instead to employ one containing a hydrophobic stationary phase, *e.g.* paraffin. In this way, the retention time for the organic component is increased while that for water is changed only to a minor extent. The water peak may, however, become distorted by this procedure.

A convenient and much used method for calculating the area under a peak is to multiply the height of the peak by the width of the peak at half the peak height (half band width). To get a correct value in this way, the peak should not be distorted. To investigate the influence of the tailing of the water peak, often encountered in GLPC-analysis of aqueous mixtures, the following experiment was made. Mixtures of water and ethyl alcohol were made up and analyzed using column No. 6. The area under each peak was measured by two methods. In the first one, the area was obtained by calculating the peak height times half the band width while, in the second, the area was planimetered. The per cent water peak area was calculated and the figures obtained placed in a diagram to give the relationship between the weight per cent of water in the mixture and the per cent area under the water peak. It was found

that, when the area was calculated by multiplying the peak height by half the band width, the deviation from linearity was not greater, than when the area was planimetered. The same result was obtained with mixtures of acetone and water. Thus it does not seem to be necessary to planimeter the water peak in the GLPC-analysis of aqueous mixtures of alcohols and ketones using triethanolamine as the stationary phase. Since the symmetry of the water peaks obtained when using columns Nos. 1—5 was nearly as good as when using column No. 6, it may be concluded that the simpler area calculation method can also be used in these cases. It should, however, be pointed out that, to get accurate values, it is necessary to make a calibration curve. Any deviation from a linear relationship is then revealed. It is also advisable to check the curve from time to time because the column may change its properties during use, *e.g.* by evaporation of the stationary phase or in other ways. For semi-quantitative work, the per cent area under the water peak may be put equal to the weight per cent of water in the mixture.

Instead of applying the internal normalization method, it is often best to base the quantitative measurements on the peak height or peak area of one or a few of the components in the mixture using either the internal standard or fixed volume method. If the latter method is employed, it is necessary to add exactly the same volume every time. The Agla micrometer syringe or capillary pipettes may be used. Recently a method for injecting exact volumes by means of ordinary syringes has also been described [7]. To exemplify the use of these methods, their application to the analysis of a water-acetone mixture will be described. In the fixed volume method, an exact volume of the mixture is injected and separated on, for example, column No. 1 (*cf.* Fig. 3). The height of the acetone peak is measured. To get the best accuracy, the procedure is repeated several times and the mean value of the acetone peak heights is taken. The per cent acetone in the mixture is read from a calibration curve obtained by injecting the same volume of mixtures containing known amounts of water and acetone using the same experimental conditions and measuring the heights of the acetone peaks. The water content is obtained by difference.

If the internal standard method is applied, a known amount of methyl ethyl ketone is added to the mixture of unknown composition as an internal standard and the mixture is run as before on column No. 1 (*cf.* Fig. 3). The height of the two ketone peaks is measured and the ratio calculated. From this ratio, the per cent acetone is obtained using a calibration curve giving the ratio of per cent acetone to per cent methyl ethyl ketone as a function of the ratio of the peak height of acetone to the peak height of methyl ethyl ketone. This method is somewhat more laborious than the former one but it generally gives the most accurate values since minor fluctuations in the operating variables are compensated for. For comparison, the analysis values for a mixture of acetone and water using the internal normalization method, fixed volume method and internal standard method using column Nos. 6 and 1 are given in Table 2. It is obvious that the fixed volume method is inferior in accuracy to the other two in this case. However, the accuracy of the fixed volume method increases when the acetone content decreases since the relative injection error decreases when larger volumes can be injected.

Table 2. Analysis values for a water-acetone mixture obtained by various methods.

Method	Acetone (wt %)		Water (wt %)		Column No.
	True value	Observed	True value	Observed or calculated	
Internal normalization	11.1	11.2 11.2 11.4 } 11.3	88.9	88.8 88.8 88.6 } 88.7	6
Internal * standard	11.1	11.0 11.1 11.2 } 11.1	88.9	88.9 **	7
Fixed volume ***	11.1	10.9 11.8 11.4 } 11.4	88.9	88.6 **	7

* Internal standard methyl ethyl ketone.
** Calculated as difference from the acetone value.
*** Injected volume 6 μl.

For trace analyses, the internal standard method or fixed volume method must be used. The measurement is in this case always based on the trace component or components. Either the peak height or peak area is used. It should be pointed out that, when using the peak height, peak height maxima are generally not seriously affected by a certain amount of overlap. As the water peak is generally rather flat, measurements of trace amounts of water must be based on the area of the water peak which impairs the accuracy and sensitivity somewhat.

EXPERIMENTAL

The analyses were performed using a Perkin Elmer Vapour Fractometer Model 154. The columns were made from aluminum tubing of 4 mm internal diameter.

The liquids used as stationary phases were heated in vacuum in a stream of nitrogen to remove low boiling impurities. Diglycerol was obtained from May and Baker Ltd, Dagenham, England, and hexantriol, Tween 80 and glycerol monooleate from T. Schuchardt, München, Germany. The other compounds used as stationary phases may be obtained from any chemical firm.

Ammonium Salts as Nitrogen Source in the Synthesis of Protein by the Ruminant

HARING LAND and ARTTURI I. VIRTANEN

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

Two cows have been fed on a diet containing an ammonium salt labelled with ^{15}N. Milk protein has been shown to contain this heavy isotope to an extent corresponding to incorporation of 17—25 % of the ammonium nitrogen into proteins. It is made plausible that the maximum incorporation into both milk and body proteins may be some 40 %. The milk collected about 14 hours after administration of the labelled salt shows the highest content of ^{15}N in the amides, followed by glutamic acid, aspartic acid and alanine. After 24 hours the labelling of most of the protein components has already become comparatively even. Histidine shows an especially low content of ^{15}N; this may be attributed to incapability of the rumen bacteria to synthesize the imidazole ring. Cystine, too, is relatively low in ^{15}N content.

An extensive literature has been published in the last three decades concerning the synthesis of protein by the ruminants, the role displayed in this synthesis by the rumen bacteria and the significance of non-protein nitrogen compounds as substitutes for proteins in the diet of the ruminants. A survey of this literature has been given by Chalmers and Synge [1]. The results of the experimental work show considerable divergence among the various authors as to the extent to which non-protein nitrogen, in the form of urea (in most of the cases), ammonium salts, ammoniated molasses, ammoniated straw, ammoniated sugarbeet pulp, dicyanamide, is effectively used in the process of protein synthesis. This difference of opinion arises mainly from the difficulty, inherent to all experimental work on nutrition problems, to start from welldefined uniform basic diets, and from the lack of a common standard of comparison. Little doubt, however, exists about the reality of the utilization of non-protein nitrogen by ruminants. A vast number of indirect experiments has been performed in which the extent of the utilization of the non-protein compound fed is inferred from either protein synthesis in an artificial rumen [2,3] or from changes in body weight or milk production of the animal under observation. Direct results, however, are rather rarely met in literature. To the

authors' knowledge the only direct evidence of protein synthesis from non-protein nitrogen by ruminants is presented in a paper by Watson *et al.*[4] They fed urea labelled with ^{15}N to sheep and were able to detect this isotope in proteins from blood, liver and kidneys in excess over the ^{15}N content of proteins of sheep fed with unlabelled urea.

The present paper gives the results of an investigation based on feeding experiments in which ammonium salt labelled with ^{15}N was fed to two cows. The experiments were conducted on the farm of one of the authors (A.I.V.). The cows received AIV-fodder, coarsely ground oats and some hay. According to the principle of the AIV preservation method the acidity of the fresh fodder is increased so that the pH of the ensilaged material does not exceed the critical value 4. In the preparation of the AIV-fodder used in these experiments, instead of strong mineral acids 1 kg of ammonium bisulphate had been added per 100 kg of fresh greenfodder in order to reach this acidity; the pH of the finished product was 3.8—3.9. The preserved material consisted of a mixture of about 70 % of red clover and 30 % of timothy, blown into the silo by means of a fan equipped with cutting blades.

When the AIV-method was developed in the years before 1930, some attempts were already made to reach the necessary acidity in the fodder mass by means of acid salts, but the quantity of salt required for non-chopped clover-rich fodder was so high (1.8—2.0 kg per 100 kg of fresh fodder) that the health of the cattle might be impaired. The amount of acid to be added decreased, however, when choppers came into use. In recent years (1953—1958) new series of preservation trials have been conducted in this laboratory by Virtanen and Kreula [5] and their results indicate that application of ammonium bisulphate or of mixtures of ammonium and sodium bisulphate is entirely feasible also in the preservation of clover. For fodderplants poorer in protein much smaller quantities of these salts suffice. Therewith the question of the utilization of ammonium nitrogen in the synthesis of amino acids and proteins in the rumen has become actual also when an effective method for preservation of fresh fodder precluding the formation of ammonia from the fodder proteins, is used.

The purpose of the present investigation was to establish the value of ammonium salts in the synthesis of proteins in the ruminant. Apart from this directly important information, knowledge of more details of the actual synthetic process might be obtained by tracing the heavy isotope in the various fractions and different amino acids of the milk proteins.

EXPERIMENTAL

Two experiments have been performed so far. During the first one, started on March 21 at approximately 4.30 P.M., the test cow Latsi with a production of about 10 kg of milk (4.3 % fat) per day was fed on a diet administered in two portions (in the morning and in the evening) each consisting of 3.4 kg of coarsely ground oats, 9.2 kg of AIV-fodder and 1 kg of hay. This corresponds to 10 Scandinavian fodder units and 1 040 g of digestible raw protein (NH_4-N subtracted) per day. The overfeeding both in fodder units and in protein was fairly high, because the food requirement corresponding to the milk production was about 8 fodder units and 850 g of digestible protein. This diet was given for 2 1/2 days before the beginning of the experiment proper; then 0.9993 g of ammonium nitrate containing 61 atom % of ^{15}N in the ammonium part was added as a fairly concentrated solution in a small volume of water to the oats. For another 5 days after the addition of the labelled ammonium salt the cow received the same diet as mentioned, and after this period returned to her normal diet. Analytical details of the diet are given in Table 1.

Table 1. Analyses of fodders used in the experiments.

	% total N	% dry matter	% NH_4—N	kg fed	g total N	g NH_4—N
	1.54	87.5	0.020			
Oats	1.53	87.6	0.020	3.4	52	0.7
	1.53	87.6	0.019			
	0.70	25.5	0.131			
AIV-fodder	0.63	26.1	0.135	9.2	60	12.1
	0.61	25.4	0.131			
	1.10	91.1	0.042			
Hay	1.22	90.9	0.044	1.0	12	0.4
	—	91.6	0.043			

According to Table 1 the NH_4-N was 10.7 % of the total N. 0.9993 g of NH_4NO_3 with 61 atom % ^{15}N in the ammonium group contains 0.181 g of NH_4-N, that is, 1.37 % of the total NH_4-N of the fodders. The amount of excess ^{15}N in it is 7.52 mg-atoms.

In the second experiment beginning on May 14 at about 4.00 P.M., another cow (Hieno) with a daily production of about 16 kg of milk (4.2 % fat) was fed on substantially the same diet; this could provide her with the required food units (10 f.u.) per day. The digestible protein in the diet was already somewhat lower than the need (1 040 g and 1 100 g, respectively). After the same preparatory feeding period as in the first experiment, 1.8953 g of ammonium sulphate containing 90.1 atom % ^{15}N was added to the food, *i.e.* 0.443 g of NH_4-N which amounts to about 3.5 % of the total NH_4-N of the diet. The excess ^{15}N administered in this case is 25.42 mg-atoms. After 5 days on the diet as mentioned before, the cow received again the customary rations, and on May 23 was brought out to pasture.

Table 4. Excess ^{15}N in milk protein and in its amino acids in the second experiment (cow Hieno).

The cows were milked twice daily. In the first experiment the milk was weighed for 12 days, in the second for 20 days. Urine and feces were not collected quantitatively. From samples of milk the ^{15}N content was determined in the total N, in the protein and the non-protein fractions separated according to Rowland [6], and in the amide-N fraction split off from the precipitated protein fraction [7]. The total-N content of the milk of the first experiment, estimated on a number of samples from various days, had an average value of 0.468 %, and a non-protein N content of 0.035 %. In addition, the ^{15}N content was estimated in samples of urine and feces, and in a few cases in the urine ammonia distilled according to Vickery *et al.* [7]; no analyses were performed on urine and feces to assess the total amount of nitrogen excreted.

From samples of milk, urine and feces collected during the second experiment similar estimations were made; the total-N content of the milk was here 0.430 % (average of 8 determinations); the non-protein N content was not determined. The amide-N content was estimated according to Vickery [7] in the protein of the milk collected on May 15 at 7.10 A.M. and at 5.15 P.M.; it amounted to 8.9 % of the total protein-N content in both cases.

From these same milk samples the protein fractions obtained by precipitation with 15 % trichloroacetic acid, were dialyzed and lyophilized. After extraction with ether to remove fatty substances the dry protein was hydrolyzed with 6 N HCl in a sealed tube at 105° for 24 h, and the hydrolysate was separated into various amino acid fractions according to Hirs, Moore and Stein [8]; their procedure was in so far modified that it permitted the separation of rather large quantities of the amino acids. Details of the separation have been published elsewhere [9]. A rigorous separation of all amino acids was not aimed at; hence methionine, *iso*leucine and leucine have been taken together, so have serine and threonine. The yield of cystine from the first protein sample was too low for further treatment. Phenylalanine and arginine, emerging together from the ion exchange column, have been separated on a cellulose column in order to keep a distinction between basic, acidic and neutral amino acids.

The various fractions of the purified amino acids were subjected to Kjeldahl digestion and the ^{15}N content was estimated in the ammonia obtained. The measurements were performed with a CEC mass spectrometer model 21−401, at an ionizing current of 90 μA and an auxiliary amplifier output of 20 V. Corrections for the presence of air have not been applied, since in no nitrogen sample the quantity of air present as indicated by the argon peak, exceeded 0.1 %. Measurements were performed on either three or four samples, each sample allowing at least four readings; the cystine sample from the second protein fraction only allowed four measurements altogether to be made. The standard deviation did not exceed 0.1 % in the most unfavourable case and was usually of the order of 0.05 %.

The results of the measurements are given in Tables 2, 3 and 4.

In Tables 2 and 3 the time given in column 2 is the time of milking; the samples of urine and feces mentioned behind the same time, were collected within one hour after that time.

DISCUSSION

From Tables 2 and 3 the high rate of uptake of ammonia into the milk becomes evident: within one hour the milk is labelled, although in the first experiment the protein fraction does not yet contain any ^{15}N, and in the second experiment the labelling of the proteins is very weak. The non-protein fraction has not been subjected to a closer investigation whether the ^{15}N occurs in the form of the ammonium ion or as amide or low-molecular peptide. Analysis of the milk collected after about 14 h after the feeding of the labelled fodder shows a high content of ^{15}N in the amide-N (0.071 atom % excess in the second experiment), whereas the total-protein N contains 0.039 atom %. Since amide-N makes up 8.9 % of the protein-N, its ^{15}N content accounts for only 15 % of the total amount of ^{15}N present in the total N. This percentage

Table 2. First experiment started on March 21 at approximately 4.30 P.M. (cow Latsi). Administered 7.52 mg-atom excess of ^{15}N as NH_4NO_3 in the NH_4; total quantity of NH_4-N in diet 13.4 g. Total N in milk: 0.468 %; non-protein N: 0.035 %.

decreases quickly to 11 % in the following milk sample. After this it approaches the value found for the total-N. The incorporation of the ammonium-N into the milk proteins seems to proceed primarily *via* the amide, followed by glutamic acid (Table 4). Aspartic acid does not play a role comparable to that of glutamic acid, for the labelling of the latter compound decreases with 45 % within 10 h, of the former with 21 %; the decrease for the total N is 18 %. With the other amino acids there is a general downward trend in the ^{15}N content, more pronounced for the smaller molecules; the basic amino acids, however, show rather an increase. Especially histidine contains little ^{15}N; if labelling is assumed to occur in the amino-N only, the atom %

Table 3. Second experiment started on May 14 at approximately 4.00 P.M. (cow Hieno). Administered 25.42 mg-atom excess of ^{15}N as $(NH_4)_2SO_4$. Total N in milk: 0.430 %; amide-N 8.9 % of protein-N.

excess of ^{15}N in this group will be three times higher than the value observed. This new value (in histidine a and *b*, respectively, 0.0024 and 0.0027) is in fair agreement with the values found for the other amino acids. Thus the low content of ^{15}N in histidine may be interpreted as incapability of the rumen bacteria to synthesize the imidazole ring. The relatively low content in cystine is an interesting point, too.

The last columns in Tables 2 and 3 give the percentage of the initially added amount of ^{15}N that was recovered from the milk. No more labelling can be detected in urine and feces after about one week, but some six weeks after the start of Expt. 1 there was still a detectable trace of ^{15}N in the milk; in Expt. 2 the measurements have not been extended to so long a period. The first cow is seen to produce a recovery value of 17.2 % in ten days; the

trailing over another four weeks has not been considered since the excess of ^{15}N is so minute by that time that it approximates to the accuracy of the measurements. The recovery value for the second cow, having a considerably higher milk production (79.3 kg over a period of five days, compared with 47.9 kg over the same period for the first cow) with a slightly lower protein content (0.430 % *versus* 0.468 %), and being fed on approximately the same rations, is evidently higher. For its calculation it must be taken into account that the values after May 20 have to be doubled, since only one sample of milk per day was investigated. Thus the total recovery found over a period of 17 days amounts to 25.4 %, the yield after this period having again been neglected. The overfeeding with protein is probably the reason for the lower utilization of ammonium nitrogen in the first experiment. In the second experiment the protein in the diet was somewhat lower than the calculated requirement, and the ammonium nitrogen utilization is seen to be about 40 % higher than in the first experiment. More experimental material is needed to elucidate the influence of the composition of the food on the utilization of non-protein nitrogen.

On the basis of the milk yields and the content of ^{15}N one arrives, for this particular diet and these particular cows, at a utilization of about 20 % for the ammonium nitrogen in the formation of milk protein. This value presents a minimum for the total utilization because the uptake into body protein has been left out of consideration. Since in these experiments no quantitative data were collected regarding the amount of nitrogen excreted in the urine and the feces, a rigorous treatment of the total utilization of the ammonium-N cannot be given. It is, however, possible to derive an approximate value along the following lines.

On the assumption that the digestibility of the total protein of oats is 80 %, of AIV-fodder 70 % and of hay 60 %, the ration fed leads to an excretion of 33 g of nitrogen in the feces per 12 h period (*cf.* Table 1 for total N fed). The urine production may be estimated at 11 kg (containing 0.6 % total N) per 10 kg of milk; for the cow of the first experiment, producing slightly less than 10 kg of milk per day during the course of the experiment, the production of urine-N amounts to another 33 g of nitrogen, *i.e.* 2 360 mg-

Table 5. Estimation of the amount of ^{15}N excreted in urine and feces in Expt. 1. Administered 7.52 mg atoms of ^{15}N. Production (per 12 h period following the time mentioned) of urine-N and of feces-N: 2 360 mg-atoms.

Date	Time	Atom % excess in urine	Atom % excess in feces	Excess ^{15}N (mg-at.) in urine + feces	% ^{15}N recoveed
21.3	17.30	0.024	0.026	1.18	15.7
22.3	7.00	0.019	0.021	0.94	12.5
22.3	17.30	0.016	0.018	0.80	10.6

atoms per 12 h. Extrapolation of the values for the atom % excess of ^{15}N in urine and feces to the first 12 h following the adminstration of the labelled ammonium salt gives the values 0.024 and 0.026, respectively, with a reasonable trustworthiness. In Table 5 the results are combined.

The further yield of ^{15}N after March 25 will still amount to a few percent, but has not been taken into consideration since measurements on urine and feces were only occasionally performed after that date. It has been found that the total percentage of ^{15}N found in urine and feces amounts to roughly 60 %. If loss of nitrogen through respiration is regarded as negligible, this would mean that from the ration fed, in which 10.8 % of the total N is present as NH_4-N, possibly 40 % of the NH_4-N is utilized for protein synthesis.

Phosphate Compounds in Respiring Mycelium of *Merulius lacrymans* (Jacq.) Fr.

JOSTEIN GOKSØYR

Botanical Laboratory, University of Bergen, and

LEIV KLUNGSØYR

Pharmacological Institute, University of Bergen, Norway

Incubation experiments with ^{32}P labelled orthophosphate have been carried out with the Cartwright strain of *Merulius lacrymans*, grown as shake cultures. Phosphate compounds found to be labelled with ^{32}P in experiments lasting up to two hours, were: pyrophosphate, ADP, ATP, GTP and UDP. On paper chromatograms, several unidentified radioactive spots were also seen. Poly-metaphosphate was identified in the residue after TCA extraction. In the barium insoluble fraction a metabolically inert phosphate compound occurred, which was believed to be tri- or tetraphosphate. This overlapped the ATP elution peak on column fractionations. Time-course experiments showed that pyrophosphate became more rapidly labelled than ATP. Both respiration and ^{32}P incorporation were strongly inhibited by 10^{-4} M 2,4-dinitrophenol.

Little information seems to be available regarding the occurrence of adenosine triphosphate (ATP) or other phosphate compounds in the Basidiomycete group of fungi. Nord and Sciarini [1] studied the presence of phosphorylation processes in *Merulius niveus* and concluded that "phosphorylation does not constitute an integrate part of the phase sequence of carbohydrate degradation by wood-rotting fungi".

As part of an investigation of the biochemistry and physiology of the wood-decomposing Basidiomycete *Merulius lacrymans*, it was therefore considered of interest to study the presence of phosphate compounds and their metabolic activity.

MATERIALS AND METHODS

The Cartwright strain of *M. lacrymans* from *Centraalbureau voor Schimmelcultures*, Baarn, Holland, has been used throughout these investigations. The fungus was grown submerged in 200 ml portions of medium in 500 ml Erlenmeyer flasks, on a reciprocal shaker at room temperature (18—22°C). The medium consisted of: glucose, 20 g; peptone,

10 g; KH_2PO_4, 1.5 g; $MgSO_4 \cdot 7\ H_2O$, 1.5 g; thiamine, 1 mg per liter. The flasks were covered with aluminium foil, and were inoculated from a surface culture or a previous shake culture which had been disintegrated in a Waring blendor running with low speed for less than 1 min. The cultures were harvested after 8—10 days of growth. pH in the medium had then fallen to about 2.5. Inoculation on agar plates revealed no presence of bacteria. The mycelium was separated from the substrate by filtering through folded filter paper. The filter was washed thoroughly by a mixture of 0.01 M KCl and 0.01 M $MgCl_2$, and the mycelium finally suspended in the same solution. pH in the suspension was about 4.5. Respiration measurements were carried out either by gas analysis, utilizing a Scholander 1/2 ml Gas Analysis Apparatus, or by Warburg technique.

For isolation and identification of phosphate compounds, the suspension of washed mycelium was incubated with carrier-free ^{32}P-labelled orthophosphate with vigorous shaking in order to obtain a high rate of respiration. To the respiring suspension, trichloroacetic acid (TCA) was added to a final concentration of 5 % and the shaking continued for a couple of minutes. The suspension was then cooled and centrifuged and the extract treated with barium acetate. The barium insoluble compounds were separated by centrifugation, treated with Dowex 50 in hydrogen form until dissolved, neutralized with KOH, centrifuged with high speed to remove mucous material and fractionated on a Dowex 1,X8 formate column according to Hurlbert *et al.*[2] Metaphosphate was isolated from the residue after the TCA precipitation as described by Klungsøyr *et al.*[3] Paper chromatography was carried out on Whatman No. 1 filter paper washed with 1 % oxalic acid. The solvent systems used, were: *n*-propanol, NH_3, H_2O (6:3:1) and *tert*-butanol, formic acid, H_2O (8:3:4). The papers were developed with the phosphate reagent of Hanes and Isherwood[4]. Radioautography of two-dimensional chromatography was carried out using Kodak X-ray film.

RESULTS

Separation and identification of phosphate compounds. A considerable number of phosphate compounds became labelled by incubation of the mycelial suspension with ^{32}P labelled orthophosphate. Fig. 1 shows a paper chromatogram of the TCA extract from an experiment when the incubation time was 2 h. Five hundred ml suspension was here incubated with 800 μC ^{32}P. Ten ml of the TCA extract was freeze-dried after removal of the TCA with ether in a continous liquid-liquid extraction apparatus, and the residue dissolved in 1 ml water. Ten μl of this solution was placed on the paper. Only a few

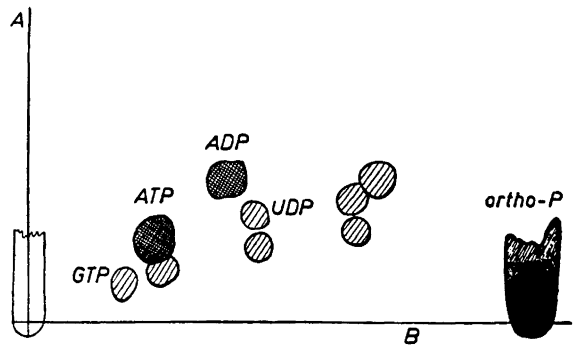

Fig. 1. Paper chromatogram of a TCA extract of *Merulius* mycelium, incubated with radioactive orthophosphate for 2 h. The degree of shading indicates the amount of radioactivity in the spots. Solvent systems: A, *n*-propanol, ammonia, water (6:3:1) and B, *tert.*-butanol, formic acid, water (8:3:4).

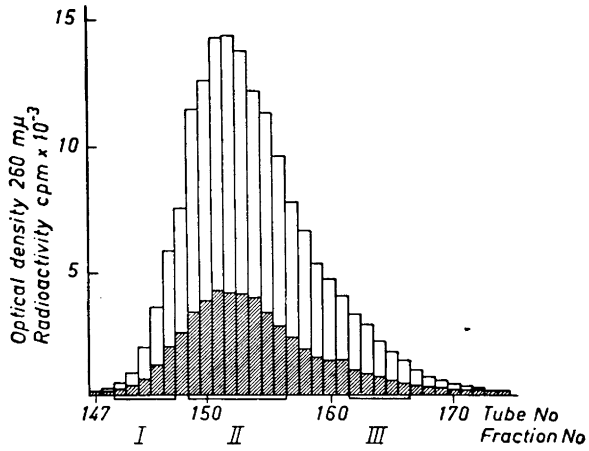

Fig. 2. Rechromatography of ATP from *Merulius* mycelium. The fractions marked I, II and III were lyophilized and analysed separately. Open columns: radioactivity in counts per min × 10^{-3}. Shaded columns: optical density at 260 mμ.

of the compounds have been identified, but there are definite radioactive spots for ATP, ADP, GTP and UDP.

From the main portion of the extract, the Ba insoluble phosphates were fractionated on an ion exchange column. Here fractions were obtained containing pyrophosphate and ADP. A fraction containing radioactivity and adenine like material absorbing at 260 mμ was obtained at the elution volume characteristic for ATP. The whole fraction was pooled, lypohilized and analyzed. The molar ratios were 4, 1 and 1, for acid labile phosphate, ribose and adenine, respectively. The substance was rechromatographed on the formate column, Fig. 2, and the tubes containing radioactivity and absorbing at 260 mμ were pooled in 3 fractions, lypohilized and analyzed separately for purine, acid labile P and radioactivity. Each fraction was examined by paper chromatography. The paper chromatography showed the presence of ATP in fractions 1 and 2, and of GTP in fraction 3, all radioactive. All three fractions gave a spot at the starting point, trailing in the direction of the ammoniacal system.

Table 1. Analysis of the three fractions of the rechromatographed triphosphate peak shown in Fig. 2.

Fraction number	I	II	III
Optical density ratio 260 mμ/275 mμ	0.428	0.422	0.676
Radioactivity Cpm/μ mole purine	9 220	9 100	8 250
Acid labile P/purine	4.7	3.05	9.15

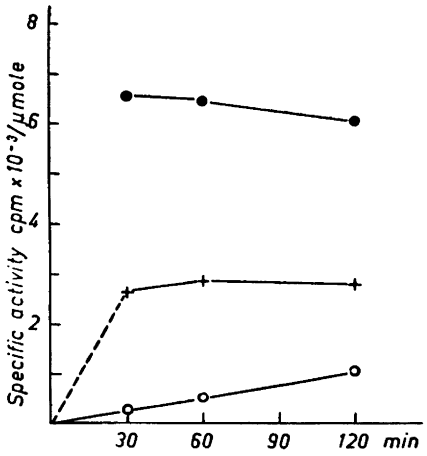

Fig. 3. The specific radioactivity in orthophosphate, pyrophosphate and ATP as a function of incubation time. The values are given as counts per min per μmole phosphorus in orthophosphate and pyrophosphate, and per 2 × μmole purine in ATP. The third phosphate in ATP is probably somewhat radioactive, so that the specific activities calculated for this compound are maximal values. ● : orthophosphate, + : pyrophosphate, ○ : ATP.

This spot contained no radioactivity, and is probably given by the phosphate compound(s) that overlaps the ATP and GTP peaks from the column. The amounts of acid labile P per μmole of purine differed widely in the three fractions (Table 1), while the radioactivities per μmole purine were the same in all of them. These results demonstrate the presence of acid labile, ribose and purine free phosphate contaminants in the isolated ATP and GTP. These metabolically inert phosphate compounds might be low molecular polyphosphates, for instance triphosphate or tetraphosphate.

About three μmoles acid labile phosphate per μmole adenin has been obtained repeatedly on the most highly purified ATP from different batches of mycelium in this fungus. This lead to the tentative conclusion that the fungus contained adenosine tetraphosphate (AQP) instead of ATP. Paper chromatography demonstrated, however, that this was not the case. Spots corresponding with ATP were consistently found, while spots corresponding with AQP (a preparation from Sigma Chem. Corp. was used as reference sample) could not be detected.

Metaphosphate. A phosphate-containing compound was isolated from the TCA insoluble residue, which was not dialyzable, gave a purple to pink colour with toluidine blue and was converted to orthophosphate by hydrolysis

Table 2. The effect of 2,4-dinitrophenol on respiration and radioactive phosphate incorporation in *Merulius* mycelium. Experimental time one hour.

	Respiration rate μl O_2 per mg dry weight and hour	^{32}P incorp., %
Control	5.5	1.10
10^{-4} M DNP	1.8	<0.01

with normal sulfuric acid at 100°C for 15 min. This polymetaphosphate was present in the fungus in comparatively large amounts. The incorporation during respiration, of ^{32}P labelled orthophosphate into the TCA insoluble fraction of the cells was negligible.

The time course of the incorporation process. An experiment was carried out in which samples of mycelium incubated with ^{32}P labelled orthophosphate were analyzed after 30, 60 and 120 min of respiration. The barium insoluble fractions of the TCA extracts were fractionated as usual, and the radioactivity in the fractions determined. The results are shown in Fig. 3. It will be seen that the specific activity in pyrophosphate increases rapidly, while that in ATP does so more slowly, and remains during the experimental period lower than that of pyrophosphate.

The effect of dinitrophenol on the incorporation. 2,4-Dinitrophenol is a potent inhibitor of oxygen uptake in *M. lacrymans*, and was also found to inhibit phosphate incorporation. Results from one experiment are shown in Table 2. The experiment was carried out in Warburg flasks, and the cells killed by adding TCA from the side arm at the end of the experimental period, which lasted one hour.

DISCUSSION

The chemical identification of ATP in *M. lacrymans* met with some difficulties. Whereas paper chromatography gave definite evidence to the presence of ATP, the column fractionation technique used obviously did not separate between ATP and some metabolically inactive phosphate which we believe to be tri- or tetraphosphate. For this reason too high values for acid labile and total phosphate were found in the ATP preparations.

The time course of ^{32}P incorporations from orthophosphate follows closely that earlier described by Klungsøyr *et al.*[3] for *Acetobacter suboxydans*. The only difference seems to be that the reaction goes considerably more slowly in *M. lacrymans;* something which probably is connected with its metabolic activity as a whole.

As far as these investigations go, they show that *M. lacrymans* contains a system for generating energy-rich phosphate bonds operating during active respiration and with ATP as the main store for such bonds. The phosphate metabolism does not seem to differ much from that of other microorganisms.

The work has been supported by grants from *A/S Norsk Varekrigsforsikrings Fond* and *Norges almenvitenskapelige forskningsråd.*

Some Reactions of 3-Reteneacetic Acid

EYLIF DYNESEN

Chemical Institute of the University of Århus, Denmark

3-Reteneacetic acid has been characterized through simple functional derivatives.

β-(3-Retene-ethanol), 1,3-dimethyl-7-*iso*propylphenanthrene, α-(3-retene)-*o*-nitrocinnamic acid and 3-(*o*-nitrostyryl)-retene have further been prepared by suitable reactions.

3-Reteneacetic acid [1] (I) has been subjected to a series of reactions. The methyl and ethyl-esters and the amide were prepared by conventional methods. Reduction of the ethyl ester(II) by lithium aluminium hydride gave β-(3-retene)-ethanol(III) in good yield. 1,3-Dimethyl-7-*iso*propylphenanthrene(V), previously prepared by total synthesis [2], could be prepared in 84 % yield by decarboxylation of I with soda lime.

In connection with other work α-(3-retene)-*o*-aminocinnamic acid was required, wherefore the corresponding nitro compound VI was prepared by condensation of *o*-nitrobenzaldehyde with 3-reteneacetic acid. The Perkin reaction in the Bakunin and Peccerillo modification [3] was applied. In this modification the free arylacetic acid is condensed with the substituted benzaldehyde by means of acetic anhydride in the presence of a tertiary amine as catalyst. The yield of VI was 40—45 %.

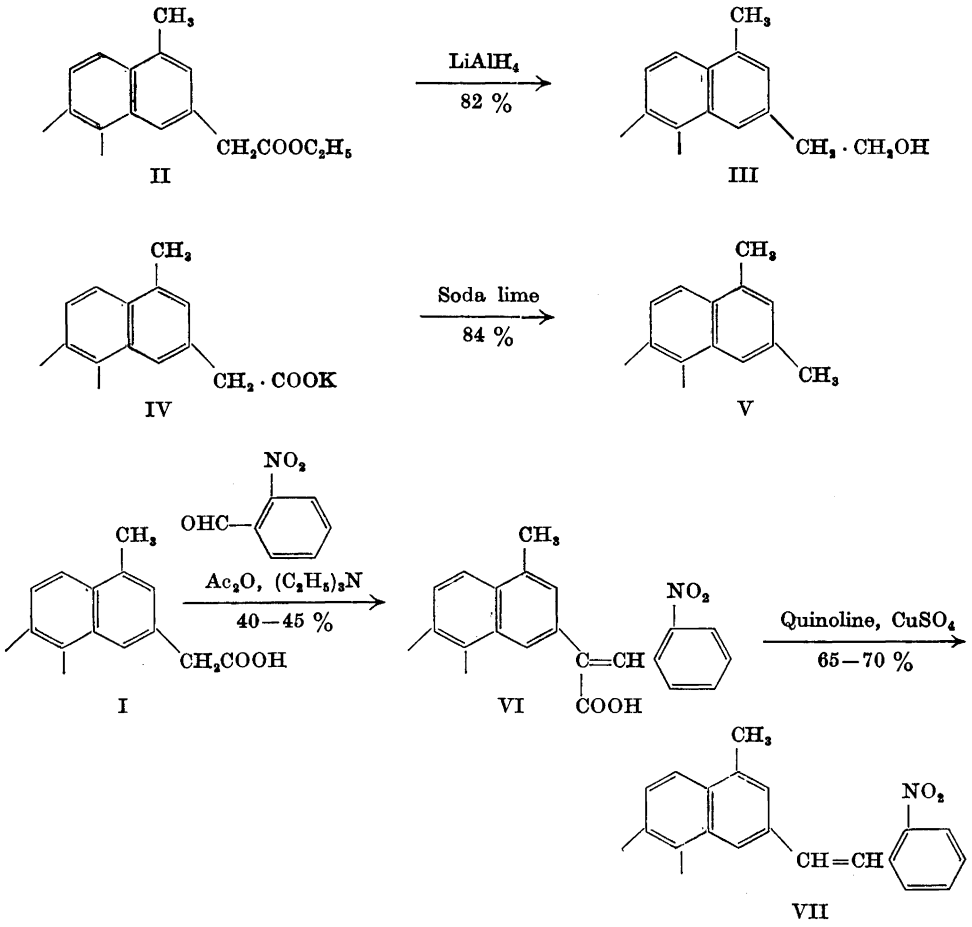
Decarboxylation of VI in quinoline with anhydrous copper sulfate according to a modification [4] of the method of Galimberti [5] gave 3-(*o*-nitrostyryl)-retene(VII) in good yield. The substance presumably was contaminated with the geometrical isomer, since the melting point was unsharp; recrystallization gave, however, a pure compound.

EXPERIMENTAL

3-Reteneacetic acid was prepared by the Willgerodt-Kindler reaction as previously reported [1].

Methyl-3-reteneacetate. A mixture of 3-reteneacetic acid (2.9 g, 0.01 mole), methanol (80 ml) and concentrated sulfuric acid (0.4 ml) was refluxed for 3 h. Yield after recrystallization from alcohol 2.7 g; m. p. 118—119.5°. (Found: C 82.2; H 7.27. Calc. for $C_{21}H_{22}O_2$ (306.4): C 82.3; H 7.24.)

Ethyl-3-reteneacetate. Prepared similarly, refluxing time 7 h. Yield after recrystallization from methanol 2.8 g; m. p. 67—68°. (Found: C 82.4; H 7.51. Calc. for $C_{22}H_{24}O_2$ (320.4): C 82.5; H 7.55.)



3-Reteneacetamide. 3-Reteneacetic acid (2.34 g, 0.008 mole) was mixed with phosphorus pentachloride (1.77 g, 10 % excess) and dry benzene (20 ml) was added. After spontaneous initial reaction the mixture was kept at 50—60° for half an hour and a clear solution was obtained. Benzene and phosphorus oxychloride were distilled off at diminished pressure. In order to remove all phosphorus oxychloride some benzene was added to the crystalline residue and evaporated to dryness and this procedure repeated. The crystals were dissolved in hot benzene and after cooling treated with concentrated ammonia water (10 ml). The mixture was left overnight. The precipitate was washed with ammonia water and recrystallized from *n*-propanol. Colourless crystals (2.0 g) m. p. 240—241.5° (subl.). (Found: C 82.5; H 7.25; N 4.82. Calc. for $C_{20}H_{21}NO$ (291.4): C 82.4; H 7.27; N 4.81.)

β-(3-Retene)-ethanol (III). Ethyl-3-reteneacetate (9.6 g, 0.03 mole) dissolved in dry ether (100 ml) was added with stirring in the course of 25 min to a suspension of lithium aluminium hydride (0.7 g) in dry ether (60 ml). The ether refluxed gently during this time and was kept refluxing for further 45 min on a water bath. With external cooling were then added successively water (25 ml) and 4 N sulfuric acid (30 ml). The ether layer was washed with sodium carbonate solution (2 %) and a saturated sodium chloride

solution and dried. After evaporation of the solvent the residue was recrystallized from benzene-hexane; yield 6.8 g (82 %) of colourless crystals with m. p. 117—118.5°. A second recrystallization brought the m. p. to 118—119°. (Found: C 85.9; H 8.00. Calc. for $C_{20}H_{22}O$ (278.4): C 86.3; H 7.97.)

Acetate of III. A mixture of III (0.6 g), acetic anhydride (5 ml) and pyridine (5 ml) was refluxed for 2.5 h and poured in water. The crystalline precipitate was recrystallized from methanol. Yield 0.4 g of white crystals, m. p. 66—67°. (Found: C 82.5; H 7.61; Calc. for $C_{22}H_{24}O_2$ (320.4): C 82.5; H 7.55.)

p-Nitrobenzoate of III. A mixture of III (2.0 g), *p*-nitrobenzoylchloride (1.5 g, 20 % excess), pyridine (10 ml) and dry benzene (20 ml) was heated on a boiling water bath for half an hour, the solution washed with water, hydrochloric acid (2 N) and sodium hydroxide (2 N). After drying the solvent was evaporated and the residue recrystallized twice from *n*-propanol. Yield 1.7 g, light yellow crystals with m. p. 122—123.5°. (Found: C 75.7; H 5.92; N 3.29. Calc. for $C_{27}H_{25}NO_4$ (427.5): C 75.9; H 5.90; N 3.28.)

1,3-Dimethyl-7-isopropylphenanthrene (V). Potassium-3-reteneacetate (IV) was prepared by neutralizing 3-reteneacetic acid(I) in hot *n*-propanol with the calculated amount of alcoholic potassium hydroxide. IV separated on cooling. IV (5 g) was intimately mixed with soda lime (10 g) and heated in a two bulb distilling apparatus with a wide side-arm. The apparatus was evacuated by means of an oil pump. At 0.5 mm pressure and a bath temperature of 325—380° the decarboxylation product distilled and the solid distillate was recrystallized from alcohol. 3.2 g (84 %) of colourless crystals, m. p. 76—77°, were obtained. M. p. reported [2] 73—76°. (Found: C 91.9; H 8.05. Calc. for $C_{19}H_{20}$ (248.4): C 91.9; H 8.12.) The picrate had m. p. 143.5—144.5°, previously reported [2] 145—146°.

α-(3-Retene)-o-nitrocinnamic acid (VI). A mixture of 3-reteneacetic acid (14.6 g, 0,05 mole), *o*-nitrobenzaldehyde (8.3 g, 0.055 mole), acetic anhydride (70 ml), and triethylamine (7.0 ml, 0.05 mole) was heated at 95—100° for 21 h. The excess acetic anhydride was decomposed by adding water (40 ml) and heating for further 1.5 h; the reaction mixture was then poured into 5 % hydrochloric acid (500 ml). The yellow product was filtered off, washed with water and dissolved in a hot solution of sodium carbonate. After cooling the rather dark coloured solution was extracted several times with ether and afterwards boiled with charcoal. On acidification of the filtrate a yellow precipitate separated. The product was recrystallized twice from glacial acetic acid. The yield was 9.7 g (45 %), yellow crystals with m. p. 257—258.5°. (Found: Equiv.wt. 422; C 75.8; H 5.40; N 3.27. Calc. for $C_{27}H_{23}NO_4$ (425.5): C 76.2; H 5.45; N 3.29.)

3-(o-Nitrostyryl)-retene (VII). A mixture of VI (0.5 g), anhydrous copper sulfate (0.15 g) and quinoline (12 ml) was heated at 215—220° for 25 min. After cooling the reaction mixture was diluted with benzene and the solution extracted several times with hydrochloric acid (2 N). Some dark coloured material, which had separated in the organic layer, was filtered off and washed with benzene. The filtrate was washed with sodium carbonate (2 %) and dried. After evaporation of the solvent the residue was dissolved in hot *n*-propanol, the solution treated with charcoal and filtered. On cooling yellow crystalline material separated. The yield was 0.3 g (68 %), m. p. 170—176°. The substance was recrystallized from glacial acetic acid, weight 0.23 g, m. p. 177.5—179°. (Found: C 81.4; H 6.10; N 3.63. Calc. for $C_{26}H_{23}O_2N$ (381.5): C 81.9; H 6.08; N 3.67.)

The analyses were performed in this laboratory by miss B. Møller.

Periodate Oxidation of Phenols

I. Monoethers of Pyrocatechol and Hydroquinone

ERICH ADLER and RUNE MAGNUSSON

Institutionen för organisk kemi, Chalmers Tekniska Högskola, Göteborg, Sweden

Treatment of monoalkyl, monobenzyl, and monophenyl ethers of pyrocatechol or hydroquinone with sodium metaperiodate leads mainly to oxidative removal of the ether substituent, with the formation of *o*- or *p*-quinone and the corresponding alcohol (or phenol). In the same way, 1- and 4-hydroxy-dibenzofuran undergo oxidative cleavage at the ring oxygen. These reactions presumably proceed *via* a quinol-like hemiketal intermediate.

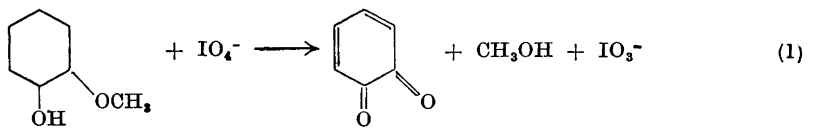
The monophenyl ether of hydroquinone gave the cleavage products (*p*-quinone and phenol), and in addition a compound, (2-hydroxyphenyl)-*p*-benzoquinone, obviously formed as a result of rearrangement and further oxidation of the intermediate.

The action of periodate on pyrocatechol and hydroquinone monoethers is discussed in comparison with that of some other specific oxidants, *e.g.*, sodium bismuthate, lead tetraacetate, and potassium nitrosodisulphonate.

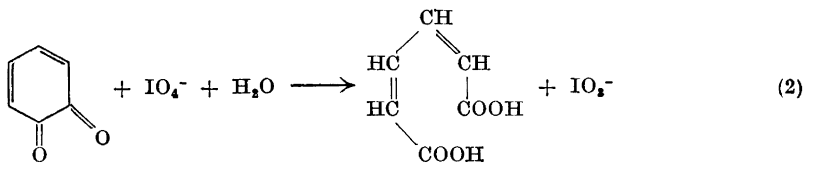
PYROCATECHOL MONOETHERS

In a previous communication [1] it was reported that the treatment of guaiacol (I) with sodium metaperiodate in aqueous or dilute acetic acid solution resulted in the rapid liberation of nearly one mole of methanol per mole of phenol. A method of estimation of the number of guaiacyl residues with a free phenolic hydroxyl group in lignin was based on this result [2].

The formation of methanol was found to be complete in a few minutes. During this time about one mole of periodate per mole of guaiacol was consumed, and the solution acquired a dark-red colour indicating the formation of *o*-benzoquinone (II). This initial reaction was followed by further periodate consumption at a lower rate and *cis, cis*-muconic acid (III) was isolated [1] from the brownish solution finally obtained. These observations indicated the following as the main reactions in the rapid initial step (1) and the subsequent slower phase (2):



I II (1)



II III (2)

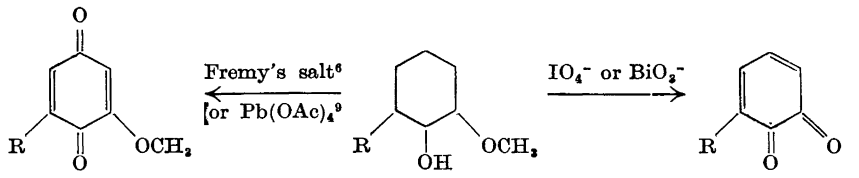
In the aqueous solvents used the oxidative cleavage by reaction (2) is accompanied by a competitive decomposition (polymerisation) of the *o*-benzoquinone primarily formed. It has been possible, however, to isolate *o*-benzoquinone in good yield by rapidly extracting the freshly prepared, dark-red aqueous mixture of guaiacol and periodate with methylene chloride. This proves the correctness of eqn. (1) for the initial step of the periodate oxidation of guaiacol.

Since oxidative demethoxylation with periodate proceeds readily with a great variety of guaiacol compounds [1], it appears to open a new way for the preparation of *o*-quinones. 4-Methyl-*o*-benzoquinone [3] was obtained in 70 % yield after short treatment of 4-methylguaiacol (creosol) with periodate in aqueous solution. This periodate method can be considered complementary to the method of Teuber [4,5], which involves *ortho*-oxidation of *p*-substituted phenols by Fremy's salt (potassium nitrosodisulphonate, $ON(SO_3K)_2$). Unlike periodate, Fremy's salt attacks the free *o*-position rather than the methoxyl group of *p*-substituted guaiacols, 4-methylguaiacol, for instance, being converted into 3-methoxy-5-methyl-*o*-benzoquinone [5].

The two oxidants mentioned also differ with respect to their behaviour towards guaiacols with a free *p*-position. The action of Fremy's salt on such phenols gives the corresponding *p*-quinones [6]; guaiacol, for instance, gives methoxy-*p*-benzoquinone (IV) in 90 % yield. In the reaction between guaiacol and periodate, however, the oxidation takes place almost exclusively at the 2-position, that is, at the ring carbon atom carrying the methoxyl group, with the formation of *o*-benzoquinone. As indicated by the formation of about 90 % of the calculated quantity of methanol, only about 10 % of the guaiacol is oxidised at the 4- and 6-positions.

The periodate method can therefore also be expected to be suitable for the preparation of *o*-quinones carrying a substituent in the 3-position and unsubstituted in the 5-position (II, R = substituent), from 6-substituted guaiacols (I, R = substituent). As yet, the action of periodate upon pyrogallol-1,3-dimethyl ether (V) has been examined and found to yield, under certain conditions, 3-methoxy-*o*-quinone (VI) as a major product.

Potassium bismuthate ($KBiO_3$), which was introduced by Rigby [7] as a glycol-splitting agent similar to periodate and lead tetraacetate, was found [8] to oxidise guaiacol in the same way as periodate, as shown in the reaction scheme below:



IV. R = H (90 %[6] or 57 %[9])
VII. R = CH_3O

I. R = H
V. R = CH_3O

II. R = H
VI. R = CH_3O

On the other hand, lead tetraacetate, although being largely equivalent to both periodate and bismuthate as a glycol-splitting agent, differs from the two latter oxidants but resembles Fremy's salt with regard to its action on guaiacols. Thus, similar to Fremy's salt [6], lead tetraacetate oxidises guaiacol and 2,6-dimethoxyphenol to give methoxy-*p*-quinone (IV) and 2,6-dimethoxy-*p*-quinone (VII) [9], respectively, without attacking the methoxyl groups.

In polar solvents such as acetone and methylene chloride, 3-methoxy-*o*-benzoquinone (VI) gave the hitherto unknown dimer, m.p. 139—140°. By the action of periodate this dimeric *o*-quinone was readily converted into 3,8-dimethoxy-1,2-naphthoquinone. Similarly, periodate oxidation of the recently described dimeric *o*-benzoquinone [20] yielded 1,2-naphthoquinone. These reactions, as well as the periodate oxidation of V, will be further discussed in following communications.

Pyrocatechol and its homologues are also rapidly oxidised by periodate, giving the corresponding *o*-quinones. The action of periodate on 4-methyl-pyrocatechol, for instance, produced 4-methyl-*o*-quinone in high yield.

The oxidative cleavage of pyrocatechol monoethers is a general reaction. An investigation was made of its application to the following ethers: 1) guaethol (VIII) (the monoethyl ether of pyrocatechol); 2) 2-hydroxydiphenyl ether (IX) (as an example of pyrocatechol monoaryl ethers); 3) 4-hydroxy-dibenzofuran (X) (as an example of a cyclic monoaryl ether of pyrocatechol).

Guaethol (VIII), in aqueous solution or in 80 % acetic acid, consumed about the same amount of periodate at about the same rate as guaiacol (Fig. 1). Ethanol was detected by gas phase chromatography in the distillate obtained from an aqueous guaethol-periodate reaction mixture after removal of excess periodate and iodate by precipitation with lead nitrate.

The initial attack of periodate on 2-hydroxydiphenyl ether (IX) in 80 % acetic acid solution was appreciably slower than on the pyrocatechol monoalkyl ethers, and there was no distinct break in the periodate consumption curve after the consumption of one mole of periodate per mole of substance (Fig. 1). As shown by the formation of phenol, the reaction was, however, similar to that with the monoalkyl ethers.

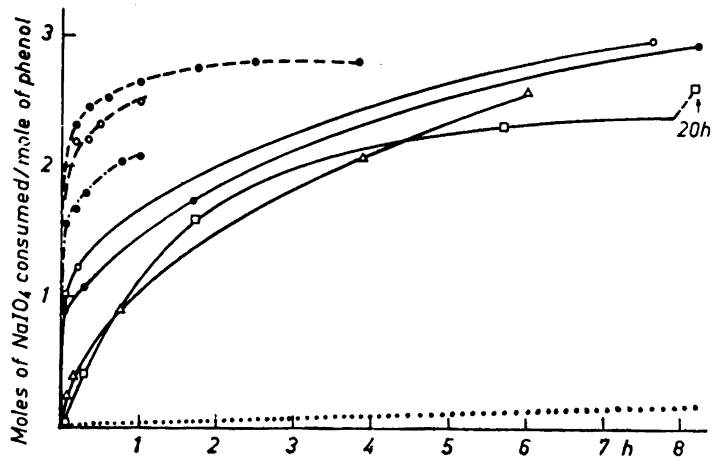


Fig. 1. Consumption of periodate by pyrocatechol monoethers. The reaction mixtures contained 10 mmole of the phenol and 70 mmole of $NaIO_4$ per litre.

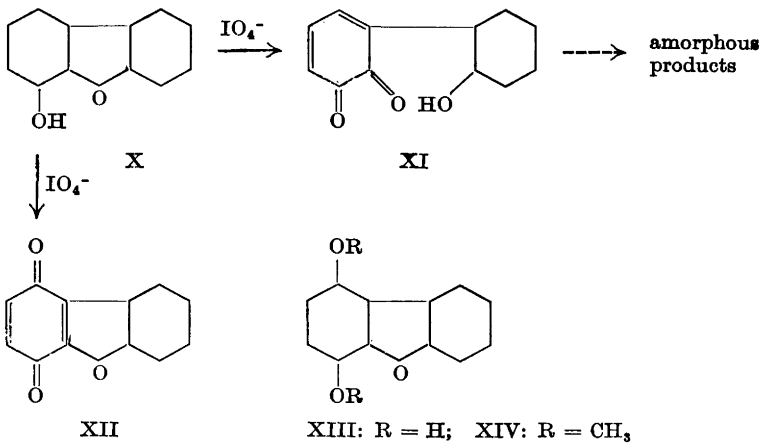
VIII: R = C_2H_5
IX: R = C_6H_5

Although excess periodate was present, phenol could be detected even after a reaction time of 48 h. Phenol, unlike pyrocatechol and its monoethers, thus reacts only very slowly with periodate (*cf.* Fig. 1). In this respect periodate differs from Fremy's salt which readily oxidises phenol to *p*-benzoquinone [6]. As will be described in a forthcoming communication, the homologues of phenol, with alkyl substituents at the *o*- or *p*-positions or at both, exhibit strongly enhanced reactivity towards periodate.

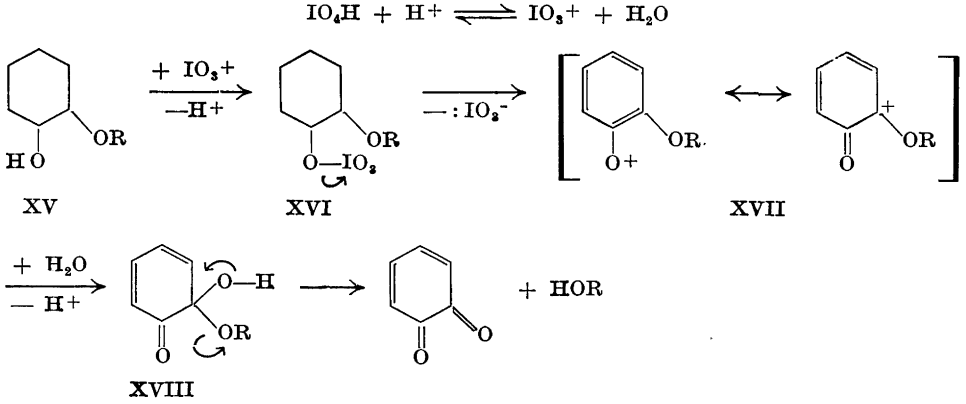
The periodate consumption curve of 4-hydroxydibenzofuran (X) (Fig. 1) was similar to that of IX, and the bulk of the material was converted into a brown, amorphous product. This may indicate that the reaction proceeded mainly in the normal way, *i.e.*, by *o*-oxidation, with the opening of the furan ring and the intermediate formation of the *o*-quinone XI, followed by polymerisation or by further periodate oxidation. A side-reaction, with *p*-oxidation of X to dibenzofuran-1,4-quinone (XII), m.p. 187—188°, occurred to an extent of about 15 %.



The structure of XII was demonstrated by reduction to the previously known 1,4-dihydroxy-dibenzofuran (XIII), m.p. 217—218°[10], and methylation of this compound to the dimethyl ether (XIV), m.p. 76—78°[10].

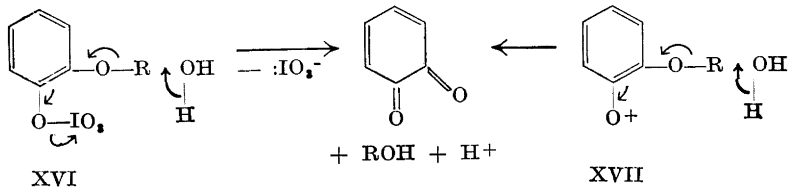
The quinone XII was regenerated in quantitative yield from the hydroquinone XIII when the latter was treated with periodate. Obviously, in compound XIII the dehydrogenation of the hydroquinone structure is more favoured than the oxidative ether cleavage (*cf.* also p. 515).

It was tentatively suggested in a previous communication [1] that the oxidative cleavage of pyrocatechol monoethers by periodate followed a radical mechanism involving two successive one-electron transfers. However, according to Levitt [11] a great variety of oxidants used in organic chemistry, including periodic acid, probably react by a two-electron transfer, thus giving rise to ionic mechanisms. Criegee [12] has adopted the views of Levitt for the mechanism of lead tetraacetate oxidation. Analogously, the main reaction between pyrocatechol monoethers and periodate can be represented as follows.



According to Levitt, the active species in periodate oxidation is the periodonium cation, IO_3^+, (or its hydrates), formed in a reversible reaction from periodic acid by the loss of OH^-. The cation would attack the pyrocatechol monoether (XV) at the site of the greatest electron density, *i.e.* at the phenolic hydroxyl group, yielding the periodic acid aryl ester XVI, the phenolic hydrogen atom being released as a proton. The ester XVI can then decompose forming an iodate anion ("two-electron transfer") and the mesomeric aroxyl cation XVII. Addition of a molecule of water to XVII would then give the *o*-quinol-like hemiketal XVIII and a proton and, finally, spontaneous decomposition of the hemiketal would yield the *o*-quinone and the alcohol HOR.

Alternatively, the ester XVI or the cation XVII may decompose directly, without the intermediate formation of the hemiketal XVIII, in a concerted reaction with a molecule of water as an electron donor:



XVI XVII

The remarkable ease of oxidative cleavage of the pyrocatechol monoethers could suggest some specific relationship between the periodate molecule and the two *ortho* oxygen atoms of the pyrocatechol component, possibly involving the initial formation of a highly reactive periodic acid *di*ester-like complex. Such an assumption, however, seems superfluous, since, as described in the following section, hydroquinone monoethers, where such a complex is not possible, are split by periodate as readily as the pyrocatechol analogues.

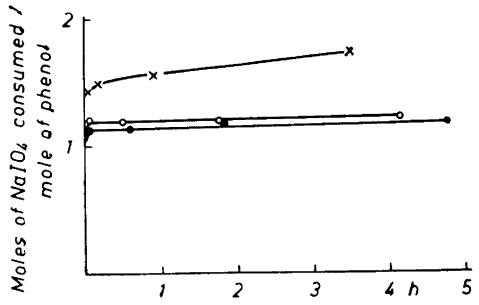


Fig. 2. Consumption of periodate by hydroquinone monoethers in 80 % acetic acid at 25°. Concentrations, same as given in Fig. 1.

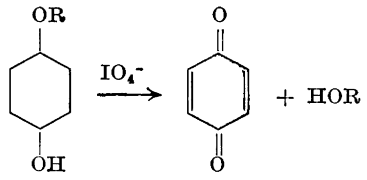
●——● Hydroquinone monomethyl ether (XIX).
O——O Hydroquinone monobenzyl ether (XX).
×——× Hydroquinone monophenyl ether (XXI).

HYDROQUINONE MONOETHERS

Hydroquinone itself is instantaneously oxidised by periodate (*cf.* also Ref.[13]) giving *p*-benzoquinone which, unlike *o*-benzoquinone, is stable in the presence of periodate. Four different monoethers of hydroquinone (XIX, XX, XXI, and XXIV) were examined.

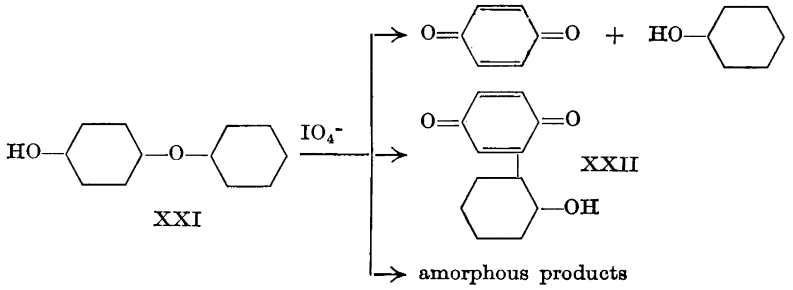
Hydroquinone monomethyl ether (XIX), when treated with excess periodate in aqueous or aqueous acetic acid solution (80 % HOAc), consumed very rapidly slightly more than one mole of periodate (Fig. 2), yielding *p*-benzoquinone and 93—94 % of the calculated amount of methanol.

Hydroquinone monobenzyl ether (XX), in 80 % acetic acid, behaved similarly (Fig. 2). Benzyl alcohol was isolated as the 3,5-dinitrobenzoate.



XIX : R = CH_3
XX : R = $CH_2C_6H_5$

The oxidation of hydroquinone monophenyl ether (XXI) was more complicated. In 80 % acetic acid it rapidly consumed about 1.4 mole of periodate. Dilution of the reaction mixture (after a reaction time of 30 min) yielded a brown, amorphous precipitate (about 14 % of the weight of compound XXI used). The expected reaction products, *p*-benzoquinone and phenol, were found in the reaction mixture; the yields of these products indicated that about 60 % of the starting material had undergone the "normal" ether cleavage reaction.



A brick-red crystalline substance, $C_{12}H_8O_3$, m.p. 196°, was also isolated from the solution in about 15 % yield. It was found to be identical with a product obtained by Grundmann [14] by the oxidation of 2,2'-dihydroxydiphenyl (XXIII) with peracetic acid. On the basis of the analytical composition and the chemical properties of the red product Grundmann considered it to be (2-hydroxyphenyl)-*p*-benzoquinone (XXII). This structure has now been

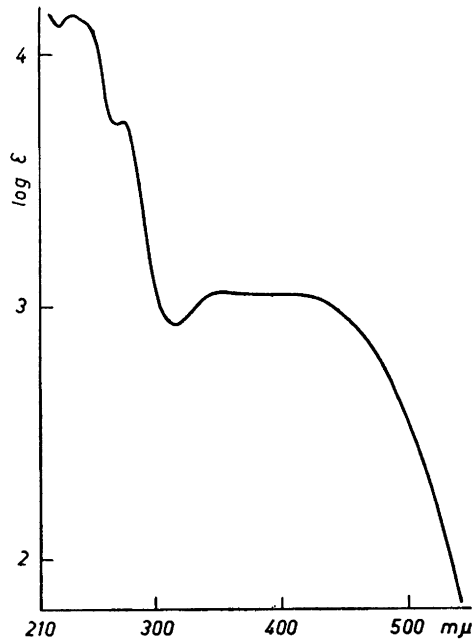


Fig. 3. Light absorption of (2-hydroxyphenyl)-*p*-benzoquinone (XXII). Solvent: 95 % ethanol.

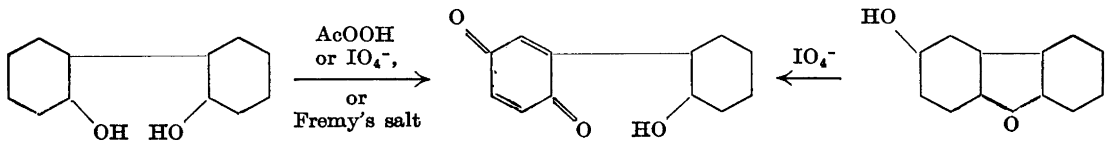
confirmed by the following observations. The red substance (light absorption curve, Fig. 3) was readily reduced by zinc dust in acetic acid to the hitherto unknown 2,2',5'-trihydroxydiphenyl (XXVII, see p. 513), obtained as a distillable colourless glass (b.p. 150°/0.001 mm Hg). Treatment of the latter product with periodate regenerated substance XXII. In harmony with the view that XXII is a *p*-quinone, it could be titrated with sodium thiosulphate [15]. The result of the titration indicated a molecular weight of 199 (calc. for $C_{12}H_8O_3$: 200). Oxidative degradation of XXII with hydrogen peroxide yielded salicylic acid, clearly indicating the presence of the 2-hydroxyphenyl residue.

The quinone XXII was formed from 2,2'-dihydroxydiphenyl (XXIII) not only by peracetic acid according to Grundmann but also — although in a lower yield — on treatment with sodium periodate. The formation of a red compound was also observed by Teuber and Rau [6] when XXIII was oxidised with Fremy's salt. The latter authors, however, could not decide whether the reaction product was XXII or an addition product of di-*p*-quinone and

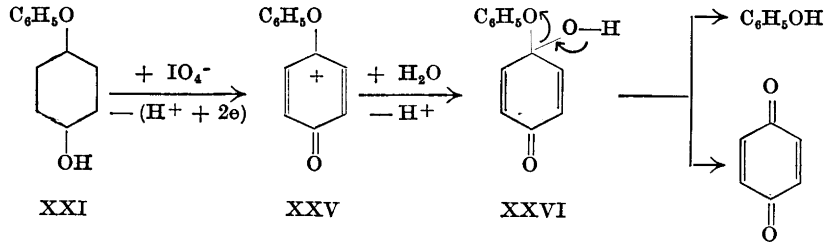


XXIII XXII XXIV

XXIII. It has now been established that the product prepared according to Teuber and Rau is identical with XXII, obtained by one of the methods mentioned above.

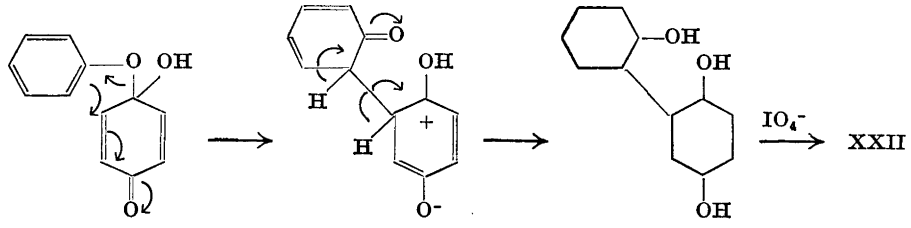
Treatment of a ring-closed analogue of XXI, 2-hydroxydibenzofuran (XXIV), with periodate resulted in cleavage of the cyclic ether bond and gave the (2-hydroxyphenyl)-*p*-benzoquinone XXII in good yield.

The mechanism of the oxidative cleavage of hydroquinone monoethers should be similar to that discussed above for the corresponding reaction of pyrocatechol monoethers. The oxidation of hydroquinone monophenyl ether (XXI), for instance, would then involve the intermediate steps of the mesomeric cation XXV and the *p*-quinol-like hemiketal XXVI, which would decompose to yield the major reaction products, phenol and *p*-quinone. The same result would be obtained by assuming concerted reactions similar to those given for the pyrocatechol series (p. 510).



XXI XXV XXVI

The side-reaction giving XXII that occurs in the oxidation of XXI, can be easily understood as the result of the rearrangement of the hypothetical *o*-quinol-like intermediate XXVI. This would yield the aromatic 2,2',5'-trihydroxydiphenyl (XXVII) which, in the presence of periodate, would be oxidised to XXII, as decribed above (p. 512). The rearrangement XXVI ⟶ XXVII is comparable to that undergone

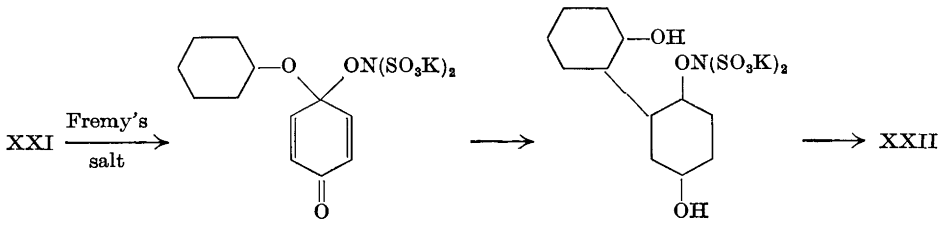


XXVI XXVII

by ordinary *p*-quinols, although here this reaction requires the presence of a strong acid (*cf.* Bamberger [16], Witkop [17]).

No systematic comparison has yet been made of the action of periodate and other specific oxidants on hydroquinone monoethers, but some preliminary conclusions can be drawn from the experimental material available. As in the case of the pyrocatechol monoethers, the action of sodium bismuthate is

quite similar to that of periodate, the oxidative cleavage of the hydroquinone monoethers into *p*-quinone and the corresponding alcohol being the main reaction [8]. It has been reported that lead tetraacetate reacts with hydroquinone monomethyl ether; however, the reaction products have not been isolated [9]. Fremy's radical does not affect the ether groupings of the monomethyl and monobenzyl ethers of hydroquinone (XIX, XX), but gives high yields of 4-methoxy and 4-benzyloxy-*o*-quinone, respectively [5]. This is analogous to the reaction between Fremy's salt and 4-alkylphenols, and is also in accordance with the production of methoxy-*p*-quinone (IV) from guaiacol [6] by the same oxidant. Surprisingly enough, it has now been found that hydroquinone monophenyl ether (XXI), when treated with Fremy's salt, is converted into (2-hydroxyphenyl)-*p*-quinone (XXII), which is also obtained as a by-product in the reaction between periodate and XXI. Since *p*-benzoquinone and phenol are not formed in the reaction between Fremy's salt and XXI it seems that the latter reaction does not proceed *via* the quinol-like intermediate XXVI, which has been assumed to be the precursor, in the periodate reaction, of the cleavage products (*p*-quinone and phenol) as well as of the rearrangement product XXII. The result of the oxidation of XXI by Fremy's salt suggests, that the primary intermediate could be the quinitrol-like substance XXVIII, which would undergo direct rearrangement to XXIX, followed by conversion of the latter into XXII.

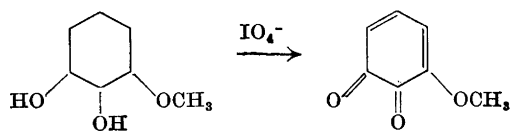


XXVIII XXIX

Quinitrol-like substances of type XXVIII have been obtained by Teuber and Götz [18], by the oxidation of phenanthrols and naphthols with Fremy's salt.

At the same time as the investigations described in the preceding sections, an examination was also made of the periodate oxidation of pyrogallol-1-methyl ether (XXX), methoxyhydroquinone (XXXI), 2,5-dimethoxyhydroquinone (XXXII), and 2,4-dimethoxyphenol (XXXIII).

Oxidation of XXX with an equimolar amount of periodate yielded 3-methoxy-*o*-quinone (VI) in a yield of 57 %. As XXX contains a free "pyro-

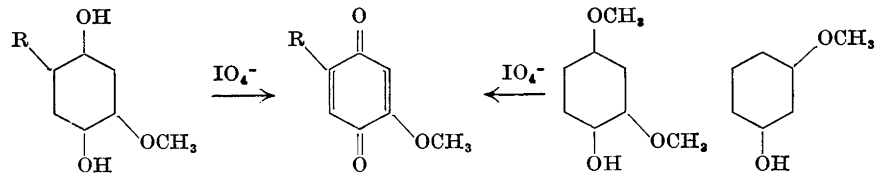


XXX VI

catechol" as well as a' "pyrocatechol monoether" grouping, the result indicates that the former grouping is more easily attacked than the latter one.

When XXX was treated with excess periodate, a 58 % yield of VI could be isolated after 2 min. About 1.5 mole of periodate was consumed in this time; on more prolonged oxidation there was further consumption of periodate. The quinone VI also consumed appreciable amounts of the oxidant (about 2 mole of periodate after 20 h). In both cases, almost one mole of methanol was liberated. This periodate degradation of 3-methoxy-*o*-quinone (VI) is being further investigated.

The hydroquinone groupings in methoxyhydroquinone (XXXI) and in 2,5-dimethoxyhydroquinone (XXXII) were so rapidly oxidised that the methoxyl groups of the "pyrocatechol monoether" groupings also present in these compounds remained unaffected (*cf.* also the oxidation of XIII, p. 509). The corresponding *p*-quinones (IV and XXXIV) were produced in practically quantitative yields; unlike the 3-methoxy-*o*-quinone (VI), they were not further attacked by periodate.



XXXI: R = H
XXXII: R = CH_3O

IV: R = H
XXXIV: R = CH_3O

XXXIII

XXXV

The preparation of *p*-quinones from the corresponding hydroquinones, by periodate oxidation, seems to be widely applicable. In addition to the examples reported above, a quantitative conversion of tetrabromohydroquinone into bromanil has also been made.

2,4-Dimethoxyphenol (XXXIII), when treated with an excess of periodate, yielded one mole of methanol and methoxy-*p*-quinone (IV). Thus, of the "pyrocatechol monoether" and the "hydroquinone monoether" groupings, both of which are present in XXXIII, the latter grouping was attacked preferentially.

A few experiments with resorcinol monomethyl ether (XXXV) confirmed the expectation that the rapid ether cleavage reaction is confined to the monoethers of the pyrocatechol and hydroquinone series. The resorcinol ether consumed periodate comparatively slowly, although appreciably faster than phenol (*cf.* Fig. 1). After a reaction time of 16 h, 0.11 mole of methanol had been liberated and a small quantity of methoxy-*p*-quinone (IV) could be isolated. Obviously, there was a slow oxidation in the positions *ortho* and *para* to the phenolic hydroxyl group, giving methoxy-*p*-quinone and methoxy-*o*-quinone. The latter appears to be the source of the methanol formed (*cf.* above).

Some of the experiments reported in the present work have been carried out by civilingenjör Britt Berggren and civilingenjör C.-G. Setterquist.

Financial support from *Statens Naturvetenskapliga Forskningsråd* is gratefully acknowledged.

EXPERIMENTAL

Periodate consumption. For oxidation in an aqueous medium a 0.02 M solution of the phenol was mixed with an equal volume of 0.14 M sodium periodate. The mixture was kept in a thermostat at 25° (in one case, *cf.* Fig. 1, at 4°) protected from direct daylight. The amount of periodate present was determined on 5 ml samples by the arsenite method.

In most cases 80 % acetic acid solutions were used, and the residual periodate was determined by a potassium iodide-thiosulphate method. As the quinones formed would consume thiosulphate, they had to be removed. The following procedure was used.

The reaction mixture sample (5 ml) was added to a separatory funnel containing 20 ml of water, and the mixture was extracted with three 10 ml portions of methylene chloride. The aqueous layer was added to a mixture of 0.1 N sodium thiosulphate (30 ml) and 10 % potassium iodide (15 ml). After the addition of a few millilitres of 2 N sulphuric acid, the unconsumed thiosulphate was determined by iodine titration. A blank determination was made on a solution without phenol, and the amount of periodate consumed was obtained by difference.

Methanol was determined as described previously [1].

Oxidation of guaiacol. a) To an ice-cold aqueous solution (150 ml) of guaiacol (3.0 g = 24.2 mmole) a similarly cooled solution of sodium metaperiodate (10.5 g = 49.1 mmole) in water (75 ml) was added at once, and the resulting dark-red mixture immediately extracted with methylene chloride (100 ml). The extract was shortly dried over anhydrous sodium sulphate, filtered, and rapidly concentrated to a volume of about 20 ml by means of a rotating vacuum evaporator. After the addition of hexane the solution deposited dark-red crystals of *o-benzoquinone*, no sharp m.p., decomposition beginning at 60—70°, as described by Willstätter and Pfannenstiel [19]; yield 64 %.

b) In another experiment the methylene chloride solution obtained as above was brought to dryness under reduced pressure, and the dark-red, crystalline residue (2.5 g) immediately treated with aqueous sulphur dioxide. From the resulting solution a very small amount of undissolved material (identified as dimeric *o*-benzoquinone, see below) was removed by filtration. Continuous extraction of the solution with ether yielded *pyrocatechol* (56 %, based on the amount of guaiacol used), m.p. 103—104° after recrystallisation from benzene-hexane.

c) If the methylene chloride solution of *o*-benzoquinone obtained according to a) was kept in the refrigerator for several hours, it deposited a brown crystalline product, which became yellow on washing with acetone. Yield 45 %. It was identified by m.p., mixed m.p., and infra-red absorption spectrum with the *dimeric o-benzoquinone* which was recently obtained [20] from acetone solutions of *o*-benzoquinone.

4-Methyl-o-benzoquinone (*homo-o-quinone*). a) Creosol (4-methylguaiacol, 414 mg = 3 mmole) dissolved in ether (5 ml), was added to an aqueous solution (100 ml) of sodium metaperiodate (706 mg = 3.3 mmole) which was cooled by ice-water. After 15 min, the orange-red reaction mixture was extracted four times with methylene chloride, the red-green dichroic extract was dried over anhydrous calcium sulphate and the solvent was removed under reduced pressure. The dark-red crystalline residue was dissolved in ether; on cooling to −60° the solution deposited red prismatic needles, m.p. 75°; yield 70 %. Recrystallisation from ether or ether-petroleum ether yielded 4-methyl-*o*-quinone, either the red modification, m.p. 80°, or the yellowish-pink modification, m.p. 65—67° [3,5]. Admixture of similar samples, obtained from *p*-cresol according to Teuber and Staiger [5], gave no depression of the m.p. The infra-red absorption spectra of the two modifications, obtained by either method, were identical.

b) 4-Methyl-*o*-quinone was obtained in a similar way by oxidation of 4-methyl-pyrocatechol (see below) with periodate. The yield of the crude product, m.p. 75°, was 95 %.

4-Methyl-pyrocatechol (*homopyrocatechol*). The orange-red aqueous solution obtained by periodate oxidation of creosol as described above was saturated with sulphur dioxide and, after addition of sodium chloride, extracted with ether. The ethereal solution was dried and evaporated, and the slightly brown, oily residue was extracted several times with boiling hexane. The combined hexane solutions yielded 4-methyl-pyrocatechol, colourless thin plates, m.p. 66—67°; yield 62 %.

Oxidation of 4-hydroxydibenzofuran (*X*). a) 4-Hydroxydibenzofuran (2.0 g = 10.9 mmole) was added in portions to a solution of sodium metaperiodate (12.0 g = 56 mmole)

in 60 % aqueous acetic acid (400 ml). The reaction mixture was shielded from daylight and kept at 25° for 15 h. The addition of water (400 ml) to the red-brown solution produced a flocculent brown precipitate which was filtered off. The filtrate was extracted with methylene chloride and the extract was washed with water, dried over anhydrous sodium sulphate and evaporated under reduced pressure. Sublimation of the residue (bath temperature 100°, 3 mm Hg) and recrystallisation of the sublimate from hexane yielded *dibenzofuran-1,4-quinone* (XII) as yellow needles, m.p. 187—188°; yield 108 mg (5 %). (Found: C 72.13, 72.12; H 3.36, 3.21. Calc. for $C_{12}H_6O_3$: C 72.73; H 3.05.)

Reduction of XII (10 mg) with zinc dust in glacial acetic acid, followed by dilution with water and extraction with ether yielded the known *1,4-dihydroxydibenzofuran* (XIII), needles, m.p. 217—219° (217—218° [10]) after recrystallisation from water.

b) 4-Hydroxydibenzofuran (XII) (3.0 g) was oxidised with periodate as above. The solid residue obtained after evaporation of the methylene chloride solution (crude quinone XII) was reduced with zinc in acetic acid and the reaction mixture was diluted with water, heated and filtered. The filtrate deposited 0.50 g of the hydroquinone XIII; yield 15 %.

Methylation of XIII with dimethyl sulphate yielded 1,4-dimethoxydibenzofuran (XIV), m.p. 76—78° (78.5° [10]) after recrystallisation from hexane.

A solution of 1,4-dihydroxydibenzofuran (XIII) (10 mg) in glacial acetic acid (1 ml) was mixed with a solution of sodium metaperiodate (60 mg) in 60 % acetic acid (2 ml). Dilution with water and extraction with methylene chloride gave the quinone XII in quantitative yield.

Oxidation of hydroquinone monomethyl ether (*XIX*). Hydroquinone monomethyl ether (1.0 g = 8.06 mmole), dissolved in water (100 ml), was oxidised with sodium metaperiodate (5.17 g = 24.2 mmole) in aqueous solution (75 ml). Extraction with methylene chloride after a reaction time of 10 min yielded *p-benzoquinone;* yield, after sublimation, 80 %.

Solutions of hydroquinone monomethyl ether (5 mmole) and sodium metaperiodate (35 mmole) in water (25 ml) were cooled to 4° and mixed. After 5 min, 15 % lead nitrate solution (25 ml) was added. The methanol formed was determined as described by Adler and Hernestam [1]. The *p*-quinone in the filtrate was irreversibly adsorbed during the filtration through the anion exchange resin. The yield of *methanol* was 15.1 mg (94 %). In a similar experiment with a reaction time of 19 h the yield of methanol was 93 %.

Oxidation of hydroquinone monobenzyl ether (*XX*). A solution of sodium metaperiodate (8.0 g) in 60 % acetic acid (50 ml) was added to a solution of XX (4.0 g) in glacial acetic acid (250 ml). After 15 min the mixture was diluted with water and extracted with methylene chloride. The methylene chloride solution was washed with sodium hydroxide solution to remove *p*-quinone and then with water, dried over anhydrous sodium sulphate and evaporated. Distillation of the liquid residue gave *benzyl alcohol* (b.p. 200—205°, about 2 ml), which yielded a 3,5-dinitrobenzoate, m.p. 112°, undepressed on admixture with authentic benzyl-3,5-dinitrobenzoate (m.p. 112°).

p-Quinone was isolated from a second experiment.

Oxidation of hydroquinone monophenyl ether (*XXI*). a) A solution of XXI (1.0 g = 5.38 mmole) in glacial acetic acid (10 ml) was mixed with sodium periodate (3.0 g = 14.0 mmole) dissolved in 60 % acetic acid (100 ml). After 30 min the mixture was diluted with water to a volume of 1 l, the brown amorphous precipitate formed was removed by filtration, and the filtrate was extracted with methylene chloride. The methylene chloride solution was washed with water and evaporated, and the residue was steam-distilled. The yellow distillate was made up to a volume of 250 ml. The ultra-violet absorption showed that the solution contained 0.21 g of *p*-quinone (yield 35 %; control experiments showed that steam distillation of *p*-quinone involves appreciable loss of material). The solution was extracted with ether. Careful evaporation of the yellow ether extract gave a red residue recrystallised from hexane to give red needles, m.p. 70°, identical with »*phenoquinone*», the addition compound of phenol (2 mole) and *p*-quinone (1 mole).

The phenoquinone isolated was combined with the residue from evaporation of the hexane mother liquor and the combined products were dissolved in aqueous sodium hydroxide and shaken with air until the quinone odour had disappeared. The mixture was then neutralised with carbon dioxide and extracted with ether. The ether extract was evaporated and the residue dissolved in water. Addition of bromine yielded *tri-*

bromophenol (0.86 g), m.p. 89°, after recrystallisation and sublimation m.p. 93.5°, undepressed by an authentic sample; yield 54 %.

b) A solution of XXI (1.62 g = 8.72 mmole) in glacial acetic acid (25 ml) was treated with sodium periodate (4.20 g = 19.6 mmole) dissolved in 60 % acetic acid (75 ml). After 30 min the mixture was diluted with water (500 ml) and the amorphous precipitate formed was collected, washed with water, and dried. Yield 13.5 % of the weight of the starting material. The filtrate was extracted several times with methylene chloride and the extract was washed with water, dried over anhydrous sodium sulphate, and evaporated. The volatile phenoquinone was removed by sublimation (0.1 mm Hg) for 2 h. Recrystallisation of the residual product from ethyl acetate gave red prisms (0.18 g), m.p. 196°. Admixture of *(2-hydroxyphenyl)-p-quinone* (XXII) prepared according to Grundmann [14], m.p. 196° after recrystallisation from ethyl acetate, did not depress the m.p. Yield 10 %. (Found: C 71.97, 72.14; H 4.37, 4.33. Calc. for $C_{12}H_8O_3$: C 71.99; H 4.03.)

Substance XXII (98.60 mg), partially dissolved in a mixture of acetic acid and water, was slowly titrated with 0.1000 N sodium thiosulphate [15]; towards the end of the titration the mixture was heated to 40°. The substance gradually dissolved, yielding a colourless solution. Thiosulphate consumed: 4.94 ml, indicating a molecular weight of 199. Calc. for $C_{12}H_8O_3$: 200.18.

2,2',5'-Trihydroxydiphenyl (XXVII). Substance XXII (166 mg), dissolved in glacial acetic acid, was reduced with zinc dust. The solution obtained was diluted with water, extracted with ether, and the ethereal solution was washed with water and aqueous sodium bicarbonate, dried over anhydrous sodium sulphate, and evaporated giving a viscous oil which distilled at 150°/0.001 mm Hg. At room temperature the distillate (106 mg) was a colourless glass. (Found: C 69.96; H 5.13. Calc. for $C_{12}H_{10}O_3$: C 71.28; H 4.99.) Attempts to obtain crystalline derivatives (acetate, methyl ether, aryloxyacetic acid) were unsuccessful.

Substance XXVII (0.1 g), dissolved in glacial acetic acid (10 ml), was added to a solution of sodium metaperiodate (0.3 g) in 60 % acetic acid (10 ml). After 5 min the mixture was diluted with water, and the red quinone XXII was extracted with ether. It was recrystallised from ethyl acetate, m.p. and mixed m.p. 196°; yield nearly quantitative.

Similar oxidation of 2,2'-dihydroxydiphenyl (XXIII) with periodate yielded the quinone XXII in 5 % yield.

Oxidative degradation of (2-hydroxyphenyl)-p-quinone (XXII). Treatment of XXII (115 mg) with alkaline hydrogen peroxide, following the procedure used by Kögl, Erxleben, and Jänecke [21] for the degradation of 4,2',5'-trihydroxydiphenyl yielded *salicylic acid*, m.p. 157—159°, undepressed by an authentic sample. Yield 23 mg (26 %).

Oxidation of 2-hydroxydibenzofuran (XXIV). Substance XXIV (0.468 mmole), dissolved in glacial acetic acid (15 ml) was oxidised with sodium metaperiodate (2.10 mmole) dissolved in 60 % acetic acid (15 ml). The quinone XXII (45 mg) was obtained; yield 49 %.

Oxidation of hydroquinone monophenyl ether (XXI) with Fremy's salt. Substance XXI (0.5 g = 2.69 mmole) dissolved in methanol (12.5 ml) was added to an aqueous solution (150 ml) of Fremy's salt (3.0 g = 11.2 mmole). A red precipitate formed instantly, m.p. 180—185°. After recrystallisation from ethyl acetate the m.p. was 195—196°, undepressed on admixture of quinone XXII. Yield 63 %.

Oxidation of pyrogallol-1-methyl ether (XXX). a) Aqueous solutions of XXX (250 ml, containing 0.35 g = 2.5 mmole) and sodium metaperiodate (250 ml, containing 0.535 g = 2.5 mmole), cooled with ice-water, were mixed, and, after 2 min, the resulting dark-red solution was repeatedly extracted with methylene chloride. The extract was shortly dried over anhydrous sodium sulphate and evaporated to dryness under reduced pressure. The residue was dissolved in boiling ether, and the ethereal solution, after filtration and cooling to −80°, deposited red-brown crystals of *3-methoxy-o-quinone* (VI) (yield 57 %), m.p. 106—109°, undepressed on admixture of VI prepared according to Willstätter and Müller [3], m.p. 107—110°. The occurrence of a weak carbonyl band at 5.75 μ in the infrared absorption curve of the periodate product indicated the presence, in the latter product, of small amounts of the dimeric 3-methoxy-*o*-quinone, which will be described in a forthcoming communication.

b) In a similar experiment aqueous solutions (25 ml) of 73.5 mg of XXX (= 0.53 mmole) and 750 mg of periodate (= 3.5 mmole) (molar ratio about 1 : 7) were mixed. The yield of 3-methoxy-*o*-quinone was 58 %.

c) In an oxidation experiment according to b) the reaction time was increased to 24 h. The reaction mixture was found to contain 14.72 mg of methanol; yield 96 %.

Oxidation of methoxyhydroquinone (XXXI). Methoxyhydroquinone (67 mg = 0.62 mmole) was added to an aqueous solution (15 ml) of sodium metaperiodate (450 mg = 2.10 mmole), and the mixture was shaken for 1 h in a separatory funnel. The resultant yellow solution contained yellow crystalline material; it was extracted with methylene chloride. The extract yielded *methoxy-p-quinone* (IV) (65.4 mg), m.p. 142—146°, undepressed by authentic material. Yield 99 %.

Oxidation of 2,5-dimethoxyhydroquinone (XXXII). An aqueous solution (15 ml) of sodium metaperiodate (450 mg = 2.10 mmole) was added to a solution of the hydroquinone (131 mg = 0.77 mmole) in water (10 ml). After 30 min the crystalline precipitate formed (120 mg) was collected; extraction of the filtrate with methylene chloride yielded 5 mg of the same product, *2,5-dimethoxy-p-quinone (XXXIV).* The substance darkens at 310° without melting. Yield 96 %. At a bath-temperature of 160—180° and 0.1 mm Hg the material sublimed almost completely.

Reduction with zinc dust in glacial acetic acid regenerated the hydroquinone XXXII, m.p. 167—70°.

Oxidation of 2,4-dimethoxyphenol (XXXIII). a) Aqueous solutions of 2,4-dimethoxyphenol (50 ml containing 168 mg = 1.1 mmole of the phenol) and of sodium metaperiodate (1.5 g = 7.0 mmole in 100 ml) were mixed; after 15 min the yellow solution was extracted with methylene chloride. The solvent was evaporated and the residue was sublimed (100°, 20 mm Hg) giving *methoxy-p-quinone* (91 mg), identified by m.p. and mixed m.p. Yield 60 %.

b) Two reaction mixtures were prepared in the same way as in a) and kept at 4°; an excess of sodium pyrosulphite was added after reaction times of 15 and 120 min, respectively. From each solution 100 millilitres were distilled off, the distillate was made alkaline and redistilled, and the amount of methanol present in the final distillate was determined [1]. Both experiments gave 0.90 mole of methanol per mole of 2,4-dimethoxyphenol.

On the Connection between Electrical Potential and Free Energy for Concentration Cells with Transference

T. FÖRLAND

N.T.N.F.'s Institutt for Silikatforskning, N.T.H., Trondheim, Norway, and

J. KROGH-MOE

Svenska Silikatforskningsinstitutet, Göteborg, Sweden

From knowledge about the transport numbers the chemical changes have been calculated in a concentration cell when an electrical charge is transported through the cell. For the case that the electrolyte is a good conductor, so changes in dipol layers can be neglected, a rigorous correlation between electromotive force and free energy of the components has been derived.

In the classical treatment of concentration cells with transference, the transport number of the cations or anions appears in the equation for the potential. *E.g.*, for a concentration cell

$$\mathrm{Ag;\ AgNO_3\ in\ H_2O(I):\ AgNO_3\ in\ H_2O(II);\ Ag}$$

where the two electrolytes are silver nitrate-water solutions of different concentrations, the E.M.F. of the cell is given by:

$$E = (t_{\mathrm{NO_3^-}})\ \frac{RT}{F}\ \ln\frac{a_{\mathrm{II}}}{a_{\mathrm{I}}}$$

Here $t_{\mathrm{NO_3^-}}$ is the transport number of the nitrate ion, R is the gass constant, T the absolute temperature, F Faraday's number, and a_{I} and a_{II} are the activities of silver nitrate in the two solutions.

It has been shown by Sundheim [1] that for a system of fused salts absolute transport numbers have no meaning. Whether the electrical charge is transported by the cations or by the anions is not a property of the fused salt, but of the experimental arrangement. As was pointed out by Förland and Krogh-Moe [2], this also applies to water solutions where hydroxyl ions take

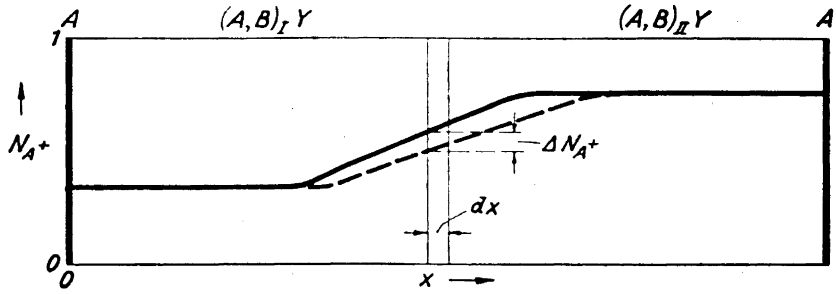

Fig. 1. The content of the component AY as a function of the distance from one side for the concentration cell A; $(A, B)_I Y : (A,B)_{II} Y$; A.

part in the electrical transport, and thus the water cannot be considered as a neutral reference frame.

The question now arises how to formulate the equation of the potential of a concentration cell when the electrolyte is a fused salt. As the fused salt lacks a reference frame, an equation like eqn. (1) obviously cannot be used.

It is also of interest to know under what conditions the liquid junction potential will be of importance, and if it is significant, how it may be calculated. Concentration cells are often experimentally simple, and it would therefore be of importance to eliminate the uncertainty connected with the liquid junction potential.

We will consider the following concentration cell

$$A; (A,B)_I Y : (A,B)_{II} Y; A$$

where the electrolytes consist of a fused mixture of two salts AY and BY (A^+ and B^+ forming cations and Y^- forming the anion) the A^+/B^+ ratio being different on the two sides of the cell. Further the electrodes are reversible only to the metal A.

In Fig. 1 is plotted the ionic fraction N_{A+} and N_{B+} of the two cations as a function of the distance x from one side of the cell. The ionic fractions are defined as

$$N_{A+} = \frac{n_{A+}}{n_{A+} + n_{B+}} \text{ and } N_{B+} = \frac{n_{B+}}{n_{A+} + n_{B+}}$$

where n with subscript indicate the number of moles of an ion. With a cell arrangement as indicated, we have $t_{Y^-} = 0$. (In a thermodynamic treatment we are not interested in whether the transport of the cations is a highly coupled process or not.)

We will assume that the transport number of A^+ is a function of the ionic fraction of A^+:

$$t_{A+} = t_{(N_{A+})} \qquad (2)$$

We may first calculate the changes taking place in the region of the concentration gradient of the cell, when an electrical charge (Q) is transported through the cell.

The transport number of A^+ at a distance x from one side of the cell we denote by $t_{A+\,(x)}$. At a distance $x + dx$ the transport number is

$$t_{A+\,(x+dx)} = t_{A+\,(x)} + \frac{\partial\, t_{A+}}{\partial\, x}\, dx = t_{A+\,(x)} + t'_{(N_{A+})}\, \frac{\partial\, N_{A+}}{\partial\, x}\, dx \qquad (3)$$

The change in the content of A^+ in the volume of thickness dx by the transport of electrical charge will be:

$$\frac{\partial\, n_{A+}}{\partial\, Q} = \frac{1}{F}\,(t_{A+\,(x)} - t_{A+\,(x+dx)}) \qquad (4)$$

and as $n_{A+} = \frac{dx \cdot q}{V} \cdot N_{A+}$ where q is the crossection of the electrolyte and V is the volume of one mole of (A,B)Y, the change in the ionic fraction of A^+ will be:

$$\frac{\partial\, N_{A+}}{\partial\, Q} = -\frac{V}{q \cdot F}\, t'_{(N_{A+})}\, \frac{\partial\, N_{A+}}{\partial\, x} \qquad (5)$$

One may notice that if $\partial N_{A+}/\partial Q$ is proportional to the concentration gradient $\partial N_{A+}/\partial x$, then the curve showing N_{A+} as a function of x will not change its slope by the transport of electricity. It will only be shifted in a parallel way towards right. From eqn. (5) one can see that this will be the case when

$$t'_{(N_{A+})} = \text{constant} \qquad (6)$$

in the concentration interval in question, or if the transport number can be expressed by an equation

$$t_{A+} = a\, N_{A+} + b \qquad (7)$$

where a and b are constants. One may further notice that the shift of the concentration gradient is equal to:

$$\left(\frac{\partial\, x}{\partial\, Q}\right)_{N_{A+}\,=\,\text{const.}} = -\frac{V}{q \cdot F}\, t'_{(N_{A+})} \qquad (8)$$

which shows that it is independent of the gradient $\partial N_{A+}/\partial x$.

One may now calculate all changes taking place in the cell by the transfer of a small electrical charge ΔQ.

At the left side electrode $\Delta Q/F$ mole of A^+ ions will form and $t_{A+\,(I)} \cdot \Delta Q/F$ mole of A^+ ions and $t_{B+\,(I)} \cdot \Delta Q/F$ mole of B^+ ions will leave this side of the cell. This change is equivalent to the introduction of $\frac{t_{B+\,(I)}}{N_{B+\,(I)}} \cdot \Delta Q/F$ mole of AY, and the simultaneous removal of $\frac{t_{B+\,(I)}}{N_{B+\,(I)}} \cdot \Delta Q/F$ mole of $(A,B)_I Y$ with the same A/B ratio as the electrolyte on this side of the cell.

The change at the right side of the cell is equivalent to removal of $\frac{t_{B+\,(II)}}{N_{B+\,(II)}} \cdot \Delta Q/F$ mole of AY and the simultaneous introduction of $\frac{t_{B+\,(II)}}{N_{B+\,(II)}} \cdot \Delta Q/F$ mole of $(A, B)_{II}$ Y with the same A/B ratio as the electrolyte on the right side of the cell.

At the same time the concentration gradient will be shifted according to eqn. (7). The changes taking place are schematically shown in Fig. 1.

The free energy change taking place in the region of the concentration gradient, when a charge ΔQ is transported through the cell, is equal to

$$\Delta F_1 = \int \frac{q \cdot dx}{V} \cdot \frac{d\Delta F}{dN_{A+}} \cdot \Delta N_{A+} \tag{9}$$

where ΔF is the free energy of mixing per one mole of the mixture AY—BY, and ΔN_{A+} is the change in the ionic fraction of A^+:

$$\Delta N_{A+} = \frac{\partial N_{A+}}{\partial Q} \cdot \Delta Q = -\frac{V \cdot \Delta Q}{q \cdot F} t'_{(N_{A+})} \frac{\partial N_{A+}}{\partial x} \tag{10}$$

Introducing this into eqn. (9) one has:

$$\Delta F_1 = -\frac{\Delta Q}{F} \int_{N_{A+\,(I)}}^{N_{A+\,(II)}} \frac{d\Delta F}{dN_{A+}} \cdot t'_{(N_{A+})}\, dN_{A+} \tag{11}$$

The total change in free energy associated with the transport of the charge ΔQ is equal to

$$\Delta F_{total} = \left[\frac{t_{B+\,(I)}}{N_{B+\,(I)}} (\Delta \bar{F}_{AY(I)} - \Delta F_{(I)}) - \frac{t_{B+(II)}}{N_{B+(II)}} (\Delta \bar{F}_{AY(II)} - \Delta F_{(II)}) - \int_{N_{A+\,(I)}}^{N_{A+\,(II)}} \frac{d\Delta F}{dN_{A+}} \cdot t'_{(N_{A+})}\, dN_{A+} \right] \frac{\Delta Q}{F} \tag{12}$$

where $\Delta F_{(II)}$ and $\Delta F_{(I)}$ are the free energy changes by mixing AY and BY to give one mole of the two electrolytes $(A,B)_{II}Y$ and $(A,B)_{I}Y$, respectively.

The liquid junction may form a dipol layer whose energy is changed by the cell reaction. However, in a system of fused salts it is reasonable to assume that this energy change is insignificant, and it will be omitted here.

Since the transfer of the charge ΔQ is not connected with any other changes in the cell than what is expressed by eqn. (12) (it can not depend on any time-dependent process as the transfer of the charge is time-independent), the E.M.F. of the cell is given by

$$E \cdot \Delta Q = \Delta F_{total}$$

or

$$E \cdot F = \frac{t_{B+\,(I)}}{N_{B+\,(I)}} \Delta\overline{F}_{AY(I)} - \frac{t_{B+\,(II)}}{N_{B+\,(II)}} \Delta\overline{F}_{AY(II)}$$

$$+ \frac{t_{B+\,(II)}}{N_{B+\,(II)}} \Delta F_{(II)} - \frac{t_{B+\,(I)}}{N_{B+\,(I)}} \Delta F_{(I)} - \int_{N_{A+\,(I)}}^{N_{A+\,(II)}} \frac{d\Delta F}{dN_{A+}} \cdot t'_{(N_{A+})} dN_{A+} \quad (13)$$

The correlation between E.M.F. of the cell and the partial free energy of one component is thus rather complicated in the general case.

For the special case when $t_{A+} = N_{A+}$ and $t_{B+} = N_{B+}$ over the concentration interval in question one obtains

$$E \cdot F = \Delta\overline{F}_{AY\,(I)} - \Delta\overline{F}_{AY\,(II)}$$

Further one will see that the E.M.F. is zero if $t_{B+} = 0$.

If the electrodes were reversible to Y, the E.M.F. would be zero if the relative transport numbers of the cations were proportional to their ionic fractions ($t_{A+} = N_{A+}$, $t_{B+} = N_{B+}$ and $t_{Y^-} = 0$ equivalent to $t_{A+} = 0$, $t_{B+} = 0$ and $t_{Y^-} = 1$). If the electrodes are reversible to Y, and $t_{B+} = -t_{Y^-} = -1$ and $t_{A+} = 1$, E.M.F. will be given by the equation

$$E \cdot F = \Delta\overline{F}_{AY\,(II)} - \Delta\overline{F}_{AY\,(I)}$$

An electrolyte of sodium silicate can formally be described as consisting of the ions Na^+, Si^{4+} and O^{2-}. A cell with two oxygen electrodes and an electrolyte of an acid sodium silicate would thus be of the latter type.

It has come to our knowledge that Sundheim [3,4] has recently derived an expression for the liquid junction potential. His derivation is based on the equations of the thermodynamics of irreversible processes, and the result is in a form different from that given above.

Colorimetric Determination of Thiosulphate in the Presence of Polythionates and Hydrogen Sulphite

NILS-HERMAN SCHÖÖN

Department of Engineering Chemistry, Chalmers Tekniska Högskola, Göteborg, Sweden

The influence of pentathionate, tetrathionate, trithionate, and hydrogen sulphite upon the colorimetric determination of thiosulphate according to the silver thiocyanate method has been studied. Furthermore, a method for thiosulphate determination based on the reaction between thiosulphate and *p*-benzoquinone, has been worked out. Under proper conditions these additions have only a slight influence.

Colorimetric methods for the determination of thiosulphate have been reported by Utsumi [1,2], Sörbo [3], Straub and Kiss [4], Budd and Bewick [5], and Stolyarov [6].

The first method given by Utsumi (the silver thiocyanate method) is based upon the reaction between solid silver thiocyanate and thiosulphate, which can be written:

$$m\ AgSCN_{(s)} + n\ S_2O_3^{2-} \rightleftharpoons Ag_m(S_2O_3)_n^{(2n-m)-} + m\ SCN^-$$

After separating the solid phase, the amount of thiocyanate can be determined colorimetrically as iron(III)thiocyanate complexes.

In the second method reported by Utsumi (the mercury(II)thiocyanate method) the determination of thiosulphate is based on the formation of thiocyanate in the reaction between thiosulphate and mercury(II) thiocyanate. The reaction may be written:

$$2\ S_2O_3^{2-} + 3\ Hg(SCN)_2 + 2\ H_2O \rightarrow Hg(SCN)_2 \cdot 2\ HgS_{(s)} + 4\ H^+ + 4\ SCN^- + 2\ SO_4^{2-}$$

Since mercury(II)thiocyanate is very slightly dissociated, it is possible to determine directly the thiocyanate ions formed in this reaction. The determination is made colorimetrically after the addition of iron(III)nitrate.

In the method reported by Sörbo (the cyanide method) thiosulphate reacts with an excess of cyanide at room temperature giving thiocyanate according to the reaction:

$$S_2O_3^{2-} + CN^- \rightarrow SCN^- + SO_3^{2-}$$

Copper(II)salt is added as a catalyst to the solution. The thiocyanate formed is determined as in the other methods. The cyanide method has also been studied by Straub and Kiss.

In the method given by Budd and Bewick thiosulphate is reduced by tin(II)chloride and aluminium to sulphide. The hydrogen sulphide driven off from the solution is determined colorimetrically by formation of methylene blue with *p*-aminodimethylaniline.

The method given by Stolyarov is based upon oxidizing the thiosulphate by cerium(IV). The amount of thiosulphate is determined indirectly by colorimetrically measuring the decrease of the concentration of cerium(IV). The determination is performed at 365 mμ where cerium(III) does not influence.

The mercury(II)thiocyanate method, the cyanide method, and the method reported by Budd and Bewick, are not applicable in the presence of polythionates since these ions react in a similar way to thiosulphate *. Sulphite also reacts with mercury(II)thiocyanate giving thiocyanate ions. In the presence of sulphite, too high values are also obtained by the silver thiocyanate method [7]. This is due to the formation of complexes containing silver and sulphite ions. Hydrogen sulphite, on the other hand, does not influence this determination, provided that the thiosulphate concentration is higher than 0.5 mM. Sulphite also influences the determination of thiosulphate according to the method by Budd and Bewick, and the method by Stolyarov.

In the present work, the influence of polythionates upon the determination of thiosulphate according to the silver thiocyanate method has been studied. The determination of thiosulphate at extremely low concentrations in the presence of hydrogen sulphite will also be dealt with. A colorimetric method, based on the reaction between thiosulphate and *p*-benzoquinone (the quinone method), is given, and the influence of polythionates and hydrogen sulphite has been studied. The investigation only includes three polythionates: trithionate, tetrathionate, and pentathionate.

I. THE SILVER THIOCYANATE METHOD

Experimental

The shaking- and filtration procedures were performed as described in a previous paper [7]. In the experiments with polythionates and thiosulphate given in Tables 2 and 3, 70 mg solid silver thiocyanate was added to 30 ml of the solution. The thiocyanate dissolved was determined colorimetrically. Ten ml iron(III)nitrate solution, 0.5 M iron(III)-nitrate and 0.5 M nitric acid were added to 15 ml of the filtered test solution. In the other experimental series, 15—20 mg radioactive silver thiocyanate (^{110}Ag being used as a tracer) was added to 30 ml of the solution.

Radioactive silver thiocyanate was used in these experiments in order to make it possible to determine the concentration of silver in the filtrate. The radioactivity measurements were performed in the same way as that described in the previous paper. The colorimetric determination was performed after addition of 5 ml 1.2 M formaldehyde and 5 ml 0.5 M iron(III) nitrate solution to 15 ml of the test solution. This large excess of formaldehyde must be added before the colorimetric determination in order to obtain a stable colour in the solution containing hydrogen sulphite. — A calibration was performed

* The colorimetric determination of polythionates according to the cyanide method and the mercury (II) thiocyanate method will be described in a forthcoming paper.

with potassium thiocyanate in order to determine the relationship between the absorbance and the concentration of thiocyanate. This calibration gave the absorbance $0.262/10^{-4}$ M thiocyanate. It may be observed that this concentration as well as the concentrations of thiosulphate and polythionates given in Tables 1—3 refer to the solution before the addition of iron(III) nitrate and formaldehyde.

The absorbance was measured at the wave-length 460 mμ by means of a spectrophotometer Beckman Model DU. The slit width was 0.02—0.03 mm and 1 cm cells were used.

In all cases, freshly boiled distilled water was used to obtain stable solutions. Trithionate and tetrathionate were prepared according to Kurtenacker and Matejka [8]. Pentathionate was prepared according to Stamm, Siepold and Goehring [9]. All the salts were more than 97 % pure.

Results

The influence of hydrogen sulphite on the determination of thiosulphate is given in Table 1. The results indicate a decrease in the dissolution of silver thiocyanate which is only to a certain extent compensated for by adding an excess of formaldehyde. In one experiment, the time of shaking was increased from 15 min to 40 min. Despite this increase in the time of reaction, no increase in the dissolution was obtained. This shows that the lower dissolution obtained for solutions containing hydrogen sulphite is not due to a lowered rate of dissolution.

In all experiments given in Table 1, the silver content of the filtrates was also measured in order to make sure that the decreased absorbance really is due to a decreased dissolution of silver thiocyanate. The results show that this explanation holds true although the decrease in dissolution found by the radiometric method is somewhat lower than the effect observed colorimetrically.

In Table 2 the interference of polythionates in the silver thiocyanate method is shown. In these experiments the time of reaction was 10 min and 16 h. For the shorter time of reaction, the dissolution of silver thiocyanate in the polythionate solutions is less than 5 % of the dissolution obtained for thiosulphate. A higher dissolution is obtained, especially for trithionate, upon increasing the time of reaction. After 16 h, the dissolution of silver thiocyanate

Table 1. Influence of hydrogen sulphite upon the determination of thiosulphate according to the silver thiocyanate method.

	Absorbance at the thiosulphate concentration			Silver content, mM at the thiosulphate concentration

	16 h	0.018	—	0.020
$S_5O_6^{2-}$	10 min	0.004	0.013	0.016
	16 h	0.022	—	0.034

in 0.1 mM trithionate amounts to 15 % of the value obtained in 0.1 mM thiosulphate. The increased dissolution is probably due to the decomposition of the polythionates and the thiosulphate giving silver sulphide among other things. A short time of reaction must therefore be used for the determination of thiosulphate according to this method.

The dissolution of silver thiocyanate in mixtures of polythionates and thiosulphate has also been studied. The results given in Table 3 show that the increase in the dissolution in the presence of polythionates is less than 5%.

II. THE QUINONE METHOD

Rzymkowski [10] has investigated a method for the determination of *p*-benzoquinone by titration with thiosulphate in acidic solution. The reaction between *p*-benzoquinone and thiosulphate proceeds, according to Rzymkowski, in three steps.

In the first step the uncoloured hydroquinone monothiosulphuric acid is formed, which in the next step reacts with quinone giving hydroquinone and the yellow quinone monothiosulphuric acid. This reaction was shown to be

Table 3. Influence of polythionates upon the determination of thiosulphate according to the silver thiocyanate method.

Test solution	Absorbance
0.1 mM $S_2O_3^{2-}$	0.211
0.1 mM $S_2O_3^{2-}$ + 0.1 mM $S_3O_6^{2-}$	0.211
0.1 mM $S_2O_3^{2-}$ + 0.1 mM $S_4O_6^{2-}$	0.215

Curve A: 33 mM quinone
Curve B: 3.3 mM quinone

reversible. In the last step, quinone monothiosulphuric acid reacts with thiosulphate giving hydroquinone-2,3-dithiosulphuric acid which is colourless. With excess quinone, this compound is probably further oxidized giving the yellow-red quinone dithiosulphuric acid. With excess quinone the solution is yellow while, with excess thiosulphate, the yellow colour disappears. The reaction has also been studied by Brauer and Staude [11] and Sandved and Holte [12].

The possibility of applying this reaction for the colorimetric determination of thiosulphate at low concentrations has been studied in the present work. The investigation reported here comprises the measurement of absorbance curves and a study of the influence of polythionates, hydrogen sulphite, and formaldehyde on the reaction. The stability of the yellow colour was also studied.

Experimental

For the measurement of the absorbance curves, 10 ml 1.7 M acetic acid and 10 ml 10 mM *p*-benzoquinone were added to 10 ml of 1, 0.5, and 0.1 mM thiosulphate. In the reference solution, the thiosulphate was replaced by 10 ml water. In the other experiments, the addition of acetic acid and *p*-benzoquinone was the same as that above. The slit width was 0.06 mm and 1 cm cells were used in all measurements. The *p*-benzoquinone was of analytical grade, from Dr. T. Schuchardt, München.

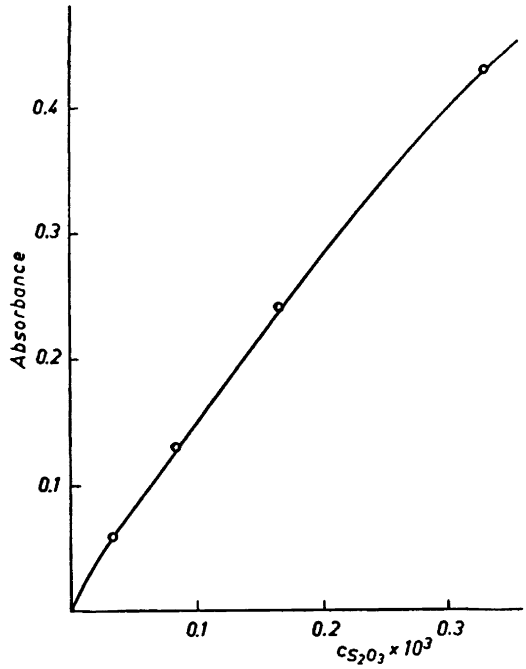

Fig. 3. Absorbance as a function of the concentration of thiosulphate.

Results

In Fig. 1, the absorbance is given as a function of the wave-length in the interval 320—440 mμ. As seen from the figure, the absorbance reaches a maximum at the wave-length 400 mμ.

All the measurements were made 2 h after the addition of the quinone solution since it was found (Fig. 2) that the absorbance increases rapidly until about 90 min after the addition of quinone solution. After this time, the absorbance is constant for at least one hour. The absorbance then decreases by only 6 % during the following 24 h. By increasing the concentration of quinone ten times, *viz.* from 3.3 to 33 mM, a stable absorbance was obtained after only 25 min of reaction. After 24 h, the absorbance was about 7 % less. For this concentrated solution, the absorbance was about 20 % higher than that for 3.3 mM quinone.

From Fig. 3 it is seen that, in the concentration interval 0.33—0.033 mM, the absorbance is not proportional to the thiosulphate content of the solution.

The behaviour of polythionates towards quinone was investigated in the same way as that described for thiosulphate. The absorbance was measured for solutions containing 0.56 M acetic acid, 3.3 mM *p*-benzoquinone, and 0.33 mM polythionate or 0.33 mM polythionate together with 0.165 mM thiosulphate.

Table 4. Influence of polythionates upon the determination of thiosulphate according to the quinone method.

Test solution	Absorbance at 400 mμ
0.33 mM $S_3O_6^{2-}$	0.002
0.33 mM $S_4O_6^{2-}$	0.005
0.33 mM $S_5O_6^{2-}$	0.000
0.165 mM $S_2O_3^{2-}$	0.241
0.165 mM $S_2O_3^{2-}$ + 0.33 mM $S_3O_6^{2-}$	0.242
0.165 mM $S_2O_3^{2-}$ + 0.33 mM $S_4O_6^{2-}$	0.240
0.165 mM $S_2O_3^{2-}$ + 0.33 mM $S_5O_6^{2-}$	0.240

The results in Table 4 show that the polythionates have no effect on the formation of the quinone thiosulphuric acids. As may be seen from Table 5, a considerable influence was obtained when hydrogen sulphite was added. The influence of hydrogen sulphite can, however, be eliminated by the addition of excess formaldehyde. Formaldehyde was in this case also added to the reference solution. At the highest concentration of hydrogen sulphite the absorbance is about 3 % too low despite the addition of formaldehyde. A corresponding decrease in the absorbance is also obtained for solutions containing only formaldehyde and thiosulphate, which shows that the decrease is not due to the presence of hydrogen sulphite. The formation of formaldehyde thiosulphuric acid [13] may to some extent explain the decrease in the absorbance. No experiments have been performed to investigate whether the intermediate compounds formed in the reaction between quinone and thiosulphate react with formaldehyde. The difference in the absorbances obtained for the experiments given in Table 4 and Table 5 may be explained by the fact that different samples of *p*-benzoquinone were used in the two series of experiments.

Table 5. Influence of hydrogen sulphite and formaldehyde upon the determination of thiosulphate according to the quinone method.

$c_{S_2O_3} \times 10^3$	$c_{SO_3} \times 10^3$	$c_{HCHO} \times 10^3$	Absorbance at 400 mμ

0.165	—	40	0.230
0.165	—	400	0.222

DISCUSSION

A comparison between the two methods for the determination of thiosulphate shows that the silver thiocyanate method is the more sensitive one, giving about twice the absorbance while, on the other hand, the quinone method is the more specific one since it is not at all influenced by polythionates. In both methods, hydrogen sulphite interferes. This interference is completely eliminated in the quinone method by the addition of formaldehyde while, in the silver thiocyanate method, it can be eliminated only to a certain extent by the addition of formaldehyde. In both methods, the relation between the absorbance and the concentration of thiosulphate is non-linear.

Studies on the Hydrolysis of Metal Ions 22

Equilibrium Studies in Self-medium; Application to the Hydrolysis of Th^{4+}

SIRKKA HIETANEN and LARS GUNNAR SILLÉN

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

It is suggested that added information on polynuclear complexes, A_pB_q, between the reagents, A and B, may be obtained by working with an ionic medium where one of the reagents, say B, forms the major part of the ions of one charge. This is termed the "self-medium method", as distinguished from the "inert medium method", *e. g.* with $NaClO_4$, in current use. The self-medium method favors complexes A_pB_q with low values for p/q so that information may be obtained about such complexes with a greater certainty than from work with inert media.

The self-medium method has been applied to the hydrolysis of Th^{4+}. The data indicate the two reactions $2Th^{4+} + 2H_2O \rightleftharpoons Th_2(OH)_2^{6+} + 2H^+$ (equil. const. β_{22}) and $2Th^{4+} + H_2O \rightleftharpoons Th_2OH^{7+} + H^+$ (β_{12}). In the medium 0.5 Th, 2.2 (Na)Cl, $\log \beta_{22} = -5.02 \pm 0.04$, $\log \beta_{12} = -2.8 \pm 0.2$. In 0.7 Th, 3.0 (Na)Cl, $\log \beta_{22} = -5.09 \pm 0.04$, $\log \beta_{12} = -2.9 \pm 0.2$. Temperature 25°C.

Symbols

A, B = reactants, here OH^- ($-H^+$) and Th^{4+}; a = concentration of free A, here $a = h^{-1}$, eqn. (17); b = concentration of free B; B = total concentration of B; E = electromotive force of cell (16); E_0 = constant in eqn (18); $f = 2u^2 + 2ku$, eqn (12); $F(h) = BZ + \Delta$, eqn (19); $F'(h)$, theoretical expression for $F(h)$; $h = [H^+]$; H = analytical excess of H^+, often negative; j = constant in term for liquid junction potential, eqn (18); k = parameter defined by eqn (11); p, q = coefficients in formula of complex A_pB_q; K'_p = equilibrium constant for formation of the "A_p group" of complexes, eqn (4); P, Q = coefficients in formula of single complex; u = normalized variable, corresponding to a, eqns (7) or (11); Z = average number of A (here OH^-) bound per B (here Th^{4+}); β_{pq} = equilibrium constant for formation of A_pB_q, eqn (1); Δ = analytical error in H, eqn (19).

In the equations, equilibrium constants, and figures, the unit M (Mole/liter) is used throughout. However, in some of the tables, and in the text, the more convenient unit mM, mmole/liter, is sometimes used.

The inert medium method

In accurate work on complicated equilibria where charged species appear, say, equilibria between a metal ion, B, and a ligand, A, it has been increasingly common, since the work of Leden [1], to add to the solvent an "inert medium", *i.e.* an excess of ions like Na^+ and ClO_4^-, which are supposed not to take part in the reactions. In the studies of the hydrolysis of cations [2] and anions [3] in this laboratory, an inert medium has practically always been used, usually 3 M $(Na)ClO_4$ for cations, and 3 M $Na(ClO_4)$ for anions.

It is assumed that the activity factors keep constant when an inert medium is used; they are conventionally set = 1. Biedermann and Sillén [4] have given some experimental evidence for this assumption, and also for the assumption that the liquid junction potential is a (linear) function of $[H^+]$ only, at least as the method is applied in this laboratory. Forthcoming papers by Biedermann [5] will make use of a large amount of experimental evidence to indicate the range of applicability of the method, and the deviations obtained when the concentrations of the reactants, A and B, cease to be negligible in comparison with those of the medium ions.

The great advantage of the inert medium method is that the calculations are much simpler and much more reliable than if the variation of the activity factors must be considered. Emf measurements give the concentrations of free ions directly, and concentrations may be used in the law of mass action. One may indeed say that only by using the inert medium method has it been possible to draw reliable conclusions on the formulas of the species formed in many complicated systems with several products, especially in those where polynuclear species appear.

The available range in B, the total concentration of B, is limited by the decreasing experimental accuracy for low values of B, and by the deviations of the activity factors at high values of B. Using 3 M $(Na)ClO_4$ as inert medium, it has been thought advisable not to go much beyond 0.1 or 0.2 M in B for polyvalent cations.

Self-medium method

We would suggest that additional information on the species formed may be obtained by what we are going to term the "self-medium" method, which implies that the ionic medium is made to consist chiefly of the ion B to be studied, with an "inert" counter ion. In the present paper on Th^{4+} hydrolysis, 0.5 M $ThCl_4$, or 0.7 M $ThCl_4$ has been used as the main constituent; for anion hydrolysis one might think of, say, 2 M Na_2CrO_4 (or $Na_2Cr_2O_7$), 4 M $NaAs(OH)_4$ *etc.* In order not to change the ionic medium, and the activity factors, too much, one must keep the added amount of the ligand A, and thus Z, fairly low.

To make possible the necessary variations in Z, one must in general either change the concentration of the counter ion slightly, or add a small amount of an inert ion of the same sign of charge as B. Both ways have been used in the present work; the second seems preferable.

Let us assume that the two reactants, A and B, form a number of complexes, A_pB_q with the formation constants β_{pq}. For each set (p, q) we have

$$[A_pB_q] = \beta_{pq}a^pb^q \tag{1}$$

From the definitions, it follows for B (the total concentration of B) and BZ (moles of A bound to B per liter):

$$B = [B] + \sum_p \sum_q q[A_pB_q] = b + \sum_p \sum_q q\beta_{pq}a^pb^q \tag{2}$$

$$BZ = \sum_p \sum_q p[A_pB_q] = \sum_p \sum_q p\beta_{pq}a^pb^q \tag{3}$$

If Z is kept at such low values that practically $b \approx B$, we have

$$BZ = \sum_p pK'_pa^p; \quad K'_p = \sum_q \beta_{pq}B^q \tag{4}$$

From data $Z(\log a)$, measured in self-medium, it would be possible to compute the constants, K'_p in (4), for instance using curve-fitting (Sillén [6]). One might formally describe K'_p as the equilibrium constant for the association reaction, $pA \rightleftharpoons A_p$, in the medium in question. We may conventionally write A_p for the whole set of complexes A_pB_q, with varying q but the same p, since self-medium data will give practically no direct information on q. Even in those cases where a small correction for B—b is necessary, the accuracy does not allow a decision on the value for q.

Information on species

It might be held as a disadvantage that the information on the formulas of the species which is obtained with the self-medium method is thus still more restricted than that with the inert medium method, which is again more restricted than that obtained from dilute solutions. On the other hand, even the "restricted" information might have been unobtainable by the other methods.

To take an example, from equilibrium studies in *dilute* borate *solutions* one may conclude that there is a mononuclear species containing one B atom and having the charge —1; from the equilibrium data alone it is, however, not possible to decide between formulas with varying amounts of the solvent, H_2O: BO_2^-, $H_2BO_3^-$, $B(OH)_4^-$. Only the last formula is, by the way, supported by structural work.

From equilibrium studies in an *inert ionic medium* such as $Na^+ClO_4^-$, one may in addition deduce the formulas and equilibrium constants of polynuclear complexes: $B_3O_3(OH)_4^-$, and $B_3O_3(OH)_5^{2-}$, or $B_4O_5(OH)_4^{2-}$, information which could not have been obtained from studies in dilute solutions (Ingri *et al.*[3]).

On the other hand, it is not possible to discern between species that differ by containing various amounts of water, and of the medium ions: "$[B_3O_3(OH)_4^-]$" is thus really = $\Sigma[B_3O_3(OH)_4(H_2O)_x(Na)_y(ClO_4)_z^{y-1-z}]$.

In this special case, there may have been no strong reason to suppose that the medium ions would play any important role; it has been tested [7] that the formulas of the species are the same, and the equilibrium constants are not much effected on changing to a different inert medium, like Li^+Br^-, or Na^+Br^-.

In other cases, this consideration may be more serious. For instance, by equilibrium studies in the medium $NH_4^+NO_3^-$, it would not be possible to distinguish between $Hg(NH_3)_2^{2+}$, $HgNH_2^+$, $Hg(OH)_2$, and other species that could briefly be written as "HgH_{-2}" (Sillén [8]). In such a case it is very important to make equilibrium studies in several different media, or to add structural evidence.

With the *self-medium* method, the information obtained would seem still more restricted since it would not be possible to distinguish between species with different numbers, q, of the reagent B; on the other hand, one might hope in this way to obtain information not available in other ways.

In the example of the borate equilibria, one might choose $Na^+B(OH)_4^-$ as self-medium (reagents A = H^+, B = $B(OH)_4^-$), and would then group together species such as AB = $B(OH)_3$ and $AB_3 = B_3O_3(OH)_5^{2-}$ in the A_1-group, and species like $A_2B_3 = B_3O_3(OH)_4^-$ and $A_2B_4 = B_4O_5(OH)_4^{2-}$ in the A_2-group. (Note that the present choice of A and B differs from that in Ref.[3]).

Similarly, in the present study on the hydrolysis of Th^{4+} with mainly $ThCl_4$ as self-medium, there is evidence for a species with a deficit of two protons, for which the formula $Th_2(OH)_2^{6+}$ seems plausible. Really, however, it would not be possible to distinguish between formulas with varying amounts of solvent and medium ions:

$$"[Th_2(OH)_2^{6+}]" = \Sigma\Sigma\Sigma[Th_qH_{-2}(H_2O)_xCl_y^{(4q-2-y)}]$$

One might thus, slightly more correctly, refer to this species as "H_{-2}" or "$(OH)_2$".

In the cases that have hitherto been studied, this limitation in the self-medium method has not proved very serious. In general the numbers of ligands have come out low, 1 or 2, and it has been possible to deduce the most important value for q fairly reliably by comparing the equlibrium constant obtained in the self-medium with data from inert media. Structural considerations may also give some guidance.

Which species are favored?

One might ask which types of complexes are favored by measurements in self-medium as compared with measurements in an inert medium with lower values of B. It is plausible to suggest that the accuracy of the experiments with different values of B will be comparable at identical values of BZ.

Suppose that there are only two complexes with the sets $(p'q')$ and $(p''q'')$, and concentrations $c' = \beta' a^{p'} B^{q'}$, $c'' = \beta'' a^{p''} B^{q''}$, since $b \approx B$ (1). If $BZ = p'c' + p''c''$ (3) is kept constant, one may easily deduce

$$\left(\frac{\partial \ln(c'/c'')}{\partial \ln B}\right)_{BZ} = \frac{(p'c' + p''c'')}{(p'p'c' + p''p''c'')} (q'p'' - q''p') \qquad (5)$$

In the expression to the right in (5), the fraction is certainly positive, provided BZ is positive, so the sign of the derivative is determined by $(q'p''—q''p')$. If all coefficients p and q are positive (we omit the case where one of p' and p'' is negative), c'/c'' will increase with B, provided $q'/p' > q''/p''$. In general, increasing B (*e.g.* using the self-medium method) will favor complexes with high values for q/p. So it might be hoped that the self-medium method would give more certain evidence for some complexes with high ratios q/p than can be obtained using an inert medium.

Some arguments might be given for comparing, instead, points of equal Z. For instance, in self-media of different B, the uncertainty from the activity factors may set a limit at roughly the same Z. If $\ln(c'/c'')$ is differentiated with respect to $\ln B$ at constant Z, the third term to the right in (5) becomes $((q'—1)p''—(q''—1)p')$. Hence, complexes with high values for $(q—1)/p$ are favored, which will in general work in the same direction.

Sometimes, the limit of the experimental range will be set by the precipitation of a solid, say $A_NB(s)$, at low Z before the uncertainty from the activity factors becomes serious. $A_NB(s)$ may, of course, also contain solvent and inert ions, but these are left out as usual. For any complex we would have at the point of precipitation, and thus at equilibrium with $A_NB(s)$

$$[A_pB_q] = \text{constant} \cdot b^{q-pN^{-1}} \approx \text{constant} \cdot B^{q-pN^{-1}}$$

Increase in B would then give a wider concentration range to be studied, and thus more information for any single complex with $p/q < N$. Of two complexes, the one with the higher value for $(Nq—p)$ will be favored.

The equilibrium constants in a self-medium may be expected to differ somewhat from those in an inert medium of the same concentration of inert counter ion. However, our experience hitherto has shown that the differences are only of the order of 0.1 in the logarithm of the formation constant.

Correcting for decrease in b

In the present work it was desirable to extend the measurements up to Z-values of around 0.10. Here, the difference between the total concentration, B, and the free concentration, b, is no longer negligible and a correction must be made.

Single complex. If the whole effect measured is due to a single complex, A_PB_Q, then from (2) and (3)

$$B = b + Q\beta_{PQ}a^P b^Q \; ; \; BZ = P\beta_{PQ}a^P b^Q \qquad (6)$$

Eliminating $b = B(1-ZQP^{-1})$, we find

$$Z(1-ZQP^{-1})^{-Q} = a^P P\beta_{PQ} B^{Q-1} = u^P \tag{7}$$

Here, u is a normalized variable corresponding to a. We may use eqn (7) to calculate a normalized curve $Z(\log u)$ and move it along the experimental data, $Z(\log a)$. If a fit is obtained for a certain set (P, Q), one may obtain β_{PQ} from the constant difference

$$\log u - \log a = P^{-1}(\log P + \log \beta_{PQ} + (Q-1) \log B) \tag{8}$$

In actual fact the shape of the curve $Z(\log u)$ is mainly determined by P. Any reasonable value of Q will only cause a minor change, in the upper part of the Z range, in comparison with the curve obtained from $Z = u^P$. This is what eqn (7) reduces to if one puts $Q = 0$ that is neglects the difference between b and B.

Two complexes. If two complexes must be considered, the experimental data $Z(\log a)$ must be compared with a family of curves $Z(\log u)_k$, where k is a parameter containing the formation constants for the two complexes. The procedure will be illustrated for the combination of two complexes AB_2 and A_2B_2, which will be useful in this paper, and in a following one on the hydrolysis of UO_2^{2+}.

From (2) and (3) we have

$$B = b + 2\beta_{12}ab^2 + 2\beta_{22}a^2b^2 \tag{9}$$

$$BZ = \beta_{12}ab^2 + 2\beta_{22}a^2b^2 \tag{10}$$

We shall define the normalized variable u (corresponding to a), the parameter k, and the useful abbreviation f:

$$u^2 = 2\beta_{22}a^2B \; ; \; ku = 2\beta_{12}aB \tag{11}$$

$$f = 2u^2 + 2ku \tag{12}$$

Eliminating b, we obtain finally from (9 to 12)

$$Z = \frac{f - ku}{1+f+\sqrt{1+2f}} = (f - ku)f^{-2}(1+f-\sqrt{1+2f}) \tag{13}$$

Using eqn (13) one may calculate a family of curve $Z(\log u)_k$, for a number of values of k, and compare them with the experimental curve $Z(\log a)$. If a fit is obtained for a certain value of k, one may notice the difference of coordinates $(\log u - \log a)$ and obtain the equilibrium constants from:

$$\log \beta_{22} = 2(\log u - \log a) - \log 2B \tag{14}$$

$$\log \beta_{12} = \log k + (\log u - \log a) - \log 2B \tag{15}$$

which are easily deduced from (11).

HYDROLYSIS OF Th^{4+} IN $ThCl_4$ SELF-MEDIUM

Composition of solutions

It was decided to use Cl^- as the inert anion, which has some advantages since practically the same solution can then be used in the reference electrode.

Our first work on the hydrolysis of thorium (Hietanen[9]) was made in 1 M (Na)ClO_4 medium, like the work of Kraus and Holmberg[10]. In the meantime, studies with 3 M (Na)Cl as inert ionic medium have been performed, which will shortly be published[11].

The total concentration, B, of Th was chosen as 0.5 or 0.7 M, and kept constant in each series. The analytical hydrogen excess, H, was varied either by varying $[Cl^-]$ or by adding Na^+, at constant $[Cl^-]$. The solutions studied had the following compositions:

Medium	B	H	$[Na^+]$	$[Cl^-]$
0.5 Th(Cl)	0.5	H	—	$2 + H$
0.5 Th, 2.2 (Na)Cl	0.5	H	$0.2 - H$	2.2
0.7 Th, 3.0 (Na)Cl	0.7	H	$0.2 - H$	3.0

The solutions were mixed, as usual in this laboratory, by a titration procedure, starting with around 40 ml of a certain solution S, and adding from a buret increasing amounts of another solution T. The value of B was the same in both solutions S and T. Usually, one of them had a positive value for H (H^+ excess), and the other a negative value. The compositions of S and T used are given in Table 1.

In our titrations with 0.5 Th(Cl), S was 0.5 M $ThCl_4$ with a certain excess of HCl, whereas T was partly hydrolysed thorium chloride with 0.5 M Th but a deficiency in Cl^-. With the others, the solution with negative H could be obtained simply by mixing $ThCl_4$, NaCl(HCl), and NaOH($NaHCO_3$) solutions in calculated amounts.

Reagents

Thorium chloride, p.a. (from Lindsay Chemical Company, West Chicago, Illinois) contained a small amount of Fe, which was removed by extraction with *iso*propyl ether from 6 M HCl solution. The HCl was removed by evaporation under a heating lamp; in general, this resulted in solutions that were partly hydrolyzed, thus had less than 4 Cl per Th, which was rather convenient for our studies.

In the first experiments, the thorium chloride solutions were prepared by evaporating thorium nitrate (puriss, Kebo) repeatedly with concentrated HCl, extracting the iron, and then evaporating again.

The solutions were analysed for Th by precipitating with oxine, igniting the precipitate, and weighing as ThO_2. The total amount of Cl^- was determined by passing the solution through a H^+ saturated ion exchanger (Wofatite KPS-200) and titrating the eluate with standard NaOH. These data gave the analytical H^+ excess of the solution, $H = [Cl^-] - 4\ [Th]_{total}$.

The sodium chloride (Merck p. a., or Baker p. a.) contained a small amount of alkaline impurity, probably carbonate, which was neutralized with HCl. For instance, 3 M NaCl needed an addition of 0.02 mM HCl.

Hydrochloric acid (p.a.) was standardized against solid $KHCO_3$, and standard NaOH. *Sodium hydrogen carbonate* (Merck p.a.) was analysed against HCl. A 50 % *sodium hydr-*

oxide solution was prepared in a polythene bottle from commercial p. a. material. The clear solution was pipetted out and diluted with de-aerated water, and the dilute solution standardized against hydrazine sulfate, and against HCl; the determinations with the two methods agreed within less than 0.1 %.

Apparatus

The reference half-cell was

$$RE\| = Ag,\ AgCl|B\ M\ ThCl_4,\ \text{equilibrated with}\ AgCl|B\ M\ ThCl_4$$

with $B = 0.5$ or 0.7 M, as in the solution to be studied.

The Ag, AgCl electrodes were prepared according to Brown [12]. The $ThCl_4$ solution in the reference electrode was equilibrated with AgCl, either by shaking with solid AgCl in a thermostated room, or by passing it twice through a tube, filled with AgCl. The solubility of AgCl in these solutions is of the order of a few mM. If the reference electrode solution is not saturated with AgCl, the AgCl may be dissolved off the solid electrode; in any case the half-cell will finally give a steady potential. The equilibration was more carefully done with 0.7 M Th, which may account for the smaller variation of E_0 (Table 1).

The hydrogen ion concentration, h, was measured in a cell

$$-Pt,H_2(1\ atm)|\text{equilibrium solution}\|RE+ \qquad (16)$$

The lightly platinized Pt electrodes were prepared approximately as described by Bates [13]. The electrode vessel was of the usual "Wilhelm" type [14], and the emfs were measured by means of a Vernier potentiometer. Our experiments were carried out in a thermostated room at 25°C, and with the cell immer-

sed in a paraffin oil thermostat at 25.0°C. As usual with the hydrogen electrode, one often had to wait 15—20 min after each addition of T from the buret to get a constant E. There was no indication of slowness in the Th^{4+} equilibria, and titrations with increasing and decreasing Z gave the same results.

Calculations

As in the other studies of cation hydrolysis equilibria [15], we shall find it convenient to write the hydrolysed complexes as $A_pB_q = Th_q(OH)_p^{(4q-p)+}$, to count formally a proton deficiency, $-H^+$, as the ligand A, and to set

$$a = h^{-1} \tag{17}$$

The primary experimental data were E, measured emf in the cell (16), (corrected for the barometric pressure, and the vapor pressure of water), and H, the analytical excess of H^+; in many of our solutions, H was negative. If the data from different experiments with the same medium were plotted in a diagram $E(H)$, these were seen to be small shifts. Now, the following equations should hold for E of cell (16), and H:

$$E = E_o - 59.15 \log h + jh \tag{18}$$

$$H = h - BZ - \Delta = h - F(h) \tag{19}$$

In eqn (18), E_o can be assumed to be a constant, when short periods like one or two days are considered. However, E_o is known to vary slightly between different reference electrodes, and also to change slightly over longer periods for one and the same reference electrode. The term jh stands for the liquid junction potential [4]; j is a constant which may be assumed to be the same in all experiments with the same medium.

In eqn (19), Δ is the possible error in the analytically determined H, which is the difference between two large numbers. BZ is a function of h, which is defined by eqns (2 and 3), or, under more special assumptions, by (4), by (6), or by (9 and 10), remembering that $a = h^{-1}$ (17). It is convenient, in the discussion, to treat the sum $BZ + \Delta$ as a single function, $F(h)$.

The fact that the curves $E(H)$ for different titrations do not coincide exactly might be ascribed to small differences in E_o, or to small differences in Δ. In the former case, there would be parallel shifts along the E-axis, in the second along the H-axis.

In order to decide whether a certain curve I can be made to coincide with another curve II, one may take a set of points from curve I, make each of these points in turn coincide with the origin of a transparent coordinate paper, and then draw on the paper the segment of curve II that falls in the nearest quadrant. If the curves I and II can be made to coincide, the segments should intersect in one point, which is the vector head of the necessary displacement.

Such plots were made, taking arbitrarily one titration as the standard for each medium. In all cases but one, the vector of displacement proved to be parallel with the E-axis: the curves could be made to coincide by a shift in

Table 2. Medium 0.5 Th(Cl). Experimental data H and E (corrected) for three titrations. Every other point given, log h calculated from E with $E_0 + 3 \cdot 59.15 = 384.1$ mV and $j = 22$ mV M^{-1}; Z from $h - H = BZ$.

E (last column in Table 1). In one case, however (marked in Table 1), a displacement of 5 mM along the H-axis was also necessary. This corresponds to an error of 0.25 % in the analysis for acid or thorium, or in the mixing of the solutions, and was a warning that unexpected errors of this order of magnitude might occur.

After these small shifts, the data obtained with each of the self-media fell on a smooth curve $E(H)$. These three sets of data were then treated separately by successive approximations, based on eqns (18) and (19). The data are given in Tables 2, 3, and 4, for every other experimental point; the Figures give every point. Points with very high Z values (> 0.25) have been left out.

For an ion which begins to hydrolyse at lower acidities than Th^{4+}, it might have been possible to determine Δ straight-forwardly by a Gran plot [16], and then E_0 and j directly from the region where $h \approx H$ by plotting $E + 59.15 \log H$ as a function of H. In the present work, the strong hydrolysis of Th^{4+} caused both plots to be curved, and so the somewhat more laborious method of successive approximations had to be used.

The aim was to find a theoretical function $F'(h)$, and two constants E_0 and j such that a) if h' is calculated from H with F' and (19), a plot of

(E + 59.15 log h') *versus* h' according to (18) will give a linear plot with the constants E_o and j, and b) if h is calculated from E, with E_o, j, and (18), then the $F(h)$ calculated from (19), $F(h) = H - h$, will give good agreement with $F'(h)$.

The linear part of the plot (E + 59.15 log H) *versus* H at high acidities was used to obtain the first approximate values E_{o1} and j_1. Using these constants and eqn (18), an auxiliary function $j_1 h(E)$ was calculated. It was then possible from the various E-values and (18) to calculate a first set of approximate values h_1. Inserting these into (19), a first approximate function $F_1(h_1) = h_1 - H$ was calculated. This function was plotted as F_1 (log h_1) and compared with various theoretical curves, and from the best fit a first theoretical function $F_1'(h)$ was chosen. The function $h_1'(H)$, defined by $h_1' - F_1'(h_1') = H$, was calculated for each experimental point. From a plot of (E + 59.15 log h_1') *versus* log h_1' and eqn (18), improved approximations E_{o2} and j_2 were obtained.

As before, with the auxiliary function $j_2 h(E)$, a new approximation h_2 was calculated from $-59.15 \log h_2 = E - E_{o2} - j_2 h_2$; h_2 was in turn used for calculating $F_2(h_2) = h_2 - H$. If the F_2 calculated from the data agreed well with the theoretical F_1' used in the calculations, an acceptable solution had been found. Otherwise, another theoretical function F_2', a better approximation to F_2, would have been adopted and a new cycle of approximations made.

In applying this procedure to the present data for thorium hydrolysis, it was first assumed that there was no analytical error, thus $\Delta = 0$. The data covered a range up to $Z \sim 0.25$. Because of the increasing uncertainty of activity factors, little attention was however paid to data with $Z > 0.1$.

The first approximation curves, F_1 (log h_1), were first compared with the theoretical curves, $F' = BZ$ *versus* log h, calculated for the single complexes A_1, A_2, or A_3, using (7) with $Q = 0$, and $P = 1$, 2, and 3. Between $Z = 0.05$ and 0.10, there was fair agreement with the A_2 curve. At lower values for Z, there were deviations and the shape approached that of the curve for the complex A_1. This would indicate that, under the present experimental conditions, the most important complexes formed are those containing 1 or 2 OH-groups, and that neither can be neglected.

In correcting for the change in b, it was assumed that in both cases the binuclear complexes predominated, thus $Th_2(OH)_2^{6+}$, and Th_2OH^{7+} — of course, possibly with extra H_2O and Cl^- attached. This assumption will be justified by arguments given in the discussion below.

A comparison with theoretical curves $F' = BZ$ *versus* log u calculated from (7) with $Q = 2$ and $P = 1$ or 2 gave the same result as before; the curves are intermediate between those for complexes with 1 and 2 A.

Next, theoretical curves were tried assuming two complexes, AB_2 and A_2B_2 (*viz.* Th_2OH^{7+} and $Th_2(OH)_2^{6+}$). Using (13), families of curves $F' = BZ$ (log u)$_k$ were calculated for a series of values of k. Successive approximations (two steps sufficed) gave the values for the parameters, and hence β_{22} and β_{12} given in Table 5, for the three sets of data ("assumption $\Delta = 0$").

The values for $Z(= F/B)$ and h, given in Tables 2—4, were calculated with E_o and j from Table 5. The corresponding plots of Z *versus* log h, compared with the theoretical curve, and of (E + 59.15 log h) *versus* h, are given in Figs 1 and 6 for 0.5 Th(Cl); in Figs 2, 4 and 7 for 0.5 Th, 2.2 (Na)Cl; and in

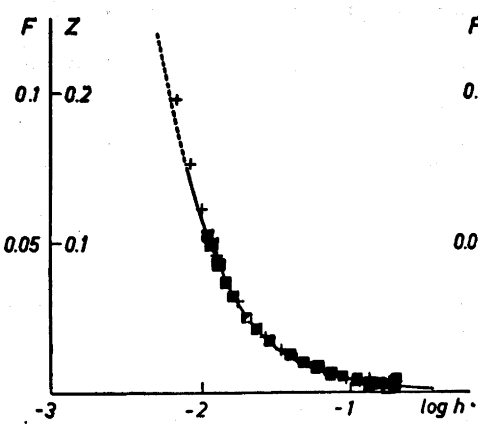

Fig. 1. Hydrolysis of Th^{4+}, medium 0.5 Th(Cl). $F = BZ$ *versus* log h. Points: calculated from experimental data $E(H)$, using E_0 and j from Table 5. Curve: calculated F', assuming $\Delta = 0$ and values for β_{22} and β_{12} in Table 5.

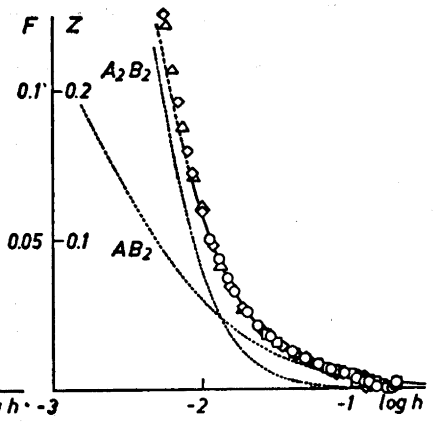

Fig. 2. Hydrolysis of Th^{4+}, medium 0.5 Th, 2.2 (Na)Cl. Experimental points and fulldrawn curve obtained as in Fig. 1. Dotted curves calculated assuming only one of the complexes present and with the same formation constant as in the full-drawn curve. See also Fig. 4.

Figs 3, and 5 for 0.7 Th, 3.0 (Na)Cl. In Figs 2, and 4 for comparison, are given also two (dotted) curves which have been calculated neglecting either AB_2 or A_2B_2, to indicate the contribution of each.

The occurrence of a single experiment with a deviation in H of 5 mM (0.01 in Z) was, however, a warning that systematic errors might exist in the analytical

	$E_0 + 3 \cdot 59.15$	384.7	381.3	360.0

Estimated uncertainty, approximately ±0.2 in log k and log β_{12}, ±0.02 in log u − log a, ±0.04 in log β_{22}, under the assumption given.

H. Now, with a large enough correction, Δ, it might be possible to fit the data to the curves for the single complex $Th_2(OH)_2^{6+} = A_2B_2$. To test, how certain the evidence for AB_2 is, another series of successive approximations was made, where it was assumed that only the complex A_2B_2 existed, thus $\beta_{12} = 0$, and an attempt was made to get a good fit by adjusting Δ and β_{22}.

The values for Δ and log β_{22} thus obtained are also given in Table 5, "assumption $\beta_{12} = 0$". The corresponding best plots for 0.5 Th, 2.2 (Na)Cl are given in Figs 8 and 9. The plot for E_0 is seen to be less linear than that obtained assuming $\Delta = 0$ (Fig 7). The E_0 plot is at any rate very sensitive to small changes in F'. However, assuming $\beta_{12} = 0$, it seemed inevitable to get two bends in the plot, whatever changes were made in F'.

Moreover, a large analytical error must be assumed to make $\beta_{12} = 0$: a value for Δ of 9 mM would correspond to an error of around 0.45 % in the analysis for Th (weighing ThO_2) or Cl^- (really a H^+ titration). Analytical errors of this order of magnitude do not seem likely, and even if β_{12} may be

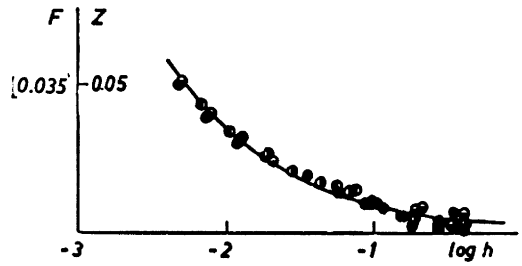

Fig. 5. Medium 0.7 Th, 3.0 (Na)Cl. Part of Fig. 3 on a larger scale.

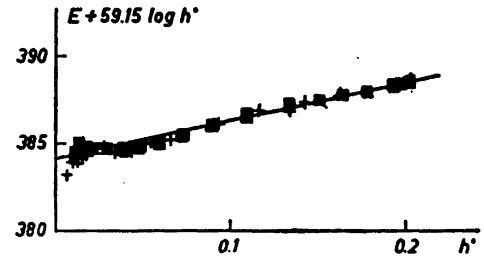

Fig. 6. Medium 0.5 Th(Cl). Abscissa: h', M, calculated from H and F' using (19) and values for β_{12} and β_{22} in Table 5. Ordinate: $E + 59.15$ (log $h' + 3$) mV. Straight line: given by values of j and E_0 in Table 5, $\Delta = 0$.

Added in proof: In Figs. 6, 7, and 9, the ordinate is mislabeled: (log $h' + 3$) was really used.

slightly in error, we think there is good evidence for the existence of the complex Th_2OH^{7+}, and for an equilibrium constant of the order of magnitude given.

We would thus prefer the values for $\Delta = 0$ and propose the following set of equilibrium constants:

Medium	log β_{12}	log β_{22}
0.5 Th, 2.2 (Na)Cl	-2.8 ± 0.2	-5.02 ± 0.04
0.7 Th, 3.0 (Na)Cl	-2.9 ± 0.2	-5.09 ± 0.04

With the medium 0.5 Th(Cl), practically the same equilibrium constants were obtained as with 0.5 Th, 2.2 (Na)Cl. The equilibrium constants thus do not seem to be very sensitive to small changes in the ionic medium. However, the constants for 0.5 Th(Cl) are left out since it seems preferable to leave the anion medium unchanged when the reactions studied are between cations;

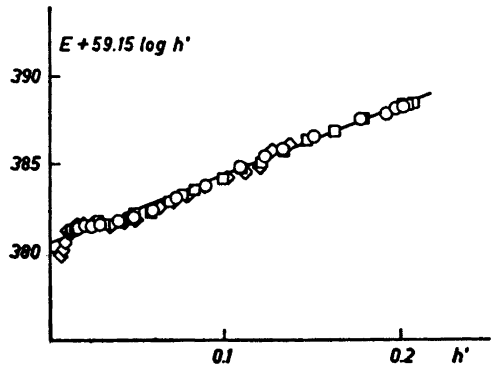

Fig. 7. Medium 0.5 Th, 2.2 (Na)Cl. $E + 59.15$ (log $h' + 3$) mV *versus* h', M, calculated as in Fig. 6.

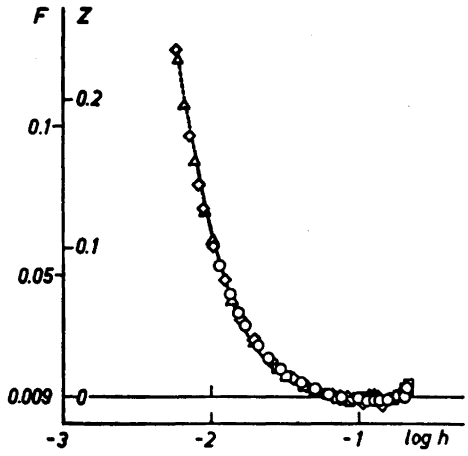

Fig. 8. Medium 0.5 Th, 2.2 (Na)Cl. Best fit assuming $\beta_{12} = 0$. $F = BZ + \Delta$ *versus* log h. Points: calculated from $E(H)$ with E_0 and j from Table 5. Curve: F' calculated with values for Δ and β_{22} from Table 5.

it has been found [4] that activity factors of cations are much more influenced by changes in the anion medium than by changes in the cation medium.

The agreement between the experimental $F(h)$ and the theoretical $F'(h)$ in Figs 1, 2 (4), and 3 (5) is very satisfactory up to beyond $Z = 0.10$. At higher values of Z, a considerable part of the ionic medium has been exchanged, and deviations are observed, especially in Fig 1, where the anionic medium changes.

The differences in E_0 and j in Table 5 are natural, considering the differences in the media.

DISCUSSION

The hydrolysis of Th^{4+} has been studied in inert medium, especially in Stockholm and Oakridge. Using 1(Na)ClO_4, Hietanen [9] found evidence for complexes $Th((OH)_3Th)_n^{(4+n)+}$, with log $\beta_{3n,n+1} \approx -7.50$ n: according to Rossotti, Rossotti and Sillén [17], the data are still better described with log $\beta_{3n,n+1} = 0.06 - 7.53\ n$.

Using 1($NaClO_4$) medium and a glass electrode, Kraus and Holmberg [10], who studied particularly the region of low Z, claimed evidence for mononuclear $ThOH^{3+}$, $Th(OH)_2^{2+}$ and dinuclear $Th_2(OH)_2^{6+}$, with the formation constants log $\beta_{11} = -4.3$, log $\beta_{21} = -7.7$, and log $\beta_{22} = -4.7$. Using measurements with 0.5 M $NaClO_4$ medium, Pan and Hseu [18] calculated, for infinite dilution, log $\beta_{11} = -3.89$ and log $\beta_{21} = -8.09$ (only mononuclear constants).

Literature data, presumably those of Hietanen, have later on been recalculated by Lefevbre [19], who has decided on a different set of complexes, with log $\beta_{21} = -7.42$, log $\beta_{22} = -4.56$, log $\beta_{12,5} = -29.5$; he also claims evidence for $Th_7(OH)_x$, with $x = 18$ to 21.

Later work in this laboratory using 3 M (Na)Cl medium [11] and studying lower concentrations, has given evidence for, in addition to the complexes

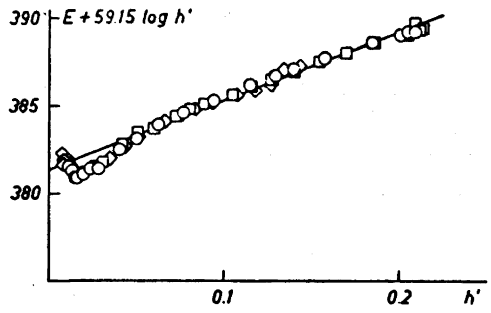

Fig. 9. Medium 0.5 Th, 2.2 (Na)Cl. Best fit assuming $\beta_{12} = 0$. $E + 59.15$ (log $h' + 3$) *versus* h', calculated as in Fig. 6.

$Th_{n+1}(OH)_{3n}^{(4+n)+}$, the complex $Th_2(OH)_2^{6+}$ with the equilibrium constant log $\beta_{22} \approx -4.7$.

We may now ask whether the formulas assigned to our complexes, $Th_2(OH)_2^{6+}$ and Th_2OH^{7+}, are plausible or not. As mentioned, a change in the number of Th-atoms would only mean a small correction in the F' curves so, strictly speaking, the only information obtainable from the data is that there are one or more complexes with 2 OH, and one or more with 1 OH; the equilibrium constants interpreted as β_{12} and β_{22} are really the over-all constants K_1' and K_2' of eqn (4).

The value for log β_{22} obtained is in good agreement with those obtained from work in inert media of comparable anionic composition [10,11]. This, in itself, would favor the assumption of 2 Th in the complex.

The idea that any of these complexes are mononuclear can, we think, easily be ruled out. If the constants interpreted here as log $\beta_{12} \approx -2.9$ and log $\beta_{22} \approx -5.0$ had really been the mononuclear log β_{11} and log β_{21}, they would have been much higher than the values deduced by earlier workers [10,18]. Moreover, if there had existed mononuclear complexes with formation constants of this order of magnitude, hydrolysis would have started at much higher h than observed in earlier experiments [9,10,11], and the "mononuclear wall" would have been pratically the only Z curve obtained.

On the other hand, a formulation with three or more Th-atoms sharing 2 or 1 OH^- would seem rather awkward geometrically, and would moreover give compositions still farther removed from the $Th_{n+1}(OH)_{3n}^{(4+n)+}$ concluded for higher degrees of hydrolysis.

So it seems to us that the formulas $Th_2(OH)_2^{6+}$ and Th_2OH^{7+}, of course probably with some H_2O and Cl^- attached, are the only plausible ones.

The Crystal Structure of $Ni_{12}P_5$

STIG RUNDQVIST and EGON LARSSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The crystal structure of $Ni_{12}P_5$ has been determined with single-crystal methods. The unit cell, containing 2 formula units, is tetragonal, $a = 8.646$ Å; $c = 5.070$ Å. The space group is $I4/m-(C_{4h}^5)$ with 16 Ni in 16(i): $x = 0.116_6$; $y = 0.182_2$; $z = 0.248$; 8 Ni in 8(h): $x = 0.368$; $y = 0.060$; 8 P in 8(h): $x = 0.195$; $y = 0.415$; and 2 P in 2(a). A comparison of $Ni_{12}P_5$ with related structures is made. Some phase-analytical observations in the Ni-P system are reported. NiP_3 is cubic, $a = 7.819$ Å; and isostructural with CoP_3, $a = 7.706$ Å. Both NiP_3 and CoP_3 belong to the $D2$ ($CoAs_3$) structure type.

Although the nickel phosphides have been the object of several investigations, the knowledge of them is still very incomplete. Therefore, an X-ray investigation of the Ni-P system has been started at this institute in order to establish the existence and compositions of the intermediate phases and to determine the crystal structures. The present paper gives an account of the crystal structure determination of the phase $Ni_{12}P_5$, which has not earlier been properly characterized. In addition, some preliminary phase-analytical observations in the Ni-P system are reported.

EXPERIMENTAL

Alloys were prepared by heating mixtures of nickel powder (99.8 %, kindly donated by Mond Nickel Co., Ltd.) and red phosphorus (99 %) in evacuated and sealed silica tubes at temperatures between 700°C and 900°C. No appreciable attack on the silica tubes was detected. The reaction products were investigated with X-ray powder methods using Guinier-type cameras with Cr$K\alpha$ and Cu$K\alpha$ radiations. Unit cell dimensions were determined using CaF_2 as internal calibration standard on each powder film. The lattice parameter values have an accuracy better than 0.05 %. For the single-crystal work, a small, roughly spherical crystal fragment was selected from a crushed $Ni_{2.4}P$ alloy. The intensity material was recorded in an ordinary Weissenberg camera with MoK radiation using the multiple-film technique with thin iron foils between successive films. The intensities were visually estimated with the aid of a standard intensity scale. No absorption correction was applied. Fourier summations were made with the Hägg-Laurent machine and with Beevers-Lipson strips.

THE Ni-P SYSTEM

Previous work on the Ni-P system is summarized in Ref.[1] As the result of a thermal and microscopical investigation in the range 0—35 at.% P, Konstantinow [2] reported the existence of the phases Ni_3P, Ni_5P_2 and Ni_2P. Ni_5P_2 was stated to undergo a polymorphic transformation. Nowotny and Henglein [3], who made an X-ray investigation in the same range of composition, found four phases with compositions close to Ni_3P, Ni_5P_2, Ni_7P_3 and Ni_2P. Ni_3P was stated to be isostructural with Fe_3P and Ni_2P isostructural with Fe_2P. The Ni_3P structure was later determined by Aronsson [4]. Using mainly tensimetric methods, Heimbrecht and Biltz [5] studied the Ni-P system and reported the existence of the following phases: $Ni_{0.83}P$, NiP_2 and NiP_3.

Our phase-analytical work with the X-ray powder method is still in progress and only a few observations will be mentioned here. In the range Ni-Ni_2P four phases have been found with compositions close to Ni_3P, $Ni_{2.5}P$, $Ni_{2.4}P$ and Ni_2P, respectively. No transformations in the solid state were observed in the range 700—900°C *. For Ni_3P we determined the tetragonal unit cell dimensions as $a = 8.954$ Å; $c = 4.387$ Å in very close agreement with the values given by Aronsson [4]. The powder pattern of $Ni_{2.5}P$ is complicated and has not yet been interpreted. The powder pattern of $Ni_{2.4}P$ (which is presumably the same phase as Nowotny and Henglein's "Ni_7P_3") could be indexed with the body-centered tetragonal unit cell $a = 8.646$ Å; $c = 5.070$ Å. Lattice parameter variations indicating an extended homogeneity range were not observed. Nowotny and Henglein indexed their "Ni_7P_3" powder pattern with a cubic unit cell ($a = 8.63$ Å), but additional weak lines indicated lower symmetry in their opinion. For Ni_2P we found the hexagonal unit cell dimensions $a = 5.864$ Å; $c = 3.385$ Å. Ni_2P belongs to the revised *C* 22 structure type [6].

In the region Ni_2P—NiP the system seems to be rather complicated, and transformations in the solid state probably occur. It was mentioned by Biltz, Heimbrecht and Meisel [7], that the X-ray powder pattern of NiP_3 was similar to that of CoP_3. This was indeed found to be the case, since our powder photographs of CoP_3 and NiP_3 could be indexed with cubic unit cells: for NiP_3 $a = 7.819$ Å and for CoP_3 $a = 7.706$ Å. These two phosphides are isostructural with $CoAs_3$ (*D* 2 type), the structure of which was determined by Oftedal [8].

DETERMINATION OF THE $Ni_{12}P_5$ CRYSTAL STRUCTURE

From powder and single-crystal data, the unit cell of the phase $Ni_{2.4}P$ was determined to be tetragonal: $a = 8.646$ Å; $c = 5.070$ Å; $c/a = 0.5864$; $U = 379.0$ Å^3. The measured density 7.44 g·cm^{-3} indicated a unit cell content of 24 Ni atoms and 10 P atoms, giving the calculated density value 7.53 g·cm^{-3}. The formula of the $Ni_{2.4}P$ phase should therefore be written $Ni_{12}P_5$.

* Professor T. Rosenqvist, Norges Tekniske Høgskole, Trondheim, Norway, has kindly informed us that X-ray powder investigations made at his institute in the range Ni-Ni_2P confirm our results. Our interpretation of the $Ni_{12}P_5$ powder pattern is in agreement with his findings.

For the structure determination, the intensity material from the layer lines 0—4 around the *c*-axis was used. The intensities from the layer lines with $l > 4$ were very difficult to estimate and were not included in the refinements.

Only reflexions with $h + k + l = 2n$ were observed. Since $|F(hkl)|$ was different from $|F(\bar{h}kl)|$ the possible space groups were $I4$, $I\bar{4}$ and $I4/m$. Using the entire intensity material, the Patterson section $P(xy0)$ was calculated. The Patterson function had a large peak at $(\frac{1}{2}, \frac{1}{2}, 0)$ [equivalent to a peak in $(0,0,\frac{1}{2})$], whose height, being roughly 2/3 of the origin peak height, showed that about 2/3 of the Ni atoms must lie in pairs with the same x and y parameters and spaced about $c/2$ apart. This indicated strongly that the space group was $I4/m$ with 16 Ni in 16(i) having a z parameter close to 1/4. Further analysis showed that the heights and positions of all large peaks in $P(x\,y\,0)$ could be interpreted by assuming the space group to be $I4/m$ with 16 Ni_I in a 16(i) position and 8 Ni_{II} in an 8(h) position.

Starting with the rough parameter values read from the Patterson map, signs were calculated for the observed $F(hk0)$ values and the electron density projection $\varrho\,(xy)$ was computed. Ni maxima were found at the expected positions and, in addition, P maxima were found at the origin and in an 8(h) position. The different x and y parameters were refined by successive difference syntheses. The scattering factors for Ni were interpolated from tables given by Thomas and Umeda [9] and those of P from Tomiie and Stam [10]. After the final refinement cycle, the R-value 8.0 % for the observed independant $hk0$ reflexions was obtained, when an empirical temperature factor with $B = 0.49$ Å^2 was applied. The following parameters were found: Ni_I in 16(i): $x = 0.116_0$; $y = 0.182_2$; Ni_{II} in 8(h): $x = 0.368$; $y = 0.060$; P_I in 8(h): $x = 0.195$; $y = 0.415$; P_{II} in 2(a) or 2(b) ($x = y = 0$). Since the observed $|F(hk0)|$ and $|F(hk4)|$ values were almost equal (apart from the normal decline) and the same was true for the $|F(hk1)|$ and $|(F(hk3)|$ values, the z parameter of the Ni_I atoms could not be very far from 1/4. With these parameters, a reasonable structure with normal interatomic distances could be visualized. Since there was apparently enough space for a P atom in both (0,0,0) and $(0,0,\frac{1}{2})$, it could not be immediately decided whether P_{II} was situated in 2(a) or in 2(b). However, a comparison of calculated and observed $|F(hk1)|$ values proved beyond doubt that P_{II} was situated in 2(a). With P_{II} in 2(a), the R-value for the recorded $|F(hk1)|$ values was 9.0 %, whereas with P_{II} in 2(b), the R-value was larger than 40 %.

It still remained to be settled whether the z_I parameter of Ni_I was appreciably different from 1/4 or not. The $F(hkl)$ values with $l = 2n$ should hardly be affected by a small shift, but the $F(hkl)$ values with $l = 2n + 1$ should be more sensitive. Starting with the z_I parameter exactly 1/4, the $F(hk3)$ values were calculated, and the R-value obtained, was 10.9 %. It was then found that the agreement was somewhat improved with a z_I-value slightly less than 1/4. The best agreement was obtained with $z_I = 0.248$, giving the R-value 10.1 %. The $F(hk1)$ values were recalculated using this z_I value and the R-value for these reflexions dropped from 9.0 % to 8.8 %. Finally the remaining $F(hk2)$ and $F(hk4)$ values were calculated, and the R-value 8.7 % for all measured reflexions was obtained after applying an overall temperature factor with

Table 2. Interatomic distances in $Ni_{12}P_5$ in Å. (Distances shorter than 3.25 Å are listed.)

Ni_I	— 5 Ni_I	: 2.45, 2.51, 2.56, 2.64 (2).
	— 3 Ni_{II}	: 2.54, 2.58, 2.73.
	— 3 P_I	: 2.24, 2.41, 2.47.
	— 1 P_{II}	: 2.25.
Ni_{II}	— 6 Ni_I	: 2.54 (2), 2.58 (2), 2.73 (2).
	— 5 Ni_{II}	: 2.51, 3.09 (4).
	— 4 P_I	: 2.22 (2), 2.60 (2).
	— 1 P_{II}	: 3.22.
P_I	— 6 Ni_I	: 2.24 (2), 2.41 (2), 2.47 (2).
	— 4 Ni_{II}	: 2.22 (2), 2.60 (2).
P_{II}	— 8 Ni_I	: 2.25 (8).
	— 4 Ni_{II}	: 3.22 (4).

$B = 0.49$ Å^2. No further refinement was considered worthwhile. Observed and calculated structure factors are given in Table 1. The final structure of $Ni_{12}P_5$ is the following:

Space group $I4/m$ — $(C_{4h}^5 h)$; $Z = 2$

16 Ni_I	in 16(i)	with	$x = 0.116_0$;	$y = 0.182_2$;	$z = 0.248$;
8 Ni_{III}	in 8(h)	with	$x = 0.368$;	$y = 0.060$;	
8 P_I	in 8(h)	with	$x = 0.195$;	$y = 0.415$;	
2 P_{II}	in 2(a).				

Interatomic distances are listed in Table 2.

DESCRIPTION OF THE STRUCTURE

A projection of the $Ni_{12}P_5$ structure on the basal plane is shown in Fig. 1. As a comparison, an analogous projection of the Ni_3P structure (according to Aronsson [4]) is shown in Fig. 2. The structure of Ni_3P is based on space group $I\bar{4}$ and the unit cell contains 24 Ni atoms (as in $Ni_{12}P_5$) and 8 P atoms. All atoms are situated in 8(g) positions with z parameters close to 0, 1/4, 1/2 and 3/4. From Figs. 1 and 2, the similarities between the two structures are easily seen. If, for instance, the Ni_I and Ni_{III} atoms in Ni_3P are moved together (indicated by arrows in Fig. 2) so as to lie directly above each other at $z = 1/4$ and $z = 3/4$, a metal atom lattice of the $Ni_{12}P_5$ type is created. In fact, the mean value of the x parameters for Ni_I and Ni_{III} in Ni_3P corresponds closely to the x parameter for Ni_I in $Ni_{12}P_5$, and the same is true for the y-parameters. The positions of the Ni_{II} and P atoms in Ni_3P correspond rather closely to the positions of Ni_{II} and P_I in $Ni_{12}P_5$.

In many transition metal phosphides, the P atoms are surrounded by nine metal atoms in a more or less regular tetrakaidecahedral arrangement. This coordination is, *e.g.*, found in the Fe_2P [6], the Co_2P [11] and in the Fe_3P [4] type structures. In $Ni_{12}P_5$, the P_I atoms have 10 near Ni neighbours, whereas the P_{II} atoms have only 8 near Ni neighbours in an almost cubic arrangement.

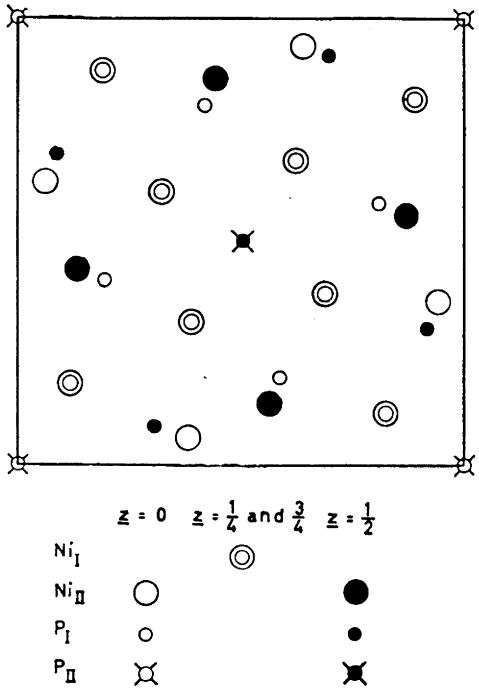

Fig. 1. The unit cell of $Ni_{12}P_5$ projected on the basal plane.

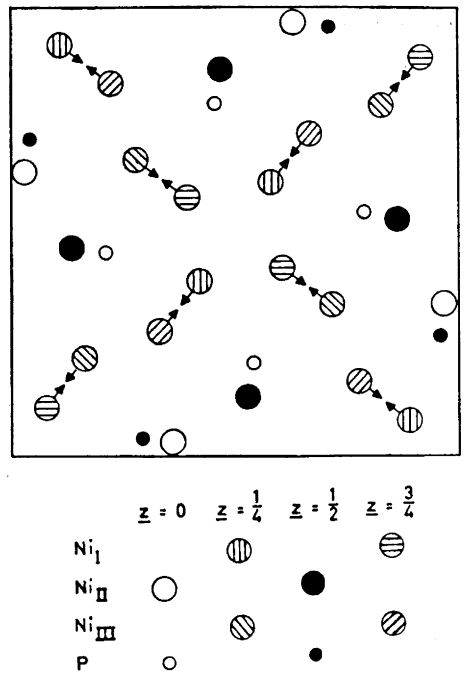

Fig. 2. The unit cell of Ni_3P projected on the basal plane. Arrows on the Ni_I and Ni_{III} atoms indicate imagined displacements towards the Ni atom arrangement in $Ni_{12}P_5$.

The tendency for higher metal atom coordination than 8 around the P_{II} atoms is perhaps indicated by the fact that P_{II} is situated in 2(*a*) and not in 2(*b*). The cubic Ni_I environment is the same for both 2(*a*) and 2(*b*) positions, but a P atom in 2(*a*) has 4 additional Ni_{II} neighbours in the same plane at a distance of 3.22 Å, whereas a hypothetical P atom in 2(*b*) has 4 neighbouring P_I atoms in the same plane at a distance of 2.73 Å.

Some Reactions between Uranium(VI) and Di-*n*-butyl Phosphate(DBP) in Chloroform and Methyl *Iso*butyl Ketone (Hexone)

DAVID DYRSSEN and FRANC KRAŠOVEC

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

The distribution of U(VI) between solutions of di-*n*-butyl phosphate (DBP = HA) in chloroform or hexone (methyl *iso*butyl ketone) and 1 M $HClO_4$—$NaClO_4$ solutions has been investigated at 25°C.

The data demonstrate the presence of a complex $UO_2(HA)_2A_2$ with four molecules of DBP per uranyl ion in both solvents at low concentrations of uranium. The constants for the equilibrium

UO_2^{2+} (aq) + 2 H_2A_2(org) ⇌ $UO_2(HA)_2A_2$ (org) + 2 H^+ (aq)

are $10^{3.58}$ (chloroform) and $10^{4.50}$ (hexone).

In addition to this complex an uranyl complex UO_2A_2 with only two molecules of DBP was found in hexone at lower concentrations of DBP. The equilibrium constant for the reaction

$$UO_2A_2 + 2\ HA \rightleftharpoons UO_2(HA)_2A_2$$

in the hexone phase was $10^{4.78}$.

With increasing uranium concentration in the chloroform phase the ratio $[U]_{org}/[DBP]_{org}$ approaches 0.5 thus indicating the composition $(UO_2)_nA_{2n}$ of the extractable uranyl complex. No definite conclusions about the degree of polymerization can be drawn from the distribution experiments, but isopiestic data of Baes *et al.*[5] indicate that n increases to 6 as $[U]_{org}/[DBP]_{org}$ approaches 0.5.

Dialkyl phosphates, $(RO)_2PO_2H$, have proved to be very useful as liquid-extracting agents for lanthanide and actinide ions of various oxidation states. Extensive work on the extraction of U(VI) from acidic sulfate-process liquors has been carried out at Oak Ridge[1] (Dapex process) and several radiochemical separation procedures have been worked out at Argonne[2]. Di-*n*-butyl phosphate (DBP) has been used at FOA[3] for the separation of ^{90}Sr and ^{90}Y.

The reactions between metal ions and the dialkyl phosphates can be correctly understood only if one takes into account the very pronounced tendency of the dialkyl phosphates to dimerize. Although Kosolapoff and Powell[4] have reported dimerization of dialkyl phosphinic acids, R_2PO_2H,

no studies on the dialkyl phosphoric acids have been published in the open literature until recently [5–7]. It was shown by Dyrssen [6] that the dimerization constant of DBP in chloroform is much larger than for carboxylic acids, and that dimerization also takes place in oxygen-containing solvents like hexone and water.

The aim of the present investigation was to study the extraction of the uranyl ion from 1 M $HClO_4$—$NaClO_4$ solutions with DBP in two different solvents, choloroform and hexone. Calculations on the distribution data throw some light on the reactions that can take place in the organic phase.

EXPERIMENTAL

Reagents. The DBP, $(C_4H_9O)_2PO_2H$, was kindly supplied by Albright and Wilson Ltd., London. Potentiometric titration with alkali and analysis for C and H showed the compound to be at least 99 % pure. The remaining non-acidic impurities are probably tri-butyl phosphate and butanol. The chloroform was washed three times with twice its volume of water to remove the 1 % alcohol. The hexone (methyl *iso*butyl ketone) was washed with alkali, acid, and finally water. The 1 M $HClO_4$-$NaClO_4$ solutions were prepared from analytical grade reagents. The solutions of U(VI) in 0.1 M $HClO_4$ + 0.9 M $NaClO_4$ were prepared from "nuclear grade" UO_3. The ^{233}U was purchased from AERE, Harwell, England. The solution contained 5 μC of ^{233}U per mg of U.

Distribution measurements. Equal volumes (5 or 10 ml) of a solution of DBP in chloroform or hexone and a 1 M $HClO_4$-$NaClO_4$ solution containing U(VI) were shaken for 2 h. The two liquid phases were then separated by centrifugation.

In the concentration range below 0.0025 M the uranium was analyzed by alpha-counting of 1 ml of the organic phase after evaporation of the solvent and removal of most of the DBP at 200°C. The distribution ratio, q, could then be calculated as

$$q = \frac{A}{C-A}$$

A = α-disintegrations per min and ml of the organic phase
C = total activity (cpm per ml) added.

For the determination of larger q-values part of the aqueous phase was shaken with an equal volume of a fresh solution of DBP (with the same concentration as in the first extraction). The distribution ratio is then calculated as

$$q = \frac{A-B}{B}$$

B = α-disintegrations per min and ml of the organic phase after the second extraction.

The alpha-activity was measured in a Tracerlab SC-16 windowless proportional counter.

Concentrations of uranium larger than 0.0025 M were analyzed spectrophotometrically at 375 mμ using a thiocyanate method [8]: The sample +1 ml of 10 % $SnCl_2$ + 0.5 ml of conc. H_2SO_4 + 15 ml of saturated NH_4SCN in acetone was diluted with water to 25 ml and measured 3 min after addition of the reagent.

The following constants, from Ref.[6], are used for the calculation of $[H_2A_2]_{org}$, $[HA]_{org}$, [HA] and $[A^-]$ (ionic strength = 1 M $HClO_4$-$NaClO_4$):

$[H^+]\,[A^-]\,[HA]^{-1} = 10^{-1.00}$
$[HA]_{org}\,[HA]^{-1} = 10^{0.34}$ (chloroform), $10^{1.49}$ (hexone)
$[H_2A_2]_{org}\,[HA]_{org}^{-2} = 10^{4.48}$ (chloroform), $10^{1.19}$ (hexone).

C_A is the initial concentration of DBP in the organic phase. [ ]$_{org}$ and [ ] denote concentrations in the organic and aqueous phases, respectively.

Table 1. The distribution of ^{233}U between chloroform and 1 M perchlorate solutions as a function of C_A and [H+]. The initial conc. of U(VI) in the aqueous phase was 2.69×10^{-6} M.

RESULTS

A. Experiments with low concentrations of U(VI). The results obtained with ^{233}U are given in Tables 1 (chloroform) and 2 (hexone). If these data are plotted as log q against log $C_A[H^+]^{-1}$, a marked difference between the two solvents is revealed (Fig. 1). The chloroform values lie on a straight line with a slope of 2. The deviation from this line at higher values of $C_A[H^+]^{-1}$ ($> 10^{-0.2}$) may be ascribed to the formation of the complexes UO_2A^+ and UO_2A_2 in the aqueous phase [9]. The values from the distribution experiments with hexone, however, lie approximately on a line with a slope equal to 2.72. The deviation from this line at higher values of q is very abrupt and may be caused by an experimental error due to the fact that the aqueous phase may be slightly contaminated with the highly radioactive and lighter hexone phase when part of the aqueous bottom-layer is drawn off for the second extraction (and determination of B). This error will have a marked influence on the measurements only at high q-values.

Since the extraction of uranium by chloroform is proportional to $C_A^2[H^+]^{-2}$ and since it is known [6] that the dimerization of DBP in chloroform is almost

Table 2. The distribution of ^{233}U between hexone and 0.1 M $HClO_4$ + 0.9 M $NaClO_4$ as a function of the initial conc. of DBP in the hexone phase, C_A. The initial conc. of U(VI) in the aqueous phase was $2.69 \cdot 10^{-6}$ M.

complete at concentrations ≥ 0.001 M, the following reaction will describe the data in Fig. 1 when $C_A[H^+]^{-1} < 10^{-0.2}$:

$$UO_2^{2+}(aq) + 2\ H_2A_2(org) = UO_2(HA)_2A_2(org) + 2\ H^+(aq)$$

The equilibrium constant may approximately ($C_A/2 = [H_2A_2]_{org}$) be calculated as

$$\log K = \log q + 2 \log [H^+] - 2 \log C_A/2 = 3.46$$

The same principle reaction was found in a study of the extraction of U(VI) with dioctyl phosphate in hexane from 2 M acid perchlorate solutions (log $K = 4.60 \pm 0.04$) recently published by Baes *et al.*[5] It has thus been demonstrated that the uranyl ion reacts with 4 molecules of dialkyl phosphates in inert solvents. Similar results have been found with other metal ions [3,10], *e.g.* $Y(HA)_3A_3$.

The results with hexone can be explained if one takes into account the existence of the DBP monomer and the uranyl complex UO_2A_2 due to reactions between these species and the solvent. The reaction with DBP leads to a fairly low value of the dimerization constant k_2 in hexone and a higher value of the distribution constant of the monomer as compared with chloroform [6]. The difference between the behavior of DBP in chloroform (fulldrawn curve)

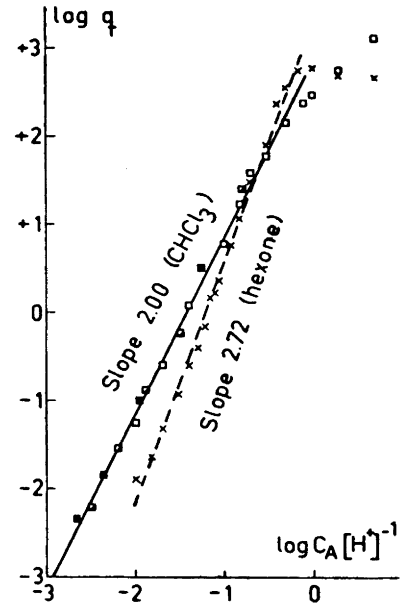

Fig. 1. The distribution of ^{233}U between a solution of di-*n*-butyl phosphate (DBP) in chloroform or hexone and 1 M $HClO_4$-$NaClO_4$. Chloroform data: □ 0.1 M H^+, ◪ 0.31 M H^+, ■ 0.91 M H^+. Hexone data: × 0.1 M H^+. q = distribution ratio $[U]_{org}/[U]_{aq}$. C_A = initial conc. of DBP in the organic phase. The data are given in Tables 1 and 2.

and hexone (dashed curve) is shown in Fig. 2 and may be explained by the fact that the oxygen atom in hexone is a good acceptor for the hydrogen atom in DBP.

Some conclusions on the reactions between UO_2A_2 and HA in hexone may be drawn from a plot of log $q[A^-]^{-2}$ against log [HA] (or log $[HA]_{org}$). The

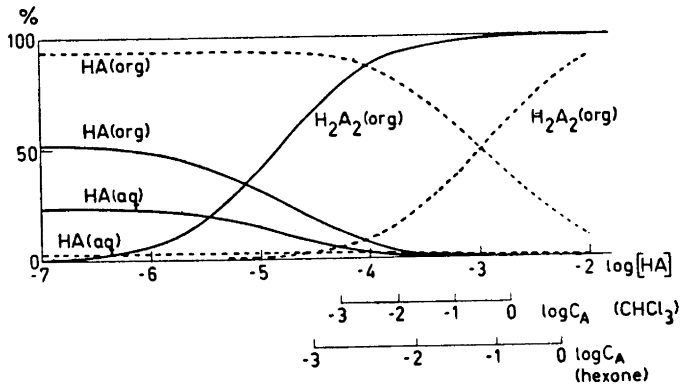

Fig. 2. The percentage of different DBP species in the two-phase systems chloroform/0.1 M $HClO_4$ + 0.9 M $NaClO_4$ (fulldrawn curves) and hexone/0.1 M $HClO_4$ + 0.9 M $NaClO_4$ (dashed curves) as a function of the conc. of HA (DBP monomer) in the aqueous phase. The volumes of the two phases are equal. $[H^+] = k_a$ and $[HA] = [A^-]$. The diagram is based on data given in the text.

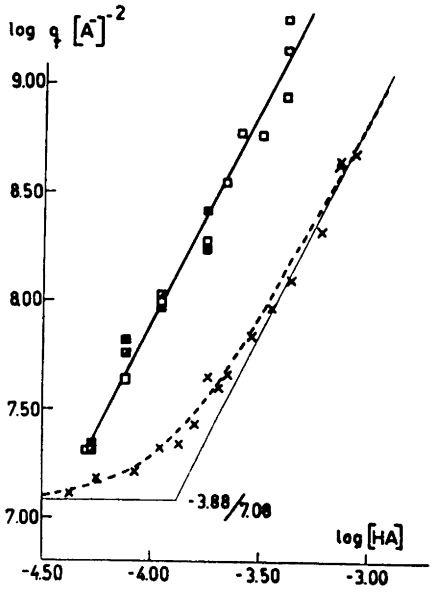

Fig. 3. Variation of $q[A^-]^{-2}$ with [HA]. These functions are calculated from data given in Tables 1 and 2. Fulldrawn line: chloroform-DBP system. Dashed curve: hexone-DBP system. The symbols and experimental points are the same as in Fig. 1. The horizontal asymptote to the hexone curve corresponds to $q[A^-]^{-2} = \lambda_2\beta_2$ and the equation for the asymptote with slope 2 is $q[A^-]^{-2} = \varkappa\lambda_2\beta_2[HA]^2$; the constants λ_2, β_2 and $\varkappa$ are defined in the text.

data in Fig. 1 (except those for $\log C_A[H^+]^{-1} > -0.2$) are therefore replotted in Fig. 3. Again the values for chloroform lie on a straight line with a slope of 2 demonstrating the presence of the complex $UO_2(HA)_2A_2$. The distribution with hexone is proportional to $[A^-]^2(1 + [HA]^2)$, which demonstrates the presence of both UO_2A_2 and $UO_2(HA)_2A_2$ in the hexone phase. The expression for the distribution ratio thus contains an additional term:

$$q = \frac{[UO_2A_2]_{org} + [UO_2(HA)_2A_2]_{org}}{[UO_2^{2+}]}$$

or, if we introduce the complexity and distribution constants β_2 and λ_2

$$\beta_2 = [UO_2A_2][UO_2^{2+}]^{-1}[A^-]^{-2};\ \lambda_2 = [UO_2A_2]_{org}[UO_2A_2]^{-1}$$

and the constant $\varkappa$ of the equilibrium

$$UO_2A_2(org) + 2\ HA(aq) = UO_2(HA)_2A_2(org)$$

$$q[A^-]^{-2} = \lambda_2\beta_2 + \varkappa\lambda_2\beta_2[HA]^2$$

The values of $\log \lambda_2\beta_2 = 7.08$ and $\log \varkappa = 7.76$ may be calculated from Fig. 3. The data give no evidence for the existence of an intermediate complex $UO_2(HA)A_2$ in appreciable amounts. Using the constants given above for the dissociation, distribution and dimerization of DBP the values of $\log K$ for the reaction

$$UO_2^{2+}(aq) + 2\ H_2A_2(org) = UO_2(HA)_2A_2(org) + 2\ H^+(aq)$$

may be calculated as 3.58 (chloroform) and 4.50 (hexone).

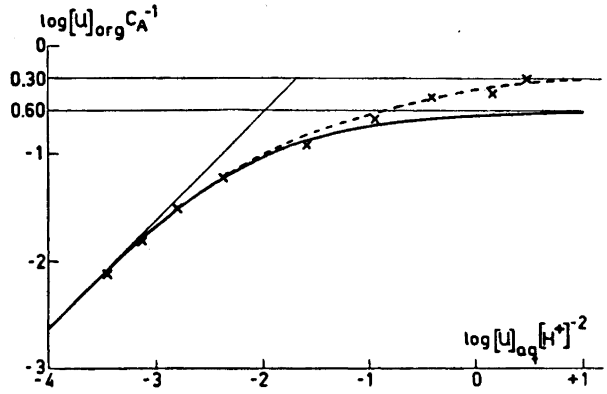

Fig. 4. The effect of increasing uranium concentration on the extraction of U(VI) by a solution of 0.04 M DBP in chloroform. The data are plotted as log $[U]_{org}C_A^{-1}$ against log $[U]_{aq}[H^+]^{-2}$. The fulldrawn curve is calculated assuming only the complex $UO_2(HA)_2A_2$ in the chloroform phase. The dashed curve is calculated assuming that, in addition to $UO_2(HA)_2A_2$, the dinuclear complex $(UO_2)_2A_4$ is formed in the chloroform phase.

Although such experiments as these cannot decide whether a complex is formed between hexone and UO_2A_2, the presence of UO_2A_2 in hexone and not in chloroform is very likely due to such a complex formation. Reactions between UO_2A_2 and hexone might be studied by distribution experiments with solutions of hexone in chloroform. Calculations on such data presuppose, however, a corresponding study of DBP in order to be able to calculate the variation of [HA] with $[\text{hexone}]_{CHCl_3}$.

It is thus possible to explain that the hexone data in Fig. 1 do not follow a straight line with a slope 2 by assuming the presence of HA and UO_2A_2 in the hexone phase. Similar values of the slope, that are higher than 2 have been reported by Stewart and Hicks [11]. However, their results are probably further complicated by the fact that they use nitric acid. It is therefore quite

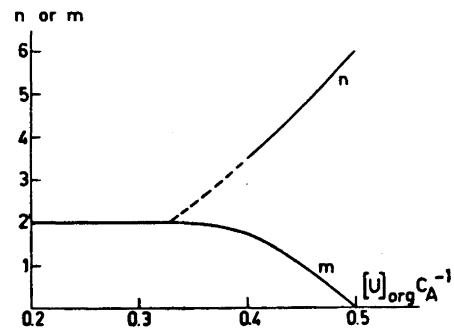

Fig. 5. Calculated mean values of n and m of the complex $(UO_2)_n(HA)_mA_{2n}$ in di-octyl phosphate-hexane solutions as a function of $[U]_{org}C_A^{-1}$. The calculations (see text) are based on data given by Baes *et al.*[5], Fig. 2.

possible that some uranium was extracted as uranyl nitrate into the organic phase (butyl ether or hexane), DBP acting like a tri-alkyl phosphate (*e.g.* TBP). Other oxygen-containing solvents such as TBP, ethers, esters, and alcohols may react in a similar way to hexone.

B. Experiments with increasing uranium concentration. In order to study the possible formation of UO_2A_2 from $UO_2(HA)_2A_2$ at higher concentrations of uranium a separate investigation was carried out with 0.04 M DBP in chloroform. The data are given in Table 3 and plotted in Fig. 4. A similar plot has been published by Baes *et al.*[5], Fig. 3 for the dioctyl phosphate-hexane system. It is seen from Fig. 4 that the ratio $[U]_{org}/C_A$ is increased above 0.25 to a limiting value of 0.5 The simple equilibria

$$UO_2^{2+}(aq) + 2\ H_2A_2(org) = UO_2(HA)_2A_2(org) + 2\ H^+(aq)$$

can thus not explain the whole extraction process.

The lower full-drawn curve in Fig. 4 is based on the reaction above using the value of $10^{3.38}$ at $C_A = 0.04$ M for the equilibrium constant, K, and calculating the free conc. of H_2A_2 in the chloroform phase as $C_A/2 - 2\ [U]_{org}$. The equation for this curve is

$$[U]_{org} = K[U]_{aq}[H^+]^{-2}(C_A/2 - 2\ [U]_{org})^2$$

This equation seems to be valid up to $[U]_{org}C_A^{-1} \sim 0.1$. The same result was found by Baes *et al.*[5] for the dioctyl phosphate-hexane system.

In order to explain the increase of $[U]_{org}C_A^{-1}$ above 0.25 several simple reactions may be considered. One might assume the formation of only mononuclear complexes, $UO_2(HA)A_2$ and UO_2A_2, or the formation of dinuclear com-

plexes such as $(UO_2)_2(HA)_2A_4$ and $(UO_2)_2A_4$. With constants for the formation of two complexes in addition to the formation constant of $UO_2(HA)_2A_2$ (K) it should be possible to explain the data in Fig. 4 very well. In fact the dashed curve in Fig. 4 has been derived assuming only the reaction (equilibrium constant = 2.25 K)

$$2\,UO_2^{2+}(aq) + 2\,H_2A_2(org) = (UO_2)_2A_4(org) + 4\,H^+(aq)$$

in addition to reaction given above (eq. const. = K). Also there might be complexes such as UO_2A^+ and UO_2A_2 formed in the aqueous phase. It is therefore not possible to draw any definite conclusions from the distribution data about the reactions in the chloroform phase at higher concentrations of uranium.

Baes *et al.*[5] have published, for solutions of U(VI) and dioctyl phosphate in *n*-hexane, some isopiestic results which indicate the formation of polymers with more than two uranyl ions. Calculations * on Fig. 2 in the work of Baes *et al.*[5] allow an approximate determination of the mean values of n and m in $(UO_2)_n(HA)_mA_{2n}$ as a function of $[U]_{org}C_A^{-1}$. The curves obtained are shown in Fig. 5. It may be seen that no change in m (= 2) seems to occur at values of $[U]_{org}C_A^{-1}$ below 0.33. It seems as if Baes *et al.*[5] have not considered a decrease in m. Viscosity measurements have lead them assume the presence of complexes with considerably higher values of n than 6. However, the viscosity properties of the dioctyl phosphate with its longer hydrocarbon groups may differ considerably from DBP (*i.e.*.. micelles may be formed much more readily).

Acknowledgement. The present investigation has been supported by Atomkommittén *(Swedish Atomic Energy Council)*, and by a grant from the *Inštitut Jozef Stefan*, Ljubljana, Yugoslavia. The authors also wish to thank Mr. H. A. C. McKay, AERE, Harwell, England, for support in obtaining the uranium-233, and Dr. H. S. Dunsmore for revising the English text. Sincere thanks are due to Professor Lars Gunnar Sillén for his advice and his criticism of the manuscript.

* For the calculation of the curves in Fig. 5 we have used the following approximate equations:

$$\begin{aligned} C_m &= [(UO_2)_n(HA)_mA_{2n}] + [H_2A_2] \\ [U]_{org} &= n[(UO_2)_n(HA)_mA_{2n}] \\ C_A &= (2n+m)[(UO_2)_n(HA)_mA_{2n}] + 2[H_2A_2] \\ C_A - 2\,C_m &= \frac{2n+m-2}{n}\cdot[U]_{org} \end{aligned}$$

If we apply this equation to the data of Baes *et al.* [5, Fig. 2], read from a smoothed curve, we obtain $\frac{2n+m-2}{n} = 2$ for $[U]_{org}C_A^{-1} < 0.33$; *i.e.*, $m = 2$; whereas n is undetermined. With decreasing $[U]_{org}C_A^{-1}$ the complex $UO_2(HA)_2A_2$ should finally dominate, *i.e.*, $n \to 1$. For values of $[U]_{org}C_A^{-1} > 0.4$ we might plausibly neglect $[H_2A_2]$ and then estimate n from $C_mC_A^{-1} = \frac{1}{2n+m}$ and $[U]_{org}C_A^{-1} = \frac{n}{2n+m}$.

Electrophoresis Studies on Blood Plasma Esterases

I. Mammalian Plasmata

KLAS-BERTIL AUGUSTINSSON

Institute of Organic Chemistry and Biochemistry, University, Stockholm, Sweden

The esterase activity of mammalian plasmata was investigated using as substrates a series of aliphatic, aromatic, heterocyclic and choline esters. Electrophoresis on cellulose columns was used for separation of the various esterases present in each plasma. The distribution of esterase activity and total protein after electrophoretic separation are reported for the plasmata of man, monkey, horse, cow, reindeer, goat, swine, cat, dog, guinea-pig, rabbit, and rat. Each esterase component was further studied as to substrate specificity and sensitivity to certain selective inhibitors.

Three types of esterases were present in the plasmata studied. An arylesterase (aromatic esterase) migrated on electrophoresis in most cases together with or close to the albumins, an aliesterase ("lipase") in the α_1-globulin region, and a cholinesterase between the α_2- and β-globulins. Within each group of esterases there were species variations in the properties of the individual enzymes. All plasmata studied contained an arylesterase which hydrolysed phenyl acetate at a higher rate than phenyl butyrate. Two arylesterases were found in the plasma of reindeer and rabbit. Aliesterases hydrolysed aliphatic and aromatic esters but not choline esters; phenyl acetate was hydrolysed at a lower rate than phenyl butyrate. Such enzymes were not detected in human, monkey, and dog plasmata. The concentration and properties of the plasma cholinesterases varied greatly with species. The ruminant plasmata had very low or no cholinesterase activity. Butyrylcholinesterase was present in the man, horse, cat, dog, and guinea-pig; propionylcholinesterase was found in the cow, rabbit, and rat; and acetylcholinesterase was present in the goat. Yet another type of cholinesterase occurred in swine plasma.

Differentiation of blood plasma esterases has previously been based mainly on substrate specificity and inhibitor experiment with orginal plasma (serum) or crude enzyme preparations. In the present investigation these enzymes were separated electrophoretically, the properties of the esterase fractions obtained were studied, and the esterase patterns of various vertebrate plasmata were compared.

The results, briefly summarized in a previous communication [1], showed that vertebrate plasmata contain three types of esterases, the characteristic features of which are as follows:

Arylesterases: aromatic esterases which hydrolyse phenyl acetate at a higher rate than phenyl butyrate; aliphatic esters are normally not attacked. They are resistant to certain organophosphorus compounds and to physostigmine, and have, in most cases, the greatest electrophoretic mobility of the three esterase groups.

Aliesterases, including lipases: both aliphatic and aromatic esters are hydrolysed, but not choline esters. There exist acetyl-, propionyl- and butyryl-aliesterases. They are sensitive to 10^{-5} M of a great number of organophosphorus compounds, but resistant to 10^{-5} M physostigmine; some of them are sensitive to higher concentrations of the latter compound. In most cases, these enzymes move electrophoretically more slowly than the arylesterases, but more rapidly than cholinesterases.

Cholinesterases: choline esters are split at a higher rate than both aliphatic and aromatic esters, the latter usually being hydrolysed at a lower rate than aliphatic esters or not at all; the specificity regarding the acyl group varies greatly. These esterases are sensitive to many organophosphorus compounds 10^{-6} M or less and to physostigmine, the latter giving complete inhibition in 10^{-5} M or lower concentration. They have the lowest electrophoretic mobility of all plasma esterases.

In the present and following reports, describing the experimental results on which the above classification is based, these three types of enzymes will be referred to, for practical reasons, as A-, B- and C-esterases respectively.

MATERIAL AND METHODS

Plasmata. Plasma was prepared from heparinized blood (venous or heart) and was free from all cells, including thrombocytes. Serum instead of plasma was used in some cases; both had the same esterase activity when tested with various substrates.

Substrates. The aliphatic, aromatic and choline derivatives used were the acetyl (Ac), propionyl (Pr), and butyryl (Bu) esters of the following radicals: *iso*amyl (Am), glycerol (T; *e. g.*, tributyrin, TBu), phenyl (Ph) and choline (Ch); also employed were acetyl-β-methylcholine (MeCh), benzoylcholine (BzCh), succinylcholine (SuCh), the carbon analogue of acetylcholine (3,3-dimethylbutyl acetate), Tween 20 (polyoxyethylene sorbitan monolaurate), procaine hydrochloride, atropine sulphate, cocaine hydrochloride, and heroin. Choline esters were all used in the form of iodides. The substrates were dissolved in a bicarbonate-CO_2 buffer solution (pH 7.4) to give 0.01 M in the reaction mixture.

The activity of some plasma protein fractions was also tested against indoxyl acetate. One half ml of the fractions from electrophoresis were added to 1.0 ml of a 10^{-3} M substrate solution. The intensity of indigo-blue dye formed in 30 min at 22°C was determined in these preliminary studies.

Esterase inhibitors. Eight compounds frequently used as selective enzyme inhibitors in recent esterase studies [2] were employed: physostigmine salicylate, tetra-*iso*propylpyrophosphoramide (*iso*-OMPA), *bis*-mono*iso*propylamino fluorophosphine oxide (mipafox), 10-(1-diethylaminopropionyl) phenothiazine hydrochloride (Astra 1397), 1,5-*bis*(4-trimethylammoniumphenyl) pentane-3-one diiodide (62C47), *bis*-(piperidinomethyl coumaranyl-5) ketone (3318CT), atoxyl (sodium arsanilate), and quinine sulphate. The compounds were dissolved in distilled water, and the enzyme preparations were incubated at 25°C for 50 min with the inhibitor solution before addition of substrate. The efficiency of esterase inhibition was expressed in pI_{50} values, *i. e.* negative logarithm of molar inhi-

Table 1. Enzymic hydrolysis of various esters by mammalian plasmata. Samples from at least three animals of each species were analysed. The activity values (b_{30}) refer to initial hydrolysis rates with a representative sample and are expressed in μl CO_2 per 0.10 ml of plasma per 30 min, corrections made for nonenzymic hydrolysis. Where values are indicated in brackets, initial hydrolysis rate was determined by extrapolation. An asterisk denotes that the activity varies greatly from individual to individual. Code names are explained in the text.

bitor concentration producing 50 % enzyme inhibition; these values were obtained by extrapolation from curves of inhibition (%)-inhibitor concentration (pI), where sufficient inhibitor was used at the higher pI levels to establish the point of complete inhibition. The active fractions obtained in electrophoresis experiments were dialysed against the bicarbonate buffer prior to testing their sensitivity to inhibitors.

Electrophoresis. Preparative column electrophoretic separation was performed with an apparatus described by Svensson [3] using cellulose powder. ("Munktell's cellulose powder", prepared according to the direction of Flodin and Kupke [4]). Electrophoretic runs were carried out in veronal buffer solution (pH 8.4, $I = 0.1$) at 5—11°C as maintained by a water-cooled jacket. Columns of two sizes were used, 3 cm × 40 cm and 1.5 cm × 40 cm (values in brackets refer in the following to the smaller column); in most cases the larger column was employed unless otherwise stated. For each run, 5 ml (1.5 ml) of buffered plasma (serum in some instances) was used. The material, previously dialysed against the buffer solution, was introduced into the column and the zone allowed to move 2—3 cm below the surface of the cellulose. The electrode vessels were filled with buffer solution and the electrophoresis started. The current was 60 mA (30 mA), provided by an applied voltage of 260 V (340 V), and the duration of runs 30 h (16 h). After the completion of electrophoresis, the liquid in the column was displaced at a rate of 10 ml per hour in 2.8 ml (1.5 ml) fractions. The protein concentration of each fraction was estimated by a modified Folin procedure [5].

Assay of esterase activity. The esterase activity was determined manometrically by the Warburg technique [2] at 25°C in a bicarbonate-CO_2 buffer solution, pH 7.4, with 2.00 ml total liquid volume per flask. Results are expressed in b_{30} values, *i. e.*, the μl of CO_2 evolved during 30 min, after correction for non-enzymic hydrolysis of the substrates. The activities reported refer to initial hydrolysis rates for 0.10 ml of plasma or esterase fraction, unless otherwise stated.

are summarized in Table 1. Activity values (b_{30} per 0.1 ml plasma) obtained with additional substrates are given in the text. The electrophoretic patterns presented in Figs. 1—12 show the rate of elution of the esterases in relation to various protein constituents, which are designated by the usual nomenclature [6]. In the legends to these figures are summarized in tabular form the relative substrate specificity and sensitivity to certain inhibitors of each esterase component. The peaks of esterase activity are designated A, B and C, corresponding to the three groups of esterases referred to in the introduction. In Table 2 the inhibitor studies are then summarized.

Human plasma (Fig. 1). The activity of human plasma in the hydrolysis of various esters has been extensively studied by many workers, and the results presented in Table 1 generally confirm previous observations, *e.g.*, that human plasma hydrolyses butyrylcholine at the highest rate of the choline esters, that the butyric acid esters of aliphatic alcohols are hydrolysed more rapidly than their other acyl homologues, and that phenyl butyrate is hydrolysed more slowly than the acetate and propionate.

On electrophoresis of human plasma two regions of high esterase activity appeared. The two peaks (A and C) are inferred to be due to the presence of at least two distinct enzymes of differing electrophoretic mobility: one (A) moved together with the albumin components and the other (C) was found between the α_2- and β-globulin fractions. A third esterase peak, demonstrated in the α-globulin region (between the peaks A and C) in most mammalian plasmata, was not detected in human plasma.

The A-esterase(s) hydrolysed phenyl acetate at a rate which was approximately 100 times greater than for phenyl butyrate. Neither the aliphatic

nor the choline esters tested were hydrolysed by this enzyme which was resistant to all the inhibitors studied. Whether more than one arylesterase was involved in this esterase peak has not yet been established. It is possible that some human plasmata contain in low concentration an esterase running electrophoretically close to but more rapidly than the main peak fraction since the esterase peak was not uniform.

The C-esterase was a typical butyrylcholinesterase of low specificity. It also hydrolysed benzoylcholine, succinylcholine, and the butyrates of both phenol and aliphatic alcohols including glycerol. In addition, this enzyme hydrolysed procaine (b_{30} 0.5), atropine (b_{30} 0.3), Tween 20 (b_{30} 16) and the carbon analogue of acetylcholine (b_{30} 20). Cocaine and heroin hydrolyses were not detected with human plasma. The C-esterase was sensitive to all inhibitors studied (Table 2), with physostigmine being the most potent, and 62C47 and quinine the less potent compounds.

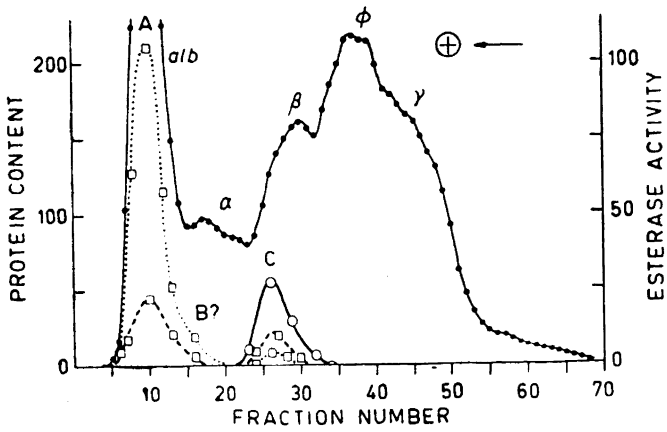

Fig. 2. Macaque-monkey plasma. Conditions as for Fig. 1. □.....□, PhAc (0.10); □— — — —□, PhPr (0.20); O———O, BuCh (0.20).

Species	Esterase component	PhAc	PhPr	PhBu	TBu	BuCh	pI_{50}

Macaque	A	105	11	1	0	0	<3	<3
	C	4	6	8	2—3	14	8.5	8.0
Mangabey	A or B	3	—	7	0	0	<3	>5
	C	50	—	95	25	150	8.4	8.0

Human plasma therefore contains two esterases. The arylesterase was responsible for 96 % of the hydrolysis of phenyl acetate and 14.5 % of that of phenylbutyrate, with the cholinesterase accounting for the remainder of the hydrolysis of these phenyl esters and for the entire activity against choline esters and triglycerides. In addition, preliminary experiments have shown that cholinesterase is responsible for more than 90 % of the hydrolysis of indoxylacetate by human plasma.

Monkey plasma (Fig. 2). Plasmata from the macaque monkey (*Macacus cynomolgus*) and the mangabey monkey (*Cercocebus torquatus*) were studied. The macaque plasma was similar to human plasma in pattern of esters hydrolysed, but the hydrolysis rates were much lower for the monkey plasma. The mangabey plasma hydrolysed choline esters at 10 times the rate of the macaque plasma, but hydrolysed the phenyl esters at a lower rate than either human or macaque plasma. Phenyl butyrate was hydrolysed more rapidly than the acetate.

The electrophoretic pattern of the macaque plasma is illustrated in Fig. 2; the legend of this figure also gives the results with the mangabey plasma. Similar to human plasma, the macaque plasma contained two distinct esterases. The A-esterase was eluted coincident with the albumin fraction and the

C-esterase between the α_2- and β-globulins. The first enzyme was a typical acetylarylesterase which was resistant to both physostigmine and certain organophosphorus compounds. Although aliesterase (B) was not detected in the macaque plasma, the activity may have been too low after electrophoresis to be determined by the techniques employed.

The butyrylcholinesterase (C) of the macaque plasma was present in low concentration compared with human and mangabey plasmata. This esterase was also responsible for the hydrolysis of tributyrin and for up to 65 % of the plasma activity against phenyl butyrate.

The mangabey plasma probably contained a B-esterase in comparatively low concentration. The low activity of the fractions did not allow assay of this enzyme for inhibition by organophosphorus compounds. Since phenyl butyrate was hydrolysed more rapidly than phenyl acetate and the esterase was eluted later than the A-esterase of macaque plasma, it appears likely that the mangabey esterase was a B-rather than an A-estrase. The butyrylcho-

linesterase, present in high concentration, was responsible for the hydrolysis of tributyrin.

Horse plasma (Fig. 3). The pattern for hydrolysis of various esters by horse plasma was similar to that for human plasma except for the hydrolysis of the triglycerides, where tripropionin was optimal for horse plasma and tributyrin for human plasma.

Horse plasma contained three types of esterases resolved in three distinct peaks by electrophoresis. The A- and B-esterases migrated between the albumin and α_1-globulin components, and the C-esterase between the α_2- and β-globulins. The A-esterase was a typical acetylarylesterase, being resistant to all inhibitors studied. *p*-Nitrophenyl acetate was hydrolysed at a lower rate than phenyl acetate. The B-type esterase hydrolysed both aromatic and aliphatic esters, the propionates being split at a higher rate than the corresponding acetates and butyrates. This enzyme was also responsible for the hydrolysis of "Tween 20" (b_{30} 35). It was less sensitive to organophosphorus compounds than most B-esterases; *e.g.*, this esterase was resistant to *iso*-OMPA, while mipafox gave the same relatively low pI_{50} value (5.7), when this

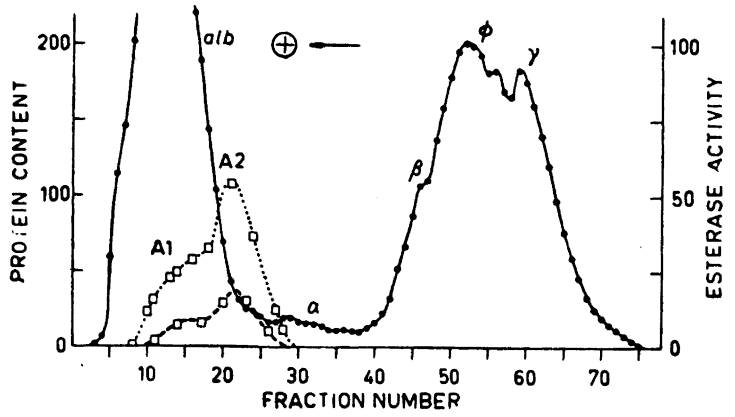

Fig. 5. Reindeer plasma. Conditions as for Fig. 1. □.....□, PhAc (0.40); □— — —□, PhPr (0.40). N.B.: the activity of the arylesterases was much lower than expected after electrophoresis (*cf.* Table 1).

Esterase component	PhAc	PhPr	PhBu	PrCh	pI_{50}	
					Phys	*iso*-OMPA
A1	7	2.5	?	0	<3	<3
A2	14	5	<1	0	<3	<3

B-esterase was assayed with a number of various substrates. Poor inhibitor efficiency was also observed with the quaternary ammonium compounds, the phenothiazine derivative (Astra 1397), atoxyl, and quinine sulphate. A better separation of the A-and B-esterases was accomplished by re-electrophoresis of the two peak fractions (inserted diagram of Fig. 3).

The C-esterase was a typical butyrylcholinesterase having the lowest specificity of the three esterases present. Its inhibition pattern was similar to that of human plasma cholinesterase. At least three enzymes in horse plasma hydrolyse aromatic esters since the cholinesterase was also active on these substrates. Indoxyl acetate was also hydrolysed by all three esterases, the C- and B-esterases being more active than the arylesterase.

Cow plasma (Fig. 4). Of the substrates tested, only the aromatic esters were hydrolysed at appreciable rates. The enzyme catalysing this reaction was a typical acetylarylesterase which had a lower electrophoretic mobility relative to that of the albumin components than was usually found for other mammalian plasma arylesterases.

Inhibitor experiments with the original cow plasma showed that tributyrin was hydrolysed by two esterases both present in very low concentration. Cholinesterase accounted for 80 % of the total hydrolysis of this ester with the remainder being hydrolysed by an esterase (probably a B-type esterase)

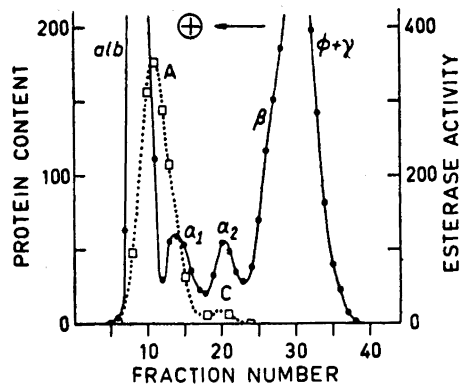

Fig. 6. Goat plasma. Electrophoresis was carried out on a small column. Otherwise, conditions were as for Fig. 1. □ ..... □, PhAc (0.10).

resistant to physostigmine and sensitive to mipafox and *iso*-OMPA. The activities of the B- and C-esterases were too low to be detected in fractions after electrophoresis.

The proportion between the hydrolysis rates for phenyl acetate and phenyl butyrate was 47:1 for the whole plasma and 218:1 for the arylesterase peak fraction; thus the activity against the butyrate was reduced much more than that against the acetate by dialysis and electrophoresis. It appears therefore that the phenyl esters were hydrolysed by at least two enzymes of cow plasma. The sensitivity of these esterases to organophosphorus compounds was not successfully tested.

The physostigmine-sensitive esterase was a propionylcholinesterase which was inhibited by excess propionylcholine (see inserted graph of Fig. 4). This esterase was sensitive to those compounds (3318CT and 62C47) which are regarded as being selective inhibitors of acetylcholinesterase (of erythrocytes and nerve tissue), and was resistant to "Astra 1397". The cholinesterase of cow plasma therefore differs greatly from the cholinesterase present in most other mammalian plasmata.

Reindeer plasma (Fig. 5). As noted for other ruminant plasmata, the reindeer plasma hydrolysed most esters at a very low rate. Although the aromatic esters were attacked more readily than the other substrates even here the hydrolysis rates were comparatively low. Two esterase peaks were found after electrophoretic separation; they were due to the presence of two acetylarylesterases (A1 and A2), the properties of which were similar, in that both

enzymes were resistant to *iso*-OMPA and physostigmine. This plasma probably does not contain any B-type esterase.

The cholinesterase present in low concentration was a butyryl- (or propionyl-) cholinesterase, the activity of which was not inhibited by high substrate concentration. This enzyme was responsible for 20 % of the plasma activity against phenyl butyrate.

Goat plasma (Fig. 6) *and sheep plasma.* The goat plasma hydrolysed phenyl acetate at a very high rate due to the presence of an acetylarylesterase. A few per cent of the phenyl acetate hydrolysis was due to a second esterase. Inhibition experiments showed this second enzyme to be a cholinesterase which had the properties of an acetylcholinesterase. It was inhibited by high concentration of acetylcholine which explains why the peak fraction C hydrolysed phenyl acetate at a higher rate than acetylcholine with the substrate concentration used (1.0×10^{-2} M). The quaternary ammonium compounds were comparatively strong inhibitors and the phenothiazine derivative (Astra 1397) was not active as an inhibitor of the acetylcholine hydrolysis. Moreover, this enzyme was only sensitive to comparatively high concentration of the organophosphorus compounds, atoxyl and quinine (Fig. 6 and Table 2).

Sheep plasma showed much the same esterase pattern as goat plasma, both regarding hydrolysis rates of various esters (Table 1), observed esterase peaks of the electrophorogram, and esterase sensitivity to various inhibitors.

Swine plasma (Fig. 7). The arylesterase concentration of swine plasma exhibits considerable individual variation (b_{30} 20—900). The results obtained with a sample having a b_{30} of 450 will be considered here. More details on swine plasma esterases, including evidence for the inheritance of the plasma arylesterase have been reported in a previous paper [7].

The main esterase present in the plasma sample analysed was an acetylarylesterase. *Para*-substitution of phenyl acetate with a nitro group increased the enzymic hydrolysis rate about eight times. With other plasma arylesterases of mammals such a substitution in the aromatic ring usually greatly decreases the hydrolysis rate. The swine esterase was resistant to all inhibitors tested. By contrast, the hydrolysis of phenyl acetate by a plasma exhibiting low activity against this substrate was strongly inhibited by all those compounds which were strong inhibitors of the cholinesterase present in low concentration. This suggests that the hydrolysis of phenyl acetate by this type of plasma was due mainly to the plasma cholinesterase. The less active the plasma was in hydrolysing phenyl acetate, the more closely did the pattern of inhibition, when assayed with phenyl acetate, resemble that of cholinesterase.

The arylesterase migrated on electrophoresis together with the albumin components. The activities against phenyl acetate and its *p*-nitro derivative moved coincident with each other. No B-esterase or other arylesterases were detected.

Due to the low activity of swine plasma on choline esters, a cholinesterase could not be traced accurately in the fractions obtained in these electrophoresis experiments. However, by running the electrophoresis on smaller columns it was possible to find this type of esterase between the α_2- and β-globulins. Experiments with whole plasma revealed that this esterase was a butyryl-

cholinesterase, the specificity of which differed from those of all other vertebrate plasmata by hydrolysing acetylcholine more rapidly than propionylcholine confirming previous results [8,9]. Benzoylcholine and succinylcholine were also hydrolysed by this enzyme. The hydrolysis of succinylcholine was unusual in that the swine plasma hydrolysed it more rapidly (comparable protein concentrations) that any other animal tissue so far studied. The hydrolysis rate of the carbon analogue of acetylcholine (3,3-dimethylbutyl acetate) was 10 % of the hydrolysis rate of the choline ester. Acetyl- β-methylcholine was not split. The swine cholinesterase also hydrolysed phenyl acetate, the hydrolysis rate being approximately the same as for butyrylcholine. In newborn animals, which irrespective of the plasma activities of the parents had low arylesterase activity, more than 97 % of the hydrolysis rate of phenyl acetate was due to a butyrylcholinesterase.

The inhibition experiments performed with swine plasma esterases have been previously reported [7].

Cat plasma (Fig. 8). The high hydrolysis rate for aromatic esters by this plasma was due to an arylesterase (probably an acetylarylesterase, in contrast to previous statements [1,10]) and a B-type esterase. The latter enzyme hydrolysed a variety of esters, the hydrolysis rates being greatly dependent on the configuration of the alcoholic group. Tripropionin was hydrolysed at a higher rate than tributyrin, the reverse being true for the phenyl and *iso*amyl derivatives. The most characteristic property of this enzyme was its high sensitivity

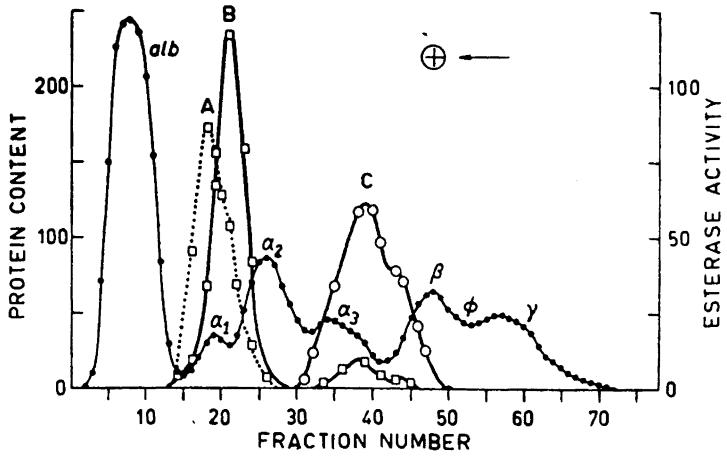

Fig. 8. Cat plasma. Conditions as for Fig. 1. □ . . . . . □, PhAc (0.01); □———□, PhBu (0.10); ○———○, BuCh (0.40), PrCh (0.80).

to atoxyl (pI_{50} 7), not found with any other plasma esterases studied in this series. Due to the unusually high mobility of the albumin component [6], the A-esterase fractions were all free from these proteins.

The cholinesterase of cat plasma was similar to other mammalian butyrylcholinesterases. It was responsible for approximately 10 % of the plasma activity against phenyl butyrate and for less than 1 % of that against phenyl acetate. The activity was found after electrophoresis between the α_3- and β-globulins and was not distributed in an uniform esterase peak. The enzyme protein seemed to move partly together with other protein constituents (possibly by complex formation). No evidence could be found by inhibition experiments and specificity studies with various fractions forming the peak or peaks that more than one cholinesterase was present. The same observations were made with three various plasma samples subjected to electrophoretic separation.

Dog plasma (Fig. 9). The esterase pattern of this plasma resembled that of human plasma in the hydrolysis of choline and aromatic esters. In comparison with human plasma the aliphatic esters were hydrolysed at a comparatively low rate by dog plasma. The main esterases present were an acetylarylesterase and a butyrylcholineasterase. Beside the main arylesterase

peak. fractions migrating on electrophoresis at a higher rate (together with the albumins) and at a lower rate (close to the α_2-globulins) were active in hydrolysing phenyl acetate. The esterases of both these "extra" fractions were resistant to *iso*-OMPA. Whether these activities were due to separate enzymes or merely due to the presence of traces of the arylesterase has not been further investigated.

The butyrylcholinesterase was found between the α_2- and β-globulins. The esterase peak was not uniform. Part of the enzyme(s) (C?) possibly moved together with other protein constituents. The specificity and sensitivity to inhibitors were the same for the active esterase constituents present in the main peak fraction and in the more rapid-moving fractions. In the cholinesterase region a B-type esterase might well have been present because the enzymic hydrolysis of phenyl butyrate by some fractions (B?) was inhibited by physostigmine only when this agent was present in higher concentration (10^{-4} M) than was necessary to inhibit completely the hydrolysis of a choline ester. If was found that 20—30 % of the phenyl butyrate hydrolysis by dog plasma was due to the cholinesterase which displayed the maximum activity against tripropionin. Before the complexity of the esterase fractions between the α_2- and β-globulins has been further investigated, it cannot be stated whether dog plasma contains a B-type esterases and more than one cholinesterase.

Guinea-pig plasma (Fig. 10). In the series of aromatic and aliphatic esters tested the propionates were hydrolysed at the highest rate. Phenyl acetate and propionate were split by at least four enzymes. The first esterase fraction eluted following electrophoresis was a propionylarylesterase which migrated more rapidly than the albumins and was responsible for about 40 % of the total hydrolysis of phenyl acetate; the assay method was not sensitive enough to measure the hydrolysis rate of phenyl butyrate in these fractions. Two esterases resistant to physostigmine but sensitive to organophosphorus compounds were separated. One (Bl) was found in the α-globulin region and hydrolysed the propionates and butyrates at a higher rate than the acetates of the aliphatic and aromatic esters. This esterase was responsible for 50 % of the hydrolysis of phenyl acetate and 60—70 % of that of phenyl butyrate. The hydrolysis of ethyl acetate and ethyl butyrate as well as of "Tween 20", the rate of which was comparatively high (b_{30} 116) with this plasma, was also catalysed by this enzyme. The second B-type esterase (B2) migrated on electrophoresis at a higher rate than cholinesterase. The *iso*amyl esters were hydrolysed by both the B-esterases but not by the C-type esterase, which had the properties of a butyrylcholinesterase. In addition to the hydrolysis of choline esters, including benzoylcholine, this C-esterase was responsible for about 15 % of the plasma activity against phenyl butyrate and 5—10 % of that against phenyl acetate.

Guinea-pig plasma was highly active in hydrolysing the carbon analogue of acetylcholine (b_{30} 150). It was characteristic of the reaction that the velocity fell off greatly with time. The enzyme responsible was the physostigmine resistant B-type esterase (B1). Heroin was also hydrolysed at a comparatively high rate by this plasma (b_{30} 12).

Rabbit plasma (Fig. 11). The esterase activity of rabbit plasma varied considerably from animal to animal, especially when aromatic esters were used as substrates. The activity of the enzymes responsible for the hydrolysis of these esters were reduced in varying degrees by dialysis against the veronal buffer. The electrophoretic pattern was in most instances difficult to interprete. There were at least three enzymes in the albumin and α_1-globulin regions which hydrolysed aromatic esters. The main esterase peak (A1) was due to an acetylarylesterase. Active fractions (A2) moving together with the albumins had esterase properties similar to those of the fractions of the main esterase peak (A1), but whether the two peaks were due to the same or different enzymes has not been further investigated.

The B-type esterase hydrolysed aliphatic and aromatic propionates and butyrates at higher rates than the acetates. It was much more sensitive to the organophosphorus compounds and to atoxyl than was the C-type esterase of this plasma. Great individual variation occurred in the concentration of this esterase.

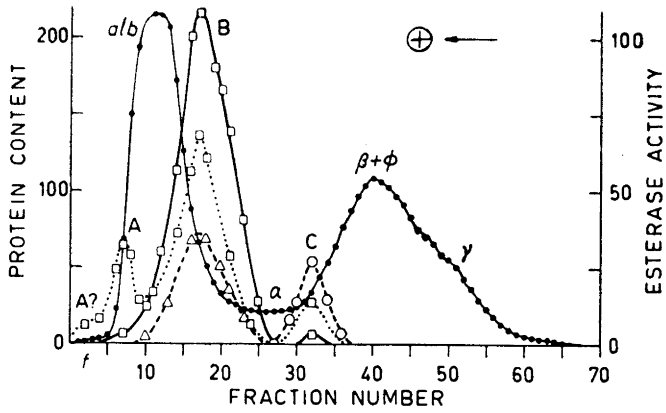

Fig. 12. Rat plasma. Conditions as for Fig. 1. □ . . . . . □, PhAc (0.05); □———□, PhBu (0.05); △— — —△, TPr (0.10); ○— — —○, PrCh (0.40).

The cholinesterase present in comparatively low concentration has the properties of an acetylcholinesterase. The activity was inhibited by high concentrations of acetylcholine (and propionylcholine). The enzyme was resistant to "Astra 1397", atoxyl and quinine, and was less sensitive to *iso*-OMPA and mipafox than other plasma cholinesterases. On the other hand, the quaternary ammonium compounds were comparatively strong inhibitors. These observations indicate that the rabbit plasma cholinesterase is of a type characteristic of acetylcholinesterase present in erythrocytes and nervous tissue of various animal species.

Preliminary experiments showed that indoxyl acetate was hydrolysed by all three types of esterases present in rabbit plasma, with the B- and C-esterases being the most active ones. This plasma hydrolysed heroin (b_{30} 10) and cocaine (b_{30} 5) at a higher rate than most other mammalian plasmata.

Rat plasma. (Fig. 12). The acetylarylesterase moved in electrophoresis at a higher rate than the albumins. Its activity was reduced during dialysis against the veronal buffer to a much greater degree than with the other esterases of this plasma. In the small amount of protein (f-component), moving faster than the albumins, arylesterase was also present. The B-type esterase hydrolysed phenyl butyrate and *iso*amyl butyrate at a higher rate than the corresponding acetates and propionates, and tripropionin more rapidly than its other acyl homologues. The broad B-esterase peak obtained

after electrophoresis probably consisted of a single enzyme because the activities of all fractions therein showed the same sensitivity to *iso*-OMPA when various esters were used as substrates. This esterase together with cholinesterase was responsible for about 40 % of the plasma hydrolysis of phenyl acetate.

The rat was one of the few mammalian species studied in this series (cf. cow, above) which had a typical propionylcholinesterase in its plasma, confirming previous observations [8]. A similar enzyme was present in mouse plasma. The propionylcholinesterase of rat plasma differed from the butyrylcholinesterases present in other plasmata in respect to inhibitory effects of various compounds (Table 2) and hydrolysis rates of choline and non-choline esters; *e.g.*, acetyl-β-methylcholine and benzoylcholine as well as phenyl acetate and propionate were split at relatively high rates.

Arylesterases as thiol enzymes. All the arylesterases studied were resistant to the selective inhibitors used (Table 2). Introductory studies were therefore performed to find inhibitors of these enzymes. Of the three main types of agents reacting with thiol groups, *p*-hydroxymercuribenzoate, iodoacetamide and *o*-iodosobenzoate, the first compound was the only powerful inhibiting agent of four different plasma arylesterases (human, cow, swine, rabbit) (pI_{50} 5—6). This suggests the presence of an active SH-group at the enzyme surface of these esterases. Aliesterases and cholinesterases were resistant to the mercaptide-forming agent (*p*-hydroxymercuribenzoate) and the alkylating agent (iodoacetomide). The oxidizing agent (*o*-iodosobenzoate) was a comparatively strong inhibitor (pI_{50} 5.0) of the cholinesterases of human and horse plasmata. A full account of these studies will be reported later.

DISCUSSION

The nature of plasma esterases has been the subject of investigation and speculation for nearly forty years. These enzymes have usually been characterized based on their substrates and sensitivity to inhibitors. Differentiation was based mainly on work with original plasma (serum) or crude enzyme preparations. Homogeneous esterase preparations such as plasma cholinesterases free from other esterases, were only rarely employed. A classification of plasma esterases is difficult to deduce from such studies due to much overlapping of properties and species differences.

As a preliminary to the present study, various preparative methods were tested for separating the esterases of vertebrate plasmata. Fractionation with ammonium sulphate gave poor separation of the two esterases present in human plasma, and even less promising results with plasmata where a more complex esterase pattern was involved. Ethanol fractionation at low temperature resulted in good separation of the two human plasma esterases. This technique was therefore employed with a number of other plasmata *, but was inadequate for separating the aryl- and aliesterases.

Except for a few studies of plasma cholinesterases [11,12] and of A- and B-esterases [13], no attempt has been made so far to separate electrophoretically

* This investigation was carried out in collaboration with Ing. H. Nihlén of Forskningslaboratoriet LKB, Stockholm.

plasma esterases. Preparative electrophoresis on cellulose columns was choosen as the technique for the present investigation, because of its adaptability for the isolation of plasma proteins in sufficient amounts to enable a study of their properties [14,15]. Phosphate and borate were found to be unsuitable as buffers for electrophoresis since the arylesterases and the aliesterases in many plasmata were not separated in these buffers. The best separation of plasma esterases was obtained with veronal buffer (pH 8.4 and $I = 0.1$). However, the various types of esterases were influenced differently by dialysis against this buffer. Species as well as esterase differences were noted in this respect. For this reason the activities of separated enzymes are not always comparable with those calculated from activity values obtained with original plasma.

The esterase peaks after electrophoresis are shown in graphs giving their relative position to known protein constituents. The absolute electrophoretic mobilities of the proteins from various plasmata cannot be compared as the fraction numbers plotted as abscissae are not the same for all plasmata. However, all electrophoresis runs and elutions were carried out under identical conditions, with the exception of temperature which varied from 5°C to 11°C in various runs.

Three types of esterases were shown for mammalian plasmata, based on electrophoretic mobility relative to known protein constituents, substrate specificity, and susceptibility to selective inhibitors. Some plasmata contain all three types, others two and still others only one. Each group of enzymes has several types, and every animal species has its own typical set of plasma esterases. When designating these esterases, the nomenclature generally accepted by most authors in this field was followed as far as possible. Since the three types of esterases have different electrophoretic mobilities under the experimental conditions used, they could be conveniently studied when separated after electrophoresis. Cholinesterases had in most cases much lower electrophoretic mobility than the aryl- and ali-esterases and were therefore easily obtained free from other esterases. Aryl- and aliesterases migrated more closely, but in most cases they could be studied separately and not in mixtures.

The presence of an aromatic esterase in human plasma has been proposed by Mounter and Whittaker [16]. Aldridge [10] found two types of serum esterases of several species hydrolysing *p*-nitrophenyl acetate, propionate and butyrate. The enzyme not inhibited by paraoxon (diethyl *p*-nitrophenyl phospate) and hydrolysing acetate at a higher rate than butyrate was called A-esterase, and the sensitive enzyme B-esterase. It turned out in the present investigation that the A-esterase is the enzyme which has the greatest electrophoretic mobility, and is resistant not only to paraoxon but to a number of other organophosphorus compounds and to physostigmine. Since this esterase hydrolyses various aromatic esters (in addition to phenyl esters, the acetates of α- and β-naphthol and indoxyl) but not aliphatic and choline esters, it was called *arylesterase*. Whether this type of esterase is also responsible for the hydrolysis of certain organophosphorus compounds will be the subject of a subsequent study. In contrast to other plasma esterases the arylesterases are highly sensitive to *p*-hydroxymercuribenzoate which suggests the presence of an active SH-group at the enzyme surface. All mammalian plasmata studied

contain this type of esterase in high concentration and it is the predominant esterase present in the plasmata of ruminants and swine.

In the earliest investigation on plasma esterases such simple esters as alkyl butyrates, fats and oils were used as substrates. "Simple esterases" having a substrate preference for short-chained fatty acid esters of simple alcohols were differentiated from "lipases" which were more active in hydrolysing esters of glycerol and fatty acids with long chains. Later it was observed that choline esters were also hydrolysed by the plasmata of several species, and that the enzyme responsible was different from "esterase" and "lipase". This led to a large amount of work on substrate specificity of plasma esterases. No clearcut line of differentiation between the various enzymes could be drawn, until Richter and Croft [17] made the observation that all enzymes classified as "cholinesterases" were completely inhibited by 10^{-5} M physostigmine, while "simple esterases" were resistant to this inhibitor dosage. These authors introduced the term *aliesterase* for the latter type of esterases. No evidence has been given so far as to the identity of this esterase type with the A- or B-esterases. It was demonstrated in the present investigation that the esterase migrating electrophoretically next to the arylesterase has the properties of a B-esterase and an aliesterase, being highly sensitive to certain organophosphorus compounds and resistant to 10^{-5} M physostigmine. This esterase hydrolyses both aliphatic and aromatic esters. Although the term aliesterase is not adequeate for this type of esterase, since some of them hydrolyse aromatic esters at a higher rate than the corresponding aliphatic ones, its use is recommended because the definition introduced by Richter and Croft is still valid. Triglycerides are also hydrolysed by this esterase, and since no special esterase hydrolysing only these esters has been detected in plasma, lipases are included in the aliesterases. Human, monkey, dog, swine and ruminant plasmata do not contain aliesterase. The hydrolysis of aliphatic esters by these plasmata is catalysed only by cholinesterases, which in these cases have a particularly low specificity for choline esters. The mammalian aliesterases of the plasmata of horse, cat, guinea-pig, rabbit and rat hydrolyse the butyrates and propionates at a higher rate than the acetates. Acetylaliesterases, however, exist in the plasmata of some lower vertebrates, as will be discussed more fully in the second paper of this series.

The specificity of *cholinesterases* present in the plasmata of various mammalian species has been studied extensively in previous investigations [8, 18, 19]. By ammonium sulphate fractionation the human plasma cholinesterase is precipitated with the albumins [18, 20, 21], but on electrophoresis it migrates between α_2- and β-globulins [11, 12]. It was demonstrated in the present investigation that this relatively low mobility under the experimental conditions used was valid also for the cholinesterases of other mammalian plasmata. These plasma esterases were therefore easily separated from the aryl- and aliesterases by electrophoresis, and for practical reasons they were designated "C-esterases" in the present study. The hydrolysis of choline esters and the high sensitivity to physostigmine are properties sufficiently distinct to regard the cholinesterases as a separate group of esterases. When only the sensitivity to certain organophosphorus compounds is considered, cholinesterases might be regarded as B-type esterases [22], but plasma cholinesterases are definitely distinct enzy-

mes differing electrophoretically and in their characteristics as esterases from the aliesterases as clearly as do the arylesterases.

Cholinesterases were present in all mammalian plasmata studied except in those of the ruminants where their activities were very low or too low for detection. Various types of plasma cholinesterases exist and overlapping of properties is very marked. This is especially true for the enzymes present in the plasmata of rabbit, swine, cow and reindeer. A butyrylcholinesterase is characteristic of several of the mammalian plasmata studied, and a propionylcholinesterase is present in rat plasma. As will be demonstrated in a second paper of this series, butyrylcholinesterase does not occur in the plasmata of lower animals, where propionyl- and acetylcholinesterases are the characteristic physostigmine-sensitive esterases instead.

This investigation has been supported by a grant from the *Swedish Natural Science Research Council*. The skilled technical assistance of Mrs. Toril Rode and Mrs. Gunnel Jonsson is gratefully acknowledged. My thanks are also due to Prof. John E. Casida who revised the English in the manuscript. A complete list of acknowledgements will be given in the second paper of this series.

ACTA CHEMICA SCANDINAVICA 13 (1959) 593—594

Synthesis of 4-*O*-Benzyl-D-Glucose

INGEMAR CROON and BENGT LINDBERG

Träkemiska avdelningen, Svenska Träforskningsinstitutet, Stockholm, Sweden

A new method for the benzylation of hydroxyl groups in carbohydrates has been developed. The method, by which alkali-labile groups, such as acetate ester groups, are not removed, has been applied for the synthesis of 4-*O*-benzyl-D-glucose.

4-*O*-Benzyl-D-glucose, which has not been prepared before, was of interest in this Department, and we therefore looked for a convenient route to this substance. 4-*O*-Methyl-D-glucose has recently been prepared [1] by methylation of methyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranoside with methyl iodide and silver oxide in dimethyl formamide, taking advantage of the facile migration of an acetyl group from the 4- to the 6-position and subsequent deacetylation and hydrolysis. An analoguous route to the benzyl ether should be attractive. The benzylation of carbohydrates has recently been summarised by Mc Closkey [2]; it has always been done using strongly alkaline conditions, under which acyl groups should be split off. The benzylation of 1,2:5,6-di-*O*-*iso*propylidene-D-glucofuranose with benzyl bromide and silver oxide in dimethyl formamide was investigated first; after hydrolysis of the product a good yield of 3-*O*-benzyl-D-glucose was obtained. Methyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranoside was then benzylated in the same way and the product was deacetylated and hydrolysed. Paper electrophoresis in borate buffer revealed the presence of three substances, with the mobilities expected [3] for glucose, and for 6-*O*- and 4-*O*-benzyl-D-glucose, of which the latter gave the strongest colour reaction. The first two substances were adsorbed on a column of Amberlite IR 400 in the borate state, a technique previously used by Richards and Lock [4] for the fractionation of methylated glucoses. This gave the presumed 4-*O*-benzyl-D-glucose in a crystalline state in 23 % yield.

The product analysed as a monobenzylated glucose and had an electrophoretic mobility of 0.17, relative to glucose, as would be expected for the 2-*O*- or 4-*O*-benzyl ether. To distinguish between these possibilities the substance was treated with aqueous calcium hydroxide, in which the former should be stable and the latter degraded, chiefly to *iso*saccharinic acid [5]. The substance was degraded to acidic material at a slower rate than that at which 3-*O*-benzyl-D-glucose was degraded in a parallel experiment. 2-*O*-Methyl-D-glucose was quite stable under these conditions. This indicated that the substance was the 4-*O*-benzyl ether and in agreement with this it

consumed 2.92 moles of periodate with the formation of 1.91 moles of formic acid. The 4-*O*-benzyl-D-glucose melted at 178—179° and showed an optical rotation of 96° → 52° in water, indicating that the crystaline material was the α-form.

EXPERIMENTAL

Melting points are corrected. Paper chromatography was carried out on Whatman No. 1 filter paper with the solvent system ethyl acetate-acetic acid-water(3:1:3).

Paper electrophoresis was carried out on Whatman No. 3 MM filter paper in borate buffer at pH 10.

3-O-Benzyl-D-glucose. 1,2:5,6-Di-*O-iso*propylidene-D-glucofuranose (3 g) was dissolved in dimethyl formamide (60 ml) and benzyl bromide (12 ml) was added. Silver oxide (12 g) was added over 60 min with vigorous stirring and external cooling with tap water. Stirring was continued for 16 h. The solids were removed by centrifuging and washed, first with dimethyl formamide (50 ml) and then with chloroform (50 ml). Potassium cyanide (1 %, 500 ml) was added to the combined solutions, which were then extracted with chloroform (3 × 100 ml). The combined chloroform solutions were washed with water (3 × 500 ml) and concentrated to a syrup. This was dissolved in a mixture of sulphuric acid (1 %, 70 ml) and ethanol (30 ml) and heated on the steam bath for 1 h after which the ethanol was distilled off and heating was continued for a further 3 h. Neutralisation with barium carbonate, filtration and concentration yielded a slightly yellow syrup (3.2 g). The syrup was fractionated on a cellulose column (80 × 4 cm), using butan-1-ol, saturated with water as solvent. The main fraction (2.6 g) gave chromatographically and electrophoretically pure 3-*O*-benzyl-D-glucose, which could be crystallised from acetone. The yield of crystalline product, m. p. 137—138°, was 2.08 g. The $R_{Gluc.}$-value was 5.5.

4-O-Benzyl-D-glucose. Methyl 2,3,4-tri-*O*-acetyl-β-D-glucopyranoside (3 g) was dissolved in dimethyl formamide (30 ml) and benzylated with benzyl bromide (12 ml) and silver oxide (12 g) as described above. The resulting syrup was deacetylated with catalytic amounts of sodium ethoxide in ethanol, hydrolysed with 8 % sulphuric acid at 100°C for 4 h, neutralised with barium carbonate and then concentrated. The mixture of free sugars gave three spots on paper electrophoresis, with M_G values 0.17, 0.66 (elongated spot) and 1.0. Filtration through a column (30 × 1.2 cm) of Amberlite IR 400 in the borate state removed the two components with the higher M_G values. The component which passed through the column (0.90 g) was chromatographically and electrophoretically pure and could be crystallised from butan-2-one. Three crystallisations yielded the pure substance (0.62 g), m. p. 178—179°, $[\alpha]_D^{20}$ +52° (c = 2.0, in water). On periodate oxidation, using 0.04 N sodium metaperiodate at room temperature for 48 h, it consumed 2.92 moles of oxidant. In a parallel experiment, 1.91 moles of formic acid were formed. The $R_{Gluc.}$ value was 5.2. (Found: C 56.1; H 6.59. Calc. for $C_{13}H_{18}O_6$: C 57.6; H 6.68.)

2-*O*-Methyl-D-glucose, 3-*O*-benzyl-D-glucose and 4-*O*-benzyl-D-glucose were dissolved in saturated aqueous calcium hydroxide and kept at room temperature. The disappearance of sugar and the formation of acids was followed by paper electrophoresis in borate buffer (pH 10) and in acetate buffer (pH 4.5), using anisidine hydrogen chloride for the former and silver nitrate-sodium ethoxide for the latter as spraying reagents. The acids formed had the same electrophoretic mobilities as *meta*- and *iso*saccharinic acid, respectively, but were not further characterized. After 3 days most of the 3-*O*-benzyl ether and about half of the 4-*O*-benzyl ether were degraded into acids. After 5 days most of the latter was also degraded. The 2-*O*-methyl-D-glucose was quite stable.

Short Communications

Separation on a Preparative Scale of Amino Acids from a Protein Hydrolysate

ÖRN WAHLROOS and HARING LAND

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

In the course of a feeding experiment with cows, the ^{15}N content of amino acids of milk proteins had to be estimated [1]. Since the heavy isotope was expected to occur in low concentrations, it was intended to perform all measurements on relatively large amounts of nitrogen (approx. 2 mg). This quantity allows some 5 or 6 measurements to be made per sample with a high accuracy. For this purpose a separation of the amino acids was attempted on a preparative scale.

The milk protein precipitated with 15 % TCA was dialyzed, freeze-dried, extracted with ether in order to remove fatty material, and hydrolyzed with 6 N hydrochloric acid at 105°C for 24 h. Since the "humine" retained part of the amino acids, it was extracted twice with boiling water. The mixture was freed from HCl by adsorption on IR-120 and elution with piperidine [2].

The hydrolyzate from 7 g of protein, dissolved in 50 ml of 0.5 N acetic acid was poured onto a column of Dowex 1-X8 [3] with a cross-sectional area of 12.5 cm², and a height of 30 cm. The flow rate was 40 ml/h and fractions of a volume of 15 ml were collected (Fig. 1).

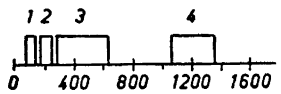

Fig. 1. Elution of the Dowex 1 column. (1) Neutral and basic amino acids; (2) Tyr; (3) Glu; (4) Asp.

The neutral and basic amino acids from the Dowex 1 column were rechromatographed on a Dowex 50-X4 column [3] with a cross-sectional area of 50 cm² and a height of 80 cm. First, the column was eluted with 4 800 ml of 1 N hydrochloric acid. Then gradient elution was applied, the gradient being of the shape [4]

$$C = C_2 - (C_2 - C_1)\,(1 - v)^{A_2/A_1}$$

where $A_1 = A_2$; A_1 and C_1 correspond to the cross-sectional area and the concentration of the mixing chamber, A_2 and C_2, respectively, to the vessel containing the hydrochloric acid of the higher concentration. The total volume of the system was 11 litres; C_1 = 1 N HCl, C_2 = 4 N HCl. In order to obtain an approximately constant gradient, A_2 and C_2 were changed to respectively $A_1/5.7$ and 5 N HCl when v/V had reached the value 0.8, v standing for the volume delivered, and V for the total volume of the system.

The column was closed with a rubber stopper through which a glass tube, adjustable in height, reached down to about 1 cm above the level of the resin. Since it was considered advisable to avoid another mixing of eluents of different strengths in the

volume above the resin, this volume was kept at a minimum. This was achieved by application of a pressure equivalent to the difference in level between the mixing chamber and the top of the resin, *via* a side tube to the air space above the resin before the eluent was allowed to flow into the column. The flow rate was continuously kept at 108 ml/h by means of a capillary. The results are plotted in Fig. 2. Phenylalanine and arginine were separated on a cellulose column.

Purity of compounds rather than a high yield was the main aim in the separation. From Table 1 the total yield from 7 g of protein is seen to be about 40 %.

Crystalline Leghemoglobin

NILS ELLFOLK*

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

The red pigment from the soya bean root nodules was first demonstrated by Kubo [1] to have a hemoglobin nature. Ellfolk and Virtanen [2] showed that this pigment was not electrophoretically homogeneous after repeated ammonium sulphate fractionations, but contained two hemin components which seemed to occur in approximately equal concentrations. This was recently confirmed by Thorogood [3] who also found a third component in addition to the above two components and possibly a fourth.

Studying different techniques the present author has found that a cellulose ion exchange column was the most convenient one to separate these different hemin components. Diethylaminoethylcellulose according to Peterson and Sober [4] was used as adsorbent. The preparation of the individual components in this way was as follows:

After crushing the nodules, leghemoglobin was extracted twice into distilled water and fractionated once with ammonium sulphate between 55–80 % saturation (23°C). After dialysis against phosphate buffer (pH 8) and then against distilled water the protein solution was put on a cellulose ion exchange (DEAE-SF) column buffered to pH 5.2 with an acetate buffer of ionic strength 0.01 μ. All the hemin proteins remain on the top of the column as a sharp band. By elution with an acetate buffer (pH 5.2, μ = 0.01) one component moved down the column. This component was found to be the electrophoretically slowest one. Using buffer of this ionic strength the other components hardly moved at all and therefore, in order to increase the elution speed, the ionic strength of the acetate buffer was increased to 0.02 μ or 0.03 μ by addition of sodium chloride.

The second component was found to be the electrophoretically faster component. Between these two bands moved a faint, broad band which electrophoresis showed to be a mixture of several proteins with no

distinct peaks. It evidently contained parts of the first and second components and also some oxidized component (choleglobin). This component was too small to allow any decision whether it contained a distinct new fraction or not. After the second band a fourth small band was eluted, which separated distinctly and the mobility of which in electrophoresis was found to be slightly higher than that of the main fast component. All the spectra of these three components showed the acid hemiglobin nature of the components.

On the top of the column there still remained a brown band which did not move though the ionic strength was increased. It was partially eluted by 3 M NaCl and its spectrum did not show any maxima or minima but the absorption increased steadily toward the ultraviolet. This component was therefore assumed to be a denaturation product of the hemin proteins.

The two main components were homogeneous in the ultracentrifuge and their sedimentation constants were the same, about 1.9 *S*. They were also homogeneous in long run electrophoresis at two different pH values, *i. e.* pH 6.1 and 9.0. The iron content of the two fractions was slightly different, the electrophoretically faster one had an iron content of 0.320 % and the electrophoretically slower one a value of 0.287 % of iron per dry weight. The diffusion coefficient $D_{20°}$ of the fast component was found to be about 11.1 *F* and that of the slower one about 8.5 *F*. On the basis of iron content the fast component has a molecular weight of 17 500 and the slower one 19 500. It is evident that the faster component is not far from spherical in shape, whereas the slower one is somewhat assymetric or highly hydrated.

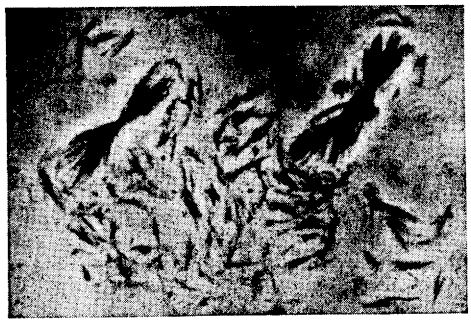

Fig. 1. Crystalline leghemoglobin, faster component, 1 130 ×.

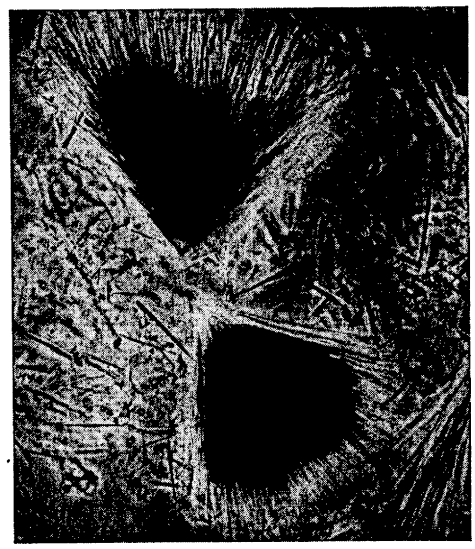

Fig. 2. Crystalline leghemoglobin, slower component, 230 ×.

Ellfolk and Virtanen [2] assumed that the slower component was not a homogeneous protein but probably an artefact of the faster component adsorbed to a neutral or basic protein. From these findings it is evident that this assumption was not correct.

Both the components were found to crystallize from ammonium sulphate solutions, 0.65 saturation, at slightly acid pH (4.8 and 4.7). Fig. 1 shows the crystals of the faster component and Fig. 2 those of the slower one.

A detailed report on these findings will be given in this journal.

Isolation of Palustric Acid from Tall Oil Rosin by Partition Chromatography *

HENRIK H. BRUUN and STEIN GÅSLAND

The Institute of Wood Chemistry, Åbo Akademi, Åbo, Finland

In 1954 Loeblich, Baldwin and Lawrence isolated a new rosin acid of the abietic series from gum and wood rosins of two American pine species; the new acid they named palustric acid [1]. In this isolation the authors employed, with minor modifications, the chromatographic method developed by Ramsay and Patterson [2] for the separation of straight-chain fatty acids. We have applied the same method to isolate the components of Finnish tall oil rosin and have also found palustric acid among the rosin acids and in amounts of 14—15 % of the total rosin acids in the tall oil rosin. In the light of previous analytical data for tall oil rosins (see references in Ref.[3]), this finding is surprising and of significance from the standpoint of the industrial utilization of tall oil rosin.

By means of the chromatographic technique we were able to separate the components of artificial binary, ternary and quaternary mixtures of rosin acids in the following order (the volume given is peak volume of the eluant): tetrahydroabietic acid 95 ml, dihydroabietic acid 150 ml, palustric acid 190 ml, dextropimaric acid 225 ml, *iso*dextropimaric acid 225 ml, *l*-abietic acid 240 ml, levopimaric acid 285 ml, neoabietic acid 360 ml, dehydroabietic acid 490 ml. As will be noted, the hydrogenated rosin acids are eluted first, followed by palustric acid which is clearly separated from these acids and from dextro- and *iso*-dextropimaric acids and *l*-abietic acid, which are eluted next. It was found that when the abietic acid content was many times as large as the pimaric acid content, the peak for dextropimaric acid was not separated from the abietic acid peak but merged with the latter so that the peak for abietic acid was wider at the left face in the chromatogram. Likewise levopimaric acid expanded the right face of the peak for abietic acid when the levopimaric acid content was much lower than the abietic acid content. The next fraction eluted consists of neoabietic acid and this is clearly separated from dehydroabietic acid which follows it. These observations are in essential agreement with the findings of Loeblich, Baldwin and Lawrence [1].

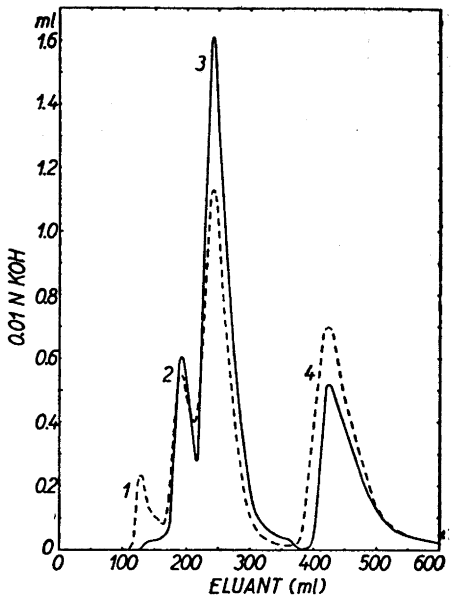

Fig. 1. Chromatogram of tall oil rosin showing the presence of palustric acid (peak 2). Ordinate: consumption of 0.0100 N alcoholic potassium hydroxide in titration of 5 ml eluant volumes (phenolphthalein as indicator). Sample *a* (———), tall oil rosin obtained by continuous distillation. Sample *b* (— — —), tall oil rosin obtained by batch distillation. For the other peaks, see text.

The chromatograms of two samples of crystalline tall oil rosins distilled by different methods are shown in Fig. 1. The samples have yielded chromatograms with four peaks. The first of these coincides with an eluant volume of 130 ml and according to the peak volumes given consists of hydrogenated rosin acids (which are present in only small quantities in sample *a*). The second peak at 190 ml lies at the peak volume for palustric acid. The third, the largest peak, undoubtedly refers to abietic acid and any small amounts of pimaric acids possibly present. We

* Paper read at the annual meeting of Finska Kemistsamfundet — Suomen Kemistiseura on December 8, 1958.

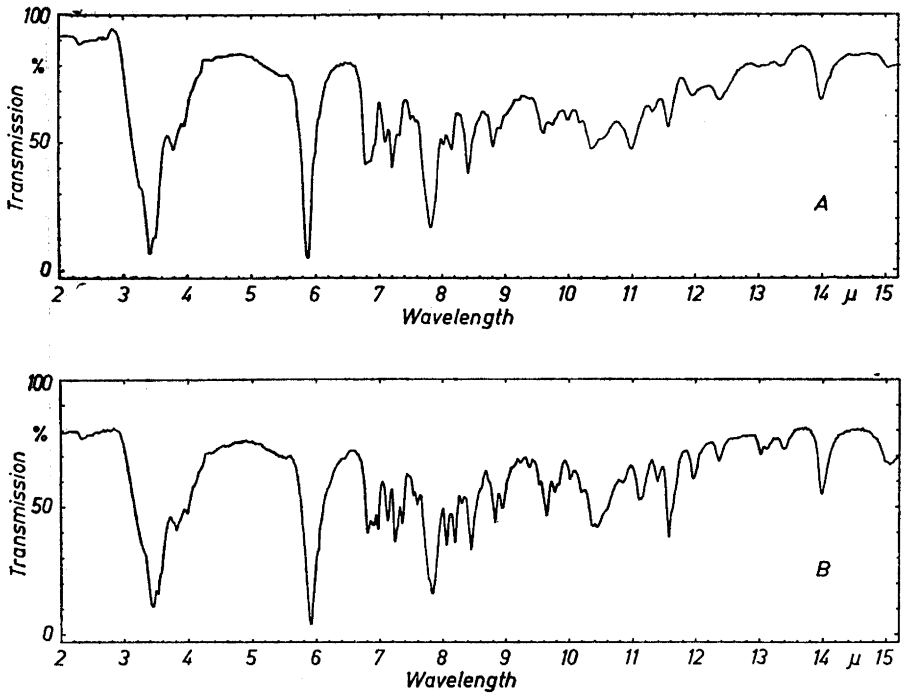

Fig. 2. Infrared absorption spectra of (A) palustric acid isolated from tall oil rosin sample *a* (peak 2 in curve for sample *a* in Fig. 1) and (B) authentic palustric acid.

have found that the addition of dextropimaric acid in an amount corresponding to 8 % of the abietic acid content to an artificial mixture of palustric and *l*-abietic acids in the proportions corresponding to those of the acids yielding peaks 2 and 3 in Fig. 1 leads to a filling up of the area between the peaks for palustric and *l*-abietic acids in the chromatogram. The dextropimaric acid contents of samples *a* and *b* are hence according to Fig. 1 in all probability less than 8 % of the abietic acid content. The shoulder at 360 ml in the chromatogram of sample *a* coincides with the peak volume of neoabietic acid. The fourth peak at 425 ml appears appreciably earlier than the peak for dehydroabietic acid in the chromatogram of the artificial mixture. The tall oil rosin thus evidently contains dehydrogenated rosin acids that differ in type from the dehydrogenated acids in the artificial mixture. The amounts of material in the peaks of the chromatogram are given in Table 1. The material of peak 2, which in view of its location in the chromatogram refers to palustric acid, represents 14—15 % of the rosin acids in both samples.

Table 1. Rosin acid contents (in g.equiv.) in peaks 1—4 in Fig. 1 as percentages of the total content of eluted rosin acids computed from the areas under the peaks.

Peak No.	Sample *a*	Sample *b*
1	< 1 %	5 %
2	14 »	15 »
3	58 »	41 »
4	27 »	39 »

In order to confirm the identity of the palustric acid (peak 2), chromatography of tall oil rosin (sample *b*) was carried out on a ten times larger scale than the above separations to obtain enough of the acid to permit the measurement of its infrared absorption. Although it was not possible

to carry out six recrystallizations from methanol as Loeblich, Baldwin and Lawrence [1] had done to obtain a constant specific rotation and melting point, but only one, the similarity of the recorded infrared absorption spectra reproduced in Fig. 2 clearly indicates that the isolated rosin acid of peak 2 consisted of palustric acid. It may be noted that the band at 12.37 μ is specific for palustric acid when the absorptions of the other rosin acids for which the eluant peak volumes were determined are taken into account (*cf.* Refs.[3-5]).

The infrared absorption spectra of rosin acid fractions of crystalline tall oil rosin (of the same origin as sample *b*) recorded by Bruun and Jalava [6] contained bands due to *l*-abietic and dehydroabietic acid but no bands characteristic of tetrahydroabietic, dihydroabietic and dextro- and *iso*dextropimaric acids (acc. to Refs.[3-4]). The chromatographic data obtained in the present study are in agreement with these observations. It may be difficult to determine from their infrared absorption the identity of the substances yielding peak 1 which amount to 5 % of the rosin acid mixtures and which possibly consist of isomeric rosin acids. This may be true also for dextropimaric acid when its content is as low as in the samples studied (according to the chromatograms of rosin acid mixtures, its content is less than 4 % of the total acids, and according to chromatograms of tall oil rosin samples from which the major part of the *l*-abietic acid was precipitated with diamylamine before chromatography, at the most 4—5 % of the total acids). — The infrared absorption spectrum of palustric acid, which spectrum was not known when the previous infrared absorption study was carried out, has its strongest bands at 8.46, 8.83, 9.65, 10.38 + 10.44, 11.11, 11.57, 11.97, 12.37 and 13.98 μ [5]. With the exception of the band at 12.37 μ, the strong and moderate bands are seen at or close to the same wavelengths as in the spectra of *l*-abietic and dehydroabietic acids, the two major components of tall oil rosin (*cf.* Refs. [3-4]). For this reason, it is difficult to detect from infrared spectra even relatively high contents of palustric acid in mixtures containing these acids. The content of 14—15 % of palustric acid deduced from the chromatographic analysis of the tall oil rosin is thus not necessarily at variance with the results of the infrared spectral studies of tall oil rosin acids [6].

Chromatographic data. Column diameter (inside): 11 mm. Adsorbent: 15.0 g of Mallinckrodt's silicic acid, A.R. Immobile solvent: 9 ml of a mixture of equal parts of furfuryl alcohol (B.D.H., technical, vacuum distilled after treatment with sodium hydroxide) and 2-aminopyridine (B.D.H., Laboratory Reagent). Eluting solvent: 2,2,4-trimethylpentane (B.D.H., Laboratory reagent): purified by distillation and passage through a column of aluminium oxide and saturated before use with the immobile solvent. The fraction volume was 5 ml. Data relating to the acid samples examined will be given in a forthcoming publication.

The authors are indebted to Mrs Karin Nilsson, Department of Medical Biochemistry, Institute of Medical Chemistry, Uppsala University, Uppsala, Sweden, for the recording of the infrared absorption curves and to Dr. E.L. Patton, Naval Stores Research Section, Olustee, U. S., for a sample of palustric acid. One of the authors (S.G.) has received a grant from the *Royal Norwegian Council for Science and Industrial Research*, which is gratefully acknowledged.

Fractionation of Alginic Acid

ARNE HAUG

Norwegian Institute of Seaweed Research, Trondheim, Norway

Up to recently, it was generally accepted that alginic acid was a linear polymer of anhydro-β-D-mannuronic acid [1]. In 1955, however, Fischer and Dörfel [2] reported the presence of guluronic acid in hydrolysates of alginic acid. The proportion of the two uronic acids varied with the species. It has not been decided whether the alginic acid in a particular seaweed plant is a homogeneous compound, or whether it is a mixture of chain molecules of different uronic acid composition. Methods for investigation of the homogeneity of alginic acid are therefore of considerable interest.

Recently McDowell [3] reported that precipitation with manganous salts separated alginate into two fractions which not only differed markedly in molecular weight, but also seemed to differ with respect to calcium-sodium ion exchange properties. He did not investigate the uronic acid composition of the fractions.

During an investigation in this laboratory of the solubility of alginates it was observed that alginate could be separated into two fractions by salt solutions.

Materials and methods. All seaweed samples used contain at least 50 plants, collected at the same time, and from a small area. The plants are dried at room temperature and ground. Fucoidin and laminarin are removed by extraction overnight with 0.2 N sulphuric acid and the alginate is extracted by shaking the seaweed samples with 3 % sodium carbonate solution at room temperature. After filtration, the alginate is precipitated by addition of alcohol to about 30 %. The precipitated sodium alginate is washed with alcohol, and the excess alcohol pressed out. The alginate sample, which contains 60—80 % alcohol, is shaken with the salt solution for 2—3 h, left overnight, shaken again for about one hour, and then centrifuged. The volume of salt solution is chosen so that the alginate concentration is approximately 0.3 %. The gel brought down by centrifugation is washed with half the original amount of salt solution. The amounts of alginate in the gel and the solution are determined gravimetrically after precipitation with alcohol and washing with alcohol and ether.

The solubility of alginate from *Laminaria digitata* f. *stenophylla* (collected at Tarva, outside the Trondheimsfjord, 3/7 1957) in potassium chloride solutions of different strengths was investigated, and the results are given in Fig. 1. Approximately one third of the alginate is soluble and two thirds insoluble in solutions which contain between 0.6 and 1 N potassium chloride, and the shape of the curve gives evidence for the presence of two different compounds.

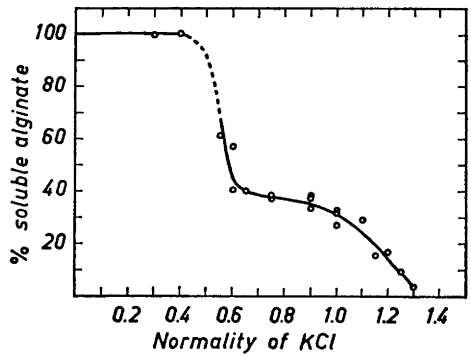

Fig. 1.

The soluble and insoluble fractions of the alginate were shaken with potassium and sodium chloride solutions of the same strength as those used in the original fractionation, and with a volume chosen to give the same alginate concentration. The results are given in Table 1 and show that there is a marked difference between the two fractions with respect to solubility in salt solutions.

Table 1.

Solvent	1st fractionation		2nd fractionation	
			Soluble	Insoluble
1 N NaCl	Soluble	29 %	84 %	16 %
	Insoluble	71 »	12 »	88 »
1 N KCl	Soluble	31 %	100 %	0 %
	Insoluble	69 »	3 »	97 »

Table 2.

	Precipitated, % 2.3 N KCl	Undissolved, % 0.75 N KCl	Undissolved, % 1.0 N KCl
L. digitata, Tarva 3/7—57	69	63	70
Ascophyllum nodosum, Lysøysund 17/9—58	58	55	60
L. hyperborea, Munkholmen 26/8—57			
Fronds	54	45	76
Stipes	—	10	27

The comparatively sharp fractionation makes it improbable that the separation is solely due to a difference in molecular weight. Determinations of viscosity gave an "apparent intrinsic viscosity" determined in a Höppler Viscometer [4] of 17.1, 18.5 and 19.3 $dl \cdot g^{-1}$ for the soluble fraction, the unfractionated alginate, and the insoluble fraction, respectively. A small part of the same *Laminaria digitata* sample as that used above was heated for 15 min to 120°C after the dry matter content had been adjusted to 60 %. The intrinsic viscosity of the alginate was thus reduced to 5.5 $dl \cdot g^{-1}$. In 1 N potassium chloride 45 % of this alginate was insoluble. These observations clearly indicate that the basis of the separation of the fractions in this way is not primarily one of molecular weight differences.

If potassium chloride was added to an alginate solution, no precipitation occurred at salt concentrations below 1.5 N. If, however, a 0.3 % solution of the *Laminaria digitata* alginate was rapidly mixed with equal volumes of saturated (4.65 N) potassium chloride, a gel-like precipitate was formed. The precipitate could be removed from the solution by centrifugation. In Table 2, the percentage of precipitated alginate is given, together with the percentage of alginate which was not dissolved in potassium chloride solution of two different strengths.

In stipes of *Laminaria hyperborea*, the gel that was formed could not be separated from the solution, even by prolonged centrifugation at 20 000 *g*. In the three other cases, the precipitated amount was approximately equal to the amount that was not dissolved in potassium chloride solution of a strength between 0.75 and 1 N. It was also shown that of the fraction that was precipitated only traces could be dissolved in 1 N potassium chloride solution, while the total amount dissolved of the fraction that was not precipitated. Fractionation by precipitation and by dissolution seems, therefore, to give the same fractions.

Alginate from *Laminaria digitata* was hydrolysed according to the method of Fischer and Dörfer [1]. Paper chromatograms of the uronic acids gave two spots with R_G values of 0.38 and 0.32, respectively, in pyridine:ethylacetate-acetic acid: water, 5:5:1:3. Chromatograms of the lactones gave two spots with R_F values 0.53 and 0.77 in pyridine:ethylacetate:water, 11:40:6. According to Fischer and Dörfel these correspond well with the movements of mannuronic and guluronic acids and their lactones. No attempts have been made to determine the uronic acids quantitatively, but on the basis of the size and intensity of the uronic acid spots, there appears to be about three times as much mannuronic as guluronic acid; this is as reported by Fischer and Dörfel.

The fractions separated by precipitation with potassium chloride solution, as described above, were hydrolysed and chromatographed. In both cases two spots with the same R_G values as those found for the unfractionated sample were observed on the uronic acid chromatograms. In the soluble fraction, however, the two spots were of approximately the same strength, while the spot corresponding to guluronic acid was weaker in the insoluble fraction than in the unfractionated sample. Even after five reprecipitations with potassium chloride solution a weak spot corresponding to guluronic acid could be observed in hydrolysates of the insoluble fraction.

The results show that alginic acid in *Laminaria digitata* is a heterogeneous compound, and can be separated into fractions which differ in solubility properties and in uronic acid composition.

The work is being continued and a detailed report will be published later.

Note on the Crystal Structure of Trivanadium Pentoxide

STIG ÅSBRINK, STIG FRIBERG and ARNE MAGNÉLI

Institute of Inorganic and Physical Chemistry, University of Stockholm, Stockholm, Sweden

and

GEORG ANDERSSON

Institute of Chemistry, University of Uppsala, Uppsala, Sweden

The existence of a vanadium oxide V_3O_5 has been reported in a previous communication [1]. The compound was found to be monoclinic with the symmetry $C2/c$ or Cc and with the unit cell dimensions

$$a = 9.98 \text{ Å}, \quad b = 5.03 \text{ Å}, \quad c = 9.84 \text{ Å}, \quad \beta = 138.8°.$$

Slight deviations in the parameter values have been observed indicating that the range of composition of the oxide has a finite width.

The observed density of 4.6 is in accordance with a unit cell content of 4 units of V_3O_5 (calculated density 4.75).

The crystal structure has been derived on the basis of single-crystal data registered by one of us (G.A.) using MoK radiation. The following preliminary parameter values were thus obtained:

12 V and 20 O in 8 sets of point positions 4(a) of space-group Cc (No. 9): (0,0,0; $\frac{1}{2},\frac{1}{2},0$) + x,y,z; $x,\bar{y},\frac{1}{2}+z$.

4 V_1:	$x = 0.088$,	$y = 0.250$,	$z = 0.464$
4 V_2:	$x = 0.412$,	$y = 0.250$,	$z = 0.536$
4 V_3:	$x = 0.000$,	$y = 0.750$,	$z = 0.250$
4 O_1:	$x = 0.04_4$,	$y = 0.60$,	$z = 0.10_2$
4 O_2:	$x = 0.13_9$,	$y = 0.10$,	$z = 0.31_1$
4 O_3:	$x = 0.36_1$,	$y = 0.90$,	$z = 0.18_9$
4 O_4:	$x = 0.45_6$,	$y = 0.40$,	$z = 0.39_8$
4 O_5:	$x = 0.25_0$,	$y = 0.40$,	$z = 0.00_6$

The arrangement of the metal atoms is centrosymmetrical ($C2/c$) while that of the oxygen atoms (derived by S.Å.) is not.

The structure is built up of VO_6 octahedra which are mutually joined by sharing corners, edges and faces. By means of the latter kind of connection, "double-octahedra" (containing V_1 and V_2 atoms) result which are similar to those occurring in the corundum-type structures, *e. g.* V_2O_3. The "double-octahedra" are mutually joined by edges to form parallel rows extending infinitely through the structure. These rows are coupled together by "single-octahedra" (containing V_3 atoms). The V—V distance of octahedra joined by faces is 2.74 Å, while the V—V distances of octahedra sharing edges are 2.96 and 3.10 Å. The V—O and O—O distances, which so far are less accurately known, occur within the ranges 1.9—2.2 and 2.5—3.1 Å, respectively. Refinement of the structure is in progress.

X-Ray studies at temperatures up to 1 000°C did not show any indications of phase transformations in V_3O_5.

The structure of V_3O_5 is essentially different from those of low- and high-Ti_3O_5 [2]. The V_3O_5 structural type has, however, been found to be present in a phase $TiCr_2O_5$ obtained in low yield by melting a mixture of the pure oxides in an electric arc furnace under an inert atmosphere [3]. (This phase seems to be stabilized by minor contents of aluminium.)

This investigation has been sponsored in part by the *Swedish Natural Science Research Council* and in part by the *Office, Chief of Research and Development, U.S. Department of Army,* through its European Office.

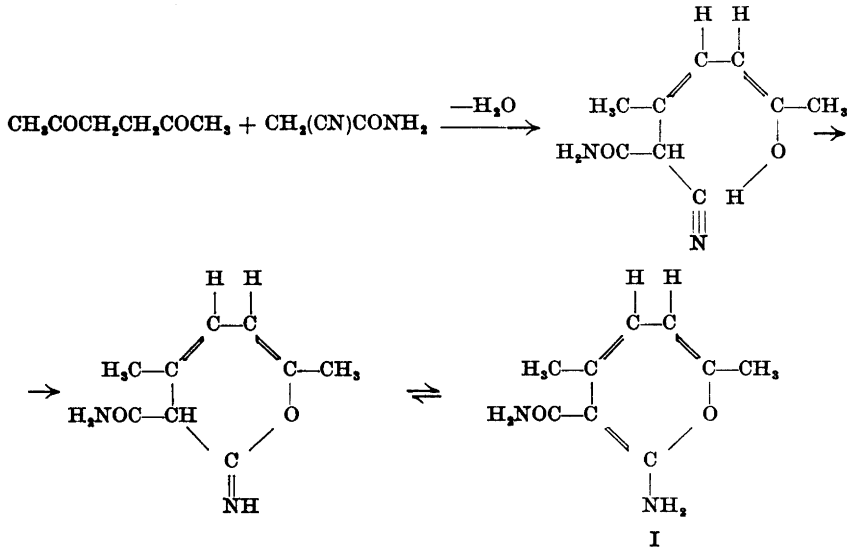
The Preparation of an Oxa*cyclo*heptatriene

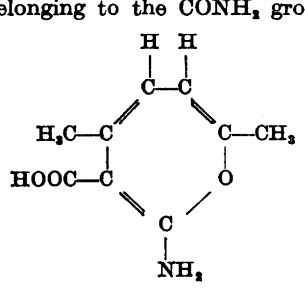
GUNNEL WESTÖÖ

Institute of Organic Chemistry, University of Lund, Lund, Sweden

In alkaline solution acetonylacetone reacts with cyanoacetamide with formation of a seven-membered ring, 2-amino-4,7-dimethyloxepine-3-carboxamide (I), according to the equation:



I is a weak base and can be titrated with perchloric acid in anhydrous medium. The structure I of the compound is supported by its IR spectrum, which has no nitrile band and only one C=O band at 1 670 cm^{-1}, belonging to the $CONH_2$ group.



II

When I is boiled with concentrated hydrochloric acid, the amide group is hydrolysed, the amino acid II being formed.

Experimental. Preparation of 2-amino-4,7-dimethyloxepine-3-carboxamide (I). Acetonylacetone (5.0 g) and cyanoacetamide (3.75 g) were dissolved in alkaline ethanol (10 ml of ethanol and 5 ml of 2.4 N sodium hydroxide solution) and allowed to stand overnight. The slightly yellow crystals formed were filtered and washed with 50 % ethanol. Yield 2.3 g. The product can be recrystallized from ethanol. M. p. about 222° (decomp.). (Found: C 60.0; H 6.7; N 15.4; O 17.7; equiv. wt. on titration with perchloric acid in acetic acid — chlorobenzene solution using methyl violet as indicator: 181. Calc. for $C_9H_{12}N_2O_2$: C 60.0; H 6.7; N 15.5; O 17.8; equiv. wt. 180.) UV absorption: $\lambda_{max.}$ = 233, 277 and 345 mμ.

Hydrolysis of I to form 2-amino-4,7-dimethyloxepine-3-carboxylic acid (II). A solution of I (5.0 g) in concentrated hydrochloric acid (75 ml) was boiled for 30 min. The acid was evaporated under reduced pressure and the dry residue was treated with water (75 ml). Sodium acetate solution was added until pH about 3 to make the precipitation of II complete. The precipitate was filtered and washed with water and ethanol. Yield 0.8 g. The product was purified by extraction of by-products with boiling ethanol for half a minute

and by recrystallization from ethanol (solution in excess of hot ethanol as rapidly as possible and evaporation of part of the solvent under reduced pressure to avoid decomposition by heat). M. p. 149° (decomp.). (Found: C 59.8; H 6.2; N 7.8; O 26.3; equiv.wt. by titration using thymolphthalein as indicator: 181. Calc. for $C_9H_{11}NO_3$: C 59.7; H 6.1; N 7.7; O 26.5; equiv.wt. 181.) The IR curve shows amino and carboxyl bands. UV absorption: $\lambda_{max.}$ = 235, 284 and 350 mμ.

o-Methoxybenzhydrol

GUST.-AD. HOLMBERG

Institutet för organisk kemi, Åbo Akademi, Åbo, Finland

o-Methoxybenzhydrol has been prepared by Stoermer and Friderici [1] by reacting *o*-methoxybenzaldehyde with phenylmagnesium iodide. Kahil and Nierenstein [2], who verified the results of Stoermer and Friderici, obtained the compound also by reduction of *o*-methoxybenzophenone. In both cases the melting point was reported to be 141°. Martynoff [3], who synthesized *o*-methoxybenzhydrol from *o*-methoxybenzaldehyde and phenylmagnesium iodide, did not report any melting point but used the crude product for the preparation of bis-*o*-methoxybenzhydryl ether.

When the experiment of Stoermer and Friderici was repeated in this laboratory with *o*-methoxybenzaldehyde and phenylmagnesium bromide the statements as to the melting point of *o*-methoxybenzhydrol could not be verified. Instead of a solid substance, an oil, b.p. 181—182°/8 mm, was obtained. The same substance was formed when *o*-methoxybenzophenone was reduced with zinc in alkaline ethanol. The identity of the oil with *o*-methoxybenzhydrol was established by preparing its 3,5-dinitrobenzoic acid by oxidizing it to *o*-methoxybenzophenone.

o-Methoxybenzhydrol can be heated in boiling xylene for several hours without any change. However, if a minute quantity of an acid is added to the solution, the substance is rapidly and quantitatively converted into bis-*o*-methoxybenzhydryl ether, m. p. 137—137.5°. This property seems to be the reason for the incorrect melting points reported previously.

When the products of the reaction between *o*-methoxybenzaldehyde and phenylmagnesium bromide were decomposed with ice and hydrochloric acid, a small quantity of bis-*o*-methoxybenzhydryl ether was isolated in spite of the fact that the reaction products were almost immediately treated with a potassium carbonate solution. If the decomposition was effected by adding ammonium chloride solution, the yield of the alcohol was slightly greater and no ether could be isolated. These observations demonstrate the instability of the alcohol towards acids.

Considering the difference in stability in the presence and absence of acids, it seems probable that the crude *o*-methoxybenzhydrol that Martynoff used in his synthesis of bis-*o*-methoxybenzhydryl ether contained a small quantity of acid.

Experimental. To a cooled Grignard reagent prepared from magnesium (3.60 g) and bromobenzene (23.55 g) in dry ether (60 ml), *o*-methoxybenzaldehyde (13.60 g) in dry ether (50 ml) was gradually added. After the mixture had been warmed in a water bath for 15 min, the products were decomposed by pouring them into a mixture of ice and dilute hydrochloric acid. The ether phase was thoroughly washed with water and a dilute potassium carbonate solution. After drying with sodium sulphate, the ether was evaporated and the residue distilled under reduced pressure. The yield of *o*-methoxybenzhydrol, b. p. 181—182°/8 mm, was 77.5 % (16.61 g). (Found: C 78.37; H 6.45. Calc. for $C_{14}H_{14}O_2$: C 78.48; H 6.59.)

The residue in the distillation flask was dissolved in a small quantity of ethanol. After a while bis-*o*-methoxybenzhydryl ether (1.26 g) crystallized. It melted after recrystallization from ethanol at 137—137.5°.

When the decomposition of the reaction products was effected with ammonium chloride solution, the yield of the alcohol was almost 80 % (17.04 g) and no bis-*o*-methoxybenzhydryl ether could be isolated. In this case the washing with potassium carbonate solution was omitted.

A sample of *o*-methoxybenzhydrol was treated with the equivalent quantity of 3,5-dinitrobenzoyl chloride in benzene and pyridine. After the solution had stood for several hours, the precipitate was filtered off and the filtrate washed with water, dilute hydrochloric acid,

and by recrystallization from ethanol (solution in excess of hot ethanol as rapidly as possible and evaporation of part of the solvent under reduced pressure to avoid decomposition by heat). M. p. 149° (decomp.). (Found: C 59.8; H 6.2; N 7.8; O 26.3; equiv.wt. by titration using thymolphthalein as indicator: 181. Calc. for $C_9H_{11}NO_3$: C 59.7; H 6.1; N 7.7; O 26.5; equiv.wt. 181.) The IR curve shows amino and carboxyl bands. UV absorption: $\lambda_{max.}$ = 235, 284 and 350 mμ.

The financial support of *Statens naturvetenskapliga forskningsråd* is gratefully acknowledged.

When the experiment of Stoermer and Friderici was repeated in this laboratory with *o*-methoxybenzaldehyde and phenylmagnesium bromide the statements as to the melting point of *o*-methoxybenzhydrol could not be verified. Instead of a solid substance, an oil, b.p. 181—182°/8 mm, was obtained. The same substance was formed when *o*-methoxybenzophenone was reduced with zinc in alkaline ethanol. The identity of the oil with *o*-methoxybenzhydrol was established by preparing its 3,5-dinitrobenzoic acid by oxidizing it to *o*-methoxybenzophenone.

o-Methoxybenzhydrol can be heated in boiling xylene for several hours without any change. However, if a minute quantity of an acid is added to the solution, the substance is rapidly and quantitatively converted into bis-*o*-methoxybenzhydryl ether, m. p. 137—137.5°. This property seems to be the reason for the incorrect melting points reported previously.

When the products of the reaction between *o*-methoxybenzaldehyde and phenylmagnesium bromide were decomposed with ice and hydrochloric acid, a small quantity of bis-*o*-methoxybenzhydryl ether was isolated in spite of the fact that the reaction products were almost immediately treated with a potassium carbonate solution. If the decomposition was effected by adding ammonium chloride solution, the yield of the alcohol was slightly greater and no ether could be isolated. These observations demonstrate the instability of the alcohol towards acids.

Considering the difference in stability in the presence and absence of acids, it seems probable that the crude *o*-methoxybenzhydrol that Martynoff used in his synthesis of bis-*o*-methoxybenzhydryl ether contained a small quantity of acid.

Experimental. To a cooled Grignard reagent prepared from magnesium (3.60 g) and bromobenzene (23.55 g) in dry ether (60 ml), *o*-methoxybenzaldehyde (13.60 g) in dry ether (50 ml) was gradually added. After the mixture had been warmed in a water bath for 15 min, the products were decomposed by pouring them into a mixture of ice and dilute hydrochloric acid. The ether phase was thoroughly washed with water and a dilute potassium carbonate solution. After drying with sodium sulphate, the ether was evaporated and the residue distilled under reduced pressure. The yield of *o*-methoxybenzhydrol, b. p. 181—182°/8 mm, was 77.5 % (16.61 g). (Found: C 78.37; H 6.45. Calc. for $C_{14}H_{14}O_2$: C 78.48; H 6.59.)

The residue in the distillation flask was dissolved in a small quantity of ethanol. After a while bis-*o*-methoxybenzhydryl ether (1.26 g) crystallized. It melted after recrystallization from ethanol at 137—137.5°.

When the decomposition of the reaction products was effected with ammonium chloride solution, the yield of the alcohol was almost 80 % (17.04 g) and no bis-*o*-methoxybenzhydryl ether could be isolated. In this case the washing with potassium carbonate solution was omitted.

A sample of *o*-methoxybenzhydrol was treated with the equivalent quantity of 3,5-dinitrobenzoyl chloride in benzene and pyridine. After the solution had stood for several hours, the precipitate was filtered off and the filtrate washed with water, dilute hydrochloric acid,

and dilute potassium carbonate solution. After drying with sodium sulphate, most of the benzene was distilled off and the residue dissolved in ether. The solution was kept for some hours in a refrigerator and the pure crystals of 3,5-nitrobenzoic *o*-methoxybenzhydryl ester, m. p. 129—130°, that separated were isolated by filtration. (Found: N 6.71. Calc. for $C_{21}H_{16}N_2O_7$: 6.86.)

o-Methoxybenzophenone (10.36 g) was reduced with zinc (9.00 g) in a solution of potassium hydroxide (12.30 g) in water (6.4 ml) and ethanol (85 ml) according to the method previously used for the preparation of di-*o*-tolylcarbinol [4]. After the mixture had been boiled for 4 h, the excess of zinc was filtered off and the filtrate poured into a cold dilute sulphuric acid solution (4 l). The crude product was taken up in ether and the ether solution washed with dilute potassium carbonate solution. After drying with sodium sulphate, the ether was evaporated and the residue distilled under reduced pressure. The yield of *o*-methoxybenzhydrol, b. p. 181—182°/8 mm, was 82 % (8.50 g). The identity of the substance was established by preparing its 3,5-dinitrobenzoic ester, which was identical with the above *o*-methoxybenzhydryl compound.

o-Methoxybenzhydrol (11.22 g) and a minute quantity of *p*-toluenesulphonic acid (0.02 g) were dissolved in xylene (100 ml). When the solution was heated in an apparatus for the determination of water, an almost quantitative amount of water distilled within 10 min. After cooling, the solution was washed with a dilute sodium hydroxide solution and the solvent was distilled off. The residue consisting of colourless crystals of crude bis-*o*-methoxybenzhydryl ether was treated with ethanol and filtered. After recrystallization from ethanol, the substance (10.14 g) melted at 137—137.5°.

When the experiment was repeated without adding *p*-toluenesulphonic acid, no water distilled within 6 h.

o-Methoxybenzhydrol (13.96 g) was stirred with a cold solution of potassium bichromate (17.7 g) and concentrated sulphuric acid (15 ml) in water (85 ml). When the exothermic reaction was over and the mixture had cooled, it was extracted with ether. The ether solution was washed twice with water, twice with dilute potassium hydroxide, and finally twice with water. After drying with sodium sulphate, the ether was evaporated and the residue distilled under reduced pressure. The yield of *o*-methoxybenzophenone, b.p. 177—178°/12 mm, was 73 % (10.12 g). Its 2,4-dinitrophenylhydrazone, prepared according to Wild [5], melted at 173—174° or at the same temperature at which a previously obtained sample melted. By mistake the melting point of this substance was incorrectly reported previously [6].

The Estimation of Iodine in Urine

GÖSTA WIDSTRÖM and KERSTIN CLAESON

Clinical Laboratories, Centrallasarettet, Danderyd, Sweden

Recently Rodger and Poole [1] have published an investigation on the determination of small amounts of iodine in urine and other biological materials. In order to get acceptable recoveries of iodine, they find it necessary to rely on a distillation method. With a dry ashing technique, slightly modified from that of Barker, Humphrey and Soley [2] for serum, we have obtained a recovery of 96 % of iodine in urine. Our modifications are founded on the experience that the losses of iodine will be smaller when K_2CO_3 is substituted for Na_2CO_3 in the incineration mixture [3], which must have a sufficient content of carboniferous material [4].

Technique: 1 ml 30 % $Zn(Ac)_2$ + 1 ml 0.5 N NaOH are mixed in the tubes used for incineration. The precipitates are allowed to stand about 30 min and centrifuged, the centrifugate is decanted, 1 or 2 ml of the urine and 2 ml of 4 N K_2CO_3 are added and thoroughly mixed with the precipitate.

The tubes are brought in an oven at 90°C in a declined position and their content is dry after 18—20 h. They are then incinerated in a furnace at 600°C for 3 h in a horizontal position. After cooling

and dilute potassium carbonate solution. After drying with sodium sulphate, most of the benzene was distilled off and the residue dissolved in ether. The solution was kept for some hours in a refrigerator and the pure crystals of 3,5-nitrobenzoic *o*-methoxybenzhydryl ester, m. p. 129—130°, that separated were isolated by filtration. (Found: N 6.71. Calc. for $C_{21}H_{16}N_2O_7$: 6.86.)

o-Methoxybenzophenone (10.36 g) was reduced with zinc (9.00 g) in a solution of potassium hydroxide (12.30 g) in water (6.4 ml) and ethanol (85 ml) according to the method previously used for the preparation of di-*o*-tolylcarbinol [4]. After the mixture had been boiled for 4 h, the excess of zinc was filtered off and the filtrate poured into a cold dilute sulphuric acid solution (4 l). The crude product was taken up in ether and the ether solution washed with dilute potassium carbonate solution. After drying with sodium sulphate, the ether was evaporated and the residue distilled under reduced pressure. The yield of *o*-methoxybenzhydrol, b. p. 181—182°/8 mm, was 82 % (8.50 g). The identity of the substance was established by preparing its 3,5-dinitrobenzoic ester, which was identical with the above *o*-methoxybenzhydryl compound.

o-Methoxybenzhydrol (11.22 g) and a minute quantity of *p*-toluenesulphonic acid (0.02 g) were dissolved in xylene (100 ml). When the solution was heated in an apparatus for the determination of water, an almost quantitative amount of water distilled within 10 min. After cooling, the solution was washed with a dilute sodium hydroxide solution and the solvent was distilled off. The residue consisting of colourless crystals of crude bis-*o*-methoxybenzhydryl ether was treated with ethanol and filtered. After recrystallization from ethanol, the substance (10.14 g) melted at 137—137.5°.

When the experiment was repeated without adding *p*-toluenesulphonic acid, no water distilled within 6 h.

o-Methoxybenzhydrol (13.96 g) was stirred with a cold solution of potassium bichromate (17.7 g) and concentrated sulphuric acid (15 ml) in water (85 ml). When the exothermic reaction was over and the mixture had cooled, it was extracted with ether. The ether solution was washed twice with water, twice with dilute potassium hydroxide, and finally twice with water. After drying with sodium sulphate, the ether was evaporated and the residue distilled under reduced pressure. The yield of *o*-methoxybenzophenone, b.p. 177—178°/12 mm, was 73 % (10.12 g). Its 2,4-dinitrophenylhydrazone, prepared according to Wild [5], melted at 173—174° or at the same temperature at which a previously obtained sample melted. By mistake the melting point of this substance was incorrectly reported previously [6].

The Estimation of Iodine in Urine

GÖSTA WIDSTRÖM and KERSTIN CLAESON

Clinical Laboratories, Centrallasarettet, Danderyd, Sweden

Recently Rodger and Poole [1] have published an investigation on the determination of small amounts of iodine in urine and other biological materials. In order to get acceptable recoveries of iodine, they find it necessary to rely on a distillation method. With a dry ashing technique, slightly modified from that of Barker, Humphrey and Soley [2] for serum, we have obtained a recovery of 96 % of iodine in urine. Our modifications are founded on the experience that the losses of iodine will be smaller when K_2CO_3 is substituted for Na_2CO_3 in the incineration mixture [3], which must have a sufficient content of carboniferous material [4].

Technique: 1 ml 30 % $Zn(Ac)_2$ + 1 ml 0.5 N NaOH are mixed in the tubes used for incineration. The precipitates are allowed to stand about 30 min and centrifuged, the centrifugate is decanted, 1 or 2 ml of the urine and 2 ml of 4 N K_2CO_3 are added and thoroughly mixed with the precipitate.

The tubes are brought in an oven at 90°C in a declined position and their content is dry after 18—20 h. They are then incinerated in a furnace at 600°C for 3 h in a horizontal position. After cooling

the ashes are brought into solution with 5 ml 1 N HCl, cautiously added in small portions with stirring. The tubes are centrifuged. To 2 ml of the clear supernatant are added 2 ml 0.1 N arsenite and the test tubes are held for at least 15 min in a water bath at 25°C for temperature equilibration. 1 ml 0.04 N ceric ammonium sulphate solution of the same temperature is then thoroughly mixed with the contents of the tubes at a noted time and the mixture is kept in the water bath for exactly 30 min when they are read in a (Beckman B) photometer at 440 mμ against distilled water as a blank. The content of iodine is calculated from a calibration curve, plotted from readings of standard solutions.

Urine contains considerably less organic material than serum, but the basic acetate formed when $Zn(Ac)_2$ is precipitated with alkali brings up the total combustible carbon to the same values as those in serum.

Table 1. Apparent iodine content in duplicates from the same urine.

$ZnSO_4$	$Zn(Ac)_2$
3.2	4.2
4.0	4.3
3.9	4.2
4.2	4.2
3.1	

As shown in Table 1 the recovery of iodine in a series of duplicates, of the same urine is improved when $ZnSO_4$ is replaced with $Zn(Ac)_2$.

In a previous publication [3] we have shown, that the substitution of K_2CO_3 for Na_2CO_3 in the incineration mixture will result in considerably smaller losses of iodide in the determination of protein-bound iodine, probably because of the lower vapour pressure of KI.

In Table 2 are given the results of two parallel series where urine samples with added $K^{131}I$ have been incinerated with K_2CO_3 and Na_2CO_3, respectively. The average recovery in the Na_2CO_3 series was 83 % against 96 % in the K_2CO_3 series.

Naturally several types of medication can invalidate the analysis of iodine in urine. Besides iodine compounds, which of course can give very high iodine values, mercurial diuretics can give falsely low values, sulfur-containing drugs, such as sulfonamides, chlorothiazide *etc.* falsely high values, because of their influence on the ceric ammonium sulfate reaction. Urines with high values of calcium must first be treated with ammonium oxalate in order to remove calcium to avoid loss of iodine as CaI_2 during the incineration [3].

Table 2. Recovery of added ^{131}I.

Sodium Hydroxide in Alcohol as a Base for the Alkylation of Ethyl Acetoacetate

ARNE BRÄNDSTRÖM

Research Laboratory, Pharmacia Ltd., Uppsala, Sweden

In the alkylation of ethyl acetoacetate by means of an alkyl bromide and an alcoholic solution of sodium ethoxide it is usually stated that the quality of the absolute alcohol is important [1]. Most handbooks recommend the use of »superdry» alcohol, *i.e.* alcohol dried with magnesium or by similar methods.

Table 1.

Alkylhalide	*Yield* %	*B. p.*
C_2H_5Br	73	76— 80°/10 mm Hg
n-C_3H_7Br	56	86— 92°/10 » »
n-C_4H_9Br	45	100—105°/10 » »
$CH_2=CH—CH_2Br$	74	90— 95°/10 » »
$C_6H_5CH_2Cl$	59	145—150°/10 » »

In a kinetic investigation of the methylation of ethyl acetoacetate Brändström [2] has recently shown that the hydrolysis of ethyl acetoacetate is slow if the amount of water present in the sodium ethoxide solution is small. This suggests that it is not so important to dry the alcohol which is to be used as a solvent in alkylation of ethyl acetoacetate. In order to test this, some alkylations of ethyl acetoacetate have been undertaken where sodium hydroxide dissolved in 99.5 % alcohol was used as a base. With alkyl halides of an intermediate reactivity such as ethyl bromide the yields obtained were only slightly lower than those obtainable with "superdry" alcohol and sodium.

The use of sodium hydroxide in alcohol is thus strongly recommended as a base in alkylations of ethyl acetoacetate with alkyl halides of an intermediate or high reactivity.

It should be noted that the same base cannot be used in the alkylations of diethyl malonate or other esters which have a much lower acidity than ethyl acetoacetate.

Experimental. 40 g (1 mole) of sodium hydroxide is dissolved in 500 ml of technical absolute alcohol (containing about 0.5 % of water) in a 1 litre three-necked flask, fitted with a stirrer, a reflux condenser and a dropping funnel. 130 g (1 mole) of ethyl acetoacetate is added followed by 1.2 moles of an alkyl halide. The mixture is refluxed for several hours until it has a neutral reaction.

About 300 ml of alcohol is then distilled off. The residue is cooled and 500 ml of water is added. The layers are separated and the aqueous layer is extracted with benzene. The combined organic layers are dried with anhydrous magnesium sulphate, and then fractionated under reduced pressure. The yields and boiling points obtained are given in Table 1.

The author is indebted to Mr. Ragnvald Lindblom for good help with the manual work.

A Method for the Preparation of *tert*-Alkylacetic Acids

ARNE BRÄNDSTROM

Research Laboratory, Pharmacia Ltd., Uppsala, Sweden

tert-Alkylacetic acids are very seldom referred to in chemical literature. The reason for this is that they are not readily available by the standard methods for the preparation of aliphatic acids. For instance, the malonic ester method has been used [1] but it gives a very low yield. The halides R-CH_2X where R is a *tert*-alkyl group are not readily available, and they do not react with cyanide ion to the corresponding nitrile. The only general method which has been used is that starting with the corresponding *tert*-alkylcyanoacetic ester which in turn can be prepared from an unsaturated cyanosubstituted ester and a Grignard reagent [2-4]. This method is, however, not very convenient for a large scale synthesis of *tert*-alkylacetic acids.

The following method is however, very useful (see p. 609).

The starting materials RCH_2CH_2Cl where R represents a tertiary alkyl group are readily available from the reaction of a tertiary chloride RCl with ethylene or by other methods [5]. All chlorides used in the following preparations are, *e.g.*, obtained from the reaction of *tert*-butyl chloride with ethylene [6].

The conversion of the chloride into the alcohol is conveniently carried out without isolating the intermediate ester by using polyethylene glycol as a solvent. The overall yield for the preparations of alcohols from the chlorides are 70—80 %.

The oxidation of the alcohols to the corresponding acids are the standard procedures using potassium permanganate or chromic acid.

Experimental. Preparation of 3,3-dimethylbutanol-1. 132 g (2 moles) of potassium hydroxide are dissolved in 600 ml of polyethylene glycole-300 in a 2 litres three-necked flask fitted with a strong stirrer, a reflux condenser, a thermometer and a dropping funnel. 120 g (2 moles) of conc. acetic acid are added with stirring. The water formed in the neutralisation is removed by distillation under reduced pressure. When the mixture starts foaming the distillation is discontinued. 241 g (2 moles)

Table 1.

A Method for the Preparation of *tert*-Alkylacetic Acids

ARNE BRÄNDSTROM

Research Laboratory, Pharmacia Ltd., Uppsala, Sweden

tert-Alkylacetic acids are very seldom referred to in chemical literature. The reason for this is that they are not readily available by the standard methods for the preparation of aliphatic acids. For instance, the malonic ester method has been used [1] but it gives a very low yield. The halides R-CH_2X where R is a *tert*-alkyl group are not readily available, and they do not react with cyanide ion to the corresponding nitrile. The only general method which has been used is that starting with the corresponding *tert*-alkylcyanoacetic ester which in turn can be prepared from an unsaturated cyanosubstituted ester and a Grignard reagent [2-4]. This method is, however, not very convenient for a large scale synthesis of *tert*-alkylacetic acids.

The following method is however, very useful (see p. 609).

The starting materials RCH_2CH_2Cl where R represents a tertiary alkyl group are readily available from the reaction of a tertiary chloride RCl with ethylene or by other methods [5]. All chlorides used in the following preparations are, *e.g.*, obtained from the reaction of *tert*-butyl chloride with ethylene [6].

The conversion of the chloride into the alcohol is conveniently carried out without isolating the intermediate ester by using polyethylene glycol as a solvent. The overall yield for the preparations of alcohols from the chlorides are 70—80 %.

The oxidation of the alcohols to the corresponding acids are the standard procedures using potassium permanganate or chromic acid.

Experimental. Preparation of 3,3-dimethylbutanol-1. 132 g (2 moles) of potassium hydroxide are dissolved in 600 ml of polyethylene glycole-300 in a 2 litres three-necked flask fitted with a strong stirrer, a reflux condenser, a thermometer and a dropping funnel. 120 g (2 moles) of conc. acetic acid are added with stirring. The water formed in the neutralisation is removed by distillation under reduced pressure. When the mixture starts foaming the distillation is discontinued. 241 g (2 moles)

$$RCH_2CH_2Cl + CH_3COOK \rightarrow RCH_2CH_2O{-}COCH_3 \xrightarrow{KOH} RCH_2CH_2OH \xrightarrow{Ox.} RCH_2COOH$$

of 1-chloro-3,3-dimethylbutane are added, and the mixture is refluxed for 17 h. The temperature is 118° at the beginning and 132° at the end of the reaction.

197 g (3 moles) of potassium hydroxide are dissolved in 150 ml of water and the solution is cautiously added to the reaction mixture, which is then refluxed for 2 h.

The alcohol is distilled with steam. The steam distillate is separated, and the water layer extracted with benzene. The combined organic layers are dried with anhydrous magnesium sulphate and distilled. The yield is 165 g (81 %) of 3,3-dimethylbutanol-1, boiling at 136—142°. 3,5-Dinitrobenzoate, m. p. 80.2—80.8°.

Preparation of 3,3-dimethylpentanol-1. The procedure given above is followed with the following modification: When the mixture has been refluxed for 17 h, the temperature is 140°. A water separator [7] is now connected to the flask, and the mixture refluxed for 3 h during which time about 35 ml of water is collected in the separator. The temperature in the flask is then 195°. The solution of potassium hydroxide in water is now added, and the procedure given above is followed.

The yield of 3,3-dimethylpentanol-1 boiling at 76—66°/10 mm is 170 g or 77 %. 3,5-Dinitrobenzoate, m. p. 51.2—51.8°.

Preparation of 3,3,4-trimethylpentanol-1. The procedure given for 3,3-dimethyl-pentanol-1 is followed. The end temperature is 205°. The yield of 3,3,4-trimethylpentanol-1 is 182 g or 69 %. The boiling point is 78—82°/10 mm Hg. The melting point of the 3,4-dinitrobenzoate is 46.6—47.2°.

Preparation of 3,3,6,6-tetramethylheptanol-1. The method given for 3,3-dimethylpentanol is followed with the modification that the water separator is connected to the flask from the beginning. The total time of reflux is 4 h during which time the temperature rises from 150° to 252°. The mixture was then allowed to cool, and the potassium hydroxide solution added. The general procedure was then followed.

The yield of 3,3,6,6-tetramethylheptanol-1 boiling at 103—108°/8 mm Hg is 294 g or 85 %.

Preparation of 3,3-dimethylbutanoic acid. A 3 litres three-necked flask is fitted with a stirrer, a reflux condensor, and a device for intermittent addition of a solid [8]. 210 g of potassium permanganate are added in portions to a refluxing mixture of 102 g (1 mole) of 3,3-dimethylbutanol, 1.5 litres of water, and 20 g of potassium carbonate. The mixture is refluxed for 15 min after the addition, and then filtered still hot. The cake of manganese dioxide is washed with hot water. The alkaline filtrate is acidified with concentrated hydrochloric acid. The layers are separated and the aqueous layer extracted with benzene. The combined organic layers are dried with anhydrous magnesium sulphate and fractionated under reduced pressure. The yield of 3,3-dimethylbutanoic acid boiling at 76—80°/8 mm is 94 g or 81 %.

Preparation of 3,3-dimethylpentanoic acid The procedure given above is followed using one mole of 3,3-dimethylpentanol. The yield of 3,3-dimethylpentanoic acid is 80.5 g or 62 % The boiling point is 93—97°/8 mm Hg.

Preparation of 3,3,4-trimethylpentanoic acid:
a) *Oxidation with potassium permanganate.* If the procedure given for 3,3-dimethylbutanoic acid is followed, much alcohol remains after the decolourisation of the permanganate solution. The alcohol is therefore removed by distillation with steam before the manganese dioxide is filtered off. 67 g of 3,3,4-trimethylpentanol, b. p. 78—82°/10 mm Hg, are thus recovered. From the alkaline solution obtained after the filtration of the manganese dioxide 39 g of 3,3,4-trimethyl-pentanoic acid are obtained. This is 53 % calculated on the alcohol not recovered. The boiling point is 105—108°/10 mm.

b) *Oxidation with chromic acid.* 118 g of 3,3,4-trimethylpentanol-1 is added to a refluxing solution of 200 g of sodium dichromate, 485 ml of water, and 140 ml of conc. sulphuric acid. The mixture is stirred and refluxed for 2 h. The reaction mixture is then distilled with steam. The distillate is separated, and the water layer is extracted with benzene. The combined organic layers are extracted with a 20 % sodium hydroxide solution. The alkaline extract is acidified with hydrochloric acid, and the acid extracted with benzene. The combined organic layers are dried with anhydrous magnesium sulphate, and fractionated under reduced pressure. The yield of 3,3,4-trimethylpentanoic acid is 55 g or 38 %.

Preparation of 3,3,6,6-tetramethylheptanoic acid. If 3,3,6,6-tetramethylheptanol-1 is oxidized with chromic acid by the method described above, 3,3,6,6-tetramethylheptanoic acid boil-

ing at 130—133°/10 mm Hg is obtained in a yield of 40 %. The acid is solid at room temperature. The melting point is 44—46°.

The author is indebted to Mr. Holger Blomster for good help with the manual work.

A New Method to Prepare Trialkylacetic Acids

ARNE BRÄNDSTRÖM

Research Laboratory, Pharmacia Ltd., Uppsala, Sweden

There are many methods given for the preparation of trialkylacetic acids[1,2] but no one is entirely convenient for a large scale preparation of these acids. They can, however, be prepared by the following satisfactory reactions, where R is a *tert*-alkyl group:

$$\begin{aligned}
&ROH \longrightarrow RCl + H_2O\\
&RCl + CH_2 = CHCl \longrightarrow RCH_2CHCl_2\\
&RCH_2CHCl_2 + KOH \longrightarrow RCH = CHCl + KCl + H_2O\\
&RCH = CHCl + 2\ Na \longrightarrow RCH = CHNa + NaCl\\
&\qquad\qquad \xrightarrow{HCl}\\
&RCH = CHNa + CO_2 \longrightarrow RCH = CHCOOH + NaCl\\
&RCH = CHCOOH + 2\ KOH \longrightarrow RCOOK + CH_3COOK + H_2
\end{aligned}$$

The yields in all these steps are excellent and the procedure very simple and rapid. Thus, great quantities of the acids are easily obtainable. As there are practically no side reactions the acids obtained are easily purified.

The procedure is demonstrated by the synthesis of pivalic acid. Other acids can be prepared by exactly the same method.

Experimental. tert-*Butyl chloride*[3]. 1 kg of *tert*-butanol is shaken with 3.4 litres of conc. hydrochloric acid for 20 min in a 5-litre separatory funnel. The organic layer is separated, washed with 1 litre of water and dried with anhydrous magnesium sulphate at —20° for 10 min. The liquid is then transferred by filtration to a 5-litre three-necked flask. The yield is 1 160 g (93 %) of pure *tert*-butyl chloride.

1,1-Dichloro-3,3-dimethylbutane[4]. The 5-litre three-necked flask containing the *tert*-butyl chloride is chilled to —25° by means of a solid carbon dioxide-acetone bath and fitted with a stirrer, a gas inlet tube ending under the liquid, a thermometer, and a gas escape tube. 25 g of powdered anhydrous aluminium chloride is added, and the gas inlet tube connected to a 1-litre flask containing 860 ml of vinyl chloride. The vinyl chloride is distilled into the reaction mixture at such a rate that the reaction temperature can be kept at —25° to —30°. — *It is very important that the reaction starts before much vinyl chloride has been added.* This can be seen as a rapid rise in temperature if the cooling bath is temporarily removed. — After the reaction has started the vinyl chloride can usually be introduced in one hour. The reaction mixture is then kept at —25° to —30° for 15 min, and is then decanted into 500 ml of water. The mixture is thoroughly shaken, separated and dried with solid potassium hydroxide for 2 h. The yield is 1 870 g (96 %) of a nearly pure 1,1-dichloro-3,3-dimethylbutane.

1-chloro-3,3-dimethylbutene-1. 780 g of potassium hydroxide are dissolved in 3.6 litres of diethylene glycol in a 10-litre three-necked flask fitted with a dropping funnel, a reflux condenser, a thermometer, and a strong stirrer. The solution is heated to 140° and the dichlor ide added. The mixture is refluxed with good stirring for 6 h, whereupon the product is distilled from the flask until the temperature in the liquid is 190°. The product is separated

ing at 130—133°/10 mm Hg is obtained in a yield of 40 %. The acid is solid at room temperature. The melting point is 44—46°.

The author is indebted to Mr. Holger Blomster for good help with the manual work.

A New Method to Prepare Trialkylacetic Acids

ARNE BRÄNDSTRÖM

Research Laboratory, Pharmacia Ltd., Uppsala, Sweden

There are many methods given for the preparation of trialkylacetic acids[1,2] but no one is entirely convenient for a large scale preparation of these acids. They can, however, be prepared by the following satisfactory reactions, where R is a *tert*-alkyl group:

$$\begin{aligned}
&ROH \longrightarrow RCl + H_2O\\
&RCl + CH_2 = CHCl \longrightarrow RCH_2CHCl_2\\
&RCH_2CHCl_2 + KOH \longrightarrow RCH = CHCl + KCl + H_2O\\
&RCH = CHCl + 2\ Na \longrightarrow RCH = CHNa + NaCl\\
&\qquad\qquad \xrightarrow{HCl}\\
&RCH = CHNa + CO_2 \longrightarrow RCH = CHCOOH + NaCl\\
&RCH = CHCOOH + 2\ KOH \longrightarrow RCOOK + CH_3COOK + H_2
\end{aligned}$$

The yields in all these steps are excellent and the procedure very simple and rapid. Thus, great quantities of the acids are easily obtainable. As there are practically no side reactions the acids obtained are easily purified.

The procedure is demonstrated by the synthesis of pivalic acid. Other acids can be prepared by exactly the same method.

Experimental. tert-*Butyl chloride*[3]. 1 kg of *tert*-butanol is shaken with 3.4 litres of conc. hydrochloric acid for 20 min in a 5-litre separatory funnel. The organic layer is separated, washed with 1 litre of water and dried with anhydrous magnesium sulphate at —20° for 10 min. The liquid is then transferred by filtration to a 5-litre three-necked flask. The yield is 1 160 g (93 %) of pure *tert*-butyl chloride.

1,1-Dichloro-3,3-dimethylbutane[4]. The 5-litre three-necked flask containing the *tert*-butyl chloride is chilled to —25° by means of a solid carbon dioxide-acetone bath and fitted with a stirrer, a gas inlet tube ending under the liquid, a thermometer, and a gas escape tube. 25 g of powdered anhydrous aluminium chloride is added, and the gas inlet tube connected to a 1-litre flask containing 860 ml of vinyl chloride. The vinyl chloride is distilled into the reaction mixture at such a rate that the reaction temperature can be kept at —25° to —30°. — *It is very important that the reaction starts before much vinyl chloride has been added.* This can be seen as a rapid rise in temperature if the cooling bath is temporarily removed. — After the reaction has started the vinyl chloride can usually be introduced in one hour. The reaction mixture is then kept at —25° to —30° for 15 min, and is then decanted into 500 ml of water. The mixture is thoroughly shaken, separated and dried with solid potassium hydroxide for 2 h. The yield is 1 870 g (96 %) of a nearly pure 1,1-dichloro-3,3-dimethylbutane.

1-chloro-3,3-dimethylbutene-1. 780 g of potassium hydroxide are dissolved in 3.6 litres of diethylene glycol in a 10-litre three-necked flask fitted with a dropping funnel, a reflux condenser, a thermometer, and a strong stirrer. The solution is heated to 140° and the dichlor ide added. The mixture is refluxed with good stirring for 6 h, whereupon the product is distilled from the flask until the temperature in the liquid is 190°. The product is separated

from the water layer in the distillate, dried with anhydrous magnesium sulphate, and then distilled through a Widmer column. The yield is 1 150 g of 1-chloro-3,3-dimethylbutene-1, b. p. 105—115°. 190 g of the dichloride, b. p. 148—153°, is recovered. This corresponds to a yield of 90 % calculated on the dichloride not recovered.

β-tert-Butylacrylic acid. A fine dispersion [5] of 270 g of sodium in 270 ml of pure kerosene, free from sulphurous compounds and aromatics, is added to 4 litres of pure kerosene contained in a 10-litre three-necked flask fitted with a stirrer, a thermometer, a gas inlet tube, a gas escape tube, and a dropping funnel. A slow stream of dry nitrogen is passed through the flask, where the temperature is adjusted to 27°. A solid carbon dioxide acetone bath is kept ready for use and about 100 ml of a solution of 593 g of 1-chloro-3,3-dimethylbutene-1 in 1 litre of kerosene is added. If the reaction starts, which is indicated by a rapid darkning of the contents in the flask and a rapid rise in the temperature, the flask is cooled so that the temperature is kept within 25—30°, and the rest of the solution added as rapidly as possible without exceeding these temperature limits. — *If* the reaction will not begin, a few ml of *n*-butanol is added to help it to start. *Under no conditions more than 200 ml of the chloride solution should be added before the reaction starts or else the reaction may go beyond control.* — When all the chloride solution has been added (about 1 h) the reaction is completed by stirring at 25—30° for 1 h.

The flask is chilled to 0° and carbonated at 0—15° by a rapid stream of dry carbon dioxide, which is bubbled through the black reaction mixture. When the temperature does not rise, even if the cooling bath is removed, carbon dioxide is introduced for 15 min more. Water is then rapidly added through the dropping funnel to destroy the excess of sodium and dissolve the sodium salts. *This can be done without danger if the reaction between the chloride and sodium had started and a stream of carbon dioxide is passed through the flask.*

The layers are separated and the aqueous layer acidified with conc. hydrochloric acid. After cooling the solid acid cake is removed, transferred to a small beaker where it is melted and decanted from the resulting small water layer. The acid thus obtained weighs 550 g (86 %), and is pure enough for the next step.

Pivalic acid [6]. 1 100 g of the acid above is carefully mixed with a solution of 1 150 g of potassium hydroxide (85—87 %) in 1 150 ml of water in a pan made of stainless steel. The pan is provided with a loose cover to avoid splashing and is heated electrically until the temperature reaches 300°. The thermometer is protected from the caustic mixture by means of a copper tube.

The slightly coloured reaction mixture is allowed to cool, dissolved in water, acidified with conc. hydrochloric acid, the organic layer separated and the water layer extracted with benzene. The combined organic layers are dried with anhydrous magnesium sulphate and distilled through a 30 cm Widmer column. After a small forefraction at 150—162°, 760 g (87 %) of pivalic acid is obtained at 162—165°. The product is completely solidified at room temperature, and melts at 34—35°. The yield is 57 % calculated on the *tert*-butanol.

The author is indebted to Mr. Ragnvald Lindblom for good help with the manual work.

A Method for the Preparation of Trialkylacetaldehydes

ARNE BRÄNDSTRÖM

Research Laboratory, Pharmacia Ltd., Uppsala, Sweden

In chemical literature there are given many methods to prepare trialkylacetaldehydes, but the starting materials are usually not readily available, and it is rather difficult to obtain even the most simple aldehyde of this kind (the trimethylacetaldehyde [1]). The following method seems, however, quite satisfactory (p. 612).

From these formulas where R is a tertiary alkyl group it can be seen that there are only readily available starting materials except possibly the sodium periodate but this reagent is easily prepared

from the water layer in the distillate, dried with anhydrous magnesium sulphate, and then distilled through a Widmer column. The yield is 1 150 g of 1-chloro-3,3-dimethylbutene-1, b. p. 105—115°. 190 g of the dichloride, b. p. 148—153°, is recovered. This corresponds to a yield of 90 % calculated on the dichloride not recovered.

β-tert-Butylacrylic acid. A fine dispersion [5] of 270 g of sodium in 270 ml of pure kerosene, free from sulphurous compounds and aromatics, is added to 4 litres of pure kerosene contained in a 10-litre three-necked flask fitted with a stirrer, a thermometer, a gas inlet tube, a gas escape tube, and a dropping funnel. A Method for the Preparation of Trialkylacetaldehydes

ARNE BRÄNDSTRÖM

Research Laboratory, Pharmacia Ltd., Uppsala, Sweden

In chemical literature there are given many methods to prepare trialkylacetaldehydes, but the starting materials are usually not readily available, and it is rather difficult to obtain even the most simple aldehyde of this kind (the trimethylacetaldehyde [1]). The following method seems, however, quite satisfactory (p. 612).

From these formulas where R is a tertiary alkyl group it can be seen that there are only readily available starting materials except possibly the sodium periodate but this reagent is easily prepared

$ROH + HCl$		RCl	93 % yield
$RCl + CH_2=CH_2$	$\xrightarrow{AlCl_3}$	RCH_2CH_2Cl	86 % yield
RCH_2CH_2Cl	$\xrightarrow{KOH}$	$RCH=CH_2$	60 % yield
$RCH=CH_2$	$\xrightarrow{HCOOH+H_2O_2}$	$RCH(OH)CH_2OH$	78 % yield
$RCH(OH)CH_2OH$	$\xrightarrow{Na_3H_2IO_6}$	$RCHO$	79 % yield

from sodium chlorate and iodine [2] and can be recovered.

The method is demonstrated by the synthesis of trimethylacetaldehyde on a large laboratory scale.

Experimental. 1-Chloro-3,3-dimethylbutane[3]. In a 20 litre flask 3 kg of *tert*-butanol are shaken with 10 litres of concentrated hydrochloric acid for 20 min. The layers are separated, the upper layer washed with 1/2 litre of water and dried with 100 g of anhydrous sodium sulphate for 15 min at —20°. The *tert*-butyl chloride which is quite pure is filtered into a 10 litre three-necked flask. The yield of *tert*-butyl chloride is 3.5 kg.

The flask is fitted with a stirrer, a gas inlet tube, a gas escape tube, and a thermometer, and is chilled in a dry ice-acetone bath to —20°. 50 g of powdered anhydrous aluminium chloride are added and pure ethylene introduced as fast as it is consumed. The temperature is kept between —17° and —20° and regulated with the cooling and the rate of stirring (which determines the rate of absorption of ethylene). When the vigorous absorption of ethylene appears to cease (after about 2 h) the liquid is decanted into 200 ml of water, the mixture well shaken, the organic layer separated, dried with solid potassium hydroxide and distilled. The fraction boiling at 115—122° is taken as 1-chloro-3,3-dimethylbutane and weighs 3 900 g.

tert-*Butylethylene.* 2 100 g of potassium hydroxide are dissolved in 9 litres of polyethyleneglycol-300 and the solution is heated to 130° in a 20 litre three-necked flask placed in a heating mantle and fitted with a dropping funnel, a stirrer and a reflux condenser, the top of which is connected to a condenser arranged for distillation into a receiver chilled to —30°. 3 600 g of 1-chloro-3,3-dimethylbutane are added at such a rate that the temperature in the flask is kept at 120—190°, and the temperature at the top of the reflux condenser is kept at 40—60° by regulating the cooling water in the mantle. When necessary, the flask is heated by means of the heating mantle. When no more distillate is obtained, the organic layer is decanted from the ice in the receiver and distilled through a column into a receiver kept at —30°. The fraction, b. p. 40—50°, is taken as *tert*-butylethylene and weighs 1 500 g.

tert-*Butylethylene glycol* [4]. 9 litres of formic acid (98—100 %) are mixed with 2.5 litres of hydrogen peroxide (30 %) and heated to 37° in a 20 litre three-necked flask fitted with a stirrer, a reflux condenser feeded with ice-water, and a dropping funnel. 1.5 g of *tert*-butylethylene are added in 1 h with vigorous stirring and external cooling with ice-water so that the temperature is kept at 37—40°. When all the *tert*-butylethylene has been added, the mixture is stirred at the same temperature for another 1 1/2 h after which it is kept at room temperature over night.

The formic acid is removed under reduced pressure by means of a water-bath kept below 55°. When no more distillate is obtained (about 10 litres), the distillation condenser is replaced by a reflux condenser. 3.2 litres of a 33 % sodium hydroxide solution are added, and the mixture refluxed with rapid stirring for 15 min and then cooled to room temperature. 1.3 litres of benzene are added and the layers separated. The water layer is extracted with 1 litre of benzene and the combined organic layers are distilled under reduced pressure. 1.4 kg of *tert*-butylethylene glycol, b. p. 95—115°/8 mm, are obtained. The residue in the distillation flask is refluxed with the aqueous layer from the separation for 15 min, the mixture extracted with 1 litre of benzene and then distilled. In this way another 250 g of *tert*-butylethylene glycol are obtained. The total yield is thus 1.65 kg. The product is completely solid at room temperature and pure enough for the next step.

Trimethylacetaldehyde. 4.15 kg of $Na_3H_2IO_6$, 1.65 kg of *tert*-butylethylene glycol and 11 litres of water are placed in a 20 litres three-necked flask fitted with a stirrer, a thermometer, a dropping funnel and a condenser

arranged for distillation under reduced pressure. The receiver is kept below —30° and the flask evaporated to about 120 mm Hg. A solution of 770 ml of conc. sulphuric acid in 1.4 litres of water is added at such a rate that the temperature in the flask can be kept at 35—40° by cooling with ice-water. The trimethylacetaldehyde distills during this addition. When the acid has been added, the flask is heated to 45° and the vacuum broken. The aldehyde in the receiver is melted and decanted from the ice. It weighs 1.06 kg and is pure enough for most purposes. If a pure product is desired, it can be obtained by distillation. In this way 950 g of pure trimethylaldehyde, b. p. 71—74°, is obtained.

From the water layer most of the sodium periodate can be recovered by treating the solution containing the sodium iodate with sodium hydroxide and chlorine [2].

Even pure trimethylacetaldehyde is slowly decomposed on standig into gaseous products, and it is advisable to release the pressure developed in the flask at intervals, and to keep it in a dark and cold place.

5-*neo*Pentyl-5-Allylbarbituric Acid and Related Compounds

I. On the Preparation of β-*tert*-Alkylpropionic Acids and Derivatives

ARNE BRÄNDSTRÖM

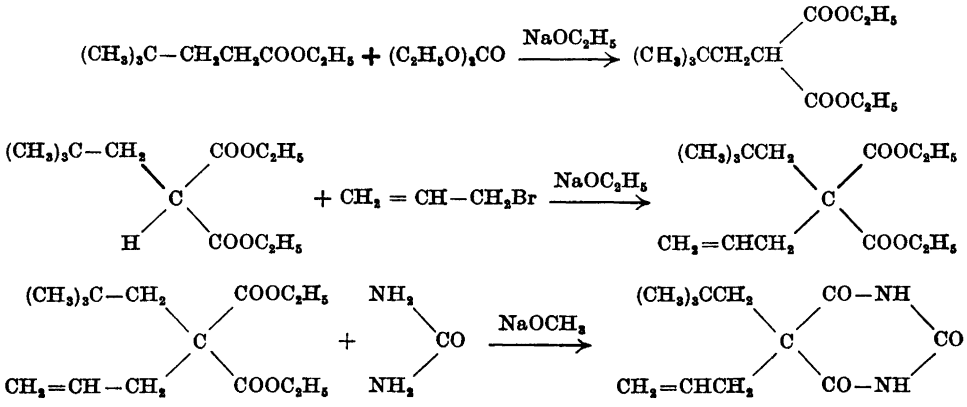
Research Laboratory, Pharmacia Ltd., Uppsala, Sweden

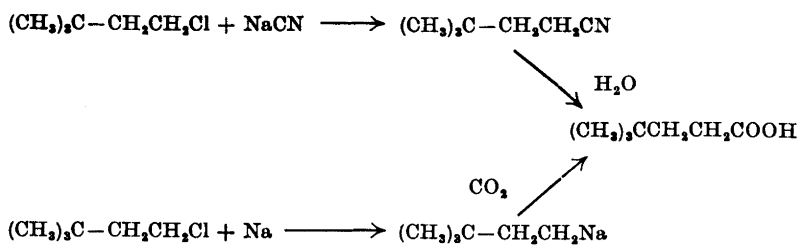
In this laboratory it has been found that *neo*pentylallylbarbituric acid is a very good sedative drug. In order to make this compound available in commercial quantities an investigation of the methods to prepare this barbiturate has been performed and in this connection some intermediates containing a branched chained structure have been prepared. Some of these compounds and methods will be described in this and the two following papers.

For this and similar methods 4,4-dimethylpentanoic acid was needed as a starting material. This compound has been prepared by Moreau and Delange [1] and later by Spindt, Stevens and Bladwin [2]. None of these methods are convenient for a large scale preparation of 4,4-dimethylpentanoic acid or the ethyl ester.

The following methods are, however, very satisfactory. They start with the readily available 1-chloro-3,3-dimethylbutane (obtainable from ethylene and *tert*-butyl chloride).

The method for the conversion of primary alkyl chlorides into cyanides has





recently been studied by Brändström [4] who found that polyethylene glycol-300 is an excellent solvent for the reaction. 3,3-Dimethylbutyl cyanide is obtained in excellent yield by this method and can easily be converted into the corresponding acid or ethyl ester by standard methods.

The preparation of carboxylic acids from alkyl chlorides *via* alkyl sodium compounds has been investigated by Morton *et al.*[5] The yields are usually somewhat low due to the fact that malonic acids are obtained as by-products. When this method is applied to the synthesis of 4,4-dimethylpentanoic acid a very good yield is obtained, probably because the *tert*-butyl group prevents the side reaction to the corresponding malonic acid.

The 4,4-dimethylpentanoic acid can also be prepared from *β-tert*-butylacrylic acid by hydrogenation.

In connection with the preparation of 4,4-dimethylpentanoic acid some homologues have been prepared by the same methods. All alkyl chlorides used in the following preparations are obtained from the reaction of *tert*-butyl chloride with ethylene [6].

Experimental. Preparation of cyanides. The method given by Brändström is followed and for the following cyanides the yields and boiling points are:

3,3-dimethylbutyl cyanide	94 %	57°— 59°/8 mm Hg
3,3-dimethylamyl cyanide	93 »	76°— 80°/8 mm Hg
3,3,4-trimethylamyl cyanide	91 »	88°— 89°/8 mm Hg
3,3,6,6-tetramethylheptyl cyanide	80 »	107°—110°/8 mm Hg

Preparation of acids. A 2 litre three-necked flask is fitted with a high speed stirrer (about 10 000 r.p.m.) a thermometer, a dropping funnel, a gas inlet tube and a gas exit tube. A slow stream of dry nitrogen is passed through the flask. 54 g of clean sodium and 800 ml of dry kerosene (free from aromatics, olefins and sulphurous compounds) are heated to 110°C. The mixture is now stirred at that temperature for 10 min. The stirrer is stopped and the flask chilled to —5° (Danger! The flask must not crack!)

The stirrer is started again. 10 ml of a solution containing 120 g of 1-chloro-3,3-dimethylbutane and 100 ml of pure kerosene are added. In some cases the reaction soon starts, which is indicated by a rapid rise in temperature and a darkning of the contents in the flask. In other cases 2 ml of butanol must be added to start the reaction. When the reaction has started, the flask is chilled in a solid carbon dioxide-acetone bath, and the rest of the chloride solution is added to the *very dark* contents in the flask at such a rate that the temperature is kept between 0° and —10°. The mixture is stirred at that temperature for 15 min after the addition.

Warning! It is very dangerous to add large quantities of the chloride solution to the sodium dispersion before the reaction has started!

The high speed stirrer is changed to an ordinary stirrer and the nitrogen replaced by pure carbon dioxide. The temperature is kept between 0° and —10° by cooling and adjusting the rates of stirring and addition of carbon dioxide. When the temperature begins to decrease, even if the rate of stirring and the stream of carbon dioxide are increased, the cooling bath is removed. If the temperature now only slowly rises, the reaction is finished.

700 ml of water is cautiously added to destroy the excess of sodium and dissolve the salts formed. The layers are separated. The aqueous layer is acidified with conc. hydro-

chloric acid, and the acid, which is liberated, is extracted with benzene. The benzene solution is dried with anhydrous sodium sulphate and then distilled under reduced pressure. The yield is 100 g or 77 % of the theoretical. The boiling point of the 4,4-dimethylpentanoic acid is 104—105°/8 mm Hg.

In exactly the same way the following acids are prepared: 4,4-Dimethylhexanoic acid, b.p. 112—120°/10 mm Hg, yield 46 %; 4,4,5-Trimethylhexanoic acid, b. p. 129—135°/8 mm Hg, yield 50 %.

Hydrolysis of cyanides. The same acids as mentioned above are conveniently prepared from the corresponding cyanides in the following way.

One mole of the cyanide is refluxed with two moles of sodium hydroxide, and 800 ml of water for 24 h or until the evolution of ammonia ceases. The resulting alkaline solution is cooled, extracted with benzene and then treated as above. The yields are almost quantitative.

Hydrogenation of β-tert-butylacrylic acid. *β-tert*-Butylacrylic acid is dissolved in 5 parts of alcohol and hydrogenated with palladium on charcoal as a catalyst at a hydrogen pressure of 50 kg/cm². The hydrogenation is rapid and an almost quantitative yield of 4,4-dimethylpentanoic acid is obtained on distillation of the filtered solution.

Preparation of esters. 475 g of 3,3-dimethylbutyl cyanide are dissolved in 1 080 ml of 99.5 % alcohol in a 5-litre flask fitted with a stirrer, a reflux condenser, and a dropping funnel. 465 ml of conc. sulphuric acid are added during one h. The mixture is then refluxed for 8 h. After cooling the mixture is poured on ice. Water is added to dissolve the salts, and the layers are then separated. The aqueous layer is extracted with benzene, and the combined organic layers are washed with a sodium carbonate solution, dried and distilled. The yield is 580 g of ethyl 4,4-dimethylpentanoate (86 %). The boiling point is 60—62°/8 mm Hg.

In exactly the same way the other cyanides could be converted into the corresponding esters.

The author is indebted to his colleagues and assistants at Pharmacia for good help with this project.

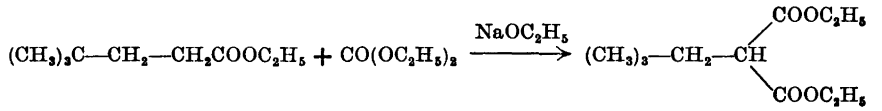
5-*neo*Pentyl-5-Allylbarbituric Acid and Related Compounds

II. On the Preparation of Diethyl *neo*Pentylmalonate and Related Compounds

ARNE BRÄNDSTRÖM

Research Laboratory, Pharmacia Ltd., Uppsala, Sweden

Diethyl *neo*pentylmalonate is an important intermediate in the synthesis of 5-*neo*-pentyl-5-allylbarbituric acid. Due to the very low reactivity of *neo*pentyl halides it cannot be prepared by alkylation of diethyl malonate but other methods must be tried. The most convenient method seems to be the following



This condensation gives an excellent yield of diethyl *neo*pentylmalonate if it is performed under forcing conditions just as described by Brändström [1]. Starting with 3,3-dimethylbutyl cyanide and diethyl carbonate the same method gives ethyl *neo*pentylcyanoacetate.

The *neo*pentyl substituted malonic and cyanoacetic esters can be alkylated just as other monoalkylated malonic and cyanoacetic esters.

Attempts to prepare diethyl *neo*pentylmalonate from ethyl 4,4-dimethylpentanoate and diethyl oxalate by a process

chloric acid, and the acid, which is liberated, is extracted with benzene. The benzene solution is dried with anhydrous sodium sulphate and then distilled under reduced pressure. The yield is 100 g or 77 % of the theoretical. The boiling point of the 4,4-dimethylpentanoic acid is 104—105°/8 mm Hg.

In exactly the same way the following acids are prepared: 4,4-Dimethylhexanoic acid, b.p. 112—120°/10 mm Hg, yield 46 %; 4,4,5-Trimethylhexanoic acid, b. p. 129—135°/8 mm Hg, yield 50 %.

Hydrolysis of cyanides. The same acids as mentioned above are conveniently prepared from the corresponding cyanides in the following way.

One mole of the cyanide is refluxed with two moles of sodium hydroxide, and 800 ml of water for 24 h or until the evolution of ammonia ceases. The resulting alkaline solution is cooled, extracted with benzene and then treated as above. The yields are almost quantitative.

Hydrogenation of β-tert-butylacrylic acid. *β-tert*-Butylacrylic acid is dissolved in 5 parts of alcohol and hydrogenated with palladium on charcoal as a catalyst at a hydrogen pressure of 50 kg/cm². The hydrogenation is rapid and an almost quantitative yield of 4,4-dimethylpentanoic acid is obtained on distillation of the filtered solution.

Preparation of esters. 475 g of 3,3-dimethylbutyl cyanide are dissolved in 1 080 ml of 99.5 % alcohol in a 5-litre flask fitted with a stirrer, a reflux condenser, and a dropping funnel. 465 ml of conc. sulphuric acid are added during one h. The mixture is then refluxed for 8 h. After cooling the mixture is poured on ice. Water is added to dissolve the salts, and the layers are then separated. The aqueous layer is extracted with benzene, and the combined organic layers are washed with a sodium carbonate solution, dried and distilled. The yield is 580 g of ethyl 4,4-dimethylpentanoate (86 %). The boiling point is 60—62°/8 mm Hg.

In exactly the same way the other cyanides could be converted into the corresponding esters.

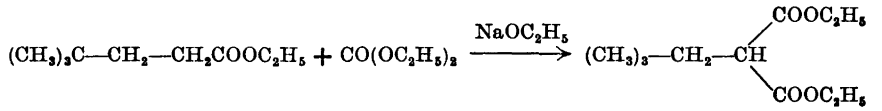
5-*neo*Pentyl-5-Allylbarbituric Acid and Related Compounds

II. On the Preparation of Diethyl *neo*Pentylmalonate and Related Compounds

ARNE BRÄNDSTRÖM

Research Laboratory, Pharmacia Ltd., Uppsala, Sweden

Diethyl *neo*pentylmalonate is an important intermediate in the synthesis of 5-*neo*-pentyl-5-allylbarbituric acid. Due to the very low reactivity of *neo*pentyl halides it cannot be prepared by alkylation of diethyl malonate but other methods must be tried. The most convenient method seems to be the following

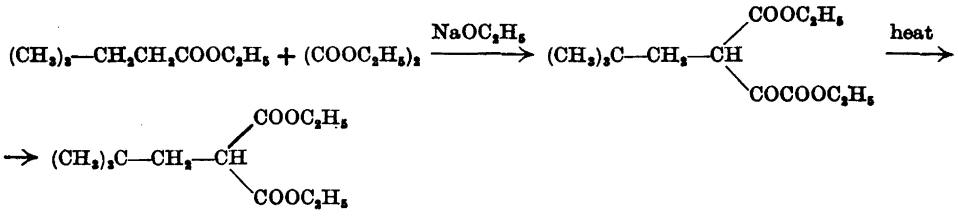


This condensation gives an excellent yield of diethyl *neo*pentylmalonate if it is performed under forcing conditions just as described by Brändström [1]. Starting with 3,3-dimethylbutyl cyanide and diethyl carbonate the same method gives ethyl *neo*pentylcyanoacetate.

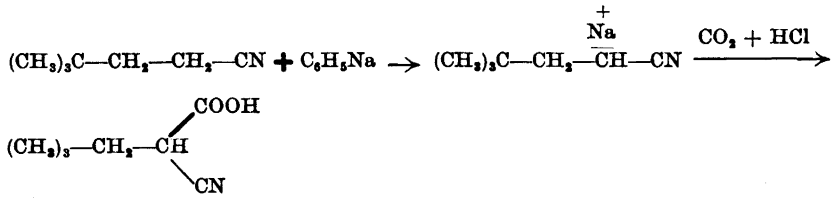
The *neo*pentyl substituted malonic and cyanoacetic esters can be alkylated just as other monoalkylated malonic and cyanoacetic esters.

Attempts to prepare diethyl *neo*pentylmalonate from ethyl 4,4-dimethylpentanoate and diethyl oxalate by a process

similar to that used for the preparation of diethyl phenylmalonate [2], *viz.*

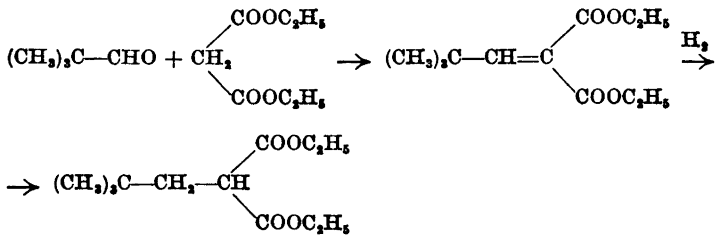


were not particularly successful. A yield of about 25 % could be obtained if the condensation was forced [3]. The following method was tried with success:



The cyano acid can be esterified to ethyl *neo*pentylcyanoacetate or to diethyl *neo*pentylmalonate, and it can be hydrolyzed to give *neo*pentylmalonic acid. The yields obtained are very good and the method is rapid but somewhat dangerous as it involves the manipulation of sodium dispersion.

Diethyl *neo*pentylmalonate can also be prepared by the following method:



This is an excellent method but trimethylacetaldehyde is not a commercially available starting material. A convenient method for a laboratory synthesis of trimethylacetaldehyde has been described by Brändström [4].

If needed in big quantities trimethylacetaldehyde might be prepared from $(CH_3)_3C-CH=CH_2$ or $(CH_3)_3C-CH=CHCl$ by oxidation with ozone [5] but as that method would probably involve many practical problems it was not tried.

Besides the *neo*pentylderivatives a number of homologues have been prepared, *e.g.* those containing the groups β,β-dimethylbutyl and β,β,γ-trimethylbutyl.

Experimental. 1. Condensations with diethyl carbonate. 2 400 ml of diethyl carbonate are heated to boiling in a 5-litre three-necked flask provided with a stirrer, a reflux condenser and a glass stopper. The heating is then interrupted and 75 g of sodium are added at such a rate that the liquid boils vigorously. — Caution! Carbon monoxide escapes through the condenser! — When the sodium has reacted, 3 moles of the ethyl ester or the cyanide are added.

The reflux condenser is replaced by a Widmer column connected to a condenser arranged for distillation. The alcohol, which is formed in the condensation reaction, is distilled off carefully but rapidly. The temperature in the top of the column is kept below 85°. In this way about 360 ml of distillate can be obtained. The reaction mixture now contains a solution or suspension of the sodium compound of the malonic ester or cyanoester in diethyl carbonate.

The flask is cooled to room temperature and the contents are poured into a mixture of 300 ml of concentrated hydrochloric acid and ice. The mixture is shaken and separated. The ester layer is dried with anhydrous sodium sulphate and the diethyl carbonate distilled off at about 50 mm Hg, whereupon the residue is subjected to a fractional distillation *in vacuo*. The yields and boiling points are given in Table 1.

Table 1. Preparation of esters

»	H	CN	65	110—114/ 8 » »
$C_2H_5C(CH_3)_2$	H	$COOC_2H_5$	65	118—128/10 » »
»	C_2H_5-	»	55	144—147/ 7 » »
»	CH_2=CH—CH_2-	»	69	150—155/15 » »
$(CH_3)_2CH$—$C(CH_3)_2$	H	»	65	130—132/ 8 » »

If a second group is to be introduced into the malonic ester or cyanoester it can be done by adding about 3.3 moles of the apropriate halide to the solution or suspension of the sodium compound mentioned above and refluxing the resulting mixture for some h (usually 1—8 h depending on the reactivity of the halide). The mixture is then cooled, poured on ice-water, acidified, separated, dried, and distilled as described above. The yields and boiling points are given in Table 1.

2. Condensations with diethyl oxalate. 3 litres of toluene and 69 g of sodium are heated to boiling in a 5-litre three-necked flask provided with a stirrer, a reflux condenser, and a dropping funnel. The stirrer is started and the heating is interrupted when the sodium begins to melt. To this mixture 180 ml of absolute alcohol are added dropwise in about 1 h. After the addition the vigorously stirred mixture is refluxed for 1 h.

The flask is cooled to 10° and the reflux condenser is replaced by a column connected to a condenser for distillation under reduced pressure. 474 g of ethyl 4,4-dimethylpentanoate and 438 g of diethyl oxalate are added. The flask is evacuated to 120 mm Hg and heated so that alcohol distills off at a temperature below 50° at the top of the column. About 800 ml of distillate are obtained. When no more alcohol distills, the flask is cooled with an ice-bath.

A mixture of 270 ml of conc. hydrochloric acid and an excess of ice is added to the contents of the flask. The mixture is effectively stirred whereupon the toluene layer is separated off, washed with water, and dried with sodium sulphate. The toluene is distilled off at reduced pressure by heating on a boiling water bath. When no more distills even if the pressure is reduced to 1 mm Hg the residue consists of ethyl 2-keto-3-carbethoxy-5,5-dimethylhexanoate, which can be purified by distillation at a pressure of at most 1 mm. B. p. 103—110/1 mm Hg.

If the crude residue is heated to boiling at ordinary pressure a vigorous evolution of carbon monoxide occurs. When this has ceased, the product is distilled under reduced pressure and thereby 175 g of diethyl *neo*pentylmalonate is obtained. B. p. 116—121/8 mm Hg.

If in the condensation above the ethyl 4,4-dimethylpentanoate is replaced by 333 g of 3,3-dimethylbutyl cyanide 210 g of ethyl 2-

keto-3-cyano-5,5-dimethylhexanoate is obtained. B. p. 140—150°/8 mm Hg. This ester does not split off carbon monoxide on heating.

3. Carboxylations of nitriles. In a 2-litre three-necked flask a dispersion of phenyl sodium is prepared from 100 g of sodium, 246 g of chlorobenzene, and 900 ml of toluene by the method given by Nobis and Moormeier [6].

The flask containing the phenyl sodium dispersion is fitted with a Hershberg stirrer [7], a thermometer, a gas inlet tube for dry nitrogen, a gas exit tube and a dropping funnel. The flask is chilled to —5° with a solid carbon dioxide-acetone bath, and a solution of 222 g of 3,3-dimethylbutyl cyanide in 200 ml of dry toluene is added at —5° to 0° during 10 min. The mixture is stirred at that temperature for 15 min and then poured into a 7-litre enamelled pan containing 1 kg of solid carbon dioxide and 100 ml of toluene. The mixture is stirred for some min and then allowed to obtain room temperature.

A few pieces of solid carbon dioxide are added (to function as a fire extinguisher), and then 2 litres of water (Caution! A considerable excess of sodium might be present!) The mixture is stirred and then separated. The aqueous layer contains the sodium salt of *neo*pentylcyanoacetic acid.

A. *Preparation of* neo*pentylmalonic acid.* 100 g of sodium hydroxide are added to the solution containing the sodium salt of *neo*pentylcyanoacetic acid. The mixture is refluxed until the evolution of ammonia ceases. The solution is cooled to room temperature and 400 ml of conc. hydrochloric acid is added while cooling so that the temperature never exceeds 30°. The solution is then extracted with three 200 ml portions of chloroform. The combined chloroform solutions are washed with 40 ml of conc. hydrochloric acid and dried with anhydrous magnesium sulphate. The chloroform is removed by distillation at reduced pressure by warming on a water-bath to 40°. The dry residue is *neo*pentylmalonic acid and weighs about 260 g. It is readily recrystallized from *cyclo*hexane, and has then a melting point of 89.5°—92°. Equiv. wt. found 86.9, calc. 87.1.

In exactly the same way the following malonic acids are prepared: β,β-dimethylbutylmalonic acid, yield of crude acid 242 g, m. p., of recrystallized product 68°—71°, equiv. wt. found 94.3, calc. 94.1; β,β,γ-trimethylbutylmalonic acid, yield of crude product 300 g, m. p. of recrystallized acid 85.5°—86.5°, equiv. wt. found 101.7, calc. 101.1.

B. *Preparation of ethyl* neo*pentylcyanoacetate.* The solution containing the sodium salt of *neo*pentylcyanoacetic acid is acidified with 250 ml of conc. hydrochloric acid at a temperature not exceeding 30°. The layers are separated and the aqueous layer is extracted with two 250 ml portions of benzene. The combined organic layers are washed with 25 ml of conc. hydrochloric acid.

To the benzene solution of *neo*pentylcyanoacetic acid 250 ml of 99.5 % alcohol and 5 ml of conc. sulphuric acid are added. The mixture is refluxed, and the water formed under the esterification removed by means of a water separator [8]. After about 8 h of reflux a second portion of 5 ml of conc. sulphuric acid is added, and the refluxing is continued until no more water is obtained (total time about 15 h). The benzene solution is cooled to room temperature, washed with 500 ml of water then with 200 ml of a 5 % sodium carbonate solution and finally dried with anhydrous magnesium sulphate. The benzene is removed by distillation and the residue is fractionated at reduced pressure. In this way 275 g of ethyl *neo*pentylcyanoacetate is obtained at 105—110°/8 mm. The forefraction contains some ethyl benzoate.

C. *Preparation of diethyl* neo*pentylmalonate.* The benzene solution containing the *neo*pentylcyanoacetic acid is concentrated by warming under reduced pressure in a water bath at a temperature not exceeding 50°. The residue weighs about 260 g. It is dissolved in 800 ml of 99.5 % alcohol, and 190 ml of conc. sulphuric acid is added whereupon the mixture is refluxed overnight with stirring. It is then cooled and poured onto ice. The layers are separated, and the aqueous layer is extracted with benzene. The combined organic layers are washed with water, then with a 5 % sodium carbonate solution, and again with water. The solution is dried with anhydrous magnesium sulphate, the benzene removed by distillation and the residue fractionated under reduced pressure. The yield is 250 g with a boiling point of 110°—115°/8 mm Hg. The forefraction contains some ethyl benzoate.

4. Introduction of a neo*pentyl group in diethyl malonate and ethyl cyanoacetate by means of trimethylacetaldehyde.* A. *Preparation of diethyl trimethylethylidenemalonate.* This ester is readily obtained by condensing trimethylacetaldehyde with diethyl malonate as described by Foreman and McElvain [9].

B. *Preparation of ethyl trimethylethylidenecyanoacetate.* If trimethylacetaldehyde is condensed with ethyl cyanoacetate by the standard method [10] ethyl trimethylethylidenecyanoacetate is obtained in a 89 % yield; b. p. 104°—111°/9 mm Hg.

C. *Preparation of diethyl* neo*pentylmalonate.* Diethyl trimethylethylidenemalonate is readily hydrogenated by means of hydrogen and pal-

ladium on charcoal. The reaction is completed in 1/2 h if alcohol is used as a solvent, and the pressure is 50 atm. The yield is quantitative. B. p. 120°—130°/11 mm Hg.

D. *Preparation of ethyl* neo*pentylcyanoacetate.* Ethyl trimethylethylidenecyanoacetate is hydrogenated as described above to ethyl *neo*pentylcyanoacetate. The yield is quantitative and the boiling point 110°—114°/8 mm Hg.

5. Alkylations of ethyl neo*pentylcyanoacetate.* A. *Preparation of ethyl ethyl*neo*pentylcyanoacetate.* 91.5 g of ethyl *neo*pentylcyanoacetate, 138 g of powdered anhydrous potassium carbonate, 275 ml of dry acetone and 94 g of ethyl iodide are refluxed with good stirring for 3 h. The resulting mixture is cooled, poured into ice-water, separated, extracted with benzene, dried and distilled under reduced pressure. In this way 100 g, 95 %, of ethyl ethyl*neo*pentylcyanoacetate is obtained. B. p. 116°—118°/7 mm Hg. This ester is recovered unchanged after refluxing with 120 ml of alcohol, and 50 ml of conc. sulphuric acid for 16 h.

B. *Preparation of ethyl allyl*neo*pentylcyanoacetate.* 41 g of ethyl *neo*pentylcyanoacetate 62 g of powdered anhydrous potassium carbonate, 125 g of dry acetone and 33 g of allylbromide are refluxed for 5 h. The mixture is then treated as above yielding 49.5 g, 99 %, of ethyl allyl*neo*pentylcyanoacetate boiling at 127°—128°/8 mm Hg.

The author is indebted to this colleagues and assistants at Pharmacia for good help with this project.

5-*neo*Pentyl-5-Allylbarbituric Acid and Related Compounds

III. On the Preparation of *neo*Pentyl-substituted Barbituric Acids

ARNE BRÄNDSTRÖM

Research Laboratory, Pharmacia Ltd., Uppsala, Sweden

Since J. von Mering in 1903 discovered the hypnotic activity of a compound he erroneously considered to be 5,5-diethylbarbituric acid [1], 5,5-disubstituted barbituric acids have been extensively studied. In Chemical Abstract Decimal Index 1917—1926 the heading "barbituric acid" covers about 5 pages, in Decimal Index 1937—1945 8 pages and in Subject Index 1956 2 pages. This shows that the interest in substituted barbituric acids is ever increasing.

In spite of the enormous interest devoted to 5,5-disubstituted barbituric acids it appears that no barbituric acid containing a *neo*pentylsubstituent in the 5 position has been described. This is still more remarkable as many very useful hypnotics are barbituric acids with a side chain in the 5 position containing five carbon atoms usually in a branched-chain arrangement.

The introduction of a *neo*pentyl group in a molecule gives often a reactivity very different from that obtained with other aliphatic groups of the same size. This is clearly demonstrated by the well-known extremely low reactivity of *neo*pentyl halides compared with that of other alkyl halides and the tendency of *neo*pentyl compounds to undergo rearrangements instead of simple substitution reactions. Therefore, it is of interest to see if the properties of *neo*pentylsubstituted barbituric acids differs from those substituted with other alkyl groups. Consequently, a number of *neo*pentylsubstituted barbituric acids have been prepared by the methods indicated in paper No. 1 in this series [2].

The chemical properties of the *neo*pentyl-substituted barbituric acids resemble those of other alkyl barbituric acids in all respects. In some cases a slight steric effect of the *neo*pentyl group could be observed resulting in a comparatively low yield in certain syntheses, but this effect is by no means as marked as that produced by a *tert*-butyl group [3].

ladium on charcoal. The reaction is completed in 1/2 h if alcohol is used as a solvent, and the pressure is 50 atm. The yield is quantitative. B. p. 120°—130°/11 mm Hg.

D. *Preparation of ethyl* neo*pentylcyanoacetate.* Ethyl trimethylethylidenecyanoacetate is hydrogenated as described above to ethyl *neo*pentylcyanoacetate. The yield is quantitative and the boiling point 110°—114°/8 mm Hg.

5. 5-*neo*Pentyl-5-Allylbarbituric Acid and Related Compounds

III. On the Preparation of *neo*Pentyl-substituted Barbituric Acids

ARNE BRÄNDSTRÖM

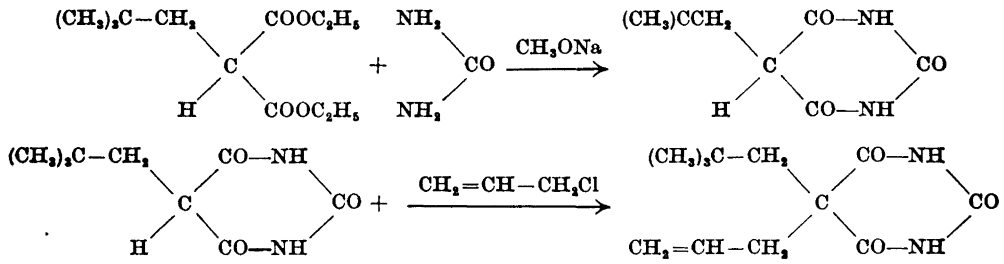
Research Laboratory, Pharmacia Ltd., Uppsala, Sweden

Since J. von Mering in 1903 discovered the hypnotic activity of a compound he erroneously considered to be 5,5-diethylbarbituric acid [1], 5,5-disubstituted barbituric acids have been extensively studied. In Chemical Abstract Decimal Index 1917—1926 the heading "barbituric acid" covers about 5 pages, in Decimal Index 1937—1945 8 pages and in Subject Index 1956 2 pages. This shows that the interest in substituted barbituric acids is ever increasing.

In spite of the enormous interest devoted to 5,5-disubstituted barbituric acids it appears that no barbituric acid containing a *neo*pentylsubstituent in the 5 position has been described. This is still more remarkable as many very useful hypnotics are barbituric acids with a side chain in the 5 position containing five carbon atoms usually in a branched-chain arrangement.

The introduction of a *neo*pentyl group in a molecule gives often a reactivity very different from that obtained with other aliphatic groups of the same size. This is clearly demonstrated by the well-known extremely low reactivity of *neo*pentyl halides compared with that of other alkyl halides and the tendency of *neo*pentyl compounds to undergo rearrangements instead of simple substitution reactions. Therefore, it is of interest to see if the properties of *neo*pentylsubstituted barbituric acids differs from those substituted with other alkyl groups. Consequently, a number of *neo*pentylsubstituted barbituric acids have been prepared by the methods indicated in paper No. 1 in this series [2].

The chemical properties of the *neo*pentyl-substituted barbituric acids resemble those of other alkyl barbituric acids in all respects. In some cases a slight steric effect of the *neo*pentyl group could be observed resulting in a comparatively low yield in certain syntheses, but this effect is by no means as marked as that produced by a *tert*-butyl group [3].



On the other hand the pharmacological properties are very interesting, especially those of 5-*neo*pentyl-5-allylbarbituric acid. This compound has the same depressive effect on the central nervous system as other barbiturates. In contrast to most barbiturates having only alkyl or alkenyl substituents in both 5 positions it has a distinct anticonvulsive effect. Therefore, in this respect it resembles 5-phenyl-5-ethylbarbituric acid. In contrast to this compound 5-*neo*pentyl-5-allylbarbituric acid has a moderate duration of effect just as most barbiturates substituted with branched chained alkyl groups.

The 5-*neo*pentyl-5-allylbarbituric acid has in contrast to, *e.g.*, 5-phenyl-5-ethylbarbituric acid and 5-*iso*amyl-5-ethylbarbituric acid a normalizing effect on rats subjected to a psychical stress.

All these pharmacological results suggest that 5-*neo*pentyl-5-allylbarbituric acid has

properties that makes it useful as a sedative drug. Clinical investigations have confirmed this assumption [4].

For the syntheses of *neo*pentylsubstituted barbituric acids all the standard methods have been tried [5]. Most of them can be used with success, but the best method seems to be the condensation of the corresponding malonic ester with urea or guanidine. For the preparation of 5-*neo*pentyl-5-allylbarbituric acid the following reactions seem to be best *(cf.* p. 620).

The condensation of diethyl *neo*pentylallylmalonate with urea seems to give a somewhat low yield of the barbituric acid probably due to steric effects. The disubstituted cyanoacetic esters containing one *neo*pentyl group do not give the corresponding iminobarbituric acid probably due to the very low reactivity of the cyano group.

Experimental. Condensations to barbituric acids. 55 *g* of sodium are dissolved in 1 100 ml of anhydrous methanol in a 3-litre three-necked flask provided with a stirrer, a reflux condenser and a stopper, and 75.5 g of dried urea and 1 mole of the malonic ester are added. The mixture is refluxed for 6 h whereupon the methanol is distilled off as completely as possible by means of an oil-bath, the temperature of which should not exceed 100°. At the end of the distillation the pressure is reduced. The contents of the flask are dissolved in water and the solution extracted with benzene to remove water insoluble products, whereupon the water-layer is acidified with conc. hydrochloric acid while cooling and stirring. The barbituric acid is filtered off, washed with water and dried in a drying oven at 80° to constant weight. The products can usually be recrystallized from dilute methanol. The yields and melting points are given in Table 1.

Allylations of 5-neopentylbarbituric acid. The method given above for the preparation of 5-*neo*pentylbarbituric acid is followed until the methanol has been distilled off. 500 ml of water is now added and the pH of the resulting solution adjusted to about 8 by careful addition of conc. hydrochloric acid (about 128 ml). At this point a slight precipitation may be present which is filtered off. 120 g of allyl bromide is added and the mixture is stirred at 40° in a 2-litre flask fitted with a stirrer, a reflux condensor, and a thermometer. After about 2 h the mixture becomes acidic (pH about 3). The barbituric acid is now filtered off, washed with water and dried. The resulting 5-*neo*pentyl-5-allylbarbituric acid is practically pure, m. p. 154—157°, but may be purified by recrystallisation from dilute methanol. The yield is 63 %, m. p. 156°.

In the method given above the allyl bromide can be replaced by an equivalent amount of allyl chloride together with a solution containing 2 g of cupric sulphate. The yield is the same as above but the product must be dissolved in a dilute sodium hydroxide solution and precipitated with hydrochloric acid in order to obtain a pure product. By rigorous exclusion of all traces of water in the condensation step yields of up to 85 % may be obtained by this method in large scale runs.

Preparation of 5-β-bromoallyl-5-neopentylbarbituric acids. 1 Mole of 1-ethyl-5-*neo*pentylbarbituric acid is dissolved in a solution of 40 g of sodium hydroxide in 1 200 ml of water. 10 g of crystallized cupric sulphate dissolved in a small quantity of water is added, and then 390 ml of 2,3-dibromopropene. The mixture is

stirred at 40° in a 3-litre three-necked flask for 20 h.

The resulting mixture is distilled under reduced pressure (about 60 mm Hg) to remove the excess of 2,3-dibromopropene. About 240 ml are thus recovered. The residue in the flask is filtered and washed with a small quantity of petroleum ether.

The product is dissolved in an ice-cold solution of 65 g of sodium hydroxide in 2 500 ml of water. An insoluble residue of about 10 g is filtered off. The solution is treated with discolouration carbon and then 10 g of ethylenediaminetetraacetic acid are added to remove cupric ions. The filtered solution is carefully added to 150 ml of concentrated hydrochloric acid. The product is filtered off, washed with water and recrystallized from methanol. The yield is 235 g (68 %) of a pure white product with a melting point of 144.8°—145.0°.

In exactly the same way the compounds in Table 2 are prepared.

On the Relation between the Reaction Velocity and Dielectric Constant of the Medium

EERO TOMMILA

Institute of Chemistry, University of Helsinki, Finland

According to Laidler and Eyring [1], the effect of the dielectric constant of the solvent on the rate of a bimolecular reaction between two dipole molecules A and B,

$$A + B \rightarrow M^* \rightarrow \text{Products},$$

can be expressed by the equation

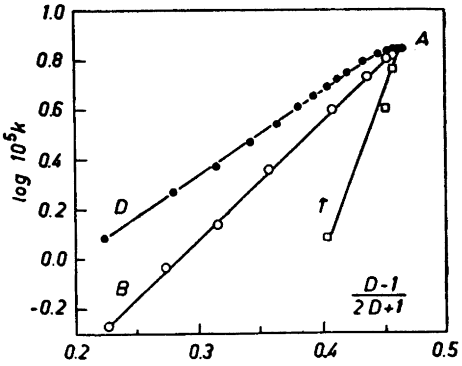

Fig. 1. Plot of log k for the reaction $(C_2H_5)_3N + C_2H_5I \rightarrow (C_2H_5)_4NI$ against $(D-1)/(2D+1)$ at 25°. A = acetone, B = benzene, D = dioxan, T = tetrahydrofuran.

where k and k_0 are the rate constants in a medium of dielectric constant D and in a medium of dielectric constant unity, respectively. The μ's and r's are the dipole moments and radii of the reactants and transition state, respectively. If the non-electrostatic term $\Sigma\Phi/kT$ is small enough to be neglected, and if μ^2_*/r^3_* is independent of the medium, the plot of log k against $(D-1)/(2D+1)$ should be a straight line for the same reaction carried out in different media. Linear plots were obtained for the reactions between pyridine and benzyl bromide and between triethylamine and benzyl bromide in benzene-ethanol mixtures, but not in benzene-nitrobenzene mixtures [1]. In cases where solvation phenomena play an important role, examination over larger areas of solvent mixtures has in general shown departure from linearity.

In Fig. 1 the eqn. (1) has been tested upon the results of some recent investigations concerning quaternary ammonium salt formation, *viz.* the reaction between triethylamine and ethyl iodide in acetone-benzene, acetone-dioxan, and acetone-tetrahydrofuran mixtures. The rate constants for 25° were calculated by the Arrhenius equation from the data of Tommila and Kauranen [2]. The dielectric constants of acetone-benzene mixtures were taken

$$\ln k = \ln k_0 - \frac{1}{kT}\,\frac{D-1}{2D+1}\left(\frac{\mu_A^2}{r_A^3} + \frac{\mu_B^2}{r_B^3} - \frac{\mu_*^2}{r_*^3}\right) + \frac{\Sigma\Phi}{kT} \qquad (1)$$

stirred at 40° in a 3-litre three-necked flask for 20 h.

The resulting mixture is distilled under reduced pressure (about 60 mm Hg) to remove the excess of 2,3-dibromopropene. About 240 ml are thus recovered. The residue in the flask is filtered and washed with a small quantity of petroleum ether.

On the Relation between the Reaction Velocity and Dielectric Constant of the Medium

EERO TOMMILA

Institute of Chemistry, University of Helsinki, Finland

According to Laidler and Eyring [1], the effect of the dielectric constant of the solvent on the rate of a bimolecular reaction between two dipole molecules A and B,

$$A + B \rightarrow M^* \rightarrow \text{Products},$$

can be expressed by the equation

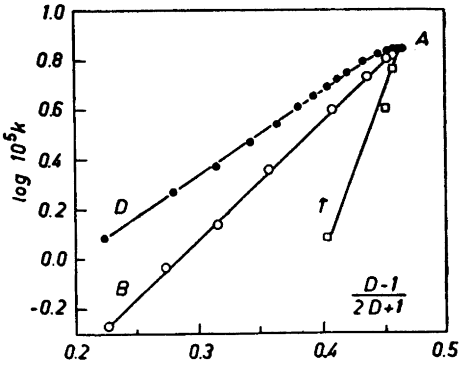

Fig. 1. Plot of log k for the reaction $(C_2H_5)_3N + C_2H_5I \rightarrow (C_2H_5)_4NI$ against $(D-1)/(2D+1)$ at 25°. A = acetone, B = benzene, D = dioxan, T = tetrahydrofuran.

where k and k_0 are the rate constants in a medium of dielectric constant D and in a medium of dielectric constant unity, respectively. The μ's and r's are the dipole moments and radii of the reactants and transition state, respectively. If the non-electrostatic term $\Sigma\Phi/kT$ is small enough to be neglected, and if μ^2_*/r^3_* is independent of the medium, the plot of log k against $(D-1)/(2D+1)$ should be a straight line for the same reaction carried out in different media. Linear plots were obtained for the reactions between pyridine and benzyl bromide and between triethylamine and benzyl bromide in benzene-ethanol mixtures, but not in benzene-nitrobenzene mixtures [1]. In cases where solvation phenomena play an important role, examination over larger areas of solvent mixtures has in general shown departure from linearity.

In Fig. 1 the eqn. (1) has been tested upon the results of some recent investigations concerning quaternary ammonium salt formation, *viz.* the reaction between triethylamine and ethyl iodide in acetone-benzene, acetone-dioxan, and acetone-tetrahydrofuran mixtures. The rate constants for 25° were calculated by the Arrhenius equation from the data of Tommila and Kauranen [2]. The dielectric constants of acetone-benzene mixtures were taken

$$\ln k = \ln k_0 - \frac{1}{kT}\,\frac{D-1}{2D+1}\left(\frac{\mu_A^2}{r_A^3} + \frac{\mu_B^2}{r_B^3} - \frac{\mu_*^2}{r_*^3}\right) + \frac{\Sigma\Phi}{kT} \qquad (1)$$

from the measurements of Drude [3] and those for acetone-dioxan and acetone-tetrahydrofuran mixtures from a recent communication of Lindberg [4]. It is seen that in acetone-benzene mixtures the plots are linear within the limits of experimental error over the whole range of the mixtures. In acetone-dioxan mixtures there is at 25° a weak deviation from the rectilinear course in the range from pure acetone to 12 % dioxan, but from the values of the rate constant one can conclude that this deviation disappears at 40° and higher temperatures. In acetone-tetrahydrofuran mixtures the number of kinetic data is too small for definite conclusions, but it seems probable that in this solvent system the plot is also linear over the whole range of mixtures.

The slope of the plots shows that in eqn. (1) the last term in the brackets is greater than the sum of the first two terms. This is quite natural, since the final products of the reaction are ionized and, accordingly, it is reasonable to assume that the dipole moment of the transition complex is large. The different slopes of the plots show that the term in brackets has different values for the three solvent systems.

The Structure and Synthesis of *Cyclo*alliin Isolated from *Allium cepa*

ARTTURI I. VIRTANEN and E. J. MATIKKALA

Laboratory of the Foundation for Chemical Research, Biochemical Institute, Helsinki, Finland

Some years ago we [1] isolated from a 70 % ethanol extract of onion after hydrolysis with 6 N HCl the crystalline hydrochloride of a sulphur-containing amino acid $C_6H_{11}O_3NS \cdot HCl$. Before hydrolysis it was not found in onion. This amino acid could be oxidized by 30 % hydrogen peroxide in glacial acetic acid to the corresponding sulphoxide which was isolated as the crystalline hydrochloride $C_6H_{11}O_4NS \cdot HCl \cdot H_2O$ (Virtanen and Bramesfeld). Because the sulphoxide could be reduced with Raney nickel back to $C_6H_{11}O_3NS$ it was clear that an amino acid sulphoxide and its thioether were in question.

Later on the sulphoxide was found as an original amino acid in onion [2]. The first isolated S-amino acid was obviously formed from the sulphoxide on treatment with strong hydrochloric acid. The amino acid sulphoxide was isolated from a 70 % ethanol extract of onion. The elementary composition of the isolated and recrystallized amino acid hydrochloride corresponded to the formula $C_6H_{11}O_4NS \cdot HCl \cdot H_2O$. (Found: C 31.31 ; H 6.37 ; N 5.90 ; S 13.60 ; Cl 15.20. Calc. C 31.09 ; H 6.09 ; N 6.04 ; S 13.84 ; Cl 15.31.) On spraying with ninhydrin it gives a greenish blue spot, its reduced S-compound a violet one, on the paper chromatogram. The sensitiveness of of the colour reaction of the sulphoxide is about 1/20, and that of the S-compound about 1/10, of that of alanine. R_F-values for the sulphoxide: 0.85 in phenol-NH_3, 0.15 in butanol-acetic acid-water, and for the S-compound: 0.90 in phenol-NH_3, 0.48 in butanol acetic acid-water [2]. Sulphoxide $[\alpha]_D^{20} -17.4°$ (in water).

There is no double bond and also no primary amino group in either of the amino acids. The nitrogen belongs to an imino group. On the basis of these facts and the elementary composition of the substance it should contain a heterocyclic ring.

Detailed investigations of the products formed by heating of the sulphoxide with 6 N HCl at 105°C for 43 h elucidated the structure of this compound. As reduction products the corresponding thioether (II) and as oxidation products 2-aminopropane-1-sulphonic acid (2-methyltaurine) (III) and cysteic acid (IV) were formed. In addition a small spot in the solvent front (phenol), probably an amine, was found on the paper chromatogram (Fig. 1). These results led to structure I for the sulphoxide and structure II for the thioether [3,4].

The elementary composition of compound III corresponded to the formula $C_3H_9O_3NS$. Paper chromatographically it was identical with synthetic 2-methyltauri-

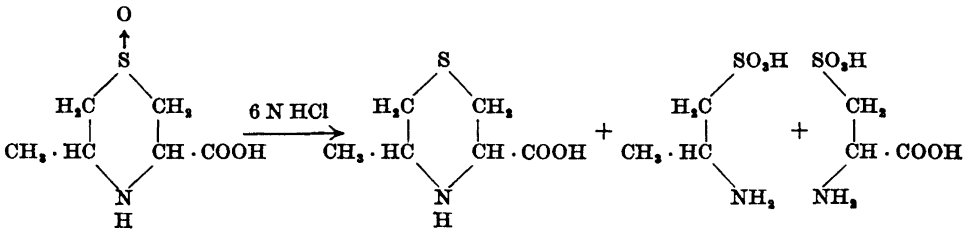
On spraying with ninhydrin it gives a greenish blue spot, its reduced S-compound a violet one, on the paper chromatogram. The sensitiveness of of the colour reaction of the sulphoxide is about 1/20, and that of the S-compound about 1/10, of that of alanine. R_F-values for the sulphoxide: 0.85 in phenol-NH_3, 0.15 in butanol-acetic acid-water, and for the S-compound: 0.90 in phenol-NH_3, 0.48 in butanol acetic acid-water [2]. Sulphoxide $[\alpha]_D^{20} -17.4°$ (in water).

There is no double bond and also no primary amino group in either of the amino acids. The nitrogen belongs to an imino group. On the basis of these facts and the elementary composition of the substance it should contain a heterocyclic ring.

Detailed investigations of the products formed by heating of the sulphoxide with 6 N HCl at 105°C for 43 h elucidated the structure of this compound. As reduction products the corresponding thioether (II) and as oxidation products 2-aminopropane-1-sulphonic acid (2-methyltaurine) (III) and cysteic acid (IV) were formed. In addition a small spot in the solvent front (phenol), probably an amine, was found on the paper chromatogram (Fig. 1). These results led to structure I for the sulphoxide and structure II for the thioether [3,4].

The elementary composition of compound III corresponded to the formula $C_3H_9O_3NS$. Paper chromatographically it was identical with synthetic 2-methyltauri-



I II III IV

3-Methyl-1,4-thiazane-5-carboxylic acid-1-oxide (*Cyclo*alliin)

3-Methyl-1,4-thiazane-5-carboxylic acid (Thioether of *cyclo*alliin)

2-Aminopropane-1-sulphonic acid (2-Methyltaurine)

Cysteic acid

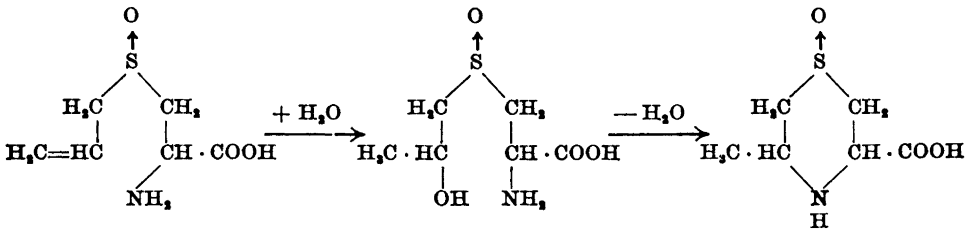
ne which was synthesized from allylamine by the method of Rumpf [4] and separated from salts in an Amberlite IR-120 column. The IR-spectra of the synthetic product and substance III were identical, and hence the formation of 2-methyltaurine as an oxidation product of amino acid I was confirmed.

Cysteic acid was characterized by paper chromatography. Beside these products a red pigment was formed which could be divided into two spots on the paper chromatogram. The chemical nature of these substances is not known yet. Since the oxidation products 2-methyltaurine and cysteic acid do not by far correspond quantitatively to the reduction product, thioether, it is probable that the coloured compounds in question are also oxidation products from *cyclo*alliin.

Because the new amino acid (3-methyl-1,4-thiazane-5-carboxylic acid-1-oxide) which occurs in onion originally has the same elementary composition as alliin, the name *cyclo*alliin is proposed for it [5]. In addition, the biosynthesis of *cyclo*alliin from alliin (V), is possible *e.g.*

The structure of *cyclo*alliin could also be confirmed through the synthesis of 3-methyl-1,4-thiazane-5-carboxylic acid. The way of the synthesis was the following (p. 625).

L-Cystein was used in the synthesis of S-allylcystein. 3 g of S-allylcystein was added to 200 ml of glacial acetic acid and the suspension, saturated with HBr at 0°C, was allowed to stay for 3 1/2 days in a sealed tube. S-Allylcystein then dissolved almost completely. Glacial acetic acid and HBr were distilled off *in vacuo* and pyridine was added to the residue, after which the mixture in a bottle with a reflux condenser was allowed to stay for 4 h in a boiling water bath. Pyridine was removed *in vacuo* and the residue was dissolved into 2.5 N HCl. The amino acids in the solution were then fractionated in a 4.3 × 61 cm column filled with Dowex 50 (200—400 mesh). The resin was in the H-form, in equilibrium with 2.5 N HCl. The dropping rate was about 1 ml/min. Fractions 1 480—2 180 ml contained an unknown amino acid, probably some hydroxyamino acid, which paper-chromatographically differed completely from the thioether of *cyclo*alliin. Fractions 2 530—3 240



V I

$$CH_2{=}CH \cdot CHBr + HS \cdot CH_2 \cdot CH(NH_2) \cdot COOH \rightarrow CH_2{=}CH \cdot CH_2 \cdot S \cdot CH_2 \cdot CH(NH_2) \cdot COOH \xrightarrow{HBr}$$

$$CH_2 \cdot CHBr \cdot CH_2 \cdot S \cdot CH_2 \cdot CH(NH_2) \cdot COOH \xrightarrow{\text{pyridine}}$$

$$CH_2 \cdot CH \cdot CH_2 \cdot S \cdot CH_2 \cdot CH \cdot COOH \xrightarrow{H_2O_2} CH_2 \cdot CH \cdot CH_2 \cdot SO \cdot CH_2 \cdot CH \cdot COOH$$
$$\quad\quad\quad

thioether of *cyclo*alliin, was oxidized with hydrogen peroxide into the corresponding sulphoxide this gave the same products both quantitatively and qualitatively as *cyclo*alliin with 6 N HCl at 105°C (Fig. 1). Their IR-spectra resembled each other, but were not identical, however.

As mentioned before, RS I travelled somewhat slower than the thioether of *cyclo*alliin on the paper chromatogram. Both were coloured with ninhydrin in the same way. Oxidized into the sulphoxide RS I gave the same products with 6 N HCl in 105°C as *cyclo*alliin. The IR-spectra differed more from each other than did those of *cyclo*alliin and RS III. Also RS IV travelled slower on the paper chromatogram than RS III, its spot was coloured more strongly with ninhydrin than were those of RS I, RS III, and the thioether of *cyclo*alliin. Also RS III is coloured with ninhydrin somewhat stronger than the natural compound. Although a compound which would have had identical IR-spectra with natural *cyclo*alliin resp. its thioether could not be separated from the synthetical products, all the known facts suggest that the three compounds RS I, RS III and RS IV are stereoisomers of the natural compound. The properties of synthetic RS III and the thioether of *cyclo*alliin are in all respects closest in resemblance.

*Cyclo*alliin represents a new type of natural amino acids. It could been found in all parts of the *Allium* species investigated (*A.cepa*, *A.sativum*, *A. porrum*). The highest content of *cyclo*alliin was found in onion imported from Hungary (3.2 g hydrochloride per kg). From a batch of onions cultivated in Finland 1.4 g per kg was isolated.

The financial support of the *Rockefeller Foundation* is gratefully acknowledged. Thanks are due to Mrs. Anneli Lehtinen for skilful technical assistance.

ACTA CHEMICA SCANDINAVICA 13 (1959) 627–640

On the Properties of a New Thiol Reagent: 6-Chloromercuri-2-nitrophenol *

STIG ÅKERFELDT

Eastern Pennsylvania Psychiatric Institute, Philadelphia, Pennsylvania, U.S.A.

6-Chloromercuri-2-nitrophenol (CMNP) has been prepared from mercury(II) acetate and *o*-nitrophenol by an improved method.

CMNP was found to react rapidly and quantitatively above pH *ca.* 3.5 with all true and with some potential thiols investigated (giving MNP-thiols). The effect of reaction time, pH and NaCl concentration on this reaction has been studied.

A method is described for quantitative determination of thiols insoluble in toluene or in 1,2-dichloroethane. Concentrations down to the order of 10 μM can thus be determined.

CMNP was found to be a specific reagent for true and potential thiols at pH 4, the only exception found being the cyanide ion.

Mixtures of MNP-thiols have been separated by paper chromatography. R_F-values for some thiols of biochemical interest are given in 4 solvent systems.

A "ghost" spot on the chromatograms was identified as 2,2′-dihydroxy-3,3′-dinitro-diphenylmercury.

Organic mercury compounds, such as the now classical *p*-chloromercuribenzoic acid [1], are among the reagents employed for thiols. As such they have the advantage of being relatively specific and fast reacting.

In this laboratory the study of a few mercury derivatives of nitrophenols was undertaken. These compounds have the advantage of being colored and their reaction with thiols can therefore be conveniently studied colorimetrically.

The substances investigated here were 4-acetoxymercuri-2-nitroresorcinol [2], 4-chloromercuri-2-nitrophenol [2], and 6-chloromercuri-2-nitrophenol [3]. Of these, 6-chloromercuri-2-nitrophenol was found to react rapidly and quantitatively with thiols above pH *ca.* 3.5. This reaction (Fig. 1) was studied in detail.

The results show that at pH 4, 6-chloromercuri-2-nitrophenol is a highly specific reagent for thiols.

---

* Some preliminary investigations for this work were carried out at the Biochemical department of the Nobel Medical Institute, Stockholm, Sweden.

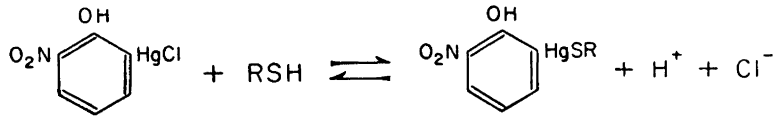

Fig. 1. The reaction between CMNP and thiols.

The reaction products of 6-chloromercuri-2-nitrophenol and various thiols have been separated by paper chromatography. The fact that these thiol derivatives are highly colored renders them especially suitable for chromatographic analysis.

The advantages of 6-chloromercuri-2-nitrophenol over some previously studied colored mercury-containing thiol reagents [4–6] (which all were azo compounds) are: a) the new reagent is easy to prepare in satisfactory yields; b) it can be used as a reagent in chromatography of thiols.

An improved method for the synthesis of 6-chloromercuri-2-nitrophenol is also reported.

MATERIALS AND METHODS

The thiols used in these investigations were from Mann Laboratories, Nutritional Biochemicals Corporation, and Eastman Company. *o*-Nitrophenol (m. p. 44–46°) was obtained from Eastman Company (samples from some other sources were less pure and gave lower yields of 6-chloromercuri-2-nitrophenol). Mercury (II) acetate was of analytical purity obtained from Merck Company. All solvents used in chromatography and elsewhere, as well as other chemicals, were of highest commercially obtainable purity. They were used without further purification.

Buffers used (unless otherwise stated):

pH 1.1– 6.6	0.1 M citrate
7.2– 9.0	0.1 M tris(hydroxymethyl)aminomethane
9.0–12	0.1 M glycine

Unless otherwise stated, all experiments were carried out at room temperature (25°C). All melting points (°C, Kofler method) are corrected. Spectrophotometric measurements were performed in 1 cm cuvettes with a Beckman Model DU spectrophotometer.

Abbreviations used:

CMNP = 6-chloromercuri-2-nitrophenol
MNP-thiol = S-(2-hydroxy-3-nitrophenyl mercuri)-thiol
EDTA = (ethylenedinitrilo) tetraacetic acid
ε_λ = molar extinction coefficient at λ mμ (1 cm cuvette)

Synthesis of 6-chloromercuri-2-nitrophenol.

The mercuration of nitrophenols with mercury (II) acetate generally proceeds easily, but the product obtained practically always seems to consist of a mixture of all theoretically likely monomercury derivatives plus considerable amounts of dimercuri derivatives [2,3,7].

Hodgson [3] synthesized 6-acetoxymercuri-2-nitrophenol by fusing mercury (II) acetate with a large excess of *o*-nitrophenol. However, the yield is poor.

Contrary to Hodgson's statement [3] that 4-acetoxymercuri-2-nitrophenol is preferentially formed by boiling mercury(II) acetate and *o*-nitrophenol in solvent media, we found that when 1-butanol, 1-propanol or methanol were employed as solvents, the 6-acetoxymercuri derivative could be isolated from the reaction product in fairly good yields. However, employing high boiling solvents like 1-butanol caused large amounts of the dimercury derivative to form, and low boiling solvents like methanol gave poor yields. In boiling 1-propanol, however, the reaction proceeded rapidly and the yield of the 6-acetoxymercuri derivative was satisfactory. As has been pointed out by previous investigators [2,3] the 6- resp. 4-acetoxymercuri-2-nitrophenols are difficult to obtain in a pure form, mainly because the dimercuri derivative, which is formed simultaneously, shows somewhat similar solubility properties as the monomercuri derivatives. We found it advantageous to convert the resulting mixture of acetoxymercuri-2-nitrophenols into their chloride forms prior to purification. CMNP could then be preferentially extracted from the crude product with acetone. Another advantage of working with the chloride is that it has a conveniently located melting point (190°) and its purity could thus be checked easily. The acetate does not melt below 300°.

It should be pointed out, however, that there is no substantial difference between the chloride and the acetate in regard to their reactivity toward thiol groups.

Procedure of preparation. To a refluxed solution of 15.0 g (0.108 mole) of *o*-nitrophenol in 50 ml 1-propanol is added 34.5 g (0.108 mole) of mercury (II) acetate in small portions during one hour. The mixture is refluxed for another hour, poured onto 200 g of cracked ice and filtered when ice cold. The yellow precipitate is washed with 50 ml of distilled water and with 25 ml of 95 % ethanol. To convert the substances into their chloride forms they are vigorously stirred for 15 min with 100 ml of a saturated solution of sodium chloride in water. The suspension is then filtered and washed free of chloride ions with distilled water and dried at room temperature in the dark.

The dry, yellow substance obtained (31—34 g) is refluxed for 15 min with 200 ml of acetone and filtered. The undissolved residue is extracted for another 15 min with 100 ml of acetone and filtered. The pooled acetone extracts are evaporated to dryness in a stream of air at room temperature. 18—20 g (yield 45—50 %) of relatively pure CMNP (melting about 185°) is thus obtained. After two recrystallizations from 95 % ethanol it melts at 190°. (Upon storage the melting point tends to drop somewhat). Further recrystallizations do not change the melting point. (Hodgson [3] reports 185°.) The product was found to be fairly soluble in most organic solvents tested, especially in acetone, ethyl acetate and in chlorinated hydrocarbons. CMNP should be stored in a dark, dry and cool place.

Mercury determinations. 0.3 g of CMNP in 50 ml distilled water were mixed with 3 g of potassium iodide and with 1 g of iodine and carefully heated with occasional stirring until a clear solution resulted. Mercury was then determined as HgS in this solution according to Ref.[8] (Found: Hg 53.48, 53.55. Calc. for $C_6H_4ClHgNO_3$ (374.17): Hg 53.61).

Position of the mercury *. 0.15 g of CMNP (0.40 mmole), 0.10 g of iodine (0.40 mmole) and 0.5 g of potassium iodide in 10 ml of distilled water were carefully heated with occasional stirring until a clear solution resulted. The solution was cooled to room temperature, acidified with a few drops of 5 % hydrochloric acid and shaken with 10 ml of ethyl acetate. The ethyl acetate phase was separated and evaporated to dryness and the resulting crystals (0.10 g) were recrystallized once from 50 % ethanol. The golden yellow crystals obtained melted at 109° as reported for 6-iodo-2-nitrophenol [3,9]. No other monoiodo-2-nitrophenol has a melting point close to the one found [10,12].

* A similar technique has been used before [3,7] but no details were given.

It has been presumed that the iodine occupies the same position in the molecule as the mercury it replaces. According to the results of Henry and Sharp [13] this is not always true when halogens (*e. g.* bromine) react with a mercury atom attached to a benzene ring. These authors found, however, that iodine treatment gave the expected derivative in all cases studied.

Furthermore, 4-chloromercuri-2-nitrophenol as prepared by Hodgson [3], has a different melting point (205°) from the one found for CMNP. It seems therefore safe to presume that the mercury in CMNP occupies the 6 position.

The acetone insoluble fraction from the synthesis was treated in a similar manner and after two recrystallizations from 50 % ethanol the product melted at 96°, possibly indicating it to be 4,6-diiodo-2-nitrophenol (m. p. 98°) [11]. However, 5-iodo-2-nitrophenol has a similar melting point (96°) [12]. Mercury determinations performed on the acetone insoluble product were inconsistent, but indicated the presence of two mercury atoms per molecule of *o*-nitrophenol.

The acetone insoluble fraction was then treated with potassium bromide and bromine in an analogous manner to the one described above. After two recrystallizations from concentrated acetic acid the brominated compound melted at 119°, close to that reported for 4,6-dibromo-2-nitrophenol (120—121°) [13].

Thus the acetone insoluble fraction mainly consists of 4,6-di(chloromercuri)- 2-nitrophenol.

Absorption spectra of CMNP. Fig. 2 shows the absorption spectra of CMNP at pH 1.6 and at pH 9.1.

For quantitative measurements the peak at 420 mμ shown only in basic solutions was found convenient to use. From Fig. 3 it is seen that the pH-optimum for absorption at this wavelength is between pH 9—10 ($\varepsilon_{420} = (5.28 \pm 0.02) \times 10^3$ at pH 9.5).

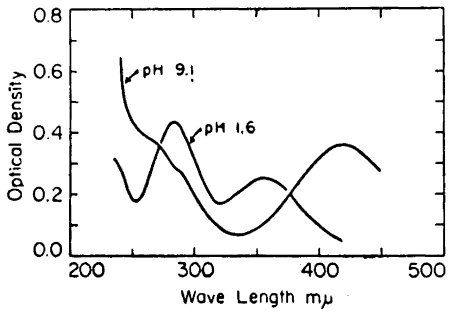

Fig. 2. Absorption spectra of CMNP (66.8 μM) at pH 1.6 and at pH 9.1.

In this pH-range the absorption follows Beer's law.

The absorption spectra of MNP-thiols were found to be almost identical with those presented in Fig. 2, provided the thiol itself does not absorb in this region. MNP-cysteine was found to have the same molar extinction coefficient as CMNP at pH 9.5 (420 mμ). That of MNP-glutathione is practically the same ($\varepsilon_{425} = (5.22 \pm 0.03) \times 10^3$) at this pH, but the absorption maximum was shifted somewhat towards longer wavelengths (425 mμ).

The color at 420 mμ (pH 9.5) was found to be stable within reasonable time limits (Table 1).

Table 1. Color stability of MNP-cysteine (85.8 μM) at pH 9.5.

Time minutes	Optical density at 420 mμ
0	0.452
60	0.453
270	0.452

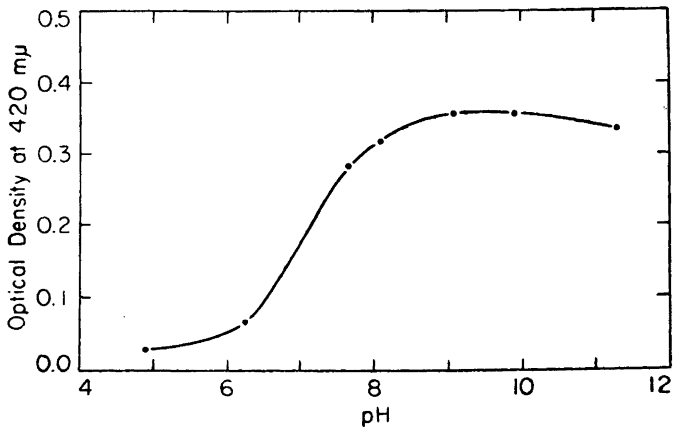

Fig. 3. Effect of pH on absorption peak at 420 mμ. Concentration of CMNP 66.8 μM.

THE REACTION BETWEEN CMNP AND THIOLS

When a thiol dissolved in a buffer of about pH 4 is shaken with a solution of CMNP in an organic solvent, *e.g.* toluene, a yellow color or precipitate generally appears in the water phase. The reaction taking place is described in Fig. 1.

Effect of pH. Cysteine and glutathione dissolved in buffers of varying pH were mechanically shaken with a solution of CMNP in toluene and the decrease in optical density at 355 mμ (the absorption at this wavelength follows Beer's law) in the toluene layer was followed. Simultaneously, blanks containing only the corresponding buffers and reagent in toluene were shaken at the same rate. The difference in optical density between the two toluene layers after completed reaction was taken as a measure of the amount of reacted thiol. From the molar extinction coefficient for CMNP in toluene ($\varepsilon_{355} = (3.91 \pm 0.02) \times 10^3$) it was thus possible to calculate the amount of reacted thiol.

As is seen from Fig. 4 both glutathione and cysteine react quantitatively (97—100 %) under the conditions employed. The difference in structure between glutathione and cysteine apparently does not have a significant influence on the pH dependence of the reaction.

Above pH 5 the reagent becomes very water soluble (Table 2) and the reaction becomes difficult to follow with the described technique. However,

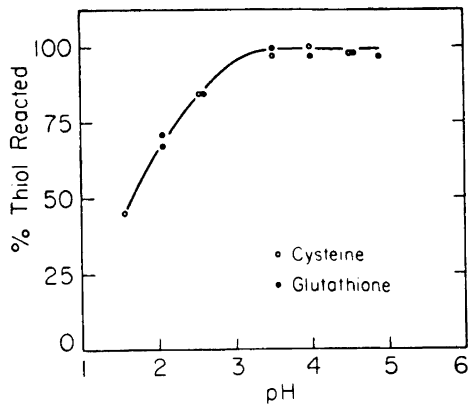

Fig. 4. Effect of pH on the reaction between cysteine, glutathione and CMNP. 6 ml 0.3 mM solutions of thiols in buffers of varying pH (blanks: 6 ml of corresponding buffer) were shaken for 1 minute at the rate of 300 cycles/min with 6 ml 0.03 % CMNP in toluene. For calculation of data see text.

it can be shown by paper chromatography that the thiols investigated also react with the reagent in the pH range 5—12.

Table 2. Distribution of CMNP between buffers and 1,2-dichloroethane. Data were obtained by shaking 0.5 % solutions of CMNP in 1,2-dichloroethane for 10 min at the rate of 300 cycles/minute with an equal volume of buffer of indicated pH. The concentration of CMNP in the water phase was calculated from the optical density at 420 mμ of the water phase after adjustment to pH 9.5. It should be noted that the distribution of CMNP between the phases is much affected by the organic solvent used.

pH	Concentration of CMNP in water phase (μM)
1.56	20
2.59	20
3.52	19
4.00	24
4.90	259

Effect of shaking time. As is shown in Fig. 5 the reaction between glutathione, cysteine and the reagent is completed within one minute under the experimental conditions used. Prolonged shaking increases the optical density in the toluene layer (*i.e.* decreases the difference in readings between blank and sample) thus showing a slight decomposition of the reaction product. This decomposition could be almost completely prevented by the addition of excess cyanide (see Fig. 5), but not by EDTA in similar concentrations.

It thus appears likely that cyanide does not act mainly by binding traces of heavy metals present (which catalyze the autooxidation of thiols) but by forming a cyanide complex with the MNP-thiol. This view is supported by the fact that cyanide, but not EDTA, reacts with CMNP itself under identical

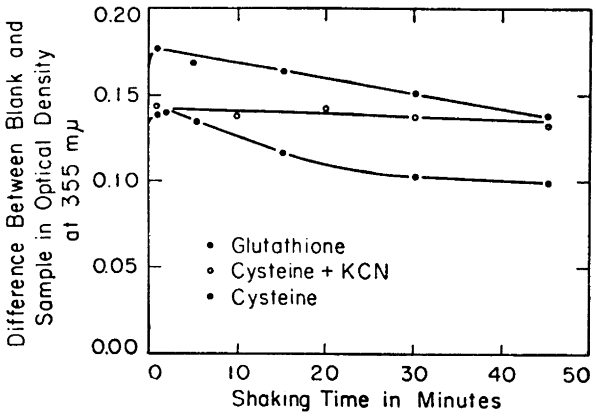

Fig. 5. Effect of shaking time on the reaction between cysteine, glutathione and CMNP. 6 ml thiol of pH 4.0 (blanks: 6 ml buffer of pH 4.0) were shaken at the rate of 300 cycles/min with 6 ml of 0.03 % CMNP in toluene. Optical density of 0.5 ml toluene phase + 3.0 ml of toluene was followed. Concentrations: Cysteine 0.25 mM; glutathione 0.32 mM. KCN in cysteine solution and in corresponding blank: 1.7 mM.

conditions. A possible degradation product is 2,2'-dihydroxy-3,3'-dinitro-diphenylmercury (see later paragraphs).

In basic solutions, however, MNP-thiols seem to be much less subject to decomposition, which can be shown by paper chromatography.

Reversibility of the reaction. By shaking a suspension of a MNP-thiol, such as MNP-glutathione, with an acid of about pH 1 the MNP-thiol is completely decomposed and all the color of the original solution can be taken up in *e.g.*, 1,2-dichloroethane. Analysis of the yellow dissociation product by paper chromatography after treatment of MNP-thiols with 0.1 M hydrochloric acid showed it to consist of CMNP contaminated with a small amount of 2,2'-dihydroxy-3,3'-dinitro-diphenylmercury (see later paragraphs about this compound).

Quantitative measurements. The results of the above experiments suggested that CMNP can be used as a quantitative reagent for thiols. Fig. 6 shows the results of the quantitative determination of cysteine.

The reaction was carried out by shaking cysteine solutions of pH 4.0 with a reagent solution in toluene, and the amount of reacted thiol was determined by measuring the decrease in optical density at 355 mμ in the toluene layer. In each instance 98—100 % reaction was obtained as calculated from ε_{355} for CMNP in toluene. The addition of cyanide to the reaction mixture gave little, if any, improvement when the shaking time was kept short. Furthermore, large excess of cyanide gave low readings.

When very small amounts of thiol were present higher accuracy was achieved by measuring the optical density of the water phase after completed shaking with CMNP. In such cases it is convenient to use a solvent for the reagent which has a density higher than 1 (*e.g.* 1,2-dichloroethane) so that a sample of the water layer can be directly pipetted off after completed reaction.

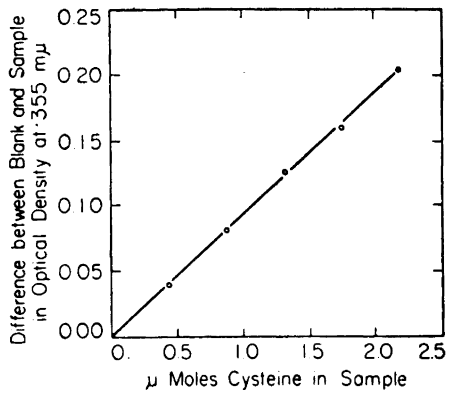

Fig. 6. Determination of cysteine with CMNP. 6 ml of cysteine solution of pH 4.0 (blanks: 6 ml buffer of pH 4.0) were shaken with 6 ml of 0.03 % CMNP in toluene for 1 minute at the rate of 300 cycles/min. The optical density of 0.5 ml toluene phase + 3.0 ml of toluene was determined.

The sample is then adjusted to pH 9.5 by the addition of a buffer of a suitable strength and the optical density at about 420 mμ is determined (the exact wavelength varies somewhat with the thiol used).

This method is generally not applicable when solutions of a high thiol concentration are used, as a precipitate then tends to form in the water-phase.

Care should be taken to avoid very high ionic strengths in the solutions to be measured as this decreases the completeness of the reaction (Fig. 7).

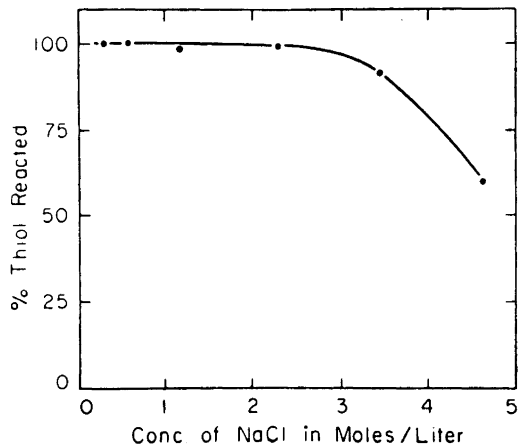

Fig. 7. Effect of NaCl concentration on the reaction between cysteine and CMNP. 0.3 mM solutions of cysteine in buffer containing various amounts of NaCl (final pH adjusted to 4.2—3.8; blanks contained the same buffer — NaCl mixtures) were shaken for 1 min at the rate of 300 cycles/min with equal volumes of 0.03 % CMNP in toluene. The reaction was followed by the decrease in optical density in the toluene phase. The amount of reacted cysteine was calculated as in Fig. 4.

With both methods a thiol concentration of 0.02 mM (3 μg cysteine/ml) gives a change in optical density of the order of 0.1.

Quantitative determination by the above methods is obviously limited to those thiols, which are not soluble in the organic solvents used.

Specificity of the reaction. As is seen from Table 3 CMNP reacts almost exclusively with true or potential thiols at pH 4, the only exception found being the cyanide ion. Thioethers, thiolactones, disulfides, sulfonic acids and sulfinic acids do not seem to react. At higher pH's, however, some substances were found to react with the reagent. *E.g.*, EDTA reacts at pH 7.

Table 3. Reactivity of compounds towards CMNP. Data were obtained by dissolving the compounds to be tested (1 – 2 mg/ml) in 1 M citrate buffer of pH 4.0 and shaking the solutions for one minute with a solution of CMNP (0.2 %) in 1,2-dichloroethane. The appearence of a yellow color or precipitate in the water phase indicated positive reaction. Reactivity values were obtained from quantitative determinations of 0.3 mM solutions of the compounds as described above (1 min shaking time).

Compounds that react with CMNP	Reactivity %	Nonreactive compounds
2-Aminoethanethiol	103	Benzenesulfinic acid
Cysteine	100	DL-(+)-*allo*-Cystathionine

PAPER CHROMATOGRAPHY OF MNP-THIOLS

Success in applying paper chromatography as a separatory means of MNP-thiols fundamentally depends on the stability of these compounds. As mentioned above MNP-thiols are not quite stable at slightly acid pH's. Fortunately, the MNP-thiols investigated were found to be more stable in alkaline solution. In fact, solutions of most investigated MNP-thiols in 0.1 M sodium hydroxide or in 1 % piperidine did not remarkably change their chromatographic properties after storage for a few days, even if the solutions were kept at room temperature.

Paper chromatography was thus attempted with the main emphasis on basic solvent systems in combination with treated and untreated varieties of paper. Out of some 300 combinations of solvents and varieties of papers tested, the best results were obtained when MNP-thiols were chromatographed on paper, which previously had been impregnated with sodium carbonate. A wide variety of solvent systems were found to be useful in combination with this paper.

"Ghost" spots. When chromatographing MNP-thiols in the manner just described, a small yellow red "ghost" spot was practically always observed accompanying the main MNP-thiol spot. This "ghost" spot had the same R_F-value independent of the MNP-thiol from which it was derived. Its position on the chromatgrams was different from that of CMNP and from MNP-H_2S. It was not identical with *o*-nitrophenol. The "ghost" spot did not contain sulfur, as judged by the cyanide-nitroprussiate reaction. Nor was it ninhydrin positive when derived from amino group containing MNP-thiols.

The size of the "ghost" spot relative to that of the parent MNP-thiol spot varied with the solvent used for the development of the chromatogram. For instance, exceptionally large "ghost" spots were obtained when using solvent systems rich in pyridine. Also, some MNP-thiols, especially MNP-cysteine, gave relatively more "ghost" spot than others. The addition of cyanide to the solvent systems did not significantly decrease the amount of "ghost" spot.

It was found, however, that if the MNP-thiols were prepared at 0° and chromatographed with the solvent systems listed in Table 4, relatively smaller amounts of "ghost" spot was present on the finished chromatograms than when they were prepared at 25°. It is thus clear that much of the compound responsible for the "ghost" spot is formed during the preparation of MNP-thiols, when this takes place at room temperature.

Furthermore, some solvent systems decompose MNP-thiols during chromatography more easily than others.

A substance with the same chromatographic and spectrophotometric properties as the "ghost" spot is formed when MNP-thiols are heated in neutral solutions (*e.g.* when attempts are made to recrystallize MNP-thiols from water or ethanol). A convenient way to obtain this substance in quantity is to boil an ethanol soluble MNP-thiol * (1 g) in 95 % ethanol (50 ml) for 30 min and to recrystallize the crystals appearing upon cooling from the same solvent. The decomposition product thus obtained is chromatographically pure.

Preliminary investigations of the compound, which does not melt below 300°, showed that it contains mercury. Upon treatment with iodine + iodide as described in earlier paragraphs, the compound is slowly converted into 6-iodo-2-nitrophenol and mercury(II) iodide. The substance did not react with thiols when the CMNP procedure was applied, suggesting that the mercury is bound by nonionizable bonds.

* *E.g.*, MNP-2-mercaptoethanol.

Using the molar extinction coefficient for CMNP at pH 9.5 (which seemed justified as an approximation method since all MNP-thiols investigated show very similar molar extinction coefficients) a molecular weight of 257 was obtained. This value, however, does not account for both the mercury and for the nitrophenol residue present. The presence of two nitrophenol residues in the substance must then be presumed. This would approximately double the molar extinction coefficient and give a molecular weight of the compound of the order of 500, which only allows for one mercury atom per molecule of compound.

Elementary analysis of the compound, finally, was in agreement with these findings. (Found: C 29.67; H 1.96; Hg 42.23. Calc. for $C_{12}H_8HgN_2O_6$ (476.81); C 30.23; H 1.69; Hg 42.07)

Thus the isolated compound is identical with 2,2'-dihydroxy-3,3'-dinitrodiphenylmercury, and the decomposition of MNP-thiols by heat *etc.* is most likely represented by the scheme in Fig. 8.

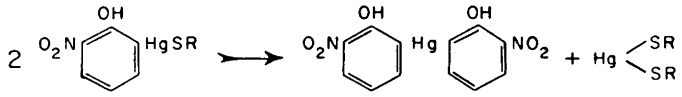

Fig. 8. Probable scheeme for the formation of "ghost" spots.

Preparation of MNP-thiols. Good yields of MNP-thiols were generally achieved by the following procedure carried out at 0°. 0.1 g thiol is dissolved in 5—10 ml of 1 M citrate buffer of pH 4 and an equivalent amount of CMNP in ethylacetate is added under vigorous stirring. A yellow precipitate appears immediately. If changed, pH is adjusted back to 4 with 0.1 M sodium hydroxide. The precipitate is filtered off and washed with 50 ml of water and with 10 ml of ethylacetate (ethylacetate soluble MNP-thiols are preferably washed with a small amount of ethanol). The substances can be further purified by dissolving them in the minimum amount of 0.1 M sodium hydroxide and reprecipitating them at pH 4 by the addition of 10 % acetic acid. After washing with water and with ethylacetate (ethanol) the MNP-thiols are dried at room temperature in the dark.

The MNP-thiols thus prepared are stable when stored in a dark, dry and cool place.

To prepare reference solutions for paper chromatography of thiols not soluble in organic solvents it is generally sufficient to shake the thiol, dissolved in buffer of pH 4 at 0°, with an excess of CMNP in 1,2-dichloroethane at 0°. After centrifugation a sample of the water phase (preferably containing some of the precipitate formed) is pipetted off and 0.1 M sodium hydroxide or 1 % piperidine is added dropwise until the solution turns yellow red (pH 9—10).

Chromatographic procedure. Whatman No. 1 papers were used exclusively. Prior to chromatography the papers were impregnated with a solution of 1 % $Na_2CO_3 \cdot H_2O$ in water by dipping the papers into the solution or by spraying them with the sodium carbonate solution until the papers were completely saturated. The papers were dried at room temperature.

For best results freshly impregnated papers should be used. The dried papers were spotted with MNP-thiols dissolved in 1 % piperidine or in 0.1 M sodium hydroxide.

All chromatograms were developed by the ascending technique and were run for 2—4 h in the dark. Longer runs are preferably carried out in a cold room at 0—4°, in order to decrease the amount of decomposition of MNP-thiols during chromatography. MNP-thiols appear as yellow spots. Amounts down to the order of 5 mμmoles/cm² are easily detected (Fig. 9).

Table 4. Approximate R_F-values of MNP-thiols chromatographed 3—4 h at room temperature on Whatman No. 1 paper impregnated with 1 % $Na_2CO_3 \cdot H_2O$.

Solvents (figures indicate volumes):
1. 95 % ethanol : water, 4:1
2. methanol : N,N-dimethylformamide : water, 3:1:1
3. 95 % ethanol : benzene : water, 4:1:1
4. 95 % ethanol : N,N-dimethylformamide : water, 3:1:1

Substance	Solvent No.			
	1.	2.	3.	4.
CLMNP	0.21	0.12	0.35	0.22
MNP-2-aminoethanethiol	0.55	0.53	0.74	0.63
MNP-cysteine	0.28	0.33	0.45	0.39
MNP-ergothioneine	0.51	0.53	0.75	0.65
MNP-glutathione	0.07	0.13	0.10	0.09
MNP-homocysteine	0.23	0.32	0.35	0.28
MNP-mercaptoacetic acid	0.41	0.47	0.61	0.58
MNP-2-mercaptoethanol	0.85	0.79	0.97	0.90
MNP-2-mercaptohistidine	0.21	0.29	0.41	0.33
2,2′-dihydroxy-3,3′-dinitro-diphenylmercury	0.41	0.51	0.69	0.67

Fig. 9. Paper chromatogram of MNP-thiols (5—10 μg/spot) developed at room temperature (2 h) on Whatman No. 1 paper impregnated with 1 % $Na_2CO_3 \cdot H_2O$. Solvent: 95 % ethanol: N,N-dimethylformamide:water = 3:1:1. The MNP-thiols used were prepared at room temperature to demonstrate the formation of 2,2′-dihydroxy-3,3′-dinitro-diphenylmercury. (The chromatogram was photographed with the aid of a blue filter.)

The solvent systems listed in Table 4 were found to give minimum amounts of "ghost" spots.

Spray reagents. In addition to the R_F-values the following spray reagents were found to be useful aides in the identification of MNP-thiols on the chromatograms. The color reactions described were all obtained on sodium carbonate impregnated paper.

1) All MNP-thiols (and CMNP) give a brown color when sprayed with *p*-nitrobenzenediazonium fluoborate (0.5 % in 50 % ethanol). Thus weak spots can be made to show up more clearly.

2) To confirm the presence of sulfur in the MNP-thiol spots the cyanide-nitroprussiate reagent [14] can be used. Of the MNP-thiols listed in Table 4 all gave an immediate redbrown spot, except MNP-ergothioneine and MNP-2-mercaptohistidine, which do not react.

3) MNP-thiols containing amino groups give brown spots when sprayed with ninhydrine (0.5 % in ethanol). The colors are best developed at room temperature. Depending on the amount of substance present positive response is obtained after 1—12 h.

4) MNP-ergothioneine and MNP-2-mercaptohistidine give grey blue spots immediately when sprayed with N,2,6-trichloro-*p*-benzoquinone imine (0.2 % in 50 % ethanol).

Effect of light on MNP-thiols. Exposure of MNP-thiol spotted chromatograms to ultraviolet radiation prior to chromatography invariably showed a deposit of a brownish colored decomposition product at the starting line on the finished chromatogram (solvent: ethanol:water, 4:1). The blank spots, which had been covered during the UV-exposure, showed no trace of this decomposition product. Even UV lamps with a low wattage (9 watts) when used at a distance of about 10 cm from the paper caused considerable decomposition during one hour.

It was noted on the finished chromatograms that the size of the "ghost" spot relative to the size of the MNP-thiol spot was not significantly changed after UV exposure. Thus the decomposition of MNP-thiols by ultraviolet light is qualitatively different from the decomposition noted by *e.g.* heat, which is represented by Fig. 8.

The author is indebted to Mrs. M. L. Kip for technical assistance.

A Hemopeptide from a Tryptic Hydrolysate of *Rhodospirillum rubrum* Cytochrome C*

SVEN PALÉUS and HANS TUPPY

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden, and Zweites Chemisches Institut der Universität, Vienna, Austria

Rhodospirillum rubrum cytochrome c purified by chromatography on carboxymethyl cellulose was subjected to hydrolysis with trypsin. A hemopeptide isolated from the digest has been found to consist of thirteen amino-acid residues arranged in a single polypeptide chain, the heme and polypeptide moieties being held together by two thioether bridges. In spite of marked dissimilarities, the sequence of amino-acids in this hemopeptide has certain characteristic features in common with the sequences previously worked out in hemopeptides prepared from other c-type cytochromes.

For the past few years the structure of cytochrome c has been studied with the aim of relating the catalytic activity of this hemoprotein to certain characteristic features of its chemical architecture. Much attention has been given to that portion of the protein moiety which adjoins the prosthetic group and which is supposed to contribute to a catalytically active site. In previous investigations [1,2] the sequence of twelve amino-acid residues including two heme-bound cysteine residues has been elucidated and found to be identical in the cytochromes of three different mammalian species (beef, horse and pig). When, however, the homologous amino-acid sequences were also determined in cytochrome c from fish (salmon)[2], bird (chicken)[2], insect (silk worm)[3] and from a fungus (yeast)[4], they appeared to be dissimilar though resembling each other more or less closely. The present communication will extend this comparative structural investigation to the c-type cytochrome produced by the photosynthetic bacterium *Rhodospirillum rubrum*, first described and subsequently studied in more detail by Kamen *et al.*[5–7]. There is a twofold interest in comparative structural work of this kind. In the first place, one may suppose that only those features which turn up invariably in all various cytochromes c, are likely to be essential to the specific catalytic function, whereas structural differences will indicate points not directly concerned with catalytic

* Presented before the 4th International Congress of Biochemistry, Vienna, September, 1958.

activity. Secondly, the species similarities and dissimilarities as revealed by comparative investigations of amino-acid sequences may give a clue to the genetic relation between the organisms from which the proteins studied have been obtained.

MATERIAL AND METHODS

Preparation of Rhodospirillum rubrum cytochrome c. Lyophilized bacterial cells were extracted with H_2SO_4 at pH 4. From the extract, the cytochrome c was obtained by fractionation with ammonium sulphate [8], dialysis and lyophilization. A sample thus prepared was kindly put at our disposal by Professor M. D. Kamen. It was further purified by chromatography on a column of CM-W cellulose (1.6 × 10 cm) prepared according to Peterson and Sober [9] and buffered with 0.015 M ammonium acetate of pH 6.5. The preparation of cytochrome c (470 mg) was dissolved in 2 ml of this buffer, reduced by the addition of solid $Na_2S_2O_4$ and transferred to the column. A dark brown, fast moving band separated from the red cytochrome band which moved slowly, if at all. When the buffer of pH 6.5 was replaced by 0.05 M ammonium acetate of pH 7.5, the red material started moving down the column and divided into three bands. The main fraction (R = 0.4, E_{270}/E_{551} = 0.96) yielded 71.5 mg of dry, salt-free cytochrome c which was used for all subsequent experiments.

Preparation of the hemopeptide and removal of the heme. After hydrolysis of the bacterial cytochrome c with trypsin, the hemopeptide formed could be precipitated from the digest with ammonium sulphate and purified by adsorption on talc and by column partition chromatography as described previously for other hemopeptides [1,2]. The hemin part of the hemopeptide was split from the peptide moiety using silver sulphate in acetic acid solution according to the method of Paul [10]. Performic acid was used to oxidize the thiol groups of cysteine residues to sulphonic acid residues. The hemin-free oxidized peptide obtained was essentially homogeneous as determined by electrophoresis on paper in a formic acid-acetic acid buffer of pH 2 [11].

Enzymic hydrolyses. The crystalline chymotrypsin used was purchased from the Worthington Biochemical Corporation. The subtilisin was a gift from Ing. M. Ottesen, Carlsberg Laboratory, Copenhagen. Digestions were carried out at pH 7.5 to 7.8 for 20 h at 25°C (with chymotrypsin) or for 24 h at 37°C (with subtilisin), the ratio between enzyme and substrate (w/w) being about 1:15.

End group determinations. For the characterization of N-terminal amino-acid residues the DNP method of Sanger [12,13] was employed. C-Terminal residues were determined using the hydrazinolysis procedure of Akabori *et al.*[14]

RESULTS

In the hydrolysate of the hemin-free oxidized polypeptide (prepared from the hemopeptide as described in the foregoing section) ten different amino-acids were identified by paper chromatography: alanine, aspartic acid, cysteic acid, glutamic acid, glycine, histidine, leucine, lysine, phenylalanine, and threonine. The lysine present in the polypeptide may be expected to be the C-terminal residue of the amino-acid sequence, since the polypeptide has been formed by the action of trypsin which is known to split bonds involving the carboxyl groups of lysine and arginine residues. The N-terminal residue was shown to be cysteic acid. After dinitrophenylation of the polypeptide and subsequent hydrolysis, however, the hydrolysate was found to contain, besides DNP-cysteic acid, free cysteic acid as well. This finding is accounted for by the presence in the polypeptide of two cysteic acid residues, one of which is terminal and the other is not.

Table 1. Determination of the amino-acid sequence in a polypeptide obtained from *Rhodospirillum rubrum* cytochrome c by tryptic hydrolysis, removal of the heme moiety, and oxidation with performic acid.

N-terminal residue (DNP method)		$CySO_3H$—. . .
C-terminal residue (specificity of trypsin)		. . .—Lys
Peptides obtained by *chymotryptic* digestion		$CySO_3H$—[Leu, Ala, $CySO_3H$, His] Thr—Phe Asp—Glu—[Gly, Ala, Asp]—Lys
Peptides found after digestion with *subtilisin*	Main split products	$CySO_3H$—Leu—Ala Thr—Phe NH_2 Asp —Lys $CySO_3H$—His [Asp, Glu, Gly, Ala]
	Minor split products	Ala—[$CySO_3H$, His] [Asp, Glu, Gly] [Thr, Phe, Asp, Glu, Gly] $CySO_3H$—[His, Thr] [Gly, Ala]
Sequence		$CySO_3H$—Leu—Ala—$CySO_3H$—His—Thr—Phe—Asp—Glu—Gly—Ala—Asp(NH_2)—Lys

Chymotryptic hydrolysis of the polypeptide (Table 1) gave rise to three main split products which were separated from each other by high-voltage electrophoresis at pH 2 and by paper chromatography in butanol-acetic acid: (I) $CySO_3H$-[Leu, Ala, $CySO_3H$, His], (II) Thr-Phe, and (III) Asp-Glu-[Gly, Ala, Asp]-Lys. Split product (I), with N-terminal cysteic acid, must be derived from the N-terminal side of the polypeptide chain and the lysine-containing peptide (III) from the C-terminal side. Thr-Phe, then, must be located between these two. After dinitrophenylation of peptide III and partial hydrolysis (with conc. HCl at 37°C, for 8 days) two ether-soluble products were separated and characterized, DNP-Asp and DNP-Asp-Glu, which demonstrates that glutamic acid must adjoin the N-terminal aspartic acid residue.

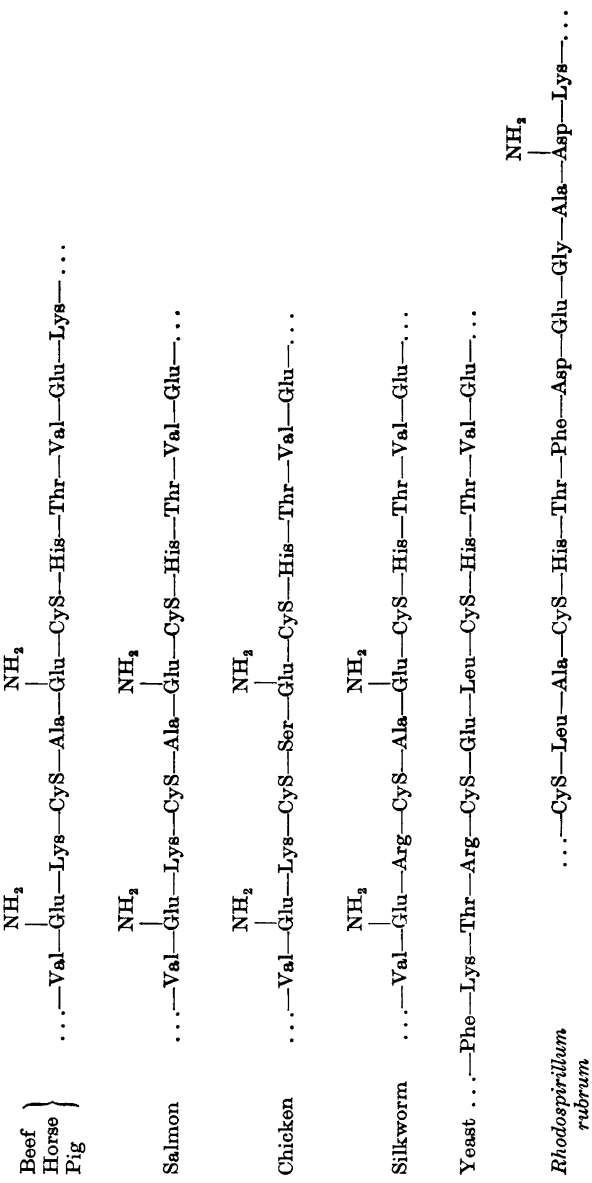
In the subtilisin hydrolysate of the polypeptide (Table 1) five products were present in relatively high concentration: $CySO_3H$-Leu-Ala, $CySO_3H$-His, Thr-Phe, [Asp, Glu, Gly, Ala], and Asp(NH_2)-Lys. Among the split products obtained in small amounts there were two tripeptides containing histidine: Ala-[$CySO_3H$,His] and $CySO_3H$-[His, Thr]. Other minor components of the hydrolysate were shown to be [Gly, Ala], [Asp, Glu, Gly], [Thr, Phe, Asp, Glu, Gly], and free alanine.

From the findings presented above it may be concluded that the amino-acid sequence in the hemin-free oxidized polypeptide is

1 2 3 4 5 6 7 8 9 10 11 12 13

$CySO_3H$-Leu-Ala-$CySO_3H$-His-Thr-Phe-Asp-Glu-Gly-Ala-Asp (NH_2)-Lys.

Table 2. Comparison of the sequences of amino-acids in the vicinity of the prosthetic group in c-type cytochromes of different organisms.



The results obtained leave it undecided whether residues 8 and 9 are free aspartic acid and free glutamic acid or whether these amino-acids are in the amide form, as asparagine and glutamine residues.

The two cysteic acid residues contained in the sequence have arisen from and taken the place of two heme-bound cysteine residues present in the original

Rhodospirillum rubrum cytochrome c and in the hemopeptide prepared from it by tryptic hydrolysis.

The specificity of trypsin already mentioned suggests that the amino-acid residue preceding the above sequence must be either lysine or arginine.

The cleavage by chymotrypsin of a bond between histidine and threonine (residues 5 and 6) may appear unexpected in view of the general belief that chymotrypsin will split bonds involving the carboxyl groups of the aromatic residues phenylalanine and tyrosine. The finding is in agreement with recent observations of Davis [15], however, who has reported that bonds involving the carboxyl groups of histidine residues are somewhat susceptible to chymotryptic hydrolysis.

A comparison of the amino-acid sequences that have been shown to occur in the vicinity of the heme moiety in different cytochromes demonstrates that they have various structural features in common (Table 2). The presence of two cysteine residues linked to side chains 2 and 4 of the porphyrin of the prosthetic group, first indicated by Theorell [16] in 1939 for beef cytochrome c, has been confirmed and found to be characteristic of all c-type cytochromes. The distance between the two cysteine residues along the polypeptide chain is always the same, two other amino-acids being situated in between. Invariably a histidine residue has been found to adjoin one of the heme-bound cysteine residues. Stereochemical considerations of Ehrenberg and Theorell [17] have indicated that the chain of amino-acids in which the two heme-bound cysteine residues and the histidine residue are included is likely to be in the form of an α-helix. This coiling will bring the histidine residue into a steric position favourable for a covalent attachment of an imidazole nitrogen to the iron of the heme disc.

There are still other structural features invariably encountered in all cytochrome c samples examined so far, such, *e.g.*, as the presence of a basic residue (lysine or arginine) close to cysteine and of a threonine residue close to histidine. The significance of these similarities is presently not known.

It is remarkable, anyhow, that in so many structural respects the cytochrome c of *Rhodospirillum rubrum* appears to resemble the c-type cytochromes of other organisms, in spite of an overall amino-acid composition, oxidation-reduction potential, and a specificity of action quite different from those of vertebrate and yeast cytochromes [18].

The authors are most indebted to Professor M. D. Kamen for a gift of *Rhodospirillum rubrum* cytochrome c.

One of the authors (S. P.) wishes in addition to express his thanks to *Statens naturvetenskapliga forskningsråd* and *Magnus Bergvalls stiftelse* for grants provided in support of this investigation.

The Oxidation of Aminotriazole by Horse Radish Peroxidase (HRP)

K. G. PAUL and E. MARGOLIASH*

Medicinska Nobelinstitutet, Biokemiska avdelningen, Stockholm, Sweden

The mutual effects of horse radish peroxidase and 3-amino-1,2,4-triazole have been studied spectrophotometrically. With the present technique no evidence was found for the formation of a compound between aminotriazole and peroxidase or any of the peroxidase-peroxide complexes. The complexes I and II reacted with aminotriazole at the rates of 460 and 200 $min^{-1}M^{-1}$ at pH 7.4 and room temperature. Aminotriazole did not inhibit the activity of horse radish peroxidase in the presence of continuously supplied hydrogen peroxide, but rather protected the peroxidase against destruction by hydrogen peroxide.

The observation that plants which had been exposed to 3-amino-1,2,4-triazole (AT) contained less chlorophyll than normal plants led to the discovery that extracts from such plants showed a subnormal catalase activity [1,2]. In livers and kidneys from rats, which have been given AT perorally, intraperitoneally, or intravenously, the catalase activity was decreased to such an extent that only 10 %, occasionally less, remained of the normal value per unit weight or nitrogen. The liver catalase activity dropped remarkably rapidly, maximal reduction being reached already after 3 h. Normal values were found on the seventh day. Blood catalase, haemoglobin, and liver cytochrome c remained normal. In experiments *in vitro* with AT and homogenized livers from normal animals or crystallized catalase considerably higher concentrations of AT were needed to bring about any decrease [2]. The *in vitro* effect could be abolished by dialysis, in contrast to the *in vivo* effect, and was attributed to some unspecific action of AT in high concentration. "Liver peroxidase" was slightly decreased after 3 h but normal again after 24 h. In another investigation [3] the same result with liver homogenate was obtained, but no inhibition of pure catalase occurred unless liver homogenate was added. It was also noticed that molecular oxygen was necessary for the effect. The δ-aminolaevulinic acid dehydrase activity in the AT-rats

* On leave from the Hebrew University—Hadassah Medical School, Jerusalem.

was found to be somewhat reduced although less than the catalase. Minimum activity, 75 % of the normal, was found 8 h after the injection of AT, and the activity had returned to normal after 36—48 h. Quite recently it was demonstrated [5,6] *in vitro* with pure catalase that AT reacts not with catalase itself but with complex I between catalase and hydrogen peroxide, resulting in a complete inhibition of catalatic activity. This reaction was irreversible and one mole of AT was incorporated into the enzyme protein for each mole of catalase haem reacted. These results explain the rapid decrease in catalase activity of liver and kidney observed *in vivo* after the administration of AT [1,2], making it unnecessary to invoke an effect of AT on the formation of the enzyme. The time for restoration of full liver catalase activity agrees well with the life span of liver catalase.

Although several factors can account for the lack of effect of AT on erythrocyte catalase *in vivo* the presence of hydrogen donors in the red cells may be the most important one [6]. Such donors would prevent the irreversible inhibition of catalase by AT by reacting rapidly with catalase-hydrogen peroxide complex I, thus competing with the slow, irreversible reaction of AT with the complex. The possibility that the effects of AT administration could be caused by some metabolite of AT rather than by AT itself was made less likely, although not excluded, by the failure to find any evidence, direct or indirect, for the participation of such a metabolite in the inhibitory reaction [5].

The less pronounced effect on δ-aminolaevulinic acid dehydrase may be caused by inhibition of action or synthesis or both, and may also be quite unspecific.

In the present investigation some of the mutual effects of another hydroperoxidase, horse radish peroxidase, and AT have been studied in the presence of hydrogen peroxide.

METHODS AND MATERIAL

AT from Light & Co Ltd was used without pretreatment. HRP (component C) had been prepared as previously described [7]. Spectra were taken with Beckman spectrophotometers. Dr. R. Ordell, Serafimerlasarettet, Stockholm, kindly put a useful DK 2 instrument at our disposal.

RESULTS AND DISCUSSION

The titration of AT (117 mg in 20 ml of water, room temperature) with molar hydrochloric acid and sodium hydroxide revealed an ionization at pH 4.35. Another group was traced at pH < 2 after correction for the acid, and a third one was seen at pH 10. Although a comparison with pyridine and aniline shows that the three groups are not immediately identifiable the titration made it possible to choose pH-values where only one form of AT is present.

The results in Table 1 show that the peroxide but not AT inactivates HRP under the given conditions and that AT to some extent protects HRP against inactivation by the peroxide. This protection may simply depend upon the continuous consumption of the peroxide passing the cellophane. During the dialysis a yellow colour appeared in the solutions inside and outside the sac.

Table 1. Activity changes in HRP during dialysis against peroxide and AT. 1.5 ml of 10 μM HRP and 20 mM AT in phosphate buffer of pH 7.4 were dialysed at 37° against 100 ml of 20 mM AT and 0.25 mM hydrogen peroxide in the same buffer. Controls were made without AT or peroxide. For the assay of the peroxidatic activity 50 μl of the solution inside the sac were diluted with 1.00 ml of water, 10 μl of the dilution being taken for the assay with 3 ml of guaiacol — buffer (pH 7) mixture. t = the time (in min after the addition of peroxide) during which the absorbancy at 470 mμ increased by 0.050 [8,9].

Hours of dialysis	HRP AT H_2O_2	HRP AT —	HRP — H_2O_2
	Peroxidase activity in min^{-1} $(1/t)$		
0	3.8	4.6	3.9
1	4.0	4.1	3.4
2	3.9	4.4	3.7
3	3.4	4.3	2.4
4	2.9	3.9	1.8
7	3.3	4.3	1.3

It faded only slowly at neutral pH but instantaneously upon acidification or alkalinization. Its formation and disappearance were followed spectrophotometrically at pH 4.9, where it seemed to have its intensity maximum (Fig. 1). As long as any peroxide remained the yellow colour increased in intensity.

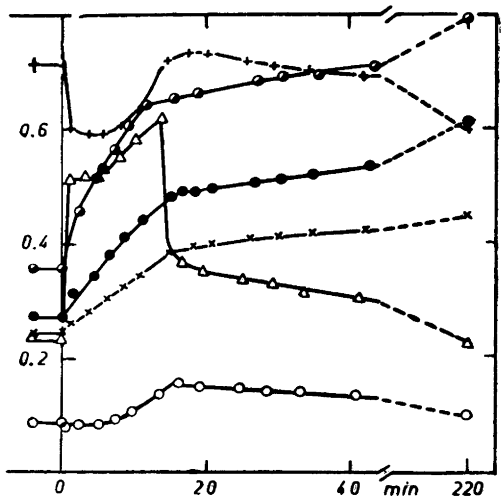

Fig. 1. Spectral changes during the reactions between HRP (10 μM), hydrogen peroxide (10 mM), and AT (5 mM) in acetate buffer of pH 4.9. The peroxide was added to the other reactants at time 0. The HRP-absorption at 460 mμ is independent of the peroxide concentration. Free HRP and complex I are isosbestic at 427 mμ, free HRP and complex II at 412 mμ.

○ 460 mμ + 412 mμ ● 268 mμ
△ 427 mμ × 285 mμ ◒ 250 mμ

When the peroxide had been consumed, as indicated by the sudden changes in the Soret band, the production of the yellow pigment ceased and the colour began to fade. The spectral changes after the termination at about 15 min of the enzymic reactions appeared as first order reactions. The changes must reflect several reactions since the specific rate constant varied from one wavelength to another and since the constant obtained at 427 mμ showed a sudden change at 55 min (Table 2).

Table 2. Specific velocity constants for the non-enzymic reactions of the primary oxidation products occurring during the time range 15—220 min in Fig. 1.

mμ	250	268	285	410	427	460
min^{-1}	1.0	1.3	1.9	−0.9	−1.2 −0.7	− 1.1

The spectral changes during the first minutes were followed by scanning the range 440—380 mμ at suitable time intervals. It was possible and advantageous to work with equimolar concentrations of HRP and peroxide. This

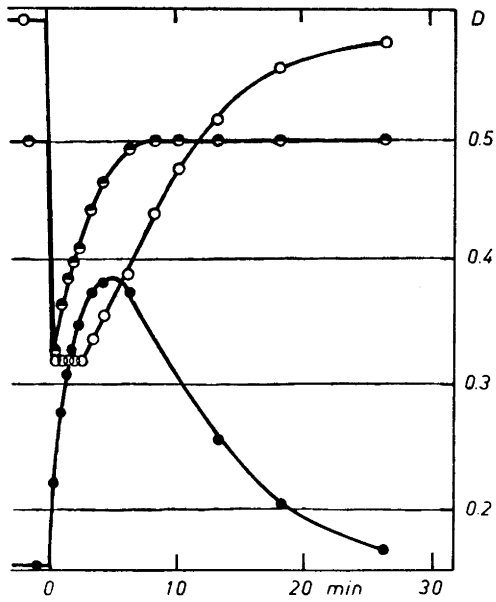

Fig. 2. Spectral changes in the Soret band region during the reactions between HRP (7 μM), hydrogen peroxide (7 μM), and AT (140 μM) in 0.1 M phosphate buffer of pH 7.4. Peroxide and AT were added simultaneously at time 0.

○ 397 mμ (complex I and complex II isosbestic)
× 412 mμ (complex II and free HRP isosbestic)
● 427 mμ (complex I and free HRP isosbestic)

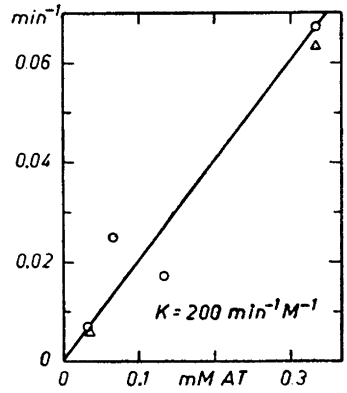

Fig. 3. Velocity constant for the appearance of free HRP (○) and disappearance of complex II (△) as a function of the concentration of AT. HRP, peroxide, and time as in Fig. 2. The values are corrected for the »spontaneous decay» of the complex.

actually converted the enzymatic system to a stoichiometric reaction. The specific rate constant for the spontaneous increase in density at 412 mμ for a solution 7 μM in HRP and 7 μM in hydrogen peroxide in 0.1 M phosphate buffer of pH 7.4 was 0.0035 min^{-1}. An example of the spectral changes during the reactions between HRP-hydrogen peroxide complexes I and II and AT is given in Fig. 2. In these experiments the contribution of the yellow pigment to the absorption in the Soret band region was negligible. With 7—350 μM AT isosbestic points were found at 397 mμ during the initial and at 412 mμ during the terminal part of the reaction. The isosbestic point for complex I/free HRP (427 mμ) could only occasionally be visualized with this technique because of the similarity in shape of the absorption curves of complex II and free HRP.

The specific velocity constant for the appearance of free HRP (Fig. 3) was obtained from the absorbancy changes occurring at 397 mμ after the isosbestic level at 412 mμ had been reached. At a few concentrations of AT it was possible to follow, with this technique, the decrease in absorption at 427 mμ sufficiently accurately to permit the calculation of the velocity constant for the disappearance of complex II (Fig. 3).

The specific velocity constant for the disappearance of complex I was calculated from the changes at 427 mμ during the first minutes when the absorbancy at 397 mμ remained constant (Fig. 4).

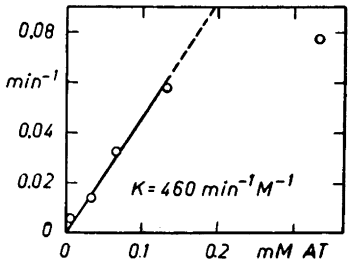

Fig. 4. Velocity constant for the disappearance of complex I. Same conditions as in Fig. 3.

Under the experimental conditions used above (Fig. 2—4) AT gave no spectrophotometrically operable compound with HRP or the HRP-peroxide complexes as long as the concentration of AT was lower than 350 uM. This is obvious from several facts. Two isosbestic points were found, and it is unlikely that both are threefold isosbestic. They were found at the wavelengths which have been reported for the isosbestic points between complex I and II (397 mμ) and complex II and free HRP (412 mμ)[10]. The velocity constants for the appearance of free HRP and the disappearance of complex II agreed fairly well (Fig. 3). At 350 μM AT, however, the disappearance of complex I was markedly hampered (Fig. 4), and the decrease in density at 397 mμ upon the addition of AT and peroxide was not instantaneous. It should be kept in mind, however, that in the case of catalase a compound between AT and the catalase-peroxide complexe was formed only at considerably higher concentrations of AT as well as of the complex. At such a high peroxide concentration as was used in the catalase experiments HRP would have been rapidly inactivated.

At the concentrations of AT used in the present investigation nothing has been found that would put AT in a class of its own as regards the reactions with HRP. The two HRP-peroxide complexes seem to react with AT at the rates of 460 and 200 min^{-1} M^{-1}, thus quite slowly. This fact, and the purity of the HRP preparation, makes the system a suitable one for studies of the peroxidative reactions.

This investigation was financially supported by *Statens Naturvetenskapliga Forskningsråd*. One of us (E.M.) is grateful for a fellowship from the *Dazian Foundation for Medical Research*.

Studies on Humic Acids

VII.* The Structure of the Dihydroxy-dioxidoterphenyl Obtained by the Action of Sulphuric Acid on *p*-Benzoquinone

HOLGER ERDTMAN and NILS E. STJERNSTRÖM

Organisk-kemiska Institutionen, Kungl. Tekniska Högskolan, Stockholm, Sweden

Acid polymerisation of *p*-benzoquinone gives, among other products, a dioxidoterphenyl for which structure V has been suggested. This has now been shown to be incorrect; the structure is very probably X. Arguments in favour of this view are presented.

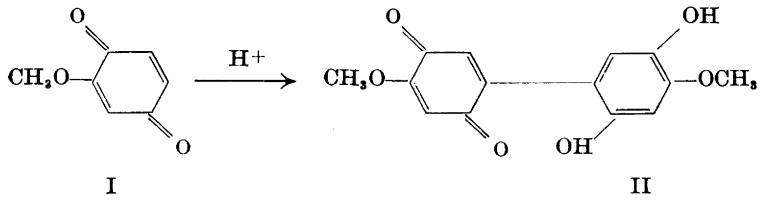
Quinones sometimes exhibit a considerable reactivity in the presence of acids undergoing intermolecular coupling reactions with the formation of di- or terphenyl derivatives and amorphous high molecular weight quinonoid products of unknown constitution which are of obvious interest in connection with the chemistry of humic acids and melanins.

Thus, even with very dilute sulphuric acid, the highly reactive methoxyquinone I is rapidly and almost quantitatively transformed into the insoluble diphenyl derivative II (or the intermolecular quinhydrone alternative) which is relatively stable to acids.[1] The far less reactive toluquinone undergoes a similar change in the presence of strong sulphuric acid with the formation of toluhydroquinone, a diphenyl derivative analogous to II (CH_3 instead of OCH_3), and about 10 % of a terphenyl derivative to which the structure III has been assigned. The main reaction product is an amorphous, quinonoid "polymer".

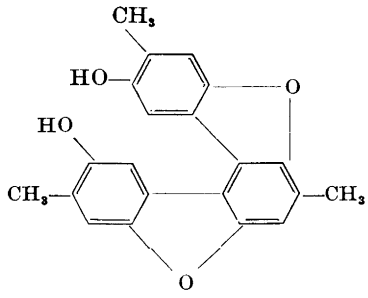
In the same way *p*-benzoquinone yields about 50 % hydroquinone, a large amount of polymeric material and a small amount of a terphenyl derivative for which structure V has been suggested [2].

It appears probable that these quinones react in a similar way with acids and alkali since hydroquinones and quinonoid polymers are formed in both cases. Intermediate low molecular weight polyphenols have been less frequently isolated from the products of alkaline decomposition of quinones but the formation of a very small amount of dihydroquinone has been demonstrated in the case of *p*-benzoquinone [3].

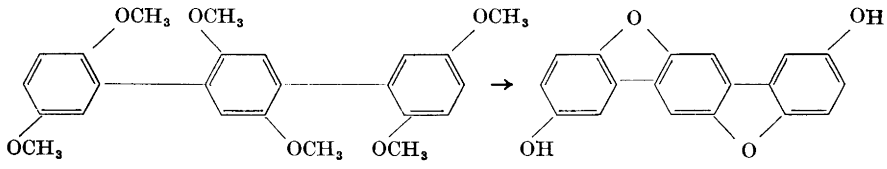
* Part VI. *Acta Chem. Scand.* 8 (1954) 1442.



I II



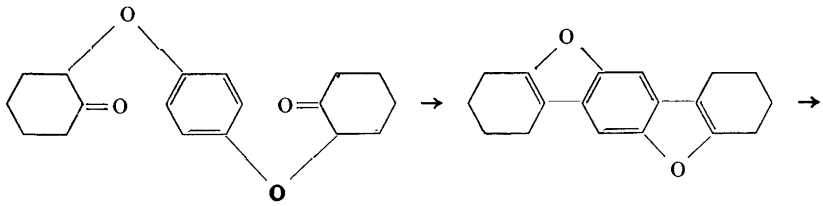
III (III a: C_2H_5 instead of CH_3)
(The positions of the alkyl groups in III and III a uncertain)



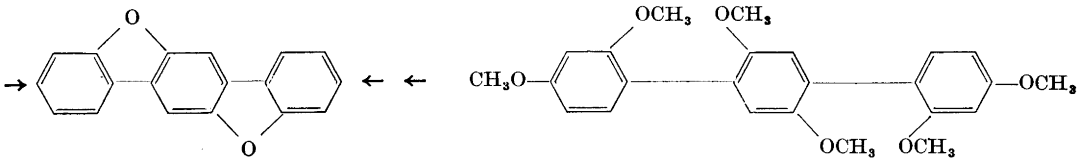
IV V

The termolecular products obtained with acids are probably intermediates in the acid polymerisation of benzoquinone and toluquinone which have been stabilised by dehydration and removed from further reactions. Methoxyquinone is exceptional in its preferential formation of a dimer.

Some years ago Schimmelschmidt [4] described the dioxidoterphenyl VIII obtained by alkali fusion of 2,2″-dichloro-2′,5′-dihydroxy-*p*-terphenyl. It melts at 265—266°. We have synthesised the same compound in a different way starting with 2-bromo*cyclo*hexanone [5] and the disodium salt of hydroquinone. These compounds reacted to give 1,4-di-(2-keto*cyclo*hexyloxy)-benzene (VI) which was treated with a polyphosphoric acid mixture to give what must be 3,4,5,6,3″,4″,5″,6″-octahydro-2,2′,5′,2″-dioxido-*p*-terphenyl (VII) as a result of intramolecular condensation. This substance was dehydrogenated with palladium to give a compound identical with Schimmelschmidt's compound VIII. The same compound has also been obtained in the following way. 4-Iodo-resorcinol dimethyl ether and 2,5-diiodo-hydroquinone dimethyl ether were condensed by the Ullmann procedure. The resulting hexamethoxyterphenyl (IX) when heated with hydrobromic acid furnished a dihydroxy-



VI VII



VIII IX

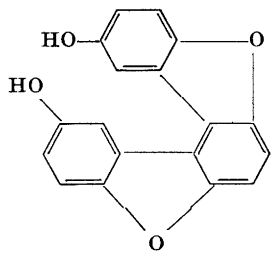
dioxido-*p*-terphenyl which on distillation with zinc dust gave compound VIII (Stjernström, forthcoming publication). Schimmelschmidt's substance must have the structure he assigned to it.

In order to relate the dihydroxy-dioxidoterphenyl from *p*-benzoquinone with Schimmelschmidt's compound it was subjected to distillation with zinc dust. The neutral product obtained was, however, isomeric, not identical with VIII. Moreover, a compound which must have the structure V was obtained by prolonged boiling of the hexamethoxyterphenyl IV [6] with hydrobromic acid. It was isomeric with the dihydroxy-dioxidoterphenyl obtained from *p*-benzoquinone and the suggested structure (V) for the compound from *p*-benzoquinone must therefore be incorrect.

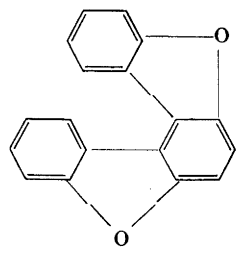
Structure V was advanced on the likely assumption that *p*-benzoquinone would polymerise stepwise and, for sterical reasons, preferentially in the 2,5-positions. In the case of toluquinone this is not possible because of the obstructing methyl groups and condensation with other molecules of toluquinone can only take place (the slight possibility of methyl group migration being ignored) in positions 5 and 6 in order to provide a tri-toluhydroquinone able to furnish a dioxidoterphenyl by dehydration.

The exact mechanism of the quinone polymerisation is not known and it is, of course, possible that the hypothesis that trihydroquinones are formed first is an oversimplification. At present, the only likely alternative to structure V for the termolecular compound from *p*-benzoquinone appears to be X and attempts were therefore made to convert compound III into X by elimination of the methyl groups.

The dimethyl ether of III was oxidised in the hope that a tricarboxylic acid might be formed which on decarboxylation should give the dimethyl ether of X. All attempts to effect this oxidation with permanganate or chromic acid invariably resulted in acid mixtures, from which no pure tricarboxylic acid could be obtained.



X



XI

On decarboxylation neutral products were obtained which were very similar to the dimethyl ether of the dihydroxy-dioxidoterphenyl from *p*-benzoquinone but they were obviously not pure compounds. As the oxidation of the methyl ether of the toluquinone product appeared to offer insurmountable difficulties ethylquinone was subjected to treatment with sulphuric acid and a termolecular product, obviously the ethyl analogue of III (III a) was obtained. The dimethyl ether of III a was oxidised with potassium permanganate in pyridine and an acid product was obtained which on decarboxylation furnished a neutral compound identical with the dimethyl ether of the termolecular product from *p*-benzoquinone.

It follows that the dihydroxy-dioxidoterphenyl from *p*-benzoquinone will almost certainly have the structure X.

EXPERIMENTAL

All melting points are uncorrected

1,4-Di-(2-ketocyclohexyloxy)-benzene (VI). 2-Bromo-*cyclo*hexanone was prepared according to Trippett [5]. Sodium (2.3 g) was dissolved in absolute ethanol (50 ml) and a solution of hydroquinone (5.5 g) in absolute ethanol (50 ml) was added. The alcohol was evaporated under reduced pressure care being taken to avoid oxidation. The dry hydroquinone sodium salt, 2-bromo*cyclo*hexanone (17.6 g) and dry benzene (200 ml) were stirred for three days in a coal gas atmosphere. After filtration and evaporation of the solvent a dark brown oil was obtained that soon crystallised partly on cooling. The crystals were collected and recrystallised from *n*-butanol. Yield 1 g. M. p. 190.5—193°. (Found: C 71.4; H 7.2. Calc. for $C_{18}H_{22}O_4$: C 71.5; H 7.3.)

3,4,5,6,3'',4'',5'',6''-Octahydro-2,2',5',2''-dioxido-p-*terphenyl (VII)*. 1,4-Di-(2-keto*cyclo*hexyloxy)-benzene (VI) (720 mg) was added to a solution of phosphorus pentoxide (10 g), in phosphoric acid (*d* 1.75, 20 ml). The mixture was stirred at 100° for 3 h and then diluted with water. The precipitate was collected, washed and dried. The gray, crude product (520 mg) was recrystallised from *n*-butanol, m. p. 201—202°. (Found: C 80.5; H 6.7. Calc. for $C_{18}H_{18}O_2$: C 81.2; H 6.8.)

2,2',5',2''-Dioxido-p-*terphenyl (VIII)*. Compound VII (150 mg) was mixed with a palladium-charcoal catalyst (10 % Pd, 100 mg) and the mixture was heated to 230° for 5 h in an atmosphere of nitrogen. The reaction product was extracted with boiling bromobenzene from which the substance crystallised on cooling. Yield 60 mg, m. p. 265.5—

266.5°. Mixed melting point with Schimmelschmidt's dioxidoterphenyl, generously placed at our disposal by Farbwerke Höchst, showed no depression (m. p. 265—266°).

2,6′,3′,2″-Dioxido-o-terphenyl (XI). 5,5″-Dihydroxy-2,6′,3′,2″-dioxido-*o*-terphenyl (X) was prepared by acid polymerisation of *p*-benzoquinone according to Erdtman [2]. This phenol (1 g) was thoroughly mixed with zinc dust (10 g) and the mixture was introduced into a hard melting glass tube (1 × 50 cm) followed by zinc dust (20 g) and zinc dust impregnated pumice. Carbon dioxide was passed through the tube to remove oxygen. The pumice and the zinc dust layer were then heated until red hot followed by similar heating of the phenol-zinc dust layer. After about twenty minutes some 300 mg of reduced material could be collected from the cool zone of the tube. The substance was recrystallised from acetic acid and sublimed *in vacuo*, m. p. 143—144°. (Found: C 83.4; H 4.0. Calc. for $C_{18}H_{10}O_2$: C 83.7; H 3.9.)

*5,5″-Dihydroxy-2,2′,5′,2″-dioxido-*p*-terphenyl (V) and its dimethyl ether.* 2,5, 2′,5′,2″, 5″-Hexamethoxy-*p*-terphenyl [6] (IV) (440 mg) was heated under reflux with hydrobromic acid (48 %, 25 ml) in an atmosphere of carbon dioxide for three days. The reaction mixture was diluted with water (100 ml) and filtered. The collected phenol (300 mg) was dark blue due to superficial oxidation. M. p. *ca* 330° (decomp.). The phenol was suspended in methanol and quantitatively converted to the corresponding dimethyl ether by methylation with an excess of dimethyl sulphate and sodium hydroxide (40 %). The dimethyl ether was recrystallised from dioxane and sublimed *in vacuo*, m. p. 255—257°. (Found: C 75.1; H 4.3. Calc. for $C_{20}H_{14}O_4$: C 75.5; H 4.4.) Neither the phenol nor its dimethyl ether were identical with the corresponding compounds from the *p*-benzoquinone polymerisation.

Phenol III a and the corresponding diacetate and dimethyl ether. Ethylquinone was prepared from ethylhydroquinone by the method described by Gulland [7] using ferric chloride as oxidising agent. Ethylquinone (28 g) was shaken for three days with a mixture of acetic acid (50 ml) and dilute sulphuric acid (33 %, 100 ml). The thick blue black precipitate was collected, washed thoroughly with water and dried in air. The dry, very finely divided material (19 g) was shaken vigorously with excess zinc dust, acetic anhydride (45 ml) and pyridine (25 ml). The reaction mixture became very hot and after boiling for some minutes it was filtered. Crystals of the diacetate of III a soon began to separate from the filtrate and after one day they were collected, washed with acetic acid and recrystallised from acetic anhydride. Yield 3.5 g, m. p. 226.5—227°. (Found: C 73.4; H 5.9. Calc. for $C_{28}H_{26}O_6$: C 73.4; H 5.7.)

The acetate was refluxed for one hour in an atmosphere of nitrogen with a mixture of conc. sulphuric acid and acetic acid (1:50, 100 ml). The reaction mixture was poured into a large volume of boiling water. The precipitated phenol was a slightly bluish powder that very rapidly darkened in the air due to superficial oxidation and melted about 230°. Yield almost quantitative.

The freshly prepared phenol suspended in methanol was methylated with an excess of dimethyl sulphate and sodium hydroxide (40 %). The reaction mixture was poured into water and the product was washed with water, dried and recrystallised from ligroin. (Yield from 2 g acetate 1.7 g.) The *methyl ether* melted at 161—162.5° after sublimation *in vacuo*. (Found: C 78.1; H 6.8. Calc. for $C_{26}H_{26}O_4$: C 77.6; H 6.5.)

Oxidation of the dimethyl ether of phenol III a and decarboxylation of the resulting acid. The dimethyl ether of phenol III a (540 mg) was dissolved in a mixture of pyridine (25 ml) and potassium hydroxide solution (5 M, 4 ml). The solution was refluxed and very finely divided potassium permanganate (4 g) was added in small portions during 1.5 h. The reaction mixture was cooled, acidified with dilute hydrochloric acid and decolourised with sulphur dioxide. The yellowish green jelly was collected by centrifuging. The jelly was treated with dilute potassium hydroxide, the neutral material was removed by filtration and the clear filtrate was acidified with hydrochloric acid. The acid amorphous precipitate was collected, washed thoroughly with water and dried in air. It did not crystallise. The dry product (114 mg) was heated for 3 h at 200° in an atmosphere of nitrogen together with a copper chromite catalyst (30 mg) and quinoline (3 ml). The filtered reaction mixture was acidified with dilute sulphuric acid and the brown precipitate collected and washed with large amounts of water. After drying and sublimation *in vacuo* 11 mg of neutral material was obtained, m. p. 173—220°. This material was fractionally sublimed *in vacuo*, a fraction, m. p. 185—200°, was isolated and recrystallised from a pyridine water mixture and sublimed *in vacuo*, m. p. 211—214°. The dimethyl

ether of phenol X from the polymerisation of *p*-benzoquinone melts at 216—218° and the mixed m. p. was 215—218°. The infrared and ultraviolet spectra of the two samples were identical.

We are grateful to Dr. B. Thomas for checking the manuscript.

On the Kinetics of the Decomposition of Cyanic Acid

II. The Carbonate Catalysis

MOGENS BALLUND JENSEN

The Royal Danish School of Pharmacy, Copenhagen, Denmark

The uncatalyzed decomposition of cyanate in dilute aqueous solution takes place according to the reactions: $OCNH + H_3O^+ \rightarrow NH_4^+ + CO_2$ (I), $OCNH + H_2O \rightarrow NH_3 + CO_2$ (II) and $OCN^- + 2H_2O \rightarrow NH_3 + HCO_3^-$ (III). Reaction III has been shown to be catalyzed by bicarbonate ion: $OCN^- + 2H_2O \rightarrow NH_3 + HCO_3^-$ (catalyzed by HCO_3^-) (IV). The results can also be interpreted in that way that reaction II is catalyzed by carbonate ion: $OCNH + H_2O \rightarrow NH_3 + CO_2$ (catalyzed by CO_3^{--}) (V). The rate expression for the decomposition of cyanate in the presence of carbonate (HCO_3^- or CO_3^{--}) is: $dc_{OCN^-}/dt = -(k_{OCNH} \cdot a_{H^+} \cdot f / K_{OCNH} + k_{OCN^-} + k' \cdot c_{HCO_3^-}) \cdot c_{OCN^-} = -(k_{OCNH} + k_{OCN^-} \cdot K_{OCNH} / a_{H^+} \cdot f + k'' \cdot c_{CO_3^{--}}) \cdot c_{OCNH}$. In this expression k' and k'' are the velocity constants for reactions IV and V, respectively. k'' is equal to $k' \cdot K_{OCNH} / K_{HCO_3^-}$, where K_{OCNH} is the acidic dissociation constant for cyanic acid and $K_{HCO_3^-}$ is the acidic dissociation constant for the bicarbonate ion. k_{OCNH} (0.047 (min^{-1}) at 18°C) and k_{OCN^-} ($10^{-6.48}$ (min^{-1}) at 18°C) are the previously determined velocity constants for reactions II and III, respectively. f is an activity coefficient.

The uncatalyzed decomposition will take place mainly according to reactions II and III in solutions where the carbonate catalysis is appreciable. The decomposition after I has therefore been disregarded in the above stated expression. (The velocity constant for reaction I is 3.61 (l $mole^{-1}$ min^{-1}) at 18°C).

k' (l $mole^{-1}$ min^{-1}) was found to be 4.76×10^{-4} (18°C), 9.21×10^{-4} (25°C) and 76.2×10^{-4} (50°C) yielding an energy of activation of 16.2 kcal $mole^{-1}$. The corresponding value of k'' is $10^{3.54}$ (l $mole^{-1}$ min^{-1}) at 18°C.

In a previously published paper [1] the decomposition of cyanic acid and cyanate in dilute aqueous solution was found to take place according to three simultaneous reactions:

$$OCNH + H_3O^+ \rightarrow NH_4^+ + CO_2 \quad \text{(I)}$$
$$OCNH + H_2O \rightarrow NH_3 + CO_2 \quad \text{(II)}$$
$$OCN^- + 2H_2O \rightarrow NH_3 + HCO_3^- \quad \text{(III)}$$

In the experiments carried out in carbon dioxide-bicarbonate buffers at pH = approx. 6.7 it was observed that the decomposition was catalyzed by the bicarbonate ion. In this pH-range the uncatalyzed decomposition will take place mainly according to reaction II. The rate in the presence of bicarbonate was found to be

$$dc_{OCN^-}/dt = -(k_{OCNH} \cdot a_{H^+} \cdot f/K_{OCNH} + k' \cdot c_{HCO_3^-}) \cdot c_{OCN^-} \quad (1)$$

Eqn. (1) can also be written

$$dc_{OCN^-}/dt = -(k_{OCNH} + k'' \cdot c_{CO_3^{--}}) \cdot c_{OCNH} \quad (2)$$

$$\text{where } k'' = k' \cdot K_{OCNH}/K_{HCO_3^-}.$$

k_{OCNH} is the velocity constant for reaction II. f is an activity coefficient. K_{OCNH} and $K_{HCO_3^-}$ are the acidic dissociation constants for cyanic acid and for the bicarbonate ion, respectively. k' is the velocity constant for the reaction

$$OCN^- + 2H_2O \rightarrow NH_3 + HCO_3^- \text{ (catalyzed by } HCO_3^-). \quad (IV)$$

Reaction IV can also be written

$$OCNH + H_2O \rightarrow NH_3 + CO_2 \text{ (catalyzed by } CO_3^{--}) \quad (V)$$

k'' is the velocity constant for reaction V. The experiments do not give any information about the actual reaction being IV or V. The value of k' was previously found to be approx. 0.0006 at 18°C.

The present investigation deals with the decomposition of cyanate in the presence of bicarbonate or carbonate, or both, under more varied conditions.

The method of analysis was the same as has been used previously, *viz.* an argentometric titration of the cyanate.

The velocity constants refer to molar concentration, the unit of time being the minute. The solutions were prepared at room temperature.

Sodium Cyanate Pure (Hopkin and Williams Ltd.) was used for the experiments. The salt was found to contain only a slight trace of carbonate.

RESULTS

The experiments on the decomposition of cyanate in solutions containing bicarbonate (pH = approx. 8.4) are listed in Table 1. The solution contained both carbonate and bicarbonate (pH = approx. 10) in runs 4 and 9.

The uncatalyzed decomposition will take place mainly according to reactions II and III in this pH-range. The rate expression may be written

$$dc_{OCN^-}/dt = -(k_{OCNH} \cdot a_{H^+} \cdot f/K_{OCNH} + k_{OCN^-} + k' \cdot c_{HCO_3^-}) \cdot c_{OCN^-} \quad (3)$$

identical with

$$dc_{OCN^-}/dt = -(k_{OCNH} + k_{OCN^-} \cdot K_{OCNH}/a_{H^+} \cdot f + k'' \cdot c_{CO_3^{--}}) \cdot c_{OCNH} \quad (4)$$

k' (mean): 0.000476 (18°C) 0.000921 (25°C) 0.00762 (50°C).

k_{OCN^-} is the velocity constant for reaction III. The velocity of the uncatalyzed decomposition, however, is negligible in comparison with that of the catalyzed in the experiments listed in Table 1. Consequently eqn. (3) will be reduced to

$$dc_{OCN^-}/dt = -k' \cdot c_{HCO_3^-} \cdot c_{OCN^-} = -k \cdot c_{OCN^-}.$$

The concentration of bicarbonate is approximately constant during each experiment and k was obtained from the expression for a unimolecular reaction: $k \cdot t = \ln a/a-x$. k and k' are listed in Table 1 ($k' = k/c_{HCO_3^-}$). k'

is 0.000476 (18°C), 0.000921 (25°C) and 0.00762 (50°C). The energy of activation is 16.2 kcal mole^{-1} calculated from the data at 18°C and 25°C, and 16.1 kcal mole^{-1} calculated from the data at 25°C and 50°C. The corresponding value of k'' is $10^{3.54}$ at 18°C. The values $10^{-3.54}$ (Ref.[1]) and $10^{-10.40}$ (Ref.[2]) for K_{OCNH} and $K_{HCO_3^-}$, respectively, have been used. $k' = 0.000476$ at 18°C is in a relatively good agreement with 0.0006 found previously in the above mentioned experiments in more acid solution.

It should be noted that ammonium ions are formed during the process, *i.e.* the gross reaction: $NH_4^+ + OCN^- \rightarrow NH_2 \cdot CO \cdot NH_2$ will also occur in solutions containing initially only cyanate. From the velocity constant for this reaction (0.000577 at 18°C [3]) can be estimated that only a small amount of urea is formed in the experiments listed in Table 1 (the concentration of NH_4^+ does not exceed 0.02).

The experiments on the decomposition of cyanate in strongly alkaline solutions of sodium carbonate and sodium hydroxide are listed in Table 2.

We get

$$dc_{OCN^-}/dt = -(k_{OCNH} \cdot a_{H^+} \cdot f/K_{OCNH} + k_{OCN^-} + k' \cdot c_{HCO_3^-}) \cdot c_{OCN^-} \simeq$$
$$-(k_{OCN^-} + k' \cdot c_{HCO_3^-}) \cdot c_{OCN^-} =$$
$$-(k_{OCN^-} + (k' \cdot K_{H_2O}/K_{HCO_3^-}) \cdot c_{CO_3^{--}}/c_{OH^-}) \cdot c_{OCN^-}$$

if we assume that the decomposition still takes place in accordance with eqn. (3). (The term $k_{OCNH} \cdot a_{H^+} \cdot f/K_{OCNH}$ is without significance in strongly alkaline solution).

Substituting $p = k' \cdot K_{H_2O}/K_{HCO_3^-}$ we get

$$dc_{OCN^-}/dt = -(k_{OCN^-} + p \cdot c_{CO_3^{--}}/c_{OH^-}) \cdot c_{OCN^-} \qquad (5)$$

or

$$dc_{OCN^-}/dt = -k \cdot c_{OCN^-}$$

where $k = k_{OCN^-} + p \cdot c_{CO_3^{--}}/c_{OH^-}$.

The concentration of carbonate and hydroxyl ion is approximately constant during each experiment. The values of k listed in Table 2 were hence calculated from the expression for a unimolecular reaction.

The experimental results in Table 2 show clearly that k depends not only upon the concentration of carbonate ion but also upon the concentration of hydroxyl ion as required from eqn. (5). The values of p calculated from $p = (k - k_{OCN^-}) \cdot c_{OH^-}/c_{CO_3^{--}}$ are also listed in Table 2 (k, c_{OH^-} and $c_{CO_3^{--}}$ are mean values). The previously determined values 0.00170 at 94°C and 0.000170 at 70°C for k_{OCN^-} have been used. Although the difference between k and k_{OCN^-} is rather small a fairly constant value for p is obtained in runs 5, 6, and 11 yielding the mean value 0.00031 for p at 94°C. The value found in run 7 has been disregarded. The difference between k and k_{OCN^-} is very small in this run ($c_{OH^-} = 0.2$). At 70°C the value 0.000032 was found for p.

Run 8 shows that the addition of sulfate instead of carbonate has very little influence on the velocity. Run 12 shows that the velocity in strongly alkaline medium is not affected by the addition of ammonia (0.1 M).

Table 2. The decomposition of OCN^- in $NaOH + Na_2CO_3$.

* k_{OCN^-} (0.00170 at 94°C 0.000170 at 70°C) is the velocity constant for the uncatalyzed reaction.

** In this run the ammonia was distilled from the filtrate from the silver cyanate and titrated. The following percentages of ammonia were found: 22.0 29.1 44.0 62.7.

An extrapolation from the data at 94°C and 70°C gives $p = 3.8 \times 10^{-6}$ at 50°C. k' calculated from this value of p by means of $k' = p \cdot K_{HCO_3^-}/K_{H_2O}$ is 0.0047 (for $K_{HCO_3^-} = 6.73 \times 10^{-11}$ (Ref.[2])) or 0.0062 (for $K_{HCO_3^-} = 8.98 \times 10^{-11}$ *); *cf.* the value 0.00762 found in run 9 (Table 1). In view of the small differences on which this calculation is based the agreement between k' calculated from p and k' found in run 9 is regarded as satisfactory. This means that eqn. (3) (or eqn. (4)) accounts for the catalyzed decomposition as well in moderately acid or basic medium as in strongly basic medium.

DISCUSSION

The catalytic effect of carbonate on the decomposition of cyanate was first observed by Masson and Masson [6] who found the formation of carbonate from sodium cyanate to be autocatalytic. More recently Lister [7] and Kemp and Kohnstam [8] have examined the carbonate catalysis.

Lister finds that the decomposition of cyanate conforms to the equation

$$dc_{OCN^-}/dt = -(k_1' \cdot c_{OCN^-} + k_2' \cdot c_{CO_3^{--}})$$

in solutions containing sodium carbonate and approximately equal moles of sodium hydroxide and sodium cyanate. This near-equality will hold throughout the reaction (the gross reaction is: $OCN^- + OH^- + H_2O \rightarrow NH_3 + CO_3^{--}$). Eqn. (5) in this case takes the form

$$dc_{OCN^-}/dt = -(k_{OCN^-} \cdot c_{OCN^-} + p \cdot c_{CO_3^{--}})$$

i.e. eqn. (5) is under the stated experimental conditions consistent with the expression of Lister. Lister has $k_2' (= p) = 6.2 \times 10^{-4}$ at 100°C. An extrapolation to 100°C from the data listed in Table 2 gives $p = 5.2 \times 10^{-4}$.

The expression proposed by Kemp and Kohnstam is in agreement with eqn. (3). At 60.1°C Kemp and Kohnstam have $k' = 0.0175$, which agrees well with $k' = 0.0164$ obtained by extrapolation from the data listed in Table 1.

The author whishes to thank Professor, Dr.phil. Carl Faurholt for his very kind interest in this investigation.

Kinetics of Solvolysis of Acetic Anhydride in Methanol-Water Mixtures

JOUKO KOSKIKALLIO

Department of Chemistry, University of Helsinki, Helsinki, Finland

The rates of simultaneous hydrolysis and methanolysis of acetic anhydride in various methanol-water mixtures were measured at three different temperatures. The great variation in the second-order rate constants of the solvolysis reactions when the composition of the solvent mixture is altered is discussed and it is concluded that both methanolysis and hydrolysis are catalysed by the weak base water. The changes observed in the ratio methanolysis/hydrolysis are discussed in terms of hydrogen bonding in the methanol-water mixtures.

In addition to the spontaneous hydrolysis and alcoholysis of acetic anhydride, these reactions are catalysed by acids and bases [1-2]. The spontaneous solvolyses of acetic anhydride in alcohol-water mixtures could be described as reactions catalysed by the weak base water. In order to study this problem the rates of hydrolysis and methanolysis of acetic anhydride were measured in different methanol-water mixtures.

EXPERIMENTAL

The water used was freshly distilled. The methanol (Merck, analytical grade) was dried with aluminium methylate [3] and distilled. Finally it was distilled over anhydrous copper sulphate. The amount of water remaining after this treatment, usually about 0.005 mole/litre, was determined by the Karl Fischer method. The aniline was freshly distilled. The acetic anhydride used was a product of Merck, analytical grade.

The solvent mixtures were made up by volume in a 100 ml volumetric flask and the components were also weighed. The solvent mixture and anhydride were separately allowed to obtain the temperature of the thermostat during about one hour. At 0°C a stirred 10 l Dewar flask thermostat, half filled with ice, was used and for other temperatures the thermostats were electrically controlled to within $\pm 0.01°$. The reaction was started by adding about one milliliter of acetic anhydride to 100 ml of the solvent which yielded an approximately 0.1 M anhydride solution. The reaction was followed by taking 5 ml samples at suitable time intervals in order to cover the range from about 10 % to 90 % change. One sample was mixed with 15 ml of saturated aniline water (about 0.3 M aniline) and titrated with 0.02 M baryta. Another sample was taken immediately after the first (about 1 min) and mixed with 20 ml of 0.6 M ammonia. The mixture

was made sligtly acid by adding 1—3 ml of 0.1 M hydrochloric acid and then titrated with 0.6 M ammonia potentiometrically (Radiometer PHM 22h). These results were interpolated to correspond to the same reaction time. The difference between these two titrations gives the amount of anhydride present in the sample.

During the reaction of acetic anhydride with methanol in dry methanol the acetic acid produced in the reaction was esterified to some extent (2—3 %). This did not interfere with the calculation of the rate of methanolysis of acetic anhydride when the method of two different titrations was used. In methanol-water mixtures the consecutive reactions of esterification of acetic acid or hydrolysis of methyl acetate would have complicated the calculations of the ratio of the rates of simultaneous hydrolysis and methanolysis of acetic anhydride. Fortunately these consecutive reactions were so slow, when compared with the solvolysis of acetic anhydride, that they could be neglected. This was verified by taking samples from mixtures in which all the anhydride had reacted.

The rate constants were calculated from the usual first-order equation, which in the case of two simultaneous first-order reactions gives the sum of the two rate constants $k_1^h + k_1^m$. The ratio of these rate constants was obtained from the mean of the ratios of the changes in the values of the aniline and ammonia titration. Thus the first-order rate constants of hydrolysis k_1^h and methanolysis k_1^m could be calculated in each solvent mixture from a single run. The experimental error of the rate constants is of the order of magnitude of about 1—2 % in cases where the rates of hydrolysis and methanolysis do no much differ from each other and increases as the proportion of the rate of reaction decreases. The results are given in Table 1.

RESULTS AND DISCUSSION

From Table 1 it is seen that the first-order rate constant of hydrolysis of acetic anhydride k_1^h decreases continuously when methanol is added to water, but the first-order rate constant of methanolysis k_1^m shows a maximum. This contrast in the behaviour of hydrolysis and methanolysis disappears in the second-order rate constants k_2^h and k_2^m. Over the whole range of solvent mixtures there is nevertheless a considerable change of the second-order rate constant, of about 80-fold in the case of hydrolysis and 320-fold in methanolysis. There are different ways of explaining these great changes in rates. If the transition state in the hydrolysis and methanolysis of acetic anhydride is much more polar than the reactants, a solvent of lower solvating power such as methanol would retard the rate. Still, methanol is a solvent of fairly high dielectric constant ($D = 35.0$ at 0°) and good solvating power. Therefore it would be necessary to postulate an highly polar transition state. But it would then be difficult to account for the increase in the second-order rate constant of methanolysis of acetic anhydride when a solvent of low dielectric constant and poor solvating power such as benzene ($D = 2.29$ at 18°) is added to methanol [4].

An other possible explanation is based on changes in the acid-base properties in the methanol-water mixtures. Water is 137 times as strong a proton acceptor as methanol [5] at 25° and about one-eighth as strong a proton donator as methanol [6] at 25°. When water is replaced by methanol there is a considerable decrease in the basicity of the solvent. The solvolyses of acetic anhydride are known to be accelerated by various bases such as hydroxyl ion [4], acetate ion [2], pyridine [1,2] and various tertiary amines [1]. The great sensitivity of acetic anhydride towards bases makes it possible to assume that the spontaneous

* extrapolated values.

solvolysis of acetic anhydride in methanol-water mixtures is catalysed by the weak base water. The catalytic rate constant of methanolysis k_k^m is obtained when the second-order rate constant of methanolysis in pure methanol k_2^m is subtracted from the rate constants in methanol-water mixtures and divided by the concentration of water. The catalytic rate constant k_k^m decreases much less than k_2^m when methanol is added to water (Table 1 and Fig. 1). The catalytic rate constant of hydrolysis k_k^h is obtained in the same way when an extrapolated value of k_2^h in absolute methanol is used. Such an extrapolation may not be quite justified, but the choice of the extrapolated value only affects the value of k_k^h at low water concentrations and has a negligible effect upon their

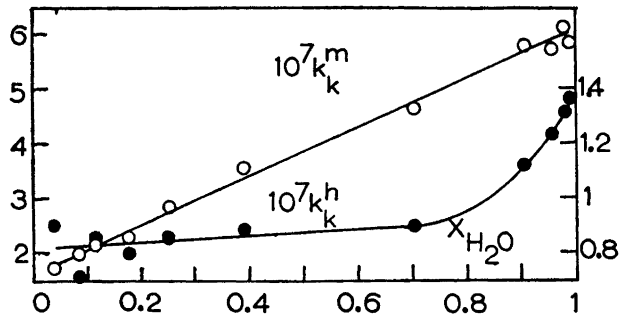

Fig. 1. The variation of the water-catalysed rates of hydrolysis and methanolysis of acetic anhydride in methanol-water mixtures.

values at water concentrations higher than 50 %. Furthermore, these rate constants change much less than the corresponding second-order rate constants k_2^h. The variation of the catalytic rate constants when the composition of the solvent is altered at the temperatures 0°, 25° and 50° is essentially the same. The remaining small changes in k_k-values with changing composition of the solvent mixture may be ascribed to solvent effects, for example hydrogen bonding.

Further insight into these "second-order" effects can be obtained from a comparison of the ratios of the rates of hydrolysis and methanolysis, because this treatment excludes the effect of water as a catalyst. From Table 1 and Fig. 2 it is seen that considerable changes in these ratios occur when temperature or solvent composition is altered. For comparison the writer's [4] previous values in ethanol-water mixtures are included, and likewise the values of Caundri [7]. In both cases the ratio of the rate constants changes in the same way when the composition of alcohol-water mixtures are altered, but the reactivities of the alcohols and water are in an unexpected order of magnitude. The rates of hydrolysis and ethanolysis are not very different from each other but the rate of methanolysis is considerably greater than that of hydrolysis, especially in mixtures with a high water concentration. This high reactivity of methanol in methanol-water mixtures may be attributed to hydrogen bonding in solvent mixtures. When methanol and water are mixed, considerable amounts of heat are evolved [8]. The strong interaction between methanol and water molecules probably occurs *via* hydrogen bonding. This can take place in two different ways, but because of the dominating acidic properties of methanol and the basic properties of water, it is likely to occur in the way: $MeOH...OH_2$. Higher hydrogen-bonded associations also occur, but their occurrence does not invalidate the following argument. The hydrogen bonding between methanol and water molecules would then make the oxygen of methanol more and the oxygen of water less nucleophilic or reactive to the anhydride molecule. The same argument also applies to ethanol-water mixtures. When the temperature is increased, the hydrogen bonds are partially broken and the ratios of the rates of alcoholysis and hydrolysis decrease. At

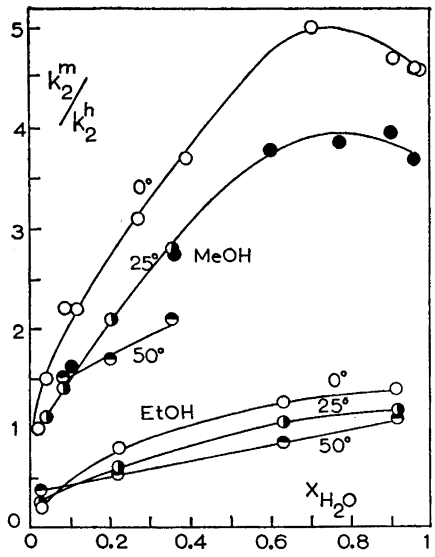

Fig. 2. The variation in the ratio of the second-order rate constants of hydrolysis and alcoholysis of acetic anhydride in methanol-water mixtures. In addition to the present values the writers previous [4] data and those of Caundri [7] (black points) are also included.

high enough temperatures the ratios could well be less than one in all mixtures of water and alcohol.

In mixtures containing less water than alcohol the ratio is decreased as the amount of water is decreased. In mixtures containing little water, all the water is hydrogen-bonded, mainly in the form MeOH...OH_2, and in addition the excess of methanol molecules are associated between themselves MeOH...OHMe. Therefore there is no change in the species reacting in the hydrolysis but an increasingly greater proportion of methanolysis occurs between the anhydride and various polymers of methanol as the amount of water in the solvent mixture decreases. On steric grounds the rate of methanolysis will decrease as compared with that of hydrolysis and the ratio of the rates will decrease as the proportion of water decreases. The reverse effect of temperature at very low water concentrations may likewise be explained on the same lines (Fig. 2).

In mixtures containing small amounts of methanol the ratio also decreases as the amount of methanol decreases. In these mixtures the methanol is mainly bonded as MeOH...OH_2 but the excess of water forms associations with itself HOH...OH_2 and these may be slightly more reactive in the hydrolysis than the associations with methanol.

The low reactivity of acetic anhydride with associations of alcohol is clearly seen from the increase in the rate when the associations are depolymerised by addition of an inert solvent such as benzene [4] and change of temperature which yields high apparent activation energies [4] in alcohols (about 18 kcal) compared with those in benzene (14 kcal) or water (10 kcal).

Kinetics of the Acid-Catalysed Solvolysis of Acetic Anhydride in Methanol-Water Mixtures

JOUKO KOSKIKALLIO

Department of Chemistry, University of Helsinki, Helsinki, Finland

The rate constants of the acid-catalysed hydrolysis and methanolysis of acetic anhydride were measured in various methanol-water mixtures. In solvent mixtures containing more than 27 % of water, the third-order rate constants are almost unaffected by the change of solvent composition. In solvent mixtures containing less than about 27 % of water, the increase of the rate constant is due to a shift in the proton transfer equilibria between the methoxonium ion, water and anhydride. From these values of the rate constants the equilibrium constant of the proton transfer reaction between methoxonium ion and water was calculated. The values obtained are $K = 209$ at 0° and 118 at 25° and they agree well with the previous investigations. With the aid of these values it was concluded that the acid-catalysed solvolysis of acetic anhydride involves a proton transfer pre-equilibrium instead of a bimolecular reaction between hydroxonium or methoxonium ions and acetic anhydride.

The hydrolysis of acetic anhydride in water and the alcoholysis in alcohols are catalysed by strong acids [1,2]. In organic solvents or in solvent mixtures with water, the rate of spontaneous hydrolysis is much less than in water, and acetic anhydride becomes more sensitive towards acids. In the present study the rates of the acid-catalysed methanolysis and hydrolysis of acetic anhydride in methanol-water mixtures were measured. From these measurements it is possible to calculate the equilibrium constant for the proton transfer reaction (1) between methoxonium ion and water and compare these values with those previously obtained by the author [3] from e.m.f. measurements.

$$MeOH_2^+ + H_2O = MeOH + H_3O^+ \qquad (1)$$

EXPERIMENTAL

The materials used in the experiments were the same as in the previous work [4]. Gaseous hydrogen chloride obtained from sodium chloride and concentrated sulphuric acid was absorbed in methanol and a sample of the solution obtained was titrated with baryta before use. The amounts of water remaining in the dried methanol were titrated by the

Karl Fischer method. The rate measurements and the calculations of the rate constants were made as before [3]. In dry methanol and also in mixtures containing less than 6 % of water the acetic acid formed in the reaction between anhydride and methanol (2)

$$AcOAc + MeOH = AcOH + AcOMe \quad (2)$$

$$AcOH + MeOH = AcOMe + H_2O \quad (3)$$

was slowly esterified with methanol (3) during the experiments. Because the method of taking two samples simultaneously [2], mixing with aniline and ammonia, and titrating, allows the calculation of the amount of anhydride in the mixture, the sum of the first-order rate constants of hydrolysis and methanolysis in methanol-water mixtures could be exactly calculated. The consecutive reaction (3) interfered only with the calculations of the ratio of the rate constants of hydrolysis and methanolysis. Fortunately, the rate of hydrolysis of acetic anhydride was small compared with that of methanolysis in the mixtures containing 6 % or less of water and hence it could be neglected. In the 5.4 % water mixture the hydrolysis was estimated at about 5 % of the methanolysis and in mixtures containing less water it was a proportionally smaller fraction of the total rate. The esterification of acetic acid (3) also produced water and since the rate of methanolysis in absolute methanol was especially sensitive to small amounts of water, the rate constants in each run decreased as the reaction proceeded. Between 0 and 50 % change the decrease was about 10 %. These rate constants were extrapolated to zero reaction time. In methanol-water mixtures the change of rate constants was much less, and the mean of the rate constants and the mean of the water concentrations were used. In mixtures containing 27 % or more water, the esterification of acetic acid or the hydrolysis of methyl acetate were negligible. Thus it was possible to calculate separately the rates of simultaneous hydrolysis and methanolysis of acetic anhydride catalysed by hydrochloric acid.

The estimated error in the rate constants of methanolysis is about ± 2 % except in the two mixtures containing more water, in which the error is about ± 5 %. In view of the unfavourable conditions for measuring the acid-catalysed hydrolysis of acetic anhydride owing to the comparatively high proportion of the spontaneous reaction and the simultaneous, faster methanolysis, these rate constants are subject to an error of about ± 20 % and are included only for a rough comparison. The results are given in Table 1, which contains the first-order rate constants of methanolysis k_1^m and hydrolysis k_1^h, from which the rate constants of the respective spontaneous solvolyses [4] have been subtracted, the catalytic rate constants k_k^m and k_k^h obtained from the first-order rate constants by dividing by the concentration of hydrochloric acid, the third-order rate constants k_s^m and k_s^h obtained by dividing the catalytic constants by the concentrations of water and methanol, respectively, and in the last columns the equilibrium constants calculated for the proton transfer equilibria 1.

RESULTS AND DISCUSSION

The equilibrium constant of the proton transfer reaction 1 is known from previous measurements (see Table 2). This equilibrium constant can also be calculated from the present kinetic measurements. The methanolysis of acetic anhydride catalysed by hydrogen chloride is especially suitable for this purposes, because the rate of the reaction is very little affected by the change in the composition of the methanol-water mixtures used as solvents. From Table 1 it is seen that between 27 % and pure water the rates of acid-catalysed methanolysis and hydrolysis change very little; the small changes observed are probably due to experimental error. At low water concentrations the rate increases as the proportion of water decreases and the change is about 30-fold between 27 and 0 % water. This change can be ascribed to changes in the distribution of protons between methanol, water and anhydride.

Table 1 shows the difference between the first-order experimental rate constants of methanolysis k_1^m and hydrolysis k_1^h in a solvent mixture containing hydrochloric acid and the rate constant of the spontaneous reaction k_o, the respective catalytic rate constants $k_k = (k_1 - k^o)/c_{HCl}$, the third-order rate constants $k_3^m = k_k^m / c_{MeOH}$ and $k_3^h = k_k^h / c_{H_2O}$ and the equilibrium constant of the proton transfer reaction 1.

This problem was first discussed by Goldschmidt [5], but he did not take into account the decrease in the concentrations of water when hydroxonium ions are formed in reaction 1. In absolute methanol there is a proton transfer equilibrium between methoxonium ions and anhydride

$$MeOH_2^+ + A = AH^+ + MeOH \qquad (4)$$

The rate of the acid-catalysed methanolysis of acetic anhydride is proportional to the concentration, or rather to the activity of the protonated anhydride. In the following calculations concentrations are used instead of activities because both the rate constants and the equilibrium constants involve only

ratios of similarly charged species and at the low electrolyte concentrations used in the experiments the changes of the ratios of the activity coefficients were small compared with the experimental error involved in determining the rate constants. The equilibrium constants obtained from rate measurements at two different acid concentrations do not differ more from each other than the experimental error (Table 1, last column).

When a base such as water is added to methanol, the concentration of methoxyl ions decreases according to reaction 1. Since only a small fraction of the protons were combined with anhydride, the concentration of the protonated anhydride is decreased in proportion to the concentration of methoxonium ions. Therefore the ratio of the rate constants of the acid-catalysed methanolysis of acetic anhydride in absolute methanol and in a methanol-water mixture is equal to the ratio of the concentrations of protonated anhydride and also the methoxonium ions in the two solvents. The difference between the total acid concentration and the methoxonium ion concentration is equal to the concentration of hydroxonium ions. Finally the concentration of water is obtained by subtracting the concentration of hydroxonium ions. All the necessary equilibrium concentrations for calculation of the equilibrium constant of reaction 1 are now known. As a first approximation, a K-value was obtained which was used to calculate the rate constant in absolute methanol from the rate constants at the lowest water concentrations. The correction was only about 1—2 %, as is seen from Table 1. The mean of these rate constants was then used to calculate the K-values shown in Table 1 in the last column. The error in K is estimated as about $\pm$ 3 %. The K-values decrease as the concentration of water increases and are probably slightly affected by the change in the concentration of hydrochloric acid, too. An extrapolation to zero water concentration yields $K = 8.3$ at 0° and $K = 4.8$ at 25°. When these values are multiplied by the concentration of methanol, values of 209 and 118 are obtained. These values may be compared with the previous values obtained by various methods.

Table 2. Values of the equilibrium constant $K = [ROH] \cdot [H_3O^+] / [H_2O] \cdot [MeOH_2^+]$.

* present work

The heat of the proton transfer reaction 1 is $\Delta H = -3.7$ kcal mole^{-1} and the entropy $\Delta S = -2.7$ cal degree^{-1} mole^{-1} as calculated from the values of K of the present work. The great difference in the basicity between methanol and water is probably due to the strong hydrogen bonding occurring in methanol. In acetic acid [9] water is only about eight times as strong a base as methanol at 25°. The heat of depolymerisation of hydrogen-bonded polymers of alcohols is of the same order of magnitude as the heat of the proton transfer reaction 1.

The activation energies and entropies calculated from the rate constants of hydrolysis in water and methanolysis in methanol given in Table 1 are

	E kcal · mole^{-1}	A l · mole^{-2} · sec^{-1}	ΔS^* at 25° cal · degree^{-1} · mole^{-1}
Hydrolysis	17.13	$3.95 \cdot 10^9$	−17.06
Methanolysis	10.97	$1.4 \cdot 10^6$	−33.2

The values of the activation energy is not far from the respective value obtained for the acid-catalysed hydrolysis of simple esters, *e. g.* ethyl acetate [10] $E = 16.76$ kcal mole^{-1}, $A = 3.75 \times 10^6$ l · mole^{-2} · sec^{-2} and $\Delta S^* = -30.5$ cal · degree^{-1} · mole^{-1}. Although the entropies of activation differ considerably the mechanism of the two reactions is probably the same, involving a fast proton transfer equilibrium 4 and a subsequent bimolecular reaction between the protonated anhydride and a water molecule to form either an intermediate addition product or a transition state. A unimolecular mechanism was proposed by Gold [1] for the acid-catalysed hydrolysis of acetic anhydride in water at 0° on the grounds that the rate was proportional to the Hammett acidity function h_0 and not to the concentration of the catalyst at high acid concentrations. The validity of this method has recently been criticized in a work of Koskikallio and Whalley [11] concerning the volume of activations of acid-catalysed hydrolyses.

The experimental activation energies given above are actually the sums of the activation energies of the slow step of the reaction and the proton transfer equilibria 4 and 5 in methanol and water, respectively.

$$H_2O^+ + A = AH^+ + H_2O \qquad (5)$$

The ratio of the equilibrium constants of the two proton transfer reactions 4 and 5 in the same solvent, *e. g.* a methanol-water mixture, is equal to the equilibrium constant of the proton transfer reaction 1 in the same solvent. Because the solvent effects are small for these reactions the above statement is approximately valid for values obtained in different solvents, *e. g.* pure methanol and water. Thus the greatest part of the difference between activation energies in water and in methanol, $\Delta E = -7.2$ kcal · mole^{-1}, is due to the heat of the proton transfer reaction 1, $\Delta H = -3.7$ kcal · mole^{-1}, and the rest of the difference is due the difference between the activation energies of the two reactions, hydrolysis and methanolysis, and their solvent effects.

Similarly, differences in the entropies of activation can be corrected for the changes in the proton transfer equilibria 4 and 5. If the concentrations of the protonated anhydride in water and in methanol containing hydrochloric acid were known, the entropies of activation of the slow step of the solvolysis of acetic anhydride could be calculated. Assuming the value of the equilibrium constant of the reaction 1 to be unaffected by the change in the composition of the solvent mixture, $K = 209$ at 0°, the ratio of the concentrations of the protonated anhydride in methanol and in water can be calculated to be $25.2 \cdot 209/55.5 = 94.2$. Because the rate is proportional to the concentrations of the protonated anhydride, this would also be the ratio of the rate constants.

It would cause a difference of about 9.0 units in the experimental activation entropies. The observed difference in the entropies is 16.1 units. Thus the differences in the rates, activation energies and entropies of the acid-catalysed solvolysis of acetic anhydride in methanol-water mixtures are partly explained by the changes in the proton transfer equilibria when the composition of the solvent mixture is altered and the remaining small differences indicate that other solvent effects are only of minor importance.

That there are fast proton transfer pre-equilibria (4 and 5) in the acid-catalysed solvolyses of acetic anhydride is obvious from the obsevration of Gold [1] that the rate of the hydrolysis is much more closely proportional to the Hammett acidity function h_0 than to the concentration of the catalyst at high acid concentrations. The same result is obtained from the present experiments. One of the possible mechanisms of the acid-catalysed solvolysis of acetic anhydride in addition to that involving a fast proton transfer pre-equilibria is a bimolecular reaction between methoxonium or hydroxonium ions and the uncharged anhydride. Because all the species are thermodynamically in equilibrium, a choice between these two mechanisms is impossible. For the following reasons the mechanism which includes the proton transfer equilibrium is more probable. If the value of $K = 209$ is used to calculate the ratio of hydroxonium and methoxonium ions in the mixture containing 27 % water, a value of $[H_3O^+]/[ROH_2^+] = 137$ is obtained. The ratio of the first-order rate constants of the acid-catalysed hydrolysis and methanolysis of acetic anhydride is $k_1^h/k_1^m = 0.132$ in the same solvent mixture. Thus the bimolecular reaction between anhydride and hydroxonium ion would be about 10^3 times slower than the corresponding reaction between anhydride and methoxonium ion. Such a large difference between these two similar reactions is unexpected. Thus the mechanism is that involving a proton transfer pre-equilibrium. According to this mechanism the ratio of the acid-catalysed methanolysis and hydrolysis (about 4 to 6) is almost identical with the value for the ratio of the spontaneous reactions in the same solvent mixtures [4]. Also this observation is in accordance with the mechanism involving the proton transfer pre-equilibrium.

The author wishes to record his indebtedness for a research grant from the *Alf. Kordelin Foundation.*

Studies on Pyrazolones

XII. Alkaline Decomposition of Furlone Yellow

GUNNEL WESTÖÖ

Institute of Organic Chemistry, University of Lund, Lund, Sweden

Alkaline hydrolysis of furlone yellow [1] (I) at room temperature gives a salt of the base II, which on acidification splits off carbon dioxide to form the compound III.

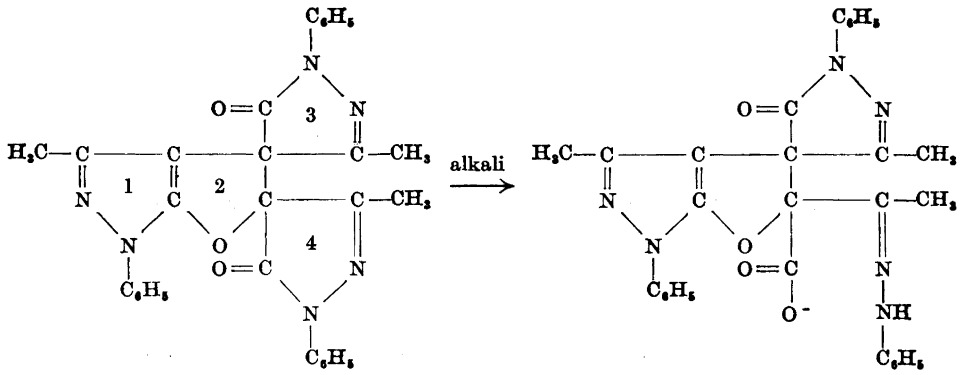
The pyrazolone ring of 1-phenyl-3-methyl-2-pyrazolin-5-ones is stable towards alkali, unless both the 4-hydrogen atoms are substituted, at least one of them by an electron-attracting group. Cleavages of pyrazolone rings by alkali have been described, *e.g.* for rubazonic acid [2] and for 1,1′-diphenyl-3,3′-dimethyl-4-cyano-[4,4′-bi-2-pyrazoline]-5,5′-dione [3]. In the present paper one of the alkaline cleavage products of furlone yellow [1] is studied.

From the acidified, alkaline hydrolysate of furlone yellow (I) a colourless compound can be isolated, the elemental analyses of which are in accordance with the structure III. The product is insoluble in aqueous alkali. In solution it decomposes in a couple of days with formation of 1,1′-diphenyl-3,3′-dimethyl-[4,4′-bi-2-pyrazoline]-5,5′-dione [2] (IV). This degradation, which is catalysed by acids and bases, excludes a cleavage of the pyrazolone ring 3 of I during the hydrolysis. As ring 1 has a stable pyrazole structure the ring 4 must have been split up in accordance with formula II. The intermediate II has not been isolated. On acidification it splits off carbon dioxide.

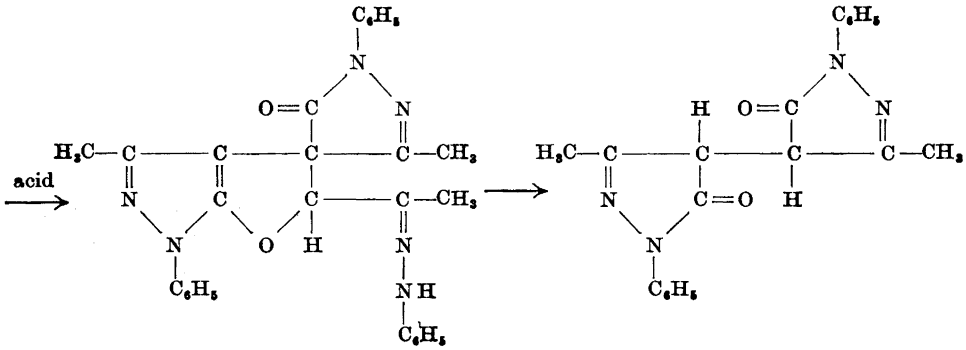
In addition coloured products of hydrolysis are formed from I. They have not been investigated and may involve cleavage of ring 3 of I.

EXPERIMENTAL

Preparation of III. Furlone yellow [1] (5.27 g) was dissolved in 300 ml of boiling ethanol, the solution was cooled to room temperature, and 2.5 N sodium hydroxide (75 ml) was added. After 2 h the solution was acidified with 2.5 N hydrochloric acid (75 ml) and immediately precipitated with water to prevent decomposition of the product III formed. The precipitate was collected by filtration, washed with water and air-dried (5.3 g). The product obtained was dissolved in ethyl acetate (150 ml, room temperature). Insoluble bispyrazolone (IV) was sometimes present and had to be removed by filtration. After evaporation of the excess of ethyl acetate at room temperature, colourless crystals of



I II



III IV

III separated on scratching. They were filtered and washed with ethyl acetate (yield 3.35 g). For further purification the treatment with ethyl acetate may be repeated. M. p. about *155°* (decomp.). (Found: C 70.9; H 5.3; N 17.1; O 6.6. Calc. for $C_{29}H_{26}N_6O_2$: C 71.0; H 5.3; N 17.1; O 6.5.)

Degradation of III with formation of IV. A solution of III (0.25 g) in chloroform (4 ml) was kept at room temperature for 24 h. The colourless precipitate formed (0.15 g) was filtered and washed with chloroform. It was almost insoluble in boiling ethanol, melted >300° (decomp.) and was oxidized by nitrous acid to form pyrazole blue. Accordingly it must be 1,1′-diphenyl-3,3′-dimethyl-[4,4′-bi-2-pyrazoline]-5,5′-dione [2] (IV). — When hydrogen chloride was passed through a benzene solution of III, the degradation to the bispyrazolone IV was rapid. Analogously the addition of alkali to an ethanol solution of III accelerated the formation of IV. (Found: C 69.1; H 5.2; N 16.4. Calc. for $C_{20}H_{18}N_4O_2$: C 69.3; H 5.2; N 16.2.)

Studies on Pyrazolones

XIII. The Reactions of 1-Phenyl-3-methyl-2-pyrazolin-5-one with Some Diketones

GUNNEL WESTÖÖ

Institute of Organic Chemistry, University of Lund, Lund, Sweden

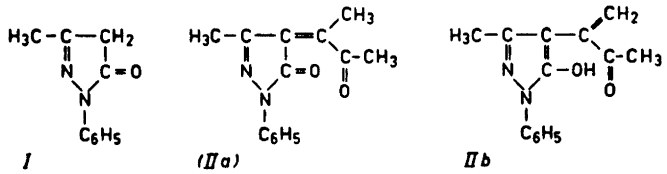
1-Phenyl-3-methyl-2-pyrazolin-5-one (I) reacts with 2,3-butanedione to form the acid 1-phenyl-3-methyl-4-(1-acetylvinyl)-5-hydroxypyrazole (II b). With 2,4-pentanedione I gives a neutral, tetracyclic product (III d) and with 2,5-hexanedione the bispyrazolone, V, which is stable in solid form but in solution is easily oxidized to VI even by the air at room temperature.

2,3-Butanedione and 1-phenyl-3-methyl-2-pyrazolin-5-one (I) react at room temperature with formation of a colourless acid, II b, a tautomer of the expected, coloured, neutral reaction product, II a. A CH_2=C-test on the acid according to Bricker and Roberts [1] was positive. The IR spectrum contains only one C=O stretching frequency (1 670 cm^{-1}) and a broad OH band around 2 500 cm^{-1} (solid state).

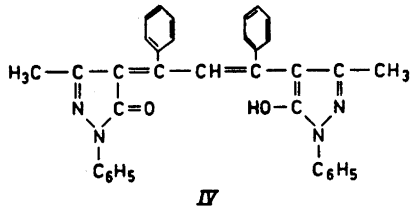
When I is heated with 2,4-pentanedione in methanol, a neutral, colourless compound separates. Piperidine catalyses the reaction. The analyses of the compound formed are in accordance with the structure III a, but since the lack of colour excludes this formula, the reaction sequence, Scheme I, leading to the structure III d, is proposed. The UV-curve of the product in methylene chloride solution (λ_{max} = 254 mμ, log ε = 4.26) is similar to the corresponding curve of 1-phenyl-3-methyl-5-methoxypyrazole in hexane [2]. The IR spectrum of the solid product also confirms the structure III d, having neither C=O, nor OH absorption bands. A very strong band at 1 090 cm^{-1} is probably associated with the ether linkages.

Only neutral solvents like ligroin, methylene chloride and chloroform dissolve the product in the cyclic form (III d). Alcoholic solutions are violet-red, indicating that III d is here in equilibrium with the open forms (ionized III b has a λ_{max} at 545 mμ). III d can be recovered from the red solutions.

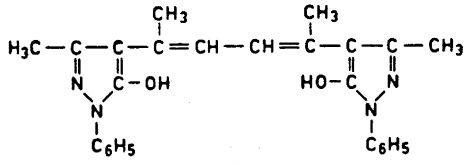
When dry hydrogen chloride is introduced into a chloroform or methylene chloride solution of III d, the ether linkages are split up, for the IR spectrum of the colourless compound which separates shows OH and NH bands. The



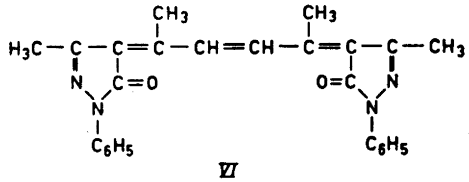
I (*IIa*) *IIb*



IV



V

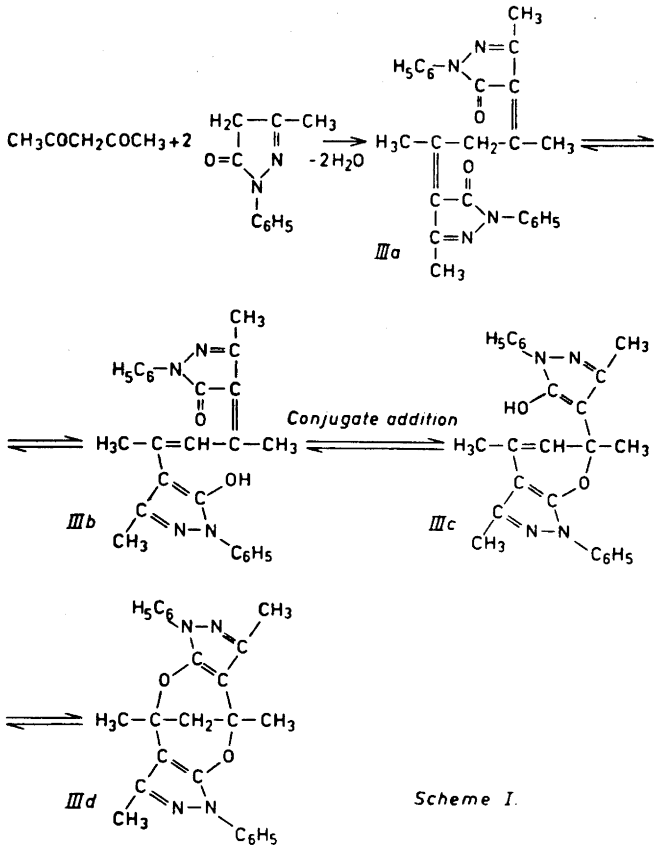


VI

structure of the reaction product is difficult to settle on account of its great instability. Both in solution and in the solid state the compound splits off hydrogen chloride with reformation of III d.

When the methyl groups in 2,4-pentanedione are exchanged for phenyl groups in the above reaction, the open form IV is strongly stabilized by resonance and no cyclization takes place. As is to be expected on account of the acidic hydroxyl group and the resonance possibilities of the corresponding ion, the colour of IV is pH-dependent, being blue in alkaline solution, red in the solid form and in acid solution.

Heating of I in 2,5-hexanedione gives rise to a colourless product, the properties of which are in accordance with the structure V. The IR curve of the compound in KBr has no carbonyl band but a broad hydroxyl band at about 2 600 cm^{-1}. V is stable in the solid state, but in solution it is rapidly oxidized by the air to form the deep red compound VI.



Scheme I.

EXPERIMENTAL

Preparation of 1-phenyl-3-methyl-4-(1-acetylvinyl)-5-hydroxypyrazole (II b). 1-Phenyl-3-methyl-2-pyrazolin-5-one (I) (10 g) was dissolved in 2,3-butanedione (30 ml), and the solution was kept at room temperature for 18 h. After cooling the crystals formed were collected by filtration and washed with cold ethanol. Yield: 11.7 g. After recrystallization from ethanol the product melted at 136° (decomp.). (Found: C 69.4; H 5.9; N 11.7; O 13.3; equiv. wt 242. Calc. for $C_{14}H_{14}N_2O_2$: C 69.4; H 5.8; N 11.6; O 13.2; equiv. wt 242.)

Preparation of III d. 2,4-Pentanedione (5.0 ml), I (5.0 g), methanol (20 ml) and one drop of piperidine were refluxed for 48 h. The piperidine was neutralized by addition of 2 drops of 5 N hydrochloric acid. The boiling was continued for 10 min. After cooling in ice for one hour, the colourless crystals, which had separated, were filtered and washed with methanol and water. Yield: 5.0 g, m. p. 171° (decomp.). The product can be recrystallized from benzene. (Found: C 72.7; H 5.9; N 13.6; O 7.7; mol. wt * 417. Calc. for $C_{25}H_{24}N_4O_2$: C 72.8; H 5.9; N 13.6; O 7.8; mol. wt 412.)

Preparation of IV. Dibenzoylmethane (2.2 g), I (3.5 g) and *n*-butanol (10 ml) were refluxed overnight. After addition of ethanol, the solution was poured into water and

* Cryoscopic determination in glacial acetic acid.

acidified with hydrochloric acid. The precipitate was filtered and washed with water. Yield of crude IV: 3.7 g. The product was recrystallized from ethanol repeatedly (0.8 g of deep red product remained). M. p. 211°. It was dried at 100° and 0.5 mm Hg. (Found: C 77.9; H 5.5; N 10.1. Calc. for $C_{35}H_{28}N_4O_2$: C 78.3; H 5.3; N 10.4.)

Preparation of V. 2,5-Hexanedione (5 ml), I (5.0 g) and ethanol (30 ml) were heated in a boiling water bath in N_2-atmosphere for 24 h. Colourless crystals of V separated. After cooling they were filtered, washed with ethanol and chloroform and dried in N_2-atmosphere. Yield: 4.45 g; m. p. about 220° (decomp.). (Found: C 73.0; H 6.2; N 13.2; O 7.6. Calc. for $C_{26}H_{26}N_4O_2$: C 73.2; H 6.15; N 13.1; O 7.5.)

V is only slightly soluble in most solvents. In solution it is easily oxidized by *e. g.*, perchloric acid or 1-phenyl-3-methyl-4,4-dibromo-2-pyrazolin-5-one and even by the air, the red compound VI being formed. In *e. g.*, methylenechloride in N_2-atmosphere, V is soluble without change of colour. When air is admitted the solution rapidly turns red. Besides by the colour change the formation of VI is proved by the IR spectrum, which, contrary to the spectrum of V, has a C=O band but no OH band. M. p. of VI: 217° (decomp.). (Found: C 73.5; H 5.9; N 13.2; O 7.7. Calc. for $C_{26}H_{24}N_4O_2$: C 73.6; H 5.7; N 13.2; O 7.5.)

The analyses were performed by Mikroanalytisches Laboratorium im Max-Planck-Institut für Kohlenforschung, Mülheim, Germany. Dr. Andreas Rosenberg, University of Uppsala, carried out the IR measurements.

The author wishes to thank *Statens naturvetenskapliga forskningsråd* for financial support.

Studies on *Cyclo*propanes

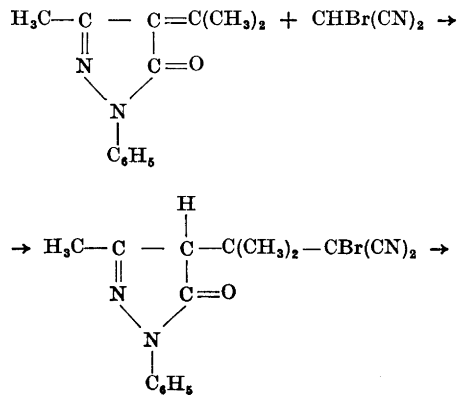
III. On the Isomerization of Certain Hexasubstituted *Cyclo*propanes

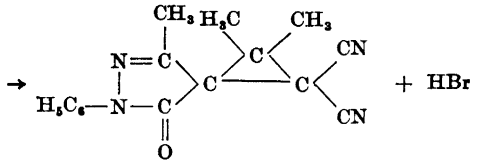
GUNNEL WESTÖÖ

Institute of Organic Chemistry, University of Lund, Lund, Sweden

The rearrangement of certain hexasubstituted *cyclo*propanes, involving cleavage of the *cyclo*propane ring with migration of a hydrogen atom from a methyl group attached to the ring, which was described in a previous paper [1], has been further studied. I a and b isomerize at elevated temperatures, IV a, b being formed. Boiling with acids or bases transforms IV a, b into V. II rearranges easily with formation of VI and VII, but no rearrangement was observed with the compounds III a–e.

The hexasubstituted, neutral *cyclo*propanes (I—III), the isomerizations of which are studied in the present investigation, all have four electrophilic groups (1,1- and 2,2-positions) and — except for III e — two alkyl groups, one of which is a methyl, attached to the *cyclo*propane ring. With the exception of III a, b and e, they have all been prepared by a Michael addition of a bromo compound to an α,β-unsaturated carbonyl compound, followed by ring closure with expulsion of hydrogen bromide, *e. g.*





Alkali has been used to catalyse the reactions.

III a has been prepared by Ramberg and Wideqvist [2] and III b by Wideqvist [3], and their method of preparation could be used also for III e.

I a and I b are both stable at room temperature even in alcoholic solution and much more resistant towards heat than were the *cyclo*propanes, described in Studies on *Cyclo*propanes I [1]. However, heating in *n*-butanol on a boiling-water bath for several hours causes rearrangement to monobasic acids, which must have the structures IV a and IV b, on account of the fact that heating with concentrated hydrochloric acid or dilute alkali solution transforms them into a monobasic acid of the structure V. A qualitative test of end unsaturation according to Bricker and Roberts [4] was distinctly positive for IV but doubtable for V. This indicates a rearrangement of V from the β,γ-unsaturated nitrile structure to the α,β-form. The IR-spectrum of V presents a nitrile stretching band at 2 200 cm^{-1}, showing that the CN group is in strong resonance [5] (α,β-form). V exhibits a remarkable stability towards hydrolysis, a fact which also supports the α,β-unsaturated structure.

The compound II is less stable than I, and rearranges on boiling in ethanol solution for half an hour. The two possible isomerization products, the acids VI and VII, are both formed. They can be separated by recrystallization from ethanol. The isomer that is least soluble in ethanol is similar to IV in being rather soluble in concentrated hydrochloric acid, indicating that it has a pyrazolonyl group in the end position (VI), enabling the formation of NH tautomer. The other isomer (VII) is insoluble in concentrated hydrochloric acid. The UV spectra support these structures. In VI as well as in VII the main absorbing group in the UV range is the pyrazolonyl group. This group can form salts with acids in VI but not in VII. In accordance with this fact, the UV curve of VII is only slightly affected by strong acids, whereas the absorption of VI is appreciably depressed at wavelengths >250 mμ.

The compounds III a—d are all stable and do not isomerize even on prolonged boiling in ethanol or *n*-butanol. III e decomposes when boiled in *n*-butanol. No isomerization products could be isolated.

Unsuccessful attempts have been made also to prepare and study *cyclo*propanes with the substituents $R_1 = R_2 = CH_3$, $R_3 = CN$, $R_4 = CN$ or $COOC_2H_5$ and $R_5 = R_6 = COCH_3$. Acetone, sodium bromoacetylacetonate and malonitrile or ethyl cyanoacetate were used as starting material, but the reaction products isolated did not contain any component emanating from the acetone and were not *cyclo*propanes. From the nitrile and the bromoacetylacetone a furan derivative was obtained and from ethyl cyanoacetate and the bromoacetylacetone a substituted pyran. These products are described in a separate paper [6].

EXPERIMENTAL

Preparation of I a. 1-Phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one (4.3 g) was dissolved in 250 ml of hot ethanol, the solution was immediately cooled to room temperature and bromomalonitrile (2.90 g) was added. As soon as it had dissolved, 2.39 N sodium hydroxide solution (8.4 ml) was added dropwise with stirring. The colourless I a soon started separating, and after 4 h it was collected by filtration and washed with 50 % ethanol. Yield: 4.5 g. The product was recrystallized from ethanol. M. p. 163° (decomp.). (Found: C 69.2; H 5.0; N 20.0. Calc. for $C_{16}H_{14}N_4O$: C 69.05; H 5.1; N 20.1.)

Preparation of I b. 1-Phenyl-3-methyl-4-*iso*propylidene-2-pyrazolin-5-one (4.3 g) and bromocyanoacetamide (3.3 g) were dissolved in 250 ml of ethanol. Sodium hydroxide (8.4 ml of 2.39 N solution) was added dropwise with stirring to the cold solution. The next day the colourless crystals which had separated were collected by filtration and washed with 50 % ethanol. Yield: 3.7 g; m. p. about 160° (very unsharp, decomp.). (Found: C 64.8; H 5.6; N 18.8; O 10.9. Calc. for $C_{16}H_{16}N_4O_2$: C 64.8; H 5.4; N 18.9; O 10.8.)

Preparation of II. 1-Phenyl-3-methyl-4-bromo-2-pyrazolin-5-one (5.07 g) was dissolved in ethanolic sodium hydroxide solution (10 ml of ethanol + 8.27 ml of 2.42 N aqueous sodium hydroxide solution) and immediately poured into a solution of 3-methyl-4-*iso*propylidene-2-isoxazolin-5-one [7] (2.78 g) in ethanol (75 ml). II separated at once. It was filtered and washed with water and ethanol. Yield of almost colourless product: 5.90 g, m. p. 160° (decomp.). The product was recrystallized by dissolving 1 g of it in 100 ml of boiling ethanol and immediate cooling of the solution in ice. (Found: C 65.4; H 5.4; N 13.5. Calc. for $C_{17}H_{17}N_3O_3$: C 65.6; H 5.5; N 13.5.)

The UV curve of II is closely related to the corresponding curves of the *cyclo*propane derivatives described in Studies on *Cyclo*propanes I [1]. The product is neutral towards thymolphthalein but is rapidly hydrolysed by alkali.

Preparation of III c. Ethyl *iso*propylidenecyanoacetate (3.06 g) and bromomalonitrile (2.90 g) were dissolved in ethanol (10 ml), and 8.55 ml of 2.34 N sodium hydroxide solution were added with stirring. III c started separating immediately, and after 3 h it was filtered and washed with 50 % ethanol. Yield: 3.3 g of colourless product; m. p. about 135° (decomp.). The product was purified by recrystallization from ethanol. (Found: C 60.8; H 5.2; N 19.35; O 14.7. Calc. for $C_{11}H_{11}N_3O_2$: C 60.8; H 5.1; N 19.35; O 14.7.)

Preparation of III d. Ethyl *sec.*-butylidenecyanoacetate (5.0 g of crude product) and bromomalonitrile (4.35 g) were dissolved in ethanol (20 ml). Sodium hydroxide (12.6 ml of 2.34 N solution) was added. III d separated in colourless crystals, and after 4 h it was filtered and washed with 50 % ethanol. Yield: 4.5 g; m. p. 89°. The product was purified by recrystallization from ethanol. M. p. 89.3°. (Found: C 62.3; H 5.7; N 18.1; O 13.7. Calc. for $C_{12}H_{13}N_3O_2$: C 62.3; H 5.7; N 18.2; O 13.8.)

Preparation of III e. 2,5-Hexanedione (1.14 g) and bromomalonitrile (2.90 g) were dissolved in ethanol (10 ml), and a solution of potassium iodide (7.0 g) in water (10 ml) was added. The following day the precipitate formed (III e) was filtered and washed with 50 % ethanol. Yield: 1.15 g. The compound was purified by recrystallization from ethanol, when a colourless, neutral product was obtained. M. p. 165—166° (decomp.). (Found: C 63.7; H 4.5; N 24.8; O 7.1. Calc. for $C_{12}H_{10}N_4O$: C 63.7; H 4.5; N 24.8; O 7.1.)

Isomerization of I a to form IV a. I a (3.0 g) was heated in 1-butanol (120 ml) on a boiling-water bath for 6—7 h. The butanol was evaporated under reduced pressure, and the crude IV a left was recrystallized repeatedly from ethanol. M. p. 163—164° (decomp.). (Found: C 69.2; H 5.1; N 20.0; O 5.6; equiv. wt 278. Calc. for $C_{16}H_{14}N_4O$: C 69.05; H 5.1; N 20.1; O 5.75; equiv. wt 278.) A CH_2=C determination according to Bricker and Roberts [4] was positive.

Boiling of IV a with a) concentrated hydrochloric acid or b) dilute sodium hydroxide solution to form V. a) IV a (1.35 g) was heated with concentrated hydrochloric acid (20 ml) on a water-bath for 3 h. The hydrochloric acid was removed under reduced pressure, and the solid residue was boiled with water. On cooling colourless crystals separated. They were filtered and washed with water. Yield: 1.03 g. After recrystallization from ethanol twice the product melted at 173° on slow heating. When the melting tube was inserted in the heating-block at ~130°, the product melted, but solidified again and then melted at ~173°. (Found: C 70.9; H 6.1; N 16.4; O 6.4; equiv. wt 252. Calc. for $C_{15}H_{15}N_3O$: C 71.1; H 6.0; N 16.6; O 6.3; equiv. wt 253.) A qualitative test on unsaturation according to Bricker and Roberts gave only weak colour. The product is not hydrolysed by concentrated hydrochloric acid, nor by 2 N sodium hydroxide solution at 100°.

b) A solution of IV a (0.2 g) in 2.4 N sodium hydroxide solution (2.5 ml) was heated on a water-bath for 8 h. On acidification V separated. It was collected by filtration and washed with water. From the solution more V could be extracted with ether. Mixed melting point with an authentic sample of V was 172°.

Isomerization of I b to form IV b. I b (2.0 g) and 1-butanol (60 ml) were heated in a boiling-water bath for 6 h. The butanol was evaporated under reduced pressure and the solid residue was recrystallized from ethanol. Yield: 1.6 g of colourless IV b; m. p. about 215° (decomp.). (Found: C 64.8; H 5.5; N 18.9; O 10.9; equiv. wt 296. Calc. for $C_{16}H_{16}N_4O_2$: C 64.85; H 5.4; N 18.9; O 10.8; equiv. wt 296.) A test on end unsaturation according to Bricker and Roberts was positive.

IV b, analogously to IV a, could be transformed into V by heating with concentrated hydrochloric acid on a boiling-water bath.

Isomerization of II to form VI and VII. A solution of II (5.05 g) in ethanol (500 ml) was boiled vigorously for half an hour. At that time so much solvent had evaporated that crystals of VI started separating. After cooling the product was collected by filtration and washed with cold ethanol. Yield of VI: 2.35 g. The compound can be recrystallized from ethanol. M. p. 187° (decomp.). (Found: C 65.6; H 5.5; N 13.5; O 15.2; equiv. wt 308. Calc. for $C_{17}H_{17}N_3O_3$: C 65.6; H 5.5; N 13.5; O 15.4; equiv. wt 311.) A qualitative test on CH_2=C according to Bricker and Roberts [4] was positive. The product is soluble in concentrated hydrochloric acid.

The mother liquor and washings from VI were evaporated to dryness in vacuum. The product obtained was recrystallized from ethanol, treated with concentrated hydrochloric acid to remove VI, filtered, washed with hydrochloric acid and water and once more recrystallized from ethanol. Yield of VII: 1.25 g, m. p. 179° (decomp.). (Found: C 65.5; H 5.7; N 13.5; O 15.5; equiv. wt 309. Calc. for $C_{17}H_{17}N_3O_3$: C 65.6; H 5.5; N 13.5; O 15.4; equiv. wt 311.) A qualitative test on end unsaturation was positive.

The UV curves of VI and VII are distinctly different (λ_{max_1} = 246 mμ, log ε_1 = 4.09 and λ_{max_2} = 275 mμ, log ε_2 = 3.98 for VI, λ_{max} = 248 mμ, log ε = 4.34 for VII).

Preparation of VIII. When bromomalonitrile (4.35 g) was dissolved in a solution of 3-methyl-4-*iso*propylidene-2-isoxazolin-5-one (4.17 g) in ethanol (150 ml), VIII started separating immediately. After 4 h it was filtered and washed with 50 % ethanol. Yield:

4.95 g of colourless product; m. p. ~173° (decomp.). The compound was recrystallized from ethanol. (Found: C 59.3; H 4.5; N 20.7. Calc. for $C_{10}H_9N_3O_3$: C 59.1; H 4.5; N 20.7.) The product is rapidly hydrolysed by alkali. A solution of the compound in concentrated acetic acid does not react with bromine at room temperature. Accordingly it does not contain the isomeric acid. The IR spectrum shows absorption at 1 025 cm^{-1}, which is within the range characteristic of *cyclo*propane rings [8,9].

Attempts to isomerize III a—e. Heating of ethanol or 1-butanol solutions of III a, b, c, d or e on a boiling-water bath did not result in rearrangements with ring cleavage. Except with III e most of the *cyclo*propane derivative could be recovered unchanged.

The analyses were performed by Mikroanalytisches Laboratorium im Max-Planck-Institut für Kohlenforschung, Mülheim, Germany. Dr Andreas Rosenberg, University of Uppsala, carried out the IR measurements.

Studies on *Cyclo*propanes

IV. On the Isomerization of 1,1-Dimethyl-2,3-dicyano-2-ethoxycarbonyl-3-*cyclo*propanecarboxamide

GUNNEL WESTÖÖ

Institute of Organic Chemistry, University of Lund, Lund, Sweden

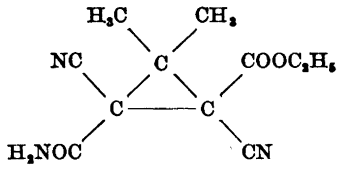
1,1-Dimethyl-2,3-dicyano-2-ethoxycarbonyl-3-*cyclo*propanecarboxamide (I) is easily rearranged to form the iminoimide II.

1,1-Dimethyl-2,3-dicyano-2-ethoxycarbonyl-3-*cyclo*propanecarboxamide (I) can be prepared from ethyl *iso*propylidenecyanoacetate and bromocyanoacetamide in alkaline solution in a way analogous to the preparations of *cyclo*propane derivatives described in Studies on *Cyclo*propanes 1—3 [1-3].

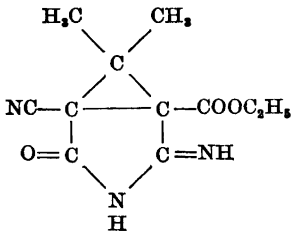
When kept in ethanol solution at room temperature for 1—2 days, the neutral I rearranges to form an amphoteric isomer, which is very weak both as an acid and as a base but can be sharply titrated in anhydrous medium with strong bases or acids. The rearrangement is strongly catalysed by bases, retarded by acids. The properties of the isomer are in accordance with the structure II. The structure III is excluded, a qualitative test on end unsaturation being distinctly negative. Thus the isomerization of I is not related to the rearrangements of the *cyclo*propanes described earlier [1,3].

The IR spectra of I and II both have an absorption band within the range characteristic of *cyclo*propane rings [4,5], I at 1 025 cm^{-1} and II at 1 005 cm^{-1}. As is to be expected the IR curve of I (in potassium bromide) shows two NH_2 stretching bands (3 150 cm^{-1} and 3 310 cm^{-1}), the spectrum of II (in potassium bromide) only one NH stretching band (3 330 cm^{-1}).

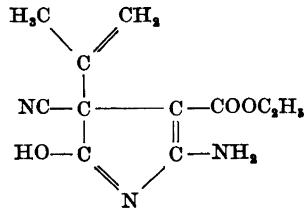
The structure II may seem strange, but ring closure with formation of iminoimides has been described earlier by, *e. g.*, Thorpe and collaborators [6-9]. Furthermore, 3,5-bridged diketopiperidines, which possess structures related to II, are stable and easily prepared as shown by Guareshi and Grande [10], Ghiglieno [11], and Wideqvist [12].



I



II



(III)

EXPERIMENTAL

Preparation of I. Sodium hydroxide (21.6 ml of 2.34 N solution) was added dropwise with stirring to a solution of ethyl *iso*propylidenecyanoacetate (7.7 g) and bromocyanoacetamide (8.2 g) in ethanol (45 ml). The precipitate formed was filtered after 5 h, washed with 50 % ethanol and air-dried. Yield of colourless product containing <50 % of I: 2.7 g. For removal of II the crude product was mixed with 5 ml of ethanol, the suspension was poured into 50 ml of 5 N hydrochloric acid, and the mixture was stirred for some minutes, filtered and washed with water and a small amount of cold ethanol. M. p. 168° (decomp.). (Found: C 56.1; H 5.6; N 17.9; O 20.3. Calc. for $C_{11}H_{13}N_3O_3$: C 56.2; H 5.6; N 17.9; O 20.4.)

The isomerization caused by bases of the neutral I to form II is so rapid that the product can be titrated as an acid in dimethylformamide solution using sodium methoxide in benzene-methanol solution as the titrant and azoviolet as the indicator. Acids retard the isomerization. Hence the compound I is stable in glacial acetic acid-chlorobenzene solution and does not consume any perchloric acid on titration using methyl violet as indicator.

Rearrangement of I to form II 1) in ethanol solution 2) in ethanol solution catalysed by alkali. 1) When a saturated ethanol solution of I was left at room temperature for a few days, colourless crystals of an isomeric, amphoteric product separated (II). In a more dilute solution the isomerization, which is almost quantitative, could be observed by UV measurements, log ε at 245 mμ increasing from 1.95 (measured in 0.05 N hydrochloric acid ethanol) to 4.06 (for a solution of recrystallized II log ε at 245 mμ was found to be 4.07). Addition of one drop of 2.5 N sodium hydroxide solution to this dilute solution of I made the isomerization complete in a few seconds. Boiling of an ethanol solution of I for ten minutes also effected isomerization. M. p. 190° (decomp.). (Found: C 56.2; H 5.8; N 17.8; O 20.4; equiv. wt on titration with perchloric acid in glacial acetic acid (solvent: chlorobenzene; indicator: methyl violet) 237; equiv. wt on titration with sodium methoxide in benzene-methanol solution (solvent: dimethylformamide; indicator: azoviolet) 236. Calc. for $C_{11}H_{13}N_3O_3$: C 56.2; H 5.6; N 17.9; O 20.4; equiv. wt 235.) II is soluble in dilute hydrochloric acid. A test on end unsaturation according to Bricker and Roberts [13] was negative.

2) A 0.83 N sodium ethoxide solution (5.38 ml) was added with stirring to the crude product from the preparation of I (1.05 g). When all crystals had dissolved (about 4 min), the solution was poured into 25 ml of 0.076 N hydrochloric acid. The colourless precipi-

tate formed was filtered and washed with water. Yield: 0.80 g. M. p. 190° (decomp.). (Found: C 56.2; H 5.6; N 17.8; O 20.5. Calc. for $C_{11}H_{13}N_3O_3$: C 56.2; H 5.6; N 17.9; O 20.4.) UV and IR curves of this product were identical with the curves of the product obtained in the preceding isomerizations.

The analyses were performed by Mikroanalytisches Laboratorium im Max-Planck-Institut für Kohlenforschung, Mülheim, Germany.

The Reactions of 3-Chloro- and 3-Bromo-2,4-pentanedione with Malonitrile and with Ethyl Cyanoacetate

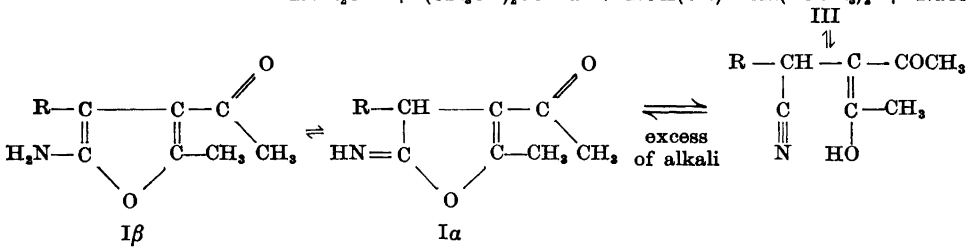
GUNNEL WESTÖÖ

Institute of Organic Chemistry, University of Lund, Lund, Sweden

2-Amino-3-cyano-4-acetyl-5-methylfuran (I a), 2-amino-3-ethoxycarbonyl-4-acetyl-5-methylfuran (I b) and 2-amino-3-ethoxycarbonyl-4,4,5-triacetyl-6-methylpyran (II) have been prepared.

When the sodium salt of 3-chloro-2,4-pentanedione reacts with malonitrile or ethyl cyanoacetate in ethanol-water solution, cyclization of the primarily formed III a, b occurs with formation of the neutral compounds, 2-amino-3-cyano-4-acetyl-5-methylfuran (I a) or 2-amino-3-ethoxycarbonyl-4-acetyl-5-methylfuran (I b).

$$RCH_2CN + (CH_3CO)_2CClNa \rightarrow RCH(CN)-CH(COCH_3)_2 + NaCl$$

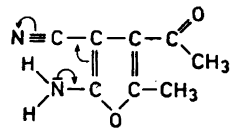


Iβ Iα

a. R=CN

b. R=$COOC_2H_5$

I a and b are stable (*cf.* unsubstituted 2-aminofuran which is very unstable), probably on account of the resonance possibilities offered by the 3-cyano- or the 3-ethoxycarbonyl groups, *e.g.*

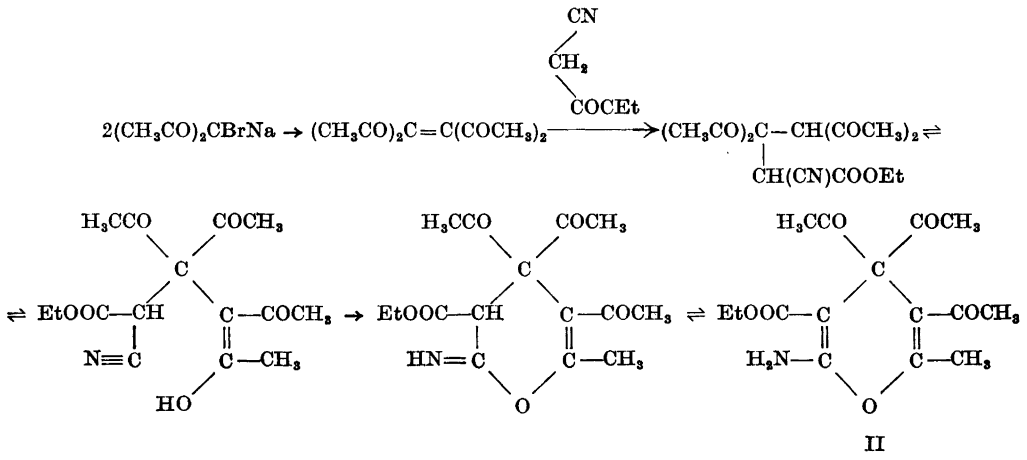


The IR absorption curve of I a (in KBr and in nujol) has one single nitrile band at 2 175 cm^{-1}. This means a displacement of about 75 cm^{-1} from the unconjugated nitrile band at 2 250 $\pm$ 10 cm^{-1}, indicating a strong resonance effect on the nitrile group [1]. A nujol suspension of the product shows absorption at 3 100 and 3 250 cm^{-1}, which is within the region characteristic of associated amino groups. After equilibration with D_2O, ND_2-bands at 2 330 and 2 500 cm^{-1} were obtained. Thus I a β is probably the main structure of the product formed. With *o*-nitrobenzaldehyde a Schiff's base can be prepared from I a, and with 2,4-dinitrophenylhydrazine a 2,4-dinitrophenylhydrazone.

The IR spectrum of I b in potassium bromide has no nitrile band and shows the expected NH_2-bands at 3 200 and 3 390 cm^{-1}.

The basic character of the amino group of I a, b is so weak that the products cannot be titrated with perchloric acid in glacial acetic acid. Excess of alkali dissolves I a and b with opening of their furan rings. On acidification ring closure with reformation of I a and I b takes place, but only in low yields because of alkaline hydrolysis of the nitrile and carbethoxy groups.

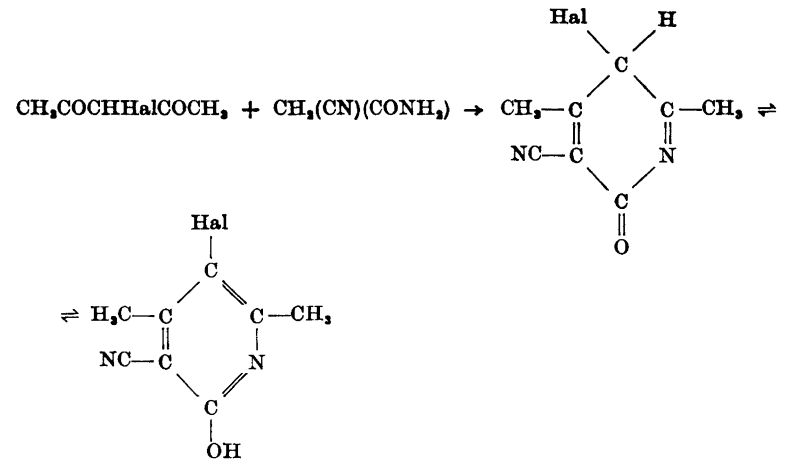
The reaction of the sodium salt of 3-bromo-2,4-pentanedione with malonitrile is analogous to the reaction described above of the corresponding chloro compound, I a being formed though in lower yield. The reactions of ethyl cyanoacetate with 3-bromo-2,4-pentanedione and with 3-chloro-2,4-pentanedione, however, are essentially different. With the bromo compound a pyran derivative, II, is formed evidently according to the equations:



II

The IR absorption curve of the product (in KBr) has no nitrile band but NH_2 stretching bands at 3 225 and 3 325 cm^{-1}. The amino group is basic enough to be titrated with perchloric acid in glacial acetic acid, though not very sharply.

It should be mentioned that the reaction of 3-chloro (or bromo)-2,4-pentanedione with cyanoacetamide in alkaline solution [2] follows other pathways than the reactions described above, pyridine derivatives being formed according to the equations



EXPERIMENTAL

Preparation of 2-amino-3-cyano-4-acetyl-5-methylfuran (I a). 3-Chloro-2,4-pentanedione (2.69 g) and malonitrile (1.32 g) were dissolved in ethanol (10 ml), and sodium hydroxide (8.26 ml of 2.42 N solution) was added. Colourless crystals of I a started separating immediately. The next day they were collected by filtration and washed with 50 % ethanol. Yield: 3.05 g, m. p. about 240° (decomp.). The product can be recrystallized from ethanol. (Found: C 58.5; H 4.85; N 17.1; O 19.5. Calc. for $C_8H_8N_2O_2$: C 58.5; H 4.9; N 17.1; O 19.5.)

2,4-Dinitrophenylhydrazone: M.p. 166—168° (decomp.) (Found: C 48.9; H 3.7; N 24.3; O 23.4. Calc. for $C_{14}H_{12}N_6O_5$: C 48.8; H 3.5; N 24.4; O 23.2.) Schiff's base with *o*-nitrobenzaldehyde (Found: C 60.6; H 4.0; N 14.0. Calc. for $C_{15}H_{11}N_3O_4$: C 60.6; H 3.7; N 14.1).

Preparation of 2-amino-3-ethoxycarbonyl-4-acetyl-5-methylfuran (I b). 3-Chloro-2,4-pentanedione (2.69 g) and ethyl cyanoacetate (2.26 g) were dissolved in ethanol (7 ml). When sodium hydroxide (8.26 ml of 2.42 N solution) was added, colourless crystals of I b soon started separating. The following day the product was filtered and washed with 50 % ethanol. Yield: 3.30 g; m. p. after recrystallization from ethanol: 136°. (Found: C 57.0; H 6.2; N 6.7; O 30.1. Calc. for $C_{10}H_{13}NO_4$: C 56.9; H 6.2; N 6.6; O 30.3.)

Preparation of 2-amino-3-ethoxycarbonyl-4,4,5-triacetyl-6-methylpyran (II). Bromine (3.2 g) was added with stirring to a cooled (12°) solution of 2,4-pentanedione (2.0 g) in 8.26 ml of 2.42 N sodium hydroxide solution and 15 ml of ethanol. After cooling the solution to 8°, sodium hydroxide (4.1 ml of 2.42 N solution) was added and — one minute later — ethyl cyanoacetate (1.38 g) and another 5.0 ml of sodium hydroxide solution. After 5 h the precipitate formed was filtered and washed with 50 % ethanol. Yield: 0.56 g; m. p. 166° (decomp.). (Found: C 58.2; H 6.2; N 4.7; O 30.9; mol. wt 320. Calc. for $C_{15}H_{19}NO_6$: C 58.2; H 6.2; N 4.5; O 31.0; mol. wt 309.)

The analyses were performed by Mikroanalytisches Laboratorium im Max-Planck-Institut für Kohlenforschung, Mülheim, Germany. Dr. Andreas Rosenberg, University of Uppsala, carried out the IR measurements.

Oxidation of Metals

The General Oxidation Equation

TOR HURLEN

Central Institute for Industrial Research, Blindern-Oslo, Norway

A detailed expression of a general rate equation for metal oxidation processes governed by the transport of material in the oxide film, is derived on the basis of Eyring's theory of absolute reaction rates and on the assumption that the transport is accomplished by defect species, *i. e.* interstitial ions and ion vacancies.

Following previous treatments by Evans and Hoar, the conditions at which this equation may be reduced to the more classical parabolic (Wagner) and inverse logarithmic (Mott-Cabrera) equations are discussed. It is further shown that the general equation under certain conditions may be satisfactorily replaced also by a cubic equation.

All the deductions have been applied to the special case of titanium being oxidized to rutile.

1.0 INTRODUCTION

On the basis of the theory of absolute reaction rates (Eyring [1]), it is possible to derive a general oxidation equation for cases of control by rate of transport of material in the oxide film. In two limiting cases, the general equation may be replaced by simpler forms known as the parabolic and inverse logarithmic equations. Under certain conditions, it may satisfactorily be replaced also by a cubic type of equation.

The general equation and its importance to metal oxidation studies seem first to have been pointed out by Evans [2], who derived a simplified, formal expression for this equation and also showed how it could be reduced to the more conventional oxidation equations. On this basis, Hoar [3] later calculated the limiting conditions of temperature and oxide film thickness under which the general equation for some metals (Fe, Zn, Cu) may be satisfactorily represented either by the inverse logarithmic equation or by the parabolic equation.

Gulbransen [4] seems to have been the first to apply the theory of absolute reaction rates to metal oxidation. He thereby derived an absolute expression for the parabolic rate constant.

To our knowledge, nobody has so far applied the absolute rate theory in deriving the general oxidation equation.

2.0 DERIVATION OF THE GENERAL EQUATION

From the absolute rate theory, the following expression for the net rate of transport (v) of a species in an ideal solution under the action of chemical and electrical potential fields, may easily be derived (see Ref.[1], pp. 552—555):

$$v = \frac{kT}{h}\lambda C \exp\left(-\frac{\Delta G_o^{\ddagger}}{RT}\right)\left[\exp\left(-\frac{\alpha\lambda zF}{RT}\frac{d\emptyset}{dx}\right) - \left(1+\lambda\frac{d\ln C}{dx}\right)\exp\left(\frac{(1-\alpha)\lambda zF}{RT}\frac{d\emptyset}{dx}\right)\right] \quad (1)$$

R is the gas constant, k the Boltzmann constant, h the Planck constant, T the Kelvin temperature, F the Faraday, $\Delta G_o^{\ddagger}$ the standard chemical energy of activation, C the concentration of the species, $\emptyset$ the inner potential, x a distance in direction of the transport, z the charge carried by a single migrating entity, λ the distance between equilibrium positions for these entities, and α the so called symmetry factor.

According to the theories of Frenkel [5] and Schottky [6], ionic crystals usually contain reversible defects (ions in interstitial positions and ion vacancies in connection with an equivalent number of quasi-free electrons and electron holes). It seems further well recognized that the transport of material in ionic crystals may be described as a transport of such defects (see *e.g.* Ref.[7]). As a normal crystal with good approximation also may be considered an ideal solution of reversible defects in a perfect crystal, the rate of transport of any one type of such defects in the crystal should be represented by eqn. (1) above.

The thickening of an oxide film on a metal certainly requires transport of material across the film. The defects, which may take part in this transport, generally are:

$O_v^{\cdot\cdot}$ (oxide ion vacancies)
$O_i^{''}$ (oxide ion interstitials)
$M_v^{z\prime}$ (metal ion vacancies)
M_i^{z+} (metal ion interstitials)

where the symbols $\cdot$ and $\prime$ represent a positive and a negative surplus charge, respectively.

During oxidation, oxide ion vacancies and metal ion interstitials will move *outwards* and oxide ion interstitials and metal ion vacancies *inwards* through the film. If we now choose the outward direction (from the metal to the gas) as our single reference direction or x-direction (instead of having to consider two transport directions), the total net rate of transport of defects through a plane at a distance x from the metal/oxide interface is given by:

$$v_x(\text{total}) = \sum_i \pm v_{i,x} \quad (2)$$

$v_{i,x}$ means here the rate of transport of the defect species i in the x direction and is given by (1) when $(d\emptyset/dx)$ and (dC/dx) are considered gradients also in this direction (not in the actual transport directions). The signs + and

— apply to positively and negatively charged species, respectively. In this way, all the rate terms in (2) become positive.

When + and — are put together as in the above equation, it will in this paper always mean that the upper sign applies to positive species and the lower to negative ones.

As both the concentration and the concentration gradient of a defect species as well as the electric potential gradient at any given time may vary from point to point within the film, it is obvious that v_x(total) also may vary. It is a question, therefore, how the momentary rate of oxidation is connected to the various momentary rates of transport in the oxide film.

What is actually measured however by gravimetric and volumetric methods of investigation of oxidation of metals, is the rate of entrance of oxygen from the gas phase into the oxide phase. The other rate processes in the system (such as the transfer of metal ions from the metal phase into the oxide phase and the migration of ions in the oxide phase) are not directly susceptible to measurements of this kind, and information on these processes must be obtained either by theoretical deductions from the oxidation measurements or by other types of measurements.

The measured oxidation rate can be assumed to be equal to the rate of entrance of oxygen into the oxide, provided the concentration of chemisorbed oxygen on the oxide surface does not change during oxidation. On this basis, the oxidation rate, v(ox), may be represented by the following formula:

$$v(\mathrm{ox}) = \lim_{x \to y} v_x(\mathrm{total}) \tag{3}$$

where y is the oxide film thickness, and where the various rates must be expressed in equivalent units (number of equivalents per unit area per unite time).

Eqn. (3) combined with (1) and (2) may thus be regarded as a general oxidation equation for cases of control by rate of transport of material in the oxide film. In practice, one also has to add the requirement that the area undergoing oxidation must be constant with time as experimental oxidation rates usually are determined on the basis of the apparent surface area of the specimens at the start of the experiment.

The general equation will be somewhat easier to handle if we introduce the following approximations:

$$v(\mathrm{ox}) = \frac{1}{V}\,(\mathrm{d}y/\mathrm{d}t) \tag{4a}$$

$$\mathrm{d}\emptyset/\mathrm{d}x = \Delta\emptyset/y \tag{4b}$$

$$\mathrm{d}C/\mathrm{d}x = \Delta C/y \tag{4c}$$

$$F\Delta\emptyset = \Delta G \tag{4d}$$

$$\alpha = \tfrac{1}{2} \tag{4e}$$

and the following substitute:

$$V\lambda(kT/h)\,\exp(-\Delta G_o^{\ddagger}/RT) = K \tag{5}$$

V is the equivalent volume of the oxide, $\Delta\emptyset$ the total potential increase in the film from metal to gas, ΔC the total concentration increase (for species

i) in the film from metal to gas, and ΔG the energy of formation of one gram-equivalent oxide at the actual oxidation conditions.

On this basis (eqns (1) to (5) above), the general oxidation equation may be written:

$$\frac{dy}{dt} = \sum_i \pm K_i C_{i,y} \left[\exp\left(-\frac{\lambda_i z_i \Delta G}{2 RT y}\right) - \left(1 + \frac{\lambda_i \Delta C_i}{y C_{i,y}}\right) \exp\left(\frac{\lambda_i z_i \Delta G}{2 RT y}\right)\right] \quad (6)$$

where $C_{i,y}$ means the limiting value of C_i for $x = y$ (*i.e.* when approaching the oxide/gas interface).

3.0 DEDUCTIONS FROM THE GENERAL EQUATION

The general oxidation equation (6) is rather clumsy. Under special conditions, however, it may be replaced by equations of simpler forms. This greatly increases its applicability and facilitates the testing of its validity.

Following previous treatments by Evans [2] and Hoar [3], we shall in the following discuss how the more classical parabolic (Wagner [8]) and inverse logarithmic (Mott-Cabrera [9]) equations may be regarded as limiting cases of the general oxidation equation. It shall also be shown how the general equation under certain conditions may be approximately, though satisfactorily, replaced even by a cubic type of equation.

The parabolic equation. At sufficiently high temperatures and large film thicknesses, the general equation (6) may be reduced to the simpler form:

$$\frac{dy}{dt} = \frac{1}{y} \sum_i \mp K_i \lambda_i C_{i,y} \left(\frac{z_i \Delta G}{RT} + \frac{\Delta C_i}{C_{i,y}} \right) \quad (7)$$

which is the parabolic oxidation equation ($y^2 = k_p t$) in its differential form.

This simplification is easily performed by extending the exponential functions in (6) and omitting the higher powers of the exponents. This is very nearly the same as omitting p^2 in the expression $6 + p^2$, where p in our case is given by:

$$p = \mp \lambda z \Delta G / 2RTy \quad (8)$$

The parabolic equation should thus be expected to represent the oxidation rate within about 10 % accuracy when $p^2 < 6/10$, which means:

$$y > \mp 0.65 \lambda z \Delta G / RT \quad (9)$$

A similar requirement has previously been pointed out by Hoar [3].

The inverse logarithmic equation. At sufficiently low temperatures and small film thicknesses, one of the exponential terms in (6) vanishes as compared to the other one, and it is easily seen that the general equation under these conditions may be reduced to:

$$\frac{dy}{dt} = \sum_i K_i C_{i,y} \exp\left(\mp \frac{\lambda_i z_i \Delta G}{2RTy}\right) \quad (10)$$

Through integration and some simplification we obtain:

$$\frac{1}{y} = \sum_i \pm 2.303 \frac{2RT}{\lambda_i z_i \Delta G} \left[\log\left(\frac{K_i C_{i,y}}{y}\right) + \log\ t\right] \tag{11}$$

assuming $y = 0$ when $t = 0$.

For small values of y, log $1/y$ may be considered a constant as compared to $1/y$, whereby (11) represents a so called inverse logarithmic oxidation equation ($1/y = \mathrm{A} - \mathrm{B} \log t$). It also gives an interpretation of the constants (A and B) in this equation.

In integrating (10) to obtain (11), one has to make the requirement that exp $(\pm\ \lambda z \Delta G/2RTy) \ll 1$, and in reducing (6) to obtain (10), the necessary requirement is that exp $(\pm\ \lambda z \Delta G/2RTy) \ll$ exp $(\mp\ \lambda z \Delta G/2RTy)$. Of these requirements, the former seems to be strongest. As this is the most difficult one to evaluate, however, we shall here assume that the other requirement is sufficient.

The inverse logarithmic equation should thus represent the general equation within about 10 % accuracy when

$$y < \mp\ \lambda z \Delta G/2.32\ RT \tag{12}$$

Also this requirement has previously been pointed out by Hoar [3].

The cubic equation. Under conditions at which exp(p) — exp$(-p)$ with sufficient accuracy might be replaced by ap^2, where a is a constant and p as given by eqn. (8), the general equation reduces to:

$$\frac{\mathrm{d}y}{\mathrm{d}t} = \frac{a}{y^2} \sum_i K_i C_{i,y} \left(\frac{\lambda_i z_i \Delta G}{2RT}\right)^2 \tag{13}$$

when $\Delta C/C_y$ is negligible compared to 1.

This is the cubic oxidation equation ($y^3 = k_c t +$ const.) in its differential form, and it gives an interpretation of the cubic rate constant (k_c).

In Fig. 1, a graphical test is made on the validity of the approximation on which the reduction of the general equation to the cubic type of equation is based. As may be seen from this test, the approximation may be considered valid with reasonable accuracy through at least a part of the film-thickness region between those covered by the inverse logarithmic equation and the parabolic equation, respectively.

In accordance with the requirements suggested there (Fig. 1), the following film-thickness limits may be given for the validity of the cubic approximation:

$$\mp\ \lambda z \Delta G/1.72\ RT > y > \mp\ \lambda z \Delta G/2.32\ RT \tag{14}$$

To our knowledge, this is the first explanation of the cubic oxidation equation not implying any assumptions as to the semiconductor properties of the oxide. The cubic equation derived by Cabrera and Mott [9] and the one derived by Engell, Hauffe, and Ilschner [10] are only valid for p-type conducting oxides. Rutile, for instance, which we are going to discuss below, is an n-conductor [11–13].

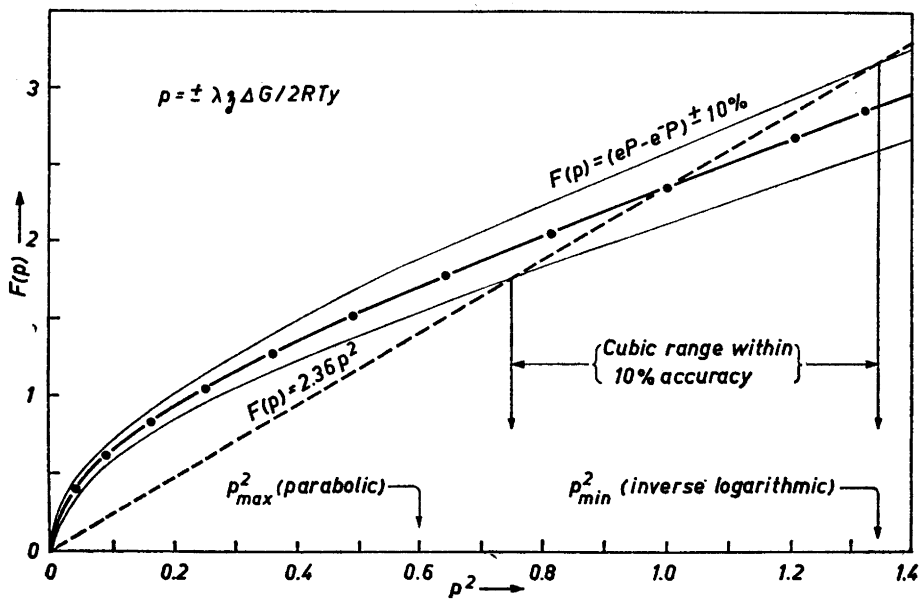

Fig. 1. Test on the validity of the "cubic" approximation (see eqn. 13).

By comparing the expressions for the parabolic (7) and the cubic (13) equations it is seen that one should expect to find the same Arrhenius energy of activation for the cubic as for the parabolic oxidation of a metal, provided the variation with temperature of the pre-exponential factors might be neglected. This could possibly be used as a basis for testing if an observed cubic and parabolic oxidation of a metal should have a common root in the general equation, or if the cubic oxidation should have another origin.

4.0 APPLICATION OF THE DEDUCTIONS

As an example, we shall here apply the above deductions to the special case of titanium being oxidized to rutile.

To simplify the discussion, we shall at first assume that it is mainly a titanium transport in rutile ($z = \pm 4$), that $\lambda = 3$ Å (which is close to the shortest Ti—Ti distance in rutile [15,16]), and that the oxidation takes place at an oxygen pressure of one atmosphere. On this basis, and using the ΔG-values given by Mah, Kelley, Gellert, King, and O'Brien [22] for rutile (see Table 1), one may from (9), (12), and (14) calculate the limiting film-thickness values for the validity of the parabolic (7), the cubic (13), and the inverse logarithmic (11) equations.

Table 1. Energy of formation of one gram-equivalent rutile at an oxygen pressure of one atmosphere (Ref.[22])

T (°K)	600	700	800	900	1 000
$-\Delta G$ (Kcal)	49.75	48.75	47.75	46.75	45.50

The results of some calculations of this kind are graphically presented in Fig. 2, where the various validity regions and their temperature dependence are clearly shown. The weight increase (w) connected to the film thickening (y), is also indicated. The following formula have been used in relating w to y:

$$w = \frac{32}{47.9 + 32} 4.2\ y$$

The shortest distance between interstitial positions for titanium ions in rutile has been shown [16] to be the half only of the shortest Ti—Ti distance in an ideal rutile lattice. If this should be determining for the elementary diffusion step, one should have to lower the film-thickness values in Fig. 2 by a factor of two in case the interstitial transport mechanism predominates over the vacancy mechanism. This is easily seen from (9), (12), and (14).

If it should be mainly an oxygen transport in rutile ($z = \pm 2$), and if a λ-value of 3 Å should apply also to this transport, the limiting film-thickness values should also in this case be the half only of those calculated on the assumption of a titanium vacancy transport (Fig. 2).

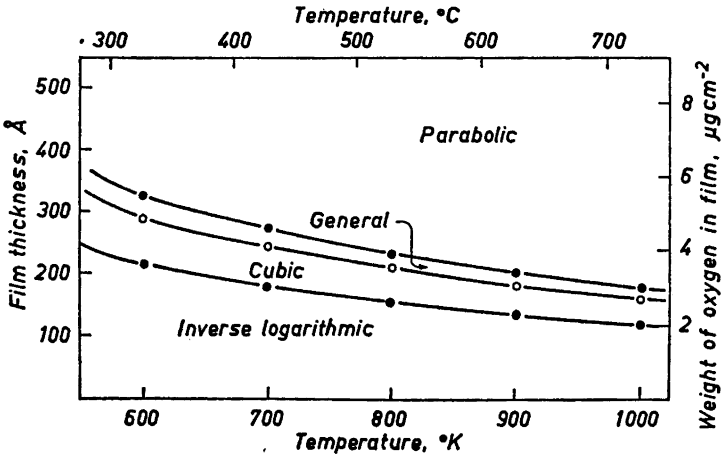

Fig. 2. Calculated regions for the validity of the varius rate equations in the case of titanium being oxidized to rutile (see text for underlying assumptions).

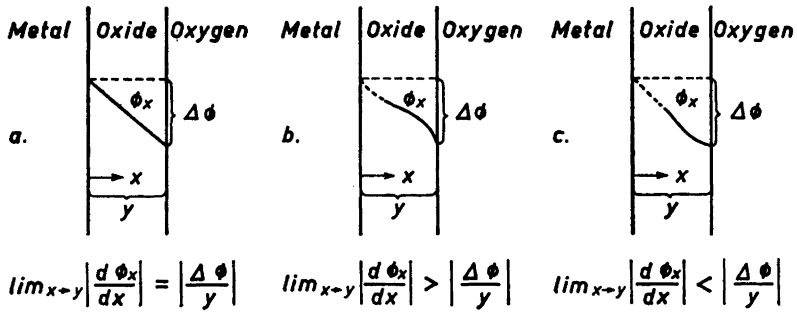

Fig. 3. Hypothetical variations of electric potential within oxide films.

If the oxidation should be governed by grain boundary diffusion instead of volume diffusion, the calculations should mainly be affected by a possible difference in the λ-values for these two types of diffusion. It seems likely, however, that this difference should be rather small, whereby a possible grain boundary diffusion should not be expected to alter the above picture very much. Another point is that a grain boundary diffusion — because of a lower energy of activation — may increase the oxidation rate and thereby decrease *the duration* of the inverse logarithmic and cubic types of oxidation at a given temperature. It is here important clearly to distinguish between time periods and film-thickness regions.

The correctness of calculations of this kind depends on the validity of the approximations (4). Of these, assumption (4b), which implies

$$\lim_{x \to y} (\mathrm{d}\Phi/\mathrm{d}x) = \Delta\Phi/y$$

probably is the most questionable one. The physical significance of this assumption is somewhat illustrated by the sketches in Fig. 3. From the general knowledge of space charge phenomena in phase boundary layers [7,17], the situation sketched in Fig. 3b seems the most probable one. This means that the limiting film-thickness values calculated from (9), (12), and (14) would be too low. It seems very difficult at present to estimate the actual electric potential gradient at the oxide/oxygen interface, to which gradient the limiting film-thicknesses should be proportional.

5.0 SUMMARY AND CONCLUSION

It has been shown how a general oxidation equation under certain conditions may be derived from the theory of absolute reaction rates, chapter 2.0, and how this equation may be represented by an inverse logarithmic, a cubic, and a parabolic type of equation at low, medium, and high values, respectively, of the oxide film thickness (chapter 3.0). These derivations do not involve any assumptions as to the semi-conductor properties of the oxide, and should apply just as well to metals forming *p*-type oxides as to those forming *n*-type oxides.

The general equation — and all the deductions made from this equation — are only valid for cases in which the oxidation is controlled by the rate of transport of material (not electrons) in the oxide film, and in which the area undergoing oxidation is constant with time. When these conditions are sufficiently satisfied, one should thus expect to observe oxidation/time curves running smoothly from an initial period of inverse logarithmic oxidation, through a medium period of cubic oxidation and general oxidation, into a final period of parabolic oxidation.

The "transitions" between the oxidation equations ought not occur at too low values of the film thickness if these values are to be measured with reasonable accuracy. From (9), (12), and (14) it is seen that metals with a high free energy of oxidation are to be expected the most suitable in this respect. Most of these unnoble metals, however, either do not fulfill the condtions on which the theory is based, or they have unsuitably high oxidation rates. All considerations of this kind taken into account, it seems that titanium might be one of the most suitable metals for testing the above theory.

Some approximate calculations have been made, therefore, of the film-thickness regions in which one should expect the inverse logarithmic, the cubic, and the parabolic equations to be satisfactory substitutes for the genral equation in the case of titanium being oxidized to rutile (chapter 4.0).

From previous work on the oxidation of titanium [17,18] is known, however, that titanium at low oxide film-thickness and low temperatures usually is not oxidized according to an inverse logarithmic equation, but rather according to a direct logarithmic one, and that this logarithmic film growth probably is best explained by the theory of Evans [19] based on the assumption of the formation of cavities at the metal/oxide interface. This assumption implies that the effective area undergoing oxidation is not constant, whereby one of the conditions for the validity of the general equation is not satisfied.

As generally discussed by Birchenall [20] and quite recently shown by Engell and Wever [21] in the case of iron, there seems to be an inherent tendency of the oxide film to try to follow the retreating metal interface by a plastic flow mechanism, thereby counteracting the cavity formation. It seems quite reasonable to assume that this effect also is present in the case of titanium, and probably also that it increases in importance both with increasing film thickness and with increasing temperature, whereby the basic conditions for the validity of the general oxidation equation subsequently may be reached.

A further discussion of this matter will be given in a separate paper on the oxidation mechanism of titanium.

Acknowledgement. This work forms part of a research project sponsored by the *Air Research and Development Command*, US Air Force, through its European Office under Contract AF 61(514)-892.

The author is moreover much indebted to Cand. real. J. Markali, Siv.ing. H. Kjøllesdal, Siv.ing. J. Lothe and other members of the staff at the Central Institute for Industrial Research, Blindern, Oslo, Norway, for helpful discussions.

Studies of Mono-C-Methylquinalizarins in Relation to a Phenolic Metabolite of *Penicillium islandicum*

STEN GATENBECK

Institute of Biochemistry, University of Lund, Lund, Sweden

A polyhydroxyanthraquinone obtained from a metabolite of *Penicillium islandicum* is shown to be a methylquinalizarin. Three isomeric methylquinalizarins have been synthesized. The isolated polyhydroxyanthraquinone has been shown to be identical with one of them, 1,4,7,8-tetrahydroxy-2-methylanthraquinone.

In an earlier paper [1] a new phenolic metabolite, called compound A, was isolated from the culture medium of *Penicillium islandicum*. As this compound is easily transformed to a polyhydroxyanthraquinone by treatment with concentrated sulfuric acid, the structure of compound A may have an interest in the view of the biogenesis of polyhydroxyanthraquinones.

Since compound A is available only in very small amounts, it has not been possible to make any derivatives or degradation experiments on it, other than the transformation to the hydroxyanthraquinone. A structural analysis of the polyhydroxyanthraquinone is apt to give some information about the unknown structure of compound A. The investigation of the structure of the anthraquinone obtained from compound A will be the subject of this paper.

The elementary analysis of the unknown anthraquinone indicates a tetrahydroxymethylanthraquinone (Found: C 61.8; H 3.9. $C_{15}H_{10}O_6$ requires: C 62.9; H 3.5).

The anthraquinone shows a weak fluorescence when dissolved in acetic acid. According to Raistrick *et al.*[2] this is a characteristic property of polyhydroxyanthraquinones with two hydroxyl groups in the *para* position to each other. The occurrence of hydroxyl groups in the *para* position is further established by the strong absorption in the region 490—520 mμ which the anthraquinone shows in ethanolic solution.

When zirconium nitrate in diluted hydrochloric acid is added to an acetone solution of the anthraquinone, a blue colouration is obtained which is the usual behaviour of a polyhydroxyanthraquinone with two hydroxyl groups in the *ortho* position [3].

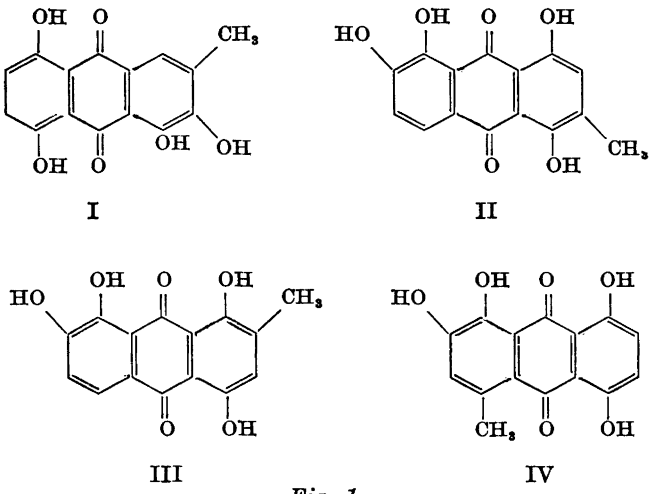

Fig. 1.

It is well known that a polyhydroxyanthraquinone with one hydroxyl group in β-position is soluble in 1 N Na_2CO_3 and there are several examples that polyhydroxyanthraquinones with more than one β-hydroxyl group is soluble in 0.5 N $NaHCO_3$. As reported in an earlier paper [1] the unknown anthraquinone is soluble in 1 N Na_2CO_3 but insoluble in 0.5 N $NaHCO_3$ which would then suggest one β-hydroxyl group in the molecule.

If the conclusions from the reactions above are true the unknown anthraquinone has to contain two hydroxyl groups in the *para* position and two hydroxyl groups in the *ortho* position. Of the latter one occupies an α-position and the other a β-position. These positions of the hydroxyl groups leave two possible alternatives. The pairs of *ortho* and *para* hydroxyl groups are either located in different rings (quinalizarin type) or the arrangement may be that of one hydroxyl group in one ring and three in the other (purpurin type). That the former alternative is the most probable is shown by two further properties of the unknown anthraquinone.

Polyhydroxyanthraquinones with hydroxyl groups in *para* position are oxidized by lead tetraacetate in glacial acetic acid to coloured diquinoid compounds. All polyhydroxyanthraquinones with *para* hydroxyl groups tested form a rather stable colouration with this reagent except for purpurin whose colour disappears rapidly since it is very easily oxidized. The unknown anthraquinone gives a stable colouration indistinguishable in appearence from that of quinalizarin. The relation of the unknown anthraquinone to quinalizarin rather than to purpurin is further indicated by the similarity of the absorption spectra of the former two compounds (Fig. 4).

As a working hypothesis the unknown anthraquinone is supposed to be a C-methylquinalizarin. Its structure is further proven by synthesis as described below.

There are theoretically four different isomers of methylquinalizarin (Fig. 1).

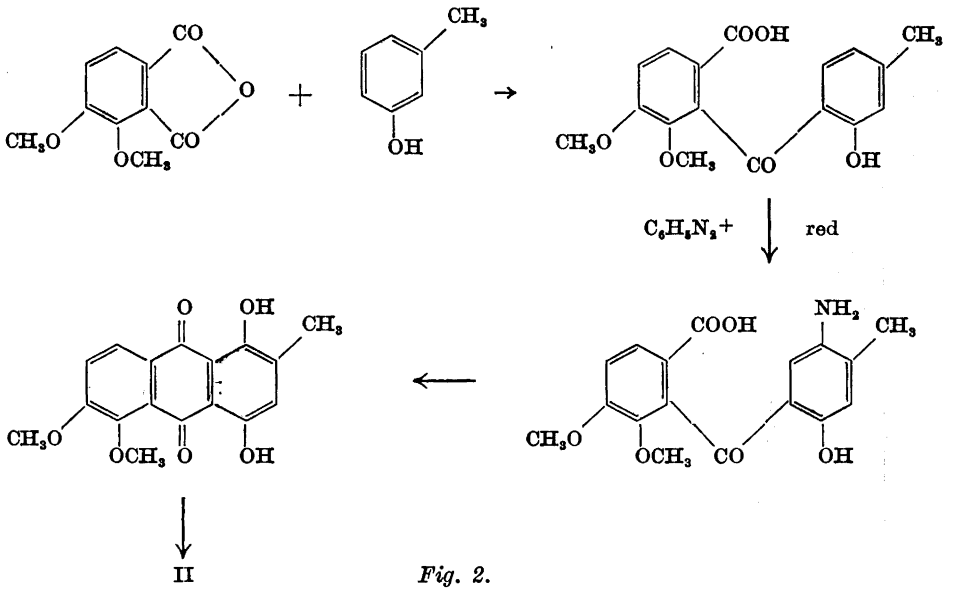

Fig. 2.

Of these four possibilities, structure IV is considered as less probable since a hydroxyanthraquinone with a C-substituent in an α-position has never been found among the mold pigments. The other three methylquinalizarins have been synthesized and their properties compared with those of the unknown anthraquinone.

I was synthesized by condensing 3,6-dihydroxyphthalic anhydride and 3-methylpyrocatechol with $AlCl_3$. I has m. p. 280—282°C and forms wool-like crystals from toluene.

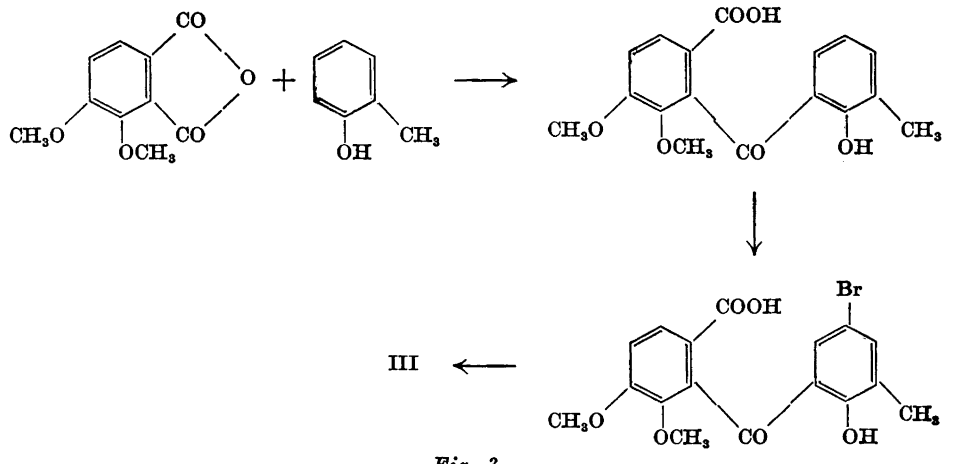

Fig. 3.

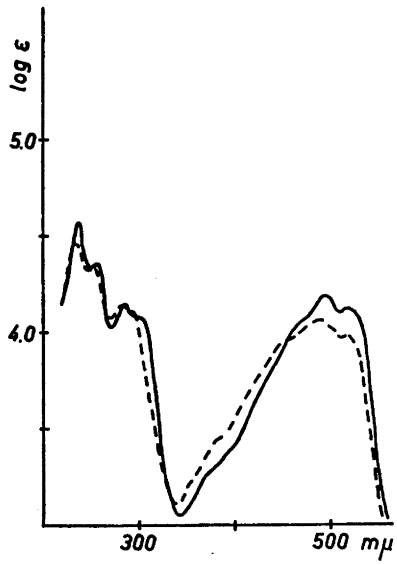

Fig. 4. Molecular extinction curves of quinalizarin — — — — — and II, III, the unknown anthraquinone ————.

II was prepared according to the reaction series in Fig. 2. It has m. p. 230°C and crystallizes in small plates from toluene.

III has been synthesized as indicated in Fig. 3 in very poor yield. It was easily obtained by a direct condensation of hemipinic anhydride and toluhydroquinone with $AlCl_3$, followed by demethylation with hydrobromic acid. III has m. p. 255°C and gives red needles when crystallized from toluene.

The unknown anthraquinone melts at 255°C and forms red needles when crystallized from toluene. The melting point of the unknown anthraquinone was not depressed on admixture with III.

II, III and the unknown anthraquinone have the same R_F value (0.75) on paper chromatogram developed in benzene-formic acid (2 %) (10:1). They have identical color reactions with methanolic magnesium acetate (blue), ethanolic ferric chloride (blue violet) and zirconium nitrate in diluted hydrochloric acid (light blue). They have practically identical absorption in UV and visible light (Fig. 4). The colors produced by I in the reactions mentioned had a tinge of red compared with those produced by the other compounds. The absorption curve of I shows small deviations from the others.

The data presented indicate the structure of the unknown anthraquinone to be identical with III.

The difference in structure of the identified anthraquinone and compound A should apparently be one molecule of water. Addition of one molecule of water to the anthraquinone gives theoretically rise to several possibilities of the structure of compound A, *e. g.* benzoylbenzoic acids, hydratized anthraquinones and naphthoquinone derivatives. These possibilities will be further investigated.

EXPERIMENTAL

Preparation of the unknown anthraquinone. Compound A was treated with concentrated H_2SO_4 (*d*, 1.84) for half an hour at room temperature. The violet sulfuric acid solution was poured onto crushed ice. The anthraquinone formed a red precipitate. After extraction with ether and evaporating the ether extract to dryness the anthraquinone was sublimed in vacuum at 150—160°C (bath temperature). The sublimate was recrystallized from acetic acid and toluene until a constant melting point (255°C) was obtained.

Synthesis of I. An intimate mixture of 0.6 g of 3,6-di-hydroxyphthalic anhydride and 0.5 g of 3-methylpyrocatechol was added in portions to 10 g of anhydrous $AlCl_3$ and 3 g of NaCl and fused together at 160°C. The temperature was kept at 160°C for 10 min after the last portion had been added. After cooling, the melt was boiled with diluted HCl for 15 min and the anthraquinone extracted with ether. The residue obtained after evaporation of the ether extract was sublimed in vacuum at 170—180°C (bath temperature). The anthraquinone was recrystallized from acetic acid and toluene (m. p. 280—282°C). (Found C 62.0; H 3.9. Calc. C 62.9; H 3.5.) At the condensation described no isomer anthraquinone was formed which was tested by paper chromatography.

The tetraacetyl derivative was prepared by boiling the anthraquinone for 2 min with acetic anhydride and a few drops of concentrated H_2SO_4. The acidic solution was poured onto crushed ice and the tetraacetylanthraquinone isolated by filtration and recrystallization from acetic acid, m. p. 208°C.

Synthesis of II. 3,4-dimethoxy-2(2-hydroxy-4-methylbenzoyl)-benzoic acid was synthesized as described by Simonsen [4].

Keeping the temperature below +5°C, a diazonium solution, prepared in the usual way from 0.852 g of aniline, was added with stirring to 2 888 g of the benzoylbenzoic acid dissolved in 50 ml of 1 N NaOH. The temperature and stirring were maintained for one hour, after which the solution was acidified with concentrated HCl. The precipitated yellow brown azocompound was filtered off, washed with water and dried at 100°C. It was recrystallized from benzene. Yield 2.4 g, m. p. 239°C.

To 2.4 g of the azocompound dissolved in 100 ml of ethanol, 8 g of solid sodium hydrosulphite was added. After heating the suspension to boiling, 300 ml of water was slowly added. The colour of the red solution faded rapidly and a lemon yellow solution was obtained. The amine precipitated in light yellow crystals on cooling the solution. (Found: N 3.9. Calc. N 4.2.) Yield 1.7 g, m. p. 148—250°C.

In a mixture of 4 ml of concentrated H_2SO_4 and 0.5 ml of water, 0.632 g of the amine was dissolved at 0°C. An equivalent amount of solid $NaNO_2$ was added in portions to the sulfuric acid solution. The reaction mixture was kept cold for half an hour at which time the solution became almost solid. Further 15 ml of concentrated H_2SO_4 were added and the temperature was raised to 150°C during half an hour and kept constant until the nitrogen evolution had ceased. After cooling to room temperature, the solution was poured onto crushed ice. The anthraquinone was filtered off and washed with water. The yield was almost quantitative. The air-dried anthraquinone was demethylated by refluxing for 12 h with a mixture of 20 ml of aqueous HBr (48 %) and 60 ml of acetic acid. The acetic acid was driven off in vacuum and the anthraquinone filtered off and washed with water. After repeated recrystallization from acetic acid and toluene it had m. p. 230°C. (Found: C 63.1; H 3.7. Calc. C 62.9; H 3.5.)

The tetraacetyl derivative was prepared in the same way as described for I, m.p. 210—212°C.

Synthesis of III. III was synthesized in two ways.

3,4-Dimethoxy-2(2-hydroxy-3-methylbenzoyl)-benzoic acid was prepared according to Jacobson and Adams [5].

In 15 ml of acetic acid, 0.709 g of the benzoylbenzoic acid (m.p. 251°C) was dissolved and then 0.115 ml of Br_2 in 5 ml of acetic acid added in small portions at 60°C. The reaction mixture was kept at 60°C for two hours and then at room temperature over night. The acetic acid was distilled off in vacuum and the residue recrystallized twice from methanol-water, m.p. 238°C.

Treatment of the bromocompound with a mixture of boric acid and concentrated H_2SO_4 at 150°C for 3 h resulted in a brown solution. III could be isolated, in very poor yield, by pouring the sulfuric acid solution on ice and extracting the water solution with ether. The ether extract was developed on a thick paper chromatogram (Whatman 3

MM) in benzene-formic acid. The anthraquinone was extracted from the paper with acetone. The acetone solution was evaporated to dryness and the anthraquinone recrystallized from acetic acid, m. p. 255°C. The amount of pure anthraquinone obtained in this way was too small for characterization.

A more convenient method for the preparation of III is to condense 0.5 g of hemipinic anhydride and 0.5 g of toluhydroquinone using the same procedure as described for the preparation of I. The demethylated product was recrystallized several times from acetic acid and toluene. Yield 0.09 g, m. p. 255°C. (Found: C 62.8; H 3.7. Calc. C 62.9; H 3.5.)

The tetraacetyl derivative was synthesized as described above, m. p. 208–210°C.

Thanks are due to Professor G. Ehrensvärd for valuable discussions.

The Occurrence of 7β-Hydroxylated Bile Acids in Human Bile

Bile Acids and Steroids 76

JAN SJÖVALL*

Department of Physiological Chemistry, University of Lund, Lund, Sweden

Ursodeoxycholic acid has been crystallized from human duodenal contents and identified by means of chromatographic properties, melting point, sulphuric acid spectra and infrared spectra. Column and paper chromatographic analyses and sulphuric acid spectra have indicated the presence of 3α,7β,12α-trihydroxycholanic acid in some human bile samples.

During a study of the quantitative relationships between bile acids in human bile, it was found that, besides the glycine and taurine conjugates of cholic, chenodeoxycholic and deoxycholic acids, some bile samples contained other compounds which behaved like bile acids on paper chromatograms [1]. The present paper gives some results regarding the nature of these compounds.

EXPERIMENTAL

The bile acid analyses were done either with gallbladder bile (collected during abdominal operations) or with duodenal contents (collected through a polyvinyl tubing introduced through the nose).

Paper chromatography of bile, duodenal contents and purified bile acids was carried out according to Sjövall [2].

Reversed-phase partition chromatography according to Sjövall [3] and Norman [4] was used for the purification of the bile acids present in the biological material.

The following phase systems were used:

Phase system	Moving phase (ml)	Stationary phase (ml)
F 1	Methanol/water 165/135	Chloroform/heptane 45/5
C 1	Methanol/water 150/150	Chloroform/*iso*octanol 15/15
C 2	Methanol/water 144/156	Chloroform/*iso*octanol 15/15

* Present address: Statens Rättskemiska Laboratorium, Stockholm 60.

When the conjugated bile acids were to be separated, about twenty volumes of ethanol were added to the bile or duodenal contents, respectively, and after filtration, the clear ethanol solution was evaporated to dryness *in vacuo*. The residue was dissolved in 1 N sodium hydroxide and, after acidification, the bile acids were extracted with butanol [5]. When the free bile acids were to be analyzed, the bile or the duodenal contents was hydrolyzed at 120°C for 6 h in 2 N sodium hydroxide. After acidification, the bile acids were extracted with ether.

Sulphuric acid spectra were recorded with a self-recording spectrophotometer (Perkin-Elmer, Spectracord 4 000) after dissolving the bile acid samples in 65 % sulphuric acid (20—40 μg per ml) and heating them for 15 min at 60°C.

RESULTS

A. 3α,7β-Dihydroxycholanic acid (ursodeoxycholic acid). Descending paper chromatography of bile and duodenal contents, with ethylene chloride/heptane 50/50 as moving phase and 70 % acetic acid as stationary phase, reveals the presence of glycocholic (GC), glycochenodeoxycholic (GCD) and glycodeoxycholic (GD) acids in human bile. In several samples, a fourth spot which is weaker than the other ones can be detected between the spots of GC and GCD. In order to purify the compound causing this spot, the conjugated bile acids from about 10 ml of gallbladder bile (patient N.A.) were subjected to reversed-phase partition chromatography with phase system C 1. The effluent from the column was collected by means of a fraction collector and titration of the fractions with 0.02 N sodium hydroxide gave titration peaks at the places of taurine conjugated bile acids, GC and GCD. The fractions containing the latter two acids were combined and paper chromatography revealed only spots of GC and GCD, respectively. The fractions between these two acids from the column chromatogram were combined and evaporated to dryness. After butanol extraction, rechromatography with phase system C 1, on a column 1/5 as large as the first column, showed a titration peak corresponding to about 3 mg of bile acid. Paper chromatography of this material produced one spot at the place of the unknown compound. The residue was then hydrolyzed and after acidification extracted with ether.

Descending paper chromatography of the hydrolyzate with ethylene chloride/heptane 20/80 as moving phase and 70 % acetic acid as stationary phase gave one spot which appeared between the spots of cholic and chenodeoxycholic acids, run simultaneously as reference compounds. The position of the spot suggested that the compound (if a bile acid) might be a dihydroxy bile acid with two equatorial hydroxyl groups which caused the relatively slow rate of movement. Therefore, ursodeoxycholic acid (3α, 7β-dihydroxycholanic acid) and hyodeoxycholic acid (3α, 6α-dihydroxycholanic acid) were used as reference compounds and the unknown substance was found to move like the acid mentioned first. The sulphuric acid spectrum of the compound, eluted from the paper chromatograms [2], was identical with that of ursodeoxycholic acid.

The taurine conjugated bile acids from the bile of patient N.A. were hydrolyzed and subjected to chromatography with phase system F 1. Titration peaks were found at places of cholic (C), ursodeoxycholic (UD) and chenodeoxycholic (CD) acids (Fig. 1). Hyodeoxycholic acid is known to be eluted at approxim-

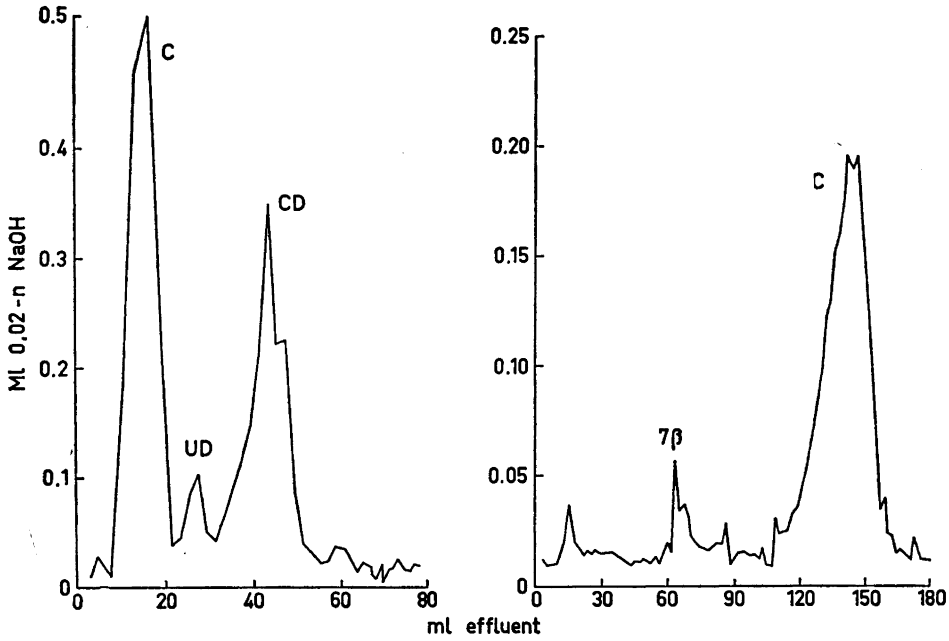

Fig. 1. Chromatography of hydrolyzed taurine conjugated bile acids from patient N.A. The front band from the chromatography with phase system F 1 (C, left curve) was rerun with phase system C 2 (right curve).

ately the same place as ursodeoxycholic acid, but paper chromatography of the peak at this place showed that the substance moved as UD.

The two samples of the compound, moving as ursodeoxycholic acid, isolated from the bile of patient N.A., were combined and weighed about 5 mg. A slow crystallization from ethyl acetate light petroleum took place, but, due to the small amount of material, only one recrystallization could be carried out resulting in crystals which had a melting point of 195—197°. The sulphuric acid spectrum was identical with that of UD.

The largest amount of the compound causing the spot between GC and GCD on the paper chromatograms was found in the duodenal contents of a one-year-old child (patient R.A.). About 10 ml of duodenal contents were hydrolyzed and the free bile acids separated with phase system F 1. Titration peaks were found at the places of C, UD and CD. The material in the fractions corresponding to UD was collected and extracted with ether from an acidified water solution. The residue, weighing about 10 mg, was dissolved in ethyl acetate and light petroleum was added. Crystals slowly appeared, were recrystallized twice, and gave about three mg of crystals which had a melting point of 201—202° not depressed by authentic ursodeoxycholic acid. Paper chromatographic behavior and sulphuric acid spectrum were identical with those of UD as was also the IR spectrum shown in Fig. 2.

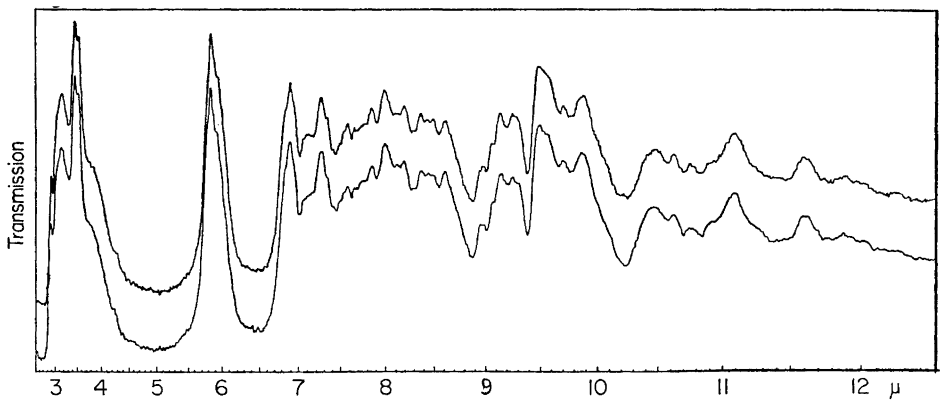

Fig. 2. Infrared spectra of authentic ursodeoxycholic acid (upper curve) and ursodeoxycholic acid isolated from the duodenal contents of patient R.A. (lower curve).

B. 3α,7β,12α-Trihydroxycholanic acid. This acid has been prepared recently by Samuelsson [6]; its presence in rat bile and feces has been demonstrated [7]. In chromatograms with phase system F 1, the acid appears together with cholic acid. In order to separate these acids, the "cholic acid bands"

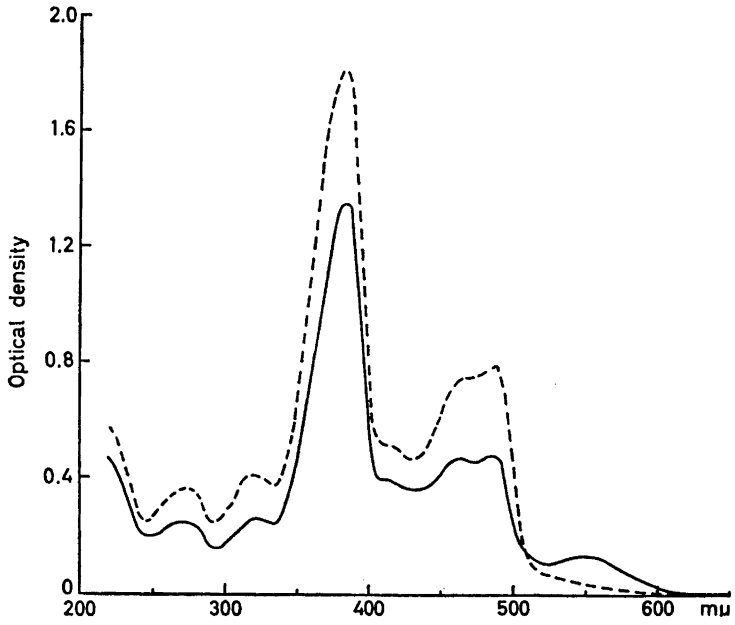

Fig. 3. Absorption spectra of 3α,7β,12α-trihydroxycholanic acid (– – – –) and the compound with identical chromatographic behaviour as this acid, isolated from the bile of patient N.A. (———). The samples were heated for 15 min at 60°C in 65 % sulphuric acid.

from patient N.A. (C, Fig. 1, left curve) and patient R.A. were subjected to chromatography with phase system C 2. The chromatogram of the band from patient N.A. is shown in Fig. 1 (right curve). A large titration peak, corresponding to cholic acid, is present (C), and there is also a minor peak at the place where 3α,7β,12α-trihydroxycholanic acid is known to be eluted [6]. Ascending paper chromatography of the material contained in these fractions, with ethylene chloride/heptane 50/50 as moving phase and 70 % acetic acid as stationary phase, showed the presence of a compound moving with the same rate as 3α,7β,12α-trihydroxycholanic acid. The sulphuric acid spectrum of this compound eluted from the chromatogram was very similar to that of 3α,7β,12α-trihydroxycholanic acid, kindly supplied by Dr. Samuelsson (Fig. 3). The low absorption maximum at 555 mμ of the compound isolated from bile, is due to the presence of small amounts of bromothymol blue used as indicator in the titration of the fractions from the column chromatography. Due to the small amounts of acid obtained from the bile (about 0.8 mg), further purification and identification could not be carried out.

The chromatogram of the "cholic acid band" from patient R.A. showed no titration peak at the place of 3α,7β,12α-trihydroxycholanic acid. However, paper chromatograms of the fractions where this acid could be expected to be eluted clearly showed a spot that had moved with the same rate as the reference acid 3α,7β,12α-trihydroxycholanic acid. If this compound was identical with the reference acid, it was present in amounts less than 1 % of the total bile acids of patient R.A.

DISCUSSION

The non-ketonic bile acids in human bile hitherto isolated are cholic, chenodeoxycholic, deoxycholic and lithocholic acids. These acids all contain hydroxyl groups in one or several of the positions 3α, 7α and 12α. Bile acids with a 7β hydroxyl group have been isolated, *e. g.* from the bile of a certain bear species and from the coypu and the rat [7-9]. The present investigation has shown the presence of ursodeoxycholic, 3α,7β-dihydroxycholanic acid, in samples of human bile and suggests the presence of 3α,7β,12α-trihydroxycholanic acid. Except in the duodenal contents of a one year old child, the ursodeoxycholic acid accounted only for a few per cent of the total bile acids as judged from the spots on the paper chromatograms. In most samples, no spot could be detected at all at the place of ursodeoxycholic acid when the amount of bile used for routine analysis of bile acids was run (a total bile acid amount of about 50 μg).

The chromatographic analysis of bile from patient N.A. showed that ursodeoxycholic acid occurred among the taurine as well as the glycine conjugated bile acids. It is therefore reasonable to assume that it was conjugated with taurine and glycine. The ratio between these conjugates was roughly equal to that of the other bile acids.

Further work must be done for the final identification of the compound behaving like 3α,7β,12α-trihydroxycholanic acid. In the rat, this acid has been shown to be formed from cholic acid, probably through the action of microorganisms in cecum [7]. Several strains of *E. coli* have been shown to oxidize

the hydroxyl group of cholic and chenodeoxycholic acids at C—7, giving a 7-keto group [10]. The 3α-hydroxy-7-ketocholanic acid, that might thus be formed from chenodeoxycholic acid in the rat cecum, is known to be converted to ursodeoxycholic acid in the rat liver [9–11]. Bile acids are known to be absorbed from the cecum [7] and ursodeoxycholic acid could thus be formed from chenodeoxycholic acid (see also Ref.[9]). Whether the 7β-hydroxylated bile acids discussed in this paper are formed in the same way, remains to be investigated. The general importance of the intestinal flora for the composition of the biliary bile acids is, however, clearly seen in the case of deoxycholic acid, which has been shown to be formed by microbial action on cholic acid in man as well as in animals [12–13].

The technical assistance of Mrs. Ann-Mari Andersson is gratefully acknowledged. This work is part of investigations supported by *Statens Medicinska Forskningsråd.*

Physical Properties of Isotopic Forms of Azeotropic Systems Formed from Acetic Acid and Some Tertiary Amines

K. E. HOLMBERG

Section for Nuclear Chemistry, Chemical Research and Production Div., AB Atomenergi, Stockholm, Sweden

Azeotropes of CH_3COOH and CH_3COOD with pyridine, trimethylamine and triethylamine have been prepared. The boiling point differences between the H and D forms of the azeotropes are larger than those between the isotopic forms of pure acetic acid. The composition and some physical properties of the azeotropes have been determined. Upon distillation of the azeotropes, there is some separation of the nitrogen isotopes and, possibly, also of the carbon and oxygen isotopes of the carboxyl group in the acetic acid.

Acetic acid gives, with suitable tertiary amines, maximum boiling point azeotropes. In these azeotropes, the strength of the chemical bond or hydrogen bond between the components will depend on the isotopic constitution of the atoms forming the bond. Different isotopic forms of the azeotropes may therefore have different compositions (*i. e.* ratios amine:acid) and different physical properties.

The azeotropes with acetic acid or acetic acid deuterated in the carboxyl group as one component and pyridine, trimethylamine or triethylamine as the other component have been prepared and investigated with respect to composition and physical properties. After Rayleigh distillation, the isotopic composition has been determined for other elements which may be involved in the compound formation, *viz.* the nitrogen of the amine and the carbon and oxygen of the carboxyl group.

The results are collected in Tables 1 and 2. For convenience, the following abbreviations are used for the azeotropes: PyHAc, PyDAc, Me_3NHAc, Me_3NDAc, Et_3NHAc, Et_3NDAc, in spite of the fact that they are not composed of equimolecular amounts of acid and amine.

The H and D forms of the azeotropes differ rather little in composition. Except for the case with pyridine, the azeotropes seem to contain a compound consisting of one mole amine and four moles acetic acid. Measurements, not

reproduced here, of the density and viscosity of mixtures of Py and HAc have shown a maximum deviation from linear relationship at about the composition Py.4HAc. It is therefore possible that the liquid pyridine-acetic acid azeotrope is a mixture of a compound Py.4HAc together with free, or less strongly bound, pyridine.

The ratio of the vapour pressures of the H and D forms of an azeotrope at the boiling point (b.p.) of the H form is larger than the corresponding ratio for acetic acid at its normal b.p. Rabinowitsch *et al.*[1] have investigated the vapour pressures of CH_3COOH and CH_3COOD at different temperatures. From their results, $p(CH_3COOD)/p(CH_3COOH)$ is 1.017 at 118°C and passes through a maximum of 1.032 at about 50°C. They give a qualitative explanation of their results.

Similar points of view may perhaps apply for the azeotropes but it is felt that a discussion is of no avail so long as we do not know the composition and amounts of the various possible associates occurring in the liquid and the vapour. An investigation to clarify this situation was beyond the scope of the present work.

The ratio of the vapour pressures of the H and D forms of an azeotrope is not to be confused with the separation factor α for H/D on distillation of the azeotrope, $\alpha = (H/D)_{vap}/(H/D)_{liq}$. The two quantities may differ since the composition of the H and D forms of the azeotrope differ, since part of the acetic acid distills as double molecules and also since the vapour phase contains a certain amount of amine.

The separation factors for the N isotopes are quite large considering the rather high distillation temperatures. The low value for the PyHAc azeotrope may be explained by the assumption above that only part of the pyridine is strongly bound by the acetic acid as Py.4HAc. If all of the Py had been bound in this way, the separation factor would be expected to be

$$1 + 0.0034\ (4/1.44) = 1.0094$$

in fair agreement with the values obtained for the other azeotropes. Of course the different structure of Py compared with the other tertiary amines may offer another explanation.

The separation factors for ^{13}C and ^{18}O are very small — of the same order as the errors of the mass spectrometer measurements. However, since they occur in the same direction in all cases, they may have some real meaning. These factors indicate that the C and O atoms of the carboxyl group are very little influenced by the formation of a compound between HAc and an amine.

EXPERIMENTAL

Preparations

Deuterated acetic acid (CH_3COOD) was prepared from acetic anhydride and D_2O (99.7 %). The acetic anhydride was purified by distillation through a 1 meter column with glass helices and reacted with the calculated amount of D_2O. The product was distilled using the 1 meter column to give a product with a 0.1°C boiling point range. The boiling point was compared with that of ordinary CH_3COOH prepared in the same way. HAc b.p.$_{760}$ = 117.70°C, DAc b.p.$_{760}$ = 116.80°C. In another experiment, however, a b.p. difference of only 0.63°C was found.

The azeotropes. Pyridine was mixed with an equal weight of HAc or DAc and the mixture was then fractionated to give a product with a 0.1—0.2°C b.p. range. Et_3NHAc and Et_3NDAc were prepared in a similar way.

HAc was added to 25 % aqueous Me_3N, water was distilled off and the remaining Me_3NHAc fractionated to a narrow b.p. range.

Me_3N was expelled by heating from its 25 % aqueous solution. The product was dried with solid NaOH and absorbed in anhydrous DAc. The resulting Me_3NDAc was fractionated to a narrow b.p. range.

Analyses

A weighed amount of azeotrope dissolved in water was washed through a cation exchanger in the H^+ form. The HAc in the eluate was titrated with standard alkali.

Physical properties

Boiling points were determined in a special all-glass apparatus with thermometer pocket and reflux cooler. Mercury thermometers were used and the pockets were filled with mercury. The H and D forms of the azeotrope were measured simultaneously. Stem and pressure corrections were applied. There may have been some uncertainty in these corrections and thus the absolute values of the boiling points may not be very exact. The b.p. differences, however, are probably correct to ±0.02°C. The rate of change of b.p. with pressure has been determined by a direct comparison with the b.p. of water at three pressures near atmospheric, generally p, $p + 20$, and $p + 40$ mm Hg.

The melting point of PyHAc was determined on a small sample in a test tube and the value is thus rather rough. It was taken as the temperature at which the greater part of the sample had passed into the liquid state. Me_3NHAc and Et_3NHAc could not be made to crystallize. They formed glasses which began to soften at about −100°C.

Densities were determined with a 10 ml pycnometer at 25.00°C.

Viscosities were determined with a probable error of less than 1 % using an Ostwald viscometer.

Rayleigh distillations

A 100—200 ml sample was distilled from a 250 ml flask surrounded by a vapour thermostat at a few (1—4) degrees above the b.p. of the azeotrope. The bottom of the flask rested on an asbestos plate with a hole through which the flask was heated with a small flame. The heating was such that the distillation occurred without the formation of bubbles. The vapour thermostat prevented refluxing from the walls of the flask and from the tube leading to the condenser. 5—10 % of the total amount were taken as a first distillate and about an equal amount was left behind as residue. The first distillate and the residue were analysed for the isotope abundance of ^{15}N, and of ^{13}C and ^{18}O in the carboxyl group of the acetic acid.

The precautions described above were such as to minimize all possibilities for introducing errors giving too high values for the separation factor. Several tests with H_2O—HDO mixtures gave separation factors of 1.0222—1.0235 instead of the accepted value of 1.026 *i. e.* the separation obtained was only 85—90 % of the expected value. Similar errors may occur in the case of the azeotropic systems. No corrections have been introduced, however, since it is not certain that the errors will be of the same magnitude as those in the case of water.

Preparations for isotopic analyses

The N of the amine was transformed by Kjeldahl digestion to NH_3 and then to H_4NCl. Pyridine was digested for several days in the presence of mercury sulphate to insure complete decomposition.

Calculated amounts of $Ba(OH)_2$ solution and sample were evaporated and dried to form anhydrous Ba acetate. This was pyrolyzed in a slow stream of nitrogen to give $BaCO_3$ which was reacted in an evacuated tube with concentrated (96 %) sulphuric acid. The CO_2 formed was purified by freezing out with liquid air and analyzed for ^{13}C and ^{18}O.

Acknowledgement. Thanks are due to Mr. R. Cedenholt for assistance with the experimental work and to AB Atomenergi for permission to publish the results. The isotope abundance measurements were performed by the Mass Spectrometer Laboratory, Karolinska Institutet, Stockholm.

Equilibrium Studies of Polyanions

III. Silicate Ions in $NaClO_4$ Medium

GÖSTA LAGERSTRÖM*

Department of Inorganic Chemistry, Royal Institute of Technology, Stockholm 70, Sweden

Equilibria in silicate solutions have been studied in 0.5 m (molal) $Na(ClO_4)$ medium at 25°C and 50°C, and in 3 m $Na(ClO_4)$ medium at 25°C, using emf's with a hydrogen electrode, at a series of total Si concentrations, B. The data are given in the form of curves $Z(\log h)_B$, or $Z(\log [OH^-])_B$, where Z is the average number of OH^- bound per $Si(OH)_4$ in the solution, thus the average negative charge per Si. The data for 0.5 m medium, $Z = 0.70$ to 1.0, could be explained in terms of the species $Si(OH)_4$, $SiO(OH)_3^-$, $SiO_2(OH)_2^{2-}$, and $Si_4O_6(OH)_2^{2-}$. The data in 3 m medium, $Z = 0.8$ to 1.6, could be explained assuming equilibria between the three mononuclear species mentioned, and in addition $Si_2O_3(OH)_4^{2-}$ and $Si_4O_8(OH)_4^{4-}$. The equilibrium constants arrived at are given in Table 5; they are not considered as final. Equilibria are rapidly obtained, and the solutions are clear, as long as no part of the solution is allowed to pass, even momentarily, into the "instability range", an area in the (B, log h) field, where a colloid precipitates. This may have been one source of error in older work.

Although silicate solutions are being used extensively for various purposes, very little is known with certainty about the formulas of the silicon-containing species. This is borne out by the survey of previous work in the following which, however, is by no means a complete historical review; for such, the reader is referred to monographs by Iler [1] and Vail [2].

The aim of the present work has been to study equilibria in silicate solutions by experimental and mathematical methods worked out in this laboratory, thus to measure data over as wide a range of concentrations as possible, and to deduce the formulas of the species present and the equilibrium constants involved.

As in the previous work on borate equilibria (Part II [3]), no electrode could be found which responds to the free anion concentration. On the other hand, the concentrations of H^+ (and OH^-) could be measured accurately using a hydrogen electrode. As previously, they were recalculated to the form $Z(\log h)_B$, and these curves (Figs 2, 3, and 4) were the basis of the calculations.

* Present address: Columbia-Southern Chemical Corporation, Barberton, Ohio, USA.

An initial difficulty was the existence of an "instability range" of the solutions, which was eventually found out and will be discussed below.

The present work, which was, like the following Part IV, generously supported by Columbia-Southern Chemical Corporation, was already completed in 1955, though the publication has been delayed for external reasons.

SYMBOLS

The symbols are in general the same as in Part II[3]. Thus, B is the total concentration of Si in the solution, b the free concentration, $[Si(OH)_4]$, h the concentration of free H^+, H the analytical excess of H^+ over H_2O and $Si(OH)_4$ (H was negative in most of our experiments), and Z is the average number of OH^- bound per $Si(OH)_4$, thus the average charge per Si.

The silicate species, or complexes, will (in analogy with other work from this laboratory [3,4]) be written as A_pB_q where A stands for a proton deficiency, ($-H^+$), or OH^-, and B for $Si(OH)_4$. Equilibrium measurements like the present ones cannot distinguish between species with various contents of water, and only indicate the charge, $p-$, and the number of Si atoms, q. For instance, A_2B_4 stands for a complex with 4 Si atoms and the charge -2. It might have been written as $Si_4O_9^{2-}$, but this is certainly not correct. In the final formulas of Table 5, it is written as $Si_4O_6(OH)_6^{2-}$ which seems plausible from what is known of the structural chemistry of silicates. However, it is only the charge and the number of Si which can be concluded from the equilibrium data.

To conform with the notations in the IUPAC Tables of Stability constants [5] the formation constants for the complexes will be denoted as β_{pq} when they are formed from $Si(OH)_4$ and OH^-, and with $^*\beta_{pq}$, when they are written with $Si(OH)_4$ and H^+ as reactants (see Table 5).

The composition of silicate solutions has often been expressed by r, the "ratio" SiO_2/Na_2O, in moles (or grams, which is practically the same). To transform r to the quantity Z, which is more practical for equilibrium calculations, we may use the relations

$$BZ = h - H - [OH^-] = h - H - K_w h^{-1} \qquad (1)$$
$$H = -2B/r$$

In solutions with silicate anions, h is always negligible in comparison with BZ, and so is $[OH^-]$, at least for $Z \leq 1$. Then we have simply $Z = 2/r$.

EXPERIMENTAL

Reagents

Sodium perchlorate, perchloric acid, and *silver perchlorate* were prepared and analysed as described in Part II[3].

From p.a. *sodium hydroxide,* a 50 % solution was prepared and filtered through a G4 Jena glass filter. Dilute solutions were prepared from this stock solution and deaerated water. The solutions were kept in polythene bottles which had previously been soaked with warm dilute alkali.

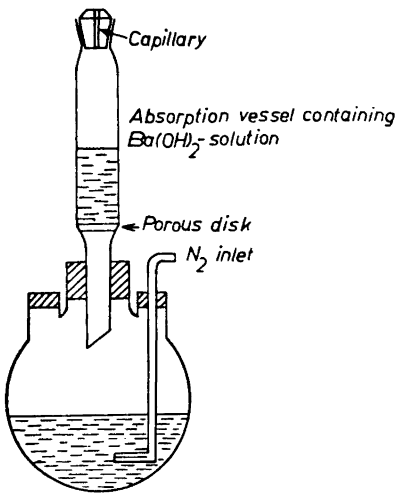

Fig. 1. Apparatus for determining carbonate ions in alkaline solution.

To analyse the 50 % stock solution, a measured quantity of it was transferred to a flask (Fig. 1), filled with nitrogen gas free from CO_2. The absorption vessel was filled with 2/3 of its volume of a $Ba(OH)_2$ solution. The NaOH solution was rapidly acidified with dilute sulfuric acid, and the CO_2 was driven off by heating and passing a stream of nitrogen. The precipitate of $BaCO_3$ was sucked off, washed with 50 % ethanol and dissolved in dilute HCl. $Ba(IO_3)_2$ was precipitated, separated, and determined by titration with $Na_2S_2O_3$ after acidification.

The dilute NaOH solutions were analysed as described in Part II[3]. The ratio CO_3^{2-}/OH^- was always less than 0.001.

A silicic acid sol was prepared by recrystallizing "sodium metasilicate", $Na_2H_2SiO_4(H_2O)_8$ twice from 5 % NaOH, dissolving it in water, and passing the solution through a H^+-saturated Dowex-50 ion-exchanger. A weighed sample of the sol was evaporated in a Pt crucible, and the residue ignited for 2 h at 950°C. The crucible was weighed, treated with HF in the usual way, and weighed again. The difference gave the concentration of SiO_2 in the solution. The sol proved to be extremely pure, with no components other than SiO_2 and water in measurable amounts.

Sodium silicate solutions were not prepared from solid sodium silicate since this product after storage will be contaminated with carbonate, which cannot then be removed. Instead, silicate solutions were prepared from silicic acid sol, NaOH solution or perchloric acid, deaerated water, and $NaClO_4$ solution.

In the analysis of the stock solutions, the concentrations were obtained in M (mole/liter), since all additions were made from burets. To recalculate the concentrations to the unit m (mole/kg H_2O), the water content of each solution was calculated from its concentration in M, and its density. All density determinations and mixing operations were carried out in a room thermostated at 25°C.

Apparatus

Since it was feared that glassware would be attacked by the alkaline solutions, a considerable effort was made to use polythene vessels. It was not possible to obtain commercially a polythene vessel of the desired size and shape and so attempts were made to coat a suitable glass vessel with polythene. However, the coating was easily scratched, and, once this was done, the alkaline solution crept in between the glass and the coating, which was a nuisance.

Next, attempts were made with all-polythene apparatus. It proved a difficult task to fit an ordinary polythene bottle with extra air-tight necks. Moreover, polythene is water-repellent; a great number of droplets splashed from the rinsing gas stream etc, and kept sitting on the polythene surface. This caused an error in the composition of the solution, which could be overcome by occasional shaking but this was objectionable for other reasons. An additional disadvantage was that polythene is opaque so that the formation of a colloid or a precipitate in the titration vessel could not be observed.

Hence, the use of glass vessels was reconsidered. The dissolution of Si from Jena-Geräte glass was investigated in a series of experiments, in which the conditions (time, volume, stirring, composition of solutions) during the emf titrations was reproduced as carefully as possible. If the Jena-Geräte glass, before the experiment, had been treated first with acid and then with alkali, the maximum concentration of dissolved Si was 0.03 mm (3×10^{-5} mole/kg H_2O). When the glass had first been treated only with alkali, no more than one tenth of this concentration was obtained. For 50°C, the figures are approximately doubled. Considering that the total concentration, B, of Si added in the experiments is 2.5—80 mm, little objection can be raised to using glass vessels and burets in the study. In order to depress the error in the experiments at 50°C, the buret containing a strongly alkaline solution was kept at 25°C and was only inserted in the vessel very rapidly each time an addition was made.

The *titration vessel* was made of Jena-Geräte glass, which proved more resistant to alkali than Pyrex. The vessel was of the same type as described in other papers from this institute, and the salt bridge was of the "Wilhelm" type [6]. The hydrogen was purified, the hydrogen and Ag, AgCl electrodes were prepared, and the emf measured as described in Part II[3].

TITRATION PROCEDURES

The cell, including the titration vessel, was kept in an oil thermostat at 25.0 ± 0.1°C, and the whole equipment kept in a room thermostated at 25°C. For the experiments at 50°C, an air thermostat of 50.0 ± 0.5°C was used.

In the various solutions, h, or (OH^-) which is equivalent, was determined by means of the cell

—Pd, H_2(1 atm)/solution studied//SE+

where the reference silver electrode is

I m $NaClO_4$//(I — 0.01)m $NaClO_4$, 0.01 m $AgClO_4$/AgCl, Ag = SE

Assuming the activity factors to be constant, the E may be represented by the equations

$$E = E_{0a} + 59.15 \log [OH^-] + E_j = E_{0a} + 59.15 \log K_w - 59.15 \log h + E_j$$

As in Part II[3], the constant E_{0a} was determined using solutions of known [OH^-]; such measurements also gave the diffusion potential $E_j = 60[OH^-]$ for $I = 0.5$, and $E_j = 10[OH^-]$ for $I = 3.0$. The values obtained for K_w are given in Table 5.

As ionic medium, 0.5 or 3.0 m $Na(ClO_4)$ was used ($I = [Na^+] = 0.5$ or 3.0.) For each titration, two solutions were prepared, S for the titration vessel, and T for the buret, both with the same total silicate concentration, B. To vary Z and log h, two different procedures were used, both extensively.

Procedure 1:

S_1: I m Na^+, B m $Si(OH)_4$, $H = -C_1(C_1$ m $OH^-)$, $(I - C_1)$ m ClO_4^-

T_1: I m Na^+, B m $Si(OH)_4$, $H = C_2(C_2$ m $H^+)$, $(I + C_2)$ m ClO_4^-

Procedure 2:

S_2: I m Na^+, B m $Si(OH)_4$, $H = -C_3(C_3$ m $OH^-)$, $(I - C_3)$ m ClO_4^-

T_2: I m Na^+, B m $Si(OH)_4$, $H = -C_4(C_4$ m $OH^-)$, $(I - C_4)$ m ClO_4^-

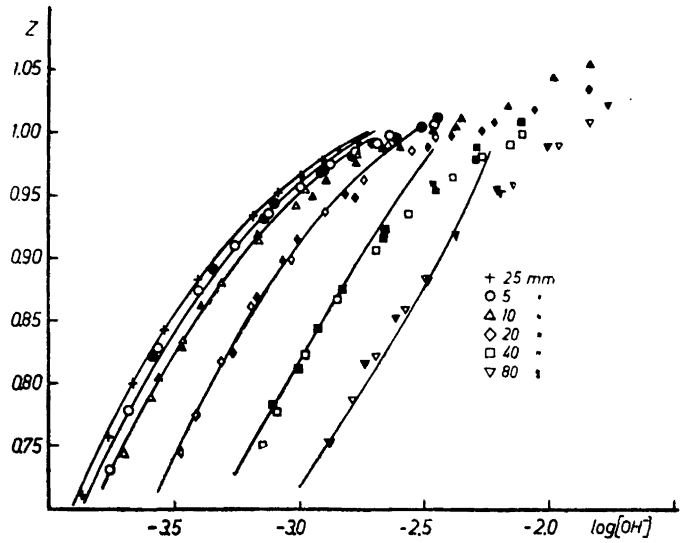

Fig. 2. Silicate equilibria, $Z(\log [OH^-])_B$, 0.5 m $Na(ClO_4)$, 25°C. Procedure 1, open symbols; procedure 2, filled symbols. Curves calculated with equilibrium constants in Table 3.

17.54	not stable		

At first, an extensive series of experiments was carried out using procedure 1. They proved to be very time-consuming, since equilibrium was obtained very slowly indeed. At first we thought — like so many previous investigators — that the formation of polysilicate anions is a slow process. It was learned by experience, however, that slow equilibria are only observed when the solution or part of it has been through a region denoted as the "instability range" (shaded in Fig. 3). With procedure 1, for instance, local excess of acid caused a precipitate of colloid, which dissolved only slowly.

With procedure 2, the composition of S_2 is chosen outside of the "instability range", but as close to it as practicable. On addition of an alkaline solution, neither precipitate nor colloid is formed, and equilibrium is established very rapidly. This procedure was preferred in later work. However, with both procedures, true equilibrium states are obtained: in Fig. 2, experiments by procedure 2 (open symbols) and procedure 1 (filled symbols) are seen to give points on the same curves in the $Z(\log [OH^-])_B$ diagram, within the experimental error.

Table 1 gives a representative part of a titration with procedure 1. After addition of 15.14 ml of T_1, the H_2 stream was replaced by N_2, and the apparatus left over night. Next morning, H_2 was again switched on, and the titration continued. After each addition of acid, E (and thus [OH^-]) decreased, first rapidly, then slowly, and finally reached a constant value. The final E-value was obtained more rapidly at the beginning of the titration than in the later part. The direction of the change is expected, if the local excess of acid first forms a precipitate, $Si(OH)_4$ (with $Z = 0$), or at least one with Z less than in the solution, and this then dissolves slowly, consuming OH^-. Before each new addition, the solution was observed to be clear and free from precipitate.

After addition of 17.54 ml, a new addition of acid caused an initial decrease of E (and OH^-), but then E increased again, which would be expected if an increasing amount of precipitate is slowly formed. A visible precipitate remained, and no constant E could be obtained.

The titrations at 50°C were very tedious, mainly because of difficulties with thermostating. Only a few series of measurements were made; for a more extensive study, an improved technique would be desirable.

The available range in B and Z was limited by the instability range, and also by some considerations of experimental accuracy. When the values of B or [OH^-] cease to be negligible in comparison with I, variations in the

activity factors may be feared. A closer limit on $[OH^-]$ was set by the difficulty of determining Z accurately at high $[OH^-]$, when BZ is obtained as the difference between two numbers of comparable magnitude.

The instability range is more pronounced in 3 m $NaClO_4$, which on the other hand permits higher Z values; thus, the two ionic media allow measurements to be made in different ranges of Z(*cf.* Fig. 2—4).

Some observations in the "instability range". In Fig. 3, for 3 m $Na(ClO_4)$ medium, the "instability range" is shaded. If a solution corresponding to a point outside this range (say, $Z = 0.8$, $B = 0.2$) was diluted with 3 m $NaClO_4$, Z remained practically constant, whereas B was lowered, and the solution eventually entered the "instability range". The solution might appear absolutely clear for some time but the E drifted, indicating slow reactions, and no equilibrium could be obtained. On longer standing the solution became turbid, and finally a precipitate formed. The precipitate might appear after a few minutes, or several hours, depending on B and Z. The maximum rate seemed to be obtained around $B = 0.020$ m. If the precipitate was separated from the apparently clear solution, and the latter heated, further precipitation occurred.

The precipitate formed at room temperature was very fluffy and voluminous; on heating it rapidly contracted to a dense, sticky substance, which finally became brittle on boiling.

SURVEY OF DATA. CALCULATION OF EQUILIBRIA

The experimental data are given in Tables 2—4, and Figs. 2—4. It is seen that the different ionic media allow different Z-ranges to be covered. In all cases, the curves $Z(\log [OH^-])_B$ are seen to differ for different B values,

proving that the solutions must contain polynuclear complexes. For low B, they are seen to approach a curve, with an inflexion point at $Z = 1.0$. Since the shape of this limiting curve agrees very well with that expected for equilibria between three mononuclear species with $Z = 0$, 1, and 2, there is every reason to conclude that at low B the predominant species are $Si(OH)_4$, $SiO(OH)_3^-$, and $SiO_2(OH)_2^{2-}$. *The mononuclear curve* was taken either as the one for the lowest concentration, or from a short extrapolation. The curve was fitted to a normalized curve for two-step equilibria [7]. The results are given in the final Table 5.

For the *polynuclear* complexes, it would have been desirable to start with an approach free from any assumptions (except possibly the constants for the mononuclear equilibria), as was done with the borate equilibria (Part II[3]). For the borates, the data for each value B could be extended to a range with $Z \sim 0$ ($B(OH)_3$ predominates) and $Z = 1$ ($B(OH)_4^-$ predominates) which made a double check possible. For the silicates, the curves for the higher B's have no experimental point where the main species of Si is known from the onset, and so the integration method [3] is impossible.

With a limited range of experimental data available, the only approach that could be invented was to start with the simplest possible hypothesis, namely that, in addition to the mononuclear complexes B, AB and A_2B, a single predominating polynuclear complex A_pB_q is formed. Using procedures outlined by Sillén [8] and applied by Biedermann and Sillén [9] and in Part II[3], sets of normalized curves $\log B$ ($\log \alpha)_Z$ were constructed for combinations of

$p = 2$, 3, and 4 with $q = 2$, 3, and 4. These normalized "projection maps" were then compared with the experimental data log $B(\log [OH^-])_Z$.

For the data in the range attainable with $I = 0.5$ m, no acceptable fit could be obtained with any complex other than A_2B_4. The agreement obtained assuming this complex and the equilibrium constants given in Table 5 is shown in Figs. 2 and 4. It seems quite satisfactory, except for $Z = 0.9$ at the highest B. One might probably obtain complete agreement, within experimental error, on assuming that A_3B_4 is also present, and assigning to it a suitable equilibrium constant.

In the experiments at $I = 3$ m, and higher Z-values (Fig. 3), fair agreement could be obtained assuming either A_3B_4 or A_4B_4 as the single polynuclear complex; with the other single complexes tested, no acceptable fit could be obtained.

Slight deviations at low values of B indicate the presence of a complex with q between 1 and 4. Fig. 3 shows the best agreement obtained assuming the species AB, A_2B, A_2B_2, and A_4B_4 and the constants in Table 5. The agreement around $Z = 1.1$ might be improved by introducing the species B, A_3B_4, and A_2B_4, which might well be expected to exist in this region.

Deviations at low B might also be explained assuming complexes with 3 B instead of A_2B_2. However, one would then have to assume such a high percentage of B_3-complexes that it is remarkable that they have not showed up in the Z-range given in Fig. 2.

One might certainly "improve" the agreement between experimental data and calculated values by increasing the number of complexes assumed. However, it is felt that such a procedure would be arbitrary, if there was no other evidence for the formulas of the complexes. As a rule, more than two independent equilibrium constants for the formation of polynuclear ions may be handled simultaneously with confidence only in experimentally very favorable cases — and silicate equilibria is not one of them.

One could certainly set to the task of refining the equilibrium constants for the A_pB_4 species more whole-heartedly, if there were other data available that would confirm the predominance of tetranuclear species, and could indicate which other q would be important.

To sum up, the data may be explained with reasonable accuracy assuming, apart from the mononuclear species B, AB, and A_2B, only tetranuclear species; although only A_2B_4 and A_4B_4 have been assumed in the calculations, it seems reasonable that at least A_3B_4 should also exist.

SURVEY OF PREVIOUS SOLUTION DATA

Contrary to common practice, we prefer to give a short survey of previous pertinent work after, rather than before the description of our work. For one thing, the concept of an "instability range" makes it easier to understand many observations by previous workers. Those who want a complete historical review, giving due credit for each step in the development of aqueous silicate chemistry, are referred to the monographs by Iler [1] and Vail [2]. Iler also summarizes the abundant literature on the precipitation of silica gel

and various metal silicates from silicate solutions, a subject which has been left out here completely.

Reversibility of silicate equilibria. There is a wide-spread belief — shared, in fact, by ourselves at the beginning of this work — that equilibria in silicate solutions are reached rather slowly. This is only partly true; on the contrary, equilibria are obtained very rapidly so long as clear solutions, free from colloid or precipitate, are studied. When the B and Z of the solution are in the "instability range", where a clear solution no longer corresponds to equilibrium, the solution changes its properties over a long period.

In the light of our present knowledge, it is for instance easy to explain the observations of Kohlrausch [10]. When a sodium silicate solution of ratio $SiO_2/Na_2O = r = 3.4$, thus $Z = 0.59$, was diluted, and then NaOH added after a certain time, the conductance of the resulting solution changed over a period of many hours. The sooner NaOH was added after the dilution, the more rapid was the approach to the final value. This is easy to understand: the concentrated solution is close on the border-line of the "instability range". On dilution, a precipitate is formed (polysilicic acid, perhaps with some adsorbed Na^+), and this then redissolves very slowly, especially if it has had time to grow. With the initial $r < 2$ ($Z > 1.0$), Kohlrausch found no such timeeffect.

Even if the average composition of a solution is kept within the "clear" area, precipitation of colloid may occur because of local excess of acid. Thus, in commercial silicate solutions, the carbon dioxide of the air has often precipitated a colloid. Titration with acid of a sodium silicate solution (as in procedure 1 above) produces local precipitates, which are not easily redissolved. Such phenomena may explain the divergence of some previous data and the time-effects observed, *e.g.*, by Treadwell and Wieland [11].

On the other hand, research workers who have taken great trouble to avoid acid impurities, such as Hägg [12], and Nauman and Debye [13], seem to agree that in clear solutions equilibria are obtained instantaneously so that the properties of a clear silicate solution depend only on its composition and not on its history.

Freezing-point data may be used to calculate the average number of silicate complexes (charged or uncharged) per Si, which will be denoted by R as in Part II. The inverted value, R^{-1}, is the average number of Si-atoms per complex. Souchay [14] titrated 0.66 M "Na_2SiO_3" with H_2SO_4 in a $Na_2SO_4(H_2O)_{10}$ melt, measuring the freezing-point. He concluded that the "Na_2SiO_3" ($Z = 2$) gives mononuclear ions ($R = 1$), whereas at the point corresponding to "$NaHSiO_3$" ($Z = 1$), he found $R^{-1} = 4$; for the predominant species Souchay gave the formula $Si_4O_{10}^{4-}$.

Thilo and Miedreich [15,16] also studied the transition point of $Na_2SO_4(H_2O)_{10}$, the melt incidentally providing constant ionic medium. In dilute solutions of $Z = 1$, they found $R = 1$ and concluded that $H_3SiO_4^-$ predominates. With increasing B, R decreases from 1.0 to ≈ 0.25, which might be interpreted by the formation of a tetrasilicate ion; however, Thilo and Miedreich do not commit themselves to giving any formula for it. They also studied solutions of the salts previously denoted as $Na_2SiO_3(H_2O)_9$ and $Na_6Si_2O_7(H_2O)_{11}$, and concluded that they are really $Na_2H_2SiO_4(H_2O)_8$ and $Na_3HSiO_4(H_2O)_5$. Since $[OH^-]$ was high it was not possible to calculate R^{-1} accurately.

Miedreich [16] has also recalculated Hägg's [12] and Harman's [17] freezing-point data for ice in sodium silicate solutions. These data are somewhat less accurate, since a correction must be made for $[Na^+]$; the activity factor correction has been neglected. Nevertheless, R varies from around 1.0 at low B to around 0.25 at high B, as before.

Alexander [18] prepared a solution of $Si(OH)_4$, from crystalline $Na_2H_2SiO_4(H_2O)_8$ and a slurry of H^+-saturated ion exchanger at 0°C. By freezing-point measurements he proved it to be mononuclear ($R = 1$). Iler [19,20] measured the freezing-point of a polysilicic acid sol, obtained from a sodium silicate solution with $Z = 0.61$, adding acid [19], or H^+ ion exchanger [20]. In the former case he found $R^{-1} = 3.25$, in the latter $R^{-1} = 4.7$; subsequent polymerization was corrected for by extrapolation to zero time.

All this might seem to support the conclusions from the present emf work that the predominant complexes are mononuclear and tetranuclear. However, it is fair to point out that freezing-point measurements for other systems have repeatedly been interpreted in ways that differ from the conclusions obtained by the emf method, which we consider far more accurate, if applied properly.

For instance, freezing-point data have been interpreted [14,21] as a proof that the main hydrolysis product of Be^{2+} is $(BeOH)_4^{4+}$, whereas the emf data of Kakihana and Sillén [22] in this laboratory give a good fit over a wide concentration range assuming $(BeOH)_3^{3+}$, and give no evidence for $(BeOH)_4^{4+}$.

Optical data. Nauman and Debye [13] studied the light-scattering of carefully filtered sodium silicate solutions. With $Z \sim 2$ and higher ($r = 1$ and lower), the calculated molecular weights were around 70, corresponding to monomers, whereas with increasing r (up to 3.75, $Z = 0.53$) they rose to a few hundreds. There may thus be polynuclear ions with a small number of Si, but certainly no "colloidal" particles in the usual sense. The viscosity of highly concentrated solutions can also be well explained without assuming large particles: the large rise in viscosity occurs, just as with sucrose, only when the molecules come very close together in the solution.

For $Z = 0.53$, Nauman and Debye observed an increase in turbidity (and thus molecular weight) with time for $B = 0.26$ M, whereas the turbidity remained constant with $B = 0.65$ M. This is another example of the instability of solutions of low Z (high r) on dilution.

Brady, Brown and Huff [23] have found and studied an increase in turbidity with time for potassium silicate solutions of $r = 3.8$, which are thus in the "instability range".

Diffusion data. Jander and Heukeshoven [24] found that the diffusion coefficient of silicate ions is the same for $B = 0.167$, 0.10, and 0.05 M in 3 M OH^-. They concluded that a single mononuclear species, SiO_3^{2-}, was present. With decreasing pH, the diffusion coefficient at first decreased and then, between pH = 13.5 and 10.9, it kept at a constant value, which was different for different B's. In this range they assumed $Si_2O_5^{2-}$ to be the predominant species.

Emf (pH) data. Several investigators have measured the pH of silicate solutions, obtained for instance during titrations of silicate with acid, or of silicic acid with alkali, or by mixing or diluting solutions of pure salts like NaH_3SiO_4. The data have in general been interpreted in terms of the dissocia-

tion constants of the acid H_4SiO_4 (in older work often called H_2SiO_3, by analogy with H_2CO_3). Some of these workers have noticed deviations which they have ascribed to the formation of polysilicate ions; with the exceptions to be mentioned below, no attempt was made to calculate the constants for their formation.

For the mononuclear constants, the following values have been given: (the figures are pK_{a1} etc, thus $-\log {}^*K_1$, ($-\log {}^*K_2$, $-\log {}^*K_3$, $-\log {}^*K_4$), in our notation) Hägg [12] (20°C) 9.13; Harman [25] (25°C) 9.4 16.3; Hahn and Klockmann [26] (20°C) 10.64; Treadwell and Wieland [11] (20°C) 9.7 12; Flint and Wells [27] 9.66 11.7 12 12; Oka, Kawagaki and Kadoya [28] (25°C) 9.51 11.77; Miedreich [16] (20°C) 9.4 11.4 13.7. Miedreich calculated the constants from his own data, and also from recalculated data of Bogue [29] (30°C), Hägg [12], and Harman [30]. Alexander, Heston and Iler [31], from the increase of solubility of "amorphous silica" with increasing pH concluded $pK_{a1} \sim 9.8$.

When comparing these data and those of the present work (Table 5) we should notice that the ionic media have been different in different papers. The differences in the constants given may be explained partly by the activity factor correction and partly by the neglect of polynuclear silicate ions by most authors.

Roller and Ervin [32] studied the solubilities of calcium silicates in solutions of various pH and $[Ca^{2+}]$. They postulated that pK_a for H_2SiO_3 and $H_3Si_2O_6^-$ is 9.8, and for $H_2Si_2O_6^{2-}$ 12.8. On this assumption they calculated for $pK_{a2} = 12.16 \pm 0.02$, and moreover $\log K\ (2H_3SiO_4^- \rightleftharpoons H_2Si_2O_6^{2-} + 2H_2O) = 3.34 \pm 0.03$.

In a previous communication by the author [33] it was shown that data for a restricted range (B,Z) could be explained assuming complexes AB_n^-, thus with charge -1. Since this mechanism cannot explain the data for the wider range now available, it will not be upheld.

From emf and freezing point data, Thilo and Krüger [34] deduced the formation of a series of complexes, $(AB)_n^{n-}$, in the brief notation, with the equilibrium constant, $\log K(nAB^- \rightleftharpoons (AB)_n^{n-}) = -1.23(n-1)$.

Conductivity titrations have been reported by Constable and Tegul [35]. From breaks in the conductivity curves they inferred the existence in the solution of "ions from $Na_4Si_3O_8$, $Na_2Si_2O_5$ and $NaHSiO_3$" at 15°C, and "$Na_2O.2SiO_2$ and $Na_2O.4SiO_2$" at 100°C. In general, the conductivity method does not seem to be well suited for studying complicated equilibria.

SOLUBILITY OF $Si(OH)_4$, AND INSTABILITY RANGE

According to several authors (Alexander, Heston and Iler [31]; Goto, Okura and Kayama [36]; and Gardner [37]) the solubility of "amorphous silica" in acidic and neutral solutions is around 2 mM $= 10^{-2.7}$ M, probably in the form of $Si(OH)_4$. Solutions of a higher concentration may be prepared, but they are unstable and a gel will eventually precipitate.

It is a natural suggestion, that this solubility should determine at least one limit to the range in which stable solutions can be obtained. To test this suggestion, the concentration $b = [Si(OH)_4]$ has been calculated as a function of $\log B$ for the constant values $Z = 0.75$ and 0.80, and $I = 0.5$, 25°C, and 50°C, using the equilibrium constants K_1, β_2, and β_{24} from Table 5. The results are given in Fig. 5.

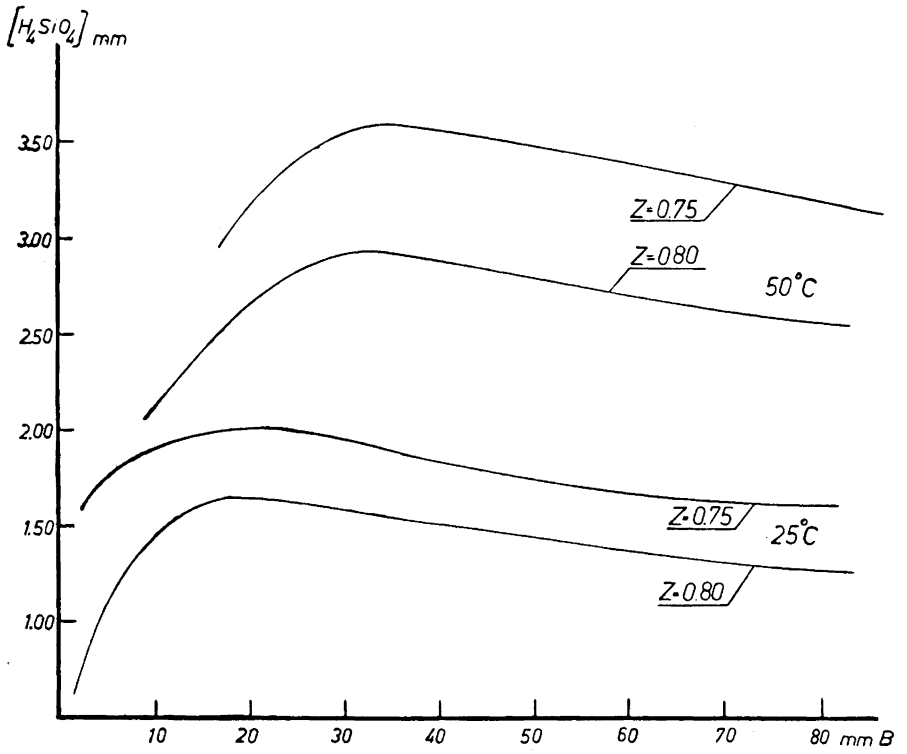

Fig. 5. Equilibrium concentration, b, of $Si(OH)_4$ calculated as a function of B, for constant $Z = 0.75$ or 0.80; 0.5 m $Na(ClO_4)$, 25°C. Equilibrium constants from Table 5.

Since h and $[OH^-]$ are negligible in comparison with B in (1), the curves will show the behavior of the solution when it is diluted with ionic medium, which keeps Z constant with good approximation.

It is seen that on dilution, b passes through a maximum, for $Z = 0.75$, and 25°C, of $b_{max} \sim 2$ mm ($B = 20$ mm) and for 50°C of $b_{max} \sim 3.6$ mm (at $B = 40$ mm). The figures 2 mm and 3.6 mm approximately correspond to the solubility of $Si(OH)_4$ at these temperatures, and it may be inferred from Fig. 5 that, at lower values for Z, the solubility will be exceeded.

This agrees with experience: stable solutions have not been obtained for $Z < 0.75$ except in the very dilute range, $B < 5$ mm, where the limiting Z-value decreases with B, and roughly seems to correspond to a saturated solution of $Si(OH)_4$.
